The most sensitive tested mammal was the Texas pocket gopher (*Geomys personatus*) with an LD50 of less than 0.05 mg 1080/kg BW (McIlroy 1986). In general, carnivorous eutherian mammals were most sensitive to 1080 and amphibians were most resistant; intermediate in sensitivity were (in that order) herbivorous eutherian mammals and marsupials, carnivorous marsupials, herbivorous-granivorous rodents, omnivorous mammals, and birds (McIlroy 1992). Very young mammals seemed more sensitive to 1080 than other members of their populations (McIlroy 1981a); no other differences in sensitivity to 1080 were found that could be related to sex, age, or nutritional status (McIlroy 1981a, 1981b; O'Brien 1988; O'Brien and Lukins 1988). Route of administration had little effect on 1080 toxicity. Oral dosages were as toxic as subcutaneous, intramuscular, intravenous, and intraperitoneal dosages (Negherbon 1959; McIlroy 1981a, 1983a). There are as yet unexplained species differences in fatal 1080 poisonings: dogs died of convulsions or respiratory paralysis, but monkeys, horses, rabbits, and humans died of ventricular fibrillations (Murphy 1986). Individuals of most species dosed with 1080 died within 7 days, but feral pigs and wedge-tailed eagles took longer (McIlroy 1981a). Ambient air temperatures in the range of 4-33° C modified the sensitivity of small mammals to 1080. In mice (*Mus* spp.) and guinea pigs (*Cavia* spp.), sensitivity was greatest at the extremes of the tested thermal regimes and not at intermediate temperatures (McIlroy 1981b; Oliver and King 1983). Raccoons (*Procyon lotor*) and feral pigs were more sensitive at elevated ambient temperatures (Eastland and Beasom 1986b; O'Brien 1988), but possums and domestic sheep were more sensitive at low temperatures (McIlroy 1982a; Eastland and Beasom 1986b). At elevated temperatures, 1080 was more toxic to feral pigs when administered in drinking water than in oat baits and, in wheat baits than in pellet baits (O'Brien 1988).

Warm-blooded species varied considerably in response to sodium fluoroacetate; primates were more resistant, and rodents and carnivores were more susceptible. Based on fatal or near-fatal cases of human poisonings, the dangerous dose for humans is 0.5-2.0 mg/kg BW (Negherbon 1959). Among the 171 species of tested mammals, for which there are data, variability was considerable in the time until signs of poisoning became apparent (0.1 h to greater than 7 days), the time to death (0.1 h to greater than 21 days), and the time until animals began to show signs of recovery (2 h to 18 days; McIlroy 1986). Signs of poisoning among herbivorous species of marsupials first appeared 1-39 h after dosing; death followed 3-156 h after dosing

(McIlroy 1982a). Australian carnivores did not show signs of 1080 poisoning for 0.6-4.8 h; first deaths occurred between 1.6 and 21 h and recovery in 0.4 to longer than 26 h (McIlroy 1981b). Marsupial carnivores generally showed signs of 1080 poisoning earlier and died or recovered quicker than marsupial herbivores and placental mammals (McIlroy 1986). After the latent period, common signs of 1080 poisoning in caged mammals included hyperexcitation, rapid breathing, and trembling. Some animals then recovered, whereas others began to vomit, convulse, or both (McIlroy 1981b). The most common signs of 1080 poisoning in 14 species of Australian rodents were depression, hypersensitivity to stimuli, respiratory distress, and convulsions; signs usually appeared 0.4-38.1 h after dosing; deaths occurred 0.7-206 h after dosing. Some species were more tolerant, perhaps because of evolutionary exposure to indigenous plants that contained fluoroacetate (McIlroy 1982b). Rabbits (*Oryctolagus* sp.) poisoned by 1080 showed increased sensitivity to noise or disturbance; those surviving high sublethal doses began recovering 5-23 h after dosing (McIlroy 1982a). Cows (*Bos* spp.) showed no signs of fatal 1080 poisoning until shortly before death; signs appeared in the following sequence: urination, staggering, falling down, slight spasms, and death 1.5-29 h after treatment (Robison 1970). Prairie dogs showed no signs of 1080 poisoning for several hours after consuming a fatal dose; death occurred 8-13 h after dosing and was preceded by a rapid respiratory rate, hyperactivity, and convulsions (Hugghins et al. 1988). In feral pigs, signs of poisoning such as vomiting, increasing lethargy, and labored breathing appeared about 6.2 h after dosing (range 1.9-47.3 h) and death, after 16.1 h (range 2.8-80 h) of dosing (McIlroy 1983a). Vomiting occurred in 98% of poisoned pigs but was unrelated to dose (O'Brien 1988) or bait type (O'Brien et al. 1988). In some animals, particularly the eastern native cat (*Dasyurus viverrinus*), the tiger cat (*Dasyurus maculatus*), and the tasmanian devil, the first sign of 1080 poisoning is the sudden onset of vomiting. Vomiting was independent of the ingested dose or mode of administration. Thereafter, animals may either recover or experience hyperexcitation, convulsions, and death (McIlroy 1981b).

Many 1080 control programs had high effectiveness without significant effects on nontarget species. Australian baits for the control of various mammalian pests usually contain 15-110 mg 1080/kg bait, although concentrations as high as 1,200 mg/kg bait are documented (McIlroy 1981b). Baiting with 1080 to control European rabbits and red foxes (*Vulpes vulpes*) in New South Wales, Australia, caused a 90% reduction in numbers of rabbits and 75%, of foxes; populations of both species began to recover soon after the campaign ended, indicating the need for continued control. Populations of nontarget birds and mammals did not seem to be affected, and no dead birds or nontarget mammals were found (McIlroy and Gifford 1991). Reports of 1080 control in Australia of wild dogs, dingoes, and their hybrids are similar (McIlroy et al. 1986b). In Tasmania, deliberate poisoning of forest-browsing pests with carrot baits containing 0.014% of 1080—the same concentration used elsewhere in Tasmania for rabbit control—resulted in 94% mortality of brushtail possum populations, 96% mortality of red-bellied pademelons, and 86% mortality of Bennett's wallabies (McIlroy 1982a). McIlroy (1982a) suggested the use of 1080 to protect island-dwelling rare or endangered species of herbivorous marsupials--a comparatively tolerant group--during control of more sensitive introduced competitors or predators such as rabbits, foxes, and feral cats.

Compound 1080 is highly toxic to some species of nontarget mammals, including domestic cats and dogs (Kalmbach 1945). Baiting of California ground squirrels with 1080 reduced squirrel populations by 85% but also killed individuals of the Heermann's kangaroo rat (*Dipodomys heermanni*), the little pocket mouse (*Perognathus longimembris*), the desert woodrat (*Neotoma lepida*), the deer mouse (*Peromyscus* sp.), and the western harvest mouse (*Reithrodontomys megalotis*); poisoned rodents contained between 5.2 and 23.1 mg 1080/kg BW and 1080-poisoned desert cottontails (*Sylvilagus audubonii*) contained 8.2 mg 1080/kg stomach content (Hegdal et al. 1986). Dead nontarget animals found in New South Wales State forests after 22 rabbit-poisoning operations between 1971 and 1975 included in decreasing order of frequency foxes, wallabies, possums, gray kangaroos, wombats, rats, hares, birds, cats, sheep, and dogs. This pattern may reflect each species' relative abundance in the target areas, access to and acceptance of baits, and ease of detectability after death by forestry personnel (McIlroy 1982a). In Australia, the animals alleged to be most at risk during rabbit or pig-poisoning campaigns with pellet, grain, or carrot baits are the kangaroos, wallabies, and wombats. For example, common wombats (*Vombatus ursinus*) and hairy-nosed wombats (*Lasiorhinus latifrons*) must consume only 10-16 g of pellet, grain or carrot baits containing 0.33 to 0.5 mg of 1080 to receive an LD50. Hairy-nosed wombats eat 120-570 g of food daily, and common wombats can eat more than 500 g of unpoisoned carrots daily, indicating that both species could easily consume lethal quantities of bait. Next at risk in descending order are livestock, brushtail possums, pigs, and various rodents and birds (McIlroy 1986). More data are needed on bait consumption rates by nontarget mammals to assess the risk from 1080 poisoning campaigns.

Laboratory studies may overestimate the risk to nontarget species from 1080 baiting. The northern quoll (*Dasyurus hallucatus*), for example, was at highest theoretical risk from aerial baiting as judged by LD50 laboratory studies with 15 species of rodents and dasyurids. But no dead quolls were found during aerial baiting to control dingoes, and all radio-tagged quolls seemed to have normal movements (King 1989). Alternatives to LD50 testing now include tissue culture, monitoring of metabolite levels in blood or tissues, and estimation of the lowest lethal dose (Calver et al. 1989a). Monitoring the level of citrate in blood plasma of animals that received a sublethal dose of 1080 has been successful with species that are large enough to provide adequate samples of blood plasma during a 24-h period but have not been attempted on Australian fauna (Calver et al. 1989a).

Because 1080 acts as an emetic, especially in coyotes and feral pigs, nontarget animals are at risk of primary poisoning from eating the vomitus (Atzert 1971; McIlroy 1983a; Rathmore 1985; O'Brien et al. 1986, 1988). Wild pigs poisoned by carrot baits for European rabbits left trails of vomitus with carrots and other ingested foods (Rathore 1985). The antiemetic compound metoclopramide (Maxolon) prevents vomiting in pigs by blocking dopamine receptors in the chemoreceptor trigger zones. The addition of metoclopramide to 1080 poison baits for wild pigs reduces vomiting and thereby reduces the poisoning risk to nontarget species. The addition of metoclopramide improves the efficiency and percentage of the kill of wild pigs because they do not develop a taste aversion to the baits. Similarly, baits containing this antiemetic at an effective concentration of 1 mg/kg BW shortened the median time for death in dogs from 151 min postdose in 1080 baits without metoclopramide to 132 min (Rathore 1985). At tested doses (1-16 mg/kg BW), metoclopramide did not decrease the frequency of vomiting by dogs but decreased the amount of vomitus (O'Brien et al. 1986).

Secondary poisoning is probable among carrion eaters feeding on rabbits and other herbivores poisoned with 1080-treated carrots, especially foxes and dingoes (secondary target species) and dogs and cats (McIlroy 1981b; McIlroy and Gifford 1992). Secondary poisoning was experienced by dogs that fed on 1080-treated rodents and prairie dogs and by cats that consumed treated rats and mice (Anonymous 1946). Some dead domestic dogs and cats were found within 450 m of a 1080-treatment area; signs of 1080 poisoning were evident, but no 1080 residues were detected by chemical analyses (Hegdal et al. 1986). Ground squirrel control with 1080 baits caused secondary poisoning of dogs, cats, coyotes, bobcats (*Lynx rufus*), skunks, and kit foxes (Hegdal et al. 1986). The high susceptibility of threatened and endangered populations of the kit fox to 1080 rodenticides, as judged by studies with nonthreatened populations of the kit fox, suggested that 1080 is a factor in their population decline (Schitoskey 1975). Sodium monofluoroacetate has a high degree of secondary toxicity in mammals, as evidenced by deaths of domestic ferrets that ate 1080-poisoned white-footed mice (*Peromyscus leucopus*; Hudson et al. 1984). Similarly, coyotes died after ingestion of 1080-poisoned ground squirrels that contained 3-6 mg of 1080 equivalent to 0.24-0.63 mg/kg BW coyote (Casper et al. 1986; Marsh et al. 1987). Coyotes that ate a single 1080-poisoned squirrel daily for 5 days or an estimated total dose of 0.12-0.27 mg/kg BW usually survived, suggesting that there is little secondary hazard from multiple small doses (Marsh et al. 1987). Carcasses and viscera from coyotes that died after ingesting 5-15 mg of 1080 were fed for 14-35 days to other coyotes, domestic dogs, striped skunks (*Mephitis mephitis*), and black-billed magpies; no evidence of secondary poisoning was seen in any tested species. Maximum residues of 1080 in dead coyote tissues in mg/kg FW were 0.66 in muscle, 0.79 in the small intestines, and 0.76 in stomach tissue (Burns et al. 1986). Tissues of 1080-poisoned coyotes did not produce secondary poisoning in Virginia opossums (*Didelphis virginiana*; Eastland and Beasom 1986a), striped skunks (Eastland and Beasom 1986a; Burns et al. 1991), raccoons (Eastland and Beasom 1986a; Hegdal et al. 1986), or badgers (*Taxidea taxus*; Hegdal et al. 1986). The hazard of secondary poisoning to predators is minimal after consuming tissues of 1080-killed black-tailed prairie dogs (*Cynomys ludovicianus*) because their tissues contained less than 0.1 mg fluoroacetate/kg FW (Hugghins et al. 1988). No mink died when fed 1080-poisoned rabbits at 40% of the total diet if the rabbit gastrointestinal tract had been removed from the carcass. This suggests that secondary toxicity from 1080 is due primarily to consumption of the unmetabolized compound from the gut of prey species (Aulerich et al. 1987). The risk to different individuals or populations depends on the species' sensitivity to 1080, the number of consumed poisoned animals, and the amounts of different consumed tissues or organs (McIlroy and Gifford 1992).

The sensitivity to 1080 poison by animals in Australia varies greatly; known LD50 values range from 0.11 to more than 800 mg/kg BW. Many native species, particularly in Western Australia, have evolved tolerances to 1080 through ingestion of native plants that contain fluoroacetate or prey that consume these plants (McIlroy 1982a; McIlroy 1992). The degree to which this tolerance is developed depends on the extent of the toxic plants in the microhabitat, the need of each species to include food species that contain fluoroacetate in its diet, and

the length of evolutionary exposure to the toxic plants (Twigg et al. 1988b; King et al. 1989; Twigg and Mead 1990). This naturally occurring resistance to the toxins allows control with 1080 to be more specific for introduced test species (Mead et al. 1985). Tolerance to fluoroacetate is present in insects, reptiles, mammals, and birds and descends in magnitude from herbivores to carnivores (Twigg and King 1991). Mammals with lower metabolic rates--such as marsupial carnivores--seem to be more tolerant than mammals with a higher metabolism--such as eutherian carnivores--to a poison such as 1080 that interferes with the metabolism (McIlroy 1981a, 1981b). Tolerance to gradually increasing doses of fluoroacetate can be induced in the mouse, rat, and rhesus monkey but not in the dog or rabbit; however, the protective effect of prior exposure to 1080 seldom persisted for more than 48 h (Chenoweth 1949). Laboratory white rats may acquire tolerances to 1080 by the ingestion of sublethal doses for a period of 5-14 days; cessation of dosing for 7 days caused a loss of tolerance (Kalmbach 1945). Some species acquired tolerances to 1080 after repeated sublethal doses, and others accumulated the chemical until a lethal threshold was reached (McIlroy 1981a). Both phenomena were unpredictable if 1080 residues in the tissues remained between doses. The required time for complete elimination of 1080 from tissues varied among species: dogs required 2-3 days, rats 36 h, and sheep as long as 1 month (McIlroy 1981a).

Sublethal concentrations of 1080 may adversely affect reproduction, growth, and behavior. In rats (*Rattus* sp.), the most vulnerable organ to 1080 poisoning is the testes and this is consistent with 1080-impaired energy production from blockage of the Krebs cycle and subsequent impairment of the carbohydrate metabolism (Sullivan et al. 1979). Subacute dietary exposure to 1080 caused dose-dependent decreases in body weights and feed consumption in mink and in European ferrets (Hornshaw et al. 1986). Toxic 1080 meat baits were usually avoided by tested, nontarget dasyurids and rodents when alternative foods were available; 12 of the 24 tested groups did not sample meat baits under these conditions (Calver et al. 1989a). Adult wild pigs given a sublethal dose of 1080 (0.5 mg/kg BW) in apple baits vomited within 30 min after eating the treated bait and avoided apple baits in future tests (Rathore 1985). Caged wild Norway rats (*Rattus norvegicus*) and black rats (*Rattus rattus*) developed a gradually increasing aversion to drinking water solutions of 1080, although this aversion was not sufficient to disrupt growth and reproduction (Kalmbach 1945).

Recommendations

It is emphasized that 1080 is a restricted pesticide that can only be used by certified applicators who received special training (Green 1946; Negherbon 1959; EPA 1985; Connolly 1993a) and that all organisms that died from 1080 poisoning must be buried or incinerated (EPA 1985). Some authorities aver that continued use of 1080 is justified and desirable and that risk is minimal to nontarget organisms. As discussed earlier, 1080 is a natural plant product, is generally highly toxic to most pests at low concentrations, is readily lost from baits after heavy dews or rainfall, is biodegraded by fungi and bacteria, and does not persist in soil or water. In New Zealand, 1080 has been used since 1954 and is still considered an essential pesticide for limiting forest and crop damage and for containing the spread of tuberculosis to livestock by brush-tailed possums (Eason et al. 1993b). It has been used to control isolated island populations of mammals that prey on endangered or threatened species of birds, for example, Arctic foxes that preyed on Aleutian Canada geese in the Aleutian Islands (Tietjen et al. 1988; Bailey 1993). In Australia and New Zealand, results of field studies suggested that 1080 poisoning campaigns had no significant effect on almost all populations of common nontarget species (McIlroy 1982a, 1992; McIlroy et al. 1986b; McIlroy and Gifford 1991; Spurr 1994), although more studies of vulnerable, rare, endangered, or uncommon species are recommended (McIlroy 1992).

However, a growing body of information questions the usefulness of 1080 in the United States. This database includes adverse effects on some nontarget organisms and endangered species; the confounding effects of the latent period, behavioral alterations, and application routes; and the development of suitable alternative chemicals. On the basis of acute oral toxicity tests, sensitive nontarget mammals and birds may consume lethal quantities of 1080 from poisoned baits or from consumption of organisms fatally poisoned with 1080 (EPA 1985). Field studies showed deaths among sensitive nontarget species that ate 1080 baits, including bees (Goodwin and Ten Houten 1991), insectivorous birds, (McIlroy 1982a; Hegdal et al. 1986), rabbits, rodents (Hegdal et al. 1986), cats, dogs (Kalmbach 1945; Green 1946; Hegdal et al. 1986), and live-stock (McIlroy 1982a, 1986). Carrion eaters and mammalian predators--especially canids and felines—experience secondary poisoning after feeding on 1080-poisoned prey (Hegdal et al. 1986; McIlroy and Gifford 1992). Sublethal effects of 1080 on growth in ferrets and on reproduction in mink are reported (Hudson et al. 1984; Hornshaw et al. 1986). Some endangered species are at risk from direct consumption of the 1080 baits or from secondary

poisoning (EPA 1985). In general, the use of 1080 in the geographic range of any endangered species is discouraged or disallowed outright in the ranges of the California condor, the San Joaquin kit fox (*Vulpes macrotis mutica*), the Aleutian Canada goose; the Morro Bay kangaroo rat (*Dipodomys heermanni morroensis*), and the salt marsh harvest mouse (*Reithrodontomys raviventris*). When exceptions are made or when 1080 use is permitted in an area known to be frequented by an endangered species, restrictions are placed on the maximum concentration of 1080 in the baits (EPA 1985).

Human consumers of meat from 1080-killed ducks are probably not adversely affected after eating an average cooked portion (Temple and Edwards 1985). The risk to humans from eating meat of domestic animals accidentally poisoned with high sublethal concentrations is minimal to low because 1080 is cleared rapidly from domestic animals--usually within a few days (Eason et al. 1994). In the absence of additional data, a minimal 3-week postponement of the slaughter or marketing of livestock that survived 1080 exposure seems prudent. No livestock in the United States contaminated with 1080 are marketed (Connolly 1993a).

No effective antidote to 1080 is currently available, and accidental poisoning of livestock and dogs is probably fatal (Green 1946; Chenoweth 1949; Peacock 1964; Atzert 1971; Mead et al. 1991). The lack of emergency treatment of 1080-poisoned humans and the unavailability of monoacetin--potentially the most effective medication for compound 1080 poisoning--in a pharmaceutical grade (EPA 1985) strongly indicate the need for a viable 1080 antidote. The search for an effective 1080 antidote is ongoing, and some candidate compounds that offer partial protection are mixtures of sodium acetate and ethanol, barbituates (Tourtellotte and Coon 1950; Peacock 1964), glycerol monoacetate (Peacock 1964; Murphy 1986), a mixture of calcium glutonate and sodium succinate (Roy et al. 1980; Omara and Sisodia 1990), and 4-methylpyrazole (Feldwick et al. 1994). The development and availability of an effective 1080 antidote should be of high priority. Until this antidote is distributed, it seems reasonable to use 1080 in the United States only after other alternatives were considered.

The interval between 1080 dosage and signs of intoxication is at least 30 min, regardless of dose or tested species, and must be considered in the evaluation of the efficacy of 1080. Coyotes, for example, may continue to kill livestock after receiving a lethal dose (Connolly and Burns 1990). And coyotes may travel some distance from their prey prior to incapacitation, making carcass recovery and program evaluation difficult--as was the case of 1080-poisoned quolls in Australia (King 1989). Similarly, many 1080-poisoned nontarget animals may have left the treated area before succumbing, thus leading to underestimation of mortality among this group (Collins 1965). Tolerance to fluoroacetates and avoidance of 1080 baits should also be considered in future 1080 poisoning campaigns by wildlife managers and by animal damage-control operators. Avoidance of 1080 toxic baits by target mammals is documented when alternative foods are available (Calver et al. 1989a) and by pigs and rats surviving sublethal exposures (Kalmbach 1945; Rathore 1985). Indigenous populations of mammals, birds, and reptiles that coexist with fluoroacetate-bearing vegetation are much less sensitive to 1080 poisoning, perhaps by as much as 2 orders of magnitude, than conspecifics lacking such exposure (Twigg et al. 1988; King et al. 1989; Twigg and Mean 1990).

The timing of application of 1080 baits is critical. In one mishap, baits were dropped from aircraft while many ground squirrels--the targeted species--were still in hibernation underground for the winter and had not emerged (Collins 1965). Aerial application of 1080 baits in a ground squirrel control program in California, although effective in controlling the squirrels, resulted in great overuse of the baits. As many as 70-77% of the poisoned baits were not eaten by the squirrels and were not recovered. Also, the yellow dye to color the baits--as a deterrent to birds--faded rapidly (Collins 1964, 1965). To protect migratory waterfowl, 1080 baits should not be applied immediately preceding or during the main waterfowl hunting season or whenever birds are abundant (Temple and Edwards 1985). To protect honeybees, 1080-poisoned jam baits should be deposited more than 400 m from apiary sites. If 1080 baits are dispersed less than 400 m from apiary sites, beekeepers should remove their hives to a more distant site (Goodwin and Ten Houten 1991). The 1080 toxicity database on aquatic organisms is insufficient for practicable formulation of criteria to protect this ecosystem. This seems to be a high-priority research need in geographic areas of intensive 1080 application.

Potential replacement chemicals for 1080 include PAPP (*para*-aminopropiophenome), DFP (1,3-difluoro-2-propanol), and various anticoagulant and nonanticoagulant toxins. PAPP is highly toxic to coyotes and domestic cats (each with LD50s of 5.6 mg/kg BW) and lethal to rats (LD50 of 177 mg/kg BW) and mice (LD50 of 233 mg/kg BW); intermediate in toxicity to bobcats (10.0) and to kit foxes (14.1 mg/kg BW; Savarie et al. 1983). DFP

is under investigation in Australia as an alternative to 1080 for management of fauna because it has a mode of action similar to that of 1080 and has an antidote in pyrazole (Mead et al. 1991). DFP is the major ingredient of the pesticide gliftor used in Russia to control rodents, particularly voles of the genus *Microtus*. Also deserving of evaluation are 4-methylpyrazole and related compounds to function as antidotes to DFP intoxication (Mead et al, 1991). In New Zealand, alternatives to 1080 under evaluation include several nonanticoagulant toxins (gliftor, cholecalciferol, calciferol, alpha-chloralase, nicotine, malathion) and anticoagulants including brodifacoum and pindone (Eason et al. 1993a).

Abstract

Ecological and toxicological aspects of polychlorinated biphenyls (PCBs) in the environment are reviewed with emphasis on biologically active congeners and fish and wildlife. Subtopics include sources and uses, chemical and biochemical properties, concentrations in field collections, lethal and sublethal effects, and recommendations for the protection of sensitive resources. All production of PCBs in the United States ceased in 1977. Of the 1.2 million tons of PCBs manufactured to date, about 65% are still in use in electrical equipment and 31% in various environmental compartments, and 4% were degraded or incinerated. The 209 PCB congeners and their metabolites show wide differences in biological effects. A significant part of the toxicity associated with commercial PCB mixtures is related to the presence of about 20 planar congeners, i.e., congeners without chlorine substitution in the *ortho* position. Toxic planar congeners, like other PCB congeners, have been detected in virtually all analyzed samples, regardless of collection locale. Planar PCB concentrations were usually highest in samples from near urban areas and in fat and liver tissues, filter-feeding bivalve molluscs, fish-eating birds, and carnivorous marine mammals. Adverse effects of planar PCBs on growth, survival, and reproduction are highly variable because of numerous biotic and abiotic modifiers, including interaction with other chemicals. In general, embryos and juveniles were the most sensitive stages tested to planar PCBs, and the chinook salmon (*Oncorhynchus tshawytscha*), domestic chicken (*Gallus* sp.), mink (*Mustela vison*), rhesus macaque (*Macaca mulatta*), and laboratory white rat (*Rattus* sp.) were among the most sensitive species. For protection of natural resources, most authorities now recommend (1) analyzation of environmental samples for planar and other potentially hazardous congeners; (2) exposure studies with representative species and specific congeners, alone and in combination with other environmental contaminants; (3) clarification of existing structure-induction-metabolism relations; and (4) more research on physiological and biochemical indicators of PCB-stress.

Key Words: Polychlorinated biphenyls, PCBs, planar PCBs, ecotoxicology, fish, wildlife, invertebrates

---

Polychlorinated biphenyls (PCBs), a group of 209 synthetic halogenated aromatic hydrocarbons, are used extensively in the electricity generating industry as insulating or cooling agents in transformers and capacitors. Because of human activities and the chemical characteristics of the products, PCBs are now distributed worldwide, and measurable concentrations occur in aquatic organisms and wildlife from North America, Europe, the United Kingdom, and the Atlantic and Pacific Oceans. PCBs elicit a variety of effects including death, birth defects, reproductive failure, liver damage, tumors, and a wasting syndrome. They bioaccumulate and biomagnify in the food chain. Legislation has prohibited virtually all uses of PCBs and their manufacture in the United States since 1979; the ban has been accompanied by declines in PCB residues in fishes and wildlife. But the current environmental burden of PCBs in water, sediments, disposal sites, deployed transformers, and other PCB containers—now estimated at more than 374 million kg, much of it localized—continues to represent a potential hazard to associated natural resources (Pal et al. 1980; Eisler 1986; Hansen 1987; Parkinson and Safe 1987; Safe 1987a, 1990, 1994; Huckins et al. 1988; Tanabe 1988; Skaare et al. 1991; Hoffman et al. 1995).

In this report we summarize the recent technical literature on PCB hazards to fishery and wildlife resources, and place special emphasis on the biologically active planar PCBs. This report is part of a continuing series of brief reviews prepared in response to requests for information from environmental specialists of the U.S. Fish and Wildlife Service and other requestors.

Sources and Uses

The Monsanto Industrial Chemical Company, the principal domestic manufacturer of PCBs, began PCB production in 1929; commercial mixtures of PCBs were also produced in Western Europe and Japan. PCBs have been used in dielectric fluids; in waxes for metal castings; as heat transfer agents; as plasticizers in paints, coatings, and carbonless copy paper; in cutting oils; in sealants and caulking compounds; and as pesticide extenders (Eisler 1986). The use of PCBs was curtailed in the United States in 1971, and sales were limited to manufacturers of capacitors and transformers; all new uses were banned in 1976 (U.S. National Oceanic and Atmospheric Administration [NOAA] 1991). In 1977, all production of PCBs was halted and no shipments were made after October. Direct and indirect sources of PCB contamination may include aerial transport of combustion products, vaporization from continental and marine areas, current and historic industrial and municipal waste discharges, precipitation, land runoff, concealed dumping, transformer fires, and accidental spills (NOAA 1991; U.S. Environmental Protection Agency [USEPA] 1992a).

The ubiquity of PCBs is indicated by their presence in environmental samples from the polar regions of air, snow, ice, water, and in living organisms (Norstrom et al. 1988; Hargrave et al. 1989; Larsson et al. 1992; Tanabe et al. 1993). The presence of PCBs in such remote areas suggests the importance of atmospheric transport. The Committee on the Assessment of Polychlorinated Biphenyls in the Environment estimated that 50-80% of the PCBs derived from the United States were now in sediments and waters of the north Atlantic Ocean (National Academy of Sciences [NAS] 1979). Of the estimated total world PCB production of 1.2 million tons to date, about 374,000 tons are now in various portions of the terrestrial, coastal, and open ocean ecospheres (Table 1). Another 783,000 tons are still in use in electrical equipment and other products or deposited in landfills and dumps (Tanabe 1988) and represent a potential source of environmental contamination. An additional 43,000 tons have been degraded or incinerated (Tanabe 1988). Long range atmospheric and oceanic transport seem to be the primary mechanism of global PCB dispersal (Kannan et al. 1989).

Chemical and Biochemical Properties

General

Polychlorinated biphenyls, a highly lipophilic group of global pollutants, consist of 209 congeners (Fig. 1) with widely different toxicity and other biological effects (Kannan et al. 1989). In vertebrates, toxicological effects of PCBs have been related to their ability to induce the cytochrome P450-dependent monooxygenase system (P450). This varies with the degree of chlorination and the arrangement of chlorine atoms on the biphenyl molecule (Skaare et al. 1991). Transformation of PCBs to hydroxylated metabolites by the cytochrome P450 system is the major pathway of PCB metabolism (Sipes and Schnellmann 1987) and occurs mainly in the liver. The rate of cytochrome P450-catalyzed hydroxylation of PCBs decreases as the number of chlorines increases and as the number of unsubstituted adjacent carbon atoms decreases. Some animals metabolize PCBs at different rates, and this is related in part to differences in the basal level of particular isozymes of cytochrome P450 present in liver. For example, the dog eliminates PCBs more rapidly than other species because it has higher levels of a constitutive isozyme of cytochrome P450 with activity toward the slowly metabolized, bioaccumulated 2,2',4,4',5,5'-hexachlorobiphenyl (Hansen 1987; Sipes and Schnellmann 1987). The reactive arene oxides formed during biotransformation can bind covalently to tissue macromolecules or conjugate with glutathione. Derivatives of glutathione conjugates and glucuronides of the hydroxylated products are major PCB metabolites. Biotransformation of xenobiotics by cytochrome P450 is not always beneficial to the organism because metabolites can be more toxic or biologically active than the parent compound (Parkinson and Safe 1987). The carcinogenic effect of certain xenobiotics depends on the conversion by cytochrome P450 to a reactive carcinogenic metabolite (Parkinson and Safe 1987). Metabolites and possible degradation pathways of selected PCBs in mammals are presented in detail by Sipes and Schnellmann (1987).

Sedimentation and volatilization are the dominant processes that determine the fate of PCBs in lakes. Both processes remove PCBs from the water, but the relative importance of the transferred amount is influenced by particulate dissolved-phase partitioning that determines the relative size of the particulate pool for sedimentation and the soluble pool for volatilization of PCBs (Millard et al. 1993). High productivity of algae increased the proportion of added PCBs that is absorbed to particulate matter and sedimented. In general, PCB volatilization losses increase under conditions of high mixing and low productivity (Millard et al. 1993).

Table 1. Estimated PCB loads in the global environment (Tanabe 1988).

Ecosystem	PCB loads, in metric tons
Terrestrial and Coastal	
Air	500
River and Lakewater	3,500
Seawater	2,400
Soil	2,400
Sediment	130,000
Biota	4,300
Open Ocean	
Air	790
Seawater	230,000
Sediment	110
Biota	270
Total (rounded)	374,000

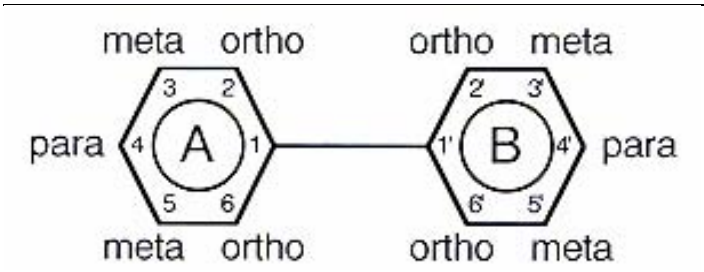

Figure 1. Structure of biphenyl (National Academy of Sciences 1979; U.S. Environmental Protection Agency 1980; Safe 1984, 1994; Eisler 1986). Polychlorinated biphenyls (PCBs) are commercially produced by chlorination of a biphenyl with anhydrous chlorine in the presence of iron filings or ferric chloride as the catalyst. Depending on the conditions under which chlorination occurred, the purified product is a complex mixture of chlorobiphenyls containing 18 to 79% chlorine. Ten possible degrees of chlorination of the biphenyl group produce 10 PCB congener groups: mono-, di-, tri-, tetra-, penta-, hexa-, hepta-, octa-, nona-, and decachlorobiphenyl. Within any congener group, a number of positional isomers are possible. For example, the tetrachlorobiphenyl group consists of 30 possible isomers and the pentachlorobiphenyl congener group contains 46 possible isomers. Not all of the 209 possible isomers are likely to be formed during the manufacturing process. In general, the most common PCB isomers formed have either an equal number of chlorine atoms on both rings, or a difference of one chlorine atom between rings. Chlorine substitution is favored at the ortho and para positions; however, commercial products are complex mixtures of isomers and congeners with no apparent positional preference for halogen substitution.

Physical Properties

Mullin et al. (1984) synthesized and determined the retention times and response factors relative to a reference standard (octachloronaphthalene) of all 209 congeners (Table 2) by using temperature-programmed, high resolution gas chromatography, and electron-capture detection methods (HRGC/ECD). The relative retention times (the ratio of congener retention time/reference standard retention time) of 187 of the 209 congeners differed and permitted HRGC column identification contingent on full or partial separation. Eleven congener pairs had the same retention times and coeluted: 60/56, 70/76, 94/61, 95/80, 133/122, 140/139, 144/135, 145/81, 163/160, 202/171, and 203/196. Of the 209 congeners, 20 can assume a planar configuration (Creaser and Al-Haddad 1989) because of the absence of chlorine substitution in the *ortho* positions (Hong et al. 1992; Fig. 1). Approximately 1% of the non-*ortho*-substituted biphenyl molecules adopt the planar configuration (Safe 1987a). Among the isomers of each homolog, the planar PCBs had the longest retention times. The presence of *ortho*-chloro substituents reduces planarity of the rings. However, congeners with 1 or 2

ortho chlorines can also assume a planar ring position (Safe 1990). Although peak resolution is greatly improved by substitution of high resolution capillary columns for packed columns, more than one candidate congener may occur at many GC peaks. Using a narrow bore column, Duinker et al. (1988a) found only 17 PCB congeners that were fully separated without potential interference from coeluting congeners.

[c] Gas chromatography peak area response of PCB relative to peak area of 1 ng of octachloronaphthalene.

[d] K_{ow} (octanol-water partition coefficient) = C_{ow}/C_{wo}, where C_{ow} is the concentration of the solute in octanol saturated with water, and C_{wo} is the concentration of the solute in water saturated with octanol.

[e] — = no data.

The transport and fate of PCBs in aquatic systems and their partitioning between sediment, water, and organisms depends largely on sorption reactions. In soils, the sorption and retention of PCB congeners is influenced by the number of chlorine atoms in the molecule, and the more highly-chlorinated PCBs tend to be more strongly bound. Relative sorption capacity and other properties of congeners also depend on PCB configuration. The soil sorption capacities of PCB congeners and their bioconcentration factors were related to octanol-water partition coefficients (Connor 1984) as follows:

$$K_{ow} = C_{ow} / C_{wo}$$

where K_{ow} is the octanol-water partition coefficient, C_{ow} the concentration of the solute in octanol saturated with water, and C_{wo} the concentration of the solute in water saturated with octanol.

K_{ow} values are used to estimate bioconcentration factors (bioaccumulation after uptake from water), soil and sediment organic carbon-water partition coefficients, toxicities, and aqueous solubilities (Woodburn et al. 1987; Hawker and Connell 1988). Techniques for measuring the K_{ow} values include the shake-flask method (Shiu and Mackay 1986), the reverse-phase thin-layer chromatography (Bruggeman et al. 1982), reverse-phase high-performance liquid chromatography (Rapaport and Eisenreich 1984), and the generator column technique (Woodburn et al. 1987; Hawker and Connell 1988), or it may be calculated by an estimation technique based on correlation with properties of compounds with known K_{ow} values. From a strong linear relation calculated between known log K_{ow} values and calculated total surface areas (TSA; correlation coefficient of 0.951 for 30 congeners), Hawker and Connell (1988) estimated K_{ow} values of individual congeners from the calculated TSA. Estimated K_{ow} values (Table 2) were previously unavailable of many PCB congeners, including toxic non-*ortho* substituted congeners found only in relatively small amounts in commercial Aroclors. Reported K_{ow} values of

some congeners vary in the literature and may not be comparable when different measuring techniques are used. Reverse-phase thin-layer chromatography (RP-TLC) and high-performance liquid chromatography (RP-HPLC) require empirical correction factors. Discrepancies in K_{OW} values between the generator column and RP-HPLC techniques for *ortho* PCBs relative to the other PCBs were resolved with an *ortho* correction factor (Woodburn et al. 1987). Non-planarity of the *ortho*-substituted PCBs may reduce the ability of the solute to interact with the stationary phase in RP-TLC (Bruggeman et al. 1982). Despite these uncertainties, the K_{OW} is routinely used in hazard evaluation and risk assessment of most organic chemicals.

Toxic Equivalency Factors

A significant part of the toxicity associated with commercial PCB mixtures is related to the presence of the small number of planar congeners. These compounds induce several similar toxic effects in mammals and birds, such as hepatotoxicity, immunotoxicity, and reproductive toxicity (Janz and Metcalfe 1991b; Brunstrom et al. 1995). Planar halogenated aromatic compounds act, in part, by a common mechanism initiated by binding to a cytosolic aryl hydrocarbon receptor. The relative toxicities of planar halogenated hydrocarbons are calculated by expressing their toxicity in relation to 2,3,7,8-TCDD, the most potent compound in this class of chemicals. Toxic equivalency factors (TEFs) are fractional potencies that relate a compound's potency to that of 2,3,7,8-TCDD. The 2,3,7,8-TCDD TEF has been used to estimate the relative toxic potencies of individual planar halogenated hydrocarbons (Safe 1987b; 1990, 1994; Janz and Metcalfe 1991b; Johansen et al. 1993). According to Safe (1990), TEF values should be derived from data on the following effects in descending order of priority: (1) long-term carcinogenicity studies; (2) reproductive studies; (3) subchronic studies that measure Ah receptor-mediated responses, such as thymic atrophy, loss in body weight, and immunotoxicity; (4) acute toxicity studies; and (5) in vivo or in vitro biochemical responses such as enzyme induction and receptor binding. Relative toxic potencies are modified by many variables including age, sex, species, and strain of the animal; the efficiency of the chemical to induce cytochrome P450 and associated monooxygenase enzyme activities, glucuronosyl and glutathione transferases, and other drug-metabolizing enzymes; and the efficiency of the organism to modulate steroid-metabolizing enzymes, induce delta aminolevulinic acid synthetase, inhibit porphyrinogen decarboxylase, decrease Ah receptor binding activity, and alter Vitamin A and thyroid hormone levels (Safe 1990, 1994).

The in vitro induction of the cytochrome P450c-dependent monooxygenases, aryl hydrocarbon hydroxylase, (AHH), or ethoxyresorufin *O*-deethylase, (EROD) by 2,3,7,8-TCDD and related halogenated aryl hydrocarbons in rat liver cells was developed as a short term quantitative bioassay for these chemicals; aromatics that do not fit this correlation are considered as congeners that are readily metabolized in vivo (Safe 1987b). Induction of either AHH or EROD activity in the H4IIE rat hepatoma cell line by PCB, PCDF, and PCDD congeners, either singly or in combination, correlates well with the in vivo toxicity of these compounds to rats (as quoted in Ankley et al. 1991). The proposed mean TEF values range up to 0.1 in non-*ortho* substituted planar PCBs, 0.0005 in mono-*ortho* substituted planar PCBs, and 0.0001 in di-*ortho* substituted planar PCBs (Table 3). Although the concentration of non-and mono-*ortho* substituted PCBs in animal tissues ranges from about 0.01 ug/kg to several micrograms per kg (about 1,000 to 100,000 times lower than the sum of total PCBs), it is significantly higher than the concentration of the highly toxic 2,3,7,8-TCDD and 2,3,4,7,8-pentachloro-dibenzofuran. Accordingly, the non- and mono-*ortho* PCBs—despite their lower toxic potency—often contribute as much or more to the 2,3,7,8-TCDD-like activity than either dioxins or furans (Johansen et al. 1993). However, the overall importance of mono-*ortho* PCBs to the TEF is questioned by Ahlborg et al. (1994), and this must be considered in future risk assessment evaluations.

A note of caution: recent studies revealed that mammal-derived TEFs underestimate the potency of planar PCB mixtures in fish (Newsted et al. 1995). For example, TEFs of non-*ortho* PCB congeners based on mortality of rainbow trout in early life stage are as much as 1,000 times lower than TEFs proposed for human risk assessment (Walker and Peterson 1991, 1994).

Table 3. Proposed toxicity equivalency values (TEF) relative to 2,3,7,8-TCDD of non-*ortho*, mono-*ortho*, and di-*ortho* planar PCBs (Safe 1990, 1994; Ahlborg et al. 1994).

PCB congener	TEF

PCB 170	0.0001
PCB 180	0.00001

Structure-Function Relations

Safe (1984, 1990) described three classes of PCB congeners on the basis of their ability to induce benzo(a)pyrene hydroxylase (also known as aryl hydrocarbon hydroxylase or AHH) and ethoxyresorufin *O*-deethylase (EROD) activities: (1) planar PCBs; (2) mono-*ortho* analogs of the planar PCBs; and (3) di-*ortho* analogs of the planar PCBs. Among the 20 possible planar PCB congeners and their analogs (Fig. 2), the most toxic in rats were PCBs 77, 126, and 169; these three congeners are approximate isostereomers of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (2,3,7,8-TCDD) and have similar toxic effects, including induction of 3-methylcholanthrene type drug-metabolizing enzymes, body weight loss, thymic atrophy, dermal disorders, hepatic damage, high binding affinity to hepatic cytosolic receptor proteins, immunotoxicity, reproductive impairment, and teratogenicity (Masse et al. 1986; Parkinson and Safe 1987; Tanabe et al. 1987; Gooch et al. 1989; Kannan et al. 1989; Janz et al. 1992; Himberg 1993; Giesy et al. 1994a). PCBs 77, 126, and 169 have been detected in eggs of terns from Lake Michigan, in marine mammals and humans, and in fish from the Hudson and Ohio Rivers (Huckins et al. 1988). However, they are difficult to detect without proper methods (Tanabe 1988; Schwartz et al. 1993).

The structural characteristics of individual PCB congeners influence their induction of various P450 activities. In mammals, PCB congeners have been characterized as 3-methylcholanthrene-type inducers, phenobarbital-type inducers, or mixed-type inducers of both. AHH and EROD activities (which are preferentially catalyzed by the P450IA gene subfamily) have been induced by planar PCBs in fish and mammals and by some mono-and di-*ortho* analogs of planar PCBs in mammals (Skaare et al. 1991).

The mechanism of toxic action of planar and mono-*ortho* planar PCBs is linked to an interaction with the 2,3,7,8-TCDD (or Ah) receptor protein. But this mechanism does not account for all observed PCB toxicities (Hansen 1987; Safe 1994). Toxic responses unrelated to Ah receptor effects have been reported of PCBs 4, 28, 31, 49, 52, 84, 95, 110, 136, and 153. For example, PCB 153 is less cytotoxic than PCB 169 but is a more effective inhibitor of intercellular communication. PCB 52 caused moderate chick embryotoxicity; however, PCBs 18 and 153 were inactive, and PCBs 84 and 118 were severely toxic but by different mechanisms (Hansen 1987).

Group I planar PCBs are 10 times more toxic and 100 times more effective as inducers of cytochrome P450c dependent monooxygenase and 70 times more effective in competitively displacing 2,3,7,8-TCDD from a rat cytosol receptor protein than Group II planar PCBs (Table 4; Safe 1990; Fig. 2). Mono-*ortho* analogs of the planar PCBs have one substituent in the *ortho* (2 or 2') position; these compounds possess diminished yet

significant EROD- or AHH-inducing capacity and also induce P450 forms that are induced by the phenobarbital class of compounds (Gooch et al. 1989). Mono-*ortho* derivatives (PCBs 105, 118, 156, and 189) may be more important in terms of 2,3,7,8-TCDD-like activity and in occurrence (Hansen 1987). Di-*ortho* analogs of the planar PCBs, that is, those with *ortho*-, *meta*-, and *para*-substituents, possess still weaker but significant AHH-inducing activity (Gooch et al. 1989). Certain di-*ortho* derivatives of the 3,3',4,4' pattern (PCBs 128, 138, 153, 170, 180) are significant components of PCB residues; however, PCBs 128, 138, and 170 have reduced 2,3,7,8-TCDD-like effects (Hansen 1987). In rats, several PCBs (105, 114, 118, 123, 126, 156, 157, 169) produced a linear correlation between the EC50 response (in vitro) of AHH induction against the ED50 (in vivo) of body weight loss, thymic atrophy, hepatic AHH, and EROD induction (Safe 1987b). The planar mono- and di-*ortho* derivatives (PCBs 105, 118, 156, 189, 128, 138, 153, 170, 180) are referred to as mixed inducers because they elicit effects similar to coadministration of phenobarbital plus methylcholanthrene (Hansen 1987).

PCB 156, a mixed inducer of microsomal enzymes, significantly increases the incidences of cleft palates by 2,3,7,8-TCDD in rodents (Birnbaum et al. 1985). Interactions among polychlorinated congeners may range from antagonism to additivity to synergism (Safe 1990), and the toxicity of individual PCBs can be raised by interaction with other PCBs (Table 5).

Quantitation

PCBs are chemically inert, non-polar compounds and relatively stable during collection and storage; however, PCB concentrations in environmental samples vary with different measurement techniques (Kratochvil et al. 1984; Huckins et al. 1990b; Lebo et al. 1992; Prest et al. 1992; Bidleman et al. 1993; Litten et al. 1993), with types of Aroclor standards used for calibration (Table 6), and with oven drying techniques (Table 7). Reports of interlaboratory comparison studies for PCB analysis show wide variations and strongly indicate a need for more rigorous quality control and assurance. In one multilaboratory study (Alford-Stevens 1988)—wherein PCBs were determined in water, soil, and sediments—percent recoveries from analysis of fortified waters averaged 60% in the high concentration sample containing 148 µg/L total PCBs and 55% in the low concentration sample of 37 µg/L. No single combination of extraction and cleanup was best for all solid samples. An analytical intercomparison exercise (International Council for the Exploration of the Sea [ICES] 1992) was conducted on solutions containing 10 PCB congeners. Of the 61 evaluated laboratories, a group of 47 laboratories produced between-group standard deviations of 1.10-1.13 by all PCB congeners except PCB 52; a group of 11 laboratories were identified as an outlier group. Only three laboratories were able to quantify PCBs 110 and 77, which coelute in most GC columns. Peak height measurements gave better reproducibility than peak area methods. In another intercomparison study, the analysis by 11 laboratories of a solution containing 12 pure congeners resulted in a variation of as much as 20% for analysis of a single congener. For the analysis of the same congeners in a fish oil, the coefficient of variation ranged from 17.4 to 132% (66.2% without outliers) and had a median of 47.1% (ICES 1992).

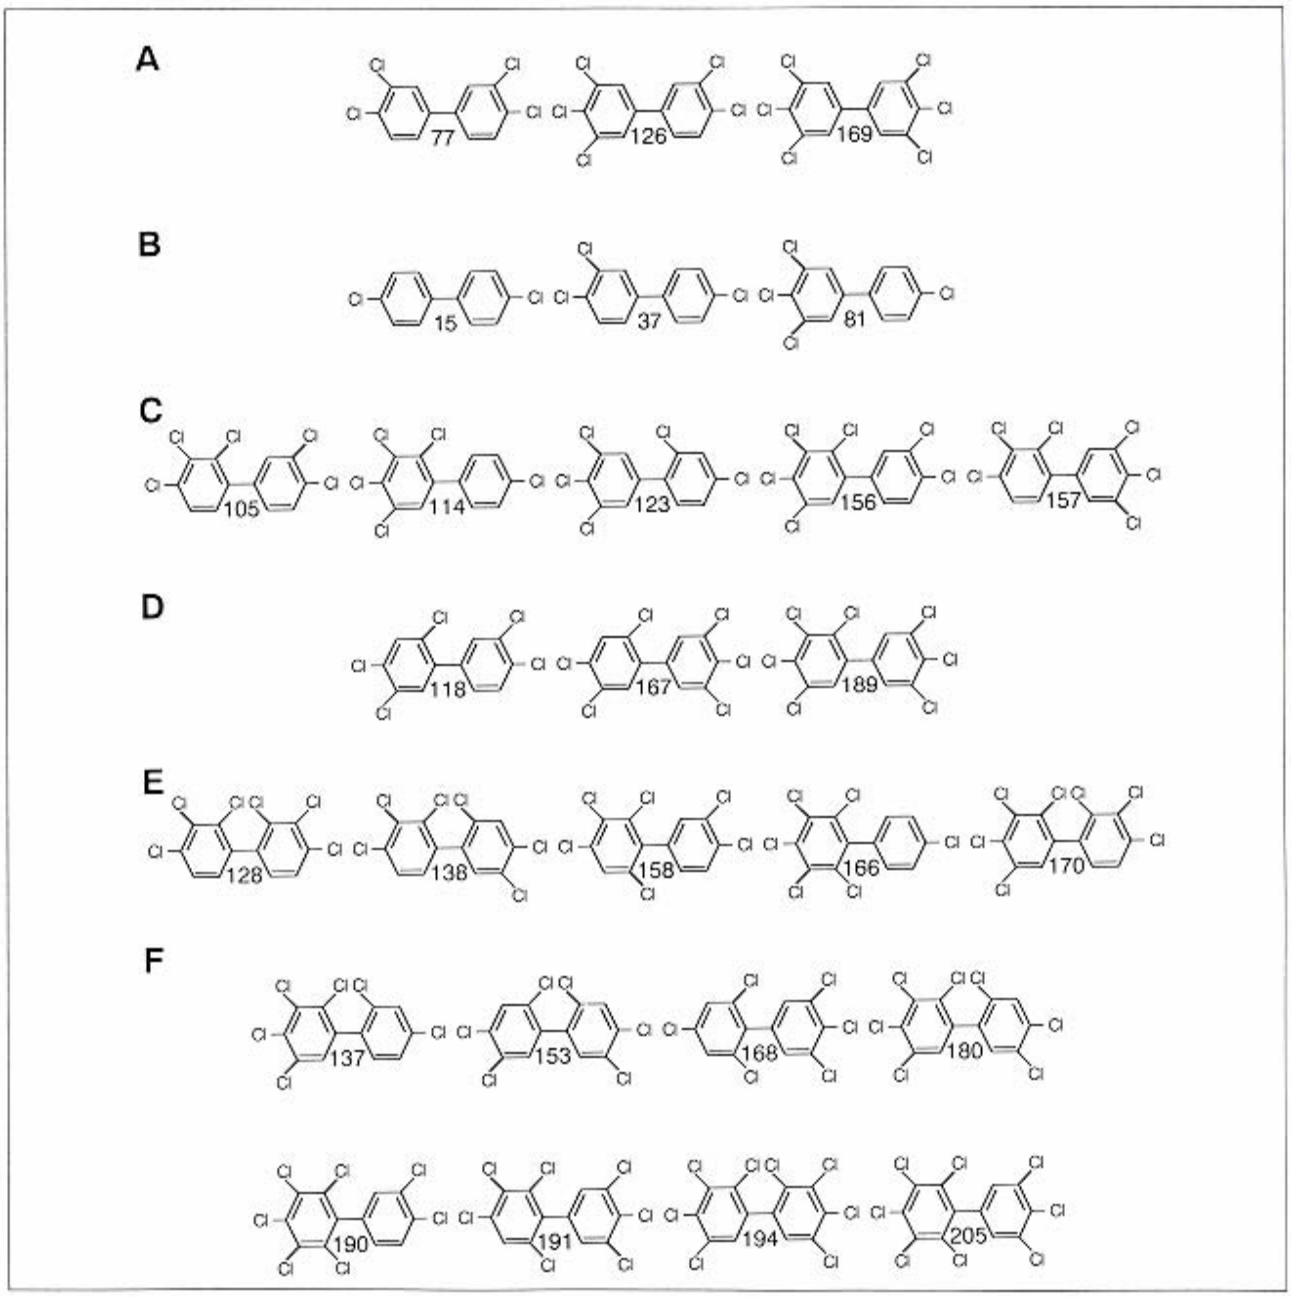

Figure 2. Planar polychlorinated biphenyls and their derivatives (Hansen 1987; Parkinson and Safe 1987; Safe 1987b, 1994; Tanabe et al. 1987; Kannan et al. 1989; de Voogt et al. 1990; Ankley et al. 1991; Sonzogni et al. 1991; Hong et al. 1992; Johansen et al. 1993). The general order of biological activity is: Group I non-*ortho* planar PCBs > Group II non-*ortho* planar PCBs > mono-*ortho* planar PCBs > di-*ortho* planar PCBs. A. Group I. Potent non-*ortho* planar PCBs. This group contains no *ortho*, 2 *para* and at least 2 *meta*-chlorines (PCBs 77, 126, and 169), and are approximate stereoisomers of 2,3,7,8-tetrachlorodibenzo-p-dioxin (2,3,7,8-TCDD). They are less potent than 2,3,7,8-TCDD but elicit similar biological responses including induction of cytochrome P450 and aryl hydrocarbon hydroxylase (AHH). This group is the most biologically active of all planar PCBs and their derivatives. B. Group II. Less-potent non-*ortho* planar PCBs (PCBs 15, 37, and 81). Group II non-*ortho* planar PCBs, when compared to Group I, were only 0.1 times as toxic, 0.01 times as effective in inducing cytochrome P455c-dependent monooxygenase, and about 0.015 times as effective in competitively displacing 2,3,7,8-TCDD from a cytosol-receptor protein in rat liver. C. Potent mono-*ortho* planar PCBs. The addition of a single *ortho*-

chlorine substituent to non-*ortho* planar PCBs 77, 81, 126, and 169 yields 8 derivatives, of which 5 (PCBs 105, 114, 123, 156, 157) were more potent when the *ortho* chlorine was adjacent to a meta hydrogen. D. Less-potent mono-ortho planar PCBs. The toxicity of non-*ortho* planar PCBs is reduced by the introduction of an *ortho*-chloro substituent, especially when it is adjacent to a *meta*-chlorine (PCBs 118, 167, 189). E. Potent di-*ortho* planar PCBs. The di-*ortho* planar PCBs are less toxic than the mono-*ortho* planar PCBs. At least 5 di-*ortho* derivatives (PCBs 128, 138, 158, 166, 170) compete with 2,3,7,8-TCDD for receptor binding sites in rat liver cytosol to induce cytochrome P450c. F. Less-potent di-*ortho* planar PCBs. These 8 di-*ortho* derivatives (PCBs 137, 153, 168, 180, 190, 191, 194, 205) are less potent than those figured in E.

Table 4. Interactive effects of PCBs on the induction of rat (*Rattus* sp.) liver microsomal cytochrome P450c (Parkinson and Safe 1987).

PCB congener and dose (µmol/kg body weight)	Microsomal enzyme activity, (nmoles product/mg protein/min)	
	Benzo (a)pyrene	Ethoxyresorufin *O*-deethylase
Control, corn oil	0.088	0.277
PCB 153 (300)	0.121	0.530
PCB 126 (0.01)	0.486	3.60

PCBs in biological samples are usually extracted by a Soxhlet column and with a nonpolar solvent such as hexane; the sample is first mixed with sodium sulfate to remove moisture. The extraction of PCBs from sediments was tested with sonication, with two sonications interspersed at a 24-h quiescent interval, with steam distillation, or with Soxhlet extraction (Dunnivant and Elzerman 1988). Comparison of the recoveries of various PCB mixtures from dry and wet sediments by the four techniques and the extraction efficiency of four solvents showed that the best overall recoveries were obtained by Soxhlet extraction and the two sonication procedures. In comparisons of solvent systems of acetone, acetonitrile, acetone-hexane (1+1), and water-acetone-isooctane (5+1.5+1), recoveries of lower chlorinated congeners (dichloro- to tetrachloro-) were usually higher with acetonitrile and recoveries of higher chlorinated congeners (tetrachloro- to heptachloro-) extracted with acetone were superior (Dunnivant and Elzerman 1988). The completeness of extraction from a sample matrix does not seem to discriminate against specific isomers; however, discrimination in the cleanup and fractionation process may occur and must be tested (Duinker et al. 1988b).

With most analytical techniques for the quantification of PCB residue levels, chromatographic separations were used, most frequently electron-capture gas chromatography (GC/ECD). With early methods, selected peaks were used to estimate total PCBs. Low resolution separations were satisfactory when packed columns that produced a pattern of peaks with measured areas were used. The patterns were compared with known amounts of Aroclor mixtures. If the Aroclor peaks in a sample closely resembled a particular Aroclor reference mixture of known weight, the total area or peak height of the sample PCBs was compared to those of the reference mixture and the weight of calculated sample PCBs (Kaiser et al. 1980). Other investigators used selected peaks to report Aroclor equivalents (Draper et al. 1991; Turle et al. 1991), but these methods are not useful when samples and Aroclor standards are dissimilar. For another procedure, response factors were used for individual Aroclor peaks as determined by GC and GC-MS procedures (Webb and McCall 1973). The sample peaks were compared with peaks from common Aroclors obtained on packed columns; retention time

windows for the early, middle, and late-eluting peaks were assigned to 3 Aroclors (1242, 1254, 1260) based on the presence or absence of specific peaks. The weight of PCB in the sample peak was calculated by multiplying its peak area by the appropriate response factor; all peaks were added to obtain a total weight of PCB. However, packed columns failed to separate and to identify many congeners because several congeners usually eluted under a single peak of identical retention time. These methods do not account for changes in composition from: interfering compounds; congener changes from hydrolysis, photodegradation, and biodegradation; selective evaporation and adsorption of certain isomers; or solubility differences resulting in different partitioning ratios among the various environmental compartments. Some researchers, who used capillary columns, estimated PCB residues on the basis of a relatively simple cleanup and analysis by high resolution GC-ECD (Duinker et al. 1988b; Maack and Sonzogni 1988; Sericano et al. 1990; Draper et al. 1991) or by HRGC/MS (Porte et al. 1988; Niimi and Oliver 1989; Harrad et al. 1992); others emphasized total PCBs, homolog subgroups, or individual congeners present in substantial amounts in the sample or in commercial mixtures (Maack and Sonzogni 1988; Niimi and Oliver 1989). And still others used total PCBs derived from the sum of homolog subgroup concentrations (Gebhart et al. 1985; Sericano et al. 1990), concentrations of individual subgroups (Gebhart et al. 1985), or the contribution of all congeners in each subgroup (Niimi and Oliver 1989).

Gas chromatography/ mass spectrometry in the electron ionization mode (GC/MS-EI) has been used to a more limited extent for routine analysis of PCBs (Alford-Stevens et al. 1985; Kuehl et al. 1991). Some interference with quantification ions can occur with EI when compounds such as PCBs 77 and 110 coelute. GC/MS has also been operated in the negative chemical ionization mode (NCI) for PCB determinations (Guevremont et al. 1987; Swackhammer et al. 1987; Erhardt-Zwabik et al. 1990). Increased selectivity is observed in the NCI mode, although interference from other compounds that readily form stable negative ions may be observed. Improvements have also been made in capillary column separations. However, the application of single long, narrow bore capillary columns does not enable investigators to attain full separation of PCB congeners (Ballschmiter and Zell 1980; Bush et al 1983; Mullin et al. 1984; Duinker et al. 1988b). Multidimensional GC (MDGC) analysis of PCBs drastically improved congener separations and the analysis of all sample constituents. Schomburg et al. (1985) connected two capillary columns of different polarities in a double oven instrument; the first column was temperature programmed, and the second was operated isothermally. Congeners of Clophen A 50 were separated by valveless flow switching. Using MDGC techniques, Duinker et al. (1988a, 1988b) analyzed PCBs 28, 52, 101, 138, 153, and 180 and positively identified PCBs 52, 101, and 180 as well as coeluting peaks of PCBs 24, 26, 29, 44, 49, 81, 84, 114, 128, 151, 169, 177, 183, 187, 189 and 194. In a following paper, Schultz et al. (1989) used the same MDGC technique to fully resolve all congeners in commercial PCB mixtures of Clophen A30, A40, A50, A60 and in Aroclors 1221, 1016, 1242, 1254, and 1260. A column of SE-54 with ECD was used to monitor the eluate, and a second, more polar column (usually OV-210) with ECD was used to obtain fully resolved single peaks. The procedure required exact timing of cuts based on retention time but fully separated the PCB congeners by gas chromatography for the first time. A total of 132 congeners at concentrations above 0.05% (w/w) were eluted as fully resolved single peaks and measured (Schultz et al. 1989).

Pattern recognition techniques that incorporate statistical methods have been used to determine spatial and temporal patterns in PCB residue data. Stalling et al. (1980, 1987), for example, characterized sample PCB profiles from 105 individual congeners, measured parameters of similarity between sample and standard mixtures, and determined whether the sample residue pattern corresponded to an Aroclor mixture. Modeling environmental samples with the individual congener concentrations provided more accurate estimations of Aroclor profiles than homolog concentrations. Intact commercial Aroclors have been characterized by automated mass spectrometric determination of weight percent distribution by homolog groups (Alford-Stevens

1986). One isomer from each level of chlorination was normally used to calibrate the MS response to all measurable isomers in that group. In another example, Macdonald et al. (1992) applied pattern recognition techniques to assess biomagnification and to characterize source patterns of multicomponent pollutants such as PCBs, PCDDs, and PCDFs in eggs of the herring gull (*Larus argentatus*) from the Great Lakes between 1983 and 1990. Turle et al. (1991) fitted a linear regression to PCB concentrations in herring gull eggs from the Great Lakes during 1970-85 and from more recent measurements. Aroclor equivalents in eggs were determined with PCB 138 as a single peak estimate for the older data and more recent PCB data as the sum of 41 congeners. The earlier choice of PCB 138 for quantitation seemed fortunate; uptake of heptachloro isomers maintained a stable percentage of total PCB egg residues over time, whereas less chlorinated congeners generally declined and more chlorinated congeners increased over time (Turle et al. 1991).

Methods were developed for routine analysis of AHH-inducing and other PCB congeners in fish by using a comparatively simple gel permeation chromatography (GPC) cleanup and GC/MS-NCI (Schmidt and Hesselberg 1992). Methane was used as the reagent gas for NCI, source temperature and pressure were optimized (1100 C and 0.9 Torr), and fragmentation of the major ions was reduced as much as 10%. A peak area correction factor for interfering ion fragmentation was obtained by instrument calibration with standards and manually applied to coeluting ions as needed (Schmidt and Hesselberg 1992). Additional methods were developed for the analysis of planar congeners. Using a carbon foam adsorbent, Huckins et al. (1978, 1980, 1988) devised procedures for the analysis of toxic non-*ortho*-chloro substituted PCB congeners and trace planar impurities in Aroclors. With carbon-foam chromatography (carbon particles suspended on a polyurethane substrate), concentrations of planar PCB congeners in Aroclors 1016, 1242, 1248, 1254, and 1260 were detected by high resolution electron capture gas chromatography (HRGC/ECD). With current chemical methods for analysis of non-*ortho*-chloro substituted planar PCBs, extraction and a preliminary clean-up, carbon chromatography, and HRGC/ECD or HRGC/MS are generally used (Feltz et al. 1995). The brands of carbon available for isolating planar PCBs include Amoco AX-21 (PX-21), Alltech SK-4, Serva SP-1, and Wako active carbon (Storr-Hansen and Cederberg 1992). All methods shared at least three characteristics: (1) they require some form of adsorption chromatography (usually with carbon) to isolate planar compounds; (2) they include several clean-up steps; and (3) they are complicated.

A semipermeable membrane device (SPMD) with a nonpolar, low density polymeric film is used to separate PCBs from large amounts (20-50 g) of lipids by dialysis in an organic solvent prior to chemical analysis (Huckins et al. 1990a; Meadows et al. 1993). Liquid-liquid phase partitioning of extracts in organic solvent with sulfuric acid has been used to convert fats and pigments into water-soluble compounds that can be separated and removed from the target analytes with water rinses. Fats may be removed by refluxing or partitioning extracts with alcoholic potassium hydroxide to form water soluble hydrolysis products. For example, Tanabe et al. (1987) and Kannan et al. (1987b) combined alkali digestion, active carbon column chromatography, fuming sulfuric acid clean-up, HRGC/ECD, and HRGC/MS confirmation for the analysis of PCBs 77, 126, and 169 in porpoise blubber. Measurement of these three highly toxic PCBs in Aroclor and Kanechlor mixtures is reported by Kannan et al. (1987a). Creaser and Al-Haddad (1989) separated five non-*ortho* substituted PCBs from a synthetic mixture containing Aroclors, organochlorine and organophosphorus pesticides, dioxins, and dibenzofurans on an HPLC column packing of porous graphite carbon (PGC). Soil samples required prior cleanup to remove coextracted organics, and elution from a multilayered column containing acid, base, and silica was followed by elution from Florisil.

Procedures are available for separating mono- and non-*ortho* chloro PCBs. Hong and Bush (1990) used sulfuric acid cleanup, low-pressure liquid chromatography with activated carbon/silica gel and HRGC/ECD to analyze four non-*ortho* and eight mono-*ortho* substituted PCBs. Haglund et al. (1990) used a non-carbon HPLC column of 2-(1-pyrenyl)ethyldimethylsylated silica (PYE) column to isolate mono- and non-*ortho* chloro PCBs from tissue samples. Isolation with this column required almost complete prior removal of lipids by sulfuric acid partitioning and subsequent gel permeation chromatography (GPC) with Bio-Beads S-X3 to remove remaining lipids. Ford et al. (1993) adapted an automated dioxin analysis system with programmable pump and valve setup for the sequential processing of non-*ortho* substituted PCBs in five blubber samples. The procedure included ball/mill tissue extraction, preliminary GPC separation and cleanup, silica gel chromatography, and automated separation of non-*ortho* substituted PCBs on AX21 activated carbon/glass fiber with three solvent systems and was followed by GC-ECD and GC/MS-EI analysis with selected ion monitoring (SIM). The application of high resolution capillary column techniques combined with the development of carbon adsorbents for the separation of planar aromatics has become a powerful tool for the identification and measurement of

single congeners in complex PCB mixtures and have facilitated the resolution and more accurate quantification of individual congeners and the correction of the presence of non-PCB interferences. But the introduction of such methods in long-term monitoring programs, where one, several, or all peaks in Aroclor standard mixtures were used to estimate total PCBs, raises the problem of comparing results among the data sets. For such purposes a value for total Aroclor can also be reported (Porte et al. 1988; Turle et al. 1991).

Concentrations in Field Collections

General

An increasing number of reports indicate the widespread presence of toxic planar PCB congeners such as the non-*ortho* substituted planar PCBs 77, 126, and 169. These PCB congeners were detectable in all Finnish food commodities of animal origin sold in Helsinki (Himberg 1993); in all samples of salmon muscle, cod liver, and seal blubber from the Baltic Sea and environs in the 1980s (Koistinen 1990); and at concentrations between 0.03-30 µg/kg fat fresh weight (FW) in a wide variety of vertebrates, including fish, marine mammals, dogs, cats, and humans (Tanabe et al. 1987). These and other planar congeners contribute the majority of the toxic potency to PCB mixtures as judged by their ability to induce AHH and EROD (Kannan et al. 1989; Ankley et al. 1991; Sonzogni et al. 1991). Detection of these toxic residues in field collections from remote areas suggests that planar PCBs are now as widely distributed as other PCB isomers (Tanabe et al. 1987). The clear positive correlation between concentrations of total PCBs and PCBs 77, 126, and 169 in all analyzed mammals suggest that the sources of planar PCB contamination to the environment are mainly commercial PCB formulations (Tanabe et al. 1987).

Nonbiological Materials

Relatively little contamination from PCBs was found in sediments from riverine and pothole wetlands at national wildlife refuges and waterfowl production areas (WPA) in the north central United States in 1980-82. PCBs were above detection levels (20 µg/kg) in less than 4% of the sediments; a similar case was recorded in fish from WPAs (Martin and Hartman 1985). Maximum total PCB concentrations in field collections of nonbiological materials were 0.000028 µg/kg in ice, 0.000125 µg/kg in snow, 12.3 µg/m^3 in air, 233 µg/L in seawater, 3,860 µg/L in sediment interstitial waters, and 1,800 mg/kg in sediments. Concentrations were comparatively elevated in urban areas, near anthropogenic activities, and at known sites of PCB contamination (Table 8).

Atmospheric transport is a major route in PCB distribution (Swackhammer et al. 1988). Deposition and evaporation studies of 17 PCB congeners in Siskiwit Lake on Isle Royale, Michigan, showed that PCB input fluxes to the lake from rain, snow, and aerosol equalled output fluxes from sedimentation and evaporation. The magnitude of the net vapor flux, calculated by difference and with the assumption that inputs equal outputs, was large and positive for almost all 17 congeners (Swackhammer et al. 1988). Low but measurable PCB concentrations (measured as Aroclor 1254) were found in air, snow, ice, seawater, and sediment in the Arctic Ocean north of Axel Heiberg Island off Canada's northern outer coast (Hargrave et al. 1989). PCB residues were relatively high in melted snow (8-125 pg/L), indicating efficient scavenging from air. The ice island area from which surface seawater samples were collected was well removed from any direct influence of river drainage, and PCB concentrations probably reflect those over much of the Arctic Ocean (Hargrave et al. 1989). PCBs were also monitored in the atmosphere of Ross Island, Antarctica, from March 1988 to January 1990 (Larsson et al. 1992). The geometric mean of total PCBs in air during this period was 15.2 pg/m^3 and the maximum concentration was 12,300 pg/m^3. The geometric mean during the Antarctic summers of 1988-89 and 1989-90 was 21 pg/m^3. During one sampling period (16-28 December 1988), PCB levels were about 100 times higher than during any other period, suggesting either irregular, long-range transport of atmospheric pollutants or volatilization of PCBs from a local dumpsite at McMurdo Base on Ross Island. PCB levels did not correlate with seasonal temperature changes, although changes in atmospheric levels were recorded. The absence of seasonal differences may be due to the cold climate and the low vapor pressure of PCBs (Bidleman et al. 1983).

[b] 1, Larsson et al. 1992; 2, Hargrave et al. 1989; 3, Hargrave et al. 1992; 4, Burgess et al. 1993; 5, Boehm 1981; 6, Eisenreich et al. 1989; 7, Oliver et al. 1989; 8, Asplund et al. 1990; 9, Buser and Muller 1986; 10, NOAA 1987; 11, Chapman et al. 1986; 12, NOAA 1991; 13, Law and Goerlitz 1974; 14, Huckins et al. 1988; 15, Smith et al. 1990; 16, Martin and Hartman 1985; 17, Stainken and Rollwagen 1979; 18, Rhee et al. 1989; 19, Elzerman et al. 1991; 20, Dunnivant et al. 1989; 21, Ginn and Pastorok 1992; 22, Ankley et al. 1992.

PCB concentrations in sediment cores from Lake Ontario were similar to production and sales data of PCBs in the United States (Eisenreich et al. 1989). Annual PCB accumulation rates in the sediments rose from about 2 ng/cm^2 in 1950 to about 40 ng/cm^2 in the 1966-69 peak years and declined in 1980 to 10-20 ng/cm^2; about 50% of the 1966-69 load was attributed to the upward mixing by oligochaete worms (Eisenreich et al. 1989). Each of several PCB congeners in Lake Ontario sediments contributed 5.7 to 7.9% of the total PCBs (PCBs 66, 110, and 56/60) and others (including PCBs 44, 52, 70/76, 101, and 153) contributed 4.0-4.7% (Oliver and Niimi 1988; Oliver et al. 1989). Surficial sediments of Lake Ontario in 1981-86 contained elevated concentrations of organochlorine compounds, including mirex, chlorobenzenes, octachlorostyrenes, DDT, 2,3,7,8-TCDD, fluorinated aromatic compounds, and PCBs (Oliver et al. 1989). Among the identified congeners, PCBs 60 (5.7%) and 118 (2.6%) are AHH-active (Smith et al. 1990). The frequency of isomers of low chlorination decreased with core depth in sediments, remained fairly stable of hexa isomers, and increased with core depth of the more highly chlorinated congeners. This pattern with depth reflects the change in use pattern over time to less highly chlorinated PCBs such as Aroclor 1016. The more highly chlorinated congeners that are disproportionately present in deeper sediments may be due to stronger partitioning to sediment and higher hydrophobicity than those of less chlorinated congeners and to the positive correlation with their high octanol-water partition coefficients (Karickoff 1981). Anaerobic dechlorination was not evident in these sediments. This contradicts the findings of others who maintain that relatively high levels of less-chlorinated PCBs in the bottom (anaerobic) core sections of Hudson River sediments were due to anaerobic dechlorination (Brown et al. 1985). Oliver et al. (1989) concluded that the total mass of PCBs in Lake Ontario sediments was about 50 tons and sufficient to impact Lake Ontario for many years. Lake Michigan sediments, analyzed for 18 planar AHH-active PCBs, total PCBs, 2,3,7,8-TCDD, and 2,3,7,8 tetrachloro-*p*-dibenzofuran (2,3,7,8-TCDF), had elevated levels of PCBs 77, 126, and 169 (Smith et al. 1990). Results suggest that the contribution of toxic equivalents—that is, the sums of congeners after the raw congener concentrations were normalized by the TEF—was greater from PCBs 77, 126, and 169 than from 2,3,7,8-TCDD and 2,3,7,8-TCDF, even in environments with significant concentrations of dioxins and dibenzofurans (Smith et al. 1990). Sediments from the Waukegan Harbor, Illinois, in 1978 contained weathered mixtures of Aroclors 1242, 1248, and 1254. Total PCB concentrations were variable between stations and ranged from 10.6 mg/kg to 13,360 mg/kg DW; 3,3',4,4'-TCB residues ranged from 5 to 27,500 µg/kg DW, or about 0.16% of the total PCBs; concentrations were higher of 2,3,3',4,4'-PCB (102 to 131,000 µg/kg DW, or 0.66%; Huckins et al. 1988).

PCB homologs and total PCBs in water, sediments, and biota were measured in Hamilton Harbor on Lake Ontario and Wheatley Harbor on Lake Erie. Hamilton Harbour receives inputs from steel mills and an incinerator plant; Wheatley Harbour receives fish-processing plant wastes. Total PCBs in sediments ranged from 608 to 14,185 µg/kg DW in Hamilton Harbour and from 166 to 1,177 µg/kg DW in Wheatley Harbour (Mudroch et al. 1989). The high PCB value in Hamilton Harbor is similar to values reported earlier in Lake Erie sediments (Frank et al. 1977). Concentrations of lower chlorinated homologs were greater in water than in sediment in both harbors (Mudroch et al. 1989). Homolog patterns in biota (oligochaetes, snails, isopods, and fish) reflected patterns in sediments but not in water. Concentrations of penta- and hexachlorobiphenyls were dominant in the oligochaetes and sediment samples from Wheatley Harbour; concentrations of these homologs also predominated in Hamilton Harbour, but the differences were less pronounced. Particle size distribution of 82-98% silt and clay (63 µm) was similar in both harbors. The concentrations of several metals (Zn, Pb, Cu, and Cr) were much higher in Hamilton Harbor, but their effect on PCB bioaccumulation is unknown (Mudroch et al. 1989).

Contaminated sediments are a major source of PCBs in aquatic environments (Dillon and Burton 1992). PCB discharges prior to 1977 from capacitor manufacturing plants on the Hudson River at Ft. Edward and Harbor Falls, New York (14 kg PCBs daily for 30 years, mostly Aroclors 1242 and 1016), contaminated 306 km of river bed between Hudson Falls and New York Harbor. By 1978, an estimated 63,500 kg of PCBs were in the river bank deposits, 134,000 kg in the upper river, and 91,000 kg in the lower river (Brown et al. 1985; Eisler 1986; Bush et al. 1987; Kennish 1992). PCB concentrations in biota and the water column are largely controlled by PCB concentrations in surficial sediments. Declines in PCB levels in Hudson River sediments corresponded to decreased use of PCBs at local capacitor-manufacturing plants (Brown et al. 1985; Kennish 1992). The stabilization of highly contaminated upper stream banks and reduced PCB releases from bed sediments contributed to lower concentrations in the water column. A model of the fate and accumulation of 7 PCB homologs in the Hudson River estuary showed that 66% of the 270,454 kg of total PCBs discharged into the estuary between 1947 and 1987 had volatilized, 6% was stored in sediments, and the rest was either dredged or lost by boundary transport to the New York Bight and Long Island Sound (Thomann et al. 1991). Total PCBs peaked in the mid-1970s and upstream loading now has a relatively small effect. The upstream PCB load above Troy, New York, accounts for about 20% of the PCB concentrations in striped bass. A steady decline of Aroclors 1016 and 1254 in upstream contribution was projected to the year 2005 and suggests that 95% of 3-6 year old striped bass in the lower Hudson would have residues below the USFDA action level of 2 mg/kg FW by the year 2004 (Thomann et al. 1991). PCB congener patterns in Hudson River sediments differed from the Aroclors discharged into the river. Sediments had comparatively enriched concentrations of certain lower-chlorinated congeners, especially *ortho*-substituted congeners, and some congeners not usually detected in commercial Aroclor mixtures. Changes in PCB composition of sediments were greater in lower portions of sediment cores than in surficial sediments (Brown et al. 1987). Two dechlorination mechanisms seemed to be operating: *meta*, *para*-dechlorinations with stepwise, selective dechlorination at the *meta* and *para* positions of certain *ortho*-substituted di- through tetra-*ortho* chlorinated biphenyls; and *ortho*, *meta*, *para*-dechlorinations, in which the dechlorinations occur at *ortho*, *meta*, or *para* positions and reactivity is favored by increasing electron affinity and relatively positive reduction potential. Both mechanisms preferentially removed toxic congeners (Brown et al. 1987). Residues of individual PCB congeners in the upstream water were similar to residues in caddisfly larvae from that system (Bush et al. 1985), although residues in the larvae were enriched with lower chlorinated congeners. Because of their relatively high water solubility and low affinity for sediment, higher concentrations of lower chlorine homologs were expected to preferentially dissolve in water. But PCB profiles of dissolved residues transported downstream in the water samples during low flow season were dominated by only three low chlorinated PCBs; more than half of the residues consisted of 2-chlorobiphenyl and 2,2'- and 2,6' dichlorobiphenyl congeners (Bush et al. 1985).

Anoxic Hudson River sediments contaminated with PCBs and dredged sediments in clay encapsulation were treated to induce or raise anaerobic biodegradation of PCBs (Rhee et al. 1989). Variations in sediment type, bacterial flora, and treatment influenced dechlorination. The addition of biphenyl under anoxic nitrogen was the most effective treatment for raising biodegradation. Unlike the findings of Brown et al. (1987), no evidence was found of accumulation of less chlorinated PCBs from biodegradation of more highly chlorinated congeners, although a faster degradation rate of less chlorinated congeners than the more highly substituted PCBs would have allowed this phenomena to occur unobserved. Hudson River sediments incubated at room temperature (25°C) under a nitrogen atmosphere or incubated with biphenyl enrichment under nitrogen for 7 months

decreased significantly in chlorobiphenyl compounds of 33 to 65%. In general, mono- and dichlorobiphenyl congeners from Hudson River sediments were not significantly degraded by the biphenyl, but biphenyl addition significantly decreased the higher chlorinated congeners (Rhee et al. 1989). In earlier studies with the same mixed bacterial culture without biphenyl addition, significant reductions were evident in Hudson River sediments of PCB congeners with as many as three chlorines (Chen et al. 1988).

Sediments in oceans, estuaries, rivers, and lakes concentrate PCBs. Organisms accumulate PCBs by way of the water column, from interstitial sediment waters, and from consumption of contaminated prey by predator species. Coastal sediments with the highest total PCB concentrations between 1984 and 1989 are usually within 20 km of population centers of more than 100,000 people (NOAA 1991) and directly correlate with sediment content of total organic carbon (Karickoff 1981). Variability in PCB content of sediments is great, and large differences between adjacent stations is not uncommon (NOAA 1988). The approximate percent PCB distribution in sediments by level of chlorination was di-3.9%, tri- 11%, tetra- 20%, penta- 24%, hexa- 21%, hepta-12%, octa- 3.9%, and nona- 1.3%. The mean PCB concentration in sediments at 233 sites was 39 µg/kg, and concentrations greater than 200,000 µg/kg were considered elevated (NOAA 1988; Table 8). In most regions of New Jersey, for example, PCB contamination of sediments and water column was negligible (Kennish 1992). But PCBs in estuarine and coastal locations of New Jersey showed elevated sediment contamination in the northeastern region—an area that included the Hudson-Raritan estuary and adjacent ocean waters of the New York Bight—where direct discharges from capacitor manufacturing plants on the upper Hudson River, dredged material, and sewage-sludge dumping were the principal sources of PCB contamination. PCB levels in teleosts from the northeastern region in 1986-87 exceeded the USFDA action level of 2,000 µg/kg and were consistent with data from previous years. Action levels were also exceeded in fishes from Camden and from the northern coast regions (Kennish 1992). PCB sediment residues in Raritan Bay in the 1970s averaged 100 µg/kg DW in a range of 3.4 to 2,035 µg/kg (Stainken and Rollwagen 1979). Water column concentrations were usually not detectable but approached 0.04 µg/L in parts of the New York Bight after sewage sludge and dredged material were deposited in the 1970s and early 1980s (Boehm 1981). Sediments near dumpsites in the New York Bight contained as many as 15,000 µg/kg PCBs (MacLeod et al. 1981), and bottom sediments in the upper Hudson River had localized contaminated areas containing more than 50,000 µg/kg (Brown et al. 1985). Nation-wide, PCB loadings in surficial sediments and mussels (*Mytilus edulis*) in the Long Island Sound were greater than in other sites (Robertson et al. 1991).

Surficial stream sediments in the San Francisco estuarine system during 1972 had high residues (350-1,400 µg/kg DW) at several locations (Phillips and Spies 1988); however, residues were highly variable between sites (Law and Goerlitz 1974). In 1984, low to intermediate concentrations of PCBs (9-60 µg/kg DW) were measured at four locations in the San Francisco Bay. Overall, congener profiles resembled Aroclor 1254 and were dominated by pentachlorobiphenyl isomers (NOAA 1987). The patterns of the 11 reported congeners were variable between areas, indicating many sources of different PCB mixtures.

Lake Hartwell in South Carolina received Aroclor 1016 and 1254 discharges for 21 years from a capacitor manufacturing plant (Elzerman et al. 1991). Analysis of sediment cores collected between 1984 and 1987 showed that samples nearest the source were relatively high in lower chlorinated PCB congeners, and downstream samples were enriched with the higher congeners; in all samples, total PCB concentrations decreased with increasing distance from the point source. The estimated total remaining PCBs was 41,000 kg (Elzerman et al. 1991). The highest PCB concentrations were in subsurface sediments, although PCB levels in surficial sediments were also elevated (Dunnivant et al. 1989). A survey of total PCBs in sediments and invertebrates in major estuaries of South Carolina showed no significant contamination. PCBs were found only in sediments (622 µg/kg) and in oysters (87 µg/kg) from the Wando River near a large ship repair and retrofitting facility; PCB residues in crabs, when present, ranged from 95 to 375 µg/kg (Marcus and Renfrow 1990).

Aquatic Organisms

Marine mammals are the most vulnerable and most probable target organisms to PCBs (Tanabe 1988). The metabolic potential to degrade organochlorine contaminants and therefore accumulate relatively high concentrations of persistent PCBs is lower in marine mammals, particularly in cetaceans, than in terrestrial mammals (Tanabe et al. 1987; Kannan et al. 1989, 1993). Dead harbour porpoises (*Phocoena phocoena*) along the Dutch coast contained 51,350-139,790 µg total PCBs/kg blubber; 35-50% of the total PCBs were PCBs 138 and 153 (Duinker et al. 1988a); a similar pattern was noted in harbour porpoises from Scandinavia in 1987-91

(Kleivane et al. 1995). The intrinsic toxicity of PCBs mainly resulted from the planar PCB congeners that imposed a greater toxic threat to marine mammals than chlorinated dioxins and furans (Tanabe 1988; Tanabe et al. 1989; Daelemans et al. 1993; Falandysz et al. 1994b). The toxic threat of planar PCBs to higher aquatic predators was primarily assessed by 2,3,7,8-tetracholoridobenzo-*p*-dioxin toxic equivalent analysis, which is based on the induction of arylhydrocarbon hydroxylase (AHH) and ethoxyresorufin *O*-deethylase (EROD; Kannan et al. 1989). The concentrations of planar PCBS in marine mammals were higher (in the order of di-*ortho* mono-*ortho* non-*ortho* congeners) and significantly higher than the levels of toxic dioxins and furans (Tanabe 1988; Tanabe et al. 1989; Kannan et al. 1989). In particular, the accumulation of PCBs 105 and 126 in carnivorous aquatic mammals is cause for considerable concern (Tanabe et al. 1987, 1989; Kannan et al. 1989; Daelamans et al. 1993; Storr-Hansen and Spliid 1993).

Declines in total PCB levels in blubber of marine mammals between the late 1960s and 1990-92 have been noted worldwide (Muir et al. 1988; Lake et al. 1995a), possibly because of the PCB ban in the mid-1970s. PCB levels in animal tissues will probably not decline in the near future because of the greater quantities of PCBs still in use than the quantity that already escaped into the open environment (Tanabe 1988). Temporal changes of PCBs in remote marine waters are slow and could be attributable to the large PCB load in the marine environment (Loganathan et al. 1990). The geographical distribution of planar PCBs with reference to total PCBs did not vary in terrestrial, coastal, and open ocean mammals, whereas those of dioxins and furans decreased from land to ocean (Tanabe et al. 1989). PCB concentrations—including planar PCBs—in blubber of striped dolphins (*Stenella coeruleoalba*) from the Mediterranean Sea in 1990 are among the highest reported in the literature (Table 9; Kannan et al. 1993). Striped dolphins affected by the western Mediterranean morbillivirus epizootic also contained extremely high concentrations of PCBs (including non-and mono-*ortho* planar congeners) and low immune suppression, suggesting that PCBS were a major factor in this epizootic; however, this needs verification. Planar PCBs in blubber of striped dolphins accounted for about 53% of total PCBs and for virtually all of the potential toxicity. Di-*ortho* planar PCBs accounted for 93.7% of all planar PCB residues in striped dolphins and for 21% of the potential toxicity, mono-*ortho* planars for 6.3% of the residues and 70.8% of the potential toxicity, and non-*ortho* planars for 0.03% of the residues and 8.2% of the potential toxicity (Kannan et al. 1993). Concentrations of PCBs in tissues of adult male striped dolphins of the same age from the Pacific coast of Japan did not change between 1979 and 1986 (Loganathan et al. 1990).

White whales (*Delphinapterus leucas*) of the St. Lawrence estuary were severely contaminated by DDT metabolites and PCBs; the highest residues were in blubber (Masse et al. 1986). Several PCB congeners known to be AHH inducers—including PCBs 138 and 153— were among the major PCB congeners detected in tissues of white whales. Because these compounds are not metabolized and persist indefinitely in tissues of the white whale, the integrated total exposure to these AAH inducers may be significant. Considerable variations by sex, age, and lipid content of the tissues in PCB concentrations were observed in white whales. Qualitative and quantitative differences in the PCB profiles of white whales were not solely related to the respective lipid content of the tissues but also to the specific nature of the lipids, which varied from one tissue to the other. The major PCB components in various tissues of white whales were PCBs 52, 99, 129, 137, 141, 153, 165, 180, and 185. Organ-specific retention of some PCB congeners occurs in white whales. PCBs 165 and 179, which were minor in blubber, were more abundant in kidney, liver, and lung. PCB 129 was more abundant in kidney and liver than in lung. Atlantic cod (*Gadus morhua*) composed a minor part of the white whale diet; however, PCB patterns in cod positively correlated with those in white whale tissues, suggesting a common source of intake. PCB congeners 52, 91, 99, 108, 118, 128, 138, 144, 149, 153, 163, and 180 were among the most abundant chlorinated biphenyls in cod liver oil and in the white whale blubber, liver, lung, kidney, and milk (Masse et al. 1986).

Table 9. PCB concentrations in field collections of selected aquatic organisms. Concentrations are in micrograms PCBs per kilogram (ppb) fresh weight (FW), dry weight (DW), or lipid weight (LW).

PCB 194	Max. 4.7 DW	35
Squid, *Illex illecebrosus argentinus*; near Falkland Islands, March 1988; muscle		
PCBs 28, 31, 44, 47, 49, 52, 66, 87, 97, 101, 105, 110, 118, 128, 138, 141, 149, 151, 153, 170, 180, 184, 187, 206	ND (= nondetectable)	3
Common mussel, *Mytilus edulis* German Bight, 6 locations; 1993; extractable organic matter; spring vs. autumn		
PCB 77	33-50 DW vs. 4-8 DW	49
PCB 81	5-7 DW vs. 2-4 DW	49
PCB 105	45-60 DW vs. 37-130 DW	49
PCB 114	Max. 1.1 DW vs. Max. 0.5 DW	49
PCB 118	75-97 DW vs. 65-520 DW	49
PCB 123	9-150 DW vs. 0.2-4 DW	49
PCB 126	4-15 DW vs. 6-12 DW	49
PCB 138	280-420 DW vs. 83-210 DW	49
PCB 156	Max. 3.9 DW vs. Max. 1.4 DW	49
PCB 169	0.0-2.1 DW vs. 0.4-4.1 DW	49
PCB 170	0.0-7.9 DW vs. 2.2-4.1 DW	49
PCB 180	18-43 DW vs. 9-23 DW	49
PCB 189	0.5-1.7 DW vs. 0.1-0.4 DW	49
Long Island Sound, New York vs. freshwater mussels (species unknown) from a contaminated site near Troy, New York; soft parts		
Total PCBs	247 DW vs. 2,734 DW	4
Total planar PCBs	11.9 DW vs. 112.9 DW	4
PCB 77	0.4 DW vs. 6.9 DW	4
PCB 81	ND vs. 0.9 DW	4
PCB 105	3.3 DW vs 27.0 DW	4
PCB 114	ND vs. 4.0 DW	4
PCB 118	8 DW vs. 53 DW	4
PCB 123	ND vs. ND	4
PCB 126	ND vs. 0.6 DW	4
PCB 156	ND vs. 1.8 DW	4
PCB 157	ND vs. 0.6 DW	4
PCB 167	0.2 DW vs. 18.6 DW	4
PCB 169	ND vs. 0.1 DW	4
PCB 189	ND vs. 0.1 DW	4
Fishes		
Bloater, *Coregonus hoyi*; whole; Lake Michigan; total PCBs		

Table 9. Taxonomic group, organism, PCB congener, and other variables	Concentration (ug/kg)[a]	Reference[b]
1972 vs. 1975	5,700 FW vs. 4,500 FW	5
1978 vs. 1982	3,100 FW vs. 2,100 FW	5
1986	1,600 FW	5
Margined flyingfish, *Cypselurus cyanopterus*; near Falkland Islands, March 1988; muscle		
PCBs 28, 31, 44, 47, 49, 52, 66, 87, 97, 101, 105, 110, 128, 141, 151, 170, 194, 206	0.01-0.1 FW	3
PCBs 118, 138, 180, 187	0.14-0.31 FW	3
PCB 153	0.45 FW	3
Fish liver oil; various species; Finland		
PCB 77	2.7 LW	6
PCB 105	30.0 LW	6
PCB 126	0.62 LW	6
PCB 169	0.13 LW	6
Fish muscle; various species sold for human consumption; Finland		
PCB 77	0.006-0.153 FW	6
PCB 105	0.113-2.7 FW	6
PCB 126	0.002-0.035 FW	6
PCB 169	ND-0.012 FW	6
Fish, 14 species, muscle; Wisconsin, 1986-87; total PCBs	1,300 (700-7,000) FW	7
Freshwater fishes; USA; nationwide; whole: adults; total PCBs measured as Aroclors 1248, 1254, and 1260; noncontaminated sites		
1976-77	Max. 70.6 FW	48
1978-79	Max. 92.8 FW	48
1980-81	Max. 11.3 FW	48
1984	Max. 6.7 FW	48
Freshwater fishes; USA; nationwide; whole; 1986-87; mostly contaminated sites		
Median	209 FW	52
Mean	1,890 FW	52
Maximum	124,000 FW	52
Atlantic cod, *Gadus morhua*		
Liver; Norway, 1988		
PCB 28	19 (0.5-64) FW	8
PCB 52	31 (0.5-144) FW	8
PCB 101	78 (0.5-533) FW	8
PCB 118	170 (1.1-653) FW	8
PCB 138	283 (1.4-918) FW	8
PCB 153	363 (1.3-1,175) FW	8
PCB 170	28 (0.4-163) FW	8
PCB 180	68 (1.1-391) FW	8
PCB 209	7 (0.3-35) FW	8
Liver; Norway 1989		
PCB 77	Max. 4.8 LW	9
PCB 105	Max. 39.0 LW	9
PCB 126	Max. 1.0 LW	9
PCB 169	Max. 0.3 LW	9

Table 9. Taxonomic group, organism, PCB congener, and other variables	Concentration (ug/kg)[a]	Reference[b]
Muscle; Baltic Sea, 1988		
PCB 77	Max. 4.2 LW	9
PCB 105	Max. 36.0 LW	9
PCBs 126, 169	ND	9
Ictalurids, 4 species (blue catfish, *Ictalurus furcatus*; black bullhead, *Ameiurus melas*; channel catfish, *Ictalurus punctatus*; flathead catfish, *Pylodictis olivaris*); whole; 1,944 km stretch of Mississippi River; July-August 1987		
Total PCBs	Max. 138 FW; Max. 2,910 LW	10
Tetrachlorobiphenyls	Max. 21 FW; Max. 671 LW	10
Pentachlorobiphenyls	Max. 56 FW; Max. 1,230 LW	10
Hexachlorobiphenyls	Max. 67 FW; Max. 870 LW	10
Heptachlorobiphenyls	Max. 12 FW; Max. 140 LW	10
Dab, *Limanda limanda* German Bight; December 1988-May 1989; total of 35 PCB congeners		
Females		
Liver (mostly PCBs 77, 138, and 153)	1,200-16,200 LW	36
Ovaries (mostly PCBs 77, 138, and 153)	2,600-4,300 LW	36
Males		
Liver	900-24,400 LW	36
Testes (mostly PCBs 15, 13, 52)	1,900-11,800	36
North Sea; January-March 1987; total PCBs		
Liver, Females	1,450 FW	11
Liver, Males	2,000 FW	11
Ovaries	2,600 FW	11
Tilefish, *Lopholatilus chamaeleonticeps*; 1981-1982; New Jersey vs. Georges Bank		
Total PCBs		
Gonad	3,373 DW vs. 1,004 DW	12
Liver	4,693 DW vs. 1,002 DW	12
Muscle	435 DW vs. 190 DW	12
Dichlorobiphenyls		
Gonad	196 DW vs. 15 DW	12
Liver	258 DW vs. 42 DW	12
Muscle	9 DW vs. 5 DW	12
Trichlorobiphenyls		
Gonad	164 DW vs. 11 DW	12
Liver	278 DW vs. 35 DW	12
Muscle	11 DW vs. 7 DW	12
Tetrachlorobiphenyls		
Gonad	1,176 DW vs. 192 DW	12
Liver	789 DW vs. 151 DW	12
Muscle	62 DW vs. 25 DW	12
Pentachlorobiphenyls		
Gonad	806 DW vs. 463 DW	12
Liver	1,273 DW vs. 358 DW	12
Hexachlorobiphenyls		
Gonad	664 DW vs. 191 DW	12
Liver	1,290 DW vs. 221 DW	12
Muscle	112 DW vs. 46 DW	12

Table 9. Taxonomic group, organism, PCB congener, and other variables	Concentration (ug/kg)[a]	Reference[b]
Heptachlorobiphenyls		
Gonad	158 DW vs. 27 DW	12
Liver	109 DW vs. 27 DW	12
Muscle	14 DW vs. 3 DW	12
Nonochlorobiphenyls		
Gonad	62 DW vs. 6 DW	12
Liver	22 DW vs. 13 DW	12
Muscle	3 DW vs. 0.5 DW	12
Decachlorobiphenyl		
Gonad	45 DW vs. 6 DW	12
Liver	24 DW vs. 16 DW	12
Muscle	2 DW vs. 0.7 DW	12
PCB 77		
Gonad	48 DW vs. 19 DW	12
Liver	86 DW vs. 45 DW	12
Muscle	62 DW vs. ND	12
PCB 126		
Gonad	ND vs. 27 DW	12
Liver	214 DW vs. 33 DW	12
Muscle	19 DW vs. 4 DW	12
Argentinian hake, *Merluccius merluccius hubbsi*; near Falklands Islands, March 1988; muscle		
PCBs 28, 31, 44, 47, 49, 87, 97, 105, 128, 141, 151, 194, 206	0.01-0.04 FW	3
PCBs 52, 66, 101, 110, 170	0.05-0.1 FW	3
PCBs 118, 138, 149, 153, 180, 187	0.11-0.28 FW	3
Striped bass, *Morone saxatilis*; muscle, New York, Long Island Sound, 1985		
Total PCBs	5,500 FW; Max. 15,000 FW	13
PCBs 48, 52, 82, 101, 118, 138, 153	Contributed at least 28% of total PCB concentration	13
New York, various locations		
Total PCBs	1,100-24,100 FW	4
Total planar PCBs	100-2,020 FW	4
PCB 77	Max. 37 FW	4
PCB 81	Max. 5 FW	4
PCB 105	Max. 562 FW	4
PCB 114	Max. 112 FW	4
PCB 118	Max. 779 FW	4
PCB 126	Max. 8 FW	4
PCB 156	Max. 202	4
PCB 157	Max. 68 FW	4
PCB 167	Max. 232 FW	4
PCB 169	Max. <0.1 FW	4
PCB 189	Max. 19 FW	4
Striped mullet, *Mugil cephalus*; Japan, May 1976; muscle		
Total PCBs	1,200 (220-3,200) FW	14
PCB 77	2.1 (0.6-4.8) FW	14
PCB 126	0.1 (0.03-0.23) FW	14
PCB 169	0.002 (0.001-0.004) FW	14

Table 9. Taxonomic group, organism, PCB congener, and other variables	Concentration (ug/kg)[a]	Reference[b]
Rainbow trout, *Oncorhynchus mykiss*;		
Lake Ontario, 1989; liver vs. muscle		
PCB 77	2.9 FW, 78 LW vs.3.3 FW, 85 LW	31
PCB 126	0.7 FW, 18 LW vs. 0.9 FW, 22 LW	31
PCB 169	0.3 FW, 8 LW vs. 0.3 FW, 9 LW	31
Red mullet, *Mullus barbatus*; Spain,		
Mediterranean coast, summers 1989, 1990; muscle		
Sum of PCBs 28, 52, 101, 118, 138, 153, 180	21.2 (7.4-33.2) FW	33
Sum of PCBs 18, 31, 44, 97, 99, 105, 110, 128, 134, 146, 149, 151, 170, 174, 177, 183, 187, 194, 201	38.4 (15.5-61.4) FW	33
Chinook salmon, *Oncorhynchus tshawytscha*;		
Lake Michigan, 1986; eggs		
Total PCBs	7,020 FW	32
PCBs 77, 105, 118, 126	0.2-12 FW	32
Fathead minnow, *Pimephales promelas*; upper Hudson River, 1985; caged juveniles exposed for 3 to 42 days during the year; whole fish	Regardless of exposure duration or season, the consistently most abundant congeners in caged fish were PCBs 37, 42, 44, 47, 48, 49, 52, 59, 61, 66, 70, 73, 75, 76, 93, 95, and 104	15
European flounder, *Platichthys flesus;*		
Norway, 1988; liver		
PCB 28	7 (0.3-68) FW	8
PCB 52	21 (0.7-609) FW	8
PCB 101	44 (1.1-1,452) FW	8
PCB 118	77 (3.2-1,693) FW	8
PCB 138	90 (1.1-1,960) FW	8
PCB 153	95 (5.7-2,088) FW	8
PCB 170	7 (0.4-158) FW	8
PCB 180	16 (1.2-296) FW	8
PCB 209	4 (0.4-88) FW	8
Paddlefish, *Polyodon spathula*;		
Ohio River, Kentucky; 1988-89;		
total PCBs; males vs. females		
Gonads	16,200 (5,600-23,000) FW vs. 7,300 (50-18,700) FW	16
Red muscle (females only)	4,200 (2,000-6,300) FW	16
White muscle	700(50-3,300) FW vs. 400 (50-1,000) FW	16
Winter flounder, *Pleuronectes americanus*		
Long Island Sound, New York, 1984-86;		
total PCBs		
Liver	420-2,400 FW	17
Ovaries	30-730 FW	17
Testes	50-190 FW	17
New Bedford Harbor, Massachusetts vs. two control sites in Rhode Island; spring, 1988; liver		
Planar PCBs		
PCB 77	391 DW vs. 4.6 DW	38
PCB 126	49 DW vs. 1.8 DW	38
PCB 169	3.7 DW vs 0.4 DW	38

Table 9. Taxonomic group, organism, PCB congener, and other variables	Concentration (ug/kg)[a]	Reference[b]
Nonplanar PCBs		
PCB 47	2,530 DW vs. 14 DW	38
PCB 52	1,100 DW vs. 6.5 DW	38
PCB 101	2,450 DW vs. 49 DW	38
PCB 105	2,200 DW vs. 92 DW	38
PCB 118	12,800 DW vs. 239 DW	38
PCB 128	1,370 DW vs. 47 DW	38
PCB 138	7,070 DW vs. 286 DW	38
PCB 151	422 DW vs. 19 DW	38
PCB 153	11,000 DW vs. 441 DW	38
PCB 180	1,010 DW vs. 141 DW	38
PCB 194	79 DW vs. 23 DW	38
PCB 195	32 DW vs. 1.4 DW	38
PCB 206	33 DW vs. 33 DW	38
PCB 209	3.1 DW vs. 20.5 DW	38
Total PCBs		
Gravid females	333,000 DW vs. 3,900 DW	38
Spent females	132,000 DW vs. 4,000 DW	38
Ripe males	124,000 DW vs. 13,300 DW	38
Sediments	8,000 DW vs. 500 DW	38
Atlantic salmon, *Salmo salar*;		
Baltic Sea and environs		
Eggs, 1988		
PCB 77	Max. 28 LW	9
PCB 105	Max. 90 LW	9
PCB 126	Max. 2.4 LW	9
PCB 169	Max. 0.6 LW	9
Muscle, 1985		
Total PCBs	Max. 332 FW	18
PCB 77	Max. 1.1 FW	18
PCBs 126, 169	ND	18
Muscle, 1988		
PCB 77	Max. 34 LW	9
PCB 105	Max. 170 LW	9
PCB 126	Max. 3.8 LW	9
PCB 169	Max. 0.8 LW	9
Brown trout, *Salmo trutta*; Catalonia, Spain; isolated mountain lakes; summers 1989, 1990; muscle		
Sum of PCBs 28, 52, 101, 118, 138, 153, 180	2.5 (1.3-3.8) FW	33
Sum of PCBs 18, 31, 44, 97, 99, 105, 110, 128, 134, 146, 149, 151, 170, 174, 177, 183, 187, 194, 201	4.8 (2.7-7.5) FW	33
Lake trout, *Salvelinus namaycush*		
Lake Ontario; total PCBs; whole fish		
1977 vs. 1978	6,800 FW vs. 8,000 FW	19
1979 vs. 1980	3,700 FW vs. 3,900 FW	19
1981 vs. 1982	2,900 FW vs. 5,300 FW	19
1983 vs. 1984	4,500 FW vs. 4,800 FW	19
1985 vs. 1986	2,500 FW vs. 3,100 FW	19
1987 vs. 1988	3,400 FW vs. 2,500 FW	19
Lake Michigan		

Table 9. Taxonomic group, organism, PCB congener, and other variables	Concentration (ug/kg)[a]	Reference[b]
Adult females; total PCBs		
1985	4,900-10,100 FW	47
1986	6,100-6,800 FW	47
1987	3,500-13,900 FW	47
Adult females; 1987; whole fish vs. eggs		
PCB 77	9.7 FW vs. 2.1 FW	47
PCB 126	4.0 FW vs. 0.65 FW	47
PCB 169	<0.4 FW vs. <0.4 FW	47
Marine Mammals		
Giant bottlenosed whale, *Berardius bairdii*; blubber		
Japan, July 1985		
Total PCBs	2,300 (1,800-2,800) FW	20,21
Di-*ortho* planars		
PCB 128	54 (36-70) FW	20,21
PCB 138	460 (260-810) FW	20,21
Mono-*ortho* planars		
PCB 105	5 (2-8) FW	20,21
PCB 118	47 (15-94) FW	20,21
PCB 156	23 (6-50) FW	20,21
Non-*ortho* planars		
PCB 77	1.3 (0.7-1.9) FW	20,21
PCB 126	0.35 (0.1-0.57) FW	20,21
PCB 169	0.24 (0.09-0.45) FW	20,21
Northern north Pacific, July 1985		
Total PCBs	2,600 (2,400-2,800) FW	14
PCB 77	1.6 (1.3-1.9) FW	14
PCB 126	0.48 (0.39-0.57) FW	14
PCB 169	0.31 (0.17-0.45) FW	14
Beluga whale, *Delphinapterus leucas*;		
Canada, St. Lawrence estuary; November 1983-December 1984; beach-stranded whales; total PCBs		
Blubber	Max. 72,200 FW	22
Kidney	Max. 10,000 FW	22
Liver	Max. 2,500 FW	22
Lung	Max. 560 FW	22
Milk	Max. 1,720 FW	22
Dolphins and toothed whales; blubber; total PCBs		
Atlantic Ocean, 1980-88; 15 species	130-190,000 FW	23
Indian Ocean, 1980-91; 5 species	520-7,900 FW	23
Pacific Ocean, 1980-86; 7 species	190-40,000 FW	23
Gray seal, *Halichoerus grypus*		
Baltic Sea and environs; 1981-87; blubber		
PCB 77	Max. 10 LW	9
PCB 105	Max. 180 LW	9
PCB 126	Max. 3 LW	9
PCB 169	Max. 2 LW	9
Nova Scotia, 1984-85; total PCBs; mother vs. pups		
Blood	6,080 LW vs. 6,240 LW	24
Blubber	16,200-30,300 LW vs. 8,800-10,400 LW	24
Milk (mother)	7,480-10,120 LW	24
Serum	10,210 LW vs. 11,840 LW	24

Table 9. Taxonomic group, organism, PCB congener, and other variables	Concentration (ug/kg)[a]	Reference[b]
Pacific white-sided dolphin, *Lagenorhynchus obliquidens*; Japan, 1981; blubber		
Total PCBs	53,00 (40,000-71,000) FW	14
PCB 77	27 (14-38) FW	14
PCB 126	3.8 (3.2-4.4) FW	14
PCB 169	1.2 (0.9-1.4) FW	14
Finless porpoise, *Neophocaena phocaenoides*; Japan, July 1985; blubber		
Total PCBs	320,000 FW	20,21
Di-*ortho* planars		
PCB 128	3,500 FW	20,21
PCB 138	35,000 FW	20,21
Mono-*ortho* planars		
PCB 105	1,200 FW	20,21
PCB 118	11,000 FW	20,21
PCB 156	160 FW	20,21
Non-*ortho* planars		
PCB 77	14 FW	14,20,21
PCB 126	0.9 FW	14,20,21
PCB 169	0.6 FW	14,20,21
Killer whale, *Orcinus orca*; blubber Died after 2 years in captivity		
Total PCBs	160,000 FW	14
PCB 77	42.0 FW	14
PCB 126	4.0 FW	14
PCB 169	3.6 FW	14
Pacific coast of Japan; July 1985		
Total PCBs	370,000 (350,000- 410,000) FW	20,21
Di-*ortho* planars		
PCB 128	8,000 (3,200-12,000) FW	20,21
PCB 138	65,000 (24,000-85,000) FW	20,21
Mono-*ortho* planars		
PCB 105	3,000 (2,300-3,600) FW	20,21
PCB 118	11,000 (6,700-14,000) FW	20,21
PCB 156	1,900 (950-3,100) FW	20,21
Non-*ortho* planars		
PCB 77	48 (39-55) FW	14,20,21
PCB 126	3.7 (2.4-4.4) FW	14,20,21
PCB 169	7.7 (2.3-12.0) FW	14,20,21
Ringed seal, *Pusa hispida*; Norway, March-April, 1990		
Blubber		
PCBs 77, 126, 169	ND-0.19 LW	25

Liver		

Table 9. Taxonomic group, organism, PCB congener, and other variables	Concentration (ug/kg)[a]	Reference[b]
PCBs 77, 126, 169	ND-0.78 LW	25
PCBs 61, 66, 105, 110, 149, 180	18-43 LW	25
PCBs 52, 101, 118	57-71 LW	25
PCBs 138, 153	115-188 LW	25
Harbor seal, *Phoca vitulina*; northeast coast of USA; 1980-92		
Blubber; 1980 vs. 1990-92		
Total	12,000 (7,300-24,300) FW vs. 6,660 (2,610-11,300) FW	51
PCB 8	ND vs. 0.9 FW	51
PCB 18	26 FW vs. 2 FW	51
PCB 28	99 FW vs. 16 FW	51
PCB 44	105 FW vs. 17 FW	51
PCB 52	661 FW vs. 213 FW	51
PCBs 66 + 95	192 FW vs. 29 FW	51
PCB 77	0.36 FW vs. 0.07 FW	51
PCB 101	897 FW vs. 500 FW	51
PCB 105	205 FW vs. 82 FW	51
PCBs 118+ 149	615 FW vs. 279 FW	51
PCB 126	1.45 FW vs. 0.53 FW	51
PCB 128	459 FW vs. 244 FW	51
PCB 138	2,990 FW vs. 1,650 FW	51
PCB 153	3,040 FW vs. 1,880 FW	51
PCB 169	0.019 FW vs. 0.013 FW	51
PCBs 170 + 190	458 FW vs. 266 FW	51
PCB 180	1,210 FW vs. 713 FW	51
PCB 187	865 FW vs. 601 FW	51
PCB 195	67 FW vs. 56 FW	51
PCB 206	72 FW vs. 79 FW	51
PCB 209	22 FW vs. 34 FW	51
Liver; 1980 vs. 1990-92		
Total	9,860 (6,290-16,000) FW vs. 6,260 (528-25,300) FW	51
PCB 8	ND vs. 1.2 FW	51
PCB 18	8.2 FW vs. 0.5 FW	51
PCB 28	27 FW vs. 10 FW	51
PCB 44	42 FW vs. 8 FW	51
PCB 52	343 FW vs. 145 FW	51
PCBs 66 + 95	127 FW vs. 9 FW	51
PCB 101	523 FW vs. 371 FW	51
PCB 105	345 FW vs. 26 FW	51
PCBs 118 + 149	470 FW vs. 196 FW	51
PCB 128	385 FW vs. 232 FW	51
PCB 138	2,250 FW vs. 1,550 FW	51
PCB 153	2,040 FW vs. 1,690 FW	51
PCBs 170 + 190	476 FW vs. 253 FW	51
PCB 180	1,160 FW vs. 696 FW	51
PCB 187	1,450 FW vs. 904 FW	51
PCB 195	85 FW vs. 60 FW	51
PCB 206	97 FW vs. 80 FW	51
PCB 209	41 FW vs. 36 FW	51

Table 9. Taxonomic group, organism, PCB congener, and other variables	Concentration (ug/kg)[a]	Reference[b]
Common porpoise, *Phocoena phocoena*		
Found dead along Dutch coast, 1971- 81		
Blubber vs. liver		
PCB 44	530 FW vs. 1 FW	26
PCB 49	900 FW vs. 5 FW	26
PCB 52	10,000 FW vs. 80 FW	26
PCB 101	3,200 FW vs. 20 FW	26
PCB 118	8,200 FW vs. 35 FW	26
PCB 138	28,900 FW vs. 280 FW	26
PCB 149	16,700 FW vs. 140 FW	26
PCB 153	32,600 FW vs. 340 FW	26
PCB 172	530 FW vs. 5 FW	26
PCB 174	3,700 FW vs. 40 FW	26
PCB 177	6,200 FW vs. 60 FW	26
PCB 180	4,000 FW vs. 80 FW	26
PCB 183	3,700 FW vs. 50 FW	26
PCB 194	700 FW vs. 10 FW	26
PCB 201	1,200 FW vs. 20 FW	26
PCB 206	360 FW vs. 7 FW	26
PCB 209	40 FW vs. 10 FW	26
Total PCBs (from above congeners)		
Blubber	51,350-139,790 FW	26
Heart	1,410-4,900 FW	26
Kidney	860-3,970 FW	26
Liver	1,190-17,400 FW	26

In gray seals (*Halichoerus grypus*), PCBs were transferred from blubber to milk by way of the circulatory system. Of the total concentration of PCBs in various tissues of maternal gray seals, PCB 153 accounted for about 30% in blubber, 20% in serum, and 30% in milk; PCB 180 accounted for 20% in blubber, 20% in serum, and 10% in milk; PCB 77 accounted for 20% in serum (Addison and Brodie 1987). In whales (*Ziphius* sp.), the dominant PCB congeners in blubber had 5-8 chlorines; PCBs 138, 153, 149, 180, and 201 accounted for about 70% of the total PCBs (Duinker et al. 1988b). In the Canadian Arctic food chain of Arctic cod (*Boreogadus saida*) to ringed seal (*Phoca hispida*) to polar bear (*Ursus maritimus*), the total PCB concentrations in µg/kg FW ranged from 4 in cod muscle to 680 in seal blubber to 4,500 in bear fat. The hexachlorobiphenyl PCB 153 accounted for 42% of the total PCBs in bear fat and for only 20% in seal blubber and 7% in cod muscle. Tri- and tetrachlorobiphenyl homologs predominated in cod, penta- and hexachlorobiphenyl congeners predominated in seal blubber, and hexa- and heptachlorobiphenyl congeners in fat of polar bears (Muir et al. 1988).

In comparison to conspecifics from noncontaminated sites, aquatic invertebrates from PCB-contaminated sites contained elevated concentrations of PCBs in tissues (Table 9). Adult aquatic insects are one of the groups considered useful and reliable indicators of PCB contamination (Wood et al. 1987; Kovats and Ciborowski 1989). Mayflies (*Hexagenia* spp.) from Lake St. Clair had PCB concentrations that reflected sediment PCB concentrations (Table 9). Observed mayfly sediment concentration ratios from PCBs linearly correlated with K_{ow} when expressed on a logarithmic basis (Gobas et al. 1989). PCB congener distributions in lake biota showed that no particular trophic level consistently accumulated the highest PCB concentrations and suggest that accumulations were associated with the organism's lipid concentrations (Table 9). A relation was consistent between the concentration of dissolved PCBs and tissue concentrations in mussels from PCB-contaminated sites, such as New Bedford Harbor, Massachusetts. Uptake of PCB congeners in blue mussels (*Mytilus edulis*) from the dissolved phase of seawater was predictable from the log of the bioconcentration factor and the log K_{ow} of the congeners (Bergen et al. 1993). Eastern oysters (*Crassostrea virginica*) from Galveston Bay, Texas, contained as much as 1,100 µg/kg total PCBs DW soft parts, whereas conspecifics from Tampa Bay, Florida contained only 580 µg/kg DW soft parts; most (54-94%) of the relative toxicity in both groups was due to PCBs 77, 126, and 169 (Sericano et al. 1994).

The partitioning of individual, highly chlorinated PCB congeners with small differences in K_{ow} values may not adequately explain the accumulations in aquatic organisms (van der Oost et al. 1988). Hydrophobic chemicals, such as PCBs, are accumulated as a consequence of chemical partitioning between the water column, the organic phase of sediment, and biotic lipids or from biomagnification, a process reflecting the ratio between uptake rate from food and elimination rate from the organism. Accumulations of six PCB congeners (PCBs 28, 52, 101, 138, 153, 180) in surficial sediments (0-20 cm) and in an aquatic food chain in Lake Nieuwe Meer—a freshwater lake near Amsterdam containing contaminated dredged materials discharged over 30 years—were low in sediments; elevated in carnivores, plankton, molluscs, crustaceans, and eels; and independent of fat content (van der Oost et al. 1988). With concentrations in organisms expressed on the basis of lipid content (C_{org}) and concentrations in sediments expressed on the basis of organic carbon (C_{sed}) the median C_{org}/C_{sed} PCB accumulation patterns in aquatic organisms showed significant differences and indicated that mechanisms other than partitioning were operating. In plankton and mollusks, C_{org}/C_{sed} ratios seemed to be independent of hydrophobicity of PCB congeners. But with ascending trophic level from plankton to molluscs to crustaceans to eels, the median C_{org}/C_{sed} ratios of higher chlorinated congeners (PCBs 138, 153, 180) increased. Differences in accumulations of individual congeners were attributed to (1) increased biomagnification of higher chlorinated congeners because increasing hydrophobicity decreased elimination rates but not uptake efficiency; (2) greater mobility of eels and different feeding habits of eels and crustaceans that impact accumulation patterns because of biomagnification and partitioning; (3) variability in the time period (limited by lifespan) available in a particular trophic level for equilibration between uptake and clearance; and (4) the tendency of equilibrium to be established at faster rates in less chlorinated congeners. In crustaceans,

C_{org}/C_{sed} ratios decreased with decreasing hydrophobicity; the opposite occurred in eels and is attributed to differences in uptake efficiencies and low elimination rates of lower chlorinated congeners in crustaceans (van der Oost et al. 1988).

A correlation exists between the concentration of lipophilic, hydrophobic, chlorinated hydrocarbons in benthic fishes and the concentration of these compounds in sediments. The correlation is affected by the solubility of the contaminants, as reflected by the octanol/water partition coefficient K_{ow} and the carbon content of the sediment (Connor 1984; Breck 1985). Connor (1984) suggested that surface sediments, which change more slowly than the water column, are useful for averaging spatial and temporal contaminant inputs; however, correlations between PCB concentrations in sediment and those in nonbenthic carnivores with limited home ranges are extremely variable.

Concentrations of total PCBs—measured as Aroclors 1248, 1254, and 1260—in adult freshwater fishes in the United States from noncontaminated sites declined between 1976 and 1984 (Table 9), and more than 90% of all analyzed samples contained measurable quantities of PCBs during this period (Schmitt et al. 1990). Total PCB concentrations in domestic freshwater fishes in 1986-87 from contaminated sites were as high as 124,000 µg/kg FW (USEPA 1992a). In general, total PCB concentrations in domestic freshwater fishes sampled between 1976 and 1984 were highest in the industrialized regions of the northeast, the Great Lakes, the upper Mississippi River, and the Ohio River (Schmitt et al. 1990). Phillips and Birchard (1990) reviewed PCB concentrations (as judged by residues of Aroclors 1016, 1221, 1232, 1242, 1248, 1254, and 1260) in sediments and fish tissues in the United States during 1978-87. During 1978-81, total PCB concentration rankings in sediments were highest in the lower Mississippi, Tennessee, South Atlantic-Gulf of Mexico, and lower Colorado regions and lowest in the Great Lakes, Arkansas, mid-Atlantic, Pacific Northwest, and Rio Grande regions. During this same period, PCB concentrations in fish tissues were highest in the Missouri, upper Colorado, California, and the Great Lakes regions and lowest in the upper Mississippi, New England, Ohio, Pacific Northwest, Tennessee, lower Mississippi, and Rio Grande regions. Sediment PCB rankings during 1982-87 were highest in the Arkansas, California, Ohio, and Missouri regions and lowest in the South Atlantic-Gulf, and Colorado regions. Total PCBs were highest in fish tissues in the upper Mississippi Region during 1982-87. The fish tissue rankings in descending order assigned to 12 regions with sufficient total PCB data were the upper Mississippi and Missouri regions, Ohio, south Atlantic-Gulf, Arkansas, Great Basin, lower Colorado, California, Pacific Northwest, Ohio, upper Colorado, and lower Mississippi. PCB rankings between fish tissues and sediments were not necessarily comparable because high levels in sediment do not necessarily result in high levels in fishes if bioconversion was significant (Phillips and Birchard 1990). Total PCB concentrations in coastal sediments and fish liver in the United States were highest in the Boston Harbor (17.1 mg/kg DW sediment, 10.5 mg/kg in liver of winter flounder, *Pleuronectes americanus*), San Diego Harbor (O.42 mg/kg DW sediment, 19.7 mg/kg in barred sand bass, *Paralbrax nebulifer*), and Elliot Bay, Washington (0.33 mg/kg sediment, 14.7 mg/kg in flathead sole, *Hippoglossoides elassodon*). Trichloro PCBs were in sediments at many sites but did not accumulate in fish livers except in the Boston Harbor. Sediments in the Boston Harbor, western Long Island Sound, and Raritan Bay were contaminated with PCB mixtures that were relatively high in tri- and tetrachlorobiphenyl isomers, although penta- and particularly hexachlorobiphenyls were the dominant isomers at most sediment sites. As expected, levels of hexachlorobiphenyls in fish livers were dominant because of the more persistent and lipophilic characteristics of increasingly chlorinated PCBs (NOAA 1987).

Variations in PCB concentrations in sediment and water in the Great Lakes can largely account for the variability between different bodies of water in fish PCB residues. Other variables include fish lipid content, position of the fish species in the food web, and trophic structure of the food chain. Collectively, these variables explain 72% of the variation in PCB concentrations of 25 species of Great Lakes fishes (Rowan and Rasmussen 1992). Tissue concentrations of PCBs in benthic and lower trophic organisms in lakes can be estimated by assuming equal lipid-normalized concentrations in biota and sediment; however, food chain transport had a greater effect on PCB concentrations in higher trophic levels (Macdonald et al. 1993). Total PCB concentrations in whole body of lake fishes were higher among older piscivores and higher with increasing lipid concentration and seemed to reflect exposure conditions at the capture site (Southworth 1990).

Eggs of chinook salmon (*Oncorhynchus tshawytscha*) from Lake Michigan in 1986 contained AHH-active PCB congeners—including PCBS 77, 105, 118, and 126—at concentrations from 0.9 to 262 µg/kg FW; concentrations of these congeners did not correlate with survival (Williams and Giesy 1992). Mortality of chinook

salmon eggs was not related to total PCB concentrations as high as 7,020 µg/kg FW (Williams and Giesy 1992). In Lake Ontario, the overall trend in total PCB concentrations in whole lake trout (*Salvelinus namaycush*) between 1977 and 1988 was a gradual decline with a half-time persistence of about 10 years (Borgmann and Whittle 1991). In Lake Michigan, total PCB concentrations declined 64% in bloaters (*Coregonus hoyi*) from 5,700 µg/kg FW in 1972 to 1,600 µg/kg FW in 1986 (Hesselberg et al. 1990). In Lake Superior, the PCB congener fingerprint in eggs of the lake trout differed from that of lake trout eggs of other Great Lakes (Mac et al. 1993). A difference between residue patterns was also identified between eggs and the parent fish, suggesting preferential deposition of congeners other than AHH-active congeners. Concentrations of individual congeners in lake trout have been declining at similar rates in the Great Lakes during a 10-year period (Mac et al. 1993).

Distribution patterns of PCB congeners in water, sediment, and four groups of biota from two lakes in Ontario contaminated by known point sources of PCBs (Lake Clear, Rice Lake) were compared with the congener distribution in Lake Scugog, a relatively clean control lake exposed only to atmospheric inputs of PCBs (Macdonald and Metcalfe 1989). Samples were analyzed for 19 PCBs. Those from Lake Clear had a distribution pattern similar to Aroclor 1254 and dominant concentrations of congeners 87, 101, and 118; this lake was contaminated with a PCB mixture similar to Aroclor 1254 in the mid to late 1970s. The sources to Rice Lake were less clear. Lake Scugog contained a higher proportion of less chlorinated PCBs, in agreement with another study of atmospheric deposition to isolated lakes (Swackhammer et al. 1988). Because the sediments contained elevated levels of organic carbon, the sediments were expected to also hold relatively large concentrations of the higher, more hydrophobic PCBs, in accord with previous reports (Karickoff 1981; Formica et al. 1988). But this was not the case; subsequent deposition of total and higher chlorinated congeners into the bottom sediments (organic carbon basis) was unexpectedly low. The proportion of higher chlorinated congeners in sediments were also lower than in biota (lipid weight basis) in all three lakes. Because dissolved organic carbon (DOC) increases the solubility of PCBs in water (Gschwend and Wu 1985), the high DOC levels may have caused partitioning of more PCBs into the water and less sorbed onto sediments. The sediments were not efficient at accumulating PCBs, although bottom sediment concentrations were higher in contaminated lakes. Adsorption of PCBs on suspended particles occurred, as anticipated; PCBs on total suspended solids were higher in contaminated lakes (978 µg/kg) than in the control lake (49 µg/kg) and reflected lake concentrations (Gschwend and Wu 1985). In a related study, Macdonald and Metcalfe (1991) analyzed the concentration and distribution of 19 PCB congeners in biota, sediments, water, and suspended solids of isolated oligotropic lakes in central Ontario that were contaminated by atmospheric deposition. The range of the total congener concentrations was 1-2 ng/L dissolved in water, 10-50 µg/kg DW in sediment, 5-10 µg/kg FW in lower trophic levels, and 10-30 µg/kg in fishes from upper trophic levels. The high proportion of trichlorobiphenyls previously reported in vapor (Duinker and Bouchertall 1989; Baker and Eisenreich 1990) and hexachlorobiphenyl congeners 153 and 138 in particulate-bound PCBs (Swackhammer et al. 1988; Duinker and Bouchertall 1989; Baker and Eisenreich 1990) were reflected in the four study lakes. PCB concentrations (lipid basis) were higher in teleosts than they were in invertebrate prey organisms.

Winter flounder from the PCB-contaminated harbor in New Bedford, Massachusetts, had grossly elevated concentrations of PCBs in their livers (as high as 333,000 µg/kg DW); concentrations were about 5 times higher than in any other fish sample collected worldwide (Table 9; Elskus et al. 1994). PCB patterns in the New Bedford Harbor showed high agreement between the exposure environment (water and sediments) and ribbed mussels (*Geukensia demissa*) and mummichogs (*Fundulus heteroclitus*); however, agreements with American eels (*Anguilla rostrata*) or grass shrimp (*Palaemonetes pugio*) were poor because, in part, of differential metabolism of PCBs by these species (Lake et al. 1995b). PCB concentrations in four species of catfishes from the Mississippi River and its tributaries in summer 1987 were highest from the Illinois River; the Ohio River at Olmsted; and the Mississippi River at Helena, Arkansas, and Arkansas City, Arkansas. These sites seem to be point sources of PCB pollution because PCB residues in catfishes above and below these sites were lower. Although PCBs were banned in 1978, the elevated levels in catfishes suggests PCB leakage from hazardous waste sites with transformer and hydraulic fluids and flame-resistant plasticizers (Leiker et al. 1991). Findings of high (greater than 4,000 µg/kg FW) total PCB levels in mature roe samples of the paddlefish (*Polyodon spathula*) from the Ohio River warranted warnings of the general public about consuming this domestic caviar (Gundersen and Pearson 1992).

The upper Hudson River was massively contaminated with PCBs from an industrial plant for several decades prior to 1975. All fishing in this section in 1976 was banned because of PCB contamination. The

prohibition is still in effect because, in part, of measurable PCB residues in caged fishes from this area (Table 9; Jones et al. 1989). Striped bass (*Morone saxatilis*) collected near Troy and Albany, New York, contained higher concentrations in muscle of PCB 77 (37 µg/kg FW) and PCB 126 (8 µg/kg FW) than conspecifics from other locations in New York (Hong et al. 1992). Almost all (99%) the PCB toxicity in muscle of striped bass was attributed to PCBs 77, 105 (62 µg/kg FW), and 126 (Hong et al. 1992).

The most prominent PCB congeners in muscle from 14 species of Wisconsin fishes in 1986-87 were PCBs 28/31, 66/95, 70/76, 101, 105, 110, 118, 138, 146, 149 and 180 (Maack and Sonzogni 1988). Congeners 105 and 118 were found in the greatest amount in fishes at 1 to 5% of the total PCB concentration of each. Congeners with responses similar to 2,3,7,8-TCDD, that is, the planar PCBs, were seldom present above detection levels. The sum of the individual congeners measured in Wisconsin fish muscle were similar to total recorded PCB values (Maack and Sonzogni 1988). Increased fish consumption by Wisconsin anglers in 1985 positively correlated with increased human serum PCB concentrations (Sonzogni et al. 1991). Human consumers of Wisconsin game fishes (chinook salmon, *Oncorhynchus tshawytscha*; yellow perch, *Perca flavescens*; walleye, *Stizostedion vitreum*) in 1986 contained various PCB congeners in their sera. PCB 153 (78% frequency of occurrence) was present at 1.46 (0.6-7.3) µg/L human serum, PCB 138 (56%) at 1.32 (0.6-6.0) µg/L, PCB 180 (42%) at 1.06 (0.6-3.5) µg/L, PCB 118 (34%) at 1.12 (0.6-5.7) µg/L, PCB 187 (11%) at 0.98 (0.6-2.2) µg/L, PCB 170 (5.8%) at 0.86 (0.6-1.4) µg/L, PCB 28 (1.2%) at 0.8 µg/L, PCB 101 (0.58%) at 0.8 µg/L, PCB 70 (0.58%) at 0.7 µg/L, and a single planar PCB—PCB 77—(0.58% frequency of occurrence) at 1.3 µg/L. PCBs 118, 138, and 180 are potentially most toxic to human consumers, as judged by the concentrations of these congeners in human sera (Sonzogni et al. 1991).

Concentrations of PCBs in female northern pikes (*Esox lucius*) from a Scandinavian lake decreased with increasing age, weight, or body length (Larsson et al. 1993). Seasonal elimination of the lipophilic contaminants in roe—which contained as much as 10 times more fat than muscle and more than 10 times the amount of pollutants than muscle—is the major route of PCB loss. Male northern pikes contained higher concentrations of PCBs than females because of the lower elimination by way of gonadal products; males showed no significant relation between age and PCB burdens in tissues (Larsson et al. 1993). Total PCB levels of 7,700 to 34,000 µg/kg LW in eggs of the Arctic char (*Salvelinus alpinus*) from Lake Geneva, Switzerland, correlated with a mortality rate of 29 to 100% (Gundersen and Pearson 1992).

On the Pacific coast and in adjacent areas of Mexico, data from more than 150 survey and monitoring programs were summarized on contamination of sediments, invertebrates, and fishes (Mearns 1992). PCBs in sediments seem to be reflected in mussels, and PCB residues from mussels collected at harbor entrances remained unchanged or were increasing. The harbors in Los Angeles-Long Beach and San Diego remained contaminated with PCBs, and PCB concentrations in sediments were reflected in fish livers. Waste management seems to have been effective in the Palos Verdes outfall area. Sediments and mussel samples in Palos Verdes from 1974-88 showed decreasing PCB levels that reflected a 100-fold reduction in PCB wastewater emissions during that period. Contamination of the coastal zone declined to levels found 30 and 40 years ago. PCB levels had declined at least one order of magnitude in teleosts and shellfish at offshore sites since the 1970s. Bays and harbors were more contaminated than the open coastal zone and must be monitored more closely; lower detection levels (0.001 to 0.01 mg/kg FW versus the current analytical limits of 0.02 mg/kg FW) were proposed to monitor the effectiveness of current source control programs (Mearns 1992).

PCBs in the Puget Sound, Washington, were measured in sediments, fish livers, and benthic invertebrates. Maximum total PCB concentrations were 2,100 µg/kg DW in sediments near Tacoma and 32,000 µg/kg DW in crab hepatopancreas and 35,000 µg/kg DW in fish liver near Seattle (Long 1981). PCB concentrations in sediments of the Puget Sound in May 1988 positively correlated with PCB concentrations in livers of several species of flatfishes in these sediments (Stein et al. 1992). Increased sediment PCB concentrations also correlated well with increased hepatic AHH and EROD activities and with increases in total hepatic GSH, all of which are acknowledged early indicators of chemical contamination by PCBs and other organic contaminants (Gooch et al. 1989; Stein et al. 1992).

PCB residues in liver of the European flounder (*Platichthys flesus*) were extremely variable, but residues of individual congeners were usually higher in fall, higher in females, and higher in flounders captured inland near a PCB point source (Marthinsen et al. 1991); a similar pattern was documented in the Atlantic cod, (*Gadus morhua*; Marthinsen et al. 1991). In the dab (*Limanda limanda*), a marine flatfish, the accumulation of PCBs 128,

138, and 163 differs significantly by sex (Knickmeyer and Steinhart 1989). Depletion of lipids from the liver of female dabs during ovary maturation is an important excretory pathway for PCBs during spawning (Knickmeyer and Steinhart 1989). PCB levels in liver of dabs were higher in spring than in winter; livers and ovaries were dominated by penta-and hexacholorobiphenyls, but the dominant PCBs in testes were tri-and tetrachlorobiphenyls (Kammann et al. 1993).

The most prominent PCB congeners at 280-323 µg/kg DW in the tilefish (*Lopholatilus chamaeleonticeps*) from Georges Bank in 1981-92 were PCBs 138 and 153 in gonad and liver; at 69-82 µg/kg DW the most prominent PCB congeners in the tilefish from New Jersey during this same period were PCBs 138 and 153 in liver (Steimle et al. 1990). Total PCB concentrations in marine coastal fishes were dominated by the hexachlorobiphenyls (Knickmeyer and Steinhart 1989), but trout from isolated mountain lakes had tri-, tetra-, and pentachlorobiphenyls as the major components of total PCBs (Sanchez et al. 1993).

Reptiles

PCBs accumulate in the fat, testes, and brain of snapping turtles *(Chelydra serpentina*), and concentrations seem to reflect the lipoprotein solubility of individual congeners (Bryan et al. 1987a; Table 10). With increasing hydrophobicity (increasing K_{OW}) of PCB congeners, accumulations increased in livers of snapping turtles; total liver PCB concentrations in adults increased with increasing age, length, and weight (Hebert et al. 1993). PCB loadings in snapping turtle eggs were not related to the body size of females or to the number of eggs in the clutch (Bishop et al. 1994). However, a positive relation between PCB loadings in liver of adult female snapping turtles and their eggs was significant (Hebert et al. 1993).

PCB 105 may be an important contributor to the toxic burden of snapping turtle populations (Hebert et al. 1993). Eggs of snapping turtles from the Great Lakes had a lower hatch rate and a significantly increased frequency of deformed hatchlings than eggs from a control site, and this seemed to be strongly associated with total PCB concentrations and PCB 105 (Bishop et al. 1991). Of the 5 toxic PCB congeners measured in the yolks, egg whites, and shells of snapping turtle eggs, PCBs 105 and 167 accounted for more than 99% of the total toxicity—as measured by 2,3,7,8-TCDD TEF equivalents—and 95% of the total toxicity resided in the yolk (Bryan et al. 1987b). Large reserves of fat in eggs of the snapping turtle do not seem to protect against toxic PCB congeners from being dispersed into egg components low in fat (Bryan et al. 1987b).

Birds

In general, total PCB concentrations in birds were usually higher in males and in eggs than in livers, in adipose tissues, in fish-eating species, and at PCB-contaminated sites; PCBs 138 and 153 tended to predominate in all samples (Table 11). The change in PCB content in livers of Norwegian raptors between 1965 and 1983 was not significant despite a marked reduction in the use of these compounds (Froslie et al. 1986). When total PCB concentrations declined, for example, in eggs of red-breasted mergansers (*Mergus serrator*) between 1977 and 1990, the relative potency of the mixture of PCBs—as measured by 2,3,7,8-TCDD equivalents—was unchanged (Williams et al. 1995).

Commercial PCB mixtures frequently contain impurities that may contribute to the 2,3,7,8-TCDD toxic equivalency factor; these impurities may include other PCBs, dioxins, dibenzofurans, naphthalenes, diphenyl ethers and toluenes, phenoxy and biphenyl anisoles, xanthenes, xanthones, anthracenes, and fluorenes (Jones et al. 1993). PCB concentrations in avian tissues sometimes positively correlate with DDE concentrations (Mora et al. 1993). Eggs of peregrine falcons (*Falco peregrinus*) from California, for example, contained measurable quantities of various organochlorine compounds, including dioxins, dibenzofurans, mirex, hexachlorobenzene, and p,p' DDE at 7.1-26.0 mg/kg FW; PCB 126 accounted for 83% of the 2,3,7,8-TCDD equivalents, but its interactions with other detectable organochlorine compounds is largely unknown (Jarman et al. 1993).

There is a relation between PCB uptake and the position of the species in the food chain. In a 3-step central-European oak-forest food chain involving the great tit *(Parus major*), caterpillars (*Tortrix viridana*, *Operophtera brumata, Erannis defoliara*), and leaves of the red oak (*Quercus* sp.), mean concentrations of PCB 153—the most abundant measured congener—rose from about 1 µg/kg DW in leaves to 10 in caterpillars to 170 in bird eggs (Winter and Streit 1992). Older juvenile tits contained 307 µg of PCB 153/kg whole body DW; these birds received PCBs from the mother during egg transfer and from the caterpillar food source during the nesting period. PCBs 101, 138, and 180 were also present in most samples but at lower concentrations than PCB 153.

Populations of *Parus major* in this area declined in recent years, and the influence of anthropogenic contaminants may be a factor (Winter and Streit 1992). Fish-eating waterfowl and seabirds had comparatively high total PCB and high planar PCB concentrations in eggs and tissues; waterfowl and seabirds that feed mainly on invertebrates had lower PCB concentrations (Focardi et al. 1988b; Borlakoglu et al. 1990; Gonzalez et al. 1991; Jones et al. 1993). PCB concentrations were higher in adipose tissues of the Arctic tern *(Sterna paradisaea*) than in those of their fish and invertebrate food items (Scharenberg 1991a). PCB concentrations in adipose tissues of cormorants, when compared to their diet of fishes, were 10 to 100 times higher than marine fishes and 100 to 1,000 times higher than freshwater fishes (Scharenberg 1991b). Double-crested cormorants (*Phalacrocorax auritus*) biomagnify total PCBs from their fish diet to their eggs—based on 2,3,7,8-TCDD equivalents—by a factor of 31.3 (Jones et al. 1994). Higher-chlorinated PCBs accumulated in tissues of the herring gull (*Larus argentatus*) to a greater extent than were present in the alewife (*Alosa pseudoharengus*), a primary food item; lower-chlorinated biphenyls, including the tetra- and penta-CBs, did not biomagnify (Braune and Norstrom 1989).

Table 10. PCB concentrations in field collections of selected reptiles. Concentrations are in ug/kg (ppb) fresh weight (FW) or lipid weight (LW).

[a] Concentrations are shown as means, range (in parentheses), and maximum (Max.).

[b] 1, Heinz et al. 1991; 2, Delaney et al. 1988; 3, Bishop et al. 1991; 4, Bishop et al. 1994; 5, Hebert et al. 1993; 6, Bryan et al. 1987a; 7, Bryan et al. 1987b.

Declining populations of Caspian terns (*Sterna caspia*)—especially populations nesting in Green Bay and Saginaw Bay between 1986 and 1990—were associated with elevated PCB concentrations in blood; the frequency of developmental abnormalities and deformities in Caspian tern populations at Saginaw Bay was almost 100 times above that recorded in the same area between 1962 and 1972 (Table 11; Mora et al. 1993). High PCB concentrations in tissues of white-tailed eagles (*Haliaeetus albicilla*) are directly connected to high concentrations in eggs and associated with eggshell thinning and low reproductive success (Falandysz et al. 1994a). A total lack of reproduction among white-tailed sea eagles in the coastal area of the southwestern Baltic Sea in the 1960s and 1970s may be related, in part, to high concentrations of PCBs 105, 118, 126, and 156 in tissues of adult eagles. It is noteworthy that concentrations of planar PCBs in adult white-tailed sea eagles were among the highest reported in wildlife and that total PCB concentrations in this species were similar to those reported in dead eagles from Sweden and Finland in the 1960s and 1970s (Falandysz et al. 1994a).

PCB 153 is the most widespread PCB in the environment because it is easily stored and retained in adipose tissue; PCB 153 was the main PCB congener in eggs of eight examined species of Italian waterfowl and accounted for 11.4-21.2% of the total PCB concentration (Focardi et al. 1988b). Infertile eggs of the endangered imperial eagle (*Aquila heliaca adalberti*) contained as much as 28.9 mg total PCBs/kg FW; PCB 153 constituted 13.5% of the total PCB loading, PCB 180 13%, PCB 138 3.2%, PCB 101 3.2%, and PCB 118 0.7% (Hernandez et al. 1989). In the endangered Audouin's gull (*Larus audouinii*), most (62%) of the total PCB burden consisted of PCBs 153, 138, 170, and 180; other important congeners were PCBs 118, 194, and 203, and each contributed about 5% (Leonozio et al. 1989). PCBs 138, 153, and 180 comprised more than 50% of the total PCB burden in eggs of the yellow-legged herring gull (*Larus cachinnans*); a similar case is made for eggs of other species of marine birds (Focardi et al. 1988a). PCBs 138, 153, and 180 were also dominant in tissues of most birds collected in Great Britain between 1988 and 1990, although total PCB concentrations ranged from 0.02 to 105 mg/kg FW and also differed considerably in different tissues from individual birds (Boumpherey et al. 1993). PCBs 138 and 153 were the most prominent congeners in eggs of 3 species of gulls collected in Spain during 1988, accounting for 10.5% and 8.7%, respectively, of the total PCB burden; other important congeners were PCBs 180 (7.5%), 170 (3.2%), 101 (1.9%), 151 (1.1%) and 194 (0.9%; Gonzalez et al. 1991).

PCB signatures in bird eggs are not constant. Eggs of the dipper (C*inclus cinclus*) from Wales and Ireland were dominated by PCB 118 in 1990, PCB 170 in 1991, and PCB 153 in 1992; 6 congeners accounted for 26-35% of the total PCBs in Welsh eggs and for 10-26% of the total in eggs from Ireland (Ormerod and Tyler 1992, 1994). In tissues of birds in Great Britain, the mono-*ortho* congeners—PCBs 105 and 118—made a high contribution (70%) to the TEF, whereas the non-*ortho* congeners (PCBs 77, 126, 169) contributed 20%, and the di-*ortho* congeners (PCBs 138, 153, 180) contributed 10% (Boumpherey et al. 1993). Young of all avian species sampled in Wisconsin accumulated PCBs 77, 105, 126, and 169. Chicks of Forster's terns (*Sterna forsteri*) had daily uptakes of 15 µg total PCBs, 0.07 µg PCB 77, 0.2 µg PCB 105, 0.006 µg for PCB 126, and 0.00014 µg PCB 169 (Ankley et al. 1993).

Concentrations of mono-*ortho* PCBs in yolk-sac of cormorants ranged from 10 to 250 mg/kg LW; high PCB residues in yolk were associated with increased cytochrome P450 and EROD activities and decreased thyroid hormone activity (van den Berg et al. 1992). Embryos of the black-crowned night heron (*Nycticorax nycticorax*) with the greatest burdens of total PCBs had increased cytochrome P450-associated monooxygenase activities and cytochrome P450 proteins, which suggests that cytochrome P450 may be a useful biomarker of exposure to

some PCB mixtures (Rattner et al. 1993). The absence of established thresholds for P450 induction indicates that more research is needed (Rattner et al. 1994) to make this a useful technique for evaluating PCB exposure.

Mammals

The highest total PCB concentrations recorded in terrestrial mammalian wildlife occurred in fat and liver tissues of species collected near urban areas; di-*ortho* congeners were the major contributors to PCB tissue burdens (Table 12). Atmospheric transport of PCBs governed uptake in terrestrial mammalian herbivores and predators; for example, PCB residues in tissues of voles and shrews in the Scandinavian peninsula directly correlated with fallout loadings (Larsson et al. 1990). An increase in atmospheric deposition of PCBs increased PCB burdens in plants, herbivores, and predators of the herbivores. But herbivores and predators differentially metabolized PCBs, raising concentrations of highly-chlorinated congeners in predators and concentrations of the more easily metabolized low-chlorinated PCBs in herbivores (Larsson et al. 1990).

Populations of mink (*Mustela vison*) declined in many areas of the world, and the declines were linked to exposures to synthetic halogenated hydrocarbons (Giesy et al. 1994b). In the Great Lakes region, mink density is lower along the shores of the Great Lakes and their tributaries where mink have access to fishes from the Great Lakes. Tissue PCB concentrations and their dioxin TEFs were considered critical in the hazard assessment of PCBs. Mink that consumed fishes below dams in Michigan were 10 to 20 times more likely to suffer PCB damage than mink consuming fishes from above the dams, as judged by the elevated concentrations of total PCBs and dioxin TEFs in fishes from below the dams (Giesy et al. 1994b). European polecats (*Mustela putorius*) collected in the Netherlands between 1985 and 1990 had PCB patterns that were independent of diet and seemed to be controlled by anal gland secretions containing elevated PCB residues (Leonards et al. 1994). Juvenile polecats contained higher PCB concentrations than adult males and females, and this is attributed to an increased elimination of PCBs by adults through anal gland secretions. In all examined polecat tissues, PCB 126 accounted for 63 to 98% of the 2,3,7,8-TCDD toxic equivalents (Leonards et al. 1994).

The use of PCBs in Germany was prohibited in 1989. From 1983 to 1991, the body fat of red foxes (*Vulpes*) in Germany showed a reduction in the mean concentration of highly-chlorinated PCBs (PCBs 138, 153, and 180) but an increase in the lower-chlorinated congeners (PCBs 24, 49, and 52). These findings suggest a trend toward a reduction of environmental contamination with highly-chlorinated biphenyls since 1983, perhaps as a consequence of metabolic degradation, whereas contamination with lower-chlorinated biphenyls from diverse sources is increasing (Georgii et al. 1994). Low-chlorinated congeners that are metabolized via reactive intermediates must be evaluated because they show weak tumor-initiating properties (Georgii et al. 1994).

Populations of bats in Europe have been declining, and PCBs together with pesticides and wood preservatives are the suspected main causes of the decline (Fernandez et al. 1993). Three species of bats collected in Spain in 1988-90 contained only a few dominant PCB congeners; PCBs 138, 153, and 180 accounted for about 80% of the total PCB burden in whole bats (Fernandez et al. 1993). But the most abundant PCB congeners in brain and liver of European otters (*Lutra*) were in the descending order of PCBs 163, 153, 138, and 170, each constituting at least 10% of the total PCB burden (Mason and Ratford 1994).

The PCB composition in tissues of polar bears (*Ursus maritimus*) suggest that polar bears—unlike other mammals—can readily metabolize PCB congeners with unsubstituted *para* positions and unsubstituted adjacent *ortho-meta* positions (Norheim et al. 1992). Six PCB congeners (PCBs 99, 138, 153, 170, 180, 194)—all with a minimum 2,2',4,4'-chlorine substitution—accounted for about 99% of the total PCB content in liver and 87% in fat; PCB 153 accounted for 37% of the total PCB loading in liver and 30% in fat. The PCB congener pattern in polar bear liver and adipose tissue is similar and seems to be independent of sex, age, nutritional status, collection locale, and PCB body burden (Norheim et al. 1992).

Lethal and Sublethal Effects

General

In all tested organisms, PCBs—especially PCBs with 2,3,7,8-TCDD-like activity—adversely affected patterns of survival, reproduction, growth, metabolism, and accumulation. Common manifestations of PCB exposure in animals include hepatotoxicity (hepatomegaly, necrosis), immunotoxicity (atrophy of lymphoid tissues, suppressed antibody responses), neurotoxicity (impaired behavior and development, catecholamine

alterations), increased abortion, low birth weight, embryolethality, teratogenicity, gastrointestinal ulceration and necrosis, bronchitis, dermal toxicity (chloracne, edema, hyperplasia), weak mutagenicity at high doses, and preneoplastic changes at low doses (Hansen 1987). At concentrations above a threshold, PCBs are potent promoters of hepatic carcinogenesis in laboratory rodents; however, there is no clear evidence of carcinogenicity of PCBs to human and animal populations from natural exposure (Hayes 1987). Induction of hepatic microsomal enzymes is one of the earliest and most sensitive responses to PCBs (Hansen 1987).

Table 12. PCB concentrations in field collections of selected mammals. Concentrations are in ug/kg (ppb) fresh weight (FW) or lipid weight (LW).

Table 12. Species, tissue, PCB congener, and other variables	**Concentration[a] in ug/kg**	**Reference[b]**

[a] Concentrations are shown as means, range (in parentheses), maximum (Max.), and nondetectable (ND).

[b] 1, Fernandez et al. 1993; 2, Georgii et al. 1994; 3, Hong et al. 1994; 4, Mason and Ratford 1994; 5, Leonards et al. 1994; 6, Norheim et al. 1992; 7, USEPA 1994.

PCB-induced toxicity patterns are highly variable. Variability, as discussed later, is attributed in part to differences between species and strains in ability to metabolize PCBs and in primary sites of action; in the age, growth rate, biomass, and lipid content of the species; in dose rate, duration of exposure, route of administration, and tested congeners; in physicochemical characteristics of the habitat during exposure; and in PCB interactions with other PCBs, other organochlorine compounds, and heavy metals. Chinook salmon (*Oncorhynchus tshawytscha*) had decreased hatch when eggs contained the equivalent of 0.1 ug 2,3,7,8-TCDD/kg fresh weight (FW); domestic chickens (*Gallus* sp.) had decreased survival and increased

developmental abnormalities when embryos had 20 µg PCB 77/kg FW; mink (*Mustela vison*) had reduced growth when fed 100 µg Aroclor 1254/kg BW daily and reduced survival at 50 µg PCB 169/kg diet; rhesus macaques (*Macaca mulatta*) had reproductive impairment when fed more than 8 µg Aroclor 1016/kg BW daily; and rats (*Rattus* sp.) had reduced litter sizes and survival when given 10 µg PCB 126/kg BW daily during gestation.

Aquatic Organisms

PCBs influence patterns of survival, reproduction, growth, enzyme activities, and accumulation in representative aquatic organisms (Table 13). Some PCB congeners at laboratory concentrations that were several orders of magnitude higher than those encountered under field conditions killed 47 to 83% of tested freshwater fishes and invertebrates in 24-48 h; however, most PCB tested congeners produced negligible mortality under these conditions (Dillon and Burton 1992; Table 13). Mortality increased when PCB 133 or PCB 177 concentrations in whole guppies (*Poecilia reticulata*) exceeded 1 µmole/g, equivalent to more than 200 mg PCB/kg whole body FW or about 4,000 mg PCB/kg on a lipid weight basis (Opperhuizen and Schrap 1988). PCBs—especially those with TCDD-type activity—adversely affect reproductive success of spawning female chinook salmon. Chinook salmon eggs that contained total PCB concentrations equivalent to 0.1 µg 2,3,7,8-TCDD equivalents/kg eggs and higher had a dose-dependent decrease in hatching success (Ankley et al. 1991). PCBs also impair the reproductive capacities of marine mammals (Kannan et al. 1993).

Table 13. Effects of PCBs on representative aquatic organisms.

Table 13. Taxonomic group, organism, PCB congener, dose, and other variables	**Effect**	**Reference[a]**
Invertebrates		
Daphnid, *Daphnia magna*; early life stages		
PCB 1; 710 ug/L	LC50 (24h)	1
PCB 2; 430 ug/L	LC50 (24h)	1
PCB 3; 420 ug/L	LC50 (24h)	1
PCB 18; 86 ug/L	47% dead in 48 h	
PCBs 28 (1.5 ug/L), 52 (74 ug/L), 77 (0.3 ug/L), 101 (1.2 ug/L), 116 (2.8 ug/L), 128 (0.4 ug/L), 153 (1.3 ug/L), 171 (1.7 ug/L), 194 (3.0 ug/L)	Negligible mortality; 87-100% survival in 48 h	1
PCB 47; 30 ug/L	LC50 (24h)	1
Zebra mussel, *Dreissena polymorpha*		
Fed alga (*Chlorella* sp.) containing 500 mg PCB 77/kg for 32 days	Maximum tissue concentration of 3.4 mg PCB 77/kg fresh weight soft parts reached in about 14 days; concentration dropped to about 2 mg/kg after 32 days	2
Fed *Chlorella* containing 500 mg PCB 169/kg for 50 days, then clean *Chlorella* diet for 45 days	Maximum tissue concentration of 3.7 mg PCB 169/kg soft parts reached in 10 days, then decline during exposure to equilibrium level of about 1 mg/kg soft parts. After 25 days of clearance, soft parts contained 0.1 mg/kg fresh weight	2

Table 13. Taxonomic group, organism, PCB congener, dose, and other variables	Effect	Reference[a]
Amphipod, *Gammarus pseudolimnaeus*		
PCBs 8, 15, 32, 155, 101; initial water concentrations of 70-210 ug/L	LC50 (96h)	1
Mysid, *Mysis relicta*; exposed to radiolabeled PCB 153 for 6 h at 4^{o}C then transferred to clean water for 26 days	Bioconcentration factor from water of 442,230; calculated half-time persistence of 220 days	10
Amphipod, *Pontoporeia hoyi*; exposed to radiolabeled PCB 153 for 6 h at 4^{o}C then transferred to clean water for 26 days	Bioconcentration factor from water of 101,660; calculated half-time persistence of 50 days	10
Vertebrates		
Rainbow trout, *Oncorhynchus mykiss*		
Eggs injected 24 to 50 h after fertilization with graded doses of various PCBs		
PCB 4; >24,200 ug/kg egg fresh weight (FW)	LD50, embryos	13
PCB 28; >24,300 ug/kg egg FW	LD50 embryos	13
PCB 52; >30,400 ug/kg egg FW	LD50, embryos	13
PCB 77		
0.578 ug/kg egg FW	At age 35 days, sac-fry contained 78% of original dose	13
1,348 (1,064-1,621) ug/kg egg FW	LD50, embryos; blue-sac syndrome	13, 14
PCB 81; 549 ug/kg egg FW	LD50, embryos; blue-sac syndrome	13
PCB 105		
67 ug/kg egg FW	At sac-fry stage 78% of original dose remained	13
>6,970 ug/kg egg FW	LD50, embryos	14
PCB 118		
1,330 ug/kg egg FW	About 81% of original dose present in sac-fry	13
>6,970->57,400 ug/kg egg FW	LD50, embryos	13, 14
PCB 126		
74 (44-83) ug/kg egg FW	LD50, embryos	13, 14
1,203 ug/kg egg FW	About 88% recovered from embryos	13
PCBs 128, 138, and 156; >115,000 ug/kg egg FW	LD50, embryos	13
PCB 153; >6,200 ug/kg FW	LD50, embryos	14
PCB 169; 7,110 (5,630-8,090) ug/kg egg FW	LD50, embryos; blue-sac syndrome	13
PCB 170; >41,100 ug/kg egg FW	LD50, embryos	13
Single intraperitoneal (ip) injection; 134 ug/kg BW of PCB 77; or 5.8 ug/kg BW of PCB 126; or 93.7 ug/kg BW of PCB 169; subadults	50% increase in liver EROD activity	12
Single ip injection of 1.0 mg PCB 77/kg BW; livers analyzed 13 days postinjection; subadult	Compared to controls, livers were elevated in levels of cytochrome P-450 (2X), ethoxycoumarin-*O*-deethylase (10X) and ethoxyresorufin-*O*-deethylase (50X)	3
Injected ip with 2,3,7,8-TCDD at 0.00037, 0.0022 or 0.0045 umol/kg BW, or with PCB 77 at 0.2, 1.1, or 2.2 umol/kg BW; subadults	50% induction of AHH (arylhydrocarbon hydroxylase) activity in liver microsomes of sexually immature trout at 0.002 umol/kg for TCDD and 0.37 umol/kg for PCB 77	3

Table 13. Taxonomic group, organism, PCB congener, dose, and other variables	Effect	Reference[a]
Single ip injection of mixture of 0.00018 umol TCDD/kg BW plus 0.1 umol/kg PCB 77; or mixture of 0.0011 umol TCDD/kg BW plus 0.6 umol PCB 77/kg BW; subadults	Mixtures of TCDD and PCB 77 produced greater than additive AHH responses	3
Single ip injection of mixture of 0.0022 umol TCDD/kg BW plus 1.1 umol PCB 77/kg BW; subadults	AHH induction response was less than additive	3
Single ip injection of PCB 77, PCB 126, or 2,3,7,8-TCDD. Liver AHH activity measured 3 days later; subadults	50% AHH induction occurred at 0.005 umol/kg BW for TCDD, 1.0 for PCB 77 and 2.2 for PCB 126. PCB 77 was 1/200 as effective in inducing AHH activity in liver as TCDD, and PCB 126 was 1/500 as effective	4
Single ip injection of 30 mg PCB 118/kg BW to immatures. Fish killed 4 days later and liver analyzed	Liver EROD (7-ethoxyresorufin *O*-deethylase) activity was 5.6 times higher than controls; AHH activity was 2.7 times higher than controls	5
Fingerlings were injected ip with ^{14}C-labeled PCB mixture at 0.3, 1, 3, 10, and 30 mg PCB/kg BW; tissues sampled up to 70 days postinjection.	At 3 days postinjection high doses of 10 and 30 mg PCB/kg BW caused elevation of liver microsomal monooxygenase activity when maximum tissue concentrations, in mg total PCB/kg FW, were 55 in bile, 12 in blood, 8 in muscle, and 8 in liver. Elevated hepatic microsomal monooxygenase activity with muscle and liver PCB concentrations of >0.3 mg/kg FW, but not 0.25 mg/kg FW	6
Fathead minnow, *Pimephales promelas*; fry		
PCB 18; 86 ug/L	83% dead in 48h	1
PCBs 28 (1.5 ug/L), 52 (74 ug/L), 77 (0.3 ug/L), 101 (1.2 ug/L), 116 (2.8 ug/L), 128 (0.4 ug/L), 153 (1.3 ug/L), 171 (1.7 ug/L), 194 (3.0 ug/L)	Negligible mortality; 97-100% survival in 48h	1
Guppy, *Poecilia reticulata*; adult males		
Fed diets containing 6-150 mg PCB 133 or PCB 197/kg diet for 191-247 days, or 550-1,400 mg/kg diet for 65 days	At 6-150 mg/kg diet, uptake efficiency was near 50%; at higher dietary loadings uptake efficiency decreased to 25%. No deaths in controls or at low dietary dosages; 13-25% mortality at 550-1,400 mg/kg diet. Prior to death, guppies were sluggish, uncoordinated, and darkly-colored; fish that died during exposure contained >0.7 umol PCB/g FW	7

Table 13. Taxonomic group, organism, PCB congener, dose, and other variables	Effect	Reference[a]
Fed PCB 133 at 550 mg/kg diet FW or PCB 197 at 530 mg/kg diet FW for 65 days, followed by a clean diet for 89 days, then reexposure to the contaminated diet for another 37 days	No PCB clearance during initial exposure; significant elimination of both PCBs when fed a clean diet. During reexposure, uptake efficiency for both PCBs was significantly higher than during the initial exposure.	8
Scup, *Stenotomus chrysops*		
Injected intraperitoneally with 1,5, or 10 mg/kg BW of PCBs 77, 105, 118, 128, or 138 and examined for increases in ethoxyresorufin *O*-deethylase (EROD) activity, immunodetectable cytochrome P450E (the EROD catalyst in scup) and in vitro translatable MRNA for P450E	Monooxygenase parameters were significantly induced only by PCB 77; translatable MRNA for P450E was induced at all doses; EROD activity and P450E were decreased at the 5 and 10 mg/kg BW doses; a positive correlation was established between PCB 77 residues in liver and decreased EROD activity at the higher doses	9

[a]1, Dillon and Burton 1992; 2, Brieger and Hunter 1993; 3, Janz and Metcalfe 1991b; 4, Janz and Metcalfe 1991a; 5, Skaare et al. 1991; 6, Melancon et al. 1989; 7, Schrap and Opperhuizen 1988; 8, Opperhuizen and Schrap 1988; 9, Gooch et al. 1989, 10, Evans and Landrum 1989; 11, Tyle et al. 1991; 12, Newsted et al. 1995; 13, Zabel et al. 1995; 14, Walker and Peterson 1991.

The relation between PCB accumulation by the freshwater alga *Scenedesmus* sp. and the compound's octanol/water partition coefficient (K_{ow}) was measured with 40 PCB compounds in a log K_{ow} range of 4.46 to 8.18, PCB concentrations between 0.03 and 1.1 µg/L, and exposures between 20 and 30 days (Swackhammer and Skoglund 1993). The accumulation process was consistent with partitioning from water into cell lipids but was slower than the growth of *Scenedesmus* (i.e., no significant uptake of PCBs from congeners with log K_{ow} > 5.0 under conditions of rapid growth or log > 7.0 under conditions of slow growth). Thus, under nonwinter field conditions, many PCB congeners never reached equilibrium concentrations (Swackhammer and Skoglund 1993). Similar results are reported of other species of freshwater algae, including *Selenastrum capricornutum*, *Anabaena* sp., and *Synedra* sp. (Stange and Swackhammer 1994).

Zebra mussels (*Dreissena polymorpha*) accumulated PCB 77 from their diet and from the surrounding lake sediments (Brieger and Hunter 1993). An uptake rate of PCB 77 by zebra mussels followed the descending order of sediment, food, and water. Tissue concentrations in mussels peaked after 10-14 days at 3.4-3.7 mg PCB 77/kg FW soft parts; equilibrium levels of PCB 77 were near 1.0 mg/kg FW. Zebra mussels are more efficient accumulators of PCBs than other bivalve molluscs to which they are attached; accordingly, high densities of zebra mussels probably influence contaminant dynamics (Brieger and Hunter 1993). A freshwater crustacean (*Mysis relicta*) plays an important role in the transfer of PCBs from sediments into the Lake Champlain food web (Lester and McIntosh 1994), and freshwater grazing and shredding benthic invertebrates promote downstream transport of PCB 153 (Sallenave et al. 1994). Marine invertebrates accumulated PCBs 52, 101, 128, 138, 151, 153, 180, 194, 206, and 209 from PCB-contaminated sediments (Pruell et al. 1993). Clams (*Macoma nasuta*) reached a steady state equilibrium in 10 days, but sandworms (*Nereis virens*) took 70-120 days. Clams showed preferential accumulation of lower molecular weight PCB congeners, and this may be due to the comparatively low lipid content in this species. Sandworms and grass shrimp (*Palaemonetes pugio*) metabolized PCBs 52, 101, and 151 (Pruell et al. 1993).

Golden shiners (*Notemigonus crysoleucas*) rapidly accumulated radiolabeled PCBs from water during 96-h exposure (Karara and McFarland 1992). The uptake rate of PCBs from water was controlled by gill blood-flow rate. About 50% of the accumulated PCBs in shiners was eliminated in 4.9 days, and this is similar to PCB elimination rates in striped bass (*Morone saxatilis*) and channel catfish (*Ictalurus punctatus*; Karara and McFarland 1992). In guppies, residual PCB concentrations increased with increasing duration of exposure; however, steady state concentrations did not occur after dietary exposure for 65 days (Schrap and Opperhuizen

1988). PCB congeners with *ortho*-chlorine substitutions (PCBs 77, 105, 118, 128, 138) were effective inducers of EROD (7-ethoxyresorufin *O*-deethylase) and AHH (aryl hydrocarbon hydroxylase) activities in marine mammals (Gooch et al. 1989) and freshwater fishes (Janz and Metcalfe 1991a; Skaare et al. 1992) but were ineffective at doses as high as 10 mg/kg BW in scup (*Stenotomus chrysops*), a marine teleost (Gooch et al. 1989). Industrial mixtures of planar and nonplanar PCBs induced AHH in fishes (Skaare et al. 1991). Mixtures of planar PCBs and dioxins, however, produced synergism of AHH activity in fish liver at low doses and antagonism at high doses; the possible antagonistic effects on nonplanar halogenated compounds may further complicate these interactions (Janz and Metcalfe 1991b). Liver is the primary target organ for the induction of cytochrome P450-dependent monooxygenases by PCBs in fishes, and the most frequently examined organ; however, in salmonids, muscle tissue is also suitable for evaluation of hepatic monooxygenase induction, as judged by PCB concentrations in muscle (Janz et al. 1992).

Birds

PCB 126 is among the most toxic of all PCB congeners to birds and the domestic chicken is the most sensitive tested species (Table 14; Hoffman et al. 1995). However, adverse effects of PCBs in birds vary markedly between species and tissues. And birds react differently to different PCB congeners and to PCB-metal mixtures. American kestrels (*Falco sparverius*) differ from Japanese quail (*Coturnix japonica*) after exposure to PCBs 105, 126, and 153; quail accumulated porphyrins in liver but kestrels did not (Elliott et al. 1991). Japanese quail dosed with PCBs 47 or 77 showed marked differences between the abilities of the small intestines and liver to metabolize porphyrin and the induction of cytochrome P450 isozymes and associated monooxygenases (Miranda et al. 1987). Pure hexachlorobiphenyls (HCBs) caused uroporphyrin accumulations and increased delta-aminolevulinic acid synthetase activity in chicken livers, and some HCBs significantly increased cytochrome P450 and *p*-nitrophenol glucuronyl transferase when given in the feed for 3 weeks at 400 mg/kg ration; however, PCBs 128 and 169 caused grosser accumulations of hepatic porphyrins than PCBs 138, 155, and 156 (Goldstein et al. 1976, 1977). PCBs 77, 136, 153, and 159 produced acute histopathological changes in chick embryo livers and selectively induced cytochrome P448-mediated mixed function oxidases; the degree of histopathologic change produced by each of the tested PCBs positively correlated with the degree of P448 inhibition (Rifkind et al. 1984). Interactions of metals with PCBs are not well documented, although some studies with Japanese quail showed that cadmium raises PCB uptake from the diet. In one study, cadmium fed at high dietary levels of 100 mg/kg ration interfered with high levels of dietary PCBs (100 mg/kg ration). In that study, muscle of treated quails had increased loadings of congeners chlorinated in the 2,4,5 position (such as PCBs 138, 153, 170, and 180), and these are comparatively toxic and resistant to metabolic degradation (Leonzio et al. 1992). More research is needed on variables known to modify PCB uptake, retention, translocation, and toxicity.

Table 14. Effects of PCBs on selected birds.

Table 14. Species, PCB congener, dose, and other variables	**Effect**	**Reference[a]**
Mallard, *Anas platyrhynchos*; PCB 77		
Single injection into egg yolk on day 5 of incubation		
0.1 mg/kg egg fresh weight (FW)	No effect on hatching rate; chicks normal	1
5.0 mg/kg egg FW	No effect on embryo survival and no gross abnormalities	2
Greylag goose, *Anser anser*		
PCB 77; single injection into egg yolk on day 5 of incubation; 1.0 mg/kg egg FW	No effect on survival or development	2
Goldeneye, *Bucephala clangula*	33% hatch vs. 52% hatch in	
PCB 77; single injection into egg yolk; 1.0 mg/kg egg FW	controls; chicks normal	1
Northern bobwhite, *Colinus virginianus*;	LD50 through hatching	16
PCB 126; single injection of egg with 0.04-0.07 mg/kg FW		
Japanese quail, *Coturnix japonica*	All compounds caused a significant	3
Adults given a single oral dose of either PCB 47 at 87.6 mg/kg body weight (BW),	increase in EROD activity and porphyrin content in small intestine	

Table 14. Species, PCB congener, dose, and other variables	Effect	Reference[a]
PCB 77 at 87.6 mg/kg BW, or Aroclor 1242 at 100 to 500 mg/kg BW. Quail were killed 48 h postdosing and liver and intestine analyzed for porphyrins and cytochrome P450 monooxygenases	and liver, and a significant increase in hepatic P450 content	
Adults fed diets for 30 days containing 100 mg cadmium/kg diet, 100 mg Aroclor 1260/kg diet, or mixture of 100 mg cadmium plus 100 mg Aroclor 1260/kg	Quail fed the mixture diet had 3 times more PCBs in muscle than the Aroclor group alone, and 70 times more PCBs than controls. The most dominant PCB congeners were 138, 153, 170, and 180	4
American kestrel, *Falco sparverius*		
Aroclor 1248; fed diets containing 3 mg/kg ration for 6 months; carcasses and egg analyzed for total PCBs (Aroclors 1248, 1254, and 1260)	Carcasses of adults had 18.5 mg total PCBs/kg FW (vs. 3.3 in controls); eggs had 5.6 mg/kg FW vs 1.5 in controls; shell thickness of eggs reduced 5%	5
Fed diets for 4 weeks containing daily doses equivalent to 3 mg PCB 105/kg BW, 0.05 mg PCB 126/kg BW, or 4.0 mg PCB 153/kg BW. Birds were killed 3 days after final treatment and livers analyzed for porphyrins, PCB residues, and activities of ethoxyresorufin *O*-deethylase (EROD), aminopyrine N-demethylase(APND), and aldrin epoxidase (AE)	PCB 105 caused significant APND induction; liver had 182.0 mg PCB 105/kg FW vs. 2.4 in corn oil controls PCB 126 induced hepatic EROD and AE; liver had 3.3 mg PCB 126/kg FW. PCB 153 induced APND and AE; liver contained 119.0 mg PCB 153/kg FW. For all dose groups, liver weights and liver porphyrin levels were normal	6
Nestlings given daily doses of PCBs 77, 105, or 126 for 10 days		
PCB 77; 1.0 mg/kg BW daily	Liver contained 892 ug PCB 77/kg FW; onset of liver necrosis	16
PCB 105; 4.0 mg/kg BW daily	Liver contained 1,677 ug PCB 105/kg FW; liver necrosis	16
PCB 126		
50 ug/kg BW daily	Liver contained 158 (68-563) ug PCB 126/kg FW; pronounced liver enlargement; lymphoid depletion of spleen	16
250 ug/kg BW daily	Liver had 380 ug PCB 126/kg FW	16
1.0 mg/kg BW daily	Liver had 1.1 (0.6-4.5) mg PCB 126/kg FW; decreased body weight	16
Egg injected through air cell with 70-100 ug PCB 126/kg FW	LD50 through hatching	16
Domestic chicken, *Gallus* sp.		
PCB 77; single dose injected into egg yolk on day 4 of fertilization		
0.0006 mg/kg egg FW	50% increase in AHH activity after 48 h	7
0.004 mg/kg egg FW	60% hatch vs. 88% in controls	1, 8
0.010 mg/kg egg FW	17% dead in 18 days; reduced thymus weight	7
0.020 mg/kg egg FW	70-100% dead by day 18; treated embryos had increased frequency of liver lesions, subcutaneous	1, 2, 8

Table 14. Species, PCB congener, dose, and other variables	Effect	Reference[a]
	edema, shortened beaks, and microphthalmia	
0.050 mg/kg egg FW	All dead within 18 days	7
0.100 mg/kg egg FW	Zero hatch; all dead	8
PCB 77; single dose injected into air sac on day 3 of incubation; 0.005 mg/kg egg FW	Whole liver homogenates had increases of 300-fold in 7 -ethoxycoumarin *O*-deethylase and 75-fold in AHH activities between days 5 and 10	15
PCB 77; single dose injected into air sac on day 13 of incubation		
0.045 mg/kg egg FW	Reduction by 50% in lymphoid cells in bursa of Fabricus	9
0.20-0.30 mg/kg egg FW	30-fold increase in AHH activity; bursa almost devoid of lymphoid cells	9
PCBs 77, 136, 153, 169; 17-day old embryos; single injection at 0.5-30,000 nmol/egg; examined for liver histopathology and induction of mixed function oxidases after 24 h	Significant alterations occurred at 0.5 nmol PCB 77/egg (about 0.003 mg/kg egg), at 5 nmol PCB 169/egg , and between 500 and 5,000 nmol PCB 153/egg. PCB 136 had no effect on liver pathology at the highest dose tested of 30,000 nmol/egg	10
Single injection of eggs of PCBs 105 (2.2 mg/kg FW), 126 (0.0006-0.0031 mg/kg FW), 157 (1.5-2.0 mg/kg FW), or 169 (0.17 mg/kg FW	LD50 through hatching	16
PCBs 128, 136, 153, 155, and 169; each was fed in diets to 1-day-old chicks for 21 days at 400 mg/kg ration		
PCB 128	Decrease in weight gain; moderate liver pathology; gross accumulations of hepatic porphyrins and increased delta-amimolevulinic acid synthetase activity	11, 12
PCB 136	Decrease in weight gain; comparatively small increase in liver weight	11
PCB 153	Decrease in weight gain; mild liver pathology	11
PCB 155	Largest increase in liver weight; significant liver pathology	11
PCB 169	All dead in 11 days; thymic involution and edema; gross accumulations of uroporphyrins in liver	11, 12
Herring gull, *Larus argentatus*		
PCB 77; single injection into egg yolk on day 5 of incubation; 1.0 mg/kg egg FW	No effect on survival or development	2
Black-headed gull, *Larus ridibundus*		
PCB 77; single injection into egg yolk of 1.0 mg/kg egg FW	No effect on hatching rate; chicks normal	1

Table 14. Species, PCB congener, dose, and other variables	Effect	Reference[a]
Wild turkey, *Meleagris gallopavo*		
PCB 77; single injection into air sac of 5-day-old embryos		
0.006 mg/kg egg FW	50% increase in AHH activity after 48 h	7
1.0 mg/kg egg FW	60% dead in 24 days	7
Ring-necked pheasant, *Phasianus colchicus*		
PCB 77; single injection into egg yolk		
0.1 mg/kg egg FW	No decrease in hatching rate; chicks normal	1
1.0 mg/kg egg FW	All embryos died	1
Common eider, *Somateria mollissima*; single injection into yolk on day 5 of incubation		
PCB 77; 1.0 mg/kg egg FW	No effect on survival	13
PCB 126; 0.1 mg/kg egg FW	35% dead on day 24 of incubation vs. 20% dead in controls	13
Common tern, *Sterna hirundo;*		
PCB 126; single egg injection with 0.045 mg/kg FW	35% embryo mortality through hatching	16
Ringed-turtle dove, *Streptopelia risoria*; fed iodine-deficient diet		
PCB 77; given 20 mg/kg BW 3 times over a 28-day period	Thyroid hyperplasia caused by low iodine diet was not enhanced by PCB 77	14
PCB 77; single dose of 60 mg/kg BW	Thyroid hyperplasia reversed within 7 days	14

[a] 1, Brunstrom and Reutergardh 1986; 2, Brunstrom 1988; 3, Miranda et al. 1987; 4, Leonzio et al. 1992; 5, Lowe and Stendell 1991; 6, Elliott et al. 1991; 7, Brunstrom and Lund 1988; 8, Brunstrom and Darnerud 1983; 9, Nikolaides et al. 1988; 10, Rifkind et al. 1984; 11, McKinney et al. 1976; 12, Goldstein et al. 1976; 13, Brunstrom et al. 1990; 14, Spear and Moon 1985; 15, Brunstrom 1986; 16, Hoffman et al. 1995.

Embryos of the domestic chicken (*Gallus* sp.) are unusually sensitive to PCB 77. Mortality and a high incidence of developmental abnormalities—including microphthalmia, beak deformities, edema, and retarded growth—were recorded in chicks at 0.02 mg PCB 77/kg egg FW, but no deaths or abnormalities were recorded in embryos of ducks, pheasants, and gulls at 0.1-1.0 mg PCB 77/kg egg FW (Table 14; Brunstrom and Lund 1988). Chicken embryos were 20 to 100 times more sensitive to PCB 77 than embryos of the wild turkey (*Meleagris gallopavo*), and this sensitivity emphasizes the uncertainties of applying toxicity data from one species of bird to predict toxic effects in other avian species (Brunstrom 1988; Brunstrom and Lund 1988). Differences in sensitivity of birds to PCB 77 may be related to differences in metabolism and in the formation of toxic metabolites and to the increased availability of Ah receptors in chicks (Brunstrom and Reutergardh 1986). For example, Ah receptors were detected in livers of 7-day-old chicken embryos but not in livers of 9-day-old turkey embryos (Brunstrom and Lund 1988).

Birds and mammals exposed to PCBs frequently react differently. PCBs generally elicit large-colloid goiters in birds; these goiters are inherently different from hyperplastic goiters produced in mammals exposed to PCBs (Spear and Moon 1985). Fish-eating seabirds, such as the razorbill (*Alca torda*), can rapidly metabolize PCB congeners that have at least one pair of adjacent unsubstituted *meta-para* combinations in the biphenyl moiety (Borlakoglu et al. 1991b). Razorbills metabolized 4-chlorobiphenyl to 4-chloro-4' hydroxybiphenyl; however, mice (*Mus* sp.) metabolized the same compound 15 times faster. PCB-exposed razorbills and rock doves (*Columba livia*) had similar concentrations of cytochrome P450 and glutathione-S-transferase enzymes, but concentrations were significantly higher in rats (*Rattus* sp.) than either avian species (Borlakoglu et al. 1991b). The relative potency of tested PCBs—as measured by EROD activity of microsomal liver enzymes—in fertile eggs of the domestic chicken were 0.02 for PCB 77, and less than 0.001 for PCB 169 (Bosveld et al. 1992); these values differ somewhat from those proposed for mammals of 0.0005 for PCB 77, and 0.01 for PCB 169 (Safe 1990). Lymphoid development in the bursa of Fabricius of the avian embryo is inhibited by TCDD-like congeners. PCB 77, for example, affects the immune system by interacting with the Ah receptor, causing

inhibition of lymphoid development in the mammalian thymus and in the avian bursa of Fabricius (Nikolaides et al. 1988). More research seems needed on the relation of avian Ah receptors to natural physiological processes.

Mammals

Deleterious effects were significant on growth, survival, reproduction, or metabolism from chronic exposures of sensitive species of tested rodents, primates, and mustelids to daily concentrations as low as 0.008 mg/kg BW of Aroclor 1016, 0.01-0.02 mg/kg BW of PCB 126, 0.01-0.05 mg/kg diet or 0.1 mg/kg BW of PCB 169, 0.09 mg/kg BW of Aroclor 1246, 0.1 mg/kg BW of Aroclor 1254, and 0.3-1.0 mg/kg diet or 0.6 mg/kg BW of PCB 77 (Table 15). Several PCBs had negligible adverse effects on tested mammals during chronic daily exposures to doses of at least 5 mg/kg ration or 5 mg/kg BW, specifically, PCBs 4, 15, 47, 52, 80, 136, 153, 155, and 167 (Table 15). Although subhuman primates seem to be more sensitive to reproductive and other adverse effects of PCBs than humans, no clear and convincing evidence associated PCB exposures with human cancers and reproductive problems (Kimbrough 1995). At present, no meaningful reproductive problems have been identified in female capacitor workers and no carcinogenicity was evident in humans having more than 1.0 mg total PCBs/L serum or more than 400 mg total PCBs/kg adipose fat (Kimbrough 1995).

Table 15. Effects of PCBs on selected mammals.

Table 15. Species, PCB congener, dose, and other variables	**Effect**	**Reference[a]**
Cotton top marmoset monkey, *Callithrix jacchus*		
PCB 77; adult females orally dosed with 0.1, 1.0, or 3.0 mg/kg body weight (BW) twice weekly for 18-28 weeks	Severe toxicity in the 3.0 mg/kg group that included body weight loss, hair loss, abnormal nail growth, scaly skin, anemia, elevated blood triglyceride and cholesterol levels, and tissue histopathology. Toxicity was less severe in the 1.0 mg/kg group and minor in the low-dose group	1
Rhesus macaque, *Macaca mulatta*		
Aroclor 1016		
>0.008 mg/kg BW daily via the diet	Adverse effects on reproduction	2
>0.028 mg/kg BW daily	Adverse effects on growth	2
Aroclor 1248; >0.09 mg/kg BW daily	Adverse effects on growth	2
Aroclor 1254; females were fed 0, 5, 20, 40, or 80 ug/kg BW daily for 6 years. During this time females were bred with non-dosed males. Resultant offspring were nursed for 22 weeks and fed no additional PCBs until they were necropsied at age 120 weeks	Total PCB concentrations in all tissues of adult females increased with increasing dosage; highest levels were in adipose tissue (Max. 141 mg/kg fresh weight [FW]; Max. 171 mg/kg lipid weight [LW]) and lowest in brain (1.1 mg/kg FW; 12.9 mg/kg LW). PCB concentrations were higher in infants from dosed dams than those nursed by controls; higher in females having a stillborn infant than those with a viable infant; and higher in those in poor health. The PCB distribution pattern in tissues from a dosed mother/infant pair was different: more hepta-chlorobiphenyls were found in the infant than in the dam	28
PCB 52		
Fed diets containing 3.0-5.0 mg/kg for 180-200 days	No clinical effects or pathologic lesions	3, 4

Table 15. Species, PCB congener, dose, and other variables	Effect	Reference[a]
PCB 77		
Fed diets containing 0.3-3.0 mg/kg ration for 1 to 6 months	Dose-and time dependent increase in chloracne; weight loss; death; and histopathology of sebaceous glands, thymus, and gastric mucosa	3
Fed diet containing 1.0 mg/kg ration for 38 days	Adverse effects on survival	4
Immature males fed diets containing 1.0 or 3.0 mg/kg ration	All were moribund in 7-14 weeks; abnormal gastric histology	5
Adult females received a total of 9 intragastric doses 20-40 days postconception; total doses were 0.6 or 3.15 mg/kg BW	All animals in both dose groups survived, but all aborted	4
Adult females given a single intravenous injection of 0.6 mg/kg BW; blood measured 1 h to 42 days postinjection	As a percentage of the total dose administered, PCB 77 concentrations in blood fell from 4.4% at 1 h to 0.14% at 42 days. About 60% of the total dose was excreted in feces, and 10% in urine	18
PCBs 136, 153, or 155; each fed in diet at 15-65 mg/kg ration for 63-122 days	No discernable deleterious effects	4
PCB 169; fed diet containing 400.0 mg/kg ration for 40 days	Concentrations in body fat increased steadily during exposure; recovery was protracted and incomplete during a 6-month observation period	4
Mouse, *Mus* sp.		
Aroclor 1254		
>1.3 mg/kg BW daily via diet	Adverse effects on reproduction	2
Single intraperitoneal injection of 500 mg/kg BW (a dose that promoted nitrosamine-initiated lung and liver tumors). The amounts of the 9 congeners that made up >90% of the PCBs present 1 day after treatment (PCBs 99, 105, 118, 128, 138, 153, 156, 170, 180) were quantified in liver, lung, and whole body for 112 days after dosing	In carcass fat, net PCB loss was attributed to metabolic loss of PCBs 105 and 138. In lung, all congeners except 153 were retained and decreased only as a function of dilution due to growth. In liver, all congeners were retained and 105 was enriched. Total PCBs in carcass averaged 80.8 mg/kg BW 24 h after treatment and about 10 mg/kg BW after 16 weeks; similar trends occurred in liver and lung. Tb 1/2 for PCB 153 was 81-101 days	6
PCB 15; pregnant mice given daily doses of 16, 32, or 64 mg/kg BW on days 6-15 of gestation and killed on day 18	Toxic to dams at 64 mg/kg BW daily, but no embryotoxicity	7
PCB 77		
Pregnant mice given 1, 2, 4, 8, 16, 32, or 64 mg/kg BW daily on days 6-15 of gestation and killed on day 18	Dose-dependent increase in incidence of malformed fetuses-especially cleft palate and hydronephrosis--at 4 mg/kg BW daily and higher. At 16 mg/kg BW and higher, dams had dose-dependent increase in weight loss, frequency of	7

Table 15. Species, PCB congener, dose, and other variables	Effect	Reference[a]
	vaginal bleeding, and other evidence of abortion	
Pregnant mice given single intravenous injection of 3.5 mg/kg BW of ^{14}C-labeled PCB 77 on days 4-17 of gestation and killed 4-96 h later	Radioactivity levels were elevated in uterine fluid and in fetuses in late gestation. No unmetabolized PCB 77 was detected in fetuses but PCB 77 metabolites (including 3,3',4,4'-tetrachloro-2-biphenylol, and methylsulphonyl- tetrachloro-biphenyl) were found in fetuses in late gestation	8
Strain C57BL/R_{ij} given single intraperitoneal injection		
15 mg/kg BW	30-40% reduction of retinol and retinyl palmitate concentrations in liver within 2-4 days	9
17 mg/kg BW	50% reduction in hepatic retinyl palmitate	9
32 mg/kg BW	50% reduction in hepatic retinol	9
Strain DBA/2; single intraperitoneal injection of 729 mg/kg BW	No reduction in hepatic retinoids	9
Single oral dose of 25, 50, or 100 mg/kg BW given to Ah-responsive pregnant mice on gestation day 11, 12, or 13; mice killed on day 18 of gestation	Dose-dependent increase in embryo deaths, resorption of the conceptus, and frequency of developmental abnormalities (cleft palate, dilated kidney pelvis, thymus hypoplasia). ED50 for cleft palate was about 100 mg PCB 77/kg BW	10
Dams received oral dose of 32 mg/kg BW daily on days 10-16 of gestation	Permanent motor dysfunction in weaning mice characterized by swift circling movements, restlessness, and hyperkinesia; spinal and cranial nerve roots abnormal	11
Ah-responsive and Ah-nonresponsive strains; females, age 10 weeks; given single intraperitoneal injection of 50 mg/kg BW; killed after 7 days	Both groups had increased body weight, increased blood EROD activity, decreased plasma retinol levels, and increased plasma total thyroid hormone levels. The Ah-responsive group also had increased hepatic pentoxyresorufin-*O*-deethylase activity, increased liver cytochrome P450 activity, and increased liver weight	12
PCB 80; pregnant mice given 64 mg/kg BW daily on days 6-15 of gestation and killed on day 18	No effect on maternal or developmental toxicity	7
PCB 169; pregnant mice given daily doses of 0.1, 1, 2, 4, 8, or 16 mg/kg BW by gavage on days 6-15 of gestation; mice killed on day 18 and dams evaluated for reproductive health and fetuses examined on day 19 for malformations	All dams survived all treatments; some lost weight during pregnancy at 8 mg/kg BW and higher. Incidence of malformed fetuses increased from 0.9% in controls, to 3.6-4.3% in the 0.1- 1.0 mg/kg groups, to 37% in the 4 mg/kg group to 61-66% in the 8-16 mg/kg groups. Fetal deaths increased at daily doses of 4 mg/kg BW and	13

Table 15. Species, PCB congener, dose, and other variables	Effect	Reference[a]
	higher, and abortions increased in the 8 and 16 mg/kg groups. Fetal liver discolored at 1 mg/kg BW daily	
Mink, *Mustela vison*		
Aroclor 1254		
0.1 mg/kg BW daily	Adverse effects on growth	2
0.115 mg/kg BW daily (1.64 mg daily)	Adverse effects on reproduction	2, 16
PCB 47; subadult females given daily intraperitoneal injections of 50 mg/kg BW for 3 days and killed 7 days after last dose	No evidence of illness or pathology. PCB 47 residues, in mg/kg FW, were 389 in fat and 38 in liver	14, 15
PCB 77; subadult females given daily intraperitoneal injections of 50 mg/kg BW for 3 days and killed 7 days after last dose	Severe anorexia,diarrhea, and melena. Significant histopathology of mucosa of the small intestine. PCB residues, in mg/kg FW, were 139 in fat and 16 in liver	14, 15
PCBs 136 and 167; each fed to adult females in the diet at 5 mg/kg ration for 3 months	No adverse effects on reproduction	16
PCB 169; fed in diet at concentrations of 0.01-0.5 mg/kg ration for 135 days		
0.01 mg/kg diet	No deaths; some weight loss and liver enlargement	17
0.05 mg/kg diet	50% mortality in 135 days	17
0.1 mg/kg diet	50% dead in 75 days	17
0.5 mg/kg diet	All dead within 73 days	17
Laboratory white rat, *Rattus* sp.		
Aroclor 1254		
Dams and resultant pups fed diets containing 0, 3, 30, or 300 mg Aroclor 1254/kg ration from conception to weaning	Most congeners that accumulated in pup tissues were concentrated in the dam's milk when compared to the feed. PCB uptake by pups was greater during lactation than during gestation. Congeners that accounted for 46% of the brain PCB content and also accumulated in a dose-dependent manner were PCBs 105, 138, 141, 153, 168, 178, 179, and 186	19
0.25 mg/kg BW daily via the diet	Adverse effects on reproduction	2
PCB 4; young males given intraperitoneal injections of 50 mg/kg BW daily for 3 days and killed 4 days after last injection	Negligible morphological effects on liver when compared to PCBs 15, 52, and 77 groups dosed at same regimens	20
PCB 28; dams dosed on days 10 to 16 of gestation by gavage with 8 or 32 mg/kg BW daily; offspring tested in mazes at age 12 to 16 weeks	Birth weight lower in high dose group; female pups--but not males--in the high dose group had learning deficits	27
PCB 47; subadult females given 3 daily injections of 50 mg/kg BW and killed 7 days after last injection	No clinical signs of illness and no significant gross or microscopic lesions. PCB 47 residues, in mg/kg FW, were 747 in fat and 28 in liver	14, 15
PCB 77		
Young adults given single intravenous injection of 0.6 mg/kg BW. Blood and tissue	In males (females), adipose tissue 4 h postinjection contained 23% (12%) of the total dose administered,	18

Table 15. Species, PCB congener, dose, and other variables	Effect	Reference[a]
concentrations analyzed 0.5 h-7 days postinjection	skin 14% (16%), liver 6.8% (8.8%), muscle 6.7% (16.2%), and blood 4.1% (4.0%); after 7 days, adipose tissue contained 2.7% (7.4%) and other tissues 0.5-2.2% (1.0-3.4%)	
Pregnant rats dosed orally on days 6-18 of gestation with 1, 3, or 10 mg/kg BW daily; fetuses were examined on day 19 for developmental abnormalities	A dose-dependent increase in mortality, intestinal histopathology, and external malformations, and decrease in fetal size and length of tibias. A daily dose of 3 mg/kg BW significantly affected fetus growth, bone development, and survival	21
Single intraperitoneal injection of 15 mg/kg BW	Significant reduction in liver and heart retinol and in liver retinylester concentrations	22
Single intraperitoneal injection of 50 mg/kg BW	Metabolites in feces included 5-hydroxy-3,4,3',4'-tetra-chlorobiphenyl, 4-hydroxy-3,5,3'4'-tetra-chlorobiphenyl, and a dihydroxy- and monohydroxy trichlorophenyl. After 5 days, unchanged PCB 77 in feces accounted for 0.8% of the initial dose, but hydroxylated metabolites constituted about 32%	23
Subadult females given 3 daily intraperitoneal injections of 50 mg/kg BW and killed 7 days after last injection	No signs of illness or histopathology. PCB 77 residues, in mg/kg FW, were 148 in fat and 138 in liver	14, 15
Adults injected intra-peritoneally for 3 days at 80 mg/kg BW daily then killed 24 h after last injection	Heme destruction in the P448-containing reconstituted monooxygenase system; reactive epoxide, or possibly nonepoxide, intermediate metabolites may participate in cytochrome P448 destruction	24
PCB 118; dams dosed on days 10 to 16 of gestation by gavage with 4 or 16 mg/kg BW daily; offspring tested in mazes at age 12-16 weeks	Birth weight lower in high-dose group; female offspring, but not males, in high-dose group had learning deficits	27
PCB 126; dams given 0.01 or 0.02 mg/kg BW by gavage every second day from days 9-19 of gestation	Reduction in litter size, body weight, and survival of sucklings; delayed spontaneous movement and neuromuscular maturation. Dams and pups had reduced body weight, and increased cytochrome P4501A1 activity	25
PCB 153		
Dams dosed on days 10 to 16 by gavage with 16 or 64 mg/kg BW daily; offspring tested on mazes at age 12 to 16 weeks	Female offspring from high-dose group had learning deficits; males were not affected	27
Immature female pups given 8, 11, 25, 51, or 59 mg/kg BW on days 20 and 21; killed on day 22	Increased uterine weight at 25 and 51 mg/kg BW, but not in other groups	26

Mink (*Mustela vison*) is among the most sensitive mammals to PCB toxicity (Aulerich et al. 1987; Edqvist et al. 1992; Table 15). Reproductive failure, especially fetal death and resorption, of PCB-fed mink is well documented (Backlin and Bergman 1992; Bergman et al. 1992b; Edqvist et al. 1992; Madej et al. 1992). The mechanisms of intra-uterine death of mink fetuses after PCB exposure are not fully understood (Backlin and Bergman 1992), although planar PCB congeners seem to be implicated (Hakansson et al. 1992). Studies showed that EROD and AHH activities were maximally induced in adult mink by PCB fractions containing non-*ortho* or mono-*ortho* chlorobiphenyls and that mink kits are about 10 times more sensitive to P450-inducers than adults (Brunstrom 1992; Kihlstrom et al. 1992). PCB-dosed mink also show altered blood chemistry (Edqvist et al. 1992), abnormal liver metabolism and histology (Edqvist et al. 1992; Bergman et al. 1992b), raised cortisol excretion (Madej et al. 1992), enhanced EROD activity (Brunstrom 1992), and altered metabolism of Vitamin A (Hakansson et al. 1992). Selective retention of certain PCBs and their hydroxylated metabolites occurred in mink muscle after 3 months of a diet containing a PCB mixture (Bergman et al. 1992a). Retention of PCBs 99, 105, 118, 138, 153, 156, and 180 was high in muscle of mink on the diet. Not retained and presumably metabolized were PCBs 44, 49, 52, 91, 92, 95, 97, 107, 132, 149, and 174 (Bergman et al. 1992a).

Estrogen receptors bind to many compounds other than natural estrogen. Several organochlorine compounds, including certain PCBs, reportedly act as estrogen mimics (Hileman 1994). Many estrogen mimics are persistent, lipid soluble compounds that are defined by their ability to stimulate the proliferation of cells in the uterus of the mouse (*Mus* spp.); in males, these mimics may also inhibit sperm production and testes growth. PCBs and their metabolites may be estrogenic to wildlife, although the evidence is not conclusive (Hileman 1994). PCB mixtures and pure individual chlorobiphenyls with a significant degree of *ortho*-substitution have elevated estrogenic activity; Aroclor 1221, for example, rich in *ortho*-chlorobiphenyl, has estrogenic activity in female rats (Korach et al. 1988). Hydroxylated metabolites of PCBs also show estrogenic hormonal activity (Korach et al. 1988; Li et al. 1994). Hydroxylation of PCBs occurs in amphibians and teleosts but at a much slower rate than that of mammals (Safe et al. 1976). Hydroxylated metabolites of PCB 3 include 4'-chloro-4-biphenylol, 4'-chloro-3,4-biphenyldiol, and 4'-chlor-3-methoxy-4-biphenylol; PCB 15 gave 4,4'-dichloro-3-biphenylol; and Aroclor 1254 yielded mono-, di-, and tri-chlorophenylols (Safe et al. 1976). PCB 77 is detoxified by metabolic hydroxylation to hydroxy biphenyl metabolites (Borlakoglu et al. 1991a). Hydroxylated PCB metabolites may be more toxic than the parent product because of their (1) estrogenic properties (Yoshimura et al. 1987); (2) tendency to accumulate in the fetus (Darnerud et al. 1986), and (3) interference with thyroxin metabolism (Brouwer et al. 1990). The ability of hydroxylated PCB metabolites to bind to the uterine estrogen receptor in rats was in increasing order of effectiveness 4-hydroxy 3,5,4'-trichlorobiphenyl, 4,4'-dihydroxy 3,5,3',5'-tetrachlorobiphenyl, 4-hydroxy 2-chlorobiphenyl, 4-hydroxy 4'-chlorobiphenyl, 4,4'-dihydroxy 2',3',5',6'-tetrachlorobiphenyl, 4,4'-dihydroxybiphenyl, and 4-hydroxybiphenyl; PCB compounds that demonstrated appreciable receptor binding activity were also active in stimulating uterine weight increases (Korach et al. 1988). More research seems needed on the estrogenic properties of hydroxylated PCB metabolites.

Long-term neurobehavioral changes were reported in children, monkeys, and rodents exposed to commercial PCB mixtures during fetal and neonatal development (Schantz et al. 1995). Perinatal exposure of rats (*Rattus* sp.) to *ortho*-substituted PCBs (PCBs 28, 118, 153) can cause long-lasting deficits in learning in females; males were not affected (Table 15).

In comparison to primates and mustelids, rodents are only moderately sensitive to intoxication by most PCBs (Abdel-Hamid et al. 1981). In rodents, PCBs 77 and 169 cause effects that are characteristic of the dioxins and furans, including P450 induction, porphyrin accumulations, and atrophy of the lymphatic organs (Abdel-Hamid et al. 1981), as well as teratogenicity in mice (Darnerud et al. 1986). Exposure of rats to PCB 126 in utero and through lactation produced fetotoxic effects, delayed physical maturation, and induced liver xenobiotic metabolizing enzymes without causing neurobehavioral effects (Bernhoft et al. 1994). In mice, PCBs

77, 126, and 169 were teratogenic in a high percentage of the fetuses from treated dams but without apparent effect on the dams (Marks et al. 1981). PCB 77, for example, was toxic to the conceptus at dose levels below those toxic to the dam when administered to pregnant CD-1 mice on days 6-15 of gestation (Marks et al. 1989). The predominant PCB-induced fetal malformations in mice were cleft palate and hydronephrosis (Marks et al. 1981). PCB 77 also interferes with retinyl ester hydrolase (REH), the enzyme responsible for the hydrolysis of vitamin A into free retinol, lowering levels of vitamin A in liver and decreasing serum concentrations of REH and retinol (Mercier et al. 1990).

Toxicokinetics of PCBs in rodents were altered when administered in mixtures (de Jongh et al. 1992). PCBs 153, 156, and 169 produced biphasic elimination patterns in mice when administered in combinations but single phase elimination when administered alone; elimination of all PCBs was more rapid after coadministration. Mixtures of PCBs 153 and 156 raised EROD activity and lengthened retention of each congener in liver; however, a mixture of PCBs 153 and 169 lowered EROD activity (de Jongh et al. 1992). Selected PCBs of low acute toxicity may increase the toxicity of compounds such as 2,3,7,8-TCDD (Birnbaum et al. 1985). Thus, PCBs 153 or 157 at sublethal dosages (20-80 mg/kg BW) did not produce cleft palate deformities in mouse embryos. But a mixture of PCB 157 and 2,3,7,8-TCDD produced a 10-fold increase in the incidence of palate deformities that were expected of 2,3,7,8-TCDD alone; palate deformities did not increase with a mixture of PCB 153 and 2,3,7,8-TCDD. The widespread environmental occurrence of PCB-PCDD and PCB-PCDF combinations suggests a need for further evaluation of the mechanism of this interaction (Birnbaum et al. 1985).

Intraspecific variability to PCBs was high, especially between genetically inbred AHH-responsive and AHH-nonresponsive strains of mice (Robertson et al. 1984). In mice, PCB 77 was metabolized and excreted more rapidly than 2,3,7,8-TCDD (d'Argy et al. 1987); in rats, PCB 77 was excreted more rapidly than PCB 47 (Shimada and Sawabe 1984). PCBs that lack adjacent hydrogen atoms in at least one of the rings are enriched in rat tissues, indicating that accumulation exceeds elimination by metabolism and excretion. PCBs with a tendency to accumulate were non-*ortho* and mono-*ortho* substituted congeners; however, PCBs with *meta-para* unsubstituted carbon atoms in at least one ring were not enriched in tissues (Borlakoglu et al. 1991a). Uptake and retention of individual PCB congeners in rats are related to properties associated with K_{OW} and high chlorination, especially in the tetra- and penta-chlorobiphenyls (Shain et al. 1986). The highly chlorinated hexa- and octa-chlorobiphenyls produced morphological changes in rats comparable to those produced by DDT, Aroclor 1254, and Aroclor 1260 (Hansell and Ecobichon 1974).

Recommendations

Proposed PCB criteria for the protection of natural resources are predicated on total PCBs and selected Aroclor compounds (Table 16) and offer minimal insight into PCB toxicokinetics. Most authorities now agree that future PCB risk assessments require (1) analysis of non-*ortho* PCBs and selected mono-*ortho* PCBs; (2) exposure studies of individual species to specific congeners alone or in combination with other compounds, including other PCB congeners, dioxins, and dibenzofurans; (3) clarification of existing structure-induction relations, and (4) more refined analytical techniques (Eisler 1986; Maack and Sonzogni 1988; Tanabe 1988; Gooch et al. 1989; Hernandez et al. 1989; Kannan et al. 1989; Tanabe et al. 1989; Borlakoglu et al. 1990; Hebert et al. 1993; Giesy et al. 1994a; Safe 1994; Walker and Peterson 1994). Marked differences between species in their abilities to metabolize specific PCB congeners must be considered in toxicity testing. Foxes and dogs, for example, in contrast to monkeys and rats, can degrade the otherwise highly persistent PCB 153 because they possess an unusual cytochrome P450 isoenzyme that metabolizes PCB 153 (Georgii et al. 1994). Also, low-chlorinated congeners that are metabolized via reactive intermediates must be critically evaluated because they show weak tumor-initiating properties (Georgii et al. 1994).

To complement PCB chemical residue analyses, the rat hepatoma cell bioassay was useful for assessing the toxic potency of PCBs in extracts from environmental samples (Tillitt et al. 1991). This in vitro bioassay of cytochrome P450IA1 catalytic activity in the H4IIE cells in response to planar halogenated hydrocarbons was considered accurate and precise. Comparison of the responses of the H4IIE cells was calibrated against their responses to 2,3,7,8-TCDD (Tillitt et al. 1991). EROD (ethoxyresorufin-*O*-deethylase) and porphyria induction measurements also potentially complement PCB chemical residue analyses and have been used to determine the toxic potencies of complex mixtures of PCBs and other halogenated aromatic hydrocarbons extracted from wildlife tissues (Kennedy et al. 1992). In one case, extracts of PCB-contaminated eggs of herring gulls (*Larus argentatus*) from the Great Lakes and of great blue herons (*Ardea herodias*) from British Columbia induced

EROD and porphyria in primary cultures of chicken embryo hepatocytes (Kennedy et al. 1992). Hepatic cytochrome P450-associated monooxygenases and cytochrome P450 proteins in embryos of the black-crowned night-heron (*Nycticorax nycticorax*) were associated with concentrations of total PCBs and 11 PCB congeners that express toxicity through the Ah receptor, and also should be considered as biomarkers for assessing PCB contamination of wetlands (Rattner et al. 1994).

The interpretation of PCB residue data is challenging from several perspectives, as judged by analysis of eggs of Forster's terns (*Sterna forsteri*) from Wisconsin (Schwartz and Stalling 1991): (1) data from a single analysis frequently contained measurable concentrations of 100 to 150 PCB congeners; (2) a single sample was not sufficient to understand the environmental distribution of PCBs; (3) source profiles of PCB inputs into the environment were poorly characterized; (4) PCB congeners in the original polluting material often merged with congeners from other sources; and (5) the contaminant mixture may have been altered by metabolism and subsequent partition into multiple environmental compartments that may be further changed by weathering or degradation. To understand these processes and to correlate residue profiles with specific toxic responses required congener-specific methods of analysis and complex statistical techniques (principal component analysis). Using these techniques, it was established that eggs of Forster's terns of two colonies differed significantly in PCB composition (Schwartz and Stalling 1991). Similar techniques were used to identify various PCB-contaminated populations of harbor seals (*Pusa vitulina*) in Denmark (Storr-Hansen and Spliid 1993).

Selected congeners should be quantified in human foodstuffs and tissues, as determined from a survey of PCB congener frequency in commercial formulations, environmental and biological samples and human tissues, and a consideration of the relative toxicity and persistence of the congeners (Jones 1988). PCBs 28, 74, 77, 99, 105, 118, 126, 128, 138, 153, 156, 169, 170, 179, and 180 reportedly account for more than 70% of the total PCB burden in any sample and should be quantified. Additionally, PCBs 8, 37, 44, 49, 52, 60, 66, 70, 82, 87, 101, 114, 158, 166, 183, 187, and 189 should be considered for quantification because of their reported occurrence or toxicity. Some PCBs are particularly prevalent in aquatic animals, especially PCBs 95, 101, 110, 118, 138, 149, 153, 180, and 187; also detected in aquatic biota and reported as important components were PCBs 26, 52, 66, 70, 99, 105, 132, 151, 170, 177, 201, and 206.

Table 16. Proposed PCB criteria for the protection of natural resources and human health.

Table 16. Resource, criterion, and other variables	Effective concentration	Reference[a]
Aquatic life protection, total PCBs		
Fish		
Diet	<500 ug/kg fresh weight (FW)	1
Eggs	<300 ug/kg FW	1
Whole body	<400 ug/kg FW	1
Marine mammals, blubber	<70 mg/kg FW	2
Medium		
Freshwater		
Acute	<2.0 ug/L	6
Chronic	<0.014 ug/L	1, 6
Saltwater		
Acute, most species	<10.0 ug/L	6
Chronic, sensitive species	<0.03 ug/L	6
Filter-feeding shellfish	<0.006 ug/L	1
Birds, total PCBs		
Brain	<300 mg/kg FW	3
Mammals		
Aroclor 1016		
Rhesus macaque	<0.008-<0.028 mg/kg body weight (BW) daily	4
Aroclor 1248		
Rhesus macaque	<0.009 mg/kg BW daily	4
Aroclor 1254		
Mink	<0.1-<0.115 mg/kg BW daily	4

Table 16. Resource, criterion, and other variables	Effective concentration	Reference[a]
Mouse	<1.3 mg/kg BW daily	4
Rat	<0.25 mg/kg BW daily	4
Human health protection, total PCBs (unless indicated otherwise)		
Air		
Aroclor 1242	<1.0 mg/m^3	6
Aroclor 1254	<0.5 mg/m^3	6
Reduced risk from cancer	<7.7 mg/kg BW daily	6
Drinking water		
Child	<1.0 ug/L	6
Adult	<4 ug/L	6
Fish, edible portion		
Canada	<2 mg/kg FW	5
United States	<2 mg/kg FW	6
New York State	<2 ug/kg FW	5

[a]1, Eisler 1986; 2, Norheim et al. 1992; 3, Bryan et al. 1987a; 4, Golub et al. 1991; 5, Hebert et al. 1993; 6, USEPA 1992b.

In the Netherlands, maximum PCB limits in fishes as dietary items for human health protection are now derived from the sum of PCBs 28, 95, 101, 138, 149, 153, and 180. From a toxicological viewpoint, other congeners may be more important. These have been identified (on the basis of ability to induce AHH) as the most toxic planars (PCBs 15, 37, 77, 81, 126, and 169), the mono-*ortho* analogues of the planar PCBs (PCBs 105, 114, 123, 156, and 189), and the di-*ortho* analogues (PCBs 128, 138, 158, 166, and 170). Of these compounds, PCBs 37, 105, 114, 128, 138, 156, and 158 occur in human tissues and PCBs 15, 77, 81, 123, 126, 166, and 169 do not occur (Jones 1988).

Patuxent Wildlife Research Center
Laurel, MD 20708

Abstract. Ecological and toxicological aspects of silver (Ag) and silver salts in the environment are briefly summarized with an emphasis on natural resources. Subtopics include sources and uses, chemistry and metabolism, concentrations in field collections, lethal and sublethal effects, and recommendations for the protection of natural resources. Elevated silver concentrations in biota occur in the vicinities of sewage outfalls, electroplating plants, mine waste sites, and silver-iodide seeded areas; in the United States, the photography industry is the major source of anthropogenic silver discharges into the biosphere. Maximum concentrations recorded in field collections, in milligrams total silver/kilogram dry weight (tissue), were 1.5 in mammals (liver), 6 in fish (bone), 14 in plants (whole), 30 in annelid worms (whole), 44 in birds (liver), 110 in mushrooms (whole), 185 in bivalve mollusks (soft parts), and 320 in gastropods (whole); humans afflicted with silver poisoning (argyria) contained 72 mg total Ag/kg dry weight skin and 1,300 mg total Ag/kg fresh weight whole body. Silver and its compounds are not known to be mutagenic, teratogenic, or carcinogenic. Under normal routes of exposure, silver does not pose serious environmental health problems to humans at less than 50 µg total Ag/L drinking water or 10 µg total Ag/m^3 air. Free silver ion, however, was lethal to representative species of sensitive aquatic plants, invertebrates, and teleosts at nominal water concentrations of 1.2 to 4.9 µg/L; at sublethal concentrations, adverse effects were significant between 0.17 and 0.6 µg/L. No data were found on effects of silver on avian or mammalian wildlife; all studied effects were on poultry, small laboratory animals, and livestock. Silver was harmful to poultry at concentrations as low as 1.8 mg total Ag/kg whole egg fresh weight by way of injection, 100 mg total Ag/L in drinking water, or 200 mg total Ag/kg in diets; sensitive mammals were adversely affected at total silver concentrations as low as 250 µg/L in drinking water, 6 mg/kg in diets, or 13.9 mg/kg whole body. Proposed criteria for the protection of living organisms from silver are listed and discussed.

Key words: Silver, plants, fish, wildlife, invertebrates, mammals, ecotoxicology.

Silver (Ag) found in the body of mammals (including humans) has no known biological purpose and is suspected of being a contaminant (Smith and Carson 1977). Silver, as ionic Ag^+, is one of the most toxic metals known to aquatic organisms in laboratory testing, although large industrial losses to the aquatic environment are probably infrequent because of its economic value as a recoverable resource (National Association of Photographic Manufacturers [NAPM] 1974; Nebeker et al. 1983). Silver, however, is of concern in various aquatic ecosystems because of the severity of silver contamination in the water column, sediments, and biota. San Francisco Bay, for example, is impacted from discharges of silver in wastewater outfalls and from the diagenic remobilization of silver from contaminated sediments in the estuary (Luoma and Phillips 1988; Rivera-Duarte and Flegal 1993).

The principal industrial use of silver is as silver halide in the manufacture of photographic imaging materials; other products include jewelry, coins, indelible inks, and eating utensils (Klaassen et al. 1986). In medicine, silver salts are used as caustics, germicides, antiseptics, and astringents; the use of silver nitrate for prophylaxis of ophthalmia neonatorum in the eyes of newborn infants is a legal requirement in some states (Klaassen et al. 1986). Long-term industrial or medical exposure to silver and its compounds may increase blood concentrations of silver to levels which can have toxic effects, such as induction of sarcomas, anemia, and enlargement of the

heart (Aoki et al. 1993). Repeated occupational handling of silver objects, especially after repeated minor injuries, may result in localized argyria—a bluish-gray discoloration of the skin at the exposed site (Fowler and Nordberg 1986). In humans, the most common noticeable effects of chronic exposure to silver and its compounds are generalized argyria, localized argyria, and argyrosis (argyria of the eye, usually; Smith and Carson 1977). Generalized argyria consists of a slate-gray pigmentation of the skin and hair caused by deposition of silver in the tissues, a silver coloration of the hair and fingernails, and a blue halo around the cornea and in the conjunctiva. Acute toxic effects in humans have resulted only from accidental or suicidal overdoses of medical forms of silver (Smith and Carson 1977).

Ecological and toxicological aspects of silver are reviewed by Smith and Carson (1977), the U.S. Environmental Protection Agency [EPA] (1980, 1987), Lockhart (1983), the U.S. Public Health Service [PHS] (1990), Andren et al. (1993, 1994), and Andren and Bober (1995). The present report is another in a series on hazards of selected contaminants to plants and animals, with an emphasis on fishery and wildlife resources. It was prepared in response to requests for information on silver from environmental specialists of the U.S. Fish and Wildlife Service.

Sources and Uses

General

About 2.47 million kg of silver are lost each year to the domestic biosphere, mostly (82%) as a result of human activities. As discussed later, the photography industry accounts for about 47% of all silver discharged into the environment from anthropogenic sources. In 1990, about 50% of the refined silver consumed domestically was used to manufacture photographic products; 25% in electrical and electronic products; 10% in electroplated ware, sterlingware, and jewelry; 5% in brazing alloys; and 10% in other products and processes.

Sources

Silver is a rare but naturally occurring metal, often found deposited as a mineral ore in association with other elements (PHS 1990). Argentite is the main ore from which silver is extracted by cyanide, zinc reduction, or electrolytic processes (Fowler and Nordberg 1986). Silver is frequently recovered as a byproduct from smelting of nickel ores in Canada, from lead-zinc and porphyry copper ores in the United States, and from platinum and gold deposits in South Africa (Smith and Carson 1977). About 12-14% of the domestic silver output is recovered from lead ores and about 4% from zinc ores. Secondary sources of silver comprise new scrap generated in the manufacture of silver-containing products; coin and bullion; and old scrap from electrical products, old film and photoprocessing wastes, batteries, jewelry, silverware, and bearings (Smith and Carson 1977).

Silver is produced in 68 countries, but most (75%) of the world's silver (excluding the former Soviet bloc) is mined in the United States, Mexico, Canada, Australia, and Japan; the United States produces about 50% of the world's supply of refined silver (Smith and Carson 1977). The primary silver mines of the United States are in the Coeur d'Alene mining district in the northern Idaho panhandle (PHS 1990). Between 1949 and 1970, the United States consistently produced less than 15% of the global silver production and consumed 34-64% (Heyl et al. 1973). Since 1951, silver consumption in the United States has exceeded its extraction from ore (PHS 1990). In 1979, about 95% of the silver in domestic production was from Idaho, Nevada, Arizona, Colorado, Utah, Montana, and Missouri (U.S. Bureau of Mines 1980). End use categories of silver consumed domestically in 1979 included photography (39%), electrical and electronic components (25%), sterlingware and electroplated materials (15%), and brazing alloys and solders (8%). In 1979, the photographic industry was located mainly in New York, and most other end use manufacturers were in Connecticut, New York, Rhode Island, and New Jersey (U.S. Bureau of Mines 1980).

World production of silver increased from 7.40 million kg in 1964 to 9.06 million kg in 1972 and to 9.67 million kg in 1982 (Fowler and Nordberg 1986). In 1986, 13.06 million kg of silver were produced globally; the United States produced 1.06 million kg in 1986 but consumed 3.94 million kg (PHS 1990). In 1990, the estimated world mine production of silver was 14.6 million kg; major producers were Mexico with 17% of the total, the United States with 14%, Peru with 12%, the former Soviet Union with 10%, and Canada with 9% (Reese 1991). In the United States during 1990, about 160 mines produced silver worth an estimated value of $320 million; most (71%) of the 1990 mine production was in Nevada (32%), Idaho (21%), Montana (11%), and Arizona (7%). In 1990, 22 major refiners of commercial grade silver and more than 5,000 silver fabricating and manufacturing firms were located primarily in the northeastern states. Of the silver imported into the United

States in 1990, 44% came from Mexico, 34% from Canada, 5% from Peru, and 4% from Chile. Most was exported after transformation to sterlingware, coinage, and other finished products. Melting and refining old scrap silver in 1990 accounted for 500,000 kg of silver (Reese 1991).

Emissions from smelting operations, manufacture and disposal of certain photographic and electrical supplies, coal combustion, and cloud seeding are some of the anthropogenic sources of silver in the biosphere (Freeman 1979). Fallout from cloud seeding with silver iodide is not always confined to local precipitation; silver residuals have been detected several hundred kilometers downwind of seeding events (Freeman 1979). In 1978, the estimated loss of silver to the environment in the United States was 2.47 million kg, mostly to terrestrial and aquatic ecosystems; the photography industry alone accounted for about 47% of all silver discharged into the environment from anthropogenic sources (Smith and Carson 1977; Table 1). In California, anthropogenic sources contributed 50% more silver to sediments of coastal basins than did natural sources, as judged by sedimentary basin fluxes of 0.09 µg/cm^2 in anthropogenic sources of silver and 0.06 µg/cm^2 in natural sources (Bruland et al. 1974). Sometimes, liquid effluents from the nuclear industry contained significant quantities of radiosilver-110m (Berthet et al.1992). In Lake Michigan, storms contribute a large fraction of the annual load of tributary-derived silver; concentrations of particle-bound silver in many rivers during storms were more than 0.1 µg/L (Shafer et al. 1995).

Table 1. Estimated release of silver to the environment in the United States in 1978 (U.S. Public Health Service 1990).

[a]Of the total silver released to the domestic environment in 1978 (2,470,700 kg), about 3.7% entered the atmosphere, 28.5% the aquatic environment, and 67.8% the terrestrial ecosystem.

Most of the silver lost to the environment each year enters terrestrial ecosystems where it is immobilized in the form of minerals, metal, or alloys; agricultural lands may receive as much as 80,000 kg of silver from photoprocessing wastes in sewage sludge. An estimated 150,000 kg of silver enter the aquatic environment every year from the photography industry, mine tailings, and electroplating (Smith and Carson 1977). During processing of photographic paper and film, silver is generally solubilized as the tightly bound thiosulfate complex. Silver thiosulfate in secondary biological waste treatment plants is converted to insoluble silver sulfide,

which is removed in the sludge; only trace amounts of complexed and adsorbed silver are discharged into the aquatic environment. The silver incorporated into the sludge is immobile and should not restrict the use of sludge for the enrichment of soils (Dagon 1973; Bard et al. 1976; Cooley et al. 1988). The atmosphere receives 300,000 kg of silver each year from a variety of sources, but atmospheric concentrations are not known to exceed the occupational threshold limit value of 10 µg total Ag/m^3 (Smith and Carson 1977).

Daily intake of total silver from all sources by humans in the United States ranges from 70 to 88 µg; diet accounted for 35-40 µg daily (EPA 1980). Sources of elevated dietary silver include seafood from areas near sewage outfalls or industrial sources and crops grown in areas with high ambient levels of silver in the air or soil (PHS 1990). Most occupational exposures to silver occur through inhalation of silver-containing dusts or dermal exposure to photographic compounds. Dermal routes of human exposure to silver include handling of silver-containing processing solutions used in radiographic and photographic materials, dental amalgams, and silver sulfadiazine cream and solutions for treating burns (PHS 1990).

Uses

Silver has been used for ornaments and utensils for almost 5,000 years, and as a precious metal, a monetary medium, and a basis of wealth for more than 2,000 years. Until the late 1960's, it was used extensively for coinage (Heyl et al. 1973). Since 1970, U.S. coinage has not contained silver, although minting of as many as 45 million silver-clad subsidiary coins has been authorized (Smith and Carson 1977). Industrial consumption of silver in the United States between 1966 and 1972 totaled 4.67 million kg, primarily in the manufacture of photographic materials, electrical contacts and conductors, and sterlingware (Table 2). In 1973, silver was used mainly in photographic materials (29%), electrical and electronic components (22%), sterlingware (20%), electroplated ware (10%), brazing wares (20%), dental and medical products, catalysts, bearings, and jewelry (9%; Heyl et al. 1973). In 1986, photographic materials accounted for 45% of the silver consumption in the United States; electrical and electronic components, 25%; jewelry, sterlingware, and electroplated ware, 11%; alloys and solders, 5%; and mirrors, dental amalgam, medical supplies, chemicals, water purification, and cloud seeding, 14% (PHS 1990). Silver, as silver iodide, is used in the United States for weather modification, including rain and snow making and hail suppression; as much as 3,110 kg of silver is used for this purpose annually (Smith and Carson 1977). Silver nitrate in hair dyes has been in use regularly for almost 200 years (EPA 1980), although its use may lead to argyria (Smith and Carson 1977). In 1990, about 50% of the refined silver consumed domestically was used to manufacture photographic and x-ray products; 25% in electrical and electronic products; 10% in electroplated ware, sterlingware, and jewelry; 5% in brazing alloys; and 10% in other uses (Reese 1991).

Table 2. Industrial domestic use of silver during 1966-72. Total silver used was 4.67 million kg (Smith and Carson 1977).

Category	Approximate percent of total
Photographic materials	28.1
Contacts and conductors	20.2
Sterlingware	17.1
Brazing alloys and solders	10.1
Electroplated ware	10.0
Batteries	5.1
Jewelry	3.3
Miscellaneous	2.4
Dental and medical supplies	1.5
Mirrors	1.2
Bearings	0.4

Because of its bacteriostatic properties, silver compounds are used in filters and other equipment to purify water of swimming pools and drinking water and in the processing of foods, drugs, and beverages (Smith and Carson 1977; EPA 1980; PHS 1990). Activated charcoal filters coated with metallic silver to yield water concentrations of 20-40 µg Ag/L are used in filtering systems of swimming pools to control bacteria (EPA 1980). Silver may also function as an algicide in swimming pools if chlorine, bromine, and iodine are absent; it prevents growth of blue-green algae at 80-140 µg Ag/L (Smith and Carson 1977). Aboard orbiting Russian space stations and spaceships, potable water is routinely treated with 100-200 µg Ag/L to eliminate microorganisms; sterilization is usually complete in 20 min (Smith and Carson 1977). Silver-containing ceramic water filters are used to purify potable water in Swiss ski resorts, German breweries, British ships, oil tankers, drilling rigs, U.S. home consumption, and more than half the world's airlines. Monovalent and metallic silver compounds are considered excellent disinfectants; however, Ag^{2+} and Ag^{3+} are about 50 to 200 times more effective than Ag^{+} or Ag^{o} (Antelman 1994), possibly because of their higher oxidation states (Kirschenbaum 1991).

Silver nitrate was used for many years as eye drops in newborns to prevent blindness caused by gonorrhea (PHS 1990). Laws in many states still require that a few drops of a 1-2% silver nitrate solution be applied to the conjunctiva of the eyes of newborn infants to prevent ophthalmia neonatorum by transmittal of gonorrhea from the mother (EPA 1980; PHS 1990). This treatment is still required in Denmark but not in Japan or Australia (EPA 1980). Silver nitrate is not used in many U.S. hospitals because of the dangers of chemical conjunctivitis and has been replaced by antibiotics (EPA 1980). In the United States, several silver-containing pharmaceuticals were used topically on skin or mucous membranes to assist in healing burn patients and to combat skin ulcers (Smith and Carson 1977; EPA 1980). Oral medicines containing silver include silver acetate-containing antismoking lozenges; breath mints coated with silver; and silver nitrate solutions for treating gum disease (PHS 1990). The widespread medical use of silver compounds for topical application to mucous membranes and for internal use became nearly obsolete in the past 50 years because of the fear of argyria and the development of sulfonamide and antibiotic microbials (Smith and Carson 1977).

Chemistry and Metabolism

General

Silver occurs naturally in several oxidation states, the most common being elemental silver (Ag^{o}) and the monovalent ion (Ag^{+}). Soluble silver salts are in general more toxic than insoluble salts; in natural waters, the soluble monovalent species is the form of environmental concern. Sorption is the dominant process that controls silver partitioning in water and its movements in soils and sediments. As discussed later, silver enters the animal body through inhalation, ingestion, and movement across mucous membranes and broken skin. The interspecies differences in the ability of animals to accumulate, retain, and eliminate silver are large. Almost all of the total silver intake is usually excreted rapidly in feces; less than 1% of the total silver intake is absorbed and retained in tissues, primarily liver, through precipitation of insoluble silver salts. In mammals, silver usually interacts antagonistically with selenium, copper, and vitamin E; in aquatic environments, ionic or free silver interferes with calcium metabolism in frogs and marine annelids and with sodium and chloride uptake in gills of fishes.

Physical and Chemical Properties

Silver is a white, ductile metal occurring naturally in the pure form and in ores (EPA 1980). Silver has the highest electrical and thermal conductivity of all metals. Some silver compounds are extremely photosensitive and are stable in air and water except for tarnishing readily when exposed to sulfur compounds (Heyl et al. 1973). Metallic silver is insoluble in water but many silver salts, such as silver nitrate, are soluble in water to 1,220 g/L (Table 3). In natural environments, silver occurs primarily in the form of the sulfide or is intimately associated with other metal sulfides, especially those of lead, copper, iron, and gold, which are all essentially insoluble (EPA 1980; PHS 1990). Silver readily forms compounds with antimony, arsenic, selenium, and tellurium (Smith and Carson 1977). Silver has two stable isotopes (^{107}Ag and ^{109}Ag) and 20 radioisotopes; none of the radioisotopes of silver occurs naturally, and the radioisotope with the longest physical half-life (253 days) is ^{110m}Ag. Several compounds of silver are potential explosion hazards: silver oxalate decomposes explosively when heated; silver acetylide (Ag_2C_2) is sensitive to detonation on contact; and silver azide (AgN_3) detonates spontaneously under certain conditions (Smith and Carson 1977).

Table 3. Some properties of silver and silver nitrate (Lockhart 1983; U.S. Public Health Service 1990).

Variable	Silver	Silver nitrate
Alternate names	Argentum, argentum crede CI 77820, shell silver, silver atom, silver colloidal, silflake, silpowder, silber	Lunar caustic fused silver nitrate, molded silver nitrate argenti, nitras, nitric acid silver (I) salt, nitric acid silver (1+) salt, silver (1+) nitrate
CAS number	7440-22-4	7761-88-8
Chemical formula	Ag	$AgNO_3$
Molecular weight	107.87	169.89
Physical state	Solid metal	Solid crystalline
Boiling point	2,212° C	Decomposes at 440 C
Solubility	Insoluble in water; soluble in nitric acid but not sulfuric acid	Soluble in water to 1,220 g/L; soluble in ethanol and acetone
Density	10.5	4.35

Silver occurs naturally in several oxidation states, usually as Ag^0 and Ag^+; other possible oxidation states of silver are Ag^{2+} and Ag^{3+} (PHS 1990). In surface fresh water, silver may be found as the monovalent ion; in combination with sulfide, bicarbonate, or sulfate; as part of more complex ions with chlorides and sulfates; and adsorbed onto particulate matter (PHS 1990). Soluble silver salts are more toxic than insoluble salts, and soluble silver ion (Ag^+) is the most toxic chemical species. In natural waters, the soluble monovalent species is the form of environmental concern (EPA 1980). The argentous ion (Ag^+) does not hydrolyze appreciably in solution and is considered to be a mild oxidizing agent (Smith and Carson 1977). Hypervalent silver species, such as Ag^{2+} and Ag^{3+}, are significantly more effective as oxidizing agents than Ag^0 and Ag^+ (Kouadio et al. 1990; Kirschenbaum 1991; Sun et al. 1991) but are unstable in aqueous environments, especially at water temperatures near 100^0 C (Smith and Carson 1977). In natural waters, silver may exist as metalloorganic complexes or adsorb to organic materials (EPA 1980). In fresh water and soils, the primary silver compounds under oxidizing conditions are bromides, chlorides, and iodides; under reducing conditions the free metal and silver sulfide predominate (PHS 1990). In river water, one study showed silver present as the monovalent ion (Ag^+) at 53-71% of the total silver, as silver chloride (AgCl) at 28-45%, and as silver chloride ion ($AgCl_2^-$) at 0.6-2.0% (PHS 1990). Increasing salinity of brackish and marine waters increase concentrations of silver chloro complexes ($AgCl^0$, $AgCl_2^-$, $AgCl_3^{2-}$, $AgCl_4^{3-}$); these chloro complexes retain some silver in dissolved form, and relatively small anthropogenic quantities can substantially enrich the environment (Luoma 1994; Andren et al. 1995). In the open ocean, the principal dissolved form of silver is $AgCl_2^-$, but the most bioavailable form may be the neutral monochloro complex AgCl (Bryan and Langston 1992).

Sorption is the dominant process that controls silver partitioning in water and its movement in soils and sediments (EPA 1980; PHS 1990). Silver may leach from soils into ground water; the leaching rate increases with decreasing pH and increasing drainage (PHS 1990). Silver adsorbs to manganese dioxide, ferric compounds, and clay minerals, and these compounds are involved in silver deposition into sediments; sorption by manganese dioxide and precipitation with halides reduce the concentration of dissolved silver, resulting in higher concentrations in sediments than in the water column (EPA 1980). Under reducing conditions, adsorbed silver in sediments may be released and subsequently reduced to metallic silver or it may combine with reduced sulfur to form the insoluble silver sulfide (EPA 1980). Sediments may be a significant source of silver to the water column. In one study, anoxic sediments containing 1.0-27.0 g Ag/kg dry weight (DW) and 10 mmoles of acid volatile sulfide/kg DW were resuspended in oxygenated seawater for several hours to days. The seawater in contact with sediment containing 10.8 g/kg had 20 µg Ag/L; seawater in contact with sediments containing 27

g Ag/kg had about 2,000 µg Ag/L, which seems to be the solubility of silver in seawater (Crecelius and Phillips 1995).

The global biogeochemical movements of silver are characterized by releases to the atmosphere, water, and land by natural and anthropogenic sources, long-range transport of fine particles in the atmosphere, wet and dry deposition, and sorption to soils and sediments (PHS 1990). The chief source of silver contamination of water is silver thiosulfate complexes in photographic developing solutions that photofinishers discard directly to sewers (Smith and Carson 1977). Secondary waste treatment converts most of the silver thiosulfate complex to insoluble silver sulfide and forms some metallic silver (Lytle 1984). About 95% of the total silver is removed in publicly owned treatment works from inputs containing municipal sewage and commercial photoprocessing effluents, and effluents contain less than 0.07 µg ionic silver/L (Lytle 1984). Silver in sewage treatment plant effluents may be associated with suspended particles or be present as thiosulfate complex, colloidal silver complex, colloidal silver chloride, silver sulfide, or soluble organic complexes (Smith and Carson 1977). Silver on suspended matter and in colloidal forms and insoluble salts ultimately settles out in the sediments. At the water treatment plant, most of the silver is precipitated after treatment with lime or adsorbed after treatment with alum-flocculent. Chlorination converts some silver to silver chloride or to a soluble silver chloride complex (Smith and Carson 1977).

Forms of silver in atmospheric emissions are probably silver sulfide, silver sulfate, silver carbonate, silver halides, and metallic silver (Smith and Carson 1977). About 50% of the silver released into the atmosphere from industrial operations is transported more than 100 km and is eventually deposited in precipitation (PHS 1990). Minute amounts of ^{110m}Ag detected in natural waters are attributed to atmospheric fallout from nuclear explosions (Smith and Carson 1977).

A variety of spectrographic, colorimetric, polarographic, and other analytical techniques are used for routine measurement of silver in biological and abiotic samples. The detection limit of silver in biological tissues with scanning electron microscopy and x-ray energy spectrometry is 0.02 µg/kg and sometimes as low as 0.005 µg/kg. In air, water, and soil samples, the preferred analytical procedures include flame and graphite furnace atomic absorption spectrometry, plasma emission spectroscopy, and neutron activation (Fowler and Nordberg 1986; PHS 1990). Sensitive voltammetry techniques using anodic stripping have recently been developed to measure free silver ion in solution at concentrations as low as 0.1 µg/L (Schildkraut 1993; Song and Osteryoung 1993).

Metabolism

The acute toxicity of silver to aquatic species varies drastically by the chemical form and correlates with the availability of free ionic silver (Wood et al. 1994). In natural aquatic systems, ionic silver is rapidly complexed and sorbed by dissolved and suspended materials that are usually present. Complexed and sorbed silver species in natural waters are at least one order of magnitude less toxic to aquatic organisms than the free silver ion (Rodgers et al. 1994). Thus, silver nitrate—which is strongly dissociated—is extremely toxic to rainbow trout (*Oncorhynchus mykiss*); the 7-day LC50 value is 9.1 µg/L. Silver thiosulfate, silver chloride, and silver sulfide are relatively benign (7-day LC50 values >100,000 µg/L), presumably because of the abilities of the anions to remove ionic silver from solution (Wood et al. 1994, 1996b; Hogstrand et al. 1996). The probable cause of hyperventilation in rainbow trout exposed to silver nitrate was a severe metabolic acidosis manifested in decreased arterial plasma pH and HCO_3^- levels. Lethality of ionic silver to trout is probably due to surface effects at the gills—disrupting Na^+, Cl^-, and H^+—causing secondary fluid volume disturbance, hemoconcentration, and eventual cardiovascular collapse (Wood et al. 1994, 1995, 1996a, 1996b). Morgan et al. (1995) suggest that the sites of action of silver toxicity in rainbow trout may be inside the cells of the gill epithelium rather than at the external surface, and that they are linked to carbonic anhydrase—a gill enzyme involved in Na^+ and Cl^- transport. Silver concentrations and metallothionein levels in gills and livers of rainbow trout increased with increasing exposure to silver; internal toxicity associated with increased silver accumulations may be lessened by the formation of silver-induced metallothioneins (Hogstrand et al. 1996). In seawater, silver nitrate is less toxic to biota than in fresh water (Wood et al. 1995). This difference is probably due to the low concentration of free Ag^+ (the toxic moiety in freshwater) in seawater and to the high levels of chloride and negatively charged Ag-chloro complexes in seawater. However, high levels of silver nitrate are

toxic to marine invertebrates despite the absence of Ag^+, and this is attributed to the bioavailability of Ag-chloro complexes; mechanisms of silver toxicity in marine fishes are still unknown (Wood et al. 1995).

Ionic silver interferes with calcium metabolism of frogs and marine polychaete worms. Silver ions cause muscle fibers of frogs (*Rana* spp.) to deteriorate by allowing excess calcium to enter the cell. Studies with frog skeletal muscle fibers exposed to 1.08 mg/L showed that silver activated the calcium ion channel by acting on sulfhydryl groups in a calcium ion channel protein (Aoki et al. 1993). In marine polychaetes contaminated with silver, the calcium content of nephridial cells was reduced, although silver was not detected in the calcium vesicles (Koechlin and Grasset 1988). Silver binds with protein sulfhydryl groups and this process protects the worm against silver poisoning (Koechlin and Grasset 1988). In marine mollusks, however, sulfide anion was the ligand of silver (Truchet et al. 1990). In marine gastropods (*Littorina littorea*), silver was stored in the basement membranes of the digestive system; in clams (*Scrobicularia plana*), it was stored in the basement membranes of the outer fold of the mantle edge and in the amoebocytes (Truchet et al. 1990). The availability of free silver in marine environments was strongly controlled by salinity because of the affinity of silver for the chloride ion (Sanders et al. 1991). Silver sorbs readily to phytoplankton and to suspended sediments. As salinity increases, the degree of sorption decreases. Nearly 80% of silver sorbed to suspended sediments at low salinities desorbs at higher salinities, but desorption does not occur when silver is associated with phytoplankton. Thus, silver incorporation in or on cellular material increases the retention of silver in the estuary, reducing the rate of transport (Sanders and Abbe 1987).

Silver may enter the body of mammals through inhalation, ingestion, and movement across mucous membranes or broken skin (Smith and Carson 1977; EPA 1980; Klaassen et al. 1986; PHS 1990). In most cases of occupational argyrosis, absorption occurs via the respiratory tract or at the eyes (Smith and Carson 1977; EPA 1980). Silver is retained by all body tissues; tissue concentrations are related to the dose, form of administered silver, and route of exposure. Silver also accumulates in mammalian tissues with increasing age of the individual, even if none is administered intentionally. Inside the body, silver is transported mainly in the protein fractions of plasma, presumably as silver albuminate or silver chloride (Smith and Carson 1977; EPA 1980). In mammals, the highest concentrations of silver are usually found in the liver and spleen and to some extent in the muscles, skin, and brain (Fowler and Nordberg 1986). The primary sites of silver deposition in the human body are the liver, skin, adrenals, lungs, muscle, pancreas, kidney, heart, and spleen; silver is also deposited in blood vessel walls, the trachea, and bronchi (Smith and Carson 1977). Dogs exposed to silver by inhalation accumulated most of the administered dose in the liver; concentrations in the lung, brain, skin, and muscle were lower (EPA 1980; Fowler and Nordberg 1986). Intravenous injection of silver produces accumulations in the spleen, liver, bone marrow, lungs, muscle, and skin (Klaassen et al. 1986). Intestinal absorption of silver by rodents, canids, and primates has been recorded at 10% or less after ingestion of radioactive silver; a value of 18% was estimated in a single human given radiosilver acetate (EPA 1980; Klaassen et al. 1986) and about 3-10% of the absorbed silver is retained in the tissues (Smith and Carson 1977). In a human given radioactive silver, more than 50% of the whole-body burden of silver was found in the liver after 16 days (Fowler and Nordberg 1986)

Deposition of silver in tissues of warm-blooded animals results from precipitation of relatively insoluble silver salts, such as silver chloride and silver phosphate (PHS 1990). These insoluble salts may be transformed into soluble silver sulfide albuminates that bind or complex with RNA, DNA, and proteins, or may be reduced to metallic silver by ascorbic acid or catecholamines. In humans with argyria, the blue or gray skin discoloration is caused by the photoreduction of silver chloride to metallic silver during exposure to ultraviolet light. Metallic silver, in turn, is oxidized and bound as black silver sulfide (PHS 1990). Silver sulfide (Ag_2S) is localized in extracellular structures such as basement membranes and in macrophageous cells (Baudin et al. 1994). Before storage as a stable mineral combination, silver binds to proteins that contain a large proportion of sulfhydryl groups such as metallothioneins (Fowler and Nordberg 1986). The last stage in the catabolic pathway of these proteins leads to storage of silver after reaction with a sulfur ligand (Baudin et al. 1994). These mechanisms explain why the liver, the most important organ for protein synthesis, shows the highest capacity for silver accumulation. High concentrations of silver in the digestive tract are linked to the numerous basement membranes contained in its tissues. Interspecies differences in the ability to accumulate, retain, and eliminate silver are large (Baudin et al. 1994).

The enzyme-inhibiting action of silver ions may be due to the binding of sulfhydryl groups of some enzymes. Binding, in certain enzymes, is probably at a histidine imidazole group; in the case of glucose oxidase, silver ions compete with molecular oxygen as a hydrogen acceptor (Smith and Carson 1977). About 60% of the silver in liver and kidneys of silver-injected rats was in the cytosol fractions bound to the high molecular weight proteins and metallothionein fractions; however, in spleen and brain only 30% of the total tissue silver was found in the cytosol fractions (Fowler and Nordberg 1986). At moderate doses (0.4 mg Ag/kg body weight [BW]) in rats, the liver handles most of the absorbed silver from the body in the bile; at higher doses, silver deposits are markedly increased in the skin (EPA 1980). In house sparrows (*Passer domesticus*), a silver-binding protein was identified in liver after radiosilver-110m injection; the protein was heat-stable, resistant to low pH, and of low molecular weight (Kumar and Bawa 1979). The properties of the hepatic silver-binding protein in birds were similar to other studied metallothioneins, but more research is needed to distinguish differences from mammalian metallothioneins (Kumar and Bawa 1979).

Most absorbed silver is excreted into the intestines by way of the liver into the bile and subsequently excreted in feces; urinary excretion of silver is generally very low (EPA 1980; Fowler and Nordberg 1986; Klaassen et al. 1986; PHS 1990). Rodents, monkeys, and dogs given radioactive silver salts by oral and other routes excreted more than 90% of the absorbed dose in the feces (Fowler and Nordberg 1986). Rats injected intravenously with radioactive silver nitrate excreted silver in bile mainly bound to a low molecular weight complex similar to glutathione (Fowler and Nordberg 1986). Excretion was faster and percentages excreted by mice, rats, monkeys, and dogs were larger when silver was administered orally than by intravenous or intraperitoneal injection (Smith and Carson 1977).

Among mammals, low doses of ingested silver were eliminated from the body within 1 week (PHS 1990). In rats, mice, and rabbits, about 99% of a single oral dose of silver was eliminated within 30 days (EPA 1980). Time for 50% clearance of silver in rats, mice, monkeys, and dogs after oral ingestion was about 1 day; this short half-time is due, in part, to fecal elimination of unabsorbed silver; the half-times were longer (1.8-2.4 days) after intravenous injection (Fowler and Nordberg 1986). Rodents dosed with silver accumulated high initial concentrations in the liver, which greatly decreased within 10 days; however, silver concentrations in spleen and brain were retained for longer periods. The biological half-time of radiosilver in rats given a single intraperitoneal injection was 40 h in whole blood, plasma, kidney, and liver; 70 h in spleen; and 84 h in brain. After exposure by inhalation, dogs cleared 59% of an administered dose of radiosilver-110m from the lungs in 1.7 days and from the liver in 9 days (Fowler and Nordberg 1986). The mean daily intake of silver in humans is about 88 µg; about 60 µg is excreted daily in the feces (Smith and Carson 1977). In humans, the whole-body effective half-time of persistence was 43 days (EPA 1980). The biological half-time of silver in the lungs of an exposed person was about 1 day; in liver it was 52 days (Fowler and Nordberg 1986). In humans, 80% of the retained silver in lung was cleared in about 1 day; 50% of the remainder was usually cleared in 3 days (EPA 1980). In persons who had accidentally inhaled radiosilver-110m, most of the inhaled silver had a half-time persistence of about 1 day, probably because of rapid mucociliary clearance, swallowing, and fecal excretion; most of the absorbed radiosilver translocated to the liver (EPA 1980).

Silver interacts competitively with selenium, vitamin E, and copper and induces signs of deficiency in animals fed adequate diets or aggravates signs of deficiency when diets lack one or more of these nutrients; antagonistic effects of silver have been described in dogs, pigs, rats, sheep, chicks, turkey poults, and ducklings (EPA 1980). Conversely, the addition of selenium, copper, or vitamin E to diets of turkey poults decreased the toxicity of diets containing 900 mg Ag/kg (Fowler and Nordberg 1986). Dietary administration of silver acetate antagonized selenium toxicity; silver prevented growth depression and death in chicks fed diets containing excess selenium (EPA 1980). The addition of selenium to the diets of rats exposed to silver in drinking water prevented growth retardation but increased the concentration of silver in liver and kidneys (Fowler and Nordberg 1986). Silver deposits in rat liver, kidneys, and other internal organs were in the form of sulfides; under high selenium exposure, the sulfur can be replaced with selenium (PHS 1990) and formation of silver selenide deposits in the liver may be considered a silver detoxification process (EPA 1980).

Concentrations in Field Collections

General

Silver is comparatively rare in the earth's crust—67th in order of natural abundance of elements; the crustal abundance is an estimated 0.07 mg/kg and predominantly concentrated in basalt (0.1 mg/kg) and igneous rocks (0.07 mg/kg; Heyl et al. 1973). Silver concentrations in nonbiological materials tend to be naturally elevated in crude oil and in water from hot springs and steam wells. Anthropogenic sources associated with the elevated concentrations of silver in nonliving materials include smelting, hazardous waste sites, cloud seeding with silver iodide, metals mining, sewage outfalls, and especially the photoprocessing industry. Silver concentrations in biota were greater in organisms near sewage outfalls, electroplating plants, mine wastes, and silver-iodide seeded areas than in conspecifics from more distant sites.

Nonbiological Materials

Maximum concentrations of total silver recorded in selected nonbiological materials were 36.5 ng/m^3 in air near a smelter in Idaho; 2.0 µg/m^3 in atmospheric dust; 0.1 µg/L in oil well brines; 4,500 ng/L in precipitation from clouds seeded with silver iodide; 6.0 µg/L in groundwater near a hazardous waste site; 8.9 µg/L in seawater from Galveston Bay, Texas; 260 µg/L in the Genesee River, New York—the recipient of photoprocessing wastes; 300 µg/L in steam wells; 300 ng/L in treated photoprocessing wastewaters; 31 mg/kg in some Idaho soils; 43 mg/L in water from certain hot springs; 50 mg/kg in granite; as much as 100 mg/kg in crude oils; 150 mg/kg in some Genesee River sediments; and 27,000 mg/kg in some solid wastes from photoprocessing effluents (Table 4). It is emphasized that only a small portion of the total silver in each of these compartments is biologically available. For example, typical publicly owned treatment works receiving photoprocessing effluents show silver removal efficiencies greater than 90%; the mean concentration of free silver ion present in the effluents from these plants ranged from 0.001 to 0.07 µg/L (Lytle 1984; Bober et al. 1992).

[a]Concentrations are shown as mean, range (in parentheses), and maximum (Max.).

[b]1, U.S. Environmental Protection Agency (EPA) 1980; 2, U.S. Public Health Service (PHS) 1990; 3, Smith and Carson 1977; 4, Freeman 1979; 5, Fowler and Nordberg 1986; 6, Connell et al. 1991; 7, Bryan and Langston 1992; 8, Morse et al. 1993; 9, Berrow 1991; 10, Bloom and Crecelius 1987; 11, National Association of Photographic Manufacturers 1974.

Silver is usually found in extremely low concentrations in natural waters because of its low crustal abundance and low mobility in water (EPA 1980). One of the highest silver concentrations recorded in fresh water, 38 µg/L, occurred in the Colorado River at Loma, Colorado, downstream of an abandoned gold-copper-silver mine, an oil shale extraction plant, a gasoline and coke refinery, and a uranium processing facility (EPA 1980). The maximum recorded value of silver in tap water in the United States was 26 µg/L—significantly higher than finished water from the treatment plant (maximum of 5.0 µg/L)—because of the use of tin-silver solders for joining copper pipes in the home, office, or factory (EPA 1980).

In general, silver concentrations in surface waters of the United States decreased between 1970-74 and 1975-79, although concentrations increased in the north Atlantic, Southeast, and lower Mississippi basins (PHS 1990). About 30 to 70% of the silver in surface waters may be ascribed to suspended particles (Smith and Carson 1977), depending on water hardness or salinity. For example, sediments added to solutions containing 2 µg Ag/L had 74.9 mg Ag/kg DW sediment after 24 h in freshwater, 14.2 mg/kg DW at 1.5% salinity and 6.9 mg/kg DW at 2.3% salinity (Sanders and Abbe 1987). Riverine transport of silver to the ocean is considerable: suspended materials in the Susquehanna River, Pennsylvania—containing as much as 25 mg silver/kg—result in an estimated transport of 4.5 metric tons of silver to the ocean each year (EPA 1980).

Emissions of silver from coal-fired power plants may lead to accumulations in nearby soils (Fowler and Nordberg 1986). Silver in soils is largely immobilized by precipitation to insoluble salts and by complexation or adsorption by organic matter, clays, and manganese and iron oxides (Smith and Carson 1977).

Silver can remain attached to oceanic sediments for about 100 years under conditions of high pH, high salinity, and high sediment concentrations of iron, manganese oxide, and organics (Wingert-Runge and Andren 1994). Estuarine sediments that receive metals, mining wastes, or sewage usually have higher silver concentrations (>0.1 mg/kg DW) than noncontaminated sediments. Silver is tightly bound by sewage sludge, and elevated silver concentrations in sediments are often characteristic of areas near sewage outfalls. In the absence of sewage, silver in oxidized sediments is associated with oxides of iron and with humic substances (Bryan and Langston 1992). Sediments in the Puget Sound, Washington, were significantly enriched in silver, in part from human activities; concentrations were higher in fine-grained particles (Bloom and Crecilius 1987). Marine annelids and clams accumulate dissolved and sediment-bound forms of silver. Uptake of silver from sediments by marine polychaete annelids decreased in sediments with high concentrations of humic substances or copper but increased in sediments with elevated concentrations of manganese or iron (Bryan and Langston 1992).

Plants and Animals

Maximum concentrations of total silver recorded in field collections of living organisms (Table 5), in milligrams silver per kilogram dry weight, were 1.5 in liver of marine mammals, 2 in liver and 6 in bone of trout from ecosystems receiving precipitation from silver-iodide seeded clouds, 7 in kidneys and 44 in liver of birds from a metals-contaminated area, 14 in marine algae and macrophytes, 30 in whole annelid worms from San Francisco Bay, 72 in skin of humans afflicted with argyria, 110 in whole mushrooms, 133 to 185 in soft parts of clams and mussels near sewage and mining waste outfalls, and 320 in whole gastropods from South San Francisco Bay. Silver concentrations in conspecifics from areas remote from anthropogenic contamination were usually lower by one or more orders of magnitude (Table 5).

Silver is a normal trace constituent of many organisms (Smith and Carson 1977). In terrestrial plants, silver concentrations are usually less than 1.0 mg/kg ash weight (equivalent to less than 0.1 mg/kg DW) and are higher in trees, shrubs, and other plants near regions of silver mining; seeds, nuts, and fruits usually contain higher silver concentrations than other plant parts (EPA 1980). Silver accumulations in marine algae (max. 14.1 mg/kg DW) are due mainly to adsorption rather than uptake; bioconcentration factors of 13,000 to 66,000 are not uncommon (PHS 1990).

Silver concentrations in mollusks vary widely between closely related species and among conspecifics from different areas (Bryan 1973; Eisler 1981; Table 5). The inherent differences in ability to accumulate silver among bivalve mollusks are well documented (oysters >> scallops >> mussels; Brooks and Rumsby 1965; Eisler 1981). The highest silver concentrations in all examined species of mollusks were in the internal organs, especially in the digestive gland and kidneys (Eisler 1981; Miramand and Bentley 1992; Table 5). Elevated concentrations of silver (5.3 mg/kg DW) in shells of limpets from uncontaminated sites suggest that silver may actively participate in carbonate mineral formation (Navrot et al. 1974), but this needs verification. In general, silver concentrations were elevated in mollusks collected near port cities and in the vicinities of river discharges (Fowler and Oregioni 1976; Berrow 1991), electroplating plant outfalls (Eisler et al. 1978; Stephenson and Leonard 1994), ocean dump sites (Greig 1979), and urban point sources including sewage outfalls (Alexander and Young 1976; Smith and Carson 1977; Martin et al. 1988; Anderlini 1992; Crecelius 1993) and from calcareous sediments rather than detrital organic or iron oxide sediments (Luoma and Jenne 1977). Season of collection (Fowler and Oregioni 1976; Sanders et al. 1991) and latitude (Anderlini 1974) also influenced silver accumulations. Seasonal variations in silver concentrations of Baltic clams (*Macoma balthica*) were associated with seasonal variations in soft tissue weight and frequently reflected the silver content in the sediments (Cain and Luoma 1990). Oysters from the Gulf of Mexico vary considerably in whole body concentrations of silver and other trace metals. Variables that modify silver concentrations in oyster tissues include the age, size, sex, reproductive stage, general health, and metabolism of the animal; water temperature, salinity, dissolved oxygen, and turbidity; natural and anthropogenic inputs to the biosphere; and chemical species and interactions with other compounds (Presley et al. 1990). Silver concentrations in whole American oysters (*Crassostrea virginica)* from the Chesapeake Bay were reduced in summer, reduced at increasing water salinities, and elevated near sites of human activity; chemical forms of silver taken up by oysters included the free ion (Ag^+) and the uncharged

$AgCl^0$ (Sanders et al. 1991; Daskalakis 1995). Declines in tissue silver concentrations of the California mussel (*Mytilus californianus*) were significant between 1977 and 1990; body burdens decreased from 10-70 mg/kg DW to less than 2 mg/kg DW and seem to be related to the termination of metal plating facilities in 1974 and decreased mass emission rates by wastewater treatment facilities (Stephenson and Leonard 1994).

Table 5. Silver concentrations (milligrams of silver per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in field collections of selected plants and animals.

Fish, muscle, 3 species	0.29-0.53 FW	53
Calcasieu River, Louisiana		
Periphyton, whole	2.1 DW	54
Hooked mussel, *Ischadium recurvum* (formerly *Brachidontes exustus)* soft parts	0.4 DW	54
American oyster, *Crassostrea virginica*; soft parts	1.0 DW	54
Zooplankton, whole	0.8 DW	54
Blue crab, *Callinectes sapidus*; muscle	0.1 DW	54
Shrimps, 2 species; muscle	0.04 DW	54
Fish, 7 species: muscle	0.1 DW	54
Poland, 1989-92		
Mushrooms, *Agaricus campestris*, whole	9-62 (6-110) DW	56
Soils	0.1-0.95 DW; Max. 1.4 DW; BCF values for silver by mushrooms from soils ranged between 60 and 330	56

[a]Concentrations are shown as mean, range (in parentheses), and maximum (Max.).

Among arthropods, pyrophosphate granules isolated from barnacles have the capability to bind and effectively detoxify silver and other metals under natural conditions (Pullen and Rainbow 1991). In a Colorado alpine lake, silver concentrations in caddisflies and chironomid larvae usually reflected silver concentrations in sediments; seston, however, showed a high correlation with lakewater silver concentrations from 20 days earlier (Freeman 1979).

In other studies, silver concentrations in fish muscles rarely exceeded 0.2 mg/kg DW and usually were less than 0.1 mg/kg fresh weight (FW); livers contained as much as 0.8 mg/kg FW, although values greater than 0.3 mg/kg FW were unusual; and whole fish contained as much as 0.2 mg/kg FW (Table 5). Livers of Atlantic cod (*Gadus morhua*) contained significantly more silver than muscles or ovaries; a similar pattern was evident in other species of marine teleosts (Hellou et al. 1992; Szefer et al. 1993; Table 5). Accumulations of silver in offshore populations of teleosts is unusual, even among fishes collected near dump sites impacted by substantial quantities of silver and other metals. For example, of seven species of marine fishes from a disposal site in the New York Bight that were examined for silver content, concentrations were highest (0.15 mg/kg FW) in muscle of blue hake (*Antimora rostrata*; Greig et al. 1976). Similarly, the elevated silver concentration of 0.8 mg/kg FW in liver of winter flounder (*Pleuronectes americanus*; Table 5) was from a specimen from the same general area (Greig and Wenzloff 1977b).

Silver concentrations in muscles of Antarctic birds were low (0.01 mg/kg DW) when compared to livers (0.02-0.46 mg/kg DW) or feces (0.18 mg/kg DW; Szefer et al. 1993; Table 5). Silver concentrations in avian tissues, especially in livers, were elevated in the vicinity of metals-contaminated areas and in diving ducks from the San Francisco Bay (Table 5). Birds with elevated concentrations of silver in tissues—as much as 44 mg/kg DW in liver in the common eider (*Somateria mollissima*)—seemed outwardly unaffected (Bryan and Langston 1992).

Silver in mammalian tissues is usually present at low or nondetectable concentrations (Klaassen et al. 1986). The concentration of silver in tissues of three species of seals collected in the Antarctic during 1989 was highest in liver (1.55 mg/kg DW; Table 5) and lowest in muscle (0.01 mg/kg DW); intermediate in value were kidney (0.29 mg/kg DW) and stomach contents (0.24 mg/kg DW; Szefer et al. 1994). The mean concentration of silver in livers from normal female California sea lions (*Zalophus calfornianus*), with normal pups, was 0.5 mg/kg DW (Martin et al. 1976; Table 5). Mothers giving birth to premature pups had only 0.4 mg Ag/kg DW liver. In general, *Zalophus* mothers delivering premature pups had lower concentrations in liver of silver, cadmium, copper, manganese, mercury, and zinc than did mothers delivering normal pups (Martin et al. 1976). Silver concentrations in tissues of Antarctic seals were related to, and possibly governed by, concentrations of other metals (Szefer et al. 1994). In muscle, silver inversely correlated with zinc; in liver, silver positively correlated with nickel, copper, and zinc; and in kidney, correlations between silver and zinc and between silver and cadmium were negative (Szefer et al. 1994). In humans, EPA (1980) states that silver is present in placentas and fetal livers, that silver concentrations in tissues increase with age, and that variations in tissue concentrations of silver are wide. The average maximum daily intake of silver from all sources by humans is 88 µg (Table 5), but very little of the silver ingested from nontherapeutic sources is retained (Smith and Carson 1977).

Lethal and Sublethal Effects

General

As discussed and documented later, free silver ion is lethal to representative species of sensitive aquatic plants, invertebrates, and teleosts at water concentrations of 1.2-4.9 µg/L. Adverse effects occur on development of trout at concentrations as low as 0.17 µg/L and on phytoplankton species composition and succession at 0.3 to 0.6 µg/L. Aquatic organisms accumulate silver from environmental sources. No data were found on effects of silver on avian or mammalian wildlife and all studied effects were on poultry and small laboratory mammals. Silver was not mutagenic, carcinogenic, or teratogenic to tested animals by normal routes of exposure. Adverse effects of silver on poultry occur at 1.8 mg/kg FW whole egg by way of injection (reduced survival), 10 mg/kg in copper-deficient diets (reduced hemoglobin), and 200 mg/kg in copper-adequate diets (growth suppression), or when the birds are given drinking water containing 100 mg Ag/L (liver necrosis). Effects of silver on sensitive species of mammals include death at 13.9-20.0 mg/kg BW by intraperitoneal injection, histopathology of kidney and brain at 250-450 µg Ag/L drinking water, tissue accumulations at 6 mg/kg diet, and

liver necrosis when fed diets containing more than 130 mg/kg. In humans, generalized argyria seems to be declining, which may be due to improved work conditions.

Terrestrial Plants

Smith and Carson (1977) report that sprays containing 9.8 mg dissolved Ag/L kill corn (*Zea mays*), and sprays containing 100-1,000 mg dissolved Ag/L kill young tomato (*Lycopersicon esculentum*) and bean (*Phaseolus* spp.) plants. Hirsch et al. (1993) planted seeds of corn, lettuce (*Lactuca sativa*), oat (*Avena sativa*), turnip (*Brassica rapa*), soybean (*Glycine max*), spinach (*Spinacia oleracea*), and Chinese cabbage (*Brassica* spp.) in soils amended with silver sulfide and sewage sludge to contain 10, 50, or 100 mg Ag/kg DW soil. All plants germinated and most grew normally at the highest soil concentration of silver tested. But growth of Chinese cabbage and lettuce was adversely affected at 10 mg Ag/kg DW soil and higher. Silver concentrations in edible portions from all plants at all soil levels of silver tested, except lettuce, were less than 80 µg/kg DW. Lettuce grown in soil containing 100 mg Ag/kg DW had about 1.2 mg Ag/kg DW (Hirsch et al. 1993).

Aquatic Organisms

In fish and amphibian toxicity tests with 22 metals and metalloids, silver was the most toxic tested element as judged by acute LC50 values (Birge and Zuiderveen 1995). In solution, ionic silver is extremely toxic to aquatic plants and animals (Nehring 1976; Nelson et al. 1976; Calabrese et al. 1977a; Gould and MacInnes 1977; Smith and Carson 1977; EPA 1980; Buhl and Hamilton 1991; Bryan and Langston 1992), and water concentrations of 1.2-4.9 µg/L killed sensitive species of aquatic organisms, including representative species of insects, daphnids, amphipods, trout, flounders, sticklebacks, guppies, and dace (Table 6). At nominal water concentrations of 0.5-4.5 µg/L, accumulations in most species of exposed organisms were high and had adverse effects on growth in algae, clams, oysters, snails, daphnids, amphipods, and trout; molting in mayflies; and histopathology in mussels (Table 6). Among all tested species, the individuals most sensitive to silver were the poorly nourished and young and those exposed to low water hardness or salinity (Smith and Carson 1977; EPA 1980; Le Blanc et al. 1984; Table 6). It is emphasized that silver-induced stress syndromes vary widely among animal classes. Among marine organisms, for example, silver ion was associated with respiratory depression in marine gastropods and cunners (*Tautagolabrus adspersus*), a teleost; however, silver ion increased oxygen consumption in six species of bivalve mollusks (Gould and MacInnes 1977).

Sensitive aquatic plants accumulated silver from water containing as little as 2 µg Ag/L to whole-cell burdens as high as 58 mg Ag/kg DW; grew poorly at 3.3-8.2 µg Ag/L during exposure for 5 days; and died at concentrations greater than 130 µg Ag/L (Table 6). Some metals seem to protect aquatic plants against adverse effects of silver. Algae in small lakes that contained elevated concentrations of metals, especially copper and nickel, had higher tolerances to silver than conspecifics reared in the laboratory under conditions of depressed concentrations of heavy metals (EPA 1980). Species composition and species succession in Chesapeake Bay phytoplankton communities were significantly altered in experimental ecosystems continuously stressed by low concentrations (0.3-0.6 µg/L) of silver (Sanders and Cibik 1988; Sanders et al. 1990). At higher concentrations of 2-7 µg/L for 3 to 4 weeks, silver inputs caused disappearance of *Anacystis marina*, a mat-forming blue-green alga; increased dominance by *Skeletonema costatum*, a chain-forming centric diatom; and increased silver concentrations in various species of phytoplankton to 8.6-43.7 Ag mg/kg DW (Sanders and Cibik 1988). Dissolved silver speciation and bioavailability were important in determining silver uptake and retention by aquatic plants (Connell et al. 1991). Silver availability was controlled by the concentration of free silver ion (Ag^+) and the concentrations of other silver complexes, such as AgCl (Sanders and Abbe 1989). Silver uptake by phytoplankton was rapid, in proportion to silver concentration, and inversely proportional to water salinity. Silver incorporated by phytoplankton was not lost as the salinity increased, and silver associated with cellular material was largely retained in the estuary (Sanders and Abbe 1989). Diatoms (*Thalassiosira* sp.), for example, readily accumulated silver from the medium. Once incorporated, silver was tightly bound to the cell membrane, even after the cells were mechanically disrupted (Connell et al. 1991).

Table 6. Effects of silver on representative aquatic plants and animals. Concentrations are in micrograms of free silver (Ag^+) per liter of medium added at start unless indicated otherwise.

Table 6. Taxonomic group, organism, silver concentration (ppb), and other variables	Effects	Reference[a]
Bacteria, algae, and macrophytes		
Bacteria, freshwater		
Escherichia coli		
1,000-2,000 (as Ag+3)	All dead in 0.5-5.0 min	1
Streptococcus faecalis		
1,000-2,000 (as Ag^{+3})	All dead in 0.5-5.0 min	1
Various species		
100-200	All dead in 15-20 min	2
Bacteria, marine		
Isolated from tubes of deep-sea polychaete annelids		
3,000	Lowest concentration tested that inhibited growth in 50% of strains during 10-day exposure	3
20,000	Silver-resistant strains (55% of all strains tested) survived at least 24 h	3
40,000	Some strains survived during 10-day exposure	3
Alga, *Chlorella* spp.		
50-100	Growth inhibition	4
Waterweed, *Elodea canadensis*		
100	Respiration inhibited	4
Freshwater algae and macrophytes, 13 species		
30-7,500	Adverse effects	4
Freshwater plants		
26	Bioconcentration factor (BCF) of X200	2
Duckweed, *Lemna minor*		
270	Phytotoxic	4
Marine algae, 3 species		
2	After 24 h algae contained 27.8-58.6 mg silver/kg dry weight (DW) at 1% salinity, 16.4-33.4 mg/kg at 1.5% salinity, and 9.8-25.2 mg Ag/kg DW at 2.0% salinity	5

Table 6. Taxonomic group, organism, silver concentration (ppb), and other variables	Effects	Reference[a]
Marine algae, 4 species; various concentrations	BCF between X13,000 and X66,000 at equlibrium	40
Freshwater alga, *Phormidium inundatum*		
80-140	Controls growth in swimming pools	2
Marine alga, *Prorocentrum mariae-lebouriae*		
3.3	50% growth reduction in 5 days at 0.75% salinity	6
6.7	50% growth reduction in 5 days at 1.5-2.25% salinity	6
8.2	50% growth reduction in 5 days at 3% salinity	6
Marine algae, various species		
Radiosilver-110m at 3.3 microcuries/L	BCF of X1,600 to X2,800 in 38 days	7
Marine plants		
60	BCF of X200	2
Alga, *Scendesmus* spp.		
100-200	100% growth inhibition	4
Marine diatom, *Skeletonema costatum*		
5.9	50% growth reduction in 5 days at 0.75% salinity	6
15.4	50% growth reduction in 5 days at 1.5% salinity	6
20.0	50% growth reduction in 5 days at 2.25-3.0% salinity	6
130-170	50% reduction in cell numbers in 96 h	4
Protozoans		
Ciliate, *Fabrea salina*; held in seawater solution containing radiosilver-110m	Bioconcentration factor (volume/volume basis) of 7,000 to 40,000 within 24 h	39
Protozoan, *Spirostomum ambiguum*		
8.8	LC50(24 h) at 2.8 mg $CaCO_3$/L	8
15.3	LC50(24 h) at 250 mg $CaCO_3$/L	8
Nematodes		
Free-living nematode, *Caenorhabditis elegans*		
102 (95% confidence interval [CI] of 10 to 4,980)	LC50(96 h)	9
5,000, (95% CI of 3,000 to 10,000)	LC50(96 h)	9

Table 6. Taxonomic group, organism, silver concentration (ppb), and other variables	Effects	Reference[a]
Mollusks		
Bay scallop, *Argopecten irradians*, juveniles		
22	Oxygen consumption elevated after 96 h	10
33	LC50(96 h);survivors with elevated silver concentrations	10
Freshwater snail, *Australorbis* sp.		
30-100	Inhibited feeding and coordination	2
Bivalves, 4 species		
10	Elevated oxygen consumption after exposure for 30-90 days	10, 11
Scallop, *Chlamys varia*, adults		
20	After 14 days soft parts contained 18 mg Ag/kg DW vs. 1.7 in controls	12
100	LC50(115 h)	12
Asiatic clam, *Corbicula fluminea*		
4.5	Adverse effects on growth after exposure for 21 days; residues of 1.65 mg Ag/kg FW soft parts were associated with reduced growth	13
7.8	No deaths in 21 days	13
26.0	Some deaths in 21 days	13
155 (116-208); exposed for 96 h then transferred to uncontaminated media for 96 h	LC50 for juveniles at end of observation period	13
Pacific oyster, *Crassostrea gigas*		
2-10	5% to 8% of embryos exposed for 48 h were abnormal (retarded shell growth, reduced size, erratic swimming behavior) vs. 1% in controls; no significant effect on embryogenesis	14
13.5-15.5	Significant effect on embryogenesis; 25-37% of embryos developed abnormally	14
18-32	95-98% of embryos exposed for 48 h were abnormal	14
20	Soft parts of adults exposed for 28 days contained 188.0 mg Ag/kg DW vs. 3.0 mg/kg DW in controls	12
Juveniles held in 20 µg Ag/L for 14 days then transferred to uncontaminated seawater for 23	No histopathology. During exposure, but not depuration, glycogen storage capacity was diminished. During depuration, silver concentrations	15

Table 6. Taxonomic group, organism, silver concentration (ppb), and other variables	Effects	Reference[a]
days	decreased from 31.3 mg/kg DW soft parts to 12.8 vs. <10.0 in controls. Most of the insoluble accumulated silver was sequestered as Ag_2S in amoebocytes and basement membranes	
100	LC50(209 h), adults	12
American oyster, *Crassostrea virginica*		
0.1 (controls) vs. 2; adults exposed for 14 days in large enclosures with natural phytoplankton assemblages	In controls, phytoplankton had 0.03 mg Ag/kg DW and oyster soft parts 0.8 mg/kg DW. In the 2.0 µg/L group, phytoplankton had 8.6 mg Ag/kg DW and oysters 2.8 mg/kg DW; oyster growth rate significantly reduced	16
5 or 7; conditions as above	Phytoplankton had 24-44 mg Ag/kg DW and oysters 4.8- 6.6 mg Ag/kg DW	16, 17
5.8	LC50(48 h), embryos	10
10	LC100(48 h), embryos	4
25	LC50(12 days), juveniles	10
500-1,000	Adults exposed for 96 h had 12.4-14.9 mg Ag/kg FW in body and 34-38 mg Ag/kg FW in gills	11
Slipper limpet, *Crepidula fornicata*		
1, 5, or 10; exposed for 24 months and observed for effects on growth, reproduction, histology and accumulations	Growth reduced in the 5 and 10 µg/L groups and reproduction inhibited in the 10 µg/L group. All test groups showed deposition of silver in connective tissues and basement membranes. Maximum silver concentrations (mg/kg FW soft parts) were recorded for the controls at 12 months (2.8), for the 1.0 µg/L group at 12 months (34.0), for the 5.0 µg/L group at 6 months (54.1), and for the 10.0 µg/L group at 6 months (86.7). After 24 months, silver-exposed groups contained between 5.4 and 8 mg Ag/kg FW soft parts	18
Zebra mussel, *Dreissena polymorpha*, adults		
400	No deaths in 28 days; soft parts at 28 days contained 147-184 mg Ag/kg DW vs. 0.02-1.8 mg/kg DW in controls	12
Quahog clam, *Mercenaria mercenaria*		
21.0	LC50(48 h), embryos	10
32.4	LC50(10 days), juveniles	10
500-1,000	Adults exposed for 96 h had 0.8-1.0 mg Ag/kg FW in soft parts and 6.9-7.6 mg Ag/kg FW in gills. Controls	11

Table 6. Taxonomic group, organism, silver concentration (ppb), and other variables	Effects	Reference[a]
	(<1.5 µg/L) had 0.4 mg Ag/kg FW soft parts and 1.6 mg/kg FW in gills	
Softshell clam, *Mya arenaria*		
100	Increased oxygen consumption after 96 h	11
500	After exposure for 96 h adults had 10.4 mg Ag/kg FW soft parts vs. 0.3 mg Ag/kg FW in controls	11
1,000	All adults died within 96 h	11
Common mussel, *Mytilus edulis*		
Exposed continuously for 21 months to 0.0 (control), 1, 5, or 10 µg Ag/L from age 2.5 months (4.5 mm in shell length) and observed for growth, accumulations, and histopathology	No effect on growth. Silver concentrations (mg/kg FW soft parts) for controls ranged between 0.2 and 0.7; maximum concentrations in the 1 µg/L group (9.1) occurred at 18 months; for the 5 µg/L group, residues were highest (11.9) at 18 months; for the 10 µg/L group, concentrations were highest (15.3) at 12 months. All silver-exposed groups had histopathology of basement membranes and connective tissues	19
Juveniles (16.1 mm shell length) and adults (53.4 mm shell length) were continuosly exposed for 12 months to 0.0 (control), 5, 25, or 50 µg Ag/L and observed for growth and accumulations	Growth inhibition of the 50 µg/L group after 6 months but growth normal after 12 months; growth of other groups as in controls. At 12 months residues, in mg Ag/kg FW soft parts, for juveniles (adults) were 0.2 (0.1) in controls, 9.9 (2.0) in the 5 µg/L group, 8.0 (2.0) in the 25 µg/L group, and 10.7 (3.0) in the 50 µg/L group	19
100	Increasing oxygen consumption with increasing water salinity	11
500 or 1,000	Adults exposed for 96 h had 3.7-5.2 mg Ag/kg FW soft parts	11
Radiosilver-110m	BCF values after 1 day were X860 in soft parts and X8 in shell; after 9 days these values were X2,550 in soft parts and X11 in shell	20
Mussel, *Mytilus galloprovincialis*, adults		
10	Growth normal after 21-month exposure	12
20	After 28 days soft parts contained 15 mg Ag/kg DW vs. 0.08 mg Ag/kg DW in controls (<0.1 µg Ag/L)	12
25	Growth depressed after 21-month exposure	12
50	Severe tissue histopathology after 14 days	12
100	LC50(110 h)	12
Mud snail, *Nassarius obsoletus*		

Table 6. Taxonomic group, organism, silver concentration (ppb), and other variables	Effects	Reference[a]
1.0	Inhibition of embryonic development	21
Clam, *Potamocorbula amurensis*; exposed for 14 days at 1.8% salinity to 0.1, 0.2, 0.5, 1.0, or 2.0 µg Ag^+/L	Silver concentrations in soft parts rose in a dose-dependent manner from <1.0 mg Ag/kg DW to about 14.0 mg/kg Ag/kg DW	42
Clam, *Scrobicularia plana*, adults		
20	Normal after 14 days	12
50	No deaths in 16 days; severe histopathology	12
100	LC50(250 h)	12
200	LC50(96 h)	12
Surf clam, *Spisula solidissima*		
10	Elevated oxygen consumption in juveniles after 96 h	10
14; 1-h exposure 60 min after fertilization	50% of embryos developed abnormally in 48 h	21
100	Lethal to juveniles in 96 h	10
Bryozoans		
Bryozoan, *Victorella* sp.		
0.18 (control), 2, or 10	Silver concentrations, in mg/kg DW whole animal, after 24 h were 11.5 in controls, 38.3 in the 2 µg/L group, and 180.0 in the 10 µg/L group	22
Arthropods		
Copepod, *Acartia tonsa*		
36	LC50(96 h)	4
Daphnid, *Daphnia magna*		
0.4-15.0	LC50(96 h) at 38-75 mg $CaCO_3$/L	4
0.9	50% of starved daphnids immobilized in 48h	23
1.6-19.4	MATC[b]	23
3.5	50% reduction in growth of nonstarved daphnids in 21 days	23
4.1	Reduced survival during 21-day exposure	23
10.5	Reproduction inhibited during 21-day exposure	23
12.5	50% of nonstarved daphnids immobilized in 48 h	23
45-49	LC50(96 h) at 255 mg $CaCO_3$/L	4

Table 6. Taxonomic group, organism, silver concentration (ppb), and other variables	Effects	Reference[a]
Daphnids, *Daphnia* spp.		
10 (0.25-49.0)	LC50(96 h)	9
Mayfly, *Ephemerella grandis*		
<1.0	LC50(14 days), naiads	24
4.0-8.8	LC50(7-15 days), adults	4
60 or 120	On death, whole mayflies contained 25.3 and 28.7 mg Ag/kg DW	24
Scud (amphipod), *Gammarus pseudolimnaeus*		
4.5 (3.7-5.5)	LC50(96 h) at 44 mg $CaCO_3$/L	25
American lobster, *Homarus americanus*		
6.0	Altered enzyme activity after 30 days but no effect on survival, oxygen consumption, or osmoregulation	10
Amphipod, *Hyalella azteca*		
0.95	No observable effects after 21-day exposure	13
1.4	Reduced growth after 20 days	13
1.9 (1.4-2.3)	LC50(96 h)	13
Mayfly, *Isonychia bicolor*		
1.6	Molting inhibited after 20 days	13
6.8 (5.5-7.8)	LC50(96 h)	13
Stonefly, *Leuctra* sp.		
0.69	Adverse effects after 12 days	13
2.5 (1.7-3.2)	LC50(96 h)	13
Mysid shrimp, *Mysidopsis bahia*		
250.0	LC50(96 h)	4
Grass shrimp, *Palaemonetes pugio*		
2.0	After 2 weeks whole shrimps contained 0.5 mg Ag/kg DW vs. 0.36 in controls	22
5.0	After 2 weeks whole shrimps had 3.7 mg Ag/kg DW	22
10.0	Whole shrimps contained 4.5 mg Ag/kg DW after exposure for 2 weeks	22
For 2 weeks shrimp ate *Artemia*	Silver concentration (mg/kg DW whole body) in	22

Table 6. Taxonomic group, organism, silver concentration (ppb), and other variables	Effects	Reference[a]
nauplii containing 0.72 mg Ag/kg DW, or bryozoans (*Victorella* sp.) containing elevated silver burdens (38-180 mg Ag/kg DW), or control bryozoans (11.5 mg Ag/kg DW)	shrimp on *Artemia* diet was 0.19 vs. 0.09 in silver-free *Artemia* diet; 0.26-0.62 in the high-silver bryozoan diet and 0.36 in the control bryozoan diet	
Stonefly, *Pteronarcys californica*		
4.0-9.0	LC50(96 h)	24
50.0	On death, whole stoneflies contained 9.1 mg Ag/kg DW	24
105.0	Dead stoneflies had 13.2 mg Ag/kg DW	24
Mayfly, *Stenonema* sp.		
3.9 (2.5-5.7)	LC50(96 h)	13
Midge, *Tanytarsus dissimilis*		
3,160 (2,490-4,010)	LC50(48 h) at 44 mg $CaCO_3$/L	25
Annelids		
Marine polychaete, *Sabella pavonina*		
Adults immersed in seawater containing 50 µgAg/L for 8 weeks then transferred to silver-free media for 8weeks	During immersion, the maximum whole-body silver concentration was 22.1 mg/kg DW vs. 0.8 in controls; main sites of accumulation were the connecting tissues of nephridia and gut. No histopathology. A constant elimination of silver in urine occurs simultaneously with silver accumulation. During depuration, new connective tissue formed and silver concentrations were reduced by 88%	26
Echinoderms		
Sea urchin, *Arbacia lixula*		
0.5	Reduced embryo development after 52 h	4
Fishes		
Mottled sculpin, *Cottus bairdi*		
5.3	LC50(96 h) at 30 mg $CaCO_3$/L	4
14.0	LC50(96 h) at 250 mg $CaCO_3$/L	4

1,400	LC50(96 h), juveniles	4
Common carp, *Cyprinus carpio*		

Table 6. Taxonomic group, organism, silver concentration (ppb), and other variables	Effects	Reference[a]
Held in radiosilver-110m solutions for 41 days then transferred to uncontaminated media for 42 days	Whole body BCF during immersion rose rapidly and progressively to X51 at day 19, then more slowly to X73 at day 41. At day 41, BCF for liver was X866, for digestive tract X560, for kidneys X299, for spleen X155, and for air bladder X109. During depuration, 68% of the silver was eliminated-- about 31% during the first 3 days and 37% in the next 39 days. In both uptake and depuration phases, 71-77% of all radiosilver was present in liver and digestive tract	27
Mummichog, *Fundulus heteroclitus*		
30-40	Inhibited liver enzyme activity after 4 days	2, 4

[b]MATC = maximum acceptable toxicant concentration. Lower value in each MATC pair indicates highest concentration tested producing no measurable adverse effect on growth, survival, reproduction, or metabolism during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

The ability to accumulate dissolved silver from the medium ranges widely between species. Some reported bioconcentration factors (mg Ag per kg FW organism/mg Ag per liter of medium) are 210 in diatoms, 240 in brown algae, 330 in mussels, 2,300 in scallops, and 18,700 in oysters (EPA 1980). Silver is the most strongly accumulated of all trace metals by marine bivalve mollusks (Luoma 1994). Studies with radiosilver-110m suggest that the half-time persistence of silver is 27 days in mussels, 44-80 days in clams, and more than 180 days in oysters (Fisher et al. 1994). In oysters and other bivalve mollusks, the major pathway of silver accumulation was from dissolved silver; uptake was negligible from silver adsorbed onto suspended sediments or algal cells, and oysters eliminated adsorbed silver in the feces (Abbe and Sanders 1990; Sanders et al. 1990). Sometimes, benthic bivalve mollusks accumulated silver from certain sediments. Sediment-bound silver was taken up by the Baltic clam (*Macoma balthica*) at 3.6 to 6.1 times the concentration in calcite sediments but less than 0.85 times from manganous, ferrous, and biogenic $CaCO_3$ sediments (EPA 1980). In oysters, silver associated with food was unavailable for incorporation, which may be due to the ability of silver to adsorb rapidly to cell surfaces and to remain tightly bound despite changes in pH or enzymatic activity (Connell et al. 1991). Silver concentrations in American oysters (*Crassostrea virginica)* held in seawater solutions containing 1.0 mg Ag/L for 96 h rose from 6.1 mg/kg FW soft parts to 14.9 mg/kg FW; in gills, these values were 5.9 and 33.9 mg/kg FW (Thurberg et al. 1974). A similar pattern was evident in common mussels (*Mytilus edulis*) and quahog clams (*Mercenaria mercenaria*; Thurberg et al. 1974). Adults of surf clams (*Spisula solidissima*) immersed for 96 h in seawater containing 10 µg Ag/L had 1.0 mg Ag/kg FW soft tissues versus 0.08 mg/kg in controls (Thurberg et al. 1975). Oysters accumulated radiosilver-110m from the medium by factors of 500 to 32,000 (Pouvreau and Amiard 1974); uptake of dissolved silver by oysters was higher at elevated temperatures in the range of 15-25^{o} C (Abbe and Sanders 1990). American oysters maintained near a nuclear power plant in Maryland that discharged radionuclides on a daily basis into the Chesapeake Bay accumulated radiosilver-110m; accumulations were higher in summer and fall than in winter and spring (Rose et al. 1988).

Marine gastropods exposed to concentrations as low as 1.0 µg Ag/L for as long as 24 months showed histopathology and accumulations as high as 34 mg Ag/kg FW soft parts; higher exposure concentrations of 5 and 10 µg Ag/L were associated with inhibited reproduction and whole-body burdens as high as 87 mg Ag/kg FW (Nelson et al. 1983). Histopathological findings in silver-exposed mussels (*Mytilus edulis*) were typical of argyria in humans and other mammals that have absorbed organic or inorganic silver compounds (Calabrese et al. 1984). Juvenile Pacific oysters (*Crassostrea gigas*) exposed for 2 weeks to solutions containing 20 µg Ag/L had high silver accumulations in tissues and a reduced capacity to store glycogen; however, after 30 days of depuration, glycogen storage capacity was restored and 80% of the soluble silver and 27% of the insoluble forms were eliminated, suggesting recovery to a normal physiological state (Berthet et al. 1990). About 70% of the insoluble silver in Pacific oysters was sequestered as Ag_2S, a stable mineral form that is not degradable, thereby limiting the risk of silver transfer through the food chain (Berthet et al. 1990). Most (69-89%) of the silver accumulated from the medium in soft tissues of oysters and clams was sequestered in amoebocytes and basement membranes; in scallops and mussels, silver was stored in basement membranes and pericardial gland. In all species of bivalve mollusks, sequestered silver was in the form of silver sulfide (Berthet et al. 1992). American oysters excreted about 60% of their accumulated silver in soft tissues within 30 days of transfer to silver-free seawater; soluble forms were preferentially eliminated and insoluble forms retained (Berthet et al.

1992). Interspecies differences in ability to retain silver among bivalve mollusks are large, even among closely related species of crassostreid oysters. For example, the half-time persistence of silver was about 149 days in American oysters but only 26 days in Pacific oysters (PHS 1990).

Among arthropods, grass shrimp (*Palaemonetes pugio*) rapidly incorporate silver dissolved in brackish water in proportion to its concentration but not from planktonic or detrital food sources containing elevated silver burdens (Connell et al. 1991). Variations in ability of decapod crustaceans to accumulate radiosilver-110m from seawater are large, as judged by concentration factors that ranged from 70 to 4,000 (Pouvreau and Amiard 1974). The reasons for this variability are unknown but may be associated with hepatopancreas morphology. It is generally acknowledged that hepatopancreas or digestive gland is the major repository of silver in decapods (Greig 1975; Greig et al. 1977a, 1977b). Aquatic insects concentrate silver in relative proportion to environmental levels (Nehring 1976), and more efficiently than most fish species (Diamond et al. 1990). Whole-body bioconcentration factors (BCF = mg total Ag per kg fresh weight tissue divided by mg total Ag per liter of medium) of silver in three species of aquatic insects ranged from 21 to 240 in water containing 30-65 mg $CaCO_3$/L during exposure of 3-15 days; in bluegill sunfish (*Lepomis macrochirus*), this value was less than 1 after exposure for 28 days (EPA 1980). Molt frequency of a mayfly (*Isonychia bicolor*) was a sensitive indicator of silver stress over time, and 1.6 µg total Ag/L over a 20-day period inhibited molting (Diamond et al. 1990).

Silver ion (Ag^+) was the most toxic chemical species of silver to fishes. Silver ion was 300 times more toxic than silver chloride to fathead minnows (*Pimephales promelas*), 15,000 times more toxic than silver sulfide, and more than 17,500 times more toxic than silver thiosulfate complex; in all cases, toxicity reflected the free silver ion content of tested compounds (LeBlanc et al. 1984); a similar pattern was noted in rainbow trout (Hogstrand et al. 1996). Silver was less toxic to fathead minnows under conditions of increasing water hardness between 50 and 250 mg $CaCO_3$/L, increasing pH between 7.2 and 8.6, and increasing concentrations of humic acid and copper; starved minnows were more sensitive to ionic silver than minnows fed regularly (Brooke et al. 1994). Eggs of rainbow trout exposed continuously to silver concentrations as low as 0.17 µg/L had increased embryotoxicity and hatched prematurely; resultant fry had a reduced growth rate (Davies et al. 1978). Removal of the egg capsule of eyed embryos of steelhead trout (*Oncorhynchus mykiss*) significantly lowered the resistance of the embryos to salts of silver, copper, and mercury but not zinc and lead (Rombough 1985). Silver accumulation in gills of juvenile rainbow trout exposed to 11 µg Ag/L for 2-3 h was significantly inhibited by various cations (Ca^{2+}, Na^+, H^+) and complexing agents (dissolved organic carbon, thiosulfate, chloride); these variables must be considered when constructing predictive models of silver binding to gills (Janes and Playle 1995).

Largemouth bass (*Micropterus salmoides*) and bluegills accumulated silver from the medium; accumulations increased with increasing concentrations of ionic silver and increasing duration of exposure (Coleman and Cearley 1974). Bioconcentration factors of radiosilver-110m for various species of teleosts were as high as 40 after 98 days (Pouvreau and Amiard 1974). However, plaice (*Pleuronectes platessa*; a marine flounder), and thornback rays (*Raja clavata*) fed nereid polychaete worms labeled with radiosilver-110m retained about 4.2% of the ingested dose after 3 days (Pentreath 1977), which suggests that the high silver concentration factors reported by Pouvreau and Amiard (1974) may have been due to loosely bound adsorbed silver. Flounders (*Pleuronectes* sp.) held for 2 months in seawater solutions containing 40 µg Ag/L had elevated silver concentrations in the gut (0.49 mg Ag/kg FW) but less than 0.05 mg/kg in all other examined tissues (Pentreath 1977). Similarly exposed rays (*Raja* sp.) contained 1.5 mg Ag/kg FW in liver, 0.6 in gut, 0.2 in heart, and 0.05-0.18 mg/kg FW in spleen, kidney, and gill filament (Pentreath 1977); liver is usually considered the major repository of silver in teleosts (Garnier et al. 1990).

Food chain biomagnification of silver in aquatic systems is unlikely at silver concentrations normally encountered in the environment (Connell et al. 1991), although regular ingestion of fish from contaminated waters may significantly affect dietary silver intake in humans (EPA 1980). Silver—as thiosulfate-complexed silver at nominal concentrations of 500 or 5,000 µg Ag/L—was concentrated and magnified over a 10-week period in freshwater food chains of algae, daphnids, mussels, and fathead minnows (Terhaar et al. 1977), although the mechanisms of accumulation in this study were imperfectly understood.

Birds and Mammals

No data were found on the effects of silver compounds on avian or mammalian wildlife. All controlled studies with silver were with domestic poultry, livestock, or small laboratory mammals. Signs of chronic silver ion intoxication in tested birds and mammals included cardiac enlargement, vascular hypertension, hepatic necrosis, anemia, lowered immunological activity, altered membrane permeability, kidney pathology, enzyme inhibition, growth retardation, and a shortened life span (Smith and Carson 1977; Freeman 1979; Fowler and Nordberg 1986; PHS 1990).

Silver affects turkeys (*Meleagris gallopavo*) and domestic chickens (*Gallus* spp.). Turkey poults on diets containing 900 mg Ag/kg feed for 4 weeks had enlarged hearts and reduced growth, hemoglobin, and hematocrit (EPA 1980). Chicken eggs injected with silver nitrate at 0.1 mg Ag/egg (equivalent to about 1.8 mg Ag/kg egg FW) had a 50% reduction in survival but no developmental abnormalities (Ridgway and Karnofsky 1952). Adverse effects of silver were reported in normal chicks fed diets containing 200 mg Ag/kg ration (growth suppression) or given drinking water containing 100 mg Ag/L (liver necrosis; Smith and Carson 1977). Chicks on copper-deficient diets had adverse effects at 10 mg Ag/kg ration (reduced hemoglobin; reversible when fed copper-adequate diet) and at 50-100 mg Ag/kg ration (growth suppression and increased mortality). Chicks that were deficient in vitamin E experienced reduced growth when given drinking water containing 1,500 mg Ag/L. Chickens infected with pathogenic strains of *Salmonella* sp. and *Escherichia coli* were cured with aerosol treatments containing 10 µg Ag/L air (Smith and Carson 1977).

Studies with small laboratory mammals—which require verification—show that long-term exposure to high levels of silver nitrate in drinking water may result in sluggishness and enlarged hearts; however, these effects have not been observed in silver-exposed humans (PHS 1990). Concentrations as high as 200 µg Ag/L in drinking water of test animals for 5 months had no significant effect on animal health or metabolism (EPA 1990). But 400 µg Ag/L for 5 months caused kidney damage, and 500 µg/L for 11 months was associated with impaired conditioned-reflex activities, immunological resistance, and altered brain nucleic acid content (EPA 1980). Diets deficient in vitamin E or selenium caused rapidly fatal hepatocellular necrosis and muscular dystrophy to rats if they contained the dietary-intake equivalent of 130 mg Ag/kg BW daily, a comparatively high silver ion intake (Smith and Carson 1977; PHS 1990).

The extent of absorption of an administered dose of silver depends on silver speciation, the presence and extent of silver-binding proteins, and other variables. But absorption is dependent mainly on the transit time through the gastrointestinal tract: the faster the transit time is, the less silver is absorbed. Transit times ranged from about 8 h in mice and rats to about 24 h in monkeys, dogs, and humans (PHS 1990). Route of administration affected the excretion rate of silver. Clearance of silver from mammals 2 days after silver was administered intravenously ranged from 15% in dogs to 82% in mice; clearance rates were intermediate in monkeys and rats. When silver was administered orally, clearance was more rapid, and extended from 90.4% in dogs to 99.6% in mice (PHS 1990). The half-time persistence of silver administered orally to mice was 0.1 day for the short-lived component and 1.6 days for the long-lived component. Other species of tested laboratory animals had biphasic or triphasic whole-body silver-excretion profiles that differed significantly from mice. Monkeys, for example, had a biphasic excretion profile with peaks at 0.3 and 3.0 days; rats had a triphasic profile with peaks at 0.1, 0.7, and 5.9 days; and dogs had half-time persistence peaks at 0.1, 7.6, and 33.8 days (PHS 1990).

Ionic silver is lethal to mice (*Mus* spp.) at 13.9 mg/kg BW by intraperitoneal injection, to rabbits (*Oryctolagus* spp.) at 20 mg/kg BW intraperitoneally, to dogs (*Canis familiaris)* at 50 mg/kg BW by intravenous injection, to humans at greater than 166 mg/kg BW in a single dose, and to rats (*Rattus* spp.) at 1,586 mg/L drinking water for 37 weeks (Table 7). Sublethal effects are reported in rabbits given 250 µg Ag/L drinking water (brain histopathology), in rats given 400 µg Ag/L drinking water for 100 days (kidney damage), in mice given 95 mg Ag/L drinking water for 125 days (sluggishness), in guinea pigs (*Cavia* sp.) given 81 mg Ag/cm^2 skin applied daily for 8 weeks (reduced growth), and in rats given diets containing 6 mg Ag/kg for 3 months (high accumulations in kidneys and liver) or 130-1,110 mg/kg (liver necrosis; Table 7).

The connections between human cancers and silver as a causal agent are tenuous (EPA 1980). All available evidence is negative or inconclusive regarding silver's ability to induce cancer, mutagenicity, or birth defects in animals by normal routes of exposure (EPA 1980; PHS 1990). Silver pellets, however, implanted

under the skin of rodents, have caused sarcomas, malignant fibrosarcomas, fibromas, fibroadenomas, and invasions of muscle with connective tissue; in these cases, silver seems to act as a nonspecific irritant rather than as a specific carcinogen (Smith and Carson 1977; EPA 1980). Intratumoral injections of colloidal silver promotes cancer growth in rats, possibly by producing an area of lowered tissue resistance that allows resistant cancer cells to grow freely (Smith and Carson 1977); however, silver nitrate seems to be a tumor inhibitor in mice (EPA 1980).

In humans, acute toxic effects of silver have resulted only from accidental or suicidal overdoses of medical forms of silver. Symptoms of acute silver poisoning in patients dying after intravenous administration of Collargo (silver plus silver oxide) included gastrointestinal disturbances, pulmonary edema, tissue necrosis, and hemorrhages in bone marrow, liver, and kidney (Smith and Carson 1977; EPA 1980). High sublethal doses of silver nitrate taken orally cause some patients to experience violent abdominal pain, abdominal rigidity, vomiting, and severe shock; systemic effects among recovering patients are unlikely, although degenerative liver changes may occur (EPA 1980). In humans, skin contact with silver compounds may cause mild allergic reactions such as rash, swelling, and inflammation (PHS 1990); industrial and medicinal exposures to silver may cause lesions of the kidneys and lungs, and arteriosclerosis (Klaassen et al. 1986); colloidal silver compounds may interfere with nasal ciliary activity (Smith and Carson 1977); and exposure to dust containing high levels of silver compounds, such as silver nitrate or silver oxide, may cause breathing problems, lung and throat irritation, and stomach pain (PHS 1990).

Table 7. Effects of silver on selected mammals.

Table 7. Organism, route of administration, dose, and other variables	**Effects**	**Reference[a]**
Domestic dog, *Canis familiaris*		
Inhalation route. Anaesthetized dogs exposed to metallic silver particles about 0.5 um in diameter; total dose deposited of 25 µg	About 3% (0.8 µg) of the deposited silver was found in liver and blood 6 h after exposure. Clearance from the lung to the blood was triphasic, with half-times of 1.7, 8.4, and 40 days	1
Intratracheal route. Elemental silver deposited in lungs	After 6 h, 96.9% remained in lungs, 2.4% in liver, 0.35% in blood, 0.14% in gall bladder and bile, 0.1% in intestines, 0.06% in kidneys, and 0.02% in stomach. After 225 days, 0.49% of the initial dose was detected in liver, and 0.01-0.03% each in brain, gall bladder, intestines, lungs and trachea, bone, stomach and contents, heart, and muscle. If lung is excluded, liver contained 77% of the total-silver body burden between 6 h and 225 days postexposure	1
Intravenous injection route		
0.003 µg/kg body weight (BW) daily	15% cleared in 2 days	1
500 mg (estimated at 50 mg/kg BW), single injection	All dead within 24 h with hemolysis and lung edema	2
Oral route; 0.005 µg/kg BW daily	90.4% cleared in 2 days	1

Table 7. Organism, route of administration, dose, and other variables	Effects	Reference[a]
Guinea pig, *Cavia* sp.		
Dermal application of 81 mg silver nitrate to 3.1 cm^2 of skin daily for 8 weeks	Growth rate reduced 10-20%	1
Humans, *Homo sapiens*		
External route		
0.25% silver nitrate solution in eyes for 3 weeks	Argyrosis	2
3-5% colloidal silver compounds in eyes for 5-10 weeks	Argyrosis	2
Inhalation route		
0.25 mg/m^3 air	Possibility of generalized argyria in 20 years	2
1-2 mg/m^3 air; occupational exposure	Argyrosis of cornea and conjunctiva	3
Clearance half-time		
Feces	>300 days	1
Lung	Biexponential profile; 1 day and 52 days	1
Urine	<54 days	1
Oral route		
80 µg/kg BW, single dose	21% of dose retained in body after 1 week	1
0.7 mg silver weekly in diet	Possibility of generalized argyria	2
2-30 g of silver nitrate, single dose	At dosages >10 g (equivalent to >166 mg Ag/kg BW for a 60-kg person), death usually occurs within a few hours to a few days	2, 3
50-260 g of metallic silver	Gastric fullness, anorexia, gastric pain, diarrhea	2, 3
>600 g over 1.2 years; given as silver nitrate to treat epilepsy and GI symptoms	Generalized argyria evident 2 years after last dose	2
Monkeys, various		
Intravenous administration of 0.01 µg/kg BW daily	44.1% excreted in 2 days	1
Oral administration of 0.01 µg/kg BW daily	94.3% cleared in 2 days	1

Table 7. Organism, route of administration, dose, and other variables	Effects	Reference[a]
Domestic mouse, *Mus* spp.		
Drinking water route; 95 mg/L for 125 days	Sluggishness	1
Intraperitoneal route		
13.9 mg/kg BW, single injection	LD50(30 days)	3
35.0 mg/kg BW, single injection; pretreated with single injection of 3.5 mg Ag/kg BW 24 h earlier	Only 3 of 10 pretreated mice died within 7 days vs. 8 of 10 nonpretreated mice	3
Intravenous injection; 1.0 µg/kg BW daily	82% cleared in 2 days	1
Oral route; 1.1 µg/kg BW daily	99.6% cleared in 2 days	1
Rabbit, *Oryctolagus* sp.		
Drinking water route		
Equivalent to 2.5 µg Ag/kg BW daily	No observable adverse effects	2
Equivalent to 25 or 250 µg Ag/kg BW daily for 11 months	Brain histopathology; altered conditioned reflexes	2
Equivalent to 500 or 5,000 µg Ag/kg BW daily for 11 months	Lowered immunological activity; pathology of vascular, nerve, brain, and spinal cord tissues	3
Intraperitoneal injection route; 20 mg/kg BW, single injection	All dead within 2 h. Silver granules in liver parenchyma and kidney tubules	3
Laboratory white rat, *Rattus* spp.		
Diet		
Equivalent to 6 mg/kg BW daily	After 12 weeks, kidneys and liver were impregnated with silver	2
130-1,110 mg/kg ration	Liver necrosis which could be prevented by adding Vitamin E	2
Drinking water route		
50 µg/L (equivalent to 0.0025 mg Ag/kg BW daily) for 11 months	Normal in all variables measured (conditioned reflex activity, gastric secretion, blood serum enzymes, histology)	3
200 µg/L for 6 months	Normal conditioned reflex activity	3
<400, 400, 700, or 1,000 µg/L for 100 days	At <400 µg/L, rats seemed healthy with normal tisssue histology. At 400 µg/L, hemorrhages noted	3

Table 7. Organism, route of administration, dose, and other variables	Effects	Reference[a]
	in kidney. At 700 µg/L, kidney and liver histopathology was evident. At 1,000 µg/L, spleen was pigmented and kidney and liver damage more pronounced	
500 µg/L (equivalent to 0.025 mg Ag/kg BW daily) for 6-11 months	Abnormal conditioned reflex activity; increased liver weight and liver RNA concentration	3
5 mg/L for 6 months	Signs of intoxication beginning at days 25-27	3
20 mg/L for 3 months	Decreased growth; abnormal liver; increased levels of blood amino acids	3
20 mg/L for 5 months	Pathology in stomach, small intestine, and liver; altered blood serum enzyne activity; growth depressed 36%	3
20 mg/L for 6 months	Increased brain DNA and RNA	2
129 mg/L (about 18 mg/kg BW daily) for 17.8 weeks	Silver accumulations in brain and central nervous system; reduced motor activity	1
634 mg/L (89 mg Ag/kg BW daily) for 2 years	No effect on male fertility; no silver deposits in testes	1
635-660 mg/L; lifetime exposure beginning shortly after weaning	Lifespan normal; hypertrophy of left ventricle, suggesting vascular hypertension; skin normal but internal organs and eyes darkened by silver deposits	3
1,200 mg/L for several months	Degenerative kidney changes	3
1,500 mg/L for 2-4 weeks; vitamin E-deficient rats	Liver necrosis and death. Prevented by adding vitamin E	2
1,586 mg/L for 37 weeks	Some deaths beginning at week 23; survivors weighed about 50% less than controls	1
2,500 mg/L for 3 months, then silver-free water for 16 months	At end of exposure livers had 6.7-7.0 mg Ag/kg FW and kidneys 3.7-7.1 mg/kg FW; 16 months after exposure livers had 1.6 mg/kg FW and kidneys 6.0 mg/kg FW	3
2,589 mg/L, (equivalent to 362 mg Ag/kg BW daily) for 2 weeks	25% died; water intake decreased beginning at day 1; survivors poorly groomed and listless	1
Intramuscular injection route		
Given radiosilver-110m alone or in combination with 4.0 mg Ag/kg BW daily for 6 days. Percent of		

Table 7. Organism, route of administration, dose, and other variables	Effects	Reference[a]
tracer dose recovered vs. percent tracer plus 4.0 mg/kg BW		
Blood	0.5 vs. 3.0	1
Bone	0.2 vs. 2.2	1
Feces	96.6 vs. 37.3	1
GI tract	1.1 vs. 8.2	1
Heart, lungs	0.06 vs. 0.6	1
Kidney	0.07 vs. 0.6	1
Liver	0.4 vs. 33.7	1
Muscle	0.2 vs. 2.4	1
Skin	0.2 vs. 7.4	1
Spleen	0.01 vs. 2.7	1
Urine	0.6 vs. 1.8	1
Intravenous injection route		
0.2 µg/kg BW daily	70.7% excreted in 2 days vs. 98.4% in 2 days when administered orally	1
Isolated hepatocytes exposed for 20 h		
<275 µg/L	Not cytotoxic	4
500, 2,000, or 5,000 µg/L	Silver accumulated in nuclear fraction of hepatocytes at all concentrations; DNA repair synthesis was stimulated at 2,000 µg/L; moderately cytotoxic at 5,000 µg/L	5
1,100 µg/L	Protein synthesis activity inhibited 50%	4
1,980 µg/L	Almost complete inhibition of protein synthesis activity	4
Subcutaneous injection route		
7 mg/kg BW, single injection	Adverse effects on spermatogenesis and on testes histology	2,3
Oral route		

Table 7. Organism, route of administration, dose, and other variables	Effects	Reference[a]
123 mg/kg BW, as silver cyanide	Acute oral LD50	6
200-400 mg/kg BW, as silver arsenate	Acute oral LD50	6
500-800 mg/kg BW, as silver nitrate	Acute oral LD50	6
Caribou, *Rangifer tarandus*		
Ratio of silver concentration (mg/kg FW) in tissues to silver concentration (mg/kg FW) in lichen diet		
Bone	Bioconcentration factor (BCF) of 3.0	3
Kidney	BCF of 1.3	3
Liver	BCF of 80.0	3
Muscle	BCF of 0.3	3

[a]1, U.S. Public Health Service 1990; 2, Smith and Carson 1977; 3, U.S. Environmental Protection Agency 1980; 4, Denizeau et al. 1990; 5, Denizeau and Marion 1989; 6, Lockhart 1983.

Chronic exposure of humans to silver or silver compounds has frequently resulted in generalized argyria (slate-gray pigmentation of the skin and hair caused by deposition of silver), localized argyria (limited areas of pigmentation usually associated with medicinal silver applications), or argyrosis (argyria of the eye). Every silver compound in common chemical use has caused generalized argyria, usually from medical and occupational exposures (Smith and Carson 1977; EPA 1980). In generalized argyria, skin pigmentation was highest in light-exposed areas, although silver concentrations in light-exposed and dark-exposed skin were the same (EPA 1980). In severe cases of argyria, the skin may become black with a metallic luster, the eyes affected to the point that vision is disturbed, and the respiratory tract impaired (Klaassen et al. 1986). Individual variability in susceptibility to argyria is great and this is probably explained by the variability in absorption and retention of silver (Smith and Carson 1977). Generalized argyria as an occupational disease is unusual but has been reported in workers that make silver nitrate or are involved in mirror plating, glass bead silvering, silver Christmas cracker manufacturing, photographic plate manufacturing, and silver mining. Generalized argyria was also associated with chronic inhalation or ingestion of silver fulminate, silver nitrate, silver albuminate, and silver cyanide (Smith and Carson 1977). Improved workplace ventilation and sanitation among silver nitrate workers effected a decline in general argyria (EPA 1980).

Localized argyria is rare and usually occurs when silver compounds contact broken skin or mucous membranes (Smith and Carson 1977). Localized argyria has been reported in workers who handle metallic silver in filing, drilling, polishing, turning, engraving, forging, soldering, or smelting operations. Silver polishers exposed for 25 years or more (range 2-38 years) sometimes exhibit increased densities in their lung x-rays due to silver impregnation of the elastic membranes of the pulmonary vessels. In one case, an Italian physician who dyed his facial hair with a silver dye for 25 years developed argyria in the conjunctiva of both eyes (Smith and Carson 1977).

Recommendations

Most measurements of silver concentrations in natural waters prior to the use of clean techniques are considered inaccurate. Until analytical capabilities that exceed the dissolved-particulate classification are developed, it will be necessary to rely on laboratory and theoretical modeling studies to fully understand chemical speciation of silver in natural waters (Andren et al. 1995).

Factors governing the environmental fate of silver are not well characterized, including silver transformations in water and soil and the role of microorganisms (PHS 1990). Food chain transfer of silver requires more current information on sources and forms of silver and data on concentrations in field collections of flora and fauna, especially near hazardous waste sites (PHS 1990). Although silver in sewage sludge is mostly immobilized, data are limited on the uptake by vegetation of silver from soils amended with silver-contaminated sewage sludge and on silver concentrations in flesh and milk of livestock pastured or fed grains raised on soils amended with sewage sludge (Smith and Carson 1977). Data are needed on partition coefficients and vapor pressures of silver compounds (PHS 1990) and on silver concentrations in emissions from cement producers and smelters and refineries of copper, lead, zinc, silver, iron, and steel (Smith and Carson 1977). Also, technology to recapture silver from waste media before it reaches the environment must be improved (PHS 1990).

In aquatic environments, more research is needed on the chemical speciation of silver to evaluate risk to the organism and its consumers (EPA 1987; Berthet et al. 1992). Most silver criteria formulated for the protection of aquatic life are now expressed as total recoverable silver per liter (Table 8). But total silver measurements do not provide an accurate assessment of potential hazard. Silver ion (Ag^{+}), for example, is probably the most toxic of all silver chemical species and must be accurately measured in the assessment of silver risks in aquatic environments (LeBlanc et al. 1984), perhaps as acid-soluble silver (EPA 1987). Little is known of the biocidal properties of Ag^{2+} and Ag^{3+} that are the active ingredients in disinfectants and used increasingly in water purification systems of drinking water and swimming pools (Antelman 1994). The effects of these silver species on organism health clearly must be researched (PHS 1990). Silver interactions with other metals and compounds in solution are not well defined. For example, mixtures of salts of silver and copper markedly increased the survival of oyster embryos, but only when copper concentrations were less than 6 µg/L and total silver less than 11 µg/L (Coglianese and Martin 1981).

Table 8. Proposed silver criteria for the protection of natural resources and human health.

Table 8. **Resource, criterion, and other variables**	**Effective silver concentration**	**Reference[a]**
Agricultural crops		
Soils	<100 mg total silver/kg dry weight soil for most species; <10 mg/kg for sensitive species	7
Freshwater aquatic life protection		
Acute exposure		
Total recoverable silver	<1.32 µg/L	1
Acid-soluble silver[b]	4-day average shall not exceed 0.12 µg/L more than once every three years; 1-h average not to exceed 0.92 µg/L more than once every 3 years	8
Acute exposure		
Total recoverable silver, in µg/L, should not exceed $e^{(1.72[\ln(\text{hardness})]-6.52}$ at any time. Examples follow		
50 mg $CaCO_3$/L	<1.2 µg/L	2

Table 8. Resource, criterion, and other variables	Effective silver concentration	Reference[a]
100 mg $CaCO_3$/L	<4.1 µg/L	2
200 mg $CaCO_3$/L	<13.0 µg/L	2
Chronic exposure	<0.12-<0.13 µg total recoverable silver/L	1, 2
Tissue residues		
Adverse effects on growth of the Asiatic clam, *Corbicula fluminea*	>1.65 mg total silver/kg soft tissues, fresh weight basis	1
Marine life protection		
Acute exposure		
Total recoverable silver	<2.3 µg/L at any time	2
Acid-soluble silver[b]	4-day average concentration not to exceed 0.92 µg/L more than once every 3 years on average and the 1-h concentration not to exceed 7.2 µg/L more than once every 3 years	8
Tissue residues		
Marine clams, soft parts		
Normal	<1 mg total silver/kg dry weight	3
Stressful or fatal	>100 mg total silver/kg dry weight	3
Human health		
Air, United States		
Current level of exposure, nationwide	100 µg total silver daily per person	2
Short-term exposure limit (15 min; up to 4 times daily with 60-min intervals at <0.01 mg Ag/m^3 air)	<0.03 mg total silver/m^3	2
Threshold limit value (8 h daily, 5 days weekly)		
Aerosol silver compounds	<0.01 mg total silver/m^3	2, 4, 5
Metallic silver dust	<0 .1 mg total silver/m^3	5
Diet, United States		
Current level of exposure	35 to 40 µg daily per person	2
Drinking water		
United States		
Long-term exposure (>10 days)	<50 µg total silver/L	2, 5, 6
Proposed long-term exposure	<90 µg total silver /L	5

Table 8. Resource, criterion, and other variables	Effective silver concentration	Reference[a]
Short-term exposure (1-10 days)	<1,142 µg total silver/L	5
California	<10 µg/L	2
Germany	<100 µg/L	2
Space vehicles		
Former Soviet Union	Max. 200 µg total silver/L	2
United States	100 to Max. 200 µg total silver/L	2
Switzerland	<200 µg total silver/L	2
Groundwater	<50 µg total silver/L	5

[a]1, Diamond et al. 1990; 2, U.S. Environmental Protection Agency (EPA) 1980; 3, Bryan and Langston 1992; 4, Smith and Carson 1977; 5, U.S. Public Health Service (PHS) 1990; 6, Fowler and Nordberg 1986; 7, Hirsch et al. 1993; 8, EPA 1987.

[b]Silver that passes through a 0.45-um membrane after the sample has been acidified to a pH between 1.5 and 2.0 with nitric acid.

The proposed human drinking water criteria of 50 to <200 µg total Ag/L do not seem to represent a hazard to human health, although much lower concentrations adversely affect freshwater and marine organisms (Smith and Carson 1977; Table 8). Proposed silver criteria for the protection of freshwater aquatic life during acute exposure now range from 1.2 to 13.0 µg total recoverable silver per liter (Table 8). If all total recoverable silver were in the ionic form, these proposed criteria would overlap the 1.2 to 4.9 µg/L range found lethal to sensitive species of aquatic plants and animals and indicates that the proposed freshwater acute silver criteria need to be reexamined. For freshwater aquatic life protection during chronic exposure, the proposed criterion of less than 0.13 µg total recoverable silver per liter (Table 8) is probably sufficient. But the proposed silver criterion of 2.3 µg total silver/L to protect marine life (Table 8) needs to be reconsidered because phytoplankton species composition and succession are significantly altered at 0.3-0.6 µg total silver/L and because some species of marine algae and mollusks show extensive accumulations at 1.0-2.0 µg total silver/L. Limited but insufficient data were available on correlations between tissue residues of silver with health of aquatic organisms (Table 8); additional research seems needed on the significance of silver residues in tissues.

Silver criteria in aquatic ecosystems are under constant revision by regulatory agencies. For example, total recoverable silver is no longer recommended by the U.S. Environmental Protection Agency in silver criteria formulation and should be replaced by dissolved silver (EPA 1995a). Dissolved silver more closely approximates the bioavailable fraction of silver in the water column than does total recoverable silver (EPA 1995b). Dissolved silver criteria recommended are about 0.85 times those of total recoverable silver under certain conditions but may vary considerably depending on other compounds present in solution (EPA 1995b).

No studies have been conducted with silver and avian or mammalian wildlife, and it is unreasonable to extrapolate the results of limited testing with domestic poultry and livestock to wildlife to establish criteria or administratively enforced standards. Research on silver and avian and terrestrial wildlife merits the highest priority in this subject area. No silver criteria are available for the protection of avian and mammalian health, and all criteria now proposed are predicated on human health (Table 8). As judged by the results of controlled studies with poultry and small laboratory mammals, safe concentrations of silver ion were less than 250 µg/L in drinking water of mammals, less than 100 mg/L in drinking water of poultry, less than 6 mg/kg in diets of mammals, less than 10 mg/kg in copper-deficient diets of poultry, less than 200 mg/kg in copper-adequate diets of poultry, and less than 1.8 mg/kg in chicken eggs. The proposed short-term (10-day) allowable limit of 1,142 µg Ag/L in drinking water for human health protection (Table 8) should be reconsidered because it is 4.6 times higher than the value that produced adverse effects in sensitive laboratory mammals. Additional animal studies

are needed to elucidate the effects of silver and silver compounds on reproduction, development, immunotoxicity, neurotoxicity, absorption, distribution, metabolism, and excretion; and on oral, dermal, and inhalation routes of exposure (PHS 1990). In animals, there is also the need to establish a target organ for intermediate exposures to silver, to establish suitable biomarkers of silver exposures and effects, and to measure effects of chronic silver exposures on carcinogenicity (PHS 1990). These studies should be implemented with suitable sentinel organisms including waterfowl, aquatic mammals, and other species of wildlife.

It is emphasized that silver and its compounds do not pose serious environmental health problems to humans from 50 µg/L in drinking water and 10 µg/m^3 in air (Smith and Carson 1977). The only proven effect of chronic exposure to silver is argyria from occupational or therapeutic exposure to much larger amounts of silver (minimum necessary absorption of 910 µg, equivalent to about 15 µg/kg BW) than can feasibly be ingested or inhaled from environmental sources. Regular ingestion of fish, meat, and plants from silver-contaminated areas probably does not cause argyria (Smith and Carson 1977). Humans at special risk to argyria include those treated with silver-containing medicinals and people marginally deficient or deficient in copper, selenium, or vitamin E (EPA 1980). There is no recognized effective treatment for argyria, although the condition seems to be relatively stationary when exposure to silver is discontinued (Fowler and Nordberg 1986). Absorption and retention of silver from food and medicinals is imperfectly understood (Smith and Carson 1977), suggesting the need for additional animal studies.

Finally, alternatives exist to the use of silver in various materials and processes. These include substitution of aluminum and rhodium for silver in mirrors and other reflecting surfaces; tantalum replacement of silver in surgical plates, pins, and sutures; using stainless steel as an alternative material to silver in the manufacture of table flatware; and, in photography, using film with reduced silver content (Reese 1991).

Abstract. This report is a selective review and synthesis of the technical literature on copper and copper salts in the environment and their effects primarily on fishes, birds, mammals, terrestrial and aquatic invertebrates, and other natural resources. The subtopics include copper sources and uses; chemical and biochemical properties; concentrations of copper in field collections of abiotic materials and living organisms; effects of copper deficiency; lethal and sublethal effects on terrestrial plants and invertebrates, aquatic organisms, birds, and mammals, including effects on survival, growth, reproduction, behavior, metabolism, carcinogenicity, mutagenicity, and teratogenicity; proposed criteria for the protection of human health and sensitive natural resources; and recommendations for additional research.

Key words: Copper, copper sulfate, metals, toxicity, deficiency, criteria, residues, agriculture, nutrition, metallothionein, fish, invertebrates, amphibians, birds, wildlife, livestock, endangered species.

Copper (Cu) is plentiful in the environment and essential for the normal growth and metabolism of all living organisms (Schroeder et al. 1966; Carbonell and Tarazona 1994). Abnormal levels of copper intake may range from levels so low as to induce a nutritional deficiency to levels so high as to be acutely toxic (U.S. Environmental Protection Agency [USEPA] 1980). Copper is probably the first metal worked by humans some 70 to 80 centuries ago (Schroeder et al. 1966). The earliest known artifacts of hammered copper date from about 6000 BCE. After 4000 BCE, melting and casting of copper was common in the Near East. Smelting was developed about 3000 BCE and bronze around 2500 BCE. Brass, a copper alloy, was developed in Roman times. Copper derives from the Latin *cuprum*, a corruption of *cyprium*, Cyprus being the source of Egyptian and Roman copper (Schroeder et al. 1966). Copper was identified in terrestrial plants in 1817 (Gallagher 1979), in marine invertebrates in 1833 (Schroeder et al. 1966), in vertebrates in 1838 (Gallagher 1979), and in hemocyanin—the blue respiratory pigment of mollusks and crustaceans—in 1880 (Schroeder et al. 1966). But the metabolic importance of copper in plants and animals was not suspected until the 1920's when diseases due to copper deficiency began to be recognized (National Academy of Sciences [NAS] 1977; Gallagher 1979). Copper deficiency in vertebrates, for example, is associated with anemia, gastrointestinal disturbances, aortic aneurisms, bone development abnormalities, and death (Aaseth and Norseth 1986).

Copper toxicosis in terrestrial higher plants is rare but occurs on mine spoils and where copper-rich manures or fungicides are used excessively (Schroeder et al. 1966; NAS 1977; Alva et al. 1995; Arduini et al. 1995). Copper is among the most toxic of the heavy metals in freshwater and marine biota (Schroeder et al. 1966; Betzer and Yevich 1975), and often accumulates and causes irreversible harm to some species at concentrations just above levels required for growth and reproduction (Hall et al. 1988). Birds and mammals, when compared to lower forms, are relatively resistant to copper. But diets containing elevated concentrations of copper are sometimes fatal to ducklings (Wood and Worden 1973) and livestock when fed for extended periods. Domestic sheep (*Ovis aries*) are the most susceptible farm animals to chronic copper poisoning and effects include liver damage, impaired reproduction, reduced resistance to diseases, jaundice, and death (Gopinath and Howell 1975; Higgins 1981; Bires et al. 1993).

Many reviews and annotated bibliographies are available on copper ecology and toxicology, including those by Eisler (1973, 1979), Eisler and Wapner (1975), NAS (1977), Eisler et al. (1978, 1979), Nriagu (1979a, 1979b), USEPA (1980), Aaseth and Norseth (1986), and Agency for Toxic Substances and Disease Registry [ATSDR] (1990). I prepared this report at the request of resource contaminant specialists of the U.S Fish and Wildlife Service; it is part of a continuing series of synoptic reviews on contaminant hazards to natural resources.

Sources and Uses

General

The United States is the major world producer and consumer of copper and its compounds. Most of the copper produced is used to manufacture electrical equipment, pipe, and machinery. Copper releases to the global biosphere—which may approach 1.8 million metric tons per year—come mostly from anthropogenic activities such as mining and smelting, industrial emissions and effluents, and municipal wastes and sewage sludge. Copper compounds are widely used as biocides to control nuisance algae and macrophytes, freshwater snails that may harbor schistosomiasis and other diseases, ectoparasites of fish and mammals, marine fouling organisms, and mildew and other diseases of terrestrial crop plants. Copper compounds are also used in agricultural fertilizers, in veterinary and medical products, in the food industry, and as a preservative of wood and other materials.

Sources

Global copper production during the past 60 centuries is estimated at 307 million metric tons, most of which (79%) occurred since 1900; annual global production of copper is now estimated at 13.6 million tons (Nriagu 1979c). Copper occurs naturally in many minerals and as uncombined metal. The three most important sources of copper are chalcocite (Cu_2S), chalcopyrite ($CuFeS_2$), and malachite ($CuCO_3 \cdot Cu(OH)_2$; ATSDR 1990). The United States is the largest global consumer and producer of copper. In 1986, domestic consumption of copper in the United States was 2.14 million metric tons and mine production was 1.14 million metric tons, mostly from mines in Arizona, New Mexico, and Michigan. The major copper deposits in the United States are of hydrothermal origin and uniformly distributed in fractures or veins (ATSDR 1990). Copper is the major toxic component in streams impacted by active placer mines (Buhl and Hamilton 1990). About 60% of copper metal is eventually recycled; in 1986, smelting of scrap copper produced an additional 0.9 million metric tons of copper. Also in 1986, 1.1 million tons of copper were imported into the United States, mostly from Canada, Chile, Peru, and Mexico (ATSDR 1990).

The amount of copper entering the global ecosystem annually is unknown, but estimates range from 211,000 metric tons (Nriagu 1979c) to 1.8 million metric tons (NAS 1977). About 80.7% of this copper is deposited in terrestrial compartments, 15.7% in the hydrosphere, and 3.6% to the atmosphere (Nriagu 1979c). The residence time for copper in the deep ocean is 1,500 years; in soils it may be retained for as long as 1,000 years; in air, copper persists for about 13 days (Nriagu 1979c). Copper in the atmosphere results mainly (73%) from human activities such as copper production and combustion of fossil fuels; the remainder is from natural sources that include seasalt sprays, windblown dusts, volcanogenic particles, and decaying vegetation (Nriagu 1979c, 1979d).

Input of copper into aquatic ecosystems increased sharply during the past century and includes inputs from waste discharges into saline waters, industrial discharges into freshwater, and leaching of antifouling marine paints and wood preservatives (Nriagu 1979c). Present anthropogenic inputs of copper are two to five times higher than natural loadings; the atmosphere is a primary recipient of these inputs (Nriagu 1979d). In mining and industrial areas, precipitation of atmospheric fallout is a significant source of copper to the aquatic environment (USEPA 1980). More than 99.9% of oceanic copper fell as clay and manganese oxide particles in precipitation (NAS 1977). In the lower Great Lakes, direct atmospheric inputs of copper—in metric tons per year—range from 55 to 2,300 for Lake Michigan, 120 to 330 for Lake Erie, and 72 to 123 for Lake Ontario; regional disparities in atmospheric deposition of copper are related to the intensity of industrial activity and to the regional wind systems (Nriagu 1979d).

Copper in soils may come from a variety of anthropogenic sources: mining and smelting activities; other industrial emissions and effluents; traffic; fly ash; dumped waste materials; contaminated dusts and rainfall; sewage and sludge; pig slurry; composted refuse; and agricultural fertilizers, pesticides, and fungicides (Nriagu 1979c; Thornton 1979; Ma 1984; ATSDR 1990; Roncero et al. 1992; Alva et al. 1995). In the case of Florida citrus groves, copper-containing fertilizers applied during the early 1900's accounted for as much as 34 kg Cu/ha annually, and routine fungicidal sprays contributed another 10 kg Cu/ha annually. Surface soils (0-15 cm) from some mature citrus groves contained as much as 540 kg Cu/ha (Alva et al. 1995). Copper deposition rates in soils are higher in cities and near highways, railroads, power plants, and industrial activities (Nriagu 1979d). But a Kansas landfill near a freshwater stream had no significant effect on copper concentrations in water, sediments, crayfish, and sunfish (Morrissey and Edds 1994).

Uses

Metallic copper end uses include electrical (70%), construction (15%), machinery (6%), transportation (4%), and ordinance (2%). The top domestic markets for copper and its alloys in 1986 were, in order of importance, plumbing, building wire, telecommunications, power utilities, in-plant equipment, air conditioning, automotive electrical, automotive nonelectrical, business electronics, and industrial valves and fittings (ATSDR 1990). A small percentage of copper production is used to manufacture chemicals, mainly copper sulfate. Of the copper sulfate used domestically, 65% is used in agriculture for fungicides, algicides, nutritional supplements, insecticides, and repellents; 28% is used industrially in froth flotation production of chromated copper arsenate wood preservatives, in electroplating, and in the manufacture of azo dyes; and 7% is used in water treatment to control nuisance algae (ATSDR 1990).

Copper is widely used to control unwanted species of freshwater algae and macrophytes (Bartley 1967; NAS 1977; USEPA 1980; Rowe and Prince 1983; Havens 1994). Chelated copper products are claimed to be effective algicides in hard water; the chelation of copper by organic compounds, such as ethanolamines or ethanolamine complexes, protects copper from precipitation and complexation (Straus and Tucker 1993). Copper sulfate is approved by the U.S. Environmental Protection Agency (USEPA) as an algicide in waters used to raise fish for human consumption (Straus and Tucker 1993). In algae, copper inhibits photosynthesis, nitrogen fixation, and phosphorus uptake; it selectively eliminates cryptophytes but spares diatoms (Havens 1994). Copper sulfate at low concentrations has been used to control freshwater algae in Wisconsin since 1918 without any conclusively proven effect on diversity or abundance of nontarget species (Mackenthun and Cooley 1952). But reduced abundance of freshwater benthos was noted in Lake Monova, Wisconsin, which received 771 metric tons of copper to control algae over a 26-year period and had sediment levels as high as 1,093 mg Cu/kg DW (Mackenthun and Cooley 1952). Copper sulfate used to control algal blooms in Wisconsin lakes at 1.25 mg Cu/L killed nontarget fishes, crustaceans, snails, and amphibians in 14 days or less; however, 0.25 mg Cu/L was not fatal to these species in 20 days (Hasler 1949). Concentrations as low as 0.03 mg Cu/L inhibited growth in two of four species of nuisance aquatic weeds in Lake Mendota, Wisconsin, and 0.3 mg Cu/L was fatal to all four species (Hasler 1949). Copper sulfate controls algae in cranberry bogs at 0.4 mg Cu/L but this concentration also kills resident fishes (Deubert and Demoranville 1970). Copper was not measurable in the surface waters of cranberry bogs within 10 days of treatment, regardless of initial copper concentration; it is probable that copper was adsorbed onto bog soils (Deubert and Demoranville 1970). In England, copper sulfate was effective at 1.0 mg Cu/L in controlling algae and most species of aquatic weeds for 1.6 km downstream of treatment for 6 months during the summer; only 0.25 mg Cu/L was necessary in autumn and winter for effective aquatic weed control (Chancellor et al. 1960). During copper treatment to control plants, aquatic snails were greatly reduced or eliminated but fishes seemed unaffected. Sensitive aquatic weeds included *Myriophyllum spicatum*, *Elodea canadensis*, *Potamogeton* spp., and *Lemna minor*; sensitive genera of algae included *Oedogonium*, *Spirogyra*, *Enteromorpha*, and *Mougeotia* (Chancellor et al. 1960).

In Iowa lakes, copper sulfate was used to control summer blooms of various species of toxic blue-green algae. Prior to treatment, blooms of *Anabaena flos-aquae*, *Aphanizomenon flos-aquae*, and *Microcystis aeruginosa* were associated with deaths of migratory waterfowl, game birds, songbirds, game, and domestic animals (Rose 1954). Most of these species of algae were controlled within 24 h by 1.0 mg Cu/L as copper sulfate. Copper treatment had no adverse effects on bottom fauna but populations of crustaceans (daphnids, copepods, entomostracans) were reduced. One year after treatment no deaths of birds or mammals were recorded (Rose 1954).

Copper salts are intentionally added to drinking water supplies of some municipalities to control growth of algae; concentrations as high as 59 µg Cu/L are maintained in New York City (USEPA 1980).

Copper compounds are used routinely and widely to control freshwater snails that serve as intermediate vectors of schistosomiasis and other diseases that afflict humans (Hasler 1949; NAS 1977; Rowe and Prince 1983; Winger et al. 1984; Al-Sabri et al. 1993). These compounds include copper sulfate, copper pentachlorophenate, copper carbonate, copper-tartaric acid, Paris green (copper arsenite-acetate), copper oxide, copper chloride, copper acetyl acetonate, copper dimethyl dithiocarbamate, copper ricinoleate, and copper rosinate (Cheng 1979). Also, many species of oyster enemies are controlled by copper sulfate dips. All tested species of marine gastropods, tunicates, echinoderms, and crabs that had been dipped for 5 seconds in a saturated solution of copper sulfate died if held in air for as little as a few seconds to 8 h; mussels, however, were resistant (MacKenzie 1961).

Copper sulfate is used to control protozoan fish ectoparasites including *Ichthyopthirius*, *Trichodina*, and *Costia*; the effectiveness of the treatment diminishes with increasing total alkalinity and total hardness of the water (Straus and Tucker 1993). Copper compounds now used to control protozoan parasites of cultured red drum (*Sciaenops ocellatus*) include copper sulfate, copper sulfate plus citric acid, and chelated copper compounds (forms of copper bound by sequestering agents, such as ethanolamine); chelated copper compounds are considered less toxic to fish than copper sulfate and at least as effective in controlling parasites (Peppard et al. 1991).

Copper is the active agent in many antifouling paints applied to watercraft (Aaseth and Norseth 1986; Hall et al. 1988). The growing use of copper-based paints subsequent to the prohibition in 1982 of tributyltin-based paints (Hall et al. 1988) is associated with elevated copper concentrations in Pacific oysters (*Crassostrea gigas*) farmed in the Bay of Arcachon, France (Claisse and Alzieu 1993).

Copper compounds are used in agriculture to treat mildew and other plant diseases; in the food industry as preservatives, additives, or coloring agents; in preservatives of wood, leather, and fabrics; in coin manufacture; and in water treatment (ATSDR 1990; Roncero et al. 1992). The use of copper-containing pesticides is traditional along the Mediterranean Coast, especially the use of Bordeaux mixture, a copper sulfate-based fungicide that has been widely used for more than a century to prevent mildew on grape vines (Romeu-Moreno et al. 1994). However, at current application rates of about 0.8 mg Cu/cm^2, Bordeaux mixture significantly reduces the life span and breeding rate of the fruit fly (*Drosophila melanogaster*) (Marchal-Segault et al. 1991).

Copper is widely used in veterinary clinics in medical products (Roncero et al. 1992). Copper sulfate is used by veterinarians to treat cattle and sheep for helminthiasis and infectious pododermatitis (NAS 1977). Cuprol (a 1% solution of cupric oleinate) is used to control lice (Aaseth and Norseth 1986). Copper is routinely used as a growth supplement in the diets of swine (*Sus* sp.) in the United Kingdom and elsewhere; diets may contain as much as 250 mg Cu/kg ration (USEPA 1980). The intensity of pig farming within about 10 km from the coast may influence copper content in estuarine sediments. For example, intensive pig farming in coastal Brittany, France, increased soil copper concentrations by 0.6 kg/ha annually and increased coastal sediment copper concentrations to as high as 49.6 mg/kg DW (Arzul and Maguer 1990).

Table 1. Some properties of copper and copper sulfate (ATSDR 1990).

Property	Copper	Copper sulfate
Chemical and other names	Copper	Cupric sulfate, blue vitriol, cupric sulphate, Roman vitriol, Salzburg vitriol, blue copperas, copper (II) sulfate
Chemical formula	Cu	$CuSO_4$
Oxidation state	0	2+
CAS (Chemical Abstract Services) number	7440-50-8	7758-98-7
Molecular weight	63.546	159.60
Color and form	Reddish solid	Blue crystals
Melting point	1,083.4º C	Decomposes slightly at >200º C
Boiling point	2,567º C	Decomposes to CuO at 650º C
Density	8.92	3.603
Solubility		
Water	Insoluble	143 g/L
Organic solvents	Insoluble	Soluble in methanol, slightly soluble in ethanol

In human medicine, metallic copper is used in some intrauterine devices, and various copper compounds are used as emetics and to treat rheumatoid arthritis (USEPA 1980; Aaseth and Norseth 1986). Some individuals wear copper bracelets as treatment for arthritis although its therapeutic value has little support (USEPA 1980).

Chemical and Biochemical Properties

General

This section demonstrates that (1) free ionic copper (Cu^{2+}) is the most toxic chemical species of copper and that copper bioavailability is modified by many biological and abiotic variables; (2) copper metabolism and sensitivity to copper of poikilotherms differs from that of mammals; and (3) copper interactions with inorganic and organic chemicals are substantial and must be considered when evaluating copper hazards to natural resources.

Chemical Properties

Copper is a soft heavy metal, atomic number 29, with a density in elemental form at 20º C of 8.92 g/cc and a melting point of 1,083.4º C (USEPA 1980; Aaseth and Norseth 1986; Table 1). Copper has two natural isotopes: Cu-63 (69.09%) and Cu-65 (30.91%; NAS 1977).

Copper exists in four oxidation states: Cu^0, Cu^{+1}, Cu^{+2}, and Cu^{+3} (ATSDR 1990). Elemental copper (Cu^0) is readily attacked by organic and mineral acids that contain an oxidizing agent and is slowly soluble in dilute ammonia; halogens attack elemental copper slowly at room temperature to yield the corresponding copper halide (USEPA 1980); elemental copper is not oxidized in water (Aaseth and Norseth 1986). Cuprous copper (Cu^{+1}) exists only in water solution when complexed, usually in a tetrahedral form, with affinity for sulfur and nitrogen ligands (Schroeder et al. 1966). Cuprous copper is unstable in aerated aqueous solution over the pH range 6 to 8, and will undergo auto-oxidation-reduction into elemental copper (Cu^0) and cupric ion (Cu^{+2}) (USEPA 1980; Aaseth and Norseth 1986). The only cuprous ion (Cu^{+1}) compounds that are stable in water are extremely insoluble ones such as cuprous chloride (CuCl; ATSDR 1990). Cuprous ion-complexes may be formed in seawater by photochemical processes and persist for several hours. The cupric ion (Cu^{+2}) is the one generally encountered in water. Cupric ions are coordinated with six water molecules in solution (ATSDR 1990). Cupric ion ordinarily forms planar, less stable chelates with nitrogen and oxygen ligands (Schroeder et al.

1966). In seawater and sediment interstitial waters, the free cupric ion (Cu^{+2}) is the most readily available and toxic inorganic species of copper; however, the free ion concentration is sensitive to complexation and is less available to aquatic biota in the presence of natural organic chelators and high salinities (Bryan and Langston 1992). Cupric ions account for about 1% of the total dissolved copper in seawater and less than 1% in freshwater (Boyle 1979). Trivalent copper (Cu^{+3}) probably does not occur naturally (Schroeder et al. 1966). Trivalent copper is strongly oxidizing and occurs only in a few compounds; none of these compounds is currently considered industrially important or environmentally significant (ATSDR 1990).

Copper speciation in freshwater is figured in detail by Leckie and Davis (1979). In freshwater, the solubility of copper salts is decreased under reducing conditions and is further modified by water pH, temperature, and hardness; size and density of suspended materials; rates of coagulation and sedimentation of particulates; and concentration of dissolved organics. The chemical form of copper in freshwater is important in controlling geochemical and biological processes. But the lack of knowledge on the adsorption characteristics of most cupric ion (Cu^{+2}) complexes contributes to uncertainties about the behavior of known copper species (Leckie and Davis 1979). Ionic copper (Cu^{+2}) and some copper hydroxyl species are correlated with high toxicity to aquatic life; however, carbonato species ($CuHCO_3^+$, $CuCO_3$, $Cu(CO_3)_2^{-2}$) are much less toxic than other copper complexes (Meador 1991). The major chemical species of copper in freshwater are $Cu(CO_3)_2^{-2}$ and $CuCO_3$ (Boyle 1979). Cupric ion is the dominant toxic copper species at pH levels less than 6; the aqueous copper carbonate complex is dominant from pH 6.0 to 9.3 (USEPA 1980). This equilibrium is altered in the presence of humic acids, fulvic acids, amino acids, cyanide, certain polypeptides, and detergents (USEPA 1980). Most cupric salts dissolve readily in freshwater to produce the aquo ion, $Cu(H_2O)_6^{+2}$ (Leckie and Davis 1979). Divalent copper chloride, nitrate, and sulfate are highly soluble in water (USEPA 1980; Table 1), but copper carbonate, cupric hydroxide, cupric oxide, and cupric sulfide will precipitate from solution or form colloidal suspensions when excess cupric ions are present (USEPA 1980).

In seawater, the major chemical species of copper are Cu(OH)Cl and $Cu(OH)_2$ and these account for about 65% of the total copper in seawater (Boyle 1979). The levels of copper hydroxide ($Cu(OH)_2$) increase from about 18% of the total copper at pH 7.0 to 90% at pH 8.6; copper carbonate ($CuCO_3$) levels drop from 30% at pH 7.0 to less than 0.1% at pH 8.6 (USEPA 1980). The dominant copper species in seawater over the entire ambient pH range are copper hydroxide, copper carbonate, and cupric ion (USEPA 1980). Bioavailability and toxicity of copper in marine ecosystems is promoted by oxine and other lipid soluble synthetic organic chelators (Bryan and Langston 1992).

Copper concentrations in sediment interstitial pore waters correlate positively with concentrations of dissolved copper in the overlying water column and are now used to predict the toxicity of test sediments to freshwater amphipods (Ankley et al. 1993). Sediment-bound copper is available to deposit-feeding clams, especially from relatively uncontaminated anoxic sediments of low pH (Bryan and Langston 1992). The bioavailability of copper from marine sediments, as judged by increased copper in sediment interstitial waters, is altered by increased acid volatile sulfide (AVS) content (Casas and Crecelius 1994). But acid volatile sulfide is not an appropriate partitioning phase for predicting copper bioavailability of freshwater sediments (Ankley et al. 1993).

Metabolism

Copper is part of several essential enzymes including tyrosinase (melanin production), dopamine beta-hydroxylase (catecholamine production), copper-zinc superoxide dismutase (free radical detoxification), and cytochrome oxidase and ceruloplasmin (iron conversion) (Aaseth and Norseth 1986). All terrestrial animals contain copper as a constituent of cytochrome *c* oxidase, monophenol oxidase, plasma monoamine oxidase, and copper protein complexes (Schroeder et al. 1966). Excess copper causes a variety of toxic effects, including altered permeability of cellular membranes. The primary target for free cupric ions in the cellular membranes are thiol groups that reduce cupric (Cu^{+2}) to cuprous (Cu^{+1}) upon simultaneous oxidation to disulfides in the membrane. Cuprous ions are reoxidized to Cu^{+2} in the presence of molecular oxygen; molecular oxygen is thereby converted to the toxic superoxide radical (O^{-2}), which induces lipoperoxidation

(Aaseth and Norseth 1986).

Aquatic Organisms. Bioavailability and toxicity of copper to aquatic organisms depends on the total concentration of copper and its speciation (Hung et al. 1990). In hard, moderately polluted waters, 43 to 88% of the copper is associated with suspended solids and not available to biota (Shaw and Brown 1974). Copper toxicity to aquatic biota is related primarily to the dissolved cupric ion (Cu^{+2}) and possibly to some hydroxyl complexes (NAS 1977; Hall et al. 1988; Hung et al. 1990). Soluble copper is largely complexed with carbonate, amino acids, or humic substances. Cupric copper—one of the most toxic forms—constitutes 0.1 to 0.2% of this soluble material (Shaw and Brown 1974). The toxicity of copper in its complexed, precipitated, or adsorbed form is less than that of the free ionic form (Hall et al. 1988; Hung et al. 1990). In aquatic invertebrates, copper causes gill damage at high concentrations, and in fishes it interferes with osmoregulation (Hodson et al. 1979). Elevated concentrations of copper interfere with oxygen transport and energy metabolism; tissue hypoxia is the cause of death and is associated with reductions in the activities of regulatory enzymes of ATP-synthesizing pathways (Hansen et al. 1992b).

In freshwater algae, movement of copper into cells occurs mainly by physical transport; the plasmalemma is the initial site of copper binding. Copper on the plasmalemma increases its permeability, as shown by the leakage of potassium and other ions from copper-treated cells and entry of copper into intracellular sites (Stokes 1979).

Marine prosobranch gastropods, like several other groups of mollusks and arthropods, normally accumulate and store copper and use it in the synthesis of hemocyanin, a blood pigment (Betzer and Yevich 1975). In gastropods, copper may elicit secretions of mucus by goblet cells; bind to hydrophilic regions of the external membranes of epithelial cells, altering their biochemical and biophysical properties; or disrupt the normal functioning of peroxidase and ferritin (Cheng 1979). Peroxidation products, such as hydroperoxides and malondialdehyde, are toxic to vital functions of membranes and cells; bivalve mollusks challenged with ionic copper show significant increases in these products (Chelomin and Belcheva 1992). Exposure of gastropods to high sublethal concentrations of copper completely inhibits succinic dehydrogenase activity at whole body concentrations between 4.7 and 11.9 mg Cu/kg DW soft parts, causes a measurable decrease in heart beat rate, and adversely affects surface epithelia, especially those covering the head-foot and rectal ridge, disrupting osmoregulation and producing water accumulation in tissues (Cheng 1979). The primary lethal effect of copper in gastropod mollusks is caused by disruption of the transporting surface epithelium (Cheng 1979).

In crabs, the gills are a major target organ of copper toxicity; waterborne copper decreases hemocyanin-oxygen affinity (Truchot and Boitel 1992). Exposure of shore crabs (*Carcinus maenas*) to lethal concentrations of copper is associated with reductions in activity of glycolytic enzymes but, unlike fishes, did not involve cellular energy deprivation (Hansen et al. 1992b). Copper-tolerant strains of aquatic mayflies (*Baetis thermicus*) have evolved in Japan. Tolerance is attributed to the ability to induce a metal-binding protein that preferentially sequesters copper over cadmium and zinc (Suzuki et al. 1989).

In fishes, the gill surface's low affinity for metal allows greater entry of the metal to the intracellular compartment. Once there, more complex binding sites are present. Binding to these ligands causes one or more of the following toxic mechanisms: (1) blocking of the essential biological functional groups of biomolecules; (2) displacing the essential metal ion in molecules; or (3) modifying the active conformation of biomolecules. These mechanisms may account for the specific inhibition of ion transport from ionic copper (Cu^{+2}) exposure (Reid and McDonald 1991). Studies with radiocopper-64 and rainbow trout (*Oncorhynchus mykiss*) show that the external gill epithelial surface has a relatively low affinity for copper, allowing copper to penetrate intracellular compartments. Copper disrupts gill function of rainbow trout by impairing transepithelial ion exchange, for example, impairing or upsetting electrolyte balance by inhibiting active uptake or stimulating passive loss (Reid and McDonald 1991). Copper toxicity to rainbow trout in hard water is related to the total concentration of soluble copper (copper carbonate, $CuCO_3$; cupric ion, Cu^{+2}) in the test medium rather than to either of these two forms alone (Shaw and Brown 1974). Long-term retention of copper accumulations in fish tissues is characterized by high half-time persistence after copper administration and binding of copper to proteins in a nonexchangeable or slowly exchangeable pool (Carbonell and Tarazona 1994).

Copper detoxifying mechanisms in fishes include the induction of metallothioneins, allowing copper retention for weeks or months after absorption without producing toxic effects (Hogstrand et al. 1991; Hylland et al. 1992; Carbonell and Tarazona 1994; Marr et al. 1995). Hepatic metallothionein contents of individual fishes usually reflect the accumulation of copper in that organ (Hogstrand et al. 1991). This strongly supports the use of metallothionein as an indicator of copper stress (Hogstrand 1991).

In tench (*Tinca tinca*), hepatic alterations observed after exposure to lethal concentrations of copper (75 mg/L for 4 to 12 days) include accumulation of various pigments in Kupffer cells and hepatocytes. Death was attributed to deficient oxygen transport and consumption and to the lytic effect of copper on various cell membranes, eventually causing massive necrosis in large areas of the liver parenchyma (Roncero et al. 1992). In rapidly growing juvenile flounders (*Paralichthys* spp.), copper blocks calcium transport, possibly through interference with gill chloride cells. Copper inhibition of calcium accumulation is alleviated by removing copper from the medium (Dodoo et al. 1992).

Mammals. Copper homeostasis plays an important role in the prevention of copper toxicity. After copper requirements are met, excess copper absorbed into gastrointestinal mucosal cells is bound to metallothionein and excreted when the cell is sloughed. Copper that eludes the intestinal barrier is stored in the liver or incorporated into bile and excreted in feces. The most likely pathway for the entry of toxic amounts of copper would be long term inhalation or entry through the skin. Both of these pathways allow copper to pass unimpeded into the blood (ATSDR 1990). The levels of copper in the mammalian body are held constant by alterations in the rate and amount of copper absorbed, its distribution, and rate and route of excretion (ATSDR 1990). Many factors interfere with copper absorption including competition for binding sites, as with zinc; chelation, as with phytates; and interaction with ascorbic acid, which aggravates copper deficiency by decreasing copper absorption and—with excess copper—reduces the toxic effects (USEPA 1980; ATSDR 1990).

Two inherited human diseases that represent abnormal copper metabolism are Menkes' syndrome and Wilson's disease. Menkes' syndrome, with symptoms similar to those of copper deficiency, is characterized by a progressive brain disease, abnormally low copper concentrations in liver and other tissues, and diminished ability to transfer copper across the absorptive cells of the intestinal mucosa (USEPA 1980; Aaseth and Norseth 1986). Wilson's disease (hepatolenticular degeneration) is the only significant example of copper toxicity in humans. Wilson's disease is an autosomal recessive disorder that affects normal copper homeostasis and is characterized by excessive retention of hepatic copper, decreased concentration of serum ceruloplasmin, impaired biliary copper excretion, and hypercupremia. Systemic manifestations of Wilson's disease are hepatic and renal lesions and hemolytic anemia (Schroeder et al. 1966; Goresky et al. 1968; Baker 1969; USEPA 1980; Aaseth and Norseth 1986; ATSDR 1990). Certain strains of mutant rats with reduced excretion of biliary copper spontaneously develop hepatitis because of the extremely gross deposition of copper in the liver (Sugawara et al. 1994). Most humans afflicted with Wilson's disease usually die before puberty, although some survive to age 35 (Schroeder et al. 1966). Postmortems of Wilson's patients show that livers had as much as 7.5% copper and kidney ash had up to 2.7% copper. There is no evidence, however, that persons with normal homeostatic mechanisms are subject to any chronic degenerative disorders resulting from modern exposures to copper (Schroeder et al. 1966). Unusually susceptible human populations to copper poisoning include those afflicted with Wilson's disease, infants and children under age one year, those with liver damage or chronic renal disease, individuals undergoing dialysis (excess copper in the dialysate), and those with an inherited deficiency of the enzyme glucose-6-phosphate dehydrogenase (ATSDR 1990).

Ingested copper travels through the gastrointestinal (GI) tract, where some of it is absorbed into the blood and becomes associated with plasma albumin and amino acids (Sugawara et al. 1994) or is used to maintain copper levels in erythrocytes (USEPA 1980). Albumin-bound copper is eventually transported to the liver; however, minor fractions are transported into the bone marrow, the erythrocytes, or other tissues (Aaseth and Norseth 1986). Most of the circulating copper is translocated within minutes. During the next few hours, blood copper concentrations increase and copper becomes an integral part of the ceruloplasmin molecule (Goresky et al. 1968). Gastrointestinal absorption is normally regulated by the copper status in the body. In general, up to 50% of small doses (i.e., less than 1 µg in rats) are absorbed, whereas large doses are absorbed to a lesser extent (Aaseth and Norseth 1986). In humans, about 40% of the dietary copper is absorbed (USEPA 1980). Absorbed copper is freely exchangeable with copper loosely bound to the alpha-globulin ceruloplasmin where it is exchanged in the cupric form (Schroeder et al. 1966). Copper is stored mainly in liver, brain, heart, kidney, and muscle; in tissues and blood cells, copper is bound to proteins, including many enzymes (Aaseth and

Norseth 1986). Amino acids facilitate the entry of copper into liver cells and a small proportion of copper in serum is bound to amino acids (Goresky et al. 1968). About 80% of the absorbed copper is bound to metallothionein in the liver; the remainder is incorporated into compounds such as cytochrome *c* oxidase (USEPA 1980; ATSDR 1990). Copper accumulations in animals are associated with increased number and increased size of copper-containing lysosomes in hepatocytes. In liver, copper is initially bound to a metallothionein-like, low molecular-weight protein and later it appears in a high-molecular weight protein, ceruloplasmin, which reenters the circulation. Ceruloplasmin transports copper to tissues and also functions as an oxidase (Aaseth and Norseth 1986). The amount of copper absorbed is usually far in excess of metabolic requirements (Sugawara et al. 1994). Of the copper retained in the body, almost all plays a particular physiological role in the function of at least 12 specific copper proteins, such as cytochrome *c* oxidase and tyrosinase. Thus, only extremely small concentrations of free copper ions are normally found in body fluids (NAS 1977).

Retention of radiocopper injected into humans is high; only 10% is excreted within 72 h in urine and feces and 50% in four weeks (Aaseth and Norseth 1986). Most (72%) of the unabsorbed copper is excreted in the feces primarily by way of the biliary duct, the salivary glands, or the intestinal mucosa; a minor portion is excreted by way of sweat and menses (Schroeder et al. 1966; USEPA 1980; ATSDR 1990). In mammals, copper is excreted mainly via the bile in association with glutathione or unidentified high molecular weight molecules; however, the transport mechanisms of copper from liver cells into bile are essentially unknown (Aaseth and Norseth 1986). In rats, biliary excretion of copper is increased by increased flow of bile, increased body temperature, or administration of adrenal steroids (Sugawara et al. 1994).

Mechanisms implicated in copper poisoning include free radical production, alteration in activities of several enzymes, and interference with metallothionein synthesis. At the cellular level, copper has several primary mechanisms of toxicity that alter protein configuration and biological activity. These include the catalysis of peroxidation reactions and subsequent generation of free radicals that damage lipids and proteins, interactions with R groups of proteins—particularly SH groups, and acting as a substituent for other metals in metalloproteins (Sanders et al. 1994). Copper, in relative excess, is a cytotoxic metal with injury related to the process of lipid peroxidation. Isolated rat hepatocytes exposed to copper solutions for as long as 90 min show a concentration- and time-related decrease in cell viability as judged by loss of intracellular potassium and aspartate aminotransferase, an increase in lipid peroxidation, and a decrease in glutathione (Stacey and Klaassen 1981). Falling disease in cattle, dogs, and chickens is associated with a cardiovascular disorder caused by reduced activity of lysal oxidase, a copper-requiring enzyme necessary for elastic tissue formation and maintenance (USEPA 1980). Metallothionein synthesis acts as a protective mechanism against buildup of excessive amounts of the essential, but potentially toxic, copper ions, possibly before the development of other control processes. In livers of newborn lambs, rabbits, mice, and hamsters copper concentrations are usually directly related to the metallothionein content in cytoplasmic fractions (Bakka and Webb 1981). In sheep, elevated serum glutamic oxaloacetic transaminase (SGOT) levels were linked to elevated copper concentrations in blood at least one to six weeks before obvious external signs of copper poisoning. SGOT measurements in sheep serum seem to constitute an adequate early warning of the approach of the hemolytic crisis and eventual death of the animal from chronic copper poisoning (MacPherson and Hemingway 1969).

Interactions

Copper interacts with numerous compounds normally found in natural waters. The amounts of the various copper compounds and complexes present in solution depend on water pH, temperature, and alkalinity and on the concentrations of bicarbonate, sulfide, and organic ligands (USEPA 1980). In animals, copper interacts with essential trace elements such as iron, zinc, molybdenum, manganese, nickel, and selenium and also with nonessential elements including silver, cadmium, mercury, and lead; interactions may be either beneficial or harmful to the organism (Kirchgessner et al. 1979). The patterns of copper accumulation, metabolism, and toxicity from these interactions frequently differ from those produced by copper alone. Acknowledgment of these interactions is essential to understanding copper toxicokinetics.

Aluminum

Mixtures of copper and aluminum (Al) were more than additive in toxicity to ova of brown trout, *Salmo trutta* (Sayer et al. 1991).

Cadmium

Exposure of algae to low sublethal concentrations of copper (0.03 µg/L) increases their sensitivity towards additional copper challenge and to cadmium (Cd) salts (Visviki and Rachlin 1994a). In freshwater clams (*Anodonta cygnea*) exposed for 46 days to a mixture of high concentrations of copper (139 µg/L) and cadmium (122 µg/L), cadmium accumulation is reduced 90% and copper accumulation reduced 50% (Holwerda 1991). Exposure of crayfish (*Cambarus bartoni*) to 12.5 µg Cd/L for 72 h results in significantly increased copper stores in the hepatopancreas; however, isopods similarly exposed had decreased copper stores in antennal glands (Mwangi and Alikhan 1993). In the presence of copper, barnacles tend to accumulate cadmium (Powell and White 1990). In fishes, copper-cadmium interactions occur in Mozambique tilapia (*Oreochromis mossambicus*) during single and combined exposures. Waterborne copper tends to increase whole body cadmium content of tilapia at all tested copper concentrations and exposure durations (as high as 400 µg Cu/L for 96 h); however, cadmium exposure tends to lower copper concentrations in tissues of tilapia (Pelgrom et al. 1994).

In birds, copper concentrations in kidneys of the willow ptarmigan (*Lagopus lagopus*) are positively correlated with concentrations of cadmium (Wren et al. 1994).

In mammals, cadmium inhibits copper absorption across the intestinal mucosa (Aaseth and Norseth 1986). Intercorrelations of copper with cadmium and zinc in livers of polar bears (*Ursus maritimus*) are probably mediated by metallothioneins, which may contain all three metals (Braune et al. 1991). In rats, copper protects against nephrotoxicity induced by cadmium, provided that copper is administered 24 h prior to cadmium insult. Specifically, rats given 12.5 mg Cu/kg BW by way of subcutaneous injection 24 h before receiving 0.4 mg Cd/kg BW—when compared to a group receiving Cd alone—did not have excessive calcium in urine and renal cortex or excessive protein in urine; thus, 2.8 mg Cu/kg BW protects against 0.25 mg Cd/kg BW (Liu et al. 1992).

Iron

Mixtures of copper and iron (Fe) salts were more than additive in toxicity to ova of brown trout (Sayer et al. 1991).

In muscle of Weddell seals (*Leptonychotes weddelli*), copper is positively correlated with iron (Szefer et al. 1994). In general, concentrations of copper in all tissues of all marine vertebrates examined are positively correlated with concentrations of iron (Eisler 1984).

The primary function of the mammalian red blood cell is to maintain aerobic metabolism while the iron atom of the heme molecule is in the ferrous (Fe^{+2}) oxidation state; however, copper is necessary for this process to occur (USEPA 1980). Excess copper within the cell oxidizes the ferrous iron to the ferric (Fe^{+3}) state. This molecule, known as methemoglobin, is unable to bind oxygen or carbon dioxide and is not dissociable (Langlois and Calabrese 1992). Simultaneous exposure of sheep to mixtures of cupric acetate, sodium chlorite, and sodium nitrite produced a dose-dependent increase in methemoglobin formation (Calabrese et al. 1992; Langlois and Calabrese 1992).

The addition of iron to diets of domestic pigs increases their resistance to copper poisoning (USEPA 1980), but this is an exception. High intake of iron, in general, adversely affects copper status in ruminants, guinea pigs, and rats; the mechanisms for this phenomenon are unknown (Yu et al. 1994). Genetically anemic and normal strains of rats fed high iron diets had reduced kidney copper concentrations in both groups; this was associated with decreased absorption and biliary excretion of copper (Yu et al. 1995).

Manganese

Copper in livers and muscles of Weddell seals was positively correlated with manganese (Mn; Szefer et al. 1994). In general, manganese and copper are positively correlated in tissues of marine vertebrates (Eisler 1984). Uptake of copper from copper-contaminated freshwater sediments by annelid worms is related to the amount of reducible manganese oxide in the sediments (Diks and Allen 1983).

Molybdenum

In terrestrial vegetation, molybdenum (Mo) and sulfur interfere with copper-induced deficiencies (Gupta 1979). Copper poisoning in cattle and other ruminants is governed by dietary concentrations of molybdenum and sulfate (Lewis et al. 1967; Todd 1969; Buckley and Tait 1981; Eisler 1989). Molybdenum and sulfur in mammalian diets cause a decrease in the availability of copper because of the formation of the biologically

unavailable copper-thiomolybdate complex (Aaseth and Norseth 1986). Cattle die when grazing for extended periods on pastures where the ratio of copper to molybdenum is less than 3 to 1, or if they are fed low copper diets containing molybdenum at 2 to 20 mg Mo/kg ration (Eisler 1989). Wilson's disease is induced in rabbits by feeding a diet high in molybdates and sulfates, suggesting that the disease is not solely the result of copper intoxication (Goresky et al. 1968).

Zinc

Copper is positively correlated with zinc in gills of two species of fishes from the Mediterranean Sea (Romeo et al. 1994). Mixtures of copper and zinc salts in marine or freshwater fishes are more-than-additive in toxicity, producing more deaths in 96 h than expected on the basis of individual components (Eisler and Gardner 1973; Birge and Black 1979; Hodson et al. 1979). Mixtures of copper and zinc are generally acknowledged to be more-than-additive in toxicity to a wide variety of aquatic organisms (Birge and Black 1979; Hodson et al. 1979; Fernandez and Jones 1990; Eisler 1993). But mixtures of copper (0 to 90 µg/L) and zinc (0 to 1,200 µg/L) are only additive in action to a marine bacterium (*Photobacterium phosphoreum*), decreasing its luminescence after exposure for 30 min (Parrott and Sprague 1993). And sometimes mixtures of copper and zinc salts are less-than-additive in action, as judged by DNA, RNA, and protein contents of newly hatched fathead minnows (*Pimephales promelas*) exposed for 4 days (Parrott and Sprague 1993).

In birds, copper and zinc are positively correlated in kidneys of the willow ptarmigan (*Lagopus lagopus*; Wren et al. 1994) and in kidneys and livers of common murres (*Uria aalge*; Stewart et al. 1994).

In mammals, copper absorption across the intestinal mucosa is inhibited by concomitant high oral intake of zinc (Aaseth and Norseth 1986). In livers from Weddell seals, copper is positively correlated with zinc (Szefer et al. 1994). The addition of zinc to swine diets protects against copper toxicosis caused by eating diets containing 250 mg Cu/kg ration (USEPA 1980).

Other Inorganics

Copper interacts with lead (Pb), magnesium (Mg), silver (Ag), and other elements. In mammals, supplemental copper promotes urinary excretion of lead from the body and loss of lead from tissues (Flora 1991). In shore crabs (*Carcinus maenas*), ionic copper displaces ionic magnesium in gills, leading to inhibition of phosphoryl transfer (Hansen et al. 1992b). In embryos of the Pacific oyster (*Crassostrea gigas*), silver—at 0.5 to 15.5 µg Ag/L—enhances adverse effects when copper concentrations exceed 6.0 µg Cu/L (Coglianse and Martin 1981). Silver positively correlates with copper in livers of Weddell seals, but in muscles the correlation is negative (Szefer et al. 1994).

In fishes, additive or more-than-additive toxicity occurs with mixtures of salts of copper and mercury, copper-zinc-phenol, and copper-nickel-zinc (Birge and Black 1979). Accumulation of copper in gills of fathead minnows during exposure to 16 µg Cu/L is reduced by added ionic calcium, which competes with copper for gill binding sites (Playle et al. 1992).

Organic Compounds

Sequestering agents, increasing salinity, sediments, and other variables all reduce toxicity and accumulation of copper in tested species of aquatic plants and invertebrates. Chelating agents, such as nitrilotriacetic acid, reduce the toxicity of ionic copper to six species of estuarine phytoplankton (Erickson et al. 1970). Sensitivity of freshwater zooplankton communities varies seasonally. Communities are most sensitive to copper stress (20 or 40 µg Cu/L) during exposure for 5 weeks in spring rather than in summer or autumn because, in part, of reduced dissolved organic carbon concentrations in the spring (Winner et al. 1990). Adverse effects of copper on survival of marine copepods are reduced or eliminated by the presence of clay minerals, diatoms, ascorbic acid, sewage effluents, water extracts of humic acids, and certain soil types (Lewis et al. 1972). Chelators, such as EDTA, and more alkaline pH increase the survival and larval developmental rates of copepods challenged with copper through increased complexation of cupric ions (Sunda et al. 1990). Natural fulvic acids, which comprise 75% of dissolved humic substances, reduce the acute toxicity of copper to rotifers (Porta and Ronco 1993). A significant reduction in radiocopper-64 accumulation by clams (*Macoma balthica*) occurs at high concentrations of dissolved organic ligands; reduction is more pronounced at 3.0% salinity than 1.0% salinity (Absil et al. 1993). The presence of sediments in assay containers reduces the toxicity of copper to freshwater gastropods (Winger et al. 1984). Copper uptake by brine shrimp (*Artemia franciscana*) increases with decreasing pH and

decreasing carbonate complexation (Blust et al. 1991). Studies with a freshwater shrimp (*Paratya australiensis*) and copper salts show that uncomplexed cupric ions are the most toxic chemical species in solutions containing nitrilotriacetic acid or glycine; however, the singly charged copper-glycine^{+} complex also appears to be mildly toxic (Daly et al. 1990a). Shrimp (*Paratya* sp.) are more resistant to copper in higher alkalinity waters (Daly et al. 1990b) and under conditions of increasing dissolved organic matter (Daly et al. 1990c).

In freshwater fishes, mixtures of copper with anionic detergents or various organophosphorus insecticides cause more-than-additive toxicity (Hodson et al. 1979). And in marine vertebrates, copper in tissues is positively correlated with metal-binding proteins (Eisler 1984). Accumulations of copper in gills of fathead minnows during exposure to 16 µg Cu/L is reduced by added EDTA, which reduces bioavailability of copper through complexation (Playle et al. 1992). Copper LC50 (96 h) values (i.e., concentrations of ionic copper in solution at the start of the test estimated to kill 50% of the test species in 96 h) to larval fathead minnows range from a low of 2 µg/L at low pH and low dissolved organic carbon to 182 µg/L at pH 6.9 and dissolved organic carbon of 15.6 mg/L (Welsh et al. 1993). Acidification and the removal of dissolved organic carbon increases the toxicity of copper to fathead minnows in natural waters of low alkalinity and explains 93% of the variability in field toxicity data for that species (Welsh et al. 1993).

In mammals, phenobarbital and phenytoin increase serum ceruloplasmin concentrations (Aaseth and Norseth 1986). Chronic copper poisoning in sheep is exacerbated when diets contain heliotrope plants (*Heliotropium* sp., *Echium* spp., *Senecio* sp.). Aggravated effects of the heliotrope plants include reduced survival and a twofold to threefold increase in liver and kidney copper concentrations when compared to control animals fed copper without heliotropes (Howell et al. 1991). Rats given acutely toxic doses of 2,3,7,8-tetrachlorodibenzo-para-dioxin had elevated concentrations of copper in liver and kidney because of impaired biliary excretion of copper (Elsenhans et al. 1991). Morphine increases copper concentrations in the central nervous system of rats, and dithiocarbamates inhibit biliary excretion (Aaseth and Norseth 1986). In human patients, urinary excretion of copper is increased after treatment with D-penicillamine, calcium disodium EDTA, or calcium trisodium diethylenetriamine penta acetic acid (Flora 1991).

Carcinogenicity, Mutagenicity, Teratogenicity

General

No definitive evidence exists demonstrating that copper or copper compounds at environmentally realistic concentrations are the causative agents in the development of carcinogenicity, mutagenicity, or teratogenicity (USEPA 1980; Aaseth and Norseth 1986; ATSDR 1990). However, under controlled conditions of grossly elevated exposures, some studies suggest that copper is a potential carcinogen in rodents (USEPA 1980; ATSDR 1990; Toussaint and Nederbragt 1993); mutagen in rodents (Aaseth and Norseth 1986; ATSDR 1990), sheep (Bires et al. 1993), and grasshoppers (Bhunya and Behura 1986); and teratogen in fish (Birge and Black 1979), rodents, and other small laboratory animals (Aaseth and Norseth 1986).

Carcinogenicity

The carcinogenic classification of copper is Group 3 or D; that is, not classifiable as to its carcinogenicity in humans (ATSDR 1990). No definitive evidence exists showing that copper or copper compounds cause cancer in mammals (USEPA 1980; Aaseth and Norseth 1986; ATSDR 1990). Although hypercupremia is sometimes associated with neoplasms (USEPA 1980), some copper compounds seem to have an inhibitory effect on the development and growth of malignant tumor cells (Aaseth and Norseth 1986). Copper is not associated with an elevated incidence of cancer in humans or animals exposed by way of inhalation, oral, dermal, or intramuscular injection routes. A slightly increased incidence of reticulum cell sarcoma was noted in mice 18 months after a single subcutaneous injection of copper 8-hydroxyquinoline, but this needs to be verified (ATSDR 1990).

Sensitivity of cancerous cells to copper may reflect cell DNA content. Two closely related rat hepatoma cell lines differed in sensitivity to copper toxicity by a factor of four; DNA content in each cell line decreased with increasing copper concentrations, but at different rates. Severity of toxicity was associated with increasing accumulations of copper in the cell nucleus and with decreasing DNA (Toussaint and Nederbragt 1993).

Mutagenicity

Grasshoppers (*Oxya velox*) injected intra-abdominally with relatively high concentrations of soluble copper showed a 1.6% frequency of chromosomal anomalies in meiotic cells of testes 24 h after injection (Bhunya and Behura 1986); however, no control data were presented. Copper-induced DNA strand breaks in rats and chromosomal aberrations and sperm abnormalities in mice suggest that copper is a potential human mutagen (ATSDR 1990). Copper salts affect chromosomes in vitro in the presence of hydrogen peroxide and ascorbic acid and can also increase the frequency of non-complementary nucleotides in the synthesized DNA double helix (Aaseth and Norseth 1986). Sheep, age 1.5 years, given about 10.7 mg Cu/kg BW daily—in addition to other metals—until they died (65 to 84 days later) show a significant increase in sister chromatid exchanges in bone marrow (Bires et al. 1993); however, the specific role of copper on survival and mutagenicity is unclear and requires verification.

Teratogenicity

Grossly elevated concentrations of dissolved copper produce teratogenicity in fish embryos. A significant number of malformed fish larvae came from eggs treated with 500 µg Cu/L (Birge and Black 1979). In studies with laboratory animals and elevated concentrations of copper salts, copper penetrates the placental barrier into the fetus; intramuscular injection of 4 mg Cu/kg BW early in pregnancy adversely affects fetal central nervous system development (Aaseth and Norseth 1986). In humans, no definitive data are available on whether copper can cause birth defects; however, incubation of human spermatozoa with metallic copper results in loss of sperm motility (Aaseth and Norseth 1986).

Concentrations in Field Collections

General

Copper concentrations in air, soil, water, sediments, and other abiotic materials are elevated as a result of human activities, especially near copper smelters and mines, urban areas, municipal and industrial wastewater outfalls, marinas containing copper-based antifouling paints, and agricultural soils receiving prolonged applications of copper-based fungicides (Table 2). Maximum copper concentrations in selected abiotic materials are 5 µg/m^3 in air, 5 µg/L in groundwater, 12 µg/L in rainwater, 300 mg/kg DW in black shales, 1,200 mg/kg DW in poultry litter, 6,500 mg/kg DW in marine sediments, 7,000 mg/kg DW in soils, and 7,700 mg/kg DW in sewage sludge (Table 2).

Table 2. Copper concentrations in selected abiotic materials.

Table 2.

Material, units of concentration, and other variables	Concentration[a]	Reference[b]
Air, µg/m^3		
Near copper smelters	1-2; Max. 5.0	1, 2
Nonurban locations	0.16-0.21; Max. 1.2	3
Remote locations	Usually <0.001; sometimes 0.001-0.003; Max. 0.012	4
South Pole	0.00004	5
Urban locations	0.15-0.18; Max. 1.6	4
United States	0.01-0.67	5
U.S. cities	Usually 0.09-0.81; sometimes 0.81-2.4; infrequently >2.4	2, 6
Uncontaminated	0.001-0.2	1, 7
Coal, µg/kg dry weight (DW)	17,000	7

Table 2.

Material, units of concentration, and other variables	Concentration[a]	Reference[b]
Drinking water, µg/L		
Conducted via copper pipes	Max. 1,000	1
Private houses		
White Plains, New York	540	6
Bridgeport, Connecticut	185	6
Vermont		
Private houses	75-1,400	6
Hospital	17-730	6
United States	134; Max. 8,350	1, 2
Glaciers, µg/kg fresh weight (FW)	0.2	7
Groundwater, µg/L		
New Jersey	About 5.0	1
Lakes and rivers, µg/L		
Canada	1-8	1
Contaminated vs. noncontaminated	50-100 vs. 1-7	6
Lake Asosca, Nicaragua, 1991-92	Usually <2.0; mean 3.1; Max. 13.1	8
Ligurian Sea drainage	<0.3-1.75 (equivalent to 3.5-7.1 tons annually)	22
New Jersey	3.0	1
Sweden; near brassworks vs. reference site	9.4 vs. 1.0	21
United States	5.3 (0.83-105.0); usually <2.0-4.2	1, 5, 7
Manure, µg/kg DW		
Cattle	5,000	1
Mine tailings, mg/kg DW		
Butte Lake, Canada, 1982	7,100	9
Municipal water supplies, µg/L	8.3 (0.6-250.0)	6
Oil, µg/kg FW		
Crude	140	7
Shale	70,000	7
Pond water, µg/L		

Table 2.

Material, units of concentration, and other variables	Concentration[a]	Reference[b]
Massachusetts	(<10-105)	1
Poultry litter, mg/kg DW	1,196	10
Precipitation, µg/L		
Soluble vs. total	6.0 vs. 12.3	4
Rocks, µg/kg DW		
Crustal and sedimentary	24,000-45,000	6, 7
Sandstones	10,000-40,000	11
Shales	30,000-150,000	11
Marine black shales	20,000-300,000	11
Seawater, µg/L		
Central Texas coast	Max. 50.0	12
Chesapeake Bay, Maryland;	11.7 (ND-80.0)	13
1985-86; dissolved		
In water flowing through		
copper pipes	45.0	6
Mediterranean, northwestern coast	Max. 22.4	12
North Sea	0.2-2.6	14
Oceanic		
Dissolved	0.15	7
Total	0.06-6.7	5, 12, 13
Surface waters		
Atlantic Ocean	0.06-0.21	1
East Arctic Ocean	0.13	1
Taiwan, coastal		
Total	10.2	15

Dissolved	7.75	15
Labile	2.19	15
Inorganic labile	2.15	15
Free labile	0.04	15

Table 2.

Material, units of concentration, and other variables	Concentration[a]	Reference[b]
Nonlabile	5.56	15
Polar nonlabile	3.81	15
Nonpolar nonlabile	1.75	15
Taiwan, near copper recycling facility		
Total	0.8-737.0	15
Dissolved	3.5-36.5	15
Particulates	0.2-723.0	15
United Kingdom estuaries		
Contaminated	3-176	14
Noncontaminated	2-3	14
Sediments, mg/kg DW		
England and Wales, streams	7-70	17
Lake Asosca, Nicaragua; 1991-92	(36.6-73.7)	8
Long Island Sound, New York;		
1984-85	190	18
Southwest England		
Carnon River (water 1,080 µg/L)	1,650: Max. 6,500	14
Fowey (water 7-21 µg/L)	50; Max. 370	14
Red River (water 17-35 µg/L)	590	14
Sweden; freshwater lakes; 1988		
3-5 km from smelter	707-2,531	19
50-80 km from smelter	37-54	19
United Kingdom estuaries,		
contaminated vs. noncontaminated	>2,000 vs. 10	14
Sediment interstitial waters, µg/L		
Butte Lake, Canada; 1982	Max. 14.8	9
Clean vs. copper-contaminated	<10 vs. 100	14
sediments		
Sewage sludge, mg/kg DW		
Missouri	390 (45-5,200)	16

Table 2.

Material, units of concentration, and other variables	Concentration[a]	Reference[b]
Primary sludge	21 (3-77)	1
United States, 23 cities	991 (126-7,729)	1
Soils, mg/kg DW		
Global	(2-250)	1, 5
Italy	51	20
Near copper production facility	7,000	1
To 100 cm depth		
Total	20	7
Organic fraction	350	7
Under oak trees	3.5	6
Under maple trees	6.0	6
United States	19 (1-70)	11, 16

[a]Concentrations are shown as means, range (in parentheses), maximum (Max.), or nondetectable (ND).

[b]1, ATSDR 1990; 2, USEPA 1980; 3, Nriagu 1979a; 4, Nriagu 1979d; 5, Aaseth and Norseth 1986; 6, Schroeder et al. 1966; 7, Nriagu 1979c; 8, Cruz et al. 1994; 9, Pedersen 1983; 10, van der Watt et al. 1994; 11, NAS 1977; 12, Neff and Anderson 1977; 13, Hall et al. 1988; 14, Bryan and Langston 1992; 15, Hung et al. 1990; 16, Beyer 1990; 17, Thornton 1979; 18, Turgeon and O'Connor 1991; 19, Johnson et al. 1992; 20, Arduini et al. 1995; 21, Hogstrand et al. 1991; 22, Migon 1993.

Copper concentrations in field collections of plants and animals are usually elevated in areas treated with copper-containing herbicides, near smelters, and from heavily urbanized and industrialized areas (Stokes 1979; Eisler 1984; Winger et al. 1984; Read and Martin 1993; Swiergosz et al. 1993; Fishelson et al. 1994; Storm et al. 1994). The amount and distribution of copper in animal tissues varies with tissue, organism age, sex, and amount of copper in the diet (Cuill et al. 1970; NAS 1977; USEPA 1980; Fishelson et al. 1994). Additional and more detailed information on copper concentrations in field collections of plants and animals is found in Jenkins (1980) and Eisler (1979, 1981).

In terrestrial vegetation, copper is usually less than 35 mg/kg DW except near smelters, where it may approach 700 mg/kg DW, and in copper-accumulator plants that may normally contain as much as 13,700 mg/kg DW (Table 3). In aquatic vegetation, copper is elevated in metals-contaminated water bodies, reaching concentrations as high as 1,350 mg/kg DW in eelgrass (*Zostera* spp.) from contaminated bays vs. 36 mg/kg DW in conspecifics from reference sites (Table 3).

Table 3. Copper concentrations (milligrams of copper per kilogram fresh weight [FW], dry weight [DW], or ash weight [AW]) in field collections of representative plants and animals.

Table 3. **Taxonomic group, organism, and other variables**	**Concentration[a] in (mg/kg)**	**Reference[b]**
Terrestrial Plants		
Red maple, *Acer rubrum*; leaf; Ontario, Canada; distance from smelter		
1.6 km	37 DW	1
2.6 km	26 DW	1
10.4 km	19 DW	1
28.9 km	16 DW	1
Copper plant mint, *Aeolanthus biformifolius*; Zaire		
Leaf	2,150-2,600 DW	1
Flower stem	2,150-3,500 DW	1
Corm	2,600-13,700 DW	1
Whole	10,000-13,700 DW	1
Agricultural crops, various	3-36 DW	2
Hair grass, *Deschampia flexuosa*; Ontario, Canada; distance from smelter		
1.7 km	726 DW	1
2.1 km	121 DW	1
7.4 km	103 DW	1
52.7 km	13 DW	1
Ferns, seven species; leaves	0.51 (0.22-0.98) FW	1
Fungi		
Seven species, whole	2.4 (1.5-3.0) FW	3
Various species		
Cap	Max. 131.7 DW	1
Spore	Max. 165.0 DW	1
Stalk	Max. 14.2 DW	1
Whole	Max. 95.9 DW	1
Grasses, various species	5 DW	2
Moss, *Hypnum cupressiforme* Wales; distance downwind from smelter		
Up to 3 km	All dead	1
8 km	62-68 DW	1
25 km	18-19 DW	1
Control site	11 DW	1
Sweden; near industries	Max. 265-580 DW	1
Legumes, various	15 DW	2
Lichens, various species		
Arctic	5 DW	4
Near copper smelter; Sudbury, Ontario	(15-20) DW	4
Tomato, *Lycopersicon esculentum*; United States		
Fruit	14 (8-34) DW	1
Leaf	(3-12) DW	1
Terrestrial plants, various species; seeds	1.1 (0.6-2.9) FW	3
Poppy, *Papaver orientale*; pods	14.3 FW	3

Table 3. Taxonomic group, organism, and other variables	Concentration[a] in (mg/kg)	Reference[b]
Lichen, *Parimelia baltimorensis*; Washington, D.C.; various years		
1938	17 DW	1
1958	22 DW	1
1970	32 DW	1
Norway spruce, *Picea abies*		
Connecticut		
Leaf	6.0 DW	1

Trees, various species; leaves	1.8 (0.6-5.2) FW	3
Tundra plants; whole; Spitsbergen, Norway; 1987		
Lichens, 14 species	1.8-36.7 DW	5
Mosses, four species	3.4-33.0 DW	5
Vascular plants, five species	3.9-10.0 DW	5
Elm, *Ulmus americana*; wood	7.9 FW	3
Corn *Zea mays*		
Grain		
East Asia	1.6 FW	1
Lower Dahomey	(1.0-2.9) DW	1
United States	8 (4-17) DW	1
From soils with Cu additions of 360 kg Cu/ha		
Grain	1.7-2.8 DW	6
Leaves	7.8-12.5 DW	6
Aquatic plants		
Algae and macrophytes; 11 species; Brazil; November 1989; whole	2.4-6.9 DW	14
Alga, *Ascophyllum nodosum*		
England; polluted bay vs. reference site	68 (46-96) DW vs. 12 (6-18) DW	1
Norway; polluted fjord vs. reference site	(45-240) DW vs. 5.5 (4-8) DW	1
Freshwater macrophytes; various species	2.5-256.0 DW	15
Water milfoil, *Myriophyllum* spp.	10.0-41.3 DW	1
Brown alga, *Pelvetia canaliculata*; whole		
Norway	55 DW	1
Scotland	5-16 DW	1
Pondweed, *Potamogeton* spp.; whole; Pennsylvania	5.0-102.9 DW	1
Eelgrass, *Zostera* spp.		
Denmark; 1979-80; metals-contaminated site vs. reference site		
Leaves	9-13 DW vs. 5-6 DW	16
Roots	27.4 DW vs. 6-7 DW	1
Portugal and Spain; contaminated bay	1,350 DW vs. (9-36) DW	1

Table 3. Taxonomic group, organism, and other variables	Concentration[a] in (mg/kg)	Reference[b]
vs. reference site		
Porifera		
Sponges; three species; whole	13-34 DW	1
Coelenterates		
Jellyfish, *Cyanea capillata*; whole		
New England	8.2 DW	1
Sweden	68.0 DW	1
Octacorals; Venezuela; whole; five species	0.9-3.1 DW	17
Terrestrial invertebrates		
Honeybee, *Apis mellifera*; Czechoslovakia; industrial locations vs. reference site; 1986-87		
Foraging workers	32-37 DW vs. 20-24 DW	7
Honey	1.1-1.7 DW vs. 0.6 DW	7
Pollen	6.1-8.2 DW vs. 5.4 DW	7
Landsnail, *Arianta arbustorum*; urban areas vs. reference site; Innsbruck, Austria; 1987; soft parts	188 (30-408) DW vs. 84 (46-104) DW	8
Bumblebee; four species of *Bombus*; queens; whole; Sweden, April 1991	18-23 (11-38) DW	9
Pine moth, *Bupalus piniarius*; pupae; whole; Finland, 1987; industrialized area vs. reference site	Max. 137 DW vs. 53 DW	10
Earthworm, *Lumbricus rubellus*; Cardiff, Wales; 1984; contaminated soils (2,740 mg Cu/kg DW soil) vs. reference site (26 mg Cu/kg DW soil)		
Anterior alimentary canal	85.4 DW vs. 18.2 DW	11
Posterior alimentary canal	64.4 DW vs. 21.1 DW	11
Remainder	23.2 DW vs. 10.1 DW	11
17-year cicadas, *Magicicada* spp.;Maryland; 1987; whole	(33.2-60.3) DW	12
Pine noctuid, *Panolis flammea*; pupae; whole; Finland, 1987; industrialized area vs. reference site	Max. 89 DW vs. 20 DW	10
Cuckoo bumblebee, *Psithyrus bohemicus*; queens; Sweden; April, 1991; whole	19 (12-29) DW	9
Spiders, whole; from old-field subjected to 11 years of nutrient enrichment (3,410 g Cu/ha yearly) vs. reference site (2-3 g Cu/ha yearly)		
Garden orb weaver, *Argiope aurantia*	110 DW vs. 80 DW	13
Wolf spiders, Lycosidae	130 DW vs. 85 DW	13
Aquatic mollusks		
Antarctic scallop, *Adamussium colbecki*; Ross Sea; 1987-88 vs. 1990		
Digestive gland	12.6 vs. 3.5 FW	18, 19

Table 3. Taxonomic group, organism, and other variables	Concentration[a] in (mg/kg)	Reference[b]
Gills	6.5 DW vs. 1.4 FW	18, 19
Gonad	4.7 DW vs. ND	18
Kidney	4.0 DW vs. ND	18
Mantle	3.5 DW vs. ND	18
Muscle	1.6 DW vs. ND	18
Freshwater mussel, *Amblema* sp.; Texas		
Digestive gland	9.5 FW	1
Foot	2.9 DW	1
Gill	6.1 DW	1
Mantle	3.6 DW	1
Blood clam, *Anadara granosa*; soft parts; Malaysia	0.7-0.8 FW; 6.3 (4.5-8.0) DW	20, 21
Freshwater mussel, *Anodonta grandis*; soft parts; Manitoba, Canada; 1986	45.3 (5-80) DW	22
Lake mussel, *Anodonta piscinalis*; gills		
No glochidia	5.4 DW	23
With glochidia	8.0 DW	23
Ocean quahog, *Arctica islandica*		
Soft parts		
Block Island Sound	10.0 DW	24
Chesapeake Bay	5.4 DW	24
Georges Bank	3.5-10.3 DW	24
New York Bight	11.3 DW	24
Western Baltic Sea, 1992-93		
Adductor muscle	1.8-2.2 DW	24
Digestive gland	13.5 DW	24
Foot	3.1 DW	24
Gills	6.7 DW	24
Kidney	40.1 DW	24
Mantle	5.0 DW	24
Soft parts	14.3-15.3 DW	24
Whelk, *Buccinum undatum*; soft parts		
Irish Sea	180 DW	1
Scotland	78 DW	1
Channeled whelk, *Busycon canaliculatum*		
Digestive gland	(32-1,135) FW	1
Muscle	(12-21) FW	1
Cephalopods; liver	150 FW	3
Scallop, *Chlamys operculis*		
Kidney	240.0 FW	1
Shell	2.1 FW	1
Soft parts	1.7 FW	1
Pacific oyster, *Crassostrea gigas*		
Shell	(1.6-2.9) DW	1
Hong Kong, 1989; various locations		
Gill	840 DW	25
Mantle	509 DW	25
Muscle	750 DW	25
Soft parts	344-422 DW; max. 1,071 DW	25
Visceral mass	383 DW	25
Arcachon Bay, France, soft parts		
1979-82	48.3-63.8 DW	26

Table 3. Taxonomic group, organism, and other variables	Concentration[a] in (mg/kg)	Reference[b]
1983-87	67.7-116.2 DW	26
1988-91	101.8-135.0 DW	26
Soft parts		
England	(340-6,480) DW	1
South Africa	33.0 DW	1
Tasmania	(9.4-84.4) DW	1
United States	(7.8-38.0) FW	1
Taiwan		
Soft parts; 1989; seawater had 5.0-23.6 µg Cu/L from discharges of copper recycling facility	4,401 DW; green in color	27
Soft parts		
From copper-contaminated environment	2,225 DW	28
As above; after 6 days in clean seawater	746 DW	28
As above; after 32 days in clean seawater	344 DW	28
American oyster, *Crassostrea virginica*		
Florida, soft parts		
From a canal lined with chromated-copper arsenate wood vs. reference site	150-200 FW vs. 10 FW; elevated concentrations were associated with greenish color and higher frequency of histopathology of digestive gland diverticula	29
Reference site oysters transplanted into above canal		
After 3 months	130 FW	29
After 4 months	220 FW; no increase in frequency of digestive gland lesions	29
North Carolina, soft parts		
Marina sites	36.7 FW	30
Open water sites	7.1 FW	30
At 12 ‰ salinity	6.0 FW	31
At 33 ‰ salinity	2.0 FW	31
Soft parts		
Alabama	20 (4-78) FW	1
Chesapeake Bay	(5-240) FW	1
Eastern USA	91 (7-517) FW	1
Georgia	(48-261) DW	1
Gulf of Mexico states	16 (6-27) FW	1
Maryland (green oysters)	Max. 1,120 DW	1
NW Atlantic	46 (11-110) DW	1
Rhode Island	121 (92-140) FW	1
Texas	161 DW	1
Virginia; 1972-73		
At 7.5 ‰ salinity	29 FW	31
At 9.5 ‰ salinity	16 FW	31
At 12 ‰ salinity	12 FW	31
At 13.5 ‰ salinity	3 FW	31
Zebra mussel, *Dreissena polymorpha*; soft parts; caged for 15-60 days; water contained 0.8-1.4 µg Cu/L and particulates had 0.3-3.2 µg Cu/L	12.6-17.7 DW	32
Freshwater mussels; two species; soft	7.8-16.2 DW	33

Table 3. Taxonomic group, organism, and other variables	Concentration[a] in (mg/kg)	Reference[b]
parts; St. Lawrence River; 1989-90; sediment copper ranged from 4 to 148 mg/kg DW		
Octopus, *Eledone cirrhosa*; English Channel;		
October 1987		
Branchial hearts	335 DW	34
Genital tract	60-66 DW	34
Gill	268 DW	34

Insects; immature benthic species; whole; from copper-contaminated river up to 60 km downstream from outfall (779 mg Cu/kg DW sediments) vs. reference site (18 mg Cu/kg DW sediments)		
Plecoptera	84 DW vs. 16-32 DW	50
Trichoptera	204 DW vs. 11-18 DW	50
Mayflies, four species; whole; nymphs	11-17 DW	1
Beach hopper (amphipod), *Orchestia gammarellus*; whole; North Sea; 1989-90; reference site vs. contaminated site	Usually <70 DW vs. >145 DW (Max. 340 DW)	51
Crayfish, *Pacifasticus leniusculus*; raw vs. cooked		
Hepatopancreas	44 FW vs. 17 FW	45
Muscle	5 FW vs. 8 FW	45
Shrimp, *Pandalus jordani*; muscle	14.3-18.2 DW	1
Brown shrimp, *Penaeus aztecus*; Texas		
Exoskeleton	32 DW	1
Muscle	18-29 DW	1
Whole	34 DW	1
Viscera	173 (65-260) DW	1
Oceanic amphipods, *Themisto* spp; whole; Antarctic and Atlantic Oceans; 1985-86	28-31 (13-79) DW	49
Aquatic annelids		
Polychaete, *Lycastis ouanaryensis*; whole; India; 1984-85; contaminated site vs. reference site	32-95 DW vs. 4-27 DW	52
Tubificid worm, *Tubifex tubifex*; whole; Illinois	23 (10-42) DW	1
Echinoderms		
Sea star (Asteroidea), *Pisaster brevispinus*; California		
Gonad	(2-10) DW	1
Hepatic caecum	(18-38) DW	1
Stomach	(5-40) DW	1
Tunicates		

Table 3. Taxonomic group, organism, and other variables	Concentration[a] in (mg/kg)	Reference[b]
Sea squirt, *Ciona intestinalis*		
California		
Tunic	55 DW	1
Viscera	73 DW	1
Sweden, whole	13 DW	1
Elasmobranchs and fishes		
Rockbass, *Ambloplites rupestris*; Ontario, Canada		
Gill	2.1 FW	1
Kidney	3.0 FW	1
Liver	4.9 FW	1
Muscle	1.7 FW	1
Jolthead porgy, *Calamus bajonado*; Puerto Rico		
Eye	1.3 FW; 6.7 DW	1
Gills	1.2 FW; 3.5 DW	1
Intestine	2.4 FW; 10.0 DW	1
Muscle	0.4 FW; 1.5 DW	1
Scales	4.9 FW; 6.9 DW	1
Vertebra	8.3 FW; 14.0 DW	1
Oceanic whitetip shark, *Carcharhinus longimanus*; Puerto Rico		
Liver	1.3 FW; 2.2 DW	1
Muscle	0.5 FW; 2.4 DW	1
Skin	8.6 FW; 21.0 DW	1
Vertebra	3.5 FW; 11.0 DW	1
White sucker, *Catostomus commersoni*; northern Ontario; September 1986; copper-contaminated site (water 9.7 µg Cu/L, sediments 232 mg/kg DW) vs. reference site (2.1 µg/L water, 10 mg/kg DW sediments)		
Feces	208 DW vs. 49 DW	53
Gill	15 DW vs. 6 DW	53
Kidney	26 DW vs. 14 DW	53
Liver	83 DW vs. 50 DW	53
Stomach Contents	155 DW vs. 7 DW	53
Blackfin icefish, *Chaenocephalus aceratus*; Antarctica; 1989		
Liver	4.5 FW	44
Muscle	1.5 DW	44
African sharp-tooth catfish, *Clarias gariepinus*; South Africa; 1988-89; metals-contaminated lake (sediments 216 mg Cu/kg DW)		
Muscle, body fat, vertebra, gonads	9-15 DW	54
Intestine, spleen, liver, kidney, heart, gills	26-46 DW	54
Brain	100 DW	54
Lake whitefish, *Coregonus clupeaformis*; liver, Lake Superior vs. Lake Michigan	2.4 FW vs. 8.5 FW	1
Bloater, *Coregonus hoyi*; liver;		

Table 3. Taxonomic group, organism, and other variables	Concentration[a] in (mg/kg)	Reference[b]
Lake Superior vs. Lake Michigan	2.4 FW vs. 7.4 FW	1
Spotted seatrout, *Cynoscion nebulosus*; whole; South Carolina; 1990-93	0.03-2.9 FW (0.0-19.0) FW	55
Adriatic anchovy, *Engraulis encrasicolus*		
Liver	3.9 FW	1
Muscle	0.7 FW	1
Whole	1.1 FW	1
Northern pike, *Esox lucius*; Ontario		
Gill	1.9 FW	1
Kidney	2.6 FW	1
Liver	10.9 FW	1
Freshwater fishes; Lake Tanganyika, Burundi; two commercially important species, *Lates* sp., *Stolothrissa* sp.)		
Gonads	2.0 DW	56
Heart	2.9 DW	56
Intestine	3.2 DW	56
Liver	11.9 DW	56
Muscle	1.7 DW	56
Whole	3.2 DW	56
Freshwater fishes; Tennessee; muscle	0.1-0.9 FW; Max. 2.2 FW	58
Freshwater fishes; USA, nationwide; whole; 8 species		
1984	0.65 FW; Max. 23.1 FW	57
1980-81	0.65 FW; Max. 24.1 FW	57
1978-79	0.82 FW; Max. 38.7 FW	57
Mummichog, *Fundulus heteroclitus*; whole		
Body length 40-51 mm	59 AW	132
Body length 54-121 mm	45-49 AW	132
Atlantic cod, *Gadus morhua*; Norway		
Gill	(4-19) DW	1
Liver	(8-18) DW	1
Muscle	(1-3) DW	1
Brown bullhead, *Ictalurus nebulosus*; Ontario, Canada		
Gill	1.8 FW	1
Kidney	2.5 FW	1
Liver	30.3 FW	1
Muscle	1.3 FW	1
Dab, *Limanda limanda*; liver; German Bight; March 1990; males vs. females	4.3-10.4 FW vs. 5.5-16.0 FW	130
Black marlin, *Makaira indica*; Australia		
Liver	4.6 (0.5-22.0) FW	1
Muscle	0.4 (0.3-1.2) FW	1
Blue marlin, *Makaira nigricans*; muscle		
Japan	0.4 (0.1-0.7) FW	1
Puerto Rico	1.3 (0.4-2.6) FW; 2.7 (1.5-10.0) DW	1
Red mullet (Mullidae), *Mullus barbatus*; gills; Coutou, France	17.6-48.1 DW	59
Hump rock cod (Notothenidae), *Notothenia gibberifrons*; Antarctica;	0.85 DW	44

Table 3. Taxonomic group, organism, and other variables	Concentration[a] in (mg/kg)	Reference[b]
1989; muscle		
Kelp bass, *Paralabrax clathratus*; California; Los Angeles site near effluent discharge of steam utility plant vs. Catalina Island (reference site)		
Eyeball	8.0 DW vs. 4.0 DW	1
Gonad	6.0 DW vs. 5.0 DW	1
Heart	1.5 DW vs. 12.0 DW	1
Liver	5.0 DW vs. 6.0 DW	1
Muscle	5.0 DW vs. 2.0 DW	1
Southern flounder, *Paralichthys lethostigma*; South Carolina; 1990-93; whole	1.1-1.9 (0.0-22.2) FW	55
Yellow perch, *Perca flavescens*; Michigan; 1993; Torch Lake (34 µg Cu/L) vs. reference site (10 µg Cu/L)		
Ovaries	5.0 DW vs. 2.1 DW	60
Testes	3.5 DW vs. 1.3 DW	60
Southern mouth brooder, *Pseudocrenilabrus philander*; South Africa; whole fish; mine-polluted impoundment	9 (4-26) DW	61
Winter flounder, *Pleuronectes americanus*		
New York		
Muscle	(0.5-1.1) FW	1
Liver	(2.7-13.8) FW	1
Texas		
Muscle	1.0 (0.6-1.5) DW	1
Skin	1.7 (1.2-2.1) DW	1
Atlantic guitarfish, *Rhinobatos lentiginosus*		
Liver	6.6 DW	1
Muscle	2.2 DW	1
Stomach	6.2 DW	1
Red drum, *Sciaenops ocellatus*; South Carolina; 1990-93; whole	0.4-9.2 (0.0-52.9) FW	55
Spanish mackerel, *Scomberomorus maculatus*		
Liver	3.3 DW	1
Muscle	2.3 DW	1
Painted comber, *Serranus cabrilla*; gills; Coutou, France	5.3-27.2 DW	59
Sharks, 10 species; British and Atlantic waters; 1984-88		
Gills	0.05-2.2 FW	62
Gonads	0.1-4.9 FW	62
Heart	0.03 FW	62
Jaws	1.7-3.3 FW	62
Kidney	0.02-4.0 FW	62
Liver	0.2-7.8 FW	62
Muscle	0.2-2.4 FW	62
Pancreas	0.7 FW	62
Skin	0.6-12.1 FW	62

Table 3. Taxonomic group, organism, and other variables	Concentration[a] in (mg/kg)	Reference[b]
Spleen	0.03-2.5 FW	62
Vertebra	0.5-5.9 FW	62
Spiny dogfish, *Squalus acanthias*		
Liver	4.5 DW	1
Muscle	2.3 DW	1
Spleen	16.0 DW	1
Bluefin tuna, *Thunnus thynnus*; Spain		
Heart	4.2 FW; 18.1 DW	1
Intestine	1.4 FW; 5.8 DW	1
Kidney	8.6 FW; 27.8 DW	1
Liver	74.0 FW; 245.0 DW	1
Ovary	(1.4-2.3) FW; (5.4-11.0) DW	1
Spleen	1.2 FW; 4.4 DW	1
Red hake, *Urophycis chuss*		
Liver	(3.2-6.0) FW	1
Muscle	(0.5-0.7) FW	1
Swordfish, *Xiphias gladius*; muscle	(0.3-1.4) FW	1
Amphibians and reptiles		
Frogs; Maryland, 1990-91; tadpoles		
Northern cricket frog, *Acris crepitans*;whole	9.8-15.7 DW	131
Gray treefrog, *Hyla versicolor*; whole	7.4-12.6 DW	131
Green frog, *Rana clamitans*		
Gut vs. remainder	21.5 DW vs. 6.7 DW	131
Frogs and toads; Yugoslavia; liver; near mercury mines		
European toad, *Bufo bufo*	56.2-81.4 FW	1
Toad, *Bombina variegata*	(5.0-5.6) FW	1
European frog, *Rana temporaria*	318.9 FW	1
Giant toad, *Bufo marinus*; liver		
Australia	Max. 1,640 DW	63
Dominican Republic		
Black livers	1,248-2,091 DW	63
Yellow livers	367-469 DW	63
American crocodile, *Crocodylus acutus*; egg; Florida	(0.9-15.0) FW	1
Birds		
Western grebe, *Aechmophorus occidentalis*;		
Puget Sound, Washington; 1985-86; sediments had 52 mg Cu/kg DW		
Diet (fish muscle)	0.3-0.5 FW	64
Liver	12.7-17.6 DW	64
Mallard, *Anas platyrhynchos*; Canada; 1975; feathers; near smelter vs. reference site	23 DW vs. 7-14 DW	65
Black duck, *Anas rubripes*		
Canada; 1975; feathers; near smelter vs. reference site	53 DW vs. 10 DW	65
Ducks, *Anas* spp.; Poland; 1988-91		
Kidney	9.9 (3.5-30.0) FW	66
Liver	58.0 (11.0-200.0) FW	66
Muscle	4.5 (2.1-10) FW	66
Geese, *Anser* spp.; Poland; 1988-91		

Table 3. Taxonomic group, organism, and other variables	Concentration[a] in (mg/kg)	Reference[b]
Liver	80 (29-160) FW	66
Muscle	4.0 (1.6-8.8) FW	66
Antarctica; February-March 1989		
Blue eyed cormorant, *Phalacrocorax atriceps*; muscle	10 DW	67
Southern giant petrel, *Macronectes giganteous*; muscle	7.2 DW	67
Adelie penguin, *Pygoscelis adeliae*		
Liver	11.9 (11.0-12.6) DW	67
Muscle	7.9 (6.5-8.5) DW	67
Chinstrap penguin, *Pygoscelis antarctica*		
Feces	37.6 (35.1-49) DW	67
Liver	12.6 (12-13) DW	67
Muscle	9.7 (9.5-10.1) DW	67
Gentoo penguin, *Pygoscelis papua*		
Liver	26.5 (24.0-27.6) DW	67
Muscle	8.2 (7.7-8.9) DW	67
Redhead, *Aythya americana*; Louisiana and Texas; 1987-88; liver	7.3 (3.9-11.5) DW	68
Canvasback, *Aythya valisineria*; Louisiana; 1987-88; liver; females	Usually 76-187 DW	69
Ruffed grouse, *Bonasa umbellus*; liver	5.2 FW	3
Lesser kestrel, *Falco naumanni*; nonviable eggs; Spain; 1988-91	3.1 (0.2-7.1) FW	3
Bald eagle, *Haliaeetus leucocephalus*; eggs		
Florida	(0.7-1.2) FW; (4.8-8.0) DW	1
Maine	(0.3-0.6) FW; (2.0-5.0) DW	1
Wisconsin	(0.5-1.2) FW; (3.0-9.0) DW	1
Willow ptarmigan, *Lagopus lagopus*; Norway; winter 1986-87; kidney; adults vs. juveniles	2.8-4.9 FW (Max. 8.0 FW) vs. 1.9-3.6 FW (Max. 5.5 FW)	71
Lesser black-backed gull, *Larus fuscus*		
Egg	1.0 FW	1
Kidney	14.0 DW	1
Liver	17.0 DW	1
Muscle	14.0 DW	1
Marine birds, New Zealand; 1975-83		
Albatrosses, eight species; adults vs. juveniles		
Feather	44.0 FW vs. 18.4-32.3 FW	72
Liver	5.0-8.6 FW vs. 12.2-225.3 FW	72
Gulls, *Larus* spp.; adults vs. juveniles		
Feather	13.1-20.0 FW vs. 25.3-60.5 FW	72
Liver	5.0-6.6 FW vs. 23.8-35.0 FW	72
Penguins, three species; liver; adults vs. juveniles	4.3-13.2 FW vs. 8.5-18.5 FW	72
Petrels, 19 species; adults vs. juveniles		
Feather	14-40 FW vs. 20-79 FW	72
Liver	4-45 FW vs. 8-75 FW	72
Shearwaters, three species of *Puffinus*; liver; adults vs. juveniles	6.4-7.2 FW vs. 4.6-446.3 FW	72
Surf scoter, *Melanitta perspicillata*; San Francisco Bay; 1985; liver; January vs.	37.8 (29.3-47.0) DW vs. 50.1 (41.3-58.3) DW	73

Table 3. Taxonomic group, organism, and other variables	Concentration[a] in (mg/kg)	Reference[b]
March		
Turkey, *Meleagris gallopavo*; Poland; 1988-91		
Kidney	3.0 (2.3-5.2) FW	66
Liver	4.7 (3.1-13.0) FW	66
Muscle	0.3 (0.2-0.4) FW	66
Brown pelican, *Pelecanus occidentalis*		
Egg		
Florida	(0.9-1.1) FW	1
South Carolina	(0.7-1.3) FW	1
Liver; Florida, Georgia, South Carolina	(4.3-9.0) FW	1
Flamingo, *Phoenicopterus ruber roseus*; France; 1988		
Blood serum, nestlings	0.25 (0.13-0.51) FW	74
Feather, adults	Max. 7.43 DW	74
Seabirds, 19 species; pelagic; North Pacific Ocean; 1982-87		
Kidney	4.7 FW	75
Liver	5.9 FW; Max. 7.7 FW	75
Muscle	5.1 FW	75
Shorebirds; Chile; November 1981-March 1982; near abandoned copper mine; liver vs. stomach contents		
Sanderling, *Calidris alba*	(9.2-11.5) FW vs. no data	76
Oyster catcher, *Haematopus ostralegus*	8.0 (6.8-8.6) FW vs. (24.4-27.2) FW	76
Kelp gull, *Larus dominicanus*	(3.8-6.3) FW vs. (0.8-3.4) FW	76
Grey gull, *Larus modestus*	6.2 (4-7.4) FW vs. (30-46.7) FW	76
Franklin's gull; *Larus pipixcan*	(4.7-5.5) FW vs. no data	76
Whimbrel, *Numenius phaeopus*	(3.9-17.8) FW vs. (6.1-86.4) FW	76
Eider, *Somateria mollissima*; Norway		
Egg	4.0 DW	1
Kidney	43.0 DW	1
Liver	367.0 DW	1
Muscle	13.0 DW	1
Tree swallow, *Tachycineta bicolor*; nestlings; acidified (pH 4.8) vs. reference (pH 6.7) lakes; Ontario, Canada; 1986-89		
Kidney	12.8 DW vs. 10.4 DW	77
Liver	42.6 DW (elevated metallothionein) vs. 17.3 DW	77
Redshank, *Tringa totanus*; liver; feeding on sandworms (*Nereis diversicolor*) containing 500-1,000 mg Cu/kg DW	30 DW	78
Marine mammals		
Gray whale, *Eschrichtius robustus*; stranded along North American west coast; 1988-91		
Brain	2.4 FW	79
Kidney	2.4 (0.5-4.9) FW	79
Liver	9.2 (0.6-25.0) FW	79
Stomach contents	21.0 (3.0-66.0) FW	79

Table 3. Taxonomic group, organism, and other variables	Concentration[a] in (mg/kg)	Reference[b]
Pilot whale, *Globicephala melaena*; stranded on Cape Cod, Massachusetts, 1986-90		
Adults		
Brain	9.1 (5.7-12.3) DW	80
Kidney	14.7 (7.4-21.0) DW	80
Liver	15.5 (9.9-20.3) DW	80
Ovary	5.5 (2.8-8.4) DW	80
Fetuses		
Brain	5.1 (4.4-6.2) DW	80
Kidney	20.0 (8.1-28.1) DW	80
Gray seal, *Halichoerus grypus*; British Isles and vicinity; 1988-89		
Blubber	<0.1 FW	81
Kidney	(3.2-27.0) FW	81
Liver	(4.0-26.0) FW	81, 82
Muscle	2.5 FW	81
Leopard seal, *Hydrurga leptonyx*; Antarctic; 1989		
Kidney	32.6 (22.5-43.8) DW	83
Liver	105.0 (98.0-116.0) DW	83
Muscle	4.0 (2.5-8.4) DW	83
Stomach contents	14.4 (13.3-16.4) DW	83
Pygmy sperm whale, *Kogia breviceps*; Argentina; found dead		
Heart	6.9 FW	84
Kidney	7.4 FW	84
Liver	10.3 FW	84
Other tissues	<2.3 FW	84
Weddell seal, *Leptonychotes weddelli*; Antarctic; 1989		
Kidney	22.8 (21.7-24.5) DW	83
Liver	57.4 (28-87) DW	83
Muscle	2.8 (2.1-3.1) DW	83
Crabeater seal, *Lobodon carcinophagus*; Antarctic 1989		
Kidney	25.6 (18.9-39.5) DW	83
Liver	71.1 (42-105) DW	83
Muscle	3.3 (2.7-4.3) DW	83
Harbour seal, *Phoca vitulina*; British Isles; 1988-89; liver	7-21 FW	82
Common harbour porpoise, *Phocoena phocoena*		
England; 1988-89; liver	6-160 FW	82
Greenland; 1988-89		
Kidney	5.5 (3.7-8.0) FW	85
Liver	12.0 (5-50) FW	85
Muscle	2.0 (1.1-5.4) FW	85
Skin	1.0 (0.6-1.9) FW	85
Whales; unidentified; 1989; found dead		
Blubber	0.2-1.7 FW	81
Liver	6.6-8.7 FW	81
Muscle	3.0 FW	81

Table 3. Taxonomic group, organism, and other variables	Concentration[a] in (mg/kg)	Reference[b]
La Plata river dolphin, *Pontoporia blainvillei*; Argentina; found dead		
Kidney	14 FW	84
Liver	16 FW	84
Other tissues	<2.8 FW	84
Striped dolphin, *Stenella coeruleoalba*; Wales; 1989; found dead		
Blubber	0.3-0.7 FW	81
Muscle	2.1 FW	81
Manatee, *Trichechus manatus*; Florida; 1977-81; liver	175.0 (4.4-1,200.0) DW	86
Dolphin, *Tursiops gephyreus*; Argentina; found dead		
Blubber	4.0 FW	84
Kidney	29.5 FW	84
Liver	77.7 FW	84
Melon	2.7 FW	84
Muscle	6.3 FW	84
Stomach contents	1.2 FW	84
Bottlenose dolphin, *Tursiops truncatus*		
England; 1988-89; liver	4-12 FW	82
Wales; 1989		
Blubber	0.9-1.1 FW	81
Muscle	2.5 FW	81
Polar bear, *Ursus maritimus*		
Canada, Northwest Territories; 1982-84; liver	81-146 DW	87
Svalbard (Arctic Ocean region); 1978-89; adults vs. juveniles		
Kidney	8.3 FW vs. 6.2 FW	88
Liver	42 FW vs. 33 FW	88
Welsh coast and Irish Sea; adults of 17 species of marine mammals; found dead; 1989-91; liver	Usually between 3.2 and 30.0 FW	89
Terrestrial mammals		
Impala, *Aepyceros melampus*; Kruger National Park, South Africa; 1989		
Kidney	(3-141) FW	90
Liver	(3-444) FW	90
Moose, *Alces alces*		
Alaska		
Hair	(5.2-11.7) DW	1
Hoof	(3.2-5.3) DW	1
Estonia; 1980-82		
Kidney	5.1 FW	91
Liver	3.1 FW	91
Poland; 1977-87; muscle	(0.9-2.6) FW	91
Sweden; 1979-80		
Kidney	(2.2-7.4) FW	91
Liver	(3.2-96.0) FW	91

Table 3. Taxonomic group, organism, and other variables	Concentration[a] in (mg/kg)	Reference[b]
Arctic fox, *Alopex lagopus*; Norway; 1984-86; liver	6.0 (2.4-26.0) FW	92
Wood mouse, *Apodemus sylvaticus*		
Kidney	(3.7-6.0) FW	1
Liver	(2.6-18.1) FW	1
Testes	(12.2-18.7) FW	1
Whole	(2.8-5.5) FW	1
Bison, *Bison bison*; Canada; 1986		
Kidney	6.7 (5.5-8.0) FW	91
Liver	35 (13-52) FW	91
European bison, *Bison bonasus*; Poland; 1987		
Kidney	4.4 FW	91
Liver	3.4 FW	91
Muscle	2.0 FW	91
Cattle, *Bos* spp.		
Poland; 1987-91		
Kidney	5.6 FW	93
Liver	29.0 FW	93
Muscle	1.2 FW	93
South Africa; 1989; found dead near copper smelter; surface soil had 103 mg Cu/kg DW (14 at reference site)		
Kidney	36 (6-83) FW; 108 DW	90
Liver	359 (161-600) FW; 1,078 DW	90
Various locations; liver	38.2-156.1 DW	94
Water buffalo, *Bubalus* sp.; Kruger National Park, South Africa; 1989; liver	Usually 18-80 FW; (6-144) FW	90
Bactrian camel, *Camelus bactrianus*; China; 1992		
Normal		
Blood	0.86 FW	95
Hair	6.4 DW	95
Camels with sway disease (severe copper deficiency)		
Nonpregnant females		
Blood	0.36 FW	95
Hair	4.3 DW	95
Pregnant camels vs. post-partum		
Blood	0.17 FW vs. 0.26 FW	95
Hair	3.0 DW vs. 3.3 DW	95
Dog, *Canis familiaris*		
Brain	3.9 FW; 19 DW	96
Kidney	6.9 FW; 26 DW	96
Liver	82 FW; 336 DW	96
Muscle	1.1 FW; 3.7 DW	96
Serum	0.7 FW	96
Whole body	2.3 FW	96
Coyote, *Canis latrans*; kidney	5.2 FW	97
Goat, *Capra hircus*; mother vs. newborn		
Hair	8.9 DW vs. 8.3 DW	1
Kidney	9.8 DW vs. 19.0 DW	1

Table 3. Taxonomic group, organism, and other variables	Concentration[a] in (mg/kg)	Reference[b]
Liver	11.3 DW vs. 63.3 DW	1
Roe deer, *Capreolus capreolus*; Poland; 1987-91		
Kidney	7.8 FW	91
Liver	28.0 FW	91
Muscle	4.5 FW	91
European red deer, *Cervus elaphus*		
The Netherlands; 1989-92		
Kidney	54-86 DW	98
Liver	14-18 DW	98
Poland; 1986-91		
Kidney	5.4 FW	91
Kidney	9.4 DW	99
Liver	12.0 FW	91

Copper concentrations in terrestrial invertebrates from industrialized areas range from 137 to 408 mg/kg DW. Soil invertebrates are not likely to accumulate copper but are important in recycling copper through terrestrial food webs. Aquatic invertebrates seldom contain as much as 95 mg Cu/kg DW, regardless of collection locale; exceptions include whole amphipods and lobster hepatopancreas (335-340 mg/kg DW) from copper-contaminated sites and many species of mollusks that normally contain 1,100-6,500 mg Cu/kg DW (Table 3).

Maximum concentrations of copper in elasmobranchs and teleosts from all collection sites range from 7-15 mg/kg DW in eyeballs, intestines, muscle, scales, vertebrae, heart, and gonads and from 16-48 mg/kg DW in gills, kidneys, skin, and spleens and reach 53 mg/kg DW in whole animals, 155 mg/kg DW in stomach contents, 208 mg/kg DW in feces, and 245 mg/kg DW in livers (Table 3).

Data on copper concentrations in field collections of amphibians and reptiles are scarce. Crocodile eggs contain as much as 60 mg Cu/kg DW; however, some toads (*Bufo* spp.) may contain as much as 2,100 mg Cu/kg DW in livers without apparent adverse effects (Table 3; Goldfischer et al. 1970).

Birds from contaminated sites may contain as much as 9-28 mg Cu/kg DW in eggs, muscle, and stomach contents; 43-53 mg/kg DW in kidneys, feces, and feathers; and 367 mg/kg DW in livers (Table 3).

Marine mammals usually contain less than 44 mg Cu/kg DW in all tissues except livers. Copper in livers seldom exceeds 116 mg/kg DW except in polar bears (146 mg/kg DW), and manatees, *Trichechus manatus*, (1,200 mg/kg DW) from a copper-contaminated site (Table 3). Maximum copper concentrations in terrestrial mammals from all collection sites are usually less than 29 mg/kg DW in all tissues except kidneys (108 mg/kg DW) and livers (1,078 mg/kg DW; Table 3).

Abiotic Materials

Copper concentrations in abiotic materials are comparatively elevated near copper smelters and urban areas (Table 2). Copper concentrations are also elevated in drinking water from copper pipes, in poultry and livestock manures, mine tailings, fossil fuels, shales (Table 2), sewage sludge, and in wastes from plating

industries, foundries, and coking plants (ATSDR 1990). Drinking waters from certain locales contain elevated concentrations of copper added intentionally to control algal growth; drinking water may account for 10-20% of the daily intake of copper in humans (USEPA 1980).

Copper is found in the rocks and minerals of the earth's crust, occurring usually as sulfides and oxides, and sometimes as metallic copper (USEPA 1980). The mean concentration of copper in the upper lithosphere ranges from 70-100 mg/kg, ranking 14th of the trace elements in this compartment (Schroeder et al. 1966). Copper in the environmental crust averages 50 mg/kg, but is higher (140 mg/kg) in ferromagnesium minerals (NAS 1977). Soil contamination by copper occurs around all known smelter locations; contamination may persist for decades, and plants and animals are often unable to survive the harsh chemical environments created (Hutchinson 1979). Italian soils have higher copper concentrations (51 mg/kg DW) than those of other European countries, probably as a result of the widespread and prolonged application of copper-based fungicides in Italian orchards and vineyards (Arduini et al. 1995).

Copper concentrations in lake sediments within a radius of 80 km from a smelter in northern Sweden are positively correlated with proximity to the smelter (Johnson et al. 1992). In some cases, lake sediments are sinks for copper, with little release to the overlying lake water. For example, copper-bearing mine tailings in Butte Lake, British Columbia, do not undergo oxidative diagenesis because of a rapid rate of accumulation and short exposure time to dissolved oxygen in bottom waters (Pedersen 1983). In Michigan, lakes with elevated concentrations of copper (34 µg/L) have low densities of fish populations (Ellenberger et al. 1994). In the Elizabeth River estuary of southern Chesapeake Bay, anthropogenic copper and other chelatable metals are present at concentrations sufficient to adversely affect growth and survival of the copepod *Acartia tonsa* (Sunda et al. 1990). In Norway, freshwater fish are present only when copper is less than 60 µg/L and some humic acids are present (Hodson et al. 1979). Successful reproduction of the spotted salamander (*Ambystoma maculatum*) occurs at low water concentrations of copper (<10 µg/L), lead, and aluminum, and high concentrations of silicon. Failed reproduction occurs at low water concentrations of silicon, and elevated concentrations of copper (>25 µg/L), lead, and aluminum (Blem and Blem 1991).

In marine ecosystems, the high copper levels measured in heavily contaminated coastal areas sometimes approach the incipient lethal concentrations for some organisms (Neff and Anderson 1977). Elevated copper concentrations in marine and estuarine environments may result from atmospheric deposition, industrial and municipal wastes, urban runoff, rivers, and shoreline erosion. Chesapeake Bay, for example, receives more than 1,800 kg of copper daily from these sources (Hall et al. 1988). Copper concentrations in abiotic marine materials are generally higher near shore than off shore. Copper is elevated in sediments of many marinas, probably from the copper antifouling bottom paints used on boats housed in these marinas (Hall et al. 1988). In New Zealand, copper concentrations in contaminated inshore sediments frequently exceed 100 mg Cu/kg DW vs. 14 mg Cu/kg DW at noncontaminated sites (Roper and Hickey 1994). The fine particle fraction of sediments collected near bulkheads made of chromated copper arsenate (CCA)-treated wood contain elevated concentrations of copper, chromium, and arsenic; metal concentrations decreased with increasing distance from the bulkhead. Sediments, for example, decreased from 11 mg Cu/kg DW in the vicinity of treated bulkheads to less than 2 mg/kg DW at more distant sites (Weis and Weis 1994).

Terrestrial Plants and Invertebrates

In general, copper concentrations in terrestrial vegetation seldom exceed 35 mg/kg DW, except near point sources of copper contamination and in certain copper-tolerant species (Table 3). The highest copper concentration recorded in nonaccumulator plants is 726 mg/kg DW in hair grass (*Deschampsia flexuosa*) near a smelter (Table 3). Several species of terrestrial plants accumulate spectacular concentrations of copper. Mint plants (*Aeolanthus* spp., *Elsholtzia* spp.) growing in copper-rich soils contain unusually high concentrations and are used as economic indicators of copper deposits in the former Soviet Union and the People's Republic of China (Jenkins 1980). The copper plant mint (*Aeolanthus biformifolius*), for example, normally contains as much as 13,700 mg Cu/kg DW whole plant (Table 3). Copper-tolerant species of mosses, lichens, fungi, and higher plants occur in Greenland, Canada, the former Soviet Union, Africa, and elsewhere. In Zambia and Rhodesia, the copper-tolerant *Becium homblei* is found only in soils containing more than 1,000 mg Cu/kg and is believed responsible for the discovery of copper deposits in those nations (Hutchinson 1979). Some species of copper-indicator plants in Zambia tolerate as much as 70,000 mg Cu/kg in the soil and accumulate as much as 3,000 mg Cu/kg in leaves (Hutchinson 1979).

Copper is not accumulated from soils by most crop plants, suggesting a soil-plant barrier for copper (Levine et al. 1989). Thus, corn (*Zea mays*) did not accumulate copper from soils treated with 365 kg of copper per surface hectare (as copper-rich pig manure or copper sulfate) over a 13-year period; corn yield is not affected under these conditions (Reed et al. 1993).

Copper burdens in terrestrial invertebrates are highest in organisms collected near industrial locations and urban areas or from copper-contaminated soils. The highest copper concentration recorded among terrestrial invertebrates is 408 mg Cu/kg DW soft parts in gastropods from urban areas (Table 3). Copper concentrations in pine moths (*Bupalus piniaria*) and pine noctuids (*Panolis flammea*) from industrialized areas range from 89-137 mg/kg DW, but are lower than dietary concentrations and suggest negligible accumulation (Heliovaara and Vaisanen 1990). Accumulations of as much as 60 mg Cu/kg DW in 17-year cicadas (*Magicicada* spp.) pose no apparent dietary threat to insectivorous birds (Clark 1992).

Earthworms from soils heavily contaminated with copper (2,740 mg/kg DW soil) can regulate copper more efficiently than cadmium and lead. However, copper is more toxic to earthworms than lead or zinc in the soil due, in part, to the inability of most soft tissues to synthesize copper-binding ligands when challenged with copper (Morgan and Morgan 1990).

In woodland ecosystems, copper concentrations in the litter horizon are rarely exceeded by those in soil animals—which play a key role in copper cycling (Wieser 1979). Meiofaunal feces comprise an efficient distributing system through which copper and other nutrients are cycled through the food web of woodland ecosystems. During a 12-month cycle the total copper bound in litter progresses through a cycle of chemical binding states. It may be released from a strongly chelated organic complex as the litter is attacked by the digestive juices of animals or it may be discharged in soluble form with the feces and become complexed again by the activity of microorganisms in these feces. When feces are ingested by coprophagous animals, such as isopods, the copper may become trapped in proteins or membrane-bound vesicles (Wieser 1979).

Aquatic Organisms

Copper is essential for the successful growth and development of many species of aquatic organisms, but its rate and extent of accumulation and retention are modified by numerous biological and abiotic variables. Abiotic variables known to modify copper concentrations in tissues of aquatic biota include water temperature, pH, salinity, and depth; the presence of other inorganics, organics, and chelators; the chemical species of copper; and proximity to anthropogenic point sources of copper. Biological variables affecting copper accumulations in marine organisms include the organism's age, size, and developmental stage; physiological or genetic adaptation to high copper substrates; inherent species differences; and tissue specificity, such as the thorax of barnacles, gill and osphradium of gastropods, and livers of teleosts (Eisler 1979). Among marine organisms, the highest accumulations are generally found in molluskan tissues and soft parts, especially those of cephalopods and oysters. In order of decreasing copper accumulations, mollusks are followed by crustaceans, macrophytes, annelids, tunicates, algae, echinoderms, and coelenterates. Lowest concentrations of copper were consistently found among the vertebrates—elasmobranchs, fishes, mammals—and strongly indicates a discrimination against copper among the highest marine trophic levels examined (Eisler 1979, 1981). Aquatic mollusks and arthropods that possess hemocyanin—a copper-containing respiratory pigment—have elevated tissue and plasma copper concentrations when compared to the ambient medium (Neff and Anderson 1977). Unlike many species of invertebrates, no vertebrate animal has a copper pigment as the main metallic constituent of blood (Schroeder et al. 1966). Marine organisms without hemocyanin have lower tissue concentrations of copper than those possessing this respiratory pigment (Neff and Anderson 1977).

Diet is the most important route of copper accumulation in aquatic animals, and food choice influences body loadings of copper. For example, whole body copper concentrations in aquatic insects from copper-contaminated rivers are highest in detritovores (as high as 102 mg/kg DW), followed by predators (54 mg/kg DW) and omnivores (43 mg/kg DW; Cain et al. 1992). Little or no biomagnification of copper is evident in freshwater food chains (Stokes 1979).

Copper concentrations in freshwater macrophytes near mining areas are elevated (as much as 256 mg/kg DW) compared to conspecifics collected from more remote sites (Stokes 1979). Bioconcentration factors (ratio

of milligrams of copper per kilogram fresh weight organism to milligrams of copper per liter of ambient water) for copper by various species of freshwater algae range from 770-83,000. In general, copper accumulations in algae are higher at pH 8 than at pH 5; under conditions of low oxygen and reduced illumination; at low ambient concentrations of calcium, cobalt, zinc, magnesium, manganese, and organic chelators; and at high ambient concentrations of fluoride (Stokes 1979). Benthic communities in the vicinity of bulkheads made of chromated copper arsenate-treated wood had elevated concentrations of these elements, reduced species richness and diversity, and reduced numbers of total organisms when compared to reference sites (Weis and Weis 1994). American oysters (*Crassostrea virginica*) from a canal lined with chromated copper arsenate-treated wood had 150 mg Cu/kg FW soft parts vs. 20 mg Cu/kg FW in oysters from a more distant site (Weis and Weis 1993).

Copper concentrations in cephalopod mollusks are, in general, higher than those in bivalve mollusks; in cephalopods, 50 to 80% of the copper is localized in the digestive gland (Miramand and Bentley 1992). Copper concentrations in tissues of clams *(Macoma balthica*) in San Francisco Bay are associated with seasonal variations in tissue weight, concentrations of copper in the sediments, and anthropogenic inputs from nearby sources (Cain and Luoma 1990). In cockles (*Cerastoderma edule*), copper concentrations in tissues decrease with increasing age, decrease in summer when compared to other seasons, and increase with increasing sediment copper concentrations (Savari et al. 1991). In the cockle (*Anadara trapezium*), tissue copper concentrations are positively related to dissolved copper concentrations in the water column and independent of sediment copper concentrations (Scanes 1993). Small freshwater clams (*Anodonta grandis*) have higher copper concentrations in soft tissues than large clams because small clams take up copper at a greater rate and excrete it more slowly than large clams (Pip 1990); a similar case is made for oysters and other bivalve mollusks (Weis et al. 1993a). Zebra mussels (*Dreissena polymorpha*) regulate body copper concentrations at water copper levels of 13 µg Cu/L and lower (Camusso et al. 1994). Proximity to point sources, such as sewage discharge plants, is associated with elevated copper burdens in common mussels, *Mytilus edulis* (Ward 1990). Copper concentrations increased in mussels (*Mytilus* spp.) analyzed in the coastal mussel watch program between the late 1970's and the late 1980's. This may be due to increased availability of copper from anthropogenic sources; however, concentrations of other metals (silver, nickel, cadmium, lead, zinc) in mussels analyzed during this period showed a decrease (Lauenstein et al. 1990).

Pacific oysters near a copper recycling facility in Taiwan have elevated concentrations of copper (as high as 4,400 mg/kg DW soft parts), a characteristic green color, and low survival after exposure to waste effluents for 3 months (Hung et al. 1990). Diet is the major pathway by which greenish-colored Pacific oysters accumulate copper; initial daily accumulation rates are as high as 214 mg Cu/kg DW soft parts (Han and Hung 1990). Elimination of 50% of the copper from green Pacific oysters with elevated copper loadings takes only 11.6 days vs. 25.1 days in reference oysters (Han et al. 1993). Elevated concentrations of copper in Pacific oysters (135 mg/kg DW soft parts) near a marina in Arcachon Bay, France, are attributed to the ban on tributyltin antifouling paints in 1982 and the subsequent growing use of copper-based antifouling paints (Claisse and Alzieu 1993). Copper concentrations in soft tissues of the American oyster are higher in oysters from low salinity waters than those from more saline waters; accumulations are not related to sediment copper concentrations in the immediate environment (Huggett et al. 1975). In Maryland, copper concentrations in tissues of the American oyster are seasonally highest in July and lowest in October and higher in low salinity waters than in high salinity waters (Roesijadi 1994). In Australia, copper concentrations in oyster soft parts from the Georges River, New South Wales, rose from 20 mg/kg FW to 46 mg/kg FW in the 1970's to as high as 93 mg/kg FW in 1987, possibly as a result of urban and industrial discharges; this concentration exceeds the recommended limit of 70 mg Cu/kg FW in shellfish edible tissues for protection of human health in Australia (Brown and McPherson 1992).

In amphipod (*Orchestia gammarellus*) crustaceans, copper concentrations vary seasonally due to variable copper loadings, are higher in organisms from contaminated sites than reference sites, and higher in females with juveniles in the brood pouch than females without juveniles (Moore et al. 1991). The existence of copper-rich granules is common to all invertebrate phyla; these granules are usually found in the digestive gland or its evolutionary equivalent, and their formation is related to high concentrations of copper in the immediate environment (Weeks 1992). The tolerance of talitrid amphipods to high concentrations of ambient copper is attributable, in part, to the formation of intracellular granules within the cells of the ventral caeca (Weeks 1992). In the shore crab (*Carcinus mediterraneus*), tissue copper concentrations are lower in winter than in summer and correlate positively with total protein and hemolymph copper contents (Devescovi and Lucu 1995). Elevated copper burdens in hemolymph of crabs probably reflects the incorporation of copper atoms in the structure of

hemocyanin, the major hemolymph protein (Depledge et al. 1993). Marine decapod crustaceans regulate tissue copper concentrations within the range of 25 to 35 mg/kg DW (Neff and Anderson 1977).

In *Limnodrilus* sp., an oligochaete worm, copper bioavailability from surficial freshwater sediments is associated with the amount of copper present in the manganese oxide fraction of the sediment. The redox potential and pH in the gut of *Limnodrilus* allows the dissolution of the manganese oxide coating, making copper and other metals available for uptake (Diks and Allen 1983).

Copper concentrations in freshwater fishes collected nationwide in the United States have not changed significantly since 1978 (Schmitt and Brumbaugh 1990). In 1984, samples with the highest copper concentrations were Mozambique tilapia *(Tilapia mossambica*) from Hawaii and white perch (*Morone americana*) from the Susquehanna River in Maryland. These locations have historically yielded fish with relatively high concentrations of copper; in Hawaii, this may develop from copper-containing pesticides (Schmitt and Brumbaugh 1990). Copper concentrations in fishes are usually higher in liver than other tissues, higher in fish from copper-contaminated lakes than reference lakes, and higher in small fish than large fish of the same species (Cuill et al. 1970; Eisler 1984; ATSDR 1990; de Wet et al. 1994; Table 3). Residue data on copper in fish that are dead on collection are probably worthless for purposes of risk assessment owing to copper accumulation after death (Eisler and Gardner 1973). Among sharks collected in British waters, copper concentrations in all tissues are highest from inshore demersal species and lowest from offshore pelagic species, with males having higher copper concentrations in liver than females (Vas 1991).

Copper concentrations in tissues of marine vertebrates tend to decrease with increasing age of the organism (Law et al. 1992). Concentrations of copper in marine and coastal vertebrates—including elasmobranchs, teleosts, and pinniped mammals—are related to the age of the animal. Regardless of species or tissues, except brain, concentrations decrease with increasing age of the organism; brain copper concentrations in marine mammals increase with organism age (Eisler 1984). Decreases in tissue copper content are also associated with spawning migrations of salmonids when entering freshwater from the sea and with reproductive cycles of cod and other gadoids (Eisler 1984). In the copper-contaminated Miramichi River, Canada, populations of Atlantic salmon (*Salmo salar*) are reduced in numbers due to poor survival and reproduction (Sprague et al. 1965). Copper-containing mine wastes entering the Northwest Miramichi River cause many adult Atlantic salmon on their normal upstream spawning migration to return prematurely downstream; about 62% do not reascend. Downstream returns of salmon rose from 1 to 3% before pollution to 10 to 22% during four years of pollution. During some periods, dissolved copper and zinc concentrations exceed the lethal levels for immature salmon and the avoidance concentrations for subadults (Sprague et al. 1965; Saunders and Sprague 1967).

In polar bears, concentrations of copper in liver are 3-5 times higher than their seal diet (Braune et al. 1991). Copper concentrations in liver and kidney of polar bears are lower in juveniles than adults (Norheim et al. 1992), which is contrary to a reverse trend noted in most species of vertebrates. Neonatal marine mammals, for example, have higher concentrations of copper in liver than those found in the mother (Law et al. 1992). The use of copper herbicides in Florida to control aquatic plants may be hazardous to the endangered manatee. Copper concentrations in livers of these aquatic herbivores from areas of high copper herbicide use are as high as 1,200 mg/kg DW. The maximum copper concentrations in livers of copper-challenged manatees are higher than any copper concentration measured in any species of free-ranging mammalian wildlife and are comparable to copper concentrations in livers of some species of domestic animals poisoned by copper (O'Shea et al. 1984).

Amphibians and Reptiles

Eggs of the Jefferson salamander (*Ambystoma jeffersonianum*) from a series of ponds that contain 1-25 µg Cu/L have—at the higher copper concentrations—a reduction in hatching success and an increase in embryonic mortality (Horne and Dunson 1995).

For reasons unknown, livers of some adult giant toads (*Bufo marinus*) normally contain grossly elevated concentrations of copper (>2,000 mg/kg DW). The toads' livers are undamaged by this level of copper, and this lack of effect is in sharp contrast to human patients with Wilson's disease (2,000 mg Cu/kg DW liver) wherein hepatocyte degeneration, necrosis, and ultimately cirrhosis result (Goldfischer et al. 1970). In toad livers, the

copper is sequestered in lysosomes, which seems to protect the cell from the toxic effects of copper. In contrast, copper in livers of humans with Wilson's disease is diffusely distributed in the cytoplasm of hepatocytes and is associated with severe and often fatal pathological changes (Goldfischer et al. 1970).

Birds

Season of collection and organism age affect copper concentrations in avian tissues. In livers of surf scoters (*Melanitta perspicillata*) from San Francisco Bay, copper concentrations are higher in March than in January; in livers of canvasbacks (*Aythya valisineria*) from Louisiana, concentrations are lower in November than later months; and in primary flight feathers of mallards (*Anas platyrhynchos*) and black ducks *(Anas rubripes*) from the vicinity of a smelter in Sudbury, Ontario, copper concentrations are highest in autumn (Ranta et al. 1978). Copper concentrations in tissues of coastal seabirds tend to decrease with increasing age (Eisler 1984). In New Zealand, younger marine birds have higher concentrations of copper in livers than adults (Lock et al. 1992). But juveniles and adults of common murres (*Uria aalge*) from Scotland have similar concentrations of copper in kidneys, livers, and muscle (Stewart et al. 1994).

In general, birds retain a very small portion of copper and other metals ingested (Bryan and Langston 1992). It is therefore noteworthy that livers of some canvasbacks collected in Louisiana (Custer and Hohman 1994) and livers of some mute swans (*Cygnus olor*) from England (Bryan and Langston 1992) both contain more than 2,000 mg Cu/kg DW. In the case of mute swans, several thousands of milligrams of copper per kilogram dry weight occur in the blackened livers; blackening is attributed to ingestion of flakes of copper-based antifouling paints (Bryan and Langston 1992). Tree swallows (*Tachycineta bicolor*) nesting near acidified aquatic ecosystems accumulate sufficient copper from the diet to induce elevated hepatic metallothionein concentrations (St. Louis et al. 1993). However, there is no evidence of copper biomagnification in the sediment food chain of sediment-pondweed-red-knobbed coot (*Fulica cristata*; van Eeden and Schoonbee 1993).

Mammals

Impalas (*Aepyceros melampus*) found dead in Kruger National Park, South Africa, had elevated concentrations of copper in livers (maximum 444 mg/kg FW) and kidneys (maximum 141 mg/kg FW); authors assert that copper poisoning is the most likely cause of death (Gummow et al. 1991), but this needs verification. Copper concentrations in bones, kidneys, and livers of white-tailed deer (*Odocoileus virginianus*) near a copper smelter and from distant sites are about the same; however, deer near the smelter have significantly elevated concentrations of cadmium in kidneys and livers, lead in bone, and zinc in kidneys (Storm et al. 1994).

Only a small portion (0.037%) of copper mining wastes discharged into riparian wetlands is bioavailable to resident rodents, as judged by measurements of copper in carcasses of mice and voles (Pascoe et al. 1994). Populations of brown-backed voles (*Clethrionomys rufocanus*) and other microtine rodents (*Microtus* spp., *Lemmus*) are low or absent in the vicinity of Russian copper-nickel smelters (Kataev et al. 1994). The reasons for this decline are unknown but may be due to a decrease in the abundance of important food plants (lichens, mosses, seed plants), and—as shown in preference studies—to an avoidance of plants from the contaminated area (Kataev et al. 1994). Bank voles (*Clethrionomys glareolus*) from areas of Poland subjected to various degrees of industrial contamination have copper concentrations in tissues comparable to those in animals from polluted sites in North America and the United Kingdom (Sawicka-Kapusta et al. 1990). Compared to animals from a reference site, muskrats (*Ondatra zibethicus*) from a site contaminated by copper and other chemicals have higher concentrations of copper in kidneys, and have smaller spleens, larger adrenals, less fat, and lower body weight (Halbrook et al. 1993).

In Poland near copper foundries, livers from cattle (*Bos* sp.) have higher copper concentrations (35-140 mg/kg FW) than cattle from agricultural regions (7-32 mg/kg FW); however, kidney copper concentrations are comparable for both regions (Falandysz 1993a). Cattle found dead in South Africa near a copper smelter have elevated levels of copper in liver (600 mg/kg FW; 1,078 mg/kg DW); airborne copper from the smelter is considered the most likely cause of death (Gummow et al. 1991). Sheep held for 150 days in a paddock near a heavily-traveled highway have significantly elevated copper concentrations in wool; these differences are not as pronounced in hair from horses (*Equus caballus*) and alpacas (*Lama pacos*) held under similar conditions (Ward and Savage 1994).

Interspecies differences in copper contents are considerable. Serum from domestic dogs (*Canis familiaris*) lacks the strong copper binding site available on the serum albumin molecule of humans and rats. Accordingly, copper concentrations in livers from dogs (82 mg/kg FW; 336 mg/kg DW) are normally about 12 times higher than those of human livers and 19 times higher than those of rat livers (Goresky et al. 1968).

Human foods that are particularly rich in copper (20-400 mg Cu/kg) include oysters, crustaceans, beef and lamb livers, nuts, dried legumes, dried vine and stone fruits, and cocoa (USEPA 1980). In humans, copper is present in every tissue analyzed (Schroeder et al. 1966). A 70-kg human male usually contains 70-120 mg of copper (USEPA 1980). The brain cortex usually contains 18% of the total copper, liver 15%, muscle 33%, and the remainder in other tissues—especially the iris and choroid of the eye. Brain gray matter (cortex) has significantly more copper than white matter (cerebellum); copper tends to increase with increasing age in both cortex and cerebellum. In newborns, liver and spleen contain about 50% of the total body burden of copper (USEPA 1980). Liver copper concentrations were usually elevated in people from areas with soft water (Schroeder et al. 1966). Elevated copper concentrations in human livers are also associated with hepatic disease, tuberculosis, hypertension, pneumonia, senile dementia, rheumatic heart disease, and certain types of cancer (Schroeder et al. 1966).

Copper Deficiency Effects

General

Adverse effects of copper deficiency are documentable in terrestrial plants and invertebrates, poultry, small laboratory animals, livestock—especially ruminants—and humans. Data are scarce or missing on copper deficiency effects in aquatic plants and animals and in avian and mammalian wildlife. Copper deficiency in sheep—the most sensitive ruminant mammal—is associated with depressed growth, bone disorders, depigmentation of hair or wool, abnormal wool growth, fetal death and resorption, depressed estrous, heart failure, cardiovascular defects, gastrointestinal disturbances, swayback, pathologic lesions, and degeneration of the motor tracts of the spinal cord (NAS 1977).

Terrestrial Plants and Invertebrates

Copper is an essential micronutrient of all higher plants studied, being a cofactor for the enzymes polyphenol oxidase, monophenol oxidase, laccase, and ascorbic acid oxidase (Schroeder et al. 1966). In copper-deficient soils, copper is strongly held on inorganic and organic exchange sites and in complexes with organic matter (Thornton 1979), causing reduced availability of copper to vegetation in these soils. Copper deficiency in terrestrial plants is usually associated with reduced growth, abnormally dark coloration in rootlets, and chlorotic leaves (Gupta 1979). In agricultural crops, copper deficiency occurs at less than 1.6 mg dissolved Cu/kg DW soil (Thornton 1979), and in sensitive plants at less than 2 to less than 5 mg total Cu/kg DW leaves (Gupta 1979). In fruit trees, copper deficiency is characterized by death of apical buds, formation of multiple buds, and yellowing (chlorosis) of the leaf margins (NAS 1977). Copper deficiency in alfalfa (*Medicago sativa*) and clover (*Trifolium* spp.) is associated with a faded green leaf color, growth inhibition, and withering (Gupta 1979). In grasses, copper deficiency is characterized by chlorosis, stunting, and necrosis and in cereals by pale color, reduced growth, and a reduction in the number of pollen grains (Gupta 1979).

Increased yields of various crops occur when copper salts are added to fertilizers at 300 to 800 mg Cu/m^3 (NAS 1977). In corn (*Zea mays*) and other vegetables, younger plants are more sensitive to copper deficiency than mature plants; in all cases, copper-deficient vegetables show chlorosis, reduced growth and reproduction, and low survival (Gupta 1979).

No evidence of copper deficiency exists in terrestrial species of invertebrates examined; however, relatively low concentrations of copper stimulated growth and reproduction. Reproduction in mites (*Platynothrus peltifer*) increases when fed diets containing 28 mg Cu/kg DW (vs. 13 mg/kg in controls) for 3 months (Denneman and van Straalen 1991). And juvenile earthworms (*Eisenia andrei*) show increased growth at 18 mg Cu/kg DW soil after 12 weeks (van Gestel et al. 1991).

Aquatic Organisms

No documented report of fatal copper deficiency is available for any species of aquatic organism. And no correlation is evident in aquatic biota for the presumed nutritional copper requirements of a species and its sensitivity to dissolved copper (Neff and Anderson 1977). Extremely low copper concentrations (5.5 and 6.7 mg/kg DW) in whole bodies of 2 of 17 species of crustaceans from the Antarctic Ocean support the hypothesis that certain Antarctic species may show copper deficiencies or reduced metal requirements (Petri and Zauke 1993).

Birds and Mammals

Copper deficiency is not a major public health concern in the United States (Percival 1995). Copper deficiency is rarely observed in humans except in cases of severely malnourished children or those with Menkes' disease—an X-linked recessively inherited disorder. This disease is a severe congenital copper deficiency marked by slow growth, progressive cerebral degeneration, convulsions, temperature instability, bone alterations, and peculiar steel-like hair (ATSDR 1990; Yoshimura et al. 1995). Treatment of Menkes' disease is now restricted to parenteral administration of copper salts, although complete prevention of neurodegradation is difficult to obtain (Yoshimura et al. 1995). Copper deficiency is sometimes reported in humans after intestinal resection surgery (reduced absorptive surface), in people who consume high levels of zinc (zinc induces intestinal metallothionein that blocks copper transport), in infants who consume a diet based on cow milk (cow milk is a poor source of copper), and in genetic cases (Percival 1995). Moderate copper deficiency also exists in burn and trauma patients, two groups at high risk for sepsis (DiSilvestro et al. 1995).

An inherited abnormal copper metabolism has been established in certain strains of mice, rats, and dogs (Sugawara and Sugawara 1994). Feeding a copper-deficient diet to these animals may prevent acute hepatitis. In rats with abnormal copper metabolism and hereditary hepatitis, the feeding of a copper-deficient diet (0.5 mg Cu/kg ration for 35 days) prevents copper accumulation (94-139 mg Cu/kg DW liver) and dysfunction. But feeding a normal diet of 30 mg Cu/kg DW ration to these rats produces liver copper concentrations of 375 mg/kg DW (Sugawara and Sugawara 1994). Administered copper protects copper-deficient strains of mice against neurodegradation, and protects ponies against selenium poisoning when pretreated with 20 or 40 mg Cu/kg BW (Stowe 1980).

Chickens (*Gallus domesticus*) given diets deficient in copper (less than 2.7 mg kg ration) have anemia, poor growth, low survival, and a high frequency of cardiovascular and skeletal lesions (Carlton and Henderson 1963, 1964a, 1964b). It is emphasized, however, that copper deficiency does not usually arise from eating a copper-poor diet because copper is found ubiquitously in foods (Percival 1995). Chickens, turkeys (*Meleagris gallopavo*), cattle, and pigs deficient in copper are prone to die suddenly (Gallagher 1979). Sudden death in some copper-deficient species is sometimes associated with rupture of a major blood vessel or rupture of the heart (Carlton and Henderson 1964b; NAS 1977; ATSDR 1990; Saari et al. 1994). Male weanling rats given a copper-deficient diet of 0.13 mg Cu/kg ration (vs. copper-normal diet of 5.7 mg Cu/kg ration) for 7 weeks show high mortality (24%) from cardiac rupture; ruptured hearts had elevated concentrations of sodium, potassium, and calcium, and depressed magnesium (Saari et al. 1994). Copper deficiency in weanling rats is confirmed by low activities of ceruloplasmin in serum and by superoxide dismutase in liver and serum (DiSilvestro et al. 1995). Skeletal deformities and leg fractures occur in copper-deficient chickens, dogs, pigs, sheep, cattle, and children because of decreased tensile strength of bones (Carlton and Henderson 1964a; NAS 1977; Gallagher 1979). In lambs from copper-deficient ewes, locomotor disturbances of gait or posture occur because of lesions of excessive myelination of the central nervous system (Gallagher 1979).

Copper deficiency in humans and other mammals is characterized by slow growth, hair loss, anemia, weight loss, emaciation, edema, altered ratios of dietary copper to molybdenum and other metals, impaired immune response, decreased cytochrome oxidase activity, central nervous system histopathology, decreased phospholipid synthesis, fetal absorption, and eventually death (NAS 1977; Gallagher 1979; Kirchgessner et al. 1979; USEPA 1980; ATSDR 1990; Percival 1995).

In laboratory white rats, signs of copper deficiency include reductions in tissue copper concentrations; reduced activities of cytochrome oxidase, superoxide dismutase, succinoxidase, and ceruloplasmin; increased activity of 7-ethoxyresorufin *O* deethylase (EROD) in small intestines; anemia associated with low hematocrit and hemoglobin; increased acute inflammatory response; increased sensitivity to endotoxins; central nervous

system lesions; and reduced phospholipid synthesis (Gallagher 1979; Johnson and Smith 1994; Schuschke et al. 1994; DiSilvestro et al. 1995). Copper-deficient rats also have prolonged sleeping times and significant reductions in activities of aniline hydroxylase and hexobarbital oxidase in liver (Moffitt and Murphy 1973). Earliest signs of copper deficiency in rats include low concentrations of copper in livers (1.4-<3.0 mg/kg DW vs. 12.6-15.0 mg/kg DW in controls); profound reductions in activities of cytochrome oxidase and succinoxidase; and reductions in hematocrit, hemoglobin, ceruloplasmin, and phospholipid synthesis (Gallagher 1979; Johnson and Smith 1994). Severe copper deficiency in rats results in anemia characteristic of defective hemoglobin synthesis resulting from abnormal use of iron by mitochondria in heme synthesis (Johnson and Smith 1994). Copper-deficient rats are extraordinarily sensitive to endotoxins and die after receiving normally sublethal doses of various endotoxins (DiSilvestro et al. 1995). Copper deficiency-induced lesions in the central nervous system are produced experimentally in rats and guinea pigs and are a characteristic feature of Menkes' disease (Gallagher 1979).

Sway disease of Bactrian camels (*Camelus bactrianus*)—characterized by anemia, emaciation, falling, fractures, and death—is caused by copper deficiency associated with high molybdenum content in soils and forage; deficiency effects are aggravated during reproduction (Zong-Ping et al. 1994).

Sheep fed copper-deficient diets of less than 2.5 mg Cu/kg DW ration (vs. a normal diet of 11.0 mg Cu/kg DW) produce a high frequency of swaybacked lambs. Swaybacks have lower concentrations of copper in liver than nonswaybacked lambs from copper-deficient ewes; both groups have lower concentrations of copper in livers than normal lambs (Lewis et al. 1967; Buckley and Tait 1981).

Copper deficiency effects are reported in mink (*Mustela vison*) and domestic swine. Copper deficiency in mink, as judged by reduced survival, occurs by feeding rations containing the equivalent of 3.5 mg Cu/kg BW daily for a period of 50 weeks (ATSDR 1990). Swine, which seem to have higher copper requirements than mink, given low copper diets equivalent to 15 to 36 mg Cu/kg BW daily for 7 days have decreased hemoglobin, hematocrit, and growth rate (ATSDR 1990).

Dietary copper deficiency increases the acute inflammatory response in rats and other small laboratory animals (Schuschke et al. 1994). The release of inflammatory mediators, such as histamine and serotonin, from mast cells increases the vascular permeability of postcapillary venules and results in edema. In copper-deficient rats, release of histamine from mast cells positively correlates with frequency of the acute inflammatory response. Copper-deficient rats (0.6 mg Cu/kg DW ration for 4 weeks) have more mast cells in muscle than copper-adequate controls given diets containing 6.3 mg Cu/kg DW ration; however, histamine content of mast cells is not affected (Schuschke et al. 1994). An early clinical sign of copper deficiency is a reduction in the number of circulating neutrophils; the mechanism for copper-deficient neutropenia (leukopenia in which the decrease in white blood cells is chiefly neutrophils) is unknown (Percival 1995). Proposed mechanisms to account for neutropenia from copper deficiency include (1) early destruction of bone marrow progenitor cells; (2) impaired synthesis of neutrophils from progenitor cells; (3) a decrease in the rate of cellular maturation in the bone marrow; (4) impaired secretion of neutrophils from the bone marrow; and (5) rapid clearance of circulating copper-deficient neutrophils (Percival 1995).

Lethal and Sublethal Effects

General

Copper is toxic to sensitive species of terrestrial vegetation at greater than 40 µg/L nutrient solution (seedlings of pines, *Pinus* spp.), at greater than 10 mg/kg DW leaves (cucumber, *Cucumis sativus*), and greater than 60 mg extractable Cu/kg DW soil (sweet orange, *Citrus sinensis*; Table 4). Among sensitive species of terrestrial invertebrates, adverse effects on survival, growth, or reproduction occur at 2 µg Cu/cm^2 on paper discs (earthworms), greater than 50 mg Cu/kg diet (larvae of gypsy moth, *Lymantria dispar*), and 53 to 70 mg Cu/kg DW soil (earthworms and soil nematodes; Table 4).

Table 4. Effects of copper on representative terrestrial plants and invertebrates.

Table 4. Organism, copper concentration or dose, and other variables	Effects	Reference[a]
Plants		
Agricultural crops from soils containing dissolved copper		
0.0-1.6 mg/kg soil	Copper deficiency in susceptible crops	1
1.7-2.4 mg/kg soil	Slight deficiency	1
2.5-4.0 mg/kg soil	Deficiency unlikely	1
>4.0 mg/kg soil	Soil well supplied with copper	1
Sweet orange, *Citrus sinensis*; 4-year old trees; M3 extractable soil copper >60 mg/kg DW (from treated plots containing about 120 kg Cu/ha)	Growth adversely affected; positive correlation between copper concentrations in feeder roots (4 to 450 mg Cu/kg DW) and M3 extractable soil copper	17
Cucumber, *Cucumis sativus*; leaves		
<2 mg/kg dry weight (DW)	Deficient	2
2-10 mg/kg DW	Sufficient	2
>10 mg/kg DW	Toxic	2
Soybean, *Glycine max*; leaves		
<4 mg/kg DW	Deficient	2
10-30 mg/kg DW	Sufficient	2
>50 mg/kg DW	Toxic	2
Pasture grasses; aboveground portions		
<5 mg/kg DW	Deficient	2
5-12 mg/kg DW	Sufficient	2
>12 mg/kg DW	Toxic	2
Seedlings of stone pine, *Pinus pinea* and maritime pine, *Pinus pinaster*; exposed to nutrient solutions containing 0.4 (controls) 4, 40, or 200 µg Cu/L for as long as 4 weeks		
4 µg/L	Slight to no enhancement of root elongation	16
40 µg/L	Taproot elongation reduced but partial growth recovery in 7 days; cell membrane damage evident after 10 days	16
200 µg/L	Root growth completely inhibited within 3 days in both species	
Faba bean, *Vicia faba*; cultured hydroponically with nutrient solutions containing 100 mg Cu/L for 24 days; shoots analyzed before (day 4) and after (day 24) 20-day infestation by the black bean aphid, *Aphis fabae*. Controls were raised in copper-free nutrient solutions	Aphid infestation caused a significant reduction in copper content of shoots from 51 mg/kg DW to 17 mg/kg; copper in control was 25 mg/kg DW prior to aphid infestation and 14 mg/kg after 20-day infestation	3
Invertebrates		
Soil nematode, *Caenorhabditis elegans*		
70 mg/kg DW sandy soil for 24 h	LC50	4
105 mg/L for 24 h; no soil	LC50	4

Table 4. Organism, copper concentration or dose, and other variables	Effects	Reference[a]
1,061 mg/kg loam substrate for 24 h	LC50	4
2,476 mg/L for 24 h; loam substrate	LC50	4
Soil ciliate, *Colpoda steini*		
250 µg/L for 24 h	Growth reduced 50%	5
Fruitfly, *Drosophila melanogaster*		
In culture medium containing 80 µg cm^2 for 4 weeks	Survival reduced 35%; copper elevated in cytoplasm, malpighian tubule epithelial cells, and other tissues	6
Earthworms, three species; 40-238 mg/kg soil; exposure duration unknown	No effect on growth, survival, or reproduction	7
Earthworm, *Eisenia andrei*; juveniles; exposure for 12 weeks		
18 mg/kg DW soil	Growth stimulated	8
56 mg/kg DW soil	No effect on growth or reproduction	8
100 mg/kg DW soil	<50% effective in reducing growth; inhibited sexual development	8
Earthworm, *Eisenia fetida*		
32 mg/kg DW soil for 56 days	No effect on cocoon production	9
53.3 (32.5-186.0) mg/kg DW soil for 56 days	Cocoon production reduced 50%	9
210 mg/kg DW soil for 56 days	No deaths	9
555 (460-678) mg/kg DW soil for 56 days	50% dead	9
683 (570-812) mg/kg DW soil for 14 days	50% dead	9
Earthworm, *Eisenia fetida andrei*		
Adults held in soil containing as much as 300 mg/kg DW for 3 weeks; resultant cocoons incubated in uncontaminated soil for 5 weeks to assess hatchability soil for 5 weeks to assess hatchability	No adverse effects on cocoon production or hatchability in soil containing 60-120 mg/kg DW; adult growth retarded during exposure at 300 mg/kg DW	10
Earthworm, *Lumbricus rubellus*		
100-150 mg/kg DW soil	Decreased cocoon production	11
150-300 mg/kg DW soil	Decrease in litter breakdown activity	11
>300 mg/kg DW soil	Reduced growth and increased mortality	11
1,000 mg/kg DW soil for 6 weeks	Lethal to 50%	11
Earthworm, *Lumbricus terrestris*		
Exposed for five days to filter paper disc containing 0.5, 1, 2, 4, or 8 µg Cu/cm^2	At 4 µg/cm^2 and higher, mortality was >90%; 20% were dead at 2 µg/cm^2 and none were dead at lower concentrations. Whole worms contained, in mg Cu/kg DW, 5.9 in controls, 28.5 in the 0.5 group, and 73.1 in the 1.0 group. At sublethal concentrations, worms had decreased lysozyme activity in coelomic fluid and coelomocytes	12
Gypsy moth, *Lymantria dispar*		
Larvae were fed diets containing 10, 50, 250, or 1,250 mg/kg ration from first instar to pupation; effects measured on development rate,	No adverse effects at 10 mg/kg diet. Significant adverse effects at 50 mg/kg and higher on development and reproductive success and at 250 mg/kg and higher on growth	13

Table 4. **Organism, copper concentration or dose, and other variables**	**Effects**	**Reference[a]**
growth, survival, and reproductive success		
Oribatid mite, *Platynothrus peltifer*		
Fed diets with 13 (control), 28, 64, 168, 598, or 1,498 mg Cu/kg DW diet for 3 months	No deaths at any dose. Reproduction increased at 28 mg/kg but decreased steadily with increasing dose. The no-observable-effect-concentration (NOEC) for reproduction was 168 mg/kg diet; the NOEC for growth was 598 mg/kg. Copper concentrations in whole mites increased significantly at dietary loadings >168 mg/kg	7
84 mg/kg DW soil	NOEC on growth, survival, or reproduction	7
Soil faunal communities		
Forest soil treated to contain 100, 200, 400, or 600 mg Cu/kg DW; nematodes and macroarthropods enumerated after 7 days	Sensitive species of nematodes and mites were reduced in number at 100 mg/kg soil; total nematode and arthropod numbers declined at 200 mg/kg and higher	14
Termites, subterranean; Karachi, Pakistan; termite-infested area (*Microtermes* spp., *Heterotermes* spp., *Coptotermes* spp., *Odontotermes* spp.)		
Fir (*Abies pindrow*) wooden stakes coated with 5% copper sulfate in gelatin solution vs. uncoated stakes	Copper-treated stakes prevented termite attack in soil up to 4 years vs. severe termite damage within 6 months in control stakes	15

[a]1, Thornton 1979; 2, Gupta 1979; 3, Crawford et al. 1990; 4, Donkin and Dusenbery 1993; 5, Forge et al. 1993; 6, Marchal-Segault et al. 1991; 7, Denneman and van Straalen 1991; 8, van Gestel et al. 1991; 9, Spurgeon et al. 1994; 10, van Gestel et al. 1989; 11, Ma 1984; 12, Goven et al. 1994; 13, Gintenreiter et al. 1993; 14, Parmelee et al. 1993; 15, Roomi et al. 1990; 16, Arduini et al. 1995; 17, Alva et al. 1995.

Sensitive species of representative freshwater plants and animals die within 96 h at waterborne copper concentrations of 5.0 to 9.8 µg/L (Hodson et al. 1979; Table 5). The most sensitive freshwater species have LC50(96 h) values between 0.23 and 0.91 µg Cu/L and include daphnids (*Daphnia* spp.), amphipods (*Gammarus pseudolimnaeus*), snails (*Physa* spp.), and chinook salmon (*Oncorhynchus tshawytscha*; USEPA 1980; Table 5). In general, mortality of tested aquatic species is greatest under conditions of low water hardness (as measured by $CaCO_3$), starvation, elevated water temperatures, and among early developmental stages (Hodson et al. 1979; Table 5). Toxicity testing of copper-contaminated sediments to amphipods (*Hyalella azteca*) and daphnids (*Daphnia magna*) using techniques of enzyme inhibition and growth rate show that these variables are more sensitive in accurately predicting copper sensitivity than LC50 (48 h) values (Kubitz et al. 1995) and should be considered when assessing risk of contaminated sediments to freshwater systems. The most sensitive saltwater species to copper have LC50 (96 h) values from 28 to 39 µg/L and include summer flounders (*Paralichthys dentatus*), copepods (*Acartia tonsa*), and softshell clams (*Mya arenaria*; USEPA 1980; Eisler 1995; Table 5). Adverse sublethal effects of copper on representative species of estuarine algae, mollusks, and arthropods frequently occur at 1 to 10 µg/L (Bryan and Langston 1992; Table 5).

Table 5. Effects of copper on representative aquatic plants and animals.

Table 5. Taxonomic group, organism, copper concentration, and other variables	**Effects**	**Reference[a]**
Plants		
Algae; mixed culture; 5 µg/L	Photosynthesis reduced	1
Aquatic weeds, fresh water		
170 µg/L for 99 days, continuous exposure	Eliminated or controlled most submerged species; adverse effects first noted at day34. Weeds contained 360 to 4,280 mg/kg dry weight (DW)	2
250-1,000 µg/L for 99 days, continuous exposure	Unsuccessful in controlling emergent aquatic weeds; successful in eliminating filamentous algae and most submerged species	2
Marine alga, *Chlamydomonas bullosa*; 49.9 µg/L for 96 h	Growth reduced 50%	3
Green alga (fresh water), *Chlamydomonas reinhardtii*		
18 µg/L for 24 h	Reduction in number of cells bearing flagella	4
21 µg/L for 7 days	Growth normal	5
32 µg/L for 7 days	Growth reduced 50%	5
60 µg/L for 10 min inhibited for 24 h	Flagella shed; flagellar refabrication	4
79 µg/L for 72 h	Growth inhibited 50%	5
Freshwater alga, *Chlorella* spp.		
1.0 µg/L	Growth reduced	1
6.3 µg/L	Photosynthesis inhibited	1
Marine alga, *Dunaliella salina*		
0.031 µg/L for 8 months	Minor adverse effects on lipid metabolism	6
380 µg/L for 96 h	Growth reduced 50%; negligible effects on cellular ultrastructure	3,6
Marine alga, *Dunaliella tertiolecta*		
8,000 µg/L for 48 h	Growth normal	7
12,000-16,000 µg/L for 48 h	Adverse effects on photosynthesis, cell division rates, and pigment metabolism	7
Euglena, *Euglena gracilis*; 10,000 µg/L for 5 days	Adverse sublethal effects, including altered free cysteine metabolism	8
Freshwater diatom, *Nitzschia palea*; 5 µg/L	Complete inhibition of growth	1
Alga, *Ochromonas danica*		
10,000 µg/L for as long as 9 days	Growth normal	11
Aquatic moss, *Rhynchostegium riparioides*; 4.5 (controls), 9, 21, or 50 µg/L for 27 days followed by 14 days in clean media	Copper accumulation plateaued after 18 days. Maximum concentrations reached in mg/kg DW, were 900 (9 µg/L group), 2,000 (20 µg/L group), and 3,500 (50 µg/L group). At end of depuration mosses had lost about 50% of accumulated copper	12

Table 5. Taxonomic group, organism, copper concentration, and other variables	Effects	Reference[a]
Freshwater alga, *Scenedesmus acutiformis*; 100 µg/L for 20 min at pH 4.8, 5.8, or 6.8 (pH 5.8) to 4,000 (pH 6.8)	Copper concentrations, in mg/kg DW, increased from 400 (pH 4.8) to 750	10
Freshwater alga, *Scenedesmus subspicatus*		
56 µg/L for 72 h	Growth normal	5
120 µg/L for 72 h	Growth reduced 50%	5
Marine alga, *Scrippsiella faeroense*; 5 µg/L for 5 days	Growth inhibited 50%	1
Marine alga, *Thalassiosira pseudonana*; 5 µg/L for 72 h	Growth inhibited 50%	1
Protists		
Freshwater protozoan ciliate, *Tetrahymena pyriformis*		
3,818 µg/L for 96 h	Growth normal	5
8,000 µg/L for 48 h	Growth inhibited 50%	5
Cnidarians		
Sea anemone, *Anemonia viridis*; 50 or 200 µg/L for 5 days	Immediate tentacle retraction; copious production of mucus; progressive visible bleaching and loss of zooxanthellae	13
Hydroid, *Campanularia flexuosa*		
1.4 µg/L for 11 days	Enzyme disruption	1
10-13 µg/L for 11 days	Growth rate reduced	1
Ctenophore, *Pleurobrachia pileus*; 33 µg/L for 24 h	Fatal to 50%	1
Rotifers		
Freshwater rotifer, *Brachionus calyciflorus*		
2.5-5.0 µg/L	MATC[b]	14
14 µg/L for 5 h	Swimming behavior impaired 50%	14
25 µg/L for 5 h	All immobilized	14
26 µg/L for 24 h	Fatal to 50%	14, 15
34 µg/L for 5 h	Feeding rate reduced 50%	15
43 µg/L for 24 h	Feeding rate reduced 50%	16
80 µg/L for 24 h	No deaths when molar ratio of fulvic acid to copper was 1:1	17
Nematodes		
Free-living nematode, *Caenorhabditis elegans*		
260 µg/L for 96 h	LC50	18
22,000 µg/L for 24 h	LC50	18
Mollusks		
Freshwater unionid mussel, *Anodonta cygnea*		
2.1 (95% confidence interval [= CI] of 0.01-7.2) µg/L for 72 h	Reduction by 50% in valve closure of glochidia; ability to infect fish reduced	19
5.3 µg/L for 48 h	Valve closure rate reduced 50%	19
Freshwater mussel, *Anodonta grandis*		
17 µg/L for 24 h	Valve closure normal	20
33 µg/L for 24 h	Valve closure rate reduced 50%	20
44 µg/L for 24 h	Fatal to 50%	20
Bay scallop, *Argopecten irradians*		
5.0 µg/L for 119 days	All dead	1

Table 5. Taxonomic group, organism, copper concentration, and other variables	Effects	Reference[a]
5.8 µg/L for 42 days	Growth rate reduced 50%	1
Freshwater snail, *Biomphalaria glabrata*; 60 µg/L for 60 h	Lethal; epithelial cell histopathology	21
Freshwater snail, *Bulinus globosus*; 707 µg/L for 24 h	LC50	22
Channeled whelk, *Busycon canaliculatum*		
100 µg/L for 54 days	Copper concentrations, in mg/kg FW, were 43 (vs. 35 in controls) in gills and25 (vs. 16) in osphradium	23
500 µg/L for 16 days	All dead	23
Snail, *Campeloma decisum*		
>30 µg/L for 24 h	Motility inhibited	24
1,700 µg/L for 96 h	LC50	24
Asiatic clam, *Corbicula fluminea*		
5.5 µg/L for 30 days	Growth normal; soft tissues contained 80 mg/kg DW (vs. 40-60 in controls)	25
8.4-26.7 µg/L for 30 days	Some deaths; growth reduction in juveniles and adults; soft parts had205-278 mg/kg DW	25
19.2 µg/L for 30 days	LC50	25
Pacific oyster, *Crassostrea gigas*		
Adults		
10 µg/L for 14 days	LC20	27
100 µg/L	No deaths in 96 h; 30% dead in 14 days	27
560 µg/L for 96 h	LC50	27
Embryos, exposed for 48 h		
5 µg/L in controls	94-98% normal development vs. 97-99%	28
6.5 µg/L	8-25% abnormal (retarded shell size, reduced growth, erratic swimming behavior)	28
10 µg/L	26-79% abnormal	28
18 µg/L	No embryos developed normally	28
American oyster, *Crassostrea virginica*; adults with soft parts containing 837 mg/kg DW were held in flowing seawater of 1-2 µg Cu/L for 56 weeks	No significant depuration; soft parts contained 746-1,526 mg/kg DW during exposure	26
Clam, *Donax incarnatus*		
4.0 µg/L for 4 h	Increased oxygen consumption and increased ammonia excretion	29
26.1 µg/L for 96 h	LC50	29
Zebra mussel, *Dreissena polymorpha* 4.5, 9, 21, or 50 µg/L for 27 days followed by 14 days in clean media	No deaths. Filtration rate reduced in 50 µg/L group during exposure but not afterwards. Maximum concentrations, in mg/kg DW soft parts, were about 30 (9 µg/L), 70 (21 µg/L), and 100 (50 µg/L); about 18% of the accumulated copper was lost during depuration	12
13 µg/L for 9 weeks	No effect on survival or filtration rate	30
>28 µg/L for 48 h	Copper accumulation	31
41-43 µg/L for 48 h to as long as 9 weeks	Filtration rate reduced 50%	30, 31
90 µg/L for 9 weeks	28% dead; 78% reduction in filtration rate	30
Black abalone, *Haliotis cracherodii*; 50	LC50	1

Table 5. Taxonomic group, organism, copper concentration, and other variables	Effects	Reference[a]
µg/L for 96 h		
Red abalone, *Haliotis rufescens*; 86 µg/L for 96 h	LC50	1
Freshwater mussel, *Lamellidens marginalis*		
250 µg/L for 96 h	Moribund; complete dissolution of crystalline style in 9.8 h; style reforms in 2.5 h on transfer to uncontaminated media and this may be useful as indicator of copper stress	32
250, 500, 750, or 1,000 µg/L for 30 days	No deaths. Initial dose-dependent increase in respiratory rate and decrease in growth rate; similar to controls by day 30	33
5,000 µg/L for 96 h	LC50	32, 33
Baltic clam, *Macoma balthica*; 40 µg/L for 48 h	Copper in soft parts was 23.5 mg/kg DW vs. 20.0 in controls	34
Clam, *Macoma liliana*; juveniles held in sediments containing <1 (controls), 5, 10, 15, 25, 30, 50, 70, or 140 mg/kg DW.	Maximal avoidance was in sediments containing 25 mg/kg and higher (interstitial water had 113 µg/L). Ability to bury in sediments was inhibited in sediments	35
Effects on avoidance in 96 h, burial rate in 90 min, and survival in 10 days were measured	Containing 15 mg/kg and higher (pore water of 120 µg/L). Reduced survival at 30 mg/kg DW sediment and higher	
Quahaug clam, *Mercenaria mercenaria*		
25 µg/L for 77 days	53% dead	1
640-6,400 µg/L	Dose-dependent increase in cytotoxicity by isolated brown cells	36
Scallop, *Mizuhopecten yessoensis*; 25 µg/L for 21 days	Hepatopancreas had 513 mg/kg DW (vs. <50 in controls); accumulations accompanied by a significant increase in hydroperoxide and malondialdehyde contents in microsomal membranes and alterations in lipid peroxidation rates	37
Softshell clam, *Mya arenaria*		
35 µg/L for 168 h	LC50 at 22º C	38, 160
39 µg/L for 96 h	LC50	1
86 µg/L for 504 h	LC50 at 17.5º C	38, 160
3,000 µg/L for 336 h	No deaths at 4º C	38, 160
Common mussel, *Mytilus edulis* 0, 1, 3.2, 10, 32, or 100 µg/L for 7 days;mantle tissue analyzed for heat shock protein 60	Adverse effects on growth in the 32 and 100 µg/L groups; dose-dependent protein increase at 3.2 µg/L and higher	39
Mussels age 2.5 months continuously exposed to 0, 1, 5, or 10 µg/L for 21 months. Growth, histopathology, and residues in soft parts measured after 12, 18, and 21 months	Growth adversely affected in the 10 µg/L group; histopathology evident in the 5 and 10 µg/L groups. After 21 months, concentrations in soft parts, in mg/kg FW, were 5.5 in controls and the 1.0 µg/L group, 19.2 in the 5 µg/L group, and 62 in the highest exposure group	40
1, 3.2, 10, 32, or 100 µg/L for 7 days	No effect on protein activity in gill and mantle at 32 µg/L and lower; increased accumulations at 100 µg/L. At 32 µg/L and higher growth was	41

Table 5. Taxonomic group, organism, copper concentration, and other variables	Effects	Reference[a]
	reduced. At 100 µg/L survival decreased and copper concentrations increased from 24 to 89 mg/kg DW in gill and from 14 to 54 mg/kg DW in mantle	
2 µg/L for 30 days	Spawning frequency reduced 50%	42
5-6 µg/L for 10 days	Growth reduced 50%	42
50 µg/L for 6 days, then transferred to clean seawater	Lysosomal destabilization in all age groups; ability to recover declined with increasing age	43
430 µg/L for 120 h	Cardiac activity reduced 50% within4 h and reduction persisted for 120 h	44
Dipped for 5 sec in $CuSO_4$ solutions containing 5, 10, 25, or 50 g/L and stored in air for 6, 24, or 48 h	Fatal at 5 to 10 g/L if kept out of water for24 h; fatal at 10-20 g/L if stored only a few hours. Oysters (*C. virginica*) survived this treatment	45
Mussel, *Mytilus galloprovincialis*		
15 µg/L for 5 days	Stimulates the synthesis of thionein-like copper-binding proteins in gill, mantle, and digestive gland	46
40 µg/L for 6 days	Gills contained 22.3 mg/kg FW (vs. 2.4 in controls); digestive gland had 6.8 mg/kg FW (3.0). Exposed mussels show stimulated lipid peroxidation rates in tissues	47
80 µg/L for 2 h	Induces the synthesis of copper-binding proteins similar to that of metallothioneins in gills and mantle	46
Common Limpet, *Patella vulgata*; 10 µg/L for 6 h	Pedal mucus production reduced 40%	48
Brown mussel, *Perna indica*		
2-6 µg/L for 4 h	Increased oxygen consumption	29
21.8 µg/L for 96 h	LC50	29
Green mussel, *Perna viridis*		
25 µg/L for 2 weeks	Reduction in filtration rate, growth, and oxygen to nitrogen ratio; histopathology of digestive cells and tissues. Residues, in mg/kg FW, were 38.2 in digestive gland vs. 2.6 in controls and 24.7 in total soft parts vs. 1.3 in controls	49
86 µg/L for 96 h	LC50	49
Snail, *Physa integra*		
15 µg/L for 6 weeks	No adverse effects on growth, survival, or feeding	24
39 µg/L for 96 h	LC50	1, 24
Apple snail, *Pomacea paludosa*; 24-57µg/L for 96 h	LC50	50
Cuttlefish, *Sepia officinalis*; eggs; 4 (control), 50, 100, or 200 µg/L for 8 weeks	Dose-dependent decrease in hatching time and survival; no external malformations	51
Freshwater snail, *Thiara tuberculata*		
450 µg/L for 20 days	Progressive decline over time in oxygen consumption	52
2,180 µg/L for 72 h	LC50; survivors had decreased oxygen consumption	52
Giant clam, *Tridacna derasa*; embryos age 1 h; exposed at 27º C		

Table 5. Taxonomic group, organism, copper concentration, and other variables	Effects	Reference[a]
0.1 µg/L for 72 h	LC50	53
1.0 µg/L for 72 h	LC65	53
10.0 µg/L for 72 h	LC91	53
Clam, *Villorita cyprinoides*		
450 µg/L for 120 h	No deaths	54
1,000, 3,000, or 5,000 µg/L for 120 h	No deaths. Hemolymph protein levels reduced at 1,000 and 3,000 µg/L, but not in 5,000 µg/L	54, 161
Freshwater mussel, *Villosa iris*		
24 µg/L for 24 h	Valve closure normal	55
27-29 µg/L for 24 h	50% reduction in valve closure	55
83 µg/L for 24 h	LC50	55
Crustaceans		
Copepod, *Acartia clausi*; 52 µg/L for 96 h	LC50	1
Copepod, *Acartia tonsa*; 31 µg/L for 96 h	LC50	1
Amphipod, *Allorchestes compressa*		
3.7 µg/L for 4 weeks	Extrapolated concentration causing detectable decreases in survival and biomass	9
10 µg/L for 4 weeks	Lowest concentration tested causing adverse effects on growth and survival; bioconcentration factor (BCF) of 51,500	9
500 µg/L for 96 h	LC50	9
Cladoceran, *Bosmina longirostris*		
1.4 µg/L for 48 h; starved	50% immobilized	56
3.7 µg/L for 48 h; fed	50% immobilized	56
16 µg/L for 15 days	Growth rate reduced	158
18 µg/L for 15 days	Survival reduced	158
Lesser blue crab, *Callinectes similis*		
50 µg/L for 118 days	No effect on survival or molting during exposure	57
250 µg/L; juveniles	LC50 (30 days); LC100 (68 days)	57
500 µg/L	50% of megalops dead in 3.7 days; 50% of juveniles dead in 7.7 days; all juveniles dead in 49 days	57
Crayfish, *Cambarus bartoni*; copper-tolerant strain exposed to 19 (controls), 125, 250, or 500 µg/L for 4 weeks; concentrations in controls (mg/kg DW) vs. all experimental groups (mg/kg DW)		
Exoskeleton	54 DW vs. 78-116 DW	58
Gills	368 DW vs. 571-1,167 DW	58
Hepatopancreas	1,778 DW vs. 1,494-2,346 DW	58
Muscle	88 DW vs. 99-129 DW	58
Viscera	92 DW vs. 158-276 DW	58
Shore crab, *Carcinus maenas*		
500 µg/L for 5-18 days	Gill histopathology; some recovery after exposure	59
500 µg/L for 28 days Controls (fed) vs. exposed (fed); values in mg/kg DW		
Carapace	5 DW vs. 51 DW	60
Midgut gland	26 DW vs. 474 DW	60
Controls (starved) vs. exposed (starved); values in mg/kg DW		
Carapace	4 DW vs. 72 DW	60

Table 5. Taxonomic group, organism, copper concentration, and other variables	Effects	Reference[a]
Midgut gland	298 DW vs. 583 DW	60
2,000 µg/L for 5 days	Some deaths; severe gill cellular hyperplasia	59
Daphnid, *Ceriodaphnia dubia*		
9.5 µg/L for 48 h	LC50 at pH 6.0-6.5	61
28 µg/L for 48 h	LC50 at pH 7.0-7.5	61
200 µg/L for 48 h	LC50 at pH 8.0-8.5	61
Cladoceran, *Chydorus sphaericus*		
3.3 µg/L for 48 h; starved	50% immobilized	56
7.6 µg/L for 48 h; fed	50% immobilized	56
Amphipod, *Corophium volutator*; exposed to <0.1, 50, or 100 µg/L for 14 days in seawater under conditions of normoxia, moderate hypoxia (29% oxygen saturation), and hypoxia (19% oxygen saturation)	Exposure to increasing levels of copper resulted in a significant increase in total body copper concentrations (from 76 to 174 mg/kg DW), and a lowering of egg production; mortality was higher at low oxygen saturations and high copper concentrations (max. 35% dead at 100 µg/L and 19% saturation)	62
Brown shrimp, *Crangon crangon*; 330 µg/L for 96 h	LC50	1
Daphnids, *Daphnia ambigua*, *D. parvula*, *D. pulex*; 49 µg/L for lifetime exposure	Reduced productivity	1
Daphnid, *Daphnia carinata*; 28 µg/L for 96 h	LC50	63
Daphnid, *Daphnia magna*		
5.9 µg/L for 21 days	Growth reduced 10%; bioconcentration factor (BCF) of 4,900; maximum whole body concentration of 43 mg/kg DW	64
10 µg/L for 96 h	LC50 at 45 mg $CaCO_3$/L	1
10 µg/L, life cycle	Inhibited reproduction	1
11.4-16.3 µg/L	MATC[b] at 51 mg $CaCO_3$/L	1
16.1 µg/L for 21 days	Growth reduced 50%	64
20-43 µg/L	MATC[b] at 104 mg $CaCO_3$/L	1
26-59 µg/L for 48 h; fed	LC50; no weight loss among survivors	65
28-58 µg/L for 48 h; starved	LC50; survivors had significant weight loss	65
59 µg/L for 26 h	Feeding rate reduced 50%	16
69 (37-110) µg/L for 21 days	LC50	64
200 µg/L for 96 h	LC50 at 226 mg $CaCO_3$/L	1
Daphnid, *Daphnia pulex*		
0.003-0.3 µg/L for 21 days	Increased reproduction	66
3 µg/L for 21 days	Impaired reproduction	66
5 µg/L for 70 days	Decreased survival beginning at day 58; no effect on reproduction	67
20-37 µg/L for 48 h	LC50	66, 67, 68
20 µg/L for 6 h daily for 70 days	Decreased survival and brood size	67
30 µg/L for 15 days	No significant effect on growth or survival	158
Daphnid, *Daphnia pulicaria*		
7.2-11.4 µg/L for 96 h	LC50 at 44-48 mg $CaCO_3$/L	1
17.8-27.3 µg/L for 96 h	LC50 at 95-245 mg $CaCO_3$/L	1
Amphipod, *Gammarus pseudolimnaeus*		
<4.6 µg/L for 15 weeks (two generations)	No adverse effects	24

Table 5. Taxonomic group, organism, copper concentration, and other variables	Effects	Reference[a]
4.6-8 µg/L	MATC[b] at 45 mg $CaCO_3$/L	1
6.2-12.9 µg/L for 5 weeks	Decreased survival	24
20 µg/L for 96 h	LC50	24
Amphipod, *Gammarus pulex*		
Immersed in solutions containing 2.6 (controls), 11, 14.6, 18.2 or 23.1 µg/L for 100 days	Population density doubled in the controls and the 11 µg/L group. Rate of increase was adversely affected at 14.6 and 18.2µg/L; the high-dose group lost population. Low-dose groups were composed mainly of juveniles; at 14.6 µg/L and higher, the number of juveniles decreased; and at 18.2µg/L and higher, number of adults decreased	69
33 µg/L for 240 h	LC50	69
Mysid shrimp, *Holmesimysis costata*; 17 µg/L for 96 h	LC50	70
American lobster, *Homarus americanus*		
48 µg/L for 96 h	Larval LC50	1
100 µg/L for 96 h	Adult LC50	1
Amphipod, *Hyalella azteca*		
1.3 (control), 5.6, 10, 18, 32, 56, or 100 µg/L for 10 weeks beginning at age 1 week	Survival reduced at 32 µg/L and higher; no significant copper accumulations over controls in all groups	71
1.3 (control), 5.6, 10, 18, 32, 56, 100, or 180 µg/L for 4 weeks; adults	Copper residues, in mg/kg DW, were 98 in controls; 122-150 for the 5.6-32 µg/L groups, and >196 for the high dose groups	71
17 µg/L for 96 h	LC50 at pH 6.0-6.5, adults	61
31 (28-35) µg/L for 10 days	LC50, juveniles	73
34 µg/L for 96 h	LC50; age 6-8 days	72
52 µg/L for 96 h	LC50; age 20-24 days	72
87 µg/L for 96 h	LC50 at pH 8.0-8.5	61
Freshwater prawn, *Macrobrachium rosenbergii*; 12 µg/L for 96 h	LC50	74
Freshwater prawn, *Macrobrachium rude*; 18-65 µg/L for 96 h	LC50-LC84	63, 75
Macroinvertebrate communities; 11.3 µg/L for 10 days	Abundance was reduced by 75% in laboratory studies vs. 44% in field experimental streams; number of taxa was reduced 56% in the laboratory vs. 10% in field streams	76
Peneid Shrimp, *Metapenaeus ensis*		
160 µg/L for 48 h	LC50 for larvae	77
250 µg/L for 2 h	Feeding inhibited >50%	77
4,760 µg/L for 48 h	LC50 for postlarvae	77
Cladoceran, *Moina irrasa*		
1.4 µg/L for 24 h	LC50 at pH 5.0, 30º C	78
2.8 µg/L for 24 h	LC50 at pH 6.5, 30º C	78
3.3 µg/L for 96 h	LC50 at pH 5.0, 20º C	78
5.5 µg/L for 48 h	LC50 at pH 5.0, 25º C	78
6.5 µg/L for 96 h	LC50 at pH 6.5, 20º C	78
7.5 µg/L for 96 h	LC50 at pH 8.0, 20º C	78
11.8 µg/L for 48 h	LC50 at pH 8.0, 25º C	78
19.7 µg/L for 24 h	LC50 at pH 8.0, 20º C	78

Table 5. Taxonomic group, organism, copper concentration, and other variables	Effects	Reference[a]
Mysid shrimp, *Mysidopsis bahia*; 38-77 µg/L	MATC[b]	1
Norway lobster, *Nephrops norvegicus*		
10 µg/L for 30 days; 4.9 cm in length	Copper concentrations were elevated in most tissues, especially ovary (to 393 from115 mg/kg DW), but not hepatopancreas or external eggs	79
100 µg/L for 14 days	LC100	79
Crab, *Paragrapsus quadridentatus*		
110-250 µg/L for 96 h	LC16-LC84 for larvae	80
170 µg/L for 96 h	LC50 for larvae	80
Freshwater shrimp, *Paratya australiensis*		
15 µg/L, continuous exposure	Mean molt period of 23 days (range20-27 days) vs. 25 days (18-36 days) for controls	81
40 µg/L for 96 h	LC50	81
Amphipod *Parhallella natalensis*; 72 µg/L for 48 h	LC50	82
Crayfish, *Procambarus clarkii*		
120 µg/L for 20 days	LC50 for larvae	83
1,300 µg/L for 20 days	LC50 for adults; increased copper concentrations at >480 µg/L in gills but not other tissues	83
3,700 µg/L for 20 days	LC50 for embryos	83
Copepod, *Pseudodiaptomus coronatus*; 138 µg/L for 96 h	LC50	1
Barnacle, *Semibalanus balanoides*; 20-90 µg/L for 100 days	Dose-dependent increase in copper loadings in bodies and egg masses	84
Copepod, *Tigriopus japonicus*; 487µg/L for 96 h	LC50	1
Copepod, *Tisbe furcata*; 37-57 µg/L	MATC[b]	85
Aquatic insects		
Midge, *Chironomus ninevah*; 0, 20, 100, 150 or 200 µg/L for 21 days (eggs through fourth stage larvae)	Statistically significant, dose-dependent decrease in gene activity of salivary gland chromosomes at 20 µg/L and higher	86
Midge, *Chironomus* sp.; 30 µg/L for 96 h	LC50 at 50 mg $CaCO_3$/L	1
Midge, *Tanytarsus dissimilis*; 16.3 µg/L for 10 days	LC50	1
Various species; 25 µg/L for 10 days in outdoor experimental streams	Mayflies were the most sensitive group with 67-100% reduction in numbers; chironomids had 80% reduction, and caddisflies were reduced by 16-30%	87
Annelids		
Ragworm, *Hediste diversicolor*		
5, 10, or 20 µg/L at four salinities and three temperatures; 1-day-old larvae	20 µg/L caused high mortality at all thermosaline regimens tested; some adverse effects noted at lower concentrations	88
247-513 µg/L for 96 h; no sediments in assay containers	LC50's at various thermosaline regimens	89
3,200-4,100 µg/L for 96 h; sediments present in assay containers	LC50's at various thermosaline regimens	89

Table 5. Taxonomic group, organism, copper concentration, and other variables	Effects	Reference[a]
Oligochaete, *Lumbriculus variegatus*		
130 µg/L for 96 h	LC50 at pH 6.0-6.5	61
500 µg/L for 96 h	LC50 at pH 8.0-8.5	61
Marine worm, *Nereis diversicolor*; 500 µg/L at three salinities and three temperatures	Mortality was greatest at 5‰ salinity (50% dead in 44 h vs. 66-82 h at higher salinities), and at 20º C (50% dead in 32 h vs. 88-106 h at lower temperatures)	90
Echinoderms		
Echinoid, *Echinometra mathaei*; 20 µg/L for 4 days	Skeletal development of larvae suppressed	1
Sea urchin, *Paracentrotus lividus*; 10-20 µg/L for 4 days	Pluteal growth retarded	1
Sea urchin, *Strongylocentrotus nudus*; adults held in seawater containing 25 µg/L for 30 days; resultant embryos reared in uncontaminated seawater for 30 days	Food consumption of adults decreased after day 16; accelerated development of pluteal stages; all developmental stages had increased activities of acid phosphatase	91
Fish		
Topsmelt, *Atherinops affinis*		
53 µg/L for 15 min; sperm	No effect on fertilization in 48 h	92
100 µg/L for 7 days; larvae, age 5-20 days	No effect	93
109 µg/L for 15 min; sperm	Egg fertilization reduced 50% in 48 h	92
123 µg/L for 96 h; larvae	No deaths	92
137 µg/L for 7 days; larvae, age 7-20 days	LC50	93
146 µg/L for 48 h; embryos	50% abnormal development	92
180 µg/L for 7 days; larvae, age 1-3 days	No deaths	93
238 µg/L for 96 h; larvae	LC50	92
365 µg/L for 7 days; larvae, age 0-5 days	LC50	93
Zebrafish, *Brachydanio rerio*		
0.05 µg/L for 16 days; eggs and larvae	Delayed hatch	94
0.25 µg/L for 16 days; eggs and larvae	No deaths	94
1.0 µg/L for 16 days; eggs	<50% hatched	94
1.0 µg/L; adults	No avoidance but inhibition of attraction response to L-alanine	95
50-150 µg/L for 7 days; adults	No adverse effects on survival or behavior; dose-dependent decrease in kidney leucocyte numbers and phagocytic response	96
Goldfish, *Carassius auratus*		
36 µg/L for 96 h	LC50 at 20 mg $CaCO_3$/L	1
300 µg/L for 96 h	LC50 at 52 mg $CaCO_3$/L	1
368 µg/L for 96 h	LC50 at 272 mg $CaCO_3$/L	97
White sucker, *Catostomus commersoni*; 12.9-33.8 µg/L	MATC[b] at 45 mg $CaCO_3$/L	1
Murrel, *Channa punctatus*; 50 or 100 µg/L for 7 days	Liver pathology	98
Catfish, *Clarias* sp.		
27, 55, or 110 µg/L for 8 weeks; whole fish analyzed for total copper at end of exposure	Copper concentrations, in mg/kg DW, were 15.7 for the low-dose group, 21.8 for the 55 µg/L group, and 31.2 for the high-dose group vs. 6.9	99

Table 5. Taxonomic group, organism, copper concentration, and other variables	Effects	Reference[a]
	DW in controls	
425 µg/L for 96 h	LC50; nonresistant strain	99
4,301 µg/L for 96 h	LC50; copper-resistant strain	100
African sharp-tooth catfish, *Clarias gariepinus*; Olifants River (water of 32-55 µg/L), South Africa		
767-991 µg/L for 96 h	10-20% dead	101
1,240-1,380 µg/L for 96 h; adults and juveniles	LC50 at 21-28º C	101
Pacific herring, *Clupea harengus pallasi*; 33 µg/L for 6 days; embryos	LC50	1
Common carp, *Cyprinus carpio*; 100 µg/L for 43 days	Skin histopathology	102
Northern pike, *Esox lucius*; 34.9-104.4 µg/L	MATC[b] at 45 mg $CaCO_3$/L	1
Freshwater fishes; eight species; embryos and larvae; 31.7-43.5 µg/L for 30-60 days	Reduced survival	103
Mummichog, *Fundulus heteroclitus*		
1,000 µg/L for 96 h	Renal and lateral line canal lesions	104
1,700-8,000 µg/L for 96 h	LC30-LC50	104, 105
Indian catfish, *Heteropneustes fossilis*		
250 µg/L; 5 h daily for 30 days	Time-dependent increase in adverse effects on blood chemistry, liver effects on blood chemistry, liver metabolism, and respiration	106
5,000 µg/L for 48-96 h	After 48 h, decreased hematocrit, erythrocyte number, and hemoglobin; after 96 h, increased liver glycogen	107, 108
10,500-25,500 µg/L for 72-96 h	LC50	107, 108
Brown bullhead, *Ictalurus nebulosus*		
4, 8, 16, 32, 64, or 104 µg/L for as long as 600 days; blood chemistry analyzed periodically	Some deaths at 104 µg/L; no deaths at lower doses; no adverse biochemical effects at 16 µg/L and lower	109
4 to 512 µg/L for as long as 20 months	Increases in liver and gill copper concentrations in survivors at 275 µg/L and higher; equilibrium reached within30 days. Copper levels in blood were the same as in controls	110
170 to 190 µg/L for 96 h; juveniles	LC50	110
Channel catfish, *Ictalurus punctatus*; fingerlings exposed for 96 h at 16 mg $CaCO_3$/L		
51-65 µg/L	LC50; chelated copper	111
54-55 µg/L	LC50; nonchelated copper	111
Exposed for 96 h at 239 mg $CaCO_3$/L		
925-1,041 µg/L	LC50; nonchelated copper	111
1,603-1,878 µg/L	LC50; chelated copper	111
Spot, *Leiostomus xanthurus*; 280 (240-330) µg/L for 96 h; adults	LC50	112
Green sunfish, *Lepomis cyanellus*; 937 (686-	LC50	97

Table 5. Taxonomic group, organism, copper concentration, and other variables	Effects	Reference[a]
1,281) µg/L for 96 h		
Bluegill, *Lepomis macrochirus*		
21-40 µg/L	MATC[b] at 45 mg $CaCO_3$/L	1, 114
31 µg/L	Consumed 27% fewer prey than controls	113
40-162 µg/L for 90 days; larvae	Reduced survival	114
40-162 µg/L for 24 months; adults	At 162 µg/L, survival was reduced, growth retarded, and spawning inhibited. Maximum copper concentrations, in mg/kg FW, in treated fish (vs. controls) were 13 in gills (3), 480 in liver (7), and44 in kidneys (22)	114
236-620 µg/L for 96 h; adults	LC50	97, 115
261 µg/L for 7 days, then subjected to a drop in dissolved oxygen over 60 min from 7.8 to 1.3 mg/L and then allowed to recover in copper-free aerated water	No deaths during copper exposure. During hypoxia; 2 of 77 died; survivors had hyperglycemia, lower plasma sodium, lower liver ATP, and higher plasma potassium than did nonexposed controls. Authors concluded that previous copper exposure causes some hypoxia responses to be accentuated in an additive manner	115
1,100 µg/L for 96 h; larvae	LC50	114
4,300 µg/L for 48 h	LC50	116
Atlantic silverside, *Menidia menidia*; 136 µg/L for 96 h; larvae	LC50	1
Tidewater silverside, *Menidia peninsulae*; 140 (110-180) µg/L for 96 h; larvae	LC50	112
Striped bass, *Morone saxatilis*		
50-100 µg/L for 96 h; larvae	LC50 at 68 mg $CaCO_3$/L	1
150 µg/L for 96 h; fingerlings	LC50 at 68 mg $CaCO_3$/L	1
2,680 µg/L for 96 h; fingerlings; 5‰ salinity	LC50	117
7,880-8,080 µg/L for 96 h; fingerlings; 10-15‰ salinity	LC50	117
Cutthroat trout, *Oncorhynchus clarki*		
37 µg/L for 96 h	LC50 at 18 mg $CaCO_3$/L	1
232 µg/L for 96 h	LC50 at 204 mg $CaCO_3$/L	1
Coho salmon, *Oncorhynchus kisutch*		
0, 15, 60, or 90 µg/L for 170 h; yearlings	No deaths; distress noted at 60 and 90 µg/L. Dose-dependent elevation in serum cortisol. When challenged with seawater, copper-exposed salmon had lowered survival and dose-dependent depression in serum chloride levels	118
5-30 µg/L for as long as 172 days; yearlings	Altered downstream migration patterns, lowered gill ATPase activity, and reduced survival. When subjected to >20 µg/L, appetite was depressed for several weeks to months	119
15.1-31.9 µg/L for 96 h; juveniles	LC50	120
18.2 µg/L for 31 days then challenged with seawater	Reduced survival during adaptation to seawater	121
24.6 µg/L for 31 days; fingerlings	Reduced survival; survivors unable to adapt to seawater	121

Table 5. Taxonomic group, organism, copper concentration, and other variables	Effects	Reference[a]
26 µg/L for 96 h; alevins	LC50 at 25 mg $CaCO_3$/L	1
46 µg/L for 96 h; adults	LC50 at 20 mg $CaCO_3$/L	1
60 µg/L for 96 h; smolts	LC50 at 95 mg $CaCO_3$/L	1
60-74 µg/L for 96 h; yearlings	LC50 at 95 mg $CaCO_3$/L	1, 119
70 or 140 µg/L for 14 weeks; fingerlings	Loss of appetite and reduced growth Copper concentrations, in mg/kg DW, at end of study for the controls, the 70 µg/L group, and the 140 µg/L group were 2.9, 5.6, and 9.8 in gills, and 5.7, 6.1, and 7.5 in kidneys	122
70 or 140 µg/L for 14 weeks; liver cytosol samples from fingerlings	Copper concentrations in the low molecular weight fractions of the 70µg/L group were higher than controls after 6 weeks and increased rapidly; those of the 140 µg/L group increased in the first 2-4 weeks then leveled off. Increasing levels of metallothioneins were detected in low molecular weight fractions of copper-exposed salmon. In the high molecular weight fractions, copper concentrations in both groups increased after 8-10 weeks	123
140 or 210 µg/L for 78 h; yearlings	Median survival times were 60 h for the low-dose group and 48 h for the high dose group; survivors had elevated serum cortisol. Livers were normal but kidney and gill histopathology was evident in both groups	118
220-280 µg/L for 168 h; fingerlings	LC50	122
310 µg/L for 168 h; prior exposure to 70 µg/L for 16 weeks; fingerlings	LC50	122
550 µg/L for 168 h; prior exposure to 140 µg/L for 16 weeks; fingerlings	LC50	122
Rainbow trout, *Oncorhynchus mykiss*		
0.1 µg/L for 1 h	Avoidance by fry	1
7.0 µg/L for 200 h; smolts	LC10	1
8.0 µg/L for 2 h	Depressed olfactory bulbar electrical responses to the standard stimulant L-serine	124
9.0 µg/L for 200 h; swimup stage	LC10	1
11.4-31.7 µg/L	MATC[b] at 45 mg $CaCO_3$/L	1
13.8 µg/L for 96 h; juveniles	LC50	120
19.0 µg/L for 200 h; alevins	LC10	1
20-30 µg/L for 96 h	LC50 at 30-32 mg $CaCO_3$/L	1
21.5 µg/L for 30 days; juveniles	No adverse effects; no altered susceptibility to *Aeromonas hydrophila* infections	125
22 µg/L for 37 to 41 weeks; two groups: age 14 days postfertilization and posthatch. Controls were held in water containing 4 µg/L	Survival of embryo group reduced 30%. Alterations in cell architecture in both treated groups were noted as early as week 8 posthatch. Both groups had irreversible histopathology of the olfactory organ after 7 months; no histopathology in controls. After 8 months,	126, 127

Table 5. Taxonomic group, organism, copper concentration, and other variables	Effects	Reference[a]
	controls preferred their own rearing water but both copper-exposed groups showed no preference; some recovery 2 to 10 weeks after removal from copper	
36 µg/L for 96 h; alevins	LC50	120
50 µg/L for 24 h; adults	No deaths; some degeneration of sensory receptors	128
50 µg/L for 21 days; juveniles	Rapid and sustained elevation of plasma cortisol levels; altered plasma cholesterol and sodium levels	129
55 µg/L for 28 days; juveniles	Initial inhibition of sodium uptake and whole body sodium content that were normal by day 28. Abnormal liver enzyme activity. Liver copper increased from 23 mg/kg FW at start to 113 mg/kg FW at day 28	164, 165
70 µg/L	Avoidance by juveniles	166
70-514 µg/L for 96 h	LC50 at 194-370 mg $CaCO_3$/L	1
75 µg/L for 24 h	LC50; survivors had complete degeneration of olfactory receptors	128
90 (50-150) µg/L; embryo through posthatch	LC50 at 28 days	162
130-140 µg/L for 24 h	LC50 at pH 6.5-7.5	130
308 µg/L for 24 h in freshwater vs. 400 µg/L for 24 h in 35‰ seawater	All dead in freshwater vs. no deaths in seawater and no major changes in plasma Na^+, Cl^-, K^+, or Ca^{2+}	131
500 or 1,000 µg/L for 2 or 24 h; fingerlings	Gill histopathology in low-dose, low exposure group; damage more severe with increasing dose and exposure	131
500 µg/L for 9 days; weight 400 g; under conditions of normal and low oxygen	No signs of respiratory dysfunction; no difference in dissolved copper uptake due to dissolved oxygen levels	133
1,200 µg/L for 6 h	LC50	130
4,560 µg/L	Juveniles attracted	166
Fed diet containing 13 or 684 mg/kg ration for 42 days and simultaneously exposed to waterborne-copper concentrations of 5, 32, 55, or 106 µg/L (low-copper diet) or 13, 38, 62, or 127 µg/L (high-copper diet)	No adverse effects on growth, survival, or food conversion efficiency. Elevated dietary copper increased copper concentrations in liver, kidney, gill, and digesta; increasing waterborne-copper concentrations produced increasing copper concentrations in liver and kidney. For fish in the high-copper diet, the diet provided 99% of the liver copper in the 38 µg/L group, 85% in the 62 µg/L group, and 73% in the 127 µg/L group	134
Fed diets containing 25.8 mg/kg DW ration (vs. 15.8 mg/kg DW in controls) for 28 days; equivalent to 69.2 mg/kg fish (130 g) daily	Fish readily ate copper-contaminated food. Elevated copper levels in gill, liver, and muscle. Some food regurgitation on days 20-28	135

Table 5. Taxonomic group, organism, copper concentration, and other variables	Effects	Reference[a]
Juveniles fed diet containing 200 mg/kg DW for 32 days followed by normal (15.8 mg/kg DW) diet for 12 days	No deaths. After 32 days whole fish contained 1.5 mg/kg FW vs 1.2 at start; copper concentrations were elevated in gill, gut, blood, skin, and mucus, but not in muscle, liver, or kidney. Copper concentrations in gill and kidney tissues were elevated 12 days after exposure, but other tissues were normal	136
Chinook salmon, *Oncorhynchus tshawytscha*		
10-38 µg/L for 96 h	LC50 in soft water	1
19 µg/L for 200 h; swimup stage	LC50	1
20 µg/L for 200 h; alevins	LC50	1
26 µg/L for 200 h; smolts	LC50	1
30 µg/L for 200 h; parr	LC50	1
54-60 µg/L for 96 h; fry	LC50	138
78-145 for 24 h; fry	LC50	138
85-130 µg/L for 96 h	LC50 in hardwater	1
Green snakehead, *Ophiocephalus punctatus*; weight 15-18 g		
5,000-7,500 µg/L for 24 h	Sublethal. Disrupted kidney and liver alkaline phosphatase and acid phosphatase activity	139
70,000 µg/L for 48 h	LC50	139
Nile tilapia, *Oreochromis niloticus* 50, 100, or 200 µg/L for 8 weeks	At end of exposure, whole fish contained 34.7 and 36.1 mg/kg DW in the two lowest-dose groups and 81.0 mg/kg DW in the high-dose group (vs. 17.4 mg/kg DW in controls)	140
964 µg/L for 96 h	LC50	140
Summer flounder, *Paralichthys dentatus*; embryos; 28 µg/L for 96 h	LC50	1
Flounder, *Paralichthys* spp.; juveniles		
6.4 µg/L for 14 days	Interference with calcium metabolism	157
448 µg/L for 14 days	LC50	157
Fathead minnow, *Pimephales promelas* 2 µg/L for 96 h; larvae	LC50 at pH 5.6 and dissolved organic carbon (DOC) of 0.2 mg/L	
10.6-18.4 µg/L	MATC[b] at 30 mg $CaCO_3$/L	
14.5-33.0 µg/L	MATC[b] at 200 mg $CaCO_3$/L	142
15 µg/L for 96 h	LC50 at pH 6.0-6.5	142
23 µg/L for 96 h	LC50 at 20 mg $CaCO_3$/L	143
44 µg/L for 96 h	LC50 at pH 7.0-7.5	1
182 µg/L for 96 h	LC50 at pH 6.9 and dissolved organic carbon of 15.6 mg/L	143
>200 µg/L for 96 h	LC50 at pH 8.0-8.5	143
210 µg/L for 96 h	LC50 at 100 mg $CaCO_3$/L	163
390 µg/L for 96 h	LC50 at 250 mg $CaCO_3$/L	163
430-470 µg/L for 96 h	LC50 in hard water; continuous flow and static assays	142
European flounder, *Platichthys flesus*		

Table 5. Taxonomic group, organism, copper concentration, and other variables	Effects	Reference[a]
Seawater-adapted; exposure for 42 days; experimentals (170 µg/L) vs. controls (3 µg/L); values in mg/kg DW tissue		
Gill	7.7 vs. 2.7	167
Kidney	13.1 vs. 4.1	167
Liver	640.2 vs. 15.6	167
Muscle	7.7 vs. 2.7	167
Freshwater-adapted; exposure for 37 days; experimentals (15 µg/L) vs. controls (5 µg/L); values in mg/kg DW tissue		
Gill	16.2 vs. 6.5	167
Kidney	28.7 vs. 14.3	167
Liver	295.6 vs. 157.8	167
Muscle	4.9 vs. 1.8	167
Guppy, *Poecilia reticulata*		
36 µg/L for 96 h	LC50 at 20 mg $CaCO_3$/L	1
112-138 µg/L for 96 h	LC50 at 67-82 mg $CaCO_3$/L	1
75-84 µg/L for 96 h	LC50 in soft water; continuous flow and static assays	142
Winter flounder, *Pleuronectes americanus*		
129 µg/L for 96 h; embryos	LC50	1
180 µg/L for 29.1 days; adults	Gill histopathology	144
560-3,200 µg/L for 29.2 days; adults	Copper-induced histopathology of kidney, liver, and gill; reduced food intake	144
Mangrove rivulus, *Rivulus marmoratus*; 1,400 µg/L for 96 h	LC50	145
Air-breathing catfish, *Saccobranchus fossilis*; 56, 100, or 320 µg/L for 28 days	Dose-dependent decrease in red and white blood cell numbers, hemoglobin, and hematocrit; histopathology in gill, skin, spleen, and kidney	146
Atlantic salmon, *Salmo salar*		
2.4 µg/L	Avoidance threshold in laboratory	147
12.8-621.0 µg/L	Dose-dependent inhibition of olfactory response; toxic effect mainly on transduction mechanisms of the olfactory receptor cells	148
16.9-20.6 µg/L	Avoidance threshold in field	147
32-125 µg/L for 96 h	LC50 at 8-20 mg $CaCO_3$/L	1, 147
Brown trout, *Salmo trutta*;		
22.0-43.2 µg/L	MATC[b] at 45 mg $CaCO_3$/L	1
103-148 (91-165) µg/L	LC50 at 48 h, juveniles	159
Brook trout, *Salvelinus fontinalis*		
2.7 (control), 4.5, 6.1, or 9.4 µg/L for two generations	No adverse effects on growth, survival, or reproduction; no elevated copper concentrations in gill, liver, kidney, muscle, or eggs	152
3.4, 5.7, 9.5, 17.4, or 32.5 µg/L for 337 days	No significant changes in blood chemistry except for measurable decrease in plasma glutamic oxalacetic transaminase activity at 17.4 and 32.5 µg/L	149

Table 5. Taxonomic group, organism, copper concentration, and other variables	Effects	Reference[a]
6-15 µg/L for 2-24 h; yearlings	Increased cough frequency, increased locomotor activity, and decreased feeding response	150
9.5-17.4 µg/L	MATC[b] at 45 mg $CaCO_3$/L and pH 7.5	151
23, 39, or 68 µg/L for 6 or 21 days	At 39 and 68 µg/L, adverse effects on blood chemistry; decreases in plasma chloride and osmolarity	149
100 µg/L for 96 h; age 14 months	LC50	151
Lake trout, *Salvelinus namaycush*; 22.0-42.3 µg/L	MATC[b] at 45 mg $CaCO_3$/L	92
Red drum, *Sciaenops ocellatus*		
250 µg/L for 96 h; juveniles	No deaths	153
520 µg/L for 96 h; juveniles	LC50 at 25º C and 8‰ salinity	153
Pearl dace, *Semotilus margarita*; 1,000-279,000 µg/L for as long as 7 h then transferred to clean water for 48 h	Decreasing survival and coordination with increasing concentration or duration of exposure after exposure to 1,000 µg/L for 6 h, 9,000 µg/L for 1 h, 74,000 µg/L for 0.33 h, or 279,000 µg/L for 0.25 h	154
Walleye, *Stizostedion vitreum*; 13-21 µg/L	MATC[b] at 35 mg $CaCO_3$/L	1
Florida pompano, *Trachinotus carolinus*; 360-510 µg/L for 96 h	LC50	1
Arctic grayling, *Thymallus arcticus*		
2.65 µg/L for 96 h; swimup fry	LC50	120
9.6 µg/L for 96 h; fry	LC50	120
23-131 µg/L for 96 h; alevins	LC50	120
Amphibians		
Marbled salamander, *Ambystoma opacum*; 50 µg/L for 96 h; embryos	97% survival 4 days posthatch	155
American toad, *Bufo americanus*; tadpoles		
10 µg/L	Avoidance	166
930 µg/L	Attraction	166
Fowler's toad, *Bufo fowleri*; 2,696 µg/L for 7 days; embryos	LC50	155
Two-lined salamander, *Eurycea bislineata*; 1,120 µg/L for 48 h; juveniles	LC50	156
Narrow-mouthed toad, *Gastrophryne carolinensis*		
10 µg/L for 4 days; embryos	34% dead 4 days after hatching	155
40 (30-50) µg/L; embryos through posthatch	LC50 (7 days)	162
50 µg/L for 72 h; embryos	LC50	155
Southern gray treefrog, *Hyla chrysoscelis*		
10 µg/L for 96h; embryos	39% dead 4 days after hatching	155
40 µg/L for 7 days; embryos	LC50	155
60 µg/L for 72 h; embryos	LC50	155
Northern leopard frog, *Rana pipiens*		
10 µg/L for 96h; embryos	34% dead 4 days after hatching	155
50 µg/L for 8 days; embryos	LC50	155

[b]MATC = Maximum acceptable toxicant concentration. Lower value in each MATC pair indicates highest concentration tested producing no measurable effect on growth, survival, reproduction, and metabolism during chronic exposure; higher value indicates lowest concentration tested producing a measurable effect.

No data are available on copper toxicity to avian wildlife. Experiments with domestic poultry show that copper accumulates in livers of mallard ducklings at dietary concentrations as low as 15 mg/kg DW ration; that gizzard histopathology and a reduction in weight gain of chicks (*Gallus* sp.) occur at 250 to 350 mg Cu/kg DW ration; and that growth of turkey poults is improved at 60 mg Cu/kg DW ration and inhibited at 120 mg/kg DW ration, with signs of gizzard histopathology at 500 mg/kg DW ration (Wood and Worden 1973; Poupoulis and Jensen 1976; NAS 1977; Kashani et al. 1986; Table 6).

Table 6. Effects of copper on selected birds

Table 6. Organism, copper dose, and other variables	Effects	Reference[a]
Mallard, *Anas platyrhynchos*		
Fed diets containing 15 or 135 mg/kg ration for 18 days; ducklings	Livers from low-dose group had 30 mg/kg dry weight (DW) at day 4 and 107 mg/kg at day 18; values for the high-dose group were 45 mg/kg at day 4, 74 mg/kg at day 7, and 254 mg/kg DW at day 18	1
For 15 days adults were given a choice of distilled water or water with 30, 60, or 100 mg/L	Ducks consumed significantly more water treated at 100 mg/L than distilled water; no preference was evident at lower doses	2
Ducks, *Anas* spp.		
Ducklings fed diets containing 15 or 50 mg/kg ration for 51 days	Livers from control ducklings had 9.3 mg/kg DW. Livers from both treated groups had about 17 mg/kg DW at day 9, 37 mg/kg at day 30, and 47 mg/kg DW at day 51	1
Ducklings fed diet containing 200 mg/kg DW ration for 58 days	Copper concentrations in livers increased from 23 mg/kg DW at day 23 to 141 mg/kg DW at day 44; at day 58 it had declined to 80 mg/kg DW	1
Domestic chicken, *Gallus* spp.		
Chicks age 1-day fed copper-deficient diet of 0.7 mg/kg ration or copper-adequate diet of 8.0 mg/kg ration for 4-6 weeks	Chicks fed copper-deficient diet had >50% mortality and high frequency of cardiovascular and skeletal lesions. Chicks on copper-adequate diet had negligible mortality, no histopathology, and normal growth	3, 4
Chicks fed diet containing 1.5 mg/kg ration for 60 days	95% dead of copper deficiency	5
Chicks fed diet containing 2.7 mg/kg ration for 60 days	Normal growth but high frequency of vascular rupture	5
Chicks fed diet containing 8.7 mg/kg feed for 60 days	Good survival and growth	5
Day-old chicks fed diets containing 10 (control), 100, 200, or 350 mg/kg ration for 25 days	Reduced weight gain in the 350 mg/kg group; other groups same as controls	6
Chicks fed diets containing 15 or 50 mg/kg ration for 51 days	Livers from controls had 5.9 mg/kg DW; treated groups were similar to controls, with copper concentrations in livers between 4.3 and 8.5 mg/kg DW	1
Adults were fed diets equivalent to 28 mg/kg body weight (BW) daily for the first week, 42 mg/kg BW daily for week 2, and 100 mg/kg BW daily until anemia, toxicosis, or death occurred	After 2 to 6 weeks, chickens were weak, anorectic, and lethargic; 35% were anemic	6
Chicks fed diet containing 200 mg/kg DW for 58 days	Maximum copper concentration in liver was 17.2 mg/kg DW at day 20; by day 58 it had dropped to 7.2 mg/kg DW	1

Table 6. Organism, copper dose, and other variables	Effects	Reference[a]
Chicks fed diets supplemented with 250, 500, or 1,000 mg/kg ration for 4 weeks	No gizzard erosion in controls; chicks fed the 250 mg/kg diet grew better than other treated groups but some had gizzard erosion. Chicks fed the 500 and 1,000 mg/kg diets had decreased growth decreased feed efficiency, and a high frequency of gizzard erosion. Severity of gizzard erosion was significantly reduced in the 500 mg/kg group (but not the 1,000 mg/kg group) by adding 0.35% cholic acid	7
Laying hens fed diets supplemented with 250, 500, 1,000, or 2,000 mg/kg ration for 48 days	Controls and the 250 mg/kg group had lower concentrations of copper in liver than those fed diets containing 500 mg/kg and higher. Copper concentration in the2,000 mg/kg group increased from 3 mg/kg DW at day 3 to 1,790 mg/kg DW at day48 (vs. 11.3 mg/kg DW in controls)	8
Turkey, *Meleagris gallopavo*		
Day-old poults fed diets containing 0, 60, 120, or 240 mg/kg ration and adequate levels of methionine for 24 weeks	Diets containing 60 mg/kg improved body weight at age 8 weeks; the 120 and 240 mg/kg diets inhibited growth for the first8 weeks but not during the next 16 weeks	9
Week-old poults fed a purified corn starch, isolated soy protein diet supplemented with 50 to 800 mg/kg ration for 3 weeks	Dose-dependent increase in mortality and decrease in growth	10
Week-old poults fed corn-soybean meal supplemented with 100 to 800 mg/kg ration	No adverse effects on survival; growth reduced only at 800 mg/kg diet	10
Day-old poults fed diet containing 500 mg/kg ration for 24 weeks	Reduced growth and increased gizzard histopathology	9

[a]1, Wood and Worden 1973; 2, Rowe and Prince 1983; 3, Carlton and Henderson 1963; 4, Carlton and Henderson 1964a; 5, Carlton and Henderson 1964b; 6, National Academy of Sciences 1977; 7, Poupoulis and Jensen 1976; 8, Stevenson and Jackson 1978; 9, Kashani et al. 1986; 10, Supplee 1964.

Copper is lethal to mammals through a variety of routes (Table 7). Single oral doses of 6-637 mg Cu/kg BW are fatal to humans. A single oral dose of 200 mg/kg BW is usually fatal to cattle. Dietary copper is lethal when eaten for extended periods at more than 80 mg Cu/kg ration in sheep (equivalent to 5.1-10.7 mg Cu/kg BW daily), more than 238 mg/kg ration in pigs, and more than 4,000 mg/kg ration in rats (equivalent to more than 133 mg Cu/kg BW daily; Table 7). Adverse sublethal effects of copper to sensitive mammals occur in human infants at drinking water concentrations more than 3 mg Cu/L; in cattle at dietary levels greater than 20 mg Cu/kg BW by way of intraperitoneal injection and more than 4.2 mg Cu/kg BW via drinking water; in sheep given daily oral doses of 7.5 to 15.0 mg Cu/kg BW or fed diets containing more than 37.3 mg Cu/kg ration; in rats at greater than 100 mg Cu/kg ration (equivalent to greater than 7.9 mg Cu/kg BW daily), greater than 400 mg Cu/L drinking water, or greater than 2.0 to 2.5 mg Cu/kg BW daily via injection; and in pigs at more than 14.5 mg Cu/kg BW daily via diet. Elevated copper concentrations (328 mg Cu/kg DW) occur in livers of surviving cattle fed diets containing 8.2 mg Cu/kg ration; of sheep (1,109 mg/kg DW liver) fed diets containing 37.3 mg Cu/kg ration; and of rats (710 mg/kg FW liver) given intraperitoneal injections of 3.75 mg Cu/kg BW daily for 18 weeks (Table 7).

Table 7. Effects of copper on selected mammals

Table 7. Organism, copper dose, and other variables	**Effects**	**Reference[a]**
Cattle, *Bos* spp.		
Fed diet containing 8.2 mg/kg ration for 333 days	Copper concentration in liver increased from 111 to 328 mg/kg dry weight (DW)	1
Fed diets containing 20 to 125 mg/kg ration for extended period	Intoxication	2
Single dose; 200 mg/kg body weight (BW)	Lethal	2
Horses, *Equus* sp.		
Horses given a single oral dose of 20 or 40 mg/kg BW were challenged 24 h later with oral doses of 2, 4, 6, or 8 mg selenium/kg BW	All horses given 20 or 40 mg/kg BW were unaffected by selenium, regardless of dosage; without copper pretreatment, signs of severe Se toxicosis—including lethargy, colic, and death—developed in horses given 6 or 8 mg Se/kg BW	3
Fed diet containing 800 mg/kg ration for 6 months	No adverse effects	4
Humans, *Homo sapiens*		
3 mg/L drinking water for 9 months	Liver damage in infants	5
30 mg/L drinking water; single exposure; total intake unknown	Vomiting, diarrhea, stomach cramps	5
6 to 637 mg/kg BW; single exposure (attempted suicides)	13 of 53 patients died; death attributed to shock and hepatic or renal complications	5
Children who died from Wilson's disease vs. normal children		
Brain	2,090 mg/kg ash weight (AW), equivalent to 31 mg/kg fresh weight (FW) or 129 mg/kg DW vs. 290 mg/kg AW	6
Heart	6,800 mg/kg AW, equivalent to 75 mg/kg FW or 298 mg/kg DW vs. 340 mg/kg AW	6
Kidney	27,160 mg/kg AW, equivalent to 299 mg/kg FW or 1,245 mg/kg DW vs. 250 mg/kg AW	6
Liver	74,570 mg/kg AW, equivalent to 820 mg/kg FW or 2,217 mg/kg DW vs. 1,300 mg/kg AW	6
Pancreas	1,200 mg/kg AW vs. 160 mg/kg AW	6
Spleen	1,930 mg/kg AW vs. 100 mg/kg AW	6
Mice, *Mus* spp.		
Strain genetically deficient in copper (Menkes disease) given subcutaneous injections of 50 µg copper chloride ($CuCl_2$) on postnatal days 7 and 10. Before therapy, liver copper concentration was 3.1 mg/kg FW (vs. 30.1 mg/kg FW in normal mice)	Seven months postinjection there was some reduction in neurodegeneration; copper was distributed normally in liver; in intestine, copper accumulated in histiocytes	7
120 µg/m^3 air for 1-2 weeks	Alveoli thickening	5
<3.3 mg/kg BW; single intraperitoneal (ip) injection	No effect on oxygen consumption or body temperature	8
3.3-8.0 mg/kg BW; single ip injection	Dose-dependent reduction in oxygen consumption and	8

Table 7. Organism, copper dose, and other variables	Effects	Reference[a]
	body temperature	
4.02 mg/kg BW; single ip injection	50% dead	8
Drinking water equivalent of 4.2 mg/kg BW daily for 850 days	Decreased growth and survival	5
Drinking water equivalent of 42.5 mg/kg BW daily as copper glutamate; lifetime exposure	Maximal lifespan reduced from 986 days to 874 days	5
640 mg/L drinking water for 850 days	Decreased survival	5
Mink, *Mustela vison*		
Dietary equivalent of 3.5 mg/kg BW daily for 50 weeks	Decreased survival (deficiency)	5
Dietary equivalent of 13.5 mg/kg BW daily for 50 weeks	Some deaths; no adverse effect on reproduction of survivors	5
Rabbit, *Oryctolagus* sp.		
600 µg/m^3 air for 4 to 6 weeks	No adverse systemic or immunological effects	5
Domestic sheep, *Ovis aries*		
Ewes were fed a copper-deficient diet of 1.3 to 2.5 mg/kg DW ration. At mating, livers contained 20 to 106 mg/kg DW; after lambing, livers contained 3 to 12.3 mg/kg DW	22 of 54 (41%) lambs from ewes fed a copper-deficient diet developed swayback; these lambs had liver concentrations of 5.9 (1.5-11.0) mg/kg DW vs. 6.9 (2.5-14) mg/kg DW in non-swaybacked lambs	11
Ewes from vicinity of copper production plant receiving daily dietary intake of 465 mg/ewe (10.7 mg/kg BW daily) vs. control ewes with average daily dietary intake of 29 mg/ewe (0.67 mg/kg BW daily)	All ewes near copper facility were dead by day 89 vs. none dead in controls. At day 35, ewes near copper production plant had 11.8 mg/kg DW in wool vs. <7 mg/kg DW in controls	9
Merino sheep, 6 to 9 months old; given 5.1 mg/kg BW 5 times weekly for 28 weeks through the mouth as copper sulfate. Heliotrope and nonheliotrope diets	Some deaths. Yellow discoloration of sclera of eye; passing of red-colored urine. Copper concentrations, in mg/kg DW, from sheep fed nonheliotrope diets were 1,394 in liver (824 in controls) and 132 in kidney (20 in controls). Sheep on heliotrope diet had 2,783 mg/kg DW in liver and 321 mg Cu/kg DW in kidney	10
Oral administration of 7.5 mg/kg BW daily for 83 days, as copper sulfate	Severe morphological changes in liver, kidney, and brain; tissue damage continued after cessation of copper and was sufficiently severe to lead to repeated hemolytic crises. Maximum copper concentrations at day 83 were 3,289 mg/kg DW in liver (138 in controls), and 683 in kidney (15 in controls)	12
Lambs fed diets containing 9.1 (control) or 37.3 mg/kg ration for 11 weeks	Normal growth and survival. At slaughter, liver copper concentrations, in mg/kg DW, were 372 in controls and 1,109 in the treated group; plasma aspartate aminotrans- ferase was elevated in the high-dose group	13
Lambs fed diets containing 11 (control), 18, or 25 mg/kg ration for 10 weeks	Survival and growth normal in all groups. Liver concentrations, in mg/kg DW,were239 (11 mg/kg group), 454 (18 mg/kg group), and 721 (25 mg/kg group)	13

Table 7. Organism, copper dose, and other variables	Effects	Reference[a]
Rams, age 4.5 to 5.5 years; daily intake of15 mg/kg BW for 50 days	Increased concentrations of copper in ejaculates (16 mg/kg DW vs. 2 in controls) and liver (1,435 mg/kg DW vs. 63). Sperm motility in test rams was significantly decreased, abnormalities were increased, and testes copper was elevated (96-101 mg/kg DW vs. 60-69 in controls)	14
Equivalent of 20 mg/kg BW daily for 9 weeks	Hemolysis	15
Lambs fed diet containing 80 mg/kg DW ration for 6 weeks	Postmortem examination of 17 lambs that died suddenly showed brain histopathology, particularly in white matter of midbrain, pons, and cerebellum. Severe liver cirrhosis and necrosis of kidney tubules. Liver copper elevated at 3,225 to 4,325 mg/kg DW	16
Laboratory white rat, *Rattus* sp.		
Dietary route		
Male weanlings fed copper-deficient (0.13 mg/kg ration) or copper-adequate (5.7 mg/kg ration) diets for 49 days	24% of the copper-deficient rats died of cardiac rupture; ruptured hearts had lower magnesium and higher sodium, phosphorus, and calcium. Copper-adequate rats had 21.7 mg/kg DW liver vs. 2.2 in copper-deficient rats in which hearts had ruptured	17
Low copper diet of 1 mg/kg DW ration vs. 5 mg/kg diet for 12 weeks	Dose-dependent increase in copper concentrations in kidney, liver, and plasma. Low Cu status increases retention of cadmium in liver	18
100 mg/kg diet for 20 weeks	Increased blood pressure	5
250 mg/kg diet for 3 months	No deaths	5
500 mg/kg diet for 3 months	Kidney damage	5
1,000 mg/kg diet for 3 months	Stomach and liver damage	5
2,000 mg/kg diet for 1 to 3 weeks	Liver and kidney damage	5
4,000 mg/kg diet (133 mg/kg BW daily) for 1 week	Increased mortality	5
6,000 mg/kg diet (300 mg/kg BW daily) for2 weeks	Weanlings died from extensive centrilobular necrosis	5
Equivalent to 7.9 mg/kg BW daily for 90 days	Increased serum glutamic oxaloacetic transaminase enzyme activity	5
Equivalent to 10 mg/kg BW daily for20 weeks	Increased blood pressure; increased hemoglobin	5
Equivalent to 40 mg/kg BW daily for30 days	Anemia, increased liver enzyme activity, increased cholesterol and urea	5
Equivalent to 130 mg/kg BW daily for18 weeks	Decreased body growth; decreased testes weight	5
Equivalent to 144 mg/kg BW daily for4 weeks	Decrease in rate of body weight gain	5
Drinking water route		
0.25, 2, or 16 mg/L for 109 to 119 days	Serum copper rose from 44 µg/L (controls) to 106 µg/L (0.25 mg/L group) to 848 (2 mg/L) to 943 µg/L (16 mg/L group); dose-dependent decrease in serum cholesterol, triglycerides, and phospholipids	19
50 or 150 mg/L for 15 to 30 days	No adverse effect on liver microsomal activity	20
398 to 450 mg/L for 15 to 30 days	Reduction in liver aniline hydroxylase activity; liver	5, 20

Table 7. Organism, copper dose, and other variables	Effects	Reference[a]
	histopathology	
Inhalation route Copper sulfate spray containing 330 g/L for daily exposures of 1 h for as long as 10 days	Concentrations of copper in liver, in mg/kg FW, were 32 after 6 hr, 84 after 5 days, and 285 after 10 days	27
Injection route 0.26 mg/rat daily as copper sulfate for 60 days; subcutaneous (sc) injection	Treated rats had 1,000 mg/kg FW liver (vs. 4.7 in controls); lowered hemoglobin, hematocrit, and red cell counts; mean survival time of 67 days; hepatic and renal histopathology	15
0.625, 1.25, 2.5, or 3.75 mg/kg BW daily for 18 weeks; intraperitoneal injection	Dose-time-dependent increase in copper concentrations in liver, spleen, and lung; little accumulation in muscle and skin. Reduced growth at 2.5 and 3.75 mg/kg BW daily; reduced survival at 3.75 mg/kg BW. Maximum copper concentrations recorded, in mg/kg FW (vs. saline controls,) were 710 in liver (<5), 212 in kidney (<10), 7 in lung (<1.5), 27 in spleen (<2.0), 6 in bone (<2.0), and 2.2 in testes (<1.6)	21
Adult males given 2 mg/kg BW daily as copper acetate for 14 days; intraperitoneal injection	Increased serum ceruloplasmin and white blood cell number	22
Other routes Isolated cells from adrenal and testes held in media containing 0.065, 0.65, or 6.5 in media containing 0.065, 0.65, or 6.5 mg/kg for 2 h	No effect at lowest doses. High dose caused decreased survival of cells from both organs and reduced testosterone production	23
Rodents, various species 3-7 mg/kg BW; single ip or sc injection	50% dead	15
Common shrew, *Sorex araneus* Newly weaned shrews fed diets equivalent to 2.13 mg/shrew daily for 12 weeks; uncontaminated diets contained 25.1 mg/kg DW ration	No effect on growth, survival, or tissue copper burdens; kidney and liver copper concentrations increased in response to cadmium dosing	24, 25
Domestic pig, *Sus* spp. Dietary equivalent of 14.6 mg/kg BW daily for 54 days	Decreased hemoglobin and hematocrit; decreased growth rate	5
Dietary equivalent of 36 mg/kg BW daily for 7 weeks	Decreased hemoglobin, altered serum enzyme activity	5
Fed diets containing <150 mg/kg ration for 9 months	No copper accumulations over controls in liver (16-48 mg/kg DW) or kidney(20-49 mg/kg DW); growth promoting effects	26
Fed diets supplemented with 238-250 mg/kg ration, as copper sulfate, from age 3 weeks for 9 months	High mortality, usually between age 14 and 20 weeks. Dead pigs had 1,300 mg/kg DW in liver and 95 mg/kg in liver; survivors had as much as 2,100 mg/kg DW liver, 670 mg/kg DW kidney, and 3.3 mg/L serum	26
Fed diets containing 700 mg/kg ration for several months	High mortality; survivors had anemia, gastric ulcers, liver pathology, and100-170 mg/kg FW in liver	15

Terrestrial Plants and Invertebrates

Copper is toxic to sensitive plants when plant nutrient solutions contain greater than 40-200 µg Cu/L, when leaves have greater than 10 to 12 mg Cu/kg DW, and when extractable copper in soils is greater than 60 mg/kg DW soil (Table 4). Excess copper inhibits root elongation and branching and reduces the ability of the plant to explore the soil for water and nutrients (Arduini et al. 1995). Root damage occurs in pine seedlings (*Pinus* spp.) after exposure for 10 days to nutrient solutions that contain 40 µg Cu/L. A lower concentration of 4 µg Cu/L has no adverse effects on root growth and morphology, while a higher concentration of 400 µg Cu/L completely inhibits root growth within 3 days (Arduini et al. 1995). Poultry litter is a useful agricultural byproduct with high nitrogen and phosphorus content and is frequently added to agricultural soils. Poultry litter from northern Georgia containing 1,196 mg Cu/kg DW and applied at a final rate of 5-15 mg Cu/kg soil to fields of Sudex (*Sorghum bicolor* x *S. sudanense*) did not affect copper levels of treated Sudex or produce any evidence of toxicity (van der Watt et al. 1994). But most terrestrial vegetation in the United States, Sweden, Wales, and other locales is usually adversely affected by emissions from copper mines, brass foundries, and copper smelters (Hutchinson 1979). Damage to vegetation persists for at least 50 years after closure of a copper smelter because of copper, arsenic, and lead in the soil. Particularly sensitive to copper in the soils are white pine (*Pinus strobus*) and red maple (*Acer rubrum*); less sensitive are Douglas fir (*Pseudotsuga menziesii*) and lodgepole pine (*Pinus contorta*; Hutchinson 1979).

Earthworms (*Eisenia fetida*) held in soils containing 53 mg Cu/kg DW show a 50% reduction in cocoon production in 56 days; 32 mg Cu/kg soil had no effect on cocoon production (Spurgeon et al. 1994). The LC50 (56 days) value for earthworms is 555 mg Cu/kg DW soil; no deaths occur at 210 mg/kg soil during this period. Copper is more toxic to *Eisenia fetida* than are salts of cadmium, zinc, or lead (Spurgeon et al. 1994). Copper adversely affects the earthworm *Lumbricus rubellus* (Ma 1984). Concentrations of 150 mg Cu/kg surface soil from an accidental spill of copper sulfate in grasslands reduced earthworm populations by about 50%; surface soil concentrations of 260 mg Cu/kg kill almost 100% of the *Lumbricus*. Copper is most toxic to *Lumbricus* at low soil pH (4.8-7.1) and at low temperatures (Ma 1984).

Tests show that the presence of soil reduces the toxicity of copper to the soil-dwelling nematode *Caenorhabditis elegans*; copper toxicity to nematodes increases with increasing densities of bacteria and increasing concentrations of sodium chloride or potassium chloride (Donkin and Dusenbery 1993). Terrestrial isopods efficiently assimilate and store copper as detoxified granules in the hepatopancreas; this activity is in contrast to many species of marine crustaceans that are unable to assimilate, detoxify, or otherwise regulate copper (Weeks and Rainbow 1993).

Aquatic Organisms

Plants

Photosynthesis and growth in sensitive species of freshwater algae are inhibited by copper concentrations of 1-6 µg/L (NAS 1977; Table 5). For sensitive species of estuarine phytoplankton, copper is lethal at 50 µg/L and most toxic under conditions of decreasing salinity, pH, and concentrations of chelators (Erickson et al. 1970). Sensitivity to copper varies widely among species of estuarine algae (Erickson et al. 1970; Table 5); some species, for example, grow normally at concentrations as high as 10 mg Cu/L during exposure for 9 days (Piccinni and Copellotti 1982). In mesocosm studies, 50 µg Cu/L caused a reduction of about 80% in total zooplankton and total algal biovolumes; the algal assemblage that persisted was dominated by diatoms (Havens 1994). Copper-resistant strains of *Euglena gracilis* challenged with high sublethal concentrations of copper for 5 days had an altered cysteine metabolism (Coppellotti 1989).

Some species of aquatic plants absorb or adsorb dissolved copper at extremely high rates (Table 5). Bioconcentration factors for copper and freshwater alga (*Chlorella* sp.) range from 203-2,000 after exposure for 14 to 30 h (USEPA 1980). Seagrass (*Heterozostera tasmanica*) in seawater containing 42 µg Cu/L for several

weeks contain 2,700 mg Cu/kg DW; seagrasses in media containing 0.3 µg Cu/L contain 2.5 mg Cu/kg DW; and intermediate values are reported for 10 µg Cu/L (306 to 564 mg/kg DW) and 20 µg/L (1,280 mg/kg DW; Ahsanullah and Williams 1991). Some freshwater aquatic macrophytes accumulate as much as 54,500 mg Cu/kg DW, as was the case for *Lemna* sp. during exposure to 1,000 µg Cu/L; a lower dose regimen of 35 µg Cu/L results in 256 mg Cu/kg DW *Lemna* (Stokes 1979).

Cnidarians

Sea anemones (*Anemonia viridis*) in seawater solutions containing 50 or 200 µg Cu/L regulate copper by expelling zooxanthellae which are shown to accumulate copper (Harland and Nganro 1990).

Mollusks

Initial effects of copper on mussels (*Mytilus* spp.) include valve closure, a reduction in filtration rates, and cardiac inhibition; these responses all serve to slow the uptake of copper through a reduction in mussel contact with the ambient environment and a reduction in blood flow within the organism (Gainey and Kenyon 1990). Copper impairs the structure and function of cellular membranes in mussels by stimulating the peroxidation of membrane lipids; end products of lipid peroxidation contribute to the formation of lipofuscins (Viarengo et al. 1990). Copper-induced lysosomal lipofuscin accumulations, together with metallothioneins, control copper residues at the cellular levels and are responsible for the short half-time persistence (6 to 8 days) of copper in the digestive gland of mussels (Viarengo et al. 1990). Concentrations of heat shock protein (hsp60) in mantle tissues of mussels exposed to copper increased in a dose-dependent manner; hsp60 may have potential as a biomarker of copper insult (Sanders et al. 1991). Copper-stressed common mussels (*Mytilus edulis*) die more quickly under conditions of anoxia, high temperatures, and low salinities (Weber et al. 1992). Concentrations of copper that cause a decrease in yields of normal larvae in populations of *Mytilus edulis* from unpolluted or mildly contaminated sites did not affect embryonic development of mussels from polluted sites; cross breeding of mussels from these sites suggests that copper tolerance in mussels is mostly maternally determined (Hoare et al. 1995a). Embryos of common mussels are more sensitive to copper than veliger larvae or postlarval spat stages (Hoare et al. 1995b). A copper-induced decrease in glochidial viability is a possible explanation for the disappearance of freshwater unionid mussels from acid- and metals-contaminated waters (Huebner and Pynnonen 1992). Hole et al. (1993) state that mussels of all ages are equally susceptible to copper and that their capacity to recover declines with increasing age; however, this phenomenon needs verification.

Bioconcentration factors for marine bivalves (ratio of milligrams of copper per kilogram fresh weight soft parts to milligrams of copper per liter of medium) vary from 85 to 28,200. Bioconcentration factors for copper are highest for American oysters after exposure for 140 days (20,700-28,200), and lowest for bay scallops (*Argopecten irradians*) after exposure for 112 days (3,310) and for softshell clams after exposure for 35 days (3,300; USEPA 1980). Copper is more toxic to embryos of the tropical giant clam (*Tridacna derasa*) than to embryos of bivalves from temperate regions (Soria-Dengg and Ochavillo 1990), possibly because many tropical species of shellfish live near their upper lethal thermal limits and are unable to withstand additional environmental stressors. Juveniles of Asiatic clams (*Corbicula fluminea*) are more sensitive than adults to ionic copper (Belanger et al. 1990).

On exposure to lethal concentrations of copper the channeled whelk (*Busycon canaliculatum*), a marine gastropod, accumulates the metal in gill and osphradium. These tissues show progressive histopathology including swelling of the gill filaments, amoebocytic infiltration of the connective tissue, and necrosis and sloughing of the mucosa (Betzer and Yevich 1975). Copper-resistant strains of freshwater gastropods are found in media containing elevated concentrations of 35 µg Cu/L (Ebele et al. 1990), suggesting physiological or genetic adaptation. Fine suspensions of copper and kaolinite mixtures are more toxic to freshwater gastropods than copper alone; toxicity is greater at pH 8 than at pH 7 (Al-Sabri et al. 1993). The authors conclude that copper is strongly adsorbed by kaolinite in alkaline media and that the acidic pH of the snail gut enhances release of ionic copper. In freshwater gastropods, ionic copper causes hypersynthesis of lysosomal enzymes and acid and alkaline phosphatases; immature gastropods are more sensitive than adults (Winger et al. 1984).

Arthropods

Life-cycle exposures of four daphnid species to graded concentrations of copper show reductions in survival at more than 40 µg/L and reductions in growth and reproduction at 40 to 60 µg/L; heavier and larger species are the most resistant to copper (Winner and Farrell 1976; Table 5). Starvation increases the sensitivity of most species of freshwater cladocerans to copper (Koivisto et al. 1992); however, there is no difference in LC50 (48

h) values between fed and starved *Daphnia magna* (Lazorchak and Waller 1993). Bioavailability and toxicity of copper to *D. magna* and other tested arthropods are usually higher under conditions of increasing acidification, ionic copper, alkalinity, and temperature, or of decreasing dissolved organic carbon (Meador 1991; Taylor et al. 1994; Zou and Bu 1994). Mixtures of copper and other metals produce additive or more-than-additive effects in *D. magna* than would be expected on the basis of individual components (Enserink et al. 1991). The concept that chronic exposures to pulses of the LC50 concentrations of copper or cadmium causes no damage to freshwater organisms—provided that the average daily concentration never exceeds the no-observable-effect concentration—was tested in daphnids. The concept was true for cadmium but not copper, and the use of pulsed exposures for establishing water quality criteria to protect aquatic life needs to be reexamined (Ingersoll and Winner 1982).

Copper uptake by aquatic arthropods occurs usually by way of the gut after eating or from the gills and other permeable surfaces in contact with the ambient medium (Weeks and Rainbow 1993). Copper accumulations by crustaceans are greatest at elevated (summer) temperatures and during molting (Powell and White 1990). A relatively high bioconcentration factor of 2,000 is documented for copper and freshwater stoneflies (*Pteronarcys californica*; USEPA 1980), but the reasons for this phenomenon are unknown. The high tolerance to copper and other metals of mayfly larvae (*Baetis thermcius*), and high copper accumulations, is attributed, in part, to the selective induction of metal binding proteins in the gut (Sumi et al. 1991; Table 3). Marine amphipods readily accumulate dissolved copper from seawater in a dose-dependent manner (Weeks and Rainbow 1991). But some species of talitrad amphipods are unable to meet their copper requirements from seawater alone and depend on dietary sources of copper (Weeks and Rainbow 1993). Mesocosm studies with freshwater zooplankton assemblages show that increasing copper concentrations in the range 0 to 50 µg/L causes a reduction in total zooplankton and changes in diversity; within 4 days, copepods became dominant at the expense of cladocerans (Havens 1994).

Soldier crabs (*Mictyris longicarpus*) accumulate copper mostly from sediments rather than the water column (Weimin et al. 1994). The fine particles of sediment trapped as food contain bioavailable fractions of copper and other metals, and these significantly correlate with metal concentrations in the body of the crab. However, copper accumulation from sediments by soldier crabs occurred only at an artificially high concentration (1,900 mg Cu/kg DW sediment), which also had toxic effects. Soldier crabs seem unable to regulate copper within their bodies (Weimin et al. 1994).

In shore crabs (*Carcinus maenas*), several days of exposure to sublethal concentrations of waterborne copper cause extensive damage to gill epithelium; at lethal concentrations, tissue hypoxia is probably the major effect of copper (Nonnotte et al. 1993). Starved shore crabs show a reduction in carapace copper concentrations and heavier midgut glands; starvation in combination with copper exposure (500 µg/L) results in an increase in copper in the carapace and a decrease in carapace calcium (Scott-Fordsmand and Depledge 1993). Shore crabs in seawater with high (10 mg/L) levels of waterborne copper show reductions in hemolymph sodium, gill sodium-potassium-ATPase activity, activities of various midgut gland enzymes (hexokinase, phosphofructokinase, pyruvate kinase), and hemolymph electrolytes (Hansen et al. 1992a, 1992b).

In the rusty crayfish (*Orconectes rusticus*), toxicity of copper at high concentrations is due to the coagulatory action on cellular proteins and to interference with respiratory processes; at low concentrations, copper causes degenerative changes in certain tissues and interferes with glutathione equilibrium (Hubschman 1967). Larvae of the red crayfish (*Procambarus clarkii*) exposed to copper as embryos are less sensitive than those exposed after hatching, suggesting acclimatization (Rice and Harrison 1983).

Annelids

Aquatic oligochaetes (*Lumbriculus variegatus*) do not accumulate significant amounts of copper when compared to controls after exposure for 30 days in sediments containing as much as 90.1 mg Cu/kg DW or in water containing as much as 2.3 µg Cu/L (Ankley et al. 1994). Larvae of the sandworm (*Nereis diversicolor*) are more resistant to copper with increasing organism age and with increasing temperature and salinity of the medium (Ozoh and Jones 1990). In adult sandworms, whole body loadings of copper usually increase with increasing temperature in the range of 12-22º C and with decreasing salinity in the range 0.7-3.1% (Ozoh 1992b); however, copper-temperature-salinity interactions are significant and complex in this species (Ozoh 1994).

Fishes

Adverse sublethal effects of copper on behavior, growth, migration, and metabolism occur in representative species of fishes at nominal water concentrations between 4 and 10 µg/L. In sensitive species of teleosts, copper adversely affects reproduction and survival from 10-20 µg Cu/L (Hodson et al. 1979; Table 5). Copper exerts a wide range of physiological effects in fishes, including increased metallothionein synthesis in hepatocytes, altered blood chemistry, and histopathology of gills and skin (Iger et al. 1994). At environmentally realistic concentrations, free copper adversely affects resistance of fishes to bacterial diseases; disrupts migration (that is, fishes avoid copper-contaminated spawning grounds); alters locomotion through hyperactivity; impairs respiration; disrupts osmoregulation through inhibition of gill Na^+-K^+-activated ATPase; is associated with tissue structure and pathology of kidneys, liver, gills, and other hematopoietic tissues; impacts mechanoreceptors of lateral line canals; impairs functions of olfactory organs and brain; and is associated with changes in blood chemistry, enzyme activities, and corticosteroid metabolism (Hodson et al. 1979). Copper-induced cellular changes or lesions occur in kidneys, lateral line, and livers of several species of marine fishes (Gardner and LaRoche 1973).

Copper-induced mortality in teleosts is reduced in waters with high concentrations of organic sequestering agents and in genetically resistant species (Hodson et al. 1979). At pH values less than 4.9 (that is, at pH values associated with increased aluminum solubility and toxicity), copper may contribute to the demise of acid-sensitive fishes (Hickie et al. 1993). Copper affects plasma Na^+ and gill phospholipid activity; these effects are modified by water temperature and hardness (Hansen et al. 1993). In red drum, copper toxicity is higher at comparatively elevated temperatures and reduced salinities (Peppard et al. 1991). Copper is acutely toxic to freshwater teleosts in soft water at concentrations between 10 and 20 µg/L (NAS 1977). In rainbow trout, copper toxicity is markedly lower at high salinities (Wilson and Taylor 1993). Comparatively elevated temperatures and copper loadings in the medium cause locomotor disorientation of tested species (Kleerekoper 1973). Copper may affect reproductive success of fish through disruption of hatch coordination with food availability or through adverse effects on larval fishes (Ellenberger et al. 1994). Chronic exposure of representative species of teleosts to low concentrations (5 to 40 µg/L) of copper in water containing low concentrations of organic materials adversely affects survival, growth, and spawning; this range is 66 to 120 µg Cu/L when test waters contain enriched loadings of organic materials (Hodson et al. 1979).

Larval and early juvenile stages of eight species of freshwater fishes are more sensitive to copper than embryos (McKim et al. 1978) or adults (Hodson et al. 1979). But larvae of topsmelt (*Atherinops affinis*) are increasingly sensitive to copper with increasing age. Topsmelt sensitivity is associated with increasing respiratory surface area and increasing cutaneous and branchial uptake of copper (McNulty et al. 1994).

Sublethal exposure of fishes to copper suppresses resistance to viral and bacterial pathogens (Rougier et al. 1994) and, in the case of the air-breathing catfish (*Saccobranchus fossilis*), affects humoral and cell-mediated immunity, the skin, and respiratory surfaces (Khangarot and Tripathi 1991). Rainbow trout exposed to 50 µg Cu/L for 24 h—a sublethal concentration—show degeneration of olfactory receptors that may cause difficulties in olfactory-mediated behaviors such as migration (Klima and Applehans 1990). The primary site of sublethal copper toxicity in rainbow trout is the ion transport system of the gills (Hansen et al. 1993). In European sea bass (*Dicentrarchus labrax*), copper compromises the defense system of red blood cells against active forms of oxygen, leading to increased membrane lipid peroxidation (Roche and Boge 1993).

Dietary copper is more important than waterborne copper in reducing survival and growth of larvae of rainbow trout (Woodward et al. 1994). Simultaneous exposure of rainbow trout to dietary and waterborne copper results in significant copper assimilation. Diet is the main source of tissue copper; however, the contribution of waterborne copper to tissue burdens increases as water concentrations rise (Miller et al. 1993).

Rate and extent of copper accumulations in fish tissues are extremely variable between species and are further modified by abiotic and biological variables. Copper accumulations in fish gills increase with increasing concentrations of free copper in solution, increasing dissolved organic carbon (DOC), and decreasing pH and alkalinity (Playle et al. 1993a, 1993b). Starved Mozambique tilapia accumulate significantly more copper from the medium in 96 h than did tilapia fed a diet containing 5.9 mg Cu/kg DW ration (Pelgrom et al. 1994). The bioconcentration factor for whole larvae of the fathead minnow was 290 after exposure for 30 h, but only 0.1 in muscle of bluegills after 660 h (USEPA 1980). Prior exposure of brown bullheads (*Ictalurus nebulosus*) to

sublethal copper concentrations for 20 days before exposure to lethal copper concentrations produces higher copper concentrations in tissues of dead bullheads than in those not previously exposed; however, the use of tissue residues is not an acceptable autopsy procedure for copper (Brungs et al. 1973). Rising copper concentrations in blood plasma of catfish (*Heteropneustes fossilis*) seem to reflect copper stress, although the catfish appear outwardly normal. Plasma copper concentrations of catfish increase from 290 µg Cu/L in controls at start to 380 µg Cu/L in survivors at 72 h (50% dead); a plasma copper concentration of 1,060 µg Cu/L at 6 h is associated with 50% mortality (Banerjee and Homechaudhuri 1990). In rainbow trout, copper is rapidly eliminated from plasma; the half-time persistence is 7 min for the short-lived component and 196 min for the long-lived component (Carbonell and Tarazona 1994).

Attraction to waters containing low (11 to 17 µg/L) concentrations of copper occurs in several species of freshwater teleosts, including goldfish (*Carassius auratus*) and green sunfish (*Lepomis cyanellus*); however, other species, including white suckers (*Catostomus commersonii*), avoid these waters (Kleerekoper 1973). In avoidance/attraction tests, juvenile rainbow trout avoided waters containing 70 µg Cu/L but were significantly attracted to water containing 4,560 µg Cu/L; a similar pattern was observed in tadpoles of the American toad, *Bufo americanus* (Birge et al. 1993). Copper concentrations in the range of 18 to 28 µg/L interfere with bluegill growth and prey choice (Sandheinrich and Atchison 1989). Copper interferes with the ability of fish to respond positively to L-alanine, an important constituent of prey odors; concentrations as low as 1 µg Cu/L inhibit this attraction response in some species (Steele et al. 1990).

Increased tolerance to copper was observed in fathead minnows after prolonged exposure to sublethal concentrations, but tolerance was not sustained on removal to clean water. Copper tolerance in fathead minnows is attributed to increased production of metallothioneins (Benson and Birge 1985). Copper tolerance in rainbow trout seems dependent on changes in sodium transport and permeability (Lauren and McDonald 1987a).

Integrated Studies

Bioconcentration and biomagnification of copper occurs in the food chain of diatom (*Skeletonema costatum*) to clam (*Donax cuneatus*) to white prawn (*Penaeus indicus*). All species accumulate copper from the medium, and clams and shrimp from the diet. Maximum concentrations after exposure to 200 µg Cu/L and diets for 10 days, in mg Cu/kg FW, are 2.8 in whole diatoms, 13.6 in clam soft parts, and 33.9 in whole shrimp (Rao and Govindarajan 1992). In the marine food chain of phytoplankton to clam *(Tellina tenuis*) to juvenile plaice (*Pleuronectes platessa*), copper accumulates in a concentration-dependent manner in viscera of plaice. All organisms held in 10, 30, or 100 µg Cu/L solutions for 100 days had reduced growth. Copper concentrations, in mg Cu/kg DW at day 100, in soft parts of clams *(T. tenuis)* were 270 in the 10 µg/L group, 470 in the 30 µg/L group, and 1,100 in the 100 µg/L group vs. less than 50 in the controls; for plaice viscera, these values were 30 in controls, 71 in the 10 µg/L group, 147 in the 30 µg/L group, and 467 mg/kg DW in the 100 µg/L group (Saward et al. 1975). Accumulations in Pacific oysters held in copper-loaded sediments are similar to those of oysters contaminated through ingestion of diatoms (*Haslea ostrearia*). However, accumulations are highest in Pacific oysters when exposed through the medium (Ettajani et al. 1992); in that study, a concentration of 30 µg Cu/L medium for 21 days results in copper concentrations of 137 mg/kg DW in diatoms and 1,320 mg/kg DW in oyster soft parts. Oysters fed contaminated diatoms in the study had 419 mg Cu/kg DW soft parts. Oysters held in sediments containing 108 mg Cu/kg DW—a level reached after exposure for 21 days to 300 µg Cu/L—had 401 mg Cu/kg DW (Ettajani et al. 1992). Copper-induced changes in population density and community metabolism occur in an aquatic mesocosm of algae, protozoans, rotifers, oligochaetes, and bacteria; death of rotifers, algae, and oligochaetes occurs at concentrations as low as 700 µg Cu/L. Adverse effects occur at 300 to 700 µg Cu/L but are negated by increasing concentrations of dissolved organic matter (Sugiura et al. 1982).

Transfer of copper from wood treated with chromated copper arsenate (CCA) occurs in estuarine algae (*Ulva* sp., *Enteromorpha* sp.), American oysters, mud snails (*Nassarius obsoletus*), and fiddler crabs (*Uca* spp.; Weis and Weis 1992). Algae, barnacles, and mussels from CCA-treated lumber show elevated concentrations of copper when compared to reference sites. The epibiotic estuarine community that forms on CCA-treated wood has lower species richness, diversity, and biomass when compared to untreated lumber (Weis et al. 1993b). Copper is trophically transferred from CCA-exposed American oysters to predatory gastropods (*Thais* sp.), resulting in reduced gastropod feeding and growth (Weis and Weis 1993).

Birds

No data are available on the toxicity of copper to avian wildlife. All studies with birds and copper use domestic chickens, ducks, or turkeys (Table 6). Copper, however, may indirectly affect avian wildlife by curtailing certain prey species. Winger et al. (1984), for example, show that apple snails (*Pomacea paludosa*) are not only extremely susceptible to copper (LC50 of 24 to 57 µg/L in 96 h; immatures most sensitive), but are the primary food of the snail kite (*Rostrhamus sociabilis*), an endangered species. The decline of the apple snail in southern Florida coincided with the use of copper-diquat to control hydrilla aquatic weeds (*Hydrilla verticillata*), with serious implications for the snail kite (Winger et al. 1984).

In the domestic chicken, adverse effects of copper occur in chicks fed diets containing 350 mg Cu/kg ration for 25 days (reduced weight gain) and in adults given a dietary equivalent of more than 28 mg Cu/kg BW (Table 6). Chicks fed diets of 500 mg Cu/kg ration show damage to the gizzard lining; damage effects are attributed to the shedding of gizzard glandular cells into the keratin-like koilin layer, disrupting koilin production (Bremner 1979). Copper-induced gizzard histopathology in growing chicks is not reversed by zinc or vitamins B_{12} or E (Poupoulis and Jensen 1976). Supplementing chick diets with copper did not prove markedly advantageous (Poupoulis and Jensen 1976), provided that normal rations had about 4 mg Cu/kg and adequate iron (Carlton and Henderson 1964b). Unlike mammals, chicks fed copper-supplemented diets do not have elevated copper concentrations in liver or signs of liver damage (Bremner 1979). Broiler hens housed on slats made of lumber pressure-treated with chromated copper arsenate showed severe foot-pad dermatitis and excessive mortality after 17 weeks; however, arsenic and cresylic acid—not copper—may be the responsible agents (Sander et al. 1994).

Ducklings (*Anas* spp.), unlike chicks, accumulate copper in livers when fed diets supplemented with high loadings of copper (Wood and Worden 1973). Domesticated mallards show a dose-time dependent increase in copper liver concentrations, with a maximum concentration of 254 mg Cu/kg DW liver (Table 6). Mallards seem to prefer drinking water containing 100 mg Cu/L over distilled water (Table 6); however, these birds were molting and this may have influenced their response because trace mineral requirements rise during molting (Rowe and Prince 1983).

In turkeys, natural diets with as much as 800 mg Cu/kg ration have no adverse effects on growth or survival. But purified diets are toxic to turkeys in three weeks, and purified diets that contain as little as 50 mg Cu/kg ration produce adverse effects (Waibel et al. 1964). Turkeys fed purified diets with supplemented copper show a dose-dependent increase in mortality and decrease in growth; these effects are attributed to a copper-accelerated dietary deterioration (Supplee 1964). Turkey growth and survival are acceptable when fed purified diets supplemented with as much as 800 mg Cu/kg ration provided that effective levels of added antioxidant (0.02% ethoxyquin) and stabilized sources of vitamins A and D are present (Supplee 1964).

Mammals

Wilson’s disease is the only naturally occurring neuropathological condition in humans and other mammals in which copper poisoning is implicated. People with Wilson’s disease have severe pathological changes in the brain, especially in the basal ganglia, and in the liver; pathology is associated with excess copper in tissues (Doherty et al. 1969). Copper concentrations in tissues from children that die from Wilson’s disease are as much as 2,217 mg/kg DW in liver and 1,245 mg/kg DW in kidney (Table 7). Long-term exposure of humans to copper dust irritates the nose, eyes, and mouth and causes headaches, dizziness, nausea, and diarrhea (USEPA 1980; ATSDR 1990). Drinking water that contains higher than normal concentrations of copper may cause vomiting, diarrhea, stomach cramps, nausea, and greenish or bluish stools and saliva. Intentionally high intakes of copper may result in liver and kidney damage, and sometimes death, especially in children. The seriousness of the effects of copper is expected to increase with increasing dose and duration of exposure (USEPA 1980; ATSDR 1990). Human tissues exposed directly to copper or copper salts will suffer adverse effects because of copper absorption. This is the case for copper bracelets on sweaty skin, for certain intrauterine devices, and for copper dental fillings (USEPA 1980). In monkeys, copper used as dental fillings in deciduous teeth causes more severe pulp damage than did other materials studied (USEPA 1980).

Mammals and birds are 100-1,000 times more resistant to copper than other animals (Schroeder et al. 1966). But excessive dietary intakes of copper by 20- to 50-fold over normal levels may have serious effects in mammals. Depending on the species, growth and food intake may be reduced, anemia may develop, and liver,

kidney, brain, and muscle may degenerate, often resulting in death (Bremner 1979; ATSDR 1990). Copper poisoning in mammals may result from consumption of plants treated with copper-containing pesticides, from the veterinary use of copper sulfate to control helminthiasis and infectious pododermatitis in cattle and sheep, and from the ingestion of contaminated soils and vegetation near copper mining and refining operations (NAS 1977). Emissions from copper mines and smelters are often associated with deaths of horses, cows, and sheep; pasture lands, in some cases, are fit for grazing only after heavy rains (Hutchinson 1979).

Ruminant mammals are significantly more sensitive to copper than nonruminant mammals and poultry (Schroeder et al. 1966; NAS 1977). Signs of copper poisoning in ruminants include vomiting, excessive salivation, abdominal pain, diarrhea with greenish-tinted feces, pathology of internal organs, elevated copper concentrations in liver, altered enzyme activities in liver and serum, and collapse and death within 24 to 48 h (NAS 1977). Young calves may develop copper toxicosis at relatively low copper intakes, especially when receiving milk-based diets; goats, however, seem resistant to copper toxicosis (Bremner 1979). Among ruminants, domestic sheep are particularly susceptible to copper insult from grazing on pastures treated with copper-containing fungicides and molluskicides or from inadvertently consuming diets specially formulated for pigs and which contain large amounts of copper as a swine growth stimulant (Todd 1969; Bremner 1979).

Chronic copper poisoning in domestic sheep is first characterized by a period of passive accumulation of copper in the tissues. This period varies from a few weeks to more than a year. During this time the animal appears outwardly normal although the liver may contain more than 1,000 mg Cu/kg DW and plasma activities of aspartate transaminase, sorbitol dehydrogenase, lactic dehydrogenase, and arginase increase, indicating that liver damage has occurred. During the last few weeks of the passive phase, and prior to the so-called toxic phase, liver histopathology of parenchymal cells and copper-containing Kupffer cells occurs. The toxic phase, which is an acute illness and referred to as the hemolytic crisis, usually results in death 2-4 days later. During this phase sheep refuse to eat but have an excessive thirst. The eyes are usually sunken. The venous blood is chocolate colored. The liver is jaundiced. The kidneys are completely gorged with hemoglobin breakdown products and the medulla and cortex are black. The spleen is enlarged, with the parenchyma a deep brown to black color. The onset of these signs in sheep is associated with liberation of copper from the liver and a massive increase in blood copper concentrations. The increased blood copper concentrations lead to an increase in blood methemoglobin and a sudden fall in the erythrocyte glutathione level immediately followed by massive hemolysis and kidney damage, leading to uremia and death. At the time of crisis, elevated serum creatine phosphokinase activity suggests that muscle cell membranes are affected, and elevated serum glutamic oxaloacetate transaminase (SGOT) and lactic dehydrogenase activities indicate progressive liver necrosis (Doherty et al. 1969; Todd 1969; Thompson and Todd 1974; Bremner 1979). It is emphasized that (1) blood copper status and liver function in sheep experimentally poisoned with copper sulfate are linked to elevated SGOT activities 1 to 6 weeks in advance of obvious external signs (MacPherson and Hemingway 1969); (2) copper chloride is 2 to 4 times more toxic to sheep than copper sulfate is (NAS 1977); and (3) the use of copper-enriched feeding stuffs increases the risk of chronic copper poisoning in sheep fed purified rations (Froslie et al. 1983). Also, sheep that accumulate higher than normal amounts of copper in the liver (i.e., 1,900 mg Cu/kg DW) are more severely affected by lupinosis (acute liver atrophy due to poisoning by ingestion of plants of *Lupinus* spp.) than sheep with normal (40 mg/kg DW) concentrations of copper in the liver (Gardiner 1967).

Copper toxicosis in lambs of domestic sheep occurs at dietary concentrations between 8 and 60 mg Cu/kg ration. The wide range of dietary concentrations is a function of copper availability. Availability, in turn, is influenced by dietary composition, genetic influence, age, breed, sex, physiological state, and interactions with other dietary constituents including iron, zinc, and molybdenum (Bremner 1979). Chronic copper poisoning in lambs occurs at dietary levels as low as 27 mg Cu/kg DW ration (Buckley and Tait 1981). During the passive phase, lambs—like adults—have normal plasma copper concentrations and seem outwardly unaffected. Unlike adults, copper accumulates in livers of lambs during a shorter period (several weeks to months vs. months to years). Signs of hemolytic crisis and death within a few days are similar for both adults and lambs. Elevated plasma aspartate aminotransferase (AAT) activity in lambs—up to 10 times higher than controls—occurs 4 to 8 weeks before the hemolytic crisis (Buckley and Tait 1981) and strongly indicates a need for more research on the usefulness of AAT and other enzymes as early indicators of copper stress. A recommended treatment for lambs diagnosed with chronic copper poisoning is 20 mL of a mixture containing 100 mg of ammonium molybdate and 1 g of sodium sulfate administered orally 5 days weekly (Doherty et al. 1969).

In domestic pigs, copper toxicosis results from eating diets containing 250 mg Cu/kg ration and is characterized by anemia, jaundice, elevated levels of Cu in serum and liver, and elevated serum AAT activity (USEPA 1980). Shortly before death, copper-poisoned pigs had white noses, poor balance, stomach histopathology, orange cirrhotic livers, anorexia, and anemia (Higgins 1981).

In rodents, copper administered by single intraperitoneal or subcutaneous injection is lethal at 3 to 7 mg Cu/kg BW (Table 7). Mice died when their drinking water had 640 mg Cu/L (Table 7). In rats, copper accumulation in kidneys and lungs is similar regardless of route of administration (Romeu-Moreno et al. 1994). Concentrations of copper in serum of rats (*Rattus* sp.) reflect dietary copper; concentrations in liver and kidney are directly related to serum Cu and ceruloplasmin (Petering et al. 1977). As serum Cu concentrations rise in rats, levels fall for serum cholesterol, triglycerides, and phospholipids (Petering et al. 1977).

Proposed Criteria and Recommendations

Proposed copper criteria for the protection of agricultural crops, aquatic life, terrestrial invertebrates, poultry, laboratory white rats, livestock, and human health are summarized in Table 8.

Table 8. Proposed copper criteria for the protection of natural resources and human health.

Table 8. Resource, criteria, and other variables	Effective copper concentration	Reference[a]
Agricultural Crops		
Irrigation water	<1.0 mg/L	1
Leaves		
Severe deficiency	<4 mg/kg dry weight (DW)	2
Deficient	<5 mg/kg DW	1, 3
Mild to moderate deficiency	4 to 5 mg/kg DW	1, 3
Deficiency rare	>6 mg/kg DW	2
Sewage sludge		
Europe, acidic soils	50 to 140 kg/ha	4
United States		
All agricultural lands	<1,000 mg/kg DW	5
Florida	<100 mg/kg DW	4
Illinois	<280 kg/ha	4
Maryland, Massachusetts	140 to 280 kg/ha[b]	4
Minnesota, Missouri	140 to 560 kg/ha[c]	4
New York		
Agricultural soils	<125 kg/ha	4
Forests	<280 kg/ha	4
Wisconsin, acidic soils	50 to 140 kg/ha	4
Soils		
Deficient	<10 mg/kg DW	6
Safe	<280 kg/ha[d]	7
M-3 extractable soil copper	<60 mg/kg DW	8
Canada		
Agricultural lands	<100 mg/kg DW	4
Acidic soils, Alberta	<200 mg/kg DW	4
Industrial and other lands	<300 mg/kg DW	4
Former Soviet Union, maximum allowable concentration	3 mg/kg DW when extracted with ammonium acetate buffer	4
The Netherlands		
Normal	50 mg/kg DW	4
Moderately contaminated	100 mg/kg DW	4
Requires remediation	>500 mg/kg DW	4
United States, New Jersey	<170 mg/kg DW	4

Table 8. Resource, criteria, and other variables	Effective copper concentration	Reference[a]
Aquatic life, fresh water		
Sediments		
Great Lakes		
Nonpolluted	<25 mg/kg DW	4
Moderately polluted	25 to 50 mg/kg DW	4
Heavily polluted	>50 mg/kg DW	4
Reduced abundance of benthos	480 to 1,093 mg/kg DW	9
Toxic to benthos	>9,000 mg/kg DW	9
Tissue concentrations; rainbow trout, *Oncorhynchus mykiss*; ratio of zinc to copper in gill or operclula		
Normal	Ratio >1.5	10
Probably copper-poisoned	Ratio 0.5 to 1.5	10
Acute copper poisoning	Ratio <0.5	10
Water		
Safe. No adverse effects on rainbow trout exposed from fertilization through 4 days after hatching		
In soft or medium water	2 to 5 µg/L	11
In hard water	5 to 8 µg/L	11
Death or teratogenicity in eggs of sensitive species of fishes and amphibians	5 to 10 µg/L	11
United States		
Safe; total recoverable copper; 24h average	<5.6 µg/L	12
Maximum allowable concentration at 50 mg $CaCO_3$/L	12 µg/L	12
Maximum allowable concentration at 100 mg $CaCO_3$/L	22 µg/L	12
Maximum allowable concentration at 200 mg $CaCO_3$/L	43 µg/L	12
Inhibits fish growth and ability of fish to discriminate prey	18 to 28 µg/L	13
The Netherlands; total recoverable copper; maximum allowable concentration	<50 µg/L	14
Aquatic life, marine		
Seawater		
Safe. Total recoverable copper, 24 h average	<4.0 µg/L; not to exceed 23 µg/L at any time	12
Safe. Maximum concentration	<5.0 µg/L	15
Sediments		
Avoidance by clams	>5 mg/kg DW	16
Clam burrowing ability inhibited (water concentrations of 113 to 120 µg Cu/L)	>15 mg/kg DW	16
Not polluted	<40 mg/kg DW	15
Moderately polluted	40 to 60 mg/kg DW	15
Very polluted	>60 mg/kg DW	15
Reduced species diversity; sensitive species absent	>200 mg/kg DW	17

Table 8. Resource, criteria, and other variables	Effective copper concentration	Reference[a]
Toxic to juvenile bivalve mollusks	>2,000 mg/kg DW	17

[b]Soil cation exchange capacity less than 5 meq/100 g for 140 kg/ha and more than 5 meq/100 g for 280 kg/ha.

[c]Soil cation exchange capacity ranges from less than 5 to more than 15 meq/100 g.

[d]Higher levels of 365 kg Cu/ha had no effect on corn yield or copper content in corn.

[e]Diet should also contain 150 mg Zn/kg and 200 mg Fe/kg to further reduce the chances of copper toxicity to pigs.

Copper is essential to normal plant growth, and copper deficiency is known in various agricultural crops such as vegetables and grains (Gupta 1979). Crops seem to be protected against copper deficiency when growing soils contain greater than 10 mg Cu/kg DW and leaves greater than 6 mg Cu/kg DW (Table 8). With

some exceptions, agricultural crops are protected against copper toxicosis when irrigation waters contain less than 1.0 mg Cu/L and soils less than 170 mg Cu/kg DW (Table 8). But adverse effects occur on root development of seedling pines at irrigation water concentrations as low as 200 µg Cu/L (Arduini et al. 1995) and on growth of citrus trees when extractable copper in the soil exceeds 60 mg/kg DW (Alva et al. 1995). States allow application of sewage sludge to agricultural soils if total copper in the sludge does not exceed 1,000 mg/kg DW (100 mg/kg DW in Florida), or if the application rate for sludge does not exceed 280 kg sewage sludge per surface acre (50 kg/ha in Wisconsin; Table 8). The practice by some localities of applying raw sewage sludge to crop soils on the basis of kg sludge/surface acre ratio should be discouraged unless the sludge is periodically analyzed for copper and other contaminants.

Proposed criteria to protect most species of freshwater aquatic life from copper toxicity or deficiency include maximum water concentrations over a 24-h period of 12 µg Cu/L in soft water and 43 µg/L in hard water, sediment concentrations less than 480 mg Cu/kg DW, and, in rainbow trout, a zinc/copper ratio in gill or opercle greater than 1.5 (Table 8). However, the proposed maximum water concentration range of 12-43 µg Cu/L exceeds the 5-10 µg/L range that is lethal or teratogenic to sensitive species of fishes and amphibians (Birge and Black 1979) and overlaps the 18-28 µg/L range that inhibits growth and ability to discriminate prey for other species (Sandheinrich and Atchison 1989). Some scientists state that laboratory studies tend to overestimate the adverse effects of copper on freshwater abundance and diversity and suggest more research on field mesocosms receiving water directly from the system under investigation (Clements et al. 1990). In marine ecosystems, copper concentrations should not exceed 23 µg Cu/L at any time, and sediments should contain less than 200 mg Cu/kg DW (Table 8). But adverse sublethal effects of copper to representative species of estuarine algae, mollusks, and arthropods frequently occur at less than 10 µg Cu/L (Bryan and Langston 1992). Also, extrapolation of laboratory data on copper and marine benthos to actual field conditions is difficult because of changing environmental conditions such as thermosaline regimes and the nature of the sediment substrate (Ozoh 1992c).

Among sensitive species of terrestrial invertebrates, earthworms show disrupted enzyme activities at whole body concentrations as low as 28.5 mg Cu/kg DW (Table 8). Soil copper concentrations between 53 and 100 mg/kg DW kill soil nematodes and soil faunal communities (Parmelee et al. 1993; Donkin and Dusenbery 1993) and cause a reduction in cocoon production of earthworms (Ma 1984; Spurgeon et al. 1994). Diets that contain between 50 and 63 mg Cu/kg ration inhibit development and reproduction in gypsy moths and oribatid mites (Denneman and van Straalen 1991; Gintenreiter et al. 1993). The wood louse (*Porcellio scaber*), an isopod, is proposed as a bioindicator of copper contamination in terrestrial ecosystems because whole body concentrations seem to reflect copper loadings in the isopod's immediate environment (Hopkin et al. 1993; Table 8). More research is recommended on isopods and other sentinel organisms.

Quantitative data are missing on copper effects on avian and mammalian wildlife, and this represents a high priority research need. Some data are available for copper and poultry and livestock, but extrapolation of these results to wildlife species is contraindicated in view of the wide range in sensitivities to copper between species. Domestic chickens show good growth and survival when their diets contain adequate iron and more than 4 and less than 200 mg Cu/kg ration (Carlton and Henderson 1964b). In sheep—and some other mammals—prior knowledge of copper stress would allow adequate time for treatment (i.e., prophylactic dosing with ammonium molybdate plus sodium sulfate or intravenous injection of chelating agents) to prevent sudden death during copper-induced hemolytic crisis (MacPherson and Hemingway 1969). In sheep, for example, elevated SGOT activity is an early indicator of copper poisoning and is measurable 1 to 6 weeks before the hemolytic crisis stage (MacPherson and Hemingway 1969). Providing prophylactic licks containing zinc sulfate and sulfur to African cattle, buffaloes, and impalas seems to be successful in protecting against the lethal effects of excess airborne copper in the grazing area (Gummow et al. 1991).

The proposed domestic drinking water criterion of less than 1.0 mg Cu/L for the protection of human health is not based on copper toxicosis but on the unpleasant taste which develops with higher levels of copper in drinking water (USEPA 1980). Increased copper levels (>1.3 mg Cu/L) in household water supplies caused by corrosion of copper plumbing materials may adversely affect infants and young children among residents of newly constructed or renovated homes (Knobeloch et al. 1994). Human groups at greatest risk to copper toxicosis now include young children subjected to unusually high concentrations of copper in soft or treated water held in copper pipes or vessels, medical patients with Wilson's disease, medical patients treated with copper-contaminated fluids in dialysis or parenteral administration, people with a glucose-6-phosphate

dehydrogenase (G-6-PD) deficiency (about 13% of the Afro-American male population has a G-6-PD deficiency) who drink water containing greater than 1.0 mg Cu/L, and occupationally exposed workers (USEPA 1980).

Other copper research areas that seem to merit additional effort include (1) establishment of specific biomarkers for copper toxicity (ATSDR 1990); (2) development of a national system to verify incidents of deficiency and excess of copper and interrelated trace elements in species of concern (NAS 1977); (3) clarification of copper interactions with molybdenum, sulfate, iron, and zinc in plant and animal metabolisms (NAS 1977; Eisler 1989, 1993); (4) the role of copper in carcinogenesis, mutagenesis, and teratogenesis (NAS 1977; ATSDR 1990) because preliminary evidence suggests that exposure to grossly elevated concentrations of copper produces teratogenicity in fish (Birge and Black 1979) and mammals (Aaseth and Norseth 1986), carcinogenicity in rodents (USEPA 1980; ATSDR 1990; Toussaint and Nederbragt 1993), and mutagenicity in rodents (ATSDR 1990), sheep (Bires et al. 1993), and grasshoppers (Bhunya and Behura 1986); (5) mechanisms by which copper deficiency results in neutropenia, with emphasis on the process of cellular differentiation and the viability of neutrophils in blood and marrow (Percival 1995); (6) copper status effects on resistance to endotoxin-induced injuries because burn and trauma patients show moderate copper deficiency and high risk to sepsis, and copper deficient rats are sensitive to endotoxins causing sepsis (DiSilvestro et al. 1995); (7) the role of aquatic organisms in copper cycling in aquatic ecosystems (Stokes 1979); (8) mechanisms of copper tolerance or acclimatization to high doses of copper (ATSDR 1990); (9) the relation between copper toxicosis, copper absorption rates, and copper retention (Stokes 1979; ATSDR 1990); (10) effects on reproduction, neurotoxicity, and immune response (ATSDR 1990); (11) biochemistry and physiology of copper proteins (NAS 1977); (12) measurement of flux rates of ionic copper from metallic copper (ATSDR 1990); and (13) determination of safe levels of copper in livestock and poultry feeds (NAS 1977), and in diets of avian and mammalian wildlife.

Conclusions

Copper discharges to the global biosphere are due primarily to human activities, especially from the mining, smelting, and refining of copper and from the treatment and recycling of municipal and industrial wastes. Some copper compounds, especially copper sulfate, also contribute to environmental copper burdens because they are widely and intensively used in confined geographic areas to control nuisance species of aquatic plants and invertebrates, diseases of terrestrial crop plants, and ectoparasites of fish and livestock.

Copper concentrations in field collections of abiotic materials and living organisms are usually elevated in the vicinity of human activities and intensive copper use. Maximum copper concentrations recorded in selected abiotic materials are 5 $\mu g/m^3$ in air, 5 µg/L in groundwater, 12 µg/L in rainwater, 1,200 mg/kg DW in poultry litter, 7,000 mg/kg DW in soils, and 7,700 mg/kg DW in sewage sludge. In terrestrial vegetation, copper is usually less than 35 mg/kg DW except near smelters where it may approach 700 mg/kg DW and in certain copper-accumulator plants that may normally contain as much as 13,700 mg/kg DW. Aquatic vegetation from copper-contaminated sites contain as much as 1,350 mg Cu/kg DW vs. 36 mg/kg DW in conspecifics from reference sites. Terrestrial invertebrates from industrialized areas may contain from 137 to 408 mg Cu/kg DW whole organism. Aquatic invertebrates seldom contain as much as 95 mg Cu/kg DW, regardless of collection locale; exceptions include whole amphipods and lobster hepatopancreas (335-340 mg/kg DW) from copper-contaminated sites and many species of mollusks that normally contain 1,100-6,500 mg Cu/kg DW. Data are scarce on copper concentrations in field populations of amphibians and reptiles: crocodile eggs may contain as much as 60 mg Cu/kg DW and livers of some toads may contain as much as 2,100 mg Cu/kg DW without apparent adverse effects. Maximum copper concentrations in tissues of fishes, elasmobranchs, birds, and marine mammals from all collection sites are low when compared to more primitive organisms and never exceed 53 mg Cu/kg DW except liver (146-367 mg/kg DW); an exception is liver from endangered manatees (1,200 mg/kg DW) collected at a site treated with a copper-containing herbicide. Maximum copper concentrations in all tissues of terrestrial mammals, regardless of collection locale, are low and seldom exceed 29 mg/kg DW except kidneys (108 mg/kg DW) and livers (1,078 mg/kg DW) from animals near a copper refinery.

Copper deficiency is not a major public health concern in the United States, although skeletal deformities and leg fractures may occur in some copper-deficient children. Copper deficiency effects occur, however, in various species of terrestrial plants (reduced growth, necrosis, reduction in number of pollen grains, death), chickens (poor growth, high frequency of cardiovascular and skeletal lesions, low survival), turkeys (sudden

death), rats (defective hemoglobin synthesis, lesions of the central nervous system, low survival, altered blood and liver enzyme activities), guinea pigs (lesions of the central nervous system), dogs (leg fractures), sheep and other ruminant mammals (sudden death, skeletal deformities), pigs (poor growth, decreased hemoglobin and erythrocytes, skeletal deformities), mink (reduced survival), and camels (anemia, emaciation, falling, fractures, death). Data are scarce or missing on copper deficiency effects in aquatic flora and fauna and in avian and terrestrial mammalian wildlife; additional studies of copper deficiency in these groups are merited. In sensitive terrestrial agricultural crops, copper deficiency occurs at less than 1.6 mg dissolved Cu/kg DW soil and less than 5 mg total Cu/kg DW leaves. For domestic chickens, copper deficiency occurs when chickens are fed diets containing less than 2.7 mg Cu/kg ration. Male weanling rats show deficiency effects when fed diets containing 0.13 mg Cu/kg ration vs. a copper-normal diet of 5.7 mg Cu/kg ration; earliest signs of copper deficiency in rats include low concentrations of copper in livers (less than 3.0 mg/kg DW vs. 12.6-15.0 mg/kg DW in controls), reductions in activities of cytochrome oxidase and succinoxidase, and prolonged sleeping times. Ewes of Bactrian camels fed copper-deficient diets of less than 2.5 mg Cu/kg DW ration (vs. normal diet of about 11.0 mg Cu/kg DW) produce a high frequency of swaybacked lambs. Copper deficiency in mink is produced at daily intake rates equivalent to 3.5 mg Cu/kg BW for 50 weeks. Swine require high intakes of copper to avoid deficiency; daily intakes of less than 36 mg Cu/kg BW are associated with reductions in growth rate, hemoglobin, and hematocrit.

Copper and its compounds are not carcinogenic, mutagenic, or teratogenic at environmentally realistic concentrations. But under controlled conditions of grossly elevated exposures some studies suggest that copper is a potential carcinogen in rodents; mutagen in rodents, sheep, and grasshoppers; and teratogen in fish and small laboratory animals. More research is needed in this area.

Bioavailability and toxicity of copper to aquatic organisms depends on the total concentration of copper and its speciation. Both availability and toxicity are significantly reduced by increased loadings of suspended solids and natural organic chelators and increased water hardness. Toxicity to aquatic life is related primarily to the dissolved cupric ion (Cu^{+2}) and possibly to some hydroxyl complexes. Cupric copper (Cu^{+2}) is the most readily available and toxic inorganic species of copper in fresh water, seawater, and sediment interstitial waters. Cupric ion accounts for about 1% of the total dissolved copper in seawater and less than 1% in fresh water. In fresh water, cupric copper and some copper hydroxyl species are correlated with high toxicity to aquatic life, although carbonato species are much less toxic than other copper complexes. More research seems needed on the adsorption characteristics of most cupric ion complexes. In solution, copper interacts with numerous inorganic and organic compounds resulting in altered bioavailability and toxicity. Acknowledgment of these interactions is essential to the understanding of copper toxicokinetics. In aquatic invertebrates, copper disrupts gill epithelium at high concentrations and in fishes it interferes with osmoregulation; death is caused by tissue hypoxia associated with disrupted ATP synthesis. Copper detoxifying mechanisms in fishes include the induction of metallothioneins, allowing copper retention for weeks or months after absorption without toxicity. In higher vertebrates, excess copper is cytotoxic and alters protein configuration and lipid peroxidation rates. Mechanisms implicated in copper poisoning of mammals include free radical production, alteration in activities of several enzymes, and inhibited metallothionein synthesis. In mammals, copper is normally excreted via the bile in association with glutathione or unidentified high molecular weight proteins.

Excess copper is toxic to representative species of plants and animals. Significant adverse effects in terrestrial plants occur at concentrations as low as 40 µg Cu/L of nutrient solution, more than 10 mg Cu/kg DW in leaves, and greater than 60 mg extractable Cu/kg DW of soil. Sensitive species of terrestrial invertebrates show a reduction in growth, survival, or reproduction at more than 50 mg Cu/kg diet or 53-70 mg Cu/kg DW of soil. Many species of freshwater plants and animals die within 96 h at waterborne copper concentrations of 5.0-9.8 µg Cu/L, and sensitive species of freshwater mollusks, crustaceans, and fishes die at 0.23-0.91 µg Cu/L within 96 h. The most sensitive tested species of marine mollusks, crustaceans, and fishes have an LC50 (96 h) range from 28-39 µg Cu/L; significant sublethal effects to representative species of estuarine algae, mollusks, and arthropods frequently occur at 1-10 µg Cu/L. Mammals and birds are at least 100 times more resistant to copper than other organisms, but ruminant mammals are significantly more sensitive to copper than nonruminant animals and poultry. Excessive dietary intakes of copper by 20- to 50-fold over normal levels may, however, have serious adverse effects on birds and mammals. No data are available on copper toxicity to avian wildlife. Studies with poultry demonstrate that copper accumulates in livers at dietary concentrations as low as 15 mg Cu/kg DW ration, inhibits growth at 120 mg Cu/kg DW ration, and causes gizzard histopathology at 250

mg Cu/kg DW ration. Copper is lethal to representative species of mammals through a variety of routes: single oral doses of 6 to 637 mg Cu/kg BW in humans and 200 mg/kg BW in cattle or diets with more than 80 mg Cu/kg ration (about 5.1 to 10.7 mg Cu/kg BW daily) fed to sheep or more than 238 mg/kg ration (more than 133 mg/kg BW daily) fed to rats. Adverse sublethal effects of copper to sensitive mammals occur in human infants at drinking water concentrations greater than 3 mg/L, in cattle at more than 4.2 mg/kg BW by way of drinking water or more than 20 mg/kg BW via diet, in sheep given daily oral doses of 7.5 to 15.0 mg/kg BW or fed diets containing more than 37.3 mg/kg ration, in rats given more than 7.9 mg/kg BW daily by way of diet (equivalent to more than 100 mg/kg DW ration), and in pigs at more than 14.5 mg/kg BW daily via diet.

Numerous and disparate copper criteria are proposed for protecting the health of agricultural crops, aquatic life, terrestrial invertebrates, poultry, laboratory white rats, and humans (Table 8); however, no copper criteria are now available for protection of avian and mammalian wildlife, and this needs to be rectified. Several of the proposed criteria do not adequately protect sensitive species of plants and animals and need to be reexamined. Other research areas that merit additional effort include biomarkers of early copper stress; copper interactions with interrelated trace elements in cases of deficiency and excess; copper status effects on disease resistance, cancer, mutagenicity, and birth defects; mechanisms of copper tolerance or acclimatization; and chemical speciation of copper, including measurement of flux rates of ionic copper from metallic copper.

NICKEL HAZARDS TO FISH, WILDLIFE, AND INVERTEBRATES: A SYNOPTIC REVIEW

by
Ronald Eisler
Patuxent Wildlife Research Center
U.S. Geological Survey
Laurel, MD 20708-4017

Abstract

Abstract. This account is a selective review and synthesis of the technical literature on nickel and nickel salts in the environment and their effects on terrestrial plants and invertebrates, aquatic plants and animals, avian and mammalian wildlife, and other natural resources. The subtopics include nickel sources and uses; physical, chemical, and metabolic properties of nickel; nickel concentrations in field collections of abiotic materials and living organisms; nickel deficiency effects; lethal and sublethal effects, including effects on survival, growth, reproduction, metabolism, mutagenicity, teratogenicity, and carcinogenicity; currently proposed nickel criteria for the protection of human health and sensitive natural resources; and recommendations for additional research.

Key words: Nickel, nickel compounds, toxicity, deficiency, cancer, residues, criteria, fishes, invertebrates, amphibians, birds, wildlife, livestock.

Introduction

In Europe, nickel (Ni) is listed on European Commission List II (Dangerous Substances Directive) and regulated through the Council of European Communities because of its toxicity, persistence, and affinity for bioaccumulation (Bubb and Lester 1996). In Canada, nickel and its compounds are included in the Priority Substances List under the Canadian Environmental Protection Act (Hughes et al. 1994). The World Health Organization (WHO) classifies nickel compounds in Group 1 (human carcinogens) and metallic nickel in group 2B (possible human carcinogen; U. S. Public Health Service [USPHS] 1993). The U.S. Environmental Protection Agency (USEPA) classifies nickel refinery dust and nickel subsulfide as Group A human carcinogens (USPHS 1993) and nickel oxides and nickel halides as Class W compounds, that is, compounds having moderate retention in the lungs and a clearance rate from the lungs of several weeks (USEPA 1980). Nickel and its compounds are regulated by USEPA's Clean Water Effluent Guideline for many industrial point sources, including the processing of iron, steel, nonferrous metals, and batteries; timber products processing; electroplating; metal finishing; ore and mineral mining; paving and roofing; paint and ink formulating; porcelain enameling; and industries that use, process, or manufacture chemicals, gum and wood, or carbon black (USPHS 1993).

Nickel is ubiquitous in the biosphere. Nickel introduced into the environment from natural or human sources is circulated through the system by chemical and physical processes and through biological transport mechanisms of living organisms (National Academy of Sciences [NAS] 1975; Sevin 1980; WHO 1991). Nickel is essential for the normal growth of many species of microorganisms and plants and several species of vertebrates, including chickens, cows, goats, pigs, rats, and sheep (NAS 1975; USEPA 1980; WHO 1991; USPHS 1993).

Human activities that contribute to nickel loadings in aquatic and terrestrial ecosystems include mining, smelting, refining, alloy processing, scrap metal reprocessing, fossil fuel combustion, and waste incineration (NAS 1975; WHO 1991; Chau and Kulikovsky-Cordeiro 1995). Nickel mining and smelting in the Sudbury, Ontario, region of Canada is associated with denudation of terrestrial vegetation and subsequent soil erosion (Adamo et al. 1996) and gradual ecological changes, including a decrease in the number and diversity of species and a reduction in community biomass of crustacean zooplankton (WHO 1991). At nickel-contaminated sites, plants accumulate nickel and growth is retarded in some species at high nickel concentrations (WHO 1991). But nickel accumulation rates in terrestrial and avian wildlife near nickel refineries are highly variable; Chau and Kulikovsky-Cordeiro (1995) claim similar variability for plants, soils, and interstitial sediment waters.

The chemical and physical forms of nickel and its salts strongly influence bioavailability and toxicity (WHO 1991). In general, nickel compounds have low hazard when administered orally (NAS 1975; USEPA 1980). In humans and other mammals, however, nickel-inhalable dust, nickel subsulfide, nickel oxide, and especially nickel carbonyl induce acute pneumonitis, central nervous system disorders, skin disorders such as dermatitis, and cancer of the lungs and nasal cavity (Graham et al. 1975; NAS 1975; USPHS 1977; Sevin 1980; Smialowicz et al. 1984; WHO 1991; Benson et al. 1995; Table 1). Nickel carbonyl is acutely lethal to humans and animals within 3-13 days of exposure; recovery is prolonged in survivors (Sevin 1980). An excess number of deaths from lung cancer and nasal cancer occurs in nickel refinery workers, usually from exposure to airborne nickel compounds (USPHS 1977). At one nickel refinery, workers had a fivefold increase in lung cancer and a 150-fold increase in nasal sinus cancer when compared to the general population (Lin and Chou 1990). Pregnant female workers at a Russian nickel hydrometallurgy refining plant, when compared to a reference group, showed a marked increase in frequency of spontaneous and threatening abortions and in structural malformations of the heart and musculoskeletal system in live-born infants with nickel-exposed mothers (Chashschin et al. 1994). Nickel is also a common cause of chronic dermatitis in humans as a result of industrial and other exposures, including the use of nickel-containing jewelry, coins, utensils, and various prostheses (NAS 1975; Chashschin et al. 1994). Additional information on ecological and toxicological aspects of nickel in the environment is presented in reviews and annotated bibliographies by Sunderman (1970), Eisler (1973), Eisler and Wapner (1975), NAS (1975), USEPA (1975, 1980, 1985, 1986), International Agency for Research on Cancer (IARC; 1976), Nielsen (1977), USPHS (1977, 1993), Eisler et al. (1978b, 1979), Norseth and Piscator (1979), Brown and Sunderman (1980), Nriagu (1980a), Sevin (1980), National Research Council of Canada (NRCC; 1981), Norseth (1986), Kasprzak (1987), Sigel and Sigel (1988), WHO (1991), Hausinger (1993), Outridge and Scheuhammer (1993), and Chau and Kulikovsky-Cordeiro (1995).

Table 1. Nickel chronology.

Table 1. Date	Event	Reference[a]
220 BCE	Nickel alloys made by the Chinese	1
1500's	Toxicity observed in miners of nickel	2
1751	Nickel isolated and identified. The name nickel was derived from "Old Nick," a gremlin to whom miners ascribed their problems	3
early 1800's	Purified nickel obtained	1
1826	Nickel toxicity in rabbits and dogs demonstrated experimentally. High doses of nickel sulfate given by stomach gavage caused gastritis, convulsions, and death; sublethal doses produced emaciation and conjunctivitis	1, 2, 4
1840's	Commercial nickel electroplating initiated	1
1850's	Commercial exploitation of nickel begins after development of technology to remove copper and other impurities	3
1850-1900	Nickel used therapeutically in human medicine to relieve rheumatism (nickel sulfate) and epilepsy (nickel bromide)	2, 5
1880's	Excess nickel found lethal to animals under controlled conditions	2
1889	Skin dermatitis in humans caused by chemicals used in nickel plating	5
1890	Extraordinary toxicity of nickel carbonyl ($Ni(CO)_4$) established	1
1893	Excess nickel found lethal to plants	2
1912	Nickel dermatitis documented	1
1915-1960	Nickel applied as fungicide found to enhance plant growth and increase yield	2

Table 1. Date	Event	Reference[a]
1926	Nickel dust caused skin dermatitis, especially in hot, industrial environments	5
1932	Increased frequency of lung and nasal cancers reported among English nickel refinery workers exposed to high concentrations of nickel carbonyl	1, 5, 6
1939-1958	Certain forms of nickel found to be carcinogenic to humans	2
1943	Certain forms of nickel found to be carcinogenic to animals	2
1965-1967	Nickel found beneficial to plants	2
1970's	Nickel deficiency leads to adverse effects in microorganisms and plants	2
1980's	Nickel found to be constituent of various essential plant enzymes	2

[a]1, Nriagu 1980b; 2, Hausinger 1993; 3, Sevin 1980; 4, Nielsen 1977; 5, U.S. Public Health Service 1977; 6, Benson et al. 1995.

This report summarizes available ecological and toxicological data on nickel, with emphasis on fishery and wildlife resources. It is part of a continuing series of brief reviews on chemical contaminants and natural resources that are prepared in response to informational requests from environmental specialists of the U.S. Fish and Wildlife Service.

Sources and Uses

General

About 250,000 people in the United States are exposed annually to inorganic nickel in the workplace. This group includes workers in the mining, refining, smelting, electroplating, and petroleum industries and workers involved in the manufacture of stainless steel, nickel alloys, jewelry, paint, spark plugs, catalysts, ceramics, disinfectants, varnish, magnets, batteries, ink, dyes, and vacuum tubes (USPHS 1977). Non-occupational exposure to nickel and its compounds occurs mainly by ingestion of foods and liquids and by contact with nickel-containing products, especially jewelry and coins (Sunderman et al. 1984; WHO 1991). Food processing adds to nickel already present in the diet through leaching from nickel-containing alloys in food-processing equipment made from stainless steel, milling of flour, use of nickel catalysts to hydrogenate fats and oils, and use of nickel-containing fungicides in growing crops (NAS 1975; USEPA 1980). Nickel contamination of the environment occurs locally from emissions of metal mining, smelting, and refining operations; from combustion of fossil fuels; from industrial activities, such as nickel plating and alloy manufacturing; from land disposal of sludges, solids, and slags; and from disposal as effluents (Cain and Pafford 1981; Chau and Kulikovsky-Cordeiro 1995). In Canada in 1988, the mining industry released a total of 11,664 tons of nickel into the air (9.4%), water (0.5%), and on land as sludges or solids (15.4%) and slags (74.7%). The global nickel cycle is unknown, but recent estimates suggest that 26,300 to 28,100 tons are introduced each year into the atmosphere from natural sources and 47,200 to 99,800 tons from human activities; airborne nickel is annually deposited on land at 50,800 tons and in the ocean at 21,800 tons (Chau and Kulikovsky-Cordeiro 1995).

Sources

More than 90% of the world's nickel is obtained from pentlandite ($(FeNi)_9S_8$), a nickel-sulfitic mineral mined underground in Canada and the former Soviet Union (Sevin 1980; IARC 1976; WHO 1991). One of the largest sulfitic nickel deposits is in Sudbury, Ontario (USPHS 1993). Nickeliferous sulfide deposits are also found in Manitoba, South Africa, the former Soviet Union, Finland, western Australia, and Minnesota (Norseth and Piscator 1979; USPHS 1993). Most of the rest of the nickel obtained is from nickel minerals such as laterite, a nickel oxide ore mined by open pit techniques in Australia, Cuba, Indonesia, New Caledonia, and the former Soviet Union (Sevin 1980). Lateritic ores are less well defined than sulfitic ores, although the nickel content (1-3%) of both ores is similar (USPHS 1993). Important deposits of laterite are located in New Caledonia, Indonesia, Guatemala, the Dominican Republic, the Philippines, Brazil, and especially Cuba, which holds 35%

of the known reserves (USPHS 1993). Nickel-rich nodules are found on the ocean floor, and nickel is also present in fossil fuels (Sevin 1980).

Total world mine production of nickel is projected to increase steadily from 7,500 metric tons in 1900 to 2 million tons by 2000 (Table 2). In 1980, nickel mine production in the United States was 14,500 tons, or about 1.8% of the world total (Kasprzak 1987). In 1986, primary nickel production ceased in the United States; secondary nickel production from scrap became a major source of nickel for industrial applications (USPHS 1993). In 1988, the United States imported 186,000 tons of primary nickel; Canada supplied 58% of the total and Norway 14% (USPHS 1993). In 1990, Canada produced 196,606 metric tons of nickel. About 63% of the total production was exported, mostly (56%) to the United States (Chau and Kulikovsky-Cordeiro 1995).

Table 2. World mine production of nickel (National Academy of Sciences 1975; International Agency for Research on Cancer 1976; Duke 1980; Kasprzak 1987; World Health Organization 1991).

Year	Metric tons
1900	7,500
1925	42,700
1950	141,000
1970	694,100
1975	753,000[a]
1980	784,100
1985	821,000[b]
2000 (projected)	>2,000,000

[a]About 32% from Canada, 18% from New Caledonia, 17% from the former Soviet Union, 10% from Australia, 5% from Cuba, 4% from the Dominican Republic, 3% from the Republic of South Africa, 2% each from Greece, Indonesia, and the United States, and 5% from other countries.

[b]Mostly from Canada, the former Soviet Union, Australia, and Cuba, in that order. The United States produced 6,900 tons in 1985.

Natural sources of airborne nickel include soil dust, sea salt, volcanoes, forest fires, and vegetation exudates and account for about 16% of the atmospheric nickel burden (Kasprzak 1987; WHO 1991; Chau and Kulikovsky-Cordeiro 1995). Human sources of atmospheric nickel—which account for about 84% of all atmospheric nickel—include emissions from nickel ore mining, smelting, and refining activities; combustion of fossil fuels for heating, power, and motor vehicles; incineration of sewage sludges; nickel chemical manufacturing; electroplating; nickel-cadmium battery manufacturing; asbestos mining and milling; and cement manufacturing (NAS 1975; IARC 1976; USEPA 1986; Kasprzak 1987; WHO 1991; USPHS 1993). In Canada in 1975, human activities resulted in the release of about 3,000 tons of nickel into the atmosphere, mostly from metallurgical operations (NRCC 1981). Between 1973 and 1981, atmospheric emissions of nickel from stacks of four smelters in the Sudbury Basin, Canada, averaged a total of 495 tons annually (WHO 1991). Industrial nickel dust emissions from a single Canadian stack 381 meters high averaged 228 tons annually (range 53-342) between 1973 and 1981; this stack accounted for 396 tons annually (range 53-896) between 1982 and 1989 (Chau and Kulikovsky-Cordeiro 1995). Three other emission stacks of Canadian nickel producers emitted an average of 226, 228, and 396 tons of nickel, respectively, each year between 1973 and 1989. Industrial emissions of nickel to the Canadian atmosphere in 1982 were estimated at 846 tons, mostly from nickel production in Ontario (48% of total) and Quebec (14%) and from industrial fuel combustion (17%). Nickel released into the air in Canada from smelting processes is likely in the form of nickel subsulfide (52%), nickel sulfate (20%), and nickel oxide (6%). Fuel combustion is also a major contributor of airborne nickel in Canada, mostly from combustion of petroleum (Chau and Kulikovsky-Cordeiro 1995). In the United States, yearly atmospheric emissions from coal and oil combustion are estimated at 2,611 metric tons (WHO 1991).

Chemical and physical degradation of rocks and soils, atmospheric deposition of nickel-containing particulates, and discharges of industrial and municipal wastes release nickel into ambient waters (USEPA 1986; WHO 1991). Nickel enters natural waterways from waste water because it is poorly removed by treatment processes (Cain and Pafford 1981). The main anthropogenic sources of nickel in water are primary nickel production, metallurgical processes, combustion and incineration of fossil fuels, and chemical and catalyst

production (USEPA 1986). The primary human sources of nickel to soils are emissions from smelting and refining operations and disposal of sewage sludge or application of sludge as a fertilizer. Secondary sources include automobile emissions and emissions from electric power utilities (USEPA 1986). Weathering and erosion of geological materials release nickel into soils (Chau and Kulikovsky-Cordeiro 1995), and acid rain may leach nickel from plants into soils as well (WHO 1991).

Uses

Most metallic nickel produced is used to manufacture stainless steel and other nickel alloys with high corrosion and temperature resistance (Norseth and Piscator 1979; Norseth 1980; WHO 1991). These alloys are used in ship building, jet turbines and heat elements, cryogenic installations, magnets, coins, welding rods, electrodes, kitchenware, electronics, and surgical implants; other nickel compounds are used in electroplating, battery production, inks, varnishes, pigments, catalysts, and ceramics (IARC 1976; Nriagu 1980b; Sevin 1980; Sunderman et al. 1984; USEPA 1986; Kasprzak 1987; USPHS 1993). Some nickel compounds are preferred for use in nickel electroplating (nickel sulfate, nickel ammonium sulfate, nickel chloride, nickel fluoborate, nickel sulfamate), refining (nickel carbonyl), nickel-cadmium batteries (nickel hydroxide, nickel fluoride, nickel nitrate), manufacture of stainless steel and alloy steels (nickel oxide), electronic components (nickel carbonate), mordant in textile industry (nickel acetate), catalysts and laboratory reagents (nickel acetate, nickel hydroxide, nickel nitrate, nickel carbonate, nickel monosulfide, nickelocene), and some—such as nickel subsulfide—are unwanted toxic byproducts (IARC 1976).

In 1973, global consumption of nickel was 660,000 tons and that of the United States 235,000 tons (Sevin 1980). End uses of nickel in the United States in 1973 were transportation (21%), chemicals (15%), electrical goods (13%), fabricated metal products (10%), petroleum (9%), construction (9%), machinery (7%), and household appliances (7%; IARC 1976); a similar pattern was evident for 1985 (Table 3). In 1988, 40% of all nickel intermediate products consumed was in the production of steel; 21% was in alloys, 17% in electroplating, and 12% in super alloys (USPHS 1993). The pattern for 1985 was similar (Table 3). In Canada, nickel is the fourth most important mineral commodity behind copper, zinc, and gold. In 1990, Canada produced 197,000 tons of nickel worth 2.02 billion dollars and was the second largest global producer of that metal (Chau and Kulikovsky-Cordeiro 1995). Most of the nickel used in the United States is imported from Canada, and secondarily from Australia and New Caledonia (USPHS 1977).

Table 3. Nickel consumption in the United States by intermediate product and end-use industry in 1985[a] (Kasprzak 1987; World Health Organization 1991).

Index	Consumption (% of total)
Intermediate product	
Stainless and alloy steels	42
Nonferrous alloys	36
Electroplating	18
Other	4
Total	100
End-use industry	
Transportation	23
Chemicals	15
Electrical equipment	12
Construction	10
Fabricated metal products	9
Petroleum	8
Household appliances	8
Machinery	8
Other	7
Total	100

[a] Nickel consumption in the United States, exclusive of scrap, was 160,000 tons.

Various nickel salts—including the sulfate, chloride, and bromide—were used in human medicine during the mid- to late-1800's to treat headache, diarrhea, and epilepsy and as an antiseptic. Therapeutic use of nickel compounds was abandoned in the early 1900's after animal studies demonstrated acute and chronic toxicity of these salts (NAS 1975; Nriagu 1980b). Some nickel salts have been incorporated into fungicides to combat plant pathogens, although their use has not been approved by regulatory agencies (NAS 1975).

Chemical and Biological Properties

General

Nickel normally occurs in the 0 and +2 oxidation states, although other oxidation states are reported (NAS 1975; Nriagu 1980b; Higgins 1995). In natural waters Ni^{2+} is the dominant chemical species in the form of $(Ni(H_2O)_6)^{2+}$ (WHO 1991; Chau and Kulikovsky-Cordeiro 1995). In alkaline soils, the major components of the soil solution are Ni^{2+} and $Ni(OH)^{+}$; in acidic soils, the main solution species are Ni^{2+}, $NiSO_4$, and $NiHPO_4$ (USPHS 1993). Most atmospheric nickel is suspended onto particulate matter (NRCC 1981).

Nickel interacts with numerous inorganic and organic compounds (Schroeder et al. 1974; Nielsen 1980a; USEPA 1980, 1985; USPHS 1993). Some of these interactions are additive or synergistic in producing adverse effects, and some are antagonistic.

Toxic and carcinogenic effects of nickel compounds are associated with nickel-mediated oxidative damage to DNA and proteins and to inhibition of cellular antioxidant defenses (Rodriguez et al. 1996). Most authorities agree that albumin is the main transport protein for nickel in humans and animals and that nickel is also found in nickeloplasmin—a nickel-containing alpha-macroglobulin—and in an ultrafilterable serum fraction similar to a nickel-histidine complex (Norseth and Piscator 1979; Sarkar 1980; Sevin 1980; USEPA 1980; Norseth 1986; Sigel and Sigel 1988; WHO 1991; USPHS 1993). Normal routes of nickel intake for humans and animals are ingestion, inhalation, and absorption through the skin (Mushak 1980; USEPA 1975, 1980, 1986; Sigel and Sigel 1988; WHO 1991; USPHS 1993). Nickel absorption is governed by the quantities inhaled or ingested and by the chemical and physical forms of the nickel. Following oral intake by mammals, nickel was found mainly in the kidneys after short-term or long-term exposure to various soluble nickel compounds; significant levels of nickel were also found in the liver, heart, lung, and fat. Nickel also crosses the placental barrier, as indicated by increases in the levels of nickel in the fetuses of exposed mothers (USPHS 1993). Inhaled nickel carbonyl results in comparatively elevated nickel concentrations in lung, brain, kidney, liver, and adrenals (USEPA 1980). Parenteral administration of nickel salts usually results in high levels in kidneys and elevated concentrations in endocrine glands, liver, and lung (USEPA 1980, 1986; WHO 1991). Nickel concentrations in whole blood, plasma, serum, and urine provide good indices of nickel exposure (Sigel and Sigel 1988).

Physical and Chemical Properties

Nickel was first isolated in 1751, and a relatively pure metal was prepared in 1804. In nature, nickel is found primarily as oxide and sulfide ores (USPHS 1977). Nickel has high electrical and thermal conductivities and is resistant to corrosion at environmental temperatures between -20 C and +30 C (Chau and Kulikovsky-Cordeiro 1995). Nickel, also known as carbonyl nickel powder or C.I. No. 77775, has a CAS number of 7440-02-0. Metallic nickel is a hard, lustrous, silvery white metal with a specific gravity of 8.9, a melting point of about 1,455 C, and a boiling point of about 2,732 C. It is insoluble in water and ammonium hydroxide, soluble in dilute nitric acid or aqua regia, and slightly soluble in hydrochloric and sulfuric acid. Nickel has an atomic weight of 58.71. Nickel is a composite of five stable isotopes: Ni-58 (68.3%), -60 (26.1%), -61 (1.1%), -62 (3.6%), and -64 (0.9%). Seven unstable isotopes have been identified: ^{56}Ni (half-life of 6 days), ^{57}Ni (36 h), ^{59}Ni (80,000 years), ^{63}Ni (92 years), ^{65}Ni (2.5 h), ^{66}Ni (55 h), and ^{67}Ni (50 sec). Radionickel-59 (^{59}Ni) and ^{63}Ni are available commercially. In addition to the 0 and +2 oxidation states, nickel can also exist as -1, +1, +3, and +4 (NAS 1975; IARC 1976; Kasprzak 1987; Nriagu 1980b; WHO 1991; Hausinger 1993; USPHS 1993; Foulds 1995; Higgins 1995).

Nickel enters surface waters from three natural sources: as particulate matter in rainwater, through the dissolution of primary bedrock materials, and from secondary soil phases. In aquatic systems, nickel occurs as soluble salts adsorbed onto or associated with clay particles, organic matter, and other substances. The divalent ion is the dominant form in natural waters at pH values between 5 and 9, occurring as the octahedral,

hexahydrate ion $(Ni(H_2O)_6)^{2+}$. Nickel chloride hexahydrate and nickel sulfate hexahydrate are extremely soluble in water at 2,400-2,500 g/L. Less soluble nickel compounds in water include nickel nitrate (45 g/L), nickel hydroxide (0.13 g/L), and nickel carbonate (0.09 g/L). Nickel forms strong, soluble complexes with OH-, SO_4^{2-}, and HCO_3^-; however, these species are minor compared with hydrated Ni^{2+} in surface water and groundwater. The fate of nickel in fresh water and marine water is affected by the pH, pE, ionic strength, type and concentration of ligands, and the availability of solid surfaces for adsorption. Under anaerobic conditions, typical of deep groundwater, precipitation of nickel sulfide keeps nickel concentrations low (IARC 1976; USEPA 1980; WHO 1991; USPHS 1993; Chau and Kulikovsky-Cordeiro 1995).

In alkaline soils, the major components of the soil solution are Ni^{2+} and $Ni(OH)^+$; in acidic soils the main solution species are Ni^{2+}, $NiSO_4$, and $NiHPO_4$ (USPHS 1993). Atmospheric nickel exists mostly in the form of fine respirable particles less than 2 μm in diameter (NRCC 1981), usually suspended onto particulate matter (USEPA 1986).

Nickel carbonyl ($Ni(CO)_4$) is a volatile, colorless liquid readily formed when nickel reacts with carbon monoxide; it boils at 43 C and decomposes at more than 50 C; this compound is unstable in air and is usually not measurable after 30 min (NRCC 1981; Norseth 1986; USPHS 1993). The intact molecule is absorbed by the lung (USEPA 1980) and is insoluble in water but soluble in most organic solvents (WHO 1991).

Analytical methods for detection of nickel in biological materials and water include various spectrometric, photometric, chromatographic, polarographic, and voltametric procedures (Sunderman et al. 1984; WHO 1991). Detection limits for the most sensitive procedures—depending on sample pretreatment and extraction and enrichment procedures—were 0.7-1.0 ng/L in liquids, 0.01-0.2 $\mu g/m^3$ in air, 1-100 ng/kg in most biological materials, and 12 μg/kg in hair (WHO 1991; Chau and Kulikovsky-Cordeiro 1995).

Metabolism

In mammalian blood, absorbed nickel is present as free hydrated Ni^{2+} ions, as small complexes, as protein complexes, and as nickel bound to blood cells. The partition of nickel among these four components varies according to the metal-binding properties of serum albumin, which is highly variable between species (NAS 1975; USEPA 1980, 1986; Kasprzak 1987). A proposed transport model involves the removal of nickel from albumin to histidine via a ternary complex composed of albumin, nickel, and L-histidine. The low molecular weight L-histidine nickel complex can then cross biological membranes (Sunderman et al. 1984; Kasprzak 1987; USPHS 1993). Once inside the mammalian cell, nickel accumulates in the nucleus and nucleolus (Sunderman et al. 1984), disrupting DNA metabolism and causing cross links and strand breaks (Kasprzak 1987; USPHS 1993; Hartwig et al. 1994). The observed redox properties of the nickel-histidine complex are crucial for maximizing the toxicity and carcinogenicity of nickel (Datta et al. 1992, 1994).

The acute toxicity and carcinogenicity of Ni_3S_2 and Ni_3S_2-derived soluble nickel (Ni^{2+}) in mice depend, in part, on the antioxidant capacity of target organs, which varies among different strains (Rodriguez et al. 1996). Experimental evidence now support the conclusion that the nickel-dependent formation of an activated oxygen species—including superoxide ion, hydrogen peroxide, and hydroxy radical—is a primary molecular event in acute nickel toxicity and carcinogenicity (WHO 1991; Hausinger 1993; Tkeshelashvili et al. 1993; Novelli et al. 1995; Stohs and Bagchi 1995; Rodriguez et al. 1996). For example, the superoxide radical (O_2^-) is an important intermediate in the toxicity of insoluble nickel compounds such as NiO and NiS (Novelli et al. 1995). One of the keys to the mechanism of nickel-mediated damage is the enhancement of cellular redox processing by nickel. Accumulated nickel in tissues elicits the production of reactive oxygen species, such as the superoxide radical, as the result of phagocytosis of particulate nickel compounds and through the interaction of nickel ions with protein ligands, which promote the activation of the Ni^{2+}/Ni^{3+} redox couple. Thus, NiS and NiO can elicit the formation of O_2^- (Novelli et al. 1995).

The most serious type of nickel toxicity is that caused by the inhalation of nickel carbonyl (Nielsen 1977). The half-time persistence of nickel carbonyl in air is about 30 min (Sevin 1980). Nickel carbonyl can pass across

cell membranes without metabolic alteration because of its solubility in lipids, and this ability of nickel carbonyl to penetrate intracellularly may be responsible for its extreme toxicity (NAS 1975). In tissues, nickel carbonyl decomposes to liberate carbon monoxide and Ni^0, the latter being oxidized to Ni^{2+} by intracellular oxidation systems. The nickel portion is excreted with urine and the carbon monoxide is bound to hemoglobin and eventually excreted through the lungs (USEPA 1980; Kasprzak 1987). Nickel carbonyl inhibits DNA-dependent RNA synthesis activity, probably by binding to chromatin or DNA and thereby preventing the action of RNA polymerase, causing suppression of messenger-RNA-dependent induction of enzyme synthesis (Sunderman 1968; NAS 1975; USEPA 1980). The lung is the target organ in nickel carbonyl poisoning (USEPA 1980). Acute human exposures result in pathological pulmonary lesions, hemorrhage, edema, deranged alveolar cells, degeneration of bronchial epithelium, and pulmonary fibrosis. The response of pulmonary tissue to nickel carbonyl is rapid: interstitial edema may develop within 1 h of exposure and cause death within 5 days. Animals surviving acute exposures show lung histopathology (USEPA 1980).

Gastrointestinal intake of nickel by humans is high compared to some other trace metals because of contributions of nickel from utensils and food processing machinery; average human dietary values range from 300 to 500 μg daily, with absorption from the gastrointestinal tract of 1-10% (USEPA 1980, 1986; Sigel and Sigel 1988). In humans, nearly 40 times more nickel was absorbed from the gastrointestinal tract when nickel sulfate was given in the drinking water (27%) than when it was given in the diet (0.7%). Uptake was more rapid in starved individuals (WHO 1991; USPHS 1993). Dogs and rats given nickel, nickel sulfate hexahydrate, or nickel chloride in the diet or by gavage rapidly absorbed 1-10% of the nickel from the gastrointestinal tract, while unabsorbed nickel was excreted in the feces (USPHS 1993).

During occupational exposure, respiratory absorption of soluble and insoluble nickel compounds is the major route of entry, with gastrointestinal absorption secondary (WHO 1991). Inhalation exposure studies of nickel in humans and test animals show that nickel localizes in the lungs, with much lower levels in liver and kidneys (USPHS 1993). About half the inhaled nickel is deposited on bronchial mucosa and swept upward in mucous to be swallowed; about 25% of the inhaled nickel is deposited in the pulmonary parenchyma (NAS 1975). The relative amount of inhaled nickel absorbed from the pulmonary tract is dependent on the chemical and physical properties of the nickel compound (USEPA 1986). Pulmonary absorption into the blood is greatest for nickel carbonyl vapor; about half the inhaled amount is absorbed (USEPA 1980). Nickel in particulate matter is absorbed from the pulmonary tract to a lesser degree than nickel carbonyl; however, smaller particles are absorbed more readily than larger particles (USEPA 1980). Large nickel particles (>2 μm in diameter) are deposited in the upper respiratory tract; smaller particles tend to enter the lower respiratory tract. In humans, 35% of the inhaled nickel is absorbed into the blood from the respiratory tract; the remainder is either swallowed or expectorated. Soluble nickel compounds were more readily absorbed from the respiratory tract than insoluble compounds (USPHS 1993). In rodents, the half-time persistence of nickel particles was a function of particle diameter: 7.7 months for particles 0.6 μm in diameter, 11.5 months for particles 1.2 μm in diameter, and 21 months for particles 4.0 μm in diameter (USPHS 1993). In rodents, a higher percentage of insoluble nickel compounds was retained in the lungs for a longer time than soluble nickel compounds, and the lung burden of nickel decreased with increasing particle size. Nickel retention was 6-10 times greater in rodents exposed to insoluble nickel subsulfide compared to soluble nickel sulfate. Lung burdens of nickel generally increased with increasing duration of exposure and increasing concentrations of various nickel compounds in the air (USPHS 1993). Animals exposed to nickel carbonyl by inhalation exhale some of the respiratory burden in 2-4 h. The remainder is slowly degraded to divalent nickel, which is oxidized, and carbon monoxide, which initially binds to hemoglobin, with nickel eventually undergoing urinary excretion (NAS 1975; Norseth and Piscator 1979; USEPA 1980; Norseth 1986).

Dermal absorption of nickel occurs in animals and humans and is related to nickel-induced hypersensitivity and skin disorders (Samitz and Katz 1976; USEPA 1986). Absorption of nickel sulfate from the skin is reported for guinea pigs, rabbits, rats, and humans (Norseth and Piscator 1979). Nickel ions in contact with the skin surface diffuse through the epidermis and combine with proteins; the body reacts to this conjugated protein (Samitz and Katz 1976; Nielsen 1977). Nickel penetration of the skin is enhanced by sweat, blood and other body fluids, and detergents (Nielsen 1977; USEPA 1980). Absorption is related to the solubility of the compound, following the general relation of nickel carbonyl, soluble nickel compounds, and insoluble nickel compounds, in that order; nickel carbonyl is the most rapidly and completely absorbed nickel compound in mammals (WHO 1991). Anionic species differ markedly in skin penetration: nickelous ions from a chloride

solution pass through skin about 50 times faster than do nickelous ions from a sulfate solution (USPHS 1993). Radionickel-57 (^{57}Ni) accumulates in keratinous areas and hair sacs of the shaved skin of guinea pigs and rabbits following dermal exposure. After 4 h, ^{57}Ni was found in the stratum corneum and stratum spinosum; after 24 h, ^{57}Ni was detected in blood and kidneys, with minor amounts in liver (USPHS 1993). As much as 77% of nickel sulfate applied to the occluded skin surface of rabbits and guinea pigs was absorbed within 24 h; sensitivity to nickel did not seem to affect absorption rate (USPHS 1993). In humans, some protection against nickel may be given by introducing a physical barrier between the skin and the metal, including fingernail polish, a polyurethane coating, dexamethasone, or disodium EDTA (Nielsen 1977).

Nickel retention in the body of mammals is low. The half-time residence of soluble forms of nickel is several days, with little evidence for tissue accumulation except in the lung (USEPA 1980, 1986). Radionickel-63 (^{63}Ni) injected into rats and rabbits cleared rapidly; most (75%) of the injected dose was excreted within 24-72 h (USEPA 1980). Nickel clears at different rates from various tissues. In mammals, clearance was fastest from serum, followed by kidney, muscle, stomach, and uterus; relatively slow clearance was evident in skin, brain, and especially lung (Kasprzak 1987). The half-time persistence in human lung for insoluble forms of nickel is 330 days (Sevin 1980).

The excretory routes for nickel in mammals depend on the chemical forms of nickel and the mode of nickel intake. Most (>90%) of the nickel that is ingested in food remains unabsorbed within the gastrointestinal tract and is excreted in the feces (NAS 1975; Sevin 1980; USEPA 1986; Kasprzak 1987; Hausinger 1993; USPHS 1993). Urinary excretion is the primary route of clearance for nickel absorbed through the gastrointestinal tract (USEPA 1976, 1986; USPHS 1993). In humans, nickel excretion in feces usually ranges between 300 and 500 μg daily, or about the same as the daily dietary intake; urinary levels are between 2 and 4 μg/L (USEPA 1980, 1986). Dogs fed nickel sulfate in the diet for as long as 2 years excreted most of the nickel in feces and 1-3% in the urine (USPHS 1993). Biliary excretion occurs in rats, calves, and rabbits, but the role of bile in human metabolism of nickel is not clear (USEPA 1980). Absorbed nickel is excreted in the urine regardless of the route of exposure. The excretory route of inhaled nickel depends on the solubility of the nickel compound. Inhalation studies show that rats excrete 70% of the nickel in soluble nickel compounds through the urine within 3 days and 97% in 21 days. Less soluble nickel compounds (nickel oxide, nickel subsulfide) are excreted in urine (50%) and feces (50%); 90% of the initial dose of nickel subsulfide was excreted within 35 days, and 60% of the nickel oxide—which is less soluble and not as rapidly absorbed as nickel subsulfide—was excreted in 90 days (USPHS 1993). The half-time persistence of inhaled nickel oxide is 3 weeks in hamsters (Sevin 1980). In addition to feces, urine, and bile, other body secretions—including sweat, tears, milk, and mucociliary fluids—are potential routes of excretion (WHO 1991). Sweat may constitute a major route of nickel excretion in tropical climates. Nickel concentrations in sweat of healthy humans sauna bathing for brief periods were 52 μg/L in males and 131 μg/L in females (USEPA 1980). Hair deposition of nickel also appears to be an excretory mechanism (as much as 4 mg Ni/kg dry weight [DW] hair in humans), but the relative magnitude of this route, compared to urinary excretion, is unclear (USEPA 1980, 1986). In the case of nickel compounds administered by way of injection, tests with small laboratory animals show that nickel is cleared rapidly from the plasma and excreted mainly in the urine (Norseth and Piscator 1979; USEPA 1980). About 78% of an injected dose of nickel salts was excreted in the urine during the first 3 days after injection in rats and during the first day in rabbits (Norseth 1986). Exhalation via the lungs is the primary route of excretion during the first hours following injection of nickel carbonyl into rats, and afterwards via the urine (Norseth and Piscator 1979).

In microorganisms, nickel binds mainly to the phosphate groups of the cell wall. From this site, an active transport mechanism designed for magnesium transports the nickel (Kasprzak 1987). In microorganisms and higher plants, magnesium is the usual competitor for nickel in the biological ion-exchange reactions. In lichens, fungi, algae, and mosses, the active binding sites are the carboxylic and hydroxycarboxylic groups fixed on the cell walls. Nickel in hyperaccumulating genera of terrestrial plants is complexed with polycarboxylic acids and pectins, although phosphate groups may also participate (Kasprzak 1987). In terrestrial plants, nickel is absorbed through the roots (USEPA 1975).

Interactions

In minerals, nickel competes with iron, cobalt, and magnesium because of similarities in their ionic radius and electronegativity (NRCC 1981). At the cellular level, nickel interferes with enzymatic functions of calcium,

iron, magnesium, manganese, and zinc (Kasprzak 1987). Binding of nickel to DNA is inhibited by salts of calcium, copper, magnesium, manganese, and zinc (WHO 1991). In toads (*Bufo arenarum*), ionic nickel interferes with voltage-sensitive ionic potassium channels in short muscle fibers (Bertran and Kotsias 1997). Among animals, plants, and microorganisms, nickel interacts with at least 13 essential elements: calcium, chromium, cobalt, copper, iodine, iron, magnesium, manganese, molybdenum, phosphorus, potassium, sodium, and zinc (Nielsen 1980a). Nickel interacts noncompetitively with all 13 elements and also interacts competitively with calcium, cobalt, copper, iron, and zinc. Quantification of these relationships would help clarify nickel-essential mineral interactions and the circumstances under which these interactions might lead to states of deficiency or toxicity (Nielsen 1980a). Mixtures of metals (arsenic, cadmium, copper, chromium, mercury, lead, zinc) containing nickel salts are more toxic to daphnids and fishes than are predicted on the basis of individual components (Enserink et al. 1991). Additive joint action of chemicals, including nickel, should be considered in the development of ecotoxicologically relevant water quality criteria (Enserink et al. 1991).

Nickel may be a factor in asbestos carcinogenicity. The presence of chromium and manganese in asbestos fibers may enhance the carcinogenicity of nickel (USEPA 1980), but this relationship needs to be verified. Barium-nickel mixtures inhibit calcium uptake in rats, resulting in reduced growth (WHO 1991). Pretreatment of animals with cadmium enhanced the toxicity of nickel to the kidneys and liver (USPHS 1993). Simultaneous exposure to nickel and cadmium—an industrial situation common in nickel and cadmium battery production—caused a significant increase in beta-2-macroglobulin excretion (Sunderman et al. 1984). Nickel or cadmium alone did not affect calcium kinetics of smooth muscle from bovine mesenteric arteries. However, mixtures of cadmium and nickel at greater than 100 nM inhibited the calcium function and may explain the vascular tension induced by nickel and other cations (Stockand et al. 1993). Smooth muscle of the ventral aorta of the spiny dogfish (*Squalus acanthias*) contracted significantly on exposure to cadmium or nickel but not to other divalent cations. Atropine inhibited vasoconstriction of shark muscle induced by cadmium, but not that induced by nickel (Evans and Walton 1990). Nickel toxicity in soybeans (*Glycine max*) was inhibited by calcium, which limited the binding of nickel to DNA (WHO 1991). Chromium-nickel mixtures were more-than-additive in toxicity to guppies (*Poecilia reticulata*) in 96-h tests (Khangarot and Ray 1990). Rabbits (*Oryctolagus* sp.) exposed by inhalation to both nickel and trivalent chromium had more severe respiratory effects than did rabbits exposed to nickel alone (USPHS 1993). In natural waters, the geochemical behavior of nickel is similar to that of cobalt (USEPA 1980). It is therefore not surprising that nickel-cobalt mixtures in drinking water of rats were additive in toxicity (WHO 1991) and that there is a high correlation between nickel and cobalt concentrations in terrestrial plants (Memon et al. 1980).

Copper-nickel mixtures have a beneficial effect on growth of terrestrial plants but are more-than-additive in toxic action to aquatic plants (NRCC 1981; WHO 1991). Nickel interacts with iron in rat nutrition and metabolism, but the interaction depends on the form and level of the dietary iron (Nielsen 1980b; USEPA 1985). Weanling rats fed diets containing nickel chloride and ferric sulfate had altered hematocrit, hemoglobin level, and alkaline phosphatase activity which did not occur when a mixture of ferric and ferrous sulfates were fed (Nielsen 1980b). In iron-deficient rats, nickel enhanced the absorption of iron administered as ferric sulfate (USPHS 1993), and nickel acted as a biological cofactor in facilitating gastrointestinal absorption of ferric ion when iron was given as ferric sulfate (USPHS 1993). Mice given a lead-nickel mixture in drinking water (57 mg Ni/L-200 mg Pb/L) for 12 days had increased urinary excretion of delta aminolevulinic acid and increased delta aminolevulinic dehydratase activity in erythrocytes when compared to groups given lead alone or nickel alone (Tomokuni and Ichiba 1990).

Magnesium competes with nickel in isolated cell studies (WHO 1991). Treatment with magnesium reduces nickel toxicity, presumably through inhibition of nickel binding to DNA (USPHS 1993; Hartwig et al. 1994). Manganese also inhibits the binding of nickel to DNA (WHO 1991), and manganese administration reduces the accumulation of nickel in some organs (Murthy and Chandra 1979). Manganese dust inhibits nickel subsulfide-induced carcinogenesis in rats following simultaneous intramuscular injection of the two compounds (USPHS 1993). Also, nickel-manganese mixtures are less-than-additive in producing cytotoxicity of alveolar macrophages in rats (WHO 1991). Nickel compounds enhance the cytotoxicity and genotoxicity of ultraviolet radiation, x-rays, and cytostatic agents such as *cis*-platinum, *trans*-platinum, and mitomycin C (Hartwig et al. 1994). Nickel is less-than-additive in toxicity to aquatic algae in combination with zinc (WHO 1991). Treatment with zinc lessens nickel toxicity, presumably by competing with nickel in binding to DNA and proteins (USEPA 1985; WHO 1991; USPHS 1993; Hartwig et al. 1994). Zinc binding sites of DNA-binding proteins, known as “finger loop domains,” are likely molecular targets for metal toxicity. Ionic nickel has a similar ionic radius to

Zn^{2+} and substitution is possible. Such substitution may disrupt nickel-induced gene expression by interfering with site-specific free radical reactions, which can result in DNA cleavage, formation of DNA protein cross links, and disturbance of mitosis (WHO 1991).

Nickel also interacts with chelating agents, phosphatases, viruses, vitamins, and polycyclic aromatic hydrocarbons (PAHs). Chelating agents mitigate the toxicity of nickel by stimulating nickel excretion (USPHS 1993). Chelators reduced the toxicity of nickel to aquatic plants, presumably by lowering nickel bioavailability (WHO 1991). Lipophilic chelating agents, such as triethylenetetramine and Cyclam (1,4,8,11-tetraazacyclotetradecane), are more effective in reducing toxicity than hydrophilic chelating agents such as EDTA, cyclohexanediamine tetraacetic acid, diethylenetriamine pentaacetic acid, and hydroxyethylenediamine triacetic acid. The greater efficacy of the lipophilic agents may be due to their ability to bind to nickel both intracellularly and extracellularly, while the hydrophilic agents can only bond extracellularly (USPHS 1993). Nickel irreversibly activates calcineurin, a multifunctional intracellular phosphatase normally activated by calcium and calmodulin (Kasprzak 1987). With nickel present, Newcastle Disease virus suppresses mouse L-cell interferon synthesis, suggesting virus-nickel synergism (USEPA 1980). Nickel interacts with vitamin C (USEPA 1985) and has a synergistic effect on the carcinogenicities of various PAHs (USEPA 1980). Rats given intratracheal doses of nickel oxide and 20-methylcholanthrene develop squamous cell carcinomas more rapidly than with 20-methylcholanthrene alone. Simultaneous exposure of rats to benzopyrene and nickel subsulfide reduced the latency period of sarcomas by 30% and induced lung histopathology at a higher frequency than either agent alone. Also, tissue retention of PAH carcinogens is prolonged with nickel exposure (USEPA 1980).

Carcinogenicity, Mutagenicity, Teratogenicity

General

Some forms of nickel are carcinogenic to humans and animals (IARC 1976; Smialowicz et al. 1984; USEPA 1986; WHO 1991; Hausinger 1993; USPHS 1993; Hartwig et al. 1994). Carcinogenicity of nickel compounds varies significantly with the chemical form of nickel, route of exposure, animal model used (including intraspecies strain differences), dose, and duration of exposure (USEPA 1980). In tests with small laboratory mammals, inducement of carcinomas of the types found in humans has only been accomplished following exposures by the respiratory route (Sunderman 1968). Inhalation studies with nickel subsulfide and nickel oxide show evidence of carcinogenicity in mammals and humans; however, the evidence based on oral or cutaneous exposure to these and other nickel compounds is either negative or inconclusive (NAS 1975; IARC 1976; Norseth 1980; USEPA 1980, 1986; WHO 1991; USPHS 1993). Nickel carbonyl and metallic nickel are carcinogenic in experimental animals, but data regarding their carcinogenicity in humans are inconclusive (USEPA 1975; Norseth 1980; USPHS 1993).

Certain nickel compounds are weakly mutagenic in a variety of test systems, but much of the evidence is inconclusive or negative (USPHS 1977, 1993; USEPA 1986; Kasprzak 1987; WHO 1991; Outridge and Scheuhammer 1993). Mutagenicity—as measured by an increased frequency of sister chromatid exchange, chromosome aberrations, cell transformations, spindle disturbances, and dominant lethal effects—is induced by various nickel compounds at high concentrations in isolated cells of selected mammals, including humans; however, these effects have not been observed in vivo (Sunderman 1981; USEPA 1986; WHO 1991; USPHS 1993). Nickel mutagenesis is thought to occur through inhibition of DNA synthesis and excision repair, resulting in an increased frequency of cross links and strand breaks (USEPA 1986; WHO 1991; USPHS 1993). DNA strand breaks occur in rat cells exposed to 5-40 mg Ni/kg medium as nickel carbonate; similar effects occur in hamster cells at 10-2,000 mg Ni/kg medium as nickel chloride and nickel subsulfide and in human cells with nickel sulfate (WHO 1991). The ability of a particular nickel compound to cause mutations is considered proportional to its cellular uptake; however, data on nickel bioavailability to cells is scarce (Niebuhr et al. 1980; USPHS 1993).

No teratogenic effects of nickel compounds occur in mammals by way of inhalation or ingestion except from nickel carbonyl (USEPA 1986; Outridge and Scheuhammer 1993). However, injection of low nickel doses results in consistent fetal malformations, particularly when nickel is administered during the organogenic stage of gestation of mammals or during the early development of domestic chick embryos (Outridge and Scheuhammer 1993). Injected doses causing teratogenic effects in rodents were as low as 1.0-1.2 mg Ni/kg body weight (BW), although more malformations resulted at higher dosages (2.3-4.0 mg/kg BW), which also increased fetal mortality and toxicity in the dam (Mas et al. 1985; Outridge and Scheuhammer 1993). Possible

causes of nickel-induced malformations include direct toxicity from high transplacental nickel levels, reduced availability of alpha-fetoprotein to fetuses, or an increase in maternal glucose levels, which induces hyperglycemia in fetuses (Mas et al. 1985; Outridge and Scheuhammer 1993).

Carcinogenicity

Epidemiological studies conducted some decades ago in England, Canada, Japan, Norway, Germany, Russia, New Caledonia, and West Virginia indicated that humans working in the nickel processing and refining industries—or living within 1 km of processing or refining sites—had a significantly increased risk of developing fatal cancers of the nose, lungs, larynx, and kidneys, and a higher incidence of deaths from nonmalignant respiratory disease (Sunderman 1968, 1981; NAS 1975; IARC 1976; USPHS 1977, 1993; Norseth and Piscator 1979; Norseth 1980; Sevin 1980; USEPA 1980; Kasprzak 1987; WHO 1991). Nasal cancers in nickel refinery workers were similar to those of the general population; however, lung cancers of nickel refinery workers had a higher frequency of squamous cell carcinomas (USPHS 1993). Smoking of tobacco contributed to the development of lung cancers in the nickel-exposed workers. Smoking about 15 cigarettes daily for 1 year adds about 1,930 μg of nickel, as nickel carbonyl, to the human lung; this amount is equivalent to a carcinogenic dose of nickel for rats (Sunderman 1970, 1981). Symptoms of cancer in humans may occur 5 to 35 years after exposure (Furst and Radding 1980; Kasprzak 1987; USPHS 1993). The incidence of human lung and nasal cancers in occupationally exposed workers are related to nickel concentration and duration of exposure (USEPA 1986). Nickel compounds implicated as carcinogens include insoluble dusts of nickel subsulfide (Ni_3S_2) and nickel oxides (NiO, Ni_2O_3), the vapor of nickel carbonyl ($Ni(CO)_4$), and soluble aerosols of nickel sulfate ($NiSO_4$), nickel nitrate ($NiNO_3$), and nickel chloride ($NiCl_2$; USPHS 1977; USEPA 1980). Soluble nickel compounds, though toxic, have relatively low carcinogenic activities (Ho and Furst 1973). In general, carcinogenicity of nickel compounds is inversely related to its solubility in water, the least soluble being the most active carcinogen (Sunderman 1968; Furst and Radding 1980; USEPA 1980; USPHS 1993). The highest risk to humans of lung and nasal cancers comes from exposure to respirable particles of metallic nickel, nickel sulfides, nickel oxide, and the vapors of nickel carbonyl (NAS 1975; USPHS 1977; Norseth and Piscator 1979; Norseth 1980; Sunderman 1981; Sunderman et al. 1984; USEPA 1986; Kasprzak 1987; WHO 1991; USPHS 1993). Cancers were most frequent when workers were exposed to soluble nickel compounds at concentrations greater than 1.0 mg Ni/m^3 air and to exposure to less soluble compounds at greater than 10.0 mg Ni/m^3 air (USPHS 1993). Nickel subsulfide appears to be the nickel compound most carcinogenic to humans, as judged by animal studies and epidemiological evidence (Furst and Radding 1980; Outridge and Scheuhammer 1993). The death rate of nickel workers from cancer has declined significantly since the mid-1920's because of improved safety and awareness (USPHS 1977, 1993).

The underlying biochemical mechanisms governing the carcinogenicity of various nickel compounds are imperfectly understood. There is general agreement that intra-cellular nickel accumulates in the nucleus, especially the nucleolar fraction (NAS 1975; USEPA 1980). Intracellular binding of nickel to nuclear proteins and nuclear RNA and DNA may cause strand breakage and other chromosomal aberrations, diminished RNA synthesis and mitotic activity, and gene expression (USEPA 1980; Kasprzak 1987). A key mechanism of the transformation of tumorous cells involves DNA damage resulting from mutation (Sigel and Sigel 1988) caused by hydroxy radical or other oxidizing species (Datta et al. 1994). Alterations in cytokine (also known as tumor necrosis factor) production is associated with fibrotic lung injury in rats. Inhaled nickel oxide is known to increase cytokine production in rats (Morimoto et al. 1995).

Nickel entering the digestive tract of mammals is likely to be noncarcinogenic. Chronic ingestion studies of various nickel compounds that lasted as long as 2 years using several species of mammals show no evidence of carcinogenesis (Outridge and Scheuhammer 1993). Inhalation is the dosing route most relevant to human occupational exposure (Sunderman et al. 1984) and probably an important route for wildlife exposure in the case of nickel powder, nickel carbonyl, and nickel subsulfide (IARC 1976).

Inhalation of airborne nickel powder at 15 mg Ni/m^3 air causes an increased frequency of lung anaplastic carcinomas and nasal cancers in rodents and guinea pigs, especially when the particles are less than 4 μm in diameter (USPHS 1977; USEPA 1980). Rats exposed to airborne dusts of metallic nickel at 70 mg Ni/m^3 air for 5 h daily, 5 days weekly over 6 months had a 40% frequency of lung cancers; the latent period for tumor development was 17 months (Sunderman 1981). A similar case is made for nickel sulfide and nickel oxide

(Sunderman 1981). In Canada, however, metallic nickel is considered “unclassifiable with respect to carcinogenicity” due to the limitations of identified studies (Hughes et al. 1994). Inhaled nickel carbonyl is carcinogenic to the lungs of rats, a species generally considered to be peculiarly resistant to pulmonary cancer (Sunderman and Donnelly 1965; NAS 1975; IARC 1976; USEPA 1980; WHO 1991). Pulmonary cancers developed in rats 24-27 months after initial exposure to nickel carbonyl, and growth and survival of rats during chronic exposure were markedly reduced (Sunderman and Donnelly 1965). Rats exposed to air containing 250 μg nickel carbonyl/L for only 30 min had a 4% incidence of lung cancer in 2-year survivors versus 0% in controls; rats exposed to 30-60 μg/L air for 30 min, three times weekly for 1 year had a 21% incidence of lung cancer in 2-year survivors (Sunderman 1970; NAS 1975). Inhaled nickel oxides do not seem to be tumorogenic to hamsters at concentrations of 1.2 mg Ni/m^3 air during exposure for 12 months (Outridge and Scheuhammer 1993). Hamsters did not develop lung tumors during lifespan inhalation exposure to nickel oxide; however, inhaled nickel oxide enhanced nasal carcinogenesis produced by diethylnitrosamine (USPHS 1977). Inhalation of nickel subsulfide produced malignant lung tumors and nasal cancers in rats in a dose-dependent manner (Ottolenghi et al. 1974; IARC 1976; USPHS 1977, 1993; WHO 1991; Benson et al. 1995; Rodriguez et al. 1996). Rats develop benign and malignant lung tumors (14% frequency vs. 0% in controls) after exposure for 78 weeks (6 h daily, 5 days weekly) to air containing 1.0 mg Ni/m^3 (as nickel subsulfide; particles <1.5 μm in diameter) and during a subsequent 30-week observation period (IARC 1976; USPHS 1977; USEPA 1980; NRCC 1981).

Local sarcomas may develop in humans and domestic animals at sites of nickel implants and prostheses made of nickel. Latency of the implant sarcomas varies from 1 to 30 years in humans (mean, 10 years) and from 1 to 11 years in dogs (mean, 5 years). No cases of malignant tumors are reported at sites of dental nickel prostheses (Kasprzak 1987).

Injection site tumors are induced by many nickel compounds that do not cause cancer in animals by other routes of exposure (USPHS 1977). In fact, most of the published literature on nickel carcinogenesis concerns injected or implanted metallic nickel or nickel compounds. However, these data seem to be of limited value in determining carcinogenic exposure levels for avian and terrestrial wildlife (Outridge and Scheuhammer 1993). The applicability of these studies to a recommendation for human workplace exposure is also questionable (USPHS 1977). Nevertheless, injection or implantation site sarcomas have been induced by many nickel compounds after one or repeated injections or implantations in rats, mice, hamsters, guinea pigs, rabbits, and cats (NAS 1975; IARC 1976; USPHS 1977, 1993; Norseth and Piscator 1979; USEPA 1980; NRCC 1981; Sunderman 1981; WHO 1991). Nickel compounds known to produce sarcomas or malignant tumors by these routes of administration (implantation, intratracheal, intramuscular, intraperitoneal, subcutaneous, intrarenal, intravenous, intratesticular, intraocular, intraosseus, intrapleural, intracerebral, intrahepatic, intraarticular, intrasubmaxillary, intraadipose, intramedullary) include nickel subsulfide, nickel carbonyl, nickel powder or dust, nickel oxide, nickel hydroxide, nickel acetate, nickel fluoride, nickelocene, nickel sulfate, nickel selenide, nickel carbonate, nickel chromate, nickel arsenide, nickel telluride, nickel antimonide, nickel-iron matte, nickel ammonium sulfate, and nickel monosulfide.

Some parenteral routes of administration were less effective than others in producing an increase in the frequency of benign or malignant tumors, including intravenous, submaxillary, and intrahepatic injection routes (Sunderman 1981). Some nickel compounds are more effective at inducing tumors than others, for example, nickel sulfate and nickel acetate induce tumors in the peritoneal cavity of rats after repeated intraperitoneal injections but nickel chloride does not (WHO 1991). Likewise, some species are more sensitive to tumor inducement by injection than others; rats, for example, are more sensitive than hamsters (USPHS 1977). Most nickel compounds administered by way of injection usually produce responses at the site of injection; however, nickel acetate injected intraperitoneally produced pulmonary carcinomas in mice (USEPA 1980). Some carcinogenic nickel compounds produce tumors only when a threshold dose is exceeded (IARC 1976; USPHS 1993), and some strains of animals are more sensitive than others. In one study, three strains of male mice (*Mus* sp.) were given a single intramuscular injection of 0.5, 2.5, 5.0, or 10.0 mg nickel subsulfide per mouse—equivalent to 19, 95, 190, or 380 mg Ni_3S_2/kg BW—and observed for 78 weeks for tumor development (Rodriguez et al. 1996). Nickel subsulfide is a water-insoluble compound suspected to damage cells through oxidative mechanisms. The highest dose injected was lethal (53-93% dead) within 7 days. The final incidence of sarcomas in the 5 mg/mouse groups ranged between 40 and 97%, with decreased survival and growth noted in all test groups. In the most sensitive strain tested, there was a dose-dependent increase in tumor frequency, with a significant increase in tumors at the lowest dose tested (Rodriguez et al. 1996).

Carcinogenic properties of nickel are modified by interactions with other chemicals (NAS 1975; USEPA 1985; WHO 1991). Nickel-cadmium battery workers exposed to high levels of both nickel and cadmium have an increased risk of lung cancer when compared to exposure from cadmium alone (WHO 1991). Some nickel compounds interact synergistically with known carcinogens (WHO 1991). Nickel chloride enhances the renal carcinogenicity of N-ethyl-N-hydroxyethyl nitrosamine in rats. Metallic nickel powder enhances lung carcinogenicity of 20-methylcholanthrene when both are administered intratracheally to rats. Nickel subsulfide in combination with benzo(a)pyrene shortens the latency time to local tumor development and produces a disproportionately higher frequency of malignant tumors. Nickel sulfate enhanced dinitrosopiperazine carcinogenicity in rats (WHO 1991). And nickel potentiated the specific effects of cobalt in rabbits by enhancing the formation of lung nodules (Johansson et al. 1991). Some chemicals inhibit nickel-induced carcinogenicity. Carcinogenicity induced by nickel subsulfide is reduced by manganese dust (Sunderman 1981; Sunderman et al. 1984; WHO 1991). Manganese protects male guinea pigs against tumorogenesis induced by nickel subsulfide, possibly due to the stimulating effect of manganese on macrophage response and by displacing nickel from the injection site (Murthy and Chandra 1979). Sodium diethyldithiocarbamate reduced tumor incidence in rats implanted with nickel subsulfide (WHO 1991). And magnesium acetate and calcium acetate inhibit lung adenoma formation in mice treated intraperitoneally with nickel acetate (WHO 1991). Nickel interactions with other suspected carcinogens, such as chromium, merit additional research (Norseth 1980). Nickel and other trace metals in asbestos fibers are responsible, in part, for the pulmonary carcinogenicity found in asbestos workers (Sunderman 1968). Nickel-sulfur mineral complexes may also have carcinogenic potential; a similar case is made for the corresponding arsenides, selenides, and tellurides (USEPA 1980).

Mutagenicity

Nickel salts gave no evidence of mutagenesis in tests with viruses (USPHS 1977), and bacterial mutagenesis tests of nickel compounds have consistently yielded negative or inconclusive results (USPHS 1977; Sunderman 1981; Sunderman et al. 1984; WHO 1991). However, nickel chloride and nickel sulfate were judged to be mutagenic or weakly mutagenic in certain bacterial eukaryotic test systems (USEPA 1985). Nickel subsulfide was positively mutagenic to the protozoan *Paramecium* sp. at 0.5 mg Ni/L (WHO 1991). Ionic Ni^{2+} was mutagenic to *Escherichia coli*; mutagenesis was enhanced by the addition of both hydrogen peroxide and tripeptide glycyl-L-histidine, suggesting that short-lived oxygen free radicals are generated (Tkeshelashvili et al. 1993). Nickel chloride hexahydrate induced respiratory deficiency in yeast cells, but this may be a cytotoxic effect rather than a gene mutation (USPHS 1977; WHO 1991).

Nickel is weakly mutagenic to plants (USPHS 1977) and insects (WHO 1991). Abnormal cell divisions occur in roots of the broad bean (*Vicia faba*) during exposure to various inorganic nickel salts at nickel concentrations of 0.1-1,000 mg/L (USPHS 1977). All nickel salts tested produced more abnormal cell divisions than did controls. In beans, nickel nitrate was the most effective inorganic nickel compound tested in producing deformed cells, abnormal arrangement of chromatin, extra micronuclei, and evidence of cell nucleus disturbances; however, nickel salts showed only weak mutagenic action on rootlets of peas, *Pisum* sp. (USPHS 1977). Nickel sulfate induced chromosomal abnormalities in root tip cells of onions, *Allium* sp. (Donghua and Wusheng 1997) and caused sex-linked recessive mutations in the fruit fly (*Drosophila melanogaster*) at 200-400 mg Ni/L culture medium (WHO 1991).

Human cells exposed to various nickel compounds have an increased frequency of chromosomal aberrations, although sister chromatid exchange frequency is unaffected. Cells from nickel refinery workers exposed to nickel monosulfide (0.2 mg Ni/m^3) or nickel subsulfide (0.5 mg Ni/m^3) showed a significant increase in the incidence of chromosomal aberrations (Boysen et al. 1980; WHO 1991; USPHS 1993). No correlation was evident between nickel exposure level and the frequency of aberrations (USPHS 1993).

In Chinese hamster ovary cells, nickel chloride increased the frequency of chromosomal aberrations and sister chromatid exchanges. Cells with aberrations increased from 8% at about 6 μg Ni/L to 21% at about 6 mg Ni/L in a dose-dependent manner (Howard et al. 1991). There is a large difference in the mutagenic potential of soluble and insoluble nickel compounds that seems to reflect the carcinogenic potential of these nickel forms (Lee et al. 1993). For example, insoluble particles less than 5 μm in diameter of crystalline nickel subsulfide—a carcinogen—produced a strong, dose-dependent mutagenic response in Chinese hamster ovary cells up to 80 times higher than in untreated cells; however, soluble nickel sulfate produced no significant increase in mutational response over background in Chinese hamster ovary cells (Lee et al. 1993). A similar response is

reported for Syrian hamster embryo cells (USPHS 1993). Interactions of carcinogens and soluble nickel salts need to be considered. Benzo(a)pyrene, for example, showed a comutagenic effect with nickel sulfate in hamster embryo cells (USEPA 1985).

In rats, nickel carbonyl is reported to cause dominant lethal mutations (WHO 1991), but this needs verification. Nickel sulfate, when given subcutaneously at 2.4 mg Ni/kg BW daily for 120 days causes infertility; testicular tissues are adversely affected after the first injection (USEPA 1980). Nickel salts given intraperitoneally to rats at 6 mg Ni/kg BW daily for 14 days did not produce significant chromosomal changes in bone marrow or spermatogonial cells (Mathur et al. 1978).

In mice, nickel chloride produces a dose-dependent increase in abnormal lymphoma cells (WHO 1991). Mice given high concentrations of nickel in drinking water, equivalent to 23 mg Ni/kg BW daily and higher, have an increased incidence of micronuclei in bone marrow (USPHS 1993). However, mice injected once with 50 mg Ni/kg BW as nickel chloride show no evidence of mutagenicity (USPHS 1977).

Teratogenicity

Nickel carbonyl at high doses is a potent animal teratogen (Sunderman et al. 1984). Inhalation exposure to nickel carbonyl caused fetal death and decreased weight gain in rats and hamsters (WHO 1991) and eye malformations in rats (Sevin 1980; Sunderman et al. 1980). Studies on hamsters, rats, mice, birds, frogs, and other species suggest that some individuals are susceptible to reproductive and teratogenic effects when given high doses of nickel by various routes of administration (USPHS 1977; Sunderman et al. 1980; USEPA 1986; WHO 1991; Hausinger 1993). Intravenous injection of nickel sulfate to hamsters at 2-25 mg/kg BW on day 8 of gestation produces developmental abnormalities (USPHS 1977; Norseth and Piscator 1979). Teratogenic malformations—including poor bone ossification, hydronephrosis, and hemorrhaging—occur in rats when nickel is administered during organogenesis, and these malformations are maximal at dose levels toxic for the dam (Mas et al. 1985). A dose of 4 mg/kg BW given intraperitoneally on day 12 or 19 of pregnancy is teratogenic in rats (Mas et al. 1985). Rats exposed continuously for three generations to drinking water containing 5 mg Ni/L produce smaller litters, higher offspring mortality, and fewer males (NAS 1975; USPHS 1977). An increase in the number of runts suggests that transplacental toxicity occurs (USPHS 1977; Norseth and Piscator 1979).

Divalent nickel is a potent teratogen for the South African clawed frog (*Xenopus laevis*). Frog embryos actively absorb Ni^{2+} from the medium and develop ocular, skeletal, craniofacial, cardiac, and intestinal malformations (Sunderman et al. 1990; Hopfer et al. 1991; Hausinger 1993; Luo et al. 1993; Hauptman et al. 1993; Plowman et al. 1994). A Ni^{2+}-binding serpin, *pNiXa*, is abundant in clawed frog oocytes and embryos; binding of Ni^{2+} to *pNiXa* may cause embryotoxicity by enhancing oxidative reactions that produce tissue injury and genotoxicity (Beck et al. 1992; Haspel et al. 1993; Sunderman et al. 1996). Another Ni^{2+}-binding protein, *pNiXc*, isolated from mature oocytes of the clawed frog, was identified as a monomer of fructose-1,6-biphosphate aldolase A and raises the possibility that aldolase A is a target enzyme for nickel toxicity (Antonijczuk et al. 1995).

Nickel is embryolethal and teratogenic to white leghorn strains of the domestic chicken (*Gallus* sp.), possibly due to the mitosis-inhibiting activity of nickel compounds (Gilani and Marano 1980). Fertilized chicken eggs injected with 0.02-0.7 mg Ni/egg as nickel chloride on days 1-4 of incubation show a dose-dependent response. All dose levels of nickel tested were teratogenic to chickens. Malformations include poorly developed or missing brain and eyes, everted viscera, short and twisted neck and limbs, hemorrhaging, and a reduction in body size. Toxicity and teratogenicity are highest in embryos injected on day 2 (Gilani and Marano 1980). Mallard (*Anas platyrhynchos*) ducklings from fertile eggs treated at age 72 h with 0.7 μg Ni as nickel mesotetraphenylporphine show a marked decrease in survival. Among survivors, there is a significant increase in the frequency of developmental abnormalities, a reduction in bill size, and a reduction in weight (Hoffman 1979).

Changes in employment practices in North America and Europe have increased the proportion of women among workers in nickel mines and refineries and in nickel-plating industries; this increase has heightened concern regarding possible fetal toxicity associated with exposures of pregnant women to nickel during gestation (Sunderman et al. 1978). One preliminary report (Chashschin et al. 1994) strongly suggests that exposure to nickel of Russian female hydrometallurgy workers causes significantly increased risks for abortion, total defects, cardiovascular defects, and defects of the musculoskeletal system.

Nonteratogenic reproductive effects of nickel include increased resorption of embryos and fetuses, reduced litter size, testicular damage, altered rates of development and growth, and decreased fertility. Nickel compounds can penetrate the mammalian placental barrier and affect the fetus (USEPA 1980; Sunderman et al. 1984; Mas et al. 1985). Intravenous administration of nickel acetate (0.7-10.0 mg Ni/kg BW) to pregnant hamsters on day 8 of gestation resulted in dose-dependent increases in the number of resorbed embryos (USEPA 1980). Rats injected intramuscularly with nickel chloride on day 8 of gestation with 12 or 16 mg Ni/kg BW produced significantly fewer live fetuses than did controls (USPHS 1977). Three generations of rats given nickel in their diets at 250-1,000 mg Ni/kg ration had increased fetal mortality in the first generation and reduced body weights in all generations at 1,000 mg/kg (USPHS 1977). Litter sizes were reduced in pregnant rats fed nickel in various forms at 1,000 mg Ni/kg ration (USEPA 1980). Rodents exposed to nickel during gestation show a decline in the frequency of implantation of fertilized eggs, enhanced resorption of fertilized eggs and fetuses, an increased frequency of stillbirths, and growth abnormalities in live-born young (Hausinger 1993). Exposure of eggs and sperm of rainbow trout to 1.0 mg Ni/L as nickel sulfate for 30 min did not affect fertilization or hatchability; however, most exposed zygotes hatched earlier than the controls (NAS 1975). Nickel salts produced testicular damage in rats and mice given oral, subcutaneous, or intratesticular doses of 10-25 mg Ni/kg BW; nickel-treated male rats were unable to impregnate females (USPHS 1977). Nickel sulfate at 25 mg Ni/kg BW daily for 120 days via the esophagus selectively damaged the testes of rats (inhibition of spermatogenesis) and resulted in a reduced procreative capacity (USPHS 1977); males were permanently infertile after 120 days on this regimen (NAS 1975).

Concentrations in Field Collections

General

Nickel is ubiquitous in the biosphere and is the 24th most abundant element in the earth's crust with a mean concentration of 75 mg/kg (Sevin 1980; Chau and Kulikovsky-Cordeiro 1995). Nickel enters the environment from natural and human sources and is distributed throughout all compartments by means of chemical and physical processes and biological transport by living organisms. Nickel is found in air, soil, water, food, and household objects; ingestion or inhalation of nickel is common, as is dermal exposure (USPHS 1977). In general, nickel concentrations in plants, animals, and abiotic materials are elevated in the vicinity of nickel smelters and refineries, nickel-cadmium battery plants, sewage outfalls, and coal ash disposal basins (NAS 1975; Kasprzak 1987; WHO 1991; USPHS 1993; Chau and Kulikovsky-Cordeiro 1995). A global inventory estimate of nickel shows that living organisms contain about 14 million metric tons of nickel, mostly (98.8%) in terrestrial plants (Table 4). But plants and animals account for only 0.00000031% of the total nickel inventory estimate of 4,500 trillion metric tons, the vast majority of the nickel being present in the lithosphere and other abiotic materials (Table 4).

Table 4. Inventory of nickel in various global environmental compartments (modified from Nriagu 1980b).

Compartment	Mean concentration (mg/kg)	Nickel in compartment (metric tons)
Lithosphere, down to 45 km	75	4,300,000,000,000,000
Sedimentary rocks	48	120,000,000,000,000
Soils, to 100 cm	16	5,300,000,000,000
Oil shale deposits	30	1,400,000,000,000
Dissolved oceanic	0.0006	840,000,000
Nickel ore reserves	>2,000	160,000,000
Coal deposits	15	150,000,000
Terrestrial litter	15	33,000,000
Terrestrial plants	6	14,000,000
Suspended oceanic particulates	95	6,600,000
Crude oil	10	2,300,000
Terrestrial animals	2.5	50,000
Swamps and marshes	7	42,000
Lakes and rivers, total	0.001	34,000
Consumers/reducers (biological)	3.5	11,000
Atmosphere	0.3	1,500
Oceanic plants	2.5	500
Lakes and rivers, plankton	4	230

Abiotic Materials

Nickel concentrations are elevated in air, water, soil, sediment, and other abiotic materials in the vicinity of nickel mining, smelting, and refining activities; in coal flyash; in sewage sludge; and in wastewater outfalls (Table 5). Maximum concentrations of nickel found in abiotic materials were 15,300 ng/L in air under conditions of extreme occupational exposure, 19.2 µg/L in seawater, 30 µg/L in rain, 240 µg/L in sewage liquids, 300 µg/L

in drinking water near a nickel refinery, 500 μg/kg in snow, 183,000 μg/L in fresh water near a nickel refinery, 4,430 μg/L in groundwater, 27,200 μg/L in waste water from nickel refineries, 1,600 mg/kg in coal flyash, 2,000 mg/kg in ultramific rocks, 24,000 mg/kg in soils near metal refineries, 53,000 mg/kg in sewage sludge, more than 100,000 mg/kg in lake sediments near a nickel refinery, and 500,000 mg/kg in some meteorites (Table 5).

Nickel in the atmosphere is mainly in the form of particulate aerosols (WHO 1991) resulting from human activities (Sevin 1980). Air concentrations of nickel are elevated near urbanized and industrialized sites and near industries that process or use nickel (USPHS 1993; Chau and Kulikovsky-Cordeiro 1995; Pirrone et al. 1996; Table 5). The greatest contributor to atmospheric nickel loadings is combustion of fossil fuels in which nickel appears mainly as nickel sulfate, nickel oxide, and complex metal oxides containing nickel (USEPA 1986). Nickel concentrations in the atmosphere of the United States are highest in winter and lowest in summer, demonstrating the significance of oil and coal combustion sources (USPHS 1993; Pirrone et al. 1996). Nickel in the atmosphere is removed through rainfall and dry deposition, locating into soils and sediments; atmospheric removal usually occurs in several days. When nickel is attached to small particles, however, removal can take more than a month (USPHS 1993). Cigarette smoke contributes significantly to human intake of nickel by inhalation; heavy smokers can accumulate as much as 15 μg of nickel daily from this source (USEPA 1980).

Most unpolluted Canadian rivers and lakes sampled between 1981 and 1992 contained 0.1-10 μg Ni/L; however, natural waters near industrial sites may contain 50-2,000 μg Ni/L (Chau and Kulikovsky-Cordeiro 1995). Nickel concentrations in snow from Montreal, Canada, are high compared with ambient air (Table 5); nickel burdens in Montreal snow are positively correlated with those of vanadium, strongly suggesting that combustion of fuel oil is a major source of nickel (USPHS 1993). In drinking water, nickel levels may be elevated due to the corrosion of nickel-containing alloys used in the water distribution system and from nickel-plated faucets (USPHS 1993). Nickel concentrations in uncontaminated surface waters are usually lower with increasing salinity or phosphorus loadings (USPHS 1993). Nickel tends to accumulate in the oceans and leaves the ocean as seaspray aerosols which release nickel-containing particles into the atmosphere (USEPA 1986).

Sediment nickel concentrations are grossly elevated near the nickel-copper smelter at Sudbury, Ontario, and downstream from steel manufacturing plants. Sediments from nickel-contaminated sites have between 20 and 5,000 mg Ni/kg DW; these values are at least 100 times lower at comparable uncontaminated sites (Chau and Kulikovsky-Cordeiro 1995). A decrease in the pH of water caused by acid rain may release some of the nickel in sediments to the water column (NRCC 1981). Transfer of nickel from water column to sediments is greatest when sediment particle size is comparatively small and when sediments contain high concentrations of clays or organics (Bubb and Lester 1996).

In soils, nickel exists in several forms, including inorganic crystalline minerals or precipitates, as free ion or chelated metal complexes in soil solution, and in various formulations with inorganic cationic surfaces (USEPA 1986). Soil nickel is preferentially adsorbed onto iron and manganese oxides (USPHS 1993; Chau and Kulikovsky-Cordeiro 1995); however, near Sudbury, Ontario, soil nickel is mostly associated with inorganic sulfides (Adamo et al. 1996). The average residence time of nickel in soils is estimated at 3,500 years, as judged by nickel concentrations in soils and estimates of the loss of nickel from continents (Nriagu 1980b). Natural levels of soil nickel are augmented by contamination from anthropogenic activities including atmospheric fallout near nickel-emitting industries, automobile traffic, and treatment of agricultural lands with nickel-containing phosphate fertilizers or municipal sewage sludge (USEPA 1980; Munch 1993). Soils with less than 3 mg Ni/kg DW are usually too acidic to support normal plant growth (NAS 1975). Nickel availability to plants grown in sludge-amended soils is correlated with soil-solution nickel (USPHS 1993). Sewage-derived fertilizers from industrial areas may contain 1,000 mg Ni/kg DW or more (NRCC 1981). In sewage sludge, a large percentage of the nickel exists in a form that is easily released from the solid matrix (USPHS 1993). Water solubility of nickel in soils and its bioavailability to plants are affected by soil pH, with decreases in pH below 6.5 generally mobilizing nickel (USPHS 1993; Chau and Kulikovsky-Cordeiro 1995).

Terrestrial Plants and Invertebrates

Nickel is found in all terrestrial plants, usually at concentrations of less than 10 mg/kg DW (NRCC 1981; Kasprzak 1987). The majority of terrestrial plants are nickel-intolerant species and are restricted to soils of relatively low nickel content; some plants without specific nickel tolerance can accumulate anomalous levels of nickel, but at a cost of reduced metabolism (Rencz and Shilts 1980). Plants grown on nickel-rich soils can accumulate high concentrations of nickel (Sigel and Sigel 1988). Crops grown in soils amended with sewage

sludge may contain as much as 1,150 mg Ni/kg DW (USEPA 1986). Vegetation near point sources of nickel, such as nickel refineries, have elevated nickel concentrations that decline with increasing distance from the source (WHO 1991; Table 6). Fruits and vegetables grown near nickel smelters contain 3-10 times more nickel in edible portions than those grown in uncontaminated areas (NRCC 1981). Trees, ferns, and grasses near nickel smelters had elevated concentrations of nickel, as much as 174 mg/kg DW in trees and ferns and 902 mg/kg DW in wavy hairgrass (*Deschampsia flexuosa*; Table 6). Nickel concentrations in lichens and other vegetation were elevated when grown on nickeliferous rocks, serpentine soils, near nickel smelters (Jenkins 1980b), near urban and industrial centers (Richardson et al. 1980), and near roadsides treated with superphosphate fertilizers (NAS 1975).

Table 6. Nickel concentrations (milligrams of nickel per kilogram fresh weight [FW] or dry weight [DW]) in field collections of representative plants and animals.

Norway	(2-7) DW	1

Table 6. Taxonomic group, organism, and other variables	Concentration (mg/kg)[a]	Reference[b]
Nova Scotia	2 DW	1
Scotland	1.4 FW; 4.9 DW	1
Duckweed, *Lemna minor*; from ponds (27 µg Ni/L) in southern Ontario, Canada	5.4-35.1 DW	5
Marine algae and macrophytes		
England, 14 species	2.7-10.3 DW	10
India, 27 species	3.5-39.1 DW	10
Japan, 60 species	0.2-31.0 DW	10
Texas, Harbour Island, 14 species	0.2-2.6 DW	10
Pond lily, *Nuphar* sp.; Ontario, Canada; nickel-contaminated areas		
Leaf	8-62 FW	1
Peduncle	3-9 FW	1
Petiole	5-35 FW	1
Root	5-14 FW	1
Laver, *Porphyra umbilicalis*; whole	0.2-9.7 DW	1
Sargassum, *Sargassum* spp.; Gulf of Mexico; whole	0.9-15.6 DW	10
Smooth cordgrass, *Spartina alterniflora*; leaves	5.3 DW	1
Terrestrial Invertebrates		
Earthworm, *Allolabophophora* sp.; whole; Maryland	12.9-37.5 DW	1
Beach flies, two species; whole; California	Max. 7.0 DW	1
Gypsy moth, *Porthetria dispar*; near ore smelter at Sudbury, Ontario, Canada vs. reference site		
Adult males; whole	8.8 DW vs. 2.9 DW	11
Larvae		
Feces	28 DW (reflects nickel content	11
of leaf diet) vs. <2 DW		
Whole	20.4 DW vs. 0.4-7.2 DW	11
Pupae	1.5 DW vs. 1.6 DW	11
Termites, *Odontotermes transvaalensis*, *Trinervitermes dispar*; whole		
Queen	20 DW	1
Soldier	100 DW	1
Worker	5,000 DW	1
Aquatic Invertebrates		
Protozoans, marine		
Foraminiferan tests	15.4-23.0 DW	10
Radiolarians, whole	3.7 DW	10
Sponge, *Halichondria* sp.; whole; Sweden	22.0 DW	1
Corals; open ocean species vs. shallow coastal zone species	<2.0-23.0 DW vs. Max. 3.0 DW	10
Mollusks		
Duck mussel, *Anodonta anatina*; Thames River, England; soft parts; near sewage outfall	Max. 46.0 DW	12
Ocean quahog, *Arctica islandica*; soft parts		
Long Island, New York; 1974-75; offshore	1.1-7.0 FW	13
New England; offshore; February vs. March	5-29 DW vs. 4-18 DW	10
Waved whelk, *Buccinum undatum*; soft parts; near sludge dump site vs. reference site	8.5 DW vs. 0.6 DW	1

Table 6. Taxonomic group, organism, and other variables	Concentration (mg/kg)[a]	Reference[b]
Scallop, *Chlamys opercularis*		
Digestive gland	4.3 DW	10
Kidneys	78.2 DW	10
Shell	(0.2-7.6) DW	10
Other tissues	0.2-1.6 DW	10
Pacific oyster, *Crassostrea gigas*; soft parts		
South Africa	Max. 2.0 DW	1
United Kingdom	(1-10) DW	1
United States	Max. 0.2 FW	1
World	0.1-1.6 DW	10
Eastern oyster, *Crassostrea virginica*; shell vs. soft parts	<1.0 DW vs. (0.9-5.4) DW; 0.19 (0.08-1.8) FW	1, 10
Common Atlantic slippersnail, *Crepidula fornicata*; United Kingdom; shell vs. soft parts	1.6 DW vs. 127.0 FW; 850.0 DW	1, 10
Red abalone, *Haliotis rufescens*; California		
Digestive gland	(3-11) DW	1, 10
Foot	(0.2-1.6) DW	1, 10
Gills	(69-112) DW	1, 10
Mantle	(19-57) DW	1, 10
Abalone, *Haliotis tuberculata*; soft parts; England	13.6-15.9 DW	14
Marine mollusks; 21 species; soft parts	Max. 3.4 FW	10
Northern quahog, *Mercenaria mercenaria*; soft parts		
United Kingdom	2.2 FW; (6.5-19.2) DW	1
United States	1.2 (0.1-2.4) FW	1
Common mussel, *Mytilus edulis*; soft parts		
France	0.5 FW; 2.4 DW	1
The Netherlands, 1985-90	0.33-0.52 FW	15
Norway	(6-43) DW	1
United Kingdom	0.4 FW; Max. 53.0 FW; 3.7 (5-12) DW	1
United States	(11-14) DW	1
Mud snail, *Nassarius* sp.; soft parts; Los Angeles, California	36 DW	1
Common limpet, *Patella vulgata*; soft parts		
Israel; near sewage discharge vs. control site	12 DW vs. 5-9 DW	1
Norway	(4-11) DW	1
United Kingdom	7.3 (2.5-24.0) DW	1
Pen shell, *Pinna nobilis*; contaminated area		
Byssus gland	200 DW	10
Gonads	74 DW	10
Nervous system	18 DW	10
Soft parts	21 DW	10
Stomach plus intestines and hepatopancreas	170 DW	10
Sea scallop, *Placopecten magellanicus*		
Long Island, New York; 1974-75; soft parts	(<0.5-3.3) FW	13
North Atlantic coast, 42 stations		
Gonads	0.2-2.5 FW	16
Muscle	<0.3-0.7 FW	16
Viscera	0.3-1.6 FW	16
Vicinity ocean disposal sites; soft parts	4.4 DW	17
Clam, *Scrobicularia plana*		

Table 6. Taxonomic group, organism, and other variables	Concentration (mg/kg)[a]	Reference[b]
Contaminated estuary, soft parts	Max. 11.9 DW	18
United Kingdom; digestive gland		
Camel estuary	10.6 DW	10
Gannel estuary	43.1 DW	10
Tamar estuary	(6.6-25.0) DW	10
Arthropods		
Amphipods; whole; Antarctica	2.2 DW	19
Green crab, *Carcinus maenas*; all tissues	6.2-12.3 FW	1
Sand shrimp, *Crangon allmanni*;	15 DW vs. 92 DW	1
Scotland; soft parts; reference site vs. waste dump site		
Seaskaters (oceanic insects), *Halobates* spp.,	6-18 DW	20
Rheumobates sp.; whole; from mangrove swamps		
American lobster, *Homarus americanus*; serum	0.012 (0.008-0.020) FW	3, 21
Marine crustaceans		
Muscle, 10 species	0.2-0.9 FW	10
Whole, various species	6.5-9.8 FW	10
Aesop shrimp, *Pandalus montagui*;	25 DW vs. 70 DW	1
soft parts; Scotland; reference site vs. waste dump site		
Caribbean spiny lobster, *Panulirus argus*; soft parts;		
Puerto Rico		
Anasco Bay	1.3 (1-2) FW; 4.5 (8-9) DW	1
West coast	4.6 (1.4-5.0) FW; 36 (22-60) DW	1
Brown shrimp, *Penaeus aztecus*; Texas		
Exoskeleton	6.2 DW; Max. 17.9 DW	1
Muscle	1.4 DW; Max. 1.9 DW	1
Viscera	5.7 DW; Max. 5.8 DW	1
Zooplankton; New York Bight vs. Long Island Sound	1.7-4.6 DW vs. 0.9-4.5 DW	22
Annelids, marine		
Sandworm, *Nereis diversicolor*; whole;	2.1-5.2 DW	10
British Columbia; various locations		
Polychaete worms, three species;	(3.8-18.7) DW	1
whole; California		
Echinoderms		
Starfish, *Asterias rubens*		
Gonad	2.4 DW	10
Pyloric caeca	4.1 DW	10
Other tissues	0.7-1.5 DW	10
Rock boring sea urchin, *Echinometra lucunter*; Puerto Rico; skeleton vs. whole	51 (42-78) DW vs. 37 DW	1
Sea urchin, *Tripneustes esculentus*; Puerto Rico		
Ovary	1.4 FW	1
Skeleton	35 (18-54) DW	1
Testes	22 FW	1
Tunicate, *Halocynthia roretzi*; whole	0.1 FW	10
Fishes and Elasmobranchs		
Rock bass, *Ambloplites rupestris*; near smelter; Sudbury, Ontario, Canada		
Gills	31.7 FW	1
Kidneys	17.3 FW	1

Table 6. Taxonomic group, organism, and other variables	Concentration (mg/kg)[a]	Reference[b]
Livers	17.0 FW	1
Muscle	12.5 FW	1
Whitetip shark, *Carcharhinus longimanus*		
Liver	0.05 FW; 0.1 DW	1
Skin	1.9 FW; 7.3 DW	1
Vertebrae	1.6 FW; 4.9 DW	1
White sucker, *Catostomus commersoni*; muscle; near smelter vs. reference site	13.2 FW vs. 0.1 FW	1
Blackfin icefish, *Chaenocephalus aceratus*; Antarctica; muscle vs. liver	0.2 DW vs. 0.3 (0.2-0.5) DW	19
Lake whitefish, *Coregonus clupeaformis*; muscle; northern Quebec; 1989-90	<0.01 FW	23
Lumpfish, *Cyclopterus lumpus*; United Kingdom; all tissues	3.2-5.2 FW	1
Northern pike, *Esox lucius*; muscle		
Canada		
Ontario; near smelter	13.3 FW	1
Northern Quebec, 1989-91	<0.05-0.05 FW	23
Illinois vs. New York	0.15 (0.08-0.19) FW vs. (0.2-3.8) FW	1
Muskellunge, *Esox masquinongy*; muscle; New York	0.2-1.3 FW	1
Chain pickerel, *Esox niger*; muscle; New York	0.1-0.25 FW	1
Pickerel, *Esox* sp.; near smelter; Sudbury, Ontario		
Gills	16.0 FW	1
Kidneys	51.6 FW	1
Livers	14.4 FW	1
Muscle	13.8 FW	1
Skipjack tuna, *Euthynnus pelamis*; muscle		
Peru	2.0 FW; 5.0 DW	1
Puerto Rico	0.5 FW; 2.2 DW	1
Fishes, 10 species; muscle; Bay of Bengal, India	0.7-6.1 DW	24
Atlantic cod, *Gadus morhua*; all tissues	1.6-4.6 FW	1
Brown bullhead, *Ameiurus nebulosus*; near smelter;		
Canada		
Gills	11.1 FW	1
Kidneys	11.8 FW	1
Livers	10.7 FW	1
Muscle	9.5 FW	1
Yellowtail flounder, *Pleuronectes ferruginea*; New York Bight; liver vs. muscle	0.2-1.1 FW vs. <0.2-0.4 FW	1
Marine fishes		
Liver; five species; New York Bight; 1971-73	<0.2-1.7 FW	25
Most species; all tissues	Usually <0.3 FW; rarely >3.0 FW in uncontaminated areas; Max. 16.0 DW	10
Muscle		
New Zealand, nine species	0.02-0.07 FW	1
United Kingdom, eight species	2.1-3.5 DW	1
Atlantic croaker, *Micropogonias*	2.7 DW vs. 3.8 DW	1

Table 6. Taxonomic group, organism, and other variables	Concentration (mg/kg)[a]	Reference[b]
undulatus; Texas; muscle vs. skin		
Smallmouth bass, *Micropterus dolomieu*; muscle; New York vs. Illinois	(0.16-1.2) FW vs. 0.13 (0.08-0.19) FW	1
Largemouth bass, *Micropterus salmoides*; muscle; New York vs. Illinois	(0.18-1.9) FW vs. 0.11 (0.05-0.23) FW	1
Dover sole, *Microstomus pacificus*; California; muscle vs. liver	0.2 (0.1-0.3) FW vs. 1.4-2.6 FW	1
Hump rock cod, *Notothenia gibberfrons*; muscle; Antarctica	0.22 DW	19
Rainbow trout, *Oncorhynchus mykiss*		
Kidney, liver	Usually <1.5 FW	5
Muscle	Usually <0.5 FW	5
Kelp bass, *Paralabrax clathratus*; California		
Gonad	1.5-2.2 DW	1
Liver	3.9-7.6 DW	1
Muscle	5.0-6.4 DW	1
Skin	9.0-10.2 DW	1
Winter flounder, *Pleuronectes americanus*		
New York Bight; muscle vs. skin	<0.3-0.5 FW vs. <0.3-1.0 FW	1
Texas; muscle vs. skin	3.3 (0.6-7.4) DW vs. 4.4 (2.9-7.4) DW	1
Lake trout, *Salvelinus namaycush*; whole less head and viscera; New York		
Ages 1-4 years	Max. 0.009 FW	1
Ages 5-8 years	Max. 0.022 FW	1
Ages 9-12 years	Max. 0.022 FW	1
Sharks, 10 species; British and Atlantic waters; 1984-88; inshore species vs. offshore species		
Gills	0.3-1.8 FW vs. 1.7-1.9 FW	26
Gonads	<0.02-8.3 FW vs. 1.7 FW	26
Heart	No data vs. 2.8 FW	26
Jaws	5.7 FW vs. 0.3 FW	26
Kidneys	0.07-1.2 FW vs. 1.6 FW	26
Liver	<0.02-0.8 FW vs. 1.9-3.2 FW	26
Muscle	<0.02-1.8 FW vs. 1.4-2.6 FW	26
Pancreas	0.9 FW vs. No data	26
Skin	<0.02-3.4 FW vs. 1.0-2.0 FW	26
Spleen	<0.02-0.8 FW vs. 1.3 FW	26
Vertebrae	0.5-2.4 FW vs. 0.2-10.8 FW	26
South Carolina; gamefish; 1990-93; whole		
Spotted seatrout, *Cynoscion nebulosus*	Max. 12.6 FW	27
Southern flounder, *Paralichthys lethostigma*	Max. 8.2 FW	27
Red drum, *Sciaenops ocellatus*	Max. 2.9 FW	27
Scup, *Stenotomus chrysops*; Texas		
Muscle	1.0 (0.5-2.0) DW	1
Skin	4.9 (2.8-7.4) DW	1
Viscera	3.5 DW	1
Amphibians		
Maryland; 1991; tadpoles		
Northern cricket frog, *Acris crepitans*; whole	2.4-10.0 DW	28
Gray treefrog, *Hyla versicolor*; whole	2.0-7.1 DW	28

Table 6. Taxonomic group, organism, and other variables	Concentration (mg/kg)[a]	Reference[b]
Green frog, *Rana clamitans*; body vs. gut coil	4.7 DW vs. 16.4 DW	28
Birds		
Wood duck, *Aix sponsa*; ducklings; liver; Ontario, Canada; polluted area	0.2 FW	29
Mallard, *Anas platyrhynchos*		
Canada; nickel-contaminated areas vs. reference site		
Liver	0.1-1.4 FW vs. 0.2 FW	29
Muscle (breast)	0.1-0.8 FW vs. 0.6 FW	29
New Jersey; Raritan Bay; contaminated environment; liver vs. salt gland	0.1-2.5 FW vs. 9.7 FW	30, 31
Primary flight feathers; 1975; various distances from nickel smelter		
20-30 km	2.0-12.5 DW; Max. 36.7 DW	32
50-60 km	0.2-3.8 DW	32
85 km	0.2-1.5 DW	32
95-140 km	0.0-4.3 DW	32
Reference site	0.0-0.4 DW	32
Black duck, *Anas rubripes*		
Canada; ducklings; nickel-contaminated vs. reference site		
Kidney	0.3 FW vs. 0.3 FW	29
Liver	0.6 FW vs. 0.4 FW	29
Canada; primary feathers; contaminated vs. noncontaminated areas	2.5-3.7 DW vs. 0.2-1.5 DW	32
Raritan Bay, New Jersey; liver vs. salt gland	0.2-2.7 FW vs. 15.2 FW	30, 31
Gadwall, *Anas strepera*; Canada; muscle; contaminated area	0.3 FW	29
Antarctica; February-March 1989		
Gentoo penguin, *Pygoscelis papua*; muscle vs. liver	<0.03 DW vs. 0.09 DW	19
Adelie penguin, *Pygoscelis adeliae*; muscle vs. liver	<0.03 DW vs. 0.06 DW	19
Chinstrap penguin, *Pygoscelis antarctica*		
Feces	3.5 (3.2-3.7) DW	19
Liver	0.07 DW	19
Muscle	<0.03 DW	19
Blue-eyed cormorant, *Phalocrocorax atriceps*; muscle	0.29 DW	19
South giant petrel, *Macronectes giganteus*; muscle	0.06 DW	19
Redhead, *Aythya americana*; Texas and Louisiana; liver; winter 1987-88	<4.0 DW	33
Ring-necked duck, *Aythya collaris*; ducklings; contaminated vs. reference location		
Kidney	0.3 FW vs. 0.1 FW	29
Liver	0.5 FW vs. 0.2 FW	29
Greater scaup, *Aythya marila*; contaminated areas		
Ontario; muscle	0.2 FW	29
New Jersey; liver vs. salt gland	0.3-3.6 FW vs. 2.7 FW	30, 31
Canvasback, *Aythya valisineria*; Louisiana; winter 1987-88; liver	Usually <1.0 DW; Max. 2.0 DW	34

Table 6. Taxonomic group, organism, and other variables	Concentration (mg/kg)[a]	Reference[b]
Ruffed grouse, *Bonasa umbellus*		
Canada; nickel-contaminated vs. reference areas		
May		
Feathers, primaries	7.3 DW vs. 2.9 DW	35
Dung	19.4 DW vs. <0.5 DW	35
Kidney	2.8 DW vs. 1.7 DW	35
Liver	1.0 DW vs. 0.9 DW	35
Muscle	1.4 DW vs. <0.5 DW	35
September		
Feathers, primaries	4.8 DW vs. 0.8 DW	35
Dung	47.7 DW vs. <0.5 DW	35

Terrestrial vegetation within 3.5 km of one of the Sudbury, Ontario, smelters had as much as 140 mg Ni/kg DW; concentrations decreased with distance from the smelter, reaching a mean concentration of about 12 mg Ni/kg DW at a distance of 60 km (Chau and Kulikovsky-Cordeiro 1995). Some vegetation near a Sudbury smelter—including lawn grasses, timothy (*Phleum pratense*), and oats (*Avena sativa*)—showed signs of nickel toxicosis; concentrations in these species ranged between 80 and 150 mg Ni/kg DW. Vegetables—beets (*Beta vulgaris*), radishes (*Raphanus* spp.), cabbages (*Brassica oleracea capitata*), and celery (*Apium graveolans*)—grown in soils about 1 km from a nickel refinery had 40-290 mg Ni/kg DW in their top portions. All of these vegetables had reduced yield, stunted growth, and chlorosis and necrosis, which were attributed to the high levels of nickel in local soils (Chau and Kulikovsky-Cordeiro 1995).

Mosses and lichens accumulate nickel readily and at least nine species are used to monitor environmental gradients of nickel (Jenkins 1980a). Maximum concentrations of nickel found in whole lichens and mosses from nickel-contaminated areas range between 420 and 900 mg/kg DW versus 12 mg/kg DW from reference sites (Jenkins 1980a). Nickel concentrations in herbarium mosses worldwide have increased dramatically during this century. In one case, nickel concentrations in *Brachythecium salebrosum* from Montreal, Canada, rose from 6 mg/kg DW in 1905 to 105 mg/kg DW in 1971 (Richardson et al. 1980).

Nickel-tolerant or accumulator species of plants are likely to be found only on nickel-rich soils (Rencz and Shilts 1980). Hyperaccumulator species usually grow on relatively infertile, nickel-rich serpentine soils and contain more than 10,000 mg Ni/kg DW (Jenkins 1980b; NRCC 1981; WHO 1991; Table 6). Leaves from some genera of nickel hyperaccumulator plants, including *Alyssum*, *Homalium*, and *Hybanthus*, growing on soils derived from volcanic rocks, which are rich in nickel, accumulate nickel to concentrations of 120,000 mg/kg DW (Kasprzak 1987; Table 6). Nickel is bound as a citrate complex in hyperaccumulator plants from New Caledonia; however, nickel accumulator plants from other locations do not contain unusually high levels of citrate, and nickel is not present as a citrate complex but as a carboxylic acid complex (Lee et al. 1978).

Terrestrial plants take up nickel from soil primarily via the roots (NRCC 1981; WHO 1991). The nickel uptake rate from soil is dependent on soil type, pH, humidity, organic content, and concentration of extractable

nickel (NAS 1975; WHO 1991). For example, at soil pH less than 6.5 nickel uptake is enhanced due to breakdown of iron and manganese oxides that form stable complexes with nickel (Rencz and Shilts 1980). The exact chemical forms of nickel that are most readily accumulated from soil and water are unknown; however, there is growing evidence that complexes of nickel with organic acids are the most favored (Kasprzak 1987). In addition to their uptake from the soils, plants consumed by humans may receive several milligrams of nickel per kilogram through leaching of nickel-containing alloys in food-processing equipment, milling of flour, and catalytic hydrogenation of fats and oils by use of nickel catalysts (USEPA 1986). Nickel reportedly disrupts nitrogen cycling and this could have serious ecological consequences for forests near nickel smelters (WHO 1991), although adverse effects of nitrogen disruption by nickel need to be verified.

Data are limited on nickel concentrations in terrestrial invertebrates. Earthworms from uncontaminated soils may contain as much as 38 mg Ni/kg DW and workers of certain termite species may normally contain as much as 5,000 mg Ni/kg DW (Table 6). Larvae of the gypsy moth (*Porthetria dispar*) near a nickel smelter had 20.4 mg Ni/kg DW; concentrations in pupae and adults were lower because these stages have higher nickel elimination rates than larvae (Bagatto et al. 1996).

Aquatic Organisms

Nickel concentrations are comparatively elevated in aquatic plants and animals in the vicinity of nickel smelters, nickel-cadmium battery plants, electroplating plants, sewage outfalls, coal ash disposal basins, and heavily populated areas (Kniep et al. 1974; Eisler et al. 1978a; Montgomery et al. 1978; Jenkins 1980a; Eisler 1981; Kasprzak 1987; Chau and Kulikovsky-Cordeiro 1995; Table 6). For example, at Sudbury, Ontario, mean nickel concentrations, in mg/kg DW, were 22 for larvae of aquatic insects, 25 for zooplankton, and 290 for aquatic weeds; maximum concentrations reported were 921 mg/kg DW in gut of crayfish (*Cambarus bartoni*) and 52 mg/kg fresh weight (FW) in various fish tissues (Chau and Kulikovsky-Cordeiro 1995; Table 6). For all aquatic species collected, nickel concentrations were highly variable between and within species; this variability is attributable, in part, to differential tissue uptake and retention of nickel, depth of collection, age of organism, and metal-tolerant strains (Bryan et al. 1977; Bryan and Hummerstone 1978; Jenkins 1980a; Eisler 1981; Chau and Kulikovsky-Cordeiro 1995; Table 6).

The bioaccumulation of nickel under field conditions varies greatly among groups. Bioconcentration factors (BCF, which equals the milligrams of nickel per kilogram fresh weight of the sample divided by the milligrams of nickel per liter in the medium) for aquatic macrophytes range from 6 in pristine areas to 690 near a nickel smelter; for crustaceans these values are 10-39; for mollusks, 2-191; and for fishes, 2-52 (Sigel and Sigel 1988). Bioconcentration factors of 1,700 have been reported for marine plankton, 800 and 40 for soft parts and shell, respectively, of some marine mollusks, and 500 for brown algae, suggesting that some food chain biomagnification may occur (NAS 1975).

Concentrations of nickel in roots of *Spartina* sp. from the vicinity of a discharge from a nickel-cadmium battery plant on the Hudson River, New York, ranged between 30 and 500 mg/kg DW and reflected sediment nickel concentrations in the range of 100-7,000 mg Ni/kg DW (Kniep et al. 1974). The detritus produced from dead algae and macrophytes is the major food source for fungi and bacteria, and in this way nickel can again enter the food chain (NRCC 1981; Chau and Kulikovsky-Cordeiro 1995). Nickel concentrations in tissues of sharks from British and Atlantic water range between 0.02 and 11.5 mg/kg FW; concentrations were highest in fish-eating, mid-water species such as the blue shark (*Prionace glauca*) and tope shark (*Galeorhinus galeus*; Vas 1991). Concentrations of nickel in livers of tautogs *(Tautoga onitis*) from New Jersey significantly decreased with increasing body length in both males and females; however, this trend was not observed in bluefish (*Pomatomus saltatrix*) or tilefish (*Lopholatilus chamaeleonticeps*; Mears and Eisler 1977).

Amphibians

In Maryland, USA, nickel concentrations in tadpoles of gray treefrogs (*Hyla versicolor*) and northern cricket frogs (*Acris crepitans*) increased with increasing soil nickel concentrations, with maximum nickel concentrations recorded of 7.1 mg/kg DW in gray treefrogs and 10.0 mg/kg DW in northern cricket frogs (Sparling and Lowe 1996). In study sites 9-66 km from Sudbury, Ontario, populations of treefrogs (*Hyla crucifer*) and American toads (*Bufo americanus*) declined. Population abundance of adult treefrogs declined with increasing atmospheric deposition of nickel, and abundance of toad tadpoles declined as nickel concentrations in pond

water rose from 3.3 μg Ni/L at more distant sites to 19.5 μg Ni/L at sites near Sudbury (Glooschenko et al. 1992).

Birds

Nickel concentrations in the organs of most avian wildlife species in unpolluted ecosystems range from about 0.1 to 2.0 mg/kg DW and occasionally reach 5.0 mg/kg DW (Eisler 1981; Outridge and Scheuhammer 1993). In nickel-contaminated areas, nickel concentrations were elevated in feathers, eggs, and internal tissues of birds when compared to conspecifics collected at reference sites (Darolova et al. 1989; Outridge and Scheuhammer 1993; Table 6). In contaminated ecosystems, mean nickel concentrations between 31 and 36 mg/kg DW occur in primary feathers of mallards (*Anas platyrhynchos*) collected 20-30 km from a nickel smelter, bone of the common tern (*Sterna hirundo*) from Hamilton Harbor, Ontario, and eggshell of the tree swallow (*Tachycineta bicolor*) from the Hackensack River, New Jersey (Table 6).

Waterfowl feeding in areas subjected to extensive nickel pollution—such as smelters and nickel-cadmium battery plants—are at special risk because waterfowl food plants in those areas contain 500-690 mg Ni/kg DW (Eastin and O'Shea 1981). Dietary items of the ruffed grouse (*Bonasa umbellus*) near Sudbury, Ontario, had 32-95 mg Ni/kg DW, whereas nickel concentrations in grouse body tissues usually contain less than 10% of the dietary level. Nickel concentrations in aspen (*Populus tremula*) from the crop of ruffed grouse near Sudbury ranged from 62 mg/kg DW in May to 136 mg/kg DW in September (Chau and Kulikovsky-Cordeiro 1995), which shows the role of season in dietary nickel composition.

Mammals

Mammalian wildlife from uncontaminated habitats usually contain less than 0.1 to about 5 mg Ni/kg DW in tissues; in nickel-contaminated areas, these same species have 0.5 to about 10 mg Ni/kg DW in tissues (Outridge and Scheuhammer 1993; Chau and Kulikovsky-Cordeiro 1995), with a maximum of 37 mg/kg DW in kidneys of the common shrew (*Sorex araneus*; Table 6). Nickel accumulations in wildlife vary greatly between species. For example, tissues of mice have higher concentrations of nickel than rats and other rodents while beavers and minks have higher nickel concentrations in their liver than birds in similar sites near Sudbury (Chau and Kulikovsky-Cordeiro 1995).

The highest concentrations in wildlife tissues from nickel-contaminated locales are associated with tissues exposed to the external environment, such as fur and skin; nickel concentrations in internal organs are usually similar, regardless of degree of contamination (Outridge and Scheuhammer 1993; Table 6). However, nickel concentrations in bone, reproductive organs, and kidneys in certain herbivorous species of wildlife and livestock are elevated when compared to other internal tissues, especially in the vicinity of nickel smelters and other nickel point sources (Outridge and Scheuhammer 1993; Kalas et al. 1995). Trophic position in the food chain, sex, and reproductive state do not seem to significantly influence the nickel body burdens of mammals (Outridge and Scheuhammer 1993), but age is an important variable and nickel generally increases in various organs with increasing age of terrestrial and marine mammals. Fetuses of a variety of wildlife and domestic species contain concentrations of nickel significantly lower than those in their mothers or in juveniles, suggesting that placental transfer of nickel is restricted. Nickel concentrations in aquatic macrophytes and lower plants in the vicinity of nickel smelters may approach or exceed dietary levels known to cause adverse effects in young animals. Sensitive species of wildlife ingesting this vegetation for extended periods could experience nickel-related toxicity or risk alterations in community structure as nickel-sensitive taxa are eliminated or their abundance is reduced (Outridge and Scheuhammer 1993).

Elevated nickel concentrations in Norwegian wildlife are linked to emissions from Russian nickel smelters (Kalas et al. 1995). In Norway, nickel concentrations were elevated in livers and kidneys of moose (*Alces alces*) and reindeer (*Rangifer tarandus*) because of atmospheric transport of wastes from nickel-processing plants of nearby Russian towns (Sivertsen et al. 1995). In Russia between 1974 and 1992, three species of voles (*Clethrionomys glareolus*, *Clethrionomys rutilus*, *Lemmus lemmus*) were eliminated from the immediate vicinity of a copper-nickel smelter that discharged 2,700 metric tons of nickel annually to the atmosphere, and these species were scarce at a moderately contaminated area 28 km south of the smelter (Kataev et al. 1994). Declines were associated with a decrease of important food plants: lichens for *C. glareolus* and *C. rutilus*, mosses for *L. lemmus*, and seed plants for other species of *Clethrionomys*. Close to the smelter, direct toxic effects of accumulated nickel and other metals also may have reduced population densities (Kataev et al. 1994).

Nickel concentrations are also elevated in rodents, shrews, soil, vegetation, and earthworms in the vicinity of roads with high automobile density (Pankakoski et al 1993). In ruminant mammals, tissue nickel concentrations were higher in winter (WHO 1991), presumably because of increased combustion of fossil fuels.

Nickel is normally present in human tissues, and under conditions of high exposure, these levels may increase significantly (WHO 1991). Nickel enters the human body through the diet, through inhalation, by absorption through the skin, and in medications (NAS 1975). The diet accounts for about 97% of the total intake and drinking water about 2.5% (Kasprzak 1987). Foods rich in nickel include tea (7.6 mg/kg DW), cereals (6.5 mg/kg DW), vegetables (2.6 mg/kg DW), and fish (1.7 mg/kg DW) (IARC 1976; Table 6). The daily dietary intake of nickel by humans in the United States ranges between 0.15 and 0.6 mg, almost all of which is excreted in the feces (NAS 1975; Norseth and Piscator 1979; USEPA 1980; NRCC 1981; Sunderman et al. 1984). Minor amounts are also excreted in sweat, urine, and hair (Kasprzak 1987). Residents of the Sudbury, Ontario, area who consume homegrown garden products ingest an average of 1.85 mg of nickel daily, of which 0.6 mg comes from the drinking water (NRCC 1981). Inhalation intake of nickel for residents of New York City is estimated at 2.4 μg daily; for Chicago, a maximum value of 13.8 μg daily is recorded; and 14.8 μg are inhaled daily by smokers of 40 cigarettes (NAS 1975; WHO 1991). Canadians in urban areas inhale 0.06-0.6 μg Ni daily; near nickel smelters this may increase to 15 μg daily (NRCC 1981). In Connecticut, serum nickel levels in newborns were normal (3 μg/L) and similar to those of their mothers (Norseth and Piscator 1979). Nickel concentrations in human serum, however, are modified by disease and stress. Concentrations are usually elevated after strokes, pregnancy, and extensive burns and are depressed in cases of cirrhosis, hypoalbuminemia, extremes of heat, and uremia (Mushak 1980; USEPA 1980, 1986).

About 727,000 workers were potentially exposed to nickel metal, nickel alloys, or nickel compounds during the period 1980-83 (USPHS 1993). Worker exposure differs from that of the general population in that the major route of exposure for nickel workers is inhalation and for the general population it is dermal contact (Sevin 1980). Nickel workers with lung cancer had elevated concentrations of 1.97 mg/kg DW in their lungs when compared to the general population (0.03-0.15 mg/kg DW; USPHS 1977). Plasma concentrations of nickel quickly reflect current exposure history to nickel (USEPA 1980). Mean nickel concentrations in plasma of humans occupationally exposed to nickel have declined by about 50% since 1976, suggesting decreased exposure due to improved safety (Boysen et al.1980).

Integrated Studies

Beaver ponds downstream from an abandoned copper-nickel ore roast yard near Sudbury, Ontario, were devoid of fish and had reduced macroinvertebrate taxon richness and diversity when compared to upstream ponds. Nickel water concentrations, in μg Ni/L, were 57 in upstream ponds, 82 in downstream ponds, and 1,800 at the station directly on the roast pit (Rutherford and Mellow 1994). Beavers (*Castor canadensis*) near nickel smelters had elevated nickel concentrations in livers and kidneys when compared to conspecifics from a reference site; accumulations were attributed to food chain contamination (Hillis and Parker 1993).

Hutchinson et al. (1975) found nickel contamination in the Sudbury, Ontario, region to be the result of aerial transport and terrestrial drainage from mining and smelting activities. Nickel concentrations in soils were elevated as far as 52 km from the source. Erosion of soils following the death of vegetation was widespread and affected an area of more than 820 km^2. Soils increased in acidity, increasing the solubility of nickel. In aquatic ecosystems, nickel was accumulated from the water column by periphyton, rooted aquatic macrophytes, zooplankton, crayfish, clams, and fishes. However, there was no evidence of food chain biomagnification of nickel in the Sudbury ecosystem (Hutchinson et al. 1975). For example, in the nickel-contaminated Wanapitei River, bioconcentration factors during summer 1974 were highest for whole periphyton (19,667), followed by whole pondweeds (11,429), sediments (5,333), whole crayfish (929), whole zooplankton (643), muscle of carnivorous fishes (329), soft tissues of clams (262), and muscle of omnivorous fishes (226) (Hutchinson et al. 1975). Higher BCF values are recorded for acid- and metal-tolerant flora (Outridge and Scheuhammer 1993).

There is little convincing evidence for the biomagnification of nickel in the food chain. Most authorities agree that nickel concentrations do not increase with ascending trophic levels of food chains and that predatory animals do not have higher concentrations (Jenkins 1980a; WHO 1991; Outridge and Scheuhammer 1993; Chau and Kulikovsky-Cordeiro 1995). The potential for biomagnification exists because algae and macrophytes have comparatively elevated concentrations of nickel; however, animals seem to be able to regulate the nickel

content of their tissues by controlled uptake and increased excretion (Jenkins 1980a; Outridge and Scheuhammer 1993).

Nickel Deficiency Effects

General

Nickel is reportedly an essential micronutrient for maintaining health in certain species of plants, invertebrates, birds, and mammals, including humans (NAS 1975; Spears et al. 1979; Sunderman et al. 1984; Norseth 1986; USEPA 1986; Sigel and Sigel 1988; Hausinger 1993; USPHS 1993; Stangl and Kirchgessner 1996, 1997). However, nickel essentiality for humans has not yet been proven (Norseth and Piscator 1979; USPHS 1993), and the evidence for marine tunicates and land snails is inconclusive (Hausinger 1993). To prevent nickel deficiency in rats and chickens, diets should contain at least 50 μg Ni/kg ration; cows and goats require more than 100 μg Ni/kg ration, perhaps reflecting the increased use of nickel by rumen bacteria (USPHS 1993). In humans, nickel deficiency is not a public health concern because daily oral intake normally exceeds 170 μg of nickel (USPHS 1993).

Nickel is considered essential to animals because it is present in the fetus or newborn, is homeostatically regulated, the metabolic pool of nickel is specifically influenced by hormonal substances or pathologic processes, certain metalloproteins contain nickel, and because nickel deficiency has been induced experimentally in certain species of birds and animals (NAS 1975; USPHS 1977; Kirchgessner and Schnegg 1980). In general, the nickel deficiency syndrome can be cured or prevented by trace amounts of nickel (NAS 1975). However, nickel administration may not be successful in reversing all abnormalities produced by nickel deprivation (USPHS 1977).

Nickel deficiency effects from dietary deprivation of nickel are now documented in at least 17 animal species, including chickens, cows, goats, pigs, rats, and sheep (USPHS 1977, 1993; Norseth and Piscator 1979; USEPA 1985; Norseth 1986; WHO 1991). According to Kirchgessner and Schnegg (1980), nickel deficiency can be induced only by very low nickel concentrations in the diet—not by its bioavailability. Signs of nickel deficiency include delayed gestation periods and fewer offspring; decreased growth and sometimes dwarfism; anemia; skin eruptions; brittle hair; reduced oxygen consumption; decreased levels of serum proteins; enhanced urinary nitrogen excretion; reduced tissue iron and zinc concentrations; reduced hemoglobin and hematocrit values; abnormal liver morphology and lipid metabolism; reduced liver glucose, lipids, glycogen, and triglycerides; and reduced activity of several enzymes, including dehydrogenases, transaminases, and alpha-amylases (USEPA 1980, 1985, 1986; WHO 1991; USPHS 1993; Stangl and Kirchgessner 1996).

Bacteria and Plants

Nickel is essential for the active synthesis of urease in plant cells and of various hydrogenases in bacteria (Thauer et al. 1980; USEPA 1986; WHO 1991; Hausinger 1993). In several species of higher plants, including jack beans (*Canavalia* sp.), soybeans (*Glycine max*), rice (*Oryza sativa*), and tobacco (*Nicotiana tabacum*), nickel is required for effective urea metabolism and urease synthesis (Kasprzak 1987; Sigel and Sigel 1988). Some terrestrial plants, such as *Alyssum* spp., accumulate nickel and require it for growth (Thauer et al. 1980). In bacteria, nickel is required for the growth of *Oscillatoria* sp. and *Alcaligenes* sp., for the synthesis of carbon monoxide dehydrogenase in *Clostridium posterianum*, and as a component of coenzyme F_{430} in *Methanobacterium* spp. (Babich and Stotzky 1982a; Kasprzak 1987). Nickel deficiency in bacteria may adversely affect reproductive processes, such as endospore formation, and cause a decrease in nickel-containing intracellular pigments in strains of *Bacillus cereus* (Thauer et al. 1980); however, both of these observations require verification.

Birds

All studies demonstrating nickel deficiency in birds were conducted on a single species, specifically, chicks of the domestic chicken, *Gallus* sp. The relevance of these results to avian wildlife species is unknown. Chicks grew normally when fed nickel-deficient diets (2-15 μg Ni/kg ration) for 3-4 weeks. But these chicks had liver histopathology, decreased concentrations of yellow lipochrome pigments in liver, low hematocrit, skin dermatitis, leg thickening, altered lengths of leg bones, and decreased plasma cholesterol (Nielsen et al. 1975a; Hausinger 1993). Adverse effects of nickel-deficient diets (<20 μg Ni/kg ration) were reversed by the addition of nickel to the diet (Ling and Leach 1979). Chicks fed diets containing 25-2,500 μg Ni/kg ration for 3-4 weeks grew

normally and all organs appeared normal (Nielsen et al. 1975a). Nickel-deficient chicks (40-80 µg Ni/kg ration), when compared to controls (3-5 mg Ni/kg ration), had swollen hock joints, reduced length-to-width ratios of tibias, scaly dermatitis of the legs, orange-yellow discoloration of the legs, fat-depleted livers, altered liver metabolism, and elevated concentrations of nickel in liver, spleen, and aorta (Sunderman et al. 1972; NAS 1975; USEPA 1980; USEPA 1985). Chicks fed nickel-deficient diets of 44 µg Ni/kg ration for 30 days had markedly lower nickel concentrations in serum and livers than did controls fed diets containing 3.4 mg Ni/kg ration; nickel-deficient chicks had 1.6 µg Ni/L in serum versus 4.2 in controls and 64 µg Ni/kg DW liver versus 82 in controls (Sunderman et al. 1972). Livers of nickel-deficient chicks had an altered gross appearance, reduced oxidative ability, and decreased lipid phosphorus concentrations (Nielsen et al. 1975a). Nickel deficiency in chicks may be associated with thyroid hormone imbalance (Nielsen et al. 1975a), but this needs verification.

Mammals

In humans, there is no evidence of a nickel deficiency syndrome (USEPA 1985) or proof that nickel is essential (Norseth and Piscator 1979; Norseth 1986).

Cows (*Bos* sp.) fed nickel-deficient diets containing less than 100 µg Ni/kg ration had reduced growth and survival (Hausinger 1993). Nickel deficiency in cows was exacerbated when diets were also low in protein, but effects were lessened when diets were supplemented with 5 mg Ni/kg ration (Spears et al. 1979). Lambs from domestic sheep (*Ovis aries*) fed a low nickel diet (30 µg Ni/kg ration) for 97 days had lower growth, higher mortality, and altered blood and tissue chemistry when compared to controls fed a diet containing 5 mg Ni/kg ration (Spears et al. 1979). Lambs given diets containing 65 µg Ni/kg DW ration had disrupted metabolism (USEPA 1980).

Adults and offspring of breeding goats (*Capra hircus*) and swine (*Sus* sp.) fed nickel-deficient diets (<100 µg Ni/kg ration) or control diets (10 mg Ni/kg ration) for 6 years had normal conception and abortion rates. However, nickel-deficient goats and pigs had delayed pregnancies, reduced litter sizes, lower birth rates, lower weight gains during suckling, and significant increases in mortality during the suckling period; mortality was 41% higher than controls in kids and 51% higher than controls in piglets (Anke et al. 1978). Nickel-deficient adult goats had lower nickel concentrations in kidneys, liver, and other tissues than did controls, specifically, 0.2-0.6 mg Ni/kg DW tissue versus 0.6-1.2 mg Ni/kg DW in controls (Anke et al. 1980a). Kids of nickel-deficient ewes (100 µg Ni/kg DW ration for 6 years vs. control diet of 300 µg Ni/kg ration) had inhibited growth starting at age 8 weeks and reduced survival (Anke et al. 1980b). During lactation, hemoglobin concentrations and hematocrits of nickel-deficient goats were significantly lower than control values (Anke et al. 1980b). Nickel-deficient pigs had rough coats, decreased growth, and impaired reproduction (USEPA 1980; Hausinger 1993).

Signs of nickel deficiency in the laboratory white rat (*Rattus* sp.) include retarded growth, anemia, a reduction in hematocrit and hemoglobin values, decreased enzyme activities (malate dehydrogenase, glucose-6-phosphate dehydrogenase, alpha amylase), a reduction in liver total lipids and phospholipids, and altered tissue concentrations of fatty acids, iron, copper, and zinc (Nielsen et al. 1975b; Norseth and Piscator 1979; Nielsen 1980b; Norseth 1986; Hausinger 1993; Stangl and Kirchgessner 1996, 1997). Nickel concentrations in fur, kidneys, and muscle of rats fed nickel-deficient diets (15 µg Ni/kg DW ration) were about 66% lower than those of controls given 20 mg Ni/kg ration (Kirchgessner and Schnegg 1980). Signs of nickel deficiency in rats were usually reversed by supplementing the diet with nickel (Ling and Leach 1979) at more than 50 µg Ni/kg ration (USEPA 1985). Rats fed nickel-deficient diets (<5 µg Ni/kg ration) for three generations produced offspring that were anemic and grew poorly in the first two generations and that had impaired reproduction in all generations (USEPA 1980; Sevin 1980). In another three-generation study, rats fed nickel-deficient diets containing 2-15 µg Ni/kg ration had increased perinatal mortality, unthrifty appearance of young rats, decreased physical activity, decreased liver cholesterol, and liver histopathology compared to controls fed diets containing 3 mg Ni/kg ration (Nielsen et al. 1975b).

Lethal and Sublethal Effects

General

Nickel toxicity reduces photosynthesis, growth, and nitrogenase activity of algae; fermentative activity of a mixed rumen microbiota; growth rate of marine bacteria; metabolism of soil bacteria; and mycelial growth, spore germination, and sporulation of fungi (Babich and Stotzky 1982a). Adverse effects of excess nickel have also been observed with yeasts, higher plants, protozoans, mollusks, crustaceans, insects, annelids, echinoderms,

fishes, amphibians, birds, and mammals (USEPA 1975). As discussed later, sensitive species of aquatic organisms are adversely affected at nominal concentrations of 11-113 μg Ni^{2+}/L.

In birds, mortality occurred in young individuals of sensitive species when rations contained more than 500 mg Ni/kg (Outridge and Scheuhammer 1993). Nickel accumulated in avian tissues at dietary loadings as low as 0.7-12.5 mg Ni/kg ration (Cain and Pafford 1981; Eastin and O'Shea 1981; Stoewsand et al. 1984); however, nickel intoxication in some species tested was not always reflected by elevated tissue nickel concentrations (Outridge and Scheuhammer 1993).

In mammals, the toxicity of nickel is a function of the chemical form of nickel, dose, and route of exposure. Exposure to nickel by inhalation, injection, or cutaneous contact is more significant than oral exposure. Toxic effects of nickel to humans and laboratory mammals are documented for respiratory, cardiovascular, gastrointestinal, hematological, musculoskeletal, hepatic, renal, dermal, ocular, immunological, developmental, neurological, and reproductive systems (NAS 1975; Nielsen 1977; USEPA 1980, 1986; WHO 1991; USPHS 1993).

Terrestrial Plants and Invertebrates

In general, the effects of long-term, low-level exposure to nickel are shown in growth inhibition with no other visible signs (WHO 1991). However, many species of plants growing on soils contaminated with excess nickel show stunted and discolored roots and tops, wilting, chlorosis, necrosis, twisted stalks, thickening of leaf tissues, and failure of leaves to fold to form compact heads (NAS 1975; Frank et al. 1982; WHO 1991; Barman and Bhargava 1997; Donghua and Wusheng 1997). In solution culture, 1 mg of soluble nickel/L is toxic to sensitive plants (NRCC 1981; Outridge and Scheuhammer 1993). Accumulations of 50 mg Ni/kg DW plant and higher are toxic to most plants (NAS 1975; NRCC 1981; WHO 1991). Depending on soil conditions and chemical form, nickel in soil is toxic when concentrations exceed 500 mg Ni/kg DW soil with more than 25 mg Ni/L extractable in a 2.5% acetic acid solution (NRCC 1981). Accumulation and toxic effects occur in vegetables grown on soils treated with sewage sludge and in vegetation close to nickel-emitting sources (WHO 1991). Nickel was shown experimentally to decrease growth of soybeans (*Glycine max*) when administered as particulate nickel through the atmosphere or in the rooting medium (Ormrod et al. 1986). Crop plants are the most sensitive group of terrestrial vegetation tested against nickel. Adverse effects on chlorophyll metabolism and growth occur at soil water concentrations as low as 1 mg Ni/L (Outridge and Scheuhammer 1993). Radishes, beets, cabbages, celery, and lettuce planted in organic soils contaminated by aerial fallout from a nearby nickel smelter and containing between 1,570 and 6,550 mg Ni/kg DW soil had decreasing yields with increasing soil nickel concentrations (Frank et al. 1982). No radishes or cabbages were suitable for marketing. Celery, lettuce, and beets were reduced from a normal yield on soil with 1,300 mg Ni/kg to zero on soils with 4,800 mg/kg. Dried cabbage heads and celery tops had as much as 400 mg Ni/kg (Frank et al. 1982). Decreased yields of alfalfa (*Medicago sativa*) occur when plant nickel content exceeds 44 mg/kg DW (NAS 1975). Decreased yield of oats (*Avena sativa*) was associated with nickel concentrations more than 60 mg/kg DW grain, more than 28 mg/kg DW oat straw, or more than 500 mg Ni/kg DW soil (NAS 1975). Signs of nickel toxicity in oats decrease in severity with increasing magnesium concentrations in culture solution during exposure for 35 days (Proctor and McGowan 1976).

Temperature, pH, chlorophyll, and various metals all modify the toxicity of nickel to fungi (Babich and Stotzky 1982b). A reduction in the toxicity of nickel to the mycelial growth rates of five species of filamentous fungi occurs when pH increases from acidic to alkaline (*Achyla* sp., *Saprolegnia* sp.); at elevated concentrations of magnesium, zinc, or lead (*Achyla* sp.); at chlorophyll or humic acid contents equivalent to 1% (*Saprolegnia* sp., *Cunninghamella blakesleeana*, *Aspergillus clavatus*); and at increased temperatures of 33 C versus 23 C (*Aspergillus flavus*; Babich and Stotzky 1982b). Growth of sensitive species of filamentous fungi is inhibited at 10 mg Ni/L and abnormal mycelia occurs at 50 mg/L (Babich and Stotzky 1982a). Histidine may govern nickel accumulation in the approximately 400 known species of nickel-hyperaccumulating plants. Nickel hyperaccumulator plants, including 48 of 170 species of *Alyssum* spp., contain as much as 3% of the dry leaf biomass as nickel (Kramer et al. 1996). Exposing hyperaccumulator species of *Alyssum* to nickel elicits a large and proportional increase in the levels of free histidine, which is shown to be coordinated with nickel in vitro. Supplying histidine to a nonaccumulating species greatly increases both nickel tolerance and capacity for nickel transport to the shoot, indicating that enhanced production of the amino acid histidine is responsible for the nickel hyperaccumulation phenotype in *Alyssum* (Kramer et al. 1996).

Data on nickel toxicity to terrestrial invertebrates are scarce. A soil concentration of 757 mg/kg DW soil is lethal to 50% of earthworms (*Eisenia foetida*) in 14 days, and higher concentrations of 1,200-12,000 mg/kg DW soil for shorter periods produces reduced growth and survival in the same species (WHO 1991). Earthworms are less sensitive to nickel if the medium is rich in microorganisms and organic matter, thus making the nickel less bioavailable (WHO 1991).

Aquatic Organisms

Signs of nickel poisoning in fishes include surfacing, rapid mouth and opercular movements and, prior to death, convulsions and loss of equilibrium (Khangarot and Ray 1990). Destruction of the gill lamellae by ionic nickel decreases the ventilation rate and may cause blood hypoxia and death (Ellgaard et al. 1995). Other signs of nickel poisoning in fishes include decreased concentrations of glycogen in muscle and liver with simultaneous increases in levels of lactic acid and glucose in blood (Ghazaly 1992), depressed hydrogen peroxide production in tissues and a reduction in superoxide dismutase (Bowser et al. 1994), and contractions of vascular smooth muscle—signs similar to those associated with hypertension in mammals (Evans et al. 1990). Ionic nickel is lethal to sensitive species of aquatic organisms at 11-113 µg/L. Deaths occur among embryos of rainbow trout at 11-90 µg/L, daphnids at 13 µg/L, embryos of channel catfish at more than 38 µg/L, embryos of the narrow-mouthed toad at 50 µg/L, and embryos of largemouth bass at 113 µg/L (Table 7). Species intermediately resistant to nickel died at 150-410 µg Ni/L, including mysid shrimp at 150 µg/L, freshwater snails at 237 µg/L, clam embryos at 310 µg/L, and embryos of salamanders at 410 µg/L (Table 7). Aquatic bacteria and yeasts are comparatively tolerant to nickel. Sensitive species of freshwater eubacteria and actinomycetes show reduced growth at 5 mg Ni/L; for marine eubacteria, growth inhibition begins at 10-20 mg/L (Babich and Stotzky 1982a). Sensitive species of yeasts show growth inhibition at 1.0 mg Ni/L (*Torulopsis glabrata*); resistant species of yeasts (*Rhodotorula* sp., *Cryptococcus terrens*) show a reduction in growth at 5-20 mg Ni/L (Babich and Stotzky 1982a; WHO 1991).

Table 7. Nickel effects on selected aquatic plants and animals.

Table 7. Taxonomic group, organism, dose, and other variables	**Effect**	**Reference[a]**
Algae and macrophytes		
Alga, *Anabaena inequalis*		
125 µg/L	Growth inhibited	1
10.0 mg/L	Photosynthesis inhibited	1
20.0 mg/L	Nitrogenase activity inhibited	1
Blue-green alga, *Anacystis nidulans*		
160 µg/L	Growth of wild strains inhibited 50%	2
1.3 mg/L	Growth of nickel-tolerant strain inhibited 50%	2
10.0 mg/L	Decreased growth in 14 days	3
50.0 mg/L	No growth in 14 days	3
Freshwater algae, four species		
100-700 µg/L	Reduced growth at 50 mg $CaCO_3$/L	4
Green algae, four species		
100 µg/L	Growth inhibition at 20 C	1
Giant kelp, *Macrocystis pyrifera*		
2.0 mg/L	Photosynthesis inhibited 50%	4
Diatom, *Navicula pelliculosa*		
100 µg/L	Growth inhibited 50% in 14 days	1
Alga, *Phaeodactylum tricornutum*		
1.0 mg/L	Reduced growth	4
Alga, *Scenedesmus acutiformis*; from lake containing 2.5 mg Ni/L		
1.9 mg/L	Growth reduced 47%	1

Table 7. Taxonomic group, organism, dose, and other variables	Effect	Reference[a]
3.0 mg/L	Growth reduced 82%	1
Marine diatom, *Thalassiosira rotula*		
30 μg/L	Growth inhibited	5
300 μg/L	Toxic threshold	5
Rotifers		
Rotifer, *Philodena acuticornis*		
2.9-7.4 mg/L	LC50 (96 h) at 25 mg $CaCO_3$/L	4
Mollusks		
Eastern oyster, *Crassostrea virginica*		
100 μg/L, embryos	None dead in 48 h	6
1.18 mg/L embryos	LC50 (48 h)	6
3.0 mg/L, embryos	All dead in 48 h	6
12.0 mg/L, larvae	LC50 (12 days); normal	7
growth in survivors		
Freshwater snail, *Juga plicifera*		
124 μg/L	No adverse effects in 96 h	1
237 μg/L	LC50 (96 h)	1
Freshwater mussel, *Lamellidens marginalis*		
Exposed for 15 days to 22 mg Ni/L; tissue concentrations, in mg/kg fresh weight (FW), experimental vs. controls		
Foot	218 vs. 122	8
Gills	570 vs. 153	8
Hepatopancreas	327 vs. 160	8
Mantle	277 vs. 145	8
Muscle	186 vs. 130	8
110 mg/L	LC50 (96 h)	8
Northern quahog, *Mercenaria mercenaria*		
100 μg/L, embryos	No deaths in 48 h	6
310 μg/L, embryos	LC50 (48 h)	6
600 μg/L, embryos	All dead in 48 h	6
5.7 mg/L, larvae	LC50 (8-10 days); survivors had reduced growth	7
Softshell clam, *Mya arenaria*; adults		
10.0-50.0 mg/L	No deaths in 168 h	9, 11
112.0 mg/L	LC50 (168 h)	9
200.0 mg/L	All dead in 168 h	9
320.0 mg/L	LC50 (96 h)	9
Common mussel, *Mytilus edulis*		
Exposed to 0, 13, 25, 30, 56 or 107 μg Ni/L for 4 weeks	No accumulations in soft parts at 30 μg/L and lower. After 4 weeks, the 56 μg/L group had 32 mg Ni/kg dry weight (DW) soft parts, and the 107 μg/L group had 41 mg Ni/kg DW soft parts vs. 12 mg/kg DW in controls	10
Exposed to 0, 20.0, 40.0, or 80.0 mg/L for 96 h	No deaths in any group. No byssal thread secretion in 40 and 80 mg/L groups. Nickel concentrations, in mg/kg DW soft parts, were 12 in controls, 400-420 in intermediate dose groups, and 820 in the high	10

Table 7. Taxonomic group, organism, dose, and other variables	Effect	Reference[a]
	dose group	
Mud snail, *Nassarius obsoletus*; adults

4.96 mg/L	LC50 (96 h) at 206 mg $CaCO_3$/L	4
Daphnid, *Daphnia pulicaria*		
1.8-2.2 mg/L	LC50 (48 h) at 44-48 mg $CaCO_3$/L	4
2.4-3.8 mg/L	LC50 (48 h) at 194-244 mg $CaCO_3$/L	4
Copepod, *Eudiaptomus padanus*		
3.6 (2.8-4.6) mg/L	LC50 (48 h)	12
Amphipod, *Gammarus* sp.		
13.0 mg/L	LC50 (96 h)	4
Amphipod, *Hyalella azteca*		
890 µg/L	LC50 (96 h) at pH 8.0-8.5	13
2.0 mg/L	LC50 (96 h) at pH 6.0-6.5	13
Mysid shrimp, *Mysidopsis bahia*		
61-141 µg/L	MATC[b]	4
Mysid shrimp, *Mysidopsis bigelowi*		
510-640 µg/L	LC50 (96 h)	4
Mysid shrimp, *Mysidopsis formosa*		

Table 7. Taxonomic group, organism, dose, and other variables	Effect	Reference[a]
150 μg/L	LC50 (96 h)	4
Copepod, *Nitocra spinipes*		
6.0 mg/L	LC50 (96 h)	15
Hermit crab, *Pagurus longicarpus*		
10.0 mg/L	No deaths in 168 h	9
47.0 mg/L	LC50 (96 h)	9
50.0 mg/L	All dead in 168 h	9
Annelids		
Oligochaete, *Lumbriculus variegatus*		
26.0 mg/L	LC50 (96 h) at pH 8.0-8.5	13
100.0 mg/L	LC50 (96 h) at pH 6.0-6.5	13
Sandworm, *Nereis diversicolor*; adults		
10.0 mg/L	No deaths in 168 h	9
25.0 mg/L	LC50 (96-168 h)	9
50.0 mg/L	All dead in 168 h	9
Polychaete annelids, three species		
17.0-49.0 mg/L	LC50 (96 h)	4
Oligochaete, *Tubifex tubifex*		
80-61,400 μg/L; various water hardnesses	LC50 (48 h) range; most sensitive in soft waters; survivors had increased respiration rate	16, 17
Echinoderms		
Sea urchin, *Arbacia punctulata*; embryos		
17.0 mg/L	More than 50% dead in 42 h	4
Starfish, *Asterias forbesi*; adults		
5.0 mg/L	No deaths in 168 h	9
13.0 mg/L	LC50 (168 h)	9
50.0 mg/L	All dead in 168 h	9
150.0 mg/L	LC50 (96 h)	9
Sea urchin, *Lytechinus pictus*; embryos; exposed continuously from fertilization through hatching to 5.8, 58, 580, 5,800, 58,000, or 580,000 μg Ni/L, as nickel chloride		
5.8 μg/L group	Normal growth and development	18
58 and 580 μg/L groups	Normal development through gastrulation, but larvae developed abnormally (no dorsoventral symmetry)	4, 18
58.0 mg/L and higher	Normal cleavage, but gastrulation unsuccessful	18
Sea urchin, *Strongylocentrotus purpuratus*		
Sperm held in 0.6, 5.9, 59, 590, or 5,900 μg Ni/L for 50 min	0.6 and 5.9 μg/L had no effect on sperm motility; 59 μg/L had initial depressing effect followed by increased motility; 590 μg/L had initial depressing effect in motility with recovery; 5,900 μg/L caused significant depression in sperm motility	19
Sea urchins, various species; embryos		
180 μg/L	No adverse effects on development	20
370-1,470 μg/L	Embryonic development inhibited	20
Fishes		

Table 7. Taxonomic group, organism, dose, and other variables	Effect	Reference[a]
Rock bass, *Ambloplites rupestris*		
2.48 mg/L	LC50 (96 h) at 26 mg $CaCO_3$/L	4
Climbing perch, *Anabas testudineus*		
146.0 mg/L for 30 days	No deaths; significant depletion of glycogen and total proteins in liver and gonads	21
American eel, *Anguilla rostrata*		
13.0 mg/L	LC50 (96 h)	4
Zebradanio, *Brachydanio rerio*; exposed from 2 h after fertilization through hatching and larval stages until day 16; 11 different doses as nickel sulfate hexahydrate		
40 µg/L	No effect on hatching time	22
>40 µg/L	Delayed hatching time	22
80 µg/L	No effect on larval survival	22
1,024 µg/L	No effect on embryonic survival	22
Goldfish, *Carassius auratus*		
500 µg/L for 2 weeks	Some accumulation in scales and otoliths, but not statistically significant	23
25 mg/L in 96 h	Swimming activity reduced 31%	24
75 mg/L	LC25 (96 h)	24
100 mg/L	LC88 (96 h)	24
Giant gourami, *Colisa fasciata*; adults		
64 mg/L as nickel sulfate (equivalent to 0.8 x LC50 [96 h] value); gonads examined after 96 h	Testicular degeneration (spermatogonial activity reduced, germ cells in testicular lobules degenerating, congested blood vessels); ovaries histologically different, oocytes resorbed	25
Common carp, *Cyprinus carpio*		
750 µg/L, larvae	LC50 (257 h) at 128 mg $CaCO_3$/L	4
1.0 mg/L for 16 days (in mixture containing 1.0 mg/L each of Cd, Cr, and Pb salts); adults	Maximum nickel concentrations, in mg/kg DW, were 77 in liver, 49 in gill, 39 in brain, and 19 in muscle; other metals tested showed time-dependent increases in tissues	26
1.3-40.0 mg/L	LC50 (96 h)	4, 27
8.0 mg/L for 15 days, adults	No deaths; disrupted protein metabolism in gills and kidneys	8
8.0 mg/L for 15 days (sublethal exposure); nickel concentrations (in mg/kg FW) in tissues of experimentals at end of exposure vs. controls		
Brain	41 vs. 25	29
Gill	103 vs. 31	29
Kidney	80 vs. 50	29
Liver	97 vs. 32	29
Muscle	58 vs. 30	29
10.4-10.6 mg/L	LC50 (96 h) at 55 mg $CaCO_3$/L	4
Carp, *Cyprinus carpio communis*		
Fingerlings; exposed to 2.5, 5, 7.5, or 10 mg Ni/L for 30 days	No deaths; protein content significantly decreased over time	30

Table 7. Taxonomic group, organism, dose, and other variables	Effect	Reference[a]
	in dose-dependent pattern in brain, intestine, and muscle	
Orange chromide, *Etroplus maculatus*		
Exposed to 10, 30, 60, 80, or 100 mg Ni/L for 96 h at 3 salinities (2.5, 5, and 15 ppt)	At 2.5 ppt salinity, whole body nickel concentrations increased from 19 to 232 mg/kg DW in a dose-dependent manner (vs. control of 12.5 mg/kg DW); for 15 ppt salinity, nickel increased from 20 to 113 mg/kg DW; in combination with copper salts, nickel uptake increased at intermediate salinities	31
Fishes; most species; adults		
4-14 mg/L	LC50 (96 h), soft water	1
24-44 mg/L	LC50 (96 h), hard water	1
Banded killifish, *Fundulus diaphanus*		
46.1 mg/L	LC50 (96 h) at 53 mg $CaCO_3$/L	4
Mummichog, *Fundulus heteroclitus*		
50 mg/L	No deaths in 168 h	9
150 mg/L	LC50 (96 h)	9
250 mg/L	All dead in 168 h	9
Channel catfish, *Ictalurus punctatus*; from fertilization through day 4 posthatch		
38 (18-68) µg/L	LC10	28
710 (490-1,010) µg/L	LC50	28
Spot, *Leiostomus xanthurus*		
70 mg/L	LC50 (96 h), adults	1
Pumpkinseed, *Lepomis gibbosus*		
5.2 mg/L	LC50 (96 h) at 20 mg $CaCO_3$/L	4
8.0 mg/L	LC50 (96 h) at 55 mg $CaCO_3$/L	4
Bluegill, *Lepomis macrochirus*		
5.4 mg/L	LC50 (96 h) at 20 mg $CaCO_3$/L	4
39.6 mg/L	LC50 (96 h) at 360 mg $CaCO_3$/L	4
Atlantic silverside, *Menidia menidia*		
8.0 mg/L	LC50 (96 h)	4
Tidewater silverside, *Menidia peninsulae*; larvae		
38.0 mg/L	LC50 (96 h)	1
Largemouth bass, *Micropterus salmoides*		
113 (61-185) µg/L; exposed from fertilization through day 4 after hatching	LC10	28
2.02 mg/L, embryos	LC50 (8 days) at 93-105 mg $CaCO_3$/L	4
2.06 (1.48-2.84) mg/L; exposed from fertilization through day 4 after hatching	LC50	28
White perch, *Morone americana*		
13.6 mg/L	LC50 (96 h) at 55 mg $CaCO_3$/L	4
Striped bass, *Morone saxatilis*		
6.2 mg/L	LC50 (96 h) at 54 mg $CaCO_3$/L	4
Coho salmon, *Oncorhynchus kisutch*		
16.7 mg/L	LC50 (96 h), alevins	32
18.0 mg/L	LC50 (96 h), juveniles	32
Rainbow trout, *Oncorhynchus mykiss*		

Table 7. Taxonomic group, organism, dose, and other variables	Effect	Reference[a]
11 µg/L; embryos exposed from fertilization through day 4 after hatching	LC10	28
23.9 µg/L	Avoidance by adults	33
<35 µg/L; chronic exposure; newly fertilized eggs	No adverse effects	33
50 µg/L; embryos exposed from fertilization through day 4 after hatching	LC50 (28 days) at 93-105 mg $CaCO_3$/L	4, 28
60 µg/L; fertilization through day 4 after hatching	LC50 at 125 mg $CaCO_3$/L	1
90 µg/L; fertilization through day 4 after hatching	LC50 at 174 mg $CaCO_3$/L	1
134 µg/L; chronic exposure of eyed eggs and larvae	No adverse effects	33
230-535 µg/L	MATC[b] at 50 mg $CaCO_3$/L	4
1.0 mg/L, as hexahydrate nickel chloride; exposure for 6 months plus 3-month postexposure observation period in uncontaminated media; juveniles	All fish appeared outwardly normal at all times; after 6 months of exposure, nickel concentrations—in mg/kg FW—were 4.0 in kidneys, 2.9 in liver, and 0.8 in muscle. Nickel concentrations following the 3-month postexposure period (controls) in mg/kg FW, were 2.5 (1.5) in kidneys, 1.8 (1.5) in liver, and 0.6 (0.5) in muscle	34
7.8-10.9 mg/L	LC50 (96 h), juveniles	32, 33
25.1 mg/L	LC50 (96 h), alevins	32
31.7 mg/L	LC50 (96 h); adults; hard water	35
35.7 mg/L, adults	LC50 (48 h) at 42 mg $CaCO_3$/L	4
Fed diet containing 61 mg Ni/kg DW ration (and other metals found in activated sewage sludge) for 10 weeks	Whole body nickel concentration increased from 0.33 mg/kg DW to 0.63 mg/kg DW	36
Isolated R1 liver cells exposed to culture media containing 84 mg Ni/L	50% inhibition of neutral red dye uptake	35
Isolated liver cells in 116 mg Ni/L	Cytotoxic	35
Tilapia, *Oreochromis niloticus*		
1.5 or 3.0 mg/L for 10 days	Significant depletion in liver and muscle glycogen; significant increase in plasma glucose; differences more pronounced at higher dose	37
Fathead minnow, *Pimephales promelas*		
109-433 µg/L	MATC[b] at 44 mg $CaCO_3$/L	4
380-730 µg/L	MATC[b] at 210 mg $CaCO_3$/L	4, 38
730-1,600 µg/L; lifetime exposure	No adverse effects on growth or survival; reproduction inhibited	38
3.1 mg/L	LC50 (96 h) at pH 8.0-8.5	13
>4.0 mg/L	LC50 (96 h) at pH 6.0-6.5	13
4.6-9.8 mg/L	LC50 (96 h) at 20 mg $CaCO_3$/L	4

Table 7. Taxonomic group, organism, dose, and other variables	Effect	Reference[a]
25.0-32.2 mg/L	LC50 (96 h) at 210 mg $CaCO_3$/L	4
42.0-44.5 mg/L	LC50 (96 h) at 360 mg $CaCO_3$/L	4
Guppy, *Poecilia reticulata*		
31.0 mg/L	LC50 (10 days)	39
36.0 mg/L	LC50 (96 h)	39
Brook trout, *Salvelinus fontinalis*		
54.4 mg/L	LC50 (48 h) at 42 mg $CaCO_3$/L	4
Lake trout, *Salvelinus namaycush*		
16.7 mg/L	LC50 (48 h) at 42 mg $CaCO_3$/L	4
Spiny dogfish, *Squalus acanthias*		
6.0-11.0 mg/L	Nickel causes in vitro contraction of vascular smooth muscle of ventral aorta	40
Nile tilapia, *Tilapia nilotica*		
1.0 mg/L for 16 days	Maximum nickel concentrations, in mg/kg DW, were 49 in liver, 42 in brain, 37 in gill, and 14 in muscle	26
Exposed to 19, 32 or 51 mg/L for up to 96 h	Dose- and time-dependent increase in blood glucose and lactic acid concentrations; liver glycogen decreased at all nickel levels and muscle glycogen decreased at the two higher levels; high nickel concentrations were associated with elevated erythrocyte number, hemoglobin, and hematocrit. Nickel accumulated in blood, liver, muscle, and especially in kidney	41
65 mg/L	LC50 (96 h)	41
Arctic grayling, *Thymallus arcticus*		
8.2 (5.6-12.0) mg/L	LC50 (96 h), alevins	32
8.7 (6.7-11.4) mg/L	LC50 (96 h), juveniles	32
Amphibians		
Marbled salamander, *Ambystoma opacum*		
410 µg/L as nickel chloride; fertilization through day 4 after hatching	LC50	28
420 µg/L, embryos	LC50 (8 days) at 93-105 mg $CaCO_3$/L	4
Fowler's toad, *Bufo fowleri*		
11.03 mg/L as nickel chloride; fertilization through day 4 after hatching	LC50	28
Egyptian toad, *Bufo regularis*		
Females given single subcutaneous injection of nickel sulphate at 3-160 mg Ni/kg BW		
73 mg/kg BW	Calculated LD50 (96 h)	42
120 mg/kg BW	Calculated LD50 (24 h)	42
Concentrations of nickel in selected tissues of nickel-exposed survivors (all groups) vs. controls at 96 h		
Whole blood	320 µg/FW (Max. 1,420 µg/L	42
at 24 h) vs. 40 µg/L		
Kidney	1.82 mg/kg FW (Max. 3.6 mg/kg	42

Table 7. Taxonomic group, organism, dose, and other variables	Effect	Reference[a]
FW at 24 h) vs. 0.11 mg/kg FW		
Liver	0.54 mg/kg FW (Max. 2.02 mg/kg	42
FW at 48 h) vs. 0.3 mg/kg FW		
Serum	0.3 mg/L vs. 0.05 mg/L	42
Skin	0.6 mg/kg FW (Max. 1.56 mg/kg	42
FW at 24 h) vs. 0.01 mg/kg FW		
Urine	2.12 mg/L (Max. 70.0 mg/L at	42
24 h) vs. not detectable		
Narrow-mouthed toad, *Gastrophryne carolinensis*		
50 µg/L as nickel chloride; fertilization through day 4 after hatching	LC50	28
50 µg/L; embryos	LC50 (7 days) at 195 mg $CaCO_3$/L	4

[b] MATC = maximum acceptable toxicant concentration. Lower value in each MATC pair is highest concentration tested producing no measurable effect on growth, survival, reproduction, or metabolism during chronic exposure; higher value is lowest concentration tested producing a measurable effect.

The biocidal properties of nickel are modified by many variables. For example, nickel is most lethal to freshwater crustaceans and fishes at pH 8.3 and least lethal at pH 6.3 (Schubauer-Berigan et al. 1993); less toxic to algae when copper is reduced or absent (NRCC 1981) and chelating agents, such as EDTA, are present (Lee and Lustigman 1996); most lethal to echinoderm embryos prior to gastrulation (Timourian and Watchmaker 1972); and more toxic to estuarine amphipods and clams under conditions of decreased salinity in the 0.5-3.5% range and increased temperature in the 5-15 C range (WHO 1991).

Representative nickel-sensitive aquatic species show sublethal effects at 11.7-125 µg Ni/L. These effects include altered immunoregulatory mechanisms in tissues of the rainbow trout at 11.7 µg/L (Bowser et al. 1994), inhibited reproduction of daphnids at 30 µg/L, growth inhibition of freshwater and marine algae at 30-125 µg/L, reduced growth of rainbow trout at 35 µg/L, accumulation from the medium by mussels at 56 µg/L, and abnormal development of sea urchin embryos at 58 µg/L (NRCC 1981; WHO 1991; Outridge and Scheuhammer 1993; Table 7).

Bioconcentration factors (BCF) for nickel vary among organisms under laboratory conditions. For freshwater species, typical BCF values for nickel are about 10 for algae, 61 for fathead minnows, and 100 for cladocerans; for marine mussels and oysters, typical BCF values range between 299 and 414 (USEPA 1980). The alga *Thalassiosira rotula* can accumulate as much as 90 mg Ni/kg DW (Dongmann and Nurnberg 1982). Other species of aquatic plants can extract nickel from water and concentrate it to as much as 10,000 mg/kg DW (NRCC 1981). The alga *Anacystis nidulans* can develop tolerance to nickel and other metals under laboratory conditions (Whitton and Shehata 1982), and this may account for high BCF values in this species. Nickel at 50 µg/L was accumulated from seawater by softshell clams (*Mya arenaria*) more rapidly during summer at water temperatures of 16-22 C than during winter temperatures of 0-10 C; no accumulations occurred at 10 µg Ni/L in winter, but clams accumulated twice as much nickel over controls in summer (Eisler 1977a). Embryos of sea urchins actively accumulate nickel from seawater at all dose levels tested (Timourian and Watchmaker 1972).

Bioconcentration factors for rainbow trout after exposure for 6 months to 1.0 mg Ni/L were 0.8 for muscle, 2.9 for liver, and 4.0 for kidneys (Calamari et al. 1982). Fish can accumulate nickel from food and water. Levels up to 13 mg Ni/kg DW occurred in northern pike (*Esox lucius*) and pickerel (*Esox* sp.) from a contaminated river (NRCC 1981). Common carp (*Cyprinus carpio*) and tilapia (*Tilapia nilotica*) exposed for 16 days to 1.0 mg Ni/L had elevated concentrations in livers of 49-77 mg Ni/kg DW (Canli and Kargin 1995). Goldfish (*Carassius auratus*) that died during immersion in solutions containing more than 35 mg Ni/L showed elevated concentrations in tissues; however, most of the nickel was washed off with water, and it is not clear if accumulation occurred after death (Kariya et al. 1968). Nickel accumulates in fish tissues and causes alterations in gill structure, including hypertrophy of respiratory and mucus cells, separation of the epithelial layer from the pillar cell system, cauterization and sloughing, and necrosis of the epithelium (Nath and Kumar 1989). Although aquatic organisms can accumulate nickel from their surroundings, there is little evidence of significant biomagnification of nickel levels along food chains (NRCC 1981; Sigel and Sigel 1988; WHO 1991).

Birds

In mallards (*Anas platyrhynchos*), nickel accumulates in tissues when diets contain as little as 12.5 mg Ni/kg DW ration (Table 8). Metabolic upset and altered bone densities occur in mallards fed diets containing 800 mg Ni/kg ration for 90 days (Cain and Pafford 1981; Eastin and O'Shea 1981). Inhibited growth and reduced survival occur in mallards at dietary loadings of 1,200 mg Ni/kg ration (Table 8). Dietary nickel concentrations of 0.074 mg Ni/kg ration have no adverse effects on Coturnix quail (*Coturnix risoria*). However, Japanese quail (*Coturnix japonica*) fed diets containing 0.71 mg Ni/kg ration have significantly elevated nickel concentrations in liver compared to controls fed diets containing 0.48 mg Ni/kg (Table 8). Increased concentrations of nickel in the diets of domestic chickens (*Gallus* sp.) were associated with decreased growth and survival and increased nickel concentrations in bone and kidney (Ling and Leach 1979). Dietary loadings of 500 mg Ni/kg ration and higher were associated with reduced growth and high mortality in some strains of chickens, but not others (Table 8). No developmental abnormalities occurred in chicks from survivors challenged by nickel during embryogenesis (USPHS 1977). Chick embryos receiving a single injected dose of 3.6 mg Ni/kg embryo, however, experienced 50% mortality within 18 days (Ridgway and Karnofsky 1952). Chicks are more resistant than embryos to injected nickel. Chicks injected with 10 mg Ni/kg BW survived but had disrupted glucose metabolism; effects were exacerbated by starvation (Nielsen 1977).

Table 8. Nickel effects on birds.

Variables		
Mallard, *Anas platyrhynchos*		
Breeding adults 20-months old fed diets containing 0, 12.5, 50, 200, or 800 mg Ni/kg ration for 90 days. All birds killed at day 90 and examined		
All groups	No effect on egg production, hatchability, or survival of ducklings; adults had normal blood chemistry and no organ histopathology; nickel accumulated in kidneys at all doses and in feathers, blood, and livers of birds fed high doses	1, 9
50 mg/kg group	Feathers contained 5.2 mg Ni/kg dry weight (DW) vs. 0.9 mg/kg DW in controls	1
800 mg/kg group	Abnormal black, tarry feces in test birds. Mean nickel concentrations, in mg/kg fresh weight (controls), were 1.9 (0.09) in kidneys, 0.52 (0.12) in livers, and 0.14 (0.005) in blood. Newly grown feathers had 68 (range 8-558) mg Ni/kg DW vs. 0.9 (0.5-1.6) mg/kg DW in controls	1
Ducklings age 1 day fed diets containing 0, 200, 800, or 1,200 mg Ni/kg fresh weight (FW) ration, as nickel sulfate, for 90 days		
800 mg/kg group and lower	No effect on growth or survival	2
800 mg/kg group	Lower bone density in females at day 60	2
1,200 mg/kg group	Tremors and paresis beginning at day 14; 71% dead by day 60. Survivors weighed less at day 28 than did birds fed other diets. Lower bone density evident at day 30. Livers and kidneys of survivors had <1.0 mg Ni/kg FW; dead birds had as much as 22.7 mg Ni/kg FW liver and 74.4 mg Ni/kg FW kidney	2
Japanese quail, *Coturnix japonica*		
For 2 generations quail ate diets containing wheat (*Triticum aestivum*) grown on sludge-amended soils (980 µg Ni/kg DW wheat) or control wheat (400 µg Ni/kg DW). Total diets contained 710 µg Ni/kg DW (sludge-grown wheat) or 480 µg Ni/kg DW (controls)	Nickel concentrations in livers of birds fed sludge-grown wheat were significantly elevated in males (210 µg Ni/kg DW vs. 130 in controls) and females (120 vs. 80 µg Ni/kg DW); mixed function oxidase activities were elevated in livers of both sexes when compared to controls	3
Coturnix quail, *Coturnix risoria*		
Fed diets containing 74 µg Ni/kg ration for 4 generations	No observed adverse effects	4
Domestic chicken, *Gallus* sp.		
Chicks given single intraperitoneal injection of 10 mg Ni (as nickel chloride)/kg body weight (BW)	Initial increase in plasma glucose after 15 min followed by hypoglycemia 60-120 min after injection. Starved chicks remained hyperglycemic during 120 min postinjection observation period	5
Day-old Plymouth Rock males fed semi-purified diets for 3 weeks		
300 mg Ni/kg diet	Reduced growth rate; elevated kidney nickel concentration of 4.2 mg/kg FW vs. 0.13 in controls	6, 9

[a]1, Eastin and O'Shea 1981; 2, Cain and Pafford 1981; 3, Stoewsand et al. 1984; 4, National Academy of Sciences 1975; 5, Nielsen 1977; 6, Ling and Leach 1979; 7, Weber and Reid 1968; 8, Ridgway and Karnofsky 1952; 9, Outridge and Scheuhammer 1993.

Mammals

Outridge and Scheuhammer (1993), in their excellent review of nickel hazards, draw six major conclusions regarding nickel toxicity to mammals. (1) Lifetime exposure of resistant species of mammals to diets containing 2,500 mg Ni/kg DW or to drinking water containing 10,000 mg Ni/L are not lethal. (2) Lethal nickel doses in mammals are usually derived from studies with laboratory animals injected with nickel and its compounds, not from realistic exposure regimens. (3) Inhaled nickel is at least 100 times more toxic than ingested nickel because it is more readily absorbed from the lungs than from the gastrointestinal tract, and death is more often the result of respiratory failure than of nervous system effects. For example, oral ingestion of 0.05 mg Ni/kg BW and inhalation at 0.005 mg Ni/m^3 are equally effective threshold doses in rats (USPHS 1977). (4) Large differences in sensitivity to nickel exist between closely related taxonomic species, such as rats and mice. (5) Threshold effects on lung function or morphology in several species of laboratory mammals occur at airborne nickel concentrations of 0.1-0.2 mg/m^3, depending on nickel compound and duration of exposure. (6) Juveniles were usually more sensitive to nickel than were adults.

Nickel salts administered by intravenous or subcutaneous injection are comparatively toxic. For all routes of parenteral administration, the LD50 (lethal dose to 50% of the sample) range for injected nickel salts is 6 mg Ni/kg BW for dogs given nickel oxide intravenously to 600 mg Ni/kg BW for mice given nickel disodium EDTA intraperitoneally (Nielsen 1977).

Several trends were evident among sensitive species of mammals tested against nickel through administration routes other than injection (Table 9). (1) Nickel carbonyl is lethal to mice, rats, and cats at 0.067-0.24 mg Ni/L. (2) Inhalation of nickel compounds other than nickel carbonyl causes significant effects in humans, rats, mice, rabbits, and dogs, with respiratory effects being most common. (3) Nickel-contaminated drinking water has adverse effects on rat reproduction and may neurologically affect the eyes of humans, although this needs to be verified. (4) Diets containing nickel carbonate, nickel chloride, or nickel sulfate cause reduced growth, disruptions of food intake and thyroid function, and emphysema and pneumonia in calves, dogs, mice, or rats. (5) Dermal application of nickel sulfate hexahydrate causes skin and testicular damage. (6) Single oral doses of 136-410 mg Ni/kg BW as nickel acetate are lethal to mice.

Table 9. Nickel effects on selected mammals.

Table. 9. Organism, route of exposure, dose, and other variables	**Effect**	**Reference[a]**
Cow, *Bos* sp.		
Diet		
63 mg Ni/kg ration for 8 weeks as nickel carbonate; male calves	Normal growth and food consumption	1, 2
250 mg Ni/kg ration for 42 days; lactating cows	Negligible transfer of nickel from diet to milk	3
250 mg Ni/kg DW ration for 8 weeks as nickel carbonate; male calves; equivalent to daily intake of 1,218 mg nickel	No accumulations in tissues; slight (13%) reduction in food intake and growth rate (11%)	1, 2
1,000 mg Ni/kg dry weight (DW) ration for 8 weeks as nickel carbonate; male calves; equivalent to daily intake of 1,410 mg nickel	Abnormal rumen fluid composition; nickel accumulations in tissues; marked reduction in food intake and growth rate. During a 6-week post exposure recovery period, growth rate was same as in controls	1,2
1,750 mg Ni/kg ration; adult females	No detectable nickel in milk	2
In vitro culture; isolated brain cells exposed for 20 h to graded concentrations of nickel chloride up to 116 mg Ni/L	Time- and dose-dependent effects on kinetics of brain microtubule polymerization; effects reversed on removal of Ni^{2+} from culture media	4
Domestic dog, *Canis familiaris*		
Diet		
0, 100, 1,000, or 2,500 mg Ni/kg ration for 2 years as nickel sulfate hexahydrate	No significant adverse effects at 1,000 mg Ni/kg ration and lower. At 2,500 mg Ni/kg, adverse effects observed on growth and blood chemistry; livers and kidneys enlarged; lung lesions; hyperplasia of bone marrow	5
Equivalent to 25 or 63 mg Ni/kg BW daily, as nickel sulfate, for 2 years	No serious adverse effects at low dose; high dose group had emphysema, pneumonia, low hematocrit, increased liver and kidney weight, and a 40% decrease in body weight gain	6
Inhalation		
2.7 mg Ni/L, as nickel carbonyl ($Ni(CO)_4$), for 75 min	LC80 (1-5 days postexposure)	8
5 to 6 mg Ni powder/m^3, 10 min daily for 6 months; observed for additional 19 months following treatment	No change in weight or general condition. At 3 months after treatment, leucocyte and primary neutrophil counts were low, and nickel was elevated in liver and kidneys. At 12 months, blood flow was reduced in small vessels of lungs. At 19 months, survivors had increased pulse and respiration rates	7
Intravenous injection, single dose		
6 to 7 mg Ni/kg BW, as nickel oxide	Lethal	2
10 to 20 mg Ni/kg BW as colloidal nickel	Death preceded by gastroenteritis,	2,9

Table. 9. Organism, route of exposure, dose, and other variables	Effect	Reference[a]
	tremors, and paralysis	
10 to 20 mg Ni/kg BW as nickel chloride Oral	Some deaths	2, 9
12 mg/kg BW daily for 200 days	Tolerated without ill effects	10
1,000-3,000 mg Ni/kg BW as powdered nickel	Tolerated	9
Subcutaneous injection; single dose of 500 mg Ni/kg BW as nickel sulfate hexahydrate	Some deaths	2
Domestic goat, *Capra* hircus; pulmonary macrophages cultured in vitro for 20 h with media containing 14.5-58.0 mg Ni/kg as nickel chloride	Concentration-dependent decrease in viability of alveolar macrophages; highest dose had survival of <50%. Death associated with release of superoxide anions	11
Guinea pig, *Cavia* sp.		
Drinking water; 2.5 mg Ni/L for 4 months were between 3.4 and 4.6 mg Ni/kg DW hair	No accumulations in hair; all values	12
Inhalation; 15 mg Ni/m^3 as elemental nickel; lifetime exposure	Excess blood, swelling, hemorrhage, and increased frequency of lesions in the pharyngeal area	7
Intravenous injection; 62 mg Ni/kg BW as nickel sulfate; single injection	LD50	2
Subcutaneous injection; males given 0.0001, 0.001 or 1.0 mg Ni/kg BW daily as nickel chloride for 15 days were mated with fertile females	No effect on female gestation period, number of litters or offspring, weight of offspring, or offspring development	7
Hamster, *Cricetus* sp.		
Gavage; 5 mg of nickel oxide	After 24 h, no increase in nickel content of lungs, liver, kidney or carcass	7
Inhalation		
Exposed to nickel oxide aerosols at concentrations of 2-160 µg/L (2 to 160 mg/m^3) and particle size of 1 to 2.5 µm	45 days after exposure about 50% of the original dose remained in lungs with no significant accumulations in other tissues	10
15 mg Ni/m^3 as elemental nickel; lifetime exposure	No significant effect on survival or health	7
39 mg Ni/m^3 as nickel oxide for 3 weeks	Inflammation and congestion of lungs; emphysema	7
48.4 mg Ni/m^3 as nickel oxide for 61 days	No deaths	6
Domestic cat, *Felis domesticus*		
Inhalation; nickel carbonyl		
0.19 mg/L for 30 min	LC50 (0.2 h-6 days after exposure)	8
3.0 mg/L for 75 min	LC50 (1-5 days after exposure)	8
Oral; 12-25 mg/Ni kg BW daily for as long as 200 days as elemental and inorganic nickel salts	Tolerated, with no apparent ill effects	2, 9, 10
Human, *Homo sapiens*		
Dermal; <59 µg Ni/L; nickel-sensitive persons	No contact allergic reaction	14
Dialysis; 23 patients; nickel leached into dialysate from a nickel-plated stainless	At plasma nickel concentrations of about 3 mg/L, patients had adverse	8

Table. 9. Organism, route of exposure, dose, and other variables	Effect	Reference[a]
steel water heater tank	effects including headaches, nausea, vomiting, and weakness; recovery occurred 3 to 13 h after cessation of dialysis	
Drinking water		
Equivalent to 0.012 or 0.05 mg Ni/L as nickel sulfate	Neurological effect on eyes at high dose; no adverse effects at low dose	6
250 mg Ni/L in contaminated drinking water	Stomach ache, increased red blood cell number, increased protein in urine	6
32 workers in an electroplating plant drank water accidentally contaminated with nickel sulfate and nickel chloride at 1,630 mg Ni/L;estimated intake of 0.5-2.5 g, equivalent to 8.3-41.6 mg/kg BW	Symptoms included nausea, vomiting, abdominal discomfort, diarrhea, giddiness, lassitude, headache, cough, and shortness of breath, and persisted for at least 2 h and sometimes 2 days. Serum nickel concentrations on day 1 after exposure were 286 (13-1,340) µg/L vs. 50 µg/L in nonaffected workers; for urine these concentrations were 5.8 (0.2-37.0) mg/L vs. 4.0 µg/L	8
Inhalation		
>0.04 mg Ni/m^3 air, usually as nickel oxide or metallic nickel	Chronic bronchitis, emphysema, reduced lung capacity, and increased incidence of deaths from respiratory disease among workers occupationally exposed	6
30 mg Ni/L air as nickel carbonyl for 30 min	Lethal	13
Chronic exposure		
Nickel aerosols, occupational exposure	Lung cancer, nasal sinusitis, chronic rhinitis	10
Nickel particulates	Chronic respiratory infections	10
Oral		
Low nickel diet fed to patients with chronic nickel dermatitis	Significant improvement in 6 weeks; adverse effects when placed on normal diet	10
Accidental ingestion of nickel sulfate crystals (15-20 grams) by 2.5 year-old female child	Death in 4 h of heart failure; blood had 7.5 mg Ni/kg, urine 50 mg/L, and liver 25 mg Ni/kg FW	6,8
Monkeys, various species; different forms of nickel in diet; as much as 1,000 mg Ni/kg ration for 24 weeks	No adverse effects on growth, behavior, or blood chemistry	10,13
Domestic mouse, *Mus* spp.		
Diet		
Young mice fed diets containing 0, 1,100 or 1,600 mg Ni/kg ration as the acetate salt for 4 weeks	Food consumption and growth reduced in the male 1,600 mg/kg group and the female 1,100 and 1,600 mg/kg groups. All nickel groups had significant decreases in liver cytochrome oxidase and isocitric dehydrogenase activities; in heart and kidney homegenates, malic dehydrogenase activity decreased in the high nickel groups	15, 16
Equivalent to >1.4 mg Ni/kg BW daily for 2 years as nickel chloride or nickel sulfate	Decreased liver weight	6

Table. 9. Organism, route of exposure, dose, and other variables	Effect	Reference[a]
Equivalent to 108 mg Ni/kg BW daily for 180 days as nickel sulfate Drinking water	Renal tubular damage at the corticomedullary junction	6
Equivalent to >23 mg Ni/kg BW for 6-30 h as nickel chloride, nickel sulfate, or nickel nitrate	Abnormal sperm in mature males	6
150 mg/L as nickel sulfate for 6 months	No deaths	6
160 mg/L as nickel chloride in drinking water of pregnant females from gestation day 2 to day 7	Increased incidence of spontaneous abortions	6
Inhalation		
Nickel carbonyl		
0.01 mg/L for 120 min	All dead	8
0.067 mg/L for 30 min	LC50 (0.2 h-6 days after exposure)	8, 9
Nickel oxide		
>3.9 mg/m^3 for as long as 13 weeks	Adverse respiratory effects including chronic inflammation, fibrosis, macrophage hyperplasia, interstitial infiltrates, and increased lung weight	6
23.6 mg/m^3 for 16 days	No deaths	6
Nickel subsulfide		
>0.11 mg/m^3 for 16-91 days	Adverse respiratory effects	6
7.3 mg/m^3 for 16 days	All dead	6
Nickel sulfate		
>0.1 mg/m^3 for 16-91 days	Adverse respiratory effects	6
1.6 mg/m^3 for 16 days	All dead	6
Single intramuscular injection of 18.3 mg Ni/kg BW as nickel chloride	Involution of thymus and suppression of cellular and humoral activity and transient immunosuppressive effects within 2 days of injection with responses returning to normal within a few days	17
Single intraperitoneal injection		
Nickel acetate		
11 mg/kg BW	Adverse effects	21
32 mg/kg BW	LD50 (48 h)	7
39-50 mg/kg BW; adult males; age 9-15 weeks	LD50 (5 days postinjection)	20
48-54 mg/kg BW; adult females; age 9-15 weeks	LD50 (5 days postinjection)	20
89-97 mg/kg BW; juveniles; age 3 weeks	LD50 (5 days postinjection)	20
Nickel chloride		
Pregnant females given 1.2, 2.0, 3.0, 3.5, 4.6, 5.7, or 6.9 mg Ni/kg BW between days 7 and 11 of gestation	Dose-related increase in fetal deaths and malformations	8
3.1 mg Ni/kg BW	Normal spleen lymphocyte function	18
Pregnant mice given 4.6 mg Ni/kg BW on day 16 of gestation and killed 2 to 48 h after injection	Maximum nickel concentrations in tissues (in mg/kg FW) were reached in blood (19.8) and placentas (3.9) 2 h following injection; those in liver (4.9), spleen (1.3), and kidneys (56.2) were	19

Table. 9. Organism, route of exposure, dose, and other variables	Effect	Reference[a]
	reached 4 h after injection; and maximum concentration in fetal tissues (1.1) was reached after 8 h. Authors estimate that all nickel is excreted in 42 to 84 h	
9.3-12.3 mg Ni/kg BW	Immunosuppression in spleen lymphocyte function	18
26 mg Ni/kg BW	LD50 (48 h)	7
Nickel chloride hexahydrate; 48 mg Ni/kg BW	LD50 (48 h)	7
Nickelocene; 27 mg Ni/kg BW	Adverse sublethal effects	21
Nickel oxide; >744 mg/kg BW	LD50 (72 h)	7
Nickel perchlorate heptahydrate; 100 mg Ni/kg BW	LD50 (12 h)	7
Nickel sulfate; 21-38 mg Ni/kg BW	LD50 (10-30 days)	7
Oral, single dose		
Nickel acetate; 136-410 mg Ni/kg BW	LD50 (72-120 h)	7, 21
Nickelocene; 186 mg/kg BW	LD50	21
Rabbit, *Oryctolagus* sp.		
Inhalation		
Metallic nickel dust		
>0.2 mg/m^3 for about 8 months	Alterations in alveolar macrophages; impaired cellular function	6
1.0 mg/m^3 for 3 or 6 months, 5 days weekly, 6 h daily; lungs examined	At both 3 and 6 months, there was a twofold to threefold increase in volume density of alveolar Type II cells; after 6 months, lungs had foci of pneumonia, suggesting a higher susceptibility to pulmonary infections due to a decrease in function of alveolar macrophages	22
Nickel carbonyl; 1.4 mg/L for 50 min	Alveolar cell degeneration within 5 days; LC80 (120 h)	8, 10
Nickel chloride; >0.2 mg/m^3 for about 8 months	Alterations in alveolar macrophages	6
Single intravenous injection; nickel chloride		
10 mg/kg BW	Transient hyperglycemia 1-4 h after injection	7
15 mg/kg BW	Pronounced hyperglycemia 1-4 h after injection, returning to normal after 24 h	7
15-20 mg/kg BW	Pancreas histopathology	7
Single subcutaneous injection; various nickel salts; 1,300 mg Ni/kg BW	Lethal	9
Laboratory white rat, *Rattus* sp.		
Dermal; nickel sulfate hexahydrate; dose equivalent to 40, 60, or 100 mg Ni/kg BW daily for 30 days (rats licked skin so exposure route may be oral in part)	No adverse effects in 40 mg/kg BW group. High dose groups had skin damage (atrophy, acanthosis, hyperkeratinization) and testicular damage abnormal seminiferous tubules, tubular lumens filled with degenerated sperm)	6,8,10
Diet		
Weanlings fed rations containing 0, 100, 500, or 1,000 mg Ni/kg, as nickel	At high doses (500, and 1,000 mg/kg), rats had depressed growth, low	38

Table. 9. Organism, route of exposure, dose, and other variables	Effect	Reference[a]
acetate, for 6 weeks	hematocrit and hemoglobin, and low tissue cytochrome oxidase and alkaline phosphatase activities; the 1,000 mg/kg group (vs. controls) had elevated nickel concentrations—in mg Ni/kg DW—of 2.1 (0.9) in heart, 40.7 (5.0) in kidney, 4.0 (0.7) in liver, and 7.2 (1.6) in testes	
0, 100, 1,000, or 2,500 mg Ni/kg ration, as nickel sulfate hexahydrate, for 2 years	No histopathology in any group; at 1,000 and 2,500 mg Ni/kg ration, rats had depressed growth, lower liver weights, and increased heart weights	5
0, 250, 500, or 1,000 mg Ni/kg ration, as nickel sulfate hexahydrate, for 3 generations; equivalent to 0.7, 12.5, 25, or 50 mg Ni/kg BW daily; reproductive study	Higher incidence of stillborns and fetal mortalities noted only in the first generation at all nickel dietary levels; weanling body weight was lower at 1,000 mg Ni/kg ration in all generations	5,6,21
0.08 mg Ni/kg ration for 55 days	No adverse effects	2
250 mg Ni/kg ration for 16 months	Normal growth	16
1,000 mg Ni/kg ration (as nickel carbonate or nickel catalysts) for 8 weeks	Normal growth	10
1,000 mg Ni/kg ration for 13 days; juveniles	Altered blood chemistry, diminished food intake, and reduced growth within a few days	39
Dietary equivalent of 1, 25, or 100 mg/kg BW daily for 4 months; nickel chloride	Thyroid function affected; decreased iodine uptake at 1 mg/kg BW, increased at 25 mg/kg BW, and decreased at 100 mg/kg BW	7
Dietary equivalent of >1.4 mg Ni/kg BW daily for 2 years; nickel chloride or nickel sulfate	Decreased liver weight	6
Drinking water		
5 mg/L; lifetime exposure	No effect on growth or survival	35, 36
5 mg/L for 3 generations; diets contained 0.31 mg Ni/kg FW ration	Significant increase in mortality of young rats in all generations; significant increase in runts in first and third generations; litter size decreased with each generation; total number of rats reduced; few males were born in the third generation	35
225 mg/L for 4 months as nickel chloride	Depressed growth rate; lower serum triglyceride and cholesterol concentrations	13,40
Inhalation		
Nickel carbonyl ($Ni(CO)_4$)		
0.1 mg/L for 20 min	Some deaths after exposure	8
0.24 mg/L for 30 min	LC50 (0.2 h-6 days)	2, 8, 9
0.24-1.0 mg/L for 30 min	Lung histopathology within 10 days	10
0.9 mg/L for 30 min	LC80 (2 h-several months)	8
100 mg/L for 15 min	About 26% of the inhaled nickel was excreted in urine within 4 days; absorption estimated at 50%	10
160 mg/m^3 on days 7-8 of gestation or 300 mg/m^3 on day 7	Increased fetal mortality; reduced body weight in live pups; 16% incidence of fetal malformations	8

Table. 9. Organism, route of exposure, dose, and other variables	Effect	Reference[a]
	(anophthalmia, microphthalmia, cystic lungs, hydronephrosis)	
Nickel chloride ($NiCl_2$); 0.05-5.0 mg/m^3	Significant decrease in iodine uptake	10
for 2 to 4 weeks	by thyroid	
Nickel dust; 15 mg/m^3; lifetime exposure	Increased frequency of adenoidal lesions and chronic sinus inflammation and ulceration	7
Nickel oxide (NiO)		
0.06 mg/m^3; lifetime exposure	Survival time decreased from 125 weeks in controls to 88 weeks; body weight loss after 13 months; alveolar proteinosis and marked lung enlargement	6
0.2 mg/m^3 for 1 year	Pneumonia and bronchial epithelial metaplasia	6
0.5 mg/m^3 for 1 month	Bronchial gland hyperplasia 20 months after exposure	6
1.6 mg/m^3 on gestation days 1-21	Decrease in fetal body weight	6
>3.9 mg/m^3 for as long as 13 weeks	Adverse respiratory effects	6
11.7 mg/m^3, 8 h daily, 5 days weekly, for 4 weeks	Significant increase in tumor necrosis factor for alveolar macrophages	24
23.6 mg/^{3} for 16 days	No deaths	6
Nickel subsulfide (Ni_3S_2)		
Equivalent to 0, 0.4, or 1.8 mg Ni/m^3; 6 h daily for as long as 22 days	The high dose group had reduced survival, nose and lung histopathology, and disrupted enzyme activity levels; survivors were lethargic and grew poorly. At day 22, nickel concentrations in lungs, in mg/kg FW, were<1.8 in controls, 12 in the low dose group and 34.0 in the high dose group	26
Equivalent to 0.11, 0.44, or 1.8 mg Ni m/^{3} for as long as 13 weeks; exposures were 6 h daily and 5 days weekly	Dose-dependent increase in pulmonary lesions; atrophy of the nasal olfactory epithelium at 0.44 mg/m^3 and higher	26
Equivalent to 0.73 mg/m^3 for 78 weeks plus 30 weeks of postexposure observation; exposure for 6 h daily and 5 days weekly	Pulmonary tumor growth (14% incidence in lung tumors vs. 1% in controls) and increased mortality (95% dead vs. 69% in controls)	6,25
7.3 mg/m^3 for 16 days	LC20	6
Nickel sulfate ($NiSO_4$)		
50 µg/rat	Half-time persistence in lung of 32 h; lung inflammatory responses disrupted lung enzyme activity	29
>0.1 mg/m^3 for as long as 13 weeks	Adverse respiratory effects	6
0.635 mg/m^3 for 16 days, 6 h daily	Induced lesions of olfactory epithelium but no measurable changes in olfactory	31

Table. 9. Organism, route of exposure, dose, and other variables	Effect	Reference[a]
	function	
1.6 mg/m^3 for 16 days	No deaths	6
Single intramuscular injection, unless noted otherwise		
Metallic nickel; 110 mg/kg BW	Lowest toxic dose	2
Nickel acetate		
Males and females given 2.32 mg Ni/kg BW daily for 4 days	Males had inhibited testosterone levels and reduced growth, while females had increased uterine weights	7
420 mg/kg BW	Lowest toxic dose	2
Nickel chloride		
Females given 1.5-2.0 mg/kg BW daily on days 6-10 of gestation	Significant intrauterine mortality, but body weight of live pups was normal	8
Females given 2.0 mg/kg BW twice daily	No congenital abnormalities on days 6-10 of gestation	34
12 mg/kg BW to pregnant and nonpregnant females; tissues analyzed 24 h following injection	Relative tissue concentrations were kidney >serum > adrenal = lung = ovary > spleen = heart = liver > muscle. Nickel concentration in pituitary gland was significantly higher in pregnant rats	34
16 mg Ni/kg BW on day 8 of gestation	Reduction in number of live pups and diminished body weight of fetus on day 20 of gestation and of weanlings 4 to 8 weeks after birth; no developmental abnormalities	34
23-98 mg/kg BW	LD50 (7 days)	7,21,23,80
Nickel oxide		
7 mg Ni/kg BW	Significantly increased levels of serum alkaline phosphatase, amylase, aspartate transaminase, and lipoperoxide. Daily injections of copper-zinc superoxide dismutase prevented these changes	28
180 mg/kg BW	Toxic	2
Nickel subsulfide		
80 mg Ni/kg BW on day 6 of gestation	Reduction in mean number of live pups	34
90 mg/kg BW	Lowest toxic dose	2
Nickel sulfate; 12-16 mg/kg BW on day 8 of gestation	Reduction in mean number of live pups; reduced body weight in fetuses on day 20 of gestation and in pups 4-8 weeks after birth	8
Nickel sulfide; 7 mg/kg BW	Disrupted serum enzyme activity	28
Single intraperitoneal injection, unless indicated otherwise		
Nickel acetate		
8 mg/kg BW	Toxic	21
24 (19-28) mg/kg BW	LD50 (48 h)	7, 8
Nickel carbonyl; 13 mg/kg BW	LD50	8
Nickel chloride		
4 mg/kg BW	Tissue concentrations at 24 h	33

Table. 9. Organism, route of exposure, dose, and other variables	Effect	Reference[a]
	(and at 15 min) after injection, in mg/kg FW, were 2.7 (16.1) in kidney, 0.3 (4.7) in liver, 1.2 (5.9) in blood, and 0.9 (1.4) in placenta	
6.0 (5.5-6.5) mg/kg BW	LD50 (7 days) for females pregnant 19 days	33
6.3 (5.6-7.1) mg/kg BW	LD50 (7 days) for females pregnant 12 days	33
8.0 mg/kg BW	Rapid transient increase in serum glucose and decrease in serum insulin	40
9.3 (8.5-10.2) mg/kg BW	LD50 (7 days) for virgin females	33
11-19 mg/kg BW	LD50 (7 days)	2, 7, 8
Nickelocene; 16-59 mg/kg BW	LD50, usually within 14 days	8, 21
Nickel oxide; >690 mg/kg BW	LD50 (3 days)	7
Nickel sulfate; 3 or 6 mg/kg BW daily for 7 or 14 days; killed 48 h after last injection	Highest nickel concentrations were in myocardium (5.7 mg/kg FW vs. 2.2 in controls) and spleen (2.1 vs. 0.6), followed by kidney, bone, and other tissues	37
Single intrarenal injection of nickel subsulfide equivalent to 39 mg/kg BW	Pronounced erythrocytosis; increased hematocrit and reticulocyte count	30
Intratracheal injection		
Nickel chloride; 1.0 mg/kg BW; examined 6 and 72 h after injection	At 6 h, tissue nickel concentrations were elevated in kidneys, lungs, adrenals, liver, pancreas, spleen, heart, and testes, in that order; by 72 h, 90% of the nickel was excreted, mostly (75%) in the urine	7
Nickel oxide; >110 mg/kg BW	LD50 (72 h)	7
Single intravenous injection of nickel carbonyl		
11 mg/kg BW; day 7 of gestation	High incidence of fetal deaths and malformations; reduced body weight in live pups	8
22 mg/kg BW	LD50, usually within 14 days	8
65 mg/kg BW	Massive lung histopathology within 6 days	10
Single oral exposure, unless indicated otherwise		
Nickel acetate		
116-120 mg/kg BW	Toxic	21
304-410 mg/kg BW	LD50 (7 days)	7, 8
Nickel chloride		
0.35 mg/kg BW daily for 28 days	Hyperglycemia, decreased body weight, reduced food and water intake	6
8.6 mg/kg BW daily for 91 days	LD25; decreased body weight in survivors	6
116 mg/kg BW	Toxic	6, 21
285 mg/kg BW	LD50, usually within 14 days	7
Nickel fluoborate ($Ni(BF_4)_2$); 500 mg/kg BW	Lethal	2
Nickel hexahydrate; 8.5 mg/kg BW daily for 91 days	Death preceded by lethargy, ataxia, irregular breathing, hypothermia, salivation, squinting, and loose stools	6

Table. 9. Organism, route of exposure, dose, and other variables	Effect	Reference[a]
Nickel nitrate ($Ni(NO_3)_2$); 1,620 mg/kg BW	LD50, usually within 14 days	2
Nickelocene		
154 mg/kg BW	Toxic	21
471-525 mg/kg BW	LD50, usually within 14 days	8
Nickel sulfate		
25 mg/kg BW daily for 120 days	Infertility	8
66 mg/kg BW	LD50, usually within 14 days	6
Single subcutaneous injection		
Nickel carbonyl; 21 mg/kg BW	LD50 within several days	8
Nickel chloride		
10 or 20 mg/kg BW; young males; observed for 7 days	Increased prolactin levels that persisted for 4 days;increased insulin levels on days 1 and 2	8
11.9 mg/kg BW	5% dead	27
59.5 mg/kg BW given 16 h prior to sacrifice	Significant increase in hepatic glutathione S-transferase activity	32

Nickel carbonyl ($Ni(CO)_4$) is the only nickel compound known to cause severe acute effects, such as pulmonary damage and death; acute toxic effects of other nickel compounds to mammals are a minor risk (Norseth and Piscator 1979; Sevin 1980; WHO 1991). In fatal cases, death occurs 3-13 days after exposure; recovery from nickel carbonyl poisoning usually occurs within 70 days after exposure, but sometimes may take up to 6 months (Sunderman 1970; Sevin 1980; WHO 1991). Nickel carbonyl is a volatile, colorless liquid formed when finely divided nickel or its compounds come into contact with carbon monoxide. It is unstable under atmospheric conditions, and if inhaled, nickel is deposited in a highly active form on the respiratory mucosa on contact. Nickel carbonyl is widely used commercially as a catalyst but is one of the most toxic gases encountered in industrial operations (Sunderman 1970; Norseth and Piscator 1979; USEPA 1980, 1986). Exposure to air containing more than 50 mg $Ni(CO)_4/m^3$ for 0.5-2.0 h may be fatal to humans (WHO 1991). Intraperitoneal injection of nickel carbonyl was the most toxic route of administration; for all routes of administration, LD50 values to various tested mammals ranged between 13 and 65 mg/kg BW (WHO 1991; Table 9). Nickel carbonyl toxicity is due, in part, to its volatility and lipophilicity (Sigel and Sigel 1988). Signs of nickel carbonyl poisoning—which strongly resemble those of viral pneumonia—include headache, vertigo, nausea, vomiting, insomnia, and irritability followed by an asymptomatic interval and then the onset of insidious, persistent signs that include chest pains, dry coughing, cyanosis, sweating, visual and gastrointestinal disturbances, severe weakness, paralysis of the hind limbs, and convulsions; the lungs are the primary target organs in all animals tested, although the liver, kidneys, adrenal glands, spleen, and brain are also affected (Sunderman 1970; Nielsen 1977; Mushak 1980; USEPA 1980, 1986; Norseth 1986; WHO 1991).

Adverse effects in mammals by inhalation of nickel compounds other than nickel carbonyl occur with aerosols of both soluble and insoluble nickel compounds (USEPA 1980). Inhalation of nickel by humans and other mammals produces respiratory, hepatic, renal, dermal, immune system, and body weight effects (WHO 1991; USPHS 1993). Respiratory effects of nickel include asthma, nasal septal perforations, chronic rhinitis and

sinusitis, and increased risk for chronic respiratory tract infections (USPHS 1977; USEPA 1986; WHO 1991); immunological, genotoxic, and carcinogenic effects were also observed (USPHS 1993). Lung reactions in the form of asthma were attributed to sensitization by nickel (Norseth and Piscator 1979). Insoluble forms of inhaled nickel are more persistent in lungs than are soluble forms, as judged by 90-day studies with nickel chloride (soluble) and nickel oxide (insoluble) given to rodents by intratracheal administration (English et al. 1981). Severity of respiratory toxicity was higher with increasing solubility of the nickel compound tested and not with increasing burden of nickel on the lung; insoluble nickel oxide had the lowest toxicity but the highest lung burden. Nickel sulfate was more toxic than nickel subsulfide, which was more toxic than nickel oxide (USPHS 1993).

Local effects noted in guinea pigs, rats, mice, and hamsters caused by inhalation of metallic nickel powder (15 mg/m^3), nickel subsulfide (0.97 mg/m^3), or nickel oxide (53 mg/m^3) include nasal sinus inflammations, ulcers, lung irritation, nickel accumulations in lungs, emphysema, and increased viral respiratory infections (Norseth 1986; WHO 1991). Rats inhaling nickel subsulfide at 2.5 mg/m^3 for 22 days had nasal and lung histopathology within 4 days and disrupted enzyme activities and elevated nickel accumulations within 7 days (Benson et al. 1995). Repeated inhalation of nickel subsulfide by rats for 3 months resulted in chronic inflammation in the lung and atrophy of the olfactory epithelium (Benson et al. 1995). Rats exposed via inhalation of nickel sulfate hexahydrate of 635 μg Ni/m^3 for 6 h daily over 16 days had no outward signs of toxicity; however, internal examination revealed lesions on the olfactory epithelium (Evans et al. 1995). Rats and mice died following inhalation exposure for 16 days to equal doses of nickel sulfate or nickel subsulfide, but not nickel oxide (USPHS 1993). Rats showed epithelial hyperplasia after inhalation exposure to aerosols of nickel chloride or nickel oxide and pulmonary fibrosis after inhalation exposure to nickel subsulfide; a similar syndrome was reported in rabbits after high level inhalation exposure to nickel-graphite dust (WHO 1991). Dogs exposed to nickel powder for 6 months by way of inhalation developed lung pneumosclerosis causing cardiac insufficiency (USPHS 1977). Rats exposed to airborne nickel dusts (100 μg Ni/m^3, 12 h daily for 2 months) had respiratory irritation (NRCC 1981). Single exposures of mice to 250 μg Ni/m^3 for 2 h depressed the humoral immune response (NRCC 1981). Rats exposed to 1,000 μg Ni dust/m^3 (5 days/week for 3-6 months) had high accumulations of nickel in the lungs and kidneys and interstitial fibrosis (NRCC 1981).

Nickel and nickel salts are comparatively nontoxic when taken orally because of homeostatic mechanisms that control nickel metabolism and limited intestinal absorption (Nielsen 1977). In cattle, young calves fed nickel carbonate at concentrations as high as 1,000 mg Ni/kg ration for 8 weeks had nephritic kidneys, with degree of severity increasing with dietary nickel level. However, dietary nickel did not affect growth or food consumption of calves or cause histopathology of the rumen, abomasum, duodenum, liver, or testes (O'Dell et al. 1970). Human and animal data indicate that death is unlikely from oral nickel exposure except when exposed accidentally to high levels (USPHS 1993). Oral exposure studies for humans were limited to acute intoxication and include death (due to cardiac arrest) and the effects of gastrointestinal (nausea, cramps, diarrhea, vomiting), hematological (increase in reticulocytes), hepatic (increase in serum bilirubin), renal (albuminuria), and neurological damage. A child that accidentally ingested 20.36 grams of Ni/kg BW as crystals of nickel sulfate died from heart failure (USPHS 1993). Oral LD50 doses of nickel chloride to rats produced depression of the nervous system, edema of the mucous membranes of the mouth and nose, diffusions from the oral cavity, lacrimation, bleeding from the nose, and diarrhea (USPHS 1977). Prior to death, rats were lethargic, ataxic, and with irregular breathing and cool body temperatures (USPHS 1993).

Nickel is a reproductive toxicant in animals. Specific effects of nickel on reproduction include degenerative changes in the testes, epididymis, and spermatozoa of rats; adverse effects on embryo viability of rats and hamsters; and delayed embryonic development of rodents (Smialowicz et al. 1984; USEPA 1986; USPHS 1993). Nickel salts given by injection cause intrauterine mortality and decreased weight gain in rats and mice (WHO 1991). Inhibited testosterone and reduced growth occur in male rats given 2.32 mg Ni/kg BW as nickel acetate via intramuscular injection. Females given the same treatment had increased uterine weights (USPHS 1977). Nickel given in drinking water of rats for three generations at concentrations which do not interfere with growth or survival (i.e., 5 mg/L) were intolerable for normal reproduction (Schroeder and Mitchener 1971). All generations of rats given nickel in drinking water had increased proportions of runts and increased neonatal mortality when compared to controls. In the third generation of nickel-treated rats, there were reductions in litter size and a reduction in the proportion of males (Schroeder and Mitchener 1971). Excess nickel also inhibits

prolactin secretion in rats. Because prolactin influences milk production, the observation that suckling pups from nickel-exposed dams were most severely affected lends support to the concept that nickel plays a role in lactation at the pituitary level (Nielsen et al. 1975b).

The most commonly observed toxic reaction to nickel and nickel compounds in the general human population is nickel dermatitis and skin sensitivity arising from dermal contact with metals containing nickel (Sunderman 1970; NAS 1975; Norseth and Piscator 1979; USEPA 1980, 1986; WHO 1991; USPHS 1993). Studies on occupational dermatitis—which is the most prevalent occupational disease—show that 8% of the cases are due to nickel (Sunderman et al. 1984). Nickel dermatitis in occupational exposure begins as an itching or burning in the web of the fingers, spreading to the fingers, the wrists, and the forearms; the eruption is similar to atopic dermatitis (NAS 1975; USEPA 1980, 1986). Once an individual is dermally sensitized to nickel, even minimal contact (i.e., 0.007-0.04 mg Ni/kg BW daily) by any route of exposure may elicit a reaction (USEPA 1980; WHO 1991; USPHS 1993; Hughes et al. 1994). Nickel, in fact, is the most common allergin tested in North America; about 1-5% of human males and 7-14% of females are contact sensitized to nickel (NAS 1975; Nielsen 1977; Sevin 1980; USEPA 1980, 1986; Sunderman et al. 1984; USPHS 1993; Ikarashi et al. 1996). Nickel contact hypersensitivity has been documented worldwide, with 10% of the female population and 1% of the male population affected. Of these, 40-50% have vesicular hand eczema that, in some cases, can be severe and lead to loss of working ability (WHO 1991). Nickel contact dermatitis is decreasing in occupational exposure, but increasing elsewhere due to increasing contact with nickel alloys in jewelry, coins, zippers, tools, pots and pans, stainless steel, detergents, prostheses, and certain hair dressings (NAS 1975; Nielsen 1977; USEPA 1980; Sunderman et al. 1984; WHO 1991; USPHS 1993). Nickel is a major allergen for women, and between 1970 and 1980 there was a two- to threefold increase in the number of cases (Sunderman et al. 1984). In recent years, the incidence of nickel allergy has increased disproportionately in young females due to an increased frequency of ear piercing by this group to accommodate nickel-plated jewelry (Ikarashi et al. 1996).

Although contact allergy to nickel is common in humans, experimental sensitization in animals is only successful under special conditions (WHO 1991). Dermal studies with nickel salts and small laboratory mammals show that primary nickel sensitization typically takes place beneath nickel-containing metal objects that are in contact with the skin for hours and exposed to friction and sweating; nickel is released from nickel-containing objects by the action of blood, sweat, or saliva; ionic nickel diffuses through the skin at sweat-duct and hair-follicle openings, with a special affinity for keratin; and that nickel subsequently binds to proteins, including animo and carboxyl groups of keratin and serum albumin (NAS 1975; USEPA 1980; USPHS 1993). Rats, guinea pigs, and rabbits absorbed and subsequently distributed 55-77% of nickel applied dermally (USPHS 1977, 1993). Dermal effects in animals after dermal exposure to nickel include distortion of the dermis and epidermis, hyperkeratinization, atrophy of the dermis, and biochemical changes (USPHS 1993; Ikarashi et al. 1996). For example, in rats treated dermally with more than 40 mg Ni/kg BW daily as nickel hexahydrate for 30 days, distortion of the epidermis and dermis occurred by day 15 and hyperkeratinization, vacuolization, hydropic degeneration of the basal layer, and atrophy of the epidermis occurred by day 30 (USPHS 1993). Skin irritation and death from nickel salts is reported in rabbits when nickel was applied dermally to abraded skin; no negative effects occurred in rabbits when the same dose was applied to intact skin (USPHS 1977). As was the case for humans, allergic reactions occur in laboratory animals after oral nickel challenge in sensitized individuals (USPHS 1993).

Nickel affects endocrine and enzymatic processes. Nickel-induced endocrine effects include inhibition of insulin production in pancreas, prolactin in hypothalamus, amylase excretion in parotid gland, and iodine uptake in thyroid (Mushak 1980; USEPA 1980, 1986; USPHS 1977; WHO 1991). Inhibition of enzyme activity by nickel is reported for RNA polymerase, ATPase, dialkyl fluorophosphate, and aspartase (NAS 1975). Inhibition of ATPase is associated with neurological abnormalities, such as tremors, convulsions, and coma; altered hormone release or action; and internal rearrangement of calcium ions in muscle that might cause paralysis and abnormal heart rhythm (Nielsen 1977). Nickel increases the duration of the action potential of excitable membranes of nerve and muscle tissues; this effect is competitive with and imitative of those of calcium (NAS 1975). Nickel hexahydrate at 14.8 mg Ni/kg BW disrupts hepatic monooxygenases; mice were more sensitive to this disruption than rats or guinea pigs (Iscan et al. 1992). Nickel is also reported to activate various enzymes, including bovine pancreatic ribonuclease, pancreatic deoxyribonuclease, carboxypeptidase, arginase, phosphoglucomutase (Sevin 1980), and calcineurin—a calmodulin-dependent phosphoprotein phosphatase (USEPA 1986). Nickel affects the activity of heme oxygenase, thereby affecting the absorption of hemoglobin iron. Nickel, like many other metals and metalloids, induces heme oxygenase activity in tissues of mice,

hamsters, and guinea pigs in a dose-related manner (Sunderman et al. 1983).

Systemic effects of nickel exposure include hyperglycemia, increased levels of plasma glucagon, damage to the pancreatic islet cells, decreased body weight, reduced food and water intake, and hypothermia (NAS 1975; USEPA 1980; USPHS 1993). Acute administration of nickel salts caused prompt hyperglucagonemia and subsequent hyperinsulinemia in rats, rabbits, and guinea pigs (WHO 1991). Nickel chloride given orally to young male rabbits at 500 µg daily for 5 months produced a decrease in liver glycogen and an increase in muscle glycogen, with prolonged hyperglycemia (NAS 1975). Nickel increased glucose metabolism in rats injected intratracheally with 0.5 mg ionic nickel. This phenomenon probably reflected the influence of nickel on the production or secretion of insulin through decreased production of pituitary hormone secretions—specifically, prolactin—which control insulin concentrations (USPHS 1977). Nickel significantly affects the activity of hepatic glutathione S-transferases (GST); these compounds play important roles in the detoxification of electrophilic xenobiotics, such as nickel, epoxides, and diolepoxides (Iscan et al. 1993), and readily eliminate the cytotoxic products of lipid peroxidation, particularly the organic peroxides (Coban et al. 1996). The influence of nickel chloride on hepatic GST activity levels depends on the animal species tested, being depressed in mice, unchanged in rats, and increased in guinea pigs (Iscan et al. 1992). In humans, nickel toxicity is not related to GST depletion or increased lipid peroxidases in vitro, whereas in rat kidney, nickel toxicity may be due to GST depletion and stimulation of lipid peroxidases (Coban et al. 1996).

Nickel affects the immune, cardiac, and excretory systems. Nickel adversely affects the immune system by reducing host resistance to bacterial and viral infections, suppressing phagocytic activity of macrophages, reducing the number of T-lymphocytes (thereby suppressing the natural kill cell activity), and increasing susceptibility to allergic dermatitis (WHO 1991; USPHS 1993). In mice, nickel chloride suppresses the activity of natural killer cells within 24 h of a single intramuscular injection (USEPA 1986). Nickel-induced cardiovascular effects include vasoconstriction, inhibition of contraction by myocardial muscle, and a reduction in coronary vascular flow (USEPA 1986; WHO 1991; USPHS 1993). Nickel salts are demonstrably cardiotoxic in dogs (Sigel and Sigel 1988). Cats injected intravenously with $NiCl_2$ had altered heart rhythms, conductivity, and calcium metabolism (Nielsen 1977). Nickel is a nephrotoxin with greatest adverse effect on the glomerular epithelium of the kidney. Kidneys from mammals exposed to nickel showed renal tubular damage, protein loss, and weight changes (USPHS 1993).

Nickel accumulations in tissues and organs of mammals vary significantly with species, route of administration, sex, and general health. No significant accumulations of nickel were observed in liver or kidney of Holstein calves fed diets containing 1,000 mg Ni/kg ration for 21 weeks (Stevens 1992). In lactating dairy cows, no transfer of soluble nickel was observed from diet to tissues (Stevens 1992). In rats, guinea pigs, rabbits, sheep, dogs, and other species of mammals, nickel tends to accumulate in kidneys and other tissues after nickel exposure (as quoted in Eastin and O'Shea 1981). Nickel-poisoned rats had elevated accumulations primarily in myocardium (5.7 mg/kg FW vs. 2.2 in controls) and spleen (2.1 mg/kg FW vs. 0.6), followed by kidney, bone, and other tissues (Mathur et al. 1978). In rats, nickel accumulated mainly in lung and secondarily in heart tissues after intratracheal administration of nickel chloride; nickel was retained for at least 40 days after dosing (Novelli and Rodrigues 1991). In rodents, nickel accumulates in endocrine tissues, including the pituitary, adrenals, and pancreas (Mushak 1980; USEPA 1980). High nickel concentrations in the pituitary gland of rodents were associated with inhibition of insulin release and decreased prolactin secretion (Clary 1975). Rat weanlings fed diets containing 500 mg Ni/kg ration as nickel acetate show elevated nickel accumulations in plasma, erythrocytes, heart, liver, testes, and especially kidneys; high accumulations were associated with reductions in growth, hematocrit, hemoglobin, cytochrome oxidase, and alkaline phosphatase (Whanger 1973; Nielsen 1977). Male guinea pigs accumulated higher concentrations of nickel in hair than did females after exposure for 4 months to drinking water containing 2.5 mg Ni/L (Scheiner et al. 1976). Invading microorganisms can change the distribution of ^{63}Ni in mice infected with coxsackie B3 virus. Infected mice had high accumulations of ^{63}Ni in the pancreas and the wall of the ventricular myocardium. Healthy mice had almost no ^{63}Ni accumulations in these tissues, but residues were elevated in blood, kidney, and lung (Ilback et al. 1992).

Excretion of ingested nickel by rats, regardless of amount ingested, usually occurs through the feces within 48 h (Ho and Furst 1973). Most nickel administered to rats through a variety of routes, and irrespective of chemical form, is usually excreted within a few days; however, excretion is slower for nickel powder and from lungs (USPHS 1977). Nickel caused a twofold increase in urinary corticoid excretion in guinea pigs (USPHS

1977), increased urinary excretion of protein in rats (USPHS 1977), and increased urinary excretion of B-2-macroglobulin in nickel refinery workers (USPHS 1993). Nickelemia was associated with increased urinary B-2-macroglobulin levels, and 5 of 11 workers with urinary nickel concentrations more than 100 µg/L had increased urinary B-2-macroglobulin (>240 µg/L; USPHS 1993).

Proposed Criteria and Recommendations

While nickel may be carcinogenic, perhaps in all forms, there is little or no detectable risk in most sectors of the nickel industry at current exposure levels, including in some processes that had previously been associated with very high lung and nasal cancer risks (WHO 1991). More research is in progress to clarify the hazards of nickel to humans, including chronic inhalation carcinogenicity studies of nickel subsulfide, nickel oxide, and nickel sulfate hexahydrate in rats and mice (USPHS 1993). Nevertheless, additional research on nickel-induced cancer has been proposed, including research on (1) route of administration (USPHS 1993); (2) oxidative state of nickel (Kasprzak 1987); (3) effect of nickel on nucleic acid synthesis (Sunderman 1981); (4) interaction effects with asbestos (USEPA 1980), zinc and magnesium (Furst and Radding 1980), tobacco smoke (NRCC 1981), and agents thought to inhibit nickel carcinogenesis, such as manganese, copper, and aluminum (Furst and Radding 1980); (5) role of diet in nickel carcinogenesis (Furst and Radding 1980) and specificity and mechanism of uptake of nickel ion from the gastrointestinal tract (Hausinger 1993); and (6) nickel immunosuppressive mechanisms, especially effects of nickel on natural killer cell activity and the relation between suppression of these cells and the known carcinogenesis of nickel compounds (Smialowicz et al. 1984). Large-scale studies are needed to establish the upper limits of cancer risk from nickel (WHO 1991).

Humans have been shown to develop sensitivity to nickel (USPHS 1993). The use of nickel in products that may release the metal when in contact with the skin should be regulated (WHO 1991). Among various subgroups of the U.S. population who may be at special risk for adverse effects of nickel are those who have nickel hypersensitivity and suffer chronic flare-ups of skin disorders with frank exposure (USEPA 1986). The role of oral nickel exposure in dermatic responses by sensitive individuals suggests that nickel-limited diets resulted in marked improvement of hand eczema and that nickel added to the diets appeared to aggravate the allergic response (USEPA 1986). More research is needed on the role of nickel in contact dermatitis, including the role of oral nickel exposure, and the pathogenesis and therapy of nickel dermatitis (NAS 1975; Sunderman et al. 1984; USEPA 1986). Additional dermal exposure studies are needed to determine if testicular effects result from both oral and dermal exposure to nickel (USPHS 1993).

Animal experimental models of nickel-induced skin sensitivity are few and have been conducted only under very specialized conditions (USEPA 1986). Studies examining the mechanism of nickel contact sensitization and its extent in wildlife are needed (USPHS 1993). The importance of the surface properties and crystalline structure of nickel compounds in relation to their reactivity and protein-binding activities is well documented. It is therefore necessary to identify clearly the nickel compounds to which exposure occurs (Sunderman et al. 1984). Acute and chronic dermal and inhalation studies using all nickel compounds would determine if certain compounds are more effective in eliciting allergic dermatitis (USPHS 1993).

To protect terrestrial vegetation against decreased growth and other toxic effects, nickel residues in leaves should contain less than 44 to less than 50 mg/kg DW, soils should contain less than 50 to less than 250 mg Ni/kg DW, and sewage sludge applied to agricultural soils should be limited to 30-140 kg Ni/surface ha at the low end and 50-560 kg/ha at the high end (Table 10). Research is needed on the direct effects on vegetation of nickel from airborne deposition, the effects of soil acidification on mobility and toxicity of nickel in soil, differences in nickel metabolism between tolerant and nickel-sensitive plants (NRCC 1981), and on the interactions of nickel and organic acids in nickel-accumulating plants and in the surrounding soils (Lee et al. 1978).

To protect freshwater plants and animals against nickel, a proposed range of less than 25 to 96 µg total recoverable Ni/L is recommended by various authorities (Table 10). This range will protect most species of freshwater biota; however, certain species have reduced survival within this range, including embryos of rainbow trout (*Oncorhynchus mykiss*) at 11 µg/L (Birge and Black 1980), daphnids (*Ceriodaphnia dubia*) at 13 µg/L (Schubauer-Berrigan et al. 1993), and embryos of the narrow-mouthed toad (*Gastrophryne carolinensis*) at 50 µg/L (Birge and Black 1980; USEPA 1980). Mixtures of metals are additive or more-than-additive in toxicity and, in some cases, will exceed the recommended water quality criteria based on the individual metals. Such additive effects were demonstrated for daphnids and rainbow trout using water quality criteria developed in the

Netherlands for mixtures of nickel salts and those of arsenic, cadmium, chromium, copper, lead, mercury, or zinc (Enserink et al. 1991). To protect marine life, the 24-h average for total recoverable Ni/L should not exceed 7.1 μg/L, and the maximum concentration should not exceed 140 μg/L at any time (Table 10). The maximum concentration level for marine life protection needs to be reexamined because 30 μg Ni/L adversely affects growth of marine diatoms (Dongmann and Nurnberg 1982), 56 μg/L results in nickel accumulations in mussels (Friedrich and Filice 1976), 58 μg/L causes abnormal sea urchin development (Timourian and Watchmaker 1972), and 59 μg/L has adverse effects on motility of sperm of sea urchins (Timourian and Watchmaker 1977). In aquatic systems, research is needed to determine the mechanisms of nickel toxicity to biota, the transport of nickel, the interaction of nickel with other inorganic and organic chemicals, and the mobility of nickel in sediments under various environmental conditions (NRCC 1981).

Table 10. Proposed nickel criteria for protection of natural resources and human health.

Table 10. Resource, criterion, and other variables	**Effective nickel concentration**	**Reference a**
Aquatic life, freshwater		
Sediments		
Great Lakes		
Safe	Less than 20 mg/kg dry weight (DW)	1
Moderately polluted	20-50 mg/kg DW	1
Heavily polluted	More than 50 mg/kg DW	1
Wisconsin; for disposal in water	Less than 100 mg/kg DW	1
Water		
Canada; safe level	Less than 25 µg/L	2
Rainbow trout, *Oncorhynchus mykiss*; safe level	Less than 29 µg/L	3
Toxic effects expected	30-50 µg/L	4
Ontario, Canada; from sediment disposal in water; final water concentration	Less than 50 µg/L	1
The Netherlands; safe level	Less than 50 µg/L	5
United States; water hardness of 50 mg $CaCO_3$/L	24-h average not to exceed 56 µg total recoverable Ni/L; maximum concentration not to exceed 1,100 µg/L at any time	6
Sweden; safe level	Less than 80 µg/L	7
United States; water hardness of 100 mg $CaCO_3$/L	24-h average not to exceed 96 µg total recoverable Ni/L; maximum concentration not to exceed 1,800 µg/L at any time	6
United States; water hardness of 200 mg $CaCO_3$/L	24-h average not to exceed 160 µg total recoverable Ni/L; maximum concentration not to exceed 3,100 µg/L at any time	6
Aquatic life, marine		
Water	24-h average not to exceed 7.1 µg total recoverable Ni/L; maximum concentration not to exceed 140 µg/L at any time	6
Birds		
Diet		
Domestic chicken, *Gallus* sp.; to prevent nickel deficiency in chicks	More than 50 µg/kg ration	8,9,10
Mallard, *Anas platyrhynchos*		
Ducklings; no adverse effects	Less than 200 mg/kg ration	4
Adults; no adverse effects	Less than 800 mg/kg ration	4
Adults; adverse effects	More than 800 mg kg fresh weight (FW) ration	11
Tissue concentrations		
Adverse effects expected; most species		
Kidney	More than 10 mg/kg DW	4

Table 10. Resource, criterion, and other variables Aquatic life, freshwater	Effective nickel concentration	Reference a
Liver	More than 3 mg/kg DW	4
Internal organs, most species		
Normal	Less than 3 mg/kg DW	4
Nickel-contaminated environments	As much as 30 mg/kg DW	4
Mallard; liver or kidney; significant exposure to dietary nickel that may be harmful	More than 1.0 mg/kg FW	11
Crops and other terrestrial vegetation		
Plant residues		
Alfalfa, *Medicago sativa*		
Normal	0.3-3.2 mg/kg DW	12
Decreased growth	44.0 mg/kg DW	12
Terrestrial vegetation		
Hyperaccumulator plants	More than 1,000 mg/kg DW	13
Most species		
Normal	0.05-5.0 mg/kg DW	13
Toxic	More than 50 mg/kg DW	13
Sewage sludge; maximum addition to agricultural soils		
Europe	30-75 kg/ha	1
South Africa	200 mg/kg DW	24
United States; soils with low exchange capacity vs. soils with high exchange capacity		
Maryland	140 kg/ha vs. 280 kg/ha	1
Massachusetts	56 kg/ha vs. 112 kg/ha	1
Minnesota and Vermont	56 kg/ha vs. 112-224 kg/ha	1
Missouri	140 kg/ha vs. 280-560 kg/ha	1
New York, all soils	34-50 kg/ha	1
Oregon	50 kg/ha vs. 100-200 kg/ha	1
Wisconsin	50-100 kg/ha vs. 150-200 kg/ha	1
Soils; suitability for crop production		
Canada; Alberta; acidic soils; acceptable	Less than 250 mg/kg DW	1
The Netherlands		
Background	50 mg/kg DW	1
Moderate contamination	100 mg/kg DW	1
Unacceptable and requires cleanup	More than 500 mg/kg DW	1
Russia; maximum acceptable concentration; extractable by ammonium acetate buffer at pH 4.6	4.0 mg/kg	1
South Africa, no phytotoxicity or elevated nickel concentrations in crops	38 mg/kg DW	24
United States; New Jersey; acceptable	Less than 100 mg/kg DW	1
Mammals, except humans		
Air		
Laboratory white rat, *Rattus* sp.		
Adverse effects; nickel sulfate	More than 0.1 mg/m^3	9
No adverse effects		
Nickel refinery dust	Equivalent to less than 0.84 mg/kg BW daily	9
Nickel subsulfide	Equivalent to less than 1.7 mg/kg BW daily	9
Nickel sulfate	Less than 0.1 mg/m^3	9
Rodents, *Mus* spp., *Rattus* spp.

b Elevated requirement may reflect increased use by rumen bacteria.

c Based on no observable adverse effects during chronic exposure to diets containing 100 mg Ni (as soluble salts) per kg ration (=5 mg Ni/kg BW daily) divided by uncertainty factor of 300.

To protect birds, diets should contain at least 50 μg Ni/kg ration to prevent nickel deficiency but less than 200 mg Ni/kg ration in the case of young birds and less than 800 mg/kg ration in the case of adults to prevent adverse effects on growth and survival (Table 10). Nickel residues in avian kidneys in excess of 10 mg/kg DW or in liver in excess of 3 mg/kg DW are sometimes associated with adverse effects (Outridge and Scheuhammer 1993); however, nickel accumulates in kidneys of mallards (*Anas platyrhynchos*) at dietary concentrations as low as 12.5 mg Ni/kg ration (Eastin and O'Shea 1981). In general, tissue concentrations of nickel were not reliable indicators of potential toxicity in mammals and birds because adverse effects, including death, frequently occurred in the absence of elevated tissue nickel concentrations (Outridge and Scheuhammer 1993). For monitoring birds, analysis of kidneys, bone, and feathers is most likely to reveal elevated exposure to environmental nickel contamination; nickel concentrations in liver and spleen often do not reflect elevated exposure (Outridge and Scheuhammer 1993).

To protect humans and other mammals, proposed air quality criteria range from 0.01 to less than 1.0 mg/m^3 for metallic nickel and slightly soluble nickel compounds, 0.015-0.5 mg/m^3 for water-soluble nickel compounds, and 0.005-0.7 mg/m^3 for nickel carbonyl (Table 10). Inhalation of nickel subsulfide concentrations (0.11-1.8 mg Ni/m^3) near the current threshold limit value of 1 mg Ni/m^3 can produce detrimental changes in the respiratory tract of rats after only a few days of exposure (Benson et al. 1995). Additional animal studies are recommended to identify minimally effective inhalation exposure levels for the various nickel compounds (USPHS 1993). Continued monitoring of nickel refining, nickel-cadmium battery manufacture, and nickel powder metallurgy installations is recommended because ambient air levels of bioavailable nickel at these installations in excess of 1 mg/m^3 can sometimes still be found (NAS 1975; Sevin 1980; Sunderman et al. 1984; Chau and Kulikovsky-Cordeiro 1995).

Most species of mammals had normal growth and survival during chronic exposure to diets equivalent to 0.8-40 mg Ni/kg BW daily (Outridge and Scheuhammer 1993). Reduced growth and survival sometimes occurred when sensitive species of wildlife were fed diets containing 500-2,500 mg Ni/kg ration, equivalent to 10-50 mg Ni/kg BW daily (Outridge and Scheuhammer 1993). Proposed criteria for nickel by way of the diet or drinking water range from 2 μg total Ni/kg BW daily (USPHS 1993) to 443 μg total Ni/kg BW daily (USEPA 1980) for soluble nickel compounds, less than 1.0 mg Ni/kg FW diet, and less than 350 μg Ni/L drinking water (Table 10). Further research is needed to clarify the role of nickel in mammalian nutrition, including dietary requirements of nickel and identification of the chemical forms of nickel present in foods and their bioavailability

(NAS 1975; Sunderman et al. 1984; Hausinger 1993). Studies are needed on the absorption and cellular uptake, transport, and metabolism of well-characterized nickel species following different routes and types of administration (NAS 1975; WHO 1991; Hausinger 1993) and on the transfer of dietary nickel to tissues of lactating dams and juveniles (Stevens 1992). Because young female laboratory mice were more susceptible to dietary nickel than were adults, it is possible that no-observable-adverse-effect-levels (NOAELs) derived from adult animals may be inappropriately high for neonates and juveniles (Outridge and Scheuhammer 1993). Studies that compare the toxicokinetics of humans and animals concurrently could be helpful in determining which species of animal is the most appropriate model for assessing the effects of nickel in human health (USPHS 1993). Animal studies designed to examine neurological effects after inhalation or oral exposure are needed to determine, in part, if human exposure to nickel will cause permanent neurological damage (USPHS 1993).

Nickel affects reproduction of selected mammals. Drinking water containing 5 mg Ni/L—equivalent to 0.2-0.4 mg Ni/kg BW daily—had adverse effects on rat reproduction and iron metabolism (Outridge and Scheuhammer 1993). Dogs given the equivalent of 1.3 mg Ni/kg BW daily had decreased litter survival (Hughes et al. 1994). Nickel is known to cross the placental barrier and reach the fetus in mammals and humans. More information is needed on the effects of in utero nickel exposure in pregnant women (USEPA 1986; Chashschin et al. 1994). Such information may be obtained using appropriate animal models (USPHS 1977). Multigenerational inhalation studies are recommended to determine if developmental effects result from both inhalation and oral exposure (USPHS 1993).

Biomarkers of nickel exposure and effects include nickel concentrations in feces and urine and changes in serum antibodies and serum proteins (USPHS 1993). Levels of carnosine, a dipeptide, seem to reflect the extent of nickel-induced damage to olfactory mucosa of rats, although the rodent olfactory system is more resilient than is the human (Evans et al. 1995). Studies on the availability of trace levels of nickel in food and water and in air would be helpful to relate levels of nickel found in the hair, nails, blood, and urine to levels of nickel in internal organs (USPHS 1993). Nickel concentrations in human tissues now considered elevated include 4.6 μg/L in serum, 11.9 μg/L in plasma, and 100-129 μg/L in urine (Table 10). Treatment of mammals suffering from nickel poisoning is usually through administration of various classes of chelating agents, including dithiocarb (sodium diethyl-dithiocarbamate—the drug of choice in the management of nickel carbonyl poisoning), EDTA salts, BAL (2,3-dimercaptopropanol), and penicillamine (Norseth and Piscator 1979; Norseth 1986). In all cases, the agents accelerate urinary excretion of absorbed nickel before extensive tissue injury occurs (USEPA 1980).

The nomenclature of nickel compounds should be further standardized (WHO 1991). Analytical methods must be developed and standardized in order to facilitate speciation of nickel compounds in atmospheric emissions, biological materials, and in other environmental samples (NAS 1975; WHO 1991). Studies are needed to elucidate the biogeochemical nickel cycle on a global scale and determine its potential for long-range transport (WHO 1991).

Conclusions

Nickel is found in air, soil, water, food, and household objects; ingestion or inhalation of nickel is common, as is dermal exposure. Recent estimates suggest that as much as 28,100 tons of nickel are introduced into the atmosphere each year from natural sources and as much as 99,800 tons from human activities. In the atmosphere, nickel is mostly suspended onto particulate matter. In natural waters the dominant chemical species is Ni^{2+} in the form of $(Ni(H_2O)_6)^{2+}$. In alkaline soils the major components of the soil solution are Ni^{2+} and $Ni(OH)^{+}$; in acidic soils the main solution species are Ni^{2+}, $NiSO_4$, and $NiHPO_4$.

Nickel is an essential micronutrient for maintaining health in certain species of plants and animals. Nickel deficiency effects from dietary deprivation of nickel have been induced experimentally in many species of birds and mammals. To prevent nickel deficiency in rats and chickens, diets should contain at least 50 μg Ni/kg ration, while cows and goats require more than 100 μg Ni/kg rations, perhaps reflecting the increased use by rumen bacteria. Nickel deficiency is not a public health concern for humans because daily oral intake is sufficient to prevent deficiency effects.

Nickel contamination from anthropogenic activities occurs locally from emissions of metal mining, smelting, and refining operations; combustion of fossil fuels; nickel plating and alloy manufacturing; land disposal of sludges, solids, and slags; and disposal as effluents. Nickel concentrations in living organisms and abiotic materials tend to be elevated in the vicinity of nickel smelters and refineries, nickel-cadmium battery plants, sewage outfalls, and coal ash disposal basins.

Adverse effects of excess nickel are documented for bacteria, algae, yeasts, higher plants, protozoans, mollusks, crustaceans, insects, annelids, echinoderms, fishes, amphibians, birds, and mammals. To protect terrestrial vegetation against decreased growth and other toxic effects, nickel concentrations in leaves should contain less than 50 mg Ni/kg DW (and in some cases less than 44 mg Ni/kg DW), growing soils should contain less than 250 mg Ni/kg DW (and in some cases <50 mg Ni/kg DW), and sewage sludge applied to agricultural soils should be limited to 30-140 kg Ni/surface ha at the low end and 50-560 kg/surface ha at the high end. To protect freshwater plants and animals against nickel, a proposed range of less than 25 to 96 μg total recoverable Ni/L is recommended by various authorities; however, certain species have reduced survival within this range. To protect marine organisms, the 24-h average for total recoverable nickel per liter should not exceed 7.1 μg/L and the maximum concentration should not exceed 140 μg/L at any time; however, certain marine organisms show adverse effects to as little as 30 μg Ni/L.

To protect young birds against adverse effects of excess nickel on growth and survival, diets should contain less than 200 mg Ni/kg ration, and diets of older birds should contain less than 800 mg Ni/kg ration. Nickel concentrations in avian tissues in excess of 10 mg/kg DW kidney or 3 mg/kg DW liver are sometimes associated with adverse effects.

Toxic effects of nickel to humans and laboratory mammals are documented for respiratory, cardiovascular, gastrointestinal, hematological, musculoskeletal, hepatic, renal, dermal, ocular, immunological, developmental, neurological, and reproductive systems. Nickel toxicity in mammals is governed by the chemical form of nickel, dose, and route of exposure. Mammalian exposure to nickel by inhalation or cutaneous contact was more significant than oral exposure. To protect humans and other mammals against respiratory effects, proposed air quality criteria are 0.01 to less than 1.0 mg/m^3 for metallic nickel and sparingly soluble nickel compounds and 0.005-0.7 mg/m^3 for nickel carbonyl. Most species of mammals tested had normal growth and survival during chronic exposure to dietary nickel (equivalent to 0.8-40 mg Ni/kg BW daily) and reduced growth and survival when fed diets containing 500-2,500 mg Ni/kg ration (equivalent to 10-50 mg Ni/kg BW daily). Proposed nickel criteria for sensitive species by way of the diet or drinking water now range from 2 to less than 443 μg total Ni/kg BW daily for soluble nickel compounds, less than 1.0 mg Ni/kg FW diet, and less than 350 μg Ni/L in drinking water. Nickel concentrations in human tissues now considered elevated include 4.6 μg/L serum, 11.9 μg/L plasma, and 100-129 μg/L urine; comparable data for mammalian wildlife are lacking.

Some forms of nickel are carcinogenic to humans and animals, but only when exposure is by the respiratory route. Toxic and carcinogenic effects of nickel compounds are associated with nickel-mediated oxidative damage to DNA and proteins and to inhibition of cellular antioxidant defenses. Some nickel compounds are weakly mutagenic in a variety of test systems, but much of the evidence is inconclusive or negative. In mammals, no teratogenic effects of nickel compounds occur by way of inhalation or ingestion, except from nickel carbonyl. Inhaled nickel carbonyl results in comparatively elevated nickel concentrations in lung, brain, kidney, liver, and adrenals and is the most hazardous form of nickel.

Overall, nickel is not an immediate threat to the health of plants, animals, and humans at environmentally encountered levels, except in the case of nickel carbonyl, and progress has been made toward minimizing or eliminating occupational nickel exposure.

Contaminant Hazard Reviews
Report No. 35

CUMULATIVE INDEX TO CHEMICALS AND TO COMMON AND SCIENTIFIC NAMES OF SPECIES LISTED IN CONTAMINANT HAZARD REVIEWS 1 THROUGH 34

by
Ronald Eisler

Patuxent Wildlife Research Center
U.S. Geological Survey
Laurel, MD 20708

CONTENTS

Abstract

Abstract. The Contaminant Hazard Reviews (CHR) series—sponsored by the U.S. Geological Survey Patuxent Wildlife Research Center—synthesizes ecotoxicological data for selected environmental contaminants, with emphasis on hazards to native species of flora and fauna. From 1985 through 1998, 34 reviews were published in various report series of the U.S. Department of the Interior on agricultural pesticides (acrolein, atrazine, carbofuran, chlordane, chlorpyrifos, diazinon, diflubenzuron, famphur, fenvalerate, mirex, paraquat, toxaphene), metals and metalloids (arsenic, boron, cadmium, chromium, copper, lead, mercury, molybdenum, nickel, selenium, silver, tin, zinc), mammalian biocides (sodium monofluoroacetate), organic industrial and municipal wastes (dioxins, pentachlorophenol, polycyclic aromatic hydrocarbons, polychlorinated biphenyls), mining wastes (cyanide), and ionizing radiations. This current report is a cumulative index to the common and scientific names of all biological species listed in the first 34 reports in the CHR series, with individual species cross-referenced with contaminant hazard review and corresponding page numbers. A similar index for chemicals is included.

Key words: Index, mirex, cadmium, carbofuran, toxaphene, selenium, chromium, polychlorinated biphenyls, dioxins, diazinon, mercury, nickel, polycyclic aromatic hydrocarbons, arsenic, chlorpyrifos, lead, tin, pentachlorophenol, atrazine, molybdenum, boron, chlordane, paraquat, cyanide, fenvalerate, diflubenzuron, zinc, famphur, acrolein, radiation, sodium monofluoroacetate, silver, copper, wildlife, birds, mammals, amphibians, reptiles, fish, invertebrates, plants

---

Introduction

A series of 34 Contaminant Hazard Reviews (CHR) was published between 1985 and 1998 under the aegis of the Patuxent Wildlife Research Center in direct response to requests for information from environmental specialists of the U.S. Fish and Wildlife Service and other scientists and resource managers in the U.S. Department of the Interior. Each CHR synthesized ecological and toxicological information of a single environmental contaminant, with emphasis on native fishery and wildlife resources. Specifically, reviews were prepared on selected agricultural insecticides, herbicides, animal control agents, metals, metalloids, organic industrial wastes, mining wastes, and ionizing radiations. Financial support for the CHR series was provided by the U.S. Fish and Wildlife Service, the National Biological Survey, the National Biological Service, and, most recently, the U.S. Geological Survey (Table). Page 66 of this report provides information on obtaining copies of the CHR reports.

This report presents an index for all chemicals and chemical trade names listed in CHR's 1 through 34; a similar index is included for the common and scientific names of all biological species. This publication is the second index to the CHR series. The first index—CHR 16 (Eisler and Corley 1989)—listed the common and scientific names of species in CHR's 1 through 15 but did not include chemicals and chemical trade names. The current index issue—CHR 35—supersedes CHR 16. This index was also prepared at the request of environmental specialists of the U.S. Fish and Wildlife Service and various natural resource managers in the U.S. Department of the Interior. It should also be a useful resource to the many other users of the CHR reviews.

Table. Publications in the Contaminant Hazard Reviews (CHR) series by CHR number, subject, report series and number, and author(s).

CHR No.	Subject	Report series and number[a]	Author(s)
1	Mirex	FWS 85 (1.1)	Eisler (1985a)
2	Cadmium	FWS 85 (1.2)	Eisler (1985b)
3	Carbofuran	FWS 85 (1.3)	Eisler (1985c)
4	Toxaphene	FWS 85 (1.4)	Eisler and Jacknow (1985)
5	Selenium	FWS 85 (1.5)	Eisler (1985d)
6	Chromium	FWS 85 (1.6)	Eisler (1986a)
7	Polychlorinated Biphenyls	FWS 85 (1.7)	Eisler (1986b)
8	Dioxins	FWS 85 (1.8)	Eisler (1986c)
9	Diazinon	FWS 85 (1.9)	Eisler (1986d)
10	Mercury	FWS 85 (1.10)	Eisler (1987a)
11	Polycyclic Aromatic Hydrocarbons	FWS 85 (1.11)	Eisler (1987b)
12	Arsenic	FWS 85 (1.12)	Eisler (1988a)
13	Chlorpyrifos	FWS 85 (1.13)	Odenkirchen and Eisler (1988)
14	Lead	FWS 85 (1.14)	Eisler (1988b)
15	Tin	FWS 85 (1.15)	Eisler (1989a)
16	Index to Species	FWS 85 (1.16)	Eisler and Corley (1989)
17	Pentachlorophenol	FWS 85 (1.17)	Eisler (1989b)
18	Atrazine	FWS 85 (1.18)	Eisler (1989c)
19	Molybdenum	FWS 85 (1.19)	Eisler (1989d)
20	Boron	FWS 85 (1.20)	Eisler (1990a)
21	Chlordane	FWS 85 (1.21)	Eisler (1990b)
22	Paraquat	FWS 85 (1.22)	Eisler (1990c)
23	Cyanide	FWS 85 (1.23)	Eisler (1991)
24	Fenvalerate	FWS 2	Eisler (1992a)
25	Diflubenzuron	FWS 4	Eisler (1992b)
26	Zinc	FWS 10	Eisler (1993)
27	Famphur	NBSY 20	Eisler (1994a)
28	Acrolein	NBSY 23	Eisler (1994b)
29	Radiation	NBS 26	Eisler (1994c)
30	Sodium Monofluoroacetate (1080)	NBS 27	Eisler (1995)
31	Planar PCBs	NBS 31	Eisler and Belisle (1996)
32	Silver	NBS 32	Eisler (1996)
33	Copper	USGS 1997-0002	Eisler (1998a)
34	Nickel	USGS 1998-0001	Eisler (1998b)

[a]FWS = Biological Report series of the U.S. Fish and Wildlife Service (CHR 1 through 26); NBSY = Biological Report series of the U.S. National Biological Survey (CHR 27 and 28); NBS = Biological Report series of the U.S. National Biological Service (CHR 29-32); USGS = Biological Science Report series of the U.S. Geological Survey (CHR 33 and 34).

Index to Chemicals

All chemicals, chemical trade names, and other substances with known biological properties listed in CHR's 1 through 34—a total of 1,570—are presented in Section 1. Each listed chemical is followed by a **boldfaced number** between **1** and **34** (this number corresponds to the CHR report number listed in Table) and nonbolded numbers that designate the pages in that report.

Index to Species

Taxonomic nomenclatures for plants and animals are under constant revision. In this report, I elected to conform as much as possible to the systems and spellings used by Scott and Wasser (1980) for plants, Swain and Swain (1948) for insects, Turgeon et al. (1988) for aquatic mollusks, Williams et al. (1989) for decapod crustaceans, Pratt (1935) and Hyman (1940, 1951a, 1951b, 1955) for miscellaneous invertebrates, Robins et al.

(1991) for fishes, Ditmars (1966) for reptiles, Edwards (1974) and Howard and Moore (1991) for birds, and Nowak and Paradiso (1983) for mammals. Individual species are arranged alphabetically by scientific and common name (Section 2). Each scientific name is followed by a **boldfaced number** between **1** and **34** (this number corresponds to the CHR report number listed in Table) and nonbolded numbers that designate the pages in that report.

In total, 2,233 species of animals and plants were cited, of which only 23 (1.03%) were listed in at least 20 CHR reports. The most widely cited species included one species of plant (corn, *Zea mays*), two species of invertebrates (freshwater crustacean, *Daphnia magna*; American oyster, *Crassostrea virginica*), seven species of teleosts (channel catfish, *Ictalurus punctatus*; bluegill, *Lepomis macrochirus*; coho salmon, *Oncorhynchus kisutch*; rainbow trout, *Oncorhynchus mykiss*; fathead minnow, *Pimephales promelas*; brook trout, *Salvelinus fontinalis*; lake trout, *Salvelinus namaycush*), three species of birds (mallard, *Anas platyrhynchos*; domestic chicken, *Gallus* sp.; Japanese quail, *Coturnix japonica*), and ten species of mammals (cow, *Bos* spp.; domestic dog, *Canis familiaris*; guinea pig, *Cavia* spp.; domestic cat, *Felis domesticus*; human, *Homo sapiens*; hamster, *Cricetus* spp.; domestic mouse, *Mus* spp.; domestic sheep, *Ovis aries*; laboratory white rat, *Rattus* spp.; and domestic pig, *Sus* spp.). It is probable that these species are not representative of unusually sensitive or endangered species, but they can be considered appropriate sentinel organisms for many species of free-living wildlife.

Acknowledgments

I thank Henry C. Bourne for computer assistance; W. Nelson Beyer, Lynda J. Garrett, and Ann Zimmerman for technical review; Shannon E. Price and Beth A. Vairin for editorial services; and Susan M. Lauritzen and Natalie Gormanous Trahan for layout.
