## **PREFACE**

(To be added)

## SUMMARY

1  
2  
3  
4 Climate change is expected to have noticeable effects in the United States: a rise in  
5 average temperatures in most regions, changes in precipitation amounts and seasonal  
6 patterns in many regions, changes in the intensity and pattern of extreme weather events,  
7 and sea level rise. Some of these effects have clear implications for energy production  
8 and use. For instance, average warming can be expected to increase energy requirements  
9 for cooling and reduce energy requirements for warming. Changes in precipitation could  
10 affect prospects for hydropower, positively or negatively. Increases in storm intensity  
11 could threaten further disruptions of the sorts experienced in 2005 with Hurricane  
12 Katrina. Concerns about climate change impacts could change perceptions and  
13 valuations of energy technology alternatives. Any or all of these types of effects could  
14 have very real meaning for energy policies, decisions, and institutions in the United  
15 States, affecting discussions of courses of action and appropriate strategies for risk  
16 management.

17  
18 This report summarizes what is currently known about effects of climate change on  
19 energy production and use in the United States. It focuses on three questions, which are  
20 listed below along with general short answers to each. Generally, it is important to be  
21 careful about answering these questions, for two reasons. One reason is that the available  
22 research literatures on many of the key issues are limited, supporting a discussion of  
23 issues but not definite conclusions about answers. A second reason is that, as with many  
24 other categories of climate change effects in the U.S., the effects depend on more than  
25 climate change alone, such as patterns of economic growth and land use, patterns of  
26 population growth and distribution, technological change, and social and cultural trends  
27 that could shape policies and actions, individually and institutionally.

28  
29 The report concludes that, based on what we know now, there are reasons to pay close  
30 attention to possible climate change impacts on energy production and use and to  
31 consider ways to adapt to possible adverse impacts and take advantage of possible

1 positive impacts. Although the report includes considerably more detail, here are the  
2 three questions along with a brief summary of the answers:

- 3
- 4 • How might climate change affect energy consumption in the United States? The  
5 research evidence is relatively clear that climate warming will mean reductions in  
6 heating requirements and increases in cooling requirements for buildings. These  
7 changes will vary by region and by season, but they will affect household energy  
8 costs and demands on energy supply institutions. In general, the changes imply  
9 increased demands for electricity, which supplies virtually all cooling energy  
10 services but only some heating services. Other effects on energy consumption are  
11 less clear.
  - 12
  - 13 • How might climate change affect energy production and supply in the United  
14 States? The research evidence about effects is not as strong as for energy  
15 consumption, but climate change could affect energy production and supply (a) if  
16 extreme weather events become more intense, (b) where regions dependent on  
17 water supplies for hydropower and/or thermal power plant cooling face reductions  
18 in water supplies, (c) where changed conditions affect facility siting decisions,  
19 and (d) where conditions change (positively or negatively) for biomass  
20 production. Most effects are likely to be modest except for possible regional  
21 effects of extreme weather events and water shortages.
  - 22
  - 23 • How might climate change have various other effects that indirectly shape energy  
24 production and consumption in the United States? The research evidence about  
25 indirect effects ranges from abundant information about possible effects of  
26 climate change policies on energy technology choices to extremely limited  
27 information about such issues as effects on energy prices or energy security.  
28 Based on this mixed evidence, it appears that climate change is very likely to  
29 affect risk management in the investment behavior of some energy institutions,  
30 and it is very likely to have some effects on energy technology R&D investments  
31 and energy resource and technology choices. In addition, climate change can be

1           expected to affect other countries in ways that in turn affect U.S. energy  
2           conditions through their participation in global and hemispheric energy markets,  
3           and climate change concerns could reinforce some driving forces behind policies  
4           focused on U.S. energy security, such as reduced reliance on oil products.  
5

6    Because of the lack of research to date, prospects for adaptation to climate change effects  
7    by energy providers, energy users, and society at large are speculative, although the  
8    potentials are considerable. It is possible that the greatest challenges would be in  
9    connection with possible increases in the intensity of extreme weather events and  
10   possible significant changes in regional water supply regimes. But adaptation prospects  
11   depend considerably on the availability of information about possible climate change  
12   effects to inform decisions about adaptive management.  
13

14   Given that the current knowledge base is so limited, this suggests that expanding the  
15   knowledge base is important to energy users and providers in the United States.

16   Priorities for such research – which should be seen as a broad-based collaboration among  
17   federal and state governments, industry, non-governmental institutions, and academia –  
18   are identified in the report.

1  
2 **CHAPTER 1. INTRODUCTION**  
3  
4

5 As a major expression of its objective to provide the best possible scientific information  
6 to support decision-making and public discussion on key climate-related issues, the U.S.  
7 Climate Change Science Program (CCSP) has commissioned 21 “synthesis and  
8 assessment products” (SAPs) to summarize current knowledge and identify priorities for  
9 research, observation, and decision support in order to strengthen contributions by  
10 climate change science to climate change related decisions.

11  
12 These reports arise from the five goals of CCSP (<http://www.climate-science.gov>), the  
13 fourth of which is to “understand the sensitivity and adaptability of different natural and  
14 managed ecosystems and human systems to climate and related global changes.” One of  
15 the seven SAPs related to this particular goal is to be concerned with analyses of the  
16 effects of global change on energy production and use (SAP 4.5). The resulting SAP, this  
17 report, has been titled “Effects of Climate Change on Energy Production and Use in the  
18 United States.”

19  
20 This topic is relevant to policy-makers and other decision-makers because most  
21 discussions to date of relationships between the energy sector and responses to concerns  
22 about climate have been very largely concerned with roles of energy production and use  
23 in climate change mitigation. Along with these roles of the energy sector as a *driver* of  
24 climate change, the energy sector is also subject to *effects* of climate change; and these  
25 possible effects – along with adaptation strategies to reduce any potential negative costs  
26 from them – have received much less attention. For instance, the U.S. National  
27 Assessment of Possible Consequences of Climate Variability and Change (NACC, 2001)  
28 considered effects on five sectors, such as water and health; but energy was not one of  
29 those sectors, even though the Global Change Research Act of 1990 had listed energy as  
30 one of several sectors of particular interest.

31

1 Because the topic has not been a high priority for research support and institutional  
2 analysis, the formal knowledge base is in many ways limited. As a starting point for  
3 discussion, this product compiles and reports what is known about likely or possible  
4 effects of climate change on energy production and use in the United States, within a  
5 more comprehensive framework for thought about this topic, and it identifies priorities  
6 for expanding the knowledge base to meet needs of key decision-makers.

## 8 **1.1 BACKGROUND**

10 Climate change is expected to have certain effects in the United States: a rise in average  
11 temperatures in most regions, changes in precipitation amounts and seasonal patterns in  
12 many regions, changes in the intensity and pattern of extreme weather events, and sea  
13 level rise [(IPCC, 2001a; NACC, 2001; also see other SAPs, including 2.1b and 3.2)].

15 Some of these effects have clear implications for energy production and use. For  
16 instance, average warming can be expected to increase energy requirements for cooling  
17 and reduce energy requirements for warming. Changes in precipitation could affect  
18 prospects for hydropower, positively or negatively. Increases in storm intensity could  
19 threaten further disruptions of the sorts experienced in 2005 with Hurricane Katrina.  
20 Concerns about climate change impacts could change perceptions and valuations of  
21 energy technology alternatives. Any or all of these types of effects could have very real  
22 meaning for energy policies, decisions, and institutions in the United States, affecting  
23 discussions of courses of action and appropriate strategies for risk management.

25 According to CCSP, a SAP has three end uses: (1) informing the evolution of the  
26 research agenda; (2) supporting adaptive management and planning; and (3) supporting  
27 policy formulation. This product will inform policymakers, stakeholders, and the general  
28 public about issues associated with climate change implications for energy production  
29 and use in the United States, increase awareness of what is known and not yet known,  
30 and support discussions of technology and policy options at a stage where the knowledge  
31 base is still at an early stage of development.

1 The central questions addressed by SAP 4.5 are:

- 2
- 3 • How might climate change affect energy consumption in the United States?
- 4
- 5 • How might climate change affect energy production and supply in the United
- 6 States?
- 7
- 8 • How might climate change affect various contexts that indirectly shape energy
- 9 production and consumption in the United States, such as energy technologies,
- 10 energy institutions, regional economic growth, energy prices, energy security, and
- 11 environmental emissions?
- 12

13 SAP 4.5 is to be completed by the end of the second quarter of CY 2007 (June 30, 2007),  
14 following a number of steps required for all SAPs in scoping the study, conducting it, and  
15 reviewing it at several stages (see the section below on How the Report Was Developed).

## 17 **1.2 THE TOPIC OF THIS SYNTHESIS AND ASSESSMENT**

### 18 **REPORT**

19

20 This report summarizes the current knowledge base about possible effects of climate  
21 change on energy production and use in the United States as a contributor to further  
22 studies of the broader topic of effects of global change on energy production and use. It  
23 also identifies where research could reduce uncertainties about vulnerabilities, possible  
24 effects, and possible strategies to reduce negative effects and increase adaptive capacity  
25 and considers priorities for strengthening the knowledge base. As is the case for most of  
26 the SAPs, it does not include new analyses of data, new scenarios of climate change or  
27 impacts, or other new contributions to the knowledge base, although its presentation of a  
28 framework for thought about energy sector impacts is in many ways new.

29

30 As indicated above, the content of SAP 4.5 includes attention to the following issues:

31

- 1 • Possible effects (both positive and negative) of climate change on energy  
2 *consumption* in the United States (Chapter 2)  
3
- 4 • Possible effects (both positive and negative) on energy *production and supply* in  
5 the United States (Chapter 3)  
6
- 7 • Possible *indirect effects* on energy consumption and production (Chapter 4)  
8

9 These chapters are followed by a final chapter which provides conclusions about what is  
10 currently known, prospects for adaptation, and priorities for improving the knowledge  
11 base.

### 12 **1.3 PREVIOUS ASSESSMENTS OF THIS TOPIC**

14  
15 As mentioned on page 1, unlike some of the other sectoral assessment areas identified in  
16 the Global Change Research Act of 1990—such as agriculture, water, and human  
17 health—energy was not the subject of a sectoral assessment in the *National Assessment of*  
18 *Possible Consequences of Climate Variability and Change*, completed in 2001 (NACC,  
19 2001). As a result, SAP 4.5 draws upon a less organized knowledge base than these other  
20 sectoral impact areas. On the other hand, by addressing an assessment area not covered in  
21 the initial national assessment, SAP 4.5 will provide new information and perspectives.

22  
23 The subject matter associated with SAP 4.5 is incorporated in two chapters of the  
24 Working Group II contribution to the Intergovernmental Panel on Climate Change  
25 (IPCC) Fourth Assessment Report (Impacts, Adaptation, and Vulnerability), scheduled  
26 for completion in 2007. Chapter 7, “Industry, Settlement, and Society,” section 7.4.2.1,  
27 is briefly summarizing the global knowledge base about possible impacts of climate  
28 change on energy production and use, reporting relevant research from the United States  
29 but not assessing impacts on the United States. Chapter 14, “North America,” is  
30 summarizing the knowledge base about possible impacts of climate change in this  
31 continent, including the U.S., in sections 14.2.8 and 14.4.8.

1

## 2 **1.4 HOW THE REPORT WAS DEVELOPED**

3

4 SAPs are developed according to guidelines established by CCSP based on processes that  
5 are open and public. These processes include a number of steps before approval to  
6 proceed, emphasizing both stakeholder participation and CCSP reviews of a formal  
7 prospectus for the report, a number of review steps including both expert reviewers and  
8 public comments, and final reviews by the CCSP Interagency Committee and the  
9 National Science and Technology Council (NSTC).

10

11 The process for producing the report was focused on a survey and assessment of the  
12 available literature, in many cases including documents that were not peer-reviewed but  
13 the authors determined to be valid. using established analytic-deliberative practices, It  
14 included identification and consideration of relevant studies carried out in connection  
15 with CCSP, the Climate Change Technology Program (CCTP), and other programs of  
16 CCSP agencies (e.g., the Energy Information Administration), and consultation with  
17 stakeholders such as the electric utility and energy industries, environmental non-  
18 governmental organizations, and the academic research community to determine what  
19 analyses have been conducted and reports have been issued. Where quantitative research  
20 results are limited, the process considers the degree to which qualitative statements of  
21 possible effects may be valid as outcomes of expert deliberation, utilizing the extensive  
22 review processes built into the SAP process to contribute to judgments about the validity  
23 of the statements.

24

25 SAP 4.5 is authored by staff from the DOE national laboratories, drawing on their own  
26 expertise and knowledge bases and also upon other knowledge bases, including those  
27 within energy corporations and utilities, consulting firms, non-governmental  
28 organizations, state and local governments, and the academic research community. DOE  
29 has assured that authorship by DOE national laboratory staff will in no way exclude any  
30 relevant research or knowledge, and every effort is being made to identify and utilize all

1 relevant expertise, materials, and other sources. For the author team of SAP 4.5, see Box  
2 1.1.

3

<b>Box 1.1. SAP 4.5 Author Team</b>

4

5 Stakeholders participated during the scoping process, have provided comments on the  
6 prospectus, and will submit comments on the product during a public comment period, as  
7 well as other comments via the SAP 4.5 web sit. The development of SAP 4.5 has  
8 included active networking by authors with centers of expertise and stakeholders to  
9 assure that the process is fully informed about their knowledge bases and viewpoints.

10

## 11 **1.5 HOW TO USE THIS REPORT**

12

13 The audience for SAP 4.5 includes scientists in related fields, decision-makers in the  
14 public sector (federal, state, and local governments), the private sector (energy  
15 companies, electric utilities, energy equipment providers and vendors, and energy-  
16 dependent sectors of the economy), energy and environmental policy interest groups, and  
17 the general public. Even though this report is unable—based on existing knowledge—to  
18 answer all relevant questions that might be asked by these interested parties, the intent is

1 to provide information and perspectives to inform discussions about the issues and to  
2 clarify priorities for research to reduce uncertainties in answering key questions.  
3 As indicated above, because of limitations in available research literatures, in some cases  
4 the report is only able to characterize categories of possible effects without evaluating  
5 what the effects are likely to be. In other cases, the report offers preliminary judgments  
6 about effects, related to degrees of likelihood: likely (2 chances out of 3), very likely (9  
7 chances out of 10), or virtually certain (99 chances out of 100).

8

9 This report avoids the use of highly technical terminology, but a glossary and list of  
10 acronyms are included at the end of the report (to be completed).

11

12

13

1  
2 **CHAPTER 2. EFFECTS OF CLIMATE CHANGE ON**  
3 **ENERGY USE IN THE UNITED STATES**

4  
5 Michael J. Scott, Pacific Northwest National Laboratory  
6 Y. Joe Huang, Lawrence Berkeley National Laboratory  
7

8  
9 **2.1 INTRODUCTION**

10  
11 As the climate of the world warms, the consumption of energy in climate-sensitive  
12 sectors is likely to change. Possible effects include:

- 13
- 14 • Changes in the amount of energy consumed in residential, commercial, and  
15 industrial buildings for space heating and cooling.
  - 16
  - 17 • Changes in energy used directly in certain processes such as residential,  
18 commercial, and industrial water heating, residential and commercial refrigeration,  
19 and industrial process cooling (e.g., in thermal power plants or steel mills).
  - 20
  - 21 • Changes in energy used to supply other resources for climate-sensitive processes,  
22 such as pumping water for irrigated agriculture and municipal uses.
  - 23
  - 24 • Changes in the balance of energy use among delivery forms and fuel types, as  
25 between electricity used for air conditioning and natural gas used for heating.
  - 26
  - 27 • Changes in energy consumption in key climate-sensitive sectors of the economy,  
28 such as transportation, construction, agriculture, and others.
  - 29

30 In the United States, some of these effects of climate change on energy consumption have  
31 been studied to the extent that there is a body of literature with empirical results. This is

1 the case with energy demand in residential and commercial buildings, where studies have  
2 been occurring for about 20 years. There is very little literature for any of the other  
3 effects mentioned above.

4  
5 This chapter summarizes current knowledge about what potential effects of climate  
6 change on energy demand in the United States. The chapter mainly focuses on the effects  
7 of climate change on energy consumption in buildings (including mainly space heating  
8 and space cooling, but also addressing net energy use, peak loads, and adaptation) that is  
9 summarized in the next section. The following sections briefly address impacts of  
10 climate change on energy use in other sectors, including transportation, construction, and  
11 agriculture, for which empirical studies are far less available. The final section presents  
12 conclusions and issues for future research.

## 14 **2.2 ENERGY CONSUMPTION IN BUILDINGS**

15  
16 U.S. residential and commercial buildings currently use about 41 exajoules of energy per  
17 year and account for 0.6 GT of carbon emitted to the atmosphere (38% of U.S. total  
18 emissions of 1.6 GT and approximately 9% of the world fossil-fuel related anthropogenic  
19 emissions of 6.7 GT (EIA, 2004a, b). U.S. residential and commercial energy  
20 consumption is expected to increase to 55 exajoules and corresponding carbon emissions  
21 to 0.8 GT by the year 2025 (EIA 2004c). These projections do not account for any  
22 temperature increases that occur as a result of global warming.

23  
24 Generally speaking, the net effect of 21<sup>st</sup> century warming on demand for energy used in  
25 buildings is expected to be at most a few percent increase or decrease, with a shift away  
26 from consumption of fuels used directly for heating (mostly natural gas in the north)  
27 toward additional consumption of electricity for cooling (especially in the south). The  
28 extent of this shift is expected to depend in part on the strength of residential adoption of  
29 air conditioning as the length of the air conditioning season and the warmth of summer  
30 increases in the north, where the market penetration of air conditioning is still quite low.  
31 The potential reaction of consumers to the longer and more intense air conditioning

1 season has been addressed in only a handful of studies (e.g., Sailor and Pavlova, 2003)  
2 and must be considered highly uncertain. There is even less information available on the  
3 offsetting effects of adaptations such as improved energy efficiency or changes in urban  
4 form that might reduce exacerbating factors such as urban heat island effects.

5  
6 Amato et al. (2005) observe that many studies worldwide have analyzed the climate  
7 sensitivity of energy use in residential, commercial, and industrial buildings and have  
8 used estimated relationships to explain energy consumption and to assist energy suppliers  
9 with short-term planning (Quayle and Diaz, 1979; Le Comte and Warren, 1981; Warren  
10 and LeDuc, 1981; Downton et al., 1988; Badri, 1992; Lehman, 1994; Lam, 1998; Yan,  
11 1998; Morris, 1999; Pardo et al., 2002). The number of studies in the U.S. analyzing the  
12 effects of climate *change* on energy demand, however, is much more limited. One of the  
13 very early studies was of the electricity sector, projecting that between 2010 and 2055  
14 climate change could increase capacity addition requirements by 14–23% relative to non-  
15 climate change scenarios, requiring investments of \$200–300 billion (\$1990) (Linder and  
16 Innglis, 1989). Following on that study in the early and mid-1990s, there have been a  
17 handful of studies that have attempted an “all fuels” approach and have focused on  
18 whether net energy demand (decreases in heating balanced against increases in cooling)  
19 would increase or decrease in residential and commercial buildings as a result of climate  
20 change (e.g., Loveland and Brown 1990; Rosenthal et al. 1995; Belzer et al. 1996;  
21 Hadley et al. 2004; Mansur et al. 2005; Scott et al. 2005; Huang 2006).

22  
23 Previous authors have taken a number of approaches to estimate the impact of climate  
24 change on energy use in U.S. buildings. Most of these researchers used simple increases  
25 in annual average temperature as the “climate” scenario and rather transient temperature  
26 increase scenarios from general circulation models such as those developed for the  
27 Intergovernmental on Climate Change (IPCC). The exceptions are Rosenthal et al. 1995,  
28 Hadley et al. 2004, Scott et al. 2005, and Huang 2006. For instance, building energy  
29 simulation models have been used to analyze the impact of climate warming on the  
30 demand for energy in individual commercial buildings only (Scott et al. 1994) and on  
31 energy consumption in a variety of commercial and residential buildings in a variety of

1 locations (Loveland and Brown 1990, Rosenthal, et al. 1995, Scott et al. 2005, and Huang  
2 2006). Other researchers have used econometrics and statistical analysis techniques  
3 (most notably the various Mendelsohn papers discussed herein, but also Belzer et al.  
4 1996, Amato et al. 2005, Ruth and Amato 2002, and Franco and Sanstad 2006). In the  
5 subsections that follow on buildings energy consumption, this chapter discusses the  
6 impacts of climate warming on space heating in buildings (divided between residential  
7 and commercial), on space cooling (again divided between residential and commercial  
8 buildings), and on net energy demand. The cooling subsection discusses the effects of  
9 increased market penetration of air conditioning. The third subsection deals with net  
10 energy consumption. The final subsection also discusses the likely effects of adaptation  
11 actions such as increased energy efficiency and changes to urban form, which could  
12 reduce the impacts of some compounding effects such as urban heat islands.

13

## 14 **2.3 EFFECTS ON ENERGY USE FOR SPACE HEATING**

15

### 16 **2.3.1 Residential Buildings and Equipment**

17

18 The impact of climate change on space heating has been projected in a number of studies  
19 for the U.S. residential sector. The studies all concluded that temperature increases from  
20 global warming would reduce the amount of energy needed for space heating, with the  
21 amount of the reduction in any specific study mainly depending on the amount of  
22 temperature change in the climate scenario, the calculated sensitivity of the building  
23 stock to warming, and the adjustments allowed in the building stock over time.

24

25 One technique to estimate the impact of climate change has been to calculate the  
26 differences in energy use between warmer and cooler locations at a point in time and then  
27 to assume that these differences reflect how energy use in the building stock and  
28 equipment responds to climate and market conditions. All locations are then assumed to  
29 would respond to warming over time in a similar way. Mendelsohn performed cross-  
30 sectional econometric analysis using data on U.S. states to determine how energy use in  
31 the residential and commercial building stock relates to climate (Morrison and

1 Mendelsohn 1999; Mendelsohn 2001), and used these cross-sectional relationships to  
2 then estimate the impact of climate change in the year 2060 on all residential and  
3 commercial buildings. Mendelsohn (2003) later expanded on this approach by providing  
4 a two-step cross-sectional model of commercial and residential building stock, which  
5 uses U.S. data and accounts for the probability that a building be cooled (which increases  
6 with the amount of warming), and its overall energy consumption as a function of climate  
7 (matched on a county basis to Energy Information Administration buildings in the  
8 Residential Energy Consumption Survey and Commercial Building Energy Consumption  
9 Survey). This was further elaborated by Mansur et al. (2005) into a complete and  
10 separate set of discrete-continuous choice models of energy demand in residential and  
11 commercial commercial buildings. In this work, the impact of climate change on  
12 consumption of energy in heating is relatively modest. When natural gas is available, the  
13 marginal impact of a 1° C increase in January temperatures in their model reduces  
14 residential electricity consumption by 3% for electricity only consumers and 2% for  
15 natural gas customers.

16

17 Scott et al. (2005), working with directly with residential end uses end uses in a building  
18 energy simulation model, projected about a 16% to 60% reduction in the demand for  
19 residential space heating energy by 2080, given no change in the housing stock and  
20 winter temperature increases ranging from 2° to 10° C, or roughly 6% and 8% decrease  
21 in space heating per degree C increase. This is roughly twice the model sensitivity of  
22 Mansur et al. (2005). The Scott, et al. analysis was driven by a variety of global  
23 circulation models (GCMs) and climate scenarios used in the IPCC 3<sup>rd</sup> Assessment  
24 Report in 2001, regionalized to sub-continent level by the Finnish Environment Institute  
25 for the IPCC (Ruosteenoja, et al. 2003).

26

27 Most recently, Huang (2006) used results from the U.K. Meteorological Service Hadley  
28 Centre GCM of projected changes in temperature, daily temperature range, cloud cover,  
29 and relative humidity by month for 0.5° grids of the earth's surface under four IPCC  
30 carbon scenarios (A1FI, A2M, B1, and B2M) for the year 2080 to adjust hourly TMY2  
31 (Typical Meteorological Year) weather files for 16 US locations. These modified weather

1 files were then used with the DOE-2 building energy simulation program to simulate the  
2 energy demand of a set of 112 prototypical single-family houses covering 8 vintages in  
3 each of the 16 locations, which span the U.S. climate zones. For the entire U.S.  
4 residential sector, the simulations showed an increase in energy use from 0 to 7%,  
5 representing up to a 10% increase in space conditioning energy use. Regional results  
6 depended on whether the climate zone was already cool or warmer. For example, in  
7 Boston the net impacts varied from a 9% to 12% decrease in energy use (12% to 16%  
8 decrease in space conditioning), while in Miami there was a 29% to 58% with the space  
9 conditioning increase from 46% to 92%. Across the different building vintages, the  
10 impact was most adverse in current houses ( 2% to 11% increases of total, 2% to 18% of  
11 space conditioning for 90's vintage houses) and less so in older houses ( -1% to 6%  
12 increases of total, -1% to 10% of space-conditioning).

13

### 14 **2.3.2 Commercial Buildings and Equipment**

15

16 Impacts in the commercial sector are similar to those in the residential sector. Belzer, et  
17 al. (1996) used a detailed data set on U.S. commercial buildings, and calculated the effect  
18 of building characteristics and temperature on energy consumption in all U.S.

19 commercial buildings. With building equipment and shell efficiencies frozen at 1990  
20 baseline levels, a 3.9° C temperature change decreased annual space heating energy  
21 requirements by 29% to 35%, or about 7.4% to 9.0% per degree C, a set of percentage  
22 increases that was not affected by either expected changes in the commercial building  
23 stock projected by the EIA, or by an “advanced” building envelope. Mansur et al. (2005)  
24 estimated that a 1° C increase in January temperatures would produce a reduction in  
25 electricity consumption of 3% for electricity. The marginal effect also reduces gas  
26 consumption by 3% and oil demand by a sizeable 12% per degree C. Huang (2006)  
27 made computer simulations of a set of 180 prototypical commercial buildings in five US  
28 climates for four IPCC carbon scenarios in 2080. Similar to the study’s residential  
29 findings, these showed that the impact of carbon change on commercial building energy  
30 use varies greatly depending on climate and building type. For the entire US commercial  
31 sector, the simulations showed an increase in energy use from 2% to 5%. While this may

1 seem small, it represents from 4% to 13% increase in space conditioning energy use. At  
2 the regional level, the impacts vary from a 0% to 2% decrease in energy use (0% to 5%  
3 decrease in space conditioning) in a cold climate such as Minneapolis, to as much as 8%  
4 to 16% increase in a hot climate such as Houston, where the space conditioning may  
5 increase from 22% to 43%). Among building types, the most adversely affected were  
6 supermarkets ( 7% to 15% increases of total energy use, 21% to 43% increase of space  
7 conditioning energy use) and hotels ( 4.4% to 8.9% increases of total energy use, 14% to  
8 29% of space-conditioning energy use). The least affected were schools (6% decrease of  
9 total energy use 11% decrease of space-conditioning energy use) and warehouses (2%  
10 decrease of total, 7% decrease of space-conditioning energy use). The reason for these  
11 decreases was the minimal amount of air-conditioning in schools and warehouses,  
12 meaning that the impact was mostly energy savings due to reduced heating. There is also  
13 an interesting energy reduction for service hot water in this study, with the simulations  
14 showing from 5-15% reductions in all climates due to increased inlet water temperature.

15

## 16 **2.4 EFFECTS ON ENERGY USE FOR SPACE COOLING AND** 17 **OTHER REFRIGERATION**

18

### 19 **2.4.1 Residential Buildings and Equipment**

20

21 According to all studies surveyed for this chapter, climate warming is expected to  
22 increase the demand for space cooling, which is provided entirely by electricity. The  
23 effect in most studies is somewhat but not entirely linear with respect to temperature and  
24 humidity, meaning that the impact in *percentage* terms increases as the temperature does.  
25 It also means that increases in cooling eventually would dominate decreases in heating as  
26 temperature rises, although that effect is not necessarily observed for the temperature  
27 increases expected in the United States during the 21<sup>st</sup> century. Electricity demand for  
28 increases roughly 5% to 15% per 1°C over the range of temperature increases projected  
29 in the studies surveyed. The impact on all electricity consumption is somewhat lower  
30 because electricity is used for a variety of non-climate-sensitive loads all regions and for  
31 space heating and water heating in some regions). Some initial work was done on energy

1 consequences of global warming by Loveland and Brown (1990) for the residential sector  
2 in a number of different locations across the country. Total energy consumption  
3 decreased by up to 22% or increased by up to 48%, for a temperature increase of 3.2°C to  
4 4°C, depending on whether the location was cold and therefore was dominated by saved  
5 heating energy, or was warm and therefore was dominated by increases in cooling. This  
6 implies about a 7% to 12% increase in cooling energy consumption per degree C.  
7 Similarly, based on a conditional consumption analysis with an econometric model,  
8 Similarly, Mansur et al. (2005) projected that when July temperatures were increased by  
9 1°C, electricity-only customers increased their electricity consumption by 5%, gas  
10 customers increased their demand for electricity by 6%, and oil customers bought 15%  
11 more electricity. Using a similar model in the special case of California, where space  
12 heating is dominated by space cooling, Mendelsohn (2003) found that total energy used  
13 for space cooling (electricity) increased non-linearly and net overall energy demand  
14 increases with a 1°C warming. In such mild cooling climates, relatively small increases in  
15 temperature can have a large impact on air-conditioning energy use by reducing the  
16 potentials for natural ventilation or night cooling. Looking specifically at residential  
17 sector cooling demand (rather than all electricity) in 2080 with a fixed building stock,  
18 Scott et al. (2005) projected nationally that an increase of 1.8° to 9.1° C summer  
19 temperatures results in a 29% to 155% increase in national annual cooling energy  
20 consumption, or roughly a 16% to 17% increase per degree C.

21

## 22 **2.4.2 Commercial/Industrial Buildings and Equipment**

23

24 Studies during the last five years generally confirm earlier work that showed a small net  
25 change in the demand for energy in buildings as a result of a 2°C average annual  
26 warming, but a significant increase in demand for electricity, mainly for space cooling  
27 (Sailor and Muñoz, 1997; Morrison and Mendelsohn, 1999; Mendelsohn, 2001; Sailor,  
28 2001; Sailor and Pavlova, 2003). Most of these studies do not directly account for  
29 improvements in energy efficiency or changes in per capita building space over time.  
30 EIA (2006) projects an increase in building residential floorspace per household of 14%  
31 during the period 2003-2030 and the ratio of commercial floorspace per member of the

1 U.S. labor force to increase by 23% in the same period. These effects are not captured by  
2 the cross-sectional econometric studies.

3 With a cross-sectional market of commercial energy demand and with building  
4 equipment and shell efficiencies frozen at 1990 baseline levels, Belzer et al. (1996) found  
5 that a 3.9°C temperature change decreased annual space heating energy requirements by  
6 53.9% or about 9.0% to 13.8% per degree C, a set of percentage increases that was not  
7 affected by either expected changes in the commercial building stock projected by the  
8 EIA, or by an “advanced” building envelope.

9

### 10 **2.4.3 Penetration of Air Conditioning, Heat Pumps (All-Electric** 11 **Heating and Cooling) and Changes in Humidity**

12

13 Although the effects of air conditioning market penetration were not explicitly identified,  
14 the late-1990s econometrically based cross sectional studies of Mendelsohn and  
15 colleagues might be argued to account for increased long run market saturations of air  
16 conditioning. (This is because warmer locations in the cross sectional studies also have  
17 higher market saturations of air conditioning as well as higher usage rates.) However,  
18 more recent studies have examined the effects directly. In one example, Sailor and  
19 Pavlova (2003) have found that potential increases in market penetration of air  
20 conditioning in response to warming might have an effect several times larger on  
21 electricity consumption than the warming itself. Using cross-sectional data and  
22 econometric techniques Mendelsohn (2003) and Mansur et al. (2005) also have estimated  
23 the effects of the market penetration of space cooling into the energy market. They also  
24 speculate that warmer climates are more likely to feature all-electric heating and cooling  
25 systems, which are a natural market for heat pumps. In general, however, the effects of  
26 adaptive response in energy demand have not been studied in the United States.

27

28 High atmospheric humidity is known to have an adverse effect on the efficiency of  
29 cooling systems in buildings in the context of climate change because of the energy  
30 penalty associated with condensing water. This was demonstrated for a small  
31 commercial building modeled with the DOE-2 building energy simulation model in Scott

1 et al. (1994), where the impact of an identical temperature increase created a much  
2 greater energy challenge for two relatively humid locations (Minneapolis and  
3 Shreveport), compared with two drier locations (Seattle and Phoenix). Mansur et al.  
4 (2005) modeled the effect of high humidity by introducing a rainfall variable into their  
5 cross-sectional equations. In their residential sector, a one-inch increase in monthly  
6 precipitation resulted in more consumption by gas users of both electricity (7%) and of  
7 gas (2%). In their commercial sector, a one-inch increase in January and July  
8 precipitation resulted in more consumption of gas (6%) and of oil (40%).  
9

## 10 **2.5 OVERALL EFFECTS OF CLIMATE CHANGE ON ENERGY** 11 **USE IN BUILDINGS** 12

### 13 **2.5.1 Annual Consumption** 14

15 Many of the U.S. studies of the impact of climate change on energy use in buildings deal  
16 with both heating and cooling and attempt to come to a “bottom line” net result for either  
17 total energy consumed or total primary energy consumed (that is, the amount of natural  
18 gas and fuel oil consumed directly in buildings and the amount of natural gas, fuel oil,  
19 and coal consumed to produce the electricity consumed in buildings.) All recent studies  
20 show similar net effects. Both net delivered and net primary energy consumption increase  
21 or decrease only a few percent; however, there is a robust result that, in the absence of  
22 conservation policy directed at space cooling, climate change would cause a significant  
23 increase in the demand for electricity in the United States, which would require the  
24 building of additional electric generation (and probably transmission facilities) worth  
25 many billions of dollars.  
26

27 In much of the United States, annual energy used for space heating dominates energy use  
28 for space cooling, so net energy consumption would be reduced by global warming.  
29 Table 2.1 summarizes the results from a number of U.S. studies of the effects of climate  
30 change on energy demand in U.S. residential and commercial buildings.  
31

3

**Table 2.1. Global Warming and Estimated Changes in Energy Demand in U.S. Residential and Commercial Buildings**

<b>Study: Author(s) and Date</b>	<b>Temperature Change (°C) and Date for Change</b>	<b>Change in Energy Consumption (%)</b>	<b>Type of Buildings and Fuel Experiencing Change</b>	<b>Cost (Savings) of Energy Consumption (\$Billion)</b>	<b>Improved Energy Efficiency Offset Evaluated?</b>	<b>Change in Energy Consumption from Efficiency Offset (%)</b>
Linder and Inglis (1989)	0.6°C to 1.6°C (2010) 3.4°C to 5.3°C (2055)	+8.8% to 19.6% +13.5% to 22.9% (capacity)	Electricity  Electricity	\$3.2 to \$6.1  \$33 to \$73	No  No	--
Loveland and Brown (1990)	3.2°C to 4.0°C (2xCO <sub>2</sub> , no date)	+10.2% to +35.0%  -22.0% to +48.1%	General office (space heating and cooling load)  Single family (space heating and cooling load)	--	Yes, -50% lighting, +50% insulation, +75% window shade	-34.4% to -50.2%  -31.5% to -44.4%
Scott, Hadley, and Wrench (1994)	3.9°C (7.0°F) (no date)	-8.0% to +6.3%, depending on location	Space heating and air conditioning (small office building in 4 cities)	--	Yes, state of technology building envelope, reduced internal loads	-51.8% to -63.8%
Rosenthal, et al. (1995)	1.8°C (2010)	-11%	Space heating and air conditioning	-\$5.5 (1991\$)	No	--
Scott, Belzer, and Sands (1996)	4°C (2030)	-13.1%	Site energy (commercial buildings only)	Not calculated	Yes, advanced building envelope	-4.5%
Sailor (2001)	3° C (sensitivity analysis: no year given)	-10.1 to +18.8% (R)  +0.1% to +8.0% (C)	Per capita residential and commercial electricity (8 states)	--	No	--
Ruth and Amato (2002)	2020 2050	-6.6% -13.9%	Heating Fuel Heating Fuel (Massachusetts)	--	No	--
Sailor and Pavlova (2003)	+20% in heating degree days (about 1°C to 2°C)	+1% to +9%	Total residential electricity with increased air conditioning market	--	No	--

1 Scott et al., (2005) projected that overall energy consumption in U.S. residential and  
2 commercial buildings is likely to decrease by about 5% in 2020 (0°C to 2.5°C warming)  
3 and as much as 20% in 2080 (for 3.5°C to 10°C warming) (11 GCMs, 8 scenarios), but  
4 would be accompanied by an increase of up to 25% in temperature-sensitive electricity  
5 consumption by 2080. This amounts to about 2% per 1°C warming. This is a “pure  
6 climate effect,” not allowing for changes in the building stock or increased market  
7 penetration of air conditioning that specifically result from climate change. Sailor also  
8 conducted this type of analysis for several categories of buildings and equipment (Sailor  
9 and Muñoz 1997, Sailor 2001, Sailor and Pavlova 2003). An overall per capita increase  
10 in residential and commercial electricity consumption of 5-15% for a 3°C average  
11 temperature increase summarizes individual state and regional results that are variable  
12 and sensitive to the specific climate scenario (Sailor, 2001), or about a 1.5% to 5%  
13 increase per 1°C warming. He found a temperature increase of 2°C is associated with an  
14 11.6% increase in residential per capita electricity used in Florida (a summer-peaking  
15 state dominated by air conditioning demand), 5% increase per 1°C warming, but a 7.2%  
16 decrease in Washington (which uses electricity extensively for heating and is a winter-  
17 peaking system), about a 3% decrease per 1°C warming.

18  
19 There are also a number of specific state-level studies with similar outcomes. For  
20 Massachusetts in 2020, Ruth and Amato (Ruth and Amato, 2002) projected a 6.6 %  
21 decline in annual heating fuel consumption (8.7% decrease in heating degree days—  
22 overall temperature change not given) and a 1.9% increase in summer electricity  
23 consumption (12% in annual cooling degree-days). Continuing their research (Amato et  
24 al. 2005), the team noted that per capita residential and commercial energy demand in  
25 Massachusetts are sensitive to temperature and that a range of scenarios of climate  
26 change may noticeably decrease winter heating fuel and electricity demands and increase  
27 summer electricity demands. For 2030, the estimated residential summer monthly  
28 electricity demand increases that averaged about 20% in the Canadian Climate Model  
29 climate scenarios and up to 40% in the Hadley Center model. Wintertime monthly  
30 natural gas demand declined by 10% to 20% in the Canadian Model scenarios and 10%  
31 to 15% in the Hadley model scenarios. Fuel oil demand was down about 20% to

1 30% in the Canadian Model scenarios and 15% to 20% in the Hadley model scenarios.  
2 For the commercial sector, electricity consumption rose about 6% in the Canadian  
3 Climate Model scenarios and up to 10% in the Hadley Center model scenarios. Winter  
4 natural gas demand declined by 7% to 14% and 6% to 8% in the respective scenarios.  
5  
6 One study that takes a somewhat different approach is Hadley et al. 2004, which  
7 translates temperatures from a single climate scenario of the Parallel Climate Model into  
8 changes in heating degree days (HDD) and cooling degree-days (CDD) population-  
9 averaged in each of the nine U.S. Census divisions (on a 65° F base –against the findings  
10 of Rosenthal et al., Belzer et al., and Mansur et al. 2005, all of which projected a lower  
11 balance point temperature for cooling and a variation in the balance point across the  
12 country). They then compared these values with 1971-2000 normal HDDs and CDDs  
13 from the National Climate Data Center for the same regions. The changes in HDD and  
14 CDD were then used to drive changes in a special version (DD-NEMS) of the National  
15 Energy Modeling System (NEMS) of the U.S. Energy Information Administration,  
16 generally used to provide official energy consumption forecasts for the *Annual Energy*  
17 *Outlook* (EIA 2006). Two advantages of this approach are that it provides a direct  
18 comparison at the regional level to official forecasts and that it provides a fairly complete  
19 picture of energy supply, demand, and endogenous price response in a market model.  
20 One disadvantage is that the DD-NEMS model only forecasted out to 2025 in their work  
21 (now, 2030), which is only on the earliest part of the period where climate change is  
22 expected to substantially affect energy demand. In this study, the regional results were  
23 broadly similar to those in Scott, *et al.* For example, they showed decreases in energy  
24 demand for heating, more than offsetting the increased demand for cooling in the north  
25 (New England, Mid-Atlantic, West North Central and especially East North Central  
26 Census Division). In the rest of the country, the increase in cooling was projected to  
27 dominate. Nationally, the *delivered* energy savings were shown to be greater than the  
28 delivered energy increases, but because of energy losses in electricity generation, primary  
29 energy consumption increased by about 3% by 2025, driving up the demand for coal and  
30 driving down the demand for natural gas. Also, because electricity costs more than gas

1 per delivered Btu, the increase in total energy cost per year was found to be about \$15  
2 billion (2001 dollars).

### 4 ***2.5.2 Peak Consumption***

6 Studies published to date agree that temperature increases with global warming would  
7 increase peak demand for electricity in most regions of the country, but the amount of the  
8 increase varies with the region or regions covered and the study methodology—in  
9 particular, whether the study allows for changes in the building stock and increased  
10 market penetration of air conditioning in response to warmer conditions. One of the few  
11 early studies of the effects of climate change on regional electricity was conducted by  
12 Baxter and Calandri (1992), using very detailed data and electricity demand forecasting  
13 models of the California Energy Commission. Under their worst case in 1990 to 2010, a  
14 1.9°C (3.4°F) increase in mean statewide temperature, the state would have required an  
15 additional peak capacity of 2,400 megawatts (MW), representing an increase of 3.7% in  
16 peak generation capacity from their 2010 base case. Uncertainties in the state’s economic  
17 growth rate would have had comparable or larger impacts on electricity demand over this  
18 20-year projected estimation.

20 Much more recently, using IPCC scenarios of climate change from the Hadley3, PCM,  
21 and GFDL climate models downscaled for California, Franco and Sanstad (2006) found  
22 high correlation between the simple average daily temperature and daily peak electricity  
23 demand in the California Independent System Operator region, which comprises most of  
24 California. They evaluated three different periods: 2005-2034, 2035-2064, and 2070-  
25 2099. In the first period, depending on the scenario and model, peak summer demand  
26 was projected to increase 1.0%-4.8%; in the second, 2.2%-10.9%; in the third, 5.6%-  
27 19.5%.

29 Some U.S. regions could benefit from lower winter demand for energy in Canada. In  
30 Québec, the Ouranos organization (Ouranos 2004) estimated that net energy demand for  
31 heating and air conditioning across all sectors could fall by 32 PJ, or 9.4 % of 2001 levels

1 by 2100 (CGCM IS92a). Seasonality of demand also would change markedly.  
2 Residential heating in Québec would fall by 15% and air conditioning would increase  
3 nearly four-fold. Commercial-institutional heating demand falls by 13% and air  
4 conditioning demand doubles. Peak (winter) electricity demand in Québec would decline.  
5 Since much of the space heating in Québec is provided by hydro-generated electricity, the  
6 decline in energy demand in the province could free up a certain amount of capacity for  
7 bordering U.S. regions in the winter. Unfortunately, Québec's summer increase in air  
8 conditioning demand would coincide with an increase of about 7% to 17% in the New  
9 York metropolitan region (Ouranos 2004), so winter savings might be only of limited  
10 assistance in the summer cooling season, unless the water not used for hydroelectric  
11 production in the winter could be stored until summer and the transmission capacity  
12 existed to move the power south (Québec's hydroelectric generating capacity is sized for  
13 the winter peak and should not be a constraint).

14

15 Scott et al. (2005) did not directly estimate effects of climate change on peak electricity  
16 demand; however, using nuclear power's 90% average capacity factor for 2004 as an  
17 upper bound estimate of baseload power plant availability, they projected that national  
18 climate sensitive demand consumption (1.4 exajoules per year by 2080) would be  
19 equivalent of roughly 48 GW, or 48 baseload power plants of 1,000 MW each. At the  
20 much lower 2003 average U.S. generation/capacity ratio of 47%, 93 GW of additional  
21 generation capacity would be required. This component of demand would be a factor in  
22 addition to any increases due to additional climate-related market penetration of air  
23 conditioning and any other causes of increased demand for electricity the national  
24 electrical system will be dealing with for the rest of the century.

25

## 26 **2.6 ADAPTATION: INCREASED EFFICIENCY AND URBAN** 27 **FORM**

28

29 Although improving building energy efficiency should help the nation cope with impacts  
30 of climate change, there is relatively little specific empirical information available on the  
31 potential impacts of such improvements. Partly this is because it has been thought that

1 warming would already be reducing energy consumption, so that the additional effects of  
2 energy efficiency have not been of much interest. Scott et al. (1994) and Belzer et al.  
3 (1996) concluded that in the commercial sector, very advanced building designs could  
4 increase the savings in heating energy due to climate warming alone. Loveland and  
5 Brown (1990), Scott, et al. (1994), and Belzer, et al. (1996) all estimated the effects of  
6 energy-efficient buildings on energy consumption in the context of climate change and  
7 also concluded that much of the increase in energy consumption due to warming could be  
8 offset by increased energy efficiency. Loveland and Brown (1990) projected that  
9 changes leading to -50% lighting, +50% insulation, +75% window shading would reduce  
10 total energy use in residential buildings by 31.5% to -44.4% in the context of a 3.2° to  
11 4°C warming. Scott et al. (1994) examined the impact of “advanced” building designs  
12 for a 48,000 square foot office building in the context of climate change in the DOE-2  
13 building energy simulation model. The building envelope was assumed to reduce heat  
14 transfer by about 70% compared to the ASHRAE 90.1 standard. It included extra  
15 insulation in the walls and ceiling, reduction in window conductivity by a factor of 6, and  
16 window shading devices. The result was that at a 3.9°C increase in annual average  
17 temperature, an advanced design building, instead of experiencing between an 8%  
18 savings in energy use (Minneapolis) and a 6.3% increase in overall energy use (Phoenix),  
19 would experience a 57.2% to 59.8% decrease in energy used. In addition, the cooling  
20 energy impact was reversed in sign—a 47% to 60% decrease instead of a 35% to 93%  
21 increase. Belzer et al. (1996) projected that with a 3.9°C increase in annual average  
22 temperature, the use of advanced buildings would increase the overall energy savings in  
23 EIA’s year 2030 projected commercial building stock from 0.47 QBtu (20.4%) to 0.63  
24 QBtu (27%). Use of advanced building designs in the 2030 commercial building stock  
25 would increase the overall energy savings by 1.15 QBtu (40.6%) relative to a 2030  
26 building stock frozen at 1990 efficiency. The cooling component of building energy  
27 consumption was only reduced rather than reversed by advanced designs in this study.  
28 Finally, Scott et al. (2005) explicitly considered the savings that might be achieved under  
29 the Department of Energy’s energy efficiency programs as projected in August 2004 for  
30 the EIA building stock in the year 2020 (temperature changes of about 0.4°C at the low  
31 end to about 2.8°C at the high end). This is the only study to have estimated the national

1 effects of actual energy efficiency programs in the context of global warming. (The  
2 analysis did not count any potential increase in energy demand due to additional climate  
3 change-induced market penetration of air conditioning). The efficiency programs were  
4 less effective if the climate did not change; however, buildings still saved between 2.0  
5 and 2.2 QBtu. This was a savings of about 4.5%, which would more than offset the  
6 growth in temperature-sensitive energy consumption due to increases in cooling and  
7 growth in building between 2005 and 2020.

8  
9 Except for Scott et al. (2005), even where studies purport to address adaptive response  
10 (e.g., Loveland and Brown 1990; Belzer et al. 1996; Mendelsohn 2001), they generally  
11 do not involve particular combinations of technologies to offset the effects of future  
12 climate warming. Regionally, Franco and Sanstad (2006) did note that the very  
13 aggressive energy efficiency and demand response targets for California’s investor-  
14 owned utilities such as those recently enacted by the California Public Utilities  
15 Commission could, if extended beyond the current 2013 horizon, provide substantial  
16 “cushioning” of the electric power system against the effects of higher temperatures.

## 18 **2.7 OTHER POSSIBLE EFFECTS, INCLUDING ENERGY USE IN** 19 **KEY SECTORS**

20  
21 With a few exceptions, it is not thought that industrial energy demand is particularly  
22 sensitive to climate change. For example, Amato et al. (2005) stated that “industrial  
23 energy demand is not estimated since previous investigations (Elkhafif, 1996; Sailor and  
24 Munoz, 1997) and our own findings indicate that it is non-temperature-sensitive.” A  
25 small number of studies have focused on other climate-sensitive industrial uses of energy  
26 such as agricultural crop drying and irrigation pumping (e.g., Darmstadter 1993; Scott et  
27 al. 1993). While it seems logical that warmer weather or extended warm seasons should  
28 result in warmer water inlet temperatures for industrial processes and higher rates of  
29 evaporation, possibly requiring additional industrial diversions, as well as additional  
30 municipal uses for lawns and gardens, the literature review conducted for this chapter did  
31 not locate any literature either laying out that logic or calculating any associated increases

1 in energy consumption for water pumping. Such increases are likely to be small relative  
2 to those in agriculture, which consumes the lion's share (40%) of fresh water withdrawals  
3 in the United States (USGS, 2004). Some observations on energy use in climate-  
4 sensitive economic sectors follow.

### 6 **2.7.1 Transportation**

7  
8 Running the air conditioning in a car reduces its fuel efficiency by approximately 12% at  
9 highway speeds (Parker 2005). A more extended hot season likely would both increase  
10 the percentage of vehicles sold with air conditioning and would increase their use. No  
11 data appear to be available on the total impact of climate change on energy consumption  
12 in automotive air conditioners, however.

13  
14 Much of the food consumed in the United States moves by refrigerated truck or rail. One  
15 of the most common methods is via a refrigerated truck-trailer combination. As of the  
16 year 2000, there were approximately 225,000 refrigerated trailers registered in the United  
17 States, and their Trailer Refrigeration Units (TRUs) used on average 0.7 to 0.9 gallons of  
18 fuel per hour to maintain 0°F. On a typical use cycle of 7200 hours per year (6 days per  
19 week, 50 weeks per year), the typical TRU would use 5,000 to 6,000 gallons of diesel per  
20 year (Shurepower, LLC 2005), or between 26 and 32 million barrels for the national fleet.  
21 Even though diesel electric hybrid and other methods are making market inroads and  
22 over time could replace a substantial amount of this diesel use with electricity from the  
23 grid when the units are parked, climate warming would add to the energy use in these  
24 systems. No data appear to be available on the total impact of climate change on energy  
25 consumption, however

26

## 1 **2.7.2 Construction**

2  
3 Warming the climate should result in more days when outdoor construction activities are  
4 possible. In many parts of the northern states, the construction industry takes advantage  
5 of the best construction weather to conduct activities such as some excavation, pouring  
6 concrete, framing buildings, roofing, and painting, while sometimes enclosing buildings,  
7 partially heating them with portable space heaters, and conducting inside finishing work  
8 during “bad” weather. The literature survey conducted for this chapter was not able to  
9 locate any studies in the United States that have investigated either the lengthening of the  
10 construction season in response to global warming or any resulting impacts on energy  
11 consumption.

## 12 13 **2.7.3 Agriculture**

14  
15 Agricultural energy use generally falls into five main categories: equipment operations,  
16 irrigation pumping, embodied energy in fertilizers and chemicals, product transport, and  
17 drying and processing. A warmer climate implies increases in the demand for water in  
18 irrigated agriculture and use of energy (either natural gas or electricity) for pumping.  
19 Though not a factor in many parts of the country, irrigation energy is a significant source  
20 of energy demand west of the 100<sup>th</sup> meridian, especially in the Pacific Southwest and  
21 Pacific Northwest. For example, irrigation load in one early climate change impact  
22 assessment increased from about 8.7% to about 9.8% of all Pacific Northwest electricity  
23 load in July (Scott et al. 1993), even with no change in acreage irrigated.

24  
25 In some parts of the country, the current practice is to keep livestock and poultry inside  
26 for parts of the year, either because it is too cold or too hot outside. Often these facilities  
27 are space-conditioned. In Georgia, for example, there are 11,000 poultry houses, and  
28 many of the existing houses are air-conditioned due to the hot summer climate (and all  
29 new ones are) (University of Georgia and Fort Valley State University 2005). Poultry  
30 producers throughout the South also depend on natural gas and propane as sources of heat  
31 to keep their birds warm during the winter (Subcommittee on Conservation, Credit, Rural

1 Development, and Research 2001). The demand for cooling livestock and poultry would  
2 be expected to increase in a warmer climate, while that for heating should fall.

3  
4 Food processing needs extensive refrigerated storage, which may take more energy in a  
5 warmer climate. However, there seem to be no U.S. studies on this subject.

## 7 **2.8 CONCLUSIONS AND ISSUES FOR RESEARCH**

8  
9 Generally speaking, the net effects of climate change in the United States on total energy  
10 demand are projected to be modest, amounting to between perhaps a 5% increase and  
11 decrease in demand per 1°C in warming in buildings, about 1.1 Quads in 2020 based on  
12 EIA 2006 projections (EIA, 2006). Existing studies do not agree on whether there would  
13 be an increase or decrease in energy consumption with changed climate because a variety  
14 of methodologies have been used, which has taken into account all of the potential effects  
15 of warming. There are differences in climate sensitivities, differences in methodological  
16 emphasis (econometric models have incorporated some market response to warming and  
17 fuel costs but not differences in building size and technology over time and space, while  
18 the opposite is true of building simulation approaches), as well as differences in climate  
19 and market scenarios. Studies of the effects of climate change on energy use outside of  
20 buildings are so rare that there is almost no set of studies to reconcile. It appears likely  
21 that some of the largest effects of climate change on energy use are in buildings,  
22 however, with other sensitivities being of secondary or tertiary importance.

- 23  
24 • Can differences between studies be reconciled? To some extent, it is possible to  
25 control for differences in climate scenarios by comparing percentage changes in  
26 energy use per a standardized amount of temperature change, as has been done in  
27 this chapter. It is also possible to search for a set of robust results and to compare  
28 impacts, for example, that come from models that have fixed technologies and no  
29 market responses with those that allow technology to evolve and businesses and  
30 individuals to respond to higher or lower energy bills.

- 1 • If effects cannot be reconciled, which results are more likely to be correct?  
2 Because of compensating market and technological responses, impacts of climate  
3 change should be less with models that allow technology to evolve and businesses  
4 and individuals to respond to higher or lower energy bills. Because they also  
5 assess more realistically the factors actually likely to be in play, they are likelier  
6 to be closer to correct. None of the models actually does all of this, but Mansur et  
7 al. (2005) probably comes the closest on the market side and Scott et al. (2005) on  
8 the technology side. Using the results from these two approaches, together with  
9 Sailor and Pavlova (2003) to inform and modify the Hadley et al. (2004) special  
10 version of NEMS probably has the best chance of being correct for buildings.  
11
- 12 • What are the impacts of climate and other major market drivers such as  
13 demographic shifts when taken together? One implication of the geographic shift  
14 of population in the United States from the north and east to the south and west is  
15 that air conditioning (space cooling) in residential and commercial buildings  
16 becomes a larger overall fraction of total national energy demand. Second,  
17 increased wealth of the population has caused increased market penetration of air  
18 conditioning and increased summer electrical demand everywhere in the nation.  
19 Recent literature has identified a strong relationship between cooling degree days  
20 and market saturation of air conditioning using an exponential saturation function  
21 (Sailor and Pavlova 2003), but the effect of increasing wealth has not been  
22 investigated, and has not been combined with demographic shifts. These factors  
23 are expected to substantially shift demand for building energy from winter heating  
24 load, provided primarily by natural gas, to summer electrical load provided by  
25 coal, nuclear, and natural gas resources. This shift from winter to summer places  
26 additional strain on regional electrical generation, transmission, and distribution  
27 systems, produces an unknown effect on the volatility of natural gas demand  
28 (possibly a reduction in season-to season variation, since winter heating demand  
29 currently dominates and would decline), and decreases the overall efficiency with  
30 which natural gas is consumed.  
31

- 1 • What surprises might we expect from entirely missing effects and sectors?  
2 Agriculture is probably the sector most likely to supply surprises. Large amounts  
3 of energy are currently expended in agriculture to provide water for irrigation and  
4 for tilling, planting and pest control (e.g. aerial spraying of crops). There is major  
5 uncertainty concerning the future locations, timing, and amounts of precipitation  
6 that can be expected. Unexpectedly high demand for irrigation or pest control in  
7 currently rain-fed crop growing regions could greatly stress both water and energy  
8 supplies.

9 David K. Schmalzer, Argonne National Laboratory

10  
11  
12 Energy production in the U.S. is dominated by fossil fuels: coal, natural gas, and  
13 petroleum (Fig. 3.1). Every existing source of energy has some vulnerability to climate  
14 variability (Table 3-1). Renewable energy sources tend to be more sensitive to climate  
15 variables; but fossil energy production can also be adversely effected by air and water  
16 temperatures and the thermoelectric cooling process that is critical to maintaining high  
17 energy efficiencies and nuclear energy requires cooling as well. In addition, extreme  
18 weather events have adverse effects on energy production, distribution, and fuel  
19 transportation as well.

20  
21 This section discusses the specific impacts on energy production and distribution  
22 associated with projected changes in temperature, precipitation, water resources, severe  
23 weather events, and sea level rise. Overall, the effects on the existing infrastructure  
24 might be categorized as modest; however, local and industry-specific impacts could be  
25 large, especially in areas that may be prone to disproportional warming (Alaska) or  
26 weather disruptions (Gulf Coast). The existing assemblage of power plants and  
27 distribution systems is likely to be more affected by ongoing unidirectional changes,  
28 compared with future systems, if future systems can be designed with the upfront  
29 flexibility to accommodate the span of potential impacts. Possible adaptation measures  
30 include technologies that minimize the impact of increases in ambient temperatures on  
31 power plant equipment, technologies that conserve water use for power plant cooling  
32 processes, planning at the local and regional level to anticipate storm and drought impacts  
33 and establish action plans, and policies that conserve both energy and water.

### 3.1 EFFECTS ON FOSSIL AND NUCLEAR ENERGY

Climate change can affect fossil and nuclear energy production, conversion, and end-user delivery in a myriad of ways. Average ambient temperatures impact heating and cooling demand, generation cycle efficiency, and cooling water requirements in the electrical sector, water requirements for energy production and refining, and Gulf of Mexico (GOM) produced water discharge requirements. Often these impacts appear “small” based on the change in system efficiency or the potential reduction in reliability but the scale of the energy industry is vast: fossil fuel-based net electricity generation exceeded 2,500 billion kWh in 2004 (EIA, 2006). A net reduction in generation of 1% due to

7  
8  
9

1 increased ambient temperature (Maulbetsch and DiFilippo, 2006) represents a drop in  
2 supply of 25 billion kWh that might need to be replaced somehow. The GOM  
3 temperature-related issue is a result of the formation of water temperature-related anoxic  
4 zones and is important because that region accounts for 20 to 30 percent of the total  
5 domestic oil and gas production in the U.S. (Figure 3.2). Constraints on produced water  
6 discharges can increase costs and reduce production, both in the GOM region and  
7 elsewhere. Impacts of extreme weather events could range from localized railroad track  
8 distortions due to temperature extremes, to regional-scale coastal flooding from  
9 hurricanes, and to watershed-scale river flow excursions from weather variations  
10 superimposed upon, or possibly augmented by, climate change. Spatial scale can range  
11 from kilometers to continent-scale; temporal scale can range from hours to multi-year.  
12 Energy impacts of episodic events can linger for months or years as illustrated by the  
13 continuing loss of oil and gas production in the GOM (MMS, 2006a, 2006b, and 2006c)  
14 eight months after the 2005 hurricanes.

15

### 16 **3.1.1 Thermoelectric Power Generation**

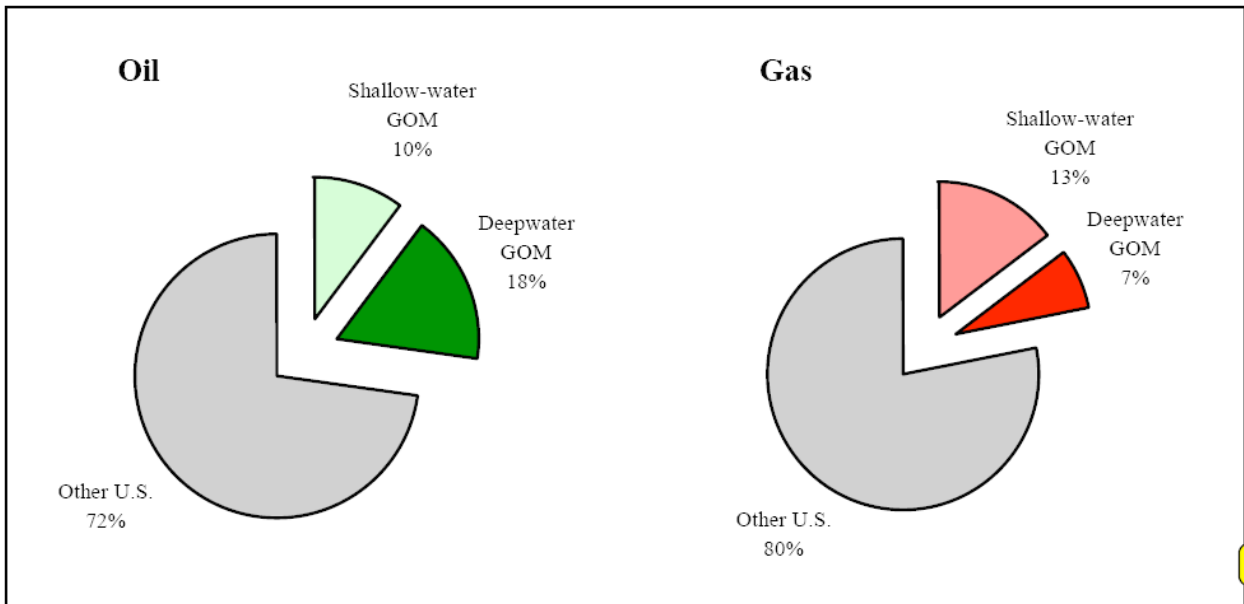

17

18 Climate change impacts on electricity generation at fossil and nuclear power plants are  
19 likely to be similar. The most direct climate impacts are related to power plant cooling  
20 and water availability.

21

22 Predicted changes in water availability throughout the world would directly affect the  
23 availability of water to existing power plants. While there is uncertainty in the nature  
24 and amount of the change in water availability in specific locations, there is agreement  
25 among climate models that there will be a redistribution of water, as well as changes in  
26 the availability by season. As currently designed, power plants require significant  
27 amounts of water and they will be vulnerable to fluctuations in water supply. Regional-  
28 scale changes would likely mean that some areas could see significant increases in water  
29 availability while other regions could see significant decreases. In those areas seeing a  
30 decline, the impact on power plant availability or even siting of new capacity could be

31

 4 MMS 2006-022).

5

6

7 **Figure 3.2. Distribution of off-shore oil and gas wells in the Gulf of Mexico (GOM)**  
 8 **and elsewhere in the U.S.**

9

10

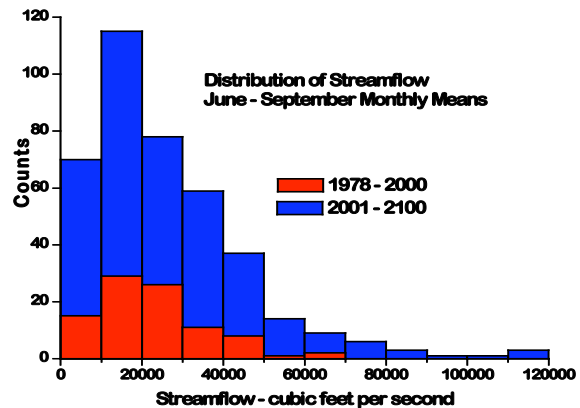

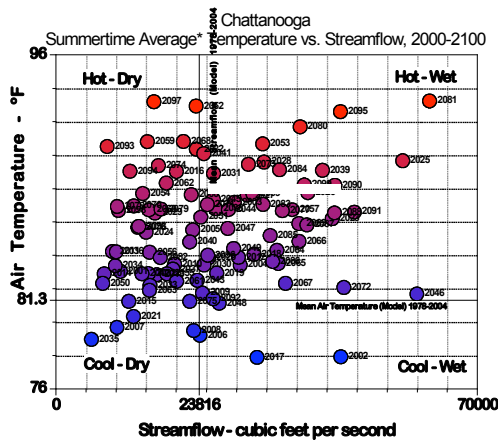

11 significant. Plant designs are flexible and new technologies for water reuse, heat  
 12 rejection, and use of alternative water sources are being developed but at present, some  
 13 impact—significant on a local level—can be foreseen. An example of such a potential  
 14 local effect is provided in Box 3.1—Chattanooga: A Case Study, which shows how  
 15 cooling conditions might evolve over the 21<sup>st</sup> century for generation in one locality.  
 16 Situations where the development of new power plants is being slowed down or halted  
 17 due inadequate cooling water are becoming more frequent throughout the U.S. (SNL,  
 18 2006).

19

20 In those areas seeing an increase in stream flows and rainfall, impacts on groundwater  
 21 levels and on seasonal flooding could have a different set of impacts. For existing plants,  
 22 these impacts could include increased costs to manage on-site drainage and run-off,  
 23 changes in coal handling due to increased moisture content or additional energy

### BOX 3.1. CHATTANOOGA: A CASE STUDY OF COOLING EFFECTS

A preliminary analysis of one IPCC climate change scenario (A1B) indicates one example of how cooling conditions might evolve over the 21st century for generation in the Chattanooga vicinity (ORNL work in progress). In this example, a slight upward trend in stream flow would provide a marginal benefit for once-through cooling, but would be offset by increasing summertime air temperatures that trigger limits on cooling water intake and downstream mixed temperatures. Closed-cycle cooling would also become less effective as ambient temperature and humidity increased. Utilities would need to maintain generation capacity by upgrading existing cooling systems or shifting generation to newer facilities with more cooling capacity. Without technology-based improvements in cooling system energy efficiency or steam-cycle efficiency, overall thermoelectric generation efficiency would decrease

1  
2 requirements for coal drying, etc. The following excerpt details the magnitude of the  
3 intersection between energy production and water use.  
4  
5 An October 2005 report produced by the National Energy Technology Laboratory stated,  
6 in part, that the production of energy from fossil fuels (coal, oil, and natural gas) is  
7 inextricably linked to the availability of adequate and sustainable supplies of water.  
8 While providing the United States with a majority of its annual energy needs, fossil fuels  
9 also place a high demand on the Nation's water resources in terms of both use and quality  
10 impacts (EIA, 2005d). Thermoelectric generation is water intensive – on average each

1 kWh of electricity generated via the steam cycle requires approximately 25 gallons of  
2 water (This number is a weighted average that captures total thermoelectric water  
3 withdrawals and generation for both once-through and recirculating cooling systems) to  
4 produce. According to the United States Geological Survey (USGS), power plants rank  
5 only slightly behind irrigation in terms of freshwater withdrawals in the United States  
6 (USGS, 2004), although irrigation withdrawals tend to be more consumptive). Water is  
7 also required in the mining, processing, and transportation of coal to generate electricity  
8 all of which can have direct impacts on water quality. Surface and underground coal  
9 mining can result in acidic, metal-laden water that must be treated before it can be  
10 discharged to nearby rivers and streams. In addition, the USGS estimates that in 2000 the  
11 mining industry withdrew approximately 2 billion gallons per day of freshwater.  
12 Although not directly related to water quality, about 10% of total U.S. coal shipments  
13 were delivered by barge in 2003 (USGS, 2004). Consequently, low river flows can  
14 create shortfalls in coal inventories at power plants.

15  
16 Freshwater availability is also a critical limiting factor in economic development and  
17 sustainability and directly impacts electric-power supply. A 2003 study conducted by the  
18 Government Accountability Office indicates that 36 states anticipate water shortages in  
19 the next ten years under normal water conditions, and 46 states expect water shortages  
20 under drought conditions (GAO, 2003). Water supply and demand estimates by the  
21 Electric Power Research Institute (EPRI) for the years 1995 and 2025 also indicate a high  
22 likelihood of local and regional water shortages in the United States (EPRI 2003). The  
23 area that is expected to face the most serious water constraints is the arid southwestern  
24 United States.

25  
26 In any event, the demand for water for thermoelectric generation will increasingly  
27 compete with demands from other sectors of the economy such as agriculture, domestic,  
28 commercial, industrial, mining, and in-stream use. EPRI projects the potential for future  
29 constraints on thermoelectric power in 2025 for Arizona, Utah, Texas, Louisiana,  
30 Georgia, Alabama, Florida, and all of the Pacific Coast states. Competition over water in  
31 the western United States, including water needed for power plants, led to a 2003

1 Department of Interior initiative to predict, prevent, and alleviate water-supply conflicts  
2 (DOI, 2003). Other areas of the United States are also susceptible to freshwater shortages  
3 as a result of drought conditions, growing populations, and increasing demand.  
4

5 Concern about water supply expressed by state regulators, local decision-makers, and the  
6 general public is already impacting power projects across the United States. For example,  
7 Arizona recently rejected permitting for a proposed power plant because of concerns  
8 about how much water it would withdraw from a local aquifer (Land Letter, 2004). An  
9 existing Entergy plant located in New York is being required to install a closed-cycle  
10 cooling water system to prevent fish deaths resulting from operation of its once-through  
11 cooling water system (Greenwire, 2003). Water availability has also been identified by  
12 several Southern States Energy Board member states as a key factor in the permitting  
13 process for new merchant power plants (Clean Air Task Force, 2004). In early 2005,  
14 Governor Mike Rounds of South Dakota called for a summit to discuss drought-induced  
15 low flows on the Missouri River and the impacts on irrigation, drinking-water systems,  
16 and power plants (Billingsgazette.com 2005). Residents of Washoe County, Nevada  
17 expressed opposition to a proposed coal-fired power plant in light of concerns about how  
18 much water the plant would use (Reno-Gazette Journal 2005). Another coal-fired power  
19 plant to be built in Wisconsin on Lake Michigan has been under attack from  
20 environmental groups because of potential effects of the facility's cooling-water-intake  
21 structures on the Lake's aquatic life (Milwaukee Journal Sentinel, 2005).  
22

23 Such events point towards a likely future of increased conflicts and competition for the  
24 water the power industry will need to operate their thermoelectric generation capacity.  
25 These conflicts will be national in scope, but regionally driven. It is likely that power  
26 plants in the west will be confronted with issues related to water rights, that is, who owns  
27 the water and the impacts of chronic and sporadic drought. In the east, current and future  
28 environmental requirements, such as the Clean Water Act's intake structure regulation,  
29 could be the most significant impediment to securing sufficient water, although local  
30 drought conditions can also impact water availability. If changing climatic conditions

1 affect historical patterns of precipitation, this may further complicate operations of  
2 existing plants, and the design and site selection of new units.

3  
4 EIA reports (EIA, 2004) net summer and winter capacity for existing generating capacity  
5 by fuel source. Coal-fired and nuclear have summer/winter ratios of 0.99 and 0.98 and  
6 average plant sizes of 220 MW and 1015 MW respectively. Petroleum, natural gas and  
7 dual fuel-fired plants show summer/winter net capacity ratios of 0.90 to 0.93, indicating  
8 higher sensitivity to ambient temperature while average plant sizes range from 12 MW to  
9 84 MW. Although large coal and nuclear generating plants report little degradation of  
10 net generating capacity from winter to summer conditions, there are reports (University  
11 of Missouri-Columbia, 2004) of plant derating and shutdowns caused by temperature-  
12 related river water level changes and thermal limits on water discharges. Actual  
13 generation in 2004 (EIA, 2004) show coal-fired units with 32% of installed capacity  
14 provided 49.8% of generation and nuclear units with 10% of installed capacity provided  
15 17.8% of power generated, indicating that these sources are much more heavily  
16 dispatched than are petroleum, natural gas and dual-fired sources. To date, this difference  
17 has been generally attributed to the lower variable costs of coal and nuclear generation,  
18 driven by fuel costs rather than temperature-related capacity constraints.

19  
20 Gas turbines, in their varied configurations, provide about 20 % of the electric power  
21 produce in the U.S. (EIA, 2006). Gas turbines in natural gas simple cycle, combined  
22 cycle (gas and steam turbine) and coal based integrated gasification combined cycle  
23 applications are effected by local ambient conditions. These conditions include for the  
24 most part local ambient temperature and pressure. Ambient temperature and pressure  
25 conditions have an immediate impact on gas turbine performance. Turbine performance  
26 is measured in terms of heat rate (efficiency) and power output. A 60 - 120°F change (60  
27 °F) in ambient temperature would have a 1-2 percentage point reduction in efficiency and  
28 a 20-25% reduction in power output (Davcock, DesJardins, and Fennell, 2004). This  
29 impact is nearly linear, so a 10 degree Fahrenheit change would produce as much as a 0.5  
30 percentage point reduction in efficiency and a 3-4% reduction in power output.  
31 Therefore, the impact of potential climate change on the fleet of existing turbines would

1 be driven by the impact that small changes in overall performance would have on both  
2 the total capacity available at any time and the actual cost of electricity.

3  
4 Turbines for NGCC and IGCC facilities are designed to run 24 hours, seven days a week  
5 but simple cycle turbines used in topping and intermediate service are designed for  
6 frequent startups and rapid ramp rates to accommodate grid dispatch requirements. Local  
7 ambient temperature conditions will normally vary by 10 – 20 °F on a 24 hour cycle and  
8 many temperate-zone areas have winter-summer swings in average ambient temperature  
9 of 25 – 35 F. Consequently, any long term climate change that would impact ambient  
10 temperature is believed to be on a scale within the design envelope of currently deployed  
11 turbines. As noted earlier, both turbine power output and efficiency vary with ambient  
12 temperature deviation from the design point. The primary impacts of longer periods of  
13 off-design operation will be modestly reduced capacity and reduced efficiency. Currently  
14 turbine-based power plants are deployed around the world in a wide variety of ambient  
15 conditions and applications, indicating that new installations can be designed to address  
16 long-term changes in operating conditions. In response to the range of operating  
17 temperatures and pressures to which gas turbines are being subjected, turbine designers  
18 have developed a host of tools for dealing with daily and local ambient conditions. These  
19 tools include inlet guide vanes, inlet air fogging (essentially cooling and mass flow  
20 addition), inlet air filters and compressor blade washing techniques (to deal with salt and  
21 dust deposited on compressor blades). These tools could also be deployed to address  
22 changes in ambient conditions brought about by long term climate change.

### 24 **3.1.2 Energy Resource Production And Delivery**

25  
26 Other than for renewable energy sources, energy resource production and delivery  
27 systems are mainly vulnerable to effects of sea level rise and extreme weather events.

28  
29 The IPCC (IPCC, 2001a) estimated a 50 cm. (20 inch) rise in sea level around North  
30 America in the next century from climate change alone. This is well within the normal  
31 tidal range and would not have any significant effect on off-shore oil and gas activities.

1 On-shore oil and gas activities could be much more impacted which could create  
2 derivative impacts on off-shore activities.

3  
4 A number of operational power plants are sited at elevations of 3 feet or less, making  
5 them vulnerable to these rising sea levels. In addition, low lying coastal regions are being  
6 considered for the siting of new plants due to the obvious advantages in delivering fuel  
7 and other necessary feedstocks. Significant percentages of other energy infrastructure  
8 assets are located in these same areas including a number of the nation's oil refineries as  
9 well as most coal import/export facilities and liquefied natural gas terminals. Given that a  
10 large percentage of the Nation's energy infrastructure lies along the coast, rising sea  
11 levels could lead to direct losses such as equipment damage from flooding or erosion, or  
12 indirect effects such as the costs of raising vulnerable assets to higher levels or building  
13 future energy projects further inland, thus increasing transportation costs.

14  
15 IPCC (2001a) and USGS (2000) have identified substantial areas of the US East Coast  
16 and Gulf Coast as being vulnerable to sea-level rise. Roughly one-third of US refining  
17 and gas processing physical plant lies on coastal plains adjacent to the GOM, hence is  
18 vulnerable to inundation, shoreline erosion, and storm surges. On-shore, but non-coastal  
19 oil and gas production and processing activities may be impacted by climate change  
20 primarily as it impacts extreme weather events, phenomena not presently well  
21 understood.

22  
23 Florida's energy infrastructure may be particularly susceptible to sea-level rise impacts.  
24 Most of the petroleum products consumed in Florida are delivered by barge to three ports  
25 (NASEO, 2005) two on the East Coast of Florida and one on the West Coast. The  
26 interdependencies of natural gas distribution, transportation fuel distribution and delivery,  
27 and electrical generation and distribution were found to be major issues in Florida's  
28 recovery from multiple hurricanes in 2004. Alaska represents a special case for climate  
29 adaptation because of the scale of the predicted impacts are expected to be greater in  
30 higher latitudes (See Box 3.2. Alaska: A Case Study).

31

### BOX 3.2. ALASKA: A CASE STUDY

Alaska represents a special case for climate adaptation because of the scale of the predicted impacts are expected to be greater in higher latitudes—some models predict an arctic temperature increase to be double the global average (ref...). In areas of the north slope, change is already being observed, as illustrated below by the changes in shoreline along the Teshekpuk Lake Special Area and the inundation of the pilings protecting the J.W. Dalton well heads and pilings (photos taken September 2004 and 2005 (ref...)).

Energy impacts specific to Alaska include:

- Warming and ensuing ice melts may provide alternative opportunities for marine transportation of fossil fuels. For example, oil from northern Russia might be delivered to New York terminals via a route over the top of the North American continent if the sea ice thins sufficiently.
- Areas of the National Petroleum Reserve -Alaska have already lost significant amounts of shore ice, in areas that are of interest to the oil industry.
- When thermokarsting (melting permafrost) occurs beneath a road, house, pipeline, etc, then the structural integrity of the facility is threatened. Technologies already exist to protect the permafrost, but may not be sufficient given predicted temperature increases.
- Negative economic and operational impacts may result from an increasingly shorter winter work season, which has shortened over the past 30 years, dropping from over 200 days in 1970 to about 100 days in 2003. A season of only 100 days translates into a minimum of two years to complete an exploration program.

1  
2 Regarding extreme weather events, which could represent more significant effects, see  
3 3.1.4. Coal production is susceptible to extreme weather events which can directly  
4 impact open-cast mining operations and coal cleaning operations of underground mines.  
5

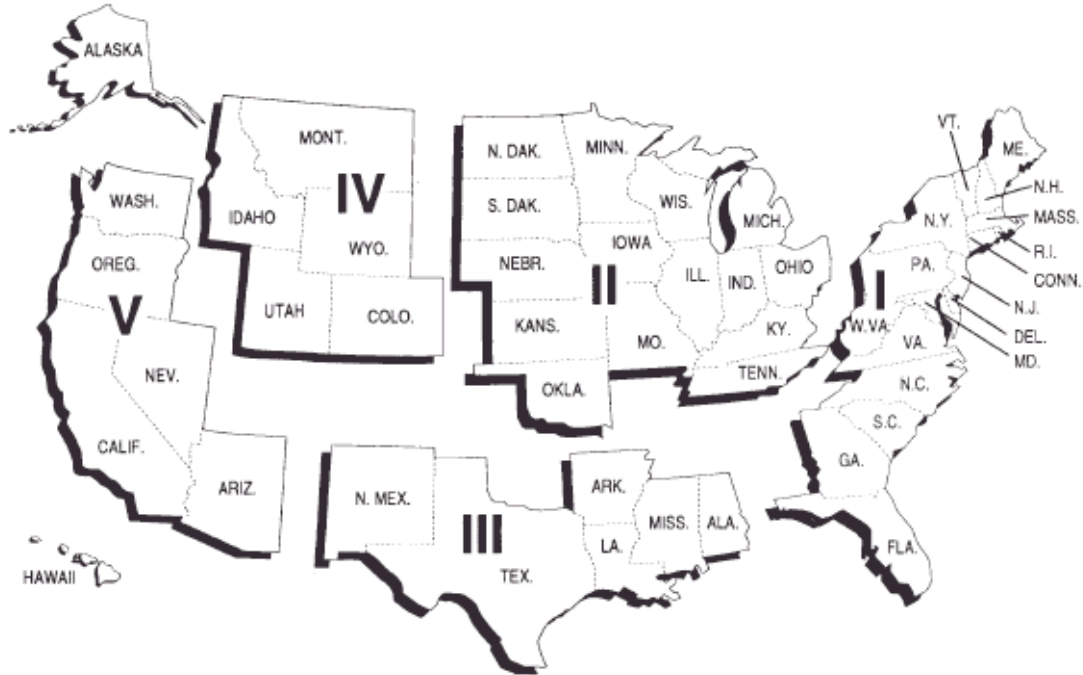

6 Potential impacts on novel resources are speculative at present. Oil shale resource  
7 development, which is considered to be water intensive, could be made more difficult if  
8 climate change further reduces annual precipitation in an already arid region that is home  
9 to the major oil shale deposits. Water availability (Struck, 2006) is beginning to be seen  
10 as a potential constraint on synthetic petroleum production from the Canadian oil sands.  
11 Coal-to-Liquids operations also require significant quantities of water.  
12

### 13 **3.1.3 Transportation of Fuels**

14

15 Roughly 65% of petroleum products supplied in the Petroleum Administration for  
16 Defense (PAD) East Coast District (Figure 3.3) arrive there via pipeline, barge, or ocean  
17 vessel (EIA, 2004). Approximately 80% of the domestic-origin product is transported by  
18 pipeline. Certain areas, e.g., Florida, are nearly totally dependent on maritime (barge)  
19 transport. About 97% of the crude oil charged to PAD I refineries is imported, arriving  
20 primarily by ocean vessels. PAD II receives the bulk of its crude oil via pipeline, roughly  
21 two-thirds from PAD III and one-third from Canada. Both pipeline and barge transport  
22 has been susceptible to extreme weather events with pipeline outages mostly driven by  
23 interdependencies with the electrical grid. In addition (see 3.3.2), increased ambient  
24 temperatures can degrade pipeline system performance, particularly when tied to  
25 enhanced oil recovery and, if practiced in the future, carbon sequestration. Moreover,  
26 (see 3.3.2), increased ambient temperatures can degrade pipeline system performance,  
27 particularly when tied to enhanced oil recovery and, if practiced in the future, carbon  
28 sequestration. The transportation of coal to end users, primarily electrical generation  
29 facilities, is dependent on rail and barge transportation modes (EIA, 2004). Barge  
30 transport is susceptible to both short term, transient weather events and to longer-term  
31 shifts in regional precipitation and snow melt patterns which may reduce the extent of

4  
5  
6 navigability of rivers and reduce or expand the annual navigable periods. In addition,  
7 offshore pipelines were impacted by Hurricane Ivan even before the arrival of Hurricane  
8 Katrina (see 3.1.4).

9  
10 **3.1.4 Extreme Events**

11  
12 Climate change may cause significant shifts in current weather patterns and increase the  
13 severity and frequency of major storms (NRC, 2002). As witnessed in 2005, hurricanes  
14 can have a debilitating impact on energy infrastructure. Direct losses to the energy  
15 industry are estimated at \$15 billion dollars (Marketwatch.com, 2006), with millions  
16 more in restoration and recovery costs. Future energy projects located in storm prone  
17 areas will face increased capital costs of hardening their assets due to both legislative and

1 insurance pressures. For example, the Yscloskey Gas Processing Plant was forced to  
2 close for six months following Hurricane Katrina, resulting in both lost revenues to the  
3 plant's owners and higher prices to consumers as alternative gas sources had to be  
4 procured. In general, the incapacitation of energy infrastructure – especially of  
5 refineries, gas processing plants and petroleum product terminals – is widely credited  
6 with driving a price spike in fuel prices across the country, which then in turn has  
7 national consequences. The potential impacts of more severe weather are not limited to  
8 hurricane-prone areas. Rail transportation lines, which transport approximately 2/3 of the  
9 coal to the nation's power plants (EIA, 2002), often closely follow riverbeds, especially  
10 in the Appalachian region. More severe rain storms can lead to flooding of rivers which  
11 then can wash out or degrade the nearby roadbeds. Flooding may also disrupt the  
12 operation of inland waterways, the second-most important method of transporting coal.  
13 With utilities carrying smaller stockpiles and projections showing a growing reliance on  
14 coal for a majority of the nation's electricity production, any significant disruption to the  
15 transportation network has serious implications for the overall reliability of the grid as a  
16 whole.

17

18 Off-shore production is susceptible to extreme weather events. Hurricane Ivan (2004)  
19 destroyed seven GOM platforms, significantly damaged 24 platforms, and damaged 102  
20 pipelines (MMS, 2006). Hurricanes Katrina and Rita in 2005 destroyed more than 100  
21 platforms and damaged 558 pipelines (MMS, 2006). Figures 3.4a, b, c, and d show the  
22 typhoon and Mars deepwater platforms before and after the 2005 hurricanes. The \$250  
23 million Typhoon platform was so severely damaged that Chevron is working with the  
24 MMS to sink it as part of the artificial reef program in the GOM; the billion dollar plus  
25 Mars platform has been repaired, and returned to production about eight months post-  
26 hurricane.

1 **3.1.5 Adaptation to Extreme Events**

2  
3 Energy assets can be protected from these impacts both by protecting the facility or  
4 relocating it to safer areas. Hardening could include reinforcements to walls and roofs,  
5 the building of dikes to contain flooding or structural improvements to transmission  
6 assets. However, the high costs of relocating or protecting energy infrastructure drives  
7 many companies to hedge these costs against potential repair costs if a disaster does  
8 strike. For example, it is currently estimated to cost up to \$10 billion to build a new  
9 refinery from the ground up (Petroleum Institute for Continuing Education, undated) and  
10 significant additional costs to fully harden a typical at-risk facility against a hurricane,  
11 compared to only a few million dollars in repairs that may or may not be required if a  
12 hurricane does strike. Relocation of rail lines also faces a similar dilemma. BNSF's  
13 capacity additions in the Powder River Basin are expected to cost over \$200 million  
14 dollars to add new track in a relatively flat region with low land prices – changes to rail  
15 lines in the Appalachian region would be many times more due to the difficult  
16 topography and higher land acquisition costs.

17  
18 Industry, government agencies, and the American Petroleum Institute met jointly in  
19 March 2006 (API, 2006) to plan for future extreme weather events. Interim guidelines for  
20 jackup (shallow water) rigs (API, 2006) and for floating rigs (API, 2006) have been  
21 developed. MMS, DOT, and several industry participants have formed a Joint Industry  
22 Program (JIP) (Stress Subsea, Inc., 2005) to develop advanced capabilities to repair  
23 damaged undersea pipelines.

24  
25 **3.2 EFFECTS ON RENEWABLE ENERGY PRODUCTION**

26  
27 Renewable energy production accounts for about 6% of the total energy production in the  
28 U.S. (Figure 3.5); biomass and hydropower are the most significant contributors (EIA,  
29 2005d). Biomass energy is primarily used for industrial process heating, with  
30 substantially increasing use for transportation fuels and additional use for electricity

1 (Source: EIA, 2005d).

2

3 **Figure 3.5. Renewable energy's share in U.S. energy supply**  
 4 (<http://www.eia.doe.gov/cneaf/solar.renewables/page/trens/highlight1.html>)

5

6 generation. Hydropower is primarily used for generating electricity, providing 270  
 7 billion kWh in 2005 (EIA, 2006d). Wind power is the fastest growing renewable energy  
 8 technology, with total generation increasing to 14 billion kWh in 2004. Because  
 9 renewable energy depends directly on ambient natural resources such as water, wind  
 10 patterns and intensity, and solar radiation, it is likely to be more sensitive to climate  
 11 variability than fossil or nuclear energy systems that rely on geological stores. At the  
 12 same time, increasing renewable energy production is a primary means for reducing  
 13 greenhouse gas emissions and thereby mitigating the impacts of potential climate change.  
 14 Renewable energy sources are therefore connected with climate change in very complex  
 15 ways: their use can affect the magnitude of climate change, while the magnitude of  
 16 climate change can affect their prospects for use.

17

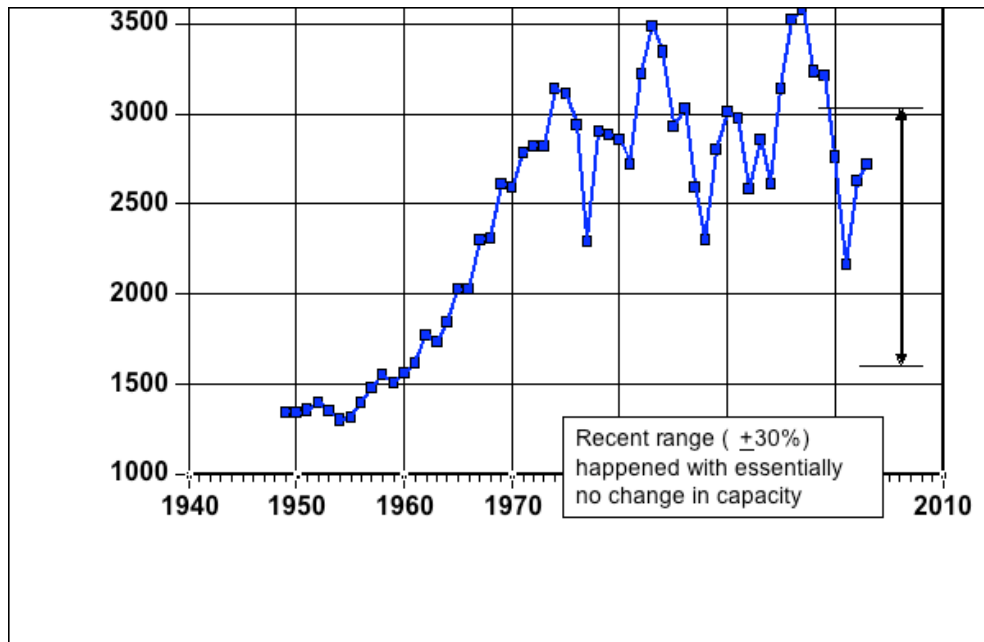

### 1 **3.2.1 Hydroelectric Power**

2  
3 Hydropower is the largest renewable source of electricity in the U.S. In the period 2000-  
4 2004, hydropower produced approximately 75% of the electricity from all renewable  
5 sources (EIA, 2006d). In addition to being a major source of base-load electricity in  
6 some regions of the U.S. (e.g., Pacific Northwest states), hydropower plays an important  
7 role in stabilizing electrical transmission grids, meeting peak loads and regional reserve  
8 requirements for generation, and providing other ancillary electrical energy benefits that  
9 are not available from other renewables. Hydropower project design and operation is  
10 very diverse; projects vary from storage projects with large, multi-purpose reservoirs to  
11 small run-of-river projects that have little or no active water storage. Approximately half  
12 of the U.S. hydropower capacity is federally owned and operated (e.g., Corps of  
13 Engineers, Bureau of Reclamation, and the Tennessee Valley Authority); the other half is  
14 at nonfederal projects that are regulated by the Federal Energy Regulatory Commission.  
15 Nonfederal hydropower projects outnumber federal projects by more than 10:1.

16  
17 The interannual variability of hydropower generation in the U.S. is very high, especially  
18 relative to other energy sources (Figure 3.6) – the difference between the most recent high  
19 (2003) and low (2001) generation years is 59 billion kWh, approximately equal to the  
20 total electricity from biomass sources and much more than the generation from all other  
21 non-hydropower renewables (EIA, 2006). The amount of water available for  
22 hydroelectric power varies greatly from year to year, depending upon weather patterns  
23 and local hydrology, as well as on competing water uses, such as flood control, water  
24 supply, recreation, and instream flow requirements (e.g., conveyance to downstream  
25 water rights, navigation, and protection of fish and wildlife). The annual variability in  
26 hydropower is usually attributed to climate variability, but there are also important  
27 impacts from multiple use operational policies and regulatory compliance.

28  
29 There have been a large number of published studies of climate impacts on water  
30 resource management and hydropower production (e.g., Miller and Brock 1988;  
31 Lettenmaier et al. 1999; Barnett et al. 2004). Significant changes are being detected now

1 in the flow regimes of many western rivers (Dettinger, 2005), consistent with the  
 2 predicted effects of global warming. The sensitivity of hydroelectric generation to both  
 3 changes in precipitation and river discharge is high, in the range 1.0 and greater (e.g.,  
 4 sensitivity of 1.0 means 1% change in precipitation results in 1% change in generation).  
 5 For example, Nash and Gleick (1993) estimated sensitivities up to 3.0 between  
 6 hydropower generation and stream flow in the Colorado Basin (i.e., change in generation  
 7 three times the change in stream flow). Such magnifying sensitivities, greater than 1.0,

33 **Figure 3.6. Historical variability of total annual production of**  
 34 **hydroelectricity from conventional projects in the U.S.**  
 35

36 occur because water flows through multiple power plants in a river basin. Climate  
 37 impacts on hydropower occur when the either the total amount or the timing of runoff is  
 38 altered, for example when natural water storage in snow pack and glaciers is reduced  
 39 under hotter climates (e.g., melting of glaciers in Alaska and the Rocky Mountains of the  
 40 U.S.).

41  
 42 Hydropower operations are also affected indirectly when air temperatures, humidity, or  
 43 wind patterns are affected by changes in climate, and these driving variables cause  
 44 changes in water quality and reservoir dynamics. For example, warmer air temperatures

1 and a more stagnant atmosphere cause more intense stratification of reservoirs  
2 behinddams and a depletion of dissolved oxygen in hypolimnetic waters (Meyer et al.,  
3 1999). Where hydropower dams have tailwaters supporting cold-water fisheries for trout  
4 or salmon, warming of reservoir releases may have unacceptable consequences and  
5 require changes in project operation that reduce power production.

6  
7 Competition for available water resources is another mechanism for indirect impacts of  
8 climate change on hydropower. These impacts can have far-reaching consequences  
9 through the energy and economic sectors, as happened in the 2000-2001 energy crises in  
10 California (Sweeney, 2002).

11  
12 Recent studies in California and elsewhere are showing how hydropower systems can  
13 adapt to climate variability by reexamining management policies (Vicuña et al., 2006).  
14 The ability of river basins to adapt is proportional to the total active storage in surface  
15 water reservoirs (e.g., Aspen Environmental Group and M-Cubed, 2005). Many water  
16 management institutions, however, are slow to take action on such adaptations.

### 17 18 **3.2.2 Biomass Power And Fuels**

19  
20 Total biomass energy production has surpassed hydroelectric energy for most years since  
21 2000 as the largest U.S. source of renewable energy, providing 46% of renewable or 4%  
22 of total U.S. energy in 2005 (EIA 2006). The largest source of that biomass energy  
23 (29%) was black liquor from the pulp and paper industry, combusted as part of a process  
24 to recover pulping chemicals which provides process heat for the mills as well as  
25 generating electricity. Wood and wood waste from sources such as lumber mills provide  
26 more than 19% (industrial sector alone) and combusted municipal solid waste and  
27 recovered landfill gas about 16%, respectively, of current U.S. biomass energy (EIA,  
28 2005d). Because energy resource generation is a byproduct of other activities in all these  
29 cases, there is little reason to expect climate change to directly impact any of these or  
30 most other sources of biomass power production derived from a waste stream. There are  
31 few examples of literature addressing this area, though Edwards notes that climate-

1 change-induced events such as timber die-offs could present short-term opportunity or  
2 long-term loss for California (Edwards, 1991).

3  
4 Liquid fuel production from biomass is highly visible as a key renewable alternative to  
5 imported oil. Current U.S. production is based largely on corn for ethanol and, to a lesser  
6 extent, soybeans for biodiesel. Because both crops are used primarily for animal feed,  
7 with only small portions going to fuel production, and because both are currently price  
8 supported, changes in crop growth rates might again not immediately affect their use for  
9 fuel. In the longer term, cellulosic feedstocks should supplant grain and oilseed crops for  
10 transportation fuel production from biomass. Cellulosic crop residues such as corn stover  
11 and wheat straw would likely be affected by climate change the same way as the crops  
12 themselves due to a rise in average temperatures, more extreme heat days, and changes in  
13 precipitation patterns and timing, with greater impact on fuel production because that  
14 would be their primary use. Potential dedicated cellulosic energy crops for biomass fuel,  
15 such as grasses and fast-growing trees, would also be directly affected by climate change.  
16 As discussed below, limited literature suggests that for at least one region, one primary  
17 energy crop candidate—switchgrass-- may benefit from climate change, both from  
18 increased temperature and increased atmospheric carbon dioxide levels.

19  
20 More specifically, about 10% of U.S. biomass energy production (EIA 2005d), enough to  
21 provide about 2% of U.S. transportation motor fuel (Federal Highway Administration,  
22 2003), currently comes from ethanol made predominantly from corn grown in the  
23 Midwest (Iowa, Illinois, Nebraska, Minnesota, and South Dakota are the largest ethanol  
24 producers). Climate change sufficient to substantially affect corn production would likely  
25 impact the resource base, but corn is price supported and currently only uses about 13%  
26 of the U.S. corn crop (livestock feed is the predominant use) (RFA, 2006). Although  
27 ethanol production did drop in 1996 following a poor corn crop and associated high  
28 prices, the combined influence of various agricultural and fuel incentive and regulatory  
29 policies probably overshadow any near-term impacts of climate change on ethanol  
30 production. Production of biodiesel from soybeans—growing rapidly, but still very  
31 small—is likely a similar situation. In the long term, however, significant crop changes—

1 and trade-offs between them, as they are generally rotated with each other—would likely  
2 have an impact in the future. Looking at Missouri, Iowa, Nebraska, and Kansas, with an  
3 eye toward energy production, Brown, et al. (2000) used a combination of the NCAR  
4 climate change scenario, regional climate, and crop productivity models to predict how  
5 corn, sorghum, and winter wheat (potential ethanol crops) and soybeans (biodiesel crop)  
6 would do under anticipated climate change. Negative impact from increased temperature,  
7 positive impact from increased precipitation, and positive impact from increased  
8 atmospheric carbon dioxide combined to yield minimal negative change under modest  
9 carbon dioxide level increase, but 5% to 12% yield increases with high carbon dioxide  
10 level increases.

11  
12 Although ethanol production from corn can still increase substantially (mandated to  
13 double under the recently enacted renewable fuel standard), it can still only meet a small  
14 portion of the need for renewable liquid transportation fuels to displace gasoline if  
15 dependence on petroleum imports is to be reduced. Processing the entire projected 2015  
16 corn crop to ethanol (highly unrealistic, of course) would only yield about 35 billion  
17 gallons of ethanol, less than 14% of the gasoline energy demand projected for that year.  
18 Biomass fuel experts are counting on cellulosic biomass as the feedstock to make larger  
19 renewable fuel production possible. A recent joint study of the U.S. Departments of  
20 Agriculture and Energy (USDA and DOE), *Biomass as Feedstock for a Bioenergy and*  
21 *Bioproducts Industry: The Technical Feasibility of a Billion-Ton Annual Supply*,  
22 projected that by 2030 enough biomass could be made available to meet 40% of 2004  
23 gasoline demand via cellulosic ethanol production and other technologies. The two  
24 largest feedstocks identified are annual crop residues and perennial dedicated energy  
25 crops (NREL 2006).

26  
27 The primary potential annual crop residues are corn stover—the leaves, stalks, and husks  
28 generally now left in the field—and wheat straw. Corn stover is the current DOE research  
29 focus in part because it is a residue with no incremental cost to grow and modest cost to  
30 harvest, but also particularly because of its potential large volume. Stover volume is  
31 roughly equivalent to grain volume and corn is the largest U.S. agricultural crop. As such

1 it would be affected by climate change in much the same way as the corn crop itself,  
2 described above.

3  
4 Frequently discussed potential dedicated perennial energy crops include fast-growing  
5 trees such as hybrid poplars and willows and grasses such as switchgrass (ORNL  
6 Bioenergy Feedstock Information Network, Agricultural Research Service Bioenergy and  
7 Energy Alternatives Program). Switchgrass is particularly attractive because of its large  
8 regional adaptability, fast growth rate, and minimal adverse environmental impact. The  
9 primary objective of the Brown, *et. al.* (2000) study referenced above for Missouri, Iowa,  
10 Nebraska, and Kansas was to see how climate change would affect growth of  
11 switchgrass. The study projected that switchgrass would do very well benefiting from  
12 both higher temperatures (unlike the grain crops) and higher atmospheric carbon dioxide  
13 levels, with yield increasing 74% with the modest CO<sub>2</sub> increase and nearly doubling with  
14 the higher CO<sub>2</sub> increase. One may not expect projected impact to be as beneficial for  
15 Southern regions already warm enough for rapid switchgrass growth or more Northern  
16 areas still colder than optimal even with climate change, but the models would need to be  
17 run.

18  
19 Because most current U.S. electric power production from biomass is tied to particular  
20 opportunities presented by other industries, changes such as timber growth rates would  
21 have less direct impact, at least for the near term.

22

### 23 **3.2.3 Wind Energy**

24

25 Wind energy currently accounts for about 2.5% of U.S. renewable energy generation' but  
26 its use is growing rapidly, and it has tremendous potential due to its close cost  
27 competitiveness with fossil fuel plants for utility-scale generation. Although policy  
28 incentives and the ability to integrate a variable resource with utility systems are also  
29 important, that near-competitiveness is a key factor. Any projected impact of climate  
30 change such as changes in seasonal wind patterns or strength would likely be significant  
31 positively or negatively since wind energy generation is a function of the cube of the

1 wind speed. Increased variability in wind patterns could also create additional challenges  
2 for accurate wind forecasting for generation and dispatch planning.

3  
4 California is currently the largest wind-power-producing state, followed by Texas, Iowa,  
5 Minnesota, Washington, and Oregon (EIA, 2005d). Development in these states is a  
6 function of policy incentives as well as available resource, but these regions would  
7 certainly be expected to continue among the main wind-power areas. North Dakota and  
8 South Dakota, while modest in wind development so far, have tremendous wind  
9 potential, particularly as technology and economics allow development of lower wind-  
10 speed regimes further from major load centers.

11  
12 One study modeled wind speed change for the United States divided into northern and  
13 southern regions under two climate-change circulation models. Overall, the Hadley  
14 Center model suggested minimal decrease in average wind speed, but the Canadian  
15 model predicted very significant decreases of 10%-15% (30%-40% decrease in power  
16 generation) by 2095. Decreases were most pronounced after 2050, in the fall for both  
17 regions, and in the summer for the northern region (Breslow and Sailor, 2002).

18  
19 Another study mapped wind power changes in 2050 based on the Hadley Center General  
20 Circulation Model—the one suggesting more modest change of the two used by Breslow  
21 and Sailor above. For most of the United States, they predicted decreased wind resources  
22 to as much as 10% on an annual basis and 30% on a seasonal basis. Wind power  
23 increased for the important Texas-Oklahoma region and for the Northern California-  
24 Oregon-Washington region, although the latter had decreased power in the summer. For  
25 the key Northern Great Plains and for the mountainous West, however, they predict  
26 decreased wind power (Segal et al., 2001). Edwards suggests that warming-induced  
27 offshore current changes could intensify summer winds for California and thus increase  
28 its wind energy potential (Edwards, 1991).

29

1 **3.2.4 Solar Energy**

2  
3 Photovoltaic (PV) electrical generation and solar water heating are suitable for much of  
4 the United States, with current deployment primarily in off-grid locations or rooftop  
5 systems where state or local tax incentives are present. For utility-scale generation, the  
6 technologies are most attractive in the Southwest with its high direct-radiation resource,  
7 where concentrating or high-efficiency PV and solar thermal generation systems can be  
8 used. California and Arizona have the only existing utility-scale systems (EIA 2005d)  
9 with additional projects being developed in Nevada and Arizona.

10  
11 Pan et al. (2004) modeled changes to global solar radiation to the 2040s based on the  
12 Hadley Center circulation model. This study projects a solar resource reduced to as much  
13 as 20% seasonally, presumably from increased cloud cover, throughout the country, but  
14 particularly in the West with its greater present resource. Increased temperature can also  
15 reduce the effectiveness of PV electrical generation and solar thermal energy collection.  
16 One international study predicts that a 2% decrease in global solar radiation will decrease  
17 solar cell output by 6% overall (Fidge and Martinsen, 2006).

18  
19 **3.2.5 Other Renewable Energy Sources**

20  
21 Climate change could affect geothermal energy production (6% of current U.S.  
22 renewable energy: (EIA 2005c) in the same way that higher temperatures reduce the  
23 efficiency of fossil-fuel-boiler electric turbines, but otherwise should not cause any  
24 impact. The United States currently makes no significant use of wave, tidal, or ocean  
25 thermal energy, but any of these could be affected by climate change. Harrison observes  
26 that wave heights in the North Atlantic have been increasing and discusses how wave  
27 energy is affected by changes in wind speed (Harrison and Wallace, 2005).

1 **3.2.6 Summary**

2

3 Of the two largest U.S. renewable energy sources, hydroelectric power generation can be  
4 expected to be directly and significantly affected by climate change, but biomass power  
5 and fuel production are likely to be only modestly impacted in the short term. The  
6 impact on hydroelectric production will vary by region, but production will likely  
7 decrease in key areas such as the Columbia River Basin and Northern California. Current  
8 U.S. electricity production from wind and solar energy is modest but anticipated to play a  
9 significant role in the future as these technologies become more cost competitive and  
10 accepted by electric utilities. As such, even modest impacts from climate change on cost  
11 effectiveness in key resource areas could substantially affect the ability of the  
12 technologies to gain broader market penetration, which is more significant than overall  
13 changes in the resource availability. At a minimum, both wind and direct-solar-radiation  
14 will likely be marked by greater variability as a result of climate change.

15

16 **3.3 EFFECTS ON ENERGY TRANSMISSION, DISTRIBUTION,**  
17 **AND SYSTEM INFRASTRUCTURE**

18

19 In addition to the direct effects on operating facilities themselves, networks for transport,  
20 electric transmission, and delivery would be susceptible to changes in stream flow,  
21 annual precipitation and seasonal patterns, storm severity, and even temperature  
22 increases, (e.g., pipelines handling supercritical fluids may be impacted by greater heat  
23 loads if temperatures increase and/or cloud cover diminishes).

24

25 **3.3.1 Electricity Transmission and Distribution**

26

27 Severe weather events and associated flooding cause direct disruptions in energy  
28 services. With more intense events, increased disruptions might be expected. Electricity  
29 reliability might also be affected as a result of increased demand combined with high soil  
30 temperatures and soil dryness (IPCC, 2001a).

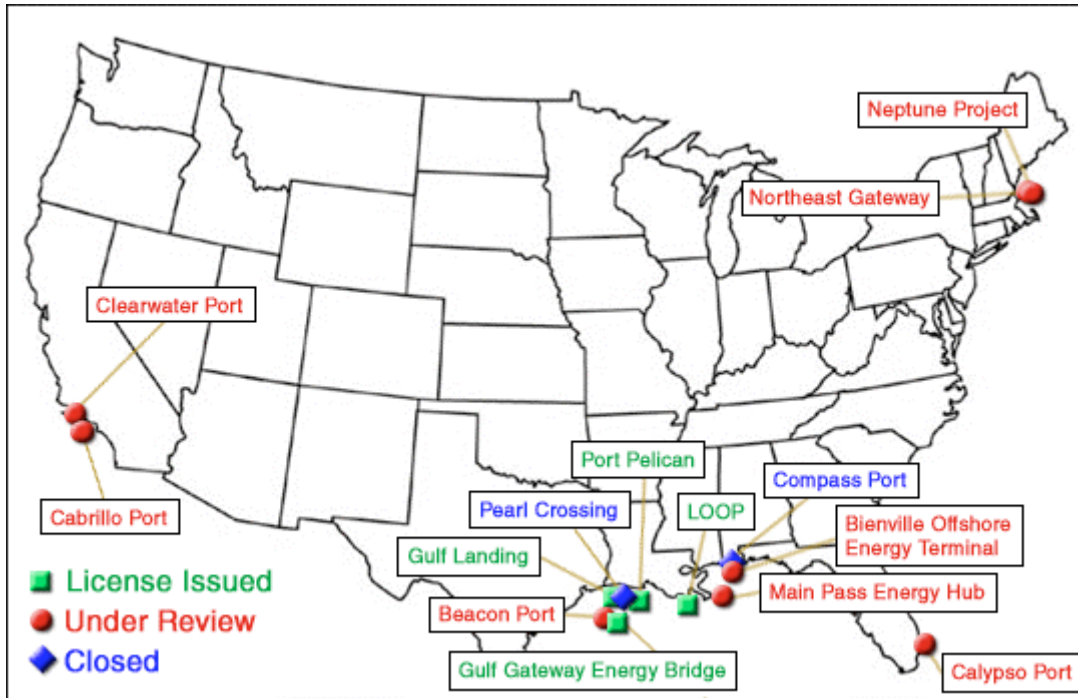

31

1 Grid technologies in use today are at least 50 years old and although “smart grid”  
2 technologies exist, they are not often employed. Two such technologies that may be  
3 employed to help offset climate impacts include upgrading the grid by employing  
4 advanced conductors that are capable withstanding greater temperature extremes and  
5 automation of electric distribution (Gellings and Yeager, 2004).

### 7 **3.3.2 Energy Resource Infrastructure**

9 A substantial part of the oil imported into the United States is transported over long  
10 distances from the Middle East and Africa in supertankers. While these supertankers are  
11 able to offload within the ports of other countries, they are too deeply drafted to enter the  
12 shallow U.S. ports and waters. This occurs because, unlike most other countries, the  
13 continental shelf area of the United States extends many miles beyond its shores and  
14 territorial waters. This leads to a number of problems related to operation of existing  
15 ports, and to programs (such as NOAA's P.O.R.T.S. Program) to improve efficiency at  
16 these ports. In addition, the Deepwater Ports Act (1975) has lead to plans to develop a  
17 number of deepwater ports for either for petroleum or LNG import. These planned  
18 facilities are concentrated in relatively few locations, in particular with a concentration  
19 along the Gulf Coast (Figure 3.7). Changes in weather patterns, leading to changes in  
20 stream flows and wind speed and direction can impact operability of existing harbors.  
21 Severe weather events can impact access to deepwater facilities or might disrupt well-  
22 established navigation channels in ports where keel clearance is a concern (DOC/DOE,  
23 2001).

24  
25 Climate change may also affect the performance of the extensive pipeline system in the  
26 United States. For example, for CO<sub>2</sub>-enhanced oil recovery, experience has shown that  
27 summer injectivity of CO<sub>2</sub> is about 15% less than winter injectivity into the same  
28 reservoir. The CO<sub>2</sub> gas temperature in Kinder Morgan pipelines during the winter are  
29

**Figure 3.7. Proposed deepwater ports for petroleum and LNG**

about 60F and in late summer about 74F. At higher temperatures, compressors and fan coolers are less efficient and are processing a warmer gas. Operators just cannot pull as much gas off the supply line with the given horsepower when the CO<sub>2</sub> gas is warm.

(source: personal communication from Ken Havens of Kinder Morgan CO<sub>2</sub>)

Efficiencies of most gas injection is similar and thus major gas injection projects like produced gas injection on the North Slope of Alaska have much higher gas injection and oil production during cold winter months. Persistently higher temperatures will have an impact on deliverability and injectivity for applications where the pipeline is exposed to ambient temperatures.

### 3.3.3 Storage And Landing Facilities

The Strategic Petroleum Reserve storage locations (EIA,2004b) that are all along the Gulf Coast, were selected because they provide the most flexible means for connecting to

1 the commercial oil transport network. Figure 3.8 illustrates their locations along the Gulf  
2 Coast in areas USGS (2000) sees as being susceptible to sea-level rise. Similarly located  
3 on the Sabine Pass is the Henry Hub, the largest gas transmission interconnection site in  
4 the U.S., connecting 14 interstate and intrastate gas transmission pipelines. Henry Hub  
5 was out of service briefly from Hurricane Katrina and for some weeks from Hurricane  
6 Rita, which made landfall at Sabine Pass.

### 8 **3.3.4 Infrastructure Planning And Considerations For New Power** 9 **Plant Siting**

10  
11 Water availability and access to coal delivery are currently critical issues in the siting of  
12 new coal-fired generation capacity. New capacity, except on coasts and large estuaries,  
13 will generally require cooling towers rather than once-through cooling water usage based  
14 on current and expected regulations (EPA, 2000) independent of climate change issues.  
15 New turbine capacity will also need to be designed to respond to the new ambient  
16 conditions.

17  
18 Siting of new nuclear units will face the same water availability issues as large new coal-  
19 fired units; they will not need to deal with coal deliverability but may depend on barge  
20 transport to allow factory fabrication rather than site fabrication of large, heavy wall  
21 vessels, as well as for transportation of any wastes that need to be stored off-site.

22  
23 Capacity additions and system reliability have recently become important areas for  
24 discussion. A number of approaches are being considered to run auctions (or other  
25 approaches) to stimulate interest in adding new capacity without sending signals that  
26 would result in over-building (as has happened in the past). Planning to ensure that both  
27 predictions of needed capacity and mechanisms for stimulating companies to build such  
28 capacity (while working through the process required to announce, design, permit, and  
29 build it) will become more important as future demand is affected by climatic shifts.  
30 Similarly, site selection may need to factor in longer-term climatic changes for

1 technologies as long-lived as coal-fired power plants (which may last for 50 - 75 years)  
2 (NARUC, 2006).

### 3.4 EFFECTS ON ENERGY INSTITUTIONS

(To be added)

Figure 3.8. Strategic Petroleum Reserve storage sites

### 3.5 SUMMARY OF KNOWLEDGE ABOUT POSSIBLE EFFECTS

37 Significant uncertainty exists about the potential impacts of climate change on energy  
38 production and distribution, in part because the timing and magnitude of climate impacts  
39 are uncertain. This report summarizes many of the key issues and provides information  
40 available on possible impacts; however this topic represents a key area for future  
41 analysis.

1 Many of the technologies needed for existing energy facilities to adapt to increased  
2 temperatures and decreased water availability are available for deployment; and, although  
3 decreased efficiencies and lower output can be expected, significant disruptions seem  
4 unlikely. Incorporating potential climate impacts into the planning process for new  
5 facilities will strengthen the infrastructure. This is especially important for water  
6 resources, as electricity generation is one of many competing applications for what may  
7 be a (more) limited resource.

8

9 There are regionally important differences in adaptation needs. This is true for the  
10 spectrum of climate impacts from water availability to increased temperatures and  
11 changing patterns of severe weather events. The most salient example is for oil and gas  
12 exploration and production in Alaska, where projected temperature increases may be  
13 double the global average and melting permafrost and changing shorelines could  
14 significantly alter the landscape and available opportunities for oil and gas production

15

16 Increased temperatures will also increase demand-side use, and the potential system-wide  
17 impacts on electricity transmission and distribution and other energy system needs are not  
18 well understood. Future planning for energy production and distribution may therefore  
19 need to accommodate possible impacts of climate change.

10  
11 **4.1 INTRODUCTION**

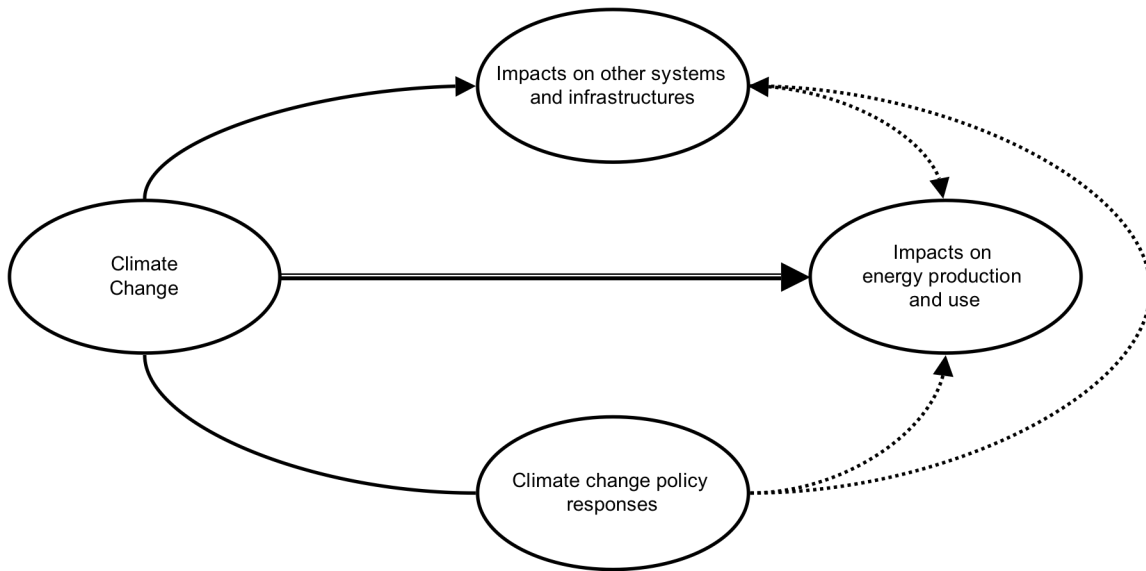

12  
13 Changes in temperature, precipitation, storms, and/or sea level are likely to have direct  
14 effects on energy production and use, as summarized above; but they may also have a  
15 number of indirect effects – as climate change affects other sectors and if it shapes energy  
16 and environmental policy-making and regulatory actions (Fig. 4.1). In some cases, it is  
17 possible that indirect effects could have a greater impact, positive or negative, on certain  
18 institutions and localities than direct effects.

19  
20 In order to provide a basis for such a discussion, this chapter of SAP 4.5 offers a  
21 preliminary taxonomy of categories of indirect effects that may be of interest, along with  
22 a summary of existing knowledge bases about such indirect effects. Some of these  
23 effects are from climate change itself, e.g., effects on electricity prices of changing  
24 conditions for hydropower production. Other effects could come from climate change  
25 related policies, (e.g., effects of stabilization-related emission ceilings on energy prices,  
26 energy technology choices, or energy sector emissions) (Table 4.1).

27  
28 Most of the existing literature is concerned with implications of climate change  
29 mitigation policies on energy technologies, prices, and emissions in the U.S. Because  
30 this literature is abundant, relatively well-known, and in some cases covered by other  
31 SAPs (such as SAP 2.2), it will be only briefly summarized here, offering links to more  
32  
33

detailed discussions. Of greater interest to some readers may be the characterization of other possible indirect effects besides these.

9

10

## **4.2 CURRENT KNOWLEDGE ABOUT INDIRECT EFFECTS**

11

12

### **4.2.1 Possible Effects On Energy Planning**

13

14

Climate change is likely to affect energy planning, nationally and regionally, because it is likely to introduce new considerations and uncertainties to institutional (and individual) risk management. Such effects can arise either through anticipated changes in climate-related environmental conditions, such as hydropower potentials, possible exposure to storm damages (see Chapter 3), or changed patterns of energy demand (see Chapter 2), or through possible changes in policies and regulations.

15

4

**(Double X indicates well-established by research literature;**

5

**X indicates some basis for anticipating an effect;**

6

**? indicates that effects are uncertain)**

7

8

9

For instance, a pathbreaking study supported by EPRI and the Japanese Central Research

10

Institute of Electric Power Industry (CRIEPI) assessed possible impacts of global climate

11

change on six utilities, five of them in the United States (ICF, 1995). The study

12

considered a variety of scenarios depicting a range of underlying climate, industry, and

13

policy conditions. It found that GHG emission reduction policies could cause large

14

increases in electricity prices, major changes in a utility's resource mix related to

15

requirements for emission controls, and significant expansions in demand-side

1 management programs. Major impacts are likely to be on Integrated Resource Planning  
2 regarding resource and capacity additions and/or plant retirements, along with broader  
3 implications of increased costs and prices. In another example, Burtraw et al., 2005  
4 analyzed a nine-state northeastern regional greenhouse gas initiative (RGGI), an  
5 allowance-based regional GHG cap-and-trade program for power sector. They found that  
6 how allowances are allocated has an effect on electricity price, consumption, and the mix  
7 of technologies used to generate electricity. Electricity price increases in most of the  
8 cases. They also note that any policy that increases energy costs in the region is likely to  
9 cause some emission leakage to other areas outside the region as electricity generation or  
10 economic activity moves to avoid regulation and associated costs.

11  
12 Electric utilities in particular are already sensitive to weather as a factor in earnings  
13 performance, and they utilize weather risk management tools to hedge against risks  
14 associated with weather-related uncertainties. Issues of interest include plans for capacity  
15 additions, system reliability assurance, and site selection for long-lived capital facilities  
16 (O'Neill, 2006). Even relatively small changes in temperature/demand can affect total  
17 capacity needs across the U.S. power sector, especially in peak periods.

18  
19 Many energy-related investments are made without a clear financial understanding of  
20 values, risks, and volatilities (Mills, et al., 2006; also see Vine, et al., 2000 and Crichton,  
21 2005), especially where newly emerging forces surrounded by uncertainties are  
22 concerned. Faced with uncertainties, many energy decision-makers on both the  
23 production and use sides choose to focus on options, such as energy efficiency  
24 improvement investments, with a high level of confidence of payoff regardless of future  
25 developments. Meanwhile, many sophisticated investors overlook energy investments  
26 that would contribute to adapting to likely climate change because risk and volatility  
27 information is limited. Given an improved risk management analysis framework,  
28 incorporating current information about exposures to climate change impacts, it is likely  
29 that investments in climate change adaptation for the energy sector would expand and  
30 new market-based opportunities for risk management would appear (also see 4.2.3  
31 below).

1

2 Current policy initiatives hint at what the future might be like, in terms of their possible  
3 effects on energy planning. U.S. national and state climate policy actions include a  
4 variety of traditional approaches such as funding mechanisms (incentives and  
5 disincentives); regulation (caps, codes and standards); technical assistance (direct or in  
6 kind); research and development; information and education; and monitoring and  
7 reporting (including impact disclosure) (Rose and Shang, 2004). Covered sectors include  
8 power generation, oil and gas, residential, commercial, industry, transportation, waste  
9 management, agriculture and forestry. These sectors cut across private and public sector  
10 facilities and programs, as well as producers and consumers of energy (Peterson and  
11 Rose, 2006).

12

13 One key issue involves the provision of financial incentives that create, encourage or  
14 force markets to reward GHG mitigation, such as preferential qualifying credit for  
15 transportation projects or energy production facilities. At the national level, clean and  
16 renewable energy technology deployment is promoted primarily through a federal  
17 production tax credit (PTC) and investment tax credit (ITC). Such incentives have been  
18 offered in the Energy Policy Act (EPA 2005) for electricity production from advanced  
19 nuclear, clean coal, biomass, municipal solid waste and other renewable energy  
20 technologies. For instance, installation of IGCC electric generation units with carbon  
21 capture and sequestration to save carbon may cost up to 20% more than traditional  
22 pulverized coal-fired units for electric power generation. Many recent studies have  
23 suggested public-private partnerships for financial and risk alleviation incentives that  
24 could help make early nuclear plants more competitive (DOE-Industry Report, 2004; the  
25 University of Chicago, 2004; MIT, 2003; Dominion and Other Industries, 2004; and  
26 Scully Capital, 2002). The EPA 2005 provides PTC, loan guarantees and federal risk  
27 insurance known as Standby Support for advanced nuclear power facilities. Since it was  
28 introduced in 1992, the PTC – which was designed to spur the deployment of  
29 technologies that are near economic competitiveness – has encouraged domestic  
30 renewable technologies, such as wind, solar and biomass (NCEP, 2004). The EPA  
31 (2005) extended most of these PTCs to 2007, except to solar technologies that ended in

1 2005. Rabe, 2006 suggests that repeated fluctuation in the federal production tax credit  
2 for renewable energy has fostered a boom-and-bust cycle for renewable development in a  
3 number of states, leaving significant lags in the development of renewables during those  
4 periods in which the credit has been terminated or its status has remained uncertain.

5  
6 Other incentive mechanisms are potentially important for GHG mitigation. According to  
7 Peterson & Rose (2006), cost sharing of fixed or variable mitigation program costs is  
8 common, such as payments to farmers for installation of best management practices or  
9 waste recovery facilities. These programs support measures that serve as alternatives to  
10 more costly energy reduction measures. Extra credit in applications for financing is  
11 common, where as preferential treatment in siting decisions can also reduce the time and  
12 risk associated with recovery of costs. By providing faster approval of the project than  
13 normal, or a higher guarantee of rate recovery, the financing costs to these projects can be  
14 substantially reduced due to the time value of money and reduction of risk premiums in  
15 financial markets. Policy makers may choose to endorse this sort of market intervention  
16 due to superior environmental performance, and a host of related co-benefits, including  
17 air quality, energy and water savings. This may be a critical issue in the future as  
18 decisions are made on the degree and type of market interventions to support emissions  
19 reduction from power generation.

20  
21 Some of the policy alternatives facilitate differentiating policies to meet special  
22 geographic needs, a critical issue given the substantial differences between state  
23 renewable portfolio standards (RPS) which force a percentage of sold (or consumed)  
24 electricity to be supplied by low emission renewable sources, and currently 22 states  
25 operate RPSs in the U.S. Economic development opportunities are paramount in all  
26 cases and environmental factors, including reduction of conventional air emissions as  
27 well as greenhouse gases, figure differently in various cases but are clearly seen as a  
28 secondary driver in many states (Rabe, 2006). To date, 39 states have developed  
29 greenhouse gas inventories and 30 states have developed some form of greenhouse gas  
30 action plan (EPA, 2003). Many initial versions of these plans were developed in  
31 anticipation of a treaty that would lead to national legislation and coordination with sub-

1 federal governments. At the time, US states were not expected to lead national policy,  
2 but the emphasis has since shifted in this direction, along with significant local  
3 government actions. Kousky and Schneider (2003) note that by mid-2003, 140 cities in  
4 the U.S. had established GHG reduction targets and had begun mitigation action  
5 planning.

6  
7 In California, the Governor's Executive Order #S-3-05, calls for an 80% reduction in  
8 climate change emissions, relative to 1990 levels, by 2050 (CEPA, 2006). As a result,  
9 the state has resolved to a series of extensive market based and policy driven demand and  
10 supply side management initiatives (Luers and Moser, 2006). According to Peterson &  
11 Rose (2006), a number of sub-federal jurisdictions have developed (or are developing)  
12 comprehensive plans that are expected to include numerical goals and timetables and a  
13 portfolio of actions across all economic sectors. Coordination with regional agreements  
14 in New England (The New England Governors/Eastern Canadian Premier's Agreement  
15 or NEG/ECP), the Northeast (the Regional Greenhouse Gas Initiative, or RGGI), the  
16 West Coast (the West Coast Climate Initiative), and the northern Midwest (the Powering  
17 the Plains initiative) are significant steps in this direction. Such regional initiatives, as  
18 explained by Kelly et al. (2005) for TX, OK and the Northeast states, promote energy  
19 market transformation with the help of public-private partnerships and create  
20 implementation projects to reduce GHG footprints. However, Peterson and Rose, (2006)  
21 indicate that many energy industries and some states have opposed the establishment of  
22 binding caps on emissions that could constrain market growth and product output.  
23 Recently, a number of design alternatives in the U.S. have been explored that modify the  
24 way standards are set for electric power generation caps to allow growth (such an output  
25 based allocation system) or provide compensation for affected parties by sharing or  
26 recycling of revenues from auction of permits. Rose et al., (2006) note that the  
27 composition and scope of RGGI participating states are changing. This refers to the  
28 considerations for expanding beyond just the electricity sector to include natural gas  
29 efficiency and soil sequestration, expanding beyond carbon dioxide to include landfill  
30 gas, SF6, HFC-23 and coal mine methane and expanding participation in the Clean  
31 Development Mechanism (CDM) and including the European Union (EU).

1  
2 Energy efficiency can contribute significantly in reducing market distortions while a cap-  
3 and-trade framework like RGGI is in place. Prindle et al., (2006) concluded that  
4 doubling the current level of energy efficiency spending in the RGGI region would have  
5 several very favorable effects on the carbon cap-and-trade system. It would reduce  
6 electricity load growth, future electricity prices, carbon emissions, carbon emission  
7 prices, and total energy bills for electricity customers of all types. Similarly, in a case-  
8 study of New York City, Kelly et al., (2005) show that energy efficiency and urban heat  
9 island mitigation strategies can significantly reduce electricity peak load, GHG emissions  
10 and energy system cost.

#### 11 12 **4.2.2 Possible Effects On Energy Production And Use *Technologies***

13  
14 Perhaps the best-documented case of indirect effects of climate change on energy  
15 production and use in the United States is effects of climate change policy on technology  
16 research and development and on technology preferences and choices.

17  
18 For instance, if the world moves toward concerted action to stabilize concentrations of  
19 greenhouse gases (GHG) in the earth's atmosphere, the profile of energy resources and  
20 technologies being used in the U.S. – on both the production and use sides – would have  
21 to change significantly (CCTP, 2005). Developing innovative energy technologies and  
22 approaches through science and technology research and development is widely seen as a  
23 key to reducing the role of the energy sector as a driver of climate change. Considering  
24 various climate change scenarios, researchers have modeled a number of different  
25 pathways in order to inform discussions about technology options that might contribute to  
26 energy system strategies (e.g., Edmonds et al, 1996; Akimoto et al., 2004; Hoffert et al.,  
27 2002; van Vuuren et al, 2004; Kainuma et al, 2004; IPCC 2005a; Kurosawa, 2004; and  
28 Pacala and Socolow, 2004). In addition, there have been important recent developments  
29 in scenario work in the areas of non-CO2 GHGs, land use and forestry emission and  
30 sinks, emissions of radiatively important non-GHG such as black and organic carbon,  
31 and analyses of uncertainties, among many issues in increasing mitigation options and

1 reducing costs (Nakicenovic and Riahi, 2003; IPCC 2005b; van Vuuren et al, 2006; and  
2 Placet et al, 2004.

3  
4 These references indicate that a high degree of emissions reductions could be achieved  
5 through combinations of many different technologies. A large number of scenario-based  
6 analyses conducted by different research groups show the importance of technology  
7 advancement, especially if R&D support is diversified. Although the full range of effects  
8 in the future is necessarily speculative, it is possible that successful development of  
9 advanced technologies could result in potentially large economic benefits. When the costs  
10 of achieving different levels of emission reductions have been compared for cases with  
11 and without advanced technologies, many of the advanced technology scenarios  
12 projected that the cost savings from advancement would be significant. Note, however,  
13 that there is considerable “inertia” in the nation’s energy supply capital stock because  
14 institutions that have invested in expensive facilities prefer not to have them converted  
15 into “stranded assets.” Note also that any kind of rapid technological transformation  
16 would be likely to have cross-commodity cost/price effects, e.g., on costs of specialized  
17 components in critical materials that are in greater demand.

### 19 **4.2.3 Possible Effects On Energy Production And Use *Institutions***

20  
21 Climate change could affect the institutional structure of energy production and use in the  
22 United States, although relatively little research has been done on such issues.

23 Institutions include energy corporations, electric utilities, governmental organizations at  
24 all scales, and non-governmental organizations. Their niches, size and structure, and  
25 operation tend to be sensitive to changes in “market” conditions from any of a variety of  
26 driving forces, these days including such forces as globalization, technological change,  
27 and social/cultural change (e.g., changes in consumer preferences). Climate change is  
28 likely to interact with other driving forces in ways that could affect institutions concerned  
29 with energy production and use.

30

1 Most of the very limited research attention to this type of effect has been focused on  
2 effects of climate change policy (e.g., policy actions to reduce greenhouse gas emissions)  
3 on U.S. energy institutions: such as on the financial viability of U.S. electric utilities  
4 (see, for instance, WWF, 2003). Other effects could emerge from changes in energy  
5 resource/technology mixes due to climate change: e.g., changes in renewable energy  
6 resources and costs or changes in energy R&D investment patterns.

7  
8 Most of these issues are speculative at this time, but identifying them is useful as a basis  
9 for further discussion. Issues would appear to include (see effects on planning, above).

#### 10 11 4.2.3.1 Effects on the institutional structure of the energy industry

12  
13 Depending on its impacts, climate change could encourage large energy firms to move  
14 into renewable energy areas that have been largely the province of smaller firms, as was  
15 the case in some instances in the wake of the energy “shocks” of the 1970s (e.g., Flavin  
16 and Lenssen, 1994). This kind of diversification into other “clean energy” fields could be  
17 reflected in horizontal and/or vertical integration, but possible effects of climate change  
18 on such issues as organizational consolidation vs. fragmentation are unknown.

#### 19 20 4.2.3.2 Effects on electric utility restructuring

21  
22 Recent trends in electric utility restructuring have included increasing competition in an  
23 open electricity supply marketplace, which has sharpened attention to keeping supply  
24 costs as low as possible. A corollary has been a reduction in the importance of state and  
25 other regulatory bodies. Some research literature suggests that one side-effect of  
26 restructuring has been a reduced willingness on the part of some utilities to invest in  
27 environmental protection beyond what is absolutely required by law and regulation  
28 (Parker, 1999; Senate of Texas, 1999). If climate change introduces new risks for utility  
29 investment planning and reliability, it is possible that policies and practices could  
30 encourage greater cooperation and collaboration rather than further increases in  
31 competition.

1

2 *4.2.3.3 Effects on the health of fossil fuel-related industries*

3

4 If climate change is associated with policy and associated market signals that  
5 decarbonization of energy systems, industries focused on the production of fossil fuels,  
6 converting them into useful energy forms, transporting them to demand centers, and  
7 providing them to users could face shrinking markets and profits. The coal industry  
8 seems especially endangered in such an eventuality. In the longer run, this type of effect  
9 depends considerably on technological change: e.g., affordable carbon capture and  
10 sequestration, fuel cells, and efficiency improvement. It is possible that industries (and  
11 regions) concentrated on fossil fuel extraction, processing, and use will seek to diversify  
12 as a hedge against risks of economic threats from climate change policy.

13

14 *4.2.3.4 Effects on other supporting institutions such as financial and insurance*  
15 *industries*

16

17 Many major financial and insurance institutions are gearing up to underwrite emission  
18 trading contracts, derivatives and hedging products, wind and biofuel crop guarantee  
19 covers for renewable energy, and other new financial products to support carbon  
20 emission trading and CDM, while they are concerned about exposure to financial risks  
21 associated with climate change impacts. In recent years, various organizations have tried  
22 to engage the global insurance industry in the climate change debate. Casualty insurers  
23 are concerned about possible litigation against companies responsible for excessive GHG  
24 emissions, and property insurers are concerned about future uncertainties in weather  
25 damage losses. However, it is in the field of adaptation where insurers are most active,  
26 and have most to contribute. 200 major companies in the financial sector around the  
27 world have signed up to the UN Environment Program's - Finance Initiative, and 95  
28 institutional investment companies have so far signed up to the Carbon Disclosure  
29 Project. They ask businesses to disclose investment-relevant information concerning  
30 their GHGs. Their website provides a comprehensive registry of GHGs from public  
31 corporations. Over 300 of the 500 largest companies in the world now report their

1 emissions on this website, recognizing that institutional investors regard this information  
2 as important for shareholders (Crichton, 2005).

### 4 **4.3 POSSIBLE EFFECTS ON ENERGY-RELATED DIMENSIONS** 5 **OF REGIONAL AND NATIONAL ECONOMIES**

7 It is at least possible that climate change could have an effect on regional economies by  
8 impacting regional comparative advantages related to energy availability and cost.  
9 Examples could include regional economies closely associated with fossil fuel production  
10 and use (especially coal) if climate change policies encourage decarbonization, regional  
11 economies dependent on affordable electricity from hydropower if water supplies  
12 decrease or increase, regional economies closely tied to coastal energy facilities that  
13 could be threatened by more intense coastal storms, and regional economies dependent  
14 on abundant electricity supplies if demands on current capacities increase or decrease due  
15 to climate change.

17 Hurricanes Katrina and Rita were particularly damaging to the energy availability to the  
18 U.S. from the Gulf Coast region, which amounts to about 30 percent and 21 percent,  
19 respectively of a normal year's crude oil and natural gas production from U.S. offshore  
20 fields (MMS, 2006). EIA (2006a) estimates that at the height of the refinery outages  
21 (September 22-25, 2005), as much as 29 percent of U.S. refining capacity and over 60  
22 percent of refining capacity in the Gulf Coast region were shut down, affecting jobs,  
23 incomes, and tax revenues in the region as well as economies in other regions. Another  
24 EIA Report published in December 2005 indicated that energy prices increased  
25 significantly compared to the same time previous year due to these hurricanes (EIA,  
26 2005c).

28 Attempts to estimate the economic impacts that could occur 50–100 years in the future  
29 have been made using various climate scenarios, but the interaction of climate and the  
30 nation's economy remains very difficult to define. Significant uncertainties therefore  
31 surround projections of climate change induced energy sector impacts on the U.S.or

1 regional economies. Changnon estimated that annual national economic losses from  
2 energy sector will outweigh the gains in years with major weather and climate extremes  
3 (Changnon, 2005). Jorgenson et. al. (2004) study impacts of climate change on various  
4 sectors of the U.S. economy from 2000 – 2100. In three optimistic scenarios, they  
5 conclude that increased energy availability and cost savings from reduced natural gas-  
6 based space heating more than compensate for increased expenditures on electricity-  
7 based space cooling. These unit cost reductions appear as productivity increases and,  
8 thus, improve the economy, whereas other three pessimistic scenarios show that  
9 electricity-based space conditioning experiences relatively larger productivity losses than  
10 does space conditioning from coal, wood, petroleum or natural gas; accordingly its  
11 (direct) unit cost rises faster and thus produces no benefits to the economy. Additionally,  
12 higher domestic prices discourage exports and promote imports leading to a worsening  
13 real trade balance. According to Mendelsohn et al., (2000), the U.S. economy will  
14 benefit from the climate change induced energy sector changes. However, Mendelsohn  
15 and Williams (2004) suggest that climate change will cause economic damages in the  
16 energy sector in every scenario. They suggest that temperature changes cause most of the  
17 energy impacts. Larger temperature increases generate significantly larger economic  
18 damages. The damages are from increased cooling expenditures required to maintain  
19 desired indoor temperatures. In the empirical studies, these cost increases outweighed  
20 benefits of the reduced heating expenditures unless starting climates are very cool  
21 (Mendelsohn and Neumann, 1999; Mendelsohn, 2001) (also see Chapter 2).

22  
23 In California, a preliminary assessment of the macroeconomic impacts associated with  
24 the climate change emission reduction strategies shows that the overall impacts of the  
25 climate change emission reduction strategies on the state's economy could be positive.  
26 Resulting impacts on the economy could translate into job and income gains for  
27 Californians. Such favorable impacts on the economy are possible because of the  
28 reduced costs associated with many of the strategies (CEPA, 2006). On the other hand,  
29 the study emphasizes that even relatively small changes in in-state hydropower  
30 generation result in substantial extra expenditure burdens on an economy for energy  
31 generation, because losses in this “free” generation must be purchased from other

1 sources; a ten percent decrease in hydroelectric supply would impose a cost of  
2 approximately \$350 million in additional electricity expenditures annually (Franco and  
3 Sanstad, 2006). Whereas electricity demand is projected to rise in California between 3  
4 to 20 percent by the end of this century, peak electricity demand would increase at a  
5 faster rate. Since annual expenditures of electricity demand in California represent about  
6 \$28 billion, even such a relatively small increases in energy demand would result in  
7 substantial extra energy expenditures for energy services in the state; a three percent  
8 increase in electricity demand by 2020 would translate into about \$930 million (in 2000  
9 dollars) in additional electricity expenditures (Franco and Sanstad, 2006). Particular  
10 concerns are likely to exist in areas where summer electricity loads already strain supply  
11 capacities (e.g., Hill and Goldberg, 2001; Kelly et al., 2005; Rosenzweig and Solecki,  
12 2001) and where transmission and distribution networks have limited capacities to adapt  
13 to changes in regional demands, especially seasonally (e.g., London Climate Change  
14 Partnership, 2002).

15  
16 Rose and others have examined effects of a number of climate change mitigation policies  
17 on U.S. regions in general and the Susquehanna River basin in particular (Rose and  
18 Oladosu, 2002; Rose and Zhang, 2004; Rose et al., 1999; Rose et al., forthcoming). In  
19 general, they find that such policy options as emission permits tradable among U.S.  
20 regions might have less than expected effects, with burdens impacting at least one  
21 Southern region which needs maximum permits but whose economy is not among the  
22 nation's strongest. Additionally, they discuss Pennsylvania's heavy reliance on coal  
23 production and use infrastructure that increases the price of internal CO2 mitigation.  
24 They suggest that the anomalies stem from the fact that new entrants, like Pennsylvania,  
25 into regional coalitions for cap-and-trade configuration may raise the permit price, may  
26 undercut existing states' permit sales, and may be able to exercise market power.  
27 Particularly, they raise an issue of the "responsibility" for emissions. Should fossil fuel  
28 producing regions take the full blame for emissions or are the using regions also  
29 responsible? They find that aggregate impacts of a carbon tax on the Susquehanna River  
30 Basin would be negative but quite modest. While Prindle et. al., (2006) suggest that  
31 adding energy efficiency savings to such a cap-and-trade scheme will considerably lower

1 the consumer energy bills, increase the economic output and personal income with a  
2 positive private-sector job growth by 2021.

3  
4 Concerns remain, however, that aggressive climate policy interventions to reduce GHG  
5 emissions could negatively affect regional economies linked to coal and other fossil  
6 energy production. Concerns also exist that climate change itself could affect the  
7 economies of areas exposed to severe weather events (positively or negatively) and areas  
8 whose economies are closely linked to hydropower and other aspects of the “energy-  
9 water nexus.”

#### 10 11 **4.4 POSSIBLE RELATIONSHIPS WITH *OTHER ENERGY-*** 12 ***RELATED ISSUES***

13  
14 Many other types of indirect effects are possible, although relatively few have received  
15 research attention. Without asserting that this listing is comprehensive, such effects  
16 might include:

##### 17 18 **4.4.1 Effects Of Climate Change In Other Countries On US Energy Production** 19 **And Use**

20  
21 We know from recent experience that climate variability outside the U.S. can affect  
22 energy conditions in the U.S.; an example is an unusually dry year in Spain in 2005  
23 which led that country to enter the international LNG market to compensate for scarce  
24 hydropower, which in turn raised LNG prices for U.S. consumption (Sen, 2005;  
25 Alexander’s Gas & Oil Connections, 2005). It is important, therefore, to consider  
26 possible effects of climate change not only on international energy product suppliers and  
27 international energy technology buyers but also on other countries whose participation in  
28 international markets could affect U.S. energy availability and prices from international  
29 sources, which could have implications for energy security (see below). Climate change-  
30 related energy supply and price effects could be coupled with other price effects of  
31 international trends on U.S. energy, infrastructures, such as effects of aggressive  
32 programs of infrastructure development on China and India.

1

23  
24  
25  
26  
27  
28  
29  
30  
31

A particularly important case is U.S. energy inputs from Canada. Canada is the largest single source of petroleum imports by the US (about 2.2 million barrels per day) and exports more than 15% of the natural gas consumed in the U.S. (EIA, 2005a, 2006). In 2004, it exported to the U.S. 33 MWh of electricity, compared with imports of 22.5 MWh (EIA, 2005b). Climate change could affect electricity exports and imports, for instance if electricity demands for space cooling increase in Canada or if climate change affects hydropower production in that country.

#### **4.4.2 Effects Of Climate Change On Energy Prices**

Climate change could affect energy prices in the U.S., more likely by adding to pressures for energy price increases than to decreases. Hurricane Katrina is a recent example of how increased exposure to severe storms due to climate change could raise energy prices, at least in the relatively short term, by disrupting energy production, storage, and transmission. This is one of several reasons why climate change might be associated with greater volatility in energy prices (Abbasi, 2005). Another possible example would be reduced production of relatively inexpensive hydropower in areas dependent on winter snowfall for production potential, where warming reduces annual snowfall. On the other hand, it can be argued that energy technology responses to climate change and related policies would reduce energy price volatility by diversifying sources, which means that overall effects of climate change on energy prices are unclear.

#### **4.4.3 Effects Of Climate Change On Environmental Emissions**

Climate change is very likely to lead to reductions in environmental emissions from energy production and use in the U.S. One possibility is that climate change will enhance the competitiveness of renewable energy alternatives as technological change reduces their costs, and their growing share in total U.S. energy production would reduce net emissions. Another possibility, perhaps a higher probability, is that climate change

1 policy will affect choices of energy resources and technologies in ways that result in  
2 reduced greenhouse gas and other environmental emissions (see indirect impacts on  
3 technologies above), including but not limited to renewable energy sources.  
4

#### 5 **4.4.4 Effects Of Climate Change On Energy Security**

6  
7 Climate change relates to energy security because different drivers of energy policy  
8 interact. As one example, some strategies to reduce oil import dependence, such as  
9 increased use of renewable energy sources in the U.S., are similar to strategies to reduce  
10 GHG emissions as a climate change response (e.g., IEA, 2004; O’Keefe, 2005). As  
11 another example, energy security relates not only to import dependence but also to energy  
12 system reliability, which can be threatened by possible increases in the intensity of severe  
13 weather events. A different kind of issue is potential impacts of abrupt climate change in  
14 the longer run. One study has suggested that abrupt climate change could lead to very  
15 serious international security threats, including threats of global energy crises, as  
16 countries act to defend and secure supplies of essential commodities (Schwarz and  
17 Randall, 2003).  
18

#### 19 **4.4.5 Effects Of Climate Change On Energy Technology And Service** 20 **Exports**

21  
22 Finally, climate change could affect U.S. energy technology and service exports. It is  
23 very likely that climate change will have some impacts on global energy technology,  
24 institutional, and policy choices. Effects of these changes on U.S. exports would  
25 probably be determined by whether the US is a leader or a follower in energy technology  
26 and policy responses to concerns about climate change. More broadly, carbon emission  
27 abatement actions by various countries are likely to affect international energy flows and  
28 trade flows in energy technology and services (e.g., Rutherford, 2001). In particular, one  
29 might expect flows of carbon-intensive energy forms and energy technologies and  
30 energy-intensive products to be affected.  
31

## 1 **4.5 SUMMARY OF KNOWLEDGE ABOUT INDIRECT EFFECTS**

2  
3 From the available research literature, it appears that the most salient indirect effects of  
4 climate change on energy production and use in the United States are likely to be changes  
5 in energy resource/technology preferences and investments, along with associated  
6 reductions in GHG emissions. Less-studied but also potentially important are possible  
7 impacts on the institutional structure of energy supply in the United States, responding to  
8 changes in perceived investment risks and emerging market and policy realities. Perhaps  
9 the most important insight from the limited current research literature is that climate  
10 change will affect energy production and use not only as a driving force in its own right  
11 but in its interactions with other driving forces such as energy security. Where climate  
12 change response strategies correspond with other issue response strategies, they can add  
13 force to actions such as reduced dependence on imported oil and gas and increased  
14 reliance on domestic non-carbon energy supply sources. Where climate change impacts  
15 contradict other driving forces for energy decisions, they are much less likely to have an  
16 effect on energy production and use.

17  
18

1  
2 **CHAPTER 5: CONCLUSIONS AND RESEARCH**  
3 **PRIORITIES**  
4

5  
6 **5.1 INTRODUCTION**  
7

8  
9 The previous chapters have summarized a variety of currently available information  
10 about effects of climate change on energy production and use in the United States. For  
11 two reasons, it is important to be careful about drawing firm conclusions about effects at  
12 this time. One reason is that the research literatures on many of the key issues are  
13 limited, supporting an identification of issues but not a resolution of most uncertainties.  
14 A second reason is that, as with many other categories of climate change effects in the  
15 U.S., the effects depend on a wide range of factors beyond climate change alone, such as  
16 patterns of economic growth and land use, patterns of population growth and distribution,  
17 technological change, and social and cultural trends that could shape policies and actions,  
18 individually and institutionally.

19  
20 Accordingly, this final chapter of SAP 4.5 will sketch out what appear, based on the  
21 current knowledge base, to be the most likely types of effects on the energy sector. These  
22 should be considered along with effects on other sectors that should be considered in risk  
23 management discussions in the near term. As indicated in Chapter 1, conclusions are  
24 related to degrees of likelihood: likely (2 chances out of 3), very likely (9 chances out of  
25 10), or virtually certain (99 chances out of 100). The chapter will then discuss issues  
26 related to prospects for energy systems in the U.S. to adapt to such effects, although  
27 literatures on adaptation are very limited. Finally, it will suggest a limited number of  
28 especially high priorities in expanding the knowledge base so that, when further  
29 assessments on this topic are carried out, conclusions about effects can be offered with a  
30 higher level of confidence.

31

## 5.2 CONCLUSIONS ABOUT EFFECTS

If one assumes that widely accepted scenarios for climate change can be accepted with relatively high levels of confidence, a number of conclusions are possible about likely effects on energy *use* in the U.S:

- Climate change will mean significant reductions in heating requirements for buildings, with different effects on energy sources for heating (e.g., electricity, natural gas, fuel oil) and by regions (virtually certain)
- Climate change will mean significant increases in cooling requirements for buildings, mainly affecting electricity supply, with different impacts by region (virtually certain)
- Net effects on energy use will differ by region, with net lower total energy requirements for buildings in net heating load areas and net higher energy requirements in net cooling load areas, with overall impacts affected by patterns of interregional migration – which are likely to be in the direction of net cooling load regions (virtually certain)
- Climate change will have particular implications for peak demands for energy, positive or negative (virtually certain)
- Other effects of climate change are less clear, but some could be non-trivial: e.g., increased energy use for water pumping and/or desalination in areas that see reductions in water supply (very likely)

A number of conclusions can be offered with relatively high levels of confidence about effects of climate change on energy *production and supply* in the U.S., but generally the research evidence is not as strong as for effects on energy use:

- 1 • Higher temperatures are likely to affect process efficiencies and water needs for  
2 thermal facilities (very likely)  
3
- 4 • Regions facing reductions in water supplies, from either reduced precipitation or  
5 reduced snowpack, are likely to experience impacts on energy systems and  
6 facilities that are sensitive to water availability, such as hydropower and thermal  
7 power plants requiring water-based cooling (very likely)  
8
- 9 • In general, the siting of new energy facilities and systems are likely to face  
10 increased restrictions, related partly to complex interactions among the wider  
11 range of water uses (likely)  
12
- 13 • More intensive extreme weather events are likely to affect energy systems in  
14 vulnerable areas, including coastal and offshore oil/gas facilities and electricity  
15 transmission lines (likely)  
16
- 17 • Sea-level rise and possible risks of increased flooding could affect energy facility  
18 siting and the operation of existing facilities, such as in coastal areas (likely)  
19
- 20 • Effects on biomass for biofuels are likely to be considerable, positively or  
21 negatively depending on crop and region, with positive impacts more likely on  
22 adaptable dedicated energy crops such as switchgrass (likely)  
23
- 24 • Overall, the current energy supply infrastructure is often located in areas where  
25 significant climate change might occur, but large-scale disruptions are not likely  
26 except during extreme weather events. Most effects on fossil and nuclear  
27 electricity components are likely to be modest decreases in cycle efficiency due to  
28 rises in air and water temperatures and/or reduced availability of cooling water.  
29

30 California is one U.S. state where impacts on both energy use and energy production  
31 have been studied with some care (See Box 5.1 California: A Case Study).

### BOX 5.1 CALIFORNIA: A CASE STUDY

California is unique in the United States as a state that has examined possible effects of climate change on its energy production and use in some detail. Led by the California Energy Commission and supported by such nearby partners as the Electric Power Research Institute, the University of California–Berkeley, and the Scripps Institution of Oceanography, the state is developing a knowledge base on this subject that could be a model for other states and regions (as well as the nation as a whole).

Generally, the analyses to date (many of which are referenced in Chapters 2 and 3) indicate that electricity demand will grow due to climate change, with an especially close relationship between peak electricity demand and temperature increases (Franco and Sanstad, 2006), and water supply – as an element of the “energy-water nexus” – will be affected by a reduction in the Sierra snowpack (by as much as 70-90 % over the coming century: Vicuña et al., 2006). Patterns of urbanization could add to pressures for further energy supplies. Adaptations to these and other climate change impacts appear possible, but they could be costly (Franco, 2005). Overall economic impacts will depend considerably on the effectiveness of response measures, which tend currently to emphasize emission reduction but also consider impact scenarios and potential adaptation measures (CEPA, 2006).

Other relevant studies of the California context for climate change effects reinforce an impression that effects of warming and snowpack reduction could be serious (Hayhoe et al., 2004) and that other ecosystems related to renewable energy potentials could be affected as well (Union of Concerned Scientists, 1999).

1

2 About *indirect effects of climate change on energy production and use* in the U.S.,  
3 conclusions are notably mixed. Conclusions related to possible impacts of climate  
4 change policy interventions on technology choice and emissions can be offered with  
5 relatively high confidence based on published research. Other types of possible indirect  
6 effects can be suggested as a basis for discussion, but conclusions must await further  
7 research

8

1 **Conclusions**

- 2
- 3 • Climate change concerns are very likely to affect perceptions and practices related  
4 to risk management in investment behavior by energy institutions (very likely)  
5
  - 6 • Climate change concerns, especially if they are expressed through policy  
7 interventions, are almost certain to affect public and private sector energy  
8 technology R&D investments and energy resource/technology choices by energy  
9 institutions, along with associated emissions (virtually certain)  
10
  - 11 • Climate change can be expected to affect other countries in ways that in turn  
12 affect US energy conditions (very likely)  
13

14 **Other Types Of Possible Effects**

- 15
- 16 • Climate change could affect the structure and health of some energy  
17 institutions in the U.S. (likely)  
18
  - 19 • Climate change effects on energy production and use could in turn affect some  
20 regional economies, either positively or negatively (likely)  
21
  - 22 • Climate change is likely to have some effects on energy prices in the U.S.,  
23 especially associated with extreme weather events (likely)  
24
  - 25 • Climate change concerns are likely to reinforce some driving forces behind  
26 policies focused on U.S. energy security, such as reduced reliance on oil  
27 products (likely)  
28

29 These conclusions add up to a picture that is cautionary rather than alarming. Since in  
30 many cases effects that could be a concern to U.S. citizens and U.S. energy institutions

1 are some decades in the future, there is time to consider strategies for adaptation to  
2 reduce possible negative impacts and take advantage of possible positive impacts.

### 4 **5.3 CONSIDERING PROSPECTS FOR ADAPTATION**

6 The existing research literature tends to treat the U.S. energy sector mainly as a driving  
7 force for climate change rather than a sector subject to impacts from climate change. As  
8 a result, there is very little literature on adaptation of the energy sector to effects of  
9 climate change, and the following discussion is therefore largely speculative.

11 Generally, both energy users and providers in the U.S. are accustomed to changes in  
12 conditions that affect their decisions. Users see energy prices fluctuate with international  
13 oil market conditions and with Gulf Coast storm behavior, and they see energy  
14 availability subject to short-term shortages for a variety of reasons (e.g., the California  
15 energy shortage of 2000 or electricity blackouts in some Northeastern cities in 2003).  
16 Energy providers cope with shifting global market conditions, policy changes, financial  
17 variables such as interest rates for capital infrastructure lending, and climate variability.  
18 In many ways, the energy sector is among the most resilient of all U.S. economic sectors,  
19 at least in terms of responding to changes within the range of historical experience.

21 For instance, electric utilities consider such planning strategies as weather-adjusted load  
22 growth forecasting, incorporating load uncertainty in both strategic and operational  
23 planning, and separating climate change signals from the noise of historic variability  
24 (Niemeyer, 2005). These are sophisticated, risk-averse institutions that care a great deal  
25 about avoiding mistakes that affect the reliability of service and/or the assurance of  
26 continued financial viability. One important guide to adaptation to climate *change* is  
27 what makes sense in adapting to climate *variability* (Franco, 2005).

29 On the other hand, such recent events as Hurricane Katrina (Box 5.2: Hurricane Katrina  
30 and the Gulf Coast: A Case Study) suggest that the U.S. energy sector is better at

**BOX 5.2 HURRICANE KATRINA AND THE GULF COAST:  
A CASE STUDY**

It is not possible to attribute the occurrence of Hurricane Katrina, August 29, 2005, to climate change; but projections of climate change say that extreme weather events are very likely to become more intense. If so (e.g., more of the annual hurricanes at higher levels of wind speed and potential damages), then the impacts of Katrina are an indicator of possible impacts of one manifestation of climate change.

Impacts of Katrina on energy systems in the region and the nation were dramatic at the time, and some impacts remained many months later. The hurricane itself impacted coastal and offshore oil and gas production, offshore oil port operation (stopping imports of more than one million bbl/d of crude oil), and crude oil refining along the Louisiana Gulf Coast. Within only a few days, oil product and natural gas prices had risen significantly across the U.S. As of mid-December 2005, substantial oil and gas production was still shut-in, and refinery shutdowns still totaled 367, 000 bbl/d (EIA, 2005) (see Chapter 3).

Possibilities for adaptation to reduce risks of damages from future Katrinas are unclear. They might include such alternatives as hardening offshore platforms and coastal facilities to be more resilient to high winds, wave action, and flooding (potentially expensive) and shifting the locations of some coastal refining and distribution facilities to less vulnerable sites, reducing their concentration in the Gulf Coast (potentially very expensive).

1

2

3 responding to relatively short-term variations and uncertainties than to changes that reach  
4 beyond the range of familiar short-term variabilities (Niemeyer, 2005). In fact, the  
5 expertise of U.S. energy institutions in reducing exposure to risks from short-term  
6 variations might tend to reduce their resilience to larger long-term changes, unless an  
7 awareness of risks from such long-term changes is heightened.

8

9 Adaptations to effects of climate change on energy *use* may focus on increased demands  
10 for space cooling in areas affected by warming. Alternatives could include reducing  
11 costs of cooling for users through energy efficiency improvement in cooling equipment  
12 and building envelopes; responding to likely increases in demands for electricity for  
13 cooling through expanded generation capacities, expanded inerties, and possibly

1 increased capacities for storage; and responding to concerns about increased peakiness in  
2 electricity loads, especially seasonally, through contingency planning for load-leveling.

3  
4 Adaptations to effects on energy *production and supply* are less straightforward to  
5 evaluate, not only because such activities are so diverse but also because they are  
6 enmeshed in so many uncertainties about climate change mitigation policymaking. The  
7 most likely effect is an increase in perceptions of uncertainty and risk in longer-term  
8 strategic planning and investment, which could seek to reduce risks through such  
9 approaches as diversifying supply sources and technologies and risk-sharing  
10 arrangements.

11  
12 Adaptation to *indirect effects* of climate change on the energy sector is likely to be  
13 bundled with adaptation to other issues for energy policy and decision-making in the  
14 U.S., such as energy security: for instance, in the development of lower carbon-emitting  
15 fossil fuel use technology ensembles and the development of alternatives to fossil fuels  
16 and effects on energy institutional structures. Issues related to effects of climate change  
17 on other countries linked with U.S. energy conditions are likely to be addressed through  
18 attention by both the public and private sectors to related information systems and market  
19 signals.

20  
21 It seems possible that adaptation challenges would be greatest in connection with possible  
22 increases in the intensity of extreme weather events and possible significant changes in  
23 regional water supply regimes. More generally, adaptation prospects appear to related to  
24 the magnitude and rate of climate change, with adaptation more likely to be able to cope  
25 with effects of lesser amounts and slower rates of change (Wilbanks et al., 2006).

26  
27 Generally, prospects for these types of adaptations depend considerably on the level of  
28 awareness of possible climate changes at a relatively localized scale and possible  
29 implications for energy production and use – the topic of this study. When the current  
30 knowledge base to support such awareness is so limited, this suggests that expanding the  
31 knowledge base is important to the energy sector in the United States.

## **5.4 PRIORITIES FOR EXPANDING THE KNOWLEDGE BASE**

Expanding the knowledge base about effects of climate change on energy production and use in the United States is not just a responsibility of the federal government. As the work of such institutions as the Electric Power Research Institute and the California Energy Commission demonstrates, a wide variety of parts of U.S. society have knowledge, expertise, and data to contribute to what should be a broad-based multi-institutional collaboration.

Recognizing that roles in these regards will differ among federal and state governments, industry, non-governmental institutions, and academia and that all parties should be involved in discussions about how to proceed, this study suggests the following priorities for expanding the knowledge base on its topic.

### **5.4.1 General Priorities**

- Improved projections of climate change and its effects on a relatively fine-grained geographic scale, especially of precipitation changes and severe weather events: e.g., in order to support evaluations of impacts at local and small-regional scales, not only in terms of gradual changes but also in terms of extremes, since many energy facility decisions are made at a relatively localized scale
- Research on implications of extreme weather events for energy system resiliency
- Research on potentials, costs, and limits of adaptation to risks of adverse effects, for both supply and use infrastructures
- Research on implications of changing regional patterns of energy use for regional energy supply institutions and consumers

- 1 • Improvements in the understanding of effects of changing conditions for  
2 renewable energy and fossil energy development and market penetration on  
3 regional energy balances and their relationships with regional economies  
4
- 5 • In particular, improvements in understanding likely effects of climate change in  
6 Arctic regions and on storm intensity to guide development and deployment of  
7 new technologies and other adaptations for energy infrastructure and energy  
8 exploration and production in these relatively vulnerable regions  
9
- 10 • Attention to linkages and feedbacks among climate change effects, adaptation,  
11 and mitigation; to linkages between effects at different geographic scales; and  
12 relationships between possible energy effects and other possible economic,  
13 environmental, and institutional changes (Parson et al., 2003; Wilbanks, 2005).  
14

#### 15 **5.4.2 Priorities Related To Major Technology Areas**

- 16
- 17 • Improving the understanding of potentials to increase efficiency improvements in  
18 space cooling  
19
- 20 • Improving information about interactions among water demands and uses where  
21 the quantity and timing of surface water discharge is affected by climate change  
22
- 23 • Improving the understanding of potentials to increase thermal power plant cooling  
24 in ways that reduce water usage (consumptive or otherwise)  
25
- 26 • Developing strategies to increase the resilience of coastal and offshore oil and gas  
27 production and distribution systems to extreme weather events  
28
- 29 • Improving information about possible climate change effects on biofuels  
30 production and market competitiveness

1  
2  
3  
4  
5  
6  
7  
8  
9  
10  
11  
12

- Pursuing strategies and improved technology potentials for adding resilience to energy supply systems that may be subject to stress under possible scenarios for climate change: e.g., energy storage approaches
- Improving understandings of potentials to improve resilience in electricity supply systems through regional inertia capacities and distributed generation

Other needs for research exist as well, and the process of learning more about this topic in coming years may change perceptions of needs and priorities; but based on current knowledge, these appear to be high priorities in the next several years.
