

This report may be used, in whole or in part, as the basis for development of clinical practice guidelines and other quality enhancement tools, or a basis for reimbursement and coverage policies. AHRQ or U.S. Department of Health and Human Services endorsement of such derivative products may not be stated or implied.

AHRQ is the lead Federal agency charged with supporting research designed to improve the quality of health care, reduce its cost, address patient safety and medical errors, and broaden access to essential services. AHRQ sponsors and conducts research that provides evidence-based information on health care outcomes; quality; and cost, use, and access. The information helps health care decisionmakers—patients and clinicians, health system leaders, and policymakers—make more informed decisions and improve the quality of health care services.

## Preface

The Agency for Healthcare Research and Quality (AHRQ) sponsors the development of Systematic Evidence Reviews (SERs) through its Evidence-based Practice Program. With guidance from the third U.S. Preventive Services Task Force\* (USPSTF) and input from Federal partners and primary care specialty societies, two Evidence-based Practice Centers—one at the Oregon Health Sciences University and the other at Research Triangle Institute-University of North Carolina—systematically review the evidence of the effectiveness of a wide range of clinical preventive services, including screening, counseling, immunizations, and chemoprevention, in the primary care setting. The SERs—comprehensive reviews of the scientific evidence on the effectiveness of particular clinical preventive services—serve as the foundation for the recommendations of the third USPSTF, which provide age- and risk-factor-specific recommendations for the delivery of these services in the primary care setting. Details of the process of identifying and evaluating relevant scientific evidence are described in the “Methods” section of each SER.

The SERs document the evidence regarding the benefits, limitations, and cost-effectiveness of a broad range of clinical preventive services and will help to further awareness, delivery, and coverage of preventive care as an integral part of quality primary health care.

AHRQ also disseminates the SERs on the AHRQ Web site (<http://www.ahrq.gov/uspstfix.htm>) and disseminates summaries of the evidence (summaries of the SERs) and recommendations of the third USPSTF in print and on the Web. These are available through the AHRQ Web site (<http://www.ahrq.gov/uspstfix.htm>), through the National Guideline Clearinghouse (<http://www.ncg.gov>), and in print through the AHRQ Publications Clearinghouse (1-800-358-9295).

We welcome written comments on this SER. Comments may be sent to: Director, Center for Practice and Technology Assessment, Agency for Healthcare Research and Quality, 6010 Executive Blvd., Suite 300, Rockville, MD 20852.

\*The USPSTF is an independent panel of experts in primary care and prevention first convened by the U.S. Public Health Service in 1984. The USPSTF systematically reviews the evidence on the effectiveness of providing clinical preventive services—including screening, counseling, immunization, and chemoprevention—in the primary care setting. AHRQ convened the third USPSTF in November 1998 to update existing Task Force recommendations and to address new topics.

The authors of this report are responsible for its content. Statements in the report should not be construed as endorsement by the Agency for Healthcare Research and Quality or the U.S. Department of Health and Human Services of a particular drug, device, test, treatment, or other clinical service.

# Structured Abstract

**Context:** Methods that improve detection of serious cervical lesions while minimizing excess screening are the key to advancing cervical cancer prevention.

**Objective:** To examine the evidence about benefits and harms of screening among older women (ages 65 and older) and those who have had hysterectomies, and to examine the diagnostic performance of new technologies and human papilloma virus (HPV) testing for detecting cervical lesions.

**Data Sources:** We identified English-language articles on cervical neoplasia, cervical dysplasia, and screening from a comprehensive search of the MEDLINE database from 1995 through June 2000. In addition, we used published systematic reviews, the second *Guide to Clinical Preventive Services*, and peer review to assure a complete update of specific topics.

**Study Selection:** We included articles that reported on screening for squamous cell carcinoma of the cervix if they included the age distribution of the study population and presented analyses stratified by age or if they included hysterectomy status as a covariate. For diagnostic tools, we required that the test be used as part of a screening strategy, that the method be compared with a reference standard, and that all cells of a 2x2 table can be completed.

**Data Extraction:** We extracted the following data from articles addressing screening among older women and those who have had a hysterectomy: study design, objectives, location and timeframe, source of the data (e.g., population-based registry), participants, screening program used, outcomes and measures, and results relevant to age and screening interval. For articles about diagnostic tests, we extracted study design, test methods, location, patient population, outcome measures (emphasizing documentation of the reference standard), prevalence of lesions, and test characteristics including sensitivity, specificity, and predictive

## Structured Abstract

---

values. We used scoring checklists to summarize strengths of the publications; we also evaluated the validity of each article and the overall quality of the evidence.

**Data Synthesis:** The evidence about age and hysterectomy is observational, predominantly from population- or care-based data. The findings are consistent: risk of cervical cancer or abnormalities falls with age; high-grade and more severe lesions are detected in fewer than 1 per 1,000 Pap tests among women older than 60 who have had prior screening; and longer histories of prior normal Pap tests further reduces risk. After hysterectomy, high-grade vaginal lesions are rare, fewer than 2 to 4 per 10,000 tests. The literature about new diagnostic tools is limited by lack of histologically validated performance. Using tools such as liquid cytology, neural-net rescreening, and computer-based review algorithms improves sensitivity; however, this improvement is predominantly for detection of low-grade lesions. The impact on specificity is poorly documented. Sensitivity of HPV testing for screening detection of high-grade lesions is competitive with conventional cytology (roughly 82%); specificity is lower (78%); and negative predictive value is good (99%). For triage of women with abnormal Pap tests, sensitivity for detecting high-grade lesions is 85%, specificity is 60%, and negative predictive value is 97%.

**Conclusion:** The yield of screening among older women who have been previously screened decreases with age; if recommendations are not modified, older women are disproportionately likely to have evaluations for false-positive findings. The prior recommendation of the US Preventive Services Task Force to discontinue Pap testing after hysterectomy for benign disease is supported. For making decisions about screening modality in US populations, evidence about these new technologies for cytology screening and HPV testing is currently limited. Controlled trials and prospective cost evaluation of new screening strategies

## **Structured Abstract**

---

in each of these areas are required. Important trials will be completed in 2001 that may clarify our conclusions.

# I. Introduction

## Background

Since introduction of cytologic screening for cervical cancer using the Papanicolaou (Pap) test in the 1950s, the incidence of invasive cervical cancer in the United States has fallen more than 100%.<sup>1</sup> No other cancer screening program has been more successful. This fall occurred despite an increase in risk factors for cervical cancer, such as younger age at initiation of sexual intercourse, more sexual partners in a lifetime, and greater prevalence of human papilloma virus (HPV) infection and cigarette smoking.

Success in prevention reflects three factors: (1) progression from early cellular abnormalities, termed low-grade dysplasia, through more severe dysplasia, to carcinoma *in situ* and invasive cancer is generally slow, allowing time for detection; (2) associated cellular abnormalities can be identified; and (3) effective treatment is available for premalignant lesions. Consequently, invasive squamous cell carcinoma of the uterine cervix is a highly preventable disease.

Introduction of screening programs in populations naïve to screening reduces cervical cancer rates by 60% to 90% within three years of implementation.<sup>2,3</sup> This reduction of mortality and morbidity with introduction of screening with the Pap test is consistent and dramatic across populations. As a result, Pap testing is one of the few preventive interventions that has received an “A” recommendation from the US Preventive Services Task Force (USPSTF) in the absence of randomized trials demonstrating effectiveness.<sup>4</sup>

### Uniform Terminology for Cervical Lesions

Figure 1 depicts the relationship between varied systems of nomenclature for describing cytologic and histologic findings. In this report we use terminology from the Bethesda System — low-grade squamous intraepithelial lesion (LSIL) and high-grade squamous intraepithelial lesion (HSIL) to describe cytology findings. When possible, we use the cervical intraepithelial neoplasia (CIN)—specifically, categories CIN 1-3—to refer to histologic findings. As necessary, we present histology findings for the groupings LSIL or HSIL if this is the most detailed summary of results provided by the investigators.

### Burden of Suffering

In the United States, approximately 12,800 new cases of cervical cancer are diagnosed and 4,800 deaths occur each year.<sup>5</sup> Incidence of cervical cancer is decreasing; US rates have decreased from 14.2 new cases per 100,000 women in 1973 to 7.8 per 100,000 in 1994. For each woman with invasive disease, there will be 4 with carcinoma in situ and 10 with cervical dysplasia.<sup>6</sup> Despite falling incidence, cervical cancer remains the ninth most common cause of cancer deaths.<sup>5</sup> Of the cancer prevention goals established in *Healthy People 2000*, including colorectal, lung, and breast cancer, cervical cancer mortality rates were the furthest off target at the mid-course review. The target for cervical cancer was reduction of mortality to 1.3 deaths per 100,000 women; the current rate remains near 2.7 deaths per 100,000, down only slightly from 2.8 per 100,000 in 1987.<sup>7</sup>

Detection of cervical cancer in its earliest stages is lifesaving, as survival of cancer of the cervix uteri depends heavily on stage at diagnosis. Although 91.5% of women will survive 5 years when the cancer is localized, only 12.6% will survive distant disease.<sup>1</sup>

### Epidemiology

#### Risk Factors

Squamous cell carcinoma of the cervix and its cytologic precursors are conditions of sexually active women. Infection with high-risk strains of HPV, generally acquired sexually, is the most important risk factor for cervical cancer. The role of HPV is described in greater detail below.

Risk factors relating to sexual behavior that are associated with increased risk include onset of intercourse at an early age and a greater number of lifetime sexual partners. These behavioral risks appear to persist even after controlling for effects of HPV infection.<sup>8</sup> A higher number of lifetime sexual partners in the male partners of cervical cancer cases compared to controls has also been noted in case-control studies.<sup>8</sup> Occupations are related to cervical cancer only through relationships with sexual behavior.<sup>8</sup> Cigarette smoking is the only nonsexual behavior consistently and strongly correlated with cervical dysplasia and cancer, independently increasing risk two- to fourfold.<sup>9-11</sup> In the United States, black race and low socioeconomic status are associated with increased risk. Recently, attention has been drawn to a positive family history as a plausible risk factor.<sup>12</sup>

#### Role of Human Papilloma Virus

HPV plays a central role in the development of cervical cancer. Using modern HPV detection methods, 95% to 100% of squamous cell cervical cancer and 75% to 95% of high-grade CIN lesions have detectable HPV DNA.<sup>13-15</sup>

HPV is a double-stranded DNA virus. The virus is transmitted to the cervix and vaginal tissues primarily by sexual intercourse.<sup>16,17</sup> HPV can infect and persist in vulvar, vaginal, and cervical tissue throughout a lifetime. This family of viruses includes those responsible for

## Chapter I. Introduction

---

genital condylomata or warts, squamous cell carcinomas of the genital tract including vaginal and vulvar cancers, and cervical cancer. More than 70 strains or types of HPV have been classified. For instance, HPV Types 6 and 11 cause warts; other types have oncogenic properties.

The best characterized types associated with cervical cancer are Types 16 and 18.<sup>18</sup> These are officially recognized by the International Agency for Research on Cancer (IARC) and the World Health Organization (WHO) as carcinogenic infectious agents. The primary difference between “oncogenic” and “non-oncogenic” virus is the interaction of two viral genes, E6 and E7, that influence cell cycle control mechanisms. Oncogenic E6 and E7 gene products can “cripple” a normal cell’s ability to control cell proliferation, which in some instances leads to cancer.

HPV is a necessary but not sufficient precursor of squamous cell carcinoma of the cervix. Among women without cervical cytology abnormalities at baseline, those with high-risk HPV types have a relative risk of developing high-grade cervical lesions (CIN 2 - 3, CIS) that is 58- to 71-fold higher than the risk for those without detectable HPV.<sup>19,20</sup>

The natural history of HPV acquisition, clearance, persistence, and possible re-infection is complex. To promote cervical cancer abnormalities, the virus must become integrated into the host genomic DNA. This event, which is essential for cancer progression, appears to be rare. In the absence of viral integration, the normal viral lifecycle produces morphologic changes in the cervical epithelium characteristic of low-grade dysplasia (LSIL). With viral integration, the oncogenic effect of the E6 and E7 proteins is enhanced and cellular changes characteristic of high-grade dysplasia and ultimately cancer are observed.<sup>21,22</sup>

## Chapter I. Introduction

---

Inter-related host factors such as age, nutritional status, immune function, smoking, and possibly silent genetic polymorphisms modulate incorporation of viral DNA. Studies of the time required from infection to incorporation are challenging to interpret because assays for viral DNA integration are difficult to perform.<sup>18</sup> Taken as a whole, however, nearly 100% of cases of carcinoma in situ and cancer are estimated to have integrated HPV DNA compared to a small minority of low-grade lesions.<sup>15</sup>

The transition time from simple viral infection to integration of DNA is unknown and may be influenced by the risk profile of population studied. For instance, although the prevalence of HPV infection is higher among immunocompromised hosts such as HIV-infected women, the speed of progression to cervical cancer is not increased. Natural history studies confirm that in the vast majority of cases, the course of infection and cervical abnormalities that progress do so in an orderly fashion from less severe to more severe lesions; de novo HSIL with HPV incorporation appearing in a short interval is rare. Thus, the sequence associated with HPV infection and development of cervical cancer is as amenable to surveillance as are cytologic changes.

In the United States, peak incidence and prevalence of HPV infection occur among women under age 25.<sup>23</sup> More than 30% of postmenopausal women, however, have detectable HPV DNA using polymerase chain reaction (PCR) detection methods.

### Screening Failures

In the United States, incident cases of squamous cell carcinoma can be attributed to different categories of failures of screening. Between 50% and 70% of cancer cases occur among women who have never been screened or who have not been screened within the past 5 years.<sup>24,25</sup> Among women who have been screened, failures may occur in 3 ways. First,

## **Chapter I. Introduction**

---

abnormalities may be identified by screening but not properly treated as a result of patient or provider failure to follow-up the abnormalities; this may occur in approximately 22% to 63% of those who receive proper screening. Second, serious abnormalities may not be present at the time of screening, and progression occurs between recommended screening intervals. When the interval is annual, such progression is rare; with 3-year intervals, this may happen in up to 50% of diagnosed cases.<sup>26</sup> Progression is more common among women under 45 years of age. Third, abnormalities may be present but are not detected by the screening test (approximately 14% to 33%).<sup>24,25</sup> The last category of failures, those related to the screening test, can be further subdivided into those that represent sampling error (cells from the abnormal area were not obtained and so could not be identified in the specimen) and those that reflect detection error (the abnormal cells are included in the specimen and are not identified as abnormal).

### **Screening Tools**

This report is focused on cervical cancer screening tools for clinical use in primary care settings. We consider traditional cytology and new cytologic technologies that are currently available to practitioners. HPV testing to identify specific types of HPV is less broadly available. Some HPV test methodologies such as Southern blot are appropriate as a gold-standard assay but not practical for widespread implementation in a cervical cancer screening program. As a result, we have focused on HPV tests suitable for high-volume use as part of primary clinical care. Basic descriptions of available cytologic and HPV screening tools are provided below.

### **Cervical Cytology: Conventional and New Technologies**

Ordinarily, cervical cancer screening specimens are obtained at the time of pelvic examination during the portion of the examination when a speculum is used to visualize the cervix and obtain a sample for cytology. The goal of sampling for cytology purpose is to sample the transformation zone: that area of the cervix where physiologic transformation from the columnar cells lining the endocervical canal to the squamous cells covering the ectocervix occurs. Cervical dysplasia and cancers arise in the transformation zone. The transformation zone is easily sampled in younger women because it is on the surface of the cervix. With increasing age, however, the transformation zone is more likely to be higher in the endocervical canal.

Various sample collection tools are available to accomplish the goal of sampling both the ectocervix and the endocervix. Meta-analysis of randomized trials supports recommendations for combined use of a spatula, preferably an extended tip spatula, for sampling the ectocervix and a brush for sampling the endocervix.<sup>27</sup>

**Conventional cervical cytology** specimens are prepared by using the collection tool to smear the specimen onto a glass microscope slide while the woman is in the examination room. Two slides or two distinct areas of the same slide are prepared to represent the ectocervical and endocervical samples. The slides are then immediately sprayed with or placed in fixative. Slides are sent to the cytology laboratory and read by technicians who review the entire slide at 10x magnification, systematically in 2mm sections.

**Thin layer cytology** is a variation of conventional cytology. The Food and Drug Administration (FDA) has approved two systems: they are ThinPrep<sup>®</sup> (Cytyc, Boxborough, MA) and AutoCyte PREP<sup>®</sup> (TriPath Imaging, formerly Autocyte, Burlington, NC), approved in May

## Chapter I. Introduction

---

1996 and June 1999, respectively. Specimens are collected in the same fashion as those for conventional cytology; however, rather than smearing the sample onto slide(s), the sample is suspended in the fixative by stirring the specimen collection spatula and brush in the fixative solution. The container is sealed and the specimen sent to the cytology laboratory in solution rather than on slides; this theoretically improves the probability of transferring a representative sample of cells to the slide. In the laboratory, technicians disperse the sample in the fixative and then collect the cells on a filter and transfer them to a microscope slide in a monolayer.

Immediate fixation and uniform spread of the cells are designed to reduce detection errors by assuring that cells are well preserved, not obscured, and more easily assessed by cytology technicians.

Both conventionally prepared and thin layer specimens read by cytotechnologists are subject to random manual rescreening of slides that were interpreted as normal at a minimum rescreening rate of 10%, as required by the Clinical Laboratories Improvement Amendments (CLIA) of 1988 (Final Rule, Federal Register, 1992).

**Computerized rescreening** is designed to automate rescreening of Pap smears initially read as negative by a cytotechnologist. PapNet<sup>®</sup> (TriPath Imaging, Inc.) uses neural-network technology to interpret computerized images of the Pap slide. The system, approved by the FDA for rescreening use in December 1995, identifies cells or other material on negative Pap slides that require review and creates a summary display of up to 128 images that may contain abnormalities. A cytotechnologist then reviews the summary images and can also return to the original slide using light microscopy. Several countries allow use of PapNet as a primary screening as well as a rescreening technology, and the literature contains studies of both forms of use.

**Algorithm-based rescreening** identifies slides that exceed a selected probability for containing abnormal cells. The AutoPap<sup>®</sup> 300QC system (Neopath, Inc.—when reviewed, now TriPath), FDA approved in May 1998, can be set for different thresholds that result in 10%, 15%, or 20% review rates. Because a classification algorithm is applied, the slides selected for review are more likely to contain abnormalities than are negative Pap slides randomly selected for review. The system is reported to identify 70% to 80% of those slides misdiagnosed as normal (i.e., false negatives) at the time of manual screening. AutoPap is also employed for both routine screening and rescreening purposes outside the United States, and publications evaluate both types of use.

We excluded review of the performance of AutoSCREEN, a product for interactive, computer-assisted screening and rescreening. Its manufacturers no longer produce it after a corporate merger between the AutoPap parent company and the original producer. We also have not reviewed approaches that require additional time, equipment, expertise, or materials at the time of the clinical pelvic examination, such as speculoscopy, screening colposcopy, or cervicography to photograph the cervix. These are not suitable for widespread implementation in the United States.

### **Tools for HPV Testing**

Cellular changes associated with HPV infection can be seen on visual examination of cervical cytologic or biopsy specimens and, to a lesser degree, at colposcopy. However, the presence of these changes is neither sensitive nor specific.

Direct HPV testing methods for assessing the presence and type of HPV are more promising; they rely on identification of HPV viral DNA. Some versions of testing are qualitative, detecting only the presence or absence of HPV DNA; some are quantitative,

## Chapter I. Introduction

---

estimating the viral burden; and some methods allow assessment of degree of integration of HPV into the host genome. Tests differ in the method for processing the DNA analyzed, the quantity of specimen required, and difficulty of analysis.

Because the family of HPV viruses is large, and because only a small group of those types is associated with cervical dysplasia and cervical cancer, tests that identify specific viral types or panels of high-risk viral types are preferable to detection of all HPV types. A multitude of laboratory methods has been applied to studying HPV. However, these approaches are not all equally applicable to screening. Considering the reliability and relative performance characteristics of the assays in controlled settings in the laboratory and their potential for application to screening, we have adopted the classification of HPV testing technologies presented in Table 1.

This is a modification of the classification used by John Cuzick, his co-authors, and an expert panel of the Health Technology Assessment Board of the UK National Health Service in their *Systematic Review of the Role of Human Papillomavirus Testing Within a Cervical Cancer Screening Program*.<sup>21</sup> Based on consultation within our team, with our USPSTF liaisons, and with other experts, we have focused our review on evaluation of clinically collected cervical samples using Hybrid Capture II (HCII) and on type-specific, the SHARP detection system, or conventional consensus PCR.

## Health Care Interventions

Reduction of morbidity and mortality associated with squamous cell carcinoma of the cervix is the ultimate goal of screening. The screening system used must be acceptable to patients and providers and detect abnormalities that are amenable to intervention. The broad

## Chapter I. Introduction

---

spectrum of cervical abnormalities detected by cytology, from low-grade changes to carcinoma in situ, is a particular challenge. HSIL warrants immediate evaluation by colposcopy, biopsy, and endocervical curettage. Patients with CIN 3/CIS receive definitive intervention, such as conization by loop electrosurgical excision procedure (LEEP), laser, or cold knife, to remove the transformation zone and confirm that no invasive disease is present. Patients with CIN 2 may be treated with conization or ablative procedures to remove or destroy the transformation zone. Appropriate intervention for atypical squamous cells of uncertain significance (ASCUS) and LSIL are active areas of research focused on determinants of progression, stability, and regression.

Current clinical care of ASCUS and LSIL increases the vigilance of follow-up and results in colposcopic evaluation for the majority of women with these diagnoses. Evaluation of ASCUS is guided by the cytologic clarification that accompanies the diagnosis: (a) reactive processes are followed with repeat Paps every 6 months until 3 normals; (b) inflammation prompts evaluation for infection, followed by repeat Pap; (c) atrophic changes are treated with topical estrogen, followed by repeat Pap; and (d) ASCUS favoring atypia is evaluated in a fashion comparable to the degree of atypia suggested (i.e., “ASCUS favor LSIL” is evaluated as LSIL). LSIL, in a patient who will be compliant with follow-up and is comfortable with expectant management, can be followed with repeat Paps every 6 months until 3 consecutive negative smears are obtained or progression is noted. Colposcopy and biopsy is preferred for high-risk patients (characteristically broadly defined and not clearly specified) and required for those with immune compromise or prior dysplasia.

As women are screened at younger ages and in larger numbers, and as tests are increasingly sensitive for detecting low-grade changes such as ASCUS and CIN 1, the

importance of assessing potential harms of screening becomes clear. The psychological effects of labeling young women with an anxiety-provoking, possibly precancerous condition, and the associated individual, health care system, and societal costs deserve attention. Ideally, screening tools would help guide selection of the intensity of intervention across the spectrum of cervical dysplasia.

For this report, we sought evidence about screening in older age groups and after hysterectomy. We also looked at methods to determine the optimal interval and at the potential contribution of new technologies and HPV testing methods to clinical prevention of cervical cancer. Furthermore, we sought evidence about the cost implications, the population to be screened, and potential harms that follow from screening.

## Prior Recommendations

### US Preventive Services Task Force

The second edition of the *Guide to Clinical Preventive Services* from the US Preventive Services Task Force gave an “A” to the recommendation of a regular Pap test for all women who are or have been sexually active and who have a cervix.<sup>4</sup>

The Task Force further stipulated (pg 112):<sup>4</sup>

There is little evidence that annual screening achieves better outcomes than screening every 3 years (“B” recommendation). The interval for each patient should be recommended by the physician based on risk factors. There is insufficient evidence to recommend for or against an upper age limit for Pap testing, but recommendations can be made on other grounds to discontinue regular testing after age 65 in women who have had regular previous screening in which the testing has been consistently normal (“C” recommendation). Women who have undergone a hysterectomy in which the cervix was removed do not require Pap testing unless the hysterectomy was performed because of cervical cancer or its precursors.

These recommendations were based on limited, although consistent, literature. The use of HPV testing, cervicography, and colposcopy lacked evidence in the literature to support routine use. Recommendations against use were based on other grounds, including poor specificity and costs.

### **Recommendations of Other Groups**

Table 2 summarizes the recommendations of 9 selected US organizations and other international groups and health systems with guidelines based on evidence review. We note information on starting age, interval, adaptation of interval for high-risk women, upper age limit for screening, and discontinuation after hysterectomy.

Intervals range from 2 to 5 years, in some cases with modification for individual risk and in some cases irrespective of risk. The most commonly advised screening interval is 3 years after a specified number of qualifying prior normal smears.

Six of the 9 groups suggest discontinuation among older women with prior normal screening history: The UK National Health Service Cancer Screening Programmes at 64; the American College of Preventive Medicine and the Institute for Clinical Systems Improvement at 65; the Canadian Task Force on Preventive Health Care at 69; and the National Cervical Cancer Screening Programs of Australia and New Zealand at age 70. Three specifically mention discontinuing testing after hysterectomy for benign disease.

No guidelines specifically address the utility or advisability of using new cytology technologies or HPV testing for screening or triage, within a screening system, except in noting that HPV infection is a high-risk factor that may guide choice of interval.

### **Analytic Framework and Key Questions**

The RTI-University of North Carolina Evidence-based Practice Center (RTI-UNC EPC), together with members of the USPSTF and other clinical and methodologic experts (see Appendix A), sought to update specific topics in the area of cervical cancer screening that have evolved rapidly in the past 5 years. This systematic evidence review (SER) updates Chapter 9 (pages 105-117) of the second *Guide to Clinical Preventive Services*.<sup>4</sup>

### **Analytic Framework**

Conceptualizing approaches to cervical cancer screening in primary care practice requires an analytic framework. Our framework (Figure 2) is not intended to provide etiologic detail; rather, it depicts the relationship between the progression of disease and the potential points of intervention to prevent morbidity and mortality. These potential points of intervention provide the rationale for the questions undertaken in this systematic review.

The pathway starts with women potentially eligible for screening. We have conceptualized screening as a process that may have more than one component. For example, a woman presenting for care may have her individual risk for cervical cancer assessed based on her past sexual history, medical history, and prior Pap test results. Using that information, clinicians determine the need for a Pap test. If a Pap test is done, the specimen may be prepared by conventional methods or new techniques. The cytology specimen may be read in the conventional manner or with pre-screening or re-screening by computer-assisted methods. Other screening studies, such as HPV testing, may be incorporated before a woman is determined to have normal or abnormal screening results.

## Chapter I. Introduction

---

We have denoted the combination of screening components in Figure 2 the “screening strategy.” Key Questions 2 and 3 (see below) focus on the role of specific components within a cervical cancer screening strategy.

In this analytic framework, women with normal findings at completion of a screening strategy return to the routine screening group. Women with abnormal screening tests progress to further evaluation. Evaluation may fail to identify any abnormalities (false-positive screening test results) or result in the diagnosis of cervical dysplasia or cancer. Among those who are diagnosed with an abnormality, the severity of dysplasia or stage of cancer is the primary determinant of treatment options and morbidity and mortality risk. The success of a screening strategy depends on early detection of pathology, which then facilitates early treatment, ultimately resulting in improved length of life, quality of life, or both for women who are screened.

### Key Questions

Our key questions are provided below. They appear in Figure 2 as Key Q1, Key Q2, and Key Q3 above the related arrows, which indicate steps in the prevention process and disease progression.

- Key Question 1: Who should be screened for cervical cancer and how often?

In developing the work plan for this SER, we specified this question broadly to prompt discussion of what focus would most contribute to guiding screening in primary care practice. We considered a range of potential topics including age at initiation of screening, need for screening among lesbian women, screening recommendations for women with HIV infection, interval of screening in the general population, screening after hysterectomy, and screening among older women including the relationship between aging and interval. Practical limitations

## Chapter I. Introduction

---

required a narrow focus. Ultimately we concurred that our work would be best focused on the screening needs of older women and on screening after hysterectomy. As a result, we restricted our examination to the evidence about the cervical cancer screening needs of older women who have had a hysterectomy.

Specifically, we asked what are the outcomes (benefits, harms, and costs) associated with screening:

- 1A. Among women age 65 and older?
- 1B. Among women who have had a hysterectomy?

Only Key Question 1A is focused on older age, interval among older women, and screening outcomes. *The remainder of the entire SER applies to all women irrespective of age.* For instance, 1B addresses screening among all women who have had a hysterectomy.

- Key Question 2: To what extent do new methods for preparing or evaluating cervical cytology improve diagnostic yield compared to conventional methods? At what cost (harms and economic)?
- Key Question 3: What is the role of HPV testing in cervical cancer screening strategies? Specifically:
  - 3A. What are the benefits, harms, and costs of using HPV testing as a screening test, or of incorporating HPV testing at the time of the screening Pap test, compared with not testing for HPV?
  - 3B. What are the benefits, harms, and costs of using HPV testing as part of a screening strategy to determine which women with an abnormal Pap test should receive further evaluation?

## Relevant Outcomes

Incidence of cervical cancer, severity of disease at the time of diagnosis, and cervical cancer mortality are relevant to all questions. However, no trials have been conducted to

## Chapter I. Introduction

---

evaluate the effectiveness of cervical cancer screening systems for improving these outcomes. Given the rarity of cervical carcinoma among women who receive any screening, much of this literature examines surrogate endpoints such as the diagnosis of dysplasia by colposcopy and/or cervical biopsies. The outcomes we have been able to assess were determined by the content of the literature. Outcome(s) of interest were tailored to the related key questions in the following fashion.

Outcomes for Key Question 1A and 1B, which address candidates for screening, include diagnosis of dysplasia, severity of dysplasia, progression of dysplasia, diagnosis of carcinoma, stage at diagnosis, and mortality. We retained cost data, if relevant to care in the United States, for background information. We also sought harms related to screening.

For Key Questions 2 and 3, which examine the test characteristics of new methods of preparing and evaluating cervical cytology and the contribution of HPV testing, the relevant outcomes include sensitivity, specificity, positive and negative predictive value, and diagnostic yield when compared to a gold standard. The standard used and the quality of evaluation of normal screening results both vary. Much of this literature is limited by failure to apply the gold standard evaluation to normal subjects, which precludes definitive assessment of specificity. We sought to evaluate the influence of these tools on the diagnoses and features listed above for Key Question 1, and we retained literature relevant to US costs for background.

Chapter II provides an overview of our methods for producing the SER. Chapter III presents the results of our literature search and synthesis organized by the key questions. We discuss the results and the limitations of the literature in Chapter IV with attention to ramifications for future research. Appendix A contains acknowledgments, Appendix B provides

## **Chapter I. Introduction**

---

additional detail about our methods, and Appendix C contains the evidence tables developed from the literature synthesis.

## II. Methods

This chapter documents procedures that the RTI-UNC Evidence-based Practice Center (EPC) used to develop this systematic evidence review (SER) on cervical cancer screening. We document the general search strategy and criteria, specify the final search terms, describe procedures for further review of abstracts and publications, explain methods used to extract information from included articles, introduce approach to summarizing findings, and detail the peer review process.

During preparation of the evidence report, EPC staff collaborated with two current members of the US Preventive Services Task Force (USPSTF). Our collaboration took place by conference call, electronic mail, traditional mail, and fax. We presented steps of the development of this SER at USPSTF meetings in February, May, and September 2000. A key consideration for the September 2000 meeting was the timing of the report with respect to the anticipated publication in the near future of results from the first randomized trial comparing cervical cancer screening tools.

### Literature Search Strategy

Our key questions guided the preliminary review of the literature. We have emphasized the identification of new research, existing syntheses of the literature, and opinions of leading medical and policy organizations, especially those reported since the completion of the second *Guide to Clinical Preventive Services*.<sup>4</sup> As part of the preliminary search, we took four steps: (1) reviewed prior USPSTF findings; (2) obtained current recommendations and/or guidelines for cervical cancer screening from the American Academy of Family Physicians, American

## Chapter II. Methods

---

Cancer Society, American College of Obstetricians and Gynecologists, Australian Health Ministers' Advisory Council, Canadian National Workshop on Screening for Cancer of the Cervix, the National Strategic Plan for Early Detection and Control of Breast and Cervical Cancer, and the UK National Health Service Cervical Cancer Screening Program; (3) identified recent relevant systematic reviews in the medical literature; and (4) consulted with USPSTF liaisons for this topic.

### **Inclusion/Exclusion Criteria**

We established overall inclusion and exclusion criteria a priori. Tables 3 and 4 present results of the search strategy with specific search terms.

Our search strategy, developed with the assistance of the RTI-UNC EPC research librarian who specializes in evidence-based literature review is described in Table 4. Using a selection of sentinel publications relevant to each key topic that were captured in the original broad search (Table 3), we specified searches that would provide focused identification of articles related to each key question. However, further specifying exhaustive searches for each question resulted in oversight of articles likely to be relevant as judged by missing sentinel articles. Key Question 1 about older age, older age and interval, and hysterectomy was the most difficult search to focus. As a result, we took an exhaustive approach to categorizing all articles obtained in the larger search. This process is described in detail below.

### Literature Reviewed

#### Citation Database

We used the search strategy in Table 4 to identify potentially relevant publications. From our first search (December 1999) we imported references into a ProCite database, which enumerates, stores, manages, and retrieves bibliographic citations; we also recorded the fate of all identified publications as they were screened for inclusion. We repeated the search in June 2000, eliminating duplicate references and adding the new additions to the ProCite database.

#### Screening of Articles

Two EPC staff independently reviewed the titles and abstracts of the articles identified and excluded those that did not meet eligibility criteria. If the reviewers disagreed, we carried the article in question forward to the next stage in which we then reviewed the full article and made a final decision about inclusion or exclusion. At each step we recorded the fate of the article in the ProCite database. Table 5 presents the disposition of articles identified as potentially relevant publications (for review of the full article), summarizing the number of publications at each step and their categorization.

Limiting the exhaustive search (search 8, Table 4) to identify only articles that reported on trials, we identified 57 articles. Of these, 25 are primary reports of randomized trials: 15 address methods to promote uptake and continuance of appropriate screening; 3 examine methods to improve follow-up of abnormal screening findings; 3 compare tools for collecting cytologic samples (i.e., type of spatula, brush or swab); 3 investigate patient education and

satisfaction; and 1 compares cytology alone to cytology with cervicography as a primary screening modality. This exercise confirmed our assessment that few data would be available from randomized controlled clinical trials to inform our review.

Because final inclusion criteria were closely linked to the intent of the key question, we give greater detail about selection of articles for each of the key questions below. Table 5 summarizes the disposition of the articles identified in the literature search and the number of full articles on each topic retained for review.

### **Key Question 1: Screening Among Older Women and After Hysterectomy**

The majority of the relevant literature identified for Key Question 1 is based on site-of-care or population-based prospective and retrospective studies and case-control studies. The large number of full articles that we retained for final abstraction reflected the need to examine the articles themselves to determine whether they provided data on benefits and risks of screening for particular groups (i.e., women age 65 and older) and in sufficient detail to clarify the relative performance of different screening intervals. We specifically sought articles that evaluated clinical risk prediction tools for assigning screening interval. Samples of the screening forms used to document decision making about inclusion of articles for Key Questions 1A and 1B appear in Appendix B.

In total, we screened 118 full articles to determine relevance. Of these, we retained 42 articles for Key Question 1A and 1B: 14 for full abstraction and 28 for supplementary information.

### Key Question 2: New Technologies for Cytology

Although our search strategy identified articles since 1995 relevant to Key Question 2 on new methods for preparing or evaluating cytology, we conducted full abstraction of only those publications that had appeared since completion of the *AHCPR Evidence Report/Technology Assessment, Number 5: Evaluation of Cervical Cytology* prepared by a team at the Duke Medical Center EPC.<sup>32</sup> Working with colleagues at the Duke EPC, we applied criteria and data extraction techniques that result in comparable reporting formats between the two evidence reviews. This approach allows us to streamline preparation of this report while capitalizing on the data previously collected to describe the performance characteristics of new cytology technologies.

The *Evaluation of Cervical Cytology* evidence report had several goals, including developing a model to estimate the costs associated with cervical cancer screening, evaluation, treatment, and follow-up of cervical cytologic abnormalities and the costs of treatment and follow-up of cervical cancer. To accomplish their modeling goals and make the best use of the existing literature, the Duke EPC included studies in which relative performance of new technologies could be assessed (e.g., use of computerized rescreening compared to conventional cytology alone) through use of expert adjudication of cytology findings with clinical confirmation of at least 50% of high-grade lesions.

Our team elected in advance of the literature review to focus primarily on studies that used clinical confirmation of cytology by colposcopy, cervical biopsy, or both (see Key Question 2 Screener in Appendix B). Specifically, we required that the new method being evaluated be

- Obtained as a screening test or adjunct to screening (i.e., not as follow-up of documented disease);

## Chapter II. Methods

---

- Compared with a reference standard of histology or colposcopy;
- Verified by use of the reference standard within an average of three months interval from the screening sample; and
- Reported in a fashion that allows completion of a 2x2 table relating the new method to the reference standard.

In the case of new Pap testing technologies, these strict criteria also required that performance of the new test could be compared to that of conventional Pap testing.

We screened 48 full articles to determine relevance for updating Key Question 2.

Overall, based on these strict inclusion criteria, only three articles were eligible for inclusion.

Virtually all excluded articles failed to use a clinical reference standard or did so only among those with a positive test without confirmation of either all or a subset of test negative tests.

Because a secondary goal of our work was to update the *Cervical Cytology* report, we relaxed our criteria to include studies that would have met the criteria for that report (which allows for a cytology reference standard). In total, we abstracted three high-quality articles and five other articles for the evidence tables and retained five for supplementary information.

For completeness, we added these new studies to the new technologies evidence table originally produced for the *Evaluation of Cervical Cytology*. The updated table is reproduced in its entirety in this report as Evidence Table 2, Appendix D. We did not identify any studies that report rates of outcomes over time, such as rates of cervical dysplasia or cervical cancer among cohorts of women receiving screening using conventional cytology compared to either new technologies alone, or to a system that adds a new technology to conventional cytology. We found no publications of randomized trials comparing individual outcomes by screening modality.

### **Key Question 3: What is the Role of HPV Testing?**

After consultation within our team and with the USPSTF in a February 2000 conference call, we restricted this portion of the review to recent literature. Although the previous *Guide to Clinical Preventive Services* recommended against use of HPV testing as an ancillary test within a screening strategy, we believed that the laboratory technology for HPV identification, classification, and measurement of viral DNA incorporation has changed so rapidly that a review of the recent literature was appropriate.

Our search identified 64 abstracts potentially relevant to this topic; once again the individual review of all abstracts identified more articles for full review than restriction of search #8 in Table 4 using a variety of electronic search strategies. In total, we screened 30 full articles to determine relevance. The strict inclusion criteria for assessing screening studies were applied to the HPV literature. Studies on this topic were more likely to include histologic verification of test results, although no prospective comparisons of individual patient outcomes or published randomized trials examine the efficacy or effectiveness of HPV testing in clinical use. Overall, 16 of these 30 articles were included for this question, 13 for full abstraction and 3 for supplementary information.

### **Cost and Harms**

The screening worksheet for each key question included additional questions to identify articles that reported on cost, cost-effectiveness, and harms, including psychological distress. When we flagged an article as potentially providing background on cost, cost-effectiveness, or other relevant economic evaluations, we subjected the article to further review by another team member.

## Chapter II. Methods

---

We reviewed 21 articles, the vast majority of which were articles that examined the cost of operating national screening systems within single payer health systems across Europe. As our goal was not cost evaluation or modeling, or critique of that literature, we wished to retain only the most relevant publications for this SER. To be considered, we required that the article reflect the cost or charges of using the screening modality in a primary care setting in the United States and that it compare new methods with conventional methods. We included four publications relevant to cost, including an evidence report from the Agency for Healthcare Research and Quality (AHRQ), as background references.

In consultation with our team members, USPSTF liaisons, and USPSTF members in telephone conference, we elected not to examine relative rates of assignment of the diagnosis of atypical squamous cells of uncertain significance (ASCUS) and cervical intraepithelial neoplasia I (CIN1) as a potential indicator of “harm.” Many such low-grade lesions regress and watchful waiting may be as effective as intervention; however, evidence at this time is insufficient to assert that detection of low-grade changes confers no benefit and only poses potential harm. Nonetheless, we have emphasized that optimal screening systems maximize identification of high-grade changes. Similarly, we have noted the potential harm of undergoing unnecessary evaluation and/or procedures, whether for diagnosis (such as colposcopy) or treatment (such as loop electrosurgical excision procedure or LEEP), but we have not further examined the harms of these procedures themselves.

# Literature Synthesis and Preparation of Systematic Evidence Review

## Data Abstraction and Development of Evidence Tables

We abstracted information about study objective, design, population, conduct, outcomes, and quality into designated sections and positions within evidence tables created in Microsoft Excel and Word. Two readers, a methodologist and a clinician-researcher, reviewed each article in an evidence table. The order of review by each pair of readers was not mandated, and both parties checked calculations of summary data, such as test sensitivity, that was generated for the tables.

To assess systematically comparable features of included articles and assure consistency, we used a checklist of potential indicators of study quality for the literature related to each key question. For Key Questions 2 and 3, we provide scores using the system designed for the *Evaluation of Cervical Cytology* evidence report, which fully documents development of the scoring system.<sup>32</sup> For Key Question 1, we incorporated indicators more relevant to cohort research, eliminating those items related purely to evaluation of diagnostic tests. Scores were assigned separately by two individuals and discussed as a group in the rare cases of substantial differences of opinion. These scores and a global categorization of the internal and external validity of the reviewed research contributed to grading of individual articles and the body of relevant literature consistent with USPSTF methods.<sup>33</sup>

### Peer Review Process

Upon completion of the draft SER incorporating the review at the September 2000 USPSTF meeting, we conducted a broad-based external review of the draft. Among the outside reviewers are representatives of key primary care professional organizations that have formal ties to the USPSTF, a representative of the Canadian Task Force on Preventive Health Care, representatives of other professional societies, clinical experts in the area of cervical cancer screening, members of the AHRQ staff, and representatives of other federal agencies. Appendix A lists the names and affiliations of all peer reviewers. We took into account the comments of these reviewers in developing the final version of this SER.

### III. Results

This chapter presents the results of our systematic review on three main issues: screening among women who are 65 years of age and older or who have had a hysterectomy, technologies for cervical cytology, and testing the human papilloma virus (HPV) as a part of cervical cancer screening. Evidence Tables detailing information from the literature examined by members of the RTI-University of North Carolina Evidence-based Practice Center (RTI-UNC EPC) can be found in Appendix C.

#### Key Question 1

##### Screening Among Women Age 65 and Older

Twelve articles since 1995 provided sufficiently detailed information about results of screening by age to examine the evidence about screening among older women (Evidence Table 1A, Appendix C). For inclusion, we required that the study include women above age 50, that data be presented stratified by age or in subanalyses that compared older to younger women, and that the denominators for the outcomes be known (e.g., the number of abnormal Pap results reported corresponds to a defined number of individual women screened or number of Pap tests obtained in a specified group of women). The majority of rejected studies were ecologic-level reports correlating population-based rates of detection of dysplasia and/or cancer with Pap testing trends, or case-control studies that matched on age and contributed only to the literature about interval, or models validated using data that would not meet the inclusion criteria.

## Chapter III. Results

---

In toto, the included studies tell different versions of the same story about the influence of age on risk for high-grade cervical lesions and cancer:

- Incidence of cervical intraepithelial neoplasia (CIN), including CIN 3 and carcinoma in situ (CIS), peaks in the mid-reproductive years and begins to decline in approximately the fourth decade of life.<sup>26,34-36</sup>
- The prevalence of CIN follows a similar pattern: diagnosis of CIN 3 and CIS is shifted toward older age at diagnosis relative to CIN 1 and 2 but still decreases with age.<sup>37-40</sup>
- This general pattern is also apparent among previously unscreened women.<sup>40,41</sup>
- Based on the incidence of cancers that arise between screening intervals, cervical cancer in older women is not more aggressive or rapidly progressive than that in younger women.<sup>42</sup>
- The rates of high-grade squamous intraepithelial lesions (HSIL) diagnosed by cytology are low among older women who have been screened: 0.2-1.9,<sup>36</sup> 0.7-1.7,<sup>40</sup> and 0.8-1.4,<sup>26</sup> per 1,000 among women ages 50 years and older.

These observations are consistent with ecologic data and natural history studies of cervical dysplasia and cancer and studies of HPV progression. Three of the included studies rely only on cytology results.<sup>26,36,37</sup> The remainder have varying degrees of histologic documentation; these range from complete or near complete histologic documentation of all cases,<sup>38,40-44</sup> to good verification of cases (72% verified<sup>39</sup> to 82% verified<sup>35</sup>) to inadequately described use of histologic “gold standard.”<sup>34</sup> None attempted to identify false negatives through evaluation of women with negative screening tests. As such, this literature reflects the quality of the cytology services deployed to screen the retrospective and prospective cohorts that make up

## Chapter III. Results

---

the study populations. Relative comparisons of the effectiveness of the screening systems and of the potential impact of screening interval cannot be made across studies.

With these caveats, we describe in greater detail selected studies of incidence of histologic or cytologic abnormalities among previously screened women, prevalence within screening programs, and the influence of interval and prior screening history on probability of detecting abnormalities.

### Incidence and Age

Each of the studies reporting incidence of CIN and more serious lesions constructed their cohort by requiring a normal Pap test as the earliest reference point. Computerized record-keeping systems from a single cytology laboratory<sup>34,35</sup> assure relative consistency of quality of examination of the baseline and subsequent Pap tests; in relatively stable populations, they also allow exclusion of women with prior documentation of abnormal cytology. Sawaya and colleagues prospectively gathered data assuring that baseline cytology for individuals entering the study was reported as normal; however, this does not exclude the possibility that participants may have had a more remote history of dysplasia evaluation or treatment.<sup>26,36,44</sup> In the reports based on the National Breast and Cervical Cancer Early Detection Program, laboratory facilities across the United States processed Pap tests;<sup>26,36</sup> in the Heart and Estrogen/progestin Replacement Study (HERS) study, a single commercial laboratory (Empire Pathology Medical Group, Garden Grove, CA) processed tests.<sup>44</sup>

Despite these distinctions and different groupings of age in the analysis of data, estimates of incidence of high-grade lesions are compatible across the studies of incidence: 1.0 per 1,000 women 41 years of age and older, screened at an interval of approximately 1 year;<sup>34</sup> 1.2 per

## Chapter III. Results

---

1,000 person-years among women 40 years of age and older;<sup>35</sup> 1.4 per 1,000 women ages 50 to 64 years and 0.8 per 1,000 women 65 and older screened at an interval of 36 months or less;<sup>26</sup> 0.6 to 1.9 per 1,000 smears in women ages 50 to 59 years; 0.2 to 1.2 in women 60 or older;<sup>36</sup> and 0.4 per 1,000 women in a post-menopausal cohort with average age of 66.<sup>44</sup> Fewer than one woman in a thousand (in some studies as few as two to six in 10,000) who were age 60 and older and had a negative smear at baseline received a new diagnosis of CIN 3 or cancer. In studies that had cases of cancer in screened populations of older women, the ratio of CIN 3 to cancer range from 4 to 1<sup>26</sup> to more than 10 to 1.<sup>40</sup>

### Prevalence

Studies of prevalence (i.e., those that include screened and unscreened women without requirement of baseline normal cytology) are also compatible with the assertion that risk of high-grade cervical abnormalities decreases with age. The only study that does not appear to support this view is that of Formso and colleagues;<sup>37</sup> they report 2.23 cytologic findings of CIN 3 per 1,000 women age 50 to 59 years; 1.96 per 1,000 for women age 60 to 69 years; and 4.24 for women ages 70 and older. The inclusion criteria specified “no prior abnormal Pap test”; this allowed inclusion of women having their first screening ever or after an extended interval. In the text, the authors noted the large proportion of older women, especially those older than 70, who had first Pap tests included in these data. Their data are based on records from the same cytology laboratory in Norway used by Gram et al.<sup>35</sup> The laboratory serves a relatively stable population in two northern counties without a formal screening program. The time periods in the analyses by Formso et al.<sup>37</sup> and Gram et al.<sup>35</sup> overlap by two years; thus, presumably individual-level data may be duplicated in these reports. Gram and colleagues sought histologic

## Chapter III. Results

---

confirmation of CIN 3 and carcinoma and achieved an 82% verification rate, whereas Formso and colleagues relied on cytology alone. The differences between their findings are certain to reflect the inclusion of unscreened women in the prevalence study<sup>37</sup> but not in the incidence study.<sup>35</sup> The differences may also reflect discrepancies between cytology and histology among older women and unstable estimates based on small numbers.

The remaining publications reflect falling risk with age and low prevalence among older women. These include the Cecchini et al. study of previously unscreened women in Italy,<sup>41</sup> Cruickshank's study<sup>39</sup> among British women who are actively advised to be screened every 3 years, and the work by Lawson and colleagues based on opportunistic screening in the US National Breast and Cervical Cancer Screening Program.<sup>40</sup> Among American women being screened for the first time in the study by Lawson et al.,<sup>40</sup> rates of CIN 3 or cancer were 2.3 per 1,000 Pap tests among women ages 50 to 64 and 1.7 per 1,000 among those ages 65 and over, followed by a reduction to 1.3 per 1,000 and 0.7 per 1,000 at the second screening opportunity.

### Screening History and Interval

The significance of prior negative smears is directly addressed by both age-adjusted and age-specific analyses in the examination by Sawaya and colleagues of the probability of abnormal Pap after 1, 2, or 3 prior normal Paps. The probability of HSIL decreases with each subsequent normal smear in women ages 30 and older. Reduction within age brackets is detailed in Evidence Table 1. Investigation of the influence of interval suggests that longer intervals are associated with similar or increased detection of high-grade lesions;<sup>26,35,43</sup> other work not reviewed here (but considered by the US Preventive Services Task Force [USPSTF] in the mid-

1990s) suggests that cancer outcomes are statistically comparable with intervals of three to five years. Three years was recommended as a conservative estimate of appropriate interval.

### **Screening among Women Who Have Had a Hysterectomy**

The 1996 USPSTF report is unequivocal: “women who have undergone a hysterectomy in which the cervix was removed do not benefit from Pap testing, unless it [the hysterectomy] was performed because of cervical cancer.”(p.111)<sup>44</sup> This opinion was based on recognition that Pap testing in the absence of a cervix no longer constitutes screening for cervical cancer. In this context the Pap test becomes screening for vaginal cancer, a yet more rare condition. Prior publications support this view.<sup>45</sup> Nonetheless, a recent publication based on practice patterns at the Marshfield Clinic (a 450-physician multi-specialty clinic in Wisconsin) suggests that more than half of women who have had total hysterectomies for benign disease continue to receive screening at an average of one test every 3.5 years.<sup>46</sup> This confirms the clinical opinion of members of our group that the majority of women continue to receive screening even after hysterectomy for benign disease.

Two additional studies documenting the low risk of cytologic abnormality after hysterectomy have been published since the 1996 USPSTF recommendations. The first, among women age 50 and older, is a cross-sectional study with a nested case-control component.<sup>47</sup> They documented that identification of dysplasia and cancer was rare (1.6/1,000 tests) in this age group, especially after hysterectomy (0.18/1,000). They also showed that, compared to matched controls, women after hysterectomy were one tenth as likely as those with a cervix to have any Pap test diagnosis of abnormality.<sup>47</sup> Likewise, Pearce and colleagues’ study of 6,265 women (with 9,610 Pap tests) who had hysterectomies for benign disease found a total of 104 abnormal

## Chapter III. Results

---

Pap test from 79 women within a two-year timeframe.<sup>48</sup> At completion of follow-up, 3 women had vaginal intraepithelial neoplasia (VAIN) and one had squamous cell carcinoma. This translates into 0.42 high-grade lesions per 1,000 Pap tests.<sup>48</sup> These articles are described in greater detail in Evidence Table 1B.

### Summary

The available evidence about age and screening outcomes is observational, from large population-based retrospective cohorts supported by registry systems, or from smaller prospective cohort studies. Despite varied study design and populations, the findings are coherent and support the assessment that risk of high-grade cervical lesions falls with age, especially among those with prior normal screening results. Because none of these studies evaluates outcomes among women who did not receive further screening after a designated age, and because none is experimental, we cannot draw direct conclusions about the anticipated results of discontinuing screening at a specific age.

Prior USPSTF recommendations to discontinue Pap testing after hysterectomy for benign disease are supported by a well-conducted study; they should be re-emphasized. Lastly, no direct comparisons between proposed screening systems, including those based on individual risk assessment, were identified. This confirms that this literature is substantially less well-developed than that of other areas of screening tests, such as colorectal cancer screening in which trials comparing annual fecal occult blood testing to sigmoidoscopy are available to inform decisionmaking.

### Key Question 2

#### New Methods for Preparing or Evaluating Cervical Cytology

Key Question 2 (To what extent do new methods for preparing or evaluating cervical cytology improve diagnostic yield compared to conventional methods?) is addressed predominantly by direct comparisons of diagnostic tests. The majority of the literature identified for Key Question 2 is based on archived laboratory specimens. These studies compare the techniques being evaluated with the results of review by a panel of cytology experts. Most often, these comparisons are conducted by subjecting specimens with a pre-selected mix of normal and abnormal cytologic results, to review by the techniques under study. In general, discrepancies between cytology reports were adjudicated by the expert panel masked to findings; rarely, subsets of normal or concordant diagnoses were also reviewed by the panel.

Very few studies of new technologies are validated by concurrent or subsequent colposcopy or histology of abnormal screening test results; even fewer include validation of normal screening test results. This means that in almost all studies identified the sensitivity, specificity, and predictive values of the technology cannot be directly assessed or compared with the test characteristics of conventional cytology in the same population.

Our search identified 196 articles on the types of technology we wished to review. We excluded 143 of these articles at the time of abstract review because they did not meet basic inclusion criteria (e.g., were commentaries, were based on experimental laboratory systems, did not have human subjects). Forty-eight full articles were retrieved; these included 23 that were found not to meet basic inclusion criteria (commentary and reviews). Of the remaining 25 articles, four were relevant new articles not previously abstracted and summarized in the *AHCPR*

## Chapter III. Results

---

*Evidence Report/Technology Assessment, Number 5: Evaluation of Cervical Cytology*; two were new articles on screening tools not covered by either systematic review (e.g., unaided visual inspection of the cervix, and cervicography); and one article was a final publication of a study that had been reviewed in draft form for *Cervical Cytology* report and had minor changes in the final published results.<sup>49</sup>

The *Cervical Cytology* report was published in February 1999<sup>32</sup> and updated in January 2000 for peer-reviewed publication.<sup>50</sup> The report includes studies with and without validation of screening tests by clinical evaluation. For convenience, the portions of the evidence tables from that report that are related to new technologies are reproduced and updated in this report (Evidence Table 2). In collaboration with the authors of the cervical cytology report, the RTI-UNC EPC team abstracted new articles in a comparable fashion.

As described in the methods section, we had planned to focus on studies that used colposcopy or histology as a gold standard for evaluation of performance of the screening system. However, such publications remain rare. At completion, we extended the prior *Cervical Cytology* review by updating final data from one article, adding three new articles based on a cytological reference standard with or without a subset of histologic verification, and adding one with an adequate colposcopic and histologic reference standard. This study applied a definitive clinical reference standard to a random sample of women with normal screening test results and permitted calculation of all test characteristics including estimation of specificity.<sup>51</sup>

Evidence Table 2 (Appendix C) summarizes 29 studies that evaluate the performance of new technologies for preparing or interpreting cervical cytology specimens: 9 evaluating liquid-based cytology collection systems (ThinPrep<sup>®</sup>); 13, neural-net rescreening or prescreening

## Chapter III. Results

---

studies (PapNet<sup>®</sup>), and 7, computer algorithms for selecting slides for rescreening or for screening (AutoPap<sup>®</sup>).

A single study evaluating ThinPrep<sup>®</sup> liquid-based cytology and other screening modalities in a population-based cohort of 8,636 Costa Rican women met strict review criteria for prospective evaluation of the test characteristics of a new screening technology.<sup>51</sup>

1. Cytology specimen obtained as a screening study;
2. Performance of new technology was evaluated by colposcopy and/or histology as the reference standard;
3. Pap and reference standard were applied within an average of three months; and
4. A validation of normal cytology results was undertaken, such that a complete 2x2 table relating the new technology to the reference standard can be completed.

The study that met these criteria used colposcopy and histology to evaluate women in three categories: (1) atypical squamous cells of uncertain significance (ASCUS) on cytology as assessed by ThinPrep, PapNet, or conventional smear; (2) positive cervigram; or (3) physical examination suspicious for cancer or gynecologic emergency (rare indication). These investigators conducted a validation substudy among a random sample of 150 women with negative screening results, thus allowing estimation of specificity and predictive values. Their reference standard was a composite of all screening tests and histology findings, called the final case diagnosis. The final case diagnosis categories were negative (including ASCUS with normal colposcopy and/or histology), low-grade squamous intraepithelial lesion (LSIL) (by histology, or by cytologic confirmation by two or more methods), HSIL (93% histologic confirmation), invasive carcinoma (100% histologic confirmation), and equivocal. Equivocal included women with a single cytologic diagnosis of LSIL, isolated positive cervigram, or

### Chapter III. Results

---

conflicting results on the basis of all the data. Because the threshold for colposcopy was ASCUS or higher, the majority of equivocal final case diagnoses are presumed to be equivocal low-grade findings although the precise make-up of this group is not clearly specified in the article.

Bearing this classification system in mind, we have calculated performance measures for ThinPrep<sup>®</sup> using two different assumptions about equivocal final diagnosis; one assumption includes them in normal, and the other in LSIL. Based on the findings of no abnormal histology among the random sample of 150 women with normal final diagnoses (i.e., all screening test negative) who were evaluated with colposcopy and biopsy, estimates of sensitivity, specificity and predictive value are based on the presumption of no false negatives, which is plausible based on the number of tests applied and the consensus process for assigning the final diagnoses. Table 6 summarizes test characteristics at different thresholds; assignment of the equivocal cases is indicated.

Two studies of ThinPrep<sup>®</sup>, known for the large size of the populations screened (>35,000 each), did not meet strict criteria. These studies provide histology results for a subset of subjects obtained within undisclosed periods of time from the screening ThinPrep<sup>®</sup>.<sup>52,53</sup> Neither used a colposcopy/histology reference standard to verify test negatives, and both studies appear to rely on histology specimens associated with clinical care for calculating sensitivity and specificity of the ThinPrep<sup>®</sup> test compared to conventional cytology.

Among 10,694 US patients in the latter study screened by ThinPrep<sup>®</sup>, 630 women had cytology diagnoses of ASCUS or more severe; 1,395 of 39,408 women screened by conventional cytology had cytology of ASCUS or more severe.<sup>53</sup> However, the estimates of sensitivity and specificity reported in the publication are based on 54 biopsy reports in the ThinPrep<sup>®</sup> group and 89 in the conventional cytology group. The authors do not specify how these “available”

## Chapter III. Results

---

biopsies were identified. They could not capture those women who had normal colposcopy, and therefore no biopsy, among those with abnormal cytology. Additionally, ThinPrep<sup>®</sup> and conventional specimens were from separate groups of women, not one of each specimen type from each individual. As a result, the sensitivity and specificity of ThinPrep<sup>®</sup> (reported as 95% and 58%, respectively) are not valid and cannot be appropriately compared with conventional cytology (reported as 85% and 36%).

The earlier study obtained split samples for ThinPrep<sup>®</sup> and conventional cytology from a cohort of 35,560 Australian women.<sup>52</sup> Within the Australian health care system, colposcopy is the recommended immediate evaluation for “inconclusive” slides in which high-grade abnormalities cannot be excluded and for cytology diagnoses of CIN1 and above. High-grade or inconclusive cytology results were reported for 433 ThinPrep<sup>®</sup> specimens and 430 conventional cytology specimens, of these, 325 (75%) and 319 (74%), respectively, had histology results. This again excludes women who had colposcopy without biopsy. However, the focus on high-grade lesions makes the probability of biopsy high, and so the proportion with follow-up is adequate. In this context, the relative true-positive and false-positive rates of the test can be used to compare performance.<sup>54</sup> The relative true-positive rate for ThinPrep<sup>®</sup> compared to conventional cytology for detecting high-grade histologic abnormalities is 1.13, suggesting a modestly higher sensitivity of Thin Prep<sup>®</sup>; the relative false-positive rate is 1.12, suggesting a modestly lower specificity.

### Neural-network Rescreening

The literature about neural-network rescreening (and screening) technology is also fundamentally limited by the lack of histologically confirmed performance measures. Applying

### Chapter III. Results

---

the same criteria outlined above, we found no studies that met the inclusion standards. One study of 160 slides originally classified by conventional cytology as ASCUS and subsequently scanned by the PapNet<sup>®</sup> system is supported by histology for all samples.<sup>55</sup> This study failed to meet criteria because the reference standard was obtained up to one year after the screening test and because the slides reviewed do not reflect a representative distribution of normal and abnormal specimens. We summarize this work and two other studies with some use of histology documentation as examples of the content of the literature.

The slides for this ASCUS review study, selected because the patients had subsequent histology on record, were re-read using PapNet<sup>®</sup>. Although the spectrum of disease is skewed and reflects a high prevalence of abnormalities, performance measures can be calculated for LSIL and HSIL given an initial ASCUS determination by conventional Pap. If histology of HPV changes only is separated from CIN 1 and included with normals, the sensitivity, specificity, positive predictive value, and negative predictive value of PapNet<sup>®</sup> categorization of LSIL or greater are 45.4%, 85.8%, 45.5%, and 85.8%, respectively. If HPV changes are included in CIN, these values are, respectively, 37.7%, 92.3%, 78.8%, and 66.1%. At a PapNet<sup>®</sup> threshold of HSIL or greater for detecting CIN 2, CIN 3, or carcinoma, the sensitivity was 27.3%, specificity was 94.2%, positive predictive value, 42.9%, and negative predictive value, 89.0%.

Jenny and colleagues hand-selected a slide set consisting of 516 abnormal slides with accompanying histologic record of abnormality and mixed them with 684 slides from women with 2 years of normal follow-up.<sup>56</sup> The study was designed to evaluate the consistency of reports between two independent PapNet<sup>®</sup> evaluations and a manual screening of the same slide set. The PapNet<sup>®</sup> evaluations identified 91% and 84% of the histologically proven abnormal specimens; conventional screening classified 78% as abnormal. The resulting true positive ratio

## Chapter III. Results

---

of PapNet<sup>®</sup> to conventional screening ranges from 1.08 to 1.16, supporting the claims that PapNet<sup>®</sup> reduces false negatives. Unfortunately, the research team missed the opportunity to evaluate all performance measures using the 2-year normal follow-up group as a fairly well-documented confirmation of test negatives. The authors do not comment on the classification of the normal slides, focusing only on the 516 slides from women with known abnormalities.

Using data from the centralized Dutch national pathology reporting program, Kok and colleagues evaluated cervical cancer outcomes and risk of screening method failure in 2 large groups: 109,104 smears evaluated by conventional screening and 245,527 slides submitted for neural-network based screening (not rescreening as in the United States) with PapNet<sup>®</sup>.<sup>57</sup> They used the reporting system to identify 71 women with a diagnosis of biopsy-confirmed squamous cell carcinoma and to locate the screening smear obtained prior to the biopsy. Of the 71 smears, 19 had been evaluated by conventional methods and 52 by PapNet<sup>®</sup> screening; there were four false negatives among the conventional screening group and five false negatives among the PapNet<sup>®</sup> slides. The balance of the 71 smears were all reported with a level of abnormality ranging from LSIL to carcinoma that prompted clinical follow-up. The false negatives were subjected to masked detailed review by both standard microscopy and PapNet<sup>®</sup>. All five PapNet<sup>®</sup> failures were confirmed to be sampling errors; i.e., the slides did not contain identifiable abnormal cells as assessed by hand review or PapNet<sup>®</sup>. The conventional screening failures did contain scant abnormal cells and constitute screening failures. Two independent, masked PapNet<sup>®</sup> re-evaluations of the slides classified three of the four as “suspicious” and the fourth as CIN 3, suggesting that the screening failures could have been averted because none of these individuals would otherwise have been returned to the 5-year routine screening interval.

### Computerized Rescreening

AutoPap<sup>®</sup> is a computerized quality control system that can be used for initial screening and for optimizing selection of high-risk slides for rescreening. Its current routine use in the United States is restricted to rescreening. We found no studies that met strict criteria for review, although we did identify two studies by the same group that employed a level of histologic verification of test performance. The first was based on an 86-slide set of smears from histology-proven HSIL cases.<sup>58</sup> This study retrospectively measured whether the system “found” these slides when they were reviewed as part of a larger study. The system can be set to determine the proportion of slides that will be rescreened; this study evaluated 10-percent and 20%- rescreening thresholds. At the 10%- review threshold, AutoPap selected 77% of the HSIL slides for assessment; at the 20%- threshold, it selected 86% for assessment. These figures are substantially higher than the expected maximum selection rate of 10% of false negatives if the standard random sample of 10% of negative slides were to be used to determine rescreening.

In a subsequent study, this group focused on ability of the AutoPap<sup>®</sup> system to aid identification of HSIL lesions.<sup>59</sup> This cytologic diagnosis should consistently be associated with clinical evaluation and histology, which improved their ability to confirm positive diagnoses although again they have no verification of the test-negative specimens. Within a parent study with 25,124 screened slides, they identified 70 slides supported by definitive diagnoses of HSIL, CIS, or invasive cancer. They compared the detection rate for these slides in the convention practice screening and the AutoPap<sup>®</sup> screening portion of the parent study. Both modalities detected 63 of 70 abnormal slides; conventional practice failed to detect five and AutoPap<sup>®</sup> failed to detect two. The performance of the two modalities was statistically equivalent.

## Chapter III. Results

---

Although we updated the evidence tables from the *Cervical Cytology* report by including two new studies about PapNet<sup>57,60</sup> and a final publication of an article available in manuscript form,<sup>49</sup> we have not summarized them in greater detail here. The reason is that these reports use cytology reference standards and do not change the overall picture of the performance of new technologies. Thus, they serve as confirmation of similar earlier publications, not as wholly new information.

### Harms

We did not identify publications that specifically address harms of new technologies for cervical cancer screening. These screening tools are implemented at the laboratory level and not at the level of clinical specimen collection, so they do not increase risk of harm from the actual specimen acquisition.

The performance characteristics of the new technologies will determine the risk of harm. Although the data are limited, on average these tools improve sensitivity and reduce specificity. This finding suggests that increased detection of low-grade lesions and false positives are the primary potential sources of harm; i.e., harm may take the form of increased evaluations, possible over-intervention, and psychological distress for the women diagnosed with abnormalities. These harms are poorly documented for conventional Pap testing and have not yet been assessed for new technologies.

### Benefits

Likewise, direct benefits of new technologies for improving care processes or outcomes are not documented. The characteristics of these new tools suggest that they can improve

## Chapter III. Results

---

detection of precancerous lesions when compared in a single screening session to conventionally prepared and interpreted cytology. However, no data are available to assess their long-term benefit if implemented in a screening system. Cervical dysplasia is at times a spontaneously resolving condition or, if progressive, a slowly developing condition. For precisely these reasons, the full system of screening—i.e., the modality used, the interval for testing, and the decisionmaking process related to evaluation and treatment—need to be evaluated in toto to compare performance characteristics properly. Prospective measurement of outcomes is essential to guiding policy.

### Costs

A central goal of the *Evaluation of Cervical Cytology* evidence report was modeling the effects on total health care costs, morbidity, and mortality of regular cervical cytologic screening using newer screening technologies compared with conventional Pap smear in women participating in screening.<sup>32</sup> Using a Markov model of a cohort of women ages 15 to 85, incorporating estimates about the natural history of HPV, and investigating one-, two-, and three-year screening intervals, they reached the following conclusions:

- The cost-effectiveness of either a technology that improves primary screening sensitivity (e.g., thin-layer cytology) or one that improves rescreening sensitivity (e.g., computerized rescreening) is directly related to the frequency of screening—longer intervals result in lower estimates of cost per life year saved.
- Findings were relatively insensitive to assumptions about cervical cancer incidence, cost of technologies, diagnostic strategies for abnormal screening results, age at onset of screening, or most of the other variables tested.

### Chapter III. Results

---

- Substantial uncertainty surrounds the estimates of sensitivity and specificity of thin-layer cytology and computerized rescreening technologies compared with each other and with conventional Pap testing. This uncertainty is not reflected in the point estimates of cost-effectiveness. Although both thin-layer cytology and computerized rescreening technologies clearly improve effectiveness at higher cost, the imprecision in estimates of effectiveness makes drawing conclusions about the relative cost-effectiveness of thin-layer cytology and computerized rescreening technologies problematic.
- Given the uncertainty surrounding these estimates, all three technologies may well fall within accepted ranges of cost-effectiveness at 3-year screening intervals. No strategy or technology used for screening more often than every 3 years results in estimates of less than \$50,000 per life-year.

This model substantially improves on prior work; it includes global costs of downstream care resulting from screening and cancers, more accurate estimates of the performance of conventional cytology than previously available, and sophisticated sensitivity analyses. However, important parameters of this model deserve note. Base assumptions include the following: (1) all women receive screening at the appropriate interval; (2) new technologies increase sensitivity without any decrement in specificity; (3) all patients receive appropriate follow-up; and (4) diagnostic evaluation of abnormal cytology detects all true abnormalities (i.e., no colposcopy or pathology errors are made). Adjusting each of these assumptions closer to actual clinical scenarios has the effect of increasing the cost-effectiveness ratio. If, as our update and the full *Cervical Cytology* report suggest, new technologies do have lower specificity than

## Chapter III. Results

---

conventional cytology, then costs and harms of false positives have important system and individual implications.

The *Cervical Cytology* report also includes systematic review of prior literature on the cost-effectiveness of cervical cytology. In summary:

- Published models examining the cost and effectiveness of Pap smear screening have consistently found Pap screening to have a significant impact on the incidence and mortality of cervical cancer and to have an acceptable range of cost-effectiveness ratios when compared with no screening.
- Estimates of Pap test accuracy used in these models generally overestimated Pap test performance, as determined by recent unbiased studies, the findings of the report itself [*Cervical Cytology*], and a previously published meta-analysis. Best estimates of Pap test performance fall outside the range used in sensitivity analyses of some models.

Many of these models have results that are consistent when important parameters of the models are varied across of broad spectrum of assumptions. Ultimately, however, all current models are tied to the limitations in this literature and must be considered temporary substitutes for prospective research.

### Summary

Overall, the quality of this literature is limited for the purposes of making decisions about choice of screening modality in the US population. We identified no randomized trials or prospective cost-effectiveness comparisons in suitable populations. In the absence of studies that

relate the findings at screening to outcomes, the linkages between comparative test performance are insufficient to judge the implications of preferentially using one system over another.

### **Key Question 3: Role of HPV Testing in Cervical Cancer Screening**

We examined two potential roles for HPV testing in cervical cancer screening. The first is focused on screening use of HPV testing, including simultaneous use with Pap testing. The second envisions a role for HPV in triaging women with abnormal screening Pap results with an emphasis on when knowledge of HPV status might modify decision-making about the need for or extent of further evaluation. Our specific questions were:

**3A. Screening Use of HPV Testing:** What are the benefits, harms, and costs of using HPV testing as a screening test, or of incorporating HPV testing at the time of the screening Pap test compared with not testing for HPV?

**3.B. Triage Use of HPV Testing:** What are the benefits, harms, and costs of using HPV testing as part of a screening strategy to determine which women with an abnormal Pap test should receive further evaluation?

We reviewed 30 potentially relevant publications. Ultimately, we abstracted 13 of these and entered their data into Evidence Tables 3A and 3B; we retained another three articles for background. The systematic review of the role of HPV testing in cervical cancer screening prepared by Cuzick and colleagues for the UK Health Technology Assessment Board of the National Health Service was a valuable aid.<sup>21</sup> Their publication influenced our decisionmaking about which testing modalities to consider appropriate for screening use, and it validated the

literature search strategy we used for this SER by confirming that we were identifying appropriate publications.

### Screening Use of HPV Testing

Six studies relevant to primary screening uses of HPV testing met four strict criteria for inclusion:

1. HPV specimen obtained and evaluated as a screening test;
2. Performance of HPV for predicting presence of CIN was evaluated by colposcopy and/or histology as the reference standard;
3. HPV test and reference standard were applied within an average of 3 months; and
4. A validation of negative HPV results was undertaken, such that a complete 2x2 table relating the HPV test findings to the reference standard can be completed.

These articles are summarized in detail in Evidence Table 3A. Table 7 extracts key features of all 6 studies and their populations to demonstrate the varied spectrum of disease in the populations screened. Although each of these studies used HPV testing in a population or clinic-based sample that enrolled consecutive women in a fashion comparable to screening use, 5 of the 6 studies used a study population at high risk for cervical dysplasia. One obtained specimens from HIV-positive German women;<sup>61</sup> 2 were based in Zimbabwe and enrolled primary care patients in a population chosen for high prevalence of HIV infection;<sup>62,63</sup> 1 selected participants in Cape Town, South Africa, with no prior screening;<sup>64</sup> and 1 enrolled women from Guanacaste Province, Costa Rica, where cervical cancer screening has been relatively unsuccessful in reducing cervical cancer incidence.<sup>65</sup> Only Cuzick and colleagues' study of 2,988 women

## Chapter III. Results

---

having routine cervical cancer screening at 40 general practitioner practices approximates screening use in routine primary care practice in the United States.<sup>21</sup>

HPV types consistently considered high risk and tested by the assays used in these studies included types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68. We have not considered performance characteristics of tests that detect only low-risk HPV types. Basic performance characteristics relating presence of high-risk HPV types to diagnoses are best summarized by considering HSIL and LSIL as separate diagnostic thresholds. For the HSIL threshold, we mean the ability of a positive HPV test to detect histology-proven HSIL or more severe lesions, such as invasive cancer. For the LSIL threshold, we mean the ability of a positive HPV test to detect histology-proven LSIL or more severe lesions, including HSIL.

### HPV Screening for Detection of High-grade Cervical Changes

The sensitivity of a positive Hybrid Capture II test for high-risk HPV types for detecting histology proven HSIL or greater ranged from 62% to 95%.<sup>21,62-65</sup> Specificity ranged from 41% to 94%.<sup>21,62-65</sup> Details of test performance for detecting high-grade lesions, including predictive values and likelihood ratios for positive and negative tests, for each HPV test modality examined in these screening-based studies appear in Table 8.

Five of the 6 HPV screening studies used Hybrid Capture II.<sup>21,61-64</sup> To report aggregate estimates of performance for detection of HSIL, we calculated summary performance measures using the aggregate numbers of true positives, false negatives, true negatives, and false positives in these studies, with a combined total enrollment of 6,793 participants. In aggregate, the sensitivity of Hybrid Capture II for detecting HSIL was 84.4%; specificity was 78.7%; positive predictive value, 23.4%; and negative predictive value, 98.5%.

## Chapter III. Results

---

These Hybrid Capture II estimates include an easily delineated group of women with HIV infection who had high prevalence of HSIL — 17.3% among the HIV-infected women in the Womack and colleagues cohort.<sup>63</sup> Excluding HIV-infected women from the aggregate test performance estimates should have the largest influence on the predictive values, because these are determined by prevalence. However, these women make up a small portion of the overall total and the estimates of performance characteristics are essentially unchanged. To further describe Hybrid Capture II performance in low-prevalence populations, we calculated aggregate data for only those studies<sup>21,62,64</sup> or arms of studies<sup>63</sup> in which the prevalence of HSIL was 10% or lower. In these conditions, sensitivity is somewhat lower at 81.6%; specificity is similar at 78.2%; positive predictive value is reduced to 18.2% and negative predictive value is 98.6%, essentially unchanged compared to the estimates that include all studies using Hybrid Capture II regardless of prevalence.

### **HPV Screening for Detection of Low-Grade Cervical Changes**

Four of the screening studies include data that allow estimation of test performance if LSIL is included among the lesions targeted for detection by HPV testing. The sensitivity of a positive Hybrid Capture II test for high-risk HPV types for detecting histology-proven LSIL or greater ranged from 45.2% to 85.9%.<sup>21,62,64</sup> Specificities were between 47.0% and 96.7%.<sup>21,62,64</sup> Details of test performance for detecting low-grade and higher lesions are provided in Table 9.

Cuzick and colleagues study of women having screening at their primary care providers' offices in the United Kingdom is likely the most comparable to screening in the United States, the relative performance of the SHARP (Digene Corp.) microtiter format PCR test and the Hybrid Capture II is of interest. Both tests delivered similar performance: sensitivity of 64.3%

## Chapter III. Results

---

versus 61.0%; specificity of 96.7% versus 95.1%; negative predictive value of 98.4% versus 98.6%, positive likelihood ratios of 19.4 versus 12.5, and negative likelihood ratios of 0.43 for both tests. In some studies, Hybrid Capture I delivers test performance comparable to SHARP PCR and Hybrid Capture II.<sup>61,65</sup> However, in the Cuzick et al. analysis (which allows direct comparison in the same cohort), the newer HPV testing modalities appear to be superior.

All of the studies that consider HPV and LSIL detection evaluated Hybrid Capture II. We calculated summary performance measures using the aggregate numbers of true positives, false negatives, true negatives, and false positives in these studies with a combined total enrollment of 5,674. In aggregate, the sensitivity of Hybrid Capture II for detecting LSIL or more severe lesion, was 67.3%; specificity, 80.1%, positive predictive value, 36.7%; and negative predictive value, 93.4%. Eliminating the HIV-positive women from the estimates,<sup>63</sup> the aggregate positive predictive value falls slightly to 35.7%; negative predictive value is essentially unchanged at 93.6%; sensitivity is 65.2%; and specificity is 81.2%. Lastly, eliminating all groups with a 10% or greater prevalence of LSIL or higher lesions, the resulting performance is sensitivity of 73.5%; specificity, 90.5%; positive predictive value, 29.2%; and negative predictive value, 98.5%.

### **Triage Use of HPV Testing**

A proposed role for HPV testing is to serve as a diagnostic tool to facilitate triage of women with an abnormal Pap tests. To estimate its test characteristics in this role included 7 articles relevant to triage uses of HPV (Evidence Table 3B, Appendix C) that met the following criteria for inclusion:

### Chapter III. Results

---

1. HPV specimen obtained or processed (or both) only for women with abnormal cytologic diagnoses on Pap testing;
2. Performance of HPV for predicting presence of CIN evaluated by colposcopy and/or histology as the reference standard;
3. HPV test and reference standard applied within an average of 3 months; and
4. A validation of negative HPV results, such that a complete 2x2 table relating the HPV test findings to the reference standard can be completed.

Table 10 summarizes the study populations and severity of disease identified in populations included in the studies relevant to HPV testing as a triage tool. Although the majority of these studies required an abnormal Pap test for enrollment, we required only that the HPV test and the colposcopy and/or histology, and not Pap testing, occur within an average of 3 months' time. Two of these studies were conducted in countries in which initial ASCUS and/or low grade cytologic findings are followed by repeat Pap testing. Colposcopy is only done if repeat cytology suggests risk of a high grade lesion.<sup>66,67</sup> This approach lengthens the time between the index Pap and the use of HPV testing and colposcopy. It also increases the probability that women undergoing colposcopy will have a histologic lesion. As a result of such cytology-based triage, the studies from Iceland and the Netherlands reflect a comparatively high prevalence of high grade lesions.<sup>66,67</sup> This finding has implications for this report because the prevalence of high grade lesions in these studies is higher than one would expect if HPV testing were used as initial triage at the time of a first abnormal Pap test, and prevalence does influence diagnostic test characteristics. These studies may not be as informative for US clinicians because within our screening approach, HPV is most attractive as a triage tool for guiding

### Chapter III. Results

---

management of patients with low grade cytologic abnormalities who will at the time of colposcopy have a much lower prevalence of high grade lesions.

The indications for the colposcopy, including indications established for the purposes of research, vary across studies; this in turn also influences the spectrum of abnormalities identified. The study cohort in Iceland had a prevalence of 54.5% of high-grade lesions compared to 15.4% among German women referred for colposcopy. Similarly, among studies that enrolled patients based on cytology findings as an entry criterion (rather than referral for colposcopy), the criteria vary from ASCUS only<sup>68</sup> to CIN 1 or CIN 2.<sup>66</sup> This means that aggregating test performance characteristics across studies is problematic. The test characteristics of high-risk HPV testing for detecting HSIL as a triage tool are summarized in Table 11.

Three strong studies selected the degree of Pap test abnormality *a priori* and then obtained histologic verification of HPV test performance. The group with the lowest risk of high-grade lesion at the time of evaluation was that assembled by Manos and colleagues within the Kaiser Permanente Medical Care Program in Northern California.<sup>68</sup> They enumerated all women at 4 medical centers who had a Pap test during a 9-month period and invited all women with ASCUS to participate if they were not pregnant and did not have a history of treatment for cervical neoplasia in the prior six months. Sixty-one percent of patients with ASCUS enrolled in the study; participants were demographically similar to non-participants. In this setting the sensitivity of Hybrid Capture II testing for high-risk HPV to detect HSIL was 89.2%; specificity was 64.1%; positive predictive value, 15.1%; negative predictive value 98.8%. For detection of LSIL and more severe lesions, the sensitivity was 76.3%; specificity, 69.5%; positive predictive value, 37.8%; and negative predictive value, 92.4%.

## Chapter III. Results

---

Herrington and colleagues studied 167 patients with 99 with persistent “borderline” smear, 39 with “wart virus changes”, and 29 with “mild dyskaryosis.”<sup>69</sup> Like women in the United States, German women with moderate or severe dysplasia are referred immediately for colposcopy and possible treatment. The group evaluated in this study is, therefore, much like the group for whom HPV triage would be of interest in the United States. In this setting, consensus PCR had sensitivity of 87.5%, specificity of 62.2%, positive predictive value of 42.2% and negative predictive value of 94.0% for detection of histology proven high-grade lesions.

Bollen and colleagues studied British women including only those with mild or moderate dysplasia or cytology.<sup>66</sup> Of the test systems they evaluated in their patient population, SHARP PCR (for high-risk HPV types) was relevant to this review. The sensitivity for detecting HSIL was 94.6%; specificity, 40.3%; positive predictive value, 39.8%; negative predictive value, 94.7%. In these 3 cytology-defined studies as well as the colposcopy-referral studies, the negative predictive value of testing for high-risk HPV types is greater than 90%, suggesting the feasibility of using negative HPV results to lengthen the time until repeat Pap test and to reduce the number of women who have colposcopy.

### Benefits

The benefits of HPV testing as a screening test, an adjunct to screening, or a triage tool are not documented in prospective cohort studies or trials evaluating outcomes among women who received conventional cytology only compared to an alternate strategy that includes HPV testing.

### Risks

We did not identify any studies that explicitly addressed negative individual, health system, or societal consequences of HPV testing other than cost, which is addressed briefly below. Comments in various publications suggest potential risks fall within 6 categories of concerns listed below, but no literature addresses the likelihood of any of these reactions or their magnitude:

1. Focusing on HPV testing will strongly identify cervical dysplasia and cancer with sexually transmitted disease (STD) and will stigmatize those with the condition.
2. Identifying cervical dysplasia with a sexually transmitted virus will result in women who perceive themselves as at low risk for STD receiving less cervical cancer screening.
3. Diagnosis of HPV infection will provoke partner discord.
4. Diagnosis of HPV infection, given low-positive predictive value, will unnecessarily label some women as high risk.
5. Labeling women as infected with a high-risk HPV types will provoke anxiety that may have unpredictable consequences such as over-intervention or poor compliance with followup.
6. HPV testing could undermine the importance of cytologic screening with providers or patients.

### Costs

Current costs and charges for HPV testing in clinical care vary widely by geographic location, test modality, laboratory contracts with vendors, and volume of specimens analyzed at

### Chapter III. Results

---

the laboratory facility. At the University of North Carolina Healthcare System, the Hybrid Capture II test kit cost \$43 in February 2001. The clinical laboratory fees were \$125 for Hybrid Capture II testing and \$160 for consensus PCR at the same time. As any other diagnostic modality, increased demand should eventually increase capacity, in part through competition, and lower costs. These market forces are not yet at work, and costs have not converged or declined.

For cost modeling purposes this uncertainty about the expense of the test can easily be handled by varying the model estimates of test cost. Adequate estimates of the cost of primary care office-based cervical cancer screening and resulting evaluation and treatment relevant to the US health care system are available.<sup>32</sup> However, the remaining parameters required for cost-effectiveness analysis hinder such estimates. Factors such as repeatability of HPV test results, incidence and types of HPV by age category, rates of progression and regression of HPV, and sensitivity and specificity for predicting outcomes over varied intervals of time are inadequately defined for using HPV tests in screening.

No recent literature specific to the United States is available to model and compare effectiveness or costs of screening or triage uses of HPV testing that have been proposed. The most complete contemporary model to date, constructed based on the United Kingdom screening system, considered adding HPV to Pap testing, replacing Pap testing with HPV testing, and adding HPV testing to surveillance of low-grade lesions versus continuing conventional surveillance. The authors concluded: “The uncertainty, as expressed by the differences between models, is so large, the results are inconclusive. Adding HPV testing to cervical cancer screening may or may not improve the (cost) effectiveness of screening. There are relatively few longitudinal HPV screening studies with enough time lapse between measurement points to

### Chapter III. Results

---

decrease uncertainty.”(p. 115)<sup>70</sup> When such models are generated they are further challenged by the lack of existing outcomes data even on a small scale to support or falsify the overall model or its components.

Overall, the quality of this literature is adequate for assessing the performance characteristics of the newer HPV testing methods. Hybrid Capture II and consensus PCR have good sensitivity and negative predictive value. This suggests a strong potential for a role in determining screening intervals and in triaging patients with abnormal cytology, especially among older women who have more stable HPV profiles. However, the quality of the literature is limited for the purposes of making decisions about implementing HPV testing in the US population for general screening or triage use. No published randomized trials or prospective comparisons in suitable populations were identified. In the absence of studies that relate the screening tools used to outcomes, the linkages between comparative test performance of HPV and cytologic screening tools are insufficient to judge the implications of preferentially using one combination of screening tools over another.

## IV. Discussion

### Context

To place choices about cervical screening in context, we need to highlight 4 factors not explicitly investigated in this systematic evidence review (SER).

First, the successes of cervical cancer screening to date, using conventional cytology, have been achieved using a diagnostic test that in other settings would be considered weak. Synthesis of the highest quality literature evaluating traditional Pap testing produces estimates that its sensitivity is 51 percent and specificity is 98 percent.<sup>32,50</sup>

Second, these test characteristics have proven adequate because cervical dysplasia is a slowly progressing and often self-resolving condition. The estimated progression time from severe dysplasia or carcinoma in situ to invasive cancer is 10 to 15 years.<sup>21,32</sup> Thus, repeated screening builds in redundant opportunities to detect abnormalities.

Third, cervical dysplasia itself does not cause morbidity or mortality. Low-grade squamous intraepithelial lesions are the most common changes detected by cytology in regularly screened populations, but they are also the most likely to resolve spontaneously. These low-grade changes are most common among young women, as are intermittent, recurrent, and resolving infection with human papilloma virus (HPV).

Fourth, an ideal screening system will optimize detection of high-grade lesions and minimize evaluation of low-grade and false-positive test results. However, this ideal can be achieved only with improved use of screening among the currently unscreened and with reliable systems for assuring follow-up of abnormal screening findings.

### Major Findings and Limitations of the Literature

#### Who Should be Screened and How Often?

We focused this question on screening among women age 65 and older and for those who have had a hysterectomy and on identifying research that directly compared methods of selecting screening interval. In summary, all the available evidence is observational, predominantly from large population-based data sources and from a small number of prospective cohort studies. Given these sources of information, the findings of these studies are highly coherent and support the following conclusions:

- The risks of high-grade cervical lesions and cancer fall with age.
- A history of prior normal Pap tests further reduces risk.
- If screening recommendations are not modified with age, older women are disproportionately likely to have evaluations for false-positive findings.

Among previously screened women with a history of normal Pap tests, fewer than 1 individual per 1,000 screened (in some scenarios as few as 1 per 10,000) screened will have a high-grade cytologic abnormality. As an example, if the sensitivity of cytology is 60 percent and the specificity is 98 percent for detection of high-grade abnormalities, then 34 women will be evaluated for high-grade squamous intraepithelial lesion for each true high-grade cervical lesion identified; moreover, two high-grade lesions will have been missed by cytology for every three cases identified. The ratio of true positives to false positives is much higher if low-grade cytologic changes are considered. In unpublished work, Sawaya and colleagues' report that 231 additional procedures — 112 extra Pap tests, 33 colposcopies, 30 biopsies, 35 endocervical curettages, 8 endometrial biopsies, 4 dilation and curettages, 7 loop electrosurgical excision procedures, and 2 cone biopsies — were done in response to 110 Pap tests reported as atypical

## Chapter IV. Discussion

---

squamous cells of unknown significance (ASCUS) or greater on cytology among a group of menopausal women from a prospective cohort.<sup>44</sup> At the conclusion of these evaluations, a case of cervical intraepithelial neoplasia 2 and a case of vaginal intraepithelial neoplasia III (not the target of cervical cancer screening) had been identified.

The literature provides fairly reliable estimates of the number of women who need to be screened to detect serious lesions. Recommendations can be made to discontinue or substantially lengthen the interval, beyond 3 years, for screening among women age 65 and older who have a history of prior normal Pap tests, depending on tolerance for missing rare cases that would have been detectable under different screening systems. The difficult trade-off between overscreening and missing rare but potentially preventable cases is a challenge for policy in this area. It suggests at minimum that women and their providers should be fully informed about the relatively larger risk of overintervention compared to the much smaller risk of failing to detect a high-grade lesion that would lead to morbidity or mortality.

Prior recommendations of the US Preventive Services Task Force to discontinue Pap testing after hysterectomy for benign disease are clearly supported and should be re-emphasized. Lastly, no direct comparisons between outcomes of proposed screening systems or interval for screening were identified. These findings confirm that this literature is substantially less well developed than that of other areas of screening tests, such as colorectal cancer screening, in which trials comparing use of screening methods over time are available to inform decision-making.

### **New Methods for Preparing or Evaluating Cervical Cytology**

This portion of our SER evaluated the performance of new technologies for preparing or interpreting the cytology specimens; these included liquid-based cytology collection systems, neural-net screening and rescreening tools, and computer algorithms for selecting slides for screening or rescreening. This literature is fundamentally limited by lack of histologically confirmed performance measures—no gold standard is used for comparisons. Of the very few studies using colposcopy and histology to verify the diagnostic test characteristics of new tools, the most common shortcoming was failure to apply the gold standard to test negative population or a subset to allow estimation of specificity.

To receive approval from the Food and Drug Administration, each of the new technologies currently in use (ThinPrep<sup>®</sup>, PapNet<sup>®</sup>, and AutoPap<sup>®</sup>) had to demonstrate improved sensitivity over conventional Pap testing. As noted in the introduction of this chapter, improving sensitivity, especially if it amplifies detection of low-grade lesions, may not be a benefit at a population level in terms of reducing the burden of morbidity and mortality associated with cervical cancer. This is especially true if increased sensitivity is accompanied by decreased specificity, requiring evaluation of a greater number of false positives and increasing costs. It is precisely these parameters that are most poorly measured in this literature.

Overall, the quality of this literature is poor for the purposes of making decisions about choice of screening systems in US populations. No randomized trials or prospective cohort studies relate use of a screening modality over time to outcomes for individual women. The cost-effectiveness of use of new technologies has only been estimated, not measured directly. The most sophisticated and thorough cost model to date is significantly hindered by the limitations of the literature. Nonetheless, it demonstrates that, at present, new technologies are

more costly than conventional cytology; only if used in screening intervals of 3 years or longer will new technologies fall within the traditional range considered to be cost-effective (\$50,000 per life-year).<sup>32</sup>

### **The Role of HPV Testing in Cervical Cancer Screening and Triage**

HPV testing will have the greatest utility if it can aid in identification of those with high-grade cervical lesions that require prompt treatment *and* confirm low-risk status among those with comparatively minor Pap test abnormalities such as ASCUS or cervical intraepithelial neoplasm (CIN) 1. The performance characteristics of tests for high-risk HPV types suggest greatest benefit will emerge from the latter role or from combinations with other screening modalities in the former role to improve detection. The current literature on diagnostic test performance is of fair quality with good use of histologic tools to verify HPV test results; its primary limitation is lack of prospective and experimental evidence for its role in screening or triage.

At least 8 studies evaluating HPV testing in large populations are under way or recently completed but not yet in the published literature.<sup>21</sup> The Atypical Squamous Cells of Undetermined Significance/Low-Grade Squamous Intraepithelial Lesions Triage Study (ALTS) in the United States has completed enrollment of 5,060 women with ASCUS diagnosed by conventional cytology and then randomized at enrollment to immediate colposcopy, HPV testing, or repeat Pap with ThinPrep<sup>®</sup>, the latter two arms are used to triage patients to colposcopy or less intensive follow-up. Participants are followed for clinical outcomes for two years from enrollment. The ThinPrep<sup>®</sup> arm was closed before completion of the trial, suggesting that HPV is at least more effective than repeat cytology using a more sensitive cytology tool.

## Chapter IV. Discussion

---

Definitive evidence on which to base recommendations and further model performance of HPV will be available from US and European trials within the year.

### Benefits and Harms

The tangible benefit of cervical cancer screening is reduction of cervical cancer morbidity and mortality by identification of treatable precursors or early stage disease. Intangible benefits (such as reassurance for those with normal Pap tests) or concurrent preventive care at the time of Pap testing (such as screening for sexually transmitted disease or contraceptive counseling) are not documented. These intangible benefits are of particular interest because presumably they play a role in the persistence of annual screening among low-risk patients. Although some observers postulate that such overscreening occurs as a result of provider habit and the tradition of the annual pelvic examination, published evidence does not address either patient or provider knowledge, attitudes, or desire for annual testing.

Harms of screening are poorly understood. The majority of relevant research documents the psychological distress associated with the having an abnormal Pap test. Qualitative studies suggest: (1) women have unmet information needs about the meaning of abnormal results and lack factual information about what to expect during subsequent evaluation; (2) they experience distress and anxiety before and after evaluation while the diagnosis is unknown; and (3) patient education interventions can successfully reduce the fear and uncertainty associated with follow-up care for abnormal Pap testing.<sup>74-80</sup> Long-term concerns of women with and without definitive diagnosis of cervical abnormality and the influence of previous evaluation and outcomes on future screening behavior are unclear.

### Future Research Needs

Future research must address outcomes of specific screening strategies, not only descriptive statistics and evaluation of test characteristics. On-going projects in the area of HPV testing may be the only areas of experimental research testing explicit hypotheses about the best approach to Pap testing. Until large randomized trials or well-designed prospective studies (capable of measuring and adjusting for anticipated biases) are done, especially ones that address topics such as age to discontinue screening and actual costs of new technologies, the relative benefits of one screening strategy over another are unproven and difficult to promote. The notable exception to indecision in the face of insufficient evidence is consumer demand for use of new technologies, at intervals unlikely to be cost-effective.

The community of cervical cancer researchers oriented towards preventive interventions and screening have consistently called for research of these types:

- Study of the factors that determine uptake and continuance of screening, provider and patient preferences, and adherence to appropriate screening, follow-up, and evaluation;
- Investigation of the potential for automated screening processes, such as computerized re-screening and screening, to reduce between laboratory variations in quality;
- Comparison of cytology technologies and HPV testing methods with a histologic reference standard including verification of the status of individuals, or a sample of individuals, with normal test results;
- Direct, prospective comparisons of screening strategies that include assessment of health outcomes and cost;

## Chapter IV. Discussion

---

- Continued study of the natural history of cervical dysplasia and HPV infection;
- Investigation of the consequences of diagnosis, evaluation, and treatment of low-grade cervical intraepithelial abnormalities or detection of HPV with respect to potential psychological distress, sexual behavior, future reproductive and sexual function, and demands on the health care system;
- Trials of preventive interventions such as HPV vaccination, use of topical retinoids, and smoking cessation intervention among women with CIN;
- Outcomes studies evaluating use of HPV testing to guide cessation of Pap testing among older women, and
- Evaluation of health care systems methods for documenting the prior Pap test history of individual women, to promote appropriate screening and use of screening resources.

Advances in detecting high-grade lesions and minimizing overscreening must go hand-in-hand with active research on promoting uptake and continuance of appropriate Pap testing. The majority of cervical cancers still occur among women who are unscreened, who are inadequately screened, and who do not receive appropriate follow-up for abnormal screening test results. As Table 5 summarized in Chapter 3, a robust literature, including randomized intervention trials, provides insight into methods to promote uptake and continuance and to improve follow-up. New approaches to screening and new tools for screening need to be deployed within a care system that improves documentation of women's screening status, enhances the knowledge of both patients and providers, and optimizes reaching the unreached.

## **Appendix A**

### **Acknowledgments**

# Appendix A Acknowledgments

This study was supported by Contract 290-97-0011 from the Agency for Healthcare Research and Quality (Task No. 3 to support the US Preventive Services Task Force). We acknowledge the ongoing guidance of David Atkins, M.D., M.P.H., Director of the Preventive Services Program at AHRQ, and the continuing support of Jacqueline Besteman, J.D., M.A., the AHRQ Task Order Officer for this project. The investigators deeply appreciate the considerable support and contributions of faculty and staff from the University of North Carolina at Chapel Hill – Russ Harris, M.D., M.P.H., Michael Pignone, M.D., M.P.H., Lynn Whitener, Dr.P.H., M.S.L.S., Barbara Starrett, M.H.A., Catherine Mills Burchell, M.A., and Scott Pohlman, M.S. We would like to express our special thanks to those who helped in so many practical ways to prepare the final document – Cheryl Roman, B.A., Christine Shia, M.A., and Melissa McPheeters, M.P.H.

We are equally grateful to Kathleen Lohr, Ph.D., Linda Lux, M.P.H., Anjolie Idicula Laubach, B.A., and Sonya Sutton, B.S.P.H., from RTI International for their continued guidance and assistance with the project and to Sheila White and Loraine Monroe for superior secretarial support. In addition, we would like to extend our thanks to the following expert peer reviewers, who provided input on an earlier version of this report: Michael L. LeFevre, M.D.,M.S.P.H., of the University of Missouri School of Medicine, Columbia, MO; Jean-Marie Moutquin, M.D., M.Sc., F.R.S.C.(C).of the Canadian Task Force on Preventive Care, Sherbrooke, Quebec; Evan Myers, M.D., M.P.H., of Duke University Medical Center, Durham, N.C.; Kenneth Noller, M.D.,

## **Appendix B**

### **Methods**

## USPSTF CERVICAL CANCER SCREENING

Article Screen & Abstract

### Key Question 1A:

#### Who should be screened for cervical cancer and how often?

Specifically, what are the outcomes (benefits, harms, and costs) associated with screening among women age 65 and older?

Initials of Reviewer \_\_\_ \_\_\_ \_\_\_      Date \_\_\_ / \_\_\_ / \_\_\_      Unique Article Identifier \_\_\_ \_\_\_ \_\_\_ \_\_\_  
(mm,dd,yy)

### SCREEN

Is this an original research article?       Yes       No

Does the study address screening/outcomes of screening for squamous cell carcinoma of the cervix?       Yes       No

Is the age distribution of the study population specified?       Yes       No

    Are women  $\geq 50$  years old included?       Yes       No

    Is stratified data about outcomes/risk/etc. provided by age?       Yes       No

Is the denominator provided from which the cases arose?       Yes       No\*

    \*If not, are rates provided that indicate the denominator is known?       Yes       No

<b>ALL ABOVE MUST BE "YES" TO INCLUDE FOR KQ3</b> <input type="checkbox"/> Include <input type="checkbox"/> Reject
--

### Other Screening Questions

Does the article include histologically verified measures of **Pap** test or **HPV** test diagnostic characteristics?       Yes       No

Does the article report findings for women who have had a **hysterectomy**?       Yes       No

Does the article report costs of screening based on actual **cost of care** in the US?       Yes       No

Does the article report **harms** of screening/testing?       Yes       No

## USPSTF CERVICAL CANCER SCREENING

Article Screen & Abstract

### Key Question 1B:

#### Who should be screened for cervical cancer and how often?

What are the outcomes (benefits, harms, and costs) associated with screening among women who have had a hysterectomy?

Initials of Reviewer \_\_\_ \_\_\_ \_\_\_ Date \_\_\_ / \_\_\_ / \_\_\_ Unique Article Identifier \_\_\_ \_\_\_ \_\_\_ \_\_\_  
(mm,dd,yy)

### SCREEN

- Is this an original research article?  Yes  No
- Does the study address screening/outcomes of screening for squamous cell carcinoma of the cervix?  Yes  No
- Are outcomes of screening compared for women with and without a hysterectomy?  Yes  No

<b>ALL ABOVE MUST BE "YES" TO INCLUDE FOR KQ3</b> <input type="checkbox"/> Include <input type="checkbox"/> Reject
--

#### Other Screening Questions

- Does the article include histologically verified measures of **Pap** test or **HPV** test diagnostic characteristics?  Yes  No
- Does the article include stratification by **age**, with women age 50 or older included?  Yes  No
- Does the article report costs of screening based on actual **cost of care** in the US?  Yes  No
- Does the article report **harms** of screening/testing?  Yes  No

## USPSTF CERVICAL CANCER SCREENING

Article Screen & Abstract

### Key Question 2:

**Do new methods for preparing/evaluating cervical cytology improve diagnostic yield?**

Initials of Reviewer \_\_\_ \_\_\_ \_\_\_      Date \_\_\_ / \_\_\_ / \_\_\_      Unique Article Identifier \_\_\_ \_\_\_ \_\_\_ \_\_\_  
(mm,dd,yy)

### SCREEN

The new method(s) under evaluation: \_\_\_\_\_

- Is this an original research article?       Yes       No
- Was Pap testing done as a screening test?       Yes       No
- Does the study include at least 50 subjects/specimens with Pap results *and* new method testing?       Yes       No
- Was the new method used for primary screening or as an adjunct to primary screening?       Yes       No
- Were Pap *and* the new method compared with a reference standard (histology/colposcopy)?       Yes       No
- Were the Pap, new test, and reference standard obtained within a three month window?       Yes       No
- Can all cells of a 2x2 table be completed?       Yes       No

<b>ALL ABOVE MUST BE "YES" TO INCLUDE FOR KQ2</b> <input type="checkbox"/> Include <input type="checkbox"/> Reject
--

### Other Screening Questions

- Does the article include stratification by **age**, with women age 50 or older included?       Yes       No
- Does the article report findings for women who have had a **hysterectomy**?       Yes       No
- Does the article report costs of screening based on actual **cost of care** in the US?       Yes       No
- Does the article report **harms** of screening/testing?       Yes       No

## USPSTF CERVICAL CANCER SCREENING

Article Screen & Abstract

### Key Question 3:

**What is the role of HPV testing in cervical cancer screening strategies?**

Initials of Reviewer \_\_\_ \_\_\_ \_\_\_ Date \_\_\_ / \_\_\_ / \_\_\_ Unique Article Identifier \_\_\_ \_\_\_ \_\_\_ \_\_\_  
(mm,dd,yy)

### SCREEN

Is this an original research article?  Yes  No

Was Pap testing done as a screening test?  Yes  No

Does the study include at least 50 subjects/specimens with Pap results *and* HPV testing?  Yes  No

Was HPV testing used for primary screening or as an adjunct to primary screening?  Yes  No

Were Pap *and* HPV testing compared with a reference standard (histology/colposcopy)?  Yes  No

Were the Pap, HPV test, and reference standard obtained within a three month window?  Yes  No  
Elapsed time: \_\_\_  DK

Can all cells of a 2x2 table be completed?  Yes  No

<b>ALL ABOVE MUST BE "YES" TO INCLUDE FOR KQ3</b> <input type="checkbox"/> Include <input type="checkbox"/> Reject
--

### Other Screening Questions

Does the article include stratification by **age**, with women age 50 or older included?  Yes  No

Does the article report findings for women who have had a **hysterectomy**?  Yes  No

Does the article report **harms** of screening/testing?  Yes  No

**Evidence Table 1A. Screening Among Older Women**

<b>Source: Author, Year</b>	<b>Study Design &amp; Characteristics</b>	<b>Stated Objective(s)</b>	<b>Location &amp; Time Period</b>	<b>Data Source(s)</b>
Cecchini et al., 1995 <sup>41</sup>	Population-based, retrospective cohort	To investigate the detection rate of CIN3 in previously unscreened women, in order to reveal trends over time in the prevalence of CIN3	Florence, Italy 1973-1992	Cervical cancer screening database; centralized colposcopy and pathology services
Gustafsson et al., 1995 <sup>81</sup>	Population-based, retrospective cohort	To estimate the efficiency of detecting cancer in situ in cytologic screening for cervical cancer at different ages with emphasis on women older than 50	Uppsala County, Sweden 1969-1988	Cervical cancer screening and pathology database

---

## Appendix C. Evidence Tables

**Evidence Table 1A. Screening Among Older Women (cont'd)**

Participants	Screening Program	Outcomes & Measures	Relevant Results	Quality Consideration
N = 287,295 Pap smears Age 20-60 at first screening or first screening within 10 years	N/A (identified cases at entry into screening)	Primary outcome = histologically proven CIN3 (n=648)	AGE: Within the age groups from 30-54 age/cohort specific rates of CIN 3 are increasing over secular time. Patterns are variable among older age groups over time.  Recent rates by age: Age 20-24 1.58 cases/1000py 25-9 2.51 30-4 4.94 35-9 4.01 40-4 4.29 45-9 3.40 50-4 3.90 55-9 1.88	Denom=2 Attrition=DNA Indications=0 (DNA) Interval=0 DNA Age=2 Relevance=0.5 Standard=2 Score=6.5  Grade=Poor
N = 118,890 women with 466,259 Pap smears in registry before diagnosis of cancer in situ or invasive cancer	Not specified	Primary outcome = cancer in situ n=1076	AGE: 17% of smears from women ≥50 yoa. CIS among ≥ 50 was 4.6%. Therefore detection ratio per thousand smears of 0.63. Contrasted with peak detection ratio of 3.3 for women ages 25-35; and combined ratio for those under 50 of 2.6.  AGE & SCREENING HISTORY: (Subanalysis – n = 5,893) Among women with 3 normal smears between 41 and 49, 60 (1%) had Class 3-5 smear after 50, including 4 CIS, 3 invasive cancers and 2 adenocarcinomas	Denom=2 Attrition=1 Indications=2 Interval=1 Age=2 Relevance=1 Standard=2 Score=11  Grade=Fair

Figure 2. Screening for Cervical Cancer: Analytic Framework

Key Questions

KQ1 Who should be screened for cervical cancer and how often?

KQ2 To what extent do new methods for preparing or evaluating cervical cytology improve diagnostic yield compared to conventional methods? At what cost (harms and economic)?

KQ3 What is the role of HPV testing in cervical cancer screening strategies?

## Chapter I. Introduction

†PCR, polymerase chain reaction.

Table 2: Recommendations of Other Groups about Pap Smear for Cervical Cancer Screening

Organization	Test Parameters	Screening Interval	Definition of High Risk	Interval for High Risk	Age to Stop Screening
American College of Obstetricians and Gynecologists, 1995	Onset of sexual activity or age 18, whichever occurs first	Annual; after 3 years of normal Paps interval may be lengthened	Women with multiple sexual partners or whose male sexual partners have had multiple partners; sexual intercourse at an early age; women whose male sexual partners have had other sexual partners with cervical cancer; women with current or prior HPV or condylomata or both; women with current or prior herpes simplex virus infections; women infected with HIV; women with a history of STDs; women who are immunosuppressed; smokers and abusers of other substances, including alcohol; women who have a history of cervical dysplasia or cervical cancer or endometrial, vaginal, or vulvar cancer; women of lower socioeconomic status	At physician discretion	No end date

**Table 2: Recommendations of Other Groups about Pap Smear for Cervical Cancer Screening (cont'd)**

<b>Organization</b>	<b>Test Parameters</b>	<b>Screening Interval</b>	<b>Definition of High Risk</b>	<b>Interval for "High Risk"</b>	<b>Age to stop screening</b>
American Society of Clinical Pathologists, 1999	Age 18 or sexually active	Once a year	Cancer, precancerous lesions, a variety of infectious conditions	3 - 6 months or colposcopy	Continuing for the rest of her life
American College of Preventive Medicine, Practice Guidelines Committee, 1996	At onset of sexual activity or age 18 if sexual history is unknown	At least 2 initial screening tests 1 year apart; then interval lengthened at discretion of patient and doctor, but not to exceed >3 year interval	Not mentioned	Not mentioned	Age 65, if no abnormal smears in the prior 9 years, unless patient has not been screened adequately

**Table 2: Recommendations of Other Groups about Pap Smear for Cervical Cancer Screening (cont'd)**

<b>Organization</b>	<b>Test Parameters</b>	<b>Screening Interval</b>	<b>Definition of High Risk</b>	<b>Interval for "High Risk"</b>	<b>Age to stop screening</b>
American Academy of Family Physicians, 1996	Women who have ever had sex and have a cervix	At least every 3 years	Not mentioned	Not mentioned	Not mentioned
Canadian Task Force on Preventive Health Care, 1992	Women > age 18 who have had sexual intercourse	Two annual screens, then every 3 years	Early onset of sexual intercourse; many sexual partners; sexual partner with many sexual partners	More frequently than 3 years	Until age 69
American Cancer Society, 2000	Sexually active or Age 18 (as prior entries)	Annually until 3 or more consecutive satisfactory examinations, then at physician discretion	Not mentioned	Not mentioned	General cancer check-up recommendations suggest annual exam continue past menopause
Institute for Clinical Systems Improvement, 2000	Sexually active women younger than age 18 and all women aged 18-64. Omit women who have had a hysterectomy with no residual cervix	3 consecutive normal smears and no dysplasia within 5 years, then less frequently, but at least every 3 years	Mandelblatt Risk Factor Table of Relative Risk	Annually until no longer show dysplasia within 5 years	Age 65
UK National Health Service Cancer Screening Programmes, 1999	Age 20. Omit women who have had a total hysterectomy for nonmalignant reasons	At least every 5 years (free cervical smear test)	Certain types of HVP; women with many sexual partners or whose partner has had many partners; long-term use of the pill; women who smoke	Not mentioned	Age 64

**Table 2: Recommendations of Other Groups about Pap Smear for Cervical Cancer Screening (cont'd)**

<b>Organization</b>	<b>Test Parameters</b>	<b>Screening Interval</b>	<b>Definition of High Risk</b>	<b>Interval for "High Risk"</b>	<b>Age to stop screening</b>
Australian National Cervical Screening Program, 1998	Women who have ever been sexually active beginning at age 18-20	Every 2 years	Not mentioned	Not mentioned	Age 70 with 2 normal Paps in prior 5 years
New Zealand National Cervical Screening Programme	Women who have ever had intercourse beginning at age 20. Women who have had a total hysterectomy for a benign condition do not require further screening	Every 3 years, except if > 5 years since last or if first smear, then repeat in 1 year's time	Sexual behavior, smoking, hormonal or contraceptive use  Immunocompromised women	More frequent screening is not recommended for women possibly at higher risk of cervical cancer as there is no evidence that such women have a shorter duration of the preinvasive stage. Immunocompromised women should be screened annually.	Age 70

## Chapter II: Methods

---

**Table 3. Overall Inclusion and Exclusion Criteria**

<b>Element</b>	<b>Inclusion</b>	<b>Exclusion</b>
Databases	MEDLINE	Other databases
Languages	English	Other languages
Populations	Human	Animal studies
Study Design	Primary research reports, cost-effectiveness analyses, meta-analyses, systematic reviews	Letters, editorials (i.e., no original data)

## Chapter II: Methods

---

**Table 4. Literature Search Results (1995-2000)**

<b>Step</b>	<b>Search History</b>	<b>Results</b>
<b>1</b>	Explode cervical neoplasm	29,318
<b>2</b>	Explode cervical dysplasia	2,331
<b>3</b>	Explode mass screening	44,349
<b>4</b>	Explode vaginal smears and screening	2,302
<b>5</b>	1 or 2	29,913
<b>6</b>	3 or 4	45,324
<b>7</b>	5 and 6	3,256
<b>8</b>	Limit 7 to human and English language and year = 1995-2000	<b>962</b>

## Chapter II: Methods

---

**Table 5. Disposition of Articles Identified by Literature Search**

<b>Categorization by Abstract Review</b>	<b>Total Identified</b>	<b>Number Excluded</b>	<b>Retained for Background</b>	<b>Retained for Review</b>
Key Question 1: Who should be screened?	351	205	28	118
