Subsamples (20 cc volume) from the sample bags were weighed and spiked with a known concentration of exotic spores (*Lycopodium*) to monitor any degradation from the chemical extraction procedure and to enable pollen concentration calculations. Samples were processed with the method recommended by Smith (1998b), with the addition of several timed decants as described below. Samples were pretreated with hydrochloric acid (10% solution) to dissolve caliche and sieved through 180-µm mesh screen to remove coarse material (rocks, roots, coarse charcoal, etc.). The fine fractions were mixed with warm sodium hexametaphosphate (less than 2% solution) and allowed to settle for eight hours in one-liter beakers, and then the muddy liquids were siphoned off. The timed decants were repeated using only distilled water until siphoned liquids were clear. The technique removes organic and inorganic particles lighter than pollen, and the end result is an efficient non-toxic method to concentrate pollen. After the physical treatments, samples were treated for 24 hours with hydrofluoric acid, rinsed in distilled water, and floated in lithium polytungstate (1.9 specific gravity). The heavy liquid separates pollen grains and particles lighter than 1.4 specific gravity from heavier fractions. The recovered light component was then acetolyzed, which reduces organics, and the residue was rinsed with alcohol, mixed with glycerol, and stored in vials.

Pollen Washes

Four artifacts were submitted for pollen washes: two ground stone, a ceramic sherd, and a mano. Sediment visible on the artifact surfaces was brushed off before washing. The artifact use surfaces were scrubbed with hot distilled water and 10 percent hydrochloric acid. The retained liquids were spiked with a known concentration of tracer tablets (*Lycopodium* spores), sieved through 0.18 mm mesh screen, and centrifuged. Samples were then processed with a hydrofluoric acid treatment followed by a heavy liquid gravity separation (lithium polytungstate 1.9 specific gravity) and acetolysis. The final extracted residues were rinsed with alcohol, mixed with glycerol, and stored in glass vials.

Standard Microscopy and Pollen Identifications

Pollen assemblages were documented by counting pollen on slide transects at 400x magnification to a 200-grain sum, if possible, then scanning the entire slide at 100x magnification to record additional taxa. Pollen aggregates (clumps of the same taxon) were included in the sum as one grain per occurrence. Numerous large aggregates are generally interpreted to represent flower anthers (Gish 1991), which indicate taxon presence and can reflect the season of deposition.

Pollen identifications were made to the lowest taxonomic level possible based on published keys (Kapp et al. 2000; Moore et al. 1991) and the Laboratory of Paleoecology pollen reference collection at Northern Arizona University. Sunflower family pollen was differentiated into seven distinct types: Asteraceae, sunflower family type (hi-spine); *Ambrosia*, bursage type (low-spine); chicory (Liguliflorae), broad spine Asteraceae, a distinct Asteraceae grain type recorded at only one site (LA 86637, multi-component scatter in the White Rock Tract), a long spine type that compares well with sunflower (*Helianthus*), and a type designated as cf. (compares favorably) marshelder (*Iva*). Pine grains were separated into small pine and large pine based primarily on size measurements, using 70 µm total length (body plus bladder) as the dividing criterion (Jacobs 1985a). The pine grains counted in the larger than 70 µm category are attributed primarily to ponderosa pine and the smaller grains are identified as piñon. There is significant overlap in the size gradient between small ponderosa pine grains and larger piñon pine (Martin 1963:20–21), and it is likely that there are misidentified grains in both pine categories.

Intensive Scanning Microscopy

An extended microscopy method modified from the Intensive Scanning Microscopy (ISM) technique developed by G. Dean (1998) was used in this analysis to analyze 65 agricultural samples and 22 select samples (e.g., burials and hearths). The C&T Project ISM data are documented in Appendix W. The technique, which has been used primarily to search for cultigen pollen in pre-Columbian fields, is based on scanning multiple slides at low magnification (typically 100x to 200x). If preservation is moderate, grains larger than about 30 µm can be easily identified at low magnifications, including squash, cotton, corn, agave (*Agave*), cacti, pine, and many of the herb types. The advantages of ISM are that the probability of finding cultigen pollen is maximized and the abundance or absence of large, rare types is quantified. Thus, ISM results can be used to evaluate the level of analysis and compare data from different sites.

After the conventional 400x magnification counts, multiple slides were scanned at 100x magnification until each sample (with two exceptions) was analyzed to a level equal to or less than 1.0 gr/g, called the threshold concentration. This threshold value was chosen because previous pollen studies of old fields have documented that cultigen pollen, if present, typically occurs at concentrations of 1.0 gr/g or greater (G. Dean 1991, 1994). Two samples from the C&T Project (burial sample 4112 from LA 12587 and a fieldhouse hearth, sample 95 from LA 85861) were analyzed to threshold concentrations of 1.81 and 1.38, respectively. The threshold concentration is determined by the following calculation:

> Threshold Concentration gr/g = [(hypothetical 1 grain of cultigen pollen/number of tracers counted) * tracer concentration] /sample weight

The ISM method works by determining how many tracer grains should be observed to find a pollen type occurring at a concentration of approximately 1.0 gr/g. Since the weight of each sample was different, the target tracer count varied, but generally sample weights were about 20 grams, requiring between 1700 and 2000 tracer grains to resolve a pollen type occurring at approximately 1.0 gr/g. One to 11 slides from each sample were scanned to reach the target threshold concentration. Any cultigens encountered during ISM scans were counted and concentration values calculated using total number of tracers tallied. Cotton and maize pollen were documented during standard counts, but cultigen pollen would have been missed in seven samples without examining a second (6 samples) or third (1 sample) slide.

Analytical Methods

Four parameters were calculated from the pollen counts: taxonomic richness, pollen concentrations, pollen percentages, and for sorted groups of samples—frequency. Taxonomic richness is the number of different pollen types identified in a sample and frequency is the number of samples a type occurs in. Frequency is typically converted to the percentage of samples considered. Pollen concentration was estimated by calculating the ratio of the pollen count to the tracer count and multiplying by the initial tracer concentration. Dividing this result by the sample weight yields the number of pollen grains per cubic centimeter of sample sediment, abbreviated gr/g. Pollen percentages represent the relative importance of each taxon in a sample ([pollen counted/pollen sum]*100).

Pollen percentages are used here to compare modern analog pollen to archaeological, but the interpretations of the archaeological samples are based on pollen concentration data for dominant taxa and taxa frequency for rare and low-count types. Pollen concentrations represent an extrapolated estimate of raw numbers of pollen grains and can reflect the abundance of plant material associated with a context. Generally analysts prefer to work with pollen percentages because the data are smoothed, but percentages mask differences in the absolute abundance of pollen between samples. For example, two samples with 10 percent corn could yield concentrations of 100,000 grains of corn in one sample and 10,000 grains of corn in the second. Pollen data are displayed graphically in seven figures in this chapter. The pollen graphics were generated using the Tilia View software program written by Eric Grimm (Grimm 1993).

RESULTS

All of the pollen counts are documented in appendices included in this volume (Appendices W through Y) and sample results are also reported in the site descriptions (Volume 2). This chapter first presents a summary of sterile pollen samples and a list of all of the pollen types identified. Next is an overview of how archaeological samples contrast with modern analog and surface control pollen data. A suite of economic pollen types are defined through contrasts between the modern and archaeological samples, followed by a discussion of data trends and patterns organized by results from gardens and the three land tracts.

Sterile Pollen Samples

The 200-grain pollen count has been an analytical standard for archaeopalynology since studies demonstrated that 70 percent to 85 percent of the taxa present in a pollen sample will be detected in a 200-grain count (Barkley 1934; P. Martin 1963). However, when there is no coherent pollen signal in samples due to progressive deterioration, the degraded assemblages are evaluated as sterile (Bryant and Hall 1993:283; Dimbleby 1985:8; Hall 1981, 1991).

In this analysis, 37 pollen samples were sterile or contained inadequate pollen to reliably represent the sample pollen population (Table 63.6); these sterile samples are generally excluded from summary calculations and interpretations. Another 33 samples were low-count samples with pollen sums between 85 and 150 grains, and these are considered in summary calculations.

Samples may have low counts or zero pollen grains for a variety of reasons, such as poor preservation or quantities of micro debris in the processed residues that obscure pollen on microscope slides. The two worst C&T Project contexts for unproductive pollen samples were the geology soil pits and pollen washes. Seventeen of 42 geology samples were sterile, which as discussed previously is attributed to poor preservation in soils. Two out of four pollen washes were sterile, which is not unusual for pollen washes (Geib and Smith 2007). Six of 23 samples from lithic scatters and 8 of 46 samples from hearths, ashpits, or other thermal features were sterile. Although the hearths ranked fourth in terms of contexts least likely to produce significant pollen counts, thermal contexts yielded some of the richest assemblages and highest values of economic taxa.

Table 63.6. Sterile pollen samples.

Site	Number of Pollen Samples	Number of Sterile Samples	Provenience
		White Rock Tract	
LA 12587	122	3	1 pollen wash (3159), 1 sub-hearth (4100), 1 pipe (1998)
		Airport Tract	
LA 86534	47	3	Kiva hearth (2204, 2205, and 2219)
LA 135290	77	7	1 pollen wash (2234), 1 wallfall (1635), geology soil pit samples (2276, 2277, 2278, 2279, and 2280)
LA 139418	18	1	Geology soil pit samples (408)
		Otowi North	
LA 21592	11	1	Field sample (30.1)
		Rendija	
LA 85403	5	1	Fieldhouse floor (50)
LA 85859	19	11	geology soil pit samples (107, 142, 338, 341, 357, 358); scatter (329, 334, 337)
LA 87430	5	1	Hearth, extramural (169)
LA 99396	10	1	Hearth, extramural (615)
LA 99397	13	4	Lithic scatter (311, 312, 319, 333)
LA 127627	6	2	Fieldhouse posthole (8, 67)
LA 127634	6	1	Fieldhouse hearth (104)
LA 127635	5	1	Fieldhouse floor (117)
Total	344	37	

Floor sediments are the best overall contexts for productive samples and cultural pollen evidence. Only two of 121 floor samples were sterile; both were from fieldhouses. There is also a subset of 14 floor samples that were collected in rooms from beneath artifacts and these contexts produced the highest representation of economic pollen types. For example, seven project samples yielded maize pollen concentrations of greater than 1000 gr/g and three of the seven samples were collected from under artifacts lying on room floors.

Pollen Types Identified

The 64 pollen types identified from project samples are listed in Table 63.7 by taxa and common name. They are organized into six categories to reflect the ethnobotanical and ecological spectrum from obvious cultigens to introduced plants. Aggregates or clumps of pollen were documented from 14 taxa and these are also listed. The sample frequencies for all 478 C&T Project pollen samples and for 13 modern analog control samples are also presented in Table 63.7. Pollen can usually be identified to the genus level, rarely the species level, and often a grain type can only be referred to a plant family. A list of plant taxa for especially broad pollen categories (e.g., cheno-am) is included in Table 63.7.

Table 63.7. Pollen types identified by taxa and common names with percent sample frequencies for C&T Project and modern analog samples.

Taxon Name	Common Name	All C&T Project Samples (*n* = 478) %	Piñon and Juniper and Pine Transition Modern Pollen (*n* = 13) %
Cultigens			
Gossypium	Cotton	1	0
Cucurbita	Squash	3	0

Carya	Pecan (exotic)	<1	0

There are six distinct unknown pollen types listed in Table 63.7, which were counted separately: a probable mustard (Brassicaceae), a member of the four o'clock family (Nyctaginaceae) characterized by a periporate grain ca. 80 µm in diameter, an Asteraceae (sunflower family) grain with broad-based spines (broad spine type), an Asteraceae grain that was identified only at LA 86637, a type referred to as "small sage," and a grain referred to as cf. marshelder (*Iva*). The small sage is an ovate to oblate grain, small (less than 30 µm diameter) with a relatively thick and tectate exine. The morphology of the pollen grain resembles sagebrush (*Artemisia*), but is smaller in size. This grain type may represent one of the weedy sages, such as carruth sage or false tarragon (*Artemisia carruthii* or *A. dracunculus*), which Foxx et al. (1997) and Foxx and Tierney (1999) have identified as diagnostic successional species on old AD 1800s fields on the Pajarito Plateau. The marshelder type is a low-spine Asteraceae grain that is similar to *Ambrosia* and *Dicoria*, but the best match is to marshelder (*Iva*), based on comparison to modern specimens of the low-spine Asteraceae taxa (*Ambrosia, Dicoria,* and *Iva*). All three genera are documented in Jemez Mountain floras (Foxx et al. 1998; Foxx and Tierney 1985).

All of the plants represented by the 64 pollen types were used by various Native American tribes in the Southwest for food, fuel, tools, medicine, ceremony, textiles, construction, and other uses (Dunmire and Tierney 1995, 1997; Foxx 2006; Moerman 1998; Rainey and Adams 2004). Dunmire and Tierney (1995) identify 304 plants known to have been subsistence resources within the Pueblo province. Vierra and Foxx (2002) showed that approximately two-thirds of these 304 species are accessible in the Jemez Mountains; most are found in the piñon and juniper woodlands, the ecosystem where most of the C&T Project sites are located. However, the occurrence of a pollen type in an archaeological sample is not enough evidence to signify cultural use (see previous section, Limitations of Pollen Data). A list of economic and subsistence resources is refined in this analysis through comparison to modern samples and associations in archaeological samples.

Modern Analog Data Compared to Archaeological Pollen

Comparison of Modern Pollen to Archaeological Spectra: The False Deforestation Signal

Modern vegetation in the White Rock and Airport Tracts is piñon and juniper woodland. The Rendija Tract is ponderosa pine with piñon and juniper because of its more mesic location in a canyon. Thirteen pollen samples collected from modern piñon and juniper communities (Smith 2007a) and five surface control samples from White Rock and Airport Tract sites were graphed with all productive floor and fill samples from roomblocks (n = 130; excluding Roomblock 3 at LA 12587), floor and fill samples (n = 24) from a select set of Rendija Tract fieldhouses, and 54 samples from garden plots (Figure 63.1). Rendija Tract fieldhouse samples included in Figure 63.1 are from archaeological sites near the two modern analog pollen sampling stations in Rendija Canyon (Stations 27 and 28 Rendija gun club; Smith 2007a). Sample pollen concentrations are shown in Figure 63.1 as well as the combined percentages from the conifers (pine, piñon, and juniper) and weedy taxa plus grass (cheno-am, sunflower family, and grass). These combinations of taxa are a common palynological device used to compare the arboreal pollen expression (AP) to non-arboreal pollen (NAP).

The pollen percentages show that modern surface control samples are dominated by AP and subsurface samples are dominated by NAP. This is the Southwestern archaeological pollen signature repeated at virtually every site located in woodland or forest where pollen samples include a modern surface control sample for comparison to archaeological samples. The other important characteristic of this classic signature is pollen concentrations, which are high in the modern control samples and plummet in the subsurface samples. Even the five surface control samples from the archaeological sites record lower pollen concentrations than the analog surface samples (Figure 63.1), suggesting that a persistent cultural imprint exists in soil samples at archaeological sites. While these trends may appear to define a clear signal of deforestation during the archaeological period (e.g., Huber and Kohler 1993), the deforestation theory does not explain the subsurface drop in pollen concentration nor why this signature is generally typical of all sites from large pueblos to seasonal fieldhouses and gardens.

Pollen samples from off-site geology soil pits compared to surface samples also produced the same signature as the archaeological samples compared to surface samples. In the soil pits there is a dramatic drop in pollen concentration and pine percentages below A horizon levels, but cheno-am and sunflower family percentages increase (see previous summary of geology soil pits). This natural preservation gradient is due to the effects of physical, chemical, and biological agents and processes in soils. These natural processes are thought to contribute to the low pollen concentration and NAP-dominant signature in the archaeological samples.

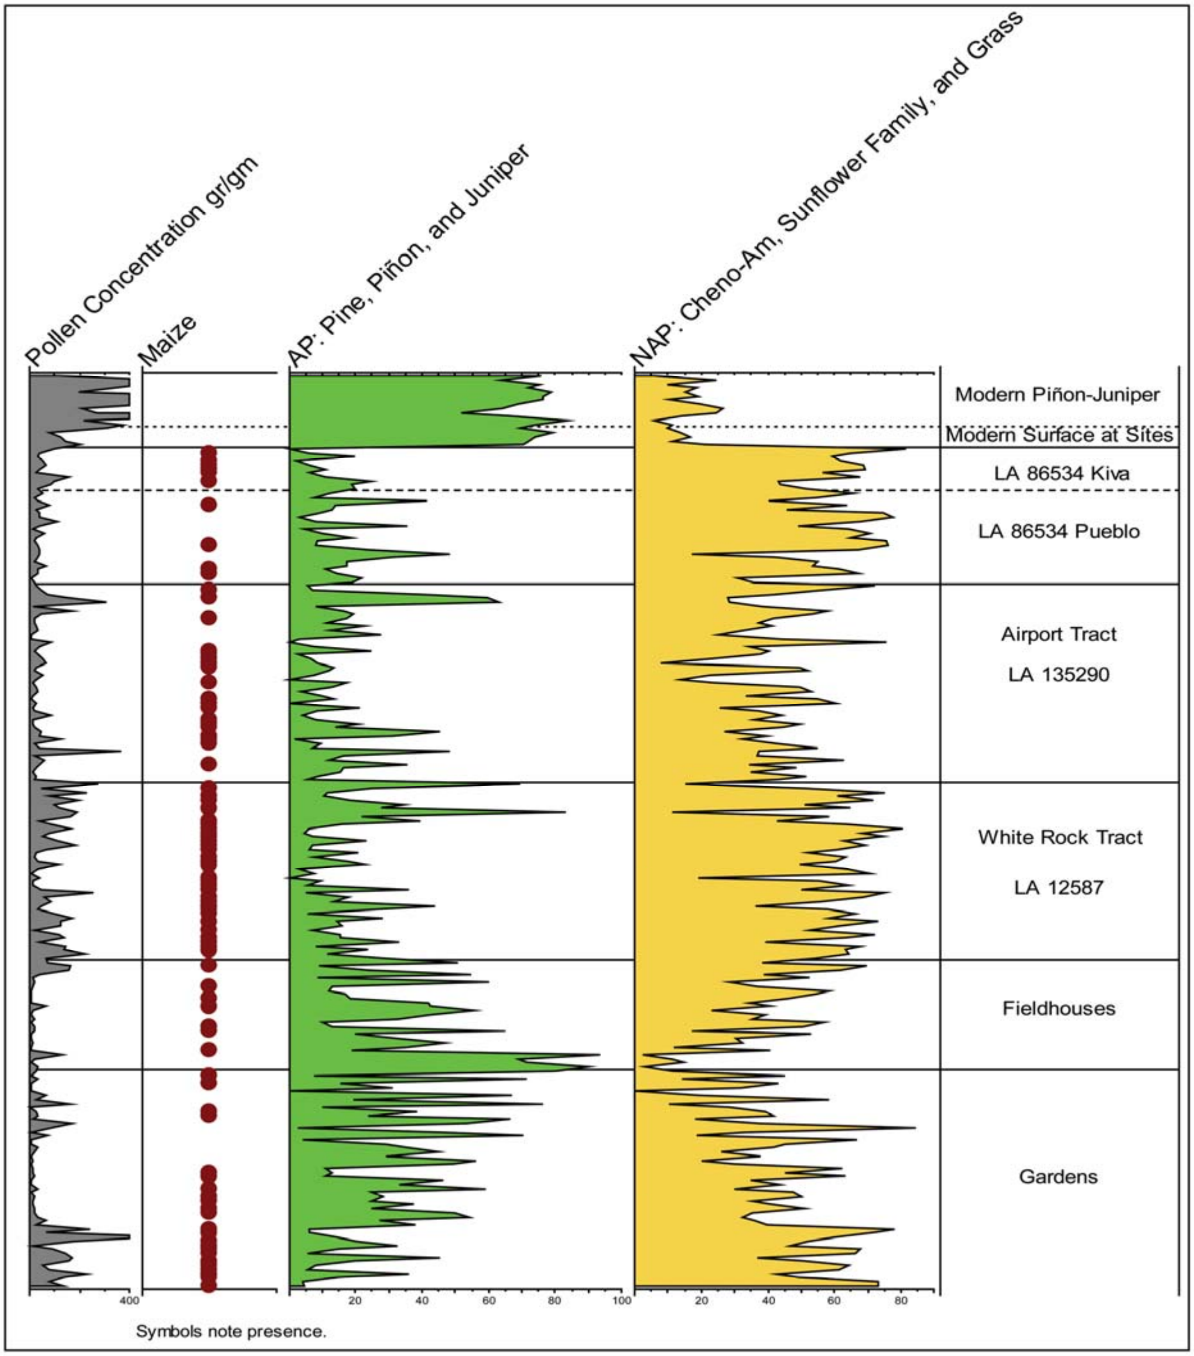

Figure 63.1. Summary percentages for arboreal pollen (AP) and non-arboreal pollen (NAP) from modern control samples, floors and fill samples from fieldhouses and pueblos (excluding Roomblock 3 at LA 12587), and gardens.

It is also true that pollen is very sensitive to local landscape changes, but the key word is *local*. Clearing a small area and constructing a pueblo can change the pollen spectra from tree dominated to weed dominated. The disturbed soils and sediments forming the site footprint are colonized by weedy taxa that dominate the pollen rain accumulating in surface sediments. There are two pairs of stations from the modern pollen analog study (Smith 2007a) that provide examples of a disturbance pollen signal overwhelming the pollen input from surrounding forest (Table 63.8). The AP and NAP percentages from these sites show that pine and juniper percentages are significantly higher in the undisturbed locations and weedy taxa characterize the disturbed areas. The wetland in Pajarito Canyon is a dramatic example of pollen sensitivity to local landscape change, as the two stations are less than 10 m apart, yet the two surface pollen samples are significantly different.

Table 63.8. Comparison of arboreal pollen (AP) and non-arboreal pollen (NAP) percentages from disturbed sites.

Modern Pollen Analog Station	Concentration gr/g	AP: Pine, Piñon, and Juniper Pollen Percentages	NAP: Cheno-Am, Sunflower Family, and Grass Pollen Percentages
25 – Natural wetland in Pajarito Canyon	48070	72	6
26 – Disturbed site (road shoulder) within 10 m of Station 25	11399	39	36
1 – Piñon and juniper south of Highway 4 west of White Rock	11626	76	6
2 – Disturbed site along Highway 4, Ancho Canyon, possible old field on first terrace; piñon and juniper woodland surrounding	12031	38	56

The dynamics of pollen movement and deposition in sediments at archaeological sites are complex and there are a number of considerations beyond the natural pollen dynamics discussed above that invalidate using archaeological pollen spectra for environmental reconstructions. The majority of pollen samples collected for the C&T Project came from roomblocks with plastered floors and adobe walls and restricted roof entry via ladders. This type of architecture limits atmospheric pollen rain to the small roof hole. After the site is abandoned, the roof drops down and seals the floor and the walls topple in on top of the rooffall. When the site is excavated, the sediment collected as pollen samples from room fill is largely composed of the rain-melted adobe materials used to construct walls and roofs. Construction debris, adobe melt, and rooffall are not adequately stable contexts to record changes in environmental pollen rain because the depositional history is too chaotic. Post-occupation sheetwash and aeolian events also contribute to mixing site sediments and to decreased pollen concentrations in subsurface sediments, as pulses of rapid sediment influx dilute ambient pollen.

The issues and considerations discussed above have been raised by other palynologists. Most analysts recognize that archaeological pollen assemblages are distorted due to cultural activities (Hall 1985; Jelinek 1966:1507). Hall (1985:116) states that,

> The cutting of timber for construction and firewood and the clearing of brush for agriculture will result in locally decreased abundance of pollen from woody plants and a corresponding increase in pollen from weeds that colonize disturbed ground.

Poor preservation in archaeological contexts is also widely acknowledged (see summary in Bryant and Hall 1993). Although the differences in the AP and NAP between modern surface and archaeological samples cannot be used to interpret environmental change during archaeological periods, the pollen data do not disprove deforestation. The best evidence for assessing human impacts during the pueblo periods is whether choices in fuel wood and construction materials changed.

Comparison of Modern and Archaeological Samples: General Trends

Figure 63.2 expands upon the previous figure to look at the individual pollen taxa that compose the AP and NAP frequencies; these data show general trends that characterize the individual sites. Cheno-am and sunflower family dominate the archaeological pollen assemblages, but sunflower family spectra behave like a background signal with no correlation to site type or context.

Pollen samples from pueblo sites have higher pollen concentrations and cheno-am percentages than fieldhouses and gardens. The maximum archaeological pollen concentrations and cheno-am percentages are from samples at LA 12587, which is the largest and longest occupied C&T Project site excavated. This site consists of two Late Coalition pueblos (Roomblock 3 was never finished), a Classic fieldhouse, and grid gardens. Fieldhouses are characterized by the smallest archaeological pollen concentrations and cheno-am percentages, with the exception of the LA 12587 garden (see below).

Pollen representation from gardens is in the middle between fieldhouses and pueblos. Cheno-am percentages from gardens are moderate and piñon and juniper values tend to be higher than structures. This pattern makes sense, as gardens were open to atmospheric pollen deposition; thus tree pollen input drives conifer percentages higher. The high pine percentages in the garden samples from Otowi (LA 21592) are also an environmental signal, as the grid garden is in a canyon, where tree density is greater than on mesa tops.

The garden sampled at LA 12587 is an exception among the gardens, with pollen concentrations and cheno-am percentages comparable to the LA 12587 roomblock. This result is interpreted in part as reflecting the fertility of the LA 12587 garden, and also the overall site history, as multi-component occupations and construction of a large site footprint may have blurred the sedimentary record.

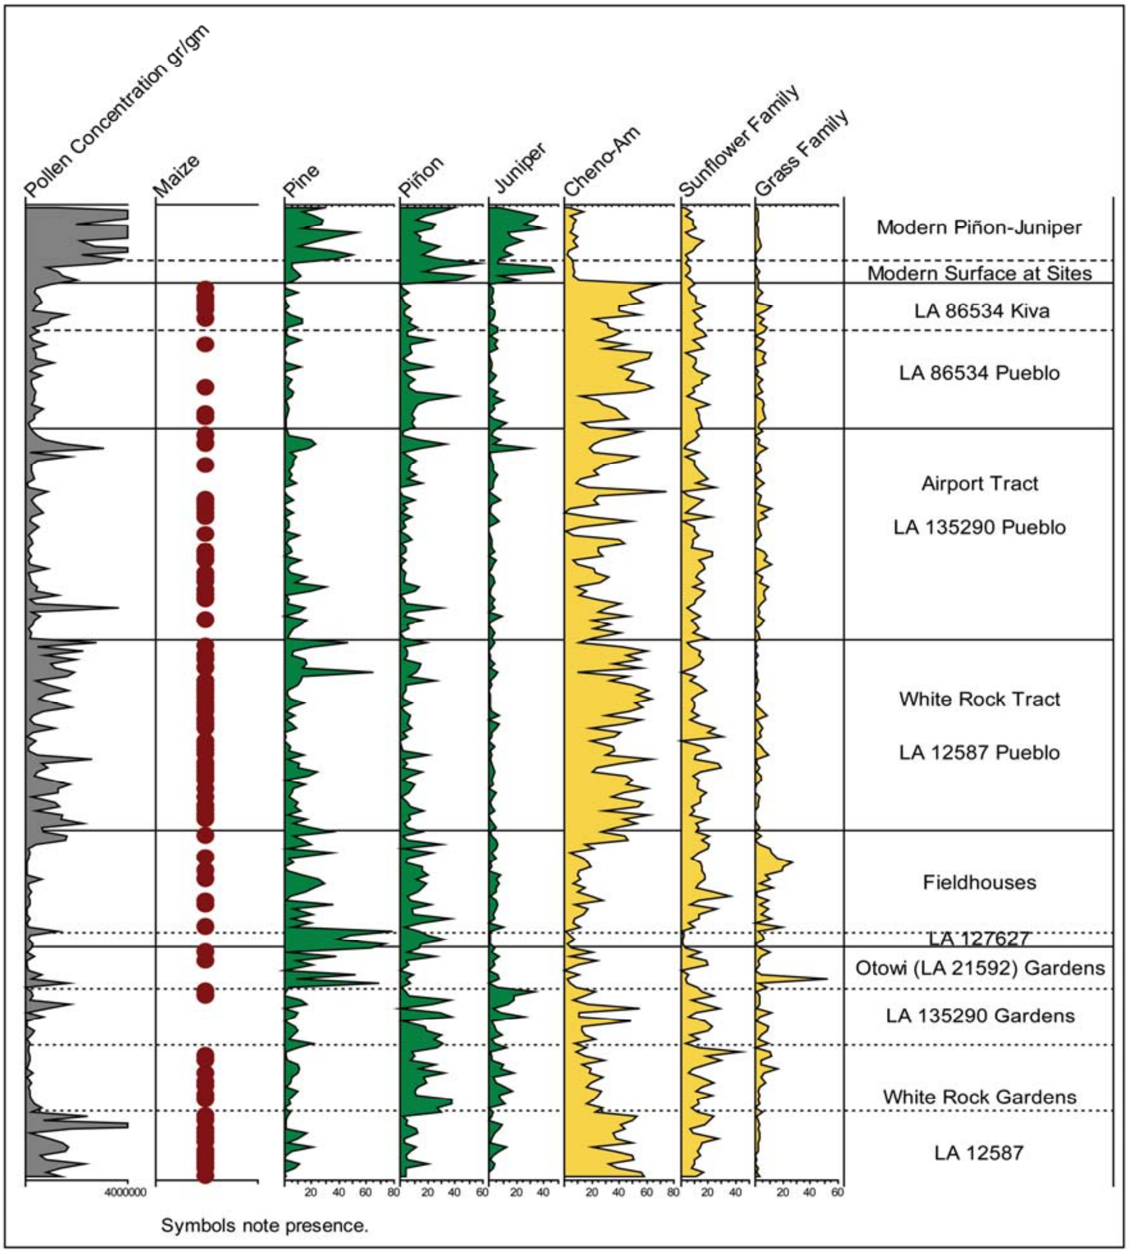

Figure 63.2. Pollen percentages from modern surface control samples, floors and fill samples from fieldhouses and pueblos (excluding Roomblock 3 at LA 12587), and gardens.

The contrasts in cheno-am between fieldhouses, gardens, and pueblos suggest that cheno-am representation is an indicator of the intensity of site use and can be used to rank the activity at sites. Cheno-am is a catch-all pollen category that encompasses the Chenopodiaceae family and *Amaranthus* genus. Common genera include saltbush (*Atriplex*) and the weed types goosefoot (*Chenopodium*), bugseed (*Corispermum hyssopifolium*), and pigweed (*Amaranthus* spp.). The introduced tumbleweed (*Salsola kali*) is another Chenopodiaceae species. Ethnographic and archaeological data show that seeds and greens from several cheno-am taxa were important staples throughout the Southwest (Dunmire and Tierney 1997; Huckell and Toll 2004; Moerman

1998; Rainey and Adams 2004). The cheno-am signature in the C&T Project pollen spectra is interpreted as a general weed signature related to intensity of site use, but it is also understood that the distinction is fuzzy between a weed and a resource. On-site and easily grown cheno-am and other "weeds" may well have been conserved, managed, or even directly cultivated for food.

There are some definite patterns in the representation of dominant pollen types by sites (Figure 63.2). Sagebrush pollen is highest at LA 135290 and cheno-am pollen percentages are noisy at this pueblo with both high and low values. There are two spikes in the pollen results shown in Figure 63.2. One is the grass pollen peak in fieldhouses, derived from floor samples at site LA 85404 in the Rendija Tract. The second is pine pollen in the post-occupation samples from LA 127627, also in the Rendija Tract. The higher pollen percentages for these taxa are interpreted to reflect floor samples versus fill; the differences in context is a theme explored in detail in the site results presented below.

Comparison of Rare Taxa between Modern and Archaeological Samples: Definition of the Economic Pollen Signature

There are several herbaceous and shrub pollen types that are absent from modern surface samples but occur in the subsurface samples, either rarely and represented by one to three grains, or more frequently but also in low numbers, usually less than 10 pollen grains. Most of these rare and low-count taxa are interpreted here as economic taxa. There are also a few types present in subsurface samples and one or more modern samples, and generally these are also considered significant, depending on the pollen abundance and context. The comparison of low count and rare pollen types between modern and archaeological samples is presented graphically in Figure 63.3. The archaeological samples include fill, floor, hearth, and posthole contexts from all of the pueblo sites, except Roomblock 3 at LA 12587, and the fill, floor, and intramural feature samples from fieldhouses. The most important economic taxa presented here are noted in Table 63.7. A few select types are emphasized below with examples from the ethnographic record.

Cultigens are the core of the C&T Project economic pollen taxa. Maize pollen is ubiquitous at all site types and from all contexts (Figure 63.3), and cotton and squash were also identified in a few samples. The occurrence of cholla pollen in the C&T Project samples is interpreted here as evidence of another important cultivated resource. Cholla does not grow in modern piñon and juniper communities in the Jemez Mountains, except at some of the larger archaeological sites, where it is restricted to the deep, well-drained substrates of collapsed walls (Foxx et al. 1998; Housely 1974). No cholla plants were documented from the 20 Los Alamos modern pollen analog stations (Smith 2007a) or in the modern vegetation near any of the excavated sites. Yet cholla pollen occurs in 63 project samples and the surface control sample from LA 12587, which likely contains some component of archaeological pollen. As noted above, surface control samples at sites appear to contain some residual archaeological signature.

All of the cacti, including cholla, are insect-pollinated plants so the pollen is not dispersed far, which means that naturally deposited cholla pollen should be uncommon in protected subsurface contexts. The cholla occurrence in the C&T Project samples is concentrated in primary contexts at the major pueblo sites (Figure 63.3; also see individual site results below) and in the garden samples, especially in the garden at LA 12587. Since cholla does not grow in the modern piñon and juniper woodland vegetation, the archaeological distribution may indicate that cholla was deliberately imported and cultivated. Housely (1974) reached the same conclusion in the western Jemez Mountains, where a species of cholla (*Opuntia imbricata*) was found growing in surface soils at certain archaeological sites outside the modern geographic and elevational range of the species.

The ethnographic history of cholla use is extensive (Curtis 1970:17, 153; Dunmire and Tierney 1995; Housely 1974:50–59; Moerman 1998; Stevenson 1915). Vegetative parts of cholla could be used throughout the year, but the most prized products are the flower buds just before opening and the fruits. The flower buds, which are gathered in the late spring around May, are prepared by steaming or roasting in pits (Greenhouse et al. 1981). Cholla flower buds are one of the few native resources that are still harvested by Indian tribes in the Southwest (Dunmire and Tierney 1995:142; Rea 1997:70). Both cholla buds and fruits could be dried and stored. Dried cholla was ground to a meal or reconstituted in soups and stews. Ceremonial and other uses are also documented in ethnographic accounts. This excerpt from Housely (1974:55) lists two of the more obscure uses.

> In Isleta, arrowheads were made from the wood, because it was thought to be infectious (Jones 1931). The coverings of thorns were eaten by warriors of Laguna and Acoma to make them strong. The stems were used like candles for a torch and the spines were used for tattooing. (Swank 1932).

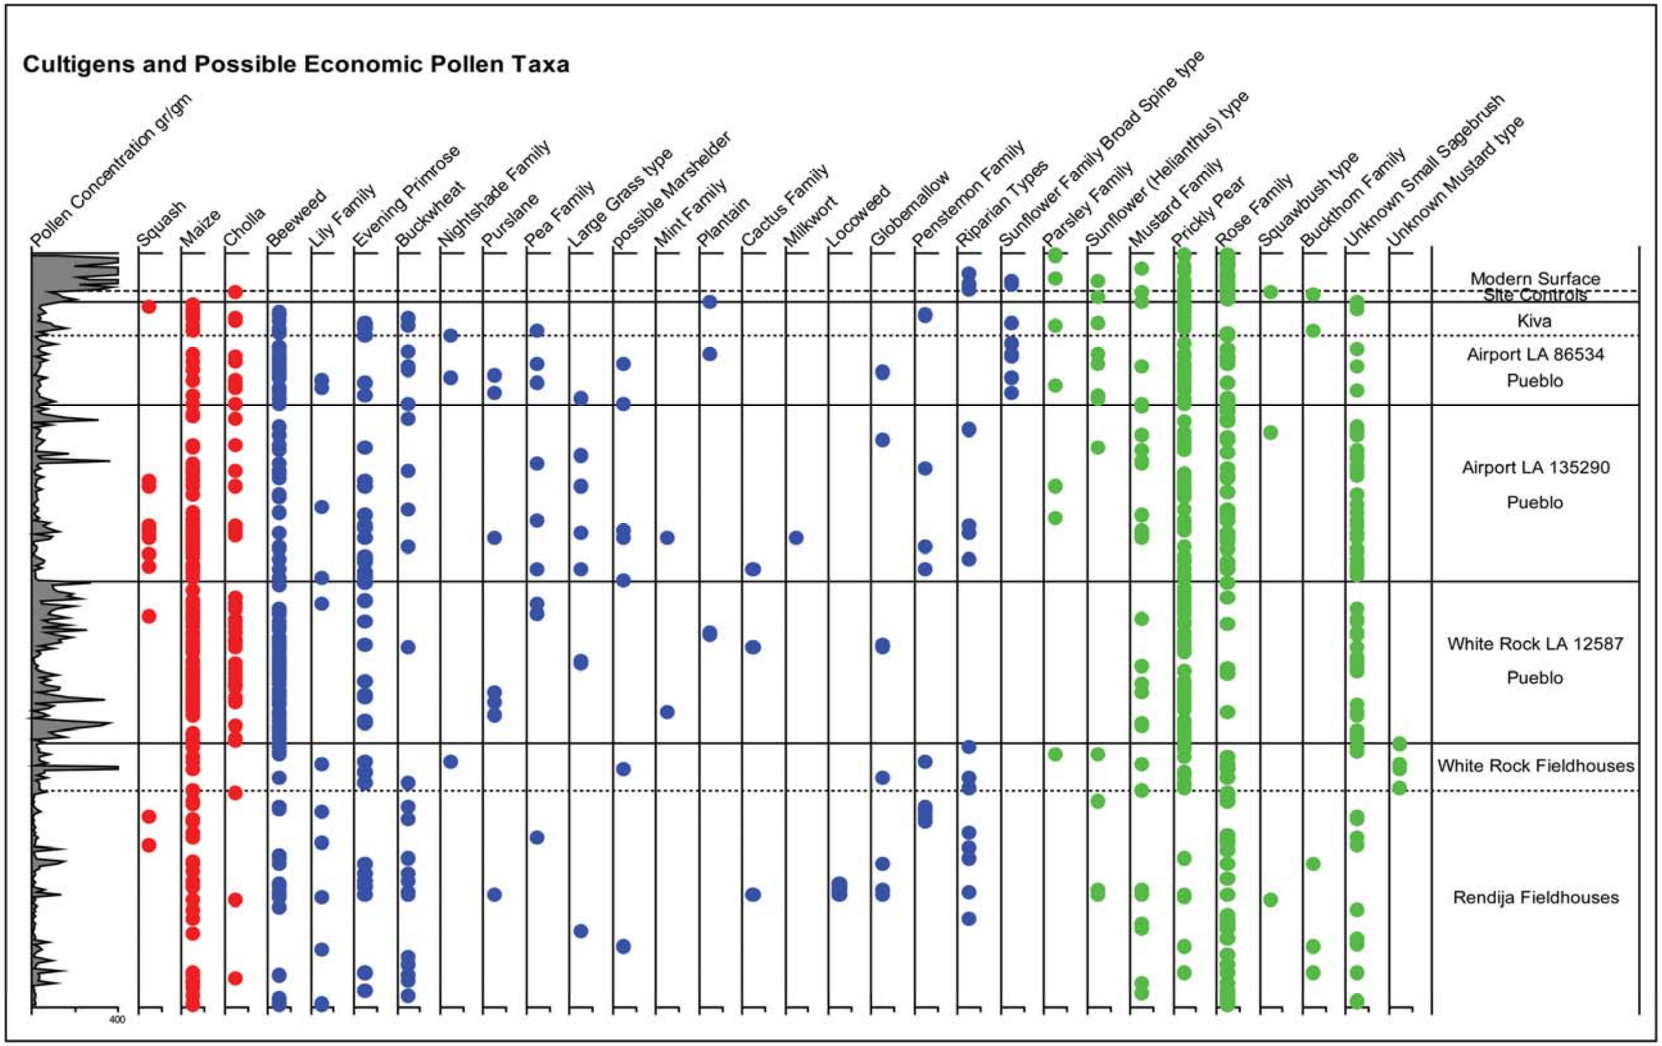

Figure 63.3. Cultigens, rare, and low-count pollen types in modern surface control samples and archaeological features.

Another cacti resource visible in the C&T Project samples is prickly pear, but the evidence for direct use is less definitive than for cholla. Several species of prickly pear are common at Los Alamos (Foxx et al. 1998) and prickly pears readily grow around archaeological sites. The pollen of prickly pear occurs in 167 of the archaeological samples and eight of the 17 modern surface samples. This cactus was undoubtedly accessible and utilized during the pueblo occupation for its sweet fruits and perhaps for its flowers (Bohrer 1986:215) and young pads, which can be boiled or baked (Dunmire and Tierney 1995:190–191). Since cholla is interpreted as a cultivated resource, it is likely that native prickly pear patches were also encouraged, managed, or directly cultivated. The cacti were too valuable a food resource not to exploit, especially since both prickly pear and cholla are easily propagated, require minimal water, and produce reliable crops year after year.

Rose family and mustard family are common pollen types in the archaeological samples that also register in modern surface samples (Figure 63.3). The rose family subsumes several shrubs that were used to make tools and implements, and chokecherry (*Prunus*) fruit, a shrub found in the wetter canyons, was widely utilized for food (Dunmire and Tierney 1995, 1997). The mustard family includes genera that were utilized for pot herbs and also for early spring greens (Moerman 1998).

Some of the other important ethnobotanical resources shown in Table 63.7 and Figure 63.3 are lily family, beeweed, evening primrose, buckwheat, purslane, and possible marshelder. Yucca is a member of the lily family that was valued as a fiber resource for making sandals, and the flowers and fruits were important food resources (Dunmire and Tierney 1995, 1997; Rainey and Adams 2004). Beeweed was used throughout the Southwest for food (greens and seeds) and medicine (Adams et al. 2002), and a superior black dye can be extracted from beeweed that is prized even today by Hopi artists. The whole beeweed plant was boiled down to a black sludge that was formed into cakes, dried, and stored (Moerman 1998). Beeweed is also an annual weed that thrives in disturbed soils and is thus another candidate for some level of cultivation or conservation around habitations. Buckwheat is an important medicinal and ceremonial plant (Moerman 1998). The Zuni used powdered buckwheat flowers for ceremonial body paint (Stevenson 1915) and the Navajo soak the whole redroot buckwheat plant (*Eriogonum racemosum*) to prepare a drink that is used for a variety of internal injuries (Mayes and Bayless Lacy 1989:133). Evening primrose pollen is common in the archaeological samples. The plant has an interesting ethnobotanical history. The roots from several evening primrose species were used for food and medicinal purposes (Moerman 1998), and an excellent fine fiber for weaving and cordage can be extracted from the plant. Marriageable Hopi women wore white flowers of evening primrose in their hair on holidays and Zuni used chewed blossoms in ceremonies (Moerman 1998:361).

The marshelder type pollen is a tentative identification, as there are two other genera with similar pollen morphology (*Ambrosia* and *Dicoria*). Marshelder, which is documented in modern floras of the Jemez Mountains (Foxx et al. 1998), is an indicator of wet ground. It is also well known as an ethnobotanical resource, especially for the seeds, and an eastern relative (*Iva annua*) was widely cultivated in the past (Doolittle 2000; Yarnell 1972).

The Palynology of Gardens on the Pajarito Plateau

Few studies of Southwest agricultural fields or features have been undertaken because farmed areas can be difficult to recognize and they lack ceramics and other material artifacts that would help date the agricultural horizons. Pollen is one of the few tools that can be used to investigate fields, but pollen evidence of agriculture is usually rare, especially from dry-farmed areas. Gardens occur near C&T Project pueblos as grids outlined with rock borders. Grid gardens at five C&T Project sites were sampled for pollen, as well as three rock piles, modern surfaces for controls, and other miscellaneous contexts (Table 63.9).

Table 63.9. Field and control samples.

Site	Number of Garden Grids Sampled	Surface Control Samples (Off Garden)	Subsurface Garden Samples	Number of Subsurface Samples with Maize Pollen (% Sample Frequency)
LA 21596 Otowi South (Smith 2007c) Grid garden	2	0	13 (5 sets of 2 to 3 samples profiling soil pits)	6 (46%)
LA 21592 Otowi North Grid garden	4	1 (plus 1 subsurface control)	9	2 (22%)
LA 139418 Airport Tract Grid garden	3	1 (average of 3 surface samples from 3 Airport Tract sites)	13 (4 sets of 3 samples profiling soil pits plus a single sample)	2 (15%)
LA 128803 White Rock Tract Grid garden	3	1	16	7 (44%)
LA 12587 White Rock Tract Uncompleted roomblock	3 (unfinished rooms)	1 (average of 5 surface samples from 2 White Rock Tract sites and a geology soil test pit)	15 from rooms and 3 surface rock piles	14 (93%)
Totals	15	4	69	31 (45%)

Maize pollen was not documented in the surface samples, but was identified in 31 of the 69 garden samples, which is a 45 percent sample frequency. Cotton pollen was documented in garden samples at two White Rock Tract sites (LA 12587 and LA 128803) and squash pollen was recovered in a single garden sample from a post-occupation Stratum at Otowi South (LA 12596).

The soil type and stratigraphic level of the samples yielding cultigen pollen provides important information that can guide archaeologists to favorable sampling locations in future investigations. Where cultigen pollen occurs can also help refine recognition of field horizons and provide information on post-occupation sediment accumulation rates. The distribution of samples with maize pollen from the garden plots is summarized in Table 63.10. The best context for recovering maize in the C&T Project grid gardens was alongside rock borders or berms, both inside and outside the grids, but not in the center. The most productive depths were in the B soil horizons or below 15 cm, which contrasts with a greater database of New Mexico field pollen studies (see Table 63.11) that shows higher cultigen pollen recovery from shallow and A horizon levels.

Table 63.10. Where maize pollen occurs in field samples.

	Number of Samples	**Number Positive Samples**	**% Frequency Positive Samples**
By Location within Grids or Other Contexts			
In center	16	4	25
Inside of a border or berm	22	11	50
Outside grid garden, but adjacent border or berm	7	4	57
Beneath berm (LA 12587)	4	3	75
Rock piles (3 samples, LA 12587)	3	3	100
Otowi South LA 12596	13	6	46
Other contexts	4	0	-
Totals	**69**	**31**	**45**
By Depth cm			
0–15 cm or A soil horizon, or at Otowi South (LA 12596), Stratum 1	23	7	30
15–47 cm or B soil horizon or at Otowi South (LA 12596) Stratum 2	33	20	61
Other sediment contexts	13	4	31

Comparisons between Garden Sites

The pollen results from Otowi South and North (LA 12596 and LA 12592), LA 139418 (Airport Tract), and LA 128803 (White Rock Tract) are presented graphically in Figure 63.4. The results between samples are generally similar, with cheno-am, sunflower family, and piñon dominant. The surface to subsurface contrasts in pollen concentrations, tree, and cheno-am pollen are the same as above. The key trait is the drop in pollen concentration from surface to subsurface contexts, which reflects the loss of surface pollen due to natural changes in pollen assemblages.

The samples from Otowi North (LA 12592) contrast with the other garden sites with higher percentages of juniper and grass in the subsurface samples compared to the modern surface. The lowest representation of maize pollen was from Otowi North and LA 139418 (only two samples at each site with maize). The low expression of maize from Otowi North is puzzling, as the grids were laid out along the north side of Bayo Canyon at the base of a talus slope, which undoubtedly delivered water from runoff percolating through the talus. Perhaps these grids were used to grow beans, which seldom leave a pollen trace. Beans are members of the legume family (Fabaceae) and tend to be self-pollinating, a syndrome characterized by minimal pollen production that stays within the flower.

The garden at LA 139418 is on top of a mesa, where soils are relatively shallow; the low maize pollen recovery at this site may reflect less productive agricultural soils compared to the other garden sites. Samples from soil pits dug into the grids at LA 139418 represent post-occupation sediment (Stratum 1), cultural fill (Stratum 2), and pre-occupation sediment (Stratum 3). There is a greater representation of prickly pear pollen in the cultural and post-occupation fill samples (Strata 1 and 2), and even more interesting is the occurrence of cattail and walnut (a riparian tree) in two separate soil pits from Stratum 2 levels. There is little pollen evidence of water indicators in any of the C&T Project samples, but this glimpse of riparian pollen may be a record of pot-watering the gardens.

The garden at LA 12587 was superimposed over an unfinished roomblock (Roomblock 3, Area 2, Rooms 19, 20, and 21). The pollen results from these grid gardens are exceptional; the highest frequency of maize pollen among the gardens comes from this site (Table 63.9). Cholla pollen was rare in garden plots, except at LA 12587, where cholla was recovered in 50 percent of the subsurface samples and one surface sample (Figure 63.4). This expression supports the interpretation presented above that cholla was imported and cultivated on the Pajarito Plateau.

Pollen concentration and cheno-am and sage percentages from LA 12587 are high, but grass and piñon frequencies are low, compared to the other garden sites. Prickly pear is another notable type. The rich representation of maize and economic cacti, especially cholla, and the greater abundance of cheno-am pollen resemble pollen assemblages recovered from collapsed pueblo rooms and features. The sediment contained within the garden grids is distinct from the underlying fill of Roomblock 3 and was probably hauled in to create the gardens. The representation of economic pollen types suggests that organic refuse was also brought in to enrich the soil or add mulch for crops. This rich economic pollen signature may reflect either an extremely productive garden or recycled economic pollen from midden or other materials added to the garden plots.

The grid gardens at LA 128803, which are downslope of LA 12587, consist of two U-shaped grids adapted from unfinished rooms to capture runoff from upslope (Drakos and Reneau 2003). The maize recovery at this site is comparable to the garden at LA 12587, but no cholla pollen was recovered and pollen concentrations and cheno-am percentages are lower.

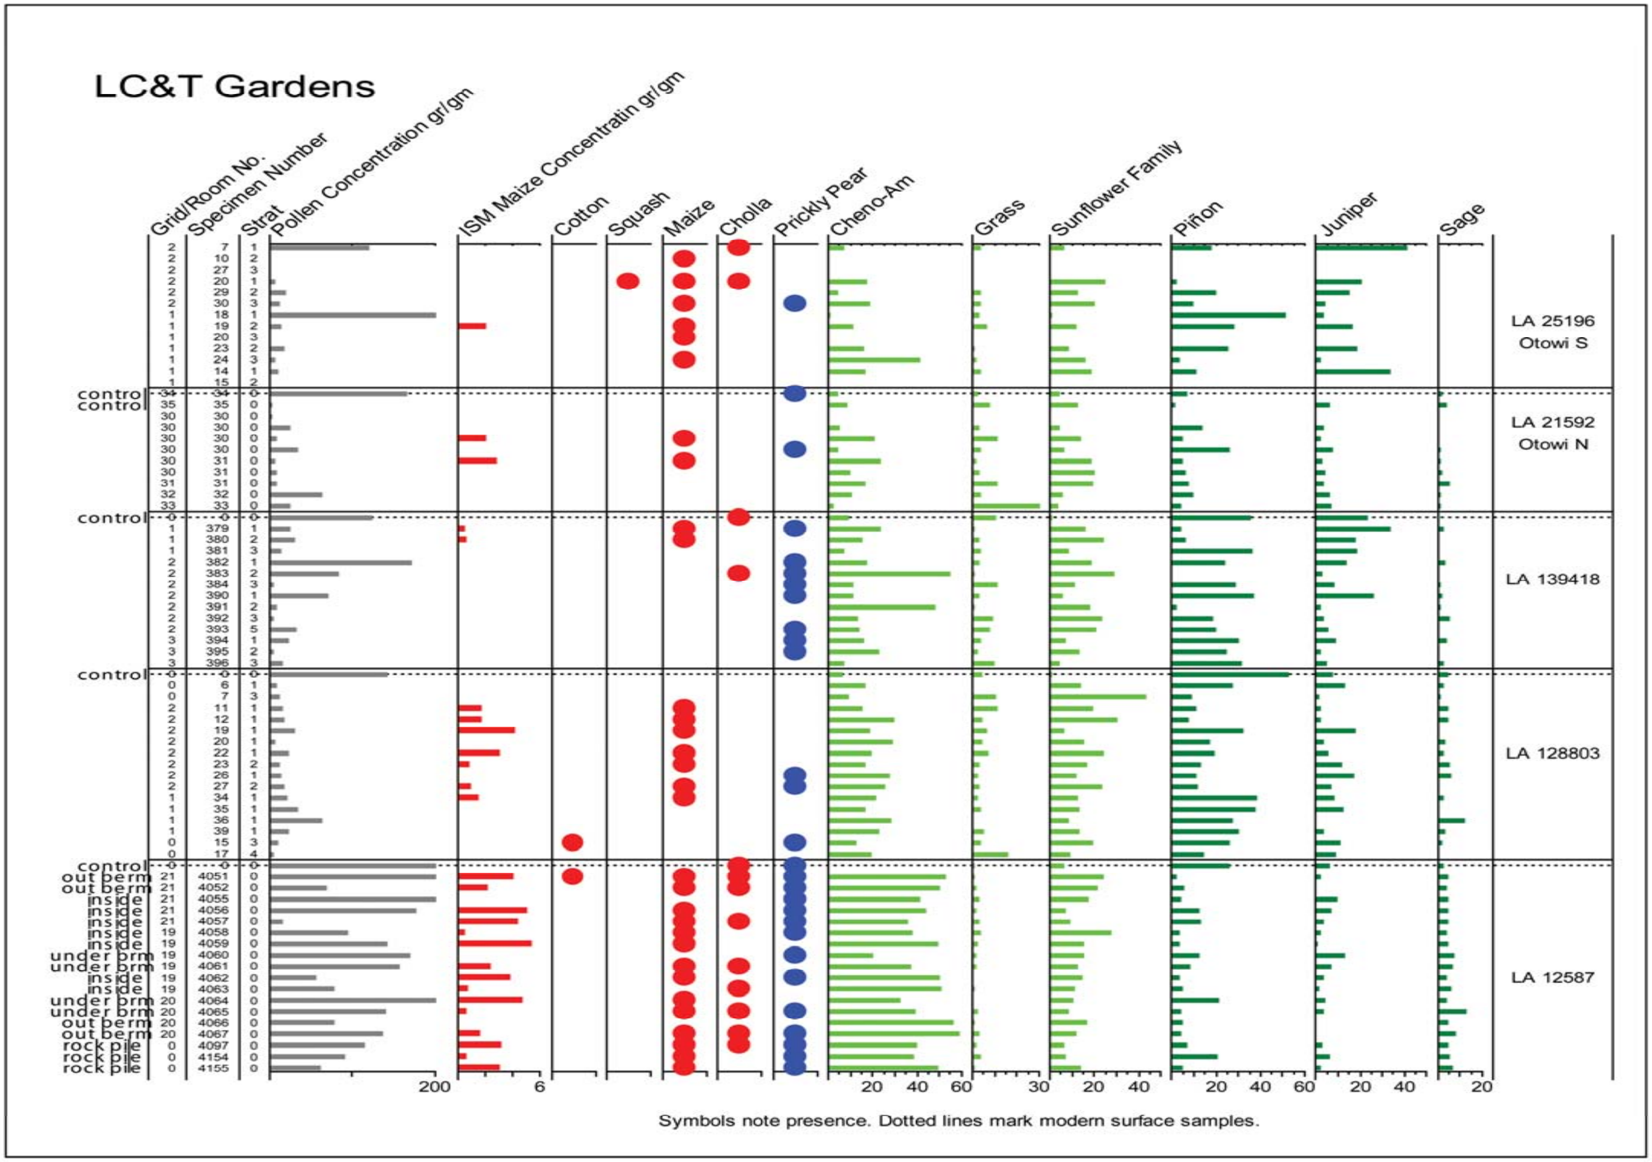

Figure 63.4. Pollen percentages from garden plots at five sites.

ISM Results and Comparison to Other Northern New Mexico Prehistoric Fields

Fifty-six of the garden samples were analyzed with the ISM procedure (see Methods Section). The 13 samples from Otowi South (LA 12596) were analyzed by conventional methods (Smith 2007b). As mentioned, the advantages of using ISM are that the abundance of cultigens can be quantified and compared between sites and regions. The ISM undertaken for the C&T Project gardens involved examining one to three slides per sample, such that each sample was analyzed to a potential cultigen concentration of less than 1.1 gr/g (range 0.25 to 1.12 gr/g). Theoretically any cultigen pollen present in the samples at concentrations of 1.1 gr/g or greater would have been detected by this level of analysis.

The ISM technique resulted in identifying maize pollen in seven garden samples that would have been missed by conventional single-slide microscopy. In the samples that produced maize, the calculated ISM concentration for maize pollen ranges from 0.4 to 5.3 gr/g (Appendix W). The C&T Project garden sites can be ranked according to field productivity by comparing the ISM maize concentrations (Figure 63.4). LA 12587 produced the most maize and other economic taxa, followed by LA 128803, which was just downhill from LA 12587. Otowi South barely ranks higher than Otowi North. Otowi South grid gardens produced a higher sample frequency of maize and cholla pollen, but higher maize concentrations were calculated from Otowi North samples. LA 139418 ranks last.

Field pollen investigations have been completed from 14 New Mexico locations (19 sites), including the C&T Project sites, and there is now a database of 340 pollen samples. The results from these studies are summarized in Table 63.11. At most sites, maize pollen was found between 0 and 20 cm, or relatively shallow, and at sample frequencies ranging from 10 percent to 70 percent (average sample frequency from 19 sites is 38%). C&T Project samples produced maize pollen from deeper soil levels (below approximately 15 cm), but the abundance and sample frequencies of maize are comparable to other New Mexico fields. LA 12587 is the exception, with the maximum maize pollen frequencies and ISM concentrations of all 19 agricultural sites (Table 63.11). This result reinforces the interpretation discussed above that garden samples from LA 12587 are different and may be incorporating trash or recycled sediment from habitation rooms.

[a]Two methods are listed in Table 63.11: the ISM, which was used for most of the studies (see Methods), and the sieve method. The sieve method is a physical technique that concentrates large pollen grains by sieving processed samples through 45 µm mesh screen and analyzing the material captured on the screen (Gish and DeLanois 1993). The assumption is that sieving concentrates pollen grains >50 µm in size, which includes cotton, maize, squash, cacti, and other herbs. Concentrations cannot be calculated using the sieve method because tracers are smaller (ca. 30 µm) than the sieve mesh and are lost.

[b]ISM concentration is calculated from number of cultigen pollen grains and total number of tracer grains encountered during Intensive Scanning Microscopy.

Pre-Columbian Cotton in Northern New Mexico and the C&T Project Cotton Evidence

The ethnographic record of cotton in the Southwest documents use of the seeds for food (Beaglehole 1937:43; L. Huckell 1993:175–176) and the fiber for textiles (Elmore 1943:62; Robbins et al. 1916:102; Teague 1998:25; Webster 2000). Cotton was also important in ceremonies and rituals and was often used as a symbol for clouds and rain (Bohrer 1977; Huckell 1993). Cotton fibers were used on ceremonial cigarettes, prayer sticks, masks, and other ceremonial items, and the Hopi placed cotton over the faces of deceased persons as a symbol of their transformation to clouds (see Huckell 1993:177). The Hopi, Zuni, and some Rio Grande pueblo weavers made ceremonial garments out of cotton (Cushing 1974; Lewton 1912:5; Robbins et al. 1916:103).

The earliest directly dated cotton in the Southwest is from an Early Ceramic structure (Feature 68) at the Eagle Ridge site in the Roosevelt Basin, southern Arizona, where cotton seeds yielded a radiocarbon date of AD 240–390 (one-sigma standard deviation from radiocarbon date of 1725±65 BP; Elson and Lindeman 1994). The oldest indirect ages for cotton also come from southern Arizona. Cotton pollen has been recovered from San Pedro age (ca. 1200–800 BC) sites along the Santa Cruz River (Cummings and Moutoux 2000), cotton seeds were recovered from Snaketown in trash mounds dated to the Sweetwater Phase (AD 100–300; Bohrer 1970), and cotton macro remains have been documented from the Early Pioneer period (AD 480) Dairy site (AZ AA 12:285) north of Tucson (Fish et al. 1992:70). In New Mexico, the evidence of cotton has been sparse, despite the rich archaeological record and first-hand accounts from Spanish missionaries and explorers in the AD 1500s.

The earliest known cotton in New Mexico is from Tularosa Cave, where cotton cord was recovered in the pre-pottery phase (200 BC–AD 1) and the Pine Lawn phase (AD 500; Bohrer 1977). At the time of Spanish contact, active cotton fields were observed in the upper Rio Grande region in the following areas (see V. Jones 1936:51): Santa Domingo, Santa Clara, Jemez Pueblo, the Chama region, Tigeux (Tiwa Sandia and Isleta Pueblos north of Albuquerque), Acoma, and Piro (southern pueblos near Socorro). Webster's (2000:179–181) summary of the early accounts of first Spanish contacts emphasizes the widespread use of cotton clothing, especially the cotton blanket or *manta*, in the northern Rio Grande pueblos. According to Webster, "not all of the Pueblo villages grew cotton, although cotton garments were worn to some extent at all villages. The Hopi, Piro, eastern Keresan, and southern Tiwa specialized in the cultivation of cotton and the production of cotton textiles" (2000:180).

There is a faint archaeological record of cotton in the Los Alamos region. At Jemez Cave, Alexander (1935) recovered cotton string and a woven cotton head band during excavations; no ages were reported for these textiles, but all of the cultural material was recovered from the upper 10 ft of fill (Alexander 1935:99). At Bandelier National Monument, in Frijoles Canyon, there are groups of cavates (Group I and M, approximately AD 1400s) with evidence of loomholes, presumed to be associated with weaving cotton (H. Toll 1995:214–216). At Burnt Mesa Pueblo (LA 60372), early Classic Room 10 (Area 1) contained loomholes (Kohler and Root 2004:185), and Steen (1977:23) reported a pottery vessel containing cleaned cotton at a Coalition period site on the Pajarito Plateau. In White Rock Canyon, a cache of cleaned cotton bolls was recovered from a small cavate (Harlow 1965); the cotton was stored in a Sankawi black-on-cream bowl (AD 1530 to 1550) that Huckell (1993:191) suggests was a ceremonial offering. An additional 15 vessels and a basket were also discovered in other cavates near the cotton cache, and a remarkably well-preserved cotton garment folded into a bowl was found in a White Rock Canyon cavate. Photographs of the White Rock Canyon caches are shown in Figure 63.5.

Photograph from LANL Historical Society. Garment found in cavate near White Rock Canyon. Dated c. AD 1400-1500 (per Laboratory of Anthropology). Privately owned. Found by children exploring west side of the river near the lookout one mile from Bandelier National Monument. A caption on one of the photographs explains that the shirt had been washed in a washing machine.

Photograph from The Atom 1965. Pots and cotton found in a cavate in White Rock Canyon.

Figure 63.5. White Rock Canyon cotton caches.

No macro remains of cotton were recovered from any of the C&T Project sites, but surprisingly, cotton pollen was documented from 11 samples from four sites (Table 63.12). Seven of the 11 pollen samples with cotton were from LA 4618 (Smith 2006a), primarily from contexts inside kivas, which suggests a correlation to historical examples of weaving centered inside kivas. Webster states,

> Early Spanish accounts describe men as the primary textile producers in Pueblo society at the time of contact and characterize weaving as a communal male activity in extramural ceremonial structures, called estufas or kivas, during the winter or agricultural off-season (2000:181).

Table 63.12. Cotton pollen from Pajarito Plateau sites.

		Kiva Room 11 sample 716, hearth deflector
		Room 16 sample 376, rooffall

Cotton plants have an interesting pollination ecology that limits the dispersal of their pollen. Cotton flowers successively, spiraling up from lower to top branches over the course of about two months (McGregor 1976:172). One flower produces approximately 45,000 self-fertile pollen grains that are large (81 to 143 µm diameter) and coated with a sticky exudate (McGregor 1976:172). Each mature flower is receptive to pollination for only one day, opening in the morning, closing in the evening, and dropping to the ground soon after, apparently retaining most of the pollen produced within the withered flower (Hasbargen 1997:39). Cotton fibers are modified hairs that develop around the seeds inside a receptacle called a boll. When bolls are harvested, the flowers remain in the field, and it seems improbable that any cotton pollen could persist on the fruits; however, there are no experimental data to test this inference. The representation of cotton pollen in the two kivas at LA 4618 (Smith 2006a) raises the possibility that cotton *flowers* were being used ceremonially in kivas.

The cotton evidence from the Pajarito Plateau (Table 63.12) suggests that cotton was grown in the White Rock and Airport Tracts (LA 12587, LA 128803, and LA 135290) and possibly at LA 4618. Although the site elevations are all above 1970 m (6500 ft), a short growing season should not have precluded cotton agriculture. The cotton variety grown was probably the Hopi short-stapled variety (*Gossypium hirsutum* var. *hirsutum* [formerly var. *punctatum*]), which can produce a crop in less than 100 days if conditions are favorable (Wright 2000:26, 27). There is a growing body of evidence for cotton farming near Flagstaff, Arizona, at elevations above 1500 m (5000 ft; Biddiscombe 2003; Hunter 2005) from at least the AD 1100s and perhaps as early as AD 900. Cotton does require more water than maize, but apparently cotton was dry-farmed in sandy soils on the Hopi Mesas (Lewton 1912:6) and along the Rio Grande valley (see Doolittle 2000:223).

The ethnographic record and cumulative pollen evidence supports a conclusion that cotton was grown on the Pajarito Plateau. The representation, however, is low, compared to floodplain fields along the upper Rio Grande. Cotton pollen was recovered in 45 percent of the samples from a field at San Ildefonso on the first terrace above the Rio Grande floodplain and in 47 percent of samples from a field system along the Chama River (see Table 63.11).

The amount of land required to grow enough cotton for weaving a manta (blanket) is dependent on the agricultural potential of the site. Huckell (1993:172–174) discusses a model that predicts a one-acre irrigated cotton field in the prime cotton belt of southern Arizona could produce enough cotton for approximately 47 blankets; in contrast, a one-acre field on the Hopi Mesas might produce enough cotton for 3 blankets. Cotton agriculture on the dry mesa tops of the Pajarito Plateau was probably not adequate to produce enough cotton for any significant number of mantas. Weaving was likely supported by trade and import of cotton from the nearby fertile Rio Grande floodplain or irrigated fields along canyon streams, such as in Frijoles Canyon in Bandelier National Monument.

White Rock Tract

There are pollen data from six sites in the White Rock Tract: one pueblo (LA 12587), one grid garden (LA 128803), one lithic and ceramic scatter (LA 86637), two fieldhouse sites (LA 127631 and LA 128805), and a historic check dam (LA 128804). Results from the grid garden at LA 128803 are summarized in the previous Palynology of Gardens section and the results from the other sites are presented below.

LA 12587 (Late Coalition Period Pueblo and Early Classic Period Fieldhouse)

Two roomblocks were excavated at this site. Roomblock 1 was a Late Coalition pueblo with three front (Rooms 2, 4/5, 7) and back (Room 1, 6, 8) rooms and an add-on (Room 9) at the south end. A single Early Classic fieldhouse (Room 3) was built on top and about in the middle of Roomblock 1 (over portions of Rooms 7, 8, and 4/5). Roomblock 3 was Late Coalition or Early Classic and contained 13 contiguous rooms, but this pueblo was never completed. Grid gardens were superimposed on top of the Roomblock 3 fill over Rooms 19, 20, and 21. Fifteen pollen samples were collected from these gardens and the results discussed in the previous section (see Palynology of Gardens on the Pajarito Plateau).

The pollen samples were sorted by contexts (fill, floor, and features) for both roomblocks (excluding the add-on Room 9 and the Classic fieldhouse Room 3) and summary sample frequencies were calculated for the major economic taxa (Table 63.13). Average pollen concentrations by context group for maize, beeweed, and the dominant weedy and tree taxa were also generated (Table 63.14). In both tables, contextual groups are organized in the vertical order of excavation with fill at the top of the table and floor and feature sample groups at the bottom.

The sample frequencies listed in Table 63.13 show that economic pollen types are present in the modern control samples with the exception of maize. The evidence for cultural pollen taxa in surface soils indicates mixing with subsurface cultural fill sediments, which is not surprising given the amount of disturbance evident from past construction and farming.

In Roomblock 1, economic pollen taxa frequencies generally increase with depth below surface fill down to floor surfaces. Maize pollen frequencies are greatest in front room hearths and the fill just above floors, but cholla and prickly pear are higher in back room floor samples. The frequency distribution of rose and evening primrose is highest in surface fill and modern control samples, which indicates that these two types may not be cultural. This result contrasts with the other pueblo sites presented below. A striking result in the frequency table is the near absence of other economic types (Table 63.13), such as lily family and purslane. Purslane occurs in three hearth samples and lily family in one wallfall sample from a back room.

In Roomblock 3, maize frequencies are highest in the wallfall and lower fill samples, which suggests that the sediment filling the uncompleted roomblock is mixed and possibly contains midden and refuse materials.

Table 63.13. LA 12587 sample frequencies of economic taxa as a percent of samples by context.

	Number of Samples	Maize	Cholla	Prickly Pear	Rose Family	Other Types (occur in 1 to 3 samples per context group)
Modern control samples	2	0	50	50	50	Evening primrose
Surface fill samples	2	0	0	0	50	Evening primrose
Roomblock 1 (excludes Room 9 addition and Room 3 fieldhouse)						
Wallfall, front rooms	7	57	0	57	0	Plantain, evening primrose

	Number of Samples	Maize	Cholla	Prickly Pear	Rose Family	Other Types (occur in 1 to 3 samples per context group)
Wallfall, back rooms	4	50	50	75	25	Lily family
Fill above floor	3	100	67	33	0	Evening primrose
Floors, front rooms	19	79	42	37	11	Cactus family, large grass, plantain, evening primrose
Floors, back rooms	4	50	50	75	25	Buckwheat
Hearths (front rooms)	10	100	30	70	10	Mint family, purslane, evening primrose
Postholes	7	29	14	71	0	Evening primrose
Roomblock 3						
Surface fill samples	2	0	50	50	0	
Wallfall	7	71	43	57	0	
Lower fill	4	75	0	50	0	
Use surface	5	60	40	40	0	Buckwheat, evening primrose

Average pollen concentrations by contexts (Table 63.14) track slightly different patterns in the distribution of maize, compared to the sample frequencies. However, it is important to recognize that in Roomblock 1 front rooms were more intensively sampled than back rooms (19 front room floor samples versus four back room floor samples). Maize is most abundant in Roomblock 1 in the back room wallfall samples, the fill above floors, and front room floors.

Beeweed is also high in front room floors and back room wallfall, but is highest in hearths, which are all in front rooms. Among the dominant taxa, grass, sagebrush, piñon, juniper, and pine exhibit the same trend for decreasing pollen concentration with depth in the sediment fill down to floors with a rebound in values in the primary cultural contexts, especially hearths and postholes. Cheno-am shows an inverse relationship to stratigraphy with lower values in the surface and upper fill and higher concentrations from wallfall down to floors and in features. However, front room floors are an exception, with low average cheno-am concentrations comparable to the modern control sample. The highest average cheno-am is from postholes. There is no trend in the distribution of sunflower family. Sunflower family consistently registers between 1000 and 2000 gr/g regardless of context, except for a maximum average value in postholes. The same trends in pollen abundance of the dominant types in Roomblock 1 generally hold for Roomblock 3. The one exception is sagebrush, which is higher in contexts below the surface fill.

Table 63.14. Average pollen concentrations by context from LA 12587 (concentrations shown in gr/g and rounded to nearest 10).

	Number of Samples	Maize	Beeweed	Cheno-Am	Sunflower Family	Grass Family	Sagebrush	Piñon	Juniper	Pine	Total Pollen Conc.

Roomblock 1

Roomblock 1 was sampled intensively and a series of samples was also taken from specific contexts to test for fine-grained changes. For example, a column of samples was collected to profile wallfall sediments in Room 4/5 and in Room 2; three remodeled floors were sampled. Pollen concentration data for dominant taxa and the presence of significant economic taxa are shown in Figure 63.6 for the majority of Roomblock 1 samples; sterile samples and special contexts, such as pollen washes, are excluded from Figure 63.6. There are several trends in the graphs that mirror the patterns described from the data in Tables 63.13 and 63.14.

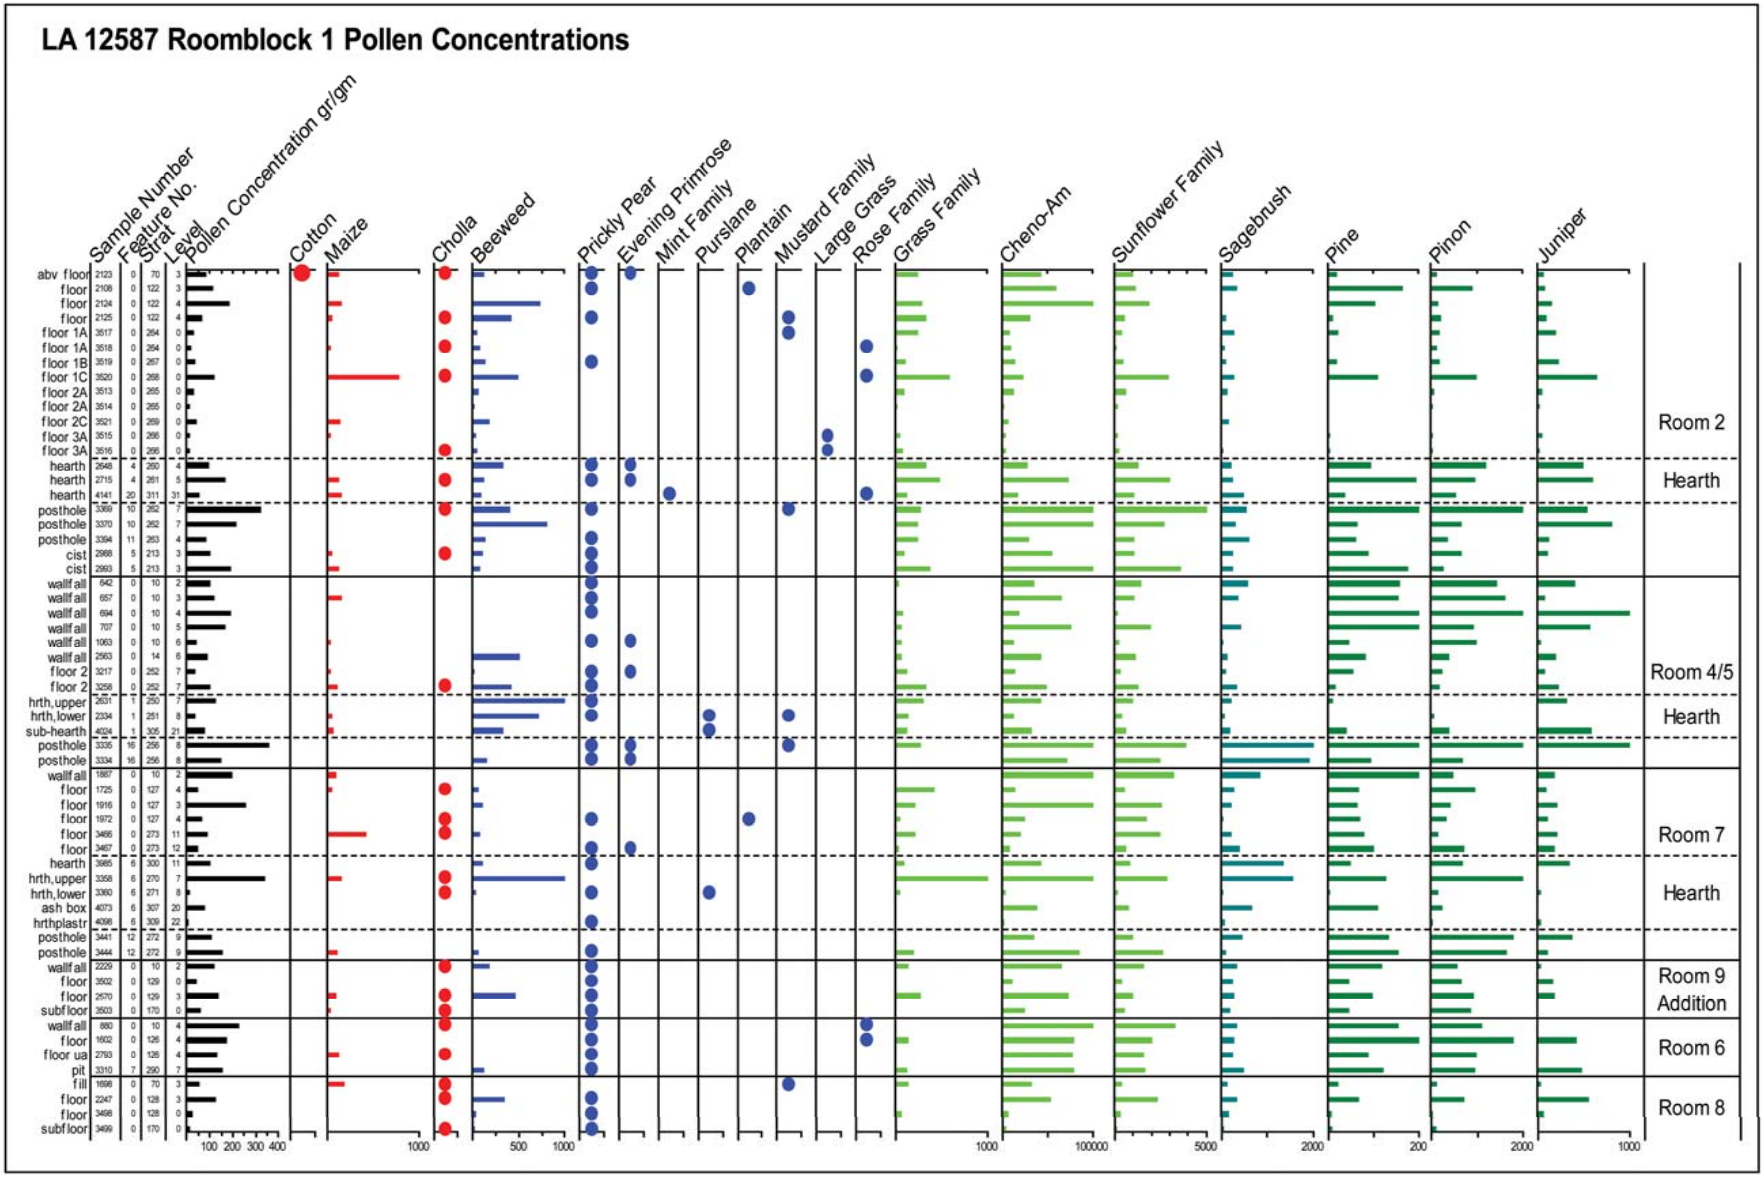

Figure 63.6. LA 12587 Roomblock 1 pollen concentration data.

One of the clear patterns shown in Figure 63.6 is that hearths and postholes produced pollen assemblages distinct from other room contexts, especially compared to floors. Room 2 is the best example of this. Three hearth and three posthole samples in Room 2 are characterized by higher pollen concentrations for all of the dominant taxa compared to floors.

Nine of the 12 floor samples analyzed from Room 2 were collected to profile three remodeled floors. There is a clear trend in the floor series of reduced pollen concentrations and economic taxa in the early floors (Floors 2 and 3). This result probably reflects better preservation in the younger Floor 1, but it is possible there is a real difference in the abundance of plant resources manipulated. If the pollen gradient is attributable to fewer plant resources, the signal might reflect shorter seasonal occupations during use of Floors 2 and 3 and a longer occupation during use of Floor 1.

Another series consists of the three hearth samples in Room 4/5, taken from the upper and lower fill of hearth Feature 1 and the sediment below the hearth. Total sample pollen concentrations in these three samples remain relatively equal, but beeweed concentrations decline sharply from upper hearth fill to sub-hearth sediment (Figure 63.6). The beeweed concentration (5467 gr/g) in the upper fill sample is the highest of all 478 C&T Project samples. The second highest project beeweed pollen concentration (1890 gr/g) comes from a hearth sample in Room 7. Data from other C&T Project sites suggest a correlation between hearth contexts and beeweed pollen abundance. Beeweed is a versatile ethnobotanical resource (Adams et al. 2002) that was widely used for food and as a dye or paint. The beeweed association with hearths suggests cooking activities, and at LA 12587 the abundance of beeweed suggests a possible specialty.

A series of six samples taken to profile wallfall in Room 4/5 show a drop in pollen concentration in the two lowest samples (level 6) and reduced values of all the dominant taxa. This trend likely reflects decreasing preservation with depth or possibly greater sediment influx in the lower samples whereby pollen is diluted. No cholla was identified in any of the wallfall samples and grass pollen concentrations are low in the wallfall compared to most other front room floor and feature samples from Roomblock 1. The lack of cholla and the decreased grass in wallfall reinforce the interpretation that these taxa are important subsistence plants. In contrast, prickly pear pollen is common in wallfall and is generally ubiquitous in site samples. Prickly pear is interpreted as both an economic resource and part of the natural pollen rain.

If all of the rooms in Roomblock 1 are considered, there is a greater representation of economic pollen types in Room 2 than other rooms, but the differences are not great. Cholla pollen is conspicuously absent from Room 4/5. Beeweed is highest in Room 2 and the hearth in Room 4/5, but low in Room 7 (except for one hearth sample). There are only two back rooms represented by a few samples from LA 12587, but the highest frequencies of prickly pear pollen are in back rooms (Figure 63.6; Table 63.13).

Burials and Miscellaneous Contexts

LA 12587 is the only site where pollen samples from human burials were analyzed. Three burials were excavated from the midden and sediment pollen samples were collected from various skeletal locations. The pollen concentrations for select taxa from the burials are compared to the average midden pollen concentrations to test whether any taxa are enhanced (Table 63.15). Grass and cholla both appear enriched in the burials. The grass pollen representation could reflect grass mats or some other grass textile. The cholla pollen might reflect offerings of flowers. Cheno-am and sunflower family pollen are more abundant in three of the burial samples than the average for the midden, and some use of these taxa may have occurred. The sunflower family encompasses several genera with showy flowers that could have been placed with the burials.

Maize pollen as single grains is not any higher in burials than middens, but aggregates of maize are higher. Maize aggregates occur in four of the five burial samples, which is the highest sample frequency by context from this site (Table 63.16). The high representation of aggregates suggests that ceremonial offering of maize pollen was part of a funerary practice.

Table 63.15. Pollen concentrations (rounded to nearest 10 gr/g) from burial samples compared to average concentrations from four midden samples at LA 12587.

	Burial 2, in Skull	Burial 2, Under Skull	Burial	Burial 3, Under Palate	Burial 3, Under Left Scapula	Midden Samples (n = 4) Average Conc.

Midden	4	1	25
Wallfall	4	1	25
Hearth	10	2	20
Front floors	19	3	16

Other samples analyzed from special contexts at LA 12587 include three pollen washes of artifacts from floor surfaces in Rooms 7 and 12, the plug from a clay pipe (Field Specimen [FS] 1998) recovered in Room 2 wallfall, a sample from an extramural grinding slick, three samples from a pile of dacite cobbles in Room 1 that may have functioned as a warming bin, and a sample of the wall mortar in Room 3. All of these samples were characterized by degraded assemblages and little evidence of economic types. Maize pollen occurs in one of the cobble pile samples from Room 1 (FS 1486) and prickly pear pollen was identified in the grinding slick sample. One of the pollen washes (Room 7, FS 3159) and the pipe sample (FS 1998) were sterile. The sample from wall mortar (FS 3003) and the grinding slick (FS 1258) were characterized by high pollen concentrations of 43,750 and 10,140 gr/g respectively, driven primarily by cheno-am and sunflower family. Sagebrush pollen was notable in the wall mortar sample. The combination of high concentration taxa in the wall mortar, cheno-am, sunflower family, and sagebrush could reflect a late summer seasonal signal for mixing of the mortar, as all three pollen categories encompass plants that typically flower after summer monsoons have started.

Room 3, a Classic period fieldhouse that was constructed over portions of Rooms 7, 8, and 4/5 in Roomblock 1, is represented by only three wallfall samples. The average pollen concentration from the wallfall samples is 11,570 gr/g, which is comparable to wallfall samples in the roomblock. The only economic taxa recorded are maize in one sample and prickly pear in two samples.

Summary

The main economic types identified from this site are maize, beeweed, cholla, and prickly pear. Squash pollen was recovered in the fill sample just above the floor of Room 4/5 and cotton pollen was documented in the fill sample just above the floor in Room 2. Cotton pollen was also identified in one garden sample from this site, and the results suggest that cotton was cultivated at LA 12587. Other interpreted potential economic pollen types include lily family, cactus family, the large grass type, mint family, and purslane. No riparian pollen types were identified from LA 12587, which is unusual given the level of construction and activity at the site.

High representation of grass, cholla, and aggregates of maize pollen in burial samples are interpreted to relate to funerary practices. The highest representation of economic taxa in the roomblocks is from Roomblock 1, Room 2. Some specialty product may have been prepared from beeweed in the hearth in Room 4/5.

White Rock Tract Sites (LA 86637, LA 127631, LA 128805, and LA 128804)

Three samples were analyzed from the multi-component lithic scatter at LA 86637. Only two economic pollen types were identified: purslane in FS 274 and prickly pear in FS 275, but there is a spike of an unknown sunflower family type that was identified only at this site and only in one sample (FS 276). The unknown LA 86637 sunflower family may be a glimpse of some use of a sunflower family taxon. The historic check dam samples at LA 128804 were more interesting. Two pairs of samples (one upslope and one downslope) were taken from the check dam. No maize or other cultigens were recovered from the samples, but cattail pollen was recovered in a downslope sample (FS 220), which suggests a nearby water source or ponded water at the check dam. There were no patterns in the concentrations of the dominant pollen types between upslope and downslope locations, but pollen concentration overall was low in the check dam samples, at less than 1500 gr/g.

Two fieldhouse sites were excavated in the White Rock Tract. Five pollen samples were analyzed from LA 127631, an Early Classic period fieldhouse, and eight samples were analyzed from LA 128805, a Middle Classic period site. Summary numbers by context for sample frequency and average pollen concentrations are listed in Table 63.17. There are some interesting contrasts between the two sites that may relate to both environment and occupation history.

Table 63.17. Comparison of results between fieldhouses at LA 127631 and LA 128805.

	LA 127631 Early Classic			**LA 128805 Middle Classic**		
	Surface	**Post-Occup. Fill**	**Floor**	**Post-Occup. Fill**	**Wallfall**	**Floor**
Number of samples	1	2	2	6	1	1
Sample Frequency						
Maize	0	50	50	0	0	100
Prickly pear	0	0	50	67	0	0
Beeweed	0	0	50	17	0	0
Other types	Rose family	Lily family, nightshade family, rose family	Sunflower (*Helianthus*), parsley family, rose family	Rose family	Cat-tail	Rose family
Average Pollen Concentration						
Sample pollen concentration	66820	4120	5540	3920	3600	5550

	LA 127631 Early Classic			LA 128805 Middle Classic		
	Surface	**Post-Occup. Fill**	**Floor**	**Post-Occup. Fill**	**Wallfall**	**Floor**
Grass	1750	220	430	80	110	230
Sagebrush	2920	210	30	120	220	150
Cheno-Am	5840	870	1120	830	340	1320
Sunflower family	2920	280	650	690	280	1160
Pine	8170	100	150	270	250	270
Piñon	28590	670	1060	820	1410	700
Juniper	12250	200	780	370	170	460

Maize occurs in the floor samples at both fieldhouses, but in terms of overall economic pollen diversity, LA 127631 is the richer site. The floor sample at LA 127631 produced maize, prickly pear, beeweed, sunflower type (*Helianthus*), parsley, and rose pollen. Maize and rose family are the only two economic taxa recovered from the single floor sample at LA 128805. The cattail pollen in the wallfall sample from LA 128805 is probably related to using water to mix mud for wall mortar and adobe. Rose family pollen is common at both sites from all contexts. Some member of the rose family was probably common in the native vegetation when both sites were occupied.

Both fieldhouses are characterized by comparable average pollen concentrations between dominant taxa, but there are small differences. Grass and piñon are higher at LA 127631 and cheno-am and sunflower family are higher at LA 128805. These contrasts suggest that there may have been more disturbed ground at LA 128805, which could result if a larger field area was being farmed nearby.

Airport Tract

Pollen samples were analyzed from four Airport Tract sites: two pueblos (LA 86534 and LA 135290), one fieldhouse (LA 141505), and one grid garden (LA 139418). Results from the grid garden at LA 139418 are summarized in the previous Palynology of Gardens section and the results from the other three sites are presented below.

LA 86534 (Middle Coalition Period Roomblock and Kiva)

LA 86534 is a Middle Coalition period roomblock with eight rooms and a kiva on the northeast side of the roomblock. Rooms 1, 2, 5, and 7 are front rooms and all four had hearths; Rooms 3, 4, 6, and 8 are back rooms. Forty-seven pollen samples were collected and analyzed: 15 samples from the kiva and 32 from the roomblock. There is also one modern surface control sample collected from this site as part of the modern pollen analog study (Smith 2007a). Summary data from samples grouped by contexts are presented in Tables 63.18 and 63.19.

There are differences in the distribution of economic taxa between roomblock contexts and between the kiva and rooms. In terms of sample frequencies (Table 63.18), maize pollen is most frequent in kiva wallfall and rooffall samples. Front room hearth samples rated higher than kiva hearths for cholla and prickly pear, but maize was more frequent in kiva hearth samples. The same pattern is generally true for room floors compared to kiva floor samples. Wild, native plant resources are clearly higher in room contexts. For example, lily family was recovered only from front room samples and rose family pollen is more frequent in room contexts, especially back rooms, where it occurs in 50 percent of the samples. Evening primrose is notable in kiva floor samples.

Table 63.18. LA 86534 sample frequencies of economic taxa as a percent of samples by context.

	Number of Samples	Squash	Maize	Cholla	Prickly Pear	Other Types (occur in 1 to 3 samples per context group)
LA 86534 modern pollen Station 13	1	0	0	0	100	
Kiva						
Post-occupation fill	3	33	33	0	67	Squash, mustard family
Wallfall	2	0	100	0	50	
Rooffall	2	0	100	50	50	
Floors	4	0	25	25	75	Sunflower (*Helianthus*), parsley family, evening primrose (3 samples), broad spine sunflower type
Ash pit	2	0	50	0	0	Rose family, pea family
Rooms						
Post-occupation fill	3	0	0	0	0	Nightshade, rose family, evening primrose
Wallfall	3	0	33	0	33	Sunflower (*Helianthus*), rose family, broad spine sunflower type
Rooffall	2	0	0	0	50	Broad spine sunflower type
Floors, front rooms	8	0	13	50	88	Lily, parsley and rose families, nightshade, evening primrose, pea family, broad spine sunflower type, marshelder

	Number of Samples	Squash	Maize	Cholla	Prickly Pear	Other Types (occur in 1 to 3 samples per context group)
Floors, back rooms	6	0	33	17	67	Rose family, purslane, mustard family
Hearths, front rooms only	5	0	40	20	60	Sunflower (*Helianthus*), rose family, purslane, evening primrose, broad spine sunflower type, marshelder

In terms of pollen abundance, kiva contexts rate higher than rooms, especially for maize and beeweed (Table 63.19). In the roomblock, only back room floors registered maize pollen in standard counts, producing a low average concentration of 10 gr/g. In the kiva, maize densities of less than 40 gr/g were calculated from all contexts with the highest values in wallfall and rooffall samples. Beeweed is most abundant in the kiva, especially the hearth samples. Average beeweed concentrations range from 530 gr/g in the two kiva hearth samples to hundreds in all other kiva contexts, except post-occupation fill samples, which had zero beeweed. In rooms, the average beeweed concentrations range from 120 gr/g from hearths and back room floors to less than 50 gr/g in all other context groups. And, like the kiva, no beeweed pollen was recovered from the post-occupation fill.

The highest average concentrations for the dominant sunflower family, sagebrush, piñon, juniper, and pine are all from kiva floor samples. The only room category that exceeds kiva contexts is rooffall, with two samples recording the maximum average cheno-am and grass pollen concentration. It is interesting that in room samples, the highest average concentrations for the weedy taxa are in the rooffall samples, and for the conifers (piñon, juniper, and pine), the high values are in different contexts. In the kiva, the highest average concentrations for all taxa are in floor samples, except for grass, which is highest in rooffall. Another characteristic visible in the average concentrations is a greater abundance of juniper pollen in rooms compared to kivas, with the highest juniper average from room hearths.

Table 63.19. Average pollen concentrations by context from LA 86534 (concentrations shown in gr/g and rounded to nearest 10).

Summary

The main economic taxa identified from LA 86534 are maize, cholla, prickly pear, and beeweed, along with squash, sunflower (*Helianthus*), lily family, purslane, and possibly rose family. There was only one occurrence of squash pollen in a post-occupation kiva fill sample. Taxa occurring in one to three samples that may also reflect ethnobotanical use include nightshade family, evening primrose, pea family, parsley family, plantain, mustard family, marshelder type, and broad spine sunflower family type. No riparian pollen types were identified from LA 86534.

The pollen results show that the absolute abundance of pollen is greatest in kiva contexts and that maize, beeweed, cholla, and prickly pear—the main economic taxa—are concentrated in the kiva. Rooms are characterized by a greater diversity of wild native resources, such as rose, lily, nightshade, purslane, and pea family. Although maize is relatively common in samples from LA 86534, it is not abundant, and it is least abundant in rooms. Beeweed, however, is abundant, with the highest concentrations in kiva samples.

LA 135290 (Middle Coalition Period Roomblock)

This site is a seven-room pueblo with two attached plaza rooms (Rooms 8 and 9). Rooms 1, 2, and 3 are front rooms; Rooms 4, 5, 6, and 7 are back rooms. Seventy-seven pollen samples were analyzed, collected primarily from room fill sequences, floors, hearths, and postholes. The pollen results from Room 2, the room with the largest floor area (14.7 m^2), are unique compared to all other C&T Project rooms, and it is possible that Room 2 was a communal or ceremonial space. Back rooms at LA 135290 (Rooms 4, 5, 6, and 7) were characterized by multiple floors, indicating remodeling and perhaps a long occupation. Two samples from extramural rock alignment Feature 18, one midden sample, and a sample from an extramural rock cluster near Room 9 were also analyzed, but these samples produced little evidence of ethnobotanical resources and are not included in this summary. Maize and lily family pollen were identified in the midden sample. The six geology soil pit samples were summarized in the previous Summary of Pajarito Plateau Pollen Analog Studies section. The A horizon soil sample from the geology study is used here as a modern surface control for LA 135290.

Squash pollen is the big story at this site. Although it was identified in only 15 of 478 project samples, 11 of these samples are from LA 135290—eight from Room 2, two from Room 6, the back storage room behind Room 2, and one from Room 7. Room 2 also produced more maize and cholla than any other room at the site, as well as the only cotton pollen (from an adobe-lined pit in Room 2).

There are few occurrences of water indicators for the project, but four LA 135290 samples produced riparian types: a floor from Room 7 produced sedge, willow, and cottonwood type pollen, a wallfall sample from Room 7 contained sedge pollen, and a Room 2 floor and Room 6 posthole yielded cottonwood type. Room 7 is an interesting room not only for the high expression of riparian types, but also because a single Room 7 floor sample from beneath a floor artifact produced the highest maize concentration (5741 gr/g) from the project.

The sample frequencies by context groups for the main economic taxa are listed in Table 63.20. Although maize, cholla, and prickly pear were recovered from post-occupation fill and wallfall, frequencies are highest from the six hearth samples in Room 2 and front room floors. The Room 2 hearth samples also produced the only site record of purslane and mint family, and the only *project* record of a pollen grain identified as milkwort (*Polygala* sp.). Several species of milkwort were used medicinally, especially different preparations of the roots (Moerman 1998). There is one species of milkwort (*Polygala alba*) listed in the modern flora of the Jemez Mountains (Foxx et al. 1998). Plantain is another uncommon type identified in an adobe-lined pit sample (Feature 4) in Room 2, which also is the same sample yielding the only cotton pollen recovered from LA 135290.

Table 63.20. LA 135290 sample frequencies of economic taxa as a percent of samples by context.

	No. of Samples	Squash	Maize	Cholla	Prickly Pear	Rose Family	Other Types (Occur in 1 to 3 samples per context group)
LA 135290 FS 2275 (geology soil pit A horizon)	1	0	0	0	0	0	
Post-occupation fill	6	0	33	17	0	67	Buckwheat, mustard family,
Wallfall, front rooms	6	0	17	17	33	17	Large grass, mustard family,
Wallfall, back rooms	7	0	29	0	43	14	Sunflower, pea, and mustard families, evening primrose
Wallfall, plaza rooms	4	0	0	0	50	50	Mustard family
Floors, front rooms	5	60	60	40	100	20	Evening primrose

	No. of Samples	Squash	Maize	Cholla	Prickly Pear	Rose Family	Other Types (Occur in 1 to 3 samples per context group)
Floors, back rooms	17	12	59	18	53	41	Parsley, pea, and mustard families, large grass, marshelder, buckwheat, evening primrose
Floors, plaza rooms	5	0	20	0	20	20	Parsley, lily, and mustard families, evening primrose
Posthole, back rooms	8	13	63	0	63	38	Lily, cactus, and pea families, large grass, evening primrose
Hearths, front room 2	6	50	100	17	17	33	Purslane, mint family, polygala, marshelder, buckwheat, mustard, evening primrose
Pits	3	33	67	33	100	0	Cotton, plantain, marshelder, evening primrose

The wallfall samples from the plaza rooms, followed by plaza room floor samples, had the least evidence of economic pollen types. The occurrence of parsley and lily family pollen in plaza room floor samples may reflect ethnobotanical use.

Some associations revealed by the contextual frequency distribution are cholla and prickly pear pollen in intramural pit samples (from Rooms 2 and 5) and in front room floor samples. The back room posthole samples produced high frequencies of all the main economic taxa except cholla pollen. Back room posthole and floor samples produced the highest frequencies of native, wild resources such as lily and pea families, and the large grass type is also associated with back room contexts.

The distribution of rose family pollen is confusing, as the highest frequencies are in post-occupation fill and wallfall samples, but there are high frequencies in back room floor and posthole samples, which suggests an economic signal. The distribution of evening primrose is clearly associated with the primary cultural contexts.

Average pollen concentrations by context for dominant and select taxa are listed in Table 63.21. The maximum concentration values for maize, beeweed, sunflower family, grass, and sagebrush are from intramural pit samples; however, the two samples from adobe-lined pit Features 3 and 4 in Room 2 are driving the high values. The third pit sample, from Room 5, did not even yield maize pollen.

Table 63.21. Average pollen concentrations by context from LA 135290 (concentrations shown in gr/g and rounded to nearest 10).

	No. of Samples	Maize	Bee-weed	Cheno-Am	Sunflower Family	Grass	Sage-brush	Piñon	Juniper	Pine	Total Pollen Conc.

Room pits	3	1120	190	940	1220	870	1200	70	60	110	6740

There are few coherent patterns in comparing pollen concentrations by context (Table 63.21). Maize abundance is high in the primary cultural contexts of floors and features and low in post-occupation fill and wallfall. Sunflower family, grass, and sagebrush are generally comparable across contexts, with a spike in sunflower family in plaza room wallfall, a spike in grass in post-occupation fill, and high sagebrush in the Room 2 hearth samples. Cheno-am is an exception, with a definite trend from high values in post-occupation fill down through wallfall in front, back, and plaza rooms, and then a significant drop in room floors and features. This pattern of decreasing abundance vertically from floors to fill is also true for piñon, juniper, and pine, with the exception of the plaza room wallfall samples, which are characterized by high values in all three conifers including the highest average piñon value.

The pollen sampling strategy at LA 135290 included several detailed series from multiple floors in back rooms (Rooms 4, 5, 6, and 7) and from the different contexts in Room 2. There was no significant difference in the pollen spectra from floor sample series in individual back rooms. This lack of sensible trends from youngest to oldest floors could indicate that pollen analysis is not sensitive enough to capture differences. Floor assemblages are mixed by reuse of construction materials, or the same general types of activities throughout the site occupation left comparable pollen assemblages.

The detailed sampling in Room 2, however, produced one of the best vertical pollen profiles from fill to floors from the C&T Project; this is probably related both to preservation and to the fact that this room was a focal point for the site. The pollen results from the Room 2 profile are shown graphically in Figure 63.7 as pollen concentrations. The sample at the top of the graph is from post-occupation fill, characterized by zero economic types and the maximum cheno-am, piñon, and juniper values. A few economic types register in wallfall samples and cheno-am and piñon are reduced from post-occupation fill. There are three floor samples, two taken from beneath artifacts, and there is also a subfloor sample; the subfloor sediments were described as outside fill brought in to level the floor before plastering. The two floor samples from beneath artifacts register the maximum maize and squash pollen concentrations, high grass and sagebrush and low cheno-am, piñon, and juniper pollen. This is the cultural pollen signature and it disappears in the subfloor sample, but comes back in the Feature 1 hearth, except for high cheno-am and juniper. There is a diluted cultural signature in the results from hearth Features 11 and 16, with low expressions of all taxa and then a strong cultural signature again in the two pit samples.

This overall profile indicates that grass and sagebrush were important resources used undoubtedly for a variety of construction, textile, fuel, and practical products. Cheno-am presents a mixed signal, with low background representation from floor samples and spikes in the pit samples and the Feature 1 hearth. Piñon is clearly an environmental pollen type and the piñon expression below wallfall is interpreted to reflect roofs restricting ambient pollen entry into the room. Raised juniper values in the Feature 1 hearth may reflect fuel wood use.

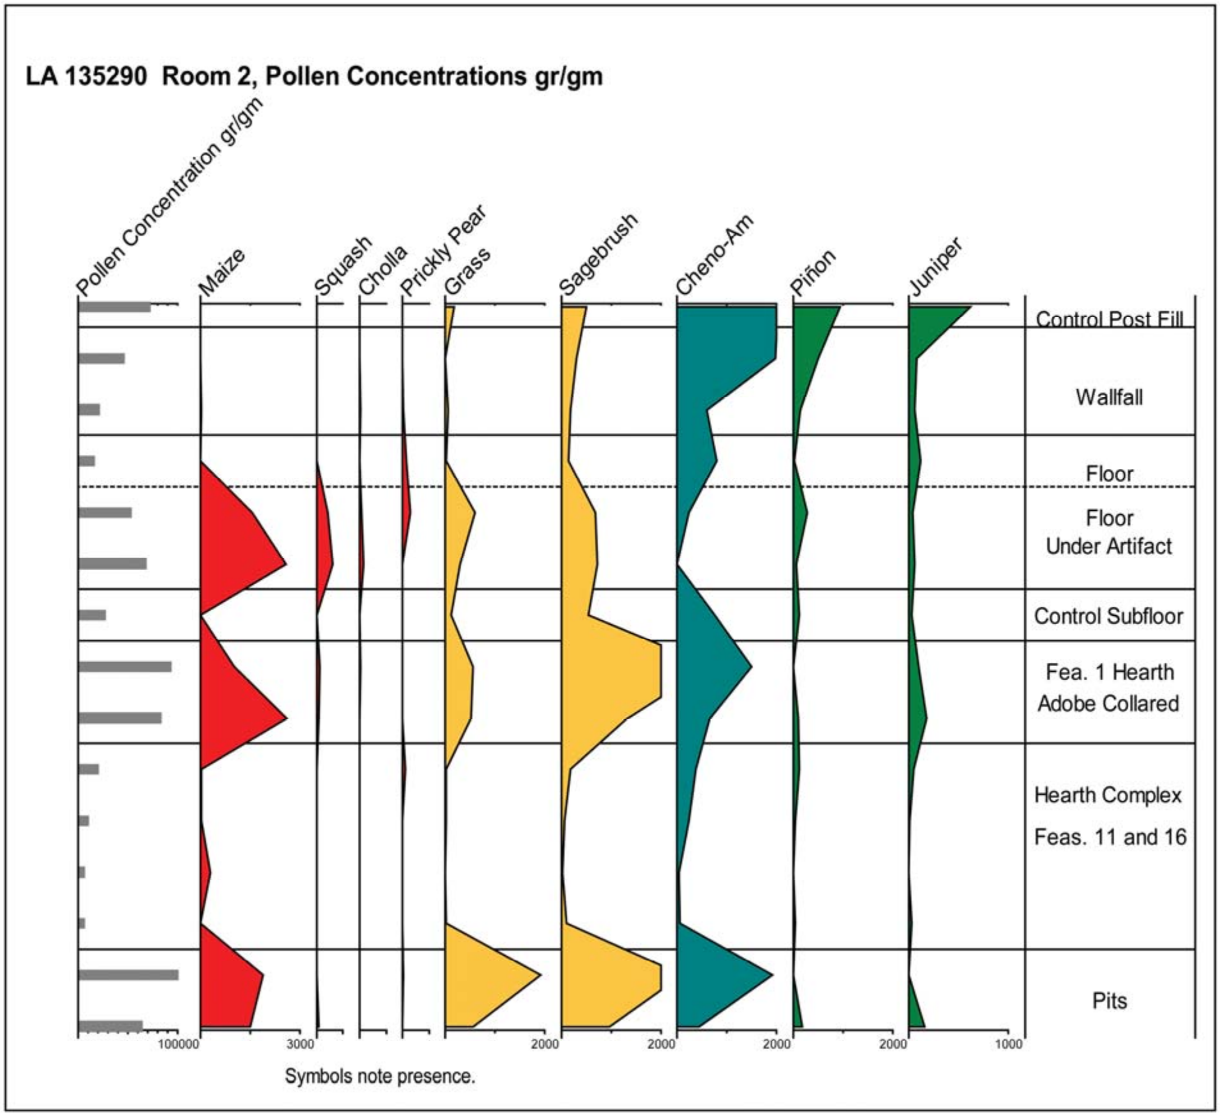

Figure 63.7. LA 135290 Room 2 pollen concentration data.

Summary

The main economic taxa recovered from LA 135290 are maize, squash, cotton, cholla, prickly pear, and beeweed. Low frequencies of lily family, purslane, mint family, parsley family, cactus family, large grass, evening primrose, buckwheat, mustard family, pea family, marshelder type, and rose family may also reflect ethnobotanical resources.

The roomblock at this site produced the project maximum values of maize and squash pollen. Clearly LA 135290 was a farming site. There are no obvious local water sources near this mesa top site, yet LA 135290 also produced the greatest project expression of riparian pollen types. The riparian signature could reflect pollen entrained in the water used to mix up adobe mud, but could also reflect some type of irrigation, perhaps pot-watering, of crops. The grid garden site at LA 139418 is not far from LA 135290 and water pollen types were also recovered at LA 139418 (see The Palynology of Gardens on the Pajarito Plateau). Another striking result in the pollen data is the abundance of economic pollen taxa in Room 2. Room 2 may have functioned as a communal or ceremonial space for the roomblock.

LA 141505 (Classic Period Fieldhouse)

Six pollen samples were analyzed from this Classic period fieldhouse: a post-occupation fill sample, two samples from the fieldhouse floor, a posthole, and one extramural sample each from a rock alignment and a rock pile. Economic types identified from floor samples include maize, beeweed, and prickly pear; walnut pollen, a riparian tree, was also recovered from a floor sample. The extramural samples produced alder (another riparian taxon), lily family, and sunflower (*Helianthus*) type.

Rendija Tract (Non-Fieldhouse Sites)

Archaic Lithic Scatters LA 85859 and LA 99397

Nineteen pollen samples were analyzed at LA 85859, an Early Archaic lithic scatter. Only eight samples produced significant counts of 80 or more pollen grains (range 88 to 243 grains) and the other 11 samples were evaluated as sterile, which is the worst return on pollen samples from any C&T Project site. Most LA 85859 samples were taken to profile soil pits, with 13 samples collected to complement the geology investigation (Drakos and Reneau 2004). Even the eight samples with significant counts were characterized by low pollen concentrations (range 260 to 780 gr/g), except for a surface sample that yielded 17,580 gr/g. As detailed in the summary of pollen results from geology soil pits (see Summary of Pajarito Plateau Pollen Analog Studies), pollen in soils is lost with depth due to physical and biological degradation, and most of the sterile pollen samples from LA 85859 were from B soil horizons. The soil stratigraphy at LA 85859 is also complicated by hillslope processes and substantial bioturbation (Drakos and Reneau 2004:35), and it is likely that the non-results are exaggerated due to the physical soils environment. Only two potential economic pollen types were identified. Beeweed pollen was documented in two samples, one from Stratum 4 (sample 336) and the second from Strata 3c/4 (sample 180), and lily family pollen occurred in sample 135 from Stratum 3c.

LA 99397 is also an Archaic lithic scatter, and similar to LA 85859, pollen samples (n = 13) were collected to profile soil pits with the result of a high proportion of sterile samples (n = 4). Nine pollen samples produced significant counts with economic taxa identified. Maize and cf. sunflower (*Helianthus*) were identified in sample 294 (Stratum 3), prickly pear in sample 317 (Stratum 5), beeweed in sample 300 (Stratum 2), and possible marshelder type pollen occurred in samples 294, 300, and 309. The co-occurrence of maize and beeweed pollen comprises a pueblo pollen signature possibly reflecting that the area of lithic scatter was a later field. A few ceramic sherds were collected in the top two strata and this site is adjacent to a Classic period fieldhouse (LA 85411) with maize pollen.

Jicarilla Apache Sites LA 85864 and LA 85869

These two sites were next to each other. Thirteen pollen samples were analyzed from LA 85869 and two samples from LA 85864; all 15 yielded significant counts. No evidence of any economic pollen types was recovered and the pollen spectra resemble natural pollen signatures (high pine and piñon and moderate cheno-am, sunflower family, and grass), except for three samples at LA 85869. These three samples were collected from a possible rock alignment (Feature 7) that after excavation proved to be a natural configuration. The pollen samples produced high percentages of sunflower family, sagebrush, and juniper, but low percentages of pine and piñon, which may reflect a subtle local natural vegetation difference, such as a drier area dominated by juniper. Two of the tipi ring samples at LA 85869 also yielded low pine and piñon percentages but high juniper, which may also reflect local microhabitat differences in the vegetation.

LA 127633 (Storage Bin)

Five pollen samples were analyzed from a storage bin (Feature 1) at LA 127633. Two of the samples are post-occupational fill and three are from the interior of the bin. No cultigens were identified and only one economic taxon was documented—lily family in a post-occupational fill sample. Pine and piñon pollen dominated all five samples, indicating that only natural pollen deposition is preserved in the fill from this feature.

LA 85407 (Serna Homestead)

Eight samples were submitted from this historic homestead site: three samples from the fill inside the cabin, two from test pits in the corral, one from a horno, and two from a reservoir feature. According to historical documents and interviews, this site was an early 1900s homestead that was seasonally occupied by the Serna family (see Chapter 32, Volume 2); the family grew corn, beans, wheat, pumpkins, and vegetables.

Maize pollen was recovered from one of the corral samples. In the cabin samples, economic pollen types included prickly pear, beeweed, and cf. sunflower (*Helianthus* type). A large grass pollen type was also identified from one of the cabin samples, which could represent Indian ricegrass or one of the cereal grasses, such as wheat. The main characteristic of the pollen results from this site is a high representation of cheno-am pollen compared to other Rendija Tract sites, which is interpreted as a weedy signature of disturbed ground.

Rendija Tract Fieldhouses

The pollen analysis included 94 pollen samples from 21 fieldhouses excavated in the Rendija Tract. Sixteen fieldhouses were built during the Classic period and five were constructed during the Coalition; two Coalition period sites contain other components (LA 99396 Archaic period lithic scatter and LA 86606 Classic period rock alignment). With one two-room exception (LA 85411), the fieldhouses are one-room structures with hard-packed floors and generally lacking interior hearths, though extramural hearths were found at a few sites. Interior hearths were recorded in seven fieldhouses and samples were analyzed from five of these hearths.

There are patterns to the distribution of economic pollen types in the Rendija Tract results (Table 63.22). First, economic taxa are associated with floors. Maize occurred in 30 percent of the floor samples (*n* = 47), compared to 23 percent of the post-occupational fill samples (*n* = 30). Cholla and squash were rare, occurring in three and two fieldhouse sites, respectively (Table 63.22), but always from floor samples. Prickly pear pollen occurred in only five samples, four floor samples and one post-occupational fill. Beeweed pollen was less common than maize, but structures registering beeweed also recorded maize, with one exception (LA 85403). Lily family pollen occurs in six samples and sunflower (*Helianthus*) in two samples.

The results from LA 85867 are unique. This was the only fieldhouse with cactus family pollen and an aggregate of cactus family was also identified. Additionally, the only project occurrence of locoweed (*Astragalus* type) was identified in three floor samples from LA 85867. It is impossible to interpret whether the locoweed reflects cultural use or some natural source (e.g., insect pollen cache), but occurrence of maize pollen, beeweed, and prickly pear in floor samples suggest there is a strong cultural signal in this structure. Several species of locoweed have medicinal and ceremonial uses and the roots of certain species were used for food (Moerman 1998).

Maize pollen is not abundant at any fieldhouse site compared to roomblocks. The maximum maize concentration from a Rendija Tract fieldhouse is 154 gr/g from a post-occupational fill sample at LA 85413. The project maximum maize concentration is 5741 gr/g from a roomblock floor sample at LA 135290 and six room samples produced maize concentrations greater than 1000 gr/g (all from LA 135290, Rooms 2 and 7). The contrast between fieldhouses and rooms is attributed to more ephemeral seasonal use of fieldhouse sites.

Although maize is low in fieldhouses, the pollen data were queried to explore any potential relationship between fieldhouse size, total sample pollen concentration, and maize concentration. Larger structures might reflect longer occupation or perhaps more people living at the site, which should result in deposition of a stronger pollen signature. The pollen results appear to support this idea. The top 10 samples with the highest maize and total sample concentration were sorted from the Rendija Tract database and a frequency distribution was calculated for three categories of fieldhouse area (Table 62.23). Only one of the smallest (less than 3.5 m^2) fieldhouses (LA 85867) recorded maize pollen (scan identification). High maize values correlate to the houses greater than 3.5 m^2 and the largest fieldhouses produced the highest sample pollen concentrations.

Rendija Tract Fieldhouses Chronological Trends

Rendija Tract fieldhouses comprise a chronological cross-section from Coalition through Early, Middle, and Late Classic periods. The pollen results from post-occupational fill and floor samples are organized chronologically (Figure 63.8). Classic period fieldhouses have a higher representation of maize than Coalition structures. Of the 39 floor samples collected from 16 Classic period fieldhouses, 12 produced maize pollen (33% sample frequency) compared to two of nine floor samples with maize pollen from five Coalition period sites (22% sample frequency). Only three Classic period sites did not produce any maize pollen, but two of the Coalition period sites lack maize. The pollen samples collected from LA 85413 produced the highest maize and beeweed concentrations of all Rendija Tract fieldhouses.

The greatest expression of economic taxa is during the Early Classic period, which is represented by five sites (Figure 63.8). Beeweed pollen is almost exclusive to Early Classic period fieldhouses and there is a higher frequency of riparian taxa and more diverse assemblages. The average number of economic and potential economic pollen taxa (n = 32) by chronological period is listed in Table 63.24. Floor samples from Early Classic period sites are characterized by 3.0 economic taxa per sample compared to 1.0–1.7 in all other periods.

Table 63.24. Average economic taxonomic richness from floor samples by period in the Rendija Tract.

Period	Number of Fieldhouse Floor Samples	Average Economic Taxa (n = 32) per Sample
Late Classic	3	1.7
Middle Classic	14	1.4
Early Middle Classic	9	1.4
Early Classic	10	3.0
Late Coalition/Classic	4	1.0
Coalition	4	1.5

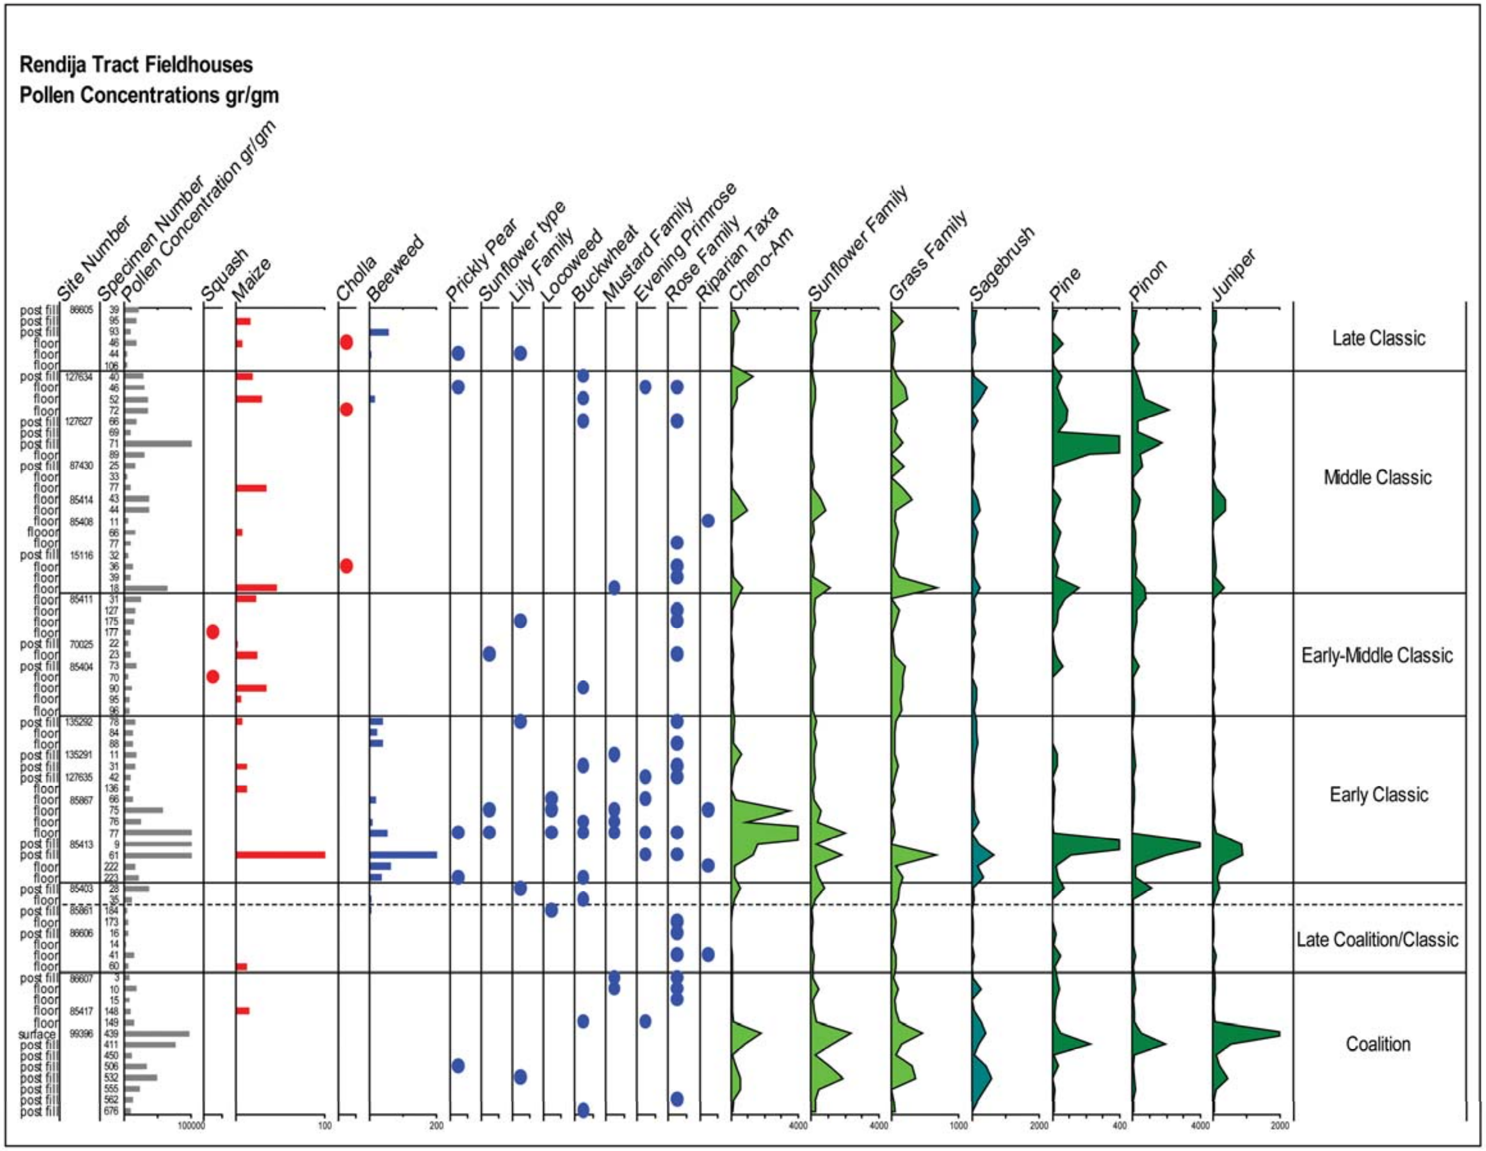

Figure 63.8. Rendija Tract fieldhouses pollen concentrations.

There are spikes in pollen concentrations at three Rendija sites—LA 127627, LA 85413, and LA 99396—but the high values are from post-occupational fill and are driven by pine, piñon, and juniper (see Figure 63.8). Sites with high pollen concentrations in floor samples are LA 85867, LA 127634, LA 85414, and LA 15116, where cheno-am, sunflower family, and grass are the source of the high values. These results are similar to pollen concentration patterns described at roomblocks and are interpreted to relate to enhanced weed signatures during site occupations. The greater representation of weedy types suggests either longer seasonal use of fieldhouses LA 85867, LA 127634, LA 85414, and LA 15116, or larger and perhaps more productive fields near the sites.

Grass pollen is notable in the majority of fieldhouses, but especially at LA 85404. Grass matting may have been used on floors or in roof materials. Cholla pollen is uncommon in fieldhouses and does not occur until the Middle and Late Classic period; cholla may have been grown at later sites on a limited basis.

COMPARISON BETWEEN SITES

Average sample pollen concentrations and economic taxa richness calculated from floor samples by site type (Table 63.25) show that there is more than twice as much pollen and a greater diversity of economic taxa on roomblock floors than fieldhouse floors. This is a statistically significant result, based on large sample populations. The contrast reflects the seasonal, ephemeral use of fieldhouses and the longer occupation and greater degree of cultural activities at roomblocks. There is also an exponentially greater abundance of maize pollen in roomblocks, which could reflect stockpiled harvests and larger, more productive gardens near the roomblocks in addition to the obvious greater intensity of human activity.

Table 63.25. Comparison of average pollen concentrations and economic taxonomic richness from floor samples by site type.

	Fieldhouses	Roomblocks
Number of structures	24	3 (24 rooms)
Floor samples	51	66
Average sample pollen conc.	2069	4677
Average maize conc.	7	191
Average economic taxa (*n* = 32 taxa) per sample	1.8	3.1

There are four Pajarito Plateau roomblock sites with detailed pollen data: LA 4618 (Smith 2006a) and the three C&T Project pueblos, LA 12587 (excluding Roomblock 3), LA 135290, and LA 86534. These four sites are compared in Table 63.26 by ranking the representation of economic taxa in floor samples. For each taxon, a score of one is assigned to the site with the greatest representation from either concentration or sample frequencies and four is assigned to the site with the lowest representation. Cheno-am is included as a disturbance indicator and other potential taxa are listed by site. Average pollen concentrations from floor samples (back and front rooms combined) are also listed in Table 63.26.

Table 63.26. Comparison of four Pajarito Plateau roomblocks; average pollen concentration and site rank (1 highest, 4 lowest) for the main economic taxa from floor samples.

	Late Coalition		Middle Coalition

Pollen concentration trends from roomblocks and fieldhouses (Table 63.25) indicate that pollen abundance is a reliable index to the degree of cultural activity at sites. Contrasts between the four roomblocks (Table 63.26) show that there is more pollen in Late Coalition period roomblocks than Middle Coalition period sites. Late Coalition period sites also have a greater abundance of cultigens, based on ranking scores in Table 63.26. The highest-ranking site is LA 4618, a Late Coalition period roomblock on Mesita del Buey with two kivas; LA 4618 produced one of the best pollen records from the Pajarito Plateau (Smith 2006a).

The highest maize concentrations and squash frequencies, however, are from LA 135290, a Middle Coalition period roomblock. The high values are due to floor samples in Room 2, which may have served as a kiva or other communal space, and if true, this would skew the comparisons between sites. There is no ambiguity concerning LA 86534. This site ranks last for representation of major economic types; cultigens are essentially missing from LA 86534. But in terms of overall diversity of other economic taxa (excluding cultigens), LA 86534 ranks first and the Late Coalition period sites rank last. It is also notable that riparian pollen types were only recorded at LA 4618 and LA 135290, the two maize sites. Riparian taxa may be an indirect indicator of agriculture, probably as a result of watering gardens.

The contrasts between the four roomblocks (Table 63.26) fit a model of agricultural intensification during the Late Coalition period, presumably from a larger population; however, the same pattern could reflect the location and history of the sites. Both of the Middle Coalition period sites are on a mesa top at higher elevations and the pair of Late Coalition period sites are lower elevation near the toe of Mesita del Buey. The pollen results from gardens indicate that the agricultural potential was higher at LA 12587, compared to the Airport mesa. Thin aeolian sand covers the Airport mesa, but soils are deeper near LA 12587 (Drakos and Reneau 2003, 2004), and both LA 12587 and LA 4618 are closer to canyons, where residents may have procured water. The two Late Coalition period sites are also near each other and are part of a larger community of pueblo sites, whereas the two Middle Coalition period sites on Airport Mesa are isolated, although there are fieldhouses nearby.

CONCLUSIONS: THE POLLEN PERSPECTIVE

Pollen is a biased tool that is useful for tracking certain subsistence plants (e.g., cholla and beeweed), but blind to a host of other ethnobotanical resources, especially root crops. Archaeo-pollen data are also generally insensitive to environmental changes due to the overwhelming local input from disturbance floras that colonize sites and fields as well as subsurface pollen degradation. The natural preservation gradient in sediments affects pollen types differentially, with more conifer pollen lost than cheno-am and sunflower family in the first 10 cm below ground surface (see Summary of Pajarito Plateau Pollen Analog Studies). These natural processes and biases are important architects of the pollen assemblages recovered from archaeological sites.

The C&T Project pollen data were analyzed differently from typical Southwest archaeopalynology. The usual data display is by pollen percentages and sample frequencies. For the C&T Project, pollen percentages were used to explore contrasts between archaeological and modern pollen spectra and sample frequencies were calculated for rare and low count pollen types (e.g., cotton, squash, and cholla). For maize and beeweed and the dominant environmental taxa, analysis was based on pollen concentrations. Concentrations estimate the abundance or density of pollen grains in samples, whereas percentages are relative measures. Pollen concentrations proved to differentiate contrasts between sites that would have been missed or at least muted if pollen percentages were the sole analytical parameter employed.

What Were the Important Subsistence Resources?

Maize pollen is everywhere on the Pajarito Plateau, attesting to a history of farming throughout the Coalition and Classic periods. Squash and cotton were grown though perhaps only at the larger pueblos. Cotton may have been cultivated for ceremonial reasons or as a special crop. This conclusion is based on the low recovery of cotton pollen from pueblos and gardens and the absence of any macrobotanical or material artifacts (e.g., spindle whorls) that would confirm a substantial cotton industry. The floodplain along the Rio Grande was the cotton Eden, as shown by a San Ildefonso field study, where almost half of 81 subsurface samples produced cotton pollen (authors' data; Table 63.11). Cholla is interpreted here as another cultivated resource, one that was imported, as cholla does not occur in the native Jemez piñon and juniper woodland. Ethnographic accounts emphasize the use of cholla flower buds for food, but there is also a deep history of ceremonial and ritual use of cholla (see Housely 1974). Cholla representation is low in the C&T Project samples, and similar to cotton, cholla may have been a special crop.

Other important resources that were undoubtedly utilized and may have been encouraged, conserved in fields and other habitats, or directly cultivated include prickly pear, other cacti, lily family (e.g., yucca), beeweed, purslane, nightshade family (e.g., tobacco), and grasses. Native resources accessible throughout the archaeological periods that register in contexts floors, hearths, and other features include mint family, plantain, buckwheat, evening primrose, mustard family, rose family, parsley family, sunflower (*Helianthus*) type, large grass type, milkwort, locoweed, and possible marshelder. Two unknown sunflower members may have been subsistence resources—the broad-spine sunflower type and a sunflower family grain unique to LA 86637, a White Rock Tract multi-component lithic and ceramic scatter. Cottonwood type, walnut, willow, alder, sedge, and cattail are scarce pollen types, but the presence of these water indicators suggests that riparian habitats existed in the region and would have been intensively utilized. The marshelder type may also have been a water indicator, as the typical habitat for marshelder is wet soils. Cheno-am taxa represent resources that were surely utilized, but trends in cheno-am pollen between contexts are not as definitive as for other types.

Pine, piñon, juniper, and oak are the pollen types representing the native trees; these were core resources for fuel, construction wood, and food (piñon nuts, juniper berries, and oak acorns). These trees were undoubtedly utilized at all of the C&T Project sites, but no analysis of these taxa was attempted, as it is impossible to tease apart any cultural signal from background atmospheric pollen rain.

Can Different Contexts Be Discriminated?

Pollen assemblages are sensitive to context. The results presented here demonstrate that pollen concentrations track cultural activity. There is a gradient in abundance by site type from low in the seasonally occupied fieldhouses to the highest pollen concentrations in Late Coalition period roomblocks. Fieldhouses and rooms with larger floor areas also tend to have higher pollen concentrations.

There are examples of pollen types associated with particular contexts, such as purslane and high values of beeweed in hearths and high grass and maize pollen aggregates in burials. The results from the extensive sampling at roomblocks show that generally, floors and features are enriched in a cultural pollen signature composed of weedy dominants (cheno-am, grass, and sagebrush) and economic taxa. Floors are the best average recorder of cultural activities, postholes are the worst, and hearths are either a bust or a treasure with some of the highest expressions of subsistence resources and sterile samples.

Differences between front rooms and back rooms were also examined in detail, with mixed results. The four pueblo sites on the Pajarito Plateau with extensive pollen data are LA 4618 (Smith 2006a) and the three C&T Project pueblos, LA 12587 (excluding Roomblock 3), LA 135290, and LA 86534. The number of sites with the highest representations by room type of the five main economic taxa (squash, maize, cholla, beeweed, and prickly pear) are tallied in Table 63.27. Cultigen abundance can be high in front or back rooms, prickly pear is associated with front rooms, and beeweed and cheno-am are usually higher in back rooms.

Table 63.27. Number of roomblocks (*n* = 4) registering the highest representation of five economic taxa and cheno-am in front or back rooms.

	Front Rooms	Back Rooms
Squash	1	1
Maize	2	2
Cholla	2	2
Prickly pear	3	1
Beeweed	1	3
Cheno-Am	1	3

Although front and back rooms yield variable results by sites for the main economic taxa, there is a consistent higher diversity of other resources in back rooms (Table 63.28). The recovery of richer assemblages from back rooms is interpreted to relate to storage of plant resources as well as deposition of other pollen types that hitchhike on raw plant materials. Front rooms were likely swept out more frequently than back rooms, which could be another factor affecting diversity.

Table 63.28. Average taxonomic richness per floor sample for 32 economic and potential economic pollen taxa.

	Front Rooms	Back Rooms
LA 12587	3.0	3.9
LA 135290	3.5	4.0
LA 86534	2.8	3.0

There are few kiva samples to compare to roomblocks, but kivas tend to have higher representation of economic taxa than roomblocks. One kiva with four floor samples (LA 86534) was represented in the C&T Project data, and at LA 4618 there are two kivas with 21 floor samples (Smith 2006a). At LA 86534, the kiva floor samples produced a greater abundance of pollen than room floors. At LA 86418, back room floors were characterized by the highest pollen concentrations and representation of economic taxa, but kiva floor samples were comparable.

What Is the Pollen Evidence for Seasonality of Occupation?

Interpreting season of occupation from archaeobotanical assemblages is complicated by human behavior, as plant resources may be harvested or traded from other locales, but stored at a site. In their review of the assumptions and problems of seasonal interpretations, Adams and Bohrer (1998) suggest that the better markers of long-term site occupation are taxonomic diversity and a strong weed signal. Continual occupation, or long-term, repeated seasonal use of sites, creates disturbed ground that is expanded as sites grow, and the exposed soils are quickly colonized by weeds. The weedy signal may also become exaggerated as these plants are utilized and perhaps managed or encouraged as companion food resources in cultivated fields and gardens, on middens, and around sites.

The C&T Project sites offer an exceptional example of the weed syndrome of long-term occupation. Pollen concentrations provide an index to the abundance of pollen, showing exponentially greater pollen abundance in the more intensely occupied pueblos. The high pollen concentrations in the pueblo samples were derived primarily from cheno-am. Taxonomic diversity also reliably mirrors occupation history. Fieldhouses were characterized by minimal numbers of pollen types compared to pueblos.

The pollen results cannot determine whether roomblocks were occupied year round, but there are seasonal signals in the data. The overwhelming evidence for maize agriculture indicates spring through early fall occupation. The interpretation of the use of cholla as a cultigen at the pueblos supports an interpretation of late spring activities, as most cacti species flower between late April and June. Lily family encompasses both early spring plants (e.g., wild onion) and late spring and early summer resources, such as yucca. The prickly pear fruits, or tunas, another resource inferred from both the macro (see Chapter 62, this volume) and pollen data at fieldhouses and pueblos, are harvested later in the summer and into the early fall months. Beeweed, several cheno-am, and sunflower family taxa are late summer through early fall resources.

Chronological Trends

No significant pollen results were interpreted from the Jicarilla Apache tipi ring sites (LA 85869 and LA 85864) or the two Archaic lithic scatters (LA 85859 and LA 99397). Cultural pollen signatures are seldom recovered from open–air contexts and the potential decreases with the age of the site. Lack of cultural pollen evidence from the Jicarilla Apache sites suggests temporary use and that the sites were not used for significant plant processing.

Four roomblock sites were compared in this chapter (Table 63.26): the three C&T Project pueblos and LA 4618 (Smith 2006a), a Late Coalition period roomblock on Mesita del Buey upslope from LA 12587 (see Chapter 14, Volume 2). The pollen results from the two Late Coalition period sites (LA 4618 and LA 12587) are exceptional with significantly greater pollen concentrations than the two Middle Coalition period sites (LA 135290 and LA 86534). The patterns of pollen representation between sites and contexts support the interpretation that there was more activity and disturbed ground at Late Coalition period sites, which fits a model for Late Coalition period agricultural intensification. However, the roomblock sites are paired by period in different settings, and the pollen results could reflect better agricultural potential or perhaps more water at the lower elevation Late Coalition period sites. Additionally, the project maximum representation of maize and squash pollen is from the Middle Coalition site LA 135290, which emphasizes that roomblocks have individual pollen signatures.

Comparisons of the Rendija Tract fieldhouses present a clearer chronological trend than the pueblos. The fieldhouses comprise an excellent database of adequate numbers of sites and samples from the Coalition through the Classic periods all from approximately the same environment. The pollen results show that more maize was grown at Classic period fieldhouses than Coalition, and that the Early Classic was in some way unique. Three Early Classic sites (LA 135292, LA 85867, and LA 85813) are characterized by the highest beeweed concentrations out of all the Rendija fieldhouses and the most diverse pollen assemblages (Figure 63.8). Three Middle Classic period fieldhouse sites (LA 15116, LA 85414, LA 127634) and one Early Classic site (LA 85867) may have been occupied longer, supported more people, or associated with more productive fields. This conclusion is based on higher pollen concentrations of weed taxa at these sites.

CHAPTER 64
ANALYSIS OF FAUNAL REMAINS FROM THE LAND CONVEYANCE AND TRANSFER PROJECT, LOS ALAMOS, NEW MEXICO

Kari M. Schmidt

INTRODUCTION

This chapter presents the results of analyses conducted on the faunal remains recovered from 23 sites excavated during the 2002 through 2005 seasons at Los Alamos National Laboratory (LANL). The majority of faunal remains came from two Coalition period habitation sites (LA 12587 and LA 86534). LA 12587 consisted of two roomblocks, three rooms underlying a grid garden, a single room (Room 3) built over Roomblock 1, and three burials, while LA 86534 included eight habitation rooms and a subterranean circular kiva. Sites from five tracts were excavated and included two sites from the White Rock Tract (LA 12587 and LA 127631), two sites from the Airport Tract (LA 86534 and LA 135290), 15 sites from the Rendija Tract (LA 85404, LA 85407, LA 85408, LA 85411, LA 85413, LA 85414, LA 85859, LA 85861, LA 85864, LA 85867, LA 85869, LA 86605, LA 86606, LA 127627, and LA 135292), three sites in the Technical Area (TA) 74 Tract (LA 21596B, LA 110126, and LA 117883), and one site (LA 61035) in the White Rock Y Tract. Faunal remains from each of these sites are described in the remainder of this chapter.

The following chapter is organized into four parts: a brief discussion of the flora and fauna common to northern New Mexico, the analytical methods employed in the analysis of the faunal remains, the results of the faunal analysis, and a discussion of their significance. The discussion section contrasts the LA 12587, LA 86534, and LA 135290 assemblages with two other Coalition period faunal assemblages that were excavated at LANL in the early 1990s (LA 4618 and LA 4624; Schmidt 2006b and Vierra et al. 2002).

FLORA AND FAUNA IN NORTHERN NEW MEXICO

By and large, the sites excavated during the course of the project are located in piñon and juniper woodland. The piñon and juniper woodland (Brown 1994) includes a number of plant species but is dominated by piñon pine (*Pinus edulis*) and juniper (*Juniperus* sp.) The understory is typically composed of a number of grasses and shrubs. Dominant grasses include grama (*Bouteloua* sp.), Indian ricegrass (*Oryzopsis hymenoides*), western wheatgrass (*Agropyron smithii*), muhleys (*Muhlenbergia* sp.), and dropseeds (*Sporobolus* spp.). Dominant shrubs include gambel oak (*Quercus gambelii*), mountain mahogany (*Cercocarpus* sp.), cliffrose (*Cowania mexicana*), Mormon tea (*Ephedra* sp.), snakeweed (*Gutierrezia* sp.), fourwing saltbush (*Atriplex canescens*), rabbitbrush (*Chrysothamnus* sp.), and sagebrush (*Artemesia* sp.). Several cacti are found in the general site area and include small yuccas (*Yucca glauca* and *Y. baccata*), prickly pears (*Opuntia* sp.), and hedgehogs (*Echinocereus* sp.).

In addition to the wide-range of floral resources supported by the piñon and juniper woodland, this biome also supports a large number of mammals. Some of the major mammal species are rodents, including numerous different species of chipmunks and squirrels (Sciuridae), wood rats (*Neotoma* sp.), and mice (*Perognathus* sp. and *Peromyscus* sp.). Mammals in the biotic communities that may have been more economically important than the rodents include rabbits (Leporidae), carnivores (from the Felidae, Canidae, Procyonidae, and Mustelidae families), and deer and elk (Cervidae). Most of the taxa represented by these families would have been accessible relatively close to the site at various times throughout the year. Large cervids would have been in the area during the winter months as it falls within their winter range.

Birds and reptiles are also present in the site area. Some of the more common species include the piñon jay (*Gymnorrhinus cyanocephalus*), quail (*Callipepla* sp.), ravens (*Corvus* sp.), raptors (Falconiformes), whiptail lizards (*Cnemidophorus* spp.), rattlesnakes (*Crotalus* sp.), spiny lizards (*Sceloporus* sp.), and various non-venomous snakes (Colubridae). While the flora and fauna on the Pajarito Plateau remain similar to conditions that may have been found in the area prehistorically (with the exception of the introduction of some nonnative grasses and trees), the relative abundances of these species has likely changed.

ANALYTICAL METHODS

The faunal remains from the C&T Project sites were analyzed and assigned to the lowest taxonomic level whenever possible. Genus and species identifications remained the ideal goal throughout the analysis, but were not always possible. Identifications were made using the comparative osteological collection at the Arizona State Museum in Tucson, Arizona, and were augmented by osteological manuals when necessary (Cohen and Serjeanston 1996; Gilbert 1993; Lawrence 1951; Olsen 1964, 1968, 1979). Provenience data recorded for each specimen included site number, field specimen (FS) number, area number, room number (where applicable), easting, northing, Stratum, and level.

The analysis followed standard zooarchaeological procedures (Grayson 1984; Klein and Cruz-Uribe 1984) and recorded the following attributes for each bone: lowest taxonomic identification, element (e.g., tibia, ulna), portion of element present (e.g., proximal, distal, or complete), side (if able to be determined), age (presence or absence of epiphyseal fusion line, epiphyses, etc.), fusion (fused or unfused), presence and degree of burning, natural taphonomic factors (e.g., root-etching, weathering), break patterns (if other than natural), pathologies, and numbers of specimens present. In addition, other surface modifications (e.g., rodent or carnivore gnawing), if present, were recorded.

Unidentifiable materials classified as mammal were separated based on size. Following Shaffer and Baker's (1992) criteria, distinctions were made between small mammals (small rodents and leporids), medium-sized mammals (large rodents such as beaver, and carnivores such as coyotes and foxes),medium/large-sized mammals (deer, pronghorn, and bighorn sheep), and large-sized mammals (elk, bison, and bear). Similar distinctions were made for birds if element identification was not possible.

Although identifications to species are always preferable, certain specific identifications were not made for several reasons. The main reason for generic identifications (as opposed to specific) is the presence of multiple species in a given area. This phenomenon occurred for cottontail rabbits. There are presently two species of cottontail rabbits in northern New Mexico (Macdonald 1995). Both the desert cottontail (*Sylvilagus audubonii*) and Nuttall's cottontail (*Sylvilagus nuttallii*) inhabit the area today. Nuttall's cottontail has been reported as far south as northern New Mexico but is probably not significant to this analysis as there are very few archaeological examples from northern New Mexico. Despite this, however, cottontail identifications were made to the generic level, *Sylvilagus* sp., and not to the specific level to avoid conflating these two species.

Unidentifiable shaft fragments were kept separate from unidentifiable, non-shaft fragments in order to assess the number of shafts relative to other fragments. This was done to gain a sense of how many long-bone elements were in the assemblage relative to non-long-bone elements.

Several methods were employed to quantify both the unidentifiable and identifiable remains during the analysis. These techniques include the number of identified specimens (NISP), the minimum number of individuals (MNI), and the calculation of lagomorph and artiodactyl indices. Each of these is discussed in detail below.

Number of Identified Specimens

The NISP is the number of bones in an assemblage that can be assigned to a particular taxon (Klein and Cruz-Uribe 1984). In early faunal analyses, this was the primary method of quantification. Determining NISP values for an assemblage is fairly simple: bones are identified to the lowest possible taxonomic level, and the numbers of identifiable specimens within that taxon are tabulated. If an assemblage has 10 left tibiae and 8 right tibiae, the NISP value is 18. NISP is the most fundamental counting unit used to determine the abundance of taxa in a given faunal assemblage (Grayson 1984), and was employed during the course of the current analysis.

Despite the need to quantify taxa in faunal assemblages, there are inherent problems with using the NISP method (Grayson 1979, 1984). First, NISP methods assume that all bones are equally affected by breakage, which cannot control for interdependence as one bone has the potential to be broken into many fragments. This creates problems for statistical measures. Second, NISP does not account for differential preservation of bones, which is dependent on density or porousness. Third, NISP methods do not control for differing number of elements in different species. Fourth, NISP is affected by differing recovery techniques, specifically screening (Cannon 1999a; Shaffer and Sanchez 1994). Finally, NISP values are affected by butchering and transport decisions. Small animals killed away from a site are more likely to be carried back whole, while only the meatiest elements of larger animals are returned to the site. Each of these issues affects specimen counts.

Minimum Number of Individuals

The MNI in an assemblage is the number that signifies how many animals represent a particular taxon. White (1953) was one of the first to use this quantification. He described the MNI calculation as, "separating the most abundant element of the species found . . . into right and left components and using the greater number as the unit of calculation" (White 1953:397). For example, an assemblage with 10 left tibiae and 8 right tibiae has an MNI of 10. This quantification method has the potential to alleviate some of the shortcomings of the NISP method, especially in terms of interdependence and fragmentation, but it is not problem-free. MNI calculations are affected by analyst choices in terms of aggregation of data (e.g., which analytic units are used, pit structures, terraces, units, levels, etc.), and also in terms of how to compute the MNI (e.g., which element will be used for calculation). In this analysis, both NISP and MNI calculations were used to take advantage of the best of both methods without ignoring their weaknesses.

Lagomorph and Artiodactyl Indices

Because large game and small game are both economically important and consistently found in faunal assemblages throughout the Southwest, their importance relative to one another is significant (Bayham and Hatch 1985; Szuter 1991). In relatively arid areas where numbers of large game are reduced in archaeological assemblages because of natural scarcity (when compared to small game; see Brown 1994), large game is more likely to be recovered at residentially used locales. Because artiodactyls (white-tail and mule deer, bighorn sheep, elk, and pronghorn) and lagomorphs (jackrabbits and cottontail rabbits) are economically important and consistently appear in faunal assemblages throughout the Southwest, understanding their importance relative to one another is important. As a result, artiodactyl indices (ratio of artiodactyl remains to the sum of artiodactyl and lagomorph remains) and lagomorph indices (ratio of cottontail remains to the sum of all lagomorph remains) were calculated. The comparison of indices will be valuable in the assessment of site function, land use, and resource exploitation at the C&T Project sites.

RESULTS OF THE FAUNAL ANALYSES

White Rock Tract

Eight sites were excavated in the White Rock Tract in 2002, and faunal remains were only recovered at two, a Late Coalition period roomblock (LA 12587) and a Late Coalition/Early Classic period fieldhouse (LA 127631) (see Figure 13.1).

LA 12587 (Roomblock)

LA 12587 is located on a wide ridge at the east end of Mesita del Buey and sits at an elevation of 1979 m (6500 ft). Cañada del Buey lies some 300 m to the north of the site, and is defined on the north by a 70-m-tall cliff face. The wide floodplain of Pajarito Canyon is approximately 400 m south of the site. Cañada del Buey and Pajarito Canyon converge just east of LA 12587 and it is at this point that the two canyons begin to angle away from each other. Piñon and juniper woodlands dominate the ridges and mesa tops surrounding the site, while the canyon bottoms are vegetated primarily by broadleaf riparian species. Ponderosa pine forests are located upslope of the site in the foothills of the Jemez Mountains. The location of the site near three distinct biomes (woodland, riparian, and coniferous forest) made access to a number of distinct species not only possible, but also likely.

In general, the overall preservation of the bones from LA 12587 is good. For the most part, bones were recovered in large fragments, and a number of complete elements were identified. Weathering on the faunal remains was present, although the frequency and severity was generally low (*n* = 18), suggesting the remains may not have been exposed to the elements for a long period of time before deposition. The bones show minimal evidence of root-etching, and no evidence of rodent gnawing, carnivore gnawing, or carnivore-digestion. Modifications resulting from burning were present on 183 pieces of bone, constituting some 28 percent of the total assemblage. Pathologies were identified on two specimens: a pocket gopher femur and pubis. Thirty-two specimens recovered from LA 12587 were worked.

Of the 649 faunal remains recovered from the excavations at LA 12587, 33 percent (*n* = 217) were identified to at least the level of class (e.g., Mammalia, Aves). The 217 identified remains were recovered from a variety of contexts. Table 64.1 lists all the taxa that were recovered from the site. Because the most abundant taxa represented in the assemblage were intrusive pocket gophers (*Thomomys* sp.), Table 64.2 presents the same data with this taxon removed. Pocket gopher burrows were extensive in the immediate site area, and the visual appearance of their bones was quite distinct from the vast majority of the other bones recovered from the site.

Table 64.1. Identified faunal remains from all contexts at LA 12587.

TAXON	TOTAL			BURNED

UNIDENTIFIED TOTAL	432	--	--	153	--	--
SITE TOTAL	**559**	**--**	**--**	**177**	**--**	**--**

Table 64.2 shows that the majority of the identified fauna (25%) at LA 12587 is turkey (*Meleagris gallopavo*), followed by cottontail (*Sylvilagus* sp.), mule deer (*Odocoileus hemionus*), indeterminate large bird, jackrabbit (*Lepus californicus*), and indeterminate medium/large mammal remains. The remainder of the assemblage consists of a wide variety of taxa, including fish, amphibians, small and large birds, rodents, and carnivores. The variation present in the assemblage attests to its location near a number of distinct biomes.

MNI for each individual taxon was derived from the most common element represented in the assemblage. The ulna was used for the turkey, the mandible was used for the kangaroo rat, the maxilla was used for the rock squirrel, and the mandible was used for the cottontail rabbit. Other taxa in the assemblage were only represented by one individual.

The faunal remains recovered from LA 12587 demonstrate that lagomorphs, specifically cottontail rabbits and jackrabbits, were important components of the subsistence assemblage, second only to the exploitation of turkey (14%). Cottontail rabbits (*Sylvilagus* spp.) were more abundant in the assemblage relative to jackrabbits (*Lepus* spp.), but both species were important. Cottontails and jackrabbits comprise almost 14 percent of the identified assemblage. The open piñon/juniper woodland and canyon riparian areas within a short distance from the site would have supported both taxa. Artiodactyls comprise just under 13 percent of the assemblage at LA 12587. Only one species, mule deer, was positively identified. A single unidentified artiodactyl remain (tooth fragment) was identified, as were ten pieces of unidentified medium- to large-sized mammal long-bone fragments. As with the leporids remains, both the open piñon/juniper woodland and canyon riparian areas would have supported artiodactyls.

In general, the exploitation of non-turkey, leporid, and artiodactyl taxa seems to have been relatively less important. Although rodents appear to have been important in the LA 12587 assemblage given their relative abundance among identified remains (46%), their presence is probably over-represented by modern, intrusive remains. This is based on several factors: they are present in all levels of the stratigraphic column, very few are burned, their general appearance is different from the non-rodent remains, and often, a particular taxon is represented in a localized area. Based on these factors, it is probable that a large majority of the rodent remains in the assemblage represent post-depositional activity at the site. The pocket mouse and pocket gopher remains are most likely intrusive while the kangaroo rat and ground squirrel remains are more likely to have been associated with the occupations of the roomblock.

The remaining 13 percent of the identified assemblage at LA 12587 consists of fish, amphibians, birds, and carnivores. The presence of these taxa also suggests that the inhabitants of the site used a broad spectrum of resources from a wide range of woodland and riparian habitats.

Because the basic unit of analysis at LA 12587 was the room, faunal remains were discussed by individual room. Tables 64.3 through 64.12 show the breakdown of recovered bones from each room. Numbers of identified specimens from the individual rooms are not high, but are fairly consistent. Faunal remains recovered from fill contexts are briefly discussed after the material from each of the rooms is presented.

Room 1 (Roomblock 1)

Room 1 is a rectangular room located in the back row of rooms at the north end of the roomblock. The room was constructed with tuff blocks and adobe mortar and contained a plastered adobe floor. The room is contiguous with Room 2 on the east and Room 6 on the south. The fill below the surface is Stratum 10, the post-occupational fill present throughout the roomblock. Wallfall was encountered in the fill both inside and outside the room, as were chunks of adobe and melted adobe along the walls indicating that the walls had been higher before abandonment. Below the post-occupational fill, excavation of the room revealed intact portions of plastered floor, mostly in the eastern and southeastern portions of the room. Stratum 200 represents deposits from outside of Room 1. The faunal remains recovered in Room 1 are fairly representative of the site in general. Unidentified remains were the most abundant, followed by the intrusive pockets gophers, and a variety of other taxa. Two unidentified bone beads were recovered from Stratum 10 (post-occupational fill). Table 64.3 shows the taxa recovered from the individual strata in Room 1.

Table 64.3. Room 1 faunal remains by Stratum.

TAXON	STRATUM NUMBER		TAXON TOTAL
	10	200	
Unidentified	16	1	17
Cottontail (*Sylvilagus* sp.)	1	0	1
Jackrabbit (*Lepus californicus*)	1	0	1
Rock squirrel (*Spermophilus variegatus*)	2	0	2
Pocket gopher (*Thomomys* sp.)	3	1	4

Pocket mouse (*Perognathus* sp.)	1	0	1
Turkey (*Meleagris gallopavo*)	0	1	1
Total	**25**	**3**	**28**

Room 2 (Roomblock 1)

Room 2 is generally rectangular in shape and is located in the northeast end of Roomblock 1. The walls in this room were constructed using both shaped and unshaped tuff blocks, adobe mortar, and chinking stones. The walls enclose a plastered adobe floor in which two hearths (Features 4 and 20) were constructed. Two groups of postholes were also identified in the floor.

Stratum 1 is the top layer of unconsolidated sandy loam identified throughout the site and ranges from 2 to 5 cm thick in this room. Stratum 10, the post-occupational fill overlying the floor of the room, ranges in depth from 34 to 48 cm, and averages 42 cm deep. This Stratum is a moderately compact brown sandy loam with varying amounts of tuff gravels, fist-sized rocks, and wallfall, including construction stone and burned and unburned adobe chunks. A 2- to 4-cm-thick Stratum lying over the floor was identified as Stratum 70. Although the color remains the same as the overlying sediment, it is less consolidated and sandier in texture. Artifacts decrease, as do chunks of burned and unburned adobe relative to those recovered from the overlying Stratum 10, except in the southeastern corner. No bones were found in association with the floor in this room. Strata 170 and 171 are both subfloor deposits, while Stratum 200 represents the exterior deposits of Room 2. Table 64.4 shows the distribution of faunal remains associated with both the interior and exterior deposits.

Table 64.4. Room 2 faunal remains by Stratum.

Turkey (*Meleagris gallopavo*)	0	1	0	0	0	0	**1**
Total	**2**	**77**	**1**	**1**	**1**	**3**	**85**

As in Room 1, the faunal remains recovered in Room 2 are representative of the relative site distribution. Unidentified remains were the most abundant, followed by the intrusive pocket gophers, cottontails, large birds, and a variety of other taxa (mice, squirrel, and turkey). Nine specimens recovered from this room were worked, and all were recovered from Stratum 10 (post-occupational fill). Items represented include two fragmented bone tubes, two whistles, three bone beads, and two identified, but polished, shaft fragments. The whistles and the bone tubes were all found in the same context (FS 2117), and were all from a large bird, probably a turkey. No diagnostic features were present on the bones.

Room 4/5 (Roomblock 1)

Positioned between Rooms 2 and 7, Room 4/5 is a habitation room contiguous with Room 6 to the west. It is rectangular in shape, 4.0 m long, and 2.8 m wide and is enclosed by masonry walls that are mostly collapsed with only one to two courses remaining. The 2.6 m remaining of the north wall is also the south wall of Room 2. The east wall is mostly missing, with the exception of a 1-m segment in the center and 0.90 m of the southeast corner. Only 0.40 m of the south wall at the southeast corner remains, and the extent of the west wall is mostly complete with a 0.70-m gap at the south end. A hearth (Feature 1) is located in the approximate center of the room, and a posthole (Feature 8) is situated in the northwest quadrant.

Stratum 1 was the underlying fill just below the surface and was a loose, unconsolidated sandy loam that varied from 2 to 8 cm deep. Stratum 10, the post-occupational fill, varied in depth from 30 to 41 cm, and evidence for rodent and root activity was prevalent. Wallfall and adobe chunks were abundant in this Stratum, as were fist-sized rocks, and tuff gravels comprised from 5 percent to 25 percent of the fill. Stratum 14 includes the fill and decayed mortar in the east-west-oriented wall that separated the room into Room 4 and Room 5. After the two rooms were excavated, the wall was removed to expose the hearth and the room was re-designated as 4/5. From the wall and fill within it, two pieces of flaked stone and 12 sherds were recovered. Stratum 252 is the upper floor (Floor 2), which had been finished with a light gray ashy plaster. Disaggregation of the floor matrix, which was a very compact, indurated layer, and slightly ashy in content, resulted in the recovery of a surprisingly high number of artifacts suggesting that the floor matrix is composed of midden material. Table 64.5 shows the distribution of faunal remains associated with excavations in this room.

Table 64.5. Room 4/5 faunal remains by Stratum.

TAXON	STRATUM NUMBER			
	10	14	252	Taxon Total
Unidentified	16	3	2	21
Indet. Rodent	1	0	0	1
Sm/med mammal	1	0	0	1
Coyote/dog (*Canis latrans/familiaris*)	1	0	0	1
Pocket gopher (*Thomomys* sp.)	1	0	0	1
Total	**20**	**3**	**2**	**25**

Very few identifiable faunal remains were recovered in Room 4/5. The distribution of bones in this room was unlike most others, with only a single rodent and coyote/dog identified. The pocket gopher remain identified in this room was intrusive, suggesting disturbance in the room. Two worked bones were recovered from Stratum 10 (post-occupational fill). An unidentified bone bead was recovered, as was a bone awl. The awl was constructed from a medium/large mammal long-bone fragment, but no diagnostic features remained, thus precluding a specific identification. The single coyote/dog specimen was a first phalanx that showed signs of moderate weathering. The bone was recovered near the surface and may have been introduced.

Room 6 (Roomblock 1)

Room 6 is the middle room in the back row of rooms and is oriented north-northeast by south-southwest. The total area of this room is 7.9 m^2 (3.6 by 2.2 m). Room 6 is south of Room 1, north of Room 8, and west of Room 4/5. The walls and floors of this room are poorly preserved, and all the walls are only one course thick. A single subfloor pit (Feature 7) was found in the room. Faunal remains were found in two strata. Stratum 1 is the loose, unconsolidated, fine-grained sandy loam that is found across the surface of the entire site, and Stratum 10 is a heterogeneous mix of sandy loam and adobe melt. In a few areas the adobe occurred in layers up to 16 cm thick. Areas of highly consolidated sandy loam, which may be areas of decayed adobe were also recorded. Occasionally a thin layer of adobe melt was found just above the floor. No faunal remains were found in association with the floor. Table 64.6 shows the distribution of faunal remains recovered in this room. Remains were only recovered from the layers of post-occupational fill.

Of the 16 pieces of bone recovered from this room, eight were identified to at least the level of class. But, it is probable that all the identified remains are intrusive. The pocket gopher remains were extensive in room deposits, suggesting significant rodent disturbance. A premaxilla from a Woodhouse's toad was recovered in level 1, but its distinctive appearance also suggests it may have been intrusive. The rest of the bones were unidentifiable scraps, precluding meaningful interpretations. No worked specimens were recovered from this room.

Table 64.6. Room 6 faunal remains by Stratum.

	1	10	Taxon Total
Unidentified	2	6	8
Woodhouse's toad (*Bufo woodhousii*)	1	0	1
Pocket gopher (*Thomomys* sp.)	0	7	7
Total	**3**	**13**	**16**

Room 7 (Roomblock 1)

Room 7 is in the southeast corner of the roomblock and is south of Room 4/5, east of Room 8, and partially below Room 3. The room is oriented north-northeast by south-southwest and only the west wall and north wall are at least partially intact. Because the shape and extent of the east and south walls cannot be defined, the room size cannot be precisely determined. Two features were identified in the room: a hearth and ash box complex (Feature 6) and four postholes (Feature 12). Faunal remains were only recovered from post-occupational fill (Strata 1 and 10). Table 64.7 shows the distribution of faunal remains recovered.

Table 64.7. Room 7 faunal remains by Stratum.

TAXON	STRATUM NUMBER

Unidentified	1	7	8
Turkey (*Meleagris gallopavo*)	0	1	1
Med/lg mammal	0	3	3
Mule deer (*Odocoileus hemionus*)	0	1	1
Total	**1**	**12**	**13**

Of the 13 pieces of bone recovered from this room, only five were identified to at least the level of class, and three were only identified as medium/large mammal long-bone fragments. The two pieces of bone identified to a specific taxon include the distal portion of a mule deer metapodial and a right turkey coracoid. Both were recovered from post-occupational fill, and both were from level three. Three pieces of worked bone were identified in the Room 7 fill. A single bone bead was recovered from level one, but diagnostic features precluded a specific identification. A bone awl, recovered from level two, was manufactured from the distal portion of a deer metatarsal. And finally, a polished long-bone shaft fragment was also recovered from level two. The shaft was from a large bird, probably turkey, but diagnostic features were absent. It is probable that the piece was part of a whistle or flute.

Room 9 (Roomblock 1)

Room 9 is a relatively long, narrow, rectangular back room oriented to the northeast. The room measured 4.9 by 1.9 m with a total area of 9.31 m^2. Faunal remains were recovered from two strata (10 and 170). Stratum 10 was post-occupational fill and includes wallfall, adobe, and rooffall. Stratum 129 consists of the patchy floor plaster found in the northern portion of the room. Stratum 170 includes the fill below floor to the natural bedrock. Table 64.8 shows the distribution of faunal remains recovered from this room.

Table 64.8. Room 9 faunal remains by Stratum.

TAXON	STRATUM NUMBER			
	10	129	170	TAXON TOTAL
Unidentified	2	6	0	14
Pocket mouse (*Perognathus* sp.)	2	0	0	2
Cottontail (*Sylvilagus* sp.)	0	1	0	1
Med/lg mammal	0	0	1	1
Total	**4**	**7**	**1**	**12**

Of the 12 pieces of bone recovered from this room, only four were identified to at least the level of class. One of the identified remains was a long-bone fragment from a medium/large-sized mammal, and two were intrusive pocket mice remains found in the post-occupational fill. A cottontail vertebral fragment was found on the floor in Room 9. The element was not burned. One piece of worked bone was recovered from this room. It was recovered in the sub-floor stratum and was manufactured from a long-bone fragment of a large bird. No diagnostic features were present, so the element it derived from was not identified. None of the bones recovered in this room were burned.

Room 10 (Roomblock 3)

Room 10 is located near the center of Roomblock 3, and Room 12 is located to the north and Room 11 is to the south. The orientation of Room 10 is north-northeast by south-southwest and it has an area of 7.8 m^2 (3.4 by 2.3 m). This room was not entirely excavated: 91N/100E was unexcavated, only a small portion of 91N/101E was partially excavated, and 90N/100E was only partially excavated. The rest of the room was dug to bedrock. Two unidentified bone fragments were recovered from the post-occupational fill in this room. Both were heavily burned and neither was worked.

Room 11 (Roomblock 3)

Room 11 is located in the southern half of Roomblock 3. It is oriented north-northeast by south-southwest and is south of Room 10 and north of Room 13. It is the largest room at the site with an area of 15.6 m^2 (6.5 by 2.4 m). Room 11 was not fully excavated. Instead the walls were exposed and three east-west-running trenches were excavated across the room. Five pieces of bone were recovered from this room, and all were from post-occupational fill. Two fragments were unidentified and two were intrusive (both pocket gopher). The first digit proximal phalanx of a turkey was recovered in level two. None of the bones were burned or modified in any way.

Room 12 (Roomblock 3)

Room 12 is located near the center of Roomblock 3. Room 14 is located to the north and Room 10 is to the south. The orientation of Room 12 is north-northeast by south-southwest and it has an area of 7.9 m^2 (3.6 by 2.2 m). The northern half of the room was excavated down to bedrock, and units in the southern half of the room were unexcavated or only partially excavated.

Three strata were excavated in this room. Stratum 201 is the post-abandonment fill of Room 12. In the absence of any indication of a floor or use surface, this Stratum was terminated at the base of the walls. In the northern half of the room enough masonry blocks were found in Stratum 201 to account for an additional half a course of wall. There is no clear distinction between Strata 201 and 208 other than the base of the wall. Stratum 208 is generally 3 to 18 cm deep, although it is somewhat thicker in the east where the base of the wall is 22 to 25 cm above bedrock. No masonry was found in this Stratum except for a small amount along and under the east wall. It seems likely that this material is wallfall from Roomblock 1. Table 64.9 shows the distribution of faunal remains from this room.

Table 64.9. Room 12 faunal remains by Stratum.

TAXON	STRATUM NUMBER		
	201	208	Taxon Total

Turkey (*Meleagris gallopavo*)	2	0	2
Large bird	2	1	3
Pocket gopher (*Thomomys* sp.)	0	2	2
Med/lg mammal	1	0	1
Total	**6**	**5**	**11**

Of the 11 pieces of bone recovered from this room, nine were identified to at least the level of class. Identified remains in the upper portion of the post-occupational fill include a large catfish vertebra, two right turkey tibiotarsi, two unidentified large bird long-bone fragments, and a medium/large-sized mammal long-bone fragment. Identified remains in the lower portion of the post-occupational fill include two intrusive pocket gopher elements (right tibia and femur) and a large bird long-bone shaft fragment. Only one of the unidentified elements was burned. One of the large bird long-bone fragments from Stratum 201 was a small fragment of a bone awl. The element was heavily polished, and the tip remained. No diagnostic features were present on the tool, so a specific assignation was not possible.

Room 14 (Roomblock 3)

Situated in the northern portion of the roomblock, Room 14 is located between Room 12 on the south and Room 16 on the north. It is a rectangular room that is 3.9 m long north-south and 2.3 m wide east-west, 9.0 m^2, and consists of masonry walls a single course high. The extent of the north wall is nearly complete, missing only the westernmost end. The east and south walls are mostly complete, and all but the southern 0.78 m of the west wall is missing. All bones recovered from this room were found in post-occupational fill. Table 64.10 shows the distribution of bones from this room.

Table 64.10. Room 14 faunal remains by Stratum.

TAXON	STRATUM NUMBER
	201
Unidentified	3
Turkey (*Meleagris gallopavo*)	1
Domestic dog (*Canis familiaris*)	1
Mule deer (*Odocoileus hemionus*)	1
Total	**6**

Six pieces of bone were recovered from this room. Three were unidentified to the level of class, and three were identified. Identified remains in the post-occupational fill include a turkey phalanx, a mule deer rib, and the fourth metacarpal from a domestic dog. Only a single unidentified bone fragment in this room was burned. None of the remains were worked.

Room 16 (Roomblock 3)

This room is situated at the northern end of Roomblock 3. Two sample trenches were excavated wall to wall across the room, one bordering the interior of the south wall and the second at mid-room, to obtain a representative sample of artifacts and samples, to discern if a floor was present, and to investigate the stratigraphy of the room. These units were dug to bedrock. No bones were recovered in Stratum 1, but all 22 pieces of bone were recovered from Stratum 201. This Stratum, which extends from Stratum 1 down to the base of the wall, was filled with wallfall, including construction-sized stone and an abundance of chinking sized stones. This layer of moderately compact brown sandy loam varied from 11 to 29 cm in depth. Table 64.11 shows the list of faunal remains recovered in this room.

Table 64.11. Room 16 faunal remains by Stratum.

TAXON	STRATUM NUMBER
	201
Unidentified	16
Turkey (*Meleagris gallopavo*)	1
Pocket gopher (*Thomomys* sp.)	4
Cottontail (*Sylvilagus* sp.)	1
TOTAL	**22**

Twenty-two pieces of bone were recovered from this room. Of this total, only six were identified to at least the level of class. Identified remains in the post-occupational fill include a small fragment of a turkey radius, four intrusive pocket gopher elements (left humerus, radius, ulna, and maxilla), and a left cottontail femur. Only a single unidentified bone fragment in this room was burned. None of the remains were worked.

Room 18 (Roomblock 3)

Room 18 is the southernmost room of Roomblock 3. It is south of Room 17 and is oriented north-northeast by south-southwest. The room has an area of 6.9 m^2 (3.0 by 2.3 m). A roughly L-shaped section of this room was dug along the north and west walls. Each leg of the L was approximately 1 m wide. The only other excavation carried out in Room 18 consists of narrow trenches dug to define the room walls. Only one piece of bone, a right pocket gopher mandible, was found in this room. It was not worked and burned, and was likely intrusive.

Trenches

A number of backhoe trenches were placed around the site. Sediments removed from these trenches were not 100 percent screened, but were gone through by hand. Piles were picked through and visible artifacts were picked up. Several produced small numbers of bones. These will be listed and described briefly below.

Trench 2. Two bones were recovered in this trench. One was a small, unidentified fragment, and the other was a left turkey (*M. gallopavo*) tibiotarsus. Neither was burned or worked.

Trench 3. Eight pieces of bones were picked up in the hand-screening of sediments removed from this trench. Three of the bones were unidentified and not burned. Three unburned turkey (*M. gallopavo*) elements were identified. These include a right coracoid, a left ulna, and a right tarsometatarsus. All elements were complete. A burned left jackrabbit (*Lepus* spp.) ischium was identified. And, the right distal end of a mule deer (*O. hemionus*) radius was identified. This element was not burned and unworked.

Trench 5. Two unidentified remains were recovered from Trench 5. Both were burned.

Trench 6. Nine pieces of bone were recovered in this trench. All derived from a single animal and from a single element, a mule deer (*O. hemionus*) cranium. None of the bones were burned.

Faunal Remains Not Associated with a Specific Room

The majority of the faunal remains (*n* = 407, 63%) recovered at LA 12587 were from non-room contexts. Most of these bones were associated with the fill above rooms, or with the deposits just outside of the roomblock. Bones recovered from contexts such as these came from four strata: Stratum 1 was the loose, post-occupational fill that was found just below the surface across the entire site, Stratum 10 was the post-occupational fill below Stratum 1 and associated with Roomblock 1, Stratum 200 was the deposits from the exterior of Roomblock 1, and Stratum 280 was the Stratum underlying Stratum 1 in the area associated with the agricultural features (Area 2). Table 64.12 shows the distribution of faunal remains recovered from these deposits.

As in the individual rooms, the distribution of taxa is heavily weighted toward turkey, mule deer, and lagomorphs (rabbits and hares). Based on their distinctive appearance, the pocket gophers are likely intrusive and therefore insignificant. Other taxa represented include the bullfrog, golden eagle, piñon jay, pocket mouse, kangaroo rat, rock squirrel, gray fox, and coyote.

Indeterminate large birds, and small-medium and medium/large-sized mammals were identified as well.

Table 64.12. Faunal remains from outside rooms.

Resource Exploitation, Land Use, and Lagomorph and Artiodactyl Indices at LA 12587

Several species of animals that have been of great economic importance throughout the prehistoric sequence in the Southwest are lagomorphs (jackrabbits and cottontails) and artiodactyls (white tail and mule deer, bighorn sheep, and pronghorn). The presence of these taxa is constant in the prehistoric faunal record, although proportionately they have varied throughout the Southwest according to site location, site function, and other factors relating to horticulture and sedentism (Szuter and Bayham 1989, 1996). Because of their consistent presence in prehistoric assemblages, researchers have derived indices to gauge the relative importance of large and small game to each other and to other taxa. Table 64.13 gives the data used in calculating the lagomorph and artiodactyl indices at LA 12587.

Table 64.13. Quantity of Sylvilagus, Lagomorph, and Artiodactyl remains from LA 12587.

Number of Cottontails	Number of all Lagomorphs	Number of Artiodactyls	Lagomorph Index	Artiodactyl Index
19	29	17	0.66	0.37

The lagomorph index is the ratio of the quantity of cottontail remains to the sum of all lagomorph remains. It generally decreases as an area is more intensively or extensively occupied (Bayham and Hatch 1985; Szuter and Bayham 1989, 1996). For example, inhabitants of more continuously or extensively occupied sites tend to exploit more jackrabbits relative to cottontails. Cottontails are generally found in areas with denser vegetative cover where they can hide from predators, while jackrabbits prefer open spaces where they can flee from predators (Legler 1970; Macdonald 1995; Szuter and Bayham 1996). As groups of people occupy an area more intensively and extensively, they likely have a greater impact on the environment, thus creating a more favorable habitat for jackrabbits than cottontails. The relatively high lagomorph index at LA 12587 may suggest that the exploitation of cottontails was quite important to its inhabitants. Conversely, it may be a simple reflection of the fairly effortless access to both the open woodland environment on the nearby mesa tops (favorable jackrabbit habitat) and the more brushy, wooded areas (favorable cottontail habitat) in the canyon bottoms.

The artiodactyl index is the ratio of artiodactyl remains divided by the sum of artiodactyl and lagomorph remains (Bayham 1982; see Table 64.13). Artiodactyl indices throughout the Southwest vary primarily as a function of site location. Sites in upland areas typically have indices above 0.30 to 0.35 (Szuter and Bayham 1996). In contrast, lower elevation sites typically have artiodactyl indices below 0.10. The artiodactyl index of 0.37 supports this trend and suggests that artiodactyl exploitation was important, but may not have been as important in terms of contributions to total dietary significance. This may reflect a natural scarcity of large game in the surrounding areas during the later part of the Coalition period, or it may reflect the exploitation of relatively easier to capture small game. Either scenario documents the use of a number of biotic communities including the riparian areas of the nearby canyons, the woodland areas of the mesa tops and ridges, and the transitional areas in between. The use of these zones suggests movement across the landscape and concomitant exploitation of the available resources in each biome. This, combined with the high percentage of maize remains recovered in the botanical assemblage, suggests that a mixed farming-foraging economy was in place during the Coalition period on the Pajarito Plateau.

LA 127631 (Late Coalition/Early Classic Period Fieldhouse)

One piece of bone was recovered from this one-room fieldhouse, which is located immediately downslope of LA 12587. The distal end of a cottontail (*Sylvilagus* sp.) femur was found on the surface before excavation. It is probable, based on the sun-bleached appearance of the specimen, that the bone was not associated with the prehistoric use of the site. The bone was not burned and unmodified and bleached white by the sun.

Airport Tract

A total of five sites were excavated in 2002 and 2003 in the Airport Tract (see Figure 13.2). Faunal remains were recovered at two sites, both of which were Middle Coalition period roomblocks (LA 86534 and LA 135290).

LA 86534 (Middle Coalition Period Roomblock)

LA 86534 is located immediately north of Highway 502 on the Los Alamos town site mesa. The site is situated at an elevation of 2149 m (7050 ft) in an area vegetated with piñon and juniper trees and interspersed with native grasses and shrubs. Piñon (and juniper woodlands dominate the ridges and mesa tops surrounding the site, while the canyon bottoms are vegetated primarily by broadleaf riparian species. Ponderosa pine forests are located upslope of the site in the foothills of the Jemez Mountains. The location of the site near three distinct biomes (woodland, riparian, and coniferous forest) made access to a number of distinct species not only possible, but also likely.

LA 86534 consisted of a compact roomblock of nine rooms, a sparse but extensive artifact scatter, and a disturbed two-track road on the northern perimeter of the site. The roomblock consisted of a rectangular block of eight rooms (four front and four back) and a circular kiva located just to the east of the roomblock. The roomblock walls were generally in good condition, with one to two courses present on the northern end and up to four courses present in the center of the rooms. The southern walls of Rooms 7 and 8 were destroyed during the construction of NM 502. Most of the artifacts were recovered from post-occupational and general room fill, although a few pieces of animal bone were recovered from floor contexts.

In general, the overall preservation of the bones from LA 86534 was good. The bones tended to be in large fragments, and a number of complete elements were identified. Weathering on the faunal remains was present, although the frequency and severity was generally low (n = 17), suggesting the remains may not have been exposed to the elements for a long period of time before deposition. The bones show minimal evidence of root-etching, and no evidence of rodent gnawing, carnivore gnawing, or carnivore-digestion. Modifications resulting from burning were present on 88 pieces of bone, constituting some 23 percent of the total assemblage. Two specimens recovered from LA 86534 were worked.

Of the 388 faunal remains recovered from the excavations at LA 86534, 52 percent (n = 202) were identified to at least the level of class. The 202 identified remains were recovered from a variety of contexts. Table 64.14 shows all the taxa that were recovered from the site. Because the most abundant taxa represented in the assemblage were intrusive pocket gophers, Table 64.15 presents the same data with this taxon removed. Pocket gopher burrows were extensive in the immediate site area, and the visual appearance of their bones was quite distinct from the vast majority of the other bones recovered from the site. Table 64.15 also does not include other intrusive rodents identified at the site (harvest mice, pocket mice, and deer mice).

Table 64.14. Identified faunal remains from all contexts at LA 86534.

Table 64.15 shows that the highest percentage of the identified fauna (24%) at LA 86534 is cottontail (*Sylvilagus* sp.), followed by mule deer (*Odocoileus hemionus*), red-tailed hawk (*Buteo jamaicensis*), rock squirrels (*Spermophilus variegatus*), and indeterminate medium/large mammal remains. The remainder of the assemblage consists of a wide variety of taxa, including amphibians, small and large birds, rodents, leporids, and carnivores. The variation present in the assemblage attests to its location near a number of distinct biomes.

Faunal remains were analyzed by individual room. Tables 64.16 through 64.24 show the breakdown of recovered bones from each room. Numbers of identified specimens from the individual rooms are not high, but are fairly consistent. Faunal remains recovered from fill contexts are briefly discussed after the material from each of the rooms is presented.

Room 1

Room 1 is a habitation room located in the northeastern corner of the roomblock and is the most northerly of the front rooms. It was constructed with tuff blocks and adobe mortar, and contained a plastered adobe floor. The room measures 2.6 m north/south by 2.48 m east/west, giving about 6.45 m^2 of interior space. The room was highly disturbed by both rodents and roots. A large juniper stump was located in the center of the room, just over the eventual location of the hearth (Feature 4) and extends to the north wall. Its roots incurred a significant amount of damage to the collar, shape, and fill of the upper use of the hearth. The fill below the surface is Stratum 1, the post-occupational fill present throughout the roomblock. Wallfall (Stratum 2) was encountered in the fill both inside and outside the room, as were chunks of adobe along the walls. Excavation of the room revealed intact portions of plastered floor, mostly in the western half of the room. The faunal remains recovered in Room 1 are fairly representative of the site in general. Unidentified remains were the most abundant, followed by a single element each from an intrusive pockets gopher, mule deer, and unidentified small-medium mammal. One bone awl was recovered from Stratum 2 (wallfall) in this room. Table 64.16 shows the distribution of taxa by strata in Room 1.

Table 64.16. Room 1 faunal remains by Stratum.

TAXON	**STRATUM NUMBER**			
	1	2	6	Taxon Total
Unidentified	2	1	0	3
Sm/med mammal	1	0	0	1
Pocket gopher (*Thomomys* sp.)	1	0	0	1
Mule deer (*Odocoileus hemionus*)	0	0	1	1
TOTAL	**4**	**1**	**1**	**6**

Room 2

Room 2 is a habitation room located in the middle of the roomblock in the northern section that measures 3.40 m north/south by 2.40 m east/west, giving an interior floor space of 7.46 m^2. Room 2 is in the front set of rooms and is located immediately south of Room 1. All units in the room were then excavated down to floor (Stratum 8). Two features were identified in the room: Feature 2 was a collared hearth located near the center of the room, and Feature 3 was the doorway between the western wall of Room 2 and the eastern wall of Room 4.

Stratum 1 was an approximately 10-cm-thick layer of post-occupational fill and consisted of the very loose and unconsolidated post-occupational fill. Some areas contained a high organic content from the duff associated with piñon and juniper trees in the area. Stratum 2 consisted of the general room fill, which contained an abundant amount of rubble wallfall and was about 25 to 30 cm thick. The Stratum was loose and unconsolidated. The bottom of Stratum 2 contained the abrupt contact with rooffall (Stratum 6 and 7). Stratum 6 is the actual rooffall layer, but

Stratum 7, only identified in Room 1, was a very thin layer of sediment between the rooffall and the floor. Stratum 8 was the floor Stratum in this room, and a single jackrabbit (*Lepus* sp.) rib was associated with the floor. Small patches of floor were present throughout the room, but there were no large contiguous areas of floor at all. Table 64.17 shows the distribution of taxa by strata in Room 2.

Table 64.17. Room 2 faunal remains by Stratum.

TAXON	STRATUM NUMBER					TAXON TOTAL
	2	6	6/7	8	14	--
Unidentified	0	2	1	0	0	**3**
Wood rat (*Neotoma* sp.)	1	0	0	0	0	**1**
Pocket gopher (*Thomomys* sp.)	0	0	0	0	1	**1**
Jackrabbit (*Lepus* sp.)	0	0	0	1	0	**1**
Mule deer (*Odocoileus hemionus*)	0	0	1	0	0	**1**
Total	**1**	**2**	**2**	**1**	**1**	**7**

As in Room 1, the faunal remains recovered in Room 2 are representative of the relative site distribution. Unidentified remains were the most abundant, followed by a single element from each of the following taxa: wood rat, pocket gophers, cottontails, jackrabbit, and mule deer. No worked bones were identified in this room.

Room 3

Room 3 is a habitation room located in the northwestern corner of the site. It is the most northerly of the back rooms and is 3.2 m north/south by 2.00 m east/west, giving about 6.4 m^2 of interior space. It is in the back row of rooms and is located immediately to the west of Room 1. In general, the room was uniformly disturbed in the northern two-thirds by roots associated with the juniper tree outside Room 3. A single doorway feature (Feature 10) was identified in the eastern wall between Rooms 1 and 3. In Room 3, Stratum 1 was an approximately 10-cm-thick layer of post-occupational fill and consisted of the very loose and unconsolidated post-occupational fill, Stratum 2 consisted of the general room fill, which contained an abundant amount of rubble wallfall and was about 25 to 30 cm thick. The bottom of Stratum 2 contained the abrupt contact with rooffall (Stratum 6 and 7). Stratum 6 is the actual rooffall layer, but Stratum 7, only definitively identified in Room 1, was a thin layer of sediment between rooffall and floor. No faunal remains were associated with the floor in this room (Stratum 8), which was only present in the southern one-third of the room and in a small patch along the north wall. The only bone recovered was partially burned proximal femur from a kangaroo rat (Table 64.18).

Table 64.18. Room 3 faunal remains by Stratum.

TAXON	STRATUM NUMBER	TAXON TOTAL
	1	
Kangaroo rat (*Dipodomys* sp.)	1	1
Total	**1**	**1**

Room 4

Room 4 is a habitation room located in the north-central portion of the roomblock and is 3.1 m north/south by 1.8 m east/west, giving about 5.58 m^2 of interior space. It is in the back row of rooms and is located immediately to the south of Room 3 and to the west of Room 2. In general, the room was in very good shape, with smaller amounts of disturbed sediments relative to other rooms at the site. A single doorway (Feature 3) was identified in the eastern wall of the room between Rooms 2 and 4. Stratum 1 was approximately 10 cm thick and consisted of the post-occupational fill, which was very loose and unconsolidated. Some areas contained a high organic content from the duff associated with piñon and juniper trees in the area. Stratum 2 consisted of general room fill, which contained an abundant amount of rubble wallfall and was about 25 to 30 cm thick. The Stratum was also loose and unconsolidated. The bottom of Stratum 2 contained the abrupt contact with rooffall (Stratum 6), which contained abundant, but usually small, fragments of adobe similar to that observed in the walls. Stratum 8 was the floor Stratum, which contained only minimal rodent disturbance in the central and eastern portions of the southern wall and in a small area in the center of the room. The floor in this room was well-preserved. Table 64.19 shows the distribution of taxa by strata in Room 4.

Table 64.19. Room 4 faunal remains by Stratum.

TAXON	STRATUM NUMBER			
	1	1,2	6,7	TAXON TOTAL
Unidentified	3	1	1	5
Turkey (*Meleagris gallopavo*)	1	0	0	1
Red-tailed hawk (*Buteo jamaicensis*)	0	0	1	1
Pocket gopher (*Thomomys* sp.)	1	0	0	1
Indeterminate rodents	0	0	1	1
Mule deer (*Odocoileus hemionus*)	2	0	0	2
Small/med mammal	0	0	1	1
TOTAL	**7**	**1**	**4**	**12**

Of the 12 pieces of bone recovered from this room, seven were identified to at least the level of class. Identified remains include a single turkey bone, one red-tailed hawk bone, one pocket gopher bone, an indeterminate rodent bone, two mule deer remains, and a single unidentified small/medium mammal long-bone fragment. No worked bones were identified in this room.

Room 5

Room 5 is a habitation room located in the south-central portion of the roomblock and is 3.50 m north/south by 2.30 m east/west, giving an interior floor space of 8.05 m^2. Room 5 is in the front set of rooms and is located immediately south of Room 2 and west of Room 9. This room is the largest of the front rooms and has an entry/exitway in the northeast corner to Room 9. The room was highly disturbed by bioturbation and, as a result, the floor was in very poor condition. Three features were identified in the room: Feature 5 was a collared hearth located near the center of the room, Feature 8 was a possible second hearth located along the southern wall, and Feature 11 was the doorway between the western wall of Room 5 and the eastern wall of Room 6. Feature 8 was in extremely poor condition and all that remained was a 10-cm section of probable collar. Both hearths were heavily disturbed and mostly destroyed.

On average, Stratum 1 was an approximately 10- to 15-cm-thick layer of post-occupational fill and consisted of the very loose and unconsolidated post-occupational fill. Stratum 2 consisted of the general room fill, which contained an abundant amount of rubble wallfall and was about 25 to 35 cm thick. Strata 1 and 2 were combined throughout this room. The bottom of Stratum 2 contained the abrupt contact with rooffall (Strata 6 and 7), and the floor (Stratum 8) was immediately below the rooffall level. Table 64.20 shows the distribution of taxa by strata in Room 5.

Table 64.20. Room 5 faunal remains by Stratum.

TAXON	STRATUM NUMBER				
	1	6	6,7	8	TAXON TOTAL
Unidentified	0	4	12	0	16
Red-tailed hawk (*Buteo jamaicensis*)	0	0	1	0	1
Indeterminate rodent	0	0	1	0	1
Pocket gopher (*Thomomys* sp.)	2	1	3	0	6
Kangaroo rat (*Dipodomys* sp.)	0	0	1	0	1
Rock squirrel (*Spermophilus variegatus*)	0	1	0	0	1
Cottontail (*Sylvilagus* sp.)	0	0	1	0	1
Coyote (*Canis latrans*)	0	0	1	0	1
Mule deer (*Odocoileus hemionus*)	0	1	0	0	1
Med/large mammal	0	1	0	1	2
Medium mammal	0	1	0	0	1
Sm/med mammal	1	0	0	0	1
TOTAL	**3**	**9**	**20**	**1**	**33**

Of the 33 pieces of bone recovered from this room, 17 were identified to at least the level of class. The pocket gopher remains are likely intrusive, and the kangaroo rat specimen may also be intrusive, as all were associated with the rooffall level. Several of the bones, including the red-tailed hawk, the cottontail, and the coyote were recovered from just above the floor. The rest of the bones recovered in this room were unidentifiable scraps. No worked specimens were recovered from this room.

Room 6

Room 6 is a habitation room located in the south-central portion of the roomblock and is 2.95 m north/south by 1.8 m east/west, giving about 5.30 m^2 of interior space. It is in the back row of rooms and is located immediately to the south of Room 4 and to the west of Room 5. In general, the room was in good shape, with a minimal amount of disturbance. No roots or stumps were identified in the room, and the floor was in decent shape with about 50 percent of the floor intact. Three features were identified in this room: these include a doorway (Feature 11), a shallow plaster-lined pit (Feature 12), and a milling bin (Feature 13).

In this room, Stratum 1 was an approximately 10-cm-thick layer of post-occupational fill and consisted of the very loose and unconsolidated post-occupational fill. Stratum 2 was the general room fill, which contained an abundant amount of rubble wallfall and was about 25 to 30 cm thick. The Stratum was also loose and unconsolidated, and the bottom of Stratum 2 contained the abrupt contact with rooffall (Stratum 6). Rooffall in this room was abundant but was usually recovered in small fragments of adobe. As with the other rooms, Stratum 8 was the floor Stratum in this room. Table 64.21 shows the distribution of taxa by strata in Room 6.

Table 64.21. Room 6 faunal remains by Stratum.

TAXON	STRATUM NUMBER			
	1	6	6,7	TAXON TOTAL
Unidentified	4	1	1	6
Pocket gopher (*Thomomys* sp.)	1	0	0	1
Indeterminate rodents	1	0	0	1
Total	**6**	**1**	**1**	**8**

Of the 8 pieces of bone recovered from this room, only two were identified to the level of class. Identified remains are likely intrusive and include a single pocket gopher and indeterminate rodent bone. No worked bones were identified in this room.

Room 7

Room 7 is a habitation room located in the southeast corner of the roomblock and is 3.1 m north/south by 2.20 m east/west, giving about 6.82 m^2 of interior space. The north/south measurements and the overall interior floor space measurement are incomplete. This is due to the fact that Room 7 is the most southerly of the front rooms and was heavily impacted by the construction of NM 502. Based on the dimensions of the room, it is likely that construction just clipped the southern wall of the room, but it was not located during excavation. Room 7 is located immediately south of Room 5 and east of Room 8. In general, the remaining portion of the room was in fair shape. The south wall was gone, the floor was only present in about half of the room, and the remaining three walls were still upright. A significantly disturbed hearth (Feature 9) was identified in the center of the room. Like the other rooms discussed thus far, Room 7 contained four distinct strata: the post-occupational fill (Stratum 1), wallfall (Stratum 2), rooffall (Stratum 3), and the floor (Stratum 8). Additionally, the fill from the central hearth (Feature 9) was identified as Stratum 19. Table 64.22 shows the distribution of taxa by strata in Room 7.

Table 64.22. Room 7 faunal remains by Stratum.

TAXON	STRATUM NUMBER	TAXON TOTAL
	6,7	
Unidentified	6	6
Pocket gopher (*Thomomys* sp.)	1	1
Total	**7**	**7**

Of the seven pieces of bone recovered from this room, only one was identified to at least the level of class. The only piece of identifiable bone recovered from this room was a pocket gopher humerus. Based on the appearance of this specimen, the bone is likely intrusive and not related to the original occupation of the site. No worked bones were identified in this room.

Room 8

Room 8 is a habitation room located in the southwest corner of the roomblock and is 2.60 m north/south by 1.80 m east/west, giving about 4.68 m^2 of interior space. The north/south measurements and the overall interior floor space measurement are incomplete. This is due to the fact that Room 8 is the most southerly of the back rooms and, like Room 7, was heavily impacted by the construction of NM 502. Based on the dimensions of the room relative to other back rooms, it is likely that construction completely obliterated the southern wall of the room and it would have been an additional meter south of where our excavations ceased. Room 8 is located immediately south of Room 6 and west of Room 7. The remaining portion of Room 8 was in poor shape. The south wall was gone, the floor was non-existent, and the remaining three walls were semi-stable at best. No features were identified in the room. Like the other rooms discussed thus far, Room 7 contained four distinct strata: the post-occupational fill (Stratum 1), wallfall (Stratum 2), rooffall (Stratum 3), and the floor (Stratum 8). Table 64.23 shows the distribution of taxa by strata in Room 8.

Table 64.23. Room 8 faunal remains by Stratum.

TAXON	STRATUM NUMBER				
	1	6	6,7	12	TAXON TOTAL
Unidentified	2	0	1	0	3
Wood rat (*Neotoma* sp.)	0	0	0	1	1
Mule deer (*Odocoileus hemionus*)	0	1	0	0	1
TOTAL	**2**	**1**	**1**	**1**	**5**

Of the five pieces of bone recovered from this room, two were identified to at least the level of class. A single wood rat ulna and a mule deer naviculocuboid were recovered in this room. No worked bones were identified in this room.

Room 9

Room 9 is located immediately east of the roomblock and is adjacent to Rooms 2 and 5. Room 9 is a subterranean, circular kiva that was constructed into bedrock. The room measures 4.3 m north/south by 4.1 m east/west, giving about 17.63 m^2 of interior space, which is by far the largest of any of the rooms. In general, the kiva was in excellent shape. The floor was well preserved and was continuous across the entire surface of the kiva floor. The bedrock walls were in good condition, and the stacked masonry walls on top of the kiva were still present in the northeast and southern areas. Stratum 1 (post-occupational fill) and Stratum 2 (wallfall) were mechanically removed to the top of the rooffall layer (Stratum 15). The rooffall Stratum (15) was removed by hand to the floor of the kiva (Stratum 17). Nine features were identified in the kiva. These include two wall niches (Features 7 and 20), a floor niche (Feature 6), a ventilator shaft (Feature 14), an entryway between Rooms 5 and 9 (Feature 15), a collared and plaster-lined hearth (Feature 16, Stratum 20), an unplastered ash pit (Feature 17, Stratum 21), a sipapu (Feature 18), and a series of five holes and a groove between the ventilator shaft and the ash pit (Feature 19). Table 64.24 shows the distribution of taxa by strata in Room 9.

TOTAL	**21**	**71**	**81**	**69**	**242**

Room 9 had far more faunal remains than any other room at this site. Unidentified remains were the most abundant, followed by the intrusive pocket gophers, cottontails, rock squirrels, red-tailed hawk, mule deer, and a variety of other taxa (rodents, jackrabbit, carnivores, and turkey). The diversity of species was also the greatest in this room. This may be related to its use as a kiva, as there are more birds in this room than at the rest of the site, as well as other unusual taxa, including toads, skunk, and coyote remains. One bone bead was recovered from the wallfall Stratum in this room.

Faunal Remains Not Associated with a Specific Room

Sixty-four bones recovered at this site were from non-room contexts. Most of these bones were associated with the fill above rooms and were recovered before the designation of room numbers, or with the deposits just outside of the roomblock. Bones recovered from contexts such as these came from three strata: Stratum 0 was the surface, Stratum 1 was the loose, post-occupational fill that was found just below the surface across the entire site, and Stratum 2 was the wallfall layer associated with the roomblock before rooms were designated. Many of these bones came from the excavations undertaken in the western portion of Area 1 before the location of the actual roomblock. Table 64.25 shows the distribution of faunal remains recovered from these deposits.

Table 64.25. Faunal remains from outside rooms.

TAXON	STRATUM NUMBER			TAXON TOTAL
	0	1	2	
Unidentified	1	19	28	48
Turkey	0	1	0	1
Indeterminate rodent	1	1	0	2
Pocket gopher	0	1	1	2
Kangaroo rat	0	1	1	2
Wood rat	0	0	1	1
Cottontail	0	1	1	2
Striped skunk	0	1	0	1
Mule deer	0	0	5	5
Med/large mammal	0	1	0	1
TOTAL	**2**	**26**	**37**	**65**

As in the individual rooms, the distribution of remains are heavily weighted toward unidentified remains, but also include turkey, mule deer, cottontails, and rodents. Based on their distinctive appearance, the pocket gopher are likely intrusive and therefore insignificant.

Heavy Fraction

A total of 142 pieces of bone were recovered from flotation samples taken from the hearths in Rooms 1, 2, 5, and 9 (Features 4, 2, 5 and 16). The majority of these bones appear to be modern in origin based on their distinct appearance and level of completeness, but many do show signs of burning and could have been introduced to the assemblage during the use-life of the hearth. This is especially true of the rodent remains (indeterminate rodent, pocket gopher, and deer mice), but may also be true for the small mammal and cottontail remains as well. Table 64.26 shows the taxa that were identified in the heavy fraction assemblage from the habitation and kiva hearths.

Table 64.26. Identified faunal remains in heavy fraction samples from hearths at LA 86534.

Common Name	Scientific Name	2 (Room 2 hearth)	4 (Room 1 hearth)	5 (Room 5 hearth)	16 (Kiva hearth)
Pelobatidae	Spadefoot toads				x
Indeterminate rodent	Rodentia		x	x	x
Deer mouse*	*Peromyscus* sp.			x	
Pocket gopher*	*Thomomys* sp.	x	x		x
Desert cottontail	*Sylvilagus audubonii*		x		x
Sm mammals	Sm mammals	x	x		x
Sm/med mammals	Sm/med mammals		x		x
Unidentified	Unidentified	x	x	x	x

x = present. *probably intrusive. Note: No faunal remains were identified during excavation in any of the hearths; all remains were recovered in flotation samples.

Based on the remains recovered and identified in the heavy fraction hearths, it does not appear that habitation hearths differ from the hearth in the kiva. The only taxon identified in the kiva hearth (Feature 16) that was not identified in the habitation hearths was spadefoot toad. The toad remains were most likely deposited in a post-occupational episode as they were fairly complete, unburned (when most of the other materials in the hearths were burned, even rodent remains), and showed signs of recent breaks.

Resource Exploitation, Land Use, and Lagomorph and Artiodactyl Indices at LA 86534

Several species of animals that have been of great economic importance throughout the prehistoric sequence in the Southwest are lagomorphs (jackrabbits and cottontails) and artiodactyls (white tail and mule deer, bighorn sheep, and pronghorn). Because of their consistent presence in prehistoric assemblages, researchers have derived indices to gauge the relative importance of large and small game to each other and to other taxa. Table 64.27 presents the data used in calculating the lagomorph and artiodactyl indices at LA 86534.

Table 64.27. Quantity of Sylvilagus, Lagomorph, and Artiodactyl remains from LA 86534.

Number of Cottontails	Number of all Lagomorphs	Number of Artiodactyls	Lagomorph Index	Artiodactyl Index
33	39	19	0.85	0.33

The lagomorph index is the ratio of the quantity of cottontail remains to the sum of all lagomorph remains (see LA 12587 discussion section for additional information on the significance of these indices). The high lagomorph index (0.87) at LA 86534 suggests that the exploitation of cottontails was quite important to its inhabitants. This is likely a reflection of the fairly effortless access to both the open woodland environment on the nearby mesa tops (favorable jackrabbit habitat) and the more brushy, wooded areas (favorable cottontail habitat) in the canyon bottoms.

The artiodactyl index is the ratio of artiodactyl remains divided by the sum of artiodactyl and lagomorph remains. Artiodactyl indices throughout the Southwest vary primarily as a function of site location. Sites in upland areas typically have indices above 0.30 to 0.35 (Szuter and Bayham 1996). In contrast, lower elevation sites typically have artiodactyl indices below 0.10. The artiodactyl index of 0.33 at LA 86534 supports this trend and suggests that artiodactyl exploitation was important. It is also likely that artiodactyls may not have been as important in terms of contributions to total dietary significance as lagomorphs, but they did comprise a significant portion of the diet. The decreased abundance of artiodactyls may reflect a natural scarcity of large game in the surrounding areas during the later part of the Coalition period, or it may reflect the exploitation of relatively easier to capture small game. Either scenario documents the use of a number of biotic communities including the riparian areas of the nearby canyons, the woodland areas of the mesa tops and ridges, and the transitional areas in between. The use of these zones suggests movement across the landscape and concomitant exploitation of the available resources in each biome. This, combined with the high percentage of maize remains recovered in the botanical assemblage, suggests that a mixed farming-foraging economy was in place during the Coalition period on the Pajarito Plateau.

LA 135290 (Roomblock)

In general, the overall preservation of the bones from LA 135290 is good. For the most part, bones tended to be in large fragments, and a number of complete elements were identified. Weathering on the faunal remains was present, although the frequency and severity was low (n = 2), suggesting the remains may not have been exposed to the elements for a long period of time before deposition. The bones show minimal evidence of root-etching and rodent gnawing, but no evidence of carnivore gnawing or carnivore-digestion. Modifications resulting from burning were present on 23 pieces of bone, constituting some 35 percent of the total assemblage. One piece of bone recovered at LA 135290 was heavily polished.

Of the 65 faunal remains recovered from the excavations at LA 135290, 52 percent (n = 34) were identified to at least the level of class. The 34 identified remains were recovered from a variety of contexts. Table 64.28 shows all the taxa that were recovered from the site. Because the most abundant taxa represented in the assemblage were intrusive pocket gophers (*Thomomys* sp.), Table 64.29 presents the same data with this taxon removed. Pocket gopher burrows were extensive in the immediate site area, and the visual appearance of their bones was quite distinct from the vast majority of the other bones recovered from the site.

Table 64.28. Identified faunal remains from all contexts at LA 135290.

With the intrusive pocket gopher remains removed from calculations (see Tables 64.28 and Table 64.29), the two most frequently recovered taxa (18%) are cottontail (*Sylvilagus* sp.) and mule deer (*Odocoileus hemionus*). After these taxa, turkeys (*Meleagris gallopavo*), rock squirrels (*Spermophilus variegatus*), and black-tailed jackrabbit (*Lepus californicus*) each comprise 13 percent of the identified assemblage. The remainder of the assemblage consists of a wide variety of taxa, including amphibians, reptiles, rodents, and carnivores. The variation present in the assemblage attests to its location near a number of distinct biomes.

Because the basic unit of analysis at LA 135290 was the room, faunal remains were analyzed by individual room. Faunal remains were recovered from six of the nine rooms. Tables 64.30 through 64.35 show the breakdown of recovered bones from each room. Numbers of identified specimens from the individual rooms are not high, but are fairly consistent. Faunal remains recovered from fill contexts are briefly discussed after the material from each of the rooms is presented.

Room 1

Room 1 is a habitation room located in the north-central portion of the roomblock. The room measures 3.8 m north/south by 3.5 m east/west, with 13.30 m^2 of interior space. After the removal of about 20 cm of post-occupational fill (Strata 1 and 2), the remainder of the room contained approximately 70 to 80 cm of Stratum 4. This was a silty clay loam soil mixed with wallfall and some adobe melt. Wallfall was generally present within 1 to 2 m of standing masonry walls, and adobe melt adjacent to the adobe western wall; whereas, the center of room contained a few small pieces of tuff with little adobe melt. The room fill had been disturbed by rodent activity, although this disturbance appears to increase with depth. On the other hand, there were fewer tuff blocks with an increase in small tuff fragments and adobe melt with depth. The lower 20 cm of room fill (Stratum 4b) exhibited an increase in the amount of charcoal, charred maize kernels, and artifacts.

The floor (Stratum 9) was heavily disturbed by rodent activity, with only about 10 percent of the surface being intact. These small intact sections were primarily situated in the northern areas of the room, consisting of a 5- to 7-cm-thick layer of adobe. The floor was defined by the presence of a burned and/or prepared adobe surface. Several pockets of ash were noted on or immediately above the level of the floor.

Four pieces of bone were recovered in Room 1. These included two medium/large-sized mammal long-bone shaft fragments, an intrusive pocket gopher cranium from level six, and a proximal turkey humerus. None of the remains were burned, and all contained recent breaks. Table 64.30 shows the bones recovered by individual Stratum in this room.

Table 64.30. Room 1 faunal remains by Stratum.

Unidentified med/lg mammal	2	2
Turkey (*Meleagris gallopavo*)	1	1
Pocket gopher (*Thomomys* sp.)	1	1
Total	**4**	**4**

Room 2

Room 2 is located in the east-central section of the roomblock. The room measures 4.4 m north/south by 3.5 m east/west, with 14.66 m^2 of interior space. An east-west test trench (93N/108-112E) was also excavated through the room to define site stratigraphy and the location of the floor. After the removal of about 5 to 15 cm of post-occupational fill (Strata 1 and 2), the remainder of the room contained a mix of Strata 3 and 4 that was 50 to 70 cm thick. Stratum 3 was a clay loam soil that was mostly situated in the western area of the room adjacent to the adobe wall, whereas Stratum 4 was a silty clay loam mixed with wall, some adobe melt, and possible roofing material (Stratum 19). The wallfall was primarily situated adjacent to the masonry northern and eastern walls, with little near the adobe western and masonry southern walls. There was a notable increase in the density of ceramics in the northeast area of the room.

Stratum 19 was identified in the central area of the room. The deposit was 5 to 10 cm thick consisting of burned chunks of adobe mixed with charcoal in grids 93N/110-112E. This material was situated on the floor and had burned this section of the floor. It presumably represents burned roofing material.

Floor 1 (Stratum 5) was first encountered in the southeastern corner of the room where there was obvious coping to the wall. The floor is very patchy due to extensive rodent disturbance, but does cover about two-thirds of the room. Most of the floor is not burned, although there is extensive burning in the central area of the room where the floor plaster is ashy and black sooted in some spots. Although the floor consists of a relatively thick 3- to 5-cm layer of adobe, it has collapsed in many sections of the room due to rodent burrows. Manganese staining is also present in some parts of the floor adjacent to the walls. Adobe coping can be found in about 90 percent of areas where the walls articulate with the floor. Nine features were identified on the floor. These consist of a collared hearth, three adobe lined pits (Stratum 32), two adjacent hearths, and three post holes. A sub-floor test pit (Stratum 43) was also excavated in this room. Table 64.31 shows the bones recovered by individual Stratum in this room.

Table 64.31. Room 2 faunal remains by Stratum.

TAXON	STRATUM NUMBER				TAXON TOTAL
	3,4	4	32	43	
Unidentified	2	11	0	0	13
Western box turtle (*Terrapene ornata*)	0	1	0	0	1
Woodrat (*Neotoma* sp.)	0	1	0	0	1
Pocket gopher (*Thomomys* sp.)	0	1	0	7	8
Rock squirrel (*Spermophilus variegatus*)	0	1	1	0	2
Cottontail (*Sylvilagus* sp.)	1	0	1	0	2
Total	**3**	**15**	**2**	**7**	**27**

As in Room 1, the faunal remains recovered in Room 2 are representative of the relative site distribution. Unidentified remains were the most abundant, followed by pocket gophers and then western box turtle, woodrat, and cottontail remains. No worked bones were identified in this room.

Room 3

Room 3 is located at the southeastern corner of the roomblock. It measures 4.0 m north/south by 3.15 m east/west, with 12.60 m^2 of interior space. Excavations proceeded from north to south in the room by grid and natural layer. The floor was exposed and a subfloor test pit (87N/110E) dug in the southeastern area of the room. After the removal of a 5- to 15-cm layer of post-occupational fill (Strata 1 and 2), most of the room fill consisted of Stratum 4a deposits. This layer consisted of wallfall with a little charcoal. In the northern part of the room it was about 30 to 40 cm thick, whereas in the southern section of the room it was only 10 to 15 cm thick. Most of the rubble was situated in the south-central part of the room with some along the north and west walls. Stratum 3b was a 5- to 10-cm-thick layer overlying the fill. This deposit exhibited a marked increase in the presence of artifacts and charcoal, without tuff rubble.

The floor (Stratum 11) in Room 3 was poorly preserved. Indeed, it was not a plastered surface as in Rooms 1 and 2, but rather a compacted living surface. The floor was defined as the surface directly underlying Stratum 4a/3b and in some areas having small burned patches. In the northern area of the room there were some sections where horizontal layers flaked off fairly easily to reveal the surface. However, these layers were continuous in other areas of the room possibly reflecting multiple fine clay lenses of washed adobe from the nearby walls. There is no evidence of the floor being coped to the walls. Table 64.32 shows the bones recovered by individual Stratum in this room.

Table 64.32. Room 3 faunal remains by Stratum.

TAXON	STRATUM NUMBER		TAXON TOTAL
	3	4	
Bullfrog (*Rana catesbeiana*)	0	1	1
Turkey (*Meleagris gallopavo*)	2	0	2
Pocket gopher (*Thomomys* sp.)	0	2	2
Jackrabbit (*Lepus californicus*)	0	1	1
Total	**2**	**4**	**6**

Of the six pieces of bone recovered from this room, all were identified to at least the level of class. Identified remains include a single bullfrog and turkey bone, two (likely intrusive) pocket gopher bones, and a single jackrabbit specimen. Only the jackrabbit bone was burned, and no worked bones were identified.

Room 5

Room 5 is located in the northwestern area of the roomblock. It measures 2.25 m north/south by 2.15 m east/west, with 4.83 m^2 of interior space. An east-west test trench (98N/107-109E) was excavated through the room to define site stratigraphy and the location of the floor. The excavation proceeded by removing the room fill by grid and natural layer to the south of the trench. After the removal of a 10-cm-thick layer of post-occupational fill (Strata 1 and 2), most of the room fill consisted of 40 to 50 cm of Stratum 3, with some Stratum 4. Stratum 4a/4b was situated adjacent to the east wall of the room. In contrast, Stratum 3a was situated in the western area of the room and Stratum 3c adjacent to the base of the walls.

Two separate floors were identified in Room 5. Floor 2 (Stratum 42 and 49) is the lowest and original floor, being equivalent to Floor 3 in Room 4. Both rooms were connected as a single room during this period, measuring 4.40 by 2.15 m in size and containing 9.46 m^2 in area. This is similar to the adjacent back room (Room 6) that contains 9.78 m^2 of space. Floor 2 was constructed by placing down a layer of adobe, on top of which was placed a thin layer of plaster. Floor 1 (Stratum 21 and 41) is very well preserved and covers the entire room, although the surface is eroded. Table 64.33 shows the bones recovered by individual Stratum in this room.

Table 64.33. Room 5 faunal remains by Stratum.

TAXON	STRATUM NUMBER		TAXON TOTAL
	3	41	
Unidentified	4	0	4
Mule deer (*Odocoileus hemionus*)	0	1	1
Total	**4**	**1**	**5**

Only a single piece of bone in this room was identified to at least the level of class. This specimen was a basal antler fragment from a mule deer. It was neither burned nor modified.

Room 6

Room 6 is located in the southwest area of the roomblock. It measures 1.75 m north/south by 1.75 m east/west, with 3.06 m^2 of interior space. An east-west test trench (93N/106-108E) was also excavated through the room to define site stratigraphy and the location of the floor. The excavation proceeded by first removing the fill to the north of the trench and then to the south by grid and natural layer. After the removal of a 10-cm-thick layer of post-occupational fill (Strata 1 and 2), most of the room fill consisted of 30 to 40 cm of Stratum 3. Stratum 4 was only defined in a small area in the south part of the room. Three distinct floors were identified in Room 6, and Floor 3 contained 15 possible postholes. Table 64.34 shows the bones recovered by individual Stratum in this room.

Table 64.34. Room 6 faunal remains by Stratum.

TAXON	STRATUM NUMBER	TAXON TOTAL
	3	
Mule deer (*Odocoileus hemionus*)	2	2
Total	**2**	**2**

Two pieces of mule deer bone were recovered in this room. Although the specimens of the metapodial could not be refit, it is likely they came from the same original element. Both contained modern breaks, both were uniformly burned, and both were from the distal end of the bone. No modified bones were recovered from this room.

Room 9

Room 9 is located in the southeastern corner of the roomblock. It is divided into northern (9A) and southern (9B) halves. The entire room measures 4.6 m north/south by 2.8 m east/west, with 11.48 m^2 of interior space. However, a dividing wall separates the room into two small areas with 7.28 m^2 and 3.96 m^2 of floor space, respectively. The fill consists of a thin 5 cm layer of Stratum 1, with 10 to 20 cm of Stratum 4 underlain with 5 to 15 cm of Stratum 3. In Room 9A the lower circa 10 cm contained a large amount of charcoal. This concentration of charcoal was missing from Room 9B. There is no prepared adobe floor in Room 9. The floor simply consists of a compacted living surface in both Room 9A (Stratum 38) and 9B (Stratum 39). The living surface was identified as a partially preserved layer of hardened adobe/sediment. Table 64.35 shows the bones recovered by individual Stratum in this room.

Table 64.35. Room 9 faunal remains by Stratum.

TAXON	STRATUM NUMBER		TAXON TOTAL
	3	4	
Unidentified sm/med mammal	1	0	1
Rock squirrel (*Spermophilus variegatus*)	1	0	1
Pocket gopher (*Thomomys* sp.)	0	1	1
Raccoon (*Procyon lotor*)	0	1	1
Mule deer (*Odocoileus hemionus*)	0	1	1
Total	**2**	**3**	**5**

Five pieces of bone were recovered in Room 9, and all were identified to at least the level of class. Identified elements include a small-medium sized mammal long-bone shaft fragment, an intrusive pocket gopher mandible from level three, a proximal rock squirrel femur, a proximal raccoon ulna, and a mule deer second phalanx. The unidentified fragment, which was also highly polished, and the rock squirrel femur were burned.

Faunal Remains Not Associated with a Specific Room

Sixteen bones recovered at this were from non-room contexts. Most of these bones were associated with the fill above rooms and were recovered before the designation of room numbers, or with the deposits just outside of the roomblock, especially in the plaza area (Area 2). Table 64.36 shows the distribution of faunal remains recovered from these deposits.

Table 64.36. Faunal remains from outside rooms.

Rendija Tract

A total of 27 sites were excavated between 2003 and 2005 in Rendija Canyon (see Figure 13.3). Faunal remains were recovered at 15 of these sites, which included a homestead (LA 85407), two Late Coalition/Early Classic period fieldhouses (LA 85404 and LA 85861), nine Classic period fieldhouses (LA 85408, LA 85411, LA 85413, LA 85414, LA 85867, LA 86605, LA 86606, LA 127627, and LA 135292), an Early Archaic period lithic scatter (LA 85859), and two Jicarilla Apache rock ring sites (LA 85864 and LA 85869).

LA 85404 (Late Coalition/Early Classic Period Fieldhouse)

One piece of bone was recovered from Room 1 (Stratum 2, Level 3) of this Late Coalition/Early Classic period fieldhouse. The bone was a mule deer (*Odocoileus hemionus*) distal metatarsal fragment (right) and was also manufactured into a partial fragment of a bone awl. The bone was unburned, but contained a possible cut-mark just above the epiphyseal fusion. The mark did not appear to be recent and was probably not incurred during excavation activities.

LA 85407 (Serna Homestead)

Twenty-seven pieces of bone were recovered during excavations at LA 85407. The site consists of the remains of a historic log cabin and various features in the surrounding area.

Cabin (Area 1)

The cabin was divided into Rooms 1 and 2. Ten bones were recovered in Room 1 and included one unfused kangaroo rat (*Dipodomys* sp.) femur, a fragment of a mule deer (*Odocoileus hemionus*) rib, a horn fragment from a domestic cow (*Bos taurus*), a fragment of an elk (*Cervus elaphus*) thoracic vertebra, two medium/large-sized mammal bones (one burned), two large-sized mammal rib fragments that both contained butcher saw marks, one large-sized mammal unidentified burned bone, and one unidentified piece of unburned bone.

Four bones were identified in the fill around the cabin and included a complete human premolar, a burned unidentified medium/large-sized mammal bone, an unidentified large-sized mammal bone, and a large-sized mammal rib that contained evidence for butchery from a large saw.

Horno (Area 3)

Three bones were identified in the area around the horno, but no bones were recovered directly from the feature fill. Analyzed bones included one medium/large-sized mammal bone fragment and two domestic cow vertebral body fragments. None of the bones were burned, and all contained evidence for old breaks.

Area 4 (Feature 2, Circular Rock Alignment)

Feature 2 was a small rock feature (Figure 12) located approximately 14 m south of the western end of the cabin. Before excavation, the feature appeared to be a small, circular concentration of rocks. The feature was excavated because it was believed to be the remains of a privy. The entire extant portion of the feature was excavated in four 1- by 1-m grid units (45-46N/91-92E). The excavations revealed that the feature was a circular rock alignment. One bone was recovered from the circular alignment and it was identified as a fragment of a domestic cow axis vertebra. It was not burned, but did contain evidence for some butchering activities.

Shed (Area 5, Room 3)

Room 3 is the remains of a wood structure located approximately 21.5 m north-northeast of the cabin. Two large wood beams were the only remains of this structure visible on the surface before excavation. These wood beams appear to have been part of the structure's south wall. Room 3 is most likely the pole shed described in Homestead Entry Survey No. 394 (see Chapter 32, Volume 2). Six bones were recovered from this feature and included one unidentified bone, one blue grouse axis vertebra (*Dendragapus obscurus*), a domestic goat (*Capra hircus*) cervical vertebra and rib fragment, and a domestic cow distal metatarsal fragment. None of these bones were burned or otherwise altered.

Corral (Area 6, Feature 3)

Feature 3 is the remains of a corral located approximately 14 m northeast of the shed. Two bones were identified in the feature: one was an unidentified small/medium-sized mammal bone and one was a medium/large-sized mammal bone fragment.

LA 85408 (Classic Period Fieldhouse)

One piece of bone was recovered from 107N/105E (Stratum 2, Level 2) from this Classic period fieldhouse. The bone was an unidentified piece of medium/large-sized mammal bone. The bone was unburned and contained an old break.

LA 85411 (Classic Period Fieldhouse)

Four pieces of bone were recovered during excavations of this Classic period fieldhouse. One bone was recovered in 104N/106E and was identified as a fragment of a mule deer (*Odocoileus hemionus*) atlas vertebra. Three bones were identified in 105N/106E and were all identified as part of a mule deer sacrum. None of the bones were burned and the pieces of the sacrum all contained recent breaks suggesting these bones may have come from a single animal.

LA 85413 (Classic Period Fieldhouse)

Twelve pieces of bone were recovered during excavations of this Classic period fieldhouse. The majority of the bones were recovered in Stratum 2 (post-occupational fill), but two bones were identified in Stratum 5, which was the living surface identified in the fieldhouse. The bones on the living surface were unidentified to the level of class and were both heavily calcined. The bones identified in Stratum 2 included two pocket gopher (*Thomomys* sp.) elements (right humerus, left mandible), five mule deer (*Odocoileus hemionus*) bones, one small/medium-sized mammal remain, one medium/large-sized mammal remain, and one unidentified remain. The mule deer elements included three rib fragments, one right calcaneus, and one right astragalus. None of the bones were burned.

LA 85414 (Classic Period Fieldhouse)

One piece of bone was recovered during excavations of this Classic period fieldhouse. The bone was recovered in 102N/105E and was identified as a fragment of the proximal metacarpal of a mule deer (*Odocoileus hemionus*). The bone was identified as a possible awl, but was definitely shaped and polished. The bone was not burned.

LA 85859 (Archaic Period Lithic Scatter)

Fourteen pieces of bone were recovered from this Early Archaic period lithic scatter. All of the bones were modern, and all were identified as pocket gopher (*Thomomys bottae*) remains. None of the bones were burned, and none showed signs of weathering. Bones were recovered throughout the excavated levels.

LA 85861 (Late Coalition/Early Classic Period Fieldhouse)

Five pieces of bone were recovered during excavations of this Late Coalition/Early Classic period fieldhouse. One piece of bone was recovered from Stratum 2 (post-occupational fill). This bone was identified as an unidentified mule deer (*Odocoileus hemionus*) second phalanx. The remaining four bones were recovered from a hearth (Feature 1, Stratum 4) and included a leporid molar and small-sized, small/medium-sized, and medium/large-sized mammal long-bone fragments. None of the remains were burned. The medium/large-sized mammal long-bone fragment was manufactured into an awl fragment.

LA 85864 (Jicarilla Rock Ring)

Four unidentified pieces of bone (FS 11) were recovered from this Jicarilla Apache rock ring. The bones were heavily burned (calcined) and were recovered in Stratum 3, Level 4 in Feature 2.

LA 85867 (Classic Period Fieldhouse)

One piece of bone was recovered during excavations of this Classic period fieldhouse. The bone was identified as an unburned rib fragment from an elk (*Cervus elaphus*) and was recovered in the post-occupational fill level (102N/102E).

LA 85869 (Jicarilla Rock Ring)

One elk (*Cervus elaphus*) scapula (FS 161) was recovered from the surface of this Jicarilla Apache rock ring. The bone was broken into three distinct pieces, was not burned and slightly weathered, and was likely from the recent death of an elk in the area. In addition, two small, unidentified mammal fragments were recovered from inside the tipi ring. These appear to be modern, and their sun-bleached appearance suggests they have been near the surface for some time.

LA 86605 (Classic Period Fieldhouse)

One piece of bone was recovered from Room 1 (Stratum 2, Level 5) of this Classic period fieldhouse. The bone was a mule deer (*Odocoileus hemionus*) distal humerus (right) that was fairly weathered and may have been exposed to the elements for quite some time before deposition. The bone was unburned and its location in the fieldhouse was point-plotted (103.35N/102.72E).

LA 86606 (Classic Period Fieldhouse)

One piece of bone was recovered during excavations of this Classic period fieldhouse. The bone was identified as a heavily burned medium/large-sized mammal long-bone fragment and was recovered in the post-occupational fill level (102N/104E).

LA 127627 (Classic Period Fieldhouse)

Two pieces of unidentified bone were recovered from this Classic period fieldhouse. The bones were both recovered from the same unit (103N/107E), both were burned, and both were very small. Both pieces of bone were recovered from the fill of the fieldhouse, and both contained old breaks.

LA 135292 (Classic Period Fieldhouse)

One piece of unidentified bone was recovered from this Classic period fieldhouse in Rendija Canyon. The bone was recovered from unit 102N/103E, was heavily burned, and was a very small fragment of cancellous bone. The bone was recovered from the upper fill of the fieldhouse and contained an old break.

TA-74 Tract

LA 110126 (Classic Period Fieldhouse)

One unidentified piece of bone (FS 5) was recovered from this Classic period fieldhouse. The bone was not burned and unmodified and came from Stratum 3 (20 to 30 cm).

LA 117883 (Archaic Period Lithic Scatter)

Five pieces of bone were recovered from this Archaic period lithic scatter. One piece of bone showed signs of burning (unidentified), but no other modifications were noted. All recovered bones came from Test Pit 2. Three unidentified bones came from 60 to 70 cm, 70 to 80 cm, and 80 to 90 cm. An unidentified medium/large-sized mammal long-bone fragment was recovered from Level 6, and a juvenile rock squirrel (*Spermophilus variegatus*) cervical vertebra was found between 80 and 90 cm.

LA 21596B (Classic Period Grid Garden)

Four pieces of bone were recovered from this Classic period grid garden. Two of the bones were unidentified and two were identified as cottontail (*Sylvilagus* sp.) remains. None of the bones were burned, and all were modified by the elements as they were found on the surface. The cottontail remains include the proximal and distal ends of a left humerus. It is likely that the fragments hailed from the same element/animal, but they could not be confidently refit. It is probable, based on the sun-bleached appearance of the specimens, that the bones were not associated with the prehistoric use of the site.

White Rock Y Tract

LA 61035 (Coalition/Classic Period Lithic and Ceramic Scatter)

Seven pieces of bone were recovered from this Coalition/Classic period lithic and ceramic artifact scatter. All of the bones were unidentifiable, and only a single bone was burned. No other modifications were present on any of the faunal remains.

CHRONOMETRIC ASSEMBLAGE GROUPS

Faunal remains from a number of different temporal periods were analyzed as part of the C&T Project. Sites include two Archaic period lithic scatters (LA 85859 and LA 117883), three Coalition period roomblocks (LA 12587, LA 86534, and LA 135290), one Ceramic period artifact scatter (LA 61035), three Late Coalition/Early Classic period fieldhouses (LA 85404, LA 85861, and LA 127631), 10 Classic period fieldhouses (LA 85408, LA 85411, LA 85413, LA 85414, LA 85867, LA 86605, LA 86606, LA 127627, LA 110126, and LA 135292), one Classic period grid garden (LA 21596B), two Jicarilla Apache rock ring sites (LA 85864 and LA 85869), and one homestead (LA 85407). Faunal assemblages from two other Coalition period roomblocks (LA 4618 and LA 4624) that were previously excavated by LANL personnel were also analyzed.

Archaic Period

Two Archaic period lithic scatters produced faunal remains. Fourteen pieces of bone were recovered from LA 85859, an Early Archaic period lithic scatter in the Rendija Tract, but all of the bones were modern and identified as pocket gopher (*Thomomys bottae*) remains. None of the bones were burned, and none showed signs of weathering. Bones were recovered throughout the excavated levels. Five pieces of bone were recovered from LA 117883, an Archaic period lithic scatter in TA-74. One piece of bone showed signs of burning (unidentified), but no other modifications were noted. All recovered bones came from Test Pit 2. An unidentified medium/large-sized mammal long-bone fragment was recovered as was a juvenile rock squirrel (*Spermophilus variegatus*) cervical vertebra.

Coalition Period Roomblocks

During the Coalition period (AD 1150–1325), the population of the Pajarito Plateau increased dramatically (Kohler 2004; Powers and Orcutt 1999b; Vierra et al. 2002). Relative to the preceding Developmental period (AD 600–1150), there was a substantial increase in the number, size, and distribution of above-ground pueblos (Vierra 2002). The increase of year-round settlements across the Pajarito Plateau substantially decreased the amount of arable land available to its inhabitants. Without a doubt, the dramatic increase in crop production during the Coalition period increased the production of a stable resource thereby reducing some of the nutritional stresses. But, the production of maize and other domesticates also altered the natural landscape and, in doing so, decreased the areas where wild foods were collected.

To examine the subsistence changes associated with the increase in crop production during the Coalition period, faunal remains from five excavated roomblocks (LA 4618, LA 4624, LA 12587, LA 86534, and LA 135290) were analyzed. Macrobotanical and pollen remains were also recovered and analyzed (Chapters 62 and 63, this volume). The macrobotanical and pollen results are summarized briefly after the faunal remains are discussed. Three sites (LA 12587, LA 86534, and LA 135290) were excavated as part of the C&T Project and were summarized earlier in this chapter. The other two sites (LA 4618 and LA 4624) were excavated in the early 1990s (Vierra et al. 2002; Schmidt 2006b). Based on ceramic assemblages recovered from each of the roomblocks (Chapter 58, this volume), the sites have been separated into Early Coalition (LA 4624), Middle Coalition (LA 86534 and LA 135290), and Late Coalition (LA 4618 and LA 12587) period samples. Chronometric dates support these temporal groupings (Chapter 69, this volume).

Data recovery activities were conducted at LA 4618 and LA 4624 in the early 1990s. LA 4624 (Figure 64.1, right) is a 25-room pueblo that is located approximately 500 m southeast of LA 4618. Excavations at LA 4624 were conducted in both habitation rooms and communal structures, and seven of the 25 rooms were partially or completely excavated. No midden deposits were identified. LA 4618 (Figure 64.1, left), a 13-room linear roomblock with both a circular and a square kiva, was excavated in 1991 and 1992. The site has a large and highly diverse artifact assemblage relative to the other sites in this sample. LA 4618 was completely excavated, and a small midden deposit was located east of the roomblock.

Table 64.37 shows the NISP from each roomblock site, the percentage of the identified remains that each taxon comprised, the total number of bones from each site, and the number of taxa identified at each site.

Of the five Coalition period sites, LA 4618 had the largest assemblage (*n* = 880). The LA 4618 assemblage also had the largest percentage of turkey remains, which constituted over 58 percent of the NISP assemblage (Table 64.37). Although it was the largest assemblage, it was not the most diverse assemblage and contained only 10 identified taxa. The LA 4618 assemblage contained the highest number of worked remains, with 15 bone awls, pendants, needles, and flutes, and over 800 bones beads (Figures 64.2 through 64.4), which were not included as part of the total site assemblage (Schmidt 2006b). Additionally, nearly 30 individual specimens and three partial turkey skeletons were recovered from floor contexts.

Figure 64.2. Bone awls from LA 4618.

Unlike the large assemblage from LA 4618, the LA 4624 excavations produced a very small collection of bones (*n* = 109), most of which were recovered from post-occupational fill (Schmidt 2002). Only four bones were associated with floor contexts at LA 4624, and all were unidentifiable to taxon. Despite the low NISP at this site, however, seven taxa were identified.

A total of 559 bones were recovered during excavations at LA 12587. Most of these were recovered from post-occupational and room fill, although only a single piece of cottontail (*Sylvilagus audubonii*) bone was recovered from the floor. The LA 12587 assemblage was the most diverse of any of the sites, with 14 identified taxa, and was one of three assemblages dominated by turkey and large bird remains, which comprised nearly 35 percent of the identified assemblage. Over 20 pieces of worked bone, including awls, needles, and flutes, and a large number of bone beads, were recovered.

Figure 64.3. Bone flute fragment from LA 4618.

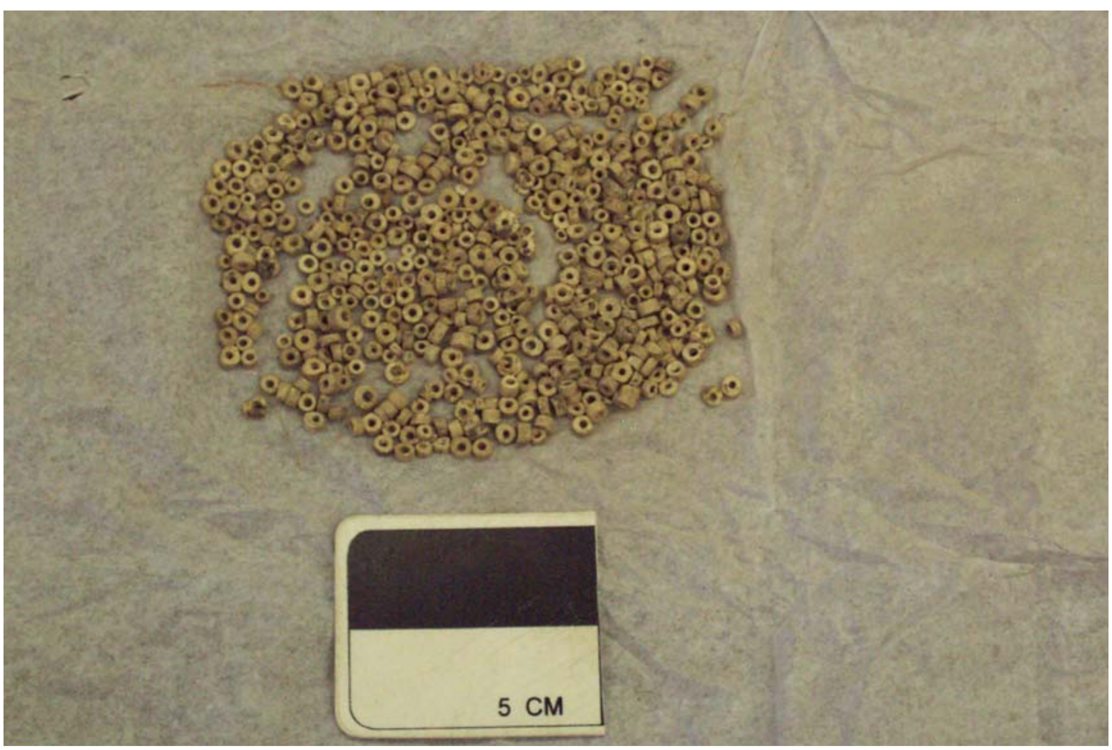

Figure 64.4. A sample of the bone beads from LA 4618.

The LA 86534 faunal assemblage was relatively small compared to the other roomblock sites, with only 322 bones recovered. Most of these bones were recovered from post-occupational fill, room fill, and kiva fill, although three pieces of bone were recovered from the floor of Room 5. Bones recovered from the floor of Room 5 include a cottontail (*Sylvilagus audubonii*) vertebra fragment, a red-tailed hawk (*Buteo jamaicensis*) coracoid, and a piece of unidentified material. The LA 86534 faunal remains were similar to the LA 12587 assemblage in terms of diversity, with 13 identified taxa. Relative to the other four sites, the LA 86534 assemblage contained the fewest turkey (*Meleagris gallopavo*) remains, comprising only three percent of the identified assemblage. But, despite the low percentage of turkey remains in the assemblage, the variety of bird taxa (n = 5) was greater than at any other site. Two bone awl fragments were recovered, but no beads were identified.

Excavations at LA 135290 produced the smallest assemblage with only 48 faunal remains, most of which were recovered from post-occupational and room fill. Of the sites discussed here, LA 135290 had one of the least diverse assemblages, which is not necessarily unexpected given the small sample size, but it had a higher percentage of deer and rabbits relative to the later assemblages, which were dominated by turkey and large bird remains. No worked bones were recovered at this site.

The faunal remains recovered from the Coalition period roomblocks are compared in Table 64.37. In general, these data do not show an increase in taxonomic diversity through time and, with the exception of LA 4618, the differences among the assemblages appear to be a function of sample size. Rabbits (Leporidae), turkeys (*Meleagris gallopavo*), and artiodactyl (Artiodactyla) remains are present at all sites regardless of time period. Turkey and large bird remains are more abundant than all other taxa at all sites except for those from the Middle Coalition period where mule deer (*Odocoileus hemionus*) are more abundant. Artiodactyl taxa are represented by mule deer and pronghorn (*Antilocapra americana*) remains, with small numbers of pronghorn identified at LA 4624 and LA 12587. In general, mule deer remains are more abundant than leporid remains (jackrabbit and cottontail rabbit) at each of the sites, which is unusual for faunal assemblages from the southwestern United States. Overall, Table 64.37 shows that NISP values for artiodactyls were consistent throughout the Coalition period, suggesting that even as populations were increasing, animal resources near the habitation locales were not exhausted.

Turkey remains, although identified in each of the roomblock assemblages, increase dramatically in the Late Coalition period assemblages. At LA 4624, turkey remains make up only six percent of the assemblage. At the Middle Coalition period sites (LA 86534 and LA 135290), their overall percent of the identified remains drops to less than five percent. At the Late Coalition period sites (LA 12587 and LA 4618), however, the percentage of turkey remains increases to 25 percent and 60 percent of the identified remains, respectively. Amphibian and carnivore remains increase during the course of the Coalition period, while the diversity of bird remains decreases through time. The ubiquity of a single animal taxon (turkey) increases dramatically throughout the course of the Coalition period, while the NISP contribution of wild taxa remains virtually unchanged or varies slightly among different taxa.

Because the diet of Coalition period occupants of the Pajarito Plateau cannot be adequately addressed without considering all subsistence materials, macrobotanical and pollen remains are briefly discussed and are compared in Table 64.38. Corn, goosefoot, pigweed, and purslane are present throughout the Coalition period and are the most common taxa encountered in flotation samples. Their consistent presence underscores the relationship between disturbance-loving weedy annuals and agricultural pursuits. Although Table 64.38 appears to show an increase in the diversity of taxa throughout the Coalition period, the disparity in sample size presents an interpretation conundrum. Until a more sizeable database from the Early Coalition period is available, the question of whether low taxa diversity is a true reflection of diet breadth in the Early Coalition or a factor of small sample size cannot be adequately determined (Chapter 62, this volume).

+ present; [1]McBride and Smith 2002; [2]Chapter 62, this volume.

When the more comparable Middle and Late Coalition macrobotanical assemblages are compared, it becomes clear that a wide variety of annual and perennial species were exploited and that agricultural efforts were an important part of the subsistence regime. The ubiquity of domesticates, annuals, perennials, and grasses for the Middle and Late Coalition is presented in Table 64.39. With the exception of the Middle Coalition grass and perennial assemblages at LA 86534, there is no discernable difference in the percent presence of domesticates, annuals, perennials, and grasses throughout the Coalition period (Chapter 62, this volume). The reason for the spike in perennial ubiquity and the very low ubiquity of grasses at LA 86534 is likely neither a factor of environment nor a change in dietary preferences; LA 135290 is just 500 m to the west and both sites date to the Middle Coalition period. Overall, the macrobotanical data indicate that corn and a wide array of wild plant resources remained stable components of the diet throughout the Coalition period (Chapter 62, this volume).

Table 64.39. A comparison of plant class ubiquity from Coalition period sites on the Pajarito Plateau (from Chapter 62, this volume).

Site	Phase	Domesticates	Annuals	Perennials	Grasses
LA 4624	Early	38	31	23	8
LA 86534	Middle	50	37	13	<1
LA 135290	Middle	49	39	4	8
LA 4618	Late	49	33	9	9
LA 12587	Late	55	29	6	10

Note: ubiquity = percent presence of the total occurrences of each plant class at a site.

In general, pollen analyses show that corn signatures increase in the Late Coalition period. Although sample sizes from the Early Coalition period are small ($n = 3$), the two Late Coalition period sites show evidence for more economically important taxa (e.g., cotton and squash) relative to the Middle Coalition period site (LA 86534) that has been analyzed (Chapter 63, this volume).

Discussion of the Coalition Period Roomblocks

Several trends in the Coalition period assemblages are highlighted. The LA 4618 faunal assemblage was dominated by bird remains, especially turkeys; LA 4624 and LA 12587 were also dominated by bird remains but generally had a more even taxonomic distribution. In contrast with these assemblages, however, the LA 135290 and LA 86534 assemblages were dominated by artiodactyls and rabbits, with birds comprising only about 10 percent of the identified taxa. Given the small sample sizes at LA 135290 (n = 48) and LA 4624 (n = 109), one would expect these sites to be the least diverse taxonomically. In fact, while they do have the two smallest values with nine and seven identified taxa, respectively, they are not significantly different from the LA 4618 assemblage, which is represented by only 10 distinct taxa but has a sample size that is 8 to 18 times larger depending on the site. Since Grayson (1984) has stated that a longer and more intensive use of a site will produce more diversity in subsistence materials, the Coalition period assemblages suggest that other factors may have been at work on the Pajarito Plateau. If length and intensity of occupation were contributing factors to the small sample size and low taxonomic diversity at these sites, it is interesting to note that two of the three sites (LA 4618 and LA 4624) have multiple kivas, a factor typically equated with more intensive site occupations. In general, sample size does not appear to directly bias the number of identified taxa at each of the roomblock sites.

The five Coalition period sites can be separated into three spatially distinct groups on the plateau. LA 86534 and LA 135290 are located within 500 m of each other on the mesa top near the Los Alamos airport. LA 12587 is located 6.5 km (4 miles) southeast of the Airport cluster just north of White Rock, New Mexico, and LA 4624 and LA 4618 are located 2.5 km (1.5 miles) northwest of LA 12587 near TA-54. Like the Airport sites, the two TA-54 sites are also located within 500 m of each other. Figure 64.5 groups the faunal assemblages by geographic location and taxonomic representation within the study area. Figure 64.5 shows that differences in faunal exploitation (e.g., more birds in the TA-54 cluster and more artiodactyls in the Airport cluster) may be tied to subtle geographic differences between the site clusters. Although these differences are not vast since all five sites are located in the central Pajarito Plateau, they do appear to contribute to the variable signatures in the faunal record.

Interestingly, the Classic period site of Tsirege, which is located in between the TA-54 and White Rock clusters, translates to "down at the bird place" in Tewa, suggesting birds may have been especially abundant in this area. However, Harrington (1916) has suggested that the name Tsirege derives from a large rock outcrop near the site that resembles a bird, and may in fact have nothing to do with elevated numbers of birds in the area. But, given the location of the TA-54 and White Rock sites, it is not entirely unexpected that the former may be true given their proximate location to large canyons. In Figure 64.5, there are clear patterns in the "bird" and "other taxa" groups, but the "rabbit" and "deer" groups are more variable. This difference is likely due to the use of rabbits and deer for food, whereas birds, with the exception of turkey, and other taxa may have been used more frequently for ritual activities. Interestingly, the presence of a kiva or kivas at a site does not appear to increase the number of taxa used primarily for ritual purposes (e.g., golden eagle) as LA 12587, the only site besides LA 135290 that does not have a kiva, contains as many ritual taxa as LA 4618, LA 4624, and LA 86534, which all have kivas.

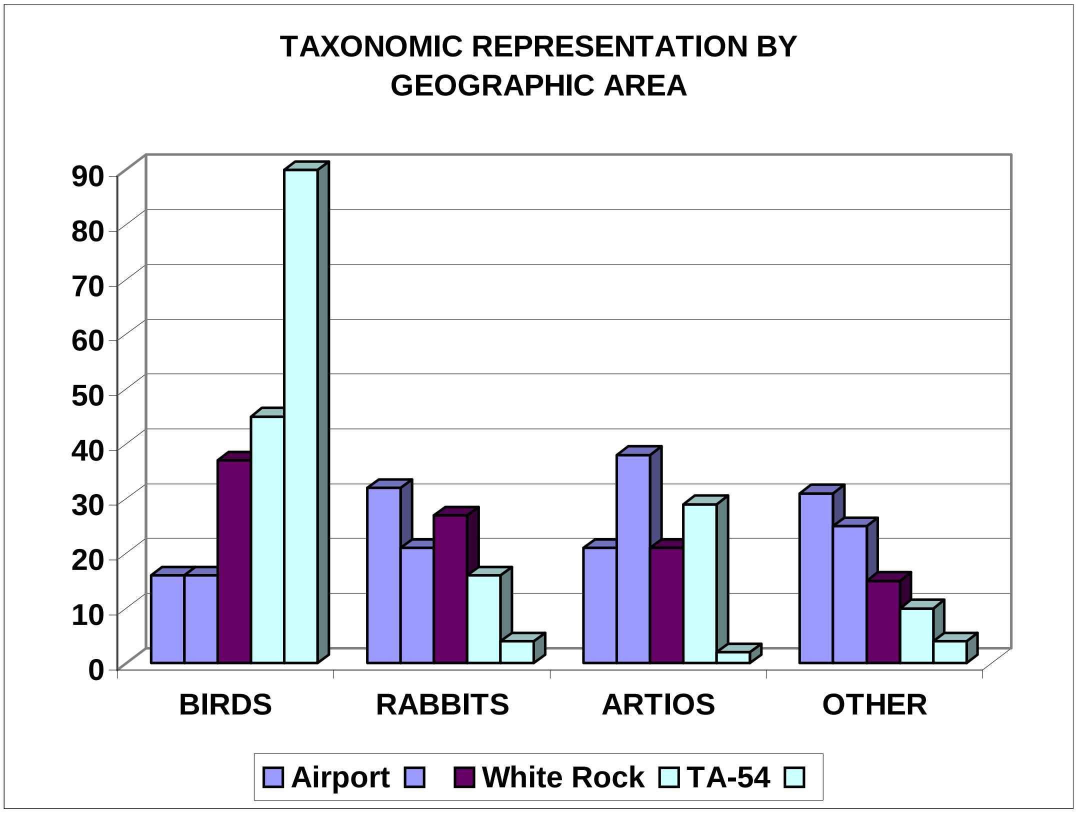

Figure 64.5. Taxonomic breakdown of Coalition period assemblages by geographic area.

As already mentioned, the importance of turkeys increased considerably during the Coalition period. While wild turkeys supplied a stable and edible source of food for the residents of the Pajarito Plateau for millennia before the Coalition period, its domestic counterpart was not skeletally identified until the Coalition period (McKusick 1980, 1986a). Additionally, Harrington (1916) notes the following in his book on the ethnozoology of the Tewa Indians:

> [Wild] turkeys breed in considerable numbers in the [Jemez] mountains … They come down into the canyons in the autumn in large numbers and congregate about the springs, where, it is said, they are slaughtered. There is no doubt that they were formerly more abundant and probably constituted an important article of food of the ancient inhabitants. The Indians long ago domesticated this bird, or at any rate, kept many of them in inclosures [sic]. It is supposed that the birds in captivity were kept for ceremonial purposes, the feathers being used in various rites. This raises some doubt as to whether the captive birds were used also for food.

Harrington's speculation about wild and domesticated turkeys may have been accurate. At LA 4618, turkeys comprise some 58 percent of the assemblage, and two distinct sizes of complete turkey bones are present (Figures 64.6 and 64.7). Interestingly, the smaller bones were recovered from the trash deposits, while the larger bones were found in the kiva and on two room floors. This may support Harrington's contention that wild turkeys were likely used as food (present in the trash at LA 4618), and domesticated turkeys were used for ceremonial purposes (present in ceremonial contexts and room floors at LA 4618), but may also be the result of sexual dimorphism with the larger turkeys representing males and the smaller turkeys representing females. More detailed studies of plateau turkey bones are needed to clarify these issues for Pajaritan subsistence. What is clear, however, is that the residents of the plateau did not ignore a readily available food source in the form of domesticated turkeys during the Coalition period.

Figure 64.6. Distinct sizes of adult femora from LA 4618.

Finally, the wide array of wild plant and animal taxa from a number of ecological areas in Coalition period assemblages indicates efforts to amass food resources were not concentrated in one area. Instead, grasslands, riparian areas, piñon/juniper and oak woodlands, and coniferous areas were all used by inhabitants of the plateau, which maintained a diversified range of dietary resources during the Coalition period. Maintaining diversity in subsistence resources is not only healthier for dietary intake in general, but it also helps to mitigate the effects of crop failure (Minnis 1985). Nonetheless, the increase in both maize and turkey remains during the Coalition period suggest these two species were becoming increasingly more important to the residents of the Pajarito Plateau. Because of the significant increase in the number of people living on the Plateau, places to live and grow food were decreasing. The use of wild animal resources decreased relative to the use of a domesticated resource (e.g., turkey), especially by the Late Coalition period. Among the plant remains, however, while maize was becoming increasingly more ubiquitous in the subsistence assemblages, the use of wild taxa continued to be equally important. Despite these subtle differences among the subsistence classes, however, residents of the plateau placed increasing emphasis on resources that provided more stable and predictable food supplies during the Coalition period.

Figure 64.7. Distinct sizes of adult tibiotarsi from LA 4618.

Late Coalition/Early Classic Period Fieldhouses

Faunal assemblages were analyzed from three Late Coalition/Early Classic period fieldhouses (LA 85404, LA 85861, and LA 127631). A mule deer (*Odocoileus hemionus*) distal metatarsal fragment (right), which was manufactured into a partial fragment of a bone awl, was identified at LA 85404 in the Rendija Tract. Five pieces of bone were identified at LA 85861, which was also located in the Rendija Tract. These included one mule deer (*Odocoileus hemionus*) second phalanx, a leporid (rabbit/hare) molar, and three unidentified mammal long-bone fragments, one of which was an awl fragment. One piece of bone was recovered from LA 127631, a site located in the White Rock Tract. The bone was identified as the distal end of a cottontail (*Sylvilagus* sp.) femur.

Classic Period Fieldhouses

Faunal remains were recovered at 10 Classic period fieldhouses (LA 85408, LA 85411, LA 85413, LA 85414, LA 85867, LA 86605, LA 86606, LA 127627, LA 110126, and LA 135292). All but one of these sites (LA 110126) was located in the Rendija Tract. LA 110126 was located in the TA-74 Tract.

One unidentified piece of medium/large-sized mammal bone was recovered from LA 85408. Four pieces of bone were analyzed from LA 85411 and included one mule deer (*Odocoileus hemionus*) atlas vertebra fragment and three pieces of a recently broken mule deer sacrum. Twelve pieces of bone were analyzed from LA 85413 and included two unidentified pieces of bone on the living surface and two pocket gopher (*Thomomys* sp.) elements (right humerus, left mandible), five mule deer (*Odocoileus hemionus*) bones (three rib fragments, one right calcaneus, and one right astragalus), one small/medium-sized mammal remain, one medium/large-sized mammal remain, and one unidentified piece of bone from the fill. None of these bones were burned.

One piece of bone was analyzed from LA 85414 and was identified as a fragment of the proximal metacarpal of a mule deer (*Odocoileus hemionus*). The bone was identified as a possible awl, but was definitely shaped and polished. The bone was not burned. One piece of bone was analyzed from LA 85867 and was identified as an unburned rib fragment from an elk (*Cervus elaphus*). The bone was probably of modern origin. One piece of bone was recovered from LA 86605 and was identified as a mule deer (*Odocoileus hemionus*) distal right humerus. The bone was unburned. One piece of bone was analyzed from LA 86606 and was identified as a heavily burned medium/large-sized mammal long-bone fragment. Two pieces of bone were analyzed from LA 127627 but were not identifiable to the level of class. One piece of bone was analyzed from LA 135292 and was identified as a very small fragment of cancellous bone. One piece of bone was analyzed from LA 110125 and was not identifiable to the level of class.

Classic Period Grid Garden

Faunal remains were analyzed from one grid garden (LA 21596B) in the White Rock Y Tract. Four pieces of bone were recovered and included two unidentified remains and the proximal and distal ends of a left cottontail (*Sylvilagus* sp.) humerus. None of the bones were burned and were recovered from the surface.

Jicarilla Rock Rings

Faunal remains from two Jicarilla Apache rock rings in the Rendija Tract were analyzed. Four unidentified pieces of bone (FS 11) were recovered from LA 85864. The bones were heavily burned (calcined). Three bones were identified at LA 85869 and included one elk (*Cervus elaphus*) scapula that was recovered from the surface and probably not associated with the Jicarilla use of the site. In addition, two small, unidentified mammal fragments were recovered from inside the rock ring.

Historic Period Homestead

Twenty-seven pieces of bone were recovered during excavations at LA 85407, the Serna Homestead, which was located in the Rendija Tract. The site consists of the remains of a historic log cabin, an horno, a circular rock alignment, a shed, and a corral. Ten bones were recovered in Room 1 of the cabin and included one unfused kangaroo rat (*Dipodomys* sp.) femur, a fragment of a mule deer (*Odocoileus hemionus*) rib, a horn fragment from a domestic cow (*Bos taurus*), a fragment of an elk (*Cervus elaphus*) thoracic vertebra, two medium/large-sized mammal bones (one burned), two large-sized mammal rib fragments that both contained butcher saw marks, one large-sized mammal unidentified burned bone, and one unidentified piece of unburned bone. Four bones were identified in the fill around the cabin and included a complete human premolar, a burned unidentified medium/large-sized mammal bone, an unidentified large-sized mammal bone, and a large-sized mammal rib that contained evidence for butchery from a large saw.

Three bones were identified in the area around the horno, but no bones were recovered directly from the feature fill. Analyzed bones included one medium/large-sized mammal bone fragment and two domestic cow vertebral body fragments. None of the bones were burned, and all contained evidence for old breaks.

Feature 2 was a small, circular rock feature (Figure 12) located approximately 14 m south of the western end of the cabin. One bone was recovered from the circular alignment and it was identified as a fragment of a domestic cow axis vertebra. It was not burned, but did contain evidence for some butchering activities.

Six bones were recovered in the probable shed and included one unidentified bone, one blue grouse axis vertebra (*Dendragapus obscurus*), a domestic goat (*Capra hircus*) cervical vertebra and rib fragment, and a domestic cow distal metatarsal fragment. None of these bones were burned or otherwise altered.

Two bones were identified in the corral. One was an unidentified small/medium-sized mammal bone and one was a medium/large-sized mammal bone fragment.

CONCLUSIONS

Over time, the inhabitants of the Pajarito Plateau were farmers, hunters, and gatherers who used the natural landscape to flourish in an arid to semi-arid environment. Evidence for what the residents of the plateau ate comes from plant and animal remains recovered from recent archaeological excavations. In this summary, analyses conducted on all the bones recovered during the C&T Project excavations were summarized, and the animal remains from five Coalition period roomblocks were highlighted and discussed; plant and pollen remains were also summarized briefly. Before the Coalition period, the hunting of game and the collection of wild resources were the primary subsistence emphases on the Pajarito Plateau (also see Schmidt and Matthews 2005). By the Coalition period, analyses of subsistence remains shows that maize and other domesticates (e.g., beans and squash) became more ubiquitous in the macrofossil record, while turkey remains dominated faunal assemblages. Even though maize farming and turkey procurement were critical components of the diet by the Coalition period, the inhabitants of the Pajarito Plateau never completely eliminated wild resources from their diet.

The excavations at the Coalition period roomblocks, demonstrate that these sites are important for understanding the formation of social identities among the inhabitants of the Pajarito Plateau. During the Coalition period, occupation of the plateau increased dramatically (Vierra 2000). Relative to the earlier Archaic and Developmental periods, there was a substantial increase in the number, size, and distribution of pueblos, substantially decreasing the amount of arable land available to the plateau's inhabitants. The dramatic increase in maize production during the Coalition period did two things for the occupants of the plateau: it increased the production of a stable resource reducing some of the nutritional stresses, but its production also altered the natural landscape and decreased the areas where wild foods were collected.

The LA 4624 (Area G) assemblage was dominated by turkey and large mammal, with fewer rabbits, hares, rodents, and carnivores (Schmidt 2002). The LA 4618 assemblage was dominated by turkey and unidentified large bird remains at almost 90 percent of the assemblage and was followed in importance by leporids (jackrabbits and cottontails) and rodents (Schmidt 2006a). LA 86534 and LA 12587 were dominated by leporids, large mammals, and rodents, and LA 12587 had a considerable amount of turkey remains. The similarity in their assemblage composition suggests a uniform subsistence strategy as the assemblages vary slightly in terms of the relative proportions of taxa, but the same taxa are consistently represented. Maize agriculture likely contributed significantly to the subsistence economy of populations on the plateau, but the hunting and gathering of wild species also continued to be important and to play a significant role.

CHAPTER 65
ANALYSIS OF HUMAN SKELETAL REMAINS FROM LA 12587

Michael A. Schillaci

INTRODUCTION

This chapter describes the results of the analysis of three human burials and miscellaneous human remains recovered from LA 12587 in the White Rock Tract (see Chapter 14, Volume 2). The primary purpose of the analysis was to estimate the age, sex, biological affinity, and stature of the burials and, where possible, the miscellaneous remains. In addition, the analysis was to describe any observed pathological conditions or developmental disorders on the remains. The chapter describes each burial separately. An inventory of the remains associated with each burial is presented in Table 65.1, and cranial and postcranial metric data are presented in Table 65.2.

Table 65.1. Inventory of human remains from LA 12587 by burial number.

Burial #	Bone	Comments
1	Right Humerus	90% complete, fragmentary distal epiphysis
1	Left Humerus	90% complete, fragmentary proximal epiphysis
1	Right Radius	90% complete, 2 large fragments
1	Left Radius	70% complete, 3 fragments, both epiphyses
1	Right Ulna	Complete
1	Left Ulna	Complete
1	Right Clavicle	Both epiphyses missing
1	Right Scapula	40% to 50% complete, 3 fragments, body is largely missing, portions of acromian and coracoids processes are present
1	Left Scapula	50% to 60% complete, 2 fragments, most of body is missing, glenoid fossa and acromian process are missing
1	Ribs	Fragments of 6 right ribs, and 11 unsided fragments
1	Vertebrae	Spinous processes of L1-L3, and 4 thoracic vertebrae, 4 centra fragments from 4 vertebrae, 6 indeterminate fragments
1	Miscellaneous	17 unidentified small bone fragments
2	Cranium	Virtually complete with mandible, nasal conchae are missing
2	Dentition	Left M^3, Right M^1, Left $M_{1,2}$, $P_{3,4}$, lower left C, lower right C, Right $P_{3,4}$
2	Right Femur	Complete
2	Left Femur	85% complete, 3 fragments including both epiphyses
2	Right Tibia	95% complete, 5 fragments, including both epiphyses
2	Left Tibia	60% complete, 18 fragments, including both epiphyses
2	Right Fibula	90% complete, distal epiphysis missing
2	Left Fibula	60% complete, 4 fragments
2	Right Humerus	Complete
2	Left Humerus	Complete, two fragments
2	Right Ulna	Virtually complete, 2 fragments

Burial #	Bone	Comments
2	Left Ulna	Complete
2	Left Radius	Complete
2	Right Os Coxa	Complete
2	Left Os Coxa	Complete
2	Sacrum	Complete
2	Right Scapula	80% complete
2	Left Scapula	70% complete
2	Sternum	Body only
2	Left Clavicle	Complete
2	Right Clavicle	Complete
2	Cervical Vertebrae	C1-C7 largely complete
2	Thoracic Vertebrae	T1-T5 largely complete, T6 is fragmentary, T7-T9 are represented by 12 fragments, T10, T11 are fragmentary, T12 complete
2	Lumbar Vertebrae	L1-L5 complete
2	Ribs	Complete right 1st rib, 8 right rib fragments, largely complete 1st left rib, 16 left rib fragments from 9 ribs; 19 unidentified rib fragments
2	Hyoid	Complete
2	Left Foot	Complete 1st metatarsal, talus, medial cuneiform, intermediate phalanx, 2nd metatarsal, lunate
2	Right Hand	Complete 2nd proximal phalanx, 3rd proximal phalanx, 4th proximal phalanx
2	Left Hand	Complete 4th metacarpal, 5th metacarpal, 1st, 2nd and 4th, or 5th proximal phalanges
2	Hand	2 distal phalanges, 2 intermediate
2	Miscellaneous	3 unidentified bone fragments
3	Cranium	Mandible (2 fragments), relatively complete facial skeleton including much of the frontal bone, maxillae and zygomatics, relatively complete left temporal, 1 fragment of the right parietal, 1 fragment of left parietal, 3 unidentified fragments
3	Dentition	Left: M^3, M^2, M^1, P^3, P^4 C, M_2, P_3, C, I_2; Right: M^3, M^2, P^3, P^4 C, M_3, M_2, M_1, P_4, P_3, C, I_2, I_1
3	Right Humerus	85% complete, distal epiphysis is fragmented
3	Left Humerus	<50 complete, approx. 60% of the diaphysis, 1 fragment of distal epiphysis
3	Left Radius	Complete
3	Right Radius	Complete, 3 fragments
3	Right Ulna	75% complete, 4 fragments
3	Left Ulna	Complete
3	Right Clavicle	80% complete, 2 fragments
3	Sacrum	70% complete

Burial #	Bone	Comments
3	Left Scapula	70% complete, glenoid fossa and much of the acromian process are missing
3	Right Scapula	30% to 40% complete w/ glenoid fossa, 3 fragments
3	Os Coxae	<50% complete, 9 fragments
3	Ribs	2 complete left ribs and 8 left rib fragments; 2 right rib fragments from 2 ribs, 10 unsided rib fragments

BURIALS

Burial 1 Mortuary Context

Burial 1 represents the partial disarticulated remains of a possible adult female. The position and orientation of this burial was disturbed during initial excavation by a backhoe. The burial was excavated at an unknown depth from fill containing both ceramic and lithic artifacts. Although the context of this burial was disturbed, a number of artifacts found in direct association with the skeletal remains likely represent burial items. These items include three pieces of ground stone (one of which exhibited red paint), several cores or core fragments, an obsidian biface fragment, one obsidian drill, five projectile points, one bone bead, 30 to 40 ceramic sherds—likely from a single Black-on-white vessel—and one small piece of shell.

Estimated Age

Due to the lack of craniodental remains and a missing pelvis, an accurate estimate of age is not possible for this skeleton. But, all epiphyses of the postcranial skeleton were fused indicating this individual was likely an adult. In addition, four vertebral body fragments from four vertebrae showed moderate to severe osteophytosis. In my experience, this level of vertebral osteophytosis is not observed until at least the third decade of life. As such, this individual was almost certainly older than 30 years at the time of death.

Estimated Sex

Unfortunately, the pelvis and cranium of this individual, which are the most reliable aspects of skeletal anatomy for estimating sex based on morphology, were missing. Use of the vertical diameter of the right humeral head (38.03 mm) to determine sex yields an estimate of female (see Stewart's [1979] method derived from the present-day population).

Biological Affinity

Due to the lack of craniodental remains it is not possible to estimate biological affinity accurately using morphology. But, the archaeological context of the remains, as well as the condition of the recovered skeletal elements, suggest strongly that this individual was a prehistoric Native American.

Estimated Stature

The only complete long bones available for estimating stature are the left and right ulnae. Unfortunately, there are not any regression formulas published for Native American, or even "Mongoloid" females. Because regression models used for estimating stature are population specific, stature could not be estimated for Burial 1 based on the available remains.

Pathological Conditions and Developmental Disorders

The right ulna exhibited a broken styloid process with associated bone remodeling on its distal epiphysis, suggesting a healed broken wrist. Degenerative osteoarthritis evidenced by osteophytosis was noted for the glenoid fossa of the left scapula, proximal left ulna, and for four vertebral bodies. One of these bodies had collapsed. Osteopinia may be indicated for both humeri. Both distal humeri exhibited septal apertures. Several enthesiopathies were noted on the distal ends of the right and left radius.

Comments

Both the humeri and radius exhibited moderately rugose muscle markings, often associated with increased or intense limb use (see Weiss 2003).

Burial 2 Mortuary Context

Burial 2 represents the partial semi-articulated remains of an adult female. The position and orientation of this primary burial were partially disturbed during initial excavation by a backhoe. The head of this individual was pointed to the southwest. Interment of this individual seems to have occurred within a bedrock niche, which might have been covered or capped with a piece of bedrock. Partial disturbance due to the initial excavation by the backhoe, however, makes this determination tentative. A number of burial items accompanied this burial, including four pieces of ground stone, three round stones, 20 black-on-white ceramic vessel sherds, one bone pendant, one chert projectile point, and one obsidian biface fragment.

Estimated Age

The age of this individual was estimated by assessing the morphological changes to the pubic symphysis and the auricular surface of the pelvis. In addition, the degree of closure for cranial sutures was used as a secondary method.

The age estimates of this individual based on the pubic symphysis ranged from 45 to 50+ years (Todd Method, Phase 9-10, right and left) to a mean estimate of 58 years (Suchey-Brooks Phase 6, right and left) (see Buikstra and Ubelaker 1994). The estimated age at death based on the auricular surface ranged from 45 to 59 (right surface, Phase 6-7 in Buikstra and Ubelaker 1994 after Lovejoy et al. 1985 and Meindl and Lovejoy 1989), and 50 to 59 years (left surface). The age estimates based on cranial sutures were similar (i.e., cranial vault score = S6, mean age 51; lateral-anterior score = S6, mean age 52 years; Buikstra and Ubelaker [1994:38]).

When all methods are considered, a range estimate of 45 to 59 years and a point estimate of 51 years is indicated.

Estimated Sex

The sex of this individual was estimated by assessing the morphology of the pelvis and cranium using the standardized protocol outlined in Buikstra and Ubelaker (1994) (Table 65.3). The estimated sex of this individual based on pelvis morphology is female. The morphology of the cranium, however, is indeterminate with respect to sex. The vertical head diameters of the humeri (right = 36.66 mm, left = 35.47 mm) support the estimate of female (see Stewart 1979). The chin of this individual was rounded, which is considered a female trait.

Table 65.3. Sex estimate scores based on morphological attributes.

Morphological Attribute	Sex Estimate Score
Pelvis (Female 1, Male 5)	
Ventral Arc	1
Subpubic Concavity	1
Ischiopubic Ramus Ridge	2
Greater Sciatic Notch	2
Preauricular Sulcus	1
Cranium (Female 1, Male 5)	
Prominance of Glabella	2
Mental Eminence	3
Mastoid Process	3
Supra-orbital Margin	3
Nuchal Crest	4

[1]attributes described in Buikstra and Ubelaker (1994)

Biological Affinity

Based on the archaeological context of the burial, the biological affiliation of this individual is Native American. Also, the cranium of this individual exhibits occipital deformation or “cradle-boarding,” which is a cultural modification typically seen in post AD 700 Pueblo Indian remains. The presence of shovel-shaped incisors, often used to identify Native American remains, was not determined based on the lack of anterior teeth recovered.

Estimated Stature

Based on the maximum length of the right femur (35.84 cm), the estimated stature of this female was only 4 foot, 8.1 inches (142.7 cm) using the regression formula presented by Genoves (1967) derived from a Mesoamerican population. Based on the maximum length of the humerus (25.4 cm), the estimated stature for this individual is approximately 4 foot, 8.3 inches (143 cm) based on Trotter and Gleser (1952) regression formula for American “white” females.

Pathological Conditions and Developmental Disorders

The pelvis of this individual was asymmetrical. When the os coxae are held together with the sacrum and viewed ventrally, the entire pelvis is shifted to the right. In addition to this asymmetry, there are several other pathological conditions observed on the pelvis. First, the auricular surface exhibits osteophytosis, perhaps indicative of arthritis at the sacroiliac joint. There was also a small lytic lesion of unknown etiology observed on the auricular surface of the left sacral ala, associated with what appears to be minor sclerotic bone formation on the auricular surface of the ilium. In addition there is a small dished-out lesion in the anterior margin of the left sacroiliac joint. The bone surface of this lesion is smooth and resorbed and seems to be the result of a space-occupying mass. Based on the bone resorption, this lesion is likely not a result of cancer (see Hershkovitz et al. 1998). It is unclear whether the two lesions on the pelvis are related.

The lumber vertebrae exhibited moderate osteophytosis along the anterior margins of the vertebral bodies. Osteophytosis was also observed for the left diarthroidal surface between the fifth lumbar and first sacral elements. The fragmentary sixth thoracic vertebra exhibits a collapsed body with an associated central fistula. Eburnation on the medial condyles of the femora and tibiae, and osteophytic lipping along the margins of the articular surfaces of the knee joint, suggest this individual suffered from severe osteoarthritis. Possible ligament damage is suggested for both knees by several ossified ligament insertions. Minor osteophytosis indicative of degenerative osteoarthritis was observed on the margins of the glenoid fossa of both the left and right scapulas. It is possible that the pelvis asymmetry, arthritic knees, and collapsed vertebra are related conditions. In any event, it seems quite likely that this individual experienced daily pain and discomfort, as well as reduced mobility.

Antemortem tooth loss resulted in significant maxillary alveolar bone loss for this individual. Only the upper left third molar and upper right first molar remain in the upper dentary. Dental carries were observed on the lower left third premolar and the lower left first molar, both near the cervical-enamel juncture. Several alveolar fistulae, likely the result of periodontal abscesses, were observed. The first abscess was observed above the upper right first molar, while the second was observed near the upper right second incisor (missing antemortem).

Comments

Occlusal wear is severe (dentin exposed for >75% of surface) for the lower dentition. Minor calculus was observed on the lingual surface of the lower dentition. The right and left humerus exhibited moderately rugose muscle markings. The body of the sternum exhibits an abnormal curvature, possibly due to postmortem processes.

Burial 3 Mortuary Context

Burial 3 represents the partial semi-articulated remains of an adult female. Although this burial appears to have been a primary burial in a formal grave that was likely covered with tuff blocks, the exact context of the interment is not identifiable due to disturbance by the initial excavation by a backhoe. Despite this disturbance, it was determined that this individual was interred with her head oriented to the east and facing north. The interment occurred within the cultural fill containing a small number of lithic and ceramic artifacts and a few pieces of ground stone and animal bone. No formal burial items or grave offerings were recovered.

Estimated Age

The age of this individual was estimated by assessing the degree of closure for cranial sutures as well as the pattern of dental eruption and occlusal wear. The composite score for cranial vault suture closure was zero, which precludes age estimation. This score does, however suggest this individual was likely younger than 30 (see Buikstra and Ubelaker 1994:38). The third molars of this individual had erupted and were in occlusion at the time of death indicating an age of greater than 20 years was likely. Based on my experience, the observed minimal occlusal wear on the third molars is consistent with an age of less than 30 years. The estimated age range for this individual, therefore, is 20 to 30 years, with a midpoint estimate of 25 years.

Estimated Sex

The sex of this individual was estimated using the morphological attributes of the pelvis and the cranium (see Buikstra and Ubelaker, 1994). Of the attributes on the pelvis typically used for estimating sex, only the greater sciatic notch and the preauricular surface were available. The score of the greater sciatic notch indicates this individual was likely female, while the score for the preauricular sulcas suggest the sex of this individual is indeterminate (Table 65.4). The average scores for the pelvis and the cranium were both 2.5, suggesting this individual was probably female. Similar to burials 1 and 2, the vertical head diameter of the right humerus (38.33 mm) supports the estimate of female for this individual (see Stewart 1979).

Table 65.4. Sex estimate scores based on morphological attributes for Burial 3[1].

Morphological Attribute	Sex Estimate Score
Pelvis (Female 1, Male 5)	
Greater Sciatic Notch	2
Preauricular Sulcus	3
Cranium (Female 1, Male 5)	
Prominance of Glabella	3
Mental Eminence	3
Mastoid Process	2
Supra-orbital Margin	2
Nuchal Crest	N/A

[1]attributes described in Buikstra and Ubelaker (1994). N/A = not available

Biological Affinity

Minor shoveling of the incisors suggests this individual was Native American. This assessment is supported by the archaeological context of the burial. Unfortunately, the cranium was fragmentary and distorted postmortem, thus precluding identification of cranial deformation.

Pathological Conditions and Developmental Disorders

There appears to have been some lytic erosion of the anterior nasal spine that is accompanied by reactive bone. This pathological condition is only slight however, and is of unknown etiology. There was a small enthesiopathy observed near the right maxillary foramen. There appears to have been a congenital agenesis of the lower left central incisor and possibly the lower left third molar. There is less than expected wear on the first and second molars and the wear gradient across these two molars is minimal. Occlusal carries were observed on the lower right and upper left third molars. The sacrum exhibited minor clefting at S5 and S4 (see Barnes 1991 for discussion). Minor osteophytosis was observed on the anterior margin of the auricular surface of the sacrum.

Comments

There appears to have been some post-depositional distortion or compression of the cranial vault. The endocranial surface exhibits erosion and distortion, presumably the result of post-depositional factors. The incisors show minor to moderate wear (see Smith's stage 4 in Buikstra and Ubelaker [1994:52, Figure 25]). The right humerus exhibits a septal aperture. Moderately rugose muscle markings were observed on the right humerus.

MISCELLANEOUS HUMAN REMAINS

Most of the miscellaneous remains described in Table 65.5 likely came from Burial 1, Burial 2, or Burial 3 based on the elements, primarily pedal, present and the estimated sex of at least one of these elements. One infant rib found with Burial 1 represents a fourth individual.

CHAPTER 66
ARCHAEOMAGNETIC DATING FINAL REPORT

Eric Blinman, J. Royce Cox, and Gary Hein

INTRODUCTION

The duration and extent of archaeological investigations associated with the Los Alamos National Laboratory's Land Conveyance and Transfer (C&T) Project provide a valuable opportunity to both apply and evaluate the effectiveness of archaeomagnetic dating. At the start of the C&T Project in 2002, the Museum of New Mexico's Archaeomagnetic Dating Laboratory (ADL) prepared a background study of archaeomagnetic dating in the northern Rio Grande Valley (Chapter 9, Volume 1). That study describes the history, theory, and practice of archaeomagnetic dating as relevant to the Pajarito Plateau and the C&T Project. The study also uses archaeomagnetic sample results provided by Dr. Robert DuBois to assess the effectiveness of two of the three prevailing archaeomagnetic calibration curves for date interpretations (Figure 66.1): SWCV2000 (Lengyel and Eighmy 2002) and the Wolfman Curve (Cox and Blinman 1999). The DuBois Curve (DuBois 1989) was constructed interactively with the DuBois data and was not assessed as part of the background study. The dating curves have different strengths and weaknesses in terms of describing the movement of the virtual geomagnetic pole (VGP) through time and supporting date range interpretations from sample results. Following up on this assessment, our focus on archaeomagnetic dating here includes an explicit curve evaluation component as well as simply inferring and reporting dates.

Over the four years of the C&T Project fieldwork, ADL staff and volunteers collected and analyzed 27 sets of archaeomagnetic specimens from 10 excavated sites. An experimental sampling technique was applied in one case, and experimental substrates were sampled in two cases. Since fine-grained chronology was a goal of the C&T Project, multiple sets of specimens were collected from features wherever possible. Results from associated radiocarbon and ceramic date estimates provide independent means of assessing both the accuracy of the archaeomagnetic dates and the effectiveness of the VGP dating curves. Luminescence dating techniques (thermoluminescence, optically stimulated luminescence, and infrared stimulated luminescence) and obsidian hydration were also applied to C&T Project contexts (Chapter 69, this volume), but those results are sufficiently equivocal that they are inadequate for assessment purposes.

This chapter is divided into five sections. The first is a brief recapitulation of the foundations and practice of archaeomagnetic dating. The second is an overview of archaeomagnetic sampling at the C&T Project sites with a discussion of substrate qualities and experimental sampling techniques. The third section is a summary of the C&T Project archaeomagnetic dating results and interpretations on a site-by-site basis. The fourth section evaluates the C&T Project archaeomagnetic chronology as compared with the results from other sites in the northern Rio Grande region. The final section reviews the nature and effectiveness of the archaeomagnetic calibration curves in terms of both describing the VGP path and supporting both the accuracy and precision of date range estimates.

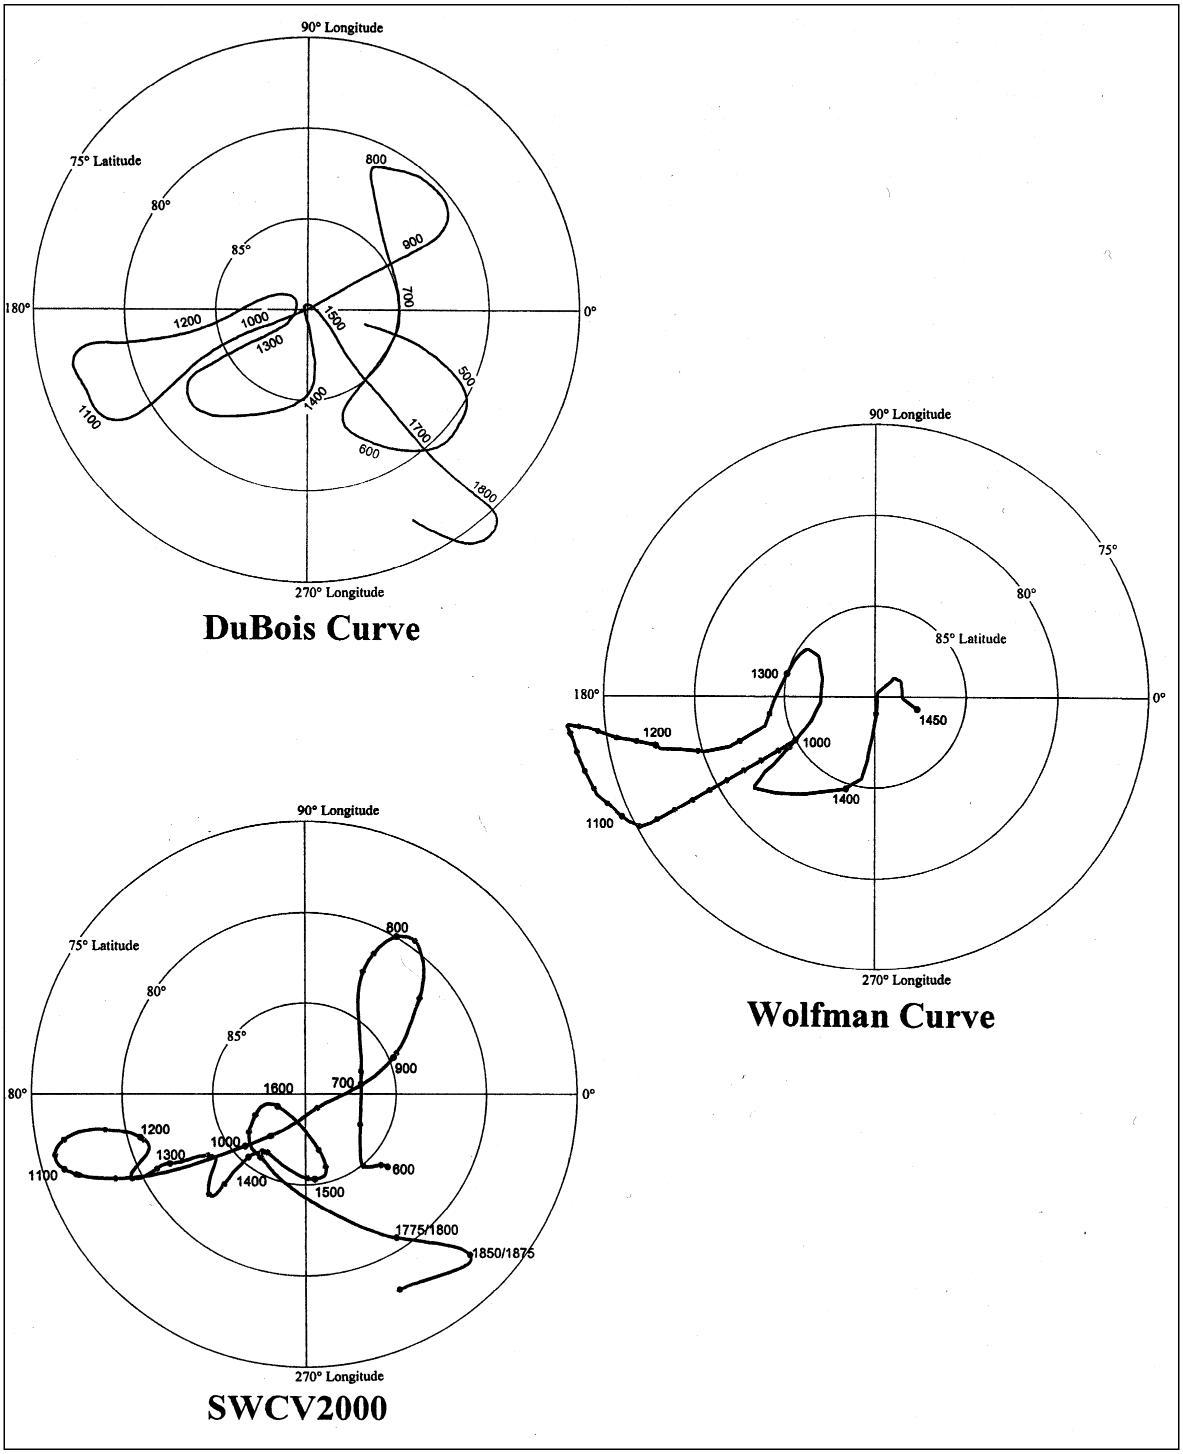

Figure 66.1. Three archaeomagnetic dating curves are used to interpret date ranges from archaeomagnetic set results in the Southwestern United States. These include the DuBois curve (DuBois 1989), the Wolfman Curve (Cox and Blinman 1999), and SWCV2000 (Lengyel and Eighmy 2002).

ARCHAEOMAGNETIC DATING

Archaeomagnetic dating derives from the acquisition of a magnetic moment (direction and strength) by susceptible minerals when they are heated and cooled (see Chapter 9, Volume 1 for additional discussions of archaeomagnetism; more complete treatments are in Sternberg 1990 and Wolfman 1984). Magnetic orientations of susceptible minerals are aligned with the earth's prevailing magnetic field upon cooling (thermal remanent magnetism or TRM), and those alignments generally persist until the material is again heated to the original or a higher temperature. Since the earth's magnetic field is constantly changing, heated earths retain a record of the past apparent or VGP position at the time of cooling. Pole positions from heated archaeological earths can be compared with the regional calibration of VGP movement through time, and the position of the sample VGP along the calibration curve can be interpreted as a date range. Successful archaeomagnetic dating requires appropriate earthen materials, fires sufficiently hot to create an alignment, recovery of carefully aligned specimens from the burned archaeological feature, laboratory measurement of the specimens to determine a mean pole position or VGP and its error term for the specimen set, and interpretation of a date range from the juxtaposition of the error ellipse of the set result and a calibration curve.

Although archaeomagnetic dating is often characterized as an "absolute dating technique," this belies uncertainties in calibration curves, measurement results, and a host of potentially confounding variables. The latter include other magnetic alignments that are acquired independently of the TRM and that influence the VGP of the sample. Some of these non-TRM alignments can be removed by progressive demagnetization that effectively removes or erases weakly held orientations. Some results appear to be uncontaminated, and the best approximation of the TRM. VGP is at the natural remanent magnetism (NRM) of the set. In other cases, progressive demagnetization "improves" the result by removing confounding magnetic moments. In these cases a "best" result is chosen from a number of alternatives based on the movement of the set VGP and changes in the magnitude of the error term of the result through the demagnetization sequence. If a result is improved by demagnetization, the intensity of the selected demagnetization level is report in Oersteds (Oe).

An archaeomagnetic dating result is expressed as a VGP centerpoint and a surrounding error ellipse. The centerpoint is the mean of the orientations of the individual specimens. An error ellipse is defined by the dispersion of the individual specimen orientations around the set mean. The error is visualized as a cone whose tip is at the location of the archaeological feature, whose axis points to the VGP centerpoint, and whose spread or dispersion is expressed in degrees. The spread (α_{95}) describes the area within which the mean centerpoint can be expected to fall 95 percent of the time assuming that the specimen orientations are representative of the orientation of the feature as a whole. The ellipse represents the cone's intersection with the earth's surface at the geographic pole. As error terms become larger, VGP locations are less precisely known and the date range interpretations become larger and less useful. Large α_{95} values also imply that the TRM contribution to a sample's magnetic orientation may be weakly expressed compared with other sources of magnetic orientations within the material. α_{95} values of less than 1° are excellent and imply a strong TRM that should be relevant for dating purposes. α_{95} values of more than 4º are imprecise and raise the possibility that the magnetic moment is less exclusively relevant to the TRM of the heating event that is of archaeological interest.

VGP calibration curves are approximations built up by the analysis of many independently dated samples (see Daly and Le Goff 1996; Lengyel and Eighmy 2002; Sternberg and McGuire 1990b). VGP curves have both a path that traces the past movement of the pole and the calibration of the path to the calendric time scale. Since the independently dated VGPs are both estimated with error and calibrated with error, VGP calibration curves are periodically redefined and improved as more data become available (such as Eighmy and Klein 1988, 1990; Hathaway et al. 1983; LaBelle and Eighmy 1995; Sternberg and McGuire 1990a). The need for improvement is revealed by failures of the curves to deal effectively with new sample results or systematic disagreements between a curve's calibration and new independently dated results (such as Cox and Blinman 1999; Lengyel and Eighmy 2002). The pole position and error term of an archaeomagnetic dating result is fixed, while the dating implications of that result will vary with the curve used to interpret the date range.

Three curves are currently in use for date estimation in the greater Southwest (see Figure 66.1). Each curve has strengths and weaknesses, and date estimates for the C&T Project results are interpreted using the Wolfman Curve (Cox and Blinman 1999), the SWCV2000 (Lengyel and Eighmy 2002), and occasionally the DuBois Curve (DuBois 1989). We believe that date ranges for the AD 1000–1450 period are more accurate if interpreted using the Wolfman Curve (see Chapter 9, Volume 1 and the discussion later in this chapter), but the SWCV2000 dates are reported for comparison. Although not relevant for the C&T Project results, we believe that dates interpreted for the AD 650–1000 period using the SWCV2000 are accurate (although precision can be improved; Cox and Blinman 1999). The DuBois Curve provides the only basis for date interpretations in the AD 400–650 period, while both the SWCV2000 and DuBois curves can be used to interpret post-AD 1450 date ranges.

The interaction between an error ellipse and the VGP calibration curve determines the estimated date range(s) for a sample result. Since dating curves are approximations and centerpoints are measured with error, few centerpoints should be expected to fall on the curve. To the extent that curve paths are accurate and that VGPs express the TRM exclusively, error ellipses should overlap the curve path. However, neither assumption can be made with absolute confidence. The most common dating convention is to assume that every curve segment that is intersected by or is immediately adjacent to an error ellipse is potentially relevant to the date interpretation of that result. Depending on location and error size, an ellipse can intersect multiple curve segments, each of which could support a valid date interpretation (although only one is correct). To estimate a date range that reflects the precision or imprecision of the VGP estimate, the oval is moved as if the centerpoint were replotted to coincide with the nearest point on each curve segment in turn. The points of intersection between the ellipse and each curve segment determine the early and late end points of the date range interpretations (rounded to the nearest five-year point outside of the ellipse).

There can be one, two, three, or even four possible date range interpretations for any individual result within the past 2000 years of polar movement. If VGP movement were known with precision for the past 10,000 years, there would be many more possible date interpretations since the wandering of the pole in the past millennia is confined to the high northern latitudes. Since only one range is actually relevant to the archaeological event that produced the TRM, independent information must be used by the archaeologist to determine which archaeomagnetic date range is appropriate. Archaeomagnetic date interpretations are thus most useful where there are multiple sources of chronology that can help focus attention on a particular date range as relevant.

C&T PROJECT SUBSTRATES AND SAMPLING TECHNIQUES

The Ancestral Puebloan architecture of the Pajarito Plateau incorporates wall, floor, and feature plasters that are rich in volcanic ash and volcanic ash-derived clays. These plasters appear to harden (sinter) at relatively low burn temperatures, resulting in a light but crisp consolidated material that does not soften or deform significantly when wet. Only a minority of the ostensibly burned examples was oxidized pink, brown, or red, and the vast majority of these plasters was buff to white in color. The hardness and texture of the plasters were the principal indications that they were burned. Hearth linings and burned room floors and plasters were preserved as indurated rinds up to several cm thick, resting on either unconsolidated earth or occasionally against rock (often rhyolite, basalt, or shaped blocks of tuff). The linings were often broken into fragments by earth pressure or tree roots, but individual fragments could be up to 200 square cm in area. Most of the architectural plasters in the C&T Project sites appear to have been carefully selected by the site builders or perhaps blended of clay and volcanic ash rather than simply consisting of subsoil from the site location.

Although generally lacking the reddish hues usually associated with good archaeomagnetic dating material, the indurated quality of hearth linings, burned floors, and burned walls encouraged our initial sampling efforts. The plasters cut relatively easily with carbide-edged saw blades, and only a few of the plasters contained pebbly material that either constrained specimen preparation or could pose problems in sample measurement. The greatest challenges were the need to sample vertical surfaces and the presence of soft or incoherent substrates underneath many of the plaster layers. A full-depth cut to accommodate normal archaeomagnetic mold placement often would have severed the specimens from any rigid support, and mold placement and leveling would have risked compromising the orientation of the specimen before casting. In order to maintain orientations through casting, many specimen cuts were kept shallow, and these specimens were broken free, trimmed, and “pushed” deeper into their molds after their initial plaster encasement had cured and their mold orientations had been taken. Pushing a specimen risks slightly distorting the inclination of the specimen within the mold, but over multiple specimens the distortion should be “random” and should affect precision rather than the accuracy of subsequent archaeomagnetic measurements.

A second problem was that plaster fragments had to be assessed for post-burning tilting due to root pressure or slumping before sampling. Any post-burning movement would result in systematic misalignment of all specimens taken from a fragment, resulting in a precise but inaccurate VGP location estimate. Sampling strategies included collecting specimens from fragments with a low risk of fragment tilt, and efforts were made to distribute specimens across multiple fragments wherever possible. In a few cases, the quality and quantity of the material allowed the collection of multiple full sets from different portions of features, addressing the question of any distortion through redundancy.

The decision to aggressively collect non-reddened plaster samples was validated by subsequent measurement results. Of the 17 samples collected from crisp plasters, 16 (94 percent) had interpretably precise error terms ($\alpha_{95} \leq 4.0°$). Of the 10 samples collected from other burned materials, only six had such precise error terms. In addition to a high proportion of interpretable results, the median precision for the plaster samples was excellent. The mean error term was 1.6º and the median was 1.3º. The quality associated with these ash plasters compares with mean and median α_{95} values of 6.0º and 3.2º for the ADL sample data file as a whole (*n* = 933). Most sets had very strong magnetic moments of 1 by 10^{-3} Oe or higher and four had moments of 1 by 10^{-2} Oe and higher. These moments are 10 to 100 times stronger than the majority of archaeomagnetic dating sets measured by the ADL. Given the variety of problems that could act to lower the precision of measurements based on these sets of specimens, the volcanic ash-rich substrate is an excellent material for the preservation of TRM vectors.

Some hearth features were constructed by using rocks set in small amounts of volcanic-ash-rich mortar. Most narrow mortar joints could not be sampled, and two sets of rock lining samples were collected to see if either tuff or rhyolite acquired TRM vectors related to the use of the fire hearth. In both cases, the rocks should have had an original magnetic orientation from the time of rock formation. Archaeomagnetic dating would only be possible if that orientation had been reset to the prevailing earth's magnetic field by the intensity of the hearth fire. Five specimens were cut from a tuff block that formed one side of a hearth (1209b), while six specimens were cut from plaster fragments elsewhere around the same hearth (1209a) (Table 66.1). The tuff specimens were imprecise (α_{95} = 24.5º) with extremely aberrant mean inclination and declination. The fire had not been hot enough to reset the TRM vectors in the sampled surface (<1 cm) of the tuff block. The specimen VGPs reflected, albeit weakly, the original magnetic orientation established when the tuff was formed.

Another hearth (sample 1307) was defined by burned sediments that were so loose and unconsolidated that they could not be sampled. One side of the hearth was lined by a rhyolite cobble that was too hard for archaeomagnetic field sampling tools. An experimental sampling technique was attempted in which "empty" plaster cubes were custom cut to fit an accessible burned surface of the cobble. Four plaster cubes were glued to the cobble face with quick-setting epoxy resin, and an edge of each cube was leveled as the epoxy cured to create an orientation axis. The orientation of the axis (strike) and the dip of the adjacent cube face were measured for each cube before removal of the cobble from the feature. A water-cooled diamond saw was used to isolate and trim the rhyolite glued to each cube, attempting to retain as much of the burned surface as possible while removing deeper unburned portions of the cobble. Once the trimming was complete, the circa 0.5-cm-thick specimen was placed in a brass mold using the faces of the adhering plaster cube for orientation (much like a "pushed" sample described above). Plaster was poured into the mold to complete the cube, and the cured specimens were subsequently measured using the strike and dip orientations.

* An aberrant specimen result was manually eliminated from the Solution rather than being eliminated by the Fisher test. NA – Result does not reflect an archaeological TRM orientation. Collectors: DT – Donald Terry, EB – Eric Blinman, GH – Gary Hein, JC – Jeffrey R. Cox, JK – Jonathan Kaplan, JN – Jennifer Nisengard

Although each rhyolite specimen had been trimmed to maximize the volume of heat-affected material in the mold, the hearth fires had not been sufficiently hot to reset the magnetic orientation of the bulk of the measured material. The α_{95} of 7.1º is too imprecise for archaeomagnetic interpretation but is consistent with the precision of many geomagnetic samples. The mean inclination and declination were extremely aberrant, unrelated to the TRM of the hearth and presumably representative of the magnetic orientation acquired when the rock formed. The result is sufficiently coherent to conclude that the field collection technique was successful in recovering the remanent orientation of the rhyolite cobble. This epoxy-plaster cube technique may be valuable in recovering samples where specimens cannot be defined through normal specimen isolation and casting approaches (vertical and undercut burned surfaces as well as thin plasters over substrates that prevent normal sampling).

The orientations of specimen molds are routinely taken in the field with a magnetic compass. The orientation readings must be corrected for the local magnetic declination at the time of collection before the calculation of VGPs for individual specimens. Declinations are usually determined by reference to the U.S. Geologic Survey Geomag International Geomagnetic Reference Field (IGRF) model (http://geomag.usgs.gov/models) and are approximations for the date and location of the sampling effort. Model-derived declinations are less likely to be accurate in heterogeneous igneous geologic settings where volcanic extrusions may create local anomalies that are too fine-grained to be represented in the global models. In 2005 two series of sun compass readings were taken while sampling to determine the local declination for comparison with the IGRF model. A land survey compass was leveled on a tripod adjacent to the site excavations. Sun orientation readings were taken throughout the day, the true sun orientation was determined, and the resulting declination estimates were averaged to determine the local declinations (Table 66.2). One obvious outlier reading was removed from each sequence.

Ignoring the outliers, standard deviations in the periodic measurements were 0.26º and 0.16º, and differences between measured and model-derived declinations were 0.61º and 0.18º. The magnitudes of the angular differences (errors) are too small to be significant in the interpretation of the resultant centerpoints or error ellipses. However, the differences in individual readings (especially if the outliers had been included) would add to the apparent dispersion of specimen results if single sun compass readings had been used for specimen orientations. The difference in measured declination between the two sites (0.41º) is larger by a magnitude than the IGRM model predicted (0.02º). This suggests that local anomalies are present and that future sampling on the Pajarito Plateau would benefit from sun-compass determinations of declination at each site to affirm that any local deviations are inconsequential to interpretation.

ARCHAEOMAGNETIC RESULTS

Twenty-two of the C&T Project archaeomagnetic set measurement results were sufficiently precise for interpretation (see Table 66.1). Of these, 21 sets were collected from Coalition period sites. One set was collected from a Protohistoric hearth.

LA 12587

The excavated rooms at this site reflect a long and complex history of growth, remodeling, and reoccupation. Burned sediments (hearth features in all cases) were located in Room 2, Room 4/5, and Room 7. Hearth 20 from Room 2 appears to be the earliest in the sequence, separated from Room 2, Hearth 4 by a significant remodeling event that relocated the hearth and possibly the walls of the room. The hearth in Room 7 (Feature 6) was significantly remodeled through its use life through the addition of linings that reduced the interior capacity of the hearth. Only one of the three lining samples (the earliest) produced a sufficiently precise result for date estimation, although another set is marginal and may be interpretable in terms of archaeomagnetic sequencing. The hearth in Room 4/5 (Feature 1) represents a single apparently late hearth in the sequence of site occupation.

Room 2, Hearth 20

Two sets of specimens were collected from Hearth 20. The first set (1214) was collected from the burned volcanic-ash-rich plaster lining of the side of the hearth. Burning caused consolidation of the plaster (effectively firing its clay content) and some reddening. There was no evidence of post-burning slumping, and the minor cracking that defined two larger fragments of the lining did not suggest any movement of either fragment. Ten specimens were collected from the lining, and two were eliminated from the final result as outliers. The result following demagnetization at 100 Oe was determined to be the best, with an error term (α_{95}) of 0.6º (Figure 66.2). A second set with only five specimens (1215) was collected from the base of the hearth as a corroboration sample. The plaster substrate was identical, but it was thinly laid over a layer of packed cobbles. Specimens were relatively thin, moderately consolidated, and heavily reduced. All five of the specimens were included in the final result following demagnetization at 50 Oe. The pole position was almost identical with that of 1214, but the error term was slightly larger (α_{95} = 1.3º) (see Figure 66.2).

Both samples were stable, both have high precision, and both record the same pole position. When compared with the Wolfman Curve, the results yield date estimates of AD 1185–1205 and AD 1175–1220, respectively (see Table 66.1). When compared with the SWCV2000, the date interpretations are slightly earlier: AD 1145–1170 and AD 1125–1185. When compared with the scatter plots of otherwise well-dated DuBois result centerpoints (AD 1125–1225 and AD 1225–1300 periods) (see Chapter 9, Volume 1, Figures 9.14 and 9.21), a circa AD 1200 interpretation appears to be appropriate.

There are no radiocarbon dates from this feature, but a stratigraphically later radiocarbon date (Hearth 4) spans the AD 1020–1280 period with an intercept at AD 1180 (Table 66.3). Pottery from the site as a whole is characterized as dating to the Middle Coalition period with evidence of persistence into the Late Coalition period.

Note: Preferred Wolfman or DuBois archaeomagnetic date range interpretations are designated in bold.

Room 2, Hearth 4

The upper hearth in Room 2 (Feature 4) was lined with cobbles that were set in a volcanic ash-based mortar. The mortar was moderately fired, turning the clay content into a moderately coherent ceramic material. Only one area of mortar between two cobbles lining one side of the hearth was of sufficient quality for sampling. The block of mortar was intact, although it was detached from the matrix behind it. There was no obvious evidence of slumping, but there was a possibility of rotation with the top of the fragment tilting inward toward the hearth center (top tilting in, bottom remaining in place). The field estimate for the maximum possible rotation was 2° along an azimuth of about 115°.

Eight of the nine specimens cut from this portion of the hearth were measured (1210), and all eight were included in the final result after demagnetization at 50 Oe with a moderate error term (α_{95} = 2.3º). The possibility of rotation means that the accuracy of this result may be in question (although the precision is not). If a correction were necessary, the centerpoint of the ellipse would be shifted to a lower latitude and slightly lower longitude but within the current error ellipse (Figure 66.3). Both the existing and a hypothetical corrected result would overlap the same segments on the Wolfman Curve, and a corrected centerpoint could potentially add an overlap with the AD 1250–1350 segment of SWCV2000.

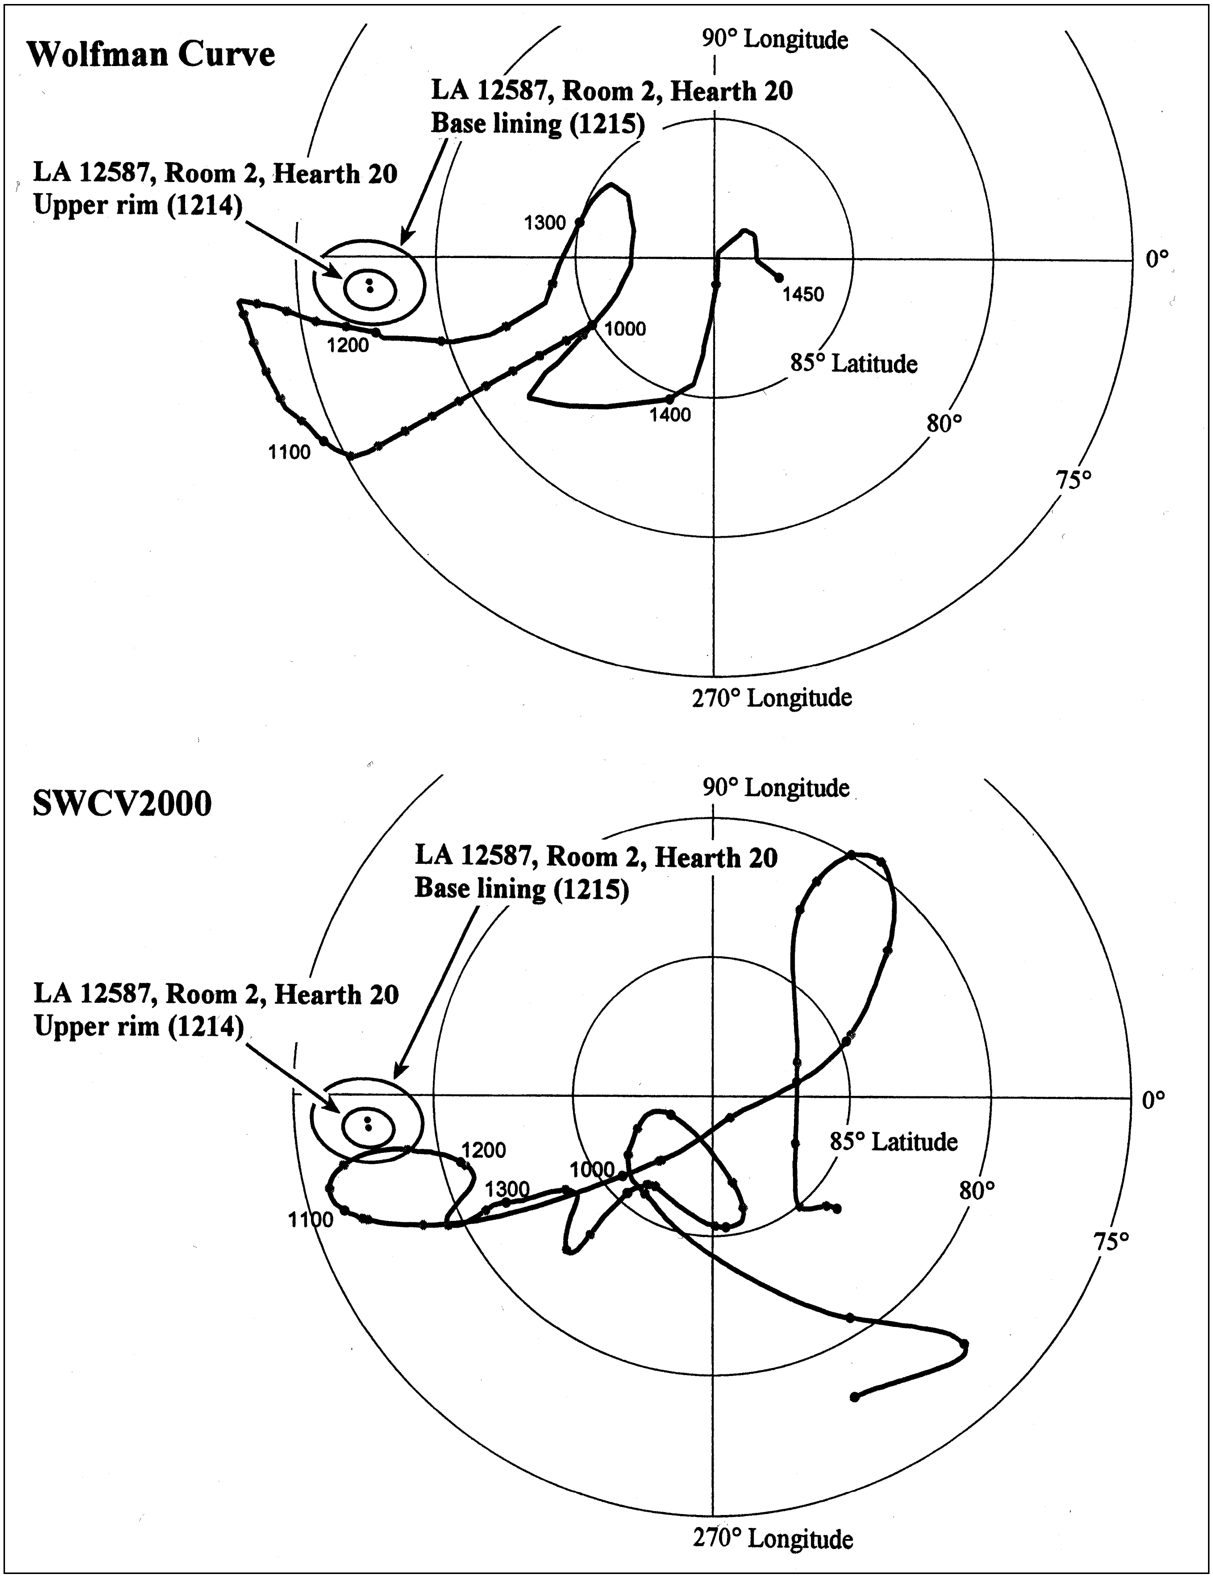

Figure 66.2. LA 12587, Room 2, Hearth 20 archaeomagnetic results for sets 1214 and 1215. Centerpoints and error ellipses are plotted against both the Wolfman Curve and SWCV2000.

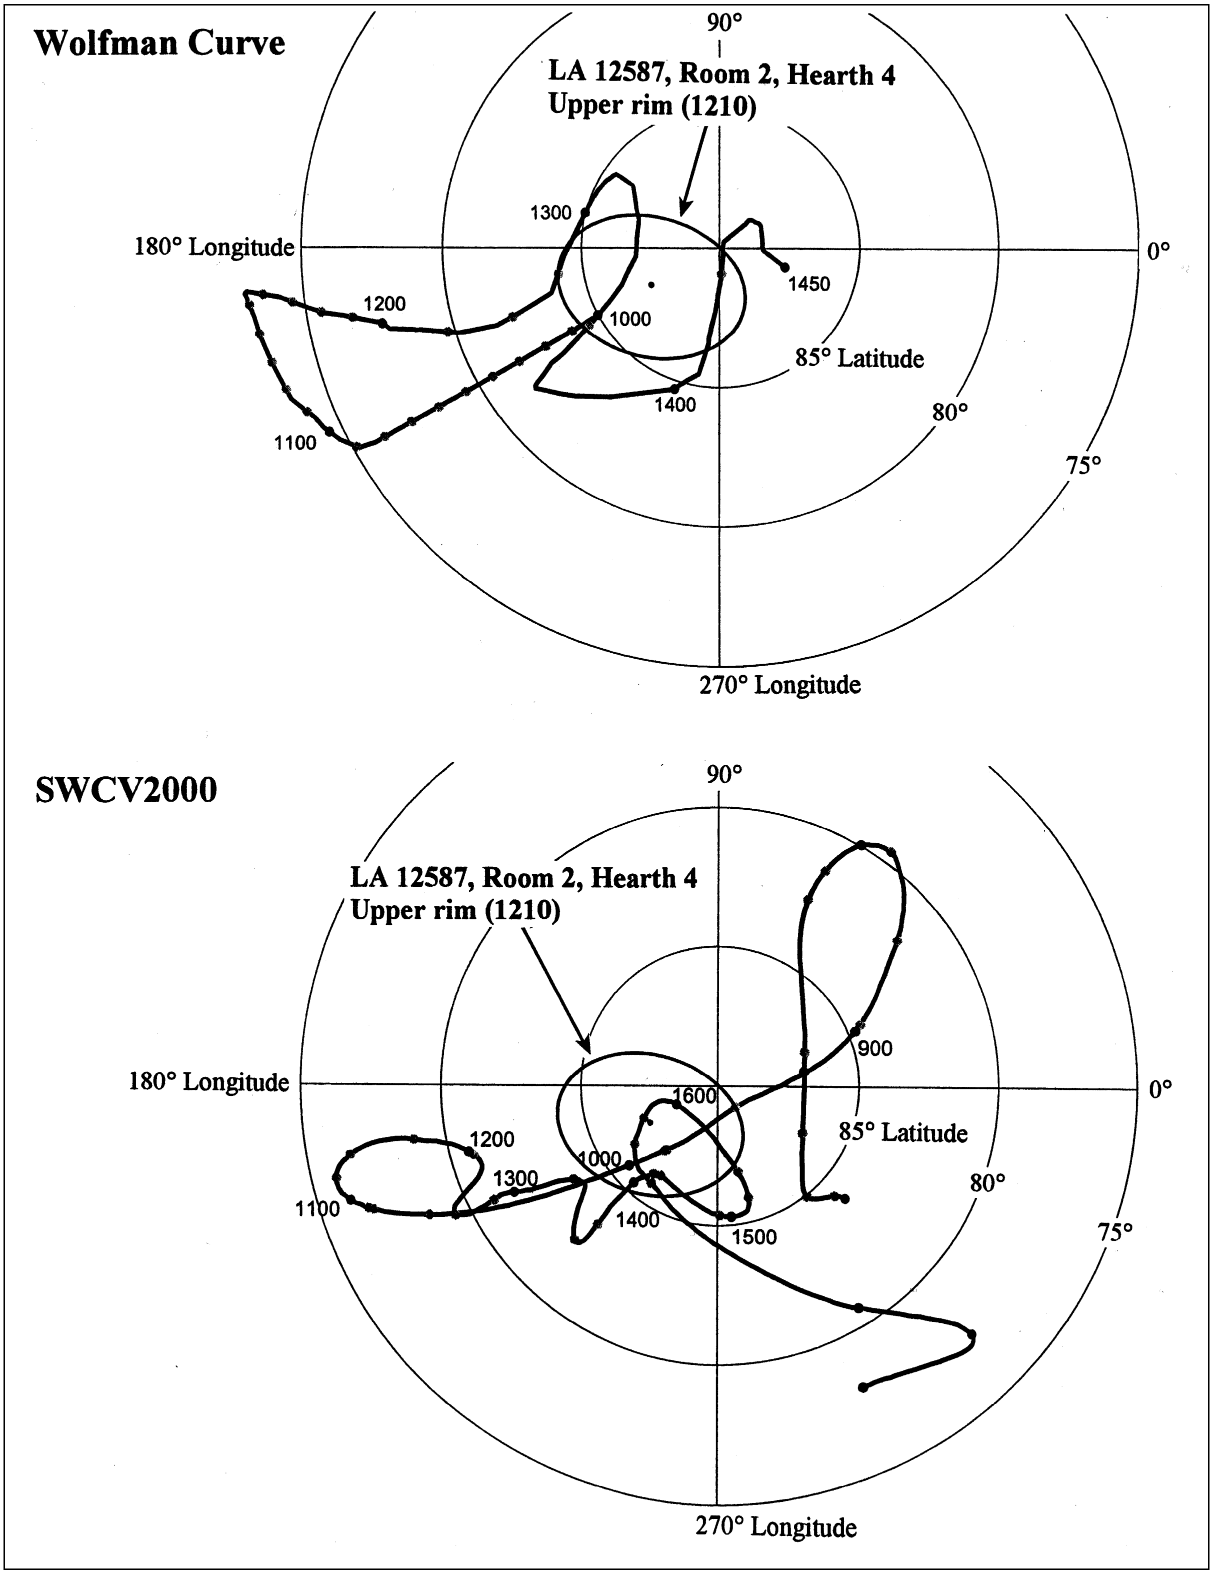

Figure 66.3. LA 12587, Room 2, Hearth 4 archaeomagnetic results for set 1210. The centerpoint and error ellipse are plotted against both the Wolfman Curve and SWCV2000.

Although this result overlaps the AD 900–1100 segment of both VGP curves, pre-AD 1100 alternatives can be eliminated based on the stratigraphically earlier result for Hearth 20. Both VGP curves yield overlaps with mid to late 14th century curve segments (and later for the SWCV2000), but these interpretations are inconsistent with the ceramic dating information from the site. The ellipse overlaps with the Wolfman Curve in the late 13th century, and the overlap would be greater if any tilt adjustment were warranted. Similarly, any adjustment would bring the ellipse into contact with the AD 1250–1350 segment of SWCV2000. These segments are associated with date estimates of AD 1245–1310 (Wolfman Curve) and AD 1275–1425 (SWCV2000).

This result can be compared with the DuBois sample centerpoints from the northern Rio Grande region (see Figures 9.14, 9.21, and 9.28 in Chapter 9, Volume 1). The result is clearly later than the scatter of centerpoints associated with the AD 1125–1225 period, and it is marginal to the AD 1225–1300 scatter. It lies within the AD 1300–1400 centerpoints, however there are ambiguities in the comparative data set between samples closely predating and postdating AD 1300. Until these ambiguities are resolved, our preferred date interpretation is that associated with the AD 1245–1310 segment of the Wolfman Curve.

A single radiocarbon assay on maize from the hearth fill produced a two-sigma calibrated date range of AD 1020–1280, with an intercept of AD 1180 (see Table 66.3).

Room 7

The hearth of Room 7 (Feature 6) underwent a series of construction and remodeling events. A relatively large partially lined cobble-and-mortar hearth was progressively decreased in size by the addition of cobble and mortar linings. The mortar included a high proportion of volcanic-ash-derived clay, which was lightly fired during each use period of the feature. Three sets of specimens were collected from the hearth at different stages in the excavation of the feature. The mortar associated with the final architectural form of the hearth was too poorly preserved to sample successfully, and none of the samples represent a last-use date for the feature. The west upper lip of an earlier manifestation of the hearth was sufficiently intact for sampling (1211), but it may have been affected by heating after remodeling. The blocks of mortar were cracked and unstable, although no material was collected that was demonstrably out of position. A second set of specimens was collected from the north rim of the hearth after the remodeled lining was removed (1212). This area of plaster lining was slightly more intact, it appeared to have been heated slightly more intensely, and it was more protected from heating during post-remodeling use of the hearth than was true of the 1211 sampling location. A final set of specimens (1213) was collected from low on the wall of the lining beneath the area sampled by the 1211 set. It was slightly more stable in appearance than the upper portion of the same wall, although it had been subjected to lower temperatures. The 1213 sampling location had been protected from significant heat after the hearth had been remodeled with the added lining.

Only one of the three results was sufficiently precise to support a date interpretation. The 1213 result was extremely incoherent (α_{95} = 10.9º), and there is no clear explanation for the high degree of imprecision. The 1211 result was too incoherent to support a formal date estimate (α_{95}

= 4.4°), but it is plotted on Figure 66.4 with the 1212 result for comparison. The 1212 result was moderately precise (α_{95} = 2.7°) after demagnetization at 50 Oe. The 1211 result probably records a pole position earlier than or contemporary with the 1212 result.

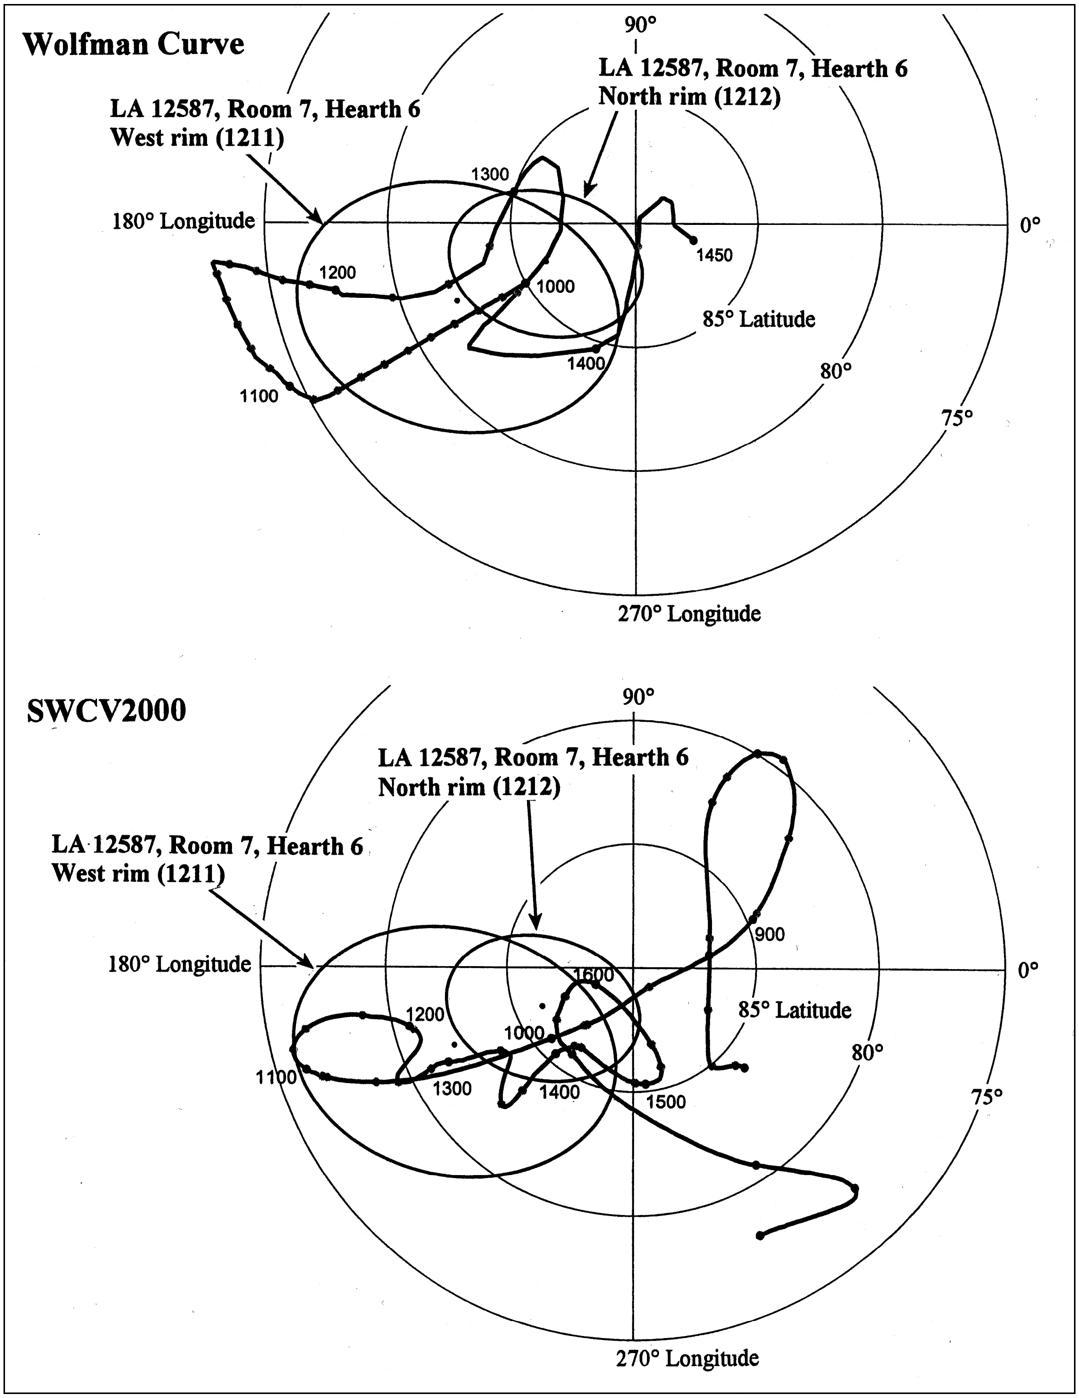

Figure 66.4. LA 12587, Room 7, Hearth 6 archaeomagnetic results for sets 1211 and 1212. Centerpoints and error ellipses are plotted against both the Wolfman Curve and SWCV2000.

The 1212 result is based on only five specimens. Four yielded VGP estimates that were only partially dispersed, but the fifth was aberrant, resulting in a α_{95} of 12.9E. Since there were only five data points, the Fisher statistic did not identify the aberrant result as an outlier, but it was removed manually from the result accepted here. The resulting ellipse intersects three segments of the Wolfman Curve, but the earliest date range (AD 930–1025) can be ruled out on contextual grounds. Both of the other ranges, AD 1235–1305 and AD 1315–1360, are plausible, but the former is more likely on the basis of other dating information from the site. The SWCV2000 yields two date ranges for the result, the earlier of which (AD 925–1015) can be ruled out. The later date range (AD 1260–1465) spans more than 200 years due to the slow looping characterization of this portion of SWCV2000. Although the early decades of this span are plausible based on independent dating information from the site, the latter half of the range is unlikely.

When compared with the scatters of pole locations in the DuBois calibration data set, the 1212 result clearly post-dates the majority of the AD 1125–1225 samples (see Figure 9.14, Volume 1). It overlaps a significant subset of both the AD 1225–1300 and AD 1300–1400 calibration points (see Figures 9.21 and 9.28 in Volume 1). Given all of the available information, including the possible direction of movement between the pre- and post-remodeled hearth pole locations, the AD 1235–1305 Wolfman Curve date range is the most likely for the intermediate remodeling of the hearth.

This is supported only on the earlier end of the range by a radiocarbon date on maize from the fill of the hearth (see Table 66.3). The calibrated age is AD 1040–1280, with an intercept of AD 1190.

Room 4/5

The hearth (Feature 1) in Room 4/5 was partially lined with a volcanic-ash-rich plaster between and over blocks and cobbles. The plaster layer could not be sampled in areas over underlying rocks, and only one area between rocks was sufficiently stable for sampling. The area of plaster was small, and only six specimens could be recovered. A large block of unplastered tuff formed a portion of the southern margin and was also burned. It was soft enough to allow sample collection with tungsten carbide-edged tools, and six additional specimens were cut from the upper edge of the block.

All of the 12 specimens were measured. When combined into a single set (at NRM), three specimens were excluded as outliers, and the resulting pole location (1209) was relatively imprecise (α_{95} = 3.3º). When the tuff block specimens were combined as a set (1209b), they yielded an extremely incoherent result (α_{95} = 24.5º) with a centerpoint in the tropical latitudes. Although some of the tuff block specimens appear to have acquired a TRM component from the hearth, the overall orientation was unrelated to the hearth. A third result was calculated (1209a) using only the specimens from the plaster lining. This result is also imprecise (α_{95} = 3.6º), but it is much more likely to approximate the true pole location than either of the other specimen combinations.

The 1209a result overlaps with three segments of the Wolfman Curve (Figure 66.5). The centerpoint is closest to the 11th century segment, but this date range (AD 1015–1130) can be ruled out on contextual grounds.

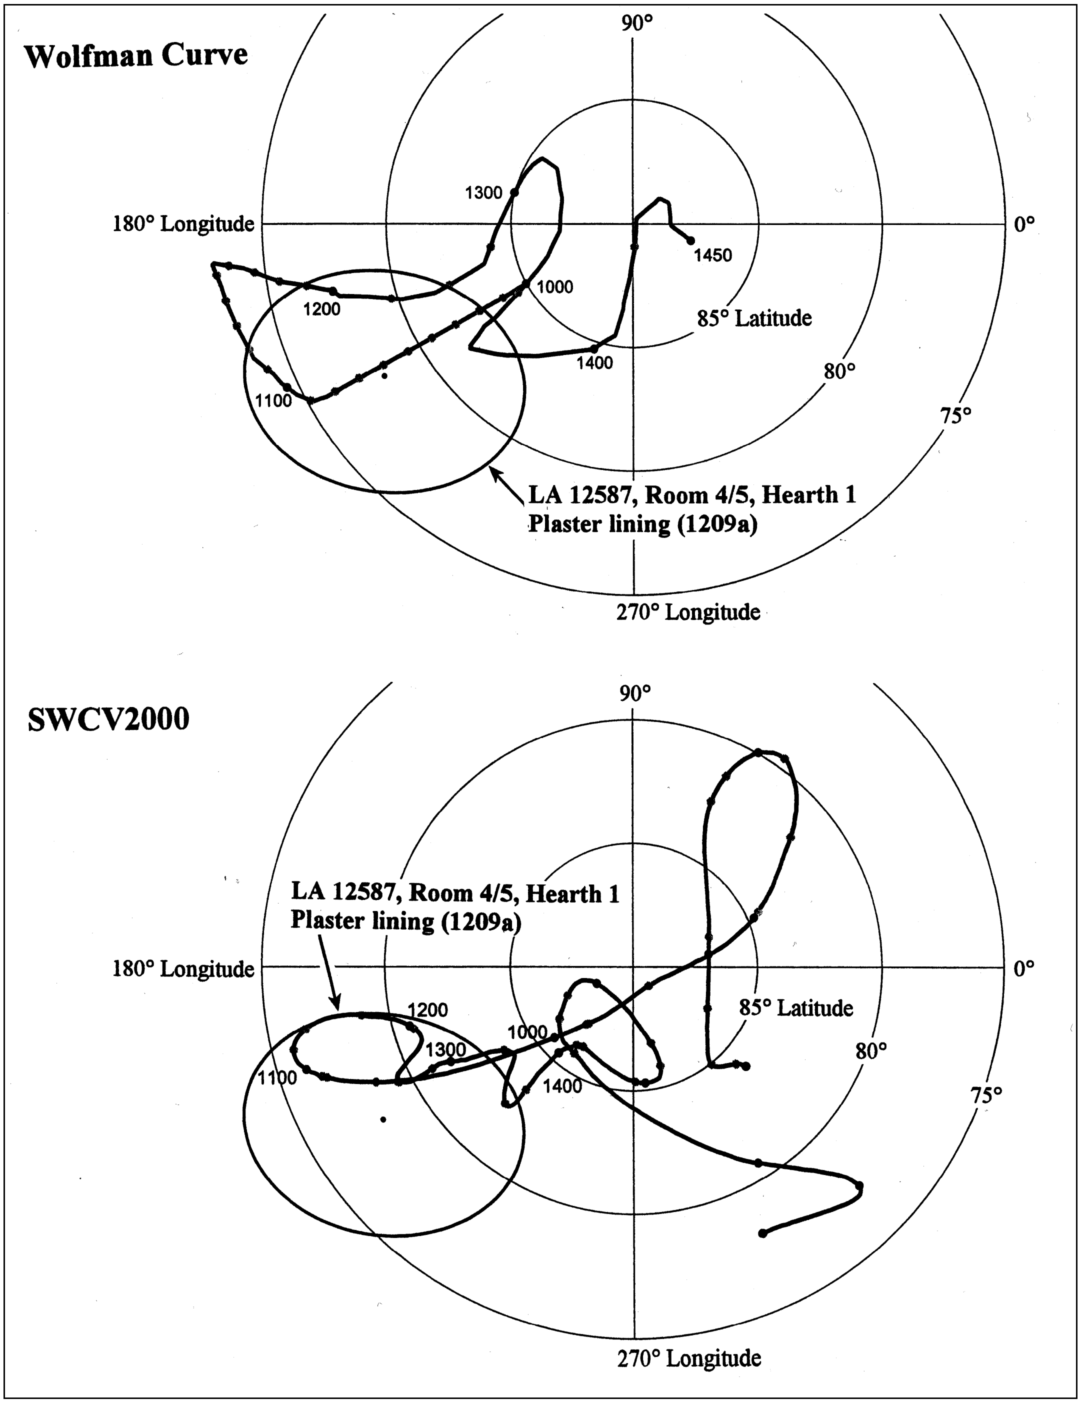

Figure 66.5. LA 12587, Room 4/5, Hearth 1 archaeomagnetic results for set 1209a (the subset of specimens cut from the plaster lining). The centerpoint and error ellipse are plotted against both the Wolfman Curve and SWCV2000.

The second segment overlapped by the ellipse yields a date range estimate of AD 1160–1275, which is plausible. The ellipse also barely overlaps the 14th century segment of the curve, and that segment yields a date range of AD 1335–1410. This date range is later than can be supported by other chronologic information. When compared with the SWCV2000, the large ellipse encompasses a 370-year range from AD 1005–1375.

When compared with the DuBois calibration data set, the ellipse overlaps the later half of the AD 1125–1225 point scatter (see Figure 9.14, Volume 1). It encompasses a majority of the AD 1225–1300 calibration centerpoints (see Figure 9.21, Volume 1), and it encompasses approximately half of the AD 1300–1400 points (see Figure 9.28, Volume 1). The contribution of this result to the interpretation of the site chronology is limited by its imprecision, but it is consistent with the other results that suggest a late 13th or perhaps early 14th century age for the final use of the hearths in the roomblock.

A radiocarbon date on maize from the hearth fill overlaps two portions of the radiocarbon calibration curve at the two-sigma level (see Table 66.3). However, only one range, AD 1270–1320, includes an intercept (AD 1290). The later date range (AD 1350–1390) is incompatible with the pottery at the site.

Summary

The interpretable archaeomagnetic results from LA 12587 are presented in Figure 66.6. The two samples from Hearth 20 of Room 2 are extremely precise, confirm each other, and are stratigraphically earlier than the other samples collected from the site. The Room 2, Hearth 4, and Room 7 VGPs fall at relatively high latitudes, and although the accuracy of the Room 2 VGP could be questioned, it is reinforced by the Room 7 result. The Room 4/5 result is less precise than the others and occupies either an intermediate position or a later position in terms of VGP movement. The possibility of a later position is based on the associated radiocarbon date, which is slightly later than those from the two other dated hearths. Based on the Wolfman Curve, the date range associated with these VGPs begins as early as AD 1200 or slightly before and carries through until the late 13th century. There is a chance that one or more of the burned features could date as late as AD 1300, but this portion of the Wolfman Curve is slightly less secure than the pre-AD 1275 portion (see Chapter 9, Volume 1).

LA 86534

This site represents a relatively discrete occupation, with evidence of remodeling and structure longevity but without evidence for distinct multiple components. Five sets of specimens were collected from burned features in three rooms and a kiva. One room hearth showed clear evidence of remodeling, and two sets were collected from its linings. Apart from these two sets, there is no clear indication of stratigraphic sequencing between the samples. The four room hearth samples were subject to post-burning disturbance from wetting and drying, freeze-thaw, and root invasion. All of the hearths were lined with a plaster composed of volcanic ash-rich soil that appears to have been derived from weathered tuff. The clay content of the plaster was sintered by the cooking and heating fires, consolidating the material to a weak ceramic consistency. However, the fires were not particularly hot, and the linings were fragile. The surface room hearth linings were cracked and subject to displacement, raising the risk of systematic error when multiple specimens were cut from single lining blocks. In addition to eliminating lining blocks from sampling consideration if there was any suggestion of movement, whenever possible, specimens were collected from multiple blocks so that any significant internal bias could be detected.

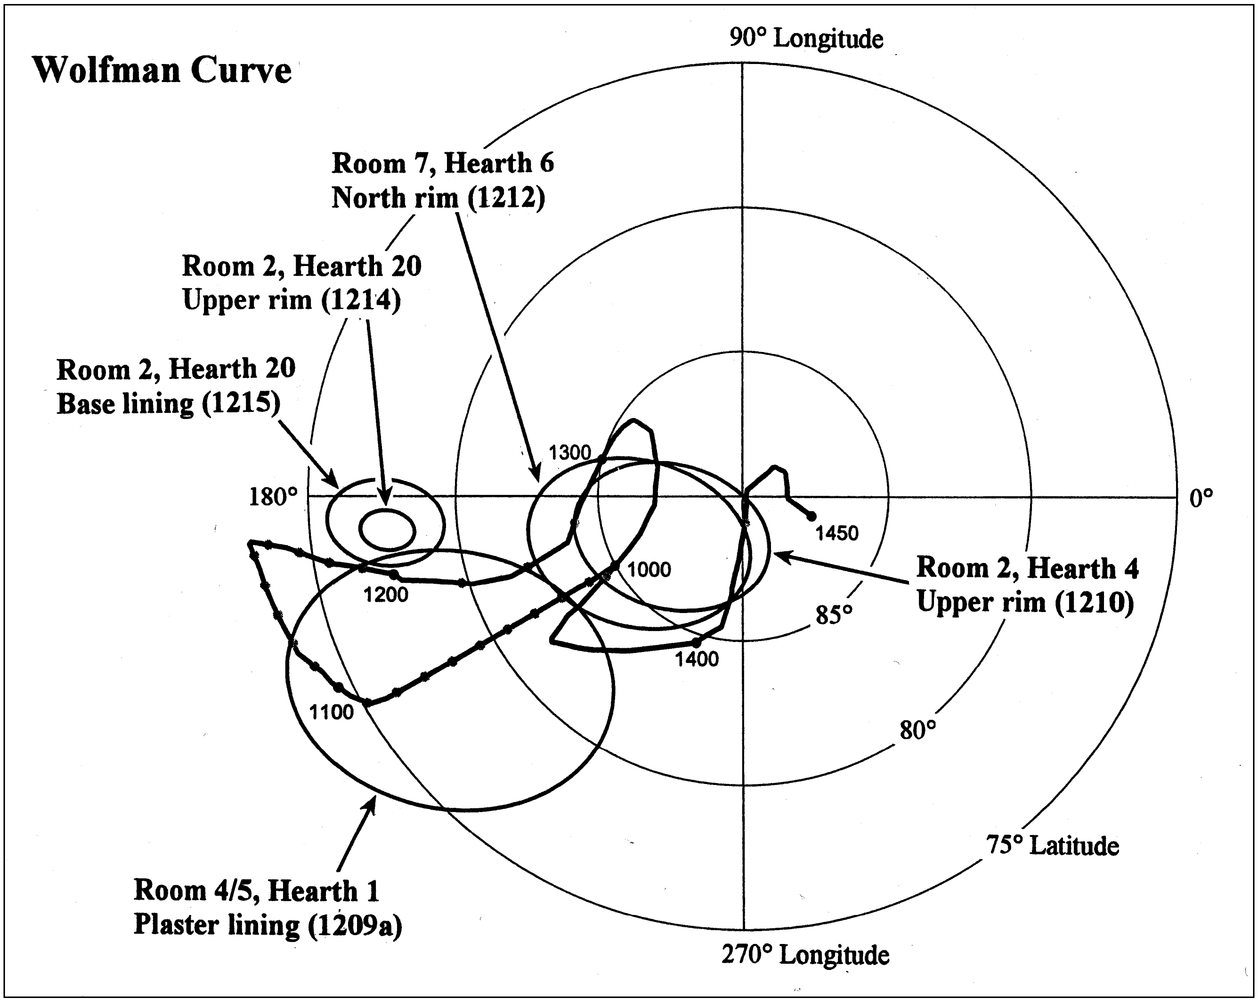

Figure 66.6. All interpretable LA 12587 archaeomagnetic ellipses plotted against the Wolfman Curve.

Room 1

The hearth, Feature 4, consisted of a depression in the floor that was loosely lined with stones and then lined with a volcanic-ash-rich plaster. The plaster lining was moderately well burned but was fragmented from weathering and root invasion. After the first set of specimens was collected, it was clear that the hearth had been remodeled at least once through the period of structure use. After the upper hearth elements were removed, a second set of specimens was collected from a lower lining. Intervening sediments were shallow, and the earlier hearth could have been slightly affected by heating events associated with the later hearth fires. In both cases, specimens could not be collected from the upper walls of the hearths due to fragmentation and displacement of the linings.

Eight specimens were collected from the upper hearth lining (1202). Only a single lining fragment was suitable for sampling, but there was no evidence that the lining had shifted its orientation. The specimens yielded a best result after demagnetization at 100 Oe, and no specimens were identified as statistical outliers. The result is moderately precise, with an α_{95} value of 1.8º (Figure 66.7). The ellipse overlaps one segment of the Wolfman Curve, and the associated date range is AD 1170–1230. It also overlaps with a single segment of the SWCV2000, and the associated date range is AD 1110–1200. When compared with the scatter plots of otherwise well-dated AD 1125–1225 and AD 1225–1300 centerpoints from DuBois data set for the northern Rio Grande region (see Figures 9.14 and 9.21, Volume 1), the ellipse encompasses a significant subset of the AD 1125–1225 results. The ellipse overlaps only a small number of the AD 1225–1300 centerpoints and is marginal to the AD 1300–1400 point scatter (see Figure 9.28, Volume 1).

Eight specimens were also collected from lining fragments from the underlying hearth (1203). The lining blocks were small and slightly unstable, and multiple lining fragments were sampled. Individual specimen vectors were relatively dispersed, yielding a large error term (α_{95} = 3.7º) after demagnetization at 150 Oe; one specimen was excluded as an outlier. The pole position is at a higher longitude than that of the overlying sample, and the two ellipses only barely overlap (see Figure 66.7). Despite its large size, the ellipse intersects only one segment of the Wolfman Curve, yielding a date range estimate of AD 1035–1140. The ellipse is adjacent to the AD 1125–1300 segment of the Wolfman Curve, and it is close enough to warrant interpretation of a date range of AD 1065–1265. The intersection of the ellipse and the SWCV2000 is much more marginal but involves two segments. Because of the size of the ellipse and the curve conformation, the date range estimates are large and overlap substantially. The range based on the closest point of intersection is AD 1010–1315, while a range of AD 1000–1390 is associated with the other segment intersection. When compared with the DuBois calibration points, overlap is partial with the AD 1125–1225 scatter (see Figure 9.14, Volume 1) and with centerpoints associated with the AD 1000–1125 period (see Figure 9.7, Volume 1). Nearly half of the AD 1225–1300 centerpoints fall within the error ellipse of the result (see Figure 9.21, Volume 1), but the ellipse is marginal to the AD 1300–1400 scatter (see Figure 9.28, Volume 1).

If we could be confident that both sets of specimens were robust, the results could be interpreted as representing a stratigraphic occupational sequence from the late 11th century through the early 13th century. However, the early end of this range is inconsistent with other dating information from the site, and the instability of the lower lining provides reason to question the accuracy of the 1203 result. Although it should be earlier than the 1202 result, the centerpoint location is far removed and the error ellipses barely overlap. Coupled with both 1203's large α_{95} value and the fragmented condition of the hearth lining, there is reason to suspect that the pole position is not representative.

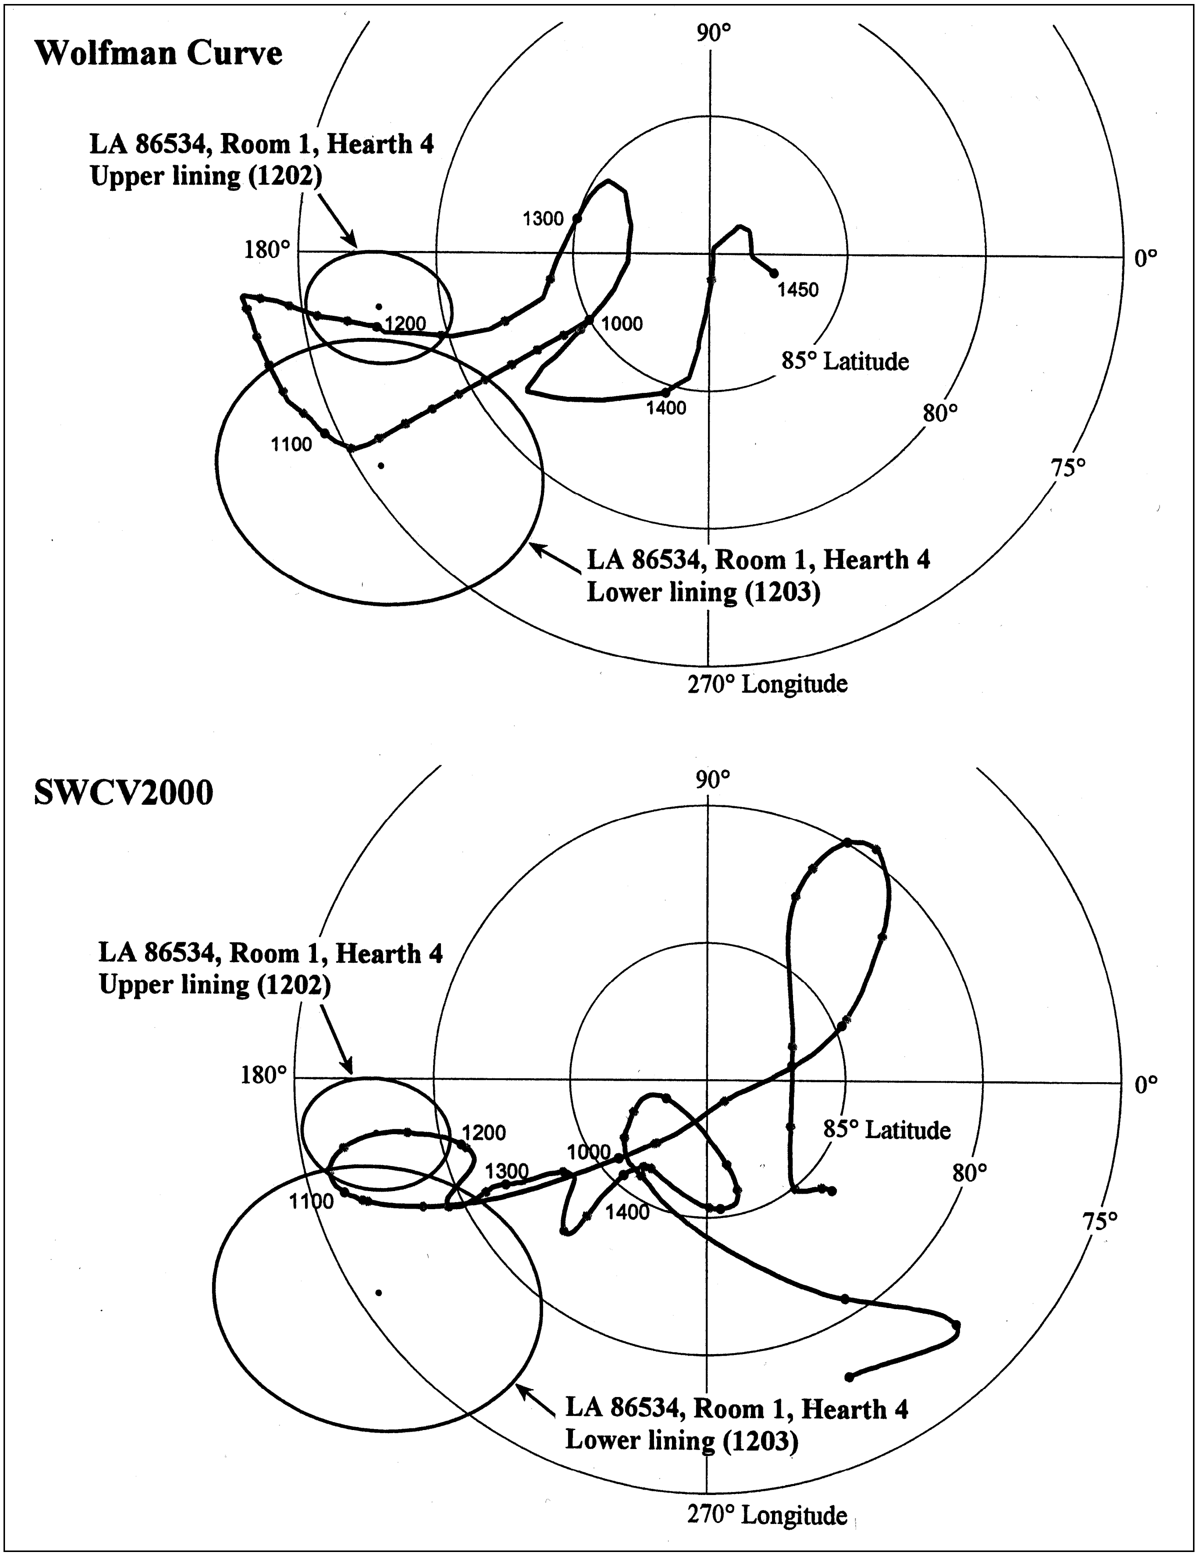

Figure 66.7. LA 86534, Room 1, Hearth 4 archaeomagnetic results for sets 1203 (earlier) and 1202 (later). Centerpoints and error ellipses are plotted against both the Wolfman Curve and SWCV2000.

By itself, the 1202 result is relatively consistent with other site dating information, suggesting use of the hearth in the late 12th or early 13th centuries. This is consistent with a radiocarbon date on maize from the hearth fill that yielded a range of AD 1040–1260 with an intercept of AD 1190 (see Table 66.3). However, both the archaeomagnetic and associated radiocarbon dates from other hearths at the site are slightly later in time.

Room 2

The hearth (Feature 2) in Room 2 consisted of a depression with tuff block walls and a lining of volcanic-derived plaster. The plaster lining was fragmented, and specimens were cut from three distinct fragments. These fragments were more stable than others within the feature, but each was at risk of having been displaced slightly by ground pressure and weathering. Eight specimens were collected as set 1204, and all but one were characterized as being “solid” during field collection.

The specimens yielded an extremely precise result ($\alpha_{95} = 0.6^{o}$) after demagnetization at 300 Oe (Figure 66.8). One specimen was excluded from the result as an outlier. In part because of its precision, the ellipse falls off of the existing curves by several standard deviations. Compared with the Wolfman Curve, the sample is closest to the AD 1225–1300 segment. When the centerpoint is replotted at the closest point on the curve segment, the resulting date range is AD 1280–1300. The AD 1300 loop of the Wolfman Curve is the weakest portion of the curve (Chapter 9, Volume 1), and a more conservative interpretation would be to push the early end of the range more toward the middle 13th century. The closest point on the SWCV2000 is around AD 1195, and the resulting date range after replotting is AD 1175–1230. The result is at the margins of the AD 1125–1225 centerpoint swarm of the DuBois calibration data set (see Figure 9.14, Volume 1), and it is further removed from the AD 1225–1300 and 1300–1400 calibration point scatters (see Figures 9.21 and 9.28, Volume 1).

The discrepancy between the high precision of the result and the relative distance of the result from both the dating curves and the scatter of DuBois calibration points is disquieting. Because the dating curves are approximations and because high precision error ellipses are small, it is not unusual for precise samples to fall off of the curves. In this case, however, the distance is large and only a single point of the DuBois data points comes close to the 1204 result. Distortion of the lining fragments is a possible explanation, but it is improbable since the plotted result includes specimens from all three fragments, and it is unlikely that all three would be displaced in exactly the same direction. A local magnetic anomaly might have affected the orientations of the specimens or of the compass reading during sample collection, resulting in a skewed but precise result location.

A radiocarbon date on maize from the hearth fill yielded a calibrated two-sigma range of AD 1240–1300 with an intercept of AD 1280 (see Table 66.3). Despite all of the caveats in interpreting the 1204 VGP location, a realistically conservative conclusion is that this sample dates to the last third of the 13th century.

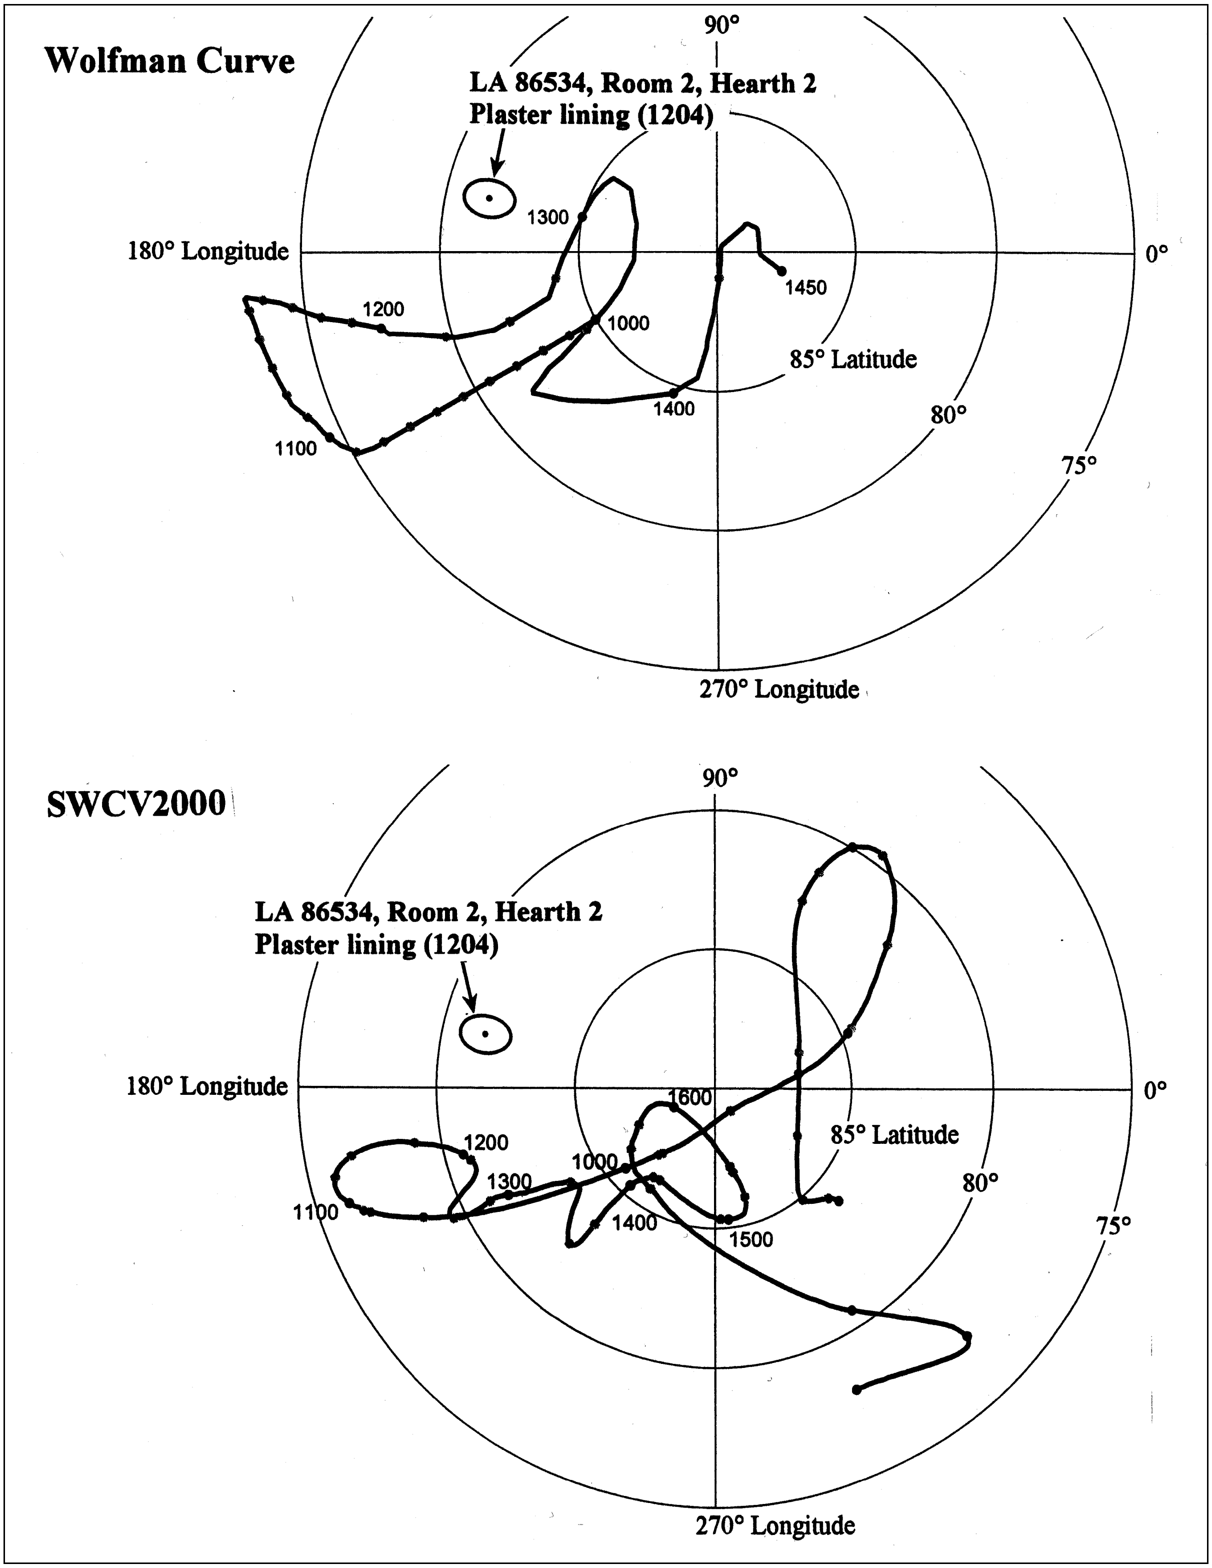

Figure 66.8. LA 86534, Room 2, Hearth 2 archaeomagnetic results for set 1204. The centerpoint and error ellipse are plotted against both the Wolfman Curve and SWCV2000.

Room 5

Specimens were collected from the plaster lining the base of Hearth 5 in Room 5 (set 1205). The plaster was relatively intact, and there is no suggestion of mass movement that might have altered the pole position. A vesicular basalt cobble was present in the fill below the hearth, but it did not appear to cause a magnetic anomaly when a compass was moved across it after the sampling was completed.

Eight specimens were collected from the lining. The best result was following demagnetization at 150 Oe and is associated with an α_{95} of 1.1^{o} using all eight specimens. The result overlaps two segments of the Wolfman Curve (Figure 66.9). The date estimate associated with the earlier segment (AD 1005–1035) can be discounted on contextual grounds. The later segment includes the middle of the 13th century, and relocation of the result centerpoint to the curve produces a date range of AD 1235–1270. The 1205 ellipse overlaps only one segment of the SWCV2000 dating curve, and the associated date estimate is AD 1265–1325. Compared with the DuBois calibration data set, the 1205 result is at the margin of the centerpoints dating to the AD 1125–1225 period. It is in the center of the AD 1225–1300 point distribution, and it overlaps a significant minority of the AD 1300–1400 centerpoints (see Figures 9.14, 9.21, and 9.28, Volume 1).

A radiocarbon date on maize from the hearth fill yielded a calibrated two-sigma range of AD 1180–1280, with an intercept at AD 1250 (see Table 66.3). The radiocarbon date is consistent with the Wolfman Curve date range that indicates a middle 13th century age for the last use of the feature.

Room 9 (Kiva)

Room 9 was excavated into tuff bedrock, and the hearth (Feature 16) was developed from a pit excavated into the bedrock floor of the kiva. The pit was lined with a volcanic ash-rich plaster, and a thick annular plaster coping was built up around the exterior of the hearth. Due to its depth below the modern ground surface and the hearth's bedrock foundation, the lining and coping suffered little weathering or mechanical damage since abandonment. The plaster coping was slightly oxidized (reddened) and well consolidated by the heat, but there was no indication of extreme heat exposure.

Eight specimens were collected from the inner surface of the coping toward the ventilator opening where the hearth material should have been exposed to the highest temperatures from fuel combustion. The best result for the set (1206) was after demagnetization at 100 Oe and included all eight specimens. The precision is good (α_{95} = 1.0E), and the error ellipse overlaps two segments of the Wolfman Curve (Figure 66.10). The date estimate associated with the earlier segment (AD 1020–1050) can be discounted on contextual grounds. The later segment includes the middle of the 13th century, and relocation of the result centerpoint to the curve produces a date range of AD 1220–1255. The 1205 ellipse also overlaps two segments of the SWCV2000 dating curve. The associated date estimates are both plausible, one at AD 1185–1240 and the other at 1250–1315. Compared with the DuBois calibration data set, the 1205 result is at the margin of the centerpoints dating to the AD 1125–1225 period (see Figure 9.14, Volume 1). The ellipse is near the center of the AD 1225–1300 point distribution, and it overlaps a minority of the AD 1300–1400 centerpoints (see Figures 9.21 and 9.28, Volume 1).

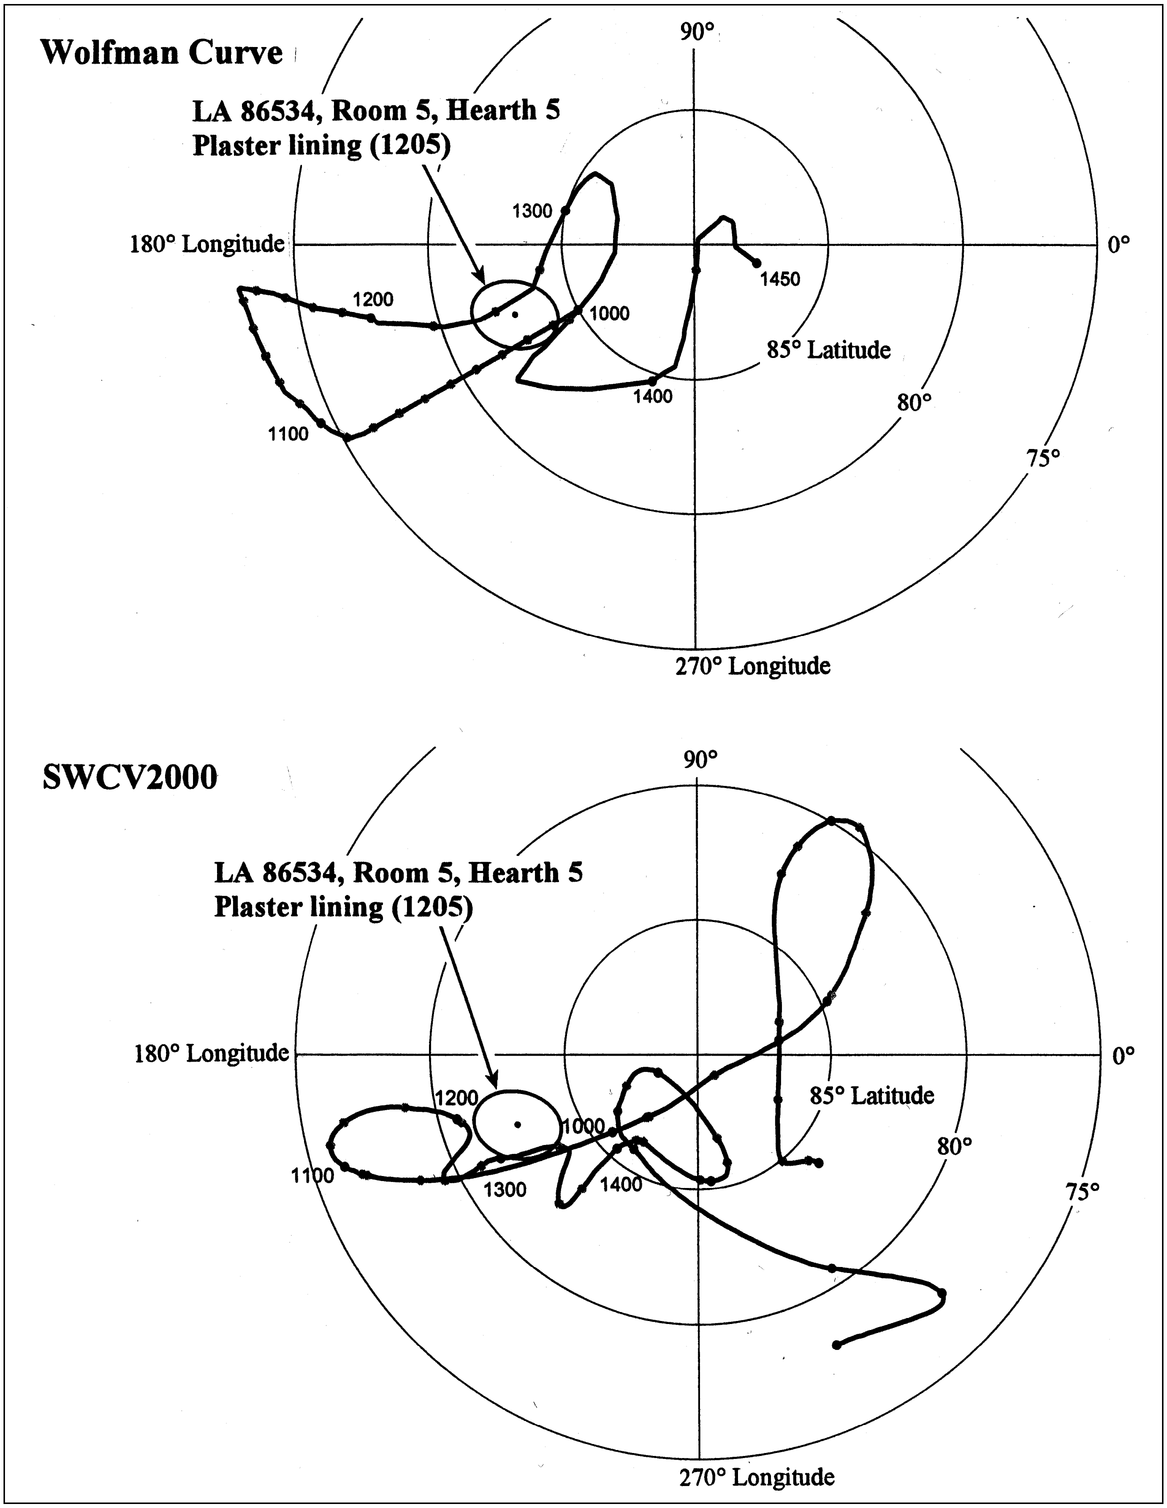

Figure 66.9. LA 86534, Room 5, Hearth 5 archaeomagnetic results for set 1205. The centerpoint and error ellipse are plotted against both the Wolfman Curve and SWCV2000.

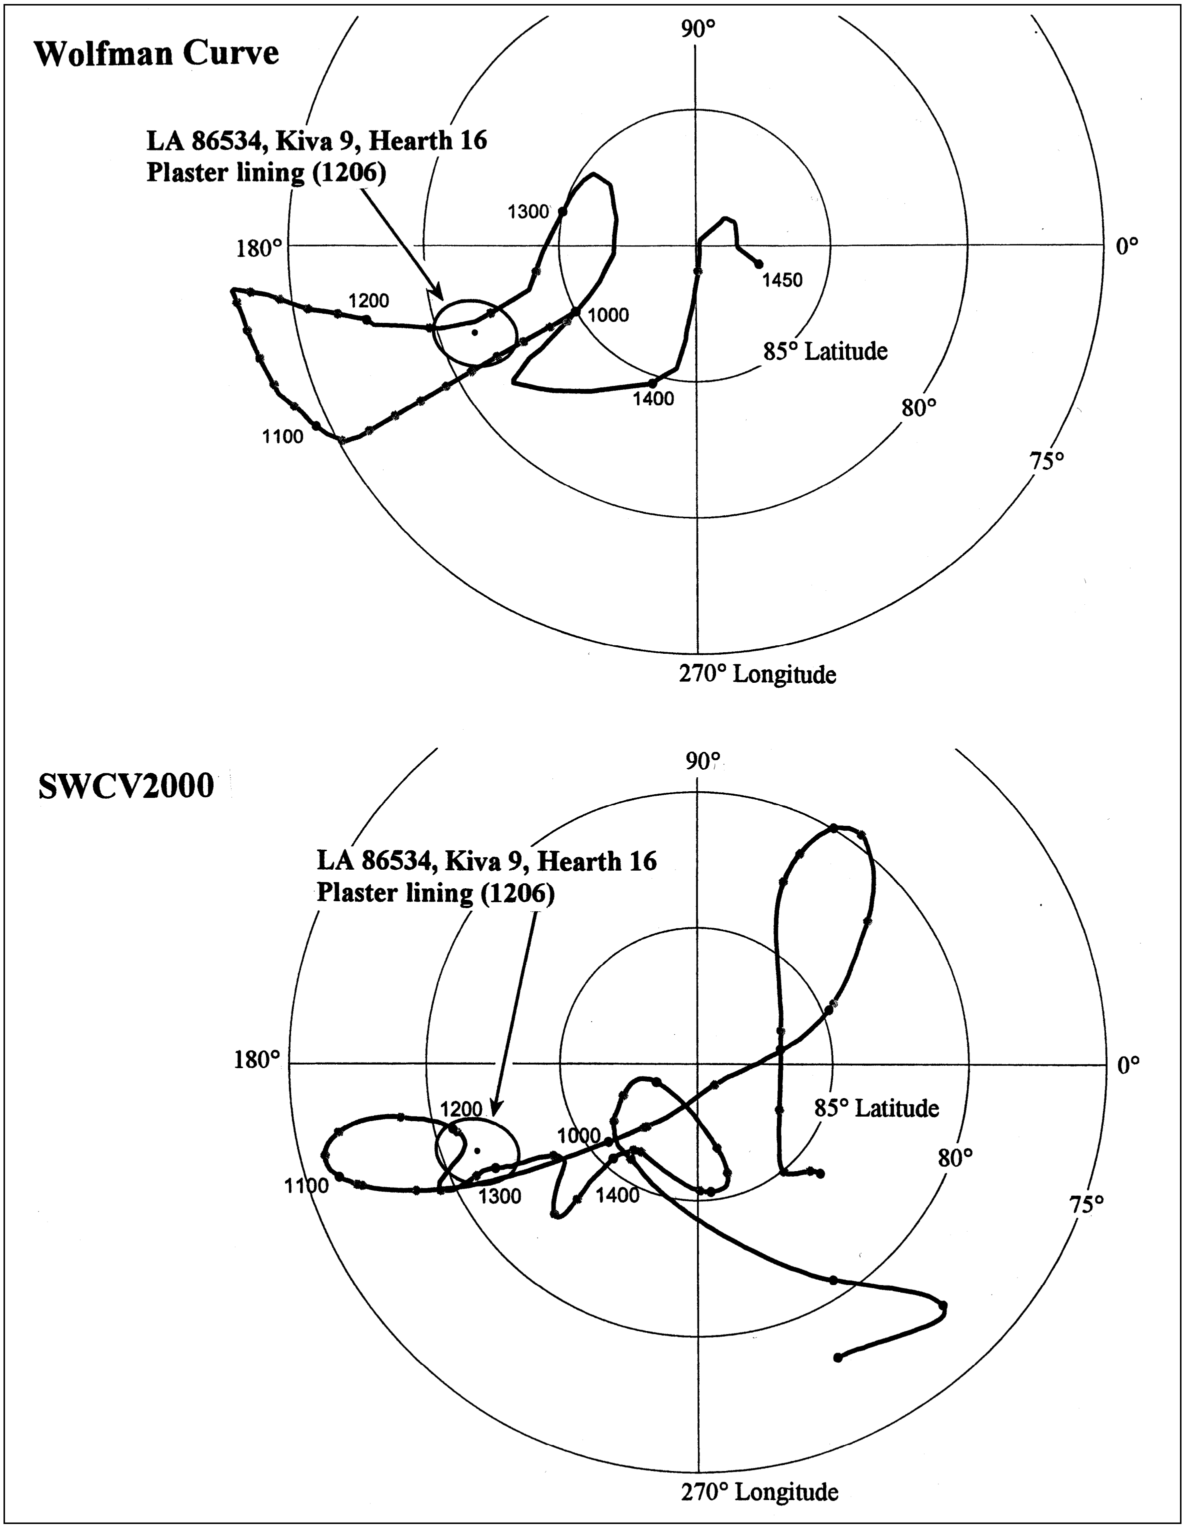

Figure 66.10. LA 86534, Kiva 9, Hearth 16 archaeomagnetic results for set 1206. The centerpoint and error ellipse are plotted against both the Wolfman Curve and SWCV2000.

A radiocarbon date on unidentified charred material from the hearth fill yielded a calibrated two-sigma range of AD 1180–1290 with an intercept at AD 1260 (see Table 66.3). This is consistent with the DuBois- and Wolfman-based interpretations of a middle 13th century date for the last use of the hearth.

Summary

The archaeomagnetic sets from LA 86534 include two anomalous results, one with high precision, and three results whose Wolfman and DuBois interpretations are consistent with associated radiocarbon dates (Figure 66.11). If the anomalous results are ignored, Room 1, Hearth 4, yielded the earliest VGP from the site with a result that falls close to AD 1200. This date would require that the hearth had been abandoned and disused for one or more generations before the abandonment of the site as a whole. The hearths from Room 5 and Kiva 9 yielded later overlapping pole positions, suggesting a probable middle 13th century age for both that would represent the abandonment of the site. Associated radiocarbon dates are consistent with all three of the "well-behaved" archaeomagnetic results. The anomalous Room 1 result (1203) is stratigraphically earlier than the non-anomalous result, but not as early as the VGP would suggest. The anomalous Room 2 sample is marginal to known calibration point scatters. Its latitude is consistent with the Room 5 and Kiva 9 results, but its longitude is much lower. The conventions used for deriving archaeomagnetic date ranges (moving centerpoints to the closest positions on potentially relevant dating curve segments) produce an age range only slightly later than Room 5 and Kiva 9 hearths, but the feature pole position is unique and the archaeomagnetic date assignment is problematic (although it is consistent with the radiocarbon date).

LA 135290

Excavations within a rubble mound and artifact scatter at this site defined the presence of a surface roomblock. No pit structures or formal middens were present. Despite the lack of formal midden accumulations, the rooms revealed a complex remodeling sequence, with multiple floors and hearths. This complexity suggests a long and relatively continuous, if not intense, occupation of the site. In addition to three cooking or heating hearths, at least three burning incidents occurred in the rooms, affecting both floors and walls. Stratigraphic relationships between archaeomagnetic sets are relatively clearly defined, increasing the interpretive potential of the results.

Room 2

Two archaeomagnetic sets were collected from hearths in Room 2. The stratigraphically earliest set (1231) was collected from Hearth 16. This hearth was associated with an undefined floor surface that would have been built and used early in the life of the roomblock, probably as part of the initial occupation. Floor 1 was built over this hearth, replacing the earlier floor. A later feature, Hearth 11 (set 1229) was associated with Floor 1, installed by cutting through and destroying part of Hearth 16. Floor 1 was directly overlain in some areas by burned structural remains, suggesting that the last use of Hearth 11 would be before or contemporary with one of the other burning incidents in the roomblock.

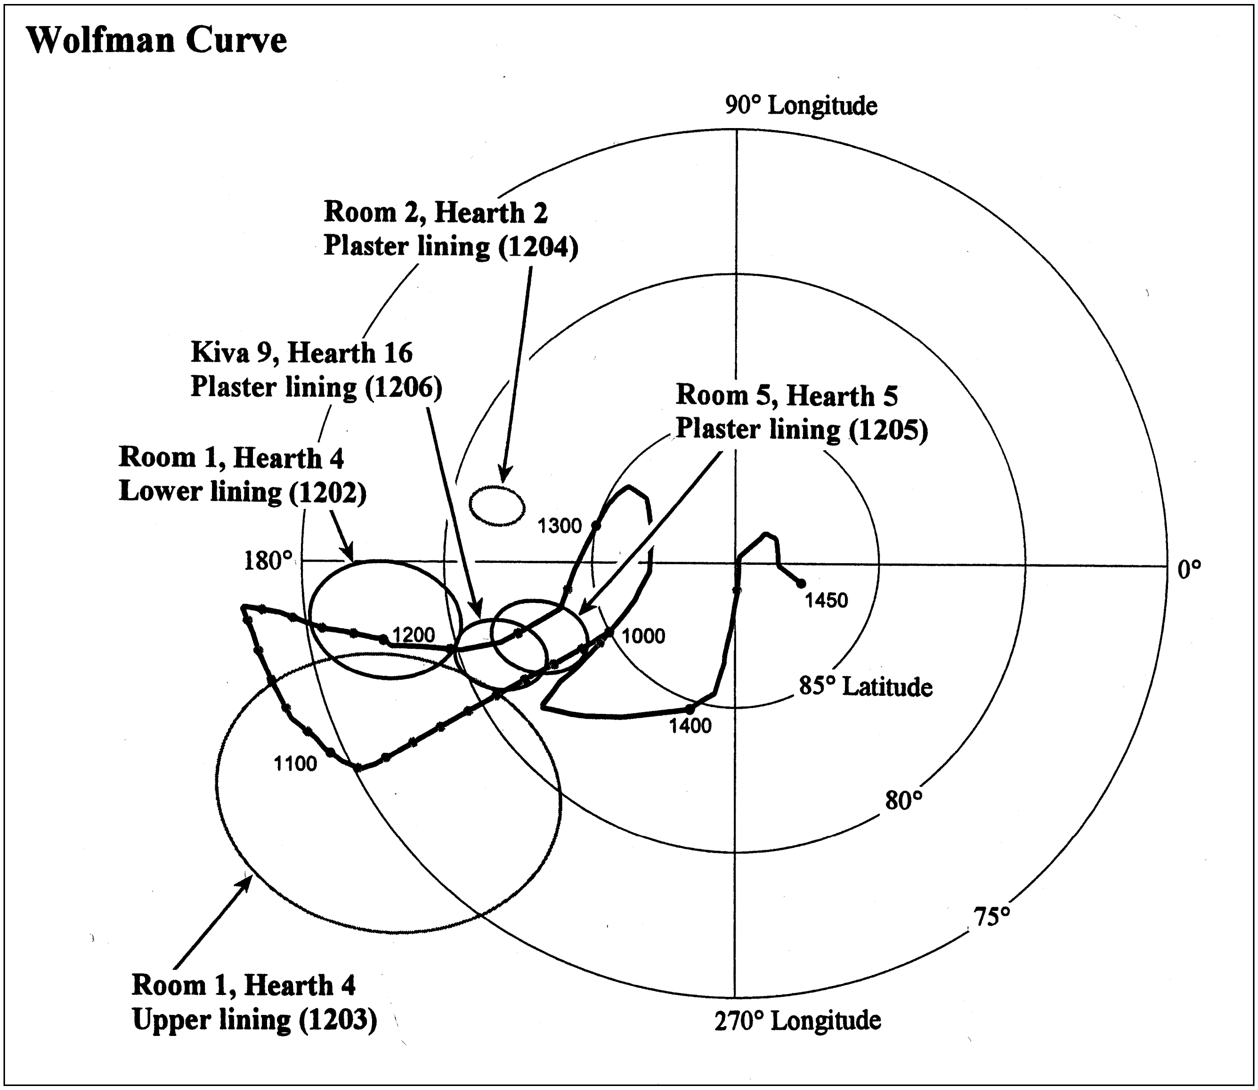

Figure 66.11. All interpretable LA 86534 archaeomagnetic ellipses plotted against the Wolfman Curve. Anomalous results are presented in gray.

Eight specimens were collected from the lower Hearth 16 (set 1231; see Table 66.1). The best VGP result followed demagnetization at 200 Oe. One specimen vector was an outlier and was eliminated from the final VGP calculation. The error term is moderate ($\forall_{95}$ = 1.7E). The error ellipse overlaps two segments of the Wolfman Curve within the AD 1100–1300 time span, resulting in two possible date ranges (Figure 66.12). The earlier and less likely range is AD 1105–1150, while the later range of AD 1155–1210 is a more probable date interpretation for the last burning of the hearth. The date range based on the SWCV2000 is AD 1035–1165, but this range is too early given contextual information. Compared with DuBois' AD 1125–1225 samples (Figure 9.14, Volume 1), the ellipse encompasses the earlier portion of the point scatter. Compared with the DuBois AD 1225–1300 centerpoints, the ellipse slightly overlaps the early end of the distribution (Figure 9.21, Volume 1). A radiocarbon date was derived from maize from the hearth fill, yielding a calibrated two-sigma range of AD 1040–1260 and an intercept of

AD 1190 (see Table 66.3). These independent chronological data support the Wolfman mid to late 12th century date interpretation.

Set 1229 was collected from Hearth 11 and consists of seven individual specimens (see Table 66.1). During the measurement process, the best result was obtained after demagnetization at 300 Oe. The error term was moderately large ($\forall_{95}$ = 2.3E), and there were no outliers in calculating the final result. The error ellipse overlaps two segments of the Wolfman calibration curve in the AD 1000–1300 time period (see Figure 66.12), but a pre-AD 1125 date possibility is unlikely given the pottery associations of the site. The most probable date range based on the Wolfman Curve is AD 1195–1275. The large range is due to the imprecise pole location estimate; the centerpoint of the result is closest to the curve at about AD 1245. The relevant date range based on the SWCV2000 is AD 1175–1325, encompassing the Wolfman Curve date range. This result overlaps the later scatter of centerpoints from the AD 1125–1225 DuBois data set (Figure 9.14, Volume 1) and a portion of the early scatter of centerpoints for the AD 1225–1300 period (Figure 9.21, Volume 1).

The two samples are in proper stratigraphic and temporal sequence, spanning the middle to late 12th century and the early to middle 13th century.

Room 4

Two archaeomagnetic sets were collected from floors within Room 4. The earliest set (1232) was collected from a portion of Floor 3 that had been thoroughly hardened by a room fire. This floor was the original floor in this portion of the roomblock, and it had been in place before the construction of what is now the south wall of Room 4. This floor is known as Floor 3 in Room 4, while the same floor installation is designated Floor 2 within the adjacent Room 5. The burned portion of this floor was against the eastern wall of Room 4. The burning of Floor 3 was followed by room abandonment, deterioration, and rodent disturbance of the non-burned portions of Floor 4. A reoccupation began with clearing of deterioration debris, chinking of rodent holes, placement of the wall subdividing Room 4 from Room 5, and installation of a 3- to 4-cm-thick layer of clean adobe to form Floor 2. The wall extended only part way across the width of the room, resulting in a doorway to Room 5 at one end. After an unknown duration of use that left no features and no artifacts, another burning incident occurred. Floor 2 was burned in the vicinity of the doorway to Room 5, along with a portion of the doorway and adjacent wall. The second archaeomagnetic set (1227) was collected from Floor 2 in the vicinity of the doorway. The sequence of abandonment, deterioration, rodent disturbance, clearing, and rebuilding was repeated after this fire as well. The final floor, Floor 1, was constructed, used, and abandoned, also with evidence of a burning incident either at or shortly after the time of abandonment. The burning of Floor 1 could not be sampled.

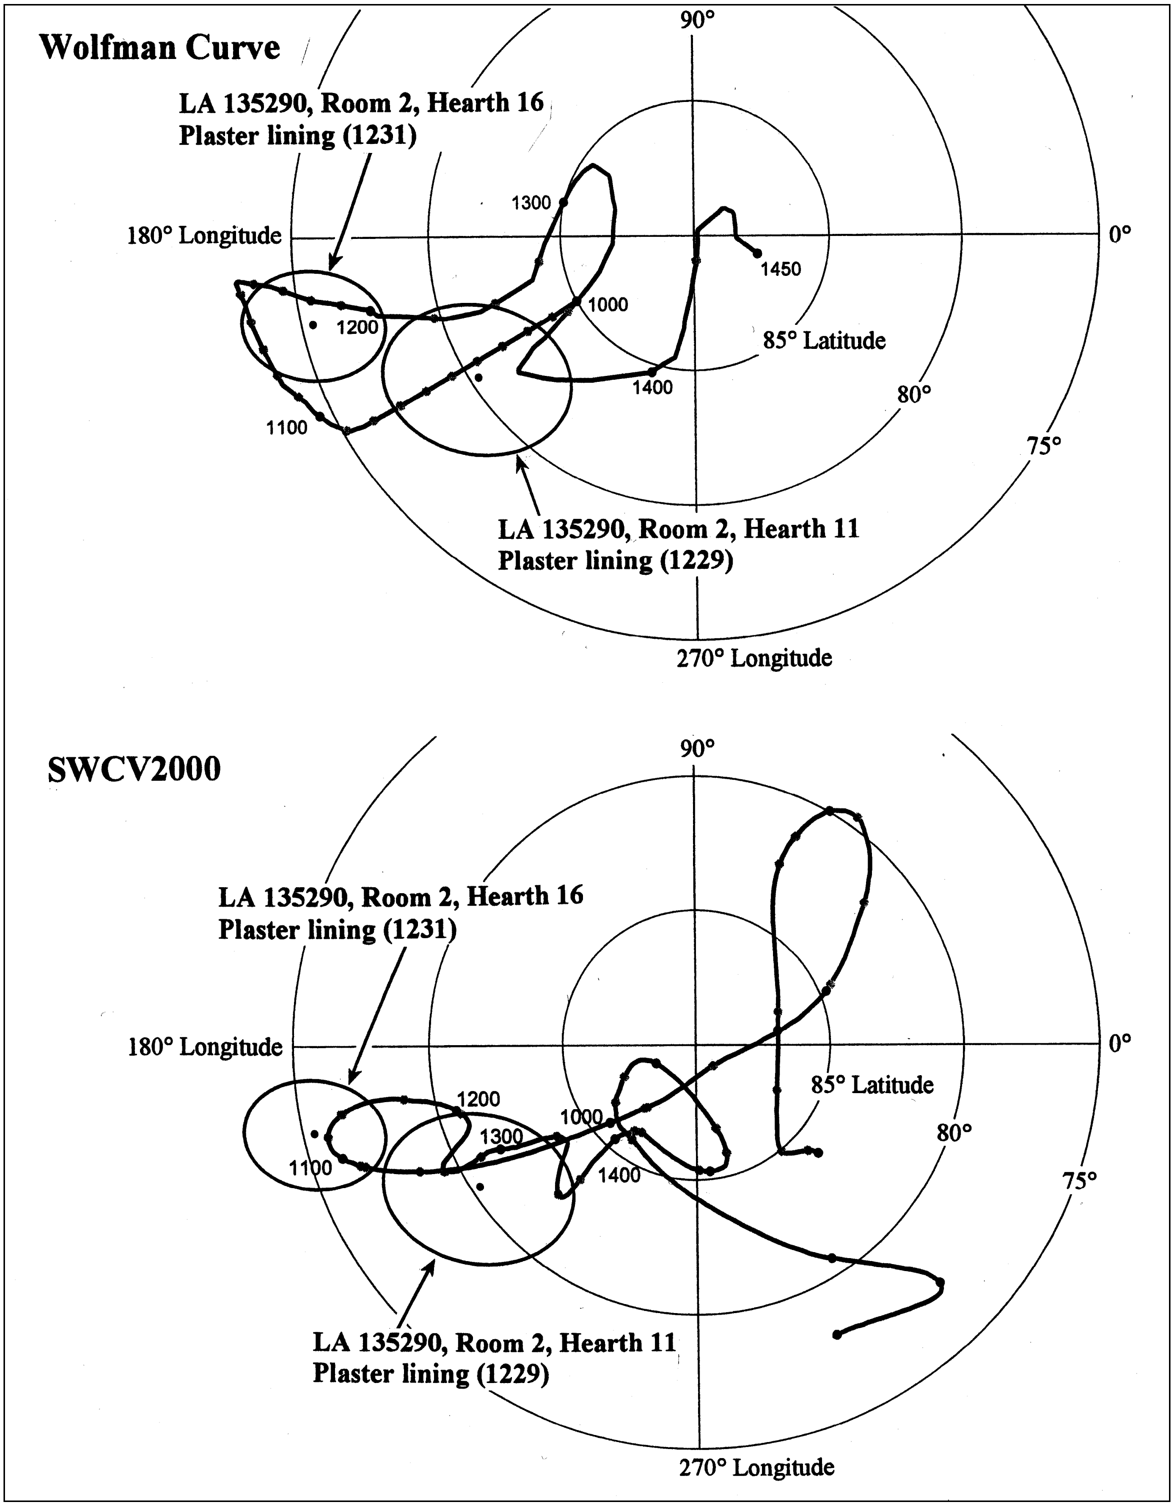

Figure 66.12. LA 135290, Room 2 archaeomagnetic results for sets 1229 (later) and 1231 (earlier). Centerpoints and error ellipses are plotted against both the Wolfman Curve and SWCV2000.

Floor 3 yielded seven specimens (1232), one of which proved to be an outlier and was eliminated from the final best result after demagnetization at 100 Oe (see Table 66.1). Precision of the result is moderate (α_{95} = 2.4º), but despite the uncertainty the ellipse overlaps only one segment of the Wolfman Curve (Figure 66.13).

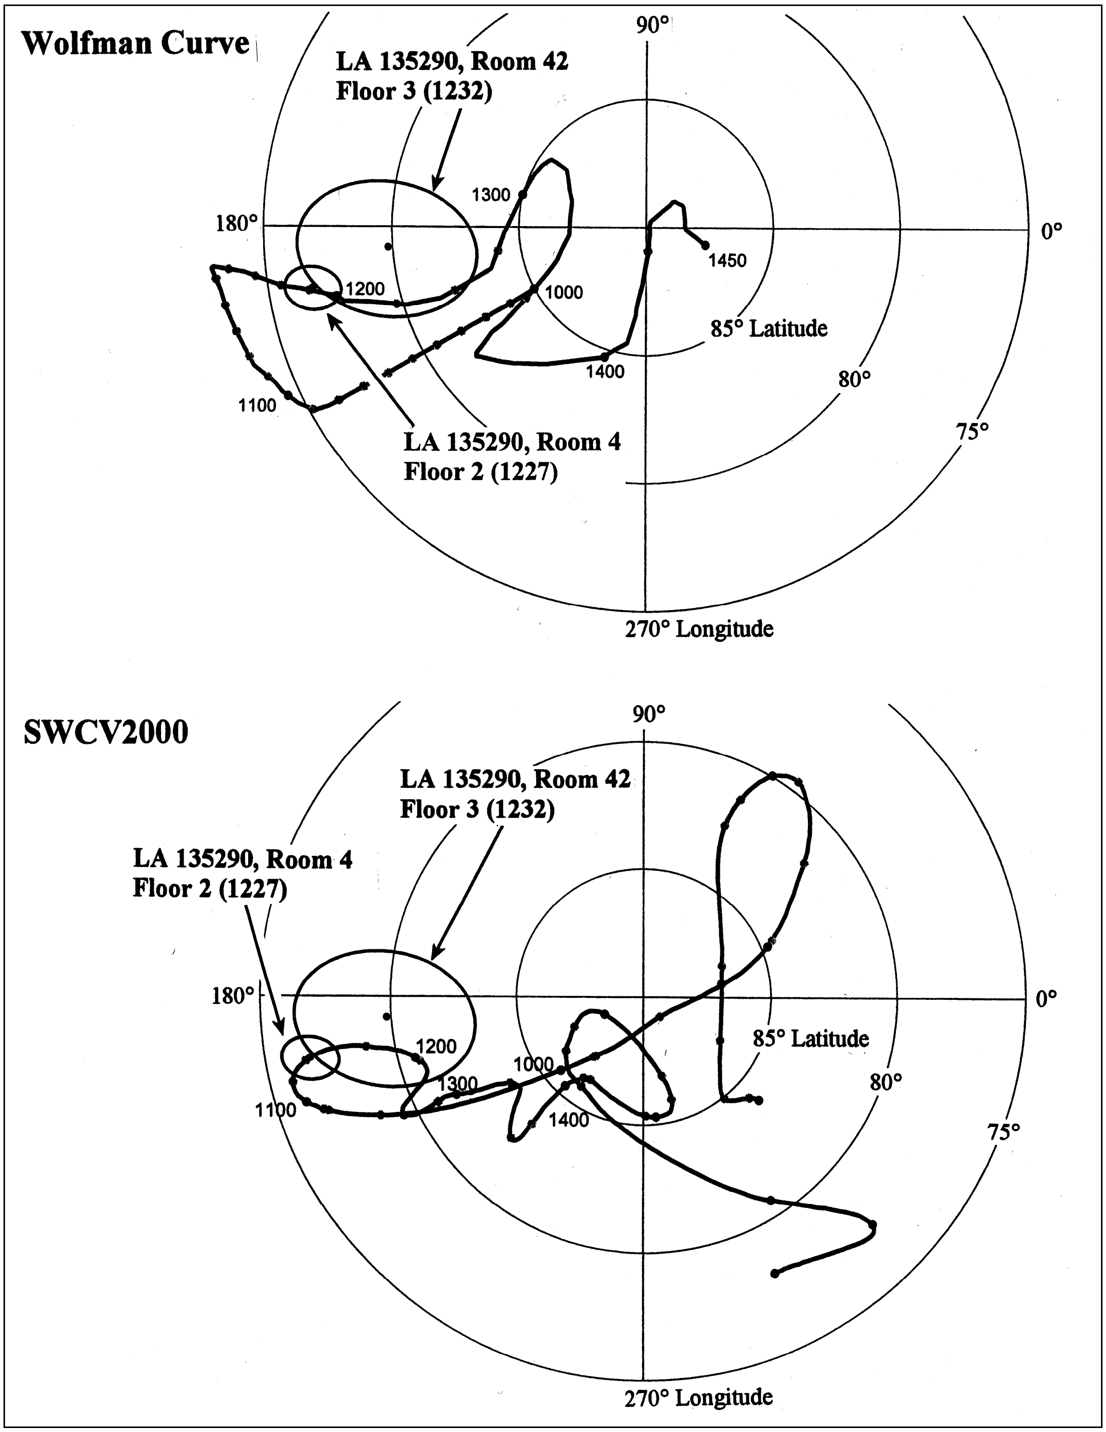

Figure 66.13. LA 135290, Room 4, Floor 3 and Floor 2 archaeomagnetic results for sets 1232 (earlier) and 1227 (later).

Intercepts of the result provide an estimated date range of AD 1180–1260. When compared with the SWCV2000, this result produces a date range of AD 1130–1305, encompassing the more precise interpretation based on the Wolfman Curve. The ellipse encompasses DuBois' sample centerpoints in the middle to late AD 1125–1225 period, but primarily those points that are at lower longitudes (Figure 9.14, Volume 1). The ellipse encompasses a smaller proportion of AD 1225–1300 DuBois centerpoints in the early to middle portion of the scatter (Figure 9.21, Volume 1).

Set 1227 was collected from Floor 2. It consisted of seven specimens, and all were included in the calculation of the final result after demagnetization at 200 Oe. The result is extremely precise (α_{95} = 0.7º), and it overlaps only a single segment of the Wolfman Curve (see Figure 66.13). The date range interpretation is AD 1180–1205. Comparison with the SWCV2000 yields a date range of AD 1125–1165, but a date this early is unlikely given the pottery at the site. When compared with the DuBois' sample centerpoints in the AD 1125–1225 period (Figure 9.14, Volume 1), the ellipse overlaps the early to middle portion of the centerpoint scatter. In the AD 1225–1300 period, the overlap is with DuBois' centerpoints in the early portion of the scatter (Figure 21, Volume 1).

The centerpoints of the two samples are in reverse stratigraphic sequence along the VGP curve, but the error ellipse of the stratigraphically earlier sample overlaps that of the later result.

Room 6

Room 6 also experienced multiple burning incidents. Floor 3 was the original floor of the room. After a period of use, the room burned, baking the floor and littering the floor with charcoal and other structural debris. Set 1226 was collected from this lower floor. Floor 2 was constructed on top of the debris from the first fire, and it also was burned after a period of use. No archaeomagnetic samples were collected from Floor 2, but a set was collected from the east wall of the room, above the level of Floor 2 (1228). This wall would have been affected by the burning incidents associated with both Floors 3 and 2, but the Floor 2 fire may be exclusively reflected in the magnetic orientation of the wall sample if the second burning reached equivalent or higher temperatures than the first. Evidence of a final floor (Floor 1) was preserved as a large unburned adobe patch in the fill above Floor 2. Floor 1 was not visibly burned.

Eight specimens were collected from Floor 3 (1226). The best result includes all eight specimens and was achieved after demagnetization at 100 Oe (see Table 66.1). The result is relatively precise (α_{95} = 1.1º) and overlaps only one segment of the Wolfman Curve (Figure 66.14). Based on that curve the ellipse intersection points yield a date range estimate of AD 1170–1210. The date range based on the SWCV2000 again appears to be slightly too early (AD 1125–1175). The ellipse encompasses DuBois' sample centerpoints in the early to middle AD 1125–1225 period (Figure 9.14, Volume 1). The ellipse is marginal to the early portion of the scatter of AD 1225–1300 DuBois centerpoints (Figure 9.21, Volume 1).

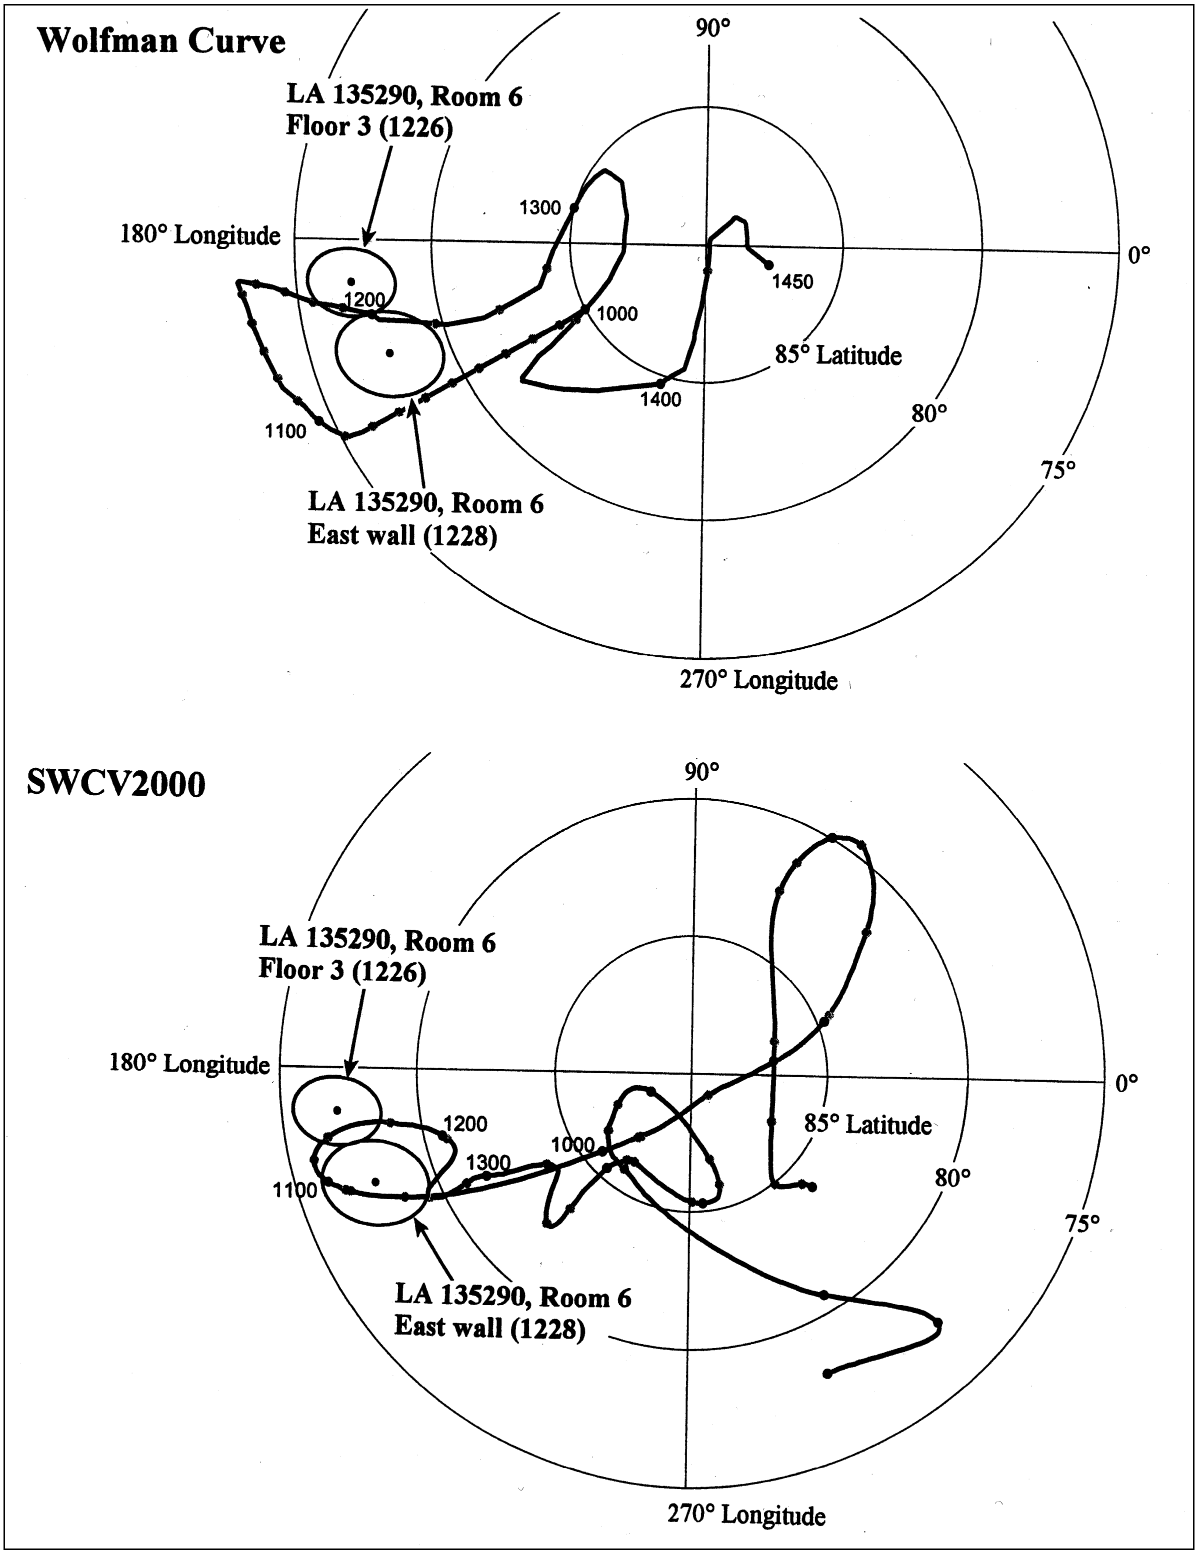

Figure 66.14. LA 135290, Room 6, Floor 3 and east wall archaeomagnetic results for sets 1226 (earlier) and 1228 (contemporary or later). Centerpoints and error ellipses are plotted against both the Wolfman Curve and SWCV2000.

Only six specimens were collected from the wall of the room (1228). They were collected between 16 and 25 cm above Floor 3, and at that elevation they would have been affected by the fire that is associated with Floor 2 as well as that of Floor 3. If the Floor 2 fire generated a similar or greater heat than the Floor 3 fire, the magnetic orientation of this set would have been influenced by both or by the Floor 2 fire alone. Despite the smaller than desirable sample size, the result after demagnetization at 100 Oe was moderate in precision (α_{95} = 1.3º). The ellipse overlaps only one segment of the Wolfman Curve, and the date range estimate based on that curve is AD 1185–1230. The corresponding date estimate based on the SWCV2000 is AD 1020–1110, which is unlikely, although the ellipse also grazes the curve at AD 1225–1290. The ellipse encompasses DuBois' sample centerpoints in the middle AD 1125–1225 period (Figure 9.14, Volume 1), and the ellipse encompasses points in the early portion of the AD 1225–1300 DuBois point scatter (Figure 9.21, Volume 1). These two results are in stratigraphic sequence along the curve.

Room 8

The floor and lower walls of Room 8 appear to have escaped significant effects of the burning incidents noted for the other rooms, although less intense burning cannot be ruled out based on two lightly heat-affected areas of the floor. Only a single floor was detected during excavation, associated with a single cylindrical hearth. The hearth itself was remodeled, but the only area that could be sampled was the lip and rim. The resulting set (1230) represents the last use of the hearth.

Eight specimens were collected from the rim of Hearth 9 (1230), representing the last use of the room. The best measurement result for the hearth sample was following demagnetization at 50 Oe (see Table 66.1). One specimen measurement was an outlier and was excluded from the final calculations. The error term is good to moderate (α_{95} = 1.3º), and the ellipse intersects two segments of the AD 1000–1300 portion of the Wolfman Curve (Figure 66.15). The early segment (middle 11th century) is unlikely based on ceramic dating evidence. The date range estimate based on the later segment is AD 1195–1240. The segment intercepts with the SWCV2000 again include one that is early (AD 1015–1050) and one at AD 1230–1285. Compared with the scatter of DuBois' centerpoints that are dated to the AD 1125–1225 period, the ellipse falls within the middle to late portion of the scatter (Figure 9.14, Volume 1). When compared with the AD 1225–1300 centerpoint scatter, the ellipse overlaps the early end of the distribution (Figure 9.21, Volume 1). A radiocarbon date on maize from the hearth fill yielded a calibrated two-sigma range of AD 1040–1260, with an intercept of AD 1190 (see Table 66.3).

Summary

The archaeomagnetic sets span most if not all of the occupation and remodeling sequences of the site. No sets represent the second construction phase of Rooms 3, 7, and 9B (there were no hearths or burning incidents recorded in the rooms). However, if these rooms were added as storage space (as appears to be the case), the hearths in Rooms 2 and 8 (1229 and 1230) should be contemporary with their use and should record the final occupation of the site. It is likely that the final occupation date is contemporary with or earlier than the final burning of the site, but there are no floor or wall samples that can be confidently attributed to this final burning episode. Without such samples we cannot assess the contemporaneity of abandonment and burning.

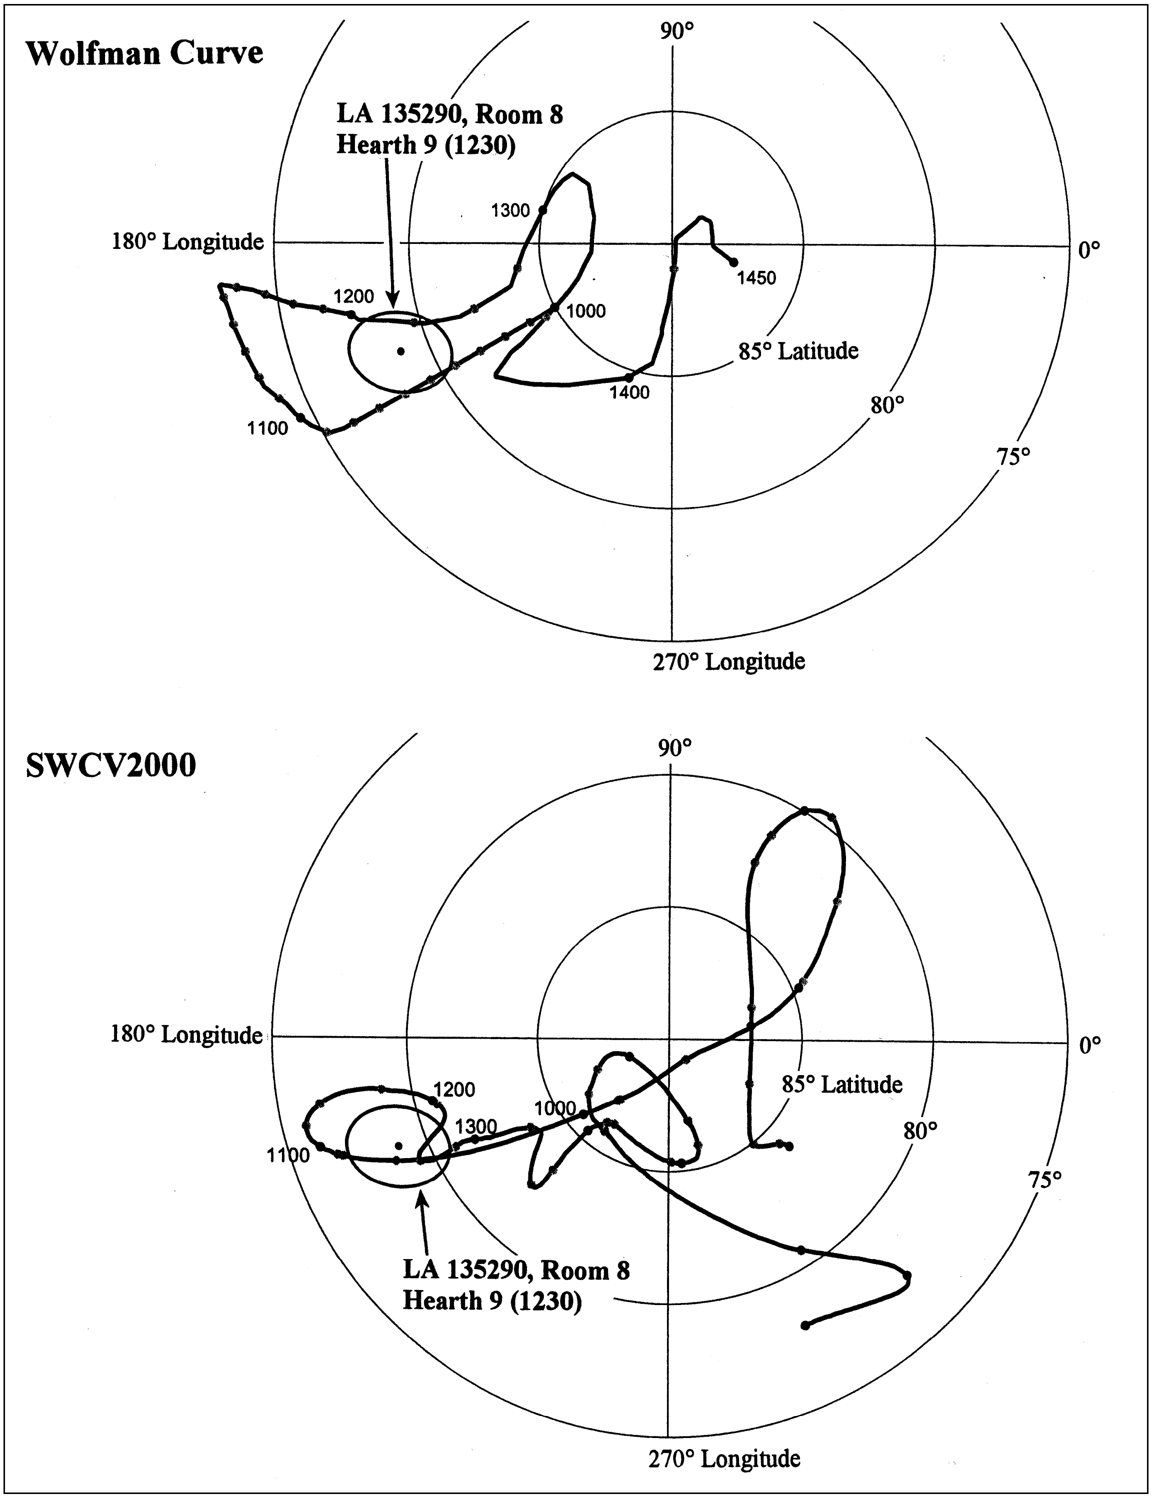

Figure 66.15. LA 135290, Room 8, Hearth 9 archaeomagnetic results for set 1230. The centerpoint and error ellipse are plotted against both the Wolfman Curve and SWCV2000.

Two sets (1227 and possibly 1228) record what appears to be the penultimate burning of the roomblock. These sets are from the Room 4 floor and the Room 6 wall. If the stratigraphic reconstruction of burning and remodeling events in this portion of the site is accurate, these two results should be contemporary. Similarly, what appears to be the first burning of this portion of the site is documented by sets from the lower floors in Rooms 4 and 6. The hearth sample from Room 2 could be either earlier than, or contemporary with, this burning event.

All of the results are portrayed together in Figure 66.16. They cluster tightly, and their centerpoints span the AD 1180–1240 segment of the Wolfman Curve.

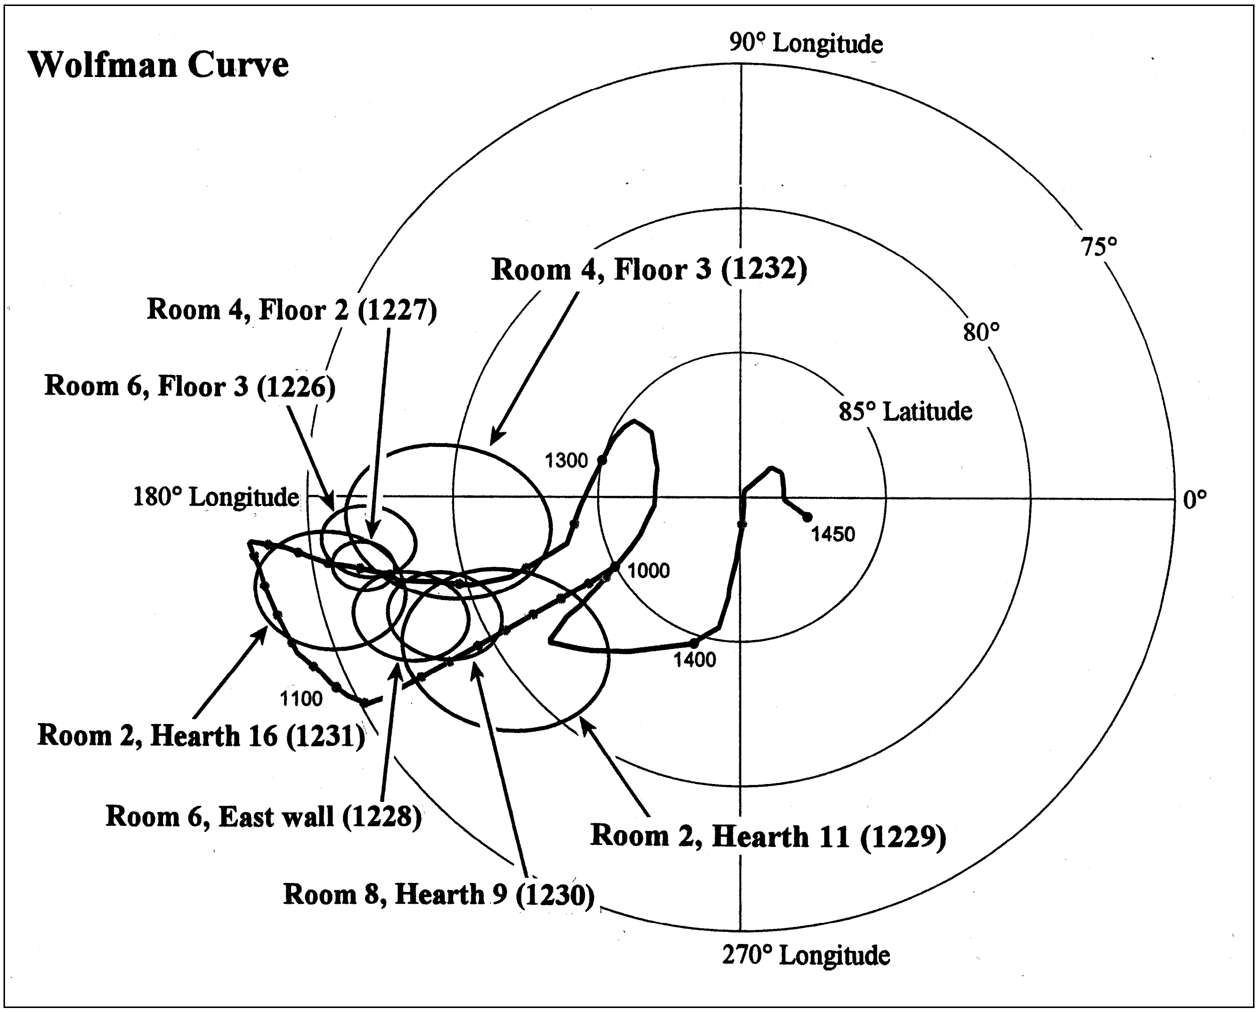

Figure 66.16. LA 135290 archaeomagnetic error ellipses plotted against the Wolfman Curve.

Room 2, Hearth 16 (1231) was expected to be the earliest sample or one of the earliest samples, and it falls at the earliest end of the series along the curve. The sets from Room 4, Floor 3 (1232) and Room 6, Floor 3 (1226) represent the first burning of the roomblock, equal to or slightly later in age than the Room 2, Hearth 16, sample. Both results are slightly later than the hearth. The Room 6, Floor 3, result is imprecise, and although its centerpoint is later in time than the Room 4 sample, its error ellipse encompasses the centerpoint and most of the ellipse for the presumably contemporary Room 4 result. Assuming that the more precise result is more accurate, the initial burning of the roomblock occurred around the last decade of the 12th century and the burning was a slightly later event than the last use of the Room 2 hearth.

The Room 4, Floor 2 (1227) and Room 6, wall (1228) samples were expected to be contemporary, representing a second major burning of the roomblock. Although clearly stratigraphically separated from the earlier floors (1226 and 1232), the archaeomagnetic date estimate for the Room 4, Floor 2 sample (1227) appears to be contemporary with the more precise of the lower floor results (1226). Both results are relatively precise, their error ellipses overlap (each encompassing the centerpoint of the other), and they are given equivalent date ranges based on the Wolfman Curve. Although we believe that the SWCV2000 is incorrect in its representation of VGP movement in the late 12th and early 13th centuries, the SWCV2000 does suggest an excursion of the pole location in the early 13th century that is in the direction of the centerpoint separations of the 1226 and 1227 results. However, the error ellipses overlap, and the centerpoint comparison may be misleading.

The second of the potentially contemporary samples, the Room 6 wall set result (1228), is less consistent with the expected temporal relationships. Although the wall sample orientation could have been affected by both the earlier Floor 3 burn and the later Floor 2 burn, we had assumed that the magnetic orientation would have been partially or totally reset by the later burn. The 1228 result location supports that assumption since there is little overlap with either of the two earlier burn results (1226 or 1232), and the 1228 VGP location is in the expected position for a later date. However, there is also little overlap with the supposedly contemporary Floor 2 sample (1227), suggesting that the wall recorded a significantly later burning event than was recorded by Floor 2. Wall samples can be subject to systematic distortion through settling or tilting of entire wall sections, producing precise-appearing but inaccurate results. No evidence of wall movement was noted during field sampling, but that possibility cannot be ruled out. If wall movement has affected the set, then the 1228 result is simply invalid. If the wall set is not distorted, the result documents an additional later burning of Room 6, possibly contemporary with the burned material noted on the floor in Room 2 and the minor burned floor patches in Room 8. Also, the location of the centerpoint for the wall sample is consistent with the possible excursion of the calibration curve that is suggested by SWCV2000 but that is not reflected in the Wolfman Curve.

Hearths in Rooms 2 (1229) and 8 (1230) were expected to document the final occupation of the site. Burned structural materials overlay the Room 2 floor, suggesting a third and final burning of the roomblock coincident with or after the final use of the hearth. Only traces of burning were present on the floor of Room 8, away from the hearth, but the hearth was architecturally associated with the final occupation of the roomblock. Neither of these traces of the final burning could be sampled for archaeomagnetic dating. The Room 2 hearth result (1229) is relatively imprecise and encompasses the centerpoint and most of the ellipse of the Room 8 result (1230). If the general position of the Room 2 result is accurate it would support abandonment as late as AD 1270, but such an interpretation is unlikely. Given the imprecision of the Room 2 result and its statistical compatibility with the Room 8 dating implications, the latter suggests abandonment around or before AD 1240. The Room 8 result also encompasses the centerpoint and most of the error ellipse of the Room 6 wall sample (1228), suggesting that they could be contemporary or closely contemporary. If they are both recording the third and presumably final burning of the roomblock, then burning and abandonment could date to AD 1225 or slightly earlier.

The suite of samples conservatively places the occupation of the roomblock within the AD 1155–1270 time range, but the more precise suite of results narrows that range slightly to AD 1170–1240. This range is consistent with the ceramic dating implications for the site and with radiocarbon dates that are associated with two burned features (see Table 66.3). Both dates are on maize, one associated with Room 2, Hearth 16 (the stratigraphically earliest archaeomagnetic dating sample) and one with Room 8, Hearth 9 (the last use component at the site). The calibrated range of the earlier sample is AD 1040–1260, with an intercept of AD 1190, while the later date is AD 1160–1270, with an intercept of AD 1220.

LA 85411

Nine specimens were collected as a set (ADL 1281) from a hearth (Feature 1) in Room 1 at the site. No specimens could be collected from the hearth walls or rim, and all were collected from the plaster lining of the hearth floor. The material was measured at NRM, and the individual specimens yielded an anomalous VGP location (32.9˚ latitude, 127.3˚ longitude) with a large dispersion of individual moments (α_{95} = 13.6˚) (see Table 66.1). Eight of the nine specimens were included in the result calculation, with one specimen omitted as an outlier. Declinations of the individual specimens were within the expected range (308º to 338º longitude), but inclinations were highly variable, ranging from –28˚ to 44˚ from horizontal. Specimen intensity was moderately strong at 10^{-3} Oe. However, the anomalous pole position and dispersed specimen orientations at NRM suggested that the sample result would not improve upon demagnetization. No demagnetization and remeasurement steps were carried out.

Error terms greater than 4.0˚ are normally considered unreliable for archaeomagnetic date interpretation, although such imprecise results usually still carry some chronologic information. In this case, the apparent pole position is extremely unusual, suggesting an inaccurate (or irrelevant) as well as imprecise result. Strong samples with aberrant pole positions due primarily to unusual inclinations can be produced by the magnetic influence of a nearby lightning strike. Lightning strikes are a common feature of the Pajarito Plateau, and it is likely that a lightning strike added a strong vertical moment to the TRM vector of this sample, rendering the specimens unusable for archaeomagnetic dating.

LA 85417

Ten specimens were collected as a set (ADL 1282) from a portion of burned floor in the northwest corner of Room 1 at the site. All 10 specimens were measured, both at NRM and after demagnetization at 50 Oe. In this case, the "best" result was the orientation after measurement at NRM (see Table 66.1). The sample was relatively incoherent, with a large error term (α_{95} = 4.0˚)

after 1 of 10 specimens was eliminated as an outlier. The ellipse overlaps the late 12th century segments of both the Wolfman and SWCV2000s (Figure 66.17).

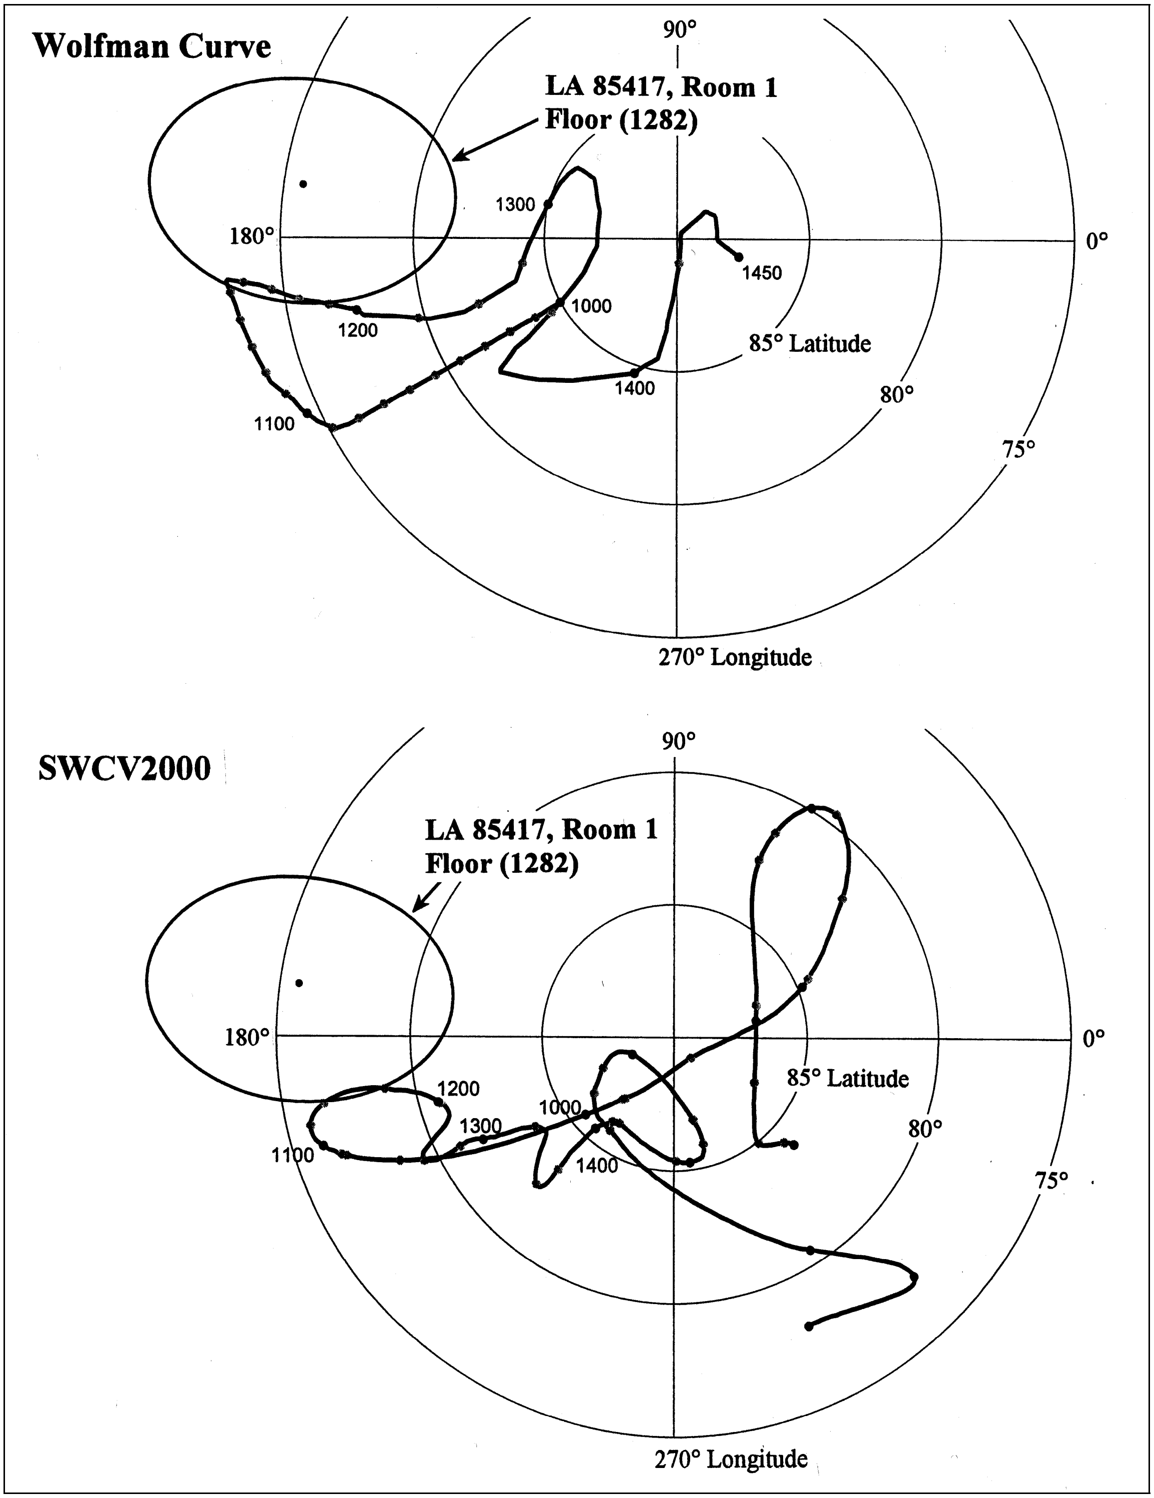

Figure 66.17. LA 85417, Room 1, floor archaeomagnetic results for set 1282. The centerpoint and error ellipse are plotted against both the Wolfman Curve and SWCV2000.

In both cases, the centerpoint is located more than 5˚ lower in longitude than the curves, and only the large error ellipse size allows the overlap with the curves. The estimated date range based on the Wolfman Curve is AD 1100–1235, whereas the date range based on SWCV2000 is AD 1010–1310. The date range is much bigger for the SWCV2000 because of the tightness of the AD 1125 loop represented in that curve and because of the size of the sample error ellipse. Compared with the scatter of DuBois' centerpoints that are dated to the AD 1125–1225 period, the ellipse encompasses the early to middle portion of the swarm at lower longitudes (Figure 9.14, Volume 1). There is no overlap with the AD 1225–1300 or 1300–1400 centerpoint scatters (Figures 9.21 and 9.28, Volume 1).

The dating implications of the archaeomagnetic pole position are that the structure burned in the Early Coalition period, probably before AD 1250 (based on the Wolfman Curve). Site excavators believed that the site could date to the Classic period (14^{th} and 15^{th} centuries AD), but laboratory analysis of pottery identified Coalition and Historic period occupations only. The Coalition pottery is consistent with the archaeomagnetic VGP implication. No radiocarbon date was obtained from the hearth fill.

LA 85861

A single surface room with a hearth was the only candidate for archaeomagnetic sampling at this site. The surface room was a fieldhouse, and associated pottery suggested an Early Classic period occupation to the field excavators. The hearth itself was rock-lined, and the interstitial plaster was too weakly burned and too disturbed for normal sample definition and collection. An experimental sampling technique was applied to a rhyolite cobble that was the most accessible stone of the hearth lining. The sampling was experimental in two ways. First, there was no guarantee that the heat of the hearth fire was sufficient to reach the Curie point of the magnetic minerals in the rock. If not, the magnetic moment of the specimens would represent the magnetic orientation of the rock at the time of its formation rather than the TRM orientation associated with the use of the hearth. The second experimental aspect of the sampling was the use of epoxy to adhere oriented plaster cube portions to the fire-exposed surface of the rock. After the adhesive had cured and the orientations of the faces of the cube portions were recorded, the rock was removed for subsequent laboratory preparation of the specimens. The rock was then cut with a water-cooled diamond masonry saw, and the specimens were trimmed to remove excess material from the interior of the cobble. Removing excess rock both removed material that would have been relatively weakly affected by hearth fires and allowed the specimen to fit within a standard 1-inch mold for plaster encasement and measurement.

Four specimens were prepared following these procedures and were submitted for measurement as ADL 1307 (see Table 66.1). The average of the specimen moments were strong (1.4 by 10^{-2}) but were more incoherent than would be expected for such strong archaeomagnetic samples (α_{95} = 7.1˚). The estimated VGP location was at 27.52˚ latitude and 22.19˚ longitude (in the Atlantic Ocean off of the northwestern coast of Africa), and the error ellipse does not approach any of the Southwestern archaeomagnetic dating curves despite its size. Although an error term as large as 7.1˚ is uninterpretable in archaeomagnetic dating, geomagnetic VGP locations are commonly this imprecise. These specimens reflect the coherence of the original magnetic orientation of the rhyolite formation, and the orientation reflects the rhyolite magnetic moment as modified by incorporation of the rock into the hearth lining. Although these results are not helpful for the dating of the LA 85861 structure, they do validate the experimental field sampling approach used in this case.

LA 85864

A single burned feature was sampled at this site. It was located within an apparent tipi ring and appears to have served as the hearth of that structure. The burned sediments were extremely variable in quality, and only two specimens were collected from well-burned material. The occupation is believed to have been Apachean within the Historic period, with historic artifacts that suggest a late 19th or early 20th century use of the site.

Seven specimens were collected (set 1234), and all seven were included in the final result (see Table 66.1). The results did not improve upon demagnetization (the best result was at NRM), and the result has poor precision ($\alpha_{95} = 3.1^{o}$). The imprecision is not simply due to the inclusion of specimens cut from weakly burned material in the set. One of the two specimens cut from well-burned material falls near the centerpoint of the result, while the other falls just outside the limit of the confidence ellipse (Figure 66.18). Only the SWCV2000 and DuBois curves cover the Protohistoric period for the Southwest. The ellipse overlaps the 1625–1850 and post-AD 1925 segments of SWCV2000. The ellipse overlaps only the modern end of the DuBois curve, but it is adjacent to the DuBois curve along the late 17th through early 19th century segment. The calibration of the SWCV2000 suggests an erratic pace of VGP movement during this time span, with a period of rapid movement before 1775 and very little movement through the early decades of the 19th century.

Dating estimation with the pre-1850 portions of both curves is relatively straight forward, yielding date ranges of AD 1600–1820 and circa AD 1675–1840 on the DuBois and SWCV2000s, respectively. Since the ellipse also overlaps the terminal ends of both curves, alternative interpretations would be AD 1730–present and AD 1850–present on the DuBois and SWCV2000s, respectively. Neither the earlier nor the later date ranges can be preferred using these sample data alone, and both are compatible with a radiocarbon date on wood that yielded a calibrated two-sigma date range of AD 1650–1890, with three intercepts at AD 1680, 1770, and 1800 (see Table 66.3).

The date interpretation for this result is hampered by both the imprecision of the 1234 result and the weak nature of the calibration curves for the Protohistoric time period. The ellipse for this result does not encompass the centerpoint for a relatively precise result from Ft. Burgwin (ADL 1184) that is independently well-dated to the early AD 1860s (see Figure 66.18). The Ft. Burgwin result is more consistent with the path of the DuBois curve but it is more consistent with the calibration of SWCV2000. If the Ft. Burgwin result is both an accurate and precise ($\alpha_{95} = 0.9^{o}$) representation of the VGP position in the early AD 1860s, and if the general direction of the true VGP path can be inferred from the two calibration curves, then it is slightly more likely that the date of the 1234 result is in the late 19th century than the late 18th century. However, due to its imprecision, a date in the late 18th century cannot be ruled out for the ADL 1234 result on the basis of archaeomagnetic data alone.

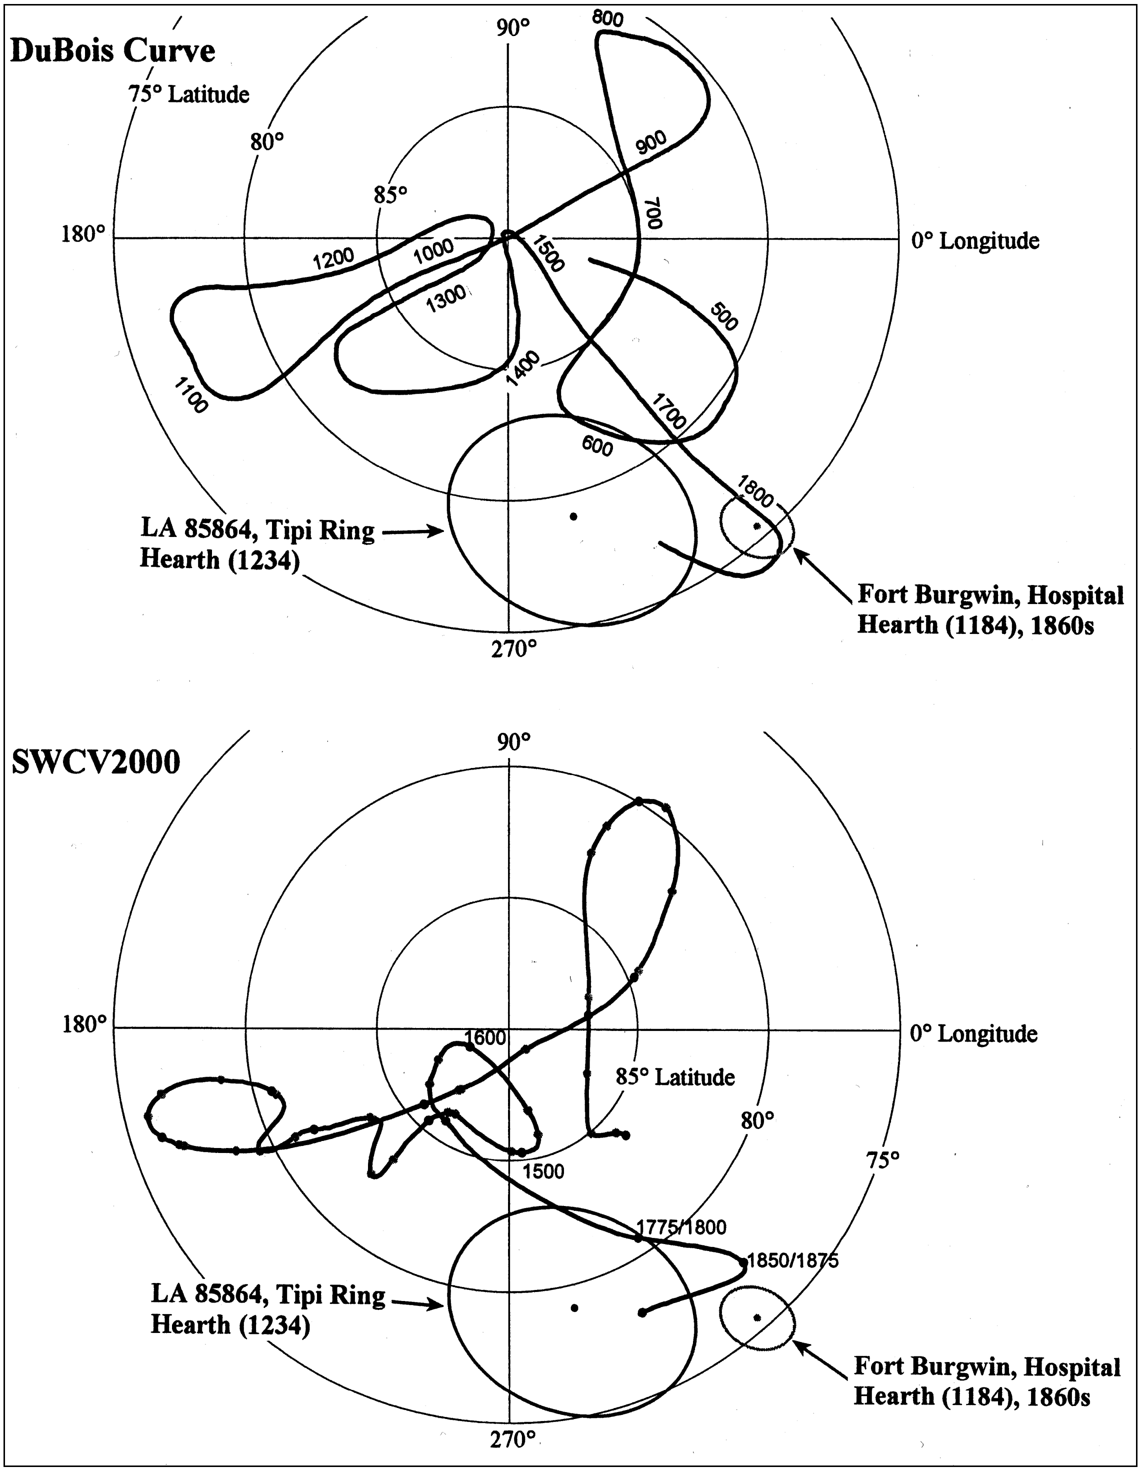

Figure 66.18. LA 85864, tipi ring hearth archaeomagnetic result for set 1234 and a comparative result from the 1860s Ft. Burgwin Hospital. The centerpoints and error ellipses are plotted against both the Wolfman Curve and SWCV2000.

LA 99396

A single hearth was suitable for archaeomagnetic sampling at this site. It was located within Room 1, and a field assessment of the very sparse associated pottery suggested a Late Developmental period age for the component. However, subsequent laboratory analysis of the pottery identified organic-painted Santa Fe Black-on-white and firmly indicates a Coalition period date assignment for the occupation.

Set 1233 was collected from Hearth 7 and consists of eight individual specimens (see Table 66.1). During the measurement process, the best result was obtained after demagnetization at 300 Oe. The error term was moderately large (α_{95} = 2.5º), and there were no outliers in calculating the final result. The error ellipse overlaps two segments of the Wolfman calibration curve in the AD 1000–1300 time period (Figure 66.19). The two possible date ranges are AD 1020–1085 and 1175–1260. Using only archaeomagnetic data, the later date range is slightly more probable since the centerpoint is closer to the later than to the earlier curve segment. When the result is compared with the SWCV2000 VGP curve, the error ellipse completely encompasses the AD 1010–1315 loop of the SWCV2000. When the centerpoint is moved to the two closest points along the pre- and post- AD 1125 segments of the SWCV2000, the resulting date estimates are AD 1010–1125 and 1155–1320. These date ranges overlap those inferred from the Wolfman Curve. The ellipse encompasses the later portion of the DuBois AD 1125–1225 centerpoints (Figure 9.14, Volume 1) and the earlier portion of the AD 1225–1300 centerpoints (Figure 9.21, Volume 1).

The laboratory analysis of the associated pottery supports the Coalition period interpretation of the archaeomagnetic date estimates (AD 1175–1260, based on the Wolfman Curve). Two radiocarbon samples, both wood, were submitted from the hearth contents (see Table 66.3). One yielded a calibrated two-sigma date range of AD 1040–1260, with an intercept at AD 1180. The second date yielded a date range of AD 1020–1200, with multiple intercepts (AD 1050, 1100, and 1140). Wood samples are expected to be either contemporary with or older than the target event, and these dates are consistent with the Coalition interpretation of the archaeomagnetic VGP.

LA 127634

A set from LA 127634 was collected in the vicinity of Feature 2, a slab-lined hearth. No specimens could be cut from either the rock lining or the interstitial plaster, but areas of the adjacent floor appeared to have been heat affected. A thin burned layer of floor was collected, overlying a soft and incoherent soil. Only five specimens were collected, and all five were measured at NRM. The precision of the result is too poor for interpretation (see Table 66.1), and the large error term (α_{95} = 31.8º) suggested that no improvement would be expected on demagnetization. The result was vaguely coherent (the large error ellipse would have encompassed the expected age of the sample), but it is likely that the burn was too light to establish a sufficiently strong TRM vector.

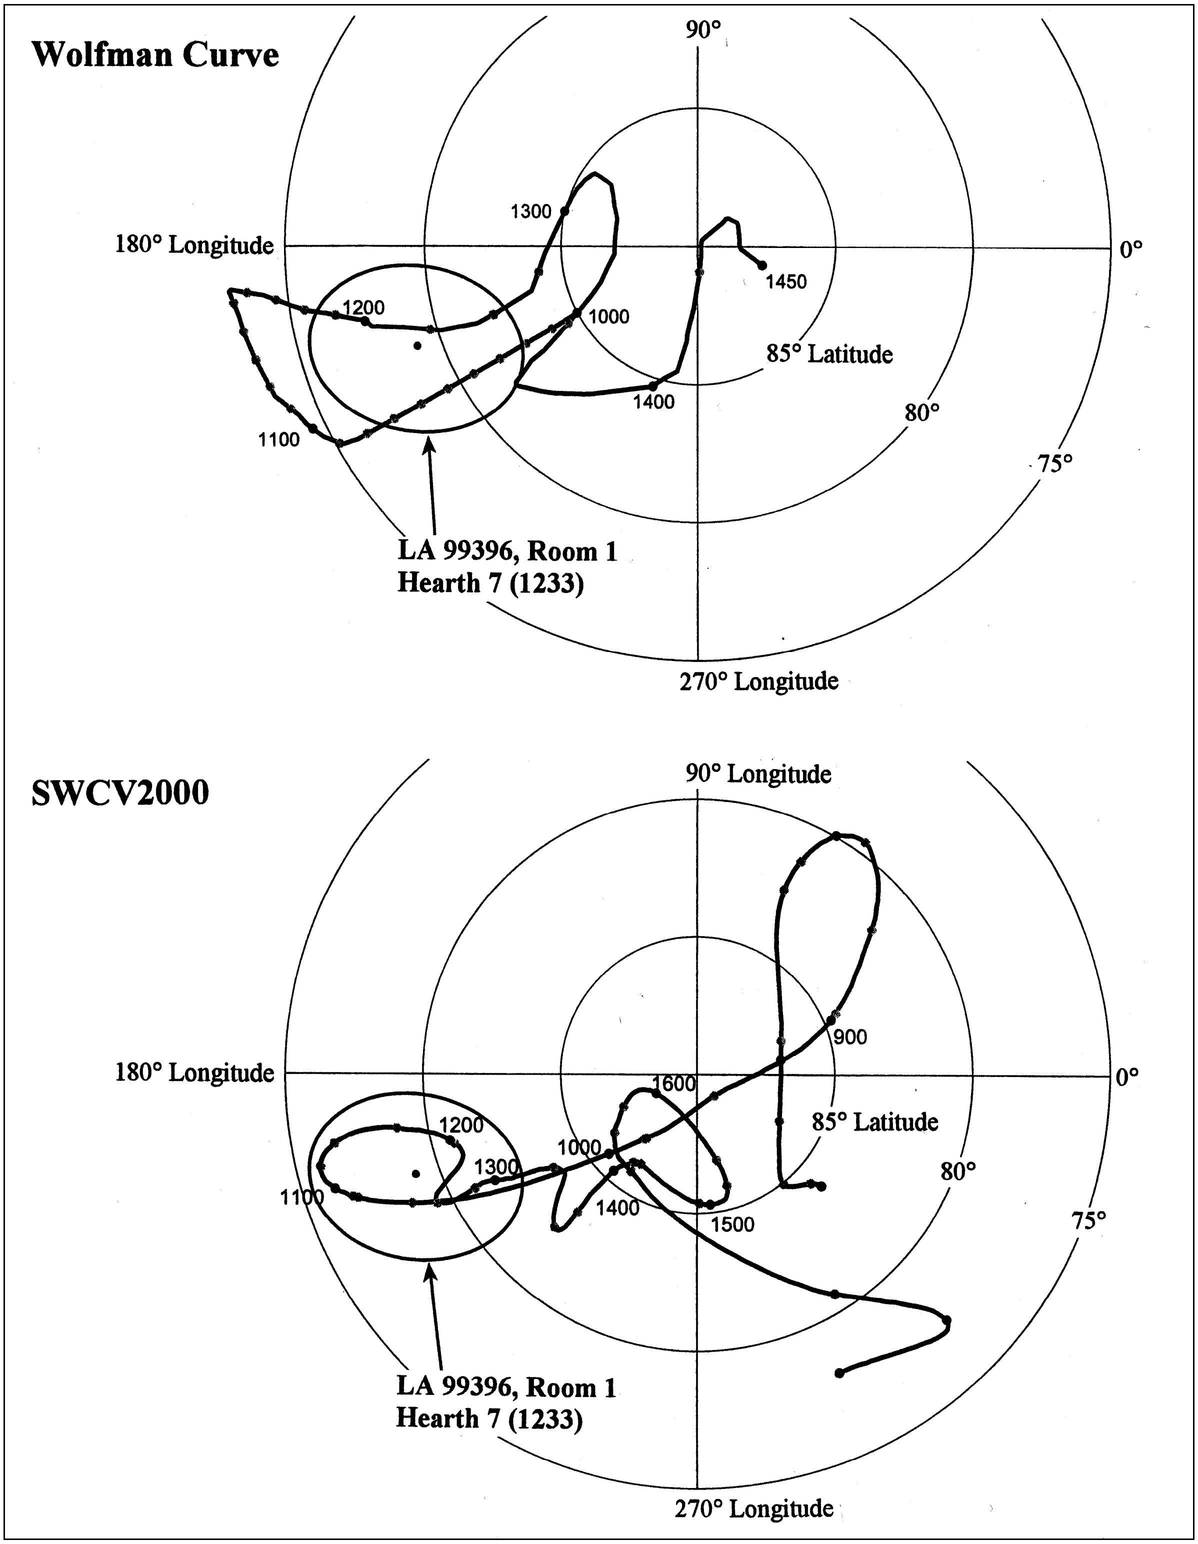

Figure 66.19. LA 99396, Room 1, Hearth 7 archaeomagnetic result for set 1233.

LA 127635

Two sets were collected from Feature 2, a plaster-lined hearth within Room 1. Both sets were collected from the upper portion of the lining, below the rim. The substrate is described as blue-gray on the surface (reduced) and oxidized to a light red within the plaster layer. Eight specimens were cut from each of the northeast and southwest portions of the rim. The southwest set was cut from substrate deeper within the hearth. Field observations included Biscuit B sherds that imply an occupation into the Late Classic period (15th century), while laboratory analysis of pottery from the site identified both Late Classic and Coalition components.

Both measurement results were coherent at NRM, and both sets were subjected to a full demagnetization protocol. The northeast set (1250) yielded a best result at NRM, while the southwest set (1251) yielded a best result after demagnetization at 100 Oe (see Table 66.1). The northeast set yielded a moderately precise VGP location (α_{95} = 1.3º), while the southwest set yielded an excellent result (α_{95} = 0.7º). Both VGP centerpoints fall along the Wolfman Curve in the AD 1200–1250 segment (Figure 66.20). The ovals do not intercept any other segments of the curve, and context suggests that no other segments need to be considered in interpretation. The two ellipses overlap, but they do not encompass each other's centerpoints. The samples should represent the same point in time (the same archaeomagnetic VGP location), and averaging would be warranted although it might lead to a spurious appearance of precision. Individually, the date range associated with set 1250 is AD 1210–1255, while the date range for set 1251 is AD 1200–1225. Since they should reflect the same burning event, their area of overlap in the Coalition period (AD 1210–1225) is a reasonable date estimate for the last use of the feature.

Slightly different date ranges are suggested by comparison with the SWCV2000. The set 1250 centerpoint is close to the SWCV2000 at about AD 1200, and the error ellipse overlaps only one segment of the curve. The SWCV2000 date range for this result is AD 1170–1245. The set 1251 error ellipse does not overlap any segments of the SWCV2000, although it is closely adjacent to both the early 11th and late 12th century segments. The early 11th century interpretation (AD 1020–1045) is probably not relevant, whereas the late 12th century date range of AD 1160–1190 is possible but somewhat early for the pottery assemblage.

The sample ellipses overlap the middle to late scatter of the DuBois 1125–1225 centerpoints (Figure 9.14, Volume 1) and the early low-longitude portion of the DuBois 1225–1300 centerpoints (Figure 9.21, Volume 1).

The archaeomagnetic results are not consistent with a 14th century (Classic period) occupation of the structure, but they are consistent with Middle Coalition occupation. Two radiocarbon dates were obtained for two samples of unidentified charred material from the hearth (see Table 66.3). The first yielded a date range of AD 1180–1280 with an intercept of AD 1250. The second yielded a date range of AD 1210–1290 with an intercept of AD 1270. Radiocarbon dates on unknown material are expected to be contemporary with or older than the target event, and these results are consistent with or slightly younger than the archaeomagnetic date range based on the Wolfman Curve.

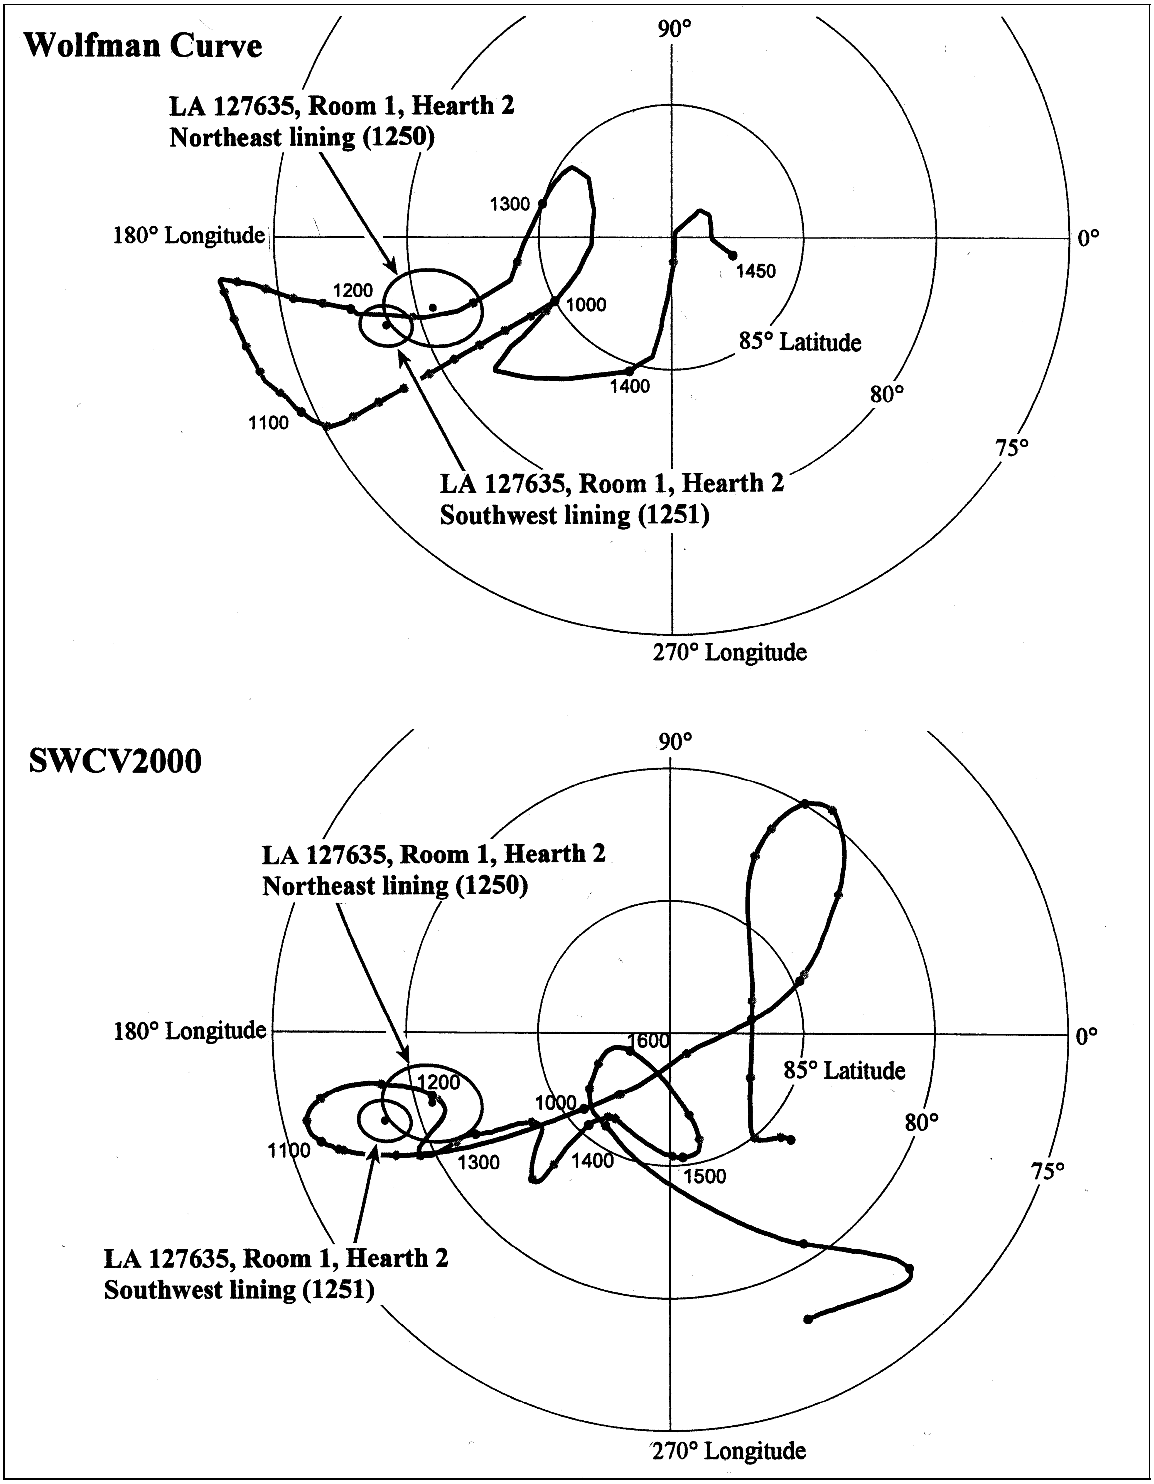

Figure 66.20. LA 127635, Room 1, Hearth 2 archaeomagnetic results for sets 1250 and 1251. Centerpoints and error ellipses are plotted against both the Wolfman Curve and SWCV2000.

Summary

Twenty-two of the 27 archaeomagnetic sets produced interpretable results. One of these was from a Protohistoric context, and the remainder were from Coalition period occupations. Two samples were collected from potential Classic (post-AD 1300) components, but they were too imprecise for date interpretation.

The Protohistoric context was a hearth within a tipi ring at LA 85864 (see Figure 66.18). The archaeomagnetic VGP does not help significantly with the dating of the occupation due to its imprecision and ambiguity between the paths and calibrations of the DuBois and SWCV2000s. The VGP appears to be either earlier or later than AD 1860, within the broad AD 1730–present window.

All of the remaining results come from contexts that date within the middle to late Coalition period based on pottery type associations. The VGP error ellipses are plotted on the Wolfman Curve in Figure 66.21, organized by precision categories. High precision results ($\forall_{95}$<1.1E) fall within the AD 1170–1275 period, with one anomalous result that could be either within this span or that could date as late as the AD 1280–1300. Centerpoints for the slightly lower precision results (1.2E<$\forall_{95}$<1.8E) fall within the AD 1170–1275 period, while their ellipses span the AD 1155–1260 period. The error ellipses of the low precision results (2.3E<$\forall_{95}$<4.0E) span a wider time range, from as early as AD 1100 through AD 1310. Six of these results look like they represent the same temporal population as the higher precision results (dominated by Middle Coalition period contexts). Two of these low precision results (1210 and 1212) are from features at LA 12587 where there is pottery and radiocarbon evidence that the site occupation may have persisted into the Late Developmental period. These two VGPs could date as late as the early 14^{th} century.

The Coalition period samples are plotted against SWCV2000 in Figure 66.22. Date interpretations based on SWCV2000 for the high precision samples would suggest that project sites could date as early as AD 1125 and as late as AD 1325. Moderate precision results overlap the AD 1020–1240 range, whereas poor precision results overlap the curve as late as the late 15^{th} century. These date ranges are in conflict with both the ceramic and radiocarbon chronologies for the site occupations. C&T Project archaeomagnetic dates based on the Wolfman Curve are both more internally consistent and appear to be more accurate than those based on SWCV2000.

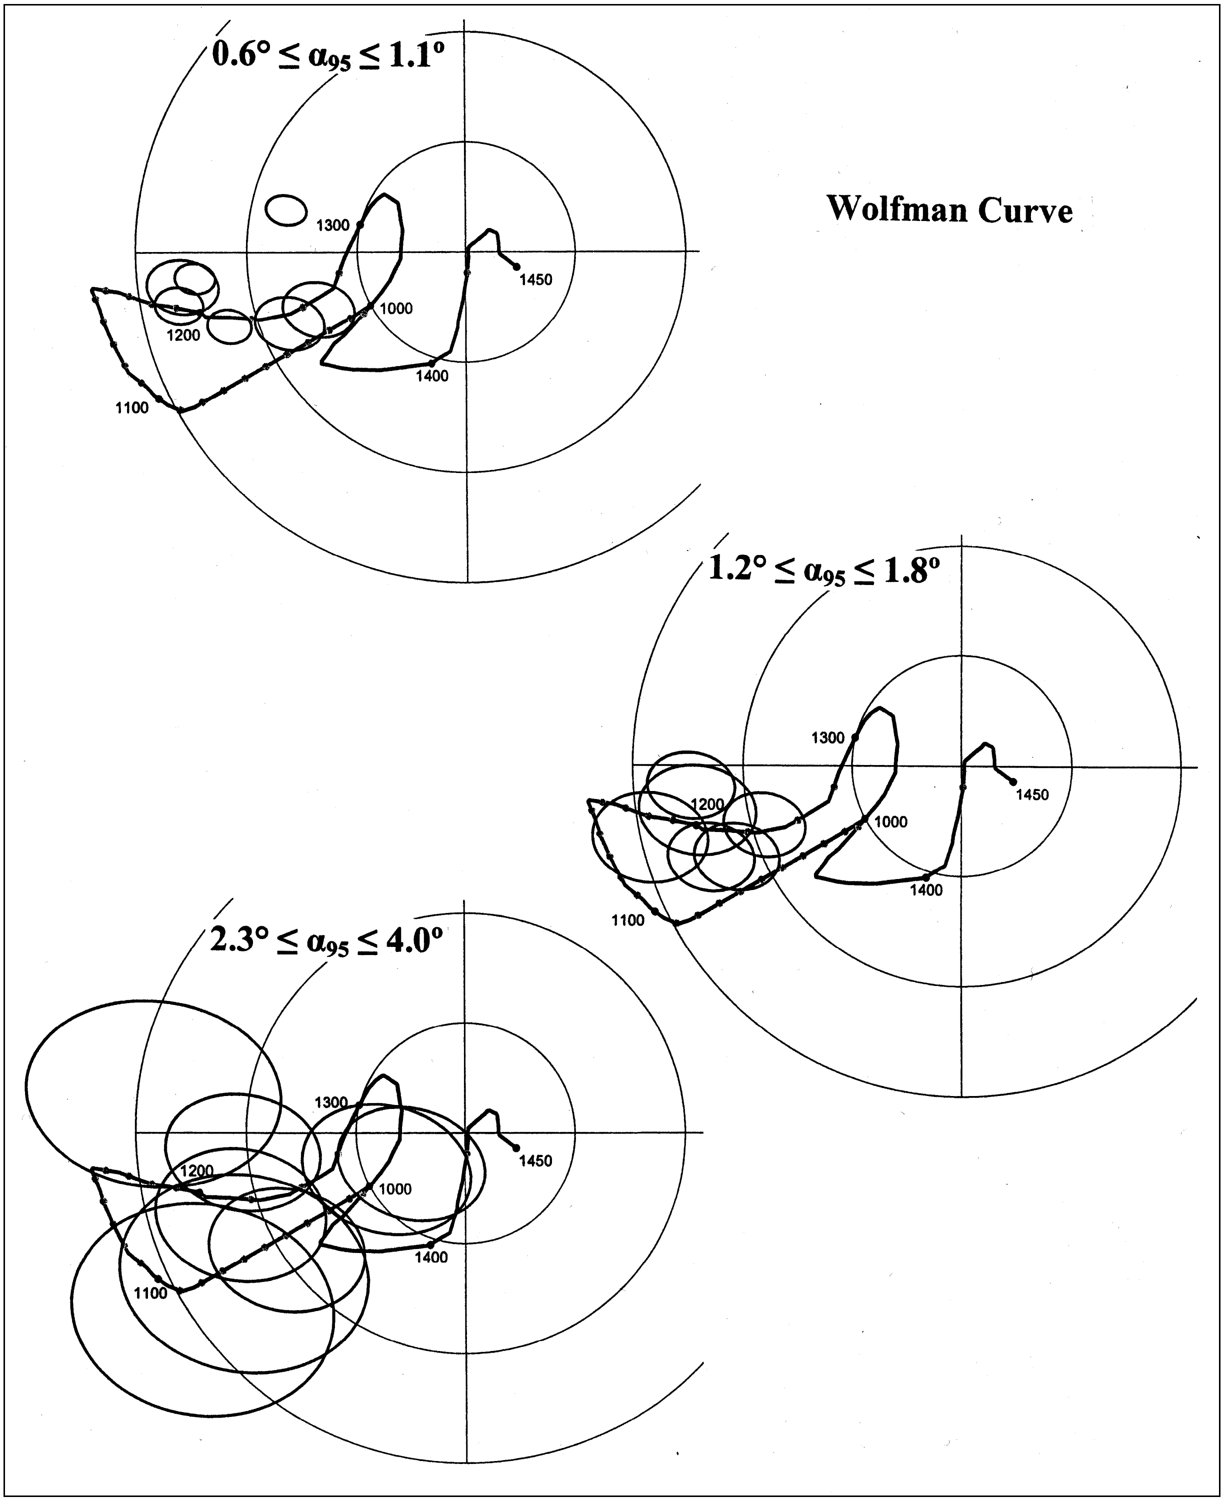

Figure 66.21. Interpretable C&T Project archaeomagnetic ellipses plotted on the Wolfman Curve. Ellipses are grouped by the sizes of their error terms: $0.6^o \leq \alpha_{95} \leq 1.1^o$; $1.2^o \leq \alpha_{95} \leq 1.8^o$; and $2.3^o \leq \alpha_{95} \leq 4.0^o$.

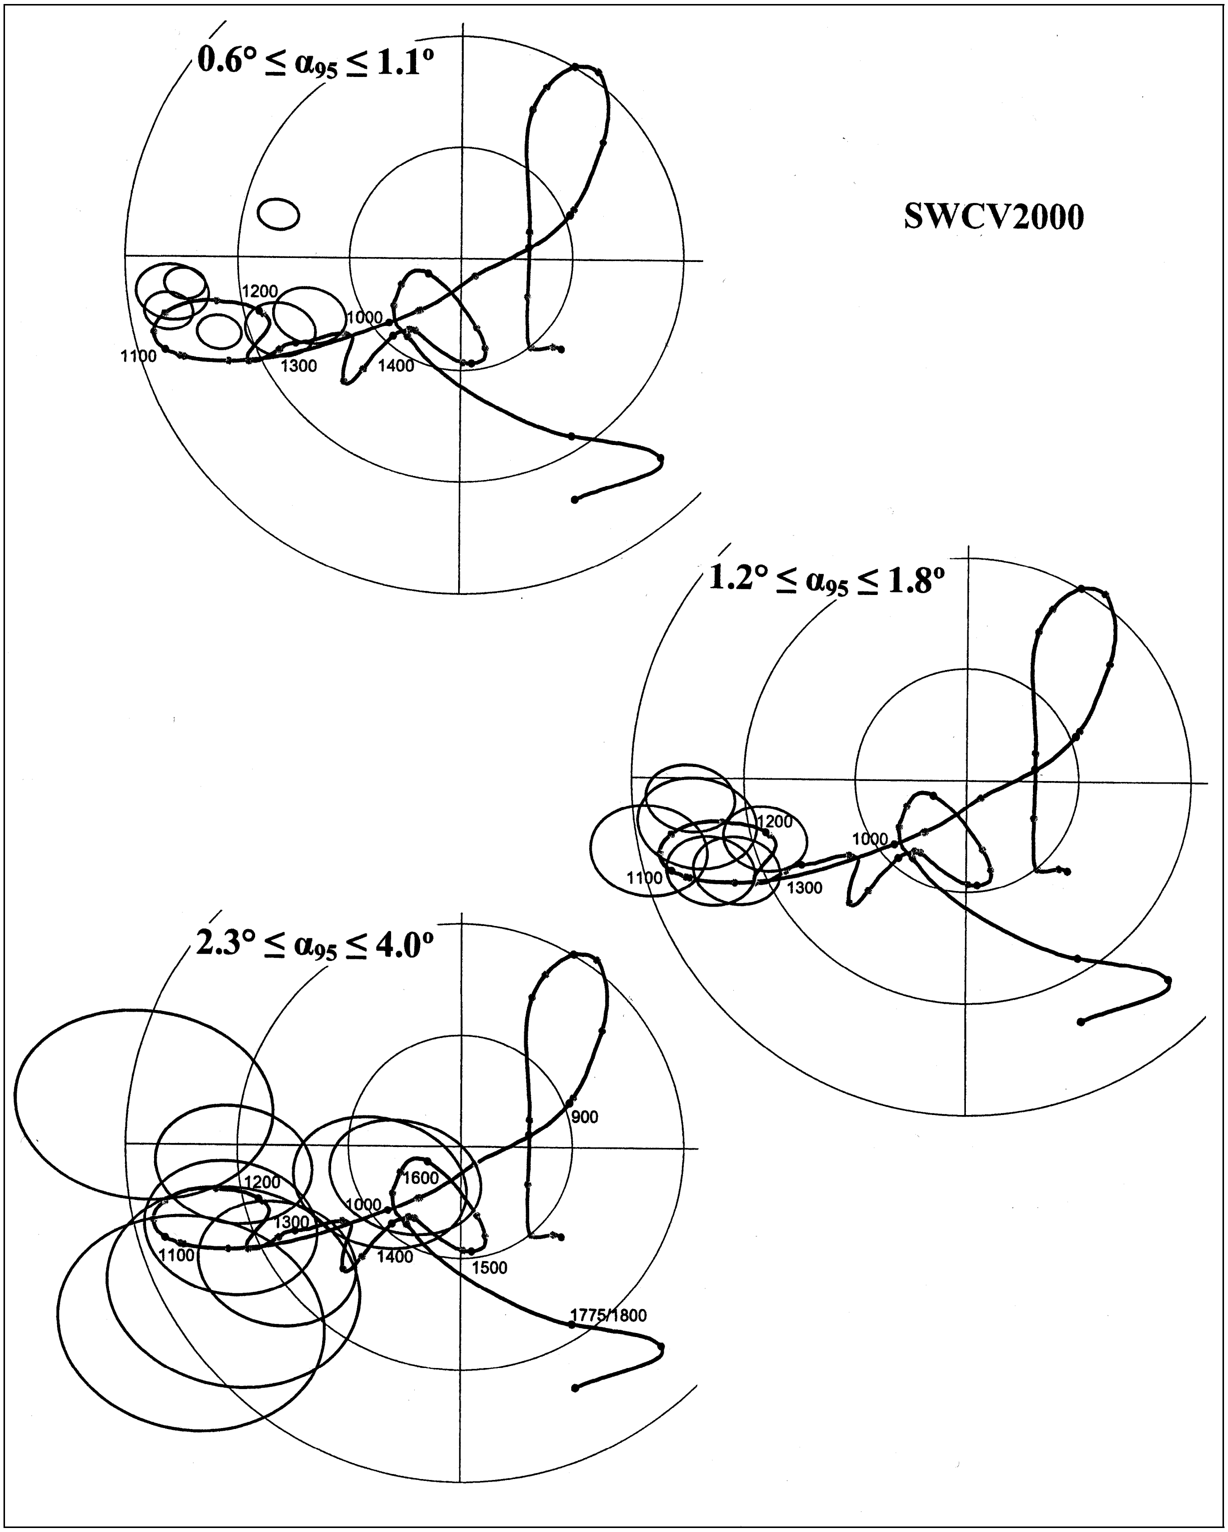

Figure 66.22. Interpretable C&T Project archaeomagnetic result ellipses plotted on SWCV2000. Ellipses are grouped by the sizes of their error terms: $0.6^o \leq \alpha_{95} \leq 1.1^o$; $1.2^o \leq \alpha_{95} \leq 1.8^o$; and $2.3^o \leq \alpha_{95} \leq 4.0^o$.

C&T Project Coalition Period Dates in Regional Context

The archaeomagnetic pole positions from the C&T Project Coalition sites are relatively consistent, but it seems prudent to test the chronology of the sites with other archaeomagnetic dating results from the northern New Mexico region. For this comparison we draw from catalogs of archaeomagnetic VGPs provided by the ADL and by Robert L. DuBois. The first purpose of this exercise is to test the contemporaneity of the C&T Project results with results from other projects. The second purpose is to assess whether the inferred bracket dates for the C&T Project occupations (late 12th through middle to late 13th centuries) are supported by archaeomagnetic VGPs and independent dates from slightly earlier and slightly later sites.

Galisteo Basin Area

Three sites in the Galisteo Basin area have yielded potentially relevant comparative samples. The results are plotted in Figures 66.23 and 66.24.

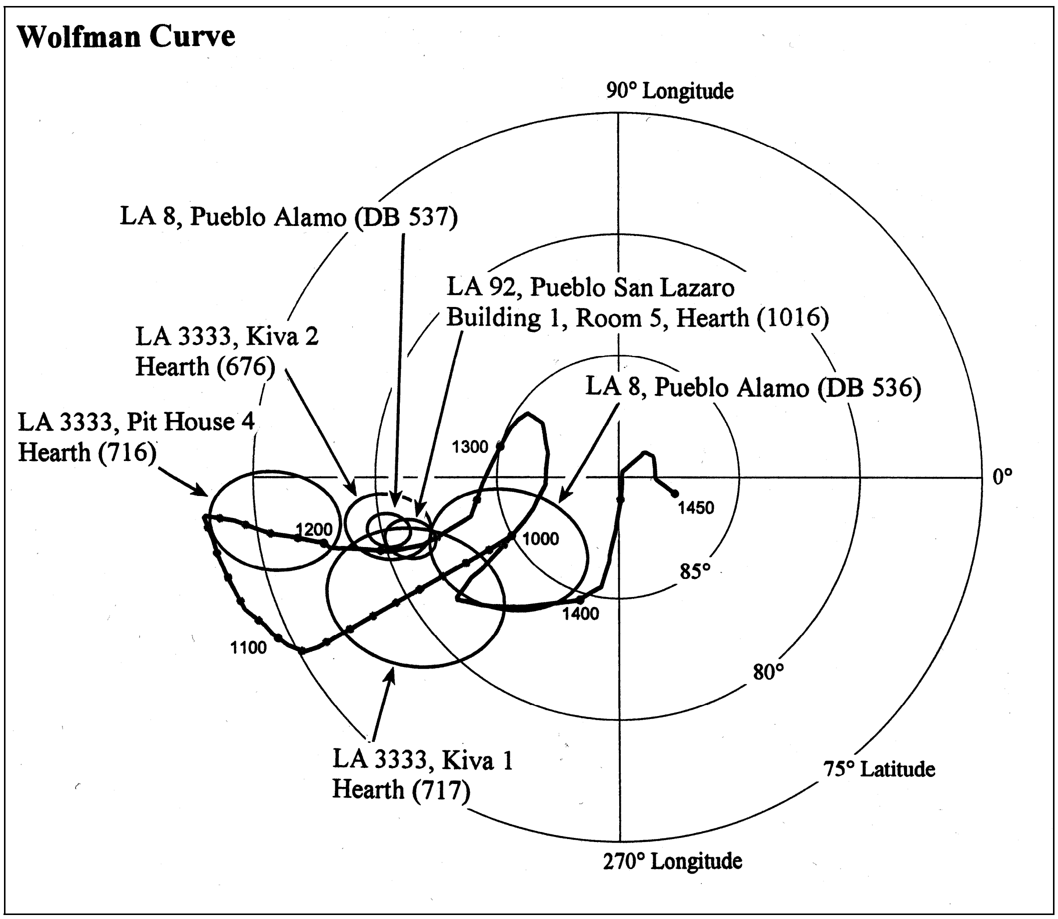

Figure 66.23. Comparative archaeomagnetic VGP results from the Galisteo Basin area plotted against the Wolfman Curve. Results from LA 3333 (676, 716, and 717) fall within the Middle Coalition period. Results from Pueblo Alamo (LA 8; DB 536 and DB 537) appear to be associated with a Late Coalition component. The result from Pueblo San Lazaro (LA 92: 1016) is believed to date to the 13th or 14th century.

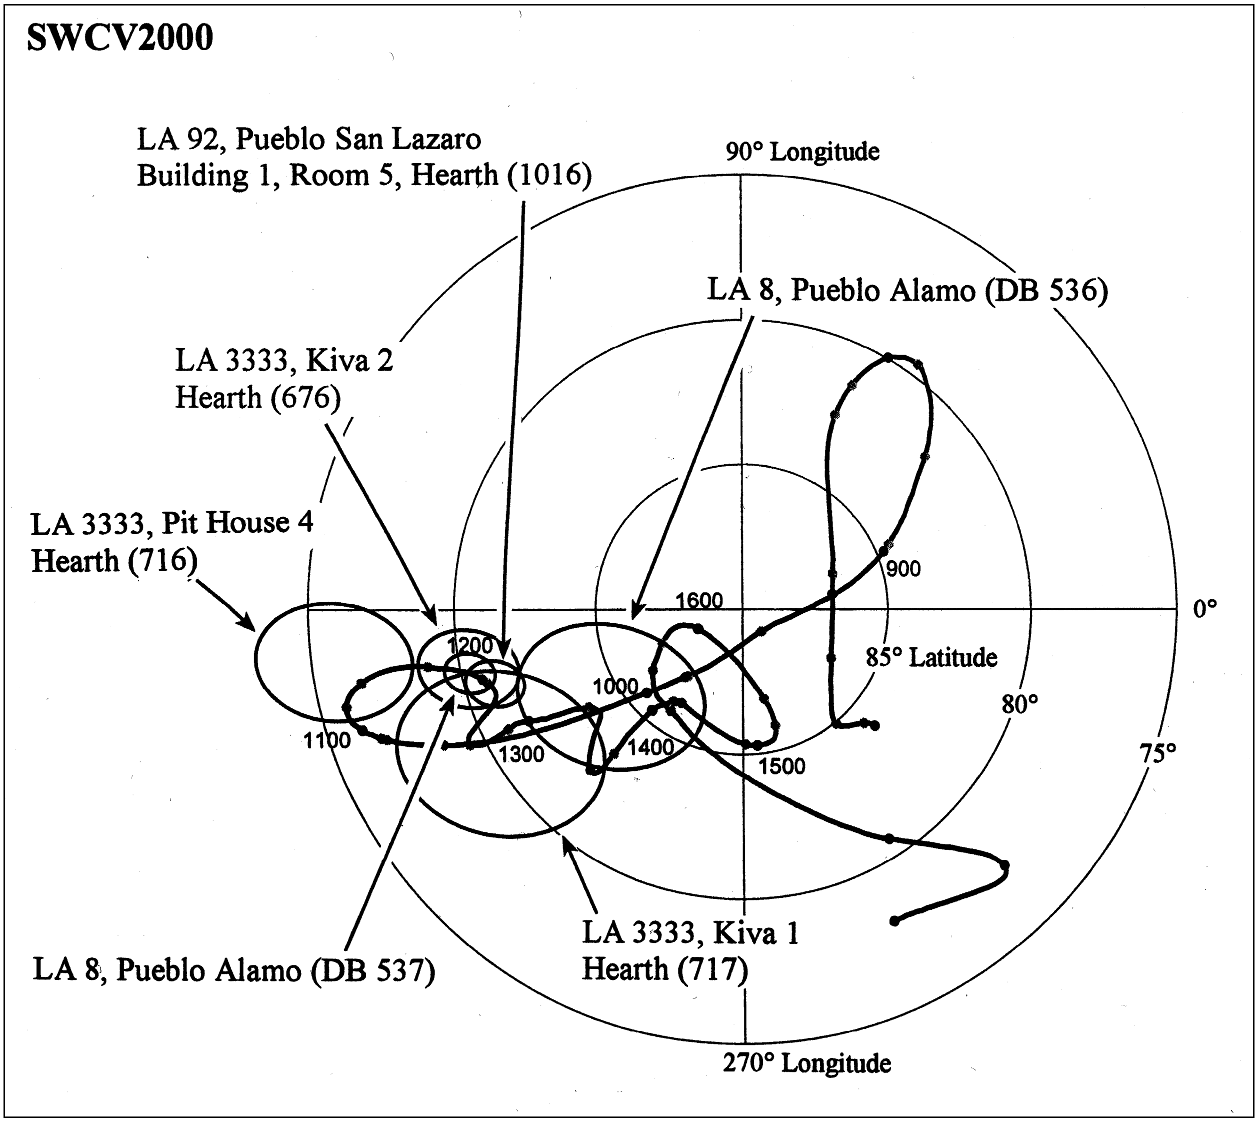

Figure 66.24. Comparative archaeomagnetic VGP results from the Galisteo Basin area plotted against SWCV2000. Results from LA 3333 (676, 716, and 717) fall within the Middle Coalition period. Results from Pueblo Alamo (LA 8; DB 536 and DB 537) appear to be associated with a Late Coalition component. The result from Pueblo San Lazaro (LA 92: 1016) is believed to date to the 13th or 14th century.

LA 3333

The occupation of LA 3333 appears to have been relatively early in the initial homesteading process of the Galisteo Basin by Puebloan farmers. Pit House 4 yielded tree-ring cutting dates of AD 1209 and 1210, and it is considered an early (if not the earliest) structure in the site occupation (Ware et al. n.d.). An archaeomagnetic set was collected from its hearth (716), with a moderate α_{95} = 2.0º. Other portions of the site had been excavated in the 1950s and 1960s, and several of these structures were reopened in the 1990s for the purpose of collecting archaeomagnetic dating samples. Kiva 1 had originally yielded tree-ring samples with cutting dates of AD 1204 and 1225 (Robinson et al. 1973:56) indicating that structure use had persisted after AD 1225. Archaeomagnetic set 717 was collected from its hearth, with a moderate α_{95} of 2.4º. Kiva 2 lacked independent dates, and its hearth was sampled as set 676.

When compared with the Wolfman Curve (see Figure 66.23), the Pit House 4 VGP (716) overlaps equivalent precision results from the C&T Project Coalition components (see Figure 66.21). The kiva results (676 and 717) are slightly later in time, consistent with the time spans seen within C&T Project sites such as LA 135290. The Wolfman Curve date range for the Pit House 4 sample from LA 3333 is AD 1140–1215, and the ellipse centerpoint is at about AD 1180. Although this range encompasses the tree-ring construction dates from the structure, it appears to be slightly too early for the structure's probable abandonment date. The result from Kiva 1 (717) is given a date range of AD 1195–1270, and its centerpoint is close to AD 1230, effectively encompassing the probable abandonment date of the structure. The Kiva 2 result is relatively precise, with a Wolfman Curve date range of AD 1205–1250, but there are no independent dates other than its similarity to Kiva 1.

The VGP and ellipse for set 716 would be dated several decades too early using SWCV2000 (see Figure 66.24), but dating conventions would result in date ranges for sets 676 and 717 that would encompass their probable abandonments.

Pueblo Alamo (LA 8)

Pueblo Alamo is at the northeast margin of the Galisteo Basin. The site was excavated for tree-ring samples by W. S. Stallings in 1931 and 1933 (Robinson et al. 1973:31–32), and it was excavated by Joe Allen in 1971 before highway construction (Allen 1973). Two DuBois archaeomagnetic sets (DB 536 and DB 537) were collected as part of the Allen excavations but are not described in Allen's preliminary report. The large numbers of tree-ring samples are not attributed to specific locations and cannot be linked specifically to Allen's excavations or the archaeomagnetic samples. However, the tree-ring samples document significant construction at the site as a whole in the 1250s and 1260s with evidence of site growth or remodeling continuing into the 1280s.

DB 537 (see Figure 66.23) is a high-precision result that coincides with the LA 3333 Kiva 2 result and falls within the area of the late half of the moderate and high precision C&T Project results. DB 536 is moderately precise and is later in time, coinciding with the two apparently late VGPs from LA 12587. These samples from Pueblo Alamo suggest later initial occupation than the C&T Project sites followed by a similar temporal progression toward abandonment. The Wolfman-based date range for the high-precision VGP from Pueblo Alamo (DB 537) pre-dates the earliest tree-ring construction dates by a decade or so. Since TRM events are usually abandonment rather than construction, the Wolfman-based age could be several decades too early. The less-precise VGP results in a date range that easily encompasses the tree-ring dates for the augmentation or remodeling of the structures at the site. If the tree-ring dates from Pueblo Alamo are applied to the similar pole positions at C&T Project sites, the occupations of some of the C&T Project sites may easily extend into and perhaps beyond the AD 1280s.

The relationships between the Pueblo Alamo VGPs and date estimates based on SWCV2000 are slightly less satisfactory than those of the Wolfman Curve (see Figure 66.24). The DB 537 result spans the AD 1180–1230 period, two decades before the earliest tree-ring documented construction at the site. The less-precise DB 536 result spans the AD 1275–1455 range, overlapping the probable date of site abandonment at the early end of the range.

San Lazaro Pueblo (LA 92)

Building 1 at San Lazaro Pueblo was defined by Nelson (1914). The rooms investigated by Nelson are associated with Glaze D pottery, and a burned room yielded tree-ring samples suggesting construction in the middle 16th century (Ware et al. 1996:55). This roomblock had been constructed over the razed remains of an earlier black-on-white period roomblock that could date to the Coalition or Early Classic periods (pre-AD 1400). In 1994 an archaeomagnetic set was collected from the hearth in Room 5 of this earlier roomblock (1016).

The VGP position of this result (see Figures 66.23 and 66.24) is only slightly different than that of DB 537 from Pueblo Alamo. Since there is no precise independent dating for this result, it serves only to reinforce the location of the path of both the Wolfman and SWCV2000 VGP curves at this point in time.

Greater Santa Fe Area

Two sites in the Santa Fe area, the U.S. Federal Courthouse and Arroyo Hondo Pueblo, have relevant comparative samples (Figure 66.25).

U.S. Federal Courthouse (LA 143460)

Excavations at LA 143460 exposed a pit structure as one element of a multi-component occupation at the Santa Fe Courthouse (Scheick 2005). The abandonment of the structure is attributed to the Early Coalition period based on Santa Fe Black-on-white and a small percentage of Kwahe'e Black-on-white pottery that had been discarded into the structure fill. If the minority of Kwahe'e Black-on-white pottery in this ceramic assemblage were in use while the trash was discarded into the abandoned structure, the VGP should slightly predate the C&T Project suite of archaeomagnetic results. If the Kwahe'e Black-on-white pottery was simply drift from prior occupations in the vicinity of the structure, the VGP is more likely contemporary with the occupations documented by the C&T Project excavations. Although a third option would be that the dating of the transition between Kwahe'e Black-on-white and Santa Fe Black-on-white technology was slightly slower in the Santa Fe area, that is less likely given the dominance of Santa Fe Black-on-white in the slightly earlier LA 3333 collections.

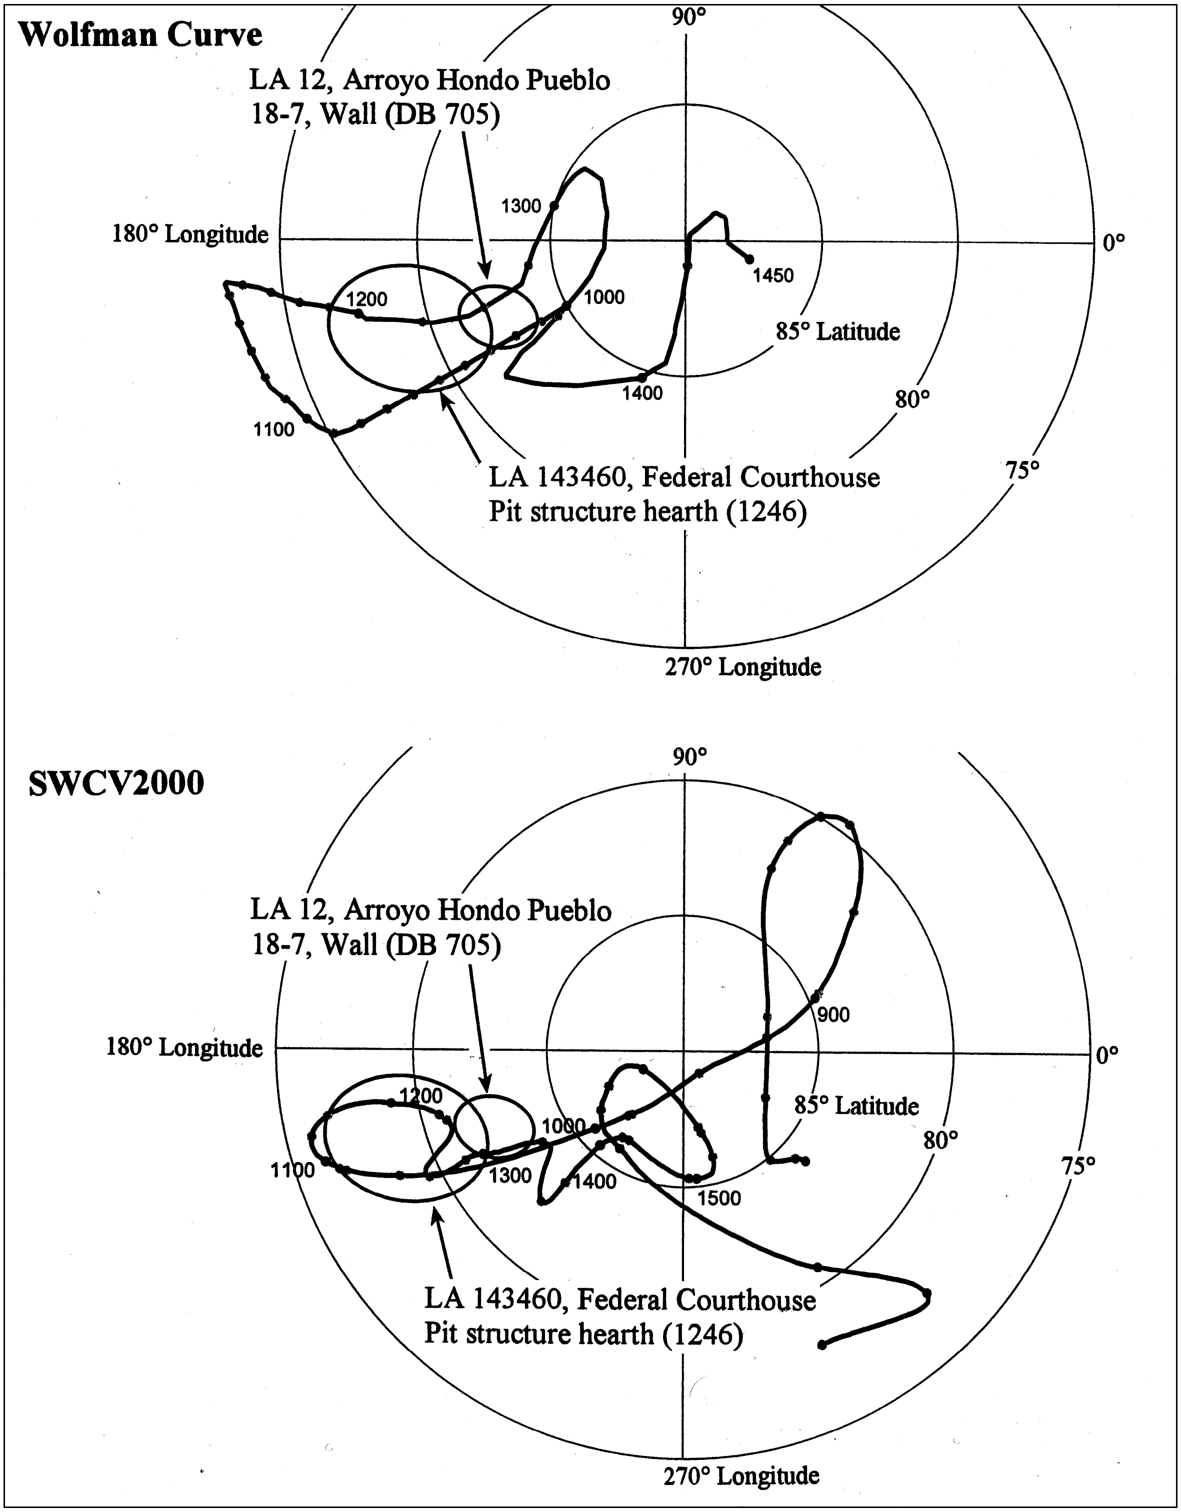

Figure 66.25. Comparative archaeomagnetic VGP results from the Santa Fe area plotted against the Wolfman and SWCV2000 curves. An Early Coalition period result (1246) is from excavations at the Federal Courthouse (LA 143460; Scheick 2005) while an Early Classic period result (DB 705) is from excavations at Arroyo Hondo Pueblo (LA 12).

The VGP for the pit structure hearth (1246) lies within or slightly later than the area of most of the C&T Project high and moderate precision results. Its date range based on the Wolfman Curve is AD 1195–1240. The result is later but slightly overlaps the ellipse associated with the Pit House 4 result from LA 3333 (dated to shortly after AD 1210). The VGP is similar or slightly earlier than the VGPs of the precise results from Pueblo Alamo, Kiva 2 from LA 3333, and San Lazaro Pueblo, Room 5.

Both the centerpoint location and the ellipse size result in a large date range (AD1155–1310) when compared with SWCV2000 (see Figure 66.25). This range encompasses most of the Coalition period and is accurate if imprecise.

Arroyo Hondo Pueblo (LA 12)

Extensive excavations were carried out at Arroyo Hondo Pueblo (LA 12) by the School for American Research. Two distinct components were present, one with construction dates in the AD 1310s through 1330s and one with construction dates in the AD 1370s through 1410s (Creamer 1993:Table 7.3). Component I appears to have been substantially abandoned by the AD 1350s, while a major fire coincided with a significant Component II abandonment before the AD 1420s. An archaeomagnetic set was collected from a burned wall of Room 18-7 (DB 705). Room 18-7 was part of construction in the AD 1310s, was destroyed by a fire, and then was rebuilt, still within the Component I occupation of the site (Creamer 1993:184). The Component I fire that established the TRM of the wall appears to have occurred between the 1310s and the1330s.

Although the error ellipse of the DB 705 result (see Figure 66.25) overlaps the Wolfman Curve at about AD 1250, it is immediately adjacent to the middle 14th century portion of the curve as well. The relevant Wolfman Curve date range for the result would be AD 1345–1365. The relevant date range based on SWCV2000 would be AD 1275–1320. Although the Wolfman and SWCV2000s allow both middle 13th and early to middle 14th century interpretations of the DB 705 pole position, the paths of the curves are substantially different during the interval between these two points in time. Focusing on the 14th century possibilities, the Wolfman Curve appears to overestimate the age of this sample by a decade or two, whereas SWCV2000 appears to underestimate it or capture the correct date at the extreme upper end of its range.

The VGP position for this sample is identical to one of the apparently later results in the C&T Project VGP series (1205; see Figure 66.11). However, the calendric date of DB 705 must be much later based on ceramics, tree-ring, and radiocarbon dates.

*Gallina Are*a

Although the available site descriptions are incomplete (Mackey and Holbrook 1978), five DuBois archaeomagnetic results are from Gallina structures or sites that have associated tree-ring dates (Robinson and Cameron 1991). DB 1069 was collected from the central hearth of a Gallina unit house (LL-1) at LA 12063; DB 1070 was collected from LA 12059; DB 1072 was collected from the central hearth of a Gallina unit house at LA 12066; DB 1074 was collected from a circular hearth of a Gallina unit house at LA 12054; and DB 1077 was collected from a hearth at a Gallina unit house at LA 12062.

These five results are plotted against both the Wolfman and SWCV2000s in Figure 66.26. The error ellipses occupy approximately the same polar region as the C&T Project Coalition period samples (see Figure 66.21). Date ranges based on Wolfman Curve ellipse intercepts are listed in Table 66.4. The limited tree-ring data that are available suggest that the sites were established in a relatively narrow time window of between AD 1228 and 1243. Construction or remodeling continued at the sites through at least AD 1247–1260, apparently encompassing more than a generation in at least two cases. The late tree-ring dates (remodeling or new construction) are more likely to correspond with the archaeomagnetic dates (although we have no details of the relationships between sampled features and dated structures at the sites). Only two of the Wolfman-based archaeomagnetic date ranges encompass the last tree-ring dates from the sites, while the other archaeomagnetic ranges fall between 10 and 30 years short of the tree-ring dates. Also, the sequence of pole positions along the Wolfman Curve does not correspond with any tree-ring based measures of chronological sequence between the sites (see Table 66.4).

Table 66.4. Selected Gallina area Coalition period archaeomagnetic dates.

DuBois Set Number	Site Number (LA)	Wolfman Curve Sequence	Wolfman Date Range (AD)	Earliest Tree-ring Cutting Date (AD)	Latest Tree-ring Date (AD)
1072	12066	1	1170–1240	1237	1253
1070	12059	2	1190–1220	1243	1256
1077	12062	3	1185–1250	1228	1260
1069	12063	4	1205–1280	1231	1259
1074	12054	5	1225–1290	1240	1247

Note: Tree-ring date information from Robinson and Cameron 1991

Date ranges for the Gallina samples are far broader when calculated using SWCV2000. The single precise sample (DB 1070) results in a late 11th century date range, approximately 150 years earlier than the tree-ring dates for the site. SWCV2000-based date ranges for two of the less-precise ellipses (DB 1072 and DB 1077) also predate their tree-ring dates, but only by a decade or two. The final two results (DB 1069 and DB 1074) encompass portions of the SWCV2000 that include the tree-ring dates of the site occupations.

Pajarito Plateau

Eight ADL and DuBois archaeomagnetic results are available from Pajarito Plateau sites to the south of the C&T Project sites. The results are plotted against the Wolfman Curve in Figure 66.27 and against SWCV2000 in Figure 66.28.

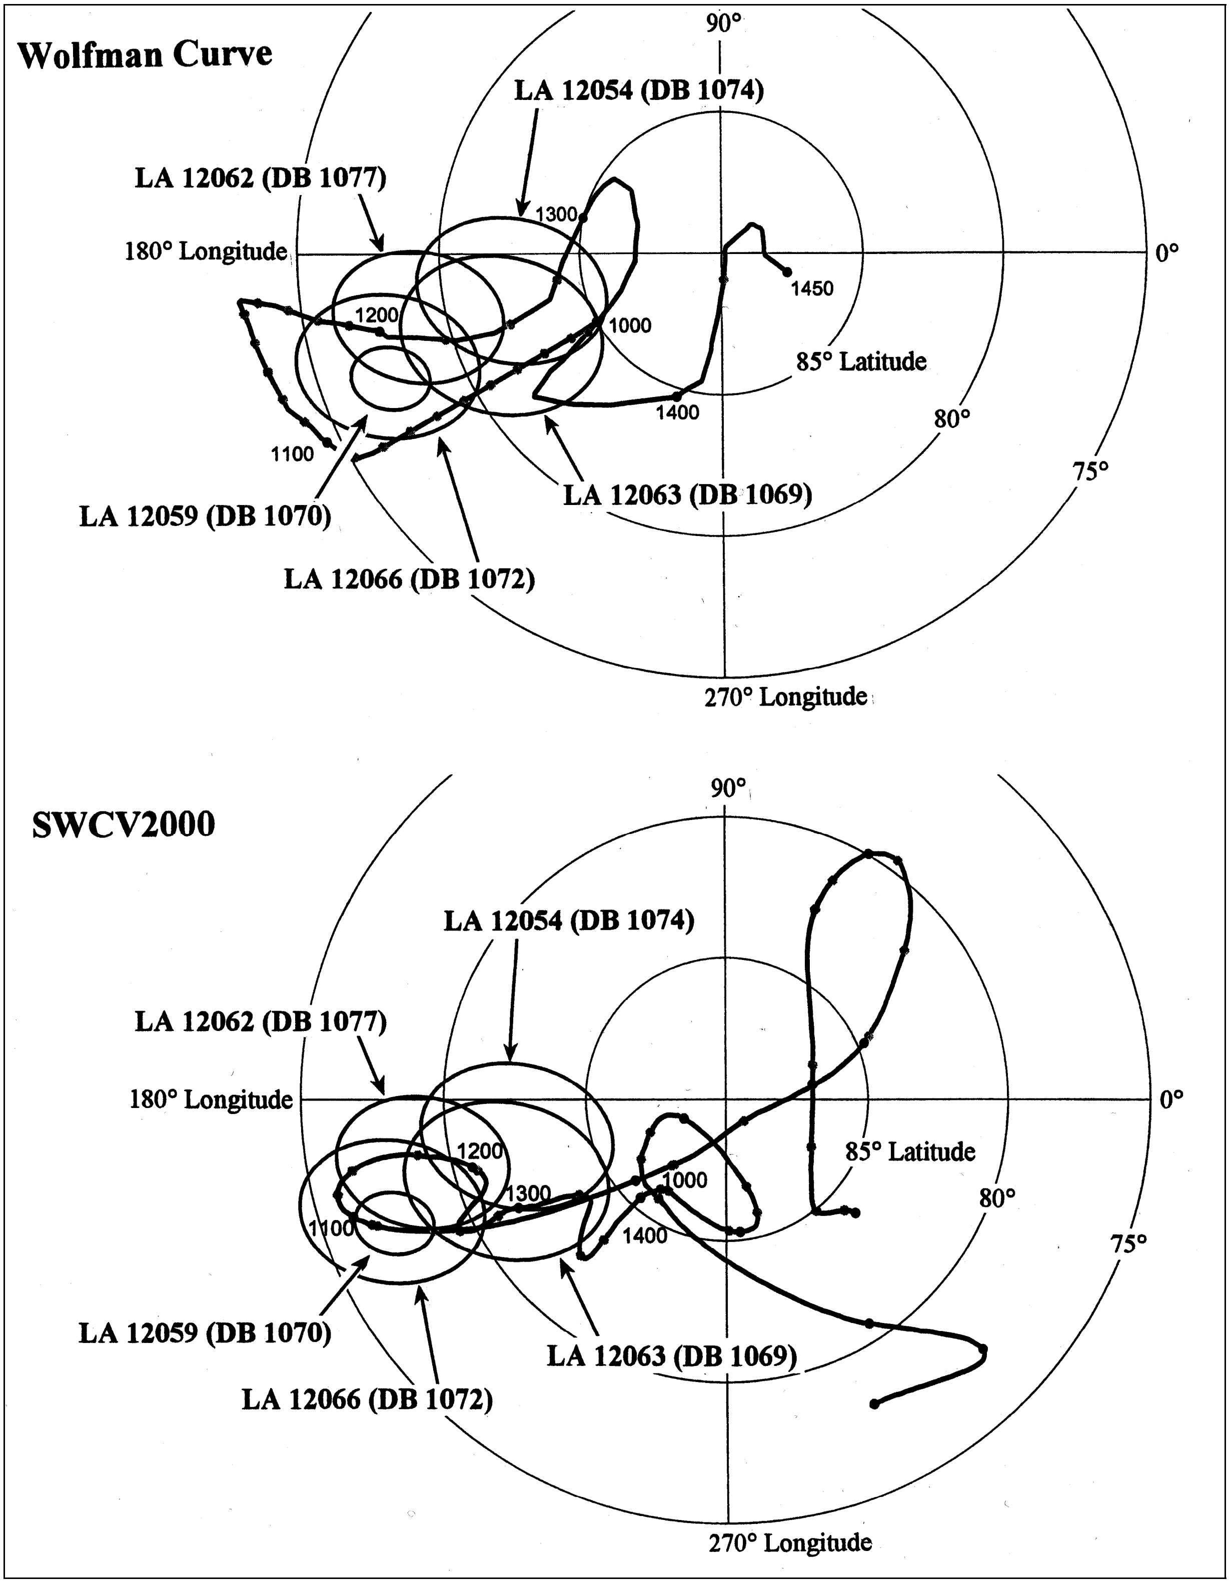

Figure 66.26. Comparative archaeomagnetic VGP results from the Gallina area plotted against the Wolfman Curve and SWCV2000.

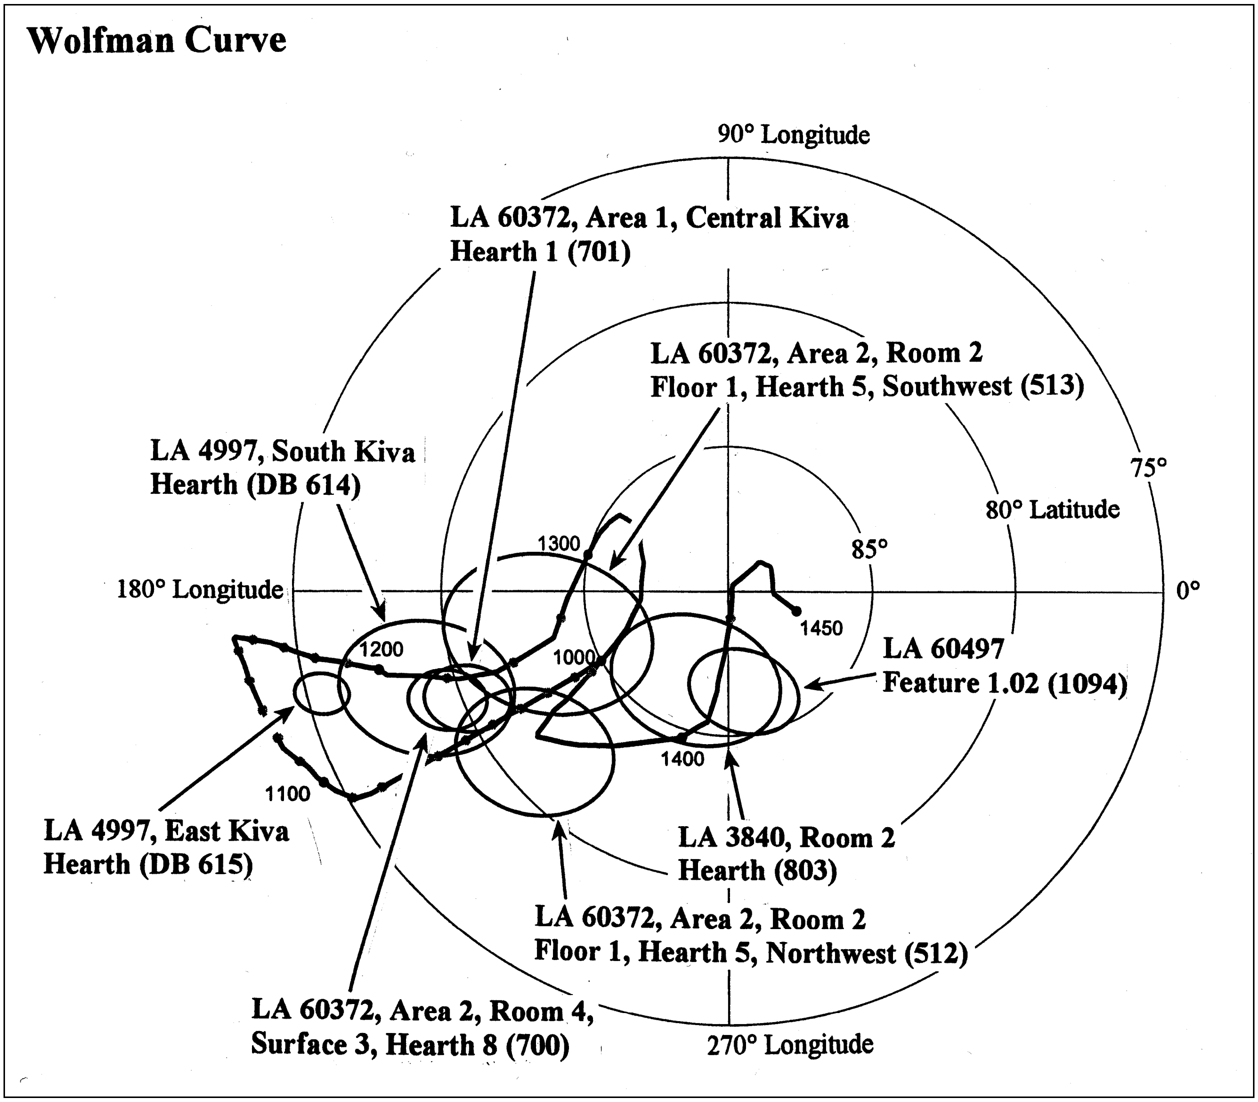

Figure 66.27. Comparative archaeomagnetic VGP results from the Pajarito Plateau plotted against the Wolfman Curve. LA 4997 and LA 60372 results are from Coalition period contexts, while LA 3840 and LA 60497 are from Classic period contexts.

Saltbush Pueblo (LA 4997)

Saltbush Pueblo (LA 4997) is a small roomblock and kiva that were excavated on the floor of Frijoles Canyon in Bandelier National Monument (Snow 1971). The kiva was constructed and then substantially remodeled at a later time. The initial construction incorporated an east-oriented hearth and ventilator system. After this occupation ceased, the kiva was rebuilt with a south-oriented hearth and ventilator and a southern recess over the ventilator tunnel. There is no evidence of the time lag between the construction and remodeling event. Three charcoal samples from room and kiva fill, believed to be fuel wood rather than construction material, yielded non-cutting tree-ring dates of AD 1194vv, 1215vv, and 1241vv. Pottery types are dominated by Santa Fe Black-on-white, but Galisteo Black-on-white and Wiyo Black-on-white are present and are assumed to be associated with the later occupation of the site (Snow 1971:33–35).

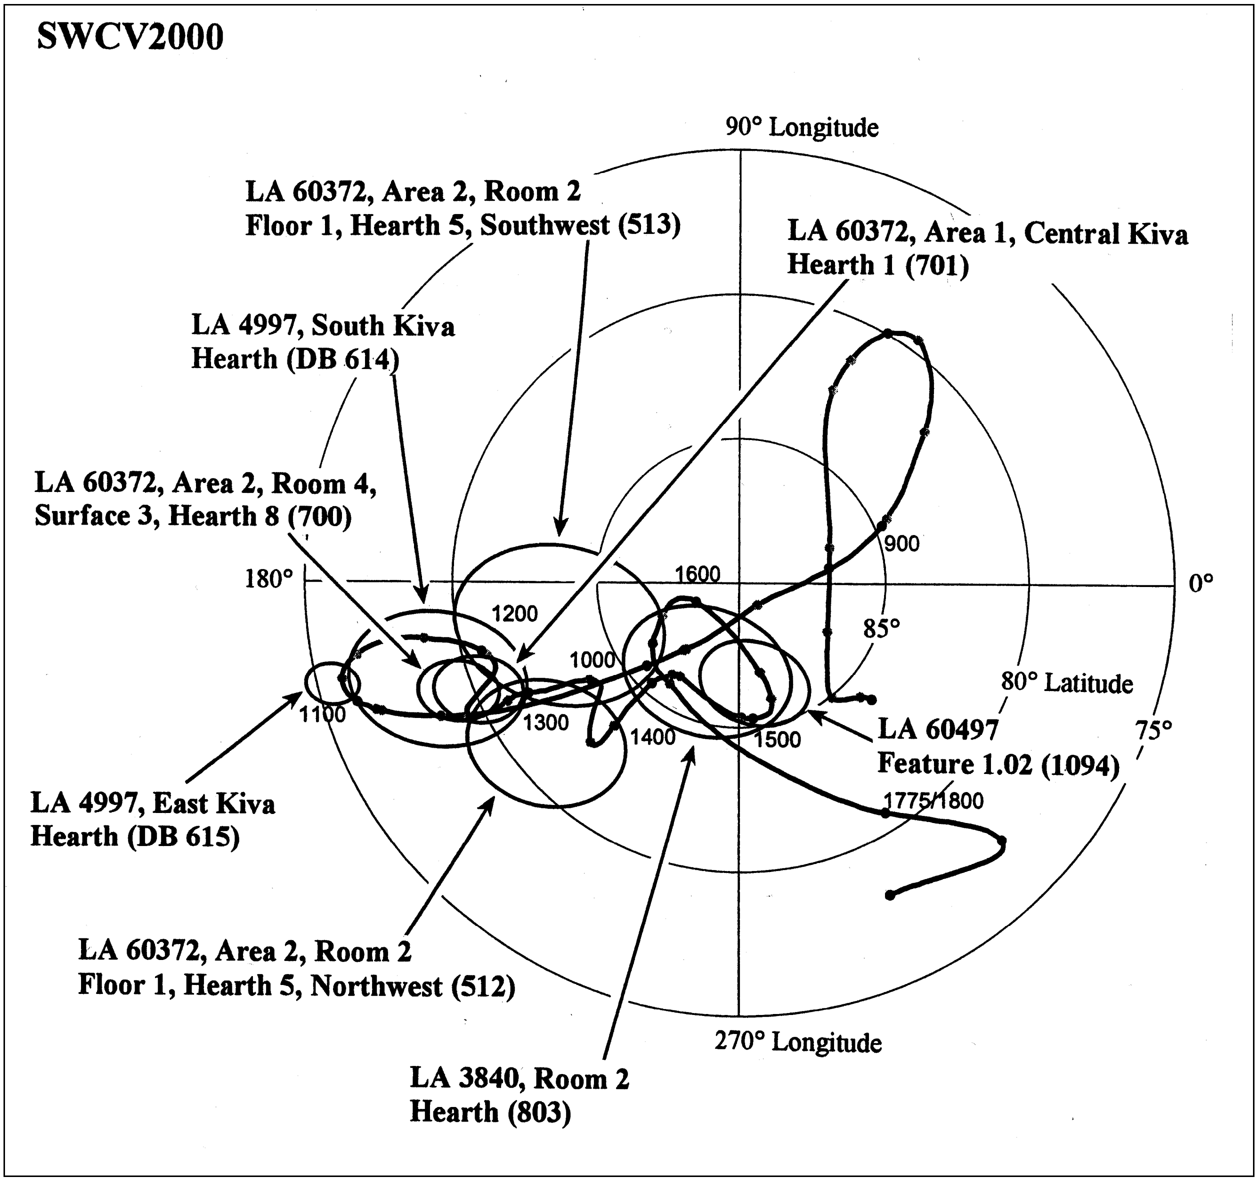

Figure 66.28. Comparative archaeomagnetic VGP results from the Pajarito Plateau plotted against SWCV2000. LA 4997 and LA 60372 results are from Coalition period contexts, while LA 3840 and LA 60497 are from Classic period contexts.

Archaeomagnetic sets were collected from both hearths (DB 615 and DB 614, respectively) and are plotted on Figures 66.27 and 66.28. The very precise VGP ellipse from earlier east-oriented kiva hearth (DB 615) is assigned a date range of AD 1175–1195 based on the Wolfman Curve (see Figure 66.27). The less-precise result from the later south-oriented kiva hearth (DB 614) is assigned a date range of AD 1185–1255. While the former date range is plausible in the absence of independent evidence, the latter date interpretation is not. Based on our current knowledge of pottery type chronologies for the Pajarito Plateau (see Chapter 58, this volume), the Galisteo Black-on-white and Wiyo Black-on-white pottery attributed to this component should post-date AD 1275 and could extend well into the 14th century.

The plausibility-implausibility of date ranges are reversed for the two VGPs when the ellipses are compared with SWCV2000 (see Figure 66.28). The precise result for DB 615 is assigned a date range of AD 1100–1140 based on SWCV2000, which would require that Kwahe'e Black-on-white be a significant contributor to the site ceramic assemblage (which it is not; Snow 1971:42). In contrast, the-less precise result from the later kiva hearth (DB 614) encompasses nearly the entire SWCV2000 VGP path between AD 1015–1300. The very end of this range is possible for the associated pottery types, but an even later date would be more probable.

The DB 615 result coincides with the earliest VGP positions from the C&T Project sites (see Figure 66.21), but there is no independent basis to assess the accuracy of this correlation. The DB 614 result does not correlate with any of the C&T Project archaeomagnetic samples due to the combination of apparent late ceramic age and relatively low latitude ellipse position.

Burnt Mesa Pueblo (LA 60372)

Burnt Mesa Pueblo (LA 60372) is within Bandelier National Monument and was excavated over several seasons (Kohler 1990; Kohler and Root 1992b, 2004). Two spatially distinct and sequential components were investigated.

Area 2 is believed to date within the AD 1250–1275 period, based on ceramics and two tree-ring cutting dates of AD 1250 from two different rooms. Two sets of archaeomagnetic specimens were collected from Room 2, Fire Pit 5 (512 and 513). The sets should have recorded a single TRM, but the ellipses overlap only slightly (see Figure 66.27). The 512 result is believed to be aberrant for unknown reasons despite its slightly smaller error term. A second hearth in Room 4 (Hearth 8) was also sampled (700) and produced an extremely precise result. This VGP ellipse barely overlaps with the results from the two Room 2 samples, and its position along the Wolfman Curve is earlier than the Room 2 results. Dating conventions obscure the VGP differences somewhat, and despite the discrepancies between the set VGPs, the Wolfman-based date ranges are AD 1210–1275, AD 1235–1300, and AD 1205–1240 (sets 513, 514, and 700, respectively). The precise result (700) is too early for the tree-ring dates by a minimum of 10 years and perhaps as much as 30 years, while the inconsistent ellipses from the Room 2 hearth are both consistent with the ceramic and tree-ring dates.

SWCV2000 interpretations of the Area 2 VGPs are more consistent with all expectations, despite the lack of coincidence between the ellipses. The 700 ellipse produces a date range that spans almost the entire 13th century. When their centerpoints are adjusted to the nearest points on the SWCV2000 segments, the two Room 2 hearth ellipses produce dates that span AD 1195–1370 (512) and AD 1130–1340 (513). These dates are accurate if not precise.

Area 1 as a whole was constructed after AD 1275 (Kohler and Root 2004). Non-cutting tree-ring dates from the roomblock cluster in the late AD 1270s, and two tree-ring samples with bark dates of AD 1316 and 1317 were recovered from the Central Kiva fill. Ceramic evidence of site use extends into the early 14th century, but that last use appears to be "sporadic." An archaeomagnetic set was collected from the kiva hearth (701) and was given three possible date ranges by Dan Wolfman (AD 1040–1075, AD 1210–1250, and AD 1355– 1380). Although the last possibility is more consistent with the tree-ring dates, the 14th century portion of the Wolfman Curve is outside the error ellipse of the result and this is a less probable interpretation on strictly archaeomagnetic grounds (see Figure 66.27). The 701 ellipse substantially overlaps the VGP centerpoint and ellipse of the earlier archaeomagnetic VGP from Area 2 (set 700), despite the clear difference in their ages (stratigraphy and pottery). The 701 result also falls within the error ellipse of the Saltbush Pueblo result (DB 614), which is also suspected of dating to the Late Coalition period on the basis of pottery. The Area 1 chronology and stratigraphic contexts of the tree-ring dates are far from clear (Kohler and Root 2004:211–212), and the archaeomagnetic results both reflect and contribute to this ambiguity.

When compared with SWCV2000, the date range associated with Area 1 kiva result (701) is still somewhat problematic (see Figure 66.28). The centerpoint coincides with the curve, and the date range of the ellipse is AD 1225–1300. The later half of the range is possible given the pottery types in the collection, but the tree-ring dates (if relevant) are several decades later and the pottery types could be later as well.

Shohakka Pueblo (LA 3840)

Testing was conducted at Shohakka Pueblo (LA 3840) in 1991 (Kohler et al. 2004). Excavation was limited to three trenches, one of which encountered Room 2. At least two floors were present in the excavation, and a hearth (Feature 2) was associated with the lower surface. Pottery in the room fill and near the upper floor included Agua Fria Glaze-on-red, Cieneguilla Glaze-on-yellow, and Largo Glaze-on-yellow in addition to polychrome examples of these Glaze A and Glaze B types. The lower floor and hearth were well sealed by the later floor, and an undetermined amount of time elapsed between abandonment of the lower and upper floors. Additional testing followed in 1997 after the Dome fire, but a second archaeomagnetic sample taken from the site at that time was too imprecise for interpretation.

The archaeomagnetic VGP for the Room 2 hearth (803) is plotted in Figures 66.27 and 66.28 against the Wolfman and SWCV2000s. The centerpoint is close to the post-AD 1400 segment of the Wolfman Curve, and that association yields a date range of AD 1395–1435. The ellipse also grazes the earlier AD 1325–1375 portion of the curve, and a date range based on that segment is AD 1325–1365. The later date range is consistent with the ceramic dating of the room fill and the site as a whole, but the earlier date range is still possible if there was any significant time lag between the initial construction and the remodeling of Room 2.

SWCV2000 yields a single probable date range for the 803 result (see Figure 66.28). When moved to the closest point on the curve, the ellipse intercepts define a range from AD 1375 to the middle to late 16th century.

LA 60497

Limited testing was carried out at LA 60497 as part of investigations following the Dome fire in 1997. Archaeomagnetic specimens were collected from Feature 1.02, a hearth in a surface room (set 1094). The associated pottery was characterized as Glaze B and Glaze C, dating roughly to the early to middle 15th century. Based on these pottery types, the VGP should post-date the result from Shohakka Pueblo.

The VGP is relatively precise (α_{95} = 1.3º), and it overlaps the early 15th century portion of the Wolfman Curve (see Figure 66.27). The associated date range is AD 1405–1445, consistent with the associated pottery types. The result coincides with a slightly later portion of SWCV2000 (see Figure 66.28). The earliest of two possible date range interpretations would be AD 1455 through the middle 16th century, slightly later than would be consistent with the pottery types in the site collection.

Cochiti Area

Excavations along NM 22 between Peña Blanca and the Pueblo of Cochiti encountered components spanning pre-ceramic agricultural features and the Historic period (Post et al. n.d.). Archaeomagnetic dating results from the Late Developmental and Coalition components are relevant to the C&T Project interpretations.

The final Late Developmental period component along NM 22 was defined by the dominance of mineral-painted Socorro Black-on-white and Kwahe'e Black-on-white pottery types and the presence of a small amount of Galisteo Black-on-white pottery. Pit Structure 76 at LA 6169 appears to be the last vestige of this component, quickly followed by the construction of Coalition period structures that were associated with Santa Fe Black-on-white pottery. The abrupt transition appears to involve a population replacement, as utility vessel pottery technology shifts at the same time as the change in whiteware types. The technological shift suggests that populations who were used to using Pajarito Plateau pottery resources had moved into the area. Pottery, stratigraphy, and architectural style provide support for the chronological sequence, but there is no source of significant chronometric dating other than the archaeomagnetic dates.

One archaeomagnetic set represents the Late Developmental component (1160), while four sets represent the immediately succeeding Coalition period occupation (1159, 1103, 1156, and 1158). Sets 1158 and 1159 were collected from separate burned features within the same Coalition period pit structure. There is no stratigraphic reason why they should not reflect substantially the same time period, but both are very precise and their error ellipses do not overlap. The overall span of the Late Developmental period through Coalition period VGP results is equivalent to that of the C&T Project Coalition period VGP results.

The Late Developmental VGP (1160) has a date range of AD 1160–1250 based on the Wolfman Curve, while the four Coalition period results span the AD 1190–1280 period (Figure 66.29). Of the two contemporary features from Pit Structure 16, the early result is dated to AD 1200–1225 while the later result is dated to AD 1240–1275. Date ranges based on SWCV2000 cover a greater range of time (see Figure 66.30). The Late Developmental VGP ellipse spans the AD 1045–1180 period while the Coalition period ellipses span the AD 1155–1340 period. Using the SWCV2000, the two contemporary sets from Pit Structure 16 are assigned to the AD 1165–1185 and AD 1275–1340 date ranges.

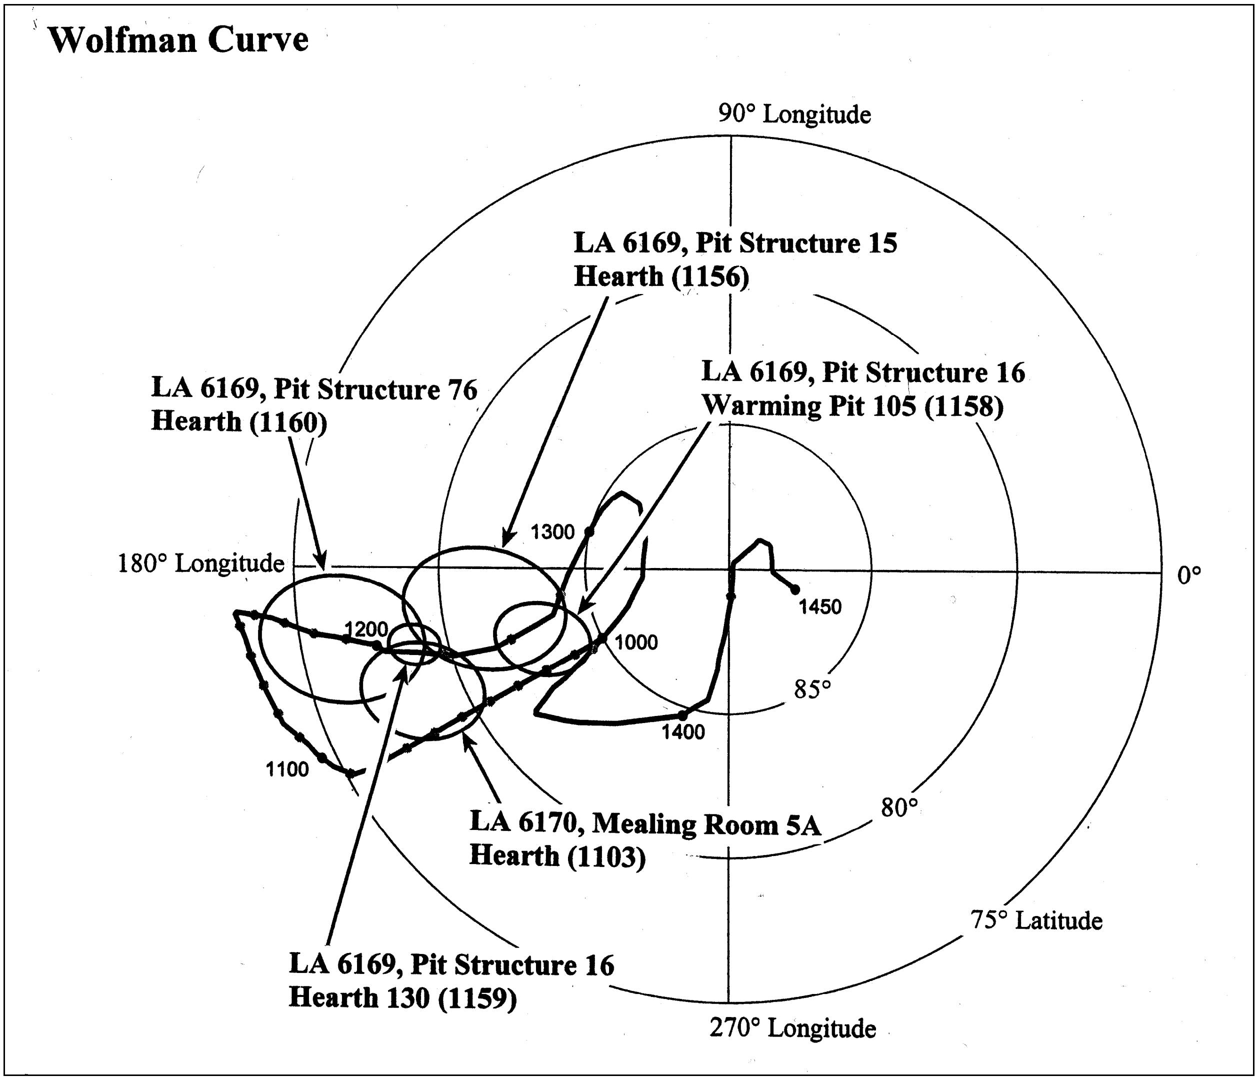

Figure 66.29. Comparative archaeomagnetic VGP results from the Cochiti area plotted against the Wolfman Curve. The Pit Structure 76 sample is from a Late Developmental period context while the other results are from Coalition period contexts.

The Late Developmental result has substantially the same pole position (and error term) as Pit House 4 at LA 3333 (see Figure 66.23) and as the early hearth in Room 2, LA 135290 of the C&T Project sites (see Figure 66.16). To the extent that the similar pole positions document contemporaneity, they define cultural differences across the geography of the northern Rio Grande region. The LA 6169 settlement represents an in situ population that maintained a previously established cultural pattern, while the C&T Project and LA 3333 sites represent the colonization of landforms by populations from elsewhere. Both LA 3333 and LA 6169 include Galisteo Black-on-white pottery, albeit in small quantities, while Galisteo Black-on-white pottery is not present in the C&T Project collections until much later within the sampled communities.

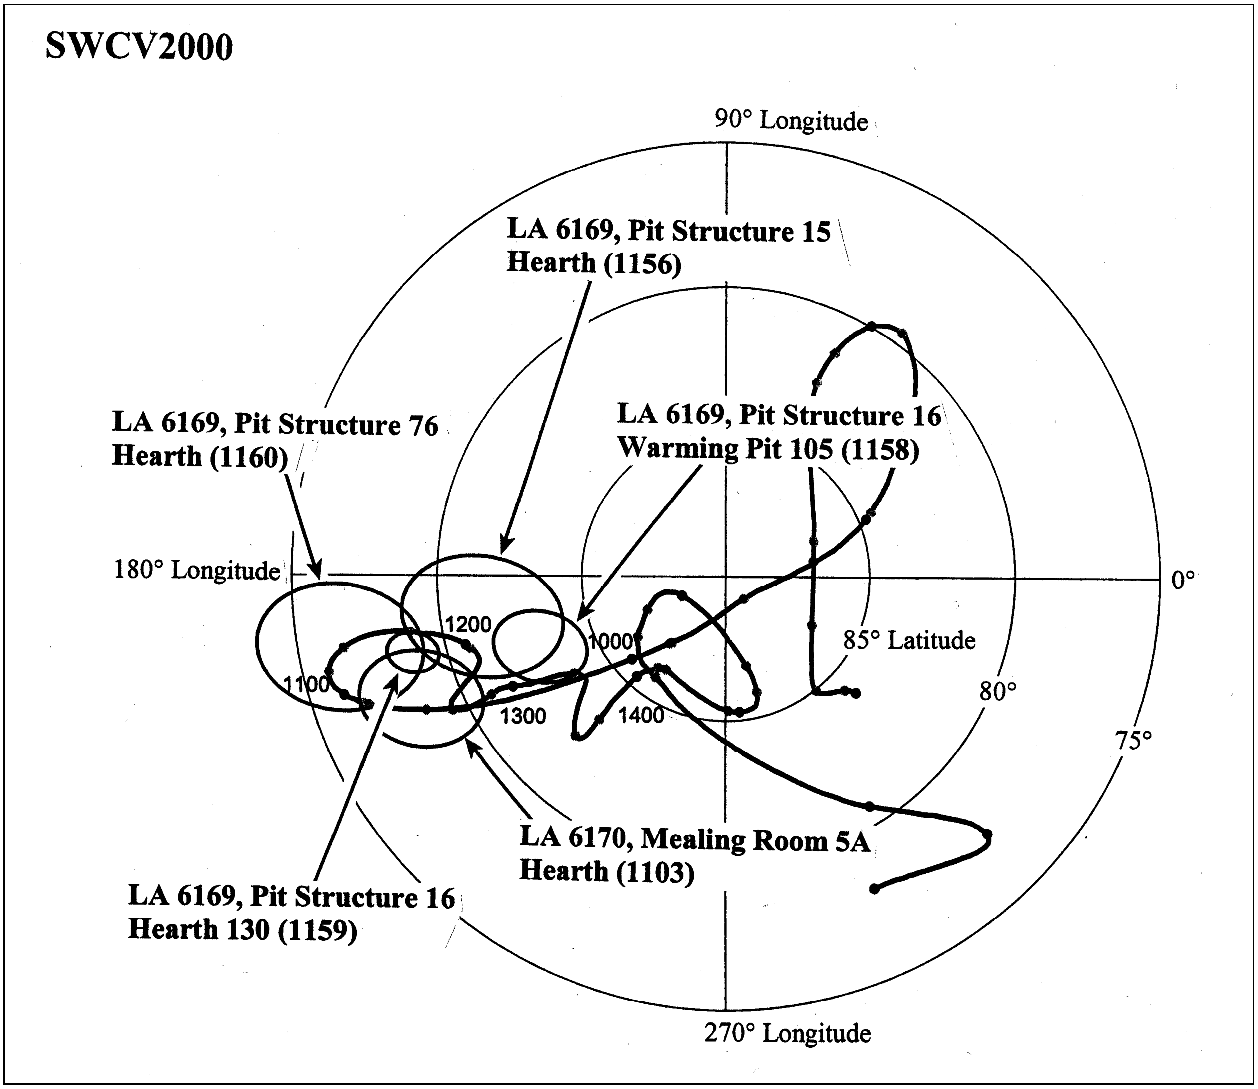

Figure 66.30. Comparative archaeomagnetic VGP results from the Cochiti area plotted against SWCV2000. The Pit Structure 76 sample is from a Late Developmental period context while the other results are from Coalition period contexts.

San Ysidro Area

Two DuBois archaeomagnetic results are available from the Albuquerque Archaeological Society excavations at AS-8 (LA 13197), part of the Cañada de las Milpas community, between the Jemez River valley and the Rio Puerco valley near the village of San Ysidro (Bice et al. 1998). The site consists of more than 40 rooms in two roomblocks joined at right angles to form two sides of a small plaza. A circular room was defined (but not excavated) adjacent to the plaza. Only a single kiva was defined. The pottery includes designs that are late Pueblo III in style, including locally produced San Ignacio Black-on-white, Santa Fe Black-on-white, and Galisteo Black-on-white. Only six tree-ring samples recovered during the excavations were datable, yielding one cutting date of AD 1273r and non-cutting dates of AD 1177, 1212 (2), 1221, and 1283. None of the tree-ring samples are from the same rooms as the archaeomagnetic dating samples.

Archaeomagnetic sets were collected from cooking features in Room W-1 (DB 1584) and Room Y-1 (DB 1585) (DB 1584 is incorrectly attributed to Room W-2 in some records). The results are relatively precise (α_{95} = 1.2º and 1.9º, respectively) and their ellipses overlap slightly (Figure 66.31). The ellipses are marginal to and appear to be later than the C&T Project ellipses of equivalent precision (see Figure 66.21).

Using the Wolfman Curve, DB 1584 intersects only one curve segment and is given a date range of AD 1245–1280. The DB 1585 ellipse overlaps two irrelevant portions of the curve (pre-AD 1040 and post-AD 1345) and barely grazes the middle 13^{th} century segment. A date range based on the latter segment is AD 1230–1290. Both interpretations are plausible but are marginally too young for the associated tree-ring dates for site construction.

Date range estimates based on SWCV2000 are more complicated due to the looping of the calibration curve at AD 1250. The ellipse for DB 1584 does not overlap any curve segment, but the centerpoint is closest to the curves at about AD 1230 and 1315. These points translate into date ranges of AD 1175–1240 or 1275–1340. The DB 1585 ellipse overlaps or is adjacent to the irrelevant pre-AD 1020 and post-AD 1650 segments. The centerpoint is close to the AD 1330 point on the curve, and the ellipse is adjacent to another segment at about AD 1230. Possible relevant date ranges would be AD 1195–1320 or 1275–1420 (intermediate ranges are also possible). In all cases, the date ranges encompass the probable dates for use of the hearths based on the tree-ring dates from the site, however the date ranges themselves have extremely low resolution (they are "accurate" but have low precision).

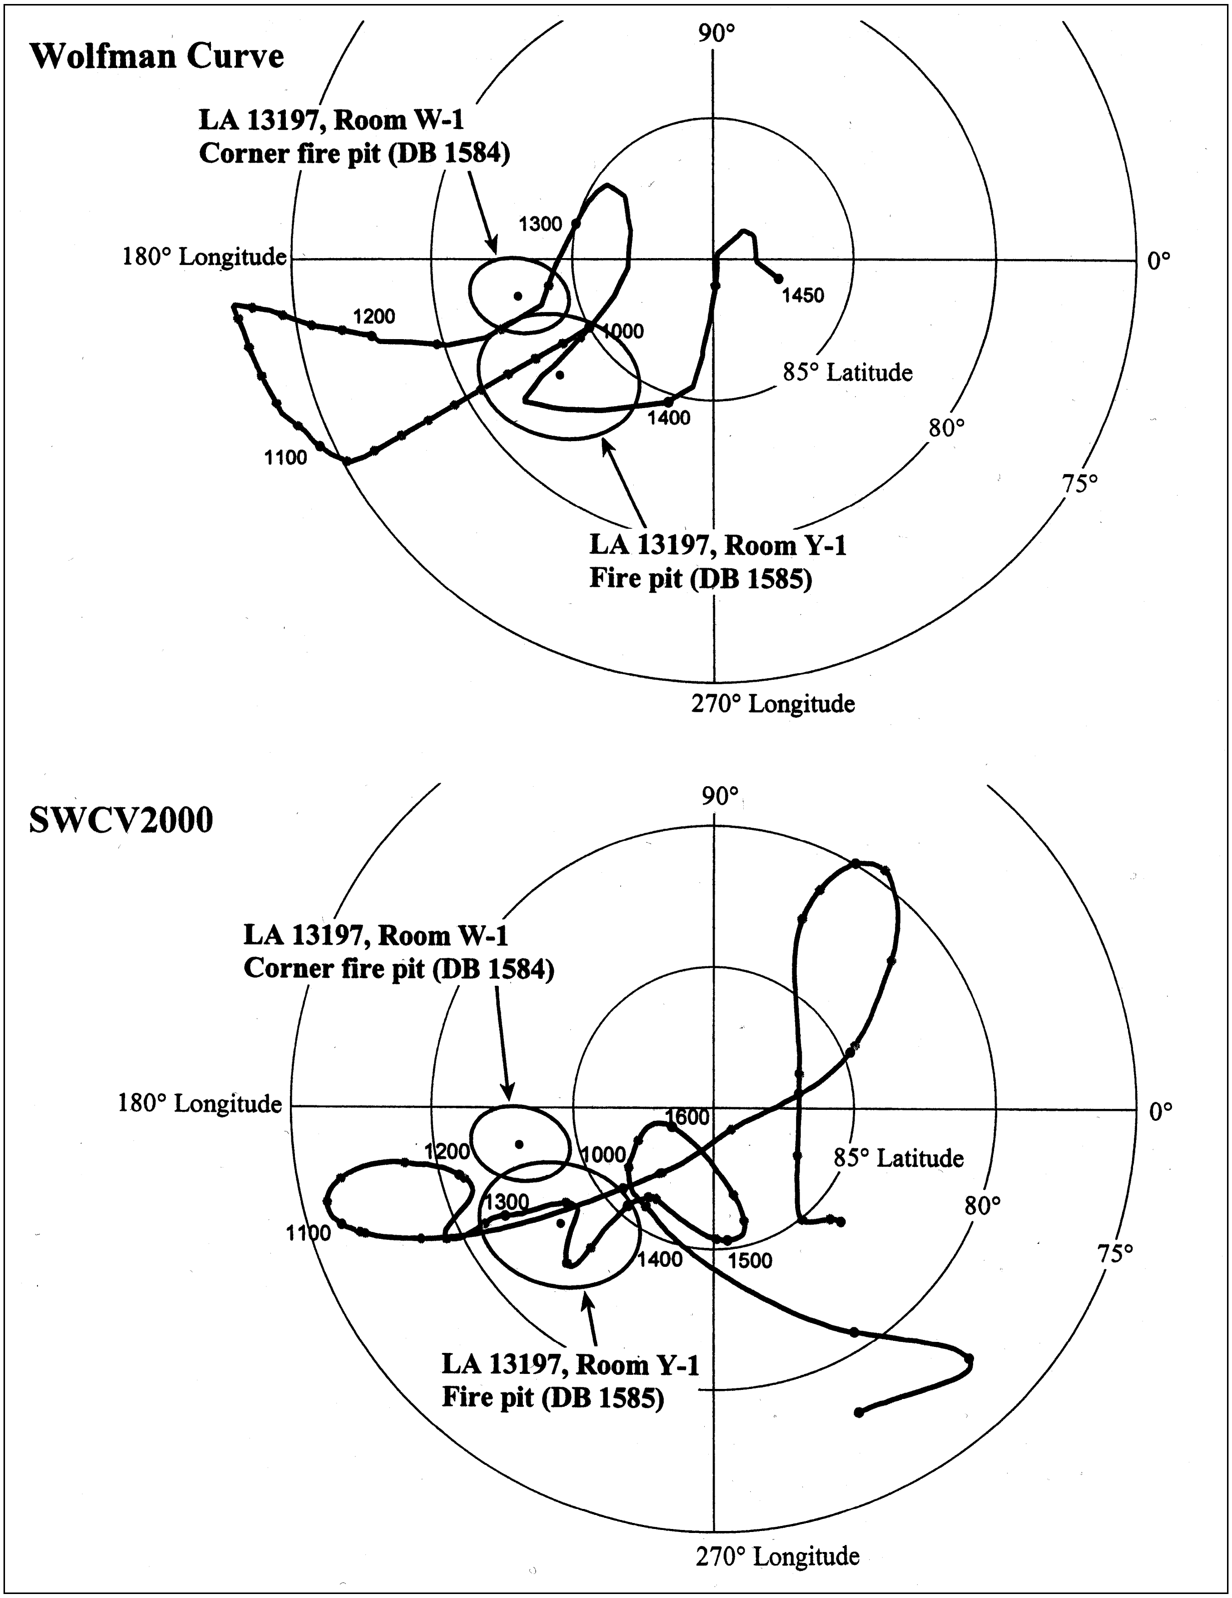

Figure 66.31. Comparative archaeomagnetic VGP results from the San Ysidro area (LA 13197) plotted against the Wolfman and SWCV2000 curves.

DISCUSSION

Regional archaeomagnetic results both validate and bracket the chronological interpretations of the C&T Project VGPs. The colonization and growth episode represented by the C&T Project sites is generally contemporary with the spread of population into the Galisteo Basin, the growth of communities in the Santa Fe area, the establishment of the Gallina communities investigated by Mackey, and the incursion of Coalition populations into the Cochiti area.

Based on the Wolfman Curve, the more precise VGP positions associated with both the C&T Project and regional components fall within the AD 1180–1265 period. These core VGP sequences are bracketed by only a few VGP positions and only a few of these are associated with independent dates. LA 3333 in the Galisteo Basin yielded a VGP at the early margin of the C&T Project results, and associated tree-ring dates suggest that structure construction and use occurred in the 1210s (slightly later than the dates suggested by the Wolfman Curve). The Late Developmental period result from LA 6169 in the Cochiti area may also be slightly earlier than the C&T Project results, but there are no independent dates to support that dating assumption other than the dominance of mineral paint in the pottery assemblage.

Several regional components that are later than the C&T Project sites are identified by pottery associations as well as absolute dates. VGPs from these apparently later sites include results from Pueblo Alamo (LA 8), Arroyo Hondo Pueblo (LA 12), the late component of Burnt Mesa Pueblo (LA 60372), LA 13197 in the San Ysidro area, and sites with glazeware on the Pajarito Plateau (LA 3840 and LA 60497). The VGPs for most of these results are at slightly higher latitudes than the C&T Project results, suggesting that the C&T Project pole positions do not extend later than the AD 1280s. However, there are two VGPs that are independently dated to the post-AD 1300 period that coincide with the C&T Project results. VGPs from Arroyo Hondo Pueblo (DB 705) and Burnt Mesa Pueblo (LA 60372; 701) fall within the later portion of the C&T Project result cluster. Both of these results are independently dated to the 1310s or 1320s, although the dating is not absolutely unambiguous.

The regional archaeomagnetic sample results were compared with both the Wolfman and the SWCV2000s. As with the C&T Project result interpretations, date ranges based on the Wolfman Curve are more consistent and usually more accurate when compared with independent dating information. However, none of the C&T Project or regional results supports the low-longitude loop of the Wolfman Curve between approximately the AD 1290 and 1325 calibration points. Also, the independently dated regional results suggest that the calibration of the Wolfman Curve may need to be adjusted in the AD 1150–1300 period. That adjustment could result in a 10 or more year increase in date estimates for ellipse intercepts along the curve path. The amount of adjustment needed appears to be greater in the vicinity of the AD 1200 calibration point and less after AD 1250. In almost all cases, such an adjustment would improve the fit between the C&T Project archaeomagnetic date ranges and the ranges of associated calibrated radiocarbon dates (see Table 66.3).

CONCLUSION

The success of the C&T Project archaeomagnetic dating program is due to an exceptionally good substrate for the formation and retention of TRM vectors, the freedom provided by the C&T Project to collect as many samples as could be accommodated by the archaeological features, and the commitment of the C&T Project staff to a broad multidisciplinary approach to chronology (Chapters 58 and 69, Volume 3).

Of the 27 sets collected, 22 produced interpretable pole location estimates (α_{95} values of 4.0° or less), one full and one partial set were unsuccessful experimental tests of the ability of hearth stones to acquire archaeological TRMs, and only four sets produced VGPs with error ellipses too imprecise for interpretation. Of the interpretable sets, one was from a Protohistoric component and the remaining 21 were from Coalition period components. Unfortunately, both of the sets collected from Classic period components were too imprecise for interpretation.

The Protohistoric period result was relatively imprecise, and the quality of the calibration curves for that time period (DuBois and SWCV2000) is weak. As a result, the contribution of the archaeomagnetic date estimate to the understanding of site chronology is far less than the other sources of dating applied to the site.

The Coalition period dates are extremely variable in precision (see Figure 66.21), but the higher precision VGPs define a several-generation span of occupation beginning in the late 12th century and extending into the middle to late 13th century. The timing of the establishment and persistence of these communities is consistent with the spread of population into new geographic niches in the region as a whole, as indicated by the comparison with the regional catalog of archaeomagnetic results.

Accuracy and precision are the major points of comparison between different dating techniques. As noted previously, the measurement precision of C&T Project samples is remarkably good. The mean error term was 1.6º and the median was only 1.3º. Whereas measurement error of the VGP can be measured and expressed statistically, the calibration curves used to estimate date ranges also contribute to apparent precision. The calibration curves are created with error and are better conceptualized as bands than lines at this point in their development. The underlying movement of the true VGP also influences apparent precision in that polar movement can be fast or slow, and the direction of VGP movement can change, creating bends, kinks, and loops. A given measurement error ellipse can encompass a short or long span of time depending on the shape as well as the rate of change of the underlying curve. Although different in location and calibration, the Wolfman and DuBois curves describe the past polar curve as relatively linear through the 13th century. In contrast, SWCV2000 characterizes the 13th century as a sharp kink. As a result, date ranges produced for the Coalition period using the Wolfman or DuBois curves are relatively precise (short). In addition to the kink, SWCV2000 assumes a relatively slower rate of VGP movement in the 12th and 14th centuries, and even ellipses with relatively small error terms can encompass long time spans. The most relevant date ranges calculated using the Wolfman Curve cover an average span of 65 years, while the same error ellipses produce and average span of 125 years when interpreted using SWCV2000.

Accuracy in archaeomagnetic dating has two dimensions. Due to the overlapping paths of VGP movement through time, accurate date estimates are dependent on the archaeologist's ability to identify the relevant portions of archaeomagnetic calibration curves. In the case of C&T Project sites, pottery and architecture of the Coalition components were key elements in focusing interpretation on the 13th century curve segments. The few cases where field assessments of feature ages were ambiguous were resolved by laboratory analysis of pottery and were confirmed by associated radiocarbon dates. The other dimension of accuracy is related to precision. As a VGP becomes less precise (the α_{95} becomes larger), the error ellipse encompasses greater lengths of the VGP paths. Date ranges based on the ellipse intercepts increase, and there is a greater likelihood that the actual date is encompassed by the range, increasing accuracy. Conversely, as VGP precision improves (as α_{95} values fall below 1.0º), the ellipse intercepts define ranges small enough to challenge the quality of curve calibrations. From whatever source, ranges of greater than 50 years decrease in usefulness in the context of interpreting Coalition period culture history, regardless of their accuracy, and ranges of less than 25 years risk encouraging an unwarranted perception of accuracy.

Another factor in considering accuracy is the relationship between precision and the TRM of interest. Standard expressions of archaeomagnetic precision consist of the dispersion of individual specimen measurements that contribute to the mean VGP. This dispersion is quantified by the α_{95} of each result, and it can be affected by the mineralogy of the substrate, the intensity of the burn, the attention to detail by the field sampling technician, and any non-systematic magnetic moments acquired by the specimens. If large ellipses were simply an expression of random variation around a mean TRM vector, a high proportion of results should significantly overlap the path of the calibration curve. There is a slight tendency for VGPs with large α_{95} values (perhaps even those with α_{95} values as low as 3.0°) to be inaccurate as well as imprecise. This is evident in Figure 66.21 where the three largest ellipses are marginal to the Wolfman Curve. This raises the possibility that systematic magnetic moments other than the TRM are influencing the apparent VGP and reducing accuracy.

Another dimension of precision can be characterized as fidelity. Multiple sets were collected from four C&T Project features. In one case (LA 12587, Hearth 6) only one of three results was sufficiently precise for interpretation, although there was overlap between the best imprecise result and the interpretable result (see Figure 66.4). The ellipses of the two sets collected from LA 86534, Room 1, Hearth 4 barely overlap despite an α_{95} of 3.7º for one of the two results (see Figure 66.7). The two sets from LA 127635, Room 1, Hearth 2 are both precise and overlap significantly, although the larger ellipse does not encompass the centerpoint of the more precise result (see Figure 66.20). The best example of fidelity from the C&T Project sampling effort is LA 12587, Room 2, Hearth 10 where two extremely precise results coincide (see Figure 66.2). In all of these cases, the paired sets were assumed to reflect the same TRM, but in only two cases do the overlaps in the error ellipses validate that assumption convincingly. This suggests that the interpretation of archaeomagnetic dates should be slightly more conservative than the date ranges derived simply from the α_{95} ellipse intercepts.

The ultimate determiner of date accuracy, assuming issues of TRM quality and measurement reliability are resolved, is the calibration curve. None of the three available curves for the Southwestern United States is fully reliable. This is reflected by the differences explored in

Blinman and Cox (see Volume 1, Chapter 9). Based on C&T Project radiocarbon dates, the date ranges based on the Wolfman Curve are accurate and consistently more accurate than date ranges based on SWCV2000. However, regional comparisons with tree-ring dated VGPs suggest that a 10 to 30 year shift in the calibration of the Wolfman Curve from AD 1150–1300 would improve the accuracy of the archaeomagnetic dates. This would effectively add 10 or more years to the beginning and end points of each date range, with the largest changes occurring around the current AD 1200 calibration point of the curve segment.

CHAPTER 67
LUMINESCENCE DATING OF CERAMICS FROM LOS ALAMOS COUNTY, NEW MEXICO – SUMMARY REPORT

James Feathers

INTRODUCTION

Over the past four years 33 ceramic samples from sites in Los Alamos County, New Mexico, have been dated by luminescence by the University of Washington laboratory. The samples have been collected from land administered by the Los Alamos National Laboratory (LANL). The results from these analyses have been presented in a series of four technical reports (Feathers 2004, 2005b, 2006, and 2007; Appendix Z). These reports also contain detailed procedures followed in the laboratory. This chapter summarizes these data in a way that will be understandable to the non-technical reader and will allow evaluation of the dates.

Luminescence dating is based on the accumulation of absorbed radiation dose in crystalline materials over time (Aitken 1985). The radiation comes from naturally occurring radionuclides within the samples and their immediate surroundings. Absorption of this radiation occurs by trapping of ionized electrons (or electron vacancies) in crystalline defects. Some of these traps are able to hold these electrons more or less indefinitely (in terms of archaeological time) and they are only released by exposure of the material to elevated heat or extended sunlight. When these electrons are released, light called luminescence is emitted. The intensity of this light is proportional to the time since the traps in the material were emptied by exposure to either heat or light. By measuring the luminescence signal and its sensitivity to radiation, producing a quantity called equivalent dose (D_e), and by assessing the natural radioactivity of the sample and its immediate surroundings (the dose rate), the time since last exposure to heat or light can be determined. The age is determined by dividing D_e by the dose rate. For the ceramic materials under consideration here, the event dated is the last exposure to sufficient heat to empty the traps. This is usually when the pottery was made, or in the case of burned adobe and floors, when this burning occurred.

Table 67.1 lists all the C&T Project samples by site. Most of the samples were retrieved from in and around adobe roomblocks. In most cases a sediment sample spatially associated with the samples was also collected. The sediment is used to assay the gamma dose rate, most of which originates in the sediment immediately surrounding the sample. It and the barely significant cosmic dose rate make up the "external dose rate," while the alpha and beta dose rates, derived from the ceramic sample itself, comprise the "internal dose rate." This distinction is due to the long ranges of gamma and cosmic radiation and the shorter ranges of alpha and beta radiation.

DOSE RATES

The radiation measurements are given in the individual reports and will not be repeated here (Feathers 2004, 2005b, 2006, and 2007). The radioactivity has been measured by a combination of alpha counting, beta counting, and flame photometry. The first two methods are direct measures of radioactivity, while flame photometry is a method for measuring total potassium. The latter allows calculation of ^{40}K, one of the major contributors to the dose rate.

The radioactivity is relatively high, reflecting the geology of the region, although there is not a lot of variation among samples. Figure 67.1 shows the distribution of the total dose rate for all samples. Most samples have dose rates between 4 and 8 Gy/ka (Gy stands for gray, the international unit for absorbed dose, and ka is 1000 years). The variation mainly reflects differences among the ceramics (internal dose rates), the radioactivity of the sediments varying much less. The lower variation among the sediments is advantageous, because it means the radioactivity across the sites does not vary much, even though the environment is complicated by the presence of roomblocks and other features. The presence of such features is thus not apt to introduce systematic error in the external dose rates. Although more varied, the ceramic radioactivity is not that different from that of the sediments, suggesting most of the ceramics were constructed of local materials.

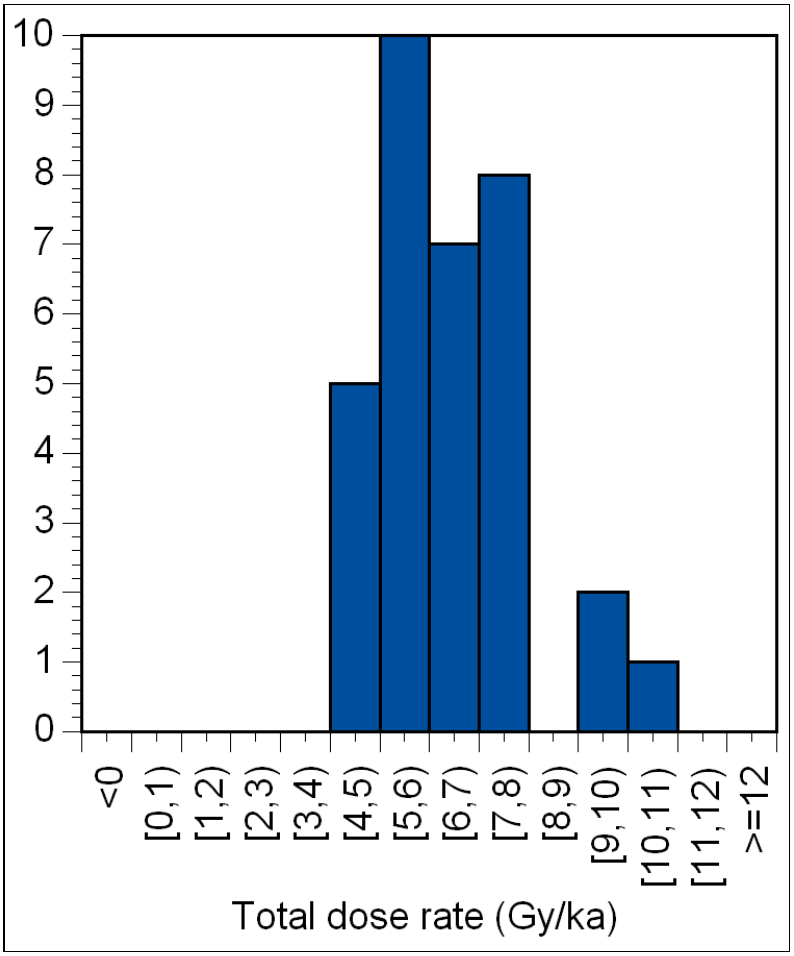

Figure 67.1. Distribution of total dose rates among ceramic samples.

A possible source of error is change in the dose rate through time. Sometimes this can be reflected in disequilibrium conditions in the uranium decay chain. The parent isotope, ^{238}U, and its daughters are a major contributor to the dose rate (the other important decay chain headed by ^{232}Th is much less likely to be out of equilibrium). Mobility of some of the elements in the decay chain can cause disequilibrium. The state of equilibrium was not measured directly, but a comparison of results from alpha counting (with flame photometry for K) and beta counting can sometimes indicate disequilibrium in the upper part of the chain. Significant differences between alpha and beta counting were measured for only five of the samples. The effect of these differences, and perhaps a reason why more differences could not be seen, is reduced by the high concentration of ^{40}K in all of these samples. The high concentration of ^{40}K (more than 2% total K in most samples) means the beta dose rate is dominated by ^{40}K, and because ^{40}K is not part of a decay chain, the effect of disequilibrium is largely confined to the alpha dose rate, only about half of which stems from the ^{238}U decay chain. In other words, although disequilibrium conditions may reflect some mobility in a few of the sherds, the effect is not likely to be strong. Of course, ^{40}K can also potentially move around, from leaching or similar processes, but the high concentrations and low variability of ^{40}K in the sediments provide no evidence of much movement. All of these considerations suggest that systematic error in the dose rate calculations is probably minimal.

EQUIVALENT DOSE

Measurement of D_e is usually the main source of error in luminescence dating. D_e is determined by calibrating the natural luminescence signal against signals produced by artificial irradiation in the laboratory. The challenge is to make sure the natural signals and the artificial signals are comparable, which can be difficult because movement of electrons among traps can alter the luminescence sensitivity of the sample.

Measurement of luminescence of ceramics in the laboratory has traditionally utilized heat as the stimulating source, i.e., heat is used to release electrons from their traps. Such luminescence is called thermoluminescence (TL). An option is to use photon stimulation, either from visible light, called optically stimulated luminescence (OSL), or from infrared light, called infrared stimulated luminescence (IRSL). OSL and IRSL have a long history of use in sediment dating (where the event being dated is last exposure to sunlight), but have just recently been applied to ceramic materials. TL, OSL, and IRSL have all been used for the ceramics in this study, but some discussion of the peculiarities of each is necessary to evaluate the results.

Many luminescence dating studies utilize sand-sized grains of quartz or feldspar, but the fine-grained nature and relatively small size of these samples limit the amount of the sand fraction available for dating. As an alternative, polymineral fine-grained dating, employing grains in the 1 to 8 μm range, is utilized in this study. These grains are retrieved from the center of the sherds by low-powered drilling and then settled in acetone to achieve the proper grain size.

Derivation of D_e for any of the stimulation methods requires construction of a growth curve, where luminescence is plotted against artificial radiation. The slope of the growth curve (i.e., how luminescence changes with dose) represents the sensitivity. Two kinds of growth curves are typically used. An additive dose curve is where differential radiation is applied to sample aliquots that still retain the natural signal. The slope of the curve is extrapolated to the dose axis to achieve an estimate of D_e, although the extrapolation is prone to error. A regeneration curve, in contrast, is where differential radiation is applied to aliquots where the natural signal has been previously removed. The natural signal is then interpolated into this curve. The problem here is that removal of the natural signal may change the sensitivity of the sample. Sensitivity change may also be a problem for additive dose if the luminescence response to artificial irradiation differs from the natural response.

The growth curves can be constructed either on multi-aliquots where different irradiations are given to different aliquots or on single aliquots, where repeated irradiations are applied to the same aliquot. TL has traditionally been measured using multi-aliquots, and in fact a viable single-aliquot method for TL has not been devised. A typical analysis uses both additive dose and regeneration techniques, taking advantage of regeneration to avoid extrapolation problems and using the additive dose to correct for any sensitivity change caused by removing the natural signal. The particular method used by our laboratory is called the slide method (Prescott et al. 1993). Any sensitivity change brought about by artificial irradiation during additive dose is not accounted for, but in practice the method has produced reasonably good dates, although sometimes there can be substantial scatter. Luminescence dating also requires the use of stable signals (i.e., traps that do not lose their electrons at ambient temperatures). For TL this is done by a plateau test, where the D_e is determined for signals from different temperature increments. Luminescence stimulated from the temperature range throughout which the D_e does not significantly differ is taken as stable signal.

A further problem with TL is the possibility of anomalous fading. This is the loss of electrons from traps that from kinetic considerations should be stable. It is thought to be caused by a process called quantum tunneling and is most often associated with feldspar minerals. Because the 1 to 8 µm fraction of ceramic materials often will contain feldspars, fading is an ubiquitous problem, and indeed many of the samples in this study exhibit fading. Fading can be detected by comparing the luminescence from aliquots that have been given equal doses but have been stored for different lengths of time. Decreasing signal with time indicates fading, although the slope of this curve can be used to correct for the effect (Huntley and Lamothe 2001). Correction, however, comes at a cost of precision.

In sum, while TL can produce reasonable results, it can also suffer from high scatter, weak or absent plateaus, fading, and problems inherent in multi-aliquot approaches. An attractive alternative is either OSL or IRSL, both developed in sediment dating. The main advantage is being able to use single-aliquots. Growth curves are commonly produced by a method called single-aliquot regenerative dose (or SAR), where repeated regeneration doses are given following measurement of the natural signal on a single aliquot (Murray and Wintle 2000). Use of equal test doses after the natural and each of the regeneration measurements allows a way to monitor and correct for sensitivity change. A preheat is used to eliminate unstable signal. The benefits of SAR are a much more precise and potentially more accurate measurement of D_e and the utilization of smaller sample amounts.

OSL has generally been used on quartz grains, and IRSL on feldspar grains. Both quartz and feldspar have an OSL signal, but only feldspar has an IRSL signal. For fine grains, where the minerals are not separated, the two have been combined in what is called the double SAR method (Banerjee et al. 2001). At each measurement step, an initial infrared stimulation is followed by an optical (usually using blue light) stimulation. The idea is that the IRSL will remove most of the feldspar signal, so that OSL is tapping mainly quartz. This would circumvent the fading problem, although not necessarily entirely because feldspar still has an OSL signal. Preliminary work from our laboratory, however, has shown that the OSL signal does not seem to fade much, while the IRSL signal often fades dramatically.

The approach in our laboratory is to use both TL and IRSL/OSL as two semi-independent means to determine D_e with the promise of much better precision and accuracy.

Before TL, OSL, and IRSL results can be compared, however, one further matter must be considered in fine-grain dating. Alpha radiation, because of its short range, is not as efficient as either beta or gamma radiation in producing luminescence—by a factor of about 10. This is taken into account by comparing growth curves using either beta or alpha irradiation. The slope ratio of the two curves is called the b-value and it is used to adjust the alpha dose rate. The b-value varies from sample to sample and from mineral to mineral, so it must be determined for TL, OSL, and IRSL for each sample. Generally, the b-value for OSL (mainly quartz) is much less than that for IRSL (mainly feldspar), with the TL value (combined quartz and feldspar) somewhere in between. Because of differential b-value, the D_e values from TL, OSL, and IRSL are not directly comparable. Rather, the age has to be calculated separately for each and then compared. Ideally the age will agree for all of them, but there are reasons why they may not. The principle reason is fading, which will affect the TL and IRSL signal, but less so the OSL signal. If fading is present, the OSL age should be greater and more accurate than either the TL or IRSL. (The OSL/IRSL b-value was not determined during the original analysis for UW1031 to UW1037. The ages were recalculated using the average OSL b-value from other sherds, 0.73 ± 0.25, as a reasonable estimate. This altered most of the ages only slightly.) D_e values and other pertinent data are given in the original reports.

AGE

Where the ages calculated from any of TL, OSL, or IRSL for any one sample are within one-sigma, a weighted average is taken as the best estimate of age. This was seldom the case for IRSL because of fading, but on 18 of the 33 samples the OSL and TL ages agreed, the latter sometimes first corrected for fading. On eight samples, the OSL was taken as the best age estimate, in seven cases because the TL signal faded and could not be corrected, and in one case (probably insufficiently fired plaster) the TL was anomalously old. On the other seven, the TL age was taken as the best estimate either because there was no OSL signal (three cases) or because the OSL signal was anomalously high (four cases).

EVALUATION

Because a luminescence dating requires the estimation of so many variables, it can be prone to error, or at least low precision. To evaluate the derived dates, I have ranked them according to the following criteria: (a) agreement in age between OSL and TL, (b) a TL plateau region extending 60°C or more, (c) OSL derivations on more than one aliquot and these derivations are consistent with a single D_e value with precision better than 15 percent, (d) precision in fitting for the TL slide of better than 15 percent, (e) no TL anomalous fading or if fading, a correction can be applied, and (f) agreement in dose rates from beta counting and alpha counting. Dates that meet all these criteria rank first (Group A). Those that deviate from only one criterion, or only slightly in two criteria are ranked second (Group B). All others rank third (Group C). Most confidence can be placed in the A and B groups, while the results from Group C should be treated with caution.

Only seven samples could be classed in Group A. Another 11 samples were assigned to Group B, and the last 15 to Group C. Most confidence can be placed in the samples from Group A and Group B. Table 67.2 sorts the samples by group, gives their age, and explains the source of uncertainly responsible for the group placement. Figure 67.2 sorts the ages by group. Except for one very young age, Group A clusters relatively tightly between AD 900–1200. The spread in ages increases for Groups B and C. This suggests the more extreme values, especially the older ages in Group C, are not too reliable.

Table 67.2. TL dates by groups.

Sample	Age (years AD)	Basis for age	Problems
Group A			
UW1031	1047±80	TL/OSL	
UW1236	1035±73	TL/OSL	
UW1237	1134±79	TL/OSL	
UW1239	1217±56	TL/OSL	
UW1242	888±62	TL/OSL	
UW1245	1859±13	TL/OSL	
UW1247	1158±63	TL/OSLi	
Group B			
UW1030	1226±68	TL	No OSL signal
UW1033	1060±109	OSL	TL anomalously old
UW1034	1188±59	TL/OSL	Poor TL plateau
UW1035	801±201	TL/OSL	OSL scatter
UW1036	1182±42	TL/OSL	Poor TL plateau

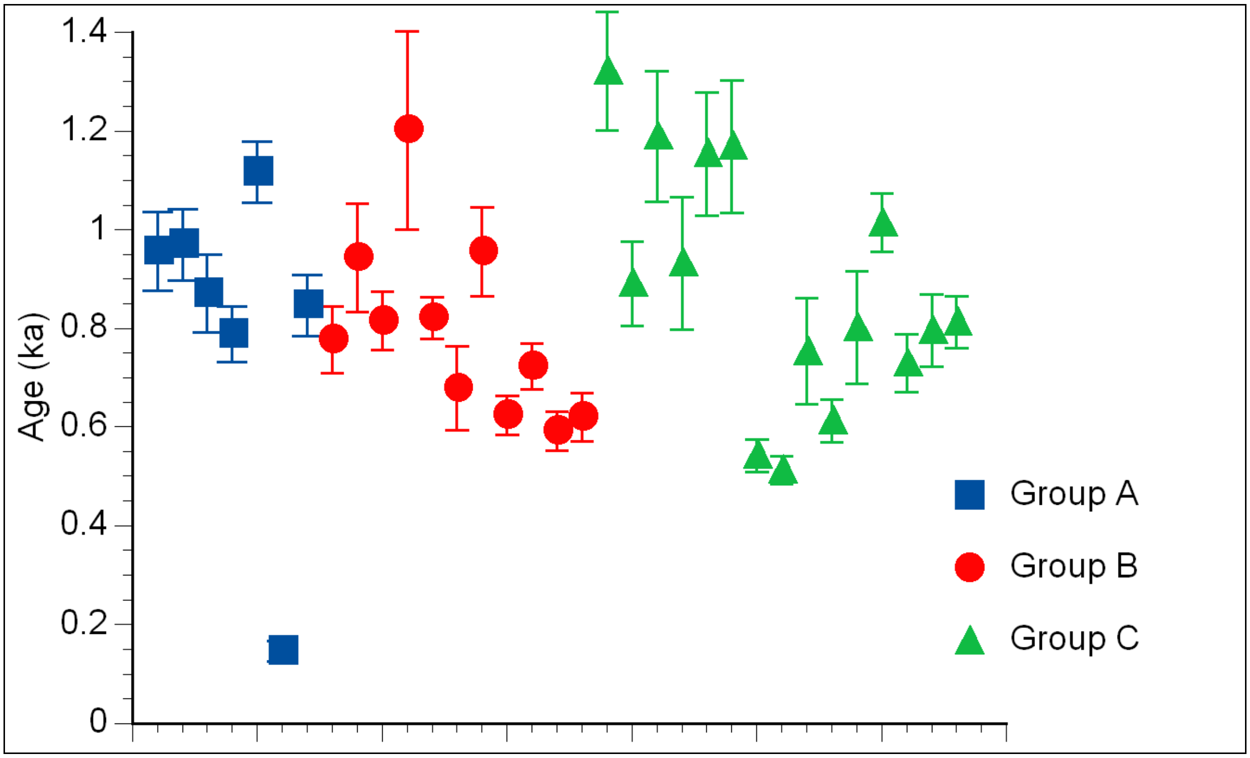

Figure 67.2. Ages of samples sorted by groups as defined in the text.

INDIVIDUAL SITES

LA 12587

Two sherds and two pieces of burned plaster were sampled from this site. Only one sample was ranked in Group C. The other three did not differ significantly from each other at two-sigma and produced a weighted average of AD 1134±47.

LA 86534

Three pieces of burned plaster were sampled for this site. All were ranked in Group B. They did not differ significantly at two-sigma and produced a weighted average of AD 1173±34.

LA 4618

Only one sample of burned adobe from a hearth was measured at this site. It was ranked in Group B and yielded an age of AD 1325±86.

LA 135290

Nine samples, including adobe, burned floor, clay hearth remnants, and sherds, were measured. Five of them were ranked in Groups A or B. Two samples from Room 4 (adobe and floor) produced a weighed average of AD 951±47, while the other three (from Rooms 6, 7, and 2/11) yielded a weighted average of AD 1161±41. A wall fragment from Room 6, but ranked in Group C, also was dated to the 12^{th} century. The other Group C samples (from Rooms 2 and 8/9) had a weighted average in the 10^{th} century. An earlier and a later occupation seems evident from this dating.

LA 85869

Only one sherd was dated from this site but it was ranked in Group A. It yielded a very young date: AD 1859±13.

LA 99396

Two sherds were dated from this site. One was ranked in Group A and one in Group C. Only the Group A date, AD 1158±63, is reliable.

LA 87430

One sherd, ranked in Group B, was dated from this site. The derived age is AD 1383±39.

LA 127634

Two sherds were dated from this site. Both were ranked in Group C, but had nearly identical ages. Weighted average is AD 1481±21.

LA 127635

Only one sherd was dated from this site and it ranked in Group C. The age is AD 1253±108.

LA 85411

Two sherds were dated from this site, but both ranked in Group C. The ages did not differ at two-sigma and the weighted average is AD 1371±40.

LA 85417

Four samples, one sherd and the others burned adobe or floor, were dated. Two ranked in Group B and the ages did not differ at two-sigma. Weighted average is AD 1362±30. The age from one of the samples from Group C did not differ significantly from this age, but the other was older and unreliable.

LA 85861

Two samples, one sherd and one burned plaster, were dated from this site. Both ranked in Group C, but were very close in age. The weighed average is AD 1199±43.

LA 85404

A sample of burned floor was dated from this site. It ranked in Group B and yielded an age of AD 1388±49.

CHAPTER 68
HYDRATION ANALYSIS OF OBSIDIAN ARTIFACTS FROM THE WHITE ROCK, AIRPORT, AND RENDIJA TRACTS, LOS ALAMOS, NEW MEXICO

Christopher M. Stevenson

INTRODUCTION

One-hundred-eighty-eight obsidian artifacts were submitted to the Diffusion Laboratory for age determination using the obsidian hydration dating method. The samples came from a total of 22 archaeological sites distributed among five land tracts. Within the White Rock Tract, six archaeological sites were dated: 12587 (*n* = 26), 86637 (*n* = 10), 127625 (*n* = 3), 127631 (*n* = 2), 128804 (*n* = 9), and 128805 (*n* = 10). The White Rock Y Track contained two dated sites: 61034 (*n* = 8) and 61035 (*n* = 8). Three archaeological sites were dated in the Airport Tract: 86534 (*n* = 14), 135290 (*n* = 7), and 139418 (*n* = 8). Within the Rendija Tract, the chronology of ten archaeological sites was investigated: 85404 (*n* = 3), 85411 (*n* = 5), 85861 (*n* = 5), 85859 (*n* = 10), 85869 (*n* = 6), 87430 (*n* = 5), 99396 (*n* = 14), 99397 (*n* = 10), 127634 (*n* = 3), and 127635 (*n* = 3). Finally, three sites were investigated in the Technical Area (TA) 74 Tract: 21596B (*n* = 2), 21596C (*n* = 3), and 117883 (*n* = 7). Analytical problems were encountered with 14 samples and this reduced the total number of dated samples to 174. These samples possessed surface flaws such as cracks, perlite inclusions or irregularities, which made the samples unsuitable for density measurement or infrared analysis.

In order to calculate the absolute date for an obsidian artifact, three analytical procedures need to be completed. First, the amount of surface hydration, or the thickness of the hydration rim formed by the inward diffusion of molecular water (Figure 68.1), needs to be measured. Second, the high-temperature hydration-rate constants for each artifact are predicted from the structural water content of the glass. Lastly, the soil temperature and relative humidity at the archaeological site is estimated so that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. The archaeological rate constants are used to convert the hydration rims to a date when the surface of the artifact was created in prehistory. Each of these analytical steps is summarized below.

HYDRATION RIM MEASUREMENTS

Once exposed to the atmosphere, an obsidian artifact will adsorb water onto its surface. This moisture diffuses into the glass structure and forms a water-rich hydration layer or rim. The obsidian hydration rim thickness in microns (*um*) can be determined by measuring the infrared absorbance of molecular water by photoacoustic spectroscopy (IR-PAS) using the procedure developed by Stevenson et al. (2001). In this method, the amount of infrared absorbance is converted to a depth using a previously established calibration.

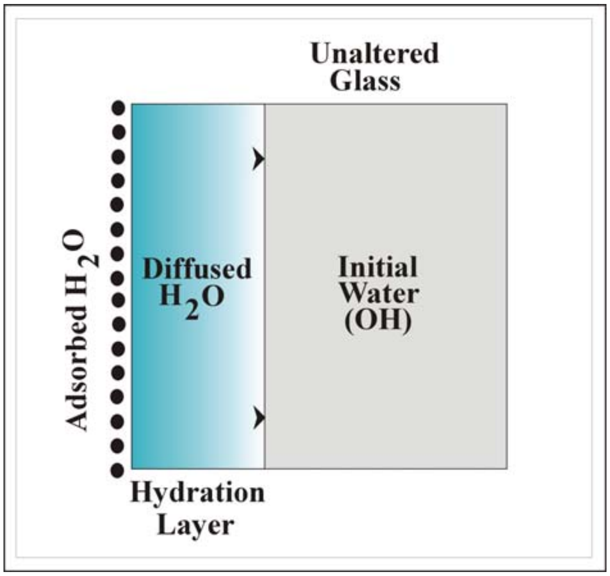

Figure 68.1. Model of the obsidian hydration layer.

In this analysis, each artifact was cut on a diamond blade saw to remove an 8-mm-square sample of obsidian, which was inserted into the photoacoustic accessory sample cup mounted on a Bomem MB-120 Fourier transform infrared spectrometer. The sample compartment was then purged with ultra-high-purity helium gas and the amount of environmental water forming the hydration layer was measured. The infrared water peak at 1630 cm^{-1} was monitored (Figure 68.2) to determine the intensity of infrared absorbance. The spectra were collected by averaging 150 scans at a resolution of 16 cm^{-1}. The height of the infrared peak is proportional to the quantity of diffused environmental water present within the glass surface (Figure 68.2). The absorbance value was converted to a rim thickness value (Table 68.1) using the regression equation [y = (10.648*ABS)-0.0413] that relates infrared absorbance to thickness in micrometers (Figure 68.3). The thickness values used to develop the calibration were measured by secondary ion mass spectrometry (SIMS) of the surface hydrogen (water) profile. The error associated with each IR-PAS measurement is estimated to be 0.1 *um* (Stevenson et al. 2001).

HYDRATION RATE DEVELOPMENT

The rates of surface water diffusion for a wide variety of obsidian compositions have been developed in the laboratory. Under conditions of high temperature and pressure (Stevenson et al. 1989, 1998), freshly flaked samples were hydrated in a saturated vapor environment (100% relative humidity) between temperatures of 150°C and 180°C for periods of up to 31 days. At the end of the reaction periods, each sample was thin sectioned and the hydration rim measured by optical microscopy. The induced rims were used to calculate the temperature dependence or activation energy (E) of reaction, and the pre-exponential factor (A) for the Arrhenius equation at 160°C. With these experimental constants, the hydration rate developed at high temperatures may be adjusted to reflect site temperature and relative humidity conditions (Figure 68.4).

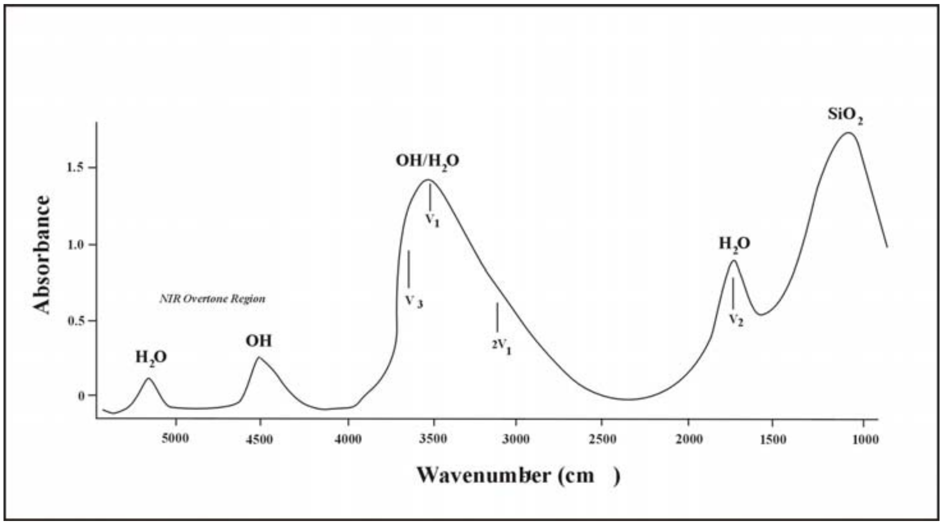

Figure 68.2. Infrared spectra of water in obsidian.

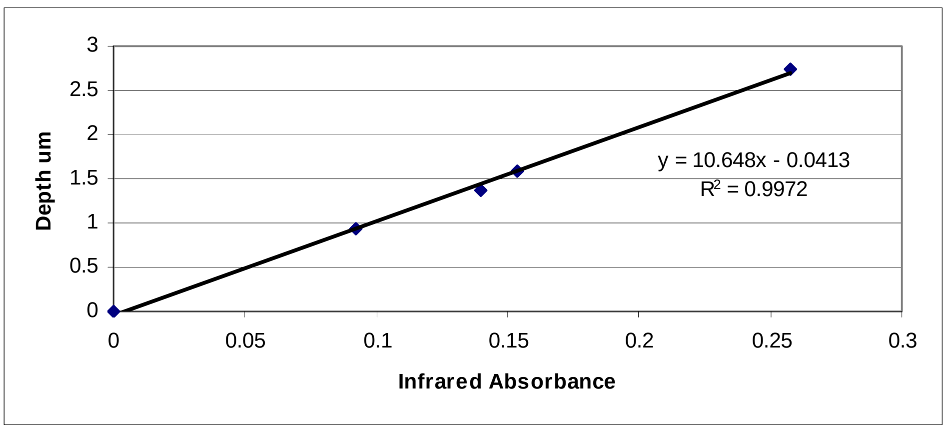

Figure 68.3. Photoacoustic calibration that relates infrared absorbance to hydration layer thickness in microns.

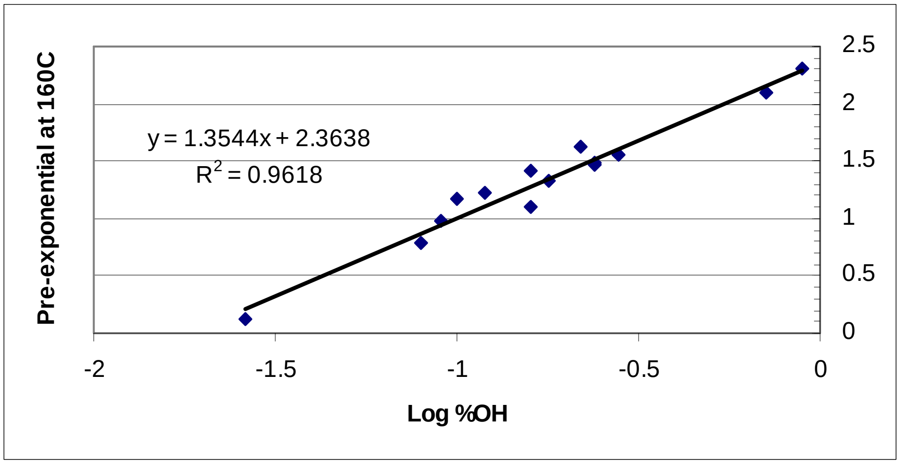
Further analysis has shown that the Arrhenius constants (A, E) may be accurately estimated from the composition of the obsidian; specifically the amount of initial water (OH) contained within the unweathered obsidian. This water is trapped within the glass structure during cooling from a liquid state and may be estimated from the density of the natural glass (Figure 68.5). OH values for the samples used in the density/OH calibration were determined by infrared transmission spectroscopy (Newman et al. 1986). A measure of the water concentration (OH) for the artifacts was determined by a non-destructive density measurement made using the Archimedes method (Ambrose and Stevenson 2004; Stevenson et al. 1996).



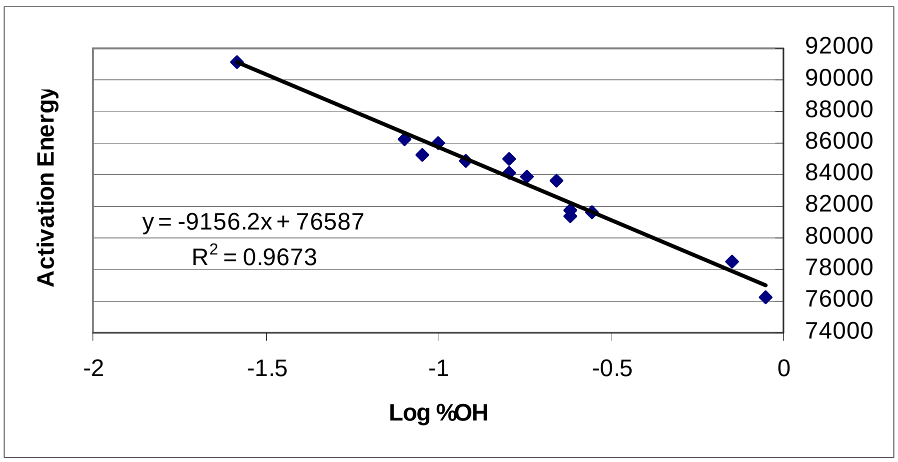


Figure 68.4. The Arrhenius constants A (top) and E (bottom) calibrated to obsidian structural water content.

In this analysis, the water content was analyzed for 176 of the total 188 samples. Fourteen samples possessed surface or internal flaws that made them unsuitable for analysis. Previous X-ray fluorescence analysis had shown that three geological sources were represented in the archaeological assemblage. The Cerro Toledo source was represented by 68 samples. The water content (OH) concentration for these items ranged between 0.12 percent and 1.52 percent with 42 of 70 samples (60%) in the 0.11percent to 0.13 percent OH range (Figure 68.6). The Valle Grande source accounted for 100 samples. The most frequent OH value was 0.13 percent with 57 of 93 samples (61%) having this value. The remaining samples exceeded this amount and ranged up to 1.37 percent OH (Figure 68.7). El Rechuelos was the last source and was represented by 11 artifacts. The OH concentration was restricted to a range of 0.12 percent to 0.19 percent with all but two samples having a value of 0.13 percent (Figure 68.8). It is clear from these descriptive statistics that a large proportion of artifacts from within the Cerro Toledo and Valle Grande sources are water rich and will have accelerated hydration rates at ambient temperatures. The small sample size from the El Rechuelos source does not allow for an accurate assessment of the flow variability with respect to water content but the presence of higher water content samples suggests that it might exhibit the same general patterning as the other two sources.

SOIL TEMPERATURE RELATIVE HUMIDITY ESTIMATION

Soil temperature and soil relative humidity significantly affect the rate of hydration. Temperature increases will accelerate the rate of hydration in an exponential manner while a decline in soil relative humidity will decrease the hydration in a linear fashion in the upper ranges (90% to 99%) (Jones et al. 1997; Mazer et al. 1991). These important parameters may be obtained through field studies using saline-based thermal cells monitors. In this project we used two versions of the thermal cell because of the changing availability of commercially available cell materials. Temperature and relative humidity measurements at the White Rock Tract used the polycarbonate cell as designed and calibrated by Trembour et al. (1988). The ground temperature at the Rendija Tract was measured with a new polystyrene cell that was identical to the Trembour cell except for the cell outer material. This change required a new calibration to be developed to establish the rate of water diffusion as a function of temperature.

Development of the calibration required timed exposures to determine the rate of water diffusion through polystyrene as a function of temperature. Four sets of cell pairs encased in their water jackets were exposed to temperatures of 25, 30, 35, and 40°C for periods up to 64 days in an incubator with a precision of +/-1°C. The weight gains of the cells were measured on a Mettler analytical balance to record the total weight gain in grams. The LOG weight gain per day was then plotted against the temperature to develop the calibration: Y = 9E-05x – 0.0014 (r^2 = 0.9874). The calibration is for temperatures between 25 and 40°C but extrapolations to lower temperatures may be made with confidence because of the high r-squared value associated with the correlation (Figure 68.9).

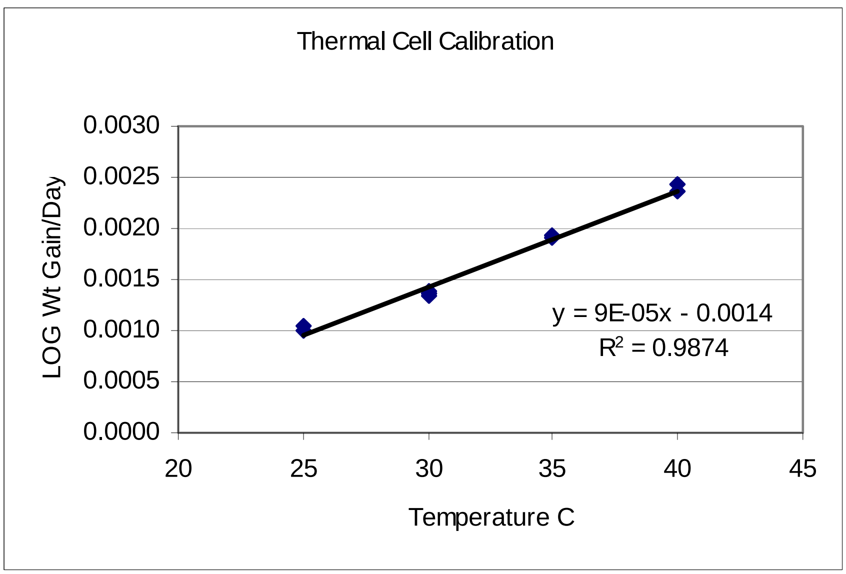

Figure 68.9. Thermal cell calibration curve that relates water weight gain per day to temperature.

Soil temperature monitoring within the project area at the White Rock (1981 m, 6500 ft) and Rendija Tracts (2020 m, 6824 ft) was completed for soil depths between 20 cm and 100 cm. The data showed the expected trends of a decreasing soil temperature with depth and a high, or increasing, relative humidity with depth. Within the White Rock Tract, the annual effective hydration temperature (382 day exposure) ranged between 15.4°C and 13.7°C depending upon the depth of the artifact below the surface of the ground (Table 68.2). The percent relative humidity was determined to be approximately 96 percent to 97 percent for all depths. At the Rendija Tract the effective hydration temperature (406 day exposure) ranged between 12.4°C and 7.5°C and the relative humidity varied between 93 percent to 102 percent (Table 68.3). We believe that the 100 cm cell pair at the Rendija Tract is in error because of the humidity that is in excess of 100 percent and the sharply lower temperature value that is 3.5 degrees lower than the 80 cm temperature value. These odd results will not be used in the age estimation process.

Table 68.2. White Rock Tract ground temperature and relative humidity.

Depth (cm)	EHT (^oC)	Percent RH
10	15.3	96
25	15.4	97
50	14.5	97
75	14.1	96
100	13.7	97

*Data collected over 382 days

Table 68.3. Rendija Tract ground temperature and relative humidity.

Depth (cm)	EHT (^oC)	Percent RH

40	11.7	97
60	11.5	--
80	11.0	93
100	7.5	102

*Data collected over 405 days

AGE ESTIMATION

Using the estimated effective hydration temperature and relative humidity, hydration rates for the obsidian artifacts was calculated. For each artifact, the estimated high-temperature hydration rate at 160^{o}C (A) was extrapolated to the hydration rate at the estimated temperature and relative humidity for the project area using the Arrhenius equation:

$$K = A\ (Rh)\ \mathrm{Exp}\ E/RT$$

where: K = archaeological hydration rate (*um*^{2}/day)
A = preexponential (*um*^{2}/day at 160^{o}C)
Rh= percent relative humidity
E = activation energy (Joules/mol)
R = universal gas constant
T = effective hydration temperature in degrees Kelvin

The hydration rate and age determinations at the estimated site temperature and relative humidity are shown in Table 68.1.

DISCUSSION AND CONCLUSION

The obsidian hydration dates presented in Table 68.1 have been calculated in a manner to compensate for most of the significant environmental and compositional parameters known to affect the rate of hydration. One of the major factors, the surface dissolution of the glass, has not been considered since this phenomenon is characteristic of tropical areas with high temperatures and alkaline soils. The client should be aware that monitoring environmental parameters is very difficult, especially for surface or near-surface artifacts where the depth of burial varies over time. This changing context can affect the temperature and relative humidity conditions and cannot be accounted for using the techniques currently available to the laboratory. However, in this study artifacts are buried within 10 to 20 cm below surface where more stable environmental conditions will be present.

The client should also be aware of the detrimental effects of forest fires or burn events on the integrity of the hydration layer. A few artifacts (e.g., 2003-18, 2003-71) have larger hydration rims in excess of five microns. These samples do not have geological surfaces and it is possible that a burn event may have impacted the hydration layer. Exposure to heat under 400°C may expand and then obliterate the hydration layer. Artifacts exposed to higher temperatures may experience accelerated re-hydration upon cooling with the result that very large hydration layers may be formed (Stevenson et al. 2004). In evaluating these dates, the context of the artifacts should be examined for evidence of burning.

It has been noticed that in almost all cases, obsidians with a structural water content in excess of 0.20 percent OH tend to have late age determinations while obsidians with a structural water content of 0.12percent to 0.13 percent OH returned ages of greater antiquity. Based upon previous experimentation, it was anticipated that water-rich glasses would have proportionally larger rims since greater structural water content would increase the rate of hydration exponentially. However, the hydration rims of most samples are within 1 to 2 microns of obsidian flakes with low water content (0.13% OH). Because the environmental parameters of the artifacts are relatively uniform within a site boundary, external environmental conditions do not seem to be a plausible explanation.

We believe there are two possibilities that may account for this patterning. First, the obsidian water content determination estimated from the artifacts may be in error. The water-rich samples may have significantly lower iron or silica contents that would reduce the artifact density and be more influential than the amount of initial water in structuring the final outcome of the density measurement. These compositional factors should be compared with the density values to see if a trend is present. Alternately, the water content assessments are correct and the explanation is a behavioral one. It is possible that at a later time in this portion of the Southwest, Native American people tended to exploit more water-rich sections of obsidian flows or utilized volcanic ejecta, a material that tends to be water rich because of the rapid cooling that prevents the release of volatiles such as carbon dioxide and water. Water-rich glasses may be easier to manipulate compared to dry obsidians.

The latter hypothesis is partially supported by the assemblage from LA 12587. Radiocarbon and archaeomagnetic dating place the use of the pueblo between AD 900–1400 with an inferred final occupation of Roomblock I at around AD 1300. The assemblage from this site tends to be water rich with 12 of 22 samples possessing structural water in excess of 0.20 percent OH and ten of these samples returned dates after AD 800. This high proportion of water-rich samples with compatible dates suggests an exploitation pattern of water-rich glasses. The presence of dates from the fifth century and back into the Archaic period also suggests that artifact scavenging and reuse was also a frequent behavior.

CHAPTER 69
AN EVALUATION OF CHRONOMETRIC DATING TECHNIQUES ON THE PAJARITO PLATEAU

Brian C. Harmon and Bradley J. Vierra

INTRODUCTION

Chronometric dating forms the backbone of archaeological research. That is, the accurate temporal placement of archaeological occupations is critical to studies that seek to understand culture change. Whether it is the transition from foraging to agricultural-based economies or the process of Ancestral Pueblo site aggregation, the accurate dating of these histories underlies our ability to identify temporal patterning and develop theory to explain this variation in human behavior. Several different chronometric dating techniques were used to develop the temporal sequence identified by the Land Conveyance and Transfer (C&T) Project archaeological excavations. Yet, the precision and accuracy of these varying techniques is still being evaluated (Nash 2000).

J. Dean (1978) provides an excellent framework for interpreting chronometric dating techniques. Obviously, archaeologists are interested in dating a specific event that occurred some time in the past (e.g., the last use of a hearth). What is sometimes forgotten is that the event that is actually being dated may actually be the death of an organism, although it is often assumed that the two incidents coincided. A more accurate statement of this relationship is provided by J. Dean (1978:226–228) who offers a set of terms to delineate the events associated with independent dates. The *dated event* refers to the age of a sample as determined by a particular dating method (e.g., AD 1170±100). The *reference event* is the event that a particular method dates (e.g., the last heating above 450°C, when an organism stopped uptaking carbon). The *target event* is the event that the archaeologist is interested in dating (e.g., the last use of a hearth). The dated event is most closely related to the reference event, but these do not necessarily coincide with the target event.

Four chronometric dating techniques were used by this project: obsidian hydration, radiocarbon, luminescence, and archaeomagnetic. Each has its own potential source of error and varying temporal precision. This chapter will therefore evaluate the accuracy of each individual dating technique and compare these to each other. Given this information, the project archaeological sites will be placed in a temporal sequence, including a comparison with the ceramic chronology.

OBSIDIAN HYDRATION DATING

Method

Stevenson (Chapter 11, Volume 1) describes the basic process of obsidian hydration dating:

> In order to calculate the absolute date for an obsidian artifact, three analytical procedures need to be completed. First, the amount of surface hydration, or the thickness of the hydration rim formed by the inward diffusion of molecular water, needs to be measured. Second, the high-temperature hydration-rate constants for each artifact are predicted from the structural water content of the glass. Lastly, the soil temperature and relative humidity at the archaeological site are estimated so that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. The archaeological rate constants are used to convert the hydration rims to a date when the surface of the artifact was created in prehistory.

There has been some debate about the reliability of obsidian hydration dating (Anovitz et al. 1999; Beck and Jones 2000; Ridings 1996; C. Stevenson et al. 1996). Recent studies have therefore focused their attention on refining this dating method. For example, more accurate techniques have been developed for measuring the thickness of the hydration layer or determining water concentration as a function of depth within the artifact (Anovitz et al. 1999; C. Stevenson et al. 1996). It has been argued that the composition of the obsidian is not the significant factor for determining the hydration rate, but rather it is the initial glass water concentration that can determine the diffusion coefficient and therefore the hydration rate. That is, obsidian that contains low quantities of structural water hydrate at lower rates than obsidian that contain high quantities of water (Mazer et al. 1992; C. Stevenson et al. 1998; C. Stevenson et al. 1996). This characteristic would also vary by obsidian source (or flow). Although hydration rates were originally calculated by cross-dating the samples with associated chronometric dates, they are currently determined through experimental (e.g., induced) laboratory procedures (e.g., Michels et al. 1983; C. Stevenson et al. 1989). This has been termed the empirical versus intrinsic approaches (Ambrose 1976; Anovitz et al. 1999). In addition, local temperature and humidity conditions also need to be measured and the effective hydration temperature calculated. This is often accomplished by placing thermal cells at varying subsurface depths at the site for a period of one year. These data provide more accurate information than weather station data for adjusting the final hydration rate formula (M. Jones et al. 1997; Lee 1969).

The nature and degree to which obsidian is hydrated can be dramatically changed by exposure to high temperatures (see Steffen 2005:32–41 for a summary of much recent work). In general, laboratory results have shown that hydration bands begin to become more diffuse/expand when exposed to temperatures of above 200°C, at temperatures between 300 and 400°C the hydration front is lost, and at temperatures above 500°C the hydration band itself is lost. Long exposure to lower temperatures appears to replicate the effects of short exposure to higher temperatures. Within this general pattern, however, there is a great deal of variability: changes in hydration band width can occur at temperatures as low or lower than 100°C and hydration bands can persist even when obsidian is exposed to temperatures as high as 900°C. Additionally, all obsidian exposed to the same conditions will not necessarily be uniformly affected.

After obsidian is heated to a high enough temperature that the hydration band is altered or lost, it will rehydrate. There is a great deal of variability in the nature of this rehydration; it can occur at rates slower, the same as, or quicker than that of unburned obsidian. In some circumstances the obsidian rehydrates poorly, with the new hydration band forming diffusely (Deal and McLemore

2002:32; Loyd 2002:138; C. Stevenson et al. 2004:564–565; Trembour 1990:177–178). The reference event for obsidian hydration dates from rehydrated artifacts will be the date of last thermal alteration; however, the obsidian hydration age may be underestimated, overestimated, or correct. There is an additional source of age overestimation. As noted above, exposure to heat can cause the hydration rim to swell, making the obsidian appear older than it really is (C. Stevenson personnel communication 2006; C. Stevenson et al. 2004).

Forest Fires

One formation process that has potentially affected all the project sites is forest fires. Between circa AD 1480 (and possibly earlier) and 1899, low intensity forest fires occurred with high frequency in the higher-elevation ponderosa pine forests of the Jemez Mountains and Pajarito Plateau, and with reduced frequencies at lower elevations and in mixed-conifer forests (C. Allen 1989:69–120, 2002b, 2004:51–54; C. Allen et al. 1996; Foxx and Potter 1984; Touchan et al. 1996). As a result "[m]any, if not most, archaeological sites at Bandelier [National Monument] have been burned repeatedly by widespread, low-intensity fires that occurred across the Pajarito Plateau in the centuries following its abandonment," (C. Allen 2004:54). Archaeological sites within the project boundaries must have been similarly affected.

Although fire effects to surface artifacts and features can be significant, fire effects are rarely found deeper than 10 cm below the soil surface (Connor et al. 1989; Lentz et al. 1996; Ruscavage-Barz and Oster 2001; Traylor et al. 1990), unless a root system allows the fire to penetrate below ground. One reason for this is that soil temperatures will not rise above 100°C so long as any moisture remains in the soil (Solomon 2002).

Sampling

Obsidian artifacts submitted for dating were not taken from obviously burned contexts (e.g., hearths) and were inspected to ensure that they were free of macroscopic signs of burning (e.g., surface sheen, crazing, cracking, and vesiculation). When possible, only obsidian artifacts from subsurface contexts were submitted for dating; however, at sites where little subsurface obsidian was recovered, surface artifacts were dated (e.g., LA 99396 and LA 99397). This selection process attempted to reduce errors and uncertainties caused by thermal alteration. Nonetheless, it is possible that a portion of the dated artifacts were exposed to heating: it is known that the Cerro Grande fire burned at 17 sites and older fires may have burned at many or all of the sites. Additionally, some sites and parts of sites were clearly burned, although not necessarily as the result of forest fires (e.g., Room 2 of LA 12587 and most of LA 135290). During analysis C. Stevenson (Chapter 68, this volume) noted at least two artifacts that he suspected of having thermally altered hydration bands from LA 12587 and LA 128804. Only about four percent of the total debitage analyzed during the project exhibited obvious evidence of having been burned.

Obsidian hydration dates were calculated in a manner to compensate for most of the significant environmental and compositional parameters known to affect the rate of hydration (Stevenson, this volume). Table 69.1 summarizes all the obsidian hydration dates obtained from the project by site. Stevenson's chapter in Volume 3 should be consulted for a list of all the individual obsidian hydration dates. Two trends become clear from a project-level examination of the data: 1) most dates fall into the Archaic period and 2) dates from any given site are scattered over thousands of years.

Table 69.1. Summary of C&T Project obsidian hydration dates (OHD) by site.

Site	No. of Samples	Earliest OHD - BC/AD	Latest OHD - BC/AD	Mean OHD - BC/AD	Mean OHD Std. Dev.

Analysis

Tract-Level Analysis

As Early and Middle Archaic sites are, on average, located at higher elevations relative to Late Archaic sites at Los Alamos National Laboratory (LANL) (Vierra et al. 2006:186–187), it is expected that Rendija Tract dates will generally be earlier than dates from the other three tracts.

This will be particularly true if Ancestral Puebloan sites are located on a landscape that has a background scatter of Archaic artifacts, or if Ancestral Puebloans are scavenging artifacts from nearby Archaic sites. In addition to being at a higher elevation than the other tracts, the Rendija Tract also consists mostly of ponderosa pine forest, whereas the other three tracts consist mostly of piñon-juniper woodland (Chapter 4, Volume 1). Consequently, sites in the Rendija Tract would have been exposed to forest fires with a greater frequency between circa AD 1480 and 1899 (see above) and to forest fires with higher intensities than would have sites in the other three tracts (Chapter 84, Volume 4). While the implications of this fire data for tract-level obsidian hydration dating is unclear, some kind of difference is expected between the Rendija Tract and the other tracts.

Figure 69.1 and Table 69.2 show the distribution of obsidian hydration dates in each tract. Early and Middle Archaic period dates are slightly more frequent in the Rendija Tract, but the tract does not display a clear "early" signal. At the tract level, differences in Archaic period land use and/or fire effects are at best barely visible.

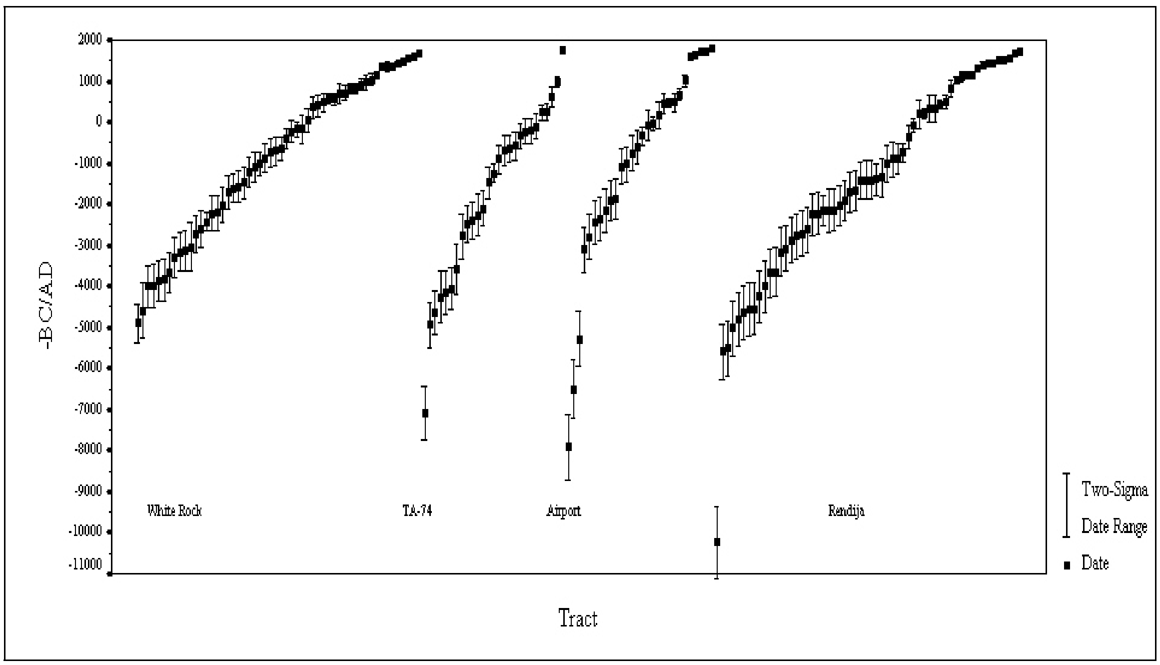

Figure 69.1. Obsidian hydration dates by tract.

Table 69.2. Frequency of obsidian hydrations dates by period per tract.

Tract	No. Samples	Paleoindian	Early Archaic	Middle Archaic	Late Archaic	Pueblo/ Modern
White Rock	54	0.000	0.130	0.315	0.481	0.370
TA-74 and White Rock Y	27	0.037	0.222	0.333	0.593	0.111
Airport	28	0.071	0.071	0.250	0.393	0.321

Tract	No. Samples	Paleoindian	Early Archaic	Middle Archaic	Late Archaic	Pueblo/ Modern
Subtotal	**109**	**0.028**	**0.138**	**0.303**	**0.541**	**0.294**
Rendija	58	0.052	0.190	0.362	0.448	0.293
Total	**167**	**0.036**	**0.156**	**0.323**	**0.509**	**0.293**

Note: Each row sums to greater than 1.000 since some dates straddle period boundaries and are counted twice.

Period-Level Analysis

Obsidian hydration dates from Coalition and Classic period roomblock and fieldhouse contexts are shown in Figure 69.2. Only 13 of 64 (20.3%) dates fall into the Coalition and Classic periods (AD 1150–1600) at two sigma (one artifact falls just short with a two-sigma late date of AD 1149). Neither artifact type nor material type appears to influence artifact dates (Table 69.3 and 69.4).

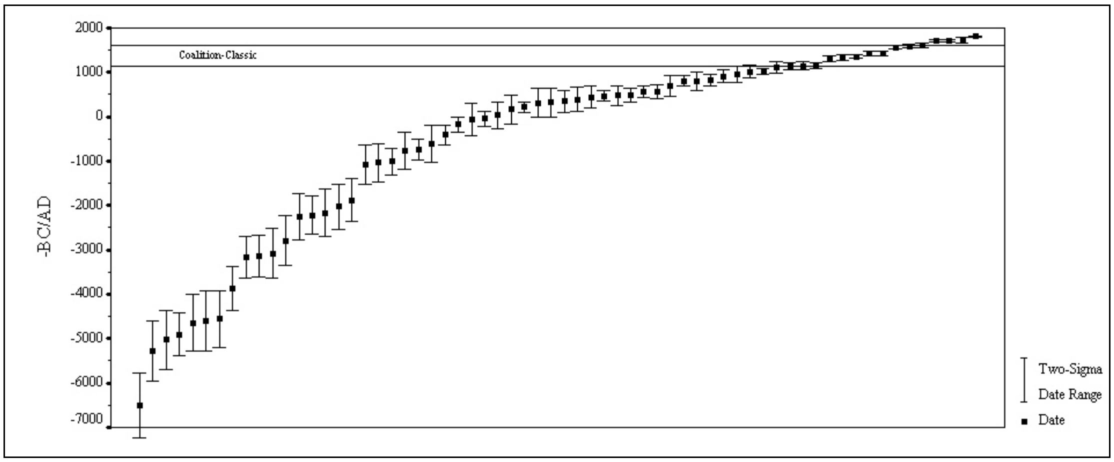

Figure 69.2. Obsidian hydration dates from roomblocks and fieldhouses.

Table 69.3. Number of hydration samples for artifact type by time period.

Artifact	Pre-Puebloan	Puebloan	Post-Puebloan	Total
Debitage	29 (61.7%)	10 (76.9%)	3 (75.0%)	42 (65.6%)
Tool	8 (17.0%)	2 (15.4%)	0 (0.0%)	10 (15.6%)
Point	10 (21.3%)	1 (7.7%)	1 (25%)	12 (18.8%)
Total	47 (100%)	13 (100%)	4 (100%)	64 (100%)

Table 69.4. Number of hydration samples for obsidian type by time period.

Obsidian	Pre-Puebloan	Puebloan	Post-Puebloan	Total
Cerro Toledo	19 (40.4%)	8 (61.5%)	0 (0.0%)	27 (42.2%)
Valle Grande	26 (55.3%)	5 (38.5%)	4 (100%)	35 (54.7%)
El Rechuelos	1 (2.1%)	0 (0.0%)	0 (0.0%)	1 (1.6%)
No Data	1 (2.1%)	0 (0.0%)	0 (0.0%)	1 (1.6%)
Total	47 (100%)	13 (100%)	4 (100%)	64 (100%)

When Coalition and Classic period obsidian hydration dates from individual sites are compared to dates derived from other methods there is weak agreement at best (Table 69.5). Clearly, obsidian hydration dating does not help to establish the date(s) of site occupation for Coalition and Classic period roomblocks and fieldhouses.

Table 69.5. Obsidian hydration dates compared to other site dates.

Site	FS*	Obsidian Hydration Date, Two-Sigma Range (AD)	Site Date[1] (AD)
135290	1055	873–1157	1160–1260
	2142	1560–1668	
86534		1545–1633	1190–1280
12587	3234	1048–1244	1275–1325
	1498	1368–1488	
85404	6	1373–1477	Early Classic
128805	71	1278–1398	1420–1500
	62	1320–1400	
85411	148	1098–1210	Early/Middle Classic
87430	107	986–1246	1430–1640
	131	1058–1226	
	127	1232–1372	
127634	8	1531–1599	1450–1650

*Field specimen 1. Based on one or more of the following: radiocarbon date(s), archaeomagnetic date(s), ceramic data.

Obsidian hydration dates from Archaic period sites are shown in Figure 69.3.

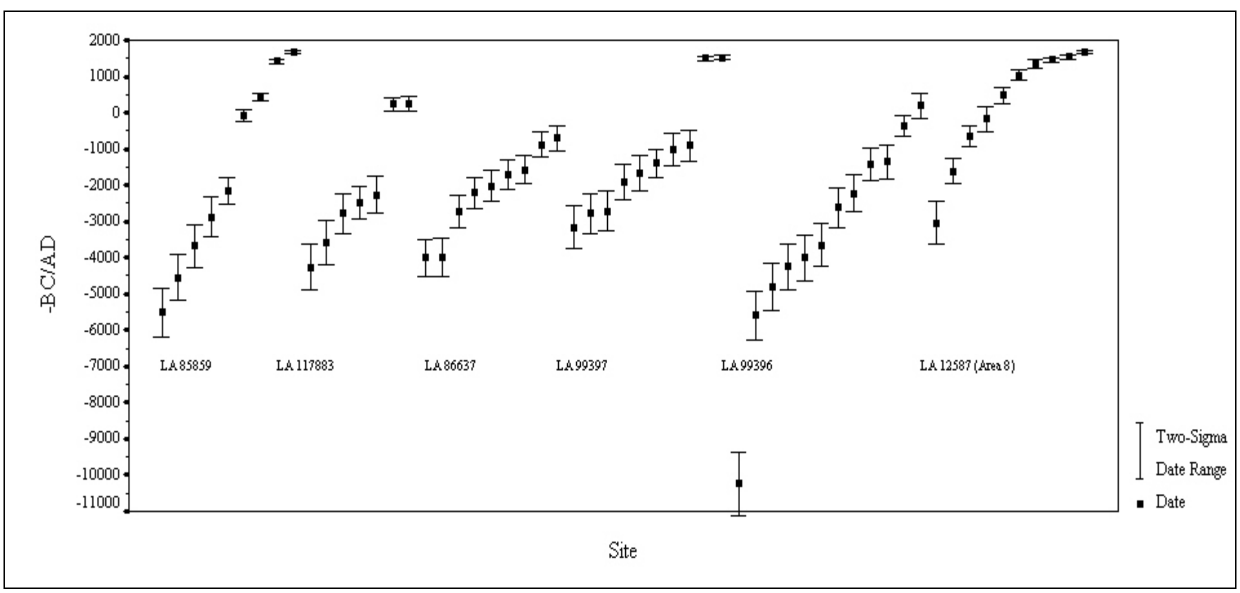

Figure 69.3. Obsidian hydration dates from Archaic period sites.

LA 117883 is situated in a secondary context and can only be dated to the Archaic period. Four Middle or Late Archaic dart points were recovered from LA 99396; obsidian hydration dates from this site fall into all three Archaic periods and there is a single earlier date. The other four sites can be assigned to a specific Archaic period based on radiocarbon dates and/or projectile point data. The obsidian hydration dates do not contradict the assessment. LA 85859 is an Early Archaic site and is thought to date to between 5300 and 4860 BC based on radiocarbon dates. If this interpretation is correct, then most of the obsidian hydration dates are too young. LA 12587 (Area 8), LA 86637, and LA 99396 are interpreted as Late Archaic sites. Obsidian hydration dates from LA 86637 and LA 99396 fall into both the Middle and Late Archaic. Of all the Archaic sites, LA 12587 (Area 8) has the latest obsidian hydration dates. This site is immediately south of the Late Coalition pueblo LA 12587 and four (40%) of the obsidian hydration dates fall into the Coalition to Classic period (curiously, only 16.7% of the obsidian hydration dates from the LA 12587 roomblock fall into the same period). Overall, however, the obsidian hydration dates from the two different parts of the site are similar (Figure 69.4).

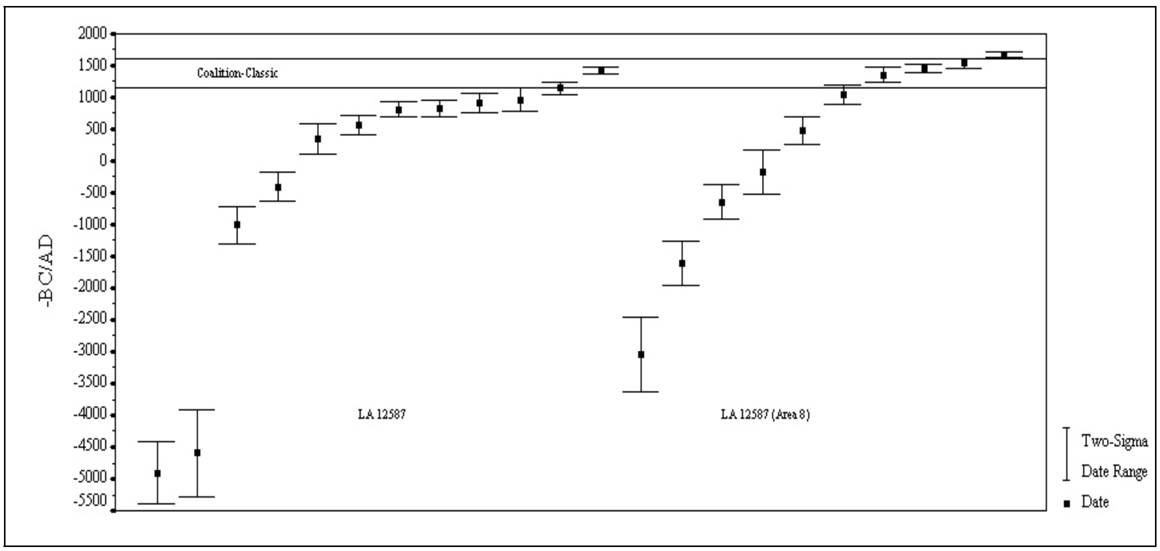

Figure 69.4. Obsidian hydration dates from LA 12587 and LA 12587 (Area 8).

Obsidian hydration dates derived from Archaic period sites generally fall into the Archaic period. However, dates from any given site span thousands of years and dates from any given site overlap many dates from any other given site. Looking at Figure 69.3 one gets the impression that LA 85859 may be slightly earlier than LA 117883, which in turn is earlier than LA 86637 and LA 99397, and that these two sites may be earlier than LA 12587 (Area 8) but this is a very weak pattern.

Table 69.6 shows the obsidian hydration dates derived from projectile points. From this small a sample size it is difficult to see much patterning, although it can be noted that eight of ten Late Archaic points do fall into the Late Archaic time span at two sigma.

Table 69.6. Obsidian hydration dates from projectile points.

Site	FS	Two-Sigma Range	Projectile Type	Base/Point Type	Period[1]
12587	2094	5383–4423 BC	Dart	Contracting Stem	Late Archaic
117883	25	3332–2240 BC	Dart	Corner-notched	Late Archaic
86637	2	2647–1783 BC	Dart	Corner-notched	Late Archaic
86534	1422	2362–1386 BC	Arrow	Corner-notched	Coalition
86637	S#3	1955–1179 BC	Dart	Armijo	Late Archaic
86534	2183	1517–641 BC	Arrow	Und.	Coalition
86637	86	1234–526 BC	Dart	Corner-notched	Late Archaic
86534	1237	1175–339 BC	Arrow	Side-notched	Coalition
86534	1266	212 BC–AD 124	Dart	Stemmed	Late Archaic
86534	1238	177 BC–AD 499	Dart	Sided-notched	Late Archaic
86534	1457	AD 357–585	Dart	Und.	Late Archaic
12587	S#2	AD 262–702	Dart	Corner-notched	Late Archaic
12587	2584	AD 419–715	Dart	Corner-notched	Late Archaic
12587	2628	AD 697–949	Arrow	Side-notched	Coalition
12587	4172	AD 785–1149	Arrow	Corner-notched	Coalition
85404	6	AD 1373–1477	Dart/Arrow	Corner-notched	Late Archaic
86534	706	AD 1692–1748	Arrow	Stemmed	Coalition

1. Based on point morphology.

Interestingly, five of these Late Archaic points were recovered from Coalition and Classic period sites and three arrow points appear to date to the Archaic period. Finally, the dart/arrow point from LA 85404 is noteworthy; during analysis it was described as resembling an arrow point, but as having a dart neck width. This artifact may be a reworked Archaic point.

Comparison to Previous Studies

Biella (1992) conducted the only previous obsidian hydration study at LANL. This was done in conjunction with the testing of a multi-component Archaic/Coalition artifact scatter (LA 70029) on Mesita del Buey. Twenty-eight obsidian artifacts were submitted for dating. Since the specific source was only determined for five artifacts, Stevenson (1992) dated the samples by using rates for both the Cerro Toledo (Obsidian Ridge) and Cerro del Medio sources. In doing so, it was determined that the artifacts dated with the Cerro del Medio rate tended to be 129 to 780 years older than when the same artifacts were dated using the Cerro Toledo rate. Nonetheless, both rates identified four separate temporal clusters at the site dating from Late Archaic and Coalition periods (Figure 69.5). This clustering is quite different from the C&T Project obsidian hydration dating results in which discreet temporal clusters are really only seen at LA 61035 and LA 139418, and to a lesser extent at LA 61034 and LA 85869. This may be the result of the relatively small sample size of dated artifacts from C&T Project sites; however, at sites where the most samples were taken the distribution of dates tends to form a curve rather than steps or clusters. Of course, it is possible that the LA 70029 clusters would break down if the all the obsidian was sourced and dated using the rates for the indicated sources.

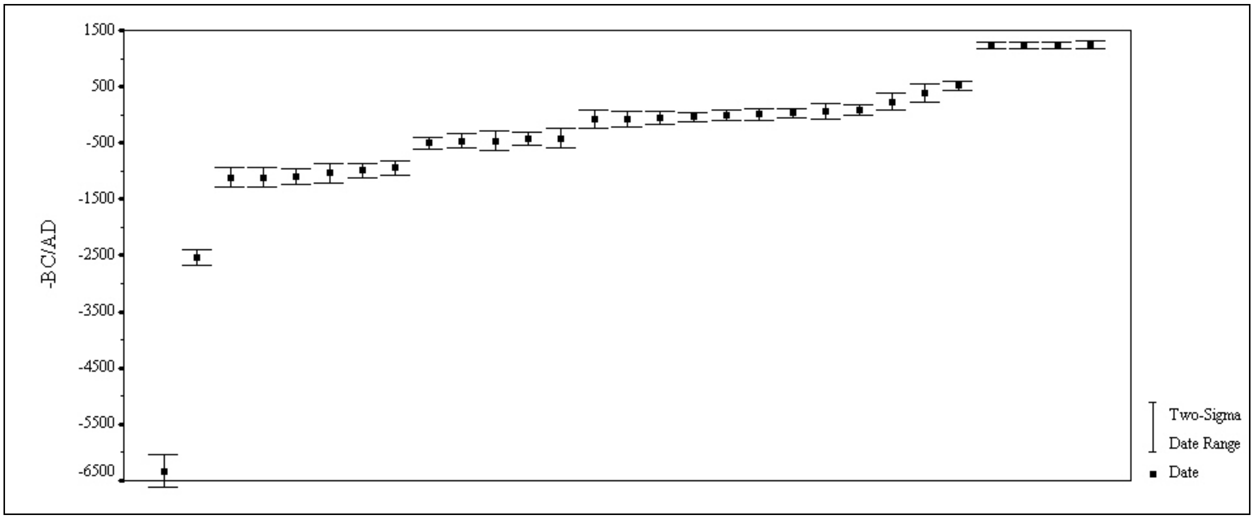

Figure 69.5. Obsidian hydration dates from LA 70025 using Cerro Toledo hydration rates for unsourced artifacts.

The largest obsidian hydration study attempted in the Northern Rio Grande was conducted by Chambers Consultants and Planners for the Abiquiu Reservoir Project (Lord and Cella 1986). Four-hundred-ninety-six obsidian samples were analyzed from 43 sites situated at an elevation of about 1890 m (6200 ft). The limited amount of pre-field time for the project precluded the use of thermal cells so temperature data derived from the nearby Abiquiu weather station were used to determine the effective hydration temperature. Two-hundred-sixteen pieces were submitted to MOHLAB for elemental source analysis and hydration dating. Four major sources were identified: El Rechuelos (Polvadera), Jemez Mountains (3525/3520), Cerro del Medio, and Cerro Toledo. The remaining artifacts were assumed to be Polvadera obsidian based on visual identification.

Figure 69.6 illustrates the relationship between obsidian hydration dates from the Abiquiu Reservoir Project projectile points and the established date ranges for projectile point types. Middle Archaic points generally date much later than expected, mostly to the first millennium AD. In contrast, the Late Archaic points span a period that includes earlier and later dates than their associated range. Arrow points date to the Late Archaic and Ceramic periods. Lord (1986) suggests that the radiocarbon and obsidian hydration dates are in general agreement. However, it is impossible to directly link any of the radiocarbon dates as listed in their report (Lord and Cella 1986:9.2) to the obsidian hydration dates because the radiocarbon dates are from subsurface contexts and the obsidian dates are mostly from surface contexts.

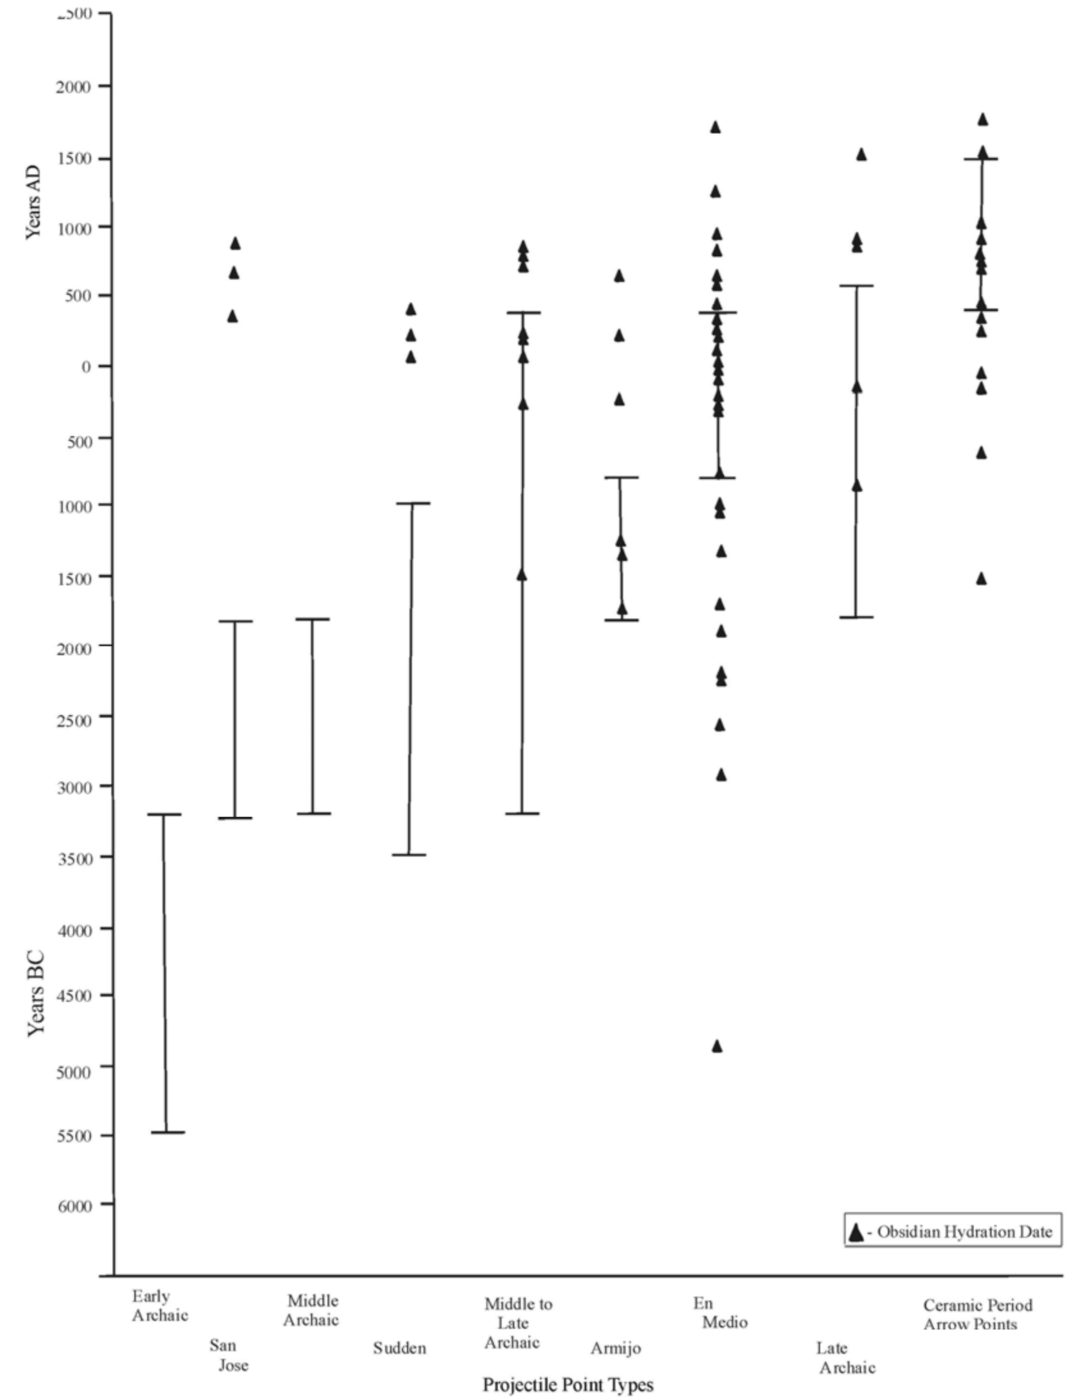

Figure 69.6. The relationship between obsidian hydration dates and the established date ranges for the projectile points.

Nonetheless, Lord and Cella suggest that the primary sources of error consist of artifact reuse, exact source determination, and effective hydration temperature calculation. That is, the source error is due to the fact that not all samples were chemically identified and that, therefore, the wrong hydration rate may have been used. In addition, information on effective hydration temperature also introduced some error as the result of using the less accurate local weather station data.

Mariah and Associates evaluated obsidian hydration dating techniques during the Ojo Line Extension Project testing (Acklen 1993) and data recovery programs (Acklen 1997). Excavations were conducted on Polvadera Mesa and Cañones Mesa, and a total of 168 obsidian hydration dates were obtained during the testing phase. Fifty-three of these were taken from 49 projectile points and 75 pieces of debitage that were mostly recovered from surface contexts. Stevenson analyzed all these samples using the then new intrinsic water content technique for separate sources. Nine thermal cells were set up to 50 cm below the surface within the project corridor from elevations ranging from 1951 to 2804 m (6400 to 9200 ft) to collect data on effective temperature and humidity. This information was then used to calculate the hydration rate for these sources using the Arrhenius equation (Acklen 1993:36).

Figure 69.7 compares the projectile point obsidian hydration dates with associated point cross-date ranges from Acklen (1993:435). As can be seen, the Early and Middle Archaic point types appear to date much later than their cross-dates, whereas, the Late Archaic types span a period that includes earlier and later dates than their associated range. Arrow points date to the Ceramic period or somewhat earlier. Most of the undetermined dart points date to the Middle and Late Archaic periods. The large side-notched dart type (e.g., Sudden) appears to date to the Late Archaic and Ceramic period, rather than the Middle Archaic. This pattern contrasts with that observed on the Baca Geothermal Project (Baker and Winter 1981), where the hydration rinds on these large side-notched points were thicker, and therefore older, than those observed on the large corner-notched points (e.g., Basketmaker II).

It is interesting that the patterning observed by comparing obsidian-dated projectile points with their associated date ranges is similar for both the Abiquiu and Ojo Line Extension Projects. That is, Middle Archaic dates seem to date much later than expected (e.g., to the first millennium AD). As suggested by Acklen (1993:438), this may represent the environmental effects of the arid Altithermal period and long-term exposure to sun, weather, and forest fires. Otherwise, the late Holocene dates for the Late Archaic and Ceramic periods are more in line with our expectations; however, some of these darts may represent lance points that were used during the later ceramic period as suggested by Bertram et al. (1989:347) (also see Vierra 1997 for a similar argument).

Archaic period dates are widely dispersed for both the Abiquiu and Ojo Line Extension Projects, as is the case with C&T Project dates. Both of these projects also reported early dates from Ancestral Pueblo projectile points, versus the early dates obtained from Puebloan contexts for the C&T Project.

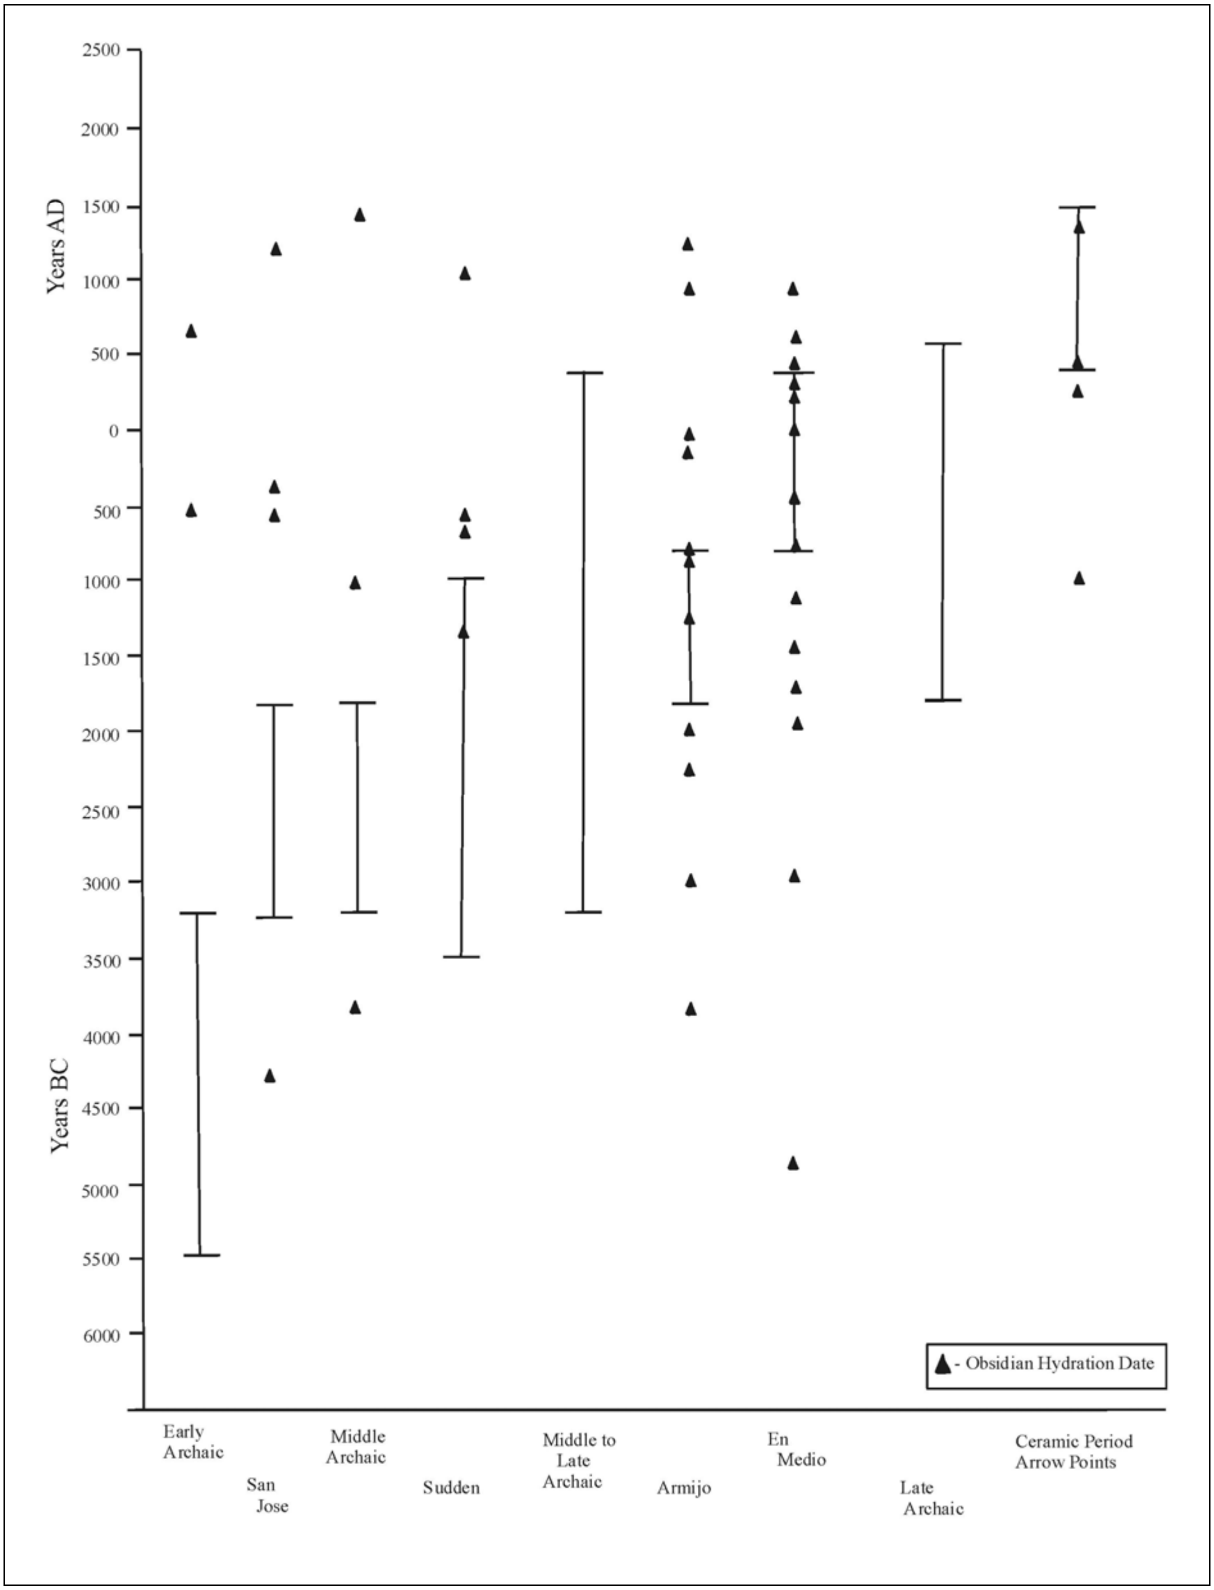

Figure 69.7. Comparison of projectile point obsidian hydration dates with associated point cross-date ranges (after Acklen 1993:435).

Discussion of Obsidian Hydration Dating

The obsidian hydration data from the C&T Project is difficult to interpret. It is possible that there is not enough control over sources of error (e.g., local temperature, humidity, artifact history, and forest fires) and that the dates are simply meaningless. A more hopeful alternative is that the dates are essentially correct. This would indicate that Archaic period sites were revisited for thousands of years. Additionally, the old dates from roomblock and fieldhouse sites raise the possibility that most (approximately 80%) of the obsidian found at Ancestral Pueblo sites was scavenged from Archaic period sites. As is usually the case, the answer probably lies somewhere in between.

Several lines of further investigation are indicated from the results of our project. In terms of controlling errors, Stevenson (Chapter 68, this volume) has pointed out that water-rich obsidians from the C&T Project returned later dates than obsidians with low water content and that, contrary to expectations, water-rich obsidians did not have proportionally larger hydration rims than obsidians with low water content. Stevenson goes on to suggest that the obsidian water content determination estimated from the artifacts may be in error and that obsidian compositional data should be compared to density values to determine if this is, in fact, the case. If the water content assessments are correct then water-rich obsidian sources may have been targeted later in prehistory, possibly due to greater ease in knapping. A final suggestion for error control is that the obsidian artifacts be subjected to finer-grained analysis aimed at detecting evidence of thermal alteration.

RADIOCARBON DATING

Radiocarbon dating is the most prevalent chronometric dating technique used in the American Southwest. The dry conditions of the region act to preserve organic remains that can be dated by this method. However, this technique has low precision, with single standard deviations often including overall periods of 100 years. Summaries of the radiocarbon dating process are presented in Michels (1973) and Taylor (1987, 2000). This discussion will therefore focus on the inherent limitations and sources of error when using this method to date archaeological contexts.

Smiley (1985:38–45) discusses a number of sources that could produce errors in the radiocarbon dating process: 1) field sampling error, which might involve the misidentification of provenience information, or sampling-mixed strata or a disturbed context; 2) built-in age, or the old wood problem, which occurs when dead wood is used during the target event (e.g., Schiffer 1982). Since the reference event occurred in advance of the target event the age of the target event will be overestimated; 3) cross-section effect, as pointed out by Long et al. (1979), samples taken from heartwood will produce older dates than samples taken from sapwood. This is a problem when there is a mixture of younger outer rings and older inner rings for a sample, which can produce an overestimation of the age of the reference event (the death of the organism) and the target event; 4) Libby half-life error, which suggests that an underestimation of the age of a sample can occur if the calculation of the Libby half-life of 5568 years is not adjusted to the more accurate figure of 5730 years. This is done by multiplying the Libby half-life date by 1.03;

5) contamination, which can affect a sample by under- or overestimating its age. Rootlets are often a source of contamination that can help underestimate the age of the sample; 6) calibration error, the amount of ^{14}C in the atmosphere fluctuates through time (Stuiver and Becker 1993). The amount of this fluctuation and its effect on radiocarbon dating was identified by comparing samples with known dendrochronologically derived dates (e.g., Becker 1993; Damon et al. 1974; Olsson 1970; Stuiver and Becker 1993; Stuiver and Seuss 1966). Thus it is necessary to convert conventional radiocarbon ages into calibrated yeas (cal yr). Calibration data sets are available for approximately the last 12,000 years. Calibrations can be made using various software programs (e.g., CALIB, OxCal); they are often also supplied by radiocarbon laboratories; 7) counting error, which generally increases as sample size decreases and as age of the sample increases. Smaller samples (e.g., 2 to 4 g of charcoal) should have extended counting times. Samples smaller than 2 g should be submitted for Accelerator Mass Spectrometry (AMS) dating; 8) lab bias, Klein et al. (1982) have shown that the analysis of the same sample by different laboratories can produce variable results; 9) isotopic fractionation, which refers to the differential metabolism of ^{14}C, ^{13}C, and ^{12}C isotopes by various plant species. Plants that discriminate against the heavier ^{14}C isotope utilize the C^3 pathway, in contrast to plants that are biased towards metabolizing ^{14}C, which utilize a C^4 pathway (trees). Radiocarbon dates from C^3 pathway plants do not need to be corrected for isotope fractionation, however C^4 pathway plants (e.g., maize) that are enriched with ^{14}C do need to be corrected. As much as 200 to 250 years could be added to the date (Bender 1968; Lowden 1969). Therefore, isotope fractionation may act to underestimate the age of a sample if not corrected. This correction needs to be made for the conventional radiocarbon dating technique, but not for the AMS technique. Additional sources of errors can be present when bone, marine samples, etc. are dated. However, no samples of these types were dated for the C&T Project.

Material quality refers to the expected degree of disparity between the dated event and the target event (Smiley 1985:68). Smiley (1985:71–72) provides a list of radiocarbon datable materials that he considers to have highest to lowest material quality. This scheme can be used in evaluating the dating potential of possible samples:

1. Annual subsistence materials, for example cultigens or charred wild seeds;
2. Samples from structural logs retaining their outer rings;
3. Sticks, twigs, or small branches;
4. Large cross-sectional pieces from beams or fuel that lack outside rings;
5. Scattered charcoal from undisturbed contexts, such as hearth fill;
6. Scattered charcoal from excavation strata or levels;
7. Unprovenienced charcoal samples.

Samples

Fifty-five samples were submitted to Beta Analytic for radiocarbon dating (Table 69.7). Fifty-two of these samples were dated using the AMS method and three samples were dated using the standard radiometric method.

Table 69.7 Radiocarbon dates from the C&T Project.

1. Sample dated using standard radiometric method.

Since no Archaic period radiocarbon samples could be directly linked with cultural activities, their utility lies in helping to date the stratigraphy and provide bounding dates for the occupation(s). Dates from Ancestral Pueblo sites are neither unexpectedly early nor late, although in a few cases the calibrated date is early compared to other dating methods (e.g., LA 85861). This may be due to the use of old wood. Unfortunately, between about AD 1460 and AD 1640 the calibration curve flattens out; at two sigma any radiocarbon date with an AD 1440 to 1600 intercept looks almost indistinguishable from any other. There are only two samples from the tipi ring sites that can be clearly linked with the Apachean occupation. The date from LA 85864 appears to be accurate but is very imprecise. None of the date ranges from the LA 85869 sample (FS 272) are in late 19th/early 20th century, the inferred period of occupation. This sample may represent the use of old wood.

Comparison of Two Dates from a Single Specimen

A maize cob (FS 2888C) and a kernel from that cob (FS 2888K) from LA 12587 were submitted for AMS radiocarbon dating. The cob returned an age of 760±40 BP (Beta-183750) and a date of cal AD 1270 with a two-sigma date range of cal AD 1210–1290. The kernel returned an age of 690±40 BP (Beta-183751) and a date of cal AD 1290 with a two-sigma date range of cal AD 1270–1320 and AD 1350–1390. The ages of these two samples are not statistically different for a two-tailed *t*-test ($t = 1.237 < t_{0.05} = 1.960$).

Comparison of AMS Dates to Standard Radiometric Dates

Three samples were dated using the standard radiometric method rather than AMS method: FS 2644 and FS 2752 from LA 12587 and FS 472 from LA 99396. Since all three of these samples came from sites with many other dates, it is possible to compare results of the two different techniques. Not surprisingly, the AMS results were more precise. FS 2725 and FS 472 have measured radiocarbon age standard deviations of 60 years while FS 2644 has a standard deviation of 70 years. In contrast, nearly all Coalition and Classic period AMS dates (*n* = 41) have standard deviation of 40 years; the only exception is FS 26 from LA 110130, which has a standard deviation of 30 years.

FS 2752 was recovered from the fill of Room 2 and its two-sigma calibrated date range of cal AD 1250–1410 is in line with the dates of other samples from the same provenience: FS 2888C (cal AD 1210–1290), FS 2888K (cal AD 1270–1320 and cal AD 1350–1390), and FS 4138 (cal AD 1280–1400). FS 2644 (cal AD 1020–1280), recovered from the hearth of Room 2, seems slightly early but is not remarkably out of place. FS 472 from LA 99396 (cal AD 1050–1100 and cal AD 1140–1290) seems slightly later than the other dates from the fieldhouse: FS 493 (cal AD 1040–1260), FS 608 (cal AD 1030–1240), FS 753 (cal AD 1020–1200), and FS 758 (cal AD 1040–1260), but again is not remarkably out of place. In general, the radiometric dates are not out of line with the AMS dates.

Intrasite Comparison of Dates

Multiple dated samples associated with a single component exist for eight sites. Figure 69.8 shows that there is considerable intrasite overlap of calibrated date ranges. LA 12587 is a minor exception with two dates that appear slightly too early, relative to the other dates. This is somewhat surprising since the dates are derived from maize samples presumably associated with the abandonment of the roomblock. It is, however, possible that these samples reflect an older component at the site.

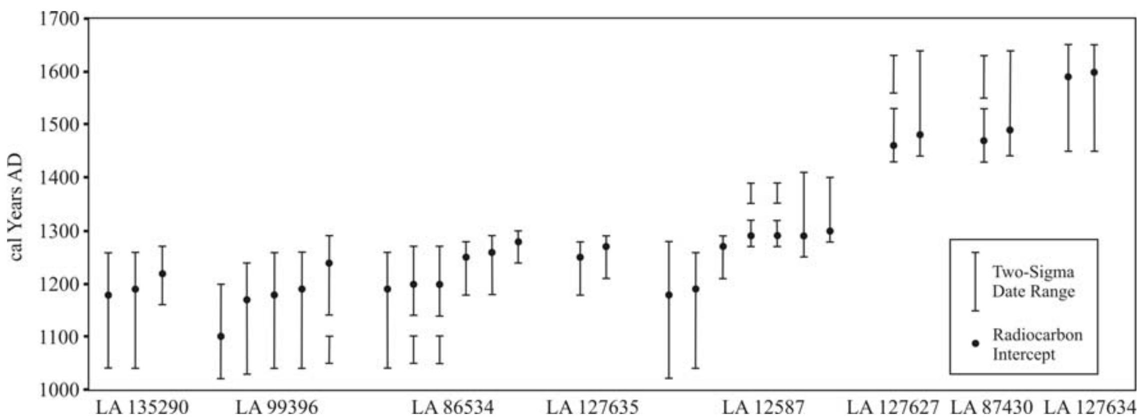

Figure 69.8. Intrasite comparison of radiocarbon dates.

ARCHAEOMAGNETIC DATING

Method

The archaeomagnetic dating method is based on two phenomena. First, that fired soils containing iron oxide minerals retain a magnetism parallel to the direction and proportional to the intensity of the magnetic field in which they cool, and second that the direction and intensity of the earth's magnetic field change through time (Wolfman 1984:364). In the American Southwest, a general curve has been calibrated using radiocarbon and tree-ring dates. The result has been the development of a curve tracing the movement of the geomagnetic pole from circa AD 600 to 1500. However, this geomagnetic field is not uniform over areas larger than about 1000 km^2. Therefore, regional refinements need to be made to this calibrated curve. Wolfman (1984:365) states that errors of ±15 to ±60 years at a 95 percent confidence level are possible when eight to ten individual samples are taken per feature (e.g., assuming a tree-ring calibrated curve). He also suggests a general error of ±25 years for the technique (Wolfman 1994:35). Given a calibrated curve, this technique can be as accurate, if not more accurate, than radiocarbon dating. Recent research has also defined that portion of the curve for northwestern New Mexico from ca. 300 BC to 75 BC (Blinman, personal communication 2000). Wolfman (1984), Eighmy (1980, 2000), and Eighmy and Sternberg (1990) should be consulted for detailed discussions of the archaeomagnetic dating technique and field collection methods.

There are several inherent problems with this dating technique. First, regional refinements are needed to accurately calibrate the curve. Second, the feature needs to be burned to a temperature that resets the magnetic orientation of the sediment. Third, the feature cannot have been disturbed since firing. Fourth, exposure to magnetic fields (e.g., lightning) could affect samples. Fifth, local magnetic anomalies could affect compass readings during field collection and thereby create an error in the calculations. Of the 12 samples taken by Wolfman (1994) on the Pajarito Plateau, only half could be accurately dated. One sample taken from a hearth within a pit structure was not sufficiently burned. Therefore, the results obtained from the samples were actually associated with the paleomagnetic orientation of the tuff bedrock within which the hearth had been cut and not the cultural use of the feature.

Indeed, Wolfman warns of the possibility of local distortions due to the presence of heavily magnetized rocks in the area. This is how he explained why two sets of samples from the same hearth yielded accurate, but different results. That is, one was affected by "magnetic material (possibly a small rock) buried in the ground below this sample" (Wolfman 1994:225). Another sample appears not to correspond with associated tree-ring dates. In this case, he suggests that the calibrated curve may need some slight revising. That is, if the curve was moved slightly west during this time period, the 95 percent confidence oval would have crossed the curve at this point. Other samples yielded poor results due to cultural and/or natural disturbance. His study would seem to indicate that features cut directly into the tuff bedrock may produce less reliable results than those that are clay-lined or dug directly into the soil. These inaccuracies might also be due to local magnetic distortion affecting the compass readings during sample collection.

Samples

Twenty-nine archaeomagnetic samples were submitted to the Archaeomagnetic Dating Laboratory (ADL) at the Office of Archaeological Studies, Museum of New Mexico. The twenty two samples that returned dates are given in Table 69.8. While the Wolfman Curve is preferred by the ADL, both Wolfman Curve and SWCV2000 dates are given. The DuBois Curve was also used for date estimation where appropriate (Chapter 66, this volume).

Table 69.8. Archaeomagnetic dates from the C&T Project.

Site	Prov.	Sample	Wolfman Curve Dates (AD)	SWCV2000 Dates (AD)	Interpretation
LA 86534	Room 1 Feature 4	1202	1170–1230	1110–1200	Late 12th to middle 13th century
	Room 1 Feature 4	1203	1035–1140 (1065–1265)	1000–1390 1010–1315	Pole position may not be representative (inaccurate)

When date ranges are expressed in parentheses, the closet point on the curve segment was outside the error ellipse when the result was originally plotted.

Of the three date columns in Table 69.8, the last column (Interpretation) is probably the most accurate. The data in this column are derived from Blinman and Cox's (Chapter 66, this volume) assessment of the size and location of the error ellipses on all three curves combined with stratigraphic and artifact assemblage data. A reading of Table 69.8 and their report in Volume 3 reveals that, while archaeomagnetic dating can be accurate and precise, this accuracy and precision are best achieved by weighing the data in the context of several different curves, reliance on the date ranges derived from a single curve may give spurious results.

For example, in two instances two archaeomagnetic dates were returned from a single hearth: Feature 20 of LA 12587 and Feature 2 of 127635 (two archaeomagnetic dates were also returned from Feature 4 of LA 86534, but one of these dates is from earlier and later remodeling events). Neither the samples from Feature 20 or Feature 2 returned exactly the same dates, although in both cases there is considerable overlap, particularly of the Wolfman Curve dates. Dates from LA 12587, LA 86534, and LA 135290 are generally internally consistent (the early dates from Feature 20 of LA 12587 should not be regarded as anomalous because this is an early hearth). LA 135290 experienced several episodes of building/occupation/burning; the archaeomagnetic dates are partially successful in documenting these different episodes (see Chapter 66, this volume for additional discussion of this site).

LUMINESCENCE DATING

Method

Luminescence dating measures the last heating event for an artifact exposed to a temperature of about 450°C. This method therefore has the potential to directly date the manufacturing event for ceramic or heat-treated lithic artifacts. Feathers states that,

> [The method] is based on the accumulation of radiation effects in crystaline materials … exposure to sufficient heat or light releases the charge … and results in a luminescence signal whose intensity is proportional to the time elapsed since the previous detrapping event … measurement involves determining the amount of radiation necessary to produce the natural luminescence signal (called the equivalent dose) and the natural dose. Dividing the equivalent dose by the dose rate results in an age (Feathers 2000:152).

The direct dating of artifacts is a major advantage of this technique over radiocarbon or tree-ring dating. For example, radiocarbon dates are prone to inaccuracies involving old wood, cross-section effect, correction, and calibration factors. In addition, questions of artifact association with the dated sample can also be an issue. Tree-rings date the construction event, but not necessarily the manufacturing event, and may also be prone to inaccuracies in artifact association. The luminescence technique can therefore be used for dating surface artifact scatters in the absence of other datable materials. However, it is unclear as to how artifacts burned by forest fires might affect the reliability of this dating technique. Aitken (1985, 1989) and Feathers (2000) should be consulted for detailed discussions of luminescence dating.

Sampling

Thirty-two samples from 12 sites were submitted to James Feathers at the University of Washington for luminescence dating (Table 69.9).

Table 69.9. Luminescence dates from the C&T Project.

1. TL = thermoluminescence, OSL = optically stimulated luminescence, IRSL = infrared stimulated luminescence
2. Degree of confidence that can be placed in result; 1 is the best, 3 is the worst (see Feathers, Chapter 67, this volume, for discussion).

Evaluation of Luminescence Dates

A Room 8 hearth (Feature 9) at LA 135290 is the only feature for which two luminescence dates were obtained. Because of the large standard deviations of both samples the two dates are not statistically differentiated by a two-tailed *t*-test ($t = 1.207 < t_{0.05} = 1.960$).

Table 69.10 shows that luminescence ages are either the same as generally accepted ceramic type dates or are older than generally accepted ceramic type dates. No dated sherd returned a luminescence age younger than expected. Among the whitewares, 50 percent of the luminescence ages fell within the generally accepted ceramic type dates, 60 percent to 70 percent of the ages fell within the ceramic type dates at one sigma, and 90 percent of the ages fell within the ceramic type dates at two sigma. There are fewer utilityware sherds in the sample and the dates of utilityware types are poorly defined, making the evaluation of luminescence dates for this ware difficult. Clearly, however, the luminescence dates for utilityware sherds are not better than for whiteware sherds.

Table 69.10. Luminescence dates from ceramic artifacts.

Ceramic Type	FS	Type Date Range[1]	Luminescence Date	Luminescence With Type Date	Date Overlap At:

Comparison to Previous Studies

Several studies involving luminescence dating have been conducted in northern New Mexico. Eighteen burned rock samples were submitted from sites excavated for the Abiquiu Reservoir project (Lord and Cella 1986). They yielded dates from <35,000 BP to AD 1820. The ancient dates appear to reflect residual geologic luminescence. Radiocarbon dates were obtained from only one of the sites and four of these dates did correspond with the AD 1700 luminescence date.

Ramenofsky and Feathers (2002) used the luminescence technique to date surface-collected ceramics from historic sites in the lower Chama Valley. They were specifically interested in determining the age of abandonment for these sites and expected luminescence dating provided more accuracy than tree-ring dating. However, only nine sherds of five types were submitted for analysis: Biscuit B (n = 2), Sankawi Black-on-cream (n = 3), Potsui'i Incised (n = 1), Kapo Black (n = 1), and Casitas Red-on-brown (n = 2). Their analysis determined that most of the dates fit the expected ceramic time ranges, although one Biscuit B sherd and one Sankawi Black-on-cream sherd did exhibit slightly later dates.

Dykeman (2000; Dykeman et al. 2002) has compared tree-ring dates with both radiocarbon and luminescence dates for protohistoric Navajo sites in northwestern New Mexico. He found that the luminescence dates were within a 40-year range of the tree-ring dates. In contrast, the radiocarbon dates provided a 90- to 120-year range that was earlier than the tree-ring dates. Significantly, however, the six of 15 TL samples (40%) that were found not to correspond with tree-ring dates were all too early.

One sample from LA 4618, a Late Coalition period roomblock at LANL, was submitted for luminescence dating. The sample consisted of burned plaster/adobe from the kiva (Room 10) hearth and dated to 1318±70 (685±70BP), which is consistent with the dates derived from radiocarbon analyses (Schmidt 2006b).

MULTIPLE DATING METHODS FOR THE SAME REFERENCE EVENT

Burned plaster/adobe from eight proveniences (six hearths, one adobe wall, and one plaster floor) was submitted for archaeomagnetic and luminescence dating. Five of the hearths contained associated burned organic matter that was submitted for radiocarbon dating. Eleven proveniences could be dated by archaeomagnetic and radiocarbon methods. Archaeomagnetic dates (derived from the Wolfman Curve) and luminescence dates are particularly interesting to compare since they both date the same reference event, that is, the last burning of the hearth (or wall, or floor). There is a technical exception to this since luminescence samples need to be heated to about 450°C to "reset," whereas, archaeomagnetic samples need to be heated to about 650°C to "reset." Thus, any event that would set the archaeomagnetic "clock" would also set the luminescence clock. However, if *cooler* heating events took place late in a feature's use life, different reference events would be dated by the two methods. This does not appear to have occurred in the case of the C&T Project, as luminescence dates are either the same as, or earlier than, the archaeomagnetic dates.

Figure 69.9 and Tables 69.11 and 69.12 compare the dates returned by different dating methods for the same provenience. (Although a radiocarbon sample was recovered from Feature 20 of LA 12587, it is not believed to be behaviorally associated *with* the feature, and is thus not included.)

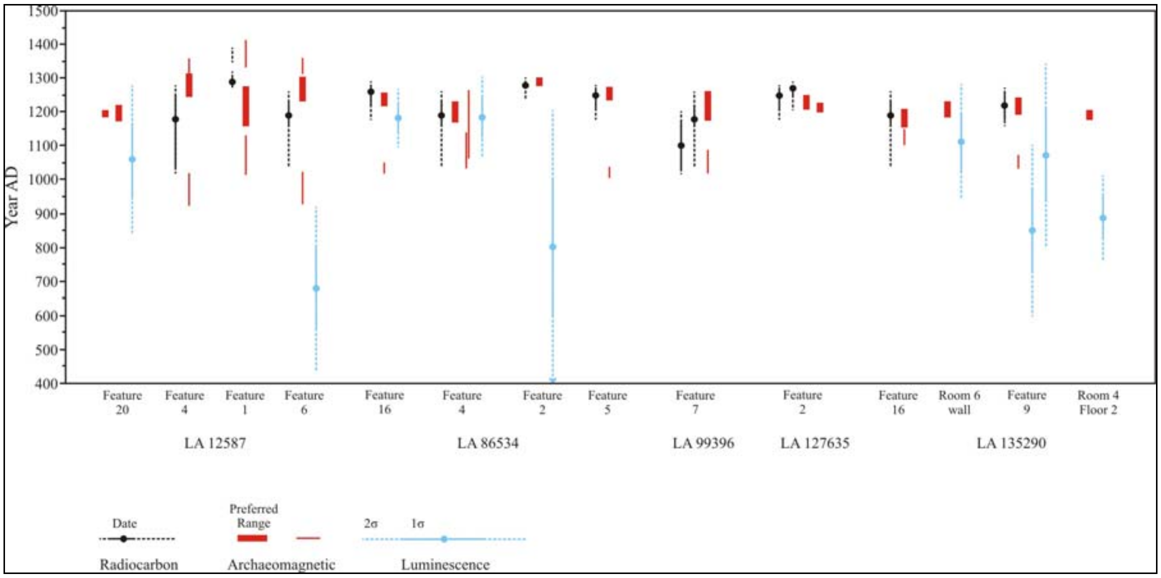

Figure 69.9. Comparison of multiple dating methods.

Table 69.11. Luminescence dates and overlap with most likely archaeomagnetic dates and one- and two-sigma radiocarbon date range.

Site	**Feature**	**Confidence**	**Archaeomagnetic**			**Radiocarbon**		
			Date	**One Sigma**	**Two Sigma**	**Date**	**One Sigma**	**Two Sigma**
LA 12587	Feature 20	2	--	--	X			
	Feature 6	3	--	--	--	--	--	--
LA 86534	Feature 16	2	--	X	X	X	X	X
	Feature 4	2	X	X	X	X	X	X

	Percent of L dates that overlap other method		12.5	50	62.5	40	60	60

X = The luminescence date overlaps with the archaeomagnetic or radiocarbon two-sigma date range at the given degree of precision; -- = The luminescence date does not overlap with the archaeomagnetic or radiocarbon two-sigma date range at the given degree of precision.

In general, there is considerable overlap between the archaeomagnetic dates and the radiocarbon dates. There is less agreement between the luminescence dates and the radiocarbon dates; the least amount of agreement is found between the luminescence dates and the archaeomagnetic dates. As with luminescence dates from ceramic sherds, luminescence dates from plaster/adobe features are either in agreement with other dates or are too early.

Table 69.12. Radiocarbon overlap with most likely archaeomagnetic date.

Summary of Chronometric Dating Methods

In general, the obsidian hydration dates from Ancestral Pueblo sites are much earlier than expected, whereas, the Archaic site dates appear to be accurate, but very imprecise. It may be that the later inhabitants were scavenging obsidian from the older surface sites. Radiocarbon and archaeomagnetic dates are generally in agreement indicating that both methods are accurate. Of the two methods, archaeomagnetic dating is often more precise, with resolution of 20 to 40 years possible for a given sample. When luminescence dates are compared with dates derived from other methods they either agree with the other dates or are too early. A similar result was obtained by Dykeman et al. (2002), although late luminescence dates are not unknown (e.g., Ramenofsky and Feathers 2002).

CERAMIC ARTIFACT DATING

Wilson (Chapter 58, this volume) assigns the C&T Project sites to the various temporal periods based on the combinations of pottery types identified. Here we build on this work by attempting to define ceramic assemblages that are characteristic of the different Ancestral Pueblo periods. Subsequently, we combine the ceramic assemblage data with other chronometric data to assign sites to periods that are as fined-grained as we can reasonably make them. To provide more data about Coalition period ceramics, the recently analyzed ceramic assemblages of three LANL pueblo sites are included in our analysis: LA 4618 (Wilson 2006), LA 4619 (Wilson 2007), and LA 4624 (Curewitz and Harmon 2002).

LA 4618 is a 13-room masonry pueblo that is located on Mesita del Buey at an elevation of 2060 m (6760 ft) (Schmidt 2006b). The pueblo consists of 11 habitation/storage rooms, one square kiva, and one circular kiva. Between 1990 and 1992, nine of the rooms and both kivas were fully excavated; the remaining two rooms were only partially excavated. Additionally, limited testing was done in a sparse midden area located immediately east of the roomblock. Five maize samples from LA 4618 returned radiocarbon dates indicating a Late Coalition period occupation (Table 69.13). Burned plaster/adobe from the hearth of the circular kiva was submitted for luminescence dating. The sample returned a date of AD 1318±70. Ten-thousand-seventy sherds of the 23,236 sherds recovered from the site were analyzed.

Table 69.13. Radiocarbon dates from LA 4618 and LA 4619.

Site	Context of sample	Laboratory (Beta)#	Conventional radiocarbon age	Intercept of radiocarbon age	2-sigma calibrated result
LA 4618	Room 3 floor	199363	730±50 BP	AD 1280	AD 1220–1310 AD 1370–1380

LA 4619 is an 80-room-plus plaza pueblo located on Mesita del Buey at an elevation of 2070 m (6800 ft) (Hoagland 2007). Based on the size of the pueblo and ceramic analysis, it is likely that the site dates to a transitional Late Coalition/Early Classic period. In 2006, 12 test units were excavated on the northern edge of the site, about 7 to 20 m north of the roomblock. The pueblo itself remains unexcavated. One-thousand-fifty-six ceramic sherds recovered from the testing were analyzed, the remaining 120 sherds were too small to identify.

LA 4624 is a 25-room pueblo located on Mesita del Buey at an elevation of 2060 m (6760 ft) (Vierra et al. 2002). In 1993, 10 of the rooms were excavated. The ceramic assemblage indicates that the site probably dates to the Early/Middle Coalition period. Two maize fragments were submitted for radiocarbon dating; one of the returned dates seems too early while the other seems too late (see Table 69.7). A total of 27,328 ceramic sherds were recovered from the partial excavation of LA 4624. Three-thousand-seven-hundred-ninety sherds were excavated from the roomblock and 23,538 were collected from the surface of the site. Of these, 1952 sherds from 56 excavation units and 1033 sherds from two surface units were analyzed.

In his analysis of the C&T Project ceramic artifacts, Wilson (Chapter 58, this volume) classified sherds into nearly 100 categories. This is too many categories for our purpose (i.e., defining "typical" period ceramic assemblages). To reduce this variability we collapsed the most diagnostic and common of Wilson's categories into categories that are close to standard ceramic types (Table 69.14). Since so few typed glazewares were recovered, these were simply grouped as glaze-on-red, glaze-on-yellow, glaze polychrome, and undetermined glazeware. Uncommon and undiagnostic types were not included in our "analysis assemblage." The analysis assemblage consists of 35,247 out of 37,905 analyzed ceramic artifacts. Of the 2658 excluded artifacts, 1636 are unpainted undifferentiated sherds.

Table 69.14. Ceramic analysis groups from the C&T Project.

Analysis Assemblage Type	Count	Original Analysis Type(s)
Kwahe'e Black-on-white	40	Kwahe'e Black-on-white solid designs
		Kwahe'e Black-on-white thin parallel lines

Sapawe Micaceous	1397	Sapawe Micaceous
Potsuwi'i Incised-like	62	Potsuwi'i Incised
		Thin, Plain, Non Micaceous Classic Period

For our initial attempt to define period assemblages we ran a number of different cluster analyses using SPSS 11.5.1. This showed us which sites had similar assemblages. Although there was some variability in how sites clustered depending on the type of analysis and the inputs used, they tended to generally cluster in the same way. Figure 69.10 shows a typical cluster; it was generated using Ward's method with a squared Euclidian distance interval measure. For this analysis, each decorated ware type was assigned the value type count/total decorated ware count and each utilityware type was assigned the value type count/total utilityware count. The Potsuwi'i Incised-like type was not included in this analysis as it was only found at LA 21596A and B. LA 139418 was not included in this analysis because nearly 70 percent of the ceramic assemblage consists of glazeware sherds. It is not necessary to use a statistical software package to know that LA 139418 is an outlier.

In Figure 69.10, the sites form into six clusters. Cluster 1 (LA 86534 to LA 141505) consists of seven sites in which the decorated ware is dominated by Santa Fe Black-on-white and the utilityware is dominated by smeared-indented corrugated. These are clearly Coalition period sites. Five of these sites are pueblos and only one, LA 99396, is located in the Rendija Tract.

Cluster 2 (LA 85417 to LA 86606) consists of four sites at which smeared-plain corrugated makes up more than 45 percent of the utilityware. Based on a finer-grained analysis of the ceramics and on other chronometric data, each of these sites appears to date to a separate time period. Except for LA 4619, these sites are Rendija Tract fieldhouses.

Cluster 3 (LA 86637 to LA 127625) consists of four sites where the most common decorated ware is undetermined biscuitware and the most common utilityware is plain gray. These are Classic period sites. Three of the sites (LA 86637, LA 127625, and LA 128805) are located in the White Rock Tract.

Cluster 4 (LA 135291 to LA 21596B) consists of six sites with mixed decorated ware assemblages and utilityware assemblages in which smeared-indented corrugated is the most common type. Based on other chronometric data, LA 85404 and LA 127635 are probably multi-component sites; the other members of Cluster 4 may also have multiple components, or are at least in an area of a generalized Coalition period background noise.

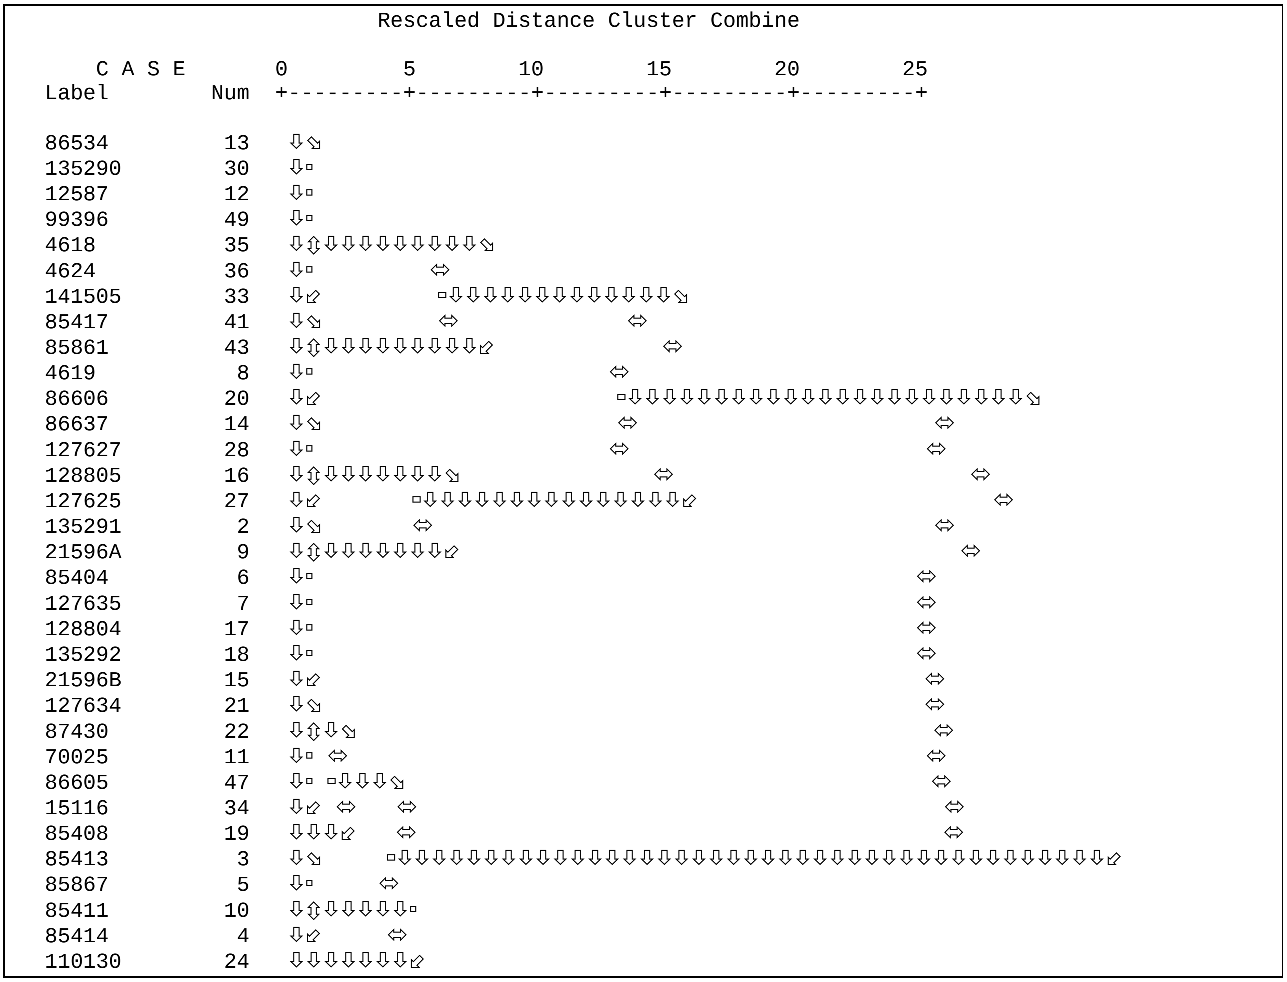

Figure 69.10. Site cluster analysis from the C&T Project.

Cluster 5 (LA 127634 to LA 85408) consists of six sites with a good deal of non-Biscuit A biscuitware and utilityware assemblages in which Sapawe Micaceous is the most common type. All of these sites are Rendija Tract fieldhouses. Most of these sites also have more decorated ware than utilityware.

Cluster 6 (LA 85413 to LA 85414) consists of four sites at which the most common decorated ware is Biscuit A and the most common utilityware is Sapawe Micaceous. All of these sites are Rendija Tract fieldhouses. LA 110130 is something of an outlier as almost 80 percent of its entire ceramic assemblage consists of Sapawe Micaceous.

Clusters 1, 5, and 6 clearly represent different temporal periods: Cluster 1 is the Coalition period, Cluster 5 is an earlier part of the Classic period, and Cluster 6 is a later part of the Classic period. Sites in Cluster 3 also date to the Classic period, although as defined by the clustering method (i.e., unidentified biscuitware and plain gray sherds) this assemblage type is not very specific. Cluster 4 also appears to have temporal significance, although in this case it is telling us that the ceramic assemblages are mixed. Cluster 2 only tells us that smeared-plain corrugated is common.

One possible drawback to the cluster analyses is that they incorporate a variety of site types and at least two periods that are characterized by distinct ceramic assemblages (i.e., the Coalition and Classic periods). Consequently, variability that exists within these categories may be obscured, especially when the number of sites included in the analysis is relatively small, as is presently the case here. It may be possible to reveal more about the chronological relationships between sites of similar types by focusing only on those site types. Here we take a closer look at the Coalition period pueblos and the Classic period fieldhouses. Table 69.15 orders the pueblo sites chronologically, from earliest to latest, based on dated materials and interpretations of the ceramic assemblages. LA 4618 and LA 12587 are nearly contemporaneous and it is possible that their positions in the table should be reversed.

Table 69.15. Percentage of whiteware and utilityware pottery by site.

Site (LA)	Whitewares				Utilitywares					
	Kwahe'e	Santa Fe	Wiyo	Galisteo	Early Plain	Indented Corrugated	Smeared-Plain Corr.	Smeared-Indented Corrugated	Plain Corrugated	Plain Gray
4624	3.69	96.30	0.00	0.00	22.19	15.28	0.08	61.12	1.31	0.00
135290	2.89	95.26	0.78	0.52	0.00	13.87	0.05	83.59	0.11	2.35
86534	0.30	95.45	2.42	0.90	0.00	19.17	0.00	74.34	0.52	5.95
4618	0.39	87.38	0.22	1.83	0.00	0.49	0.90	96.06	1.19	1.33
12587	0.07	93.16	2.94	1.91	0.00	5.67	12.16	72.79	0.43	8.93
4619	0.00	68.00	21.33	4.00	0.00	0.00	45.34	15.54	4.59	34.5

Table 69.15 shows that there are some clear temporal trends in the data. For example, over time Kwahe'e Black-on-white decreases in frequency while Wiyo Black-on-white and Galisteo Black-on-white increase. However, these three types make up only a small percentage of the decorated ware assemblages and so these patterns may not be very robust. No utilityware type shows a gradual increase or decrease overtime, although there are clear changes between the frequencies of some types. Unfortunately these changes do not happen in lock-step. For example, indented corrugated is common at LA 4624, LA 135290, and LA 86534 and uncommon at the other sites. On the other hand, smeared-plain corrugated is virtually absent from LA 4624, LA 135290, LA 86534, and LA 4618, is uncommon at LA 12587, and is common at LA 4619.

Based on the data in Table 69.15, LA 4619 clearly has a different ceramic assemblage from the other sites. LA 4624 stands out as different because of the presence of early plainware; otherwise it is very similar to LA 135290 and LA 86534. It is much more difficult to distinguish between LA 135290, LA 86534, LA 4618, and LA 12587. For example, based on the frequency of Kwahe'e Black-on-white, one might argue that LA 135290 is earliest, LA 86534 and LA 4618 are contemporaneous, and LA 12587 is latest. Based on the frequency of Wiyo Black-on-white, on the other hand, one could argue that LA 135290 is earliest, LA 86534 and LA 12587 are contemporaneous, and LA 4618 is latest. The lack of clear differences in the ceramic assemblages of these pueblo sites (excluding LA 4169) is perhaps not surprising given the small sample size.

Table 69.16 presents some aspects of the ceramic assemblages of Classic period fieldhouses. These sites are deemed to date to the Classic period based on dated material from the sites and/or impression of the ceramic assemblages. The fieldhouses can be divided into two distinct groups based on the ratio of Biscuit A to all typed biscuitware. The lowest ratio of the earlier group is 0.615385 and the highest ratio of the later group is 0.214286. Also noteworthy is the fact that the latest ceramic types, Biscuit C and Sankawi Black-on-cream, are only found at sites in the later group.

Table 69.16. Classic period fieldhouse ceramics.

Site	Cluster	Biscuit A	A2	Decorated	SIC	SPC	Plain Gray	Micaceous	Late Ware

15116	5	0.00	0.00	0.77	0.21	0.00	0.10	0.68	
110126		0.00	0.00	0.81	0.00	0.00	0.00	1.00	
86605	5	0.00	0.00	0.86	0.00	0.00	0.00	1.00	c, s

Biscuit A = Biscuit A count / (Biscuit A + Biscuit B + Biscuit C + Biscuit B/C count); A2 = Biscuit A count / (Biscuit B + Biscuit C + Biscuit B/C count); Decorated = Percent of analysis assemblage composed of decorated ware; SIC, SPC, Plain Gray, Micaceous = percent of utilityware assemblage composed of given type; c = presence of Biscuit C; s = presence of Sankawi Black-on-cream.

The earlier group can be divided into two sub-groups: one in which the utilityware assemblage is dominated by smeared-indented corrugated, and one in which it is dominated by Sapawe

Micaceous. LA 127631, with smeared-plain corrugated as the most common utilityware type, does not fit into either group. Within the smeared-indented corrugated sub-group, LA 127635 has a Coalition period component and LA 85404 may have a Coalition period component (see below). These earlier components may account for the high frequency of smeared-indented corrugated sherds in the assemblages of these sites. Alternatively, since later utilitywares (e.g., plain gray and Sapawe Micaceous) are uncommon at all three smeared-indented corrugated sites, these sites may have been used in the Classic period before these types became common (i.e., in the Early Classic).

In the later group there is a good overlap between sites with ceramic assemblages composed of more than 60 percent decorated wares and sites with utilityware assemblages dominated by Sapawe Micaceous. Both of these assemblage traits are found at LA 15116, LA 86605, LA 110126, and LA 127634. At LA 85408, most of the ceramic assemblage consists of decorated wares but the most common utilityware is plain gray. However, a little over 46 percent of the utilityware does consist of Sapawe Micaceous. Sapawe Micaceous is the most common utilityware at LA 87430 and LA 110130, although decorated ware makes up only a small part of the ceramic assemblage at these sites. LA 128805 and LA 127627 are similar in that the most common utilityware at both sites is plain gray; LA 85403 and LA 135292 are common in that smeared-indented corrugated makes up most of the utilityware, although since there are only six sherds in the LA 85403 analysis assemblage, perhaps it is best not to make too much of this. LA 86606 is the only site where smeared-plain corrugated is the most common type. It is unclear if the variation seen in this later group has a temporal component to it.

In Table 69.16, LA 70025 falls into the early group whereas in the cluster analysis (Figure 69.10) this site fell into Cluster 5 (interpreted as the latest cluster). In other cluster analyses, LA 70025 is sometimes grouped within LA 85411, LA 85413, LA 85414, and LA 85867. Typed biscuitware from this site consists of eight Biscuit A sherds and five Biscuit B/C body sherds (i.e., an approximately even split between early and later biscuitware). Perhaps LA 70025 is temporally intermediate between the earlier group and the later group in Table 69.16. A different way to consider the relationship between Biscuit A and the later Biscuitwares is given in the fourth column of Table 69.16. Here the intermediate nature of LA 70025 is shown; LA 85411 can also be interpreted as an intermediate site.

ARCHAEOLOGICAL SITE TEMPORAL SEQUENCE

In this section we combine the archaeomagnetic, luminescence, obsidian hydration, radiocarbon, projectile point, and ceramic data to assign the project sites to specific periods and dates. This includes the Archaic, Ancestral Pueblo, and Historic periods, with relevant subdivisions.

Archaic Period

Four sites have been assigned to the Archaic period, although other surface scatters appear to contain Archaic components. LA 85859, LA 99396, and LA 99397 are all lithic scatters situated in the Rendija Tract. Three charcoal dates were submitted from the lower levels of LA 85859 providing a calibrated intercept range from 5300 to 4860 BC. This site presumably dates to the Early Archaic period.

LA 99396 and LA 99397 can tentatively be assigned to the Middle to Late Archaic period. LA 99396 is a multi-component site that contains an Archaic and Ceramic period component. The Archaic component consists of a surface lithic scatter with possible Middle to Late Archaic points. Obsidian hydration dates indicate a possible Middle to Late Archaic period occupation. Lastly, LA 99397 is a surface scatter with subsurface deposits. Two charcoal dates from the upper levels provided calibrated intercepts of 380 and 160 BC, with obsidian hydration dates ranging from the Middle to Late Archaic period. A single possible Late Archaic site was identified in the White Rock Tract. LA 12587 (Area 8) contains Late Archaic projectile points.

Ancestral Pueblo Period

Table 69.17 summarizes the Ancestral Pueblo temporal sequence for the C&T Project sites. It has been separated into nine categories: Indeterminate Pueblo, Indeterminate Coalition, Coalition 1, Coalition 2, Coalition2/Classic 1, Indeterminate Classic, and Classic 1 to 3. These categories do not conform to the traditional early, middle, and late classifications used in other sections of this report; however, they do clearly define the sequence as represented by the excavated site data.

Table 69.17. Ancestral Pueblo site temporal sequence.

Indeterminate Pueblo	Indeterminate Coalition	Coalition 1	Coalition 2	Coal. 2/ Classic 1	Indeterminate Classic	Classic 1	Classic 2	Classic 3
86531	85404+?	85417	4618	4619	*85861*	85404	70025	15116
127633?	86606	86533-	12587		127625	85411	85411?	85403

						135291		110130
								127627?
								127634
								128804
								128805
								135292

Indeterminate Ancestral Pueblo

LA 86531 (Artifact Scatter)

Only one smeared-indented corrugated sherd was recovered during excavation. During the initial recording of the site (Hoagland et al. 2000:7–99), it was described as consisting of five to seven pot drops: one or two Wiyo Black-on-white vessels, one Biscuit B (Biscuit B/C?) vessel, one Sankawi Black-on-cream vessel, and one or two smeared-indented corrugated vessels. This rather odd mix of types spans the Late Coalition to Late Classic periods. A radiocarbon sample dated to AD 1180–1280 (i.e., pre-Wiyo Black-on-white) further confuses the issue.

LA 127633 (Rock Feature)

The only artifact found at this site was a plain gray sherd. No dateable samples were recovered. On the basis of geomorphic data Drakos and Reneau (Chapter 57, this volume) suggest that LA 127633 is one of the youngest Classic period sites in the Rendija Tract.

Indeterminate Coalition

LA 85404 (Fieldhouse)

Most chronometric data indicate that this site dates to Classic 1 (see below). However, the presence of 17 Santa Fe Black-on-white sherds and the domination of the utilityware assemblage by smeared-indented corrugated sherds may indicate an initial Coalition period occupation.

LA 86606 (Fieldhouse)

The ceramic assemblage at this site is puzzling. There are six Santa Fe Black-on-white sherds and nine biscuitware sherds (one Biscuit A, one Biscuit B, two Biscuit C, and five Biscuit B/C). The most common utilitywares are smeared-plain corrugated and smeared-indented corrugated. There are eight sherds of plain gray and none of Sapawe Micaceous. The presence of Santa Fe Black-on-white and smeared-indented corrugated sheds suggests an initial Coalition period occupation.

LA 86607 (Fieldhouse)

Ceramic artifacts include four Santa Fe Black-on-white sherds and three smeared-indented sherds. This indicates a Coalition period date for the site, but does not allow for finer resolution.

Coalition 1 (AD 1160–1280)

LA 4624 (Roomblock)

The ceramic assemblage of this site is discussed in detail above. Based on the ceramic assemblage, this site likely pre-dates, or partially pre-dates, LA 86534 and LA 135290.

LA 85417 (Fieldhouse)

The ceramic assemblage at this site consists almost entirely of smeared-plain corrugated sherds (89.1%); the only decorated ware is a Santa Fe Black-on-white sherd. The hearth returned an archaeomagnetic date of AD 1100–1235. Three of the four luminescence dates from the site are generally later than AD 1235. Assuming the archaeomagnetic date is correct, this site is tentatively assigned to Coalition 1, although it could well date later. The presence of 24 buffware with mica slip sherds indicates the site probably has a historic component.

LA 86533 (Artifact Scatter)

LA 86533 is primarily an Archaic period artifact scatter, however, three Santa Fe Black-on-white sherds and five smeared-indented corrugated sherds were collected from the site. Most of these sherds were found immediately south of LA 86534. This may represent use of the site by the inhabitants of LA 86534; alternatively, the sherds may have been redeposited from LA 86534 by natural processes.

LA 86534 (Roomblock)

The ceramic assemblage from this site is discussed in detail above. The archaeomagnetic data suggests that the site dates to the middle to late 13th century. Most of the radiocarbon and luminescence dates fall into this time period, although these two methods also indicate the possibility of an early 13th century use of the site. Taking into account all of the chronometric data, LA 86534 is interpreted as at least partially post-dating LA 4624 and LA 135290.

LA 99396 (Fieldhouse)

The LA 99396 ceramic assemblage largely consists of Santa Fe Black-on-white and smeared-indented corrugated sherds. An archaeomagnetic sample from the hearth returned a date of AD 1175–1260 and several radiocarbon dates from the site are similar. The AD 1175–1260 date range is similar to date ranges from other Coalition 1 period sites, particularly LA 86534.

LA 127635 (Fieldhouse)

The variety of ceramic types found at LA 127635 (Santa Fe Black-on-white, Wiyo Black-on-white, Biscuit A, smeared-indented corrugated, Sapawe Micaceous, and plain gray) suggest that it is a multi-component site. Archaeomagnetic dates from the hearth returned dates of AD 1210–1250 and AD 1200–1225; radiocarbon samples from the hearth returned dates of AD 1180–1280 and AD 1210–1290. The luminescence date from the hearth is not inconsistent with the other dates at AD 1043–1471. These dates are in line with other Coalition 1 period dates, suggesting that this was the time period for the initial occupation of LA 127635.

LA 135290 (Roomblock)

The ceramic assemblage from this site is discussed in detail above. The archaeomagnetic data suggest that the site dates to the late 12th or early/middle 13th century. The radiocarbon dates fall into this time period. Taking into account all of the chronometric data, LA 135290 is interpreted as at least partially post-dating LA 4624 and at least partially pre-dating LA 86534.

Coalition 2 (AD 1250–1325)

LA 4618 (Roomblock)

The ceramic assemblage from this site is discussed in detail above. Radiocarbon dates suggest that the site was inhabited between circa AD 1250–1300. These dates are slightly earlier than those from LA 12587 but certain ceramic indicators (see above) indicate that LA 4618 may slightly post-date LA 12587.

LA 12587 (Roomblock)

The ceramic assemblage from this site is discussed in detail above. Most of the chronometric data indicate that the site was abandoned between AD 1275–1325. LA 12587 is difficult to temporally place. Two archaeomagnetic dates from a subfloor hearth returned dates of circa AD 1200, indicating some kind of habitation of the site in Coalition 1. There is no other chronometric evidence of this component. The rest of the archaeomagnetic dates and most of the radiocarbon dates indicate the site was abandoned. The site was probably occupied from the middle/late 13th century to the early 13th century. A light scatter of later ceramics is present as the result of Classic period use.

LA 85861 (Fieldhouse)

The whiteware ceramic assemblage of LA 85861 is dominated by Coalition period types (40 Santa Fe Black-on-white sherds and two Wiyo Black-on-white sherds); however, eight biscuitware sherds are also present, including two Biscuit B sherds and one Biscuit B/C body sherd. The utilityware assemblage mainly consists of smeared-plain corrugated and smeared-indented corrugated sherds. A radiocarbon date from the hearth returned a date of AD 1020–1200 (old wood?). A sample of the wall plaster returned a luminescence date of AD 1087–1299 and one of the smeared-plain corrugated sherds returned a luminescence date of AD 1065–1357. It appears the site was initially inhabited during the Coalition period and was reused, perhaps in a different manner and/or not as intensively, in the Classic 2 and/or Classic 3 period. Noting the presence of Wiyo Black-on-white and assuming that the smeared-plain corrugated sherds are associated with the initial occupation and that the later half of the luminescence date ranges are accurate, the earlier component of LA 85861 is very tentatively assigned to the Coalition 2 period.

Coalition 2/Classic 1

LA 4619 (Roomblock)

The ceramic assemblage of this site is discussed above. There are no dated samples from LA 4619 but based on the roomblock architecture, in addition to the ceramic assemblage, this site post-dates LA 12587 and LA 4618.

Indeterminate Classic

LA 85861 (Fieldhouse)

A handful of biscuitware and Sapawe Micaceous sherds may indicate that LA 85861 has a Classic period component in addition to a Coalition 2 component (see above). Three of the eight biscuitware sherds are Biscuit B or Biscuit B/C sherds so this component probably dates to either the Classic 2 or Classic 3 period.

LA 127625 (Artifact Scatter)

Few sherds were recovered from this sparse artifact scatter. Based on the presence of one Biscuit B/C sherd, six unidentified Biscuitware sherds, and one glazeware sherd, this site is dated to the Classic period.

LA 128803 (Grid Garden)

No artifacts were recovered from this site, but a radiocarbon sample returned a date of cal AD 1320–1350 and 1390–1440.

LA 139418 (Grid Garden/Artifact Scatter).

Most of the LA 139418 ceramics were recovered from the artifact scatter. Nearly 70 percent of the ceramic assemblage consists of glazeware sherds. It is not clear if the artifact scatter ceramics are associated with the use of the grid garden.

LA 141505 (Fieldhouse)

While only 29 sherds were recovered from LA 141505, they consist of a range of types including Kwahe'e Black-on-white, Santa Fe Black-white, smeared-indented corrugated, Sapawe Micaceous, and glazewares. This combination of pottery could reflect both Coalition and Classic period occupations; however, all these artifacts were recovered from post-occupational fill and none were recovered from the floor. Therefore, the earlier ceramics may be derived from the nearby roomblock, LA 135290. If so, the Classic period ceramics would support the geomorphic interpretation that the site dates to the later time (i.e., Classic) period.

Classic 1

LA 85404 (Fieldhouse)

The presence of eight Biscuit A sherds, nine Sapawe Micaceous sherds (however, the most common utilityware is smeared-indented corrugated), and 34 glazeware sherds, indicates a Classic 1 period occupation of the site. A luminescence sample from the floor of the structure returned a date of AD 1290–1486. However, a radiocarbon sample returned a younger date than expected: cal AD 1430–1530 and cal AD 1560–1630. This site may have an earlier Coalition period component (see above).

LA 85411 (Fieldhouse)

The presence of Biscuit A and Sapawe Micaceous sherds indicated a Classic 1 period occupation. A radiocarbon sample from the hearth returned a date of cal AD 1290–1410, and two luminescence samples of burned plaster returned dates of AD 1309–1410 and AD 977–1433. The presence of 18 Biscuit B and Biscuit B/C sherds may indicate a late Classic 1 date, or perhaps that use of the site continued into the early 15th century.

LA 85413 (Fieldhouse).

The ceramic assemblage is dominated by Biscuit A and Sapawe Micaceous sherds. There are no later biscuitwares. Fifteen glazeware sherds are present, including a Cieneguilla Glaze-on-yellow sherd (AD 1325–1425). A radiocarbon sample returned a younger date than expected: cal AD 1440–1640.

LA 85414 (Fieldhouse)

The few decorated ceramics recovered from the site consist of biscuitwares and glazewares, indicative of a Classic period habitation. This conclusion is supported by the fact that Sapawe Micaceous makes up to 88.9 percent of the utilityware assemblage. On the basis of one Biscuit A sherd and no later biscuitwares, the site is tentatively assigned to the Classic 1 period.

LA 85867 (Fieldhouse)

The ceramic assemblage consists almost entirely of Biscuit A and Sapawe Micaceous sherds, clearly placing the site in the Classic 1 period.

LA 127631 (Fieldhouse)

Based on the few ceramics recovered from LA 127631, the site could date to either the Coalition or Classic 1 period. Based on a radiocarbon date of cal AD 1300–1430, this site is tentatively assigned to the Classic 1 period.

LA 127635 (Fieldhouse).

This site was initially occupied in the Coalition 1 period; however, the presence of Biscuit A and Sapawe Micaceous indicates that this site was reused in the Classic 1 period.

LA 135291 (Fieldhouse)

The ceramic assemblage consists of Biscuit A sherds, unidentified biscuitware sherds, smeared-indented corrugated sherds, and plain gray sherds. No Sapawe Micaceous sherds where found. The presence of Biscuit A indicates a Classic 1 period occupation.

Classic 2

LA 70025 (Fieldhouse)

The decorated ware assemblage of LA 70025 includes eight Biscuit A sherds and five Biscuit B/C sherds. This may indicate a temporally intermediate position for the site between the Classic 1 and Classic 3 period. The utilityware assemblage consists mostly of Sapawe Micaceous sherds.

LA 85411 (Fieldhouse)

Given the presence of seven Biscuit B sherds and 11 Biscuit B/C sherds in addition to 43 Biscuit A sherds, this site may have been occupied during the Classic 2 period. Dated samples from the site suggest that it was occupied no later than the early 15th century.

LA 86637 (Artifact Scatter/Fieldhouse)

Given the mixed ceramic assemblage of this site it may have a number of components. As biscuitwares make up most of the decorated ceramics there is clearly a Classic period component at LA 86637. Identified biscuitwares consist of three Biscuit A sherds, two Biscuit B sherds, and two Biscuit B/C sherds. On the basis of this mix of early and late biscuitwares, LA 86637 is assigned to the Classic 2 period.

Classic 3

LA 15116 (Fieldhouse)

The biscuitware assemblage does not include any Biscuit A sherds and the most common utilityware is Sapawe Micaceous. This indicates a Classic 3 period occupation.

LA 85403 (Fieldhouse)

Very few ceramics were recovered from this site. A radiocarbon date of cal AD 1470–1660 places this site in the Classic 3 period.

LA 85408 (Fieldhouse)

Although few Biscuit A sherds are present, the biscuitware assemblage is dominated by Biscuit B/C sherds. The utilityware is equally divided between plain gray and Sapawe Micaceous.

LA 86605 (Fieldhouse)

The biscuitware assemblage does not include any Biscuit A sherds and the most common utilityware is Sapawe Micaceous. A radiocarbon sample returned a date of cal AD 1440–1640.

LA 86606 (Fieldhouse)

In addition to Santa Fe Black-on-white sherds there are nine biscuitware sherds (one Biscuit A, one Biscuit B, two Biscuit C, and five Biscuit B/C). The most common utilitywares are smeared-plain corrugated and smeared-indented corrugated. There are eight sherds of plain gray and no Sapawe Micaceous sherds. On the basis of the mix of the biscuitwares, LA 86606 is tentatively assigned a Classic 3 period component.

LA 87430 (Fieldhouse)

Although few Biscuit A sherds are present, the biscuitware assemblage is dominated by Biscuit B/C sherds. The utilityware assemblage consists mostly of Sapawe Micaceous sherds. Two radiocarbon samples returned dates of cal AD 1440–1640, and cal AD 1430–1530 and cal AD 1550–1630. A luminescence sample returned a date of AD 1305–1461.

LA 110126 (Fieldhouse)

Few sherds were recovered from this site; the entire ceramic assemblage consists of seven Biscuit B sherds, two unidentified biscuitware sherds, and one Sapawe Micaceous sherd.

LA 110130 (Fieldhouse)

Nineteen Sapawe Micaceous sherds were recovered during excavation. However, during the initial site recording five Biscuit B sherds were observed (Hoagland et al. 2000:7–103). A radiocarbon sample returned a date of cal AD 1450–1640.

LA 127627 (Fieldhouse)

Identified biscuitware sherds consist of one Biscuit B sherd and one Biscuit B/C sherd. Other decorated ceramics include 14 unidentified biscuitware sherds and three glazeware sherds. The utilityware is divided between plain gray, smeared-indented corrugated, and Sapawe Micaceous (in descending order of frequency). Two radiocarbon samples returned dates of cal AD 1440–1640, and cal AD 1430–1530 and cal AD 1560–1630.

LA 127634 (Fieldhouse)

Although few Biscuit A sherds are present, the biscuitware assemblage is dominated by Biscuit B/C sherds. The utilityware assemblage consists mostly of Sapawe Micaceous sherds. Two radiocarbon samples both returned dates of cal AD 1450–1650. Two luminescence samples returned dates of cal AD 1398–1530 and cal AD 1438–1550.

LA 128804 (Check Dam/Artifact Scatter)

The decorated ware assemblage of LA 128804 includes four Santa Fe Black-on-white sherds, one Wiyo Black-on-white sherd, two Biscuit A sherds, eight Biscuit B sherds, 15 unidentified biscuitware sherds, and 22 glazeware sherds. Smeared-indented corrugated is the most common utilityware type. The later decorated ware types are indicative of a Classic period occupation. It is not clear if the earlier ceramic types are evidence of an earlier component or if they are simply part of generalized Coalition period background noise. Because there are more Biscuit B sherds than Biscuit A sherds present, this site is tentatively assigned to the Classic 3 period.

LA 128805 (Fieldhouse)

The decorated ceramic assemblage at LA 128805 includes assorted biscuitwares (including three Biscuit A sherds and 11 later biscuitware sherds) and 18 glazeware sherds. The most common utilityware type is plain gray; Sapawe Micaceous is the next most common type. A radiocarbon sample returned a date of cal AD 1420–1500.

LA 135292 (Fieldhouse)

Although few Biscuit A sherds are present, the biscuitware assemblage is dominated by Biscuit B/C sherds. The utilityware assemblage consists mostly of smeared-indented corrugated sherds.

Discussion

Coalition Period

What appears to distinguish Coalition period ceramic assemblages are the utilitywares: indented corrugated is early, whereas smeared-plain corrugated and plain gray become more frequent later (smeared-indented corrugated is always the most common type, except for perhaps at Coalition/Classic period transition sites). Kwahe'e Black-on-white is more common earlier, while Wiyo Black-on-white and Galisteo Black-on-white are more common later, although in all cases the frequency of these decorated types relative to the assemblage is very small.

Sites assigned to Coalition 1 period have dates from the late 12th century to the middle/late 13th century. This date range corresponds fairly well with the standard range of the Early Coalition (AD 1150–1250). Within this period some sites can be identified as being earlier or later than others, although there is not enough data to break this time period into finer segments. No site in this study has a whiteware assemblage that contains a large amount of Kwahe'e Black-on-white. There are sites like this in Bandelier National Monument (e.g., Orcutt 1999:Table 3.5) and it is our impression that some sites at LANL have a greater amount of mineral painted ware than does LA 4624. The question is, what time period do these sites date to. The Bandelier Archeological Survey assigns their Kwahe'e Black-on-white sites to circa AD 1150–1220 (Orcutt 1999:Tables 3.5 and 3.6). However, LA 135290, which has only a small amount of Kwahe'e Black-on-white (in an absolute sense) was probably inhabited as early as the late 12th century and LA 4624 (also with only a small amount of Kwahe'e Black-on-white) was probably inhabited slightly earlier. It is possible that the Kwahe'e Black-on-white "rich" sites at LANL actually date to the Developmental period and that Santa Fe Black-on-white replaced Kwahe'e Black-on-white at LANL earlier than at Bandelier.

Sites assigned to the Coalition 2 period have dates in the middle/late 13th century to the early 14th century. This date range corresponds well with the standard range of the Late Coalition (AD 1250–1325).

Only LA 4619 is assigned to the Coalition 2/Classic 1 period. Unfortunately, there are no dated samples from this site. However, since it contains a significant amount of Wiyo Black-on-white and very little Biscuit A, it probably dates to the early 14th century.

Classic Period

Sites assigned to Classic 1 period have a good deal of Biscuit A and few or no later biscuitware sherds; this suggests a middle to late 14th century occupation (i.e., after the introduction of Biscuit A and before the introduction of Biscuit B). However, radiocarbon dates from two of these sites—LA 85404 and LA 85413—returned dates of cal AD 1430–1530 and cal AD 1560–1630, and cal AD 1440–1640, respectively. These dates may represent a later use of the sites, or may be unrelated to cultural activities. Other dates from Classic 1 period sites do not conflict with a middle to late 14th century interpretation, but are not precise enough to confirm it.

The Classic 2 period is defined by an approximately even mix of Biscuit A and Biscuit B/Biscuit B/C sherds. The temporal ranges of these two types overlap in the early to middle 15th century.

Sites assigned to the Classic 3 period are characterized by many Biscuit B and Biscuit B/C sherds and few or no Biscuit A sherds. At most sites the most common utilityware is Sapawe Micaceous and at some sites there is more decorated ware then utilityware. Given the relative absence of Biscuit A sherds, these sites probably post-date the middle 15th century. This interpretation is supported by the radiocarbon and luminescence date ranges, few of which include dates before AD 1430. Given the imprecision of radiocarbon dates from this time period and the imprecision of luminescence dates in general, an end date for this period is more difficult to determine. Given the paucity of Biscuit C and Sankawi Black-on-cream sherds recovered from Classic 3 period sites, it seems unlikely that they were inhabited later than the early 15th century. Nonetheless, the range could extend to the middle 15th to early 16th centuries.

Historic Sites

LA 85869 is a Jicarilla Apache tipi ring site. Five radiocarbon samples were submitted from the site, however, only one returned a date that is clearly associated with the occupation. The 260±40 BP date has several calibrated two-sigma ranges, starting at AD 1520 and ending at AD 1950. A single micaceous sherd did yield a luminescence date of AD 1859±13. The historic bead and metal and ceramic artifacts also indicate a late 19th or early 20th century occupation at the site.

LA 85407 is the Serna Homestead site in Rendija Canyon. Eight wood construction elements from the cabin and corral were submitted to the Dendrochonology Laboratory at the University of Arizona for tree-ring dating. All the samples were ponderosa pine, with five of the eight yielding dates. However, none provided cutting dates due to the poor preservation of the outside rings, leading to a couple of interpretations. The simplest is that the entire structure was built sometime after 1900, based on the 1900+vv date from Room 2. The historic metal and glass artifacts indicate a late 19th to early 20th century occupation and the ceramics a post-1913 date. This corresponds with oral interviews that indicate the homestead was occupied in the early 1900s.

CHAPTER 70
GROUND PENETRATING RADAR: 2002 AND 2003 FIELD SEASONS

Kimberly Henderson, Jennifer E. Nisengard, and John S. Issacson

Surveys using ground penetrating radar (GPR) were conducted at five of the eight sites excavated in 2002 and one site in 2003 as part of the C&T Project (Table 70.1). Three of the sites (LA 127625, LA 128804, and LA 86637) were not subject to GPR survey due to time constraints, site location, and material characteristics. Each of the sites was subject to tree thinning and ground clearing before conducting the GPR survey. The 400-MHz GPR antenna used for survey must be flush with the ground surface at all times, and the operator must slide the level antenna over the surface. It is therefore important to clear all potential hazards (Figure 70.1). Once cleared, a site grid was established using a Brunton compass, an electronic theodolite, or a Nikon 521 digital station (EDM) before the survey. The grid was subsequently used during site excavation so that the GPR and excavation data could be tied together. GPR data is collected in east to west transects of varying lengths, with a 0.5-m separation between transects. The grid area is intended to be larger than the site in an effort to use GPR to delineate site boundaries. Results from the C&T Project GPR surveys varied as a result of a variety of factors discussed in subsequent sections. One of the sites, LA 12587, was surveyed five times to account for changes in soil moisture and expanding site boundaries and to identify subterranean features.

Table 70.1. Excavated C&T Project sites subject to GPR survey in 2002.

Site Number	Grid Size (m)	Goals and Results	EDM
LA 86534	32 by 25	The GPR survey of the site delineated wall alignments, but the grid area was not wide enough to include the kiva.	No
LA 12587	37 by 23	The main portion of site surveyed (the central mound). Transects ranged from 13 to 23 m in length due to the presence of large trees.	Yes
LA 127631	9 by 7	One- to three-room structure, the grid area a bit too small, and as a result the survey did not account for all subsurface features.	No
LA 128805	11 by 10	One- to three-room structure, the data were somewhat unclear although a general location of a room was possible.	No
LA 12587	28 by 19	The center of site was surveyed, including the mound. Wall alignments were visible in the reflection profiles, although they were difficult to identify using amplitude time slice images.	Yes
LA 12587	16 by 10	Northern portion of the site surveyed, grid gardens were suspected, alignments were visible although difficult to identify using the amplitude time slice images.	Yes
LA 128803	10 by 12	The site is a grid garden (a stone hoe was identified on	No

Site Number	Grid Size (m)	Goals and Results	EDM
		the surface). The agricultural features were not identified during an analysis of the GPR data.	
LA 135290 (Q-272)	24 by 22	Multiple geophysical surveys were conducted at the site; the site was excavated during the 2003 field season.	No
LA 12587	22 by 18	Eastern and southern portions of mound surveyed, alignments in the southern portion were additional rooms (as per excavation).	Yes
LA 12587	27 by 10	Further east than the earlier survey, in search of a subterranean structure. No feature was identified, and excavations revealed only wallfall and undulating bedrock in this area.	Yes

Figure 70.1. J. Isaacson, a University of Denver Graduate Student, and L. Conyers conduct a GPR survey at a pueblo roomblock. The GPR antenna is housed within the orange box, which must remain flush with the ground surface.

GPR Background

The use of GPR and other non-invasive geophysical techniques (i.e., seismic refraction, thermal remote sensing, and magnotometry) to aid archaeological research is relatively new (Conyers

1995; Conyers and Goodman 1997; De Vore 1990; Goodman et al. 1994; Hargrave 1999; Imai et al. 1987; Isaacson 1995; Malagodi et al. 1996; Scollar et al. 1990; Whitten et al. 1993; Zeidler 1997). GPR has been useful in the identification of areas of contamination, to relocate various materials, and to distinguish geological features (Smith and Jol 1995), however, its potential contributions to archaeological research have only begun to be demonstrated. GPR works using a continuously moving unit to transmit subsurface electromagnetic data to an above ground antenna (Conyers and Goodman 1997:23). These data are transmitted in real time to the surface (Figure 70.2). These real time units are capable of providing data about buried structural remains, subterranean features, and potential burials (Conyers and Goodman 1997; Malagodi et al. 1996). There is a certain amount of *noise* (i.e., masonry rubble as a result of wall collapse) in raw GPR data, and these data must be processed to make them appropriate for interpretation (Conyers and Goodman 1997:77). For this reason, data acquisition and subsequent data analysis are the central components of all GPR projects.

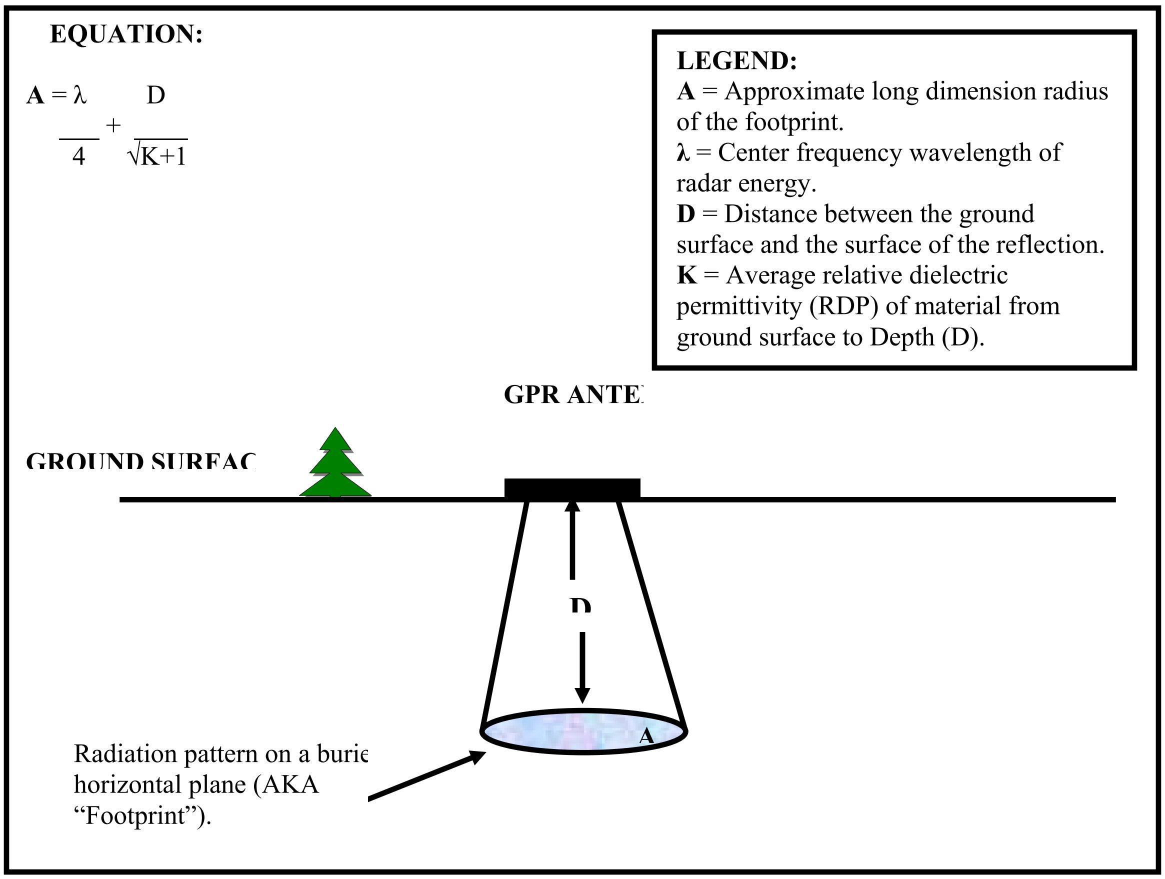

Figure 70.2. Equation and diagram demonstrating how GPR works to create a reflection of a buried item (modified from Conyers and Goodman 1997:36).

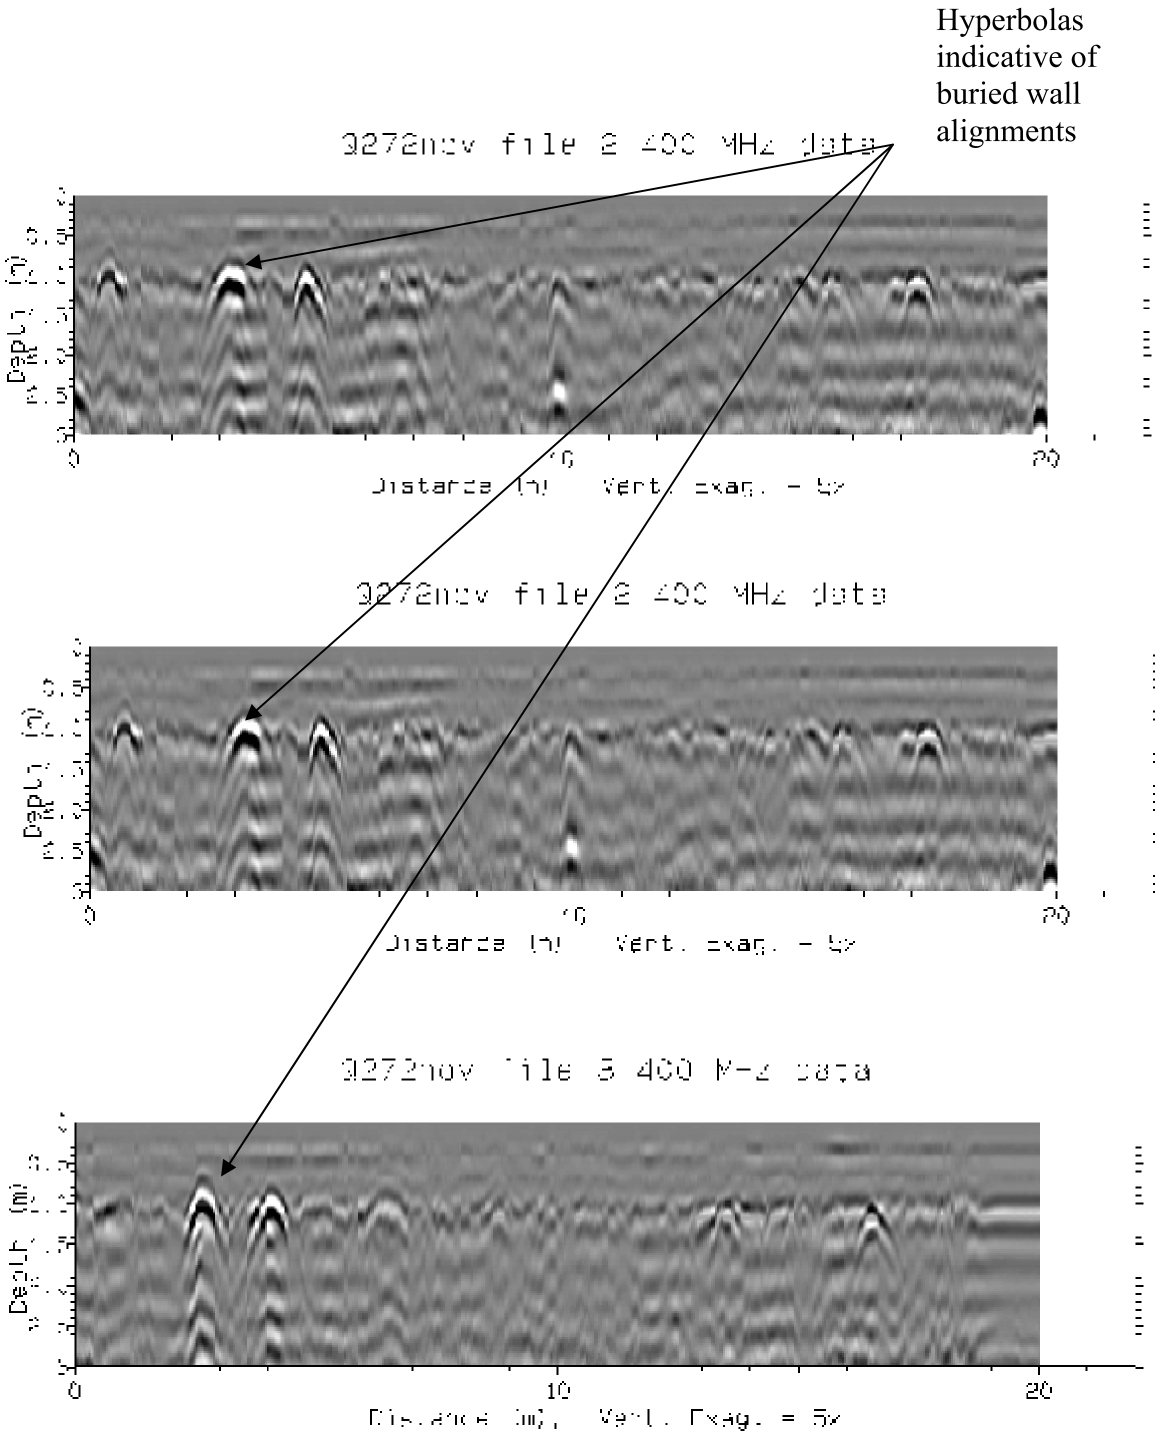
Non-invasive techniques do have limitations. For example, thermal remote sensing must be tuned to the seasonal, regional, and diurnal variations in thermal optimal conditions. GPR, on the other hand, is sensitive to the dielectric properties of soils and soil moisture. However, one important advantage of GPR surveys over other geophysical methods is that the subsurface stratigraphy, archaeological features, and soil layers at a site can be mapped in real depth. This is possible because the timing of the received radar pulses can be converted into depth once the velocity of the radar waves travel through the ground is known (Conyers and Goodman 1997; Smith and Jol 1995). The accuracy of depth calculations depends on a calibration of the electrical properties of the soil as well as its moisture content (also known as relative dielectric permitivity or RDP). When these factors are understood, a high-resolution map of the subsurface can be produced.

The three-dimensional approach discussed here is known as amplitude time-slice analysis and is relatively new, but it has potential to accurately resolve archaeological features (Conyers and Goodman 1997). The availability over the past 10 years of powerful microprocessors has revolutionized the ability to process GPR data in three dimensions (Scollar et al. 1990). Unfortunately, studies in a controlled environment to accurately calibrate the regional soils, moisture content, and optimal conditions for data acquisition remain largely unexplored (although see Isaacson et al. 1999 for an example of a controlled geophysical test bed).

Results of the 2002–2003 C&T Project Site Surveys

GPR data are processed using a program created by Larry Conyers at the University of Denver called GPR Process©. Once processed, the data can be used to create a variety of images, including amplitude time-slice maps. An amplitude time-slice image is created by assigning a specific color to each of the reflected wave amplitudes. Although colors can be manipulated, the higher amplitudes will always be more visible than are lower amplitudes (Conyers and Goodman 1997:27). Amplitude time-slice maps are relatively easy to produce and provide a colorful depiction of an entire GPR survey area. For this reason, we initially used these images as the primary tool for locating buried deposits at the C&T Project sites (see Figures 70.4, 70.5, 70.6a, 70.6b, 70.7, and 70.8). Unfortunately, the amount of surface and buried masonry rubble, or *noise*, at all of these sites made it difficult to clearly differentiate between the rubble and the intact archaeological features.

To provide a clearer picture of the buried cultural deposits at sites scheduled for excavation, we turned to the raw data reflection profiles (Figures 70.3a, 70.3b, and 70.3c). In the reflection profiles, buried objects are represented by hyperbolas of varying widths; a single hyperbola visible in only one file is usually the result of noise. Hyperbolas that are consistently visible in several adjacent profiles reflect buried architectural features (i.e., wall foundations, partially collapsed walls, or subterranean features or structures). Figures 70.3a, 70.3b, and 70.3c provide examples of reflection profiles indicative of a possible buried wall at a site scheduled for excavation during the 2003 fiscal year. In this case, the continuous hyperbolas visible on the left side of the profiles continued to be visible in 12 of the subsequent profiles not depicted here. Multiple hyperbolas in the same location in a profile are a good indication of a substantial buried feature.



Figures 70.3. A (top), b (middle), and c (bottom). Reflection profiles from a pueblo roomblock site scheduled for excavation in 2003. The continuous hyperbolas are indications of buried archaeological features.

Following excavation, in-depth data analysis of the relevant surveys was done in an attempt to understand these data in relation to the actual subsurface architecture, site development process, and the natural geology. Once excavation had been completed, the location of all of the architecture was then mapped digitally and overlaid on to the image maps and was noted on each raw data profile. This was done in order to get an idea of what the image maps represented and to determine the nature and type of radar reflection when it encountered subsurface architecture and other features.

Airport Tract

LA 86534

Conyers surveyed LA 86534 in December 2001, using a 32- by 25-m grid. The results of his survey were encouraging. Room alignments were visible in the amplitude time-slice maps; however, in some places it was difficult to differentiate the walls from the wallfall. The excavation of LA 86534 provided some degree of "ground proofing" in that room alignments did correlate to the amplitude time-slice maps (Figure 70.4).

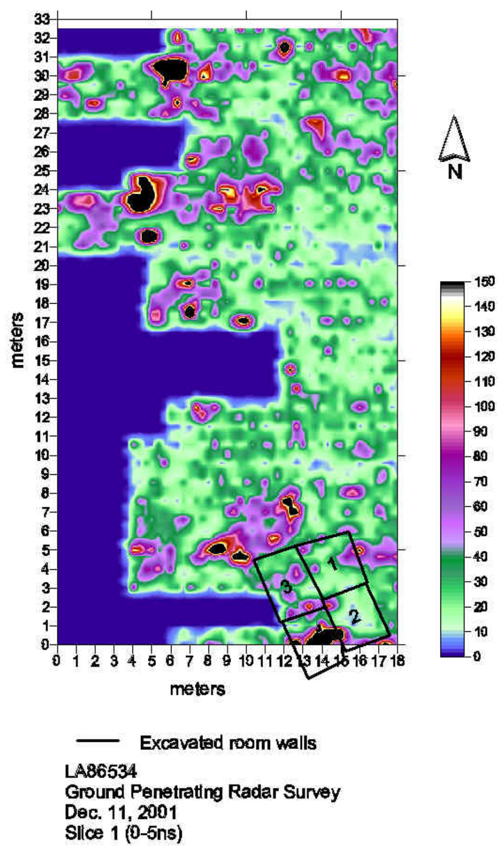


Figure 70.4. LA 86534 amplitude slice map with excavated walls noted with solid black lines.

Post excavation analysis of the raw data profiles was somewhat successful in that the location of structure walls was possible to discern but difficult due to the weakened signal in the near-field zone and the proximity of the architecture to the surface (Figure 70.5).

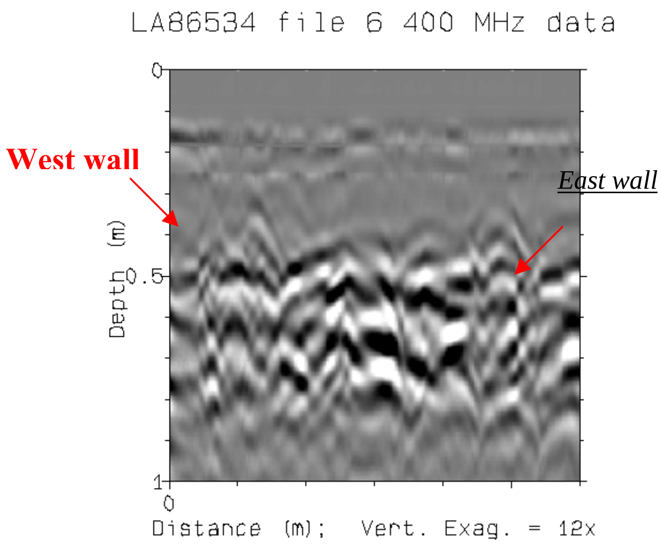

Figure 70.5. LA 86534 raw data profile of Room 1; note location of walls and relationship to hyperbolic reflections.

In Figure 70.5, there is clear reflective activity in the form of hyperbolic reflections that correlate to the subsurface architecture. Out of the 12 profiles included from this roomblock, Figure 70.5 is the only one that produced such clear reflections. The rest were somewhat obscured by room fill and site disturbance from road construction. This area of disturbance was originally thought to be the location of the roomblock and so survey parameters were limited to its boundaries and therefore, we did not survey far enough to the east or south to identify the rest of the roomblock (another 4 rooms) or kiva that was found during excavation.

LA 135290

LA 135290 (Q-272) is a pueblo roomblock site west of LA 86534 that was excavated during the 2003 season (Chapter 25, Volume 2). GPR surveys were conducted when conditions at the site were very dry and again after a storm to account for changes in the dielectric permitivity of the subsurface deposits. The site was also subjected to several geophysical surveys including seismic refraction, GPR, and magnetometry.

The GPR surveys at LA 135290 were conducted in May and December of 2002. In general, the grid parameters were the same for both surveys, covering a 24- by 22-m area that encompassed a mound with visible rock alignments on the surface. The purpose of the surveys was to identify the extent of the site, including the location of a possible kiva, and to determine location and number of rooms in the roomblock. The two surveys were significantly different in terms of moisture content in the soil. Unlike the May survey that was conducted during a dry period, the December survey was done just after a snowstorm and there was much more water content in the soil matrix. Data acquisition of these two surveys also differed in regard to the profiling direction. The May survey profiling was done along the north-south axis while the December survey was done along the east-west axis. These two factors made a big difference in radar reflection patterns and resolution (Figure 70.6a and 70.6b).

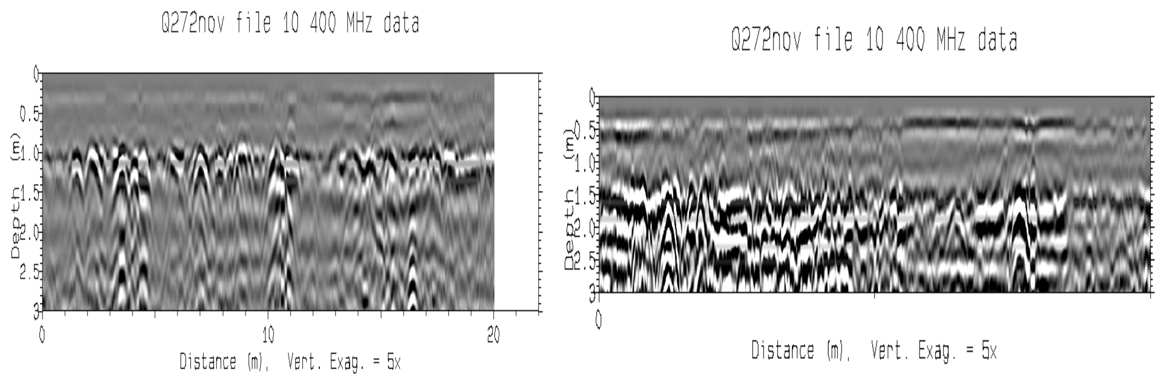

Figure 70.6. Raw data profiles from LA 135290 during a) the May survey (left) and b) the December survey (right).

Although the two profiles in Figure 70.6 are different in terms of profiling direction, each one is representative of the difference in energy reflection as the antenna traversed over the roomblock. Figure 70.6b illustrates the effects of added moisture on the overall resolution of the archaeological features. Notice that in Figure 70.6b, there are stronger reflections lower in the profile than in Figure 70.6a. As you move deeper within this soil context, the clay content increases therefore the amount of water absorption also increases. The increase in water content with depth has slowed the signal down and enhanced the materials within the rooms.

Amplitude slice maps of the December survey definitely illustrate the difficulty of imaging roomblocks with a large amount of rubble fill. Figure 70.7 shows the known location of the roomblock although the exact boundaries are still unclear. The circle in the northeast corner of the image is the proposed location, at least from this set of data, of the kiva. Other geophysical studies done at the site have located the kiva as part of the easternmost edge of the roomblock. Due to the large amount of rubble fill, it is very difficult to discern from this particular survey what could simply be another room from what might be a kiva in that area. As a whole, these other studies, magnetometer and seismic refraction, provide a map of buried deposits at the site, including features that have been interpreted as individual walls. According to these data the wall foundations are resting on the natural bedrock surface, rather than being dug into bedrock, as has been the case at other sites on the Pajarito Plateau. Excavations in 2003 did not locate a kiva at LA 135290.

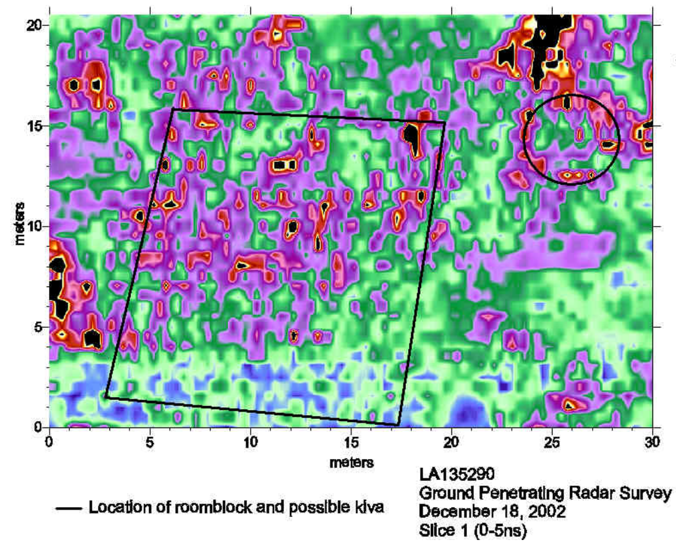

Figure 70.7. LA 135290 amplitude slice map showing general location of roomblock.

White Rock Tract

LA 12587

LA 12587 was subject to five GPR surveys over a six-month period, partially due to a desire to gain the best possible data and partially due to the fact that the site's boundaries increased as excavations proceeded. The initial survey encompassed a 37- by 23-m area. The west to east transects, however, varied in length from 13 to 23 m. This grid area included the central mound, the circular rock features to the west of the mound, and the linear agricultural features to the north of the mound (see map of LA 12587). The second survey was 28 by 19 m, had varying transect lengths, and focused on the central mound area. At this point, a Nikon EDM was used to gather point location data for more than 200 masonry rubble blocks on the surface of the site. These data were overlaid onto the amplitude time-slice maps to distinguish surface rubble from buried deposits. The success of this process was limited.

As the site boundary expanded and more trees were cleared, we conducted a third survey of a 16- by 10-m area in the northern portion of the site where surface indications suggested the presence of agricultural features. The fourth survey included areas to the south and east of the central mound to determine whether or not additional architectural features, including a possible kiva and masonry rooms, were present. Although no kiva was detected, several wall alignments to the south were identified during the processing of these data. Subsequent excavations in the southern portion of the site exposed an additional roomblock. The fifth and final survey at LA 12587 expanded the area further to the east in search of a kiva. Interestingly, the fourth and fifth surveys provided data to suggest that there was some kind of circular feature to the east of the roomblock. Excavation of this area revealed undulations in the natural bedrock that were incorrectly interpreted as architectural features. Undulating bedrock is another unanticipated aspect of the natural geology that will need to be accounted for in future GPR surveys.

Once excavations were completed, further analysis of the first survey was done, which included plotting and drawing the results of the excavation on each of the slice maps. It should be noted that improved processing techniques were applied to the original data at this time, therefore the image maps reveal much more than the images used to interpret the site previously. The improved images do reveal wall alignments but they are not obvious without the "guidance" of the drawn architecture (see Figure 70.8a and b).

a)

b)

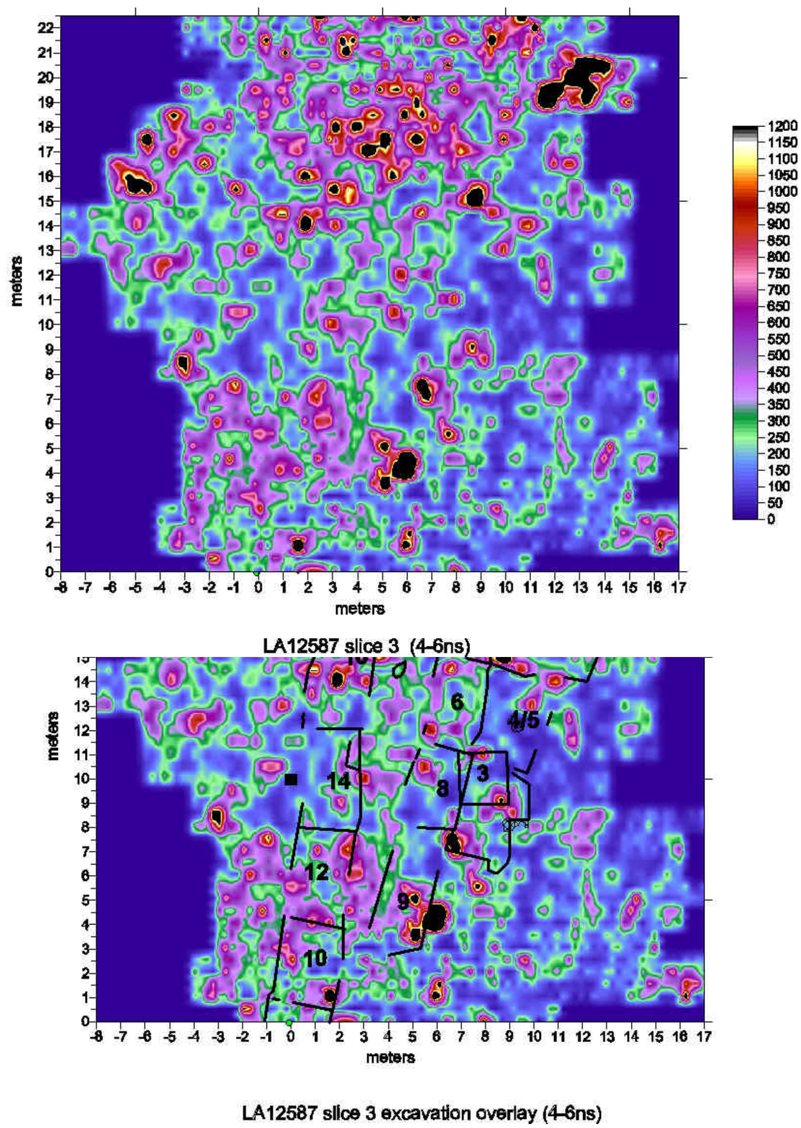

Figure 70.8. LA12587 amplitude slice maps a) without plotted excavation and b) with plotted excavation.

Figure 70.8a does not reveal any obvious wall alignments. After the location of the excavation was drawn on the map, these alignments become more visible. For example, the wall alignments of Rooms 2 and 6 are particularly visible, although somewhat intermittent in the imaging (refer to Figure 70.8b). Clear associations between the imaging results and the excavation results vary from room to room and across the entire site in these particular images for several reasons. First of all, these amplitude slice maps are sliced at particular intervals that do not correspond with changes in topography or varying depth of the cultural features, therefore clearly distinct wall alignments cannot be expected. Without topographic correction at a very small scale, different amplitude slices will image different parts of the wall according to their depth so intermittent imaging of these walls is not that surprising. Software programs for topographic correction of radar data during analysis are still under development.

Another reason for the discontinuous appearance of the wall alignments is that the remaining architecture also varies in construction. For example, in some of the rooms all that remains are the foundation stones without any capstones or courses and in other rooms there are up to two courses still standing. This would definitely create a difference in signal reflection with the more significant walls having much higher amplitudes than the others, therefore also contributing to the intermittent appearance of the wall alignments. In some cases the walls are simply not there any longer. Further complicating the matter is the simple fact that, during site formation processes, the once intact walls have collapsed in different directions making it very difficult to discriminate actual wall from wallfall and room fill. This type of event is particularly detrimental to radar interpretation especially in cases where the construction materials are identical to the natural geology, which is the case here. The less contrast there is between the cultural materials and the natural geology of the area, the more difficult it is to differentiate those materials.

Lastly, interpreting these data is also complicated by the limitations of radar technology itself. As mentioned before, different antenna frequencies emit radar pulses that penetrate at different depths and speeds depending on the type of context and moisture content. A dual 400-mhz antenna was used on all of the surveys in this report. This antenna can generally penetrate to approximately 3 m in depth and produces a pulse to about 25 to 45 cm in wavelength depending on the context (Conyers and Goodman 1997:45). The average width of the walls at this site ranges between 20 to 30 cm with top depths no greater than approximately 10 to 15 cm below the surface and bottom depths at approximately 40 cm. Depending on the relative dielectric permitivity (not determined at the time of survey, therefore only estimates can be made) of the soil in combination with the "near-field" effect (see Conyers and Goodman 1997:55), it is possible that the 400-mhz antenna was unable to resolve features this small at such shallow depths.

Due to the fact that the amplitude maps did not give a clear idea of where the wall alignments were, we began to look closely at the raw data profiles. The location of each wall was annotated on each profile and then studied for patterns that could be recognizable. This process was somewhat successful using a program called GprViewr version 1.1 created in July of 2003 by Jeffrey Lucius and Larry Conyers. This program allows you to view the individual profiles and filter out the background noise and adjust the gains as necessary. This process was quite helpful in interpreting these data and we soon discovered that most of the important reflections are in the first few nanoseconds including the near-field zone.

In Figure 70.9, hyperbolic reflections are slightly visible indicating the exact locations of the west and east wall in Room 16. This is a good example of how the near-field effect can weaken the signal as it couples with the ground surface. During excavation, the walls were found just 6 cm below the surface and it was noted that only the foundation remained of what used to be at least a couple of courses high at abandonment. It was also noted that there was considerable amounts of wallfall in the room fill. This is very apparent in the raw data profile as there are stronger reflections indicating the contrast between inside and outside of the room.

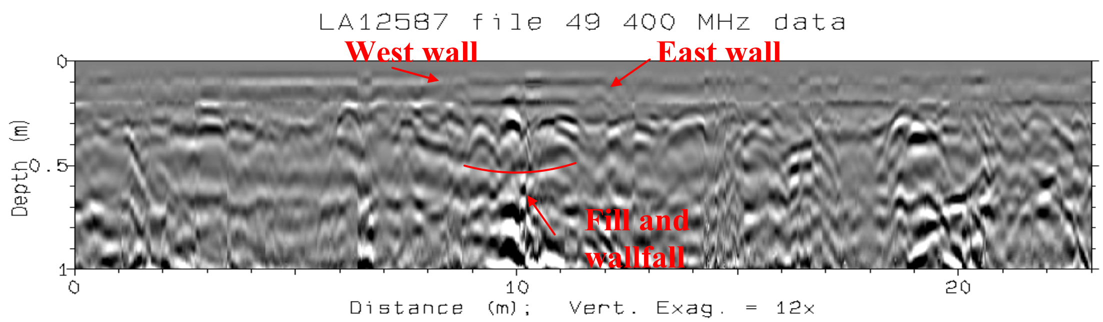

Figure 70.9. LA12587 profile of Room 16 with shallow hyperbolic reflections indicating walls with room fill and wallfall.

All of the known architecture was plotted on each data profile and analyzed in this fashion. Due to many of the limitations discussed above, we were not able to clearly discern each room in each profile as well as what is found in Figure 70.9. Consequently we were also unable to resolve any other cultural features, such as floors or hearths that were further complicated by the large amounts of wallfall and rubble in many of the rooms. Nonetheless, the complete analysis process did provide a good test for equipment, collection methods, and processing improvements for later surveys.

LA 127631

LA127631 is a small one-room structure that was surveyed using a 9- by 7-m grid in May 2002 (Figure 70.10a and b). Data reflected in amplitude time-slice maps for this site were relatively ambiguous. Surface indications suggested that there was one small triangular structure at the site. Amplitude time-slice maps did not provide clearly defined indications of wall alignments. We did manipulate the amplitude time slice by smoothing it, however, the proposed room location did not change (Figure 70.10a and b). The size of the grid, or the integrity of the architectural remains, may have impacted the results.

Excavation of this small site revealed a one-room fieldhouse encountered within grid coordinates 104N/104E, so the proposed location was just north of the actual structure and only encompassed a small part of the northwest corner.

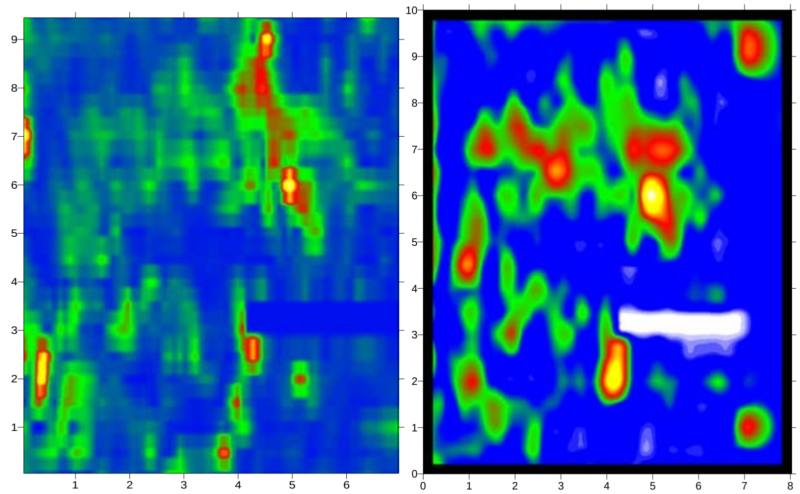

Figure 70.10a and b. LA 127631, with room locations based on the amplitude time-slice map and on the profiles from the site (scale is in meters). The data have been smoothed in the image on the right; however, the proposed room location remains approximately the same.

Further processing of the data after excavation was complete shows the actual location of the structure (Figure 70.11). The amplitude slice in Figure 70.11 has been processed with less interpolation between profiles improving resolution of each reflection providing much less distortion of the data. Even with the improved accuracy of reflection imaging, the location of the structure is still not readily visible. Reasons for this relate directly to the depth of the structure, which is only 20 cm below the surface. Again, this is a result of the inability of the 400-mhz antenna to clearly resolve 20-cm-wide walls at shallow depths.

Resolution was also limited by transect spacing. Due to the elliptical pattern or cone shape of the radiation as the signal penetrates the soil, there is some overlap of this cone between transects. This overlap is limited by many factors, but the most important of those is depth and relative RDP (Conyers and Goodman 1997:36). To summarize briefly, the cone's footprint is generally smaller in diameter at shallower depths. The structure at LA127631 is only 2 by 1.5 m in size.

Fifty-centimeter transects were used to collect the data and were too large to achieve good repeatability of the reflection from profile to profile, therefore limiting resolution and imaging capabilities. As it turns out, the environment in which the site is located is undergoing active erosion, including a small arroyo just west of the structure. The strong reflections seen in Figure 70.7 are essentially a visual of those erosional activities.

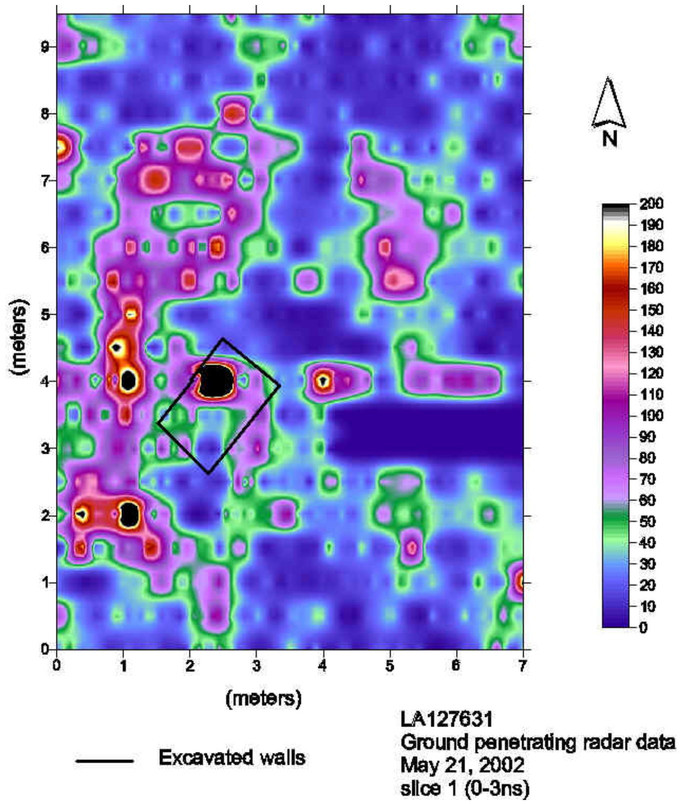

Figure 70.11. LA127631 Amplitude slice map (0 to 3 ns) with excavation overlay.

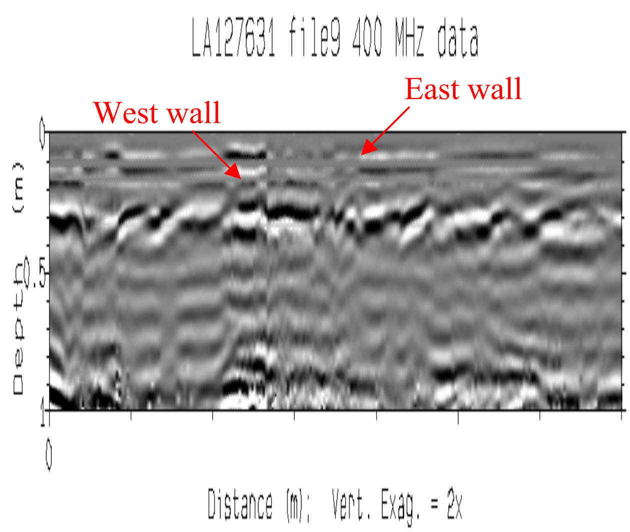

Figure 70.12. LA127631 profile with annotations indicating structure walls.

The raw data profiles were also analyzed after excavation was completed. Although the analysis of these data was limited due to the factors mentioned previously, they did yield some results. Out of the four profiles that the structure was located in, there were only two that actually crossed the walls at an angle good enough to produce hyperbolic reflections. The profile shown in Figure 70.12 does reveal the actual location of the west and east wall, respectively. The hyperbolic reflections are a bit vague due to the near-field effect but they are there.

Again, this site is another example of how collection methods and limitations of the equipment have affected the success of amplitude slice imaging and resolution of the archaeology.

LA 128803

LA128803 is a Classic period grid garden. A stone hoe found on the surface lent further support to this contention. The site is composed of several basalt rock alignments located on a northeast-facing slope. The GPR grid used at the site was 10 by 12 m and the original amplitude time slices did not reveal identifiable features. After excavation was completed, further analysis and processing was done. After applying improved processing techniques that limit the amount of interpolation between data profiles, the grid feature was much more visible in the slice maps. Surprisingly, the results of the image map not only revealed the actual location of the grid garden feature that was excavated but it also suggests other areas in which the feature may continue (Figure 70.13). Soil samples for pollen and flotation analysis were taken from inside and outside of the feature so further study of those materials will verify whether or not the imaging successfully revealed a continuation of the cultural deposit. The shallow nature of this feature and the angle at which the radar signal crossed the alignments has made it difficult to clearly identify them in the raw data profiles consistently. Nevertheless, there are some profiles in which the alignments can be located by the hyperbolic reflections in the near-field zone (Figure 70.14).

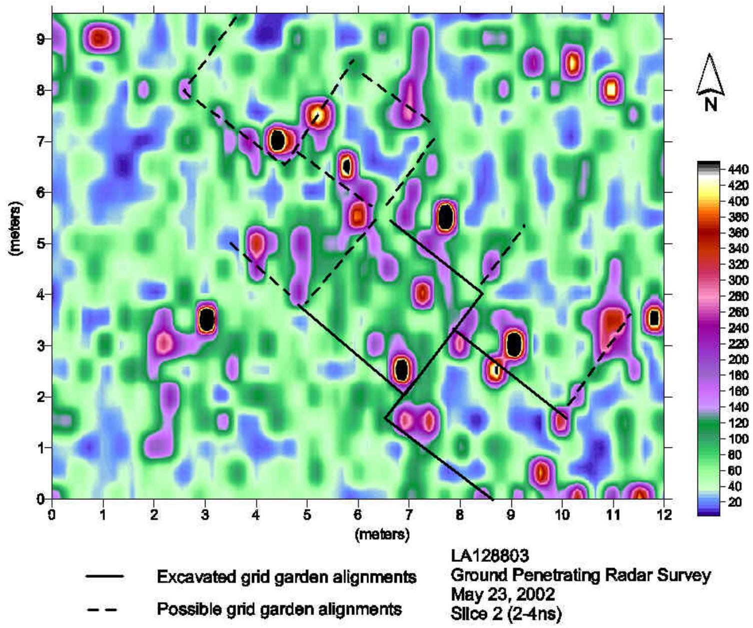

Figure 70.13. LA 128803, a grid garden. Actual excavated features are identified with solid lines and the potential linear features are indicated by a dotted line.

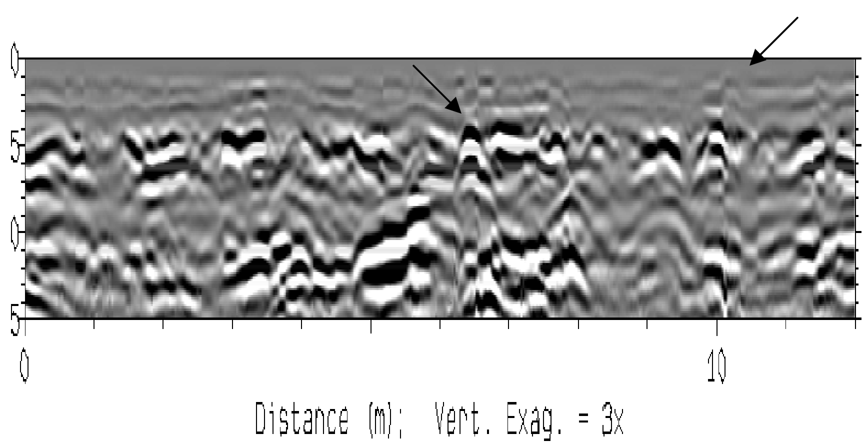

Figure 70.14. LA128803 raw data profile. Note hyperbolic reflections indicating locations of rock alignments.

The overall success of radar prospection at this site is largely a result of the original site development at the time of occupation. It is still subject to many of the limitations and problems of the previously discussed sites in terms of depth and size of the archaeological features, but where it differs is in the material and construction. Unlike the other sites, the feature was constructed out of basalt from local outcrops instead of the natural tuff. It also appears, according to the geomorphologic analysis of the site, that the native fill was removed from inside of each grid and replaced with a more arable mixture of soil. A more arable soil would have been more effective for retaining water making it significantly different than the surrounding soil on the surface. This difference has certainly impacted the ability of the radar signal to detect a more distinct contrast between the natural context and the culturally constructed one, therefore improving the imageability of the data.

LA 128805

LA128805 is a one-room structure that was surveyed using an 11- by 10-m grid (Figure 70.15). There was a great deal of surface rubble at the site when it was surveyed and as a result the antenna was not coupled with the ground surface at all times. When decoupling occurs, the resulting data are impacted; this was the case at this site. The initial interpretation for the site was that it was a two-room structure. Excavation of the site revealed a one-room structure built of tuff blocks up to two courses high. It is likely that the extensive amount of surface rubble at

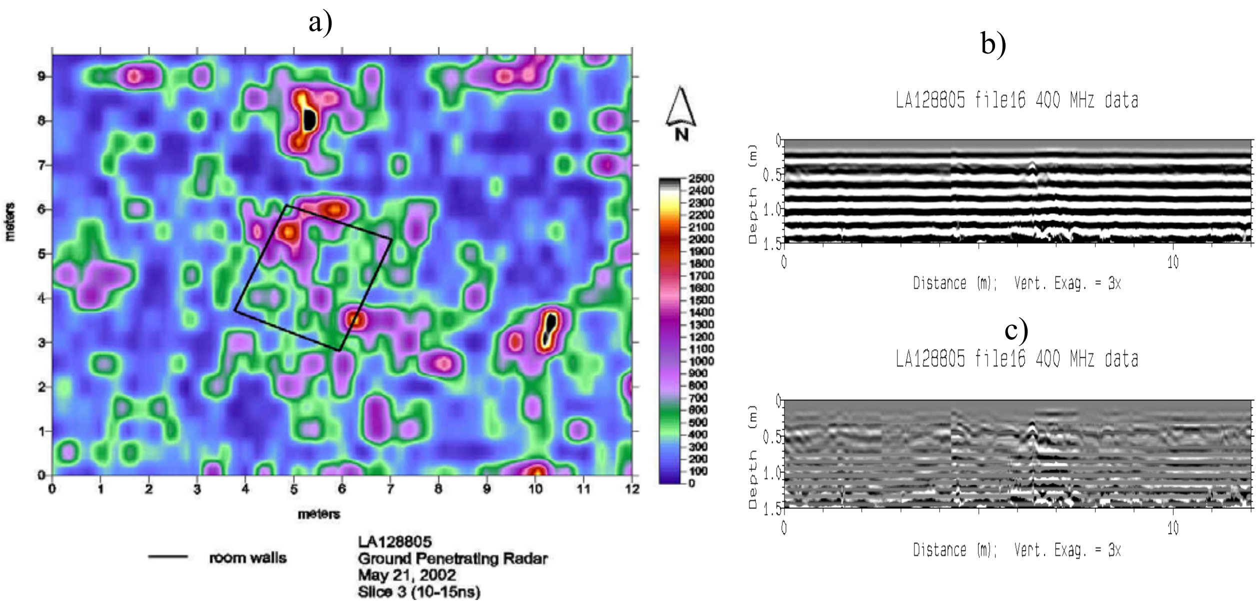

Figure 70.15. LA 128805 a) amplitude slice map with location of excavations indicated by black line, b) raw data profile with severe banding due to frequency interference and decoupling, and c) raw data profile.

the site created so much noise that it was not possible to distinguish wall alignments from the amplitude slice maps. These data were further analyzed after excavation was completed and new slice amplitude maps were created. The new slice maps (Figure 70.15a), however, did not provide any clear indications of wall alignments either. The most significant reason for this is most likely due to a shallow deposition to the floor of the feature of only 31 cm and most of the fieldhouse was already visible on the surface. These data were collected with a 400-mhz antenna, which has limited resolution capabilities at shallow depths. Other factors that further complicated the data include impacts to the structure from heavy erosion, the presence of a small drainage along the southern edge of the structure, and significant amounts of decoupling that caused high reflections as a result of the signal traveling through air.

During examination of the raw data profiles it was immediately evident that there was significant signal interference that resulted in the severe banding of the recorded data shown in Figure 70.15b. This type of interference is a result of FM radio transmission or other electronic devices that are in use at the time of data collection (Conyers and Goodman 1997:75). Background filtering was applied (Figure 70.15c), but there was still subsequent impact to reflection clarity, therefore limiting the analysis of the raw data in comparison to the amplitude slice imaging results.

Future Directions

In the initial year of GPR research at Los Alamos National Laboratory, the Cultural Resources Management Team surveyed five sites as part of the C&T Project as well as three additional sites. Results from these surveys have provided several lessons learned. First, there are several environmental and geological issues to consider when doing GPR. One of the most important concerns is that soil moisture has a great impact on the speed at which GPR can move through local sediment. The dielectric permitivity of the sediment changes as the amount of moisture absorption and retention changes with increased depth. The survey done at LA 135290 illustrated how this dynamic directly affects the quality of signal resolution. Our results were greatly impacted by this factor, as many of the surveys were conducted during a period of severe drought, therefore limiting resolution of architectural detail. A different problem, although somewhat related, is that the dielectric permitivity of the tuff blocks used to construct site architecture can be almost identical to that of the surrounding sediments, particularly during times of drought. The less contrast between the cultural materials and the natural geology, the more difficult they are to segregate. Several of the surveys in this study demonstrate this difficulty. Perhaps the addition of water would help to solve this particular problem, but further research needs to be done first to determine its consistent effect on sites in this area. There are still many questions that need to be answered with regard to how GPR works in this environment especially with regard to signal absorption by the native tuff. Attention to these issues will certainly make future surveys much more successful.

Second, many of the other problems that were discovered during post-excavation data processing deal mostly with collection methodology and equipment limitations in relation to signal resolution. The inadequacy of the 400-mhz antenna to resolve much above 40 cm at these sites is the most glaring constraint that needs to be addressed in further surveys. Soil velocity and approximate depth of the architecture needs to be assessed before survey to select the most adequate antenna that will provide the desired results. Many of the 2002 surveys might have been much more successful if a higher frequency antenna was used to achieve better resolution at shallow depths. It is not to say, though, that these other antennas do not have their own limitations to consider but it would be beneficial to survey each site with at least two different frequencies to get a better data sample, especially if the velocity of the material is unknown. Transect spacing also affects resolution and should be adjusted when doing surveys at many of the archaeological sites on the plateau. All of the 2002 surveys were collected with 50-cm transects. In general, 50-cm spacing is usually adequate when you are trying to resolve features that are at least a meter in depth and are at least 50 cm in size. Many of the features in these surveys measure under these parameters, therefore 25-cm spacing would be much more appropriate for better data acquisition and consistency.

We have also learned that attention to grid set up and parameters is very important for good surveying results. First and foremost, the grid boundaries at a site should be substantially larger than those based on visual surveys of where the majority of the site architecture is located. At LA 12587, rooms were discovered in areas where there were no surface indications of architecture. At LA 86534 the kiva was encountered in a roadbed also exhibiting no surface indications of a subterranean feature. Larger grid dimensions would have been much more beneficial at both of these sites. The angle of the grid should also be thought out in terms of how the energy will come into contact with the size and shape of the archaeological features. Diagonal profiling in respect to linear architecture is usually recommended, but unfortunately it makes clear recognition of point sources, which produce hyperbolic reflections, more difficult to determine in the raw data. This collection method causes the reflection to sort of stretch out and become less enhanced making raw data analysis much more complicated than necessary. When time and money are available, surveys in both directions in which the signal is directly perpendicular to the linear architecture would be more advantageous especially in contexts where there is very low contrast and image interpretation is limited. Although doing this would make it a little more difficult to correlate the GPR grids to the excavation grids, it would not be impossible if the exact bearing of north was known.

There are some smaller suggestions that should be considered when doing further surveys that could also make a difference in post-acquisition data processing and interpretation in future surveys. Some of these include surface mapping of all of the vegetation, geologic formations, and surface debris; slowing down data acquisition to limit problems with decoupling; adjusting the low-pass filter to guard against signal interference from radio frequencies; and profiling in one direction only to limit inconsistencies in data reflection from profile to profile.

Overall, we hope that our effort to combine GPR and archaeology will help guide excavations at sites like LA 135290 (Q-272) and others. Excavation allows us to ground truth our interpretations of the GPR data and to develop a better understanding of what buried cultural features should look like in reflection profiles and amplitude time-slice images. Once that understanding has been achieved, then future GPR surveys will not only guide site testing and excavation but they will also provide a foundation for project planning, which would include budgeting time and funding and ultimately improving estimates for approximate project completion.

CHAPTER 71
INTRASITE SPATIAL ANALYSIS

Brian C. Harmon, Gregory D. Lockard, and Bradley J. Vierra

INTRODUCTION

This chapter presents a preliminary study of the spatial organization of the C&T Project sites. These data may provide some important insights into site function, occupying group size/structure, and settlement history. As defined by Binford, site structure is the "spatial distribution of artifacts, features, and fauna on archaeological sites" (1983:144). It is the spatial relationships between facilities and artifact distributions that provide information on internal site organization and activities. On hunter-gatherer sites, this might be as simple as the distribution of artifacts around a campsite. In contrast, agricultural communities may include architectural floor plans, construction sequences, and associated midden deposits. Together, this spatial information provides a productive avenue of research for understanding past settlement organization.

ARCHAIC SITE STRUCTURE

Three of the Archaic period sites excavated during the C&T Project are in eroded contexts (LA 12587 [Area 8], LA 99396, and LA 99397). It is hardly surprising that features were not found at any of these sites. Site structure data, such as variations in the distribution of different artifact types, are unlikely to be preserved at these sites. Nevertheless, artifact distribution data from LA 99396 were examined. The large size of the site (1385 m^2) and the fact that all artifacts recovered from the site were analyzed suggested that if intrasite patterning could be detected it would most likely be detected at LA 99396. No patterns were found in the distribution of chipped stone debitage, although some patterning was seen in the distribution of chipped stone tools. Geomorphic evidence suggests that the habitation surface at LA 85859 has not been eroded away, although the soil horizon is highly bioturbated and the precise depth of the occupational surface is unknown.

LA 12587 (Area 8)

The Archaic period component of LA 12587 is distributed within the 5200-m^2 site area. However, it probably represents a remnant lag deposit due to the erosion of an unknown amount of mesa top soils. The artifact scatter is located in an area of thin soils that overlie tuff bedrock. Soils in the vicinity of the artifact scatter lack Bw horizons and instead exhibit A-BC or A-C horizons. This weak soil development is consistent with a possibly less than 500-year age for the colluvium. The site is in an actively eroding surface with minimal potential for the preservation of intact archaeological deposits (Chapter 57, this volume).

LA 85859

LA 85859 is a 368-m^2 Archaic lithic scatter on a northeast-facing hillslope underlain by Qct pumice. The Qct pumice is overlain by a buried soil in colluvium up to 80 cm thick that has an inferred middle Holocene age of 6.7 to 7.4 ka. The middle Holocene soil profiles are truncated, and are overlain by a late Holocene colluvial deposit less than 25 cm thick. The distribution of the artifacts at the site suggests that they were not transported from upslope areas; that is, there appears to be little or no horizontal displacement of the assemblage. However, there is evidence for substantial bioturbation and vertical transport of artifacts since site abandonment. The precise depth of the original occupation surface could be not isolated, but probably occurs in the upper portion of the middle Holocene deposit (Chapter 57, this volume).

Although the Archaic period occupation surface at LA 85859 has been significantly disturbed, it has not been removed. The absence of features at this site may, therefore, indicate that no archaeologically detectable features were present when LA 85859 was occupied. Artifacts from eight 1- by 1-m excavations units have been analyzed. While this sample represents 37 percent of the artifacts recovered from the site it only reflects a 24 percent areal sample of the excavated units, which may not be sufficient artifact distribution analysis. However, given the *relatively* intact nature of Archaic period deposits at LA 85859, a future analysis of the distribution of artifact types within the upper portion of the middle Holocene deposit (i.e., Strata 3A and 3B) may be warranted.

LA 99396

LA 99396 is a 1385-m^2 multicomponent site consisting of an Archaic period lithic artifact scatter and a Coalition period one-room fieldhouse. The site is situated on the broad, open, southeast-facing slope of a saddle. Headwater cutting of several small washes has created an area of shallow erosion across much of the southeastern portion of the site. The local stratigraphy consists of late Holocene eolian or slopewash deposits generally less than 15 cm thick that overlie late Pleistocene or early Holocene eolian deposits, late Holocene (1 to 2 ka) swale fill deposits, or pumice. Most of the artifacts at LA 99396 appear to have been reworked into the less-than-1000-year-old late Holocene colluvium. It is possible that the Archaic artifacts in the late Pleistocene to early Holocene deposits are in a somewhat better context; however, it is likely that much of the Archaic site component, including the occupation surface, has been eroded away, with the artifacts transported downslope and concentrated in a shallow gully below the site (Chapter 57, this volume). Figure 71.1 shows how the distribution of surface artifacts has been shaped by erosion and topography.

While there is no evidence of *in situ* Archaic period deposits at LA 99396, although it was thought that the different lithic debitage types might exhibit some spatial patterning across the site. Figure 71.2 illustrates that there is no difference in the surficial distribution of angular debris, core flakes, biface flakes, and microdebitage across the site; however, the artifacts are distributed in roughly two clusters. One is situated in the northeastern section and the other in the south-central section of the site. Both contain evidence of core reduction and tool production/maintenance activities.

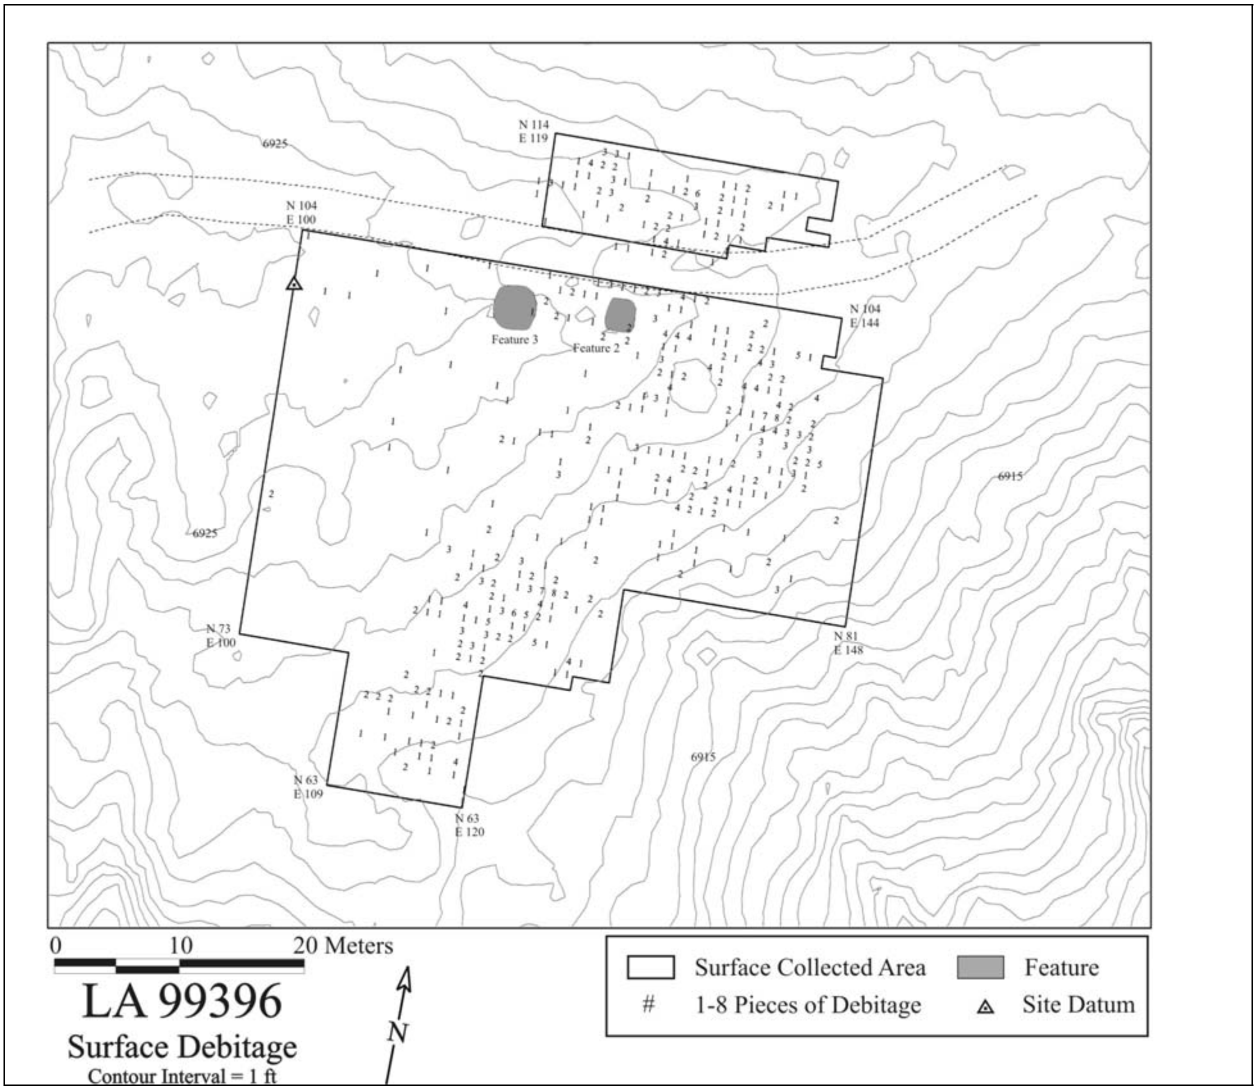

Figure 71.1. LA 99396 surface distribution chipped stone debitage.

The northeastern cluster also includes a few ceramic artifacts and a possible Coalition period fieldhouse, so this area is presumably multi-component. There is, however, some patterning in the distribution of chipped stone tools (Figure 71.3). The tools spatially cluster into these two groups: the northeastern cluster which consists mostly of bifaces, but also includes projectile points and retouched pieces; and the south-central cluster that consists of fewer, but more diverse tools. Both areas presumably contain Archaic materials, but the south-central cluster may be less contaminated by the subsequent Ceramic period occupation.

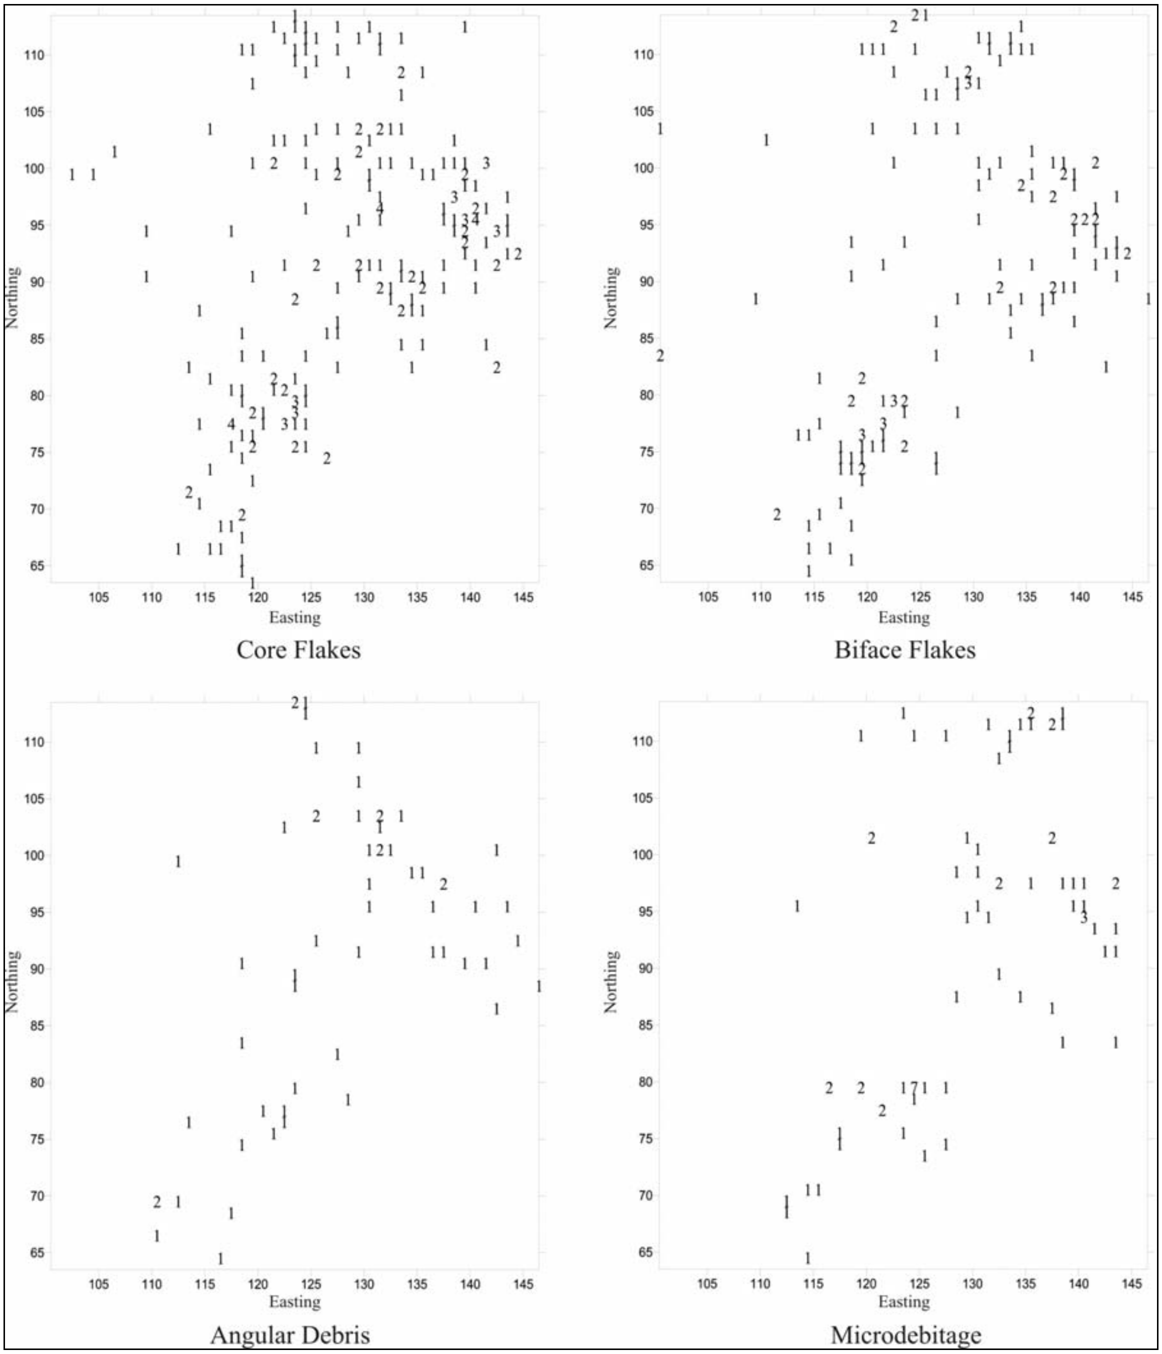

Figure 71.2. LA 99396 surface distribution of core flakes, biface flakes, angular debris, and microdebitage (numbers represent artifact count in a given grid unit).

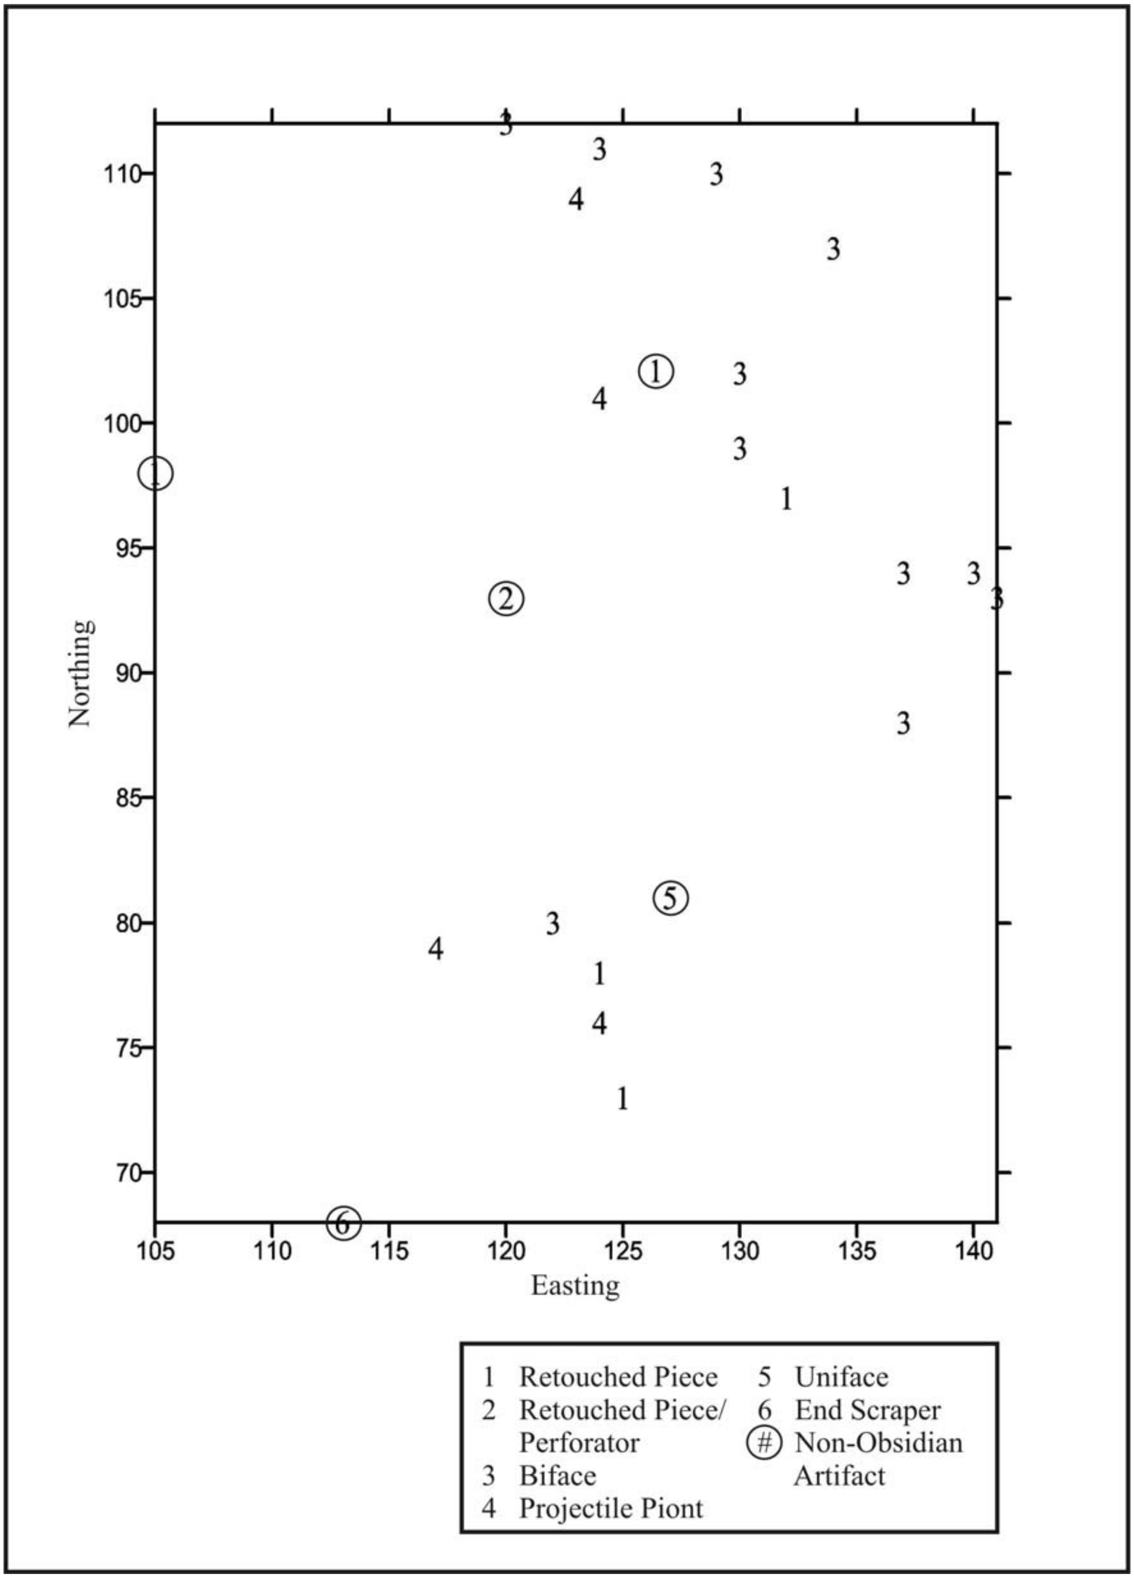

Figure 71.3. LA 99396 distribution of all chipped stone tools.

LA 99397

The LA 99397 lithic scatter is distributed over a 1500-m^2 area. It is situated on a northeast-facing hillslope that forms the shoulder of a generally southeast-to-northwest-trending ridge crest. Site stratigraphy includes thin late Holocene colluvial and eolian deposits less than 25 cm thick that overlie late Pleistocene to early Holocene colluvial deposits or late Holocene (1 to 2 ka) swale fill deposits. Several areas of the site exhibit a late Holocene surface gravel cap or weak desert pavement. Most of the artifacts at LA 99397 appear to have been reworked into the less-than-1000-years-old late Holocene colluvium and the approximately 1 to 2 ka late Holocene swale fill deposits. It is possible that the Archaic artifacts in the late Pleistocene to early Holocene deposits are in a somewhat better context; however, it is likely that the occupation surface has eroded away (Chapter 57, this volume). Figure 71.4 shows that a majority of the surface artifacts from LA 99397 are clustered in a drainage and drainage head in the eastern part of the site.

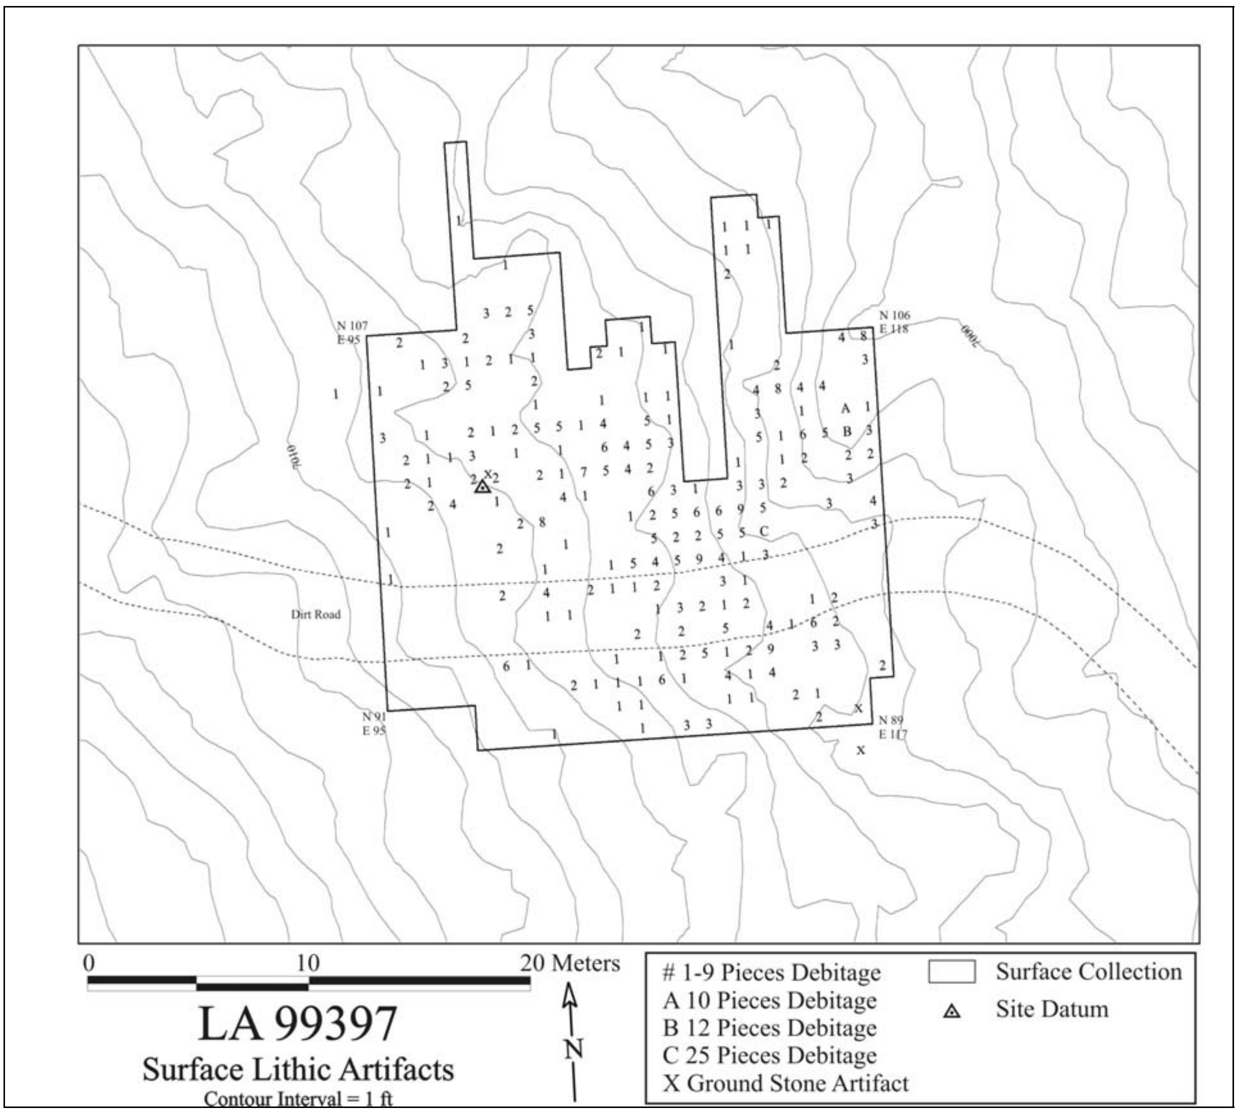

Figure 71.4. LA 99397 surface artifact distribution.

ANCESTRAL PUEBLO SITE STRUCTURE

Information on the site structure analysis of the three Coalition period roomblock sites excavated during the C&T Project is presented in this chapter. Site structure data for two additional excavated sites will also be included for comparison (LA 4618 and LA 4624) (Schmidt 2006b and Vierra et al. 2002, respectively). All of these roomblock sites have a broadly similar site structure (Figure 71.5). That is, they consist of multiple-row roomblocks that are oriented roughly north-south and a midden, or at least a diffuse artifact scatter, which is located to the east of the roomblock.

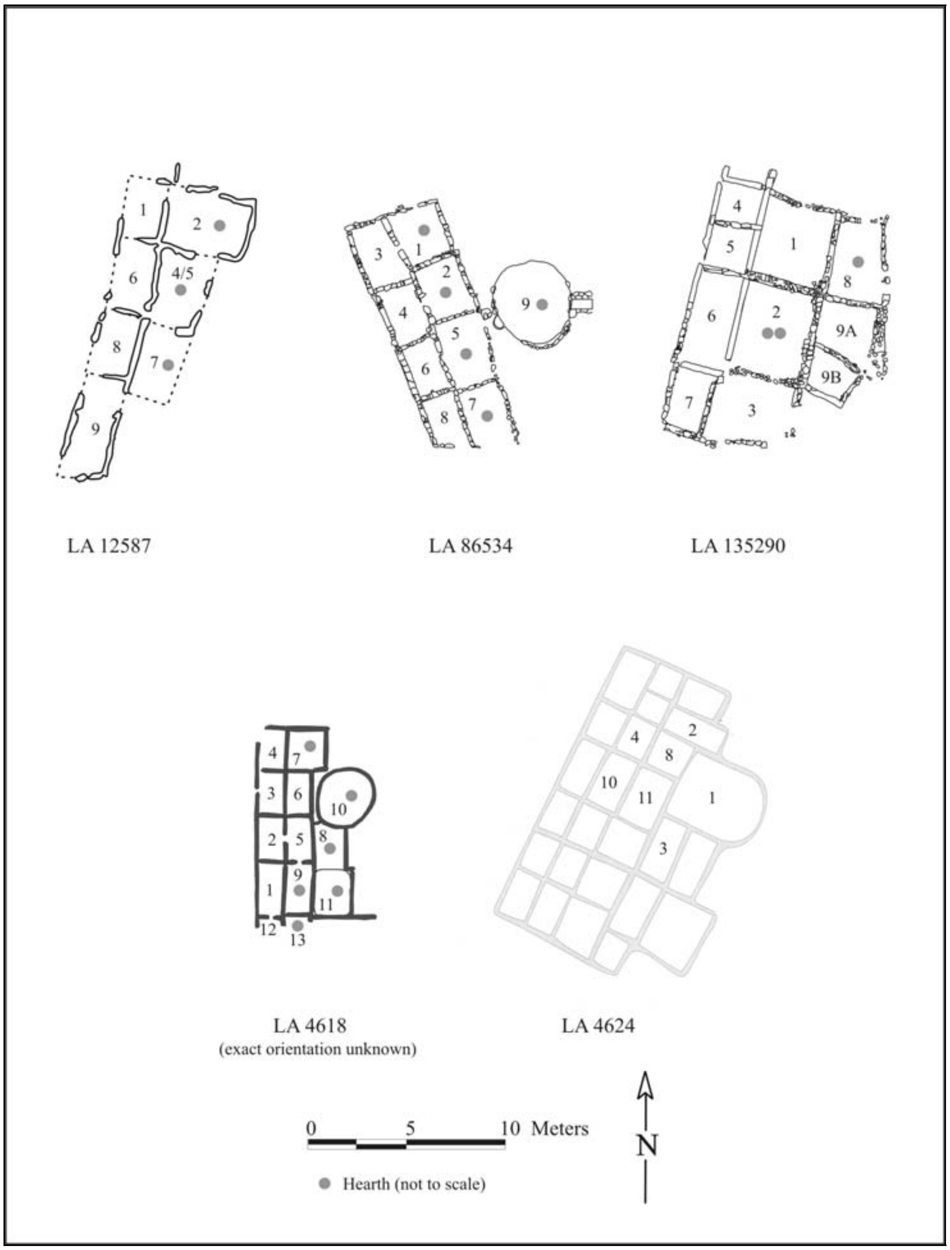

Figure 71.5. Roomblock ground plans.

Ceremonial rooms, when present, are the sole easternmost rooms or are in the easternmost row of rooms. Habitation rooms tend to be located in the front of the roomblock (east) and the storage rooms in the back of the roomblock (west). This general site layout is widespread across the Pajarito Plateau and is common before the Late Coalition/Early Classic period transition (Carlson and Kohler 1990:9–10; Steen 1977:10–11; Van Zandt 1999).

Within this broad pattern, however, there is variation in roomblock orientation, construction methods, number and nature of rooms, number and nature of ceremonial rooms, and amount of remodeling/number of building episodes that is described below. Each of these sites is presented in chronological order from earlier to later Coalition period.

LA 4624

LA 4624 is a 26-room pueblo that was probably inhabited in the late 12th and possibly early 13th century (Vierra et al. 2002). The back (west) of the roomblock is formed by three regular rows of rectangular rooms; whereas, the front (east) of the roomblock is formed by two irregular rows of rooms. The roomblock is oriented northeast-southwest. A 3300-m^2 midden is located to the east of the roomblock.

The rooms can be grouped into three categories, based on size: there are 13 rooms smaller than 5 m^2, 11 rooms between 5 and 7 m^2, and two rooms larger than 10 m^2 (Nisengard 2002). Most of the smallest rooms are located in the back two rows of the roomblock; most of the 5- to 7-m^2 rooms are located in the front three rows of the roomblock; and the two largest rooms are both located in the front row. All rooms are square or rectangular in shaped except for the largest room, which is D-shaped. The pueblo was only partially excavated and the single floor feature encountered was a hearth in the D-shaped room.

Most of the walls at LA 4624 are constructed of shaped and unshaped tuff blocks. One of the best preserved walls is the north wall of Room 3. This wall consists of a foundation of large tuff slabs (approximately 54 by 37 cm) and upper courses of smaller unshaped tuff blocks (20 by 10 cm to 20 by 20 cm). Preserved plaster, up to 2 cm thick, is present on some walls. In at least one case, the wall plaster is coped with the floor plaster. In addition to tuff block masonry, some wall segments consist of hard-packed adobe set with small chinking stones and potsherds.

Recovered roofing material consists of chunks of adobe and pieces of charcoal. These materials were often found lying directly on the floor. Ponderosa pine, piñon pine, and juniper are the most common species in the charred macrobotanical assemblage recovered from rooffall strata. Floors consist of hard-packed sediments with intermittent areas of ash and smoke staining. In some instances, the dark charcoal staining is likely the result of burned roof materials that had collapsed onto the floor. The construction history of the roomblock is unknown. No outside activity areas were found during the excavation of LA 4624, although four rock alignments of unknown association are present on the periphery of the site.

LA 135290

LA 135290 is a 10-room pueblo that was inhabited sometime between the late 12th and early/middle 13th century. When the roomblock was initially constructed it consisted of six rooms arranged in a blocky L-shape. At a later date, three additional rooms were added causing the roomblock to have a rectangular footprint. At some point a wall was constructed in one of the original rooms, transforming it into two smaller rooms (see Figure 71.5, Rooms 4 and 5). The roomblock is oriented northeast-southwest. There is no midden at LA 135290, although some surface artifacts were found to the southeast and east of the roomblock.

Rooms range in size from 3.96 to 15.66 m^2, but there are no classes of room size, as there are in LA 4618. Both the largest room and third largest room contain hearths. One of these rooms (Room 8) is in the front row of rooms, whereas the other (Room 2) is in the second row of rooms. It is likely that the east (front) walls of Rooms 9A and 9B (and possibly Room 8) were never full-standing walls, indicating that these rooms might have been ramada-like structures.

The initial wall construction at LA 135290 included both the use of puddled adobe and coursed tuff block masonry. Most of the masonry exhibits little or no shaping. While 15- to 20-cm-thick subfloor adobe footings are present under most walls, there are instances of basal upright stones set into adobe mortar at floor level (e.g., the north wall of Room 1) and of basal masonry set into adobe-lined depressions below floor level (e.g., the south wall of Room 2). The lower 40 to 60 cm of the back room walls are built of puddled adobe. Two courses of unshaped tuff block masonry cap the west adobe wall of Room 6 and wallfall indicates that the upper portion of the west wall of Room 1 (i.e., the east wall of Rooms 4 and 5) was also built of masonry. It is possible that all of the back room walls were built this way. The south wall of Room 8, while not a back room wall, was also built in the coursed masonry-over-adobe style. The back rooms appear to have been intentionally burned, perhaps with the intention of fire-hardening the wall and floor adobe, making it difficult for rodents to burrow into the rooms.

The remaining initial construction walls consist of masonry. The basal course of most walls consists of large tuff blocks (20 to 30 cm high by 10 to 30 cm wide) and adobe mortar. However, the basal courses of the north wall of Room 1 and the south wall of Room 9A are distinct. The base of the Room 1 wall consists of 40- to 45-cm-high and 15- to 20-cm-wide uprights staggered at 20- to 40-cm intervals. The long axes of these uprights are perpendicular to the length of the wall. Adobe mortar set with smaller tuff pieces (10 to 20 cm) fills the space between uprights. The south wall of 9A consists of a double row of tuff uprights. Upper courses of all walls consist of horizontally placed tuff blocks (20 to 50 cm long and 10 to 20 cm wide) and adobe mortar. Small adobe buttresses (approximately 50 cm long) are present on the outside northeast and northwest corner of Room 4 and the outside southeast corner of Room 6. Fragmentary remains indicate that masonry walls were covered with plaster and in some instances up to 10 cm of adobe.

The walls of later rooms are more fragmentary than the walls of the initial construction. Earlier and later construction methods appear to be similar although the lower portions of the Room 7 walls, a new back room, were built with masonry instead of adobe. Similarly, the later wall that divided Room 4/5 into two rooms was built entirely of masonry.

No roofing materials were identified. Floors associated with the initial construction of LA 135290 consist of 3 to 7 cm of compact adobe often overlain by a thin plaster wash. Multiple flooring and multiple floor repair episodes took place in the back rooms. Coping between wall and floor plaster is present in Room 2. Room 9A is the only room of the initial construction that does not have a formal floor. In this room the floor consists of compacted sediments. The floors of the later rooms are similarly informal, consisting only of a compact surface.

The initial occupation of LA 135290 involved the construction of Rooms 1, 2, 4, 5, 6, 8, and 9A. Three separate remodeling/reoccupation episodes are evident by the presence of multiple floors in Rooms 4/5 and 6, multiple features in Room 2, and a remodeled hearth in Room 8. Lastly, Rooms 3, 7, and 9B were added on to the existing roomblock.

The top of the Bwb1 soil horizon to the east of the pueblo is much more compact than elsewhere on the site. This presumably is due to trampling and foot traffic within the area. Also present to the east of the pueblo are two north-south oriented rock alignments. Each alignment forms a low berm about 7.50 m long and 0.50 m wide. It is unclear if this feature is contemporaneous to the pueblo or post-dates it. No other outdoor activity areas were found.

LA 86534

LA 86534 is a nine-room pueblo that was inhabited sometime between the late 12th century and the middle/late 13th century. The roomblock consists of a double row of four rooms fronted by a subterranean circular kiva. The roomblock is oriented north-northwest by south-southeast. A diffuse artifact scatter is located to the northeast and east of the roomblock and covers an area roughly 250 and 550 m^2, respectively. The back rooms are between 5.31 and 6.40 m^2 in size and contain few features, none of which were hearths. The front rooms range in size from 6.45 to 8.05 m^2 and all contain hearths. The kiva is 17.63 m^2 in size and contains eight different feature classes.

At LA 86534, the walls were built of unshaped and shaped tuff blocks and adobe mortar. Wall foundations at the site consist of upright tuff blocks set in shallow adobe mortar-filled trenches. These blocks are roughly shaped and are slightly smaller than the tuff blocks used in wall construction. The general size of the basal upright stones is approximately 25 by 15 by 10 cm, while the general size of wall blocks is approximately 40 by 20 by 10 cm. The upper walls consist of regular courses of horizontally laid shaped and unshaped tuff blocks. In several isolated places in each room a tan clay plaster covered the interior walls. It is likely that the entire wall face was originally plastered over. In general there is little architectural variability between one wall and another.

The fill of all rooms contained abundant, but usually small, fragments of adobe similar to that observed in the walls. Although these fragments could represent rooffall, wall debris, or both, it is most likely that they represent rooffall given the presence of [beam] impressions and fingerprints on several of the chunks. No postholes were identified in the rooms, suggesting that the walls were load-bearing and indicating that the roof was not substantial.

Room floors were thinly plastered with fine clay mud, identical to and occasionally coping into the surviving wall plaster. Where they were well preserved, the floors are compact and appear to have been burnished. It is probable that all eight rooms of the roomblock were built within a short period of time and possibly in a single building episode. It is not clear when the kiva was built, but it is likely that it was built at the same time as the rest of the roomblock given the connecting feature between it and one of the other rooms. There is no evidence of subsequent remodeling of the roomblock. In summation, LA 86534 appears to have been built in a single building episode and with a single architectural style. No evidence of exterior activity areas was found at LA 86534.

LA 4618

LA 4618 is a 13-room pueblo that was inhabited between the middle and late 13th century (Schmidt 2006b). The roomblock consists of two rows of five rooms fronted by a subterranean circular kiva. A second episode of construction added two rooms to the south of the kiva, creating a new (third) front row of rooms. One of these new rooms is an aboveground square kiva. The roomblock is aligned more-or-less north-south; however there are no data on the exact orientation. A sparse midden is located immediately east of the roomblock. A denser midden is expected at a pueblo of this size and the density of the midden may, in fact, be underestimated (Schmidt and Vierra 2006:233). An opening in the back wall of Room 3 and an artifact scatter below it may indicate that trash was also disposed of to the west of the roomblock.

The rooms can be grouped into three sizes: six rooms are smaller than 6.5 m^2, four rooms are between 7.4 and 8.7 m^2, and one room (the circular kiva) is 14.4 m^2 (two rooms were only partially excavated and their size could not be determined). Rooms 7 and 8 and possibly Rooms 9 and 13 contain hearths. However, only Rooms 7 and 9 are in the middle size category. Room 8 is a "small" room and the size of Room 13 is unknown. Rooms 1 (in the middle size category), 2, 3, and 5 (in the small size category) each contain a single small subfloor pit. Rooms 10 and 11 are both clearly ceremonial rooms as they each contain a suite of features that includes a hearth, an ash box, a deflector, a vent shaft, a possible sipapu, and wall niches. Room 11, however, is in the middle size category.

The walls are built of shaped and unshaped tuff blocks and adobe mortar. Wall foundations were not recorded, but upper walls consist of regular courses of horizontally laid shaped tuff blocks and chinking stones. Basal courses consist of large upright tuff blocks in at least some rooms. On average, tuff blocks are 40 by 20 by 10 cm in size. In several isolated places in each of the rooms, a tan clay plaster covered the tuff blocks of the interior walls. It is likely that the entire wall face was originally plastered over. In general there is little architectural variability between one wall and another.

The fill of all rooms contained abundant, but usually small, fragments of adobe similar to that observed in the walls. Although these fragments could represent rooffall, wall debris, or both, it is most likely that they represent rooffall given the presence of both plant and finger impressions on several of the chunks. No postholes were identified in the rooms, suggesting that the walls were load-bearing and indicating that the roof was not substantial. Room floors were thinly plastered with fine clay mud that is identical to, and occasionally copes into, the surviving wall plaster.

It is likely that Rooms 1 through 7, Room 9, Room 12, and Room 13 were all built during a single episode of construction; Room 10, the circular kiva, may also have been built at this time. Rooms 8 and 11 were added to the roomblock at a later time as is evidenced by the fact that their walls are abutted to the original front wall. The eastern and northern walls of Room 8 abut the circular kiva, suggesting it was built after Room 10. However, there is no evidence to show how much time elapsed between the first and second episodes of building. Instances of remodeling include a possible enlargement of Room 1 and the sealing of a doorway between Rooms 2 and 5. No outside activity areas were identified; however, this may be the result of the excavation plan, which focused on the roomblock itself.

LA 12587

LA 12587 is a seven-room pueblo that was inhabited sometime between the middle 13th century and early 14th century. The roomblock consists of two rows of rooms: four back rooms and three front rooms. The roomblock is oriented north-northeast by south-southwest. A 1350-m^2 midden is located to the east of the roomblock. Before the abandonment of this roomblock, construction began, but was not finished, on a second roomblock immediately to the west of the original roomblock. Several Classic period agricultural features are also present at LA 12587, including a fieldhouse that is situated on top of the original roomblock. Only the original structure is described here.

The four back rooms are between 6.1 and 9.3 m^2 in size and contain few features, none of which are hearths. The smallest front room is larger than the largest back room; the three front rooms range in size from 9.9 to 11.2 m^2 and all contain hearths and postholes. One of the front rooms also contains an ash box and deflector.

Walls are built of shaped and unshaped tuff blocks, adobe mortar, and chinking stones. Additionally, dacite cobbles are occasionally used as masonry and one adobe block was encountered during excavation. Most basal courses consist of large tuff uprights set into adobe and/or sunk beneath the floor surface. In one wall these uprights are covered with multiple layers of adobe (turtlebacks) forming a thick platform upon which the overlying course is laid. In several walls the basal course consists of core and veneer segments separated by upright tuff blocks that are perpendicular to the length of the wall. The veneer consists of a thick layer of adobe set with small tuff stones. The core consists of sediment and rubble. The basal course of one wall consists of two parallel rows of upright tabular tuff blocks. Sediment and rubble probably filled the space between these uprights. The few upper courses still present consist of coursed shaped and unshaped tuff blocks set in adobe and reinforced with chinking stones. In several isolated places a layer of plaster is present on the walls. It is likely that the entire wall face was originally plastered over.

Little rooffall was found at LA 12587 save in the southwest corner of the Room 2. Here rooffall consists of reed-impressed adobe chunks, chunks of burned adobe, and a partly charred juniper beam fragment.

Formally prepared floors were found in all rooms. Floor construction was often initiated with the deposition of small tuff rocks over the irregular Bw or Btk horizon or the bedrock surface. Next a thick layer of adobe was placed over the rocks to create a level surface and allowed to dry. Finally, one or more layers of plaster were then applied to the surface of the adobe and smoothed, resulting in an even floor surface. In many instances coping is present between the floor and the wall.

The six matching front and back rooms appear to have been built during a single construction episode. Because of poor corner preservation it is not clear if Room 9 was also built as this time or was added at a later date. Up to three floors (i.e., discrete layers of adobe) are present in the front rooms and several floors have multiple layers of plaster (possibly indicating seasonal rejuvenation of the floor).

While no clearly defined exterior activity areas were found at LA 12587, several features were found that may be associated with exterior activities. These features consist of an ashy stain in the midden that may be the remains of an informal hearth (Feature 3), a small cist built against the exterior of the east wall of Room 2 (Feature 5), a northern extension of the central wall of Roomblock 1 and an associated floor surface and ash stain (Feature 21), and a set of six bedrock grinding slicks immediately west of Roomblock 1 (Feature 13). Feature 21 may not be an exterior activity area; instead it may represent a remodeling episode. It is not clear which component of the site Feature 13 is associated with.

Room Function

Within linear Coalition period pueblos on the Pajarito Plateau the larger front rooms have traditionally been interpreted as habitation rooms and the smaller back rooms as storage rooms (e.g., Carlson and Kohler 1990:10). Ceremonial rooms are a third functional class. Figure 71.6 shows the distribution of room sizes for LA 4618, LA 12587, LA 86534, and LA 135290. The figure also indicates whether or not a room is a formal ceremonial room, how many types of features are in each room, and whether or not a hearth is present in the room (LA 4624 is not included in the figure due to lack of room feature data). Several patterns are apparent in this illustration. First, within any given roomblock the larger a room is the more likely it is to contain a hearth; larger rooms are also more likely to contain more types of features. These larger rooms with hearths are often in the front row of rooms and never in the back row (see Figure 71.5).

Table 71.1 shows how many and what types of features are present in each room of the four pueblos depicted in Figure 71.5. Formal ceremonial rooms are the largest, or nearly the largest, rooms in a roomblock and contain the most types of feature. All three ceremonial rooms in Table 71.1 contain a hearth, an ash box, a deflector, a vent shaft, a sipapu, two wall niches, and at least one other type of feature. Rooms with hearths are larger than rooms without hearths and contain at least one other feature type half the time (most often one or more postholes). Rooms without hearths rarely contain more than one type of feature and contain no features about half of the time. The most common small room feature is a subfloor pit.

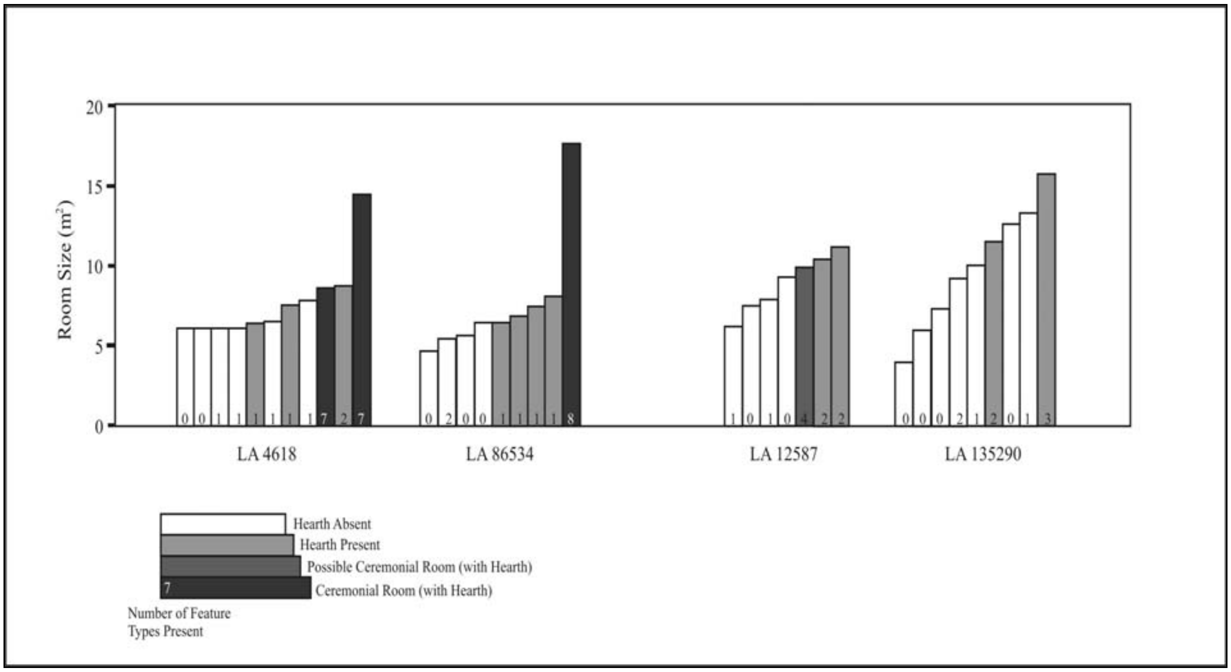

Figure 71.6. Room size at several Pajarito Plateau roomblocks.

In general, the tripartite ceremonial/habitation/storage room classification holds, however there is clearly more variability than this. Room 7 of LA 12587 appears to be “intermediate” between the ceremonial and habitation class. Like the formal ceremonial rooms it contains an ash box and deflector, but it does not contain any other “ceremonial” features. While Room 7 is the smallest habitation room at LA 12587, the east wall is absent causing uncertainty in estimating the room size; however, it is possible the room was up to 12 m^2, which would make it the largest room at the site. Further, use of the terms “habitation” and “storage” should, perhaps, be treated as classification terms, and not taken as literal interpretations of room function. For example, a massive amount of charred maize was recovered from Room 2 of LA 12587 indicating that cobs were stored in, or on the roof of, the room. The presence of a milling bin in Room 6 of LA 86534 indicates that milling activities also occurred in smaller back rooms. It is possible that there are functional differences between “storage” rooms that have features and those that do not. Finally, Rooms 9A and 9B of LA 135290, ramada-like rooms, may be in another functional category.

Table 71.1. Room feature information for selected roomblock sites.

Type	Site-Room	Loom Holes	Upright Block	Floor Groove	Floor Niche	Wall Niche	Sipapu	Vent Shaft	Deflector	Ash Box	Hearth	Posthole	Small Pit	Pot Rest	Milling Bin	Adobe Basin	Rock Feature	No Feature

	135290-9B																	X

C = Ceremonial, C/H = Ceremonial(?) and Habitation, H = Habitation, S = Storage

Regardless of how many room classes one wishes to make it is always possible to differentiate between storage (smaller, no hearth) and habitation (larger, with hearth) rooms within a roomblock. However, across roomblocks there is no standard size range for either type of room. One pattern that is evident is that at sites with formal ceremonial rooms, habitation and storage rooms tend to be smaller than habitation and storage rooms at sites without formal ceremonial rooms (see Figure 71.6). LA 4624, although not depicted in Figure 71.5, also fits this pattern; the largest non-ceremonial room at the site is 7.0 m^2 in size. This raises the possibility that there are functional differences between sites with and without formal ceremonial rooms (aside from obvious ceremonial functions). For example McBride (Chapter 62, this volume) has noted that maize kernels are more common at sites without formal ceremonial than at sites with ceremonial structures. That is, maize kernels were recovered from 52 percent and 41 percent of the flotation samples from LA 12587 and LA 135290, respectively, versus, 23 percent and 15 percent of the flotation samples from LA 4618 and LA 86534, respectively. McBride suggests that the non-kiva sites may reflect a greater emphasis on agricultural activities.

FIELDHOUSE SITE STRUCTURE

Twenty of the fieldhouses consist of a single room, with only one having two rooms. Seventeen of the one-room fieldhouses are rectangular in form and one is circular. The form of the two remaining one-room fieldhouses could not be determined due to extensive disturbance of their wall foundations. Enough of the wall foundations remained at one of these sites, however, to indicate that it was probably rectangular. The two-room fieldhouse was composed of a rectangular room and a smaller attached (and probably later) room that was trapezoidal in shape.

The wall foundations of the fieldhouses are generally constructed of dacite cobbles and/or slabs. In the case of 17 of the fieldhouses, the entire wall masonry consists of only dacite cobbles. The remaining fieldhouses have masonry that consists of a mix of dacite cobbles, tuff cobbles, and/or shaped blocks.

The height of the masonry was estimated for 16 of the fieldhouses. Estimated masonry heights were calculated based on the volume of wallfall removed during excavation and the overall length, average thickness, and average height of the extant portions of the walls. Estimated masonry heights for all 16 fieldhouses ranged between 0.94 and 1.63 m, with an average of 1.17 m. An examination of the distribution, however, indicates that there are several outliers. The calculated masonry heights of two sites (LA 85408 and LA 85417) are significantly higher than the average. Both of these sites were located in rocky areas. As a result, a significant amount of natural rock surrounding the fieldhouses was most likely included in the calculation of wallfall volume.

The estimated masonry heights of three other sites (LA 127635, LA 86607, and LA 15116) were significantly lower than the average. Much of the rock from the site with the lowest height (LA 127635) appears to have been utilized to construct a later fieldhouse located nearby (LA 127634). This may also be the case for the site with the second lowest height (LA 86607), which is located near a fieldhouse with ceramics of the same phase (LA 86606). The site with the third lowest height (LA 15116) is the only circular fieldhouse. This fieldhouse had very haphazard and poorly constructed walls and may have had a different function than the better-constructed, rectangular fieldhouses (e.g., it may have been a hunting blind rather than an agricultural fieldhouse). Excluding these potential outliers, the average estimated masonry height is 1.17 m, which is virtually identical to the overall average. The exclusion of the outliers, however, produces a tighter range of 0.94 to 1.63 m, which probably more accurately reflects the actual range in variation of the masonry heights of Ancestral Pueblo fieldhouses on the northern Pajarito Plateau.

There are no gaps in the wall foundations of most of the fieldhouses. This indicates that the entryways to these structures included a doorsill, which was most likely designed to keep out dust. Consequently, the location of the entryway could only be definitively determined for six of the fieldhouses. An educated guess as to the location of the entryway, however, was possible for an additional 11 fieldhouses. These data indicate that entryways were most commonly located to the east (n = 8), followed by the south (n = 4), and north (n = 2). East entryways were presumably popular because they took the greatest advantage of morning light from the rising sun. In those situations where it could be determined with certainty that the entryway did not face east, the decision to place it elsewhere appears to be a result of the structure's location. For example, if the fieldhouse was located on a slope, the entryway often faced downhill.

The upper portions of the walls and the roofs of the fieldhouses were most likely composed of wattle and daub. At most of the sites, however, only a few pieces of burned adobe, if any, were recovered. At one site (LA 85417), on the other hand, hundreds of pieces of burned adobe were encountered, many of which still had well-preserved wattle impressions. The preservation of daub at this site appears to be the result of a fire, which most likely destroyed the fieldhouse during or shortly after the site's occupation. The architectural remains from this site, together with the few pieces of burned adobe found at many of the other fieldhouses, indicate that the superstructures of Ancestral Pueblo fieldhouses on the northern Pajarito Plateau were constructed of wattle and daub.

No prepared floors were encountered within 13 of the fieldhouses. Excavation of most of these fieldhouses terminated at the top of the sterile and compact Bt horizon. Based on the height of this soil horizon relative to wall foundations, it most likely served as the foundation for the structures' floors, which are not preserved. Small patches of a thin clay floor were encountered directly on top of the Bt horizon in five fieldhouses. In all cases, these patches of floor were preserved as a result of exposure to heat. Large portions of a thin clay floor are preserved in three fieldhouses. In all three cases, the extant portions of the floors are concentrated around, and preserved as a result of the heat produced by, internal hearths. Finally, a well-preserved clay floor was encountered throughout the interior of a single fieldhouse (LA 85417). This is the same fieldhouse that was associated with hundreds of pieces of adobe that burned during a fire that destroyed the structure. Fortunately, the heat from this fire also preserved the floor. The floor is composed of a layer of clay a few centimeters thick on top of the Bt horizon. It does not appear to have been plastered. Most if not all of the fieldhouses probably had a similar floor.

Hearths were encountered at six of the fieldhouse sites. Three of these had a single internal hearth, one had a single external hearth, and one had both an internal and external hearth.

Finally, the two-room fieldhouse contained an internal hearth in each room. All of the hearths were simple pits with dacite cobbles and/or slabs forming all or part of their walls and/or bases. All of the hearths appear to have been lined with adobe, which was in various states of preservation. Some of the hearths also had evidence of an adobe collar around the hearth. In all cases, however, this adobe collar was in a very poor state of preservation. Maize was recovered from flotation samples from the hearths at five of the six sites, tobacco from the hearths at three of the six sites, and beans from a single hearth. A number of other species were also recovered from these hearths, which were presumably wild plants collected from nearby.

The number of artifacts recovered from the fieldhouse sites ranges from 9 to 772, with an average of 253. These artifact counts include ceramics, chipped stone, ground stone, faunal remains, and shell. The numbers do not include an Archaic component at LA 99396, which dramatically inflates the chipped stone artifact count. An above average number of artifacts were recovered from all five of the sites that contained hearths. All but two of the 15 sites without hearths, on the other hand, contained a below average number of artifacts. This suggests that the sites with hearths were more intensively occupied or occupied for a longer period of time than sites without hearths.

TIPI RING SITE STRUCTURE

Two late 19th or early 20th century tipi rings sites were excavated during the C&T Project. LA 85869 consists of two rock rings that are approximately 33 m apart on a northwest to southeast bearing. LA 85864 consists of a single rock ring that is located approximately 100 m to the north of LA 85859. Given the spatial proximity of both sites, it is possible that all three tipi rings are contemporaneous. Based on site type, the presence of *coscojo* fragments, glass trade beads, possible cone tinklers fragments, and micaceous ceramics (including sherds from at least one Cimarron Micaceous vessel), the cultural affiliation of LA 85864 and LA 85869 is interpreted as being Jicarilla Apache (see Appendix N).

Anschuetz (2000:22–23) notes that middle to late 19th century Jicarilla Apache tipi rings in the Rio del Oso Valley vary in size from 2.5 to 5.0 m in diameter (average and standard deviation = 3.9±0.8 m) and are composed of 4 and 60 stones (average and standard deviation = 14.0±9.0 stones). Many of these tipi rings have a central ash stain in their interiors and at least one ash and fire-cracked rock concentration a short distance to the east. The interior features include shallow, unlined earthen basin and rock-lined variants. In size and stone count, the LA 85864 and LA 85869 tipi rings are similar to the Rio del Oso Valley tipi rings (Table 71.2). Each C&T Project tipi ring has a central shallow unlined thermal feature; however, the only exterior thermal feature recorded is a possible hearth of unknown temporal affiliation at LA 85869. This feature is located approximately 15 m to the northwest of the nearest tipi ring.

Table 71.2. Tipi ring dimensions and stone counts.

Tipi Ring	Size (interior dimensions in m)	No. of Stones
LA 85864		
Feature 1	4.50 m north-south by 5.00 m east-west	13

Tipi Ring	Size (interior dimensions in m)	No. of Stones
LA 85869		
Feature 2	4.23 m north-south by 3.92 m east-west	22
Feature 4	3.25 m north-south by 3.75 m east-west	11

While structurally similar, each tipi ring has a different artifact assemblage associated with it. The LA 85864 artifact assemblage consists of three micaceous ceramic sherds from two vessels. Although three Coalition and/or Classic period sherds were also recovered, these are probably not associated with the Apachean occupation. Subsistence remains consist of four unidentified burned bone fragments recovered from the hearth and a charred and badly eroded possible wheat caryopsis (or seed). The paucity of artifacts may be due in part to the significant amount of erosion that has occurred to the immediate south and east of the tipi ring. The LA 85869 Feature 2 assemblage (i.e., artifacts found in and around the tipi ring) consists of 156 glass beads, 13 pieces of chipped stone debitage, three micaceous ceramic sherds from a single vessel, a .50 cal lead rifle ball, a split-shot lead sinker, and a small fragment of metal. The LA 85869 Feature 4 assemblage consists of a sandstone mano fragment, a dacite millingstone, three *coscojo* fragments, three possible cone tinkler fragments, a .50-caliber lead/alloy rifle ball with an impact surface, a straight pin or round wire fragment, and a can fragment cut into a 3.0 cm long strip. There is a 20- by 12-m chipped stone debitage scatter composed predominantly of obsidian artifacts immediately to the east of Feature 4. The debitage assemblage reflects a primary emphasis on the later stages of core reduction and a secondary emphasis on tool production/maintenance. A charred goosefoot seed was recovered from the thermal feature of this tipi ring; however, it is unknown if this seed is present due to food processing or of a wind blown seed.

Anschuetz (2000:23) notes that one-hand manos frequently occur in the northeast quadrant of the Rio del Oso Valley tipi ring interiors. This is where the senior woman of a household characteristically sat, worked, and slept (Felipe Ortega, personal communication 1998 in Anschuetz 2000:23). A mano fragment was located in the northeast quadrant of Feature 4, while a millingstone was located in the southeast quadrant of the ring. In general, most of the artifacts were found in the southeast quadrant of Feature 4 and nearly all the artifacts were found in the east half of the feature. In Feature 2 most of the lithic artifacts were found in the southern third and most of the beads were found in the eastern half of the feature.

CHAPTER 72
THE NATIVE AMERICAN CONSULTATION AND COMPLIANCE PROCESS FOR THE LAND CONVEYANCE AND TRANSFER PROJECT

W. Bruce Masse

INTRODUCTION

Native American compliance and consultation activities formed a significant component of the Land Conveyance and Transfer (C&T) Project archaeological excavations. This chapter outlines aspects of the compliance and consultation process. Specific highlights include (1) the determination of cultural affiliation for Los Alamos National Laboratory (LANL) lands with respect to the Native American Graves Protection and Repatriation Act of 1990 (NAGPRA); (2) Traditional Cultural Properties (TCPs); (3) consultation field visits and educational outreach for culturally affiliated tribes; (4) the development of the NAGPRA Intentional Excavation Plan and its implementation during and after project excavation, including the hiring and use of Tribal Monitors; (5) the repatriation of NAGPRA remains and objects to the Pueblo of San Ildefonso. Issues relating to the Tribal Monitor program and its ultimate success are further discussed in Volume 4 (Chapter 84). Because of the importance of NAGPRA cultural affiliation and the Intentional Excavation Agreement not only to the C&T Project itself but to the overall conduct of Native American tribal consultation and compliance at LANL, the text of these documents is provided below.

Figure 72.1. Laboratory Director Pete Nanos, Pueblo of San Ildefonso Governor John Gonzales, and Elmer Torres of the Laboratory Tribal Relations Team meet with C&T Project leadership at LA 135290 (October 16, 2003).

LEGAL BACKGROUND

Two laws provide the bulk of the federal requirements and guidance pertaining to Native American compliance and consultation activities associated with large-scale archaeological excavation on federal lands. These are the National Historic Preservation Act of 1966 (NHPA) and its subsequent amendments and NAGPRA. Other laws, regulations, Executive Orders, and policy directives also touch upon aspects of Native American compliance and consultation with regard to archaeological excavation at LANL, but NHPA and NAGPRA are the primary drivers.

Native American compliance and consultation associated with NHPA took three specific forms for the C&T Project archaeological excavations. The first was that of the review of the C&T Project survey report (Hoagland et al. 2000) in accordance with Section 106 of NHPA. The second was that of the identification and evaluation of potential TCPs. Although this action is typically conducted as part of the Section 106 process for the review of the survey report, as described below much of the actual consultation process was accomplished separate from the C&T Project itself. The third action in support of the NHPA was that of the development and review of the C&T Project data recovery plan (Vierra et al. 2002), which in addition to the Los Alamos Site Office (LASO) was approved by the Pueblo of San Ildefonso, the State Historic Preservation Officer (SHPO), and the federal Advisory Council on Historic Preservation (ACHP).

Native American compliance and consultation associated with NAGPRA took four specific forms for the C&T Project archaeological excavations. The first was the preparation of a study to assist in the formal determination by LASO of NAGPRA cultural affiliation with respect to human remains, associated funerary items, sacred objects, and objects of cultural patrimony (LANL 2007a). The second was the preparation of an Intentional Excavation Plan (NAGPRA Excavation Plan) for use by LASO and project excavators with culturally affiliated tribes (LANL 2007b). The third was the establishment of a Tribal Monitor program to assist during project excavations (encouraged but not required by NAGPRA). The fourth and final action was that of the actual NAGPRA repatriation process itself after the completion of the excavations.

NAGPRA CULTURAL AFFILIATION AT LOS ALAMOS NATIONAL LABORATORY

Background

NAGPRA is designed to develop a systematic process for determining the right of lineal descendants, Native Hawaiian organizations, and Indian tribes to certain Native American human remains, funerary objects, sacred objects, or objects of cultural patrimony with which they are affiliated. This law is particularly relevant to cases of intentional excavation and inadvertent discovery on federal lands, such as LANL.

In order to determine the rightful ownership of human remains and objects covered by NAGPRA, it is necessary for the federal agency to identify lineal descendants or Indian tribes who may be culturally affiliated with such discovered remains and objects.

Ownership under NAGPRA is stated as follows:

> *The ownership or control of Native American cultural items which are excavated or discovered on Federal or tribal lands after [1990] shall be (with priority given in the order listed)—*
>
> > *(1) in the case of Native American human remains and associated funerary objects, in the lineal descendants of the Native American; or*
> > *(2) in any case in which such lineal descendants cannot be ascertained, and in the case of unassociated funerary objects, sacred objects, and objects of cultural patrimony—*
> >
> > > *(A) in the Indian tribe…on whose tribal land such objects or remains were discovered;*
> > > *(B) in the Indian tribe…which has the closest cultural affiliation with such remains or objects and which, upon notice, states a claim for such remains or objects; or*
> > > *(C) if the cultural affiliation of the objects cannot be reasonably ascertained and if the objects were discovered on Federal land that is recognized by a final judgment of the Indian Claims Commission or the United States Court of Claims as the aboriginal land of some Indian tribe—*
> > >
> > > > *(1) in the Indian tribe that is recognized as aboriginally occupying the area in which the objects were discovered, if upon notice, such tribe states a claim for such remains or objects, or*
> > > > *(2) if it can be shown by a preponderance of the evidence that a different tribe has a stronger cultural relationship with the remains or objects than the tribe or organization specified in paragraph (1), in the Indian tribe that has the strongest demonstrated relationship, if upon notice, such tribe states a claim for such remains or objects.*

Cultural affiliation as defined under NAGPRA:

> *…means that there is a relationship of shared group identity which can reasonably be traced historically or prehistorically between members of a present-day Indian tribe or Native Hawaiian organization and an identifiable earlier group. Cultural affiliation is established when the preponderance of the evidence – based on geographical, kinship, biological, archaeological, linguistic, folklore, oral tradition, historical evidence, or other information or expert opinion – reasonably leads to such a conclusion.*

In brief, the three key steps for determining ownership of human remains and associated and unassociated objects under NAGPRA are first, to determine if there are known lineal descendants; second, in those cases where lineal descendants cannot be identified, to determine which Indian tribes are culturally affiliated; and third, in those cases where both lineal descendants and cultural affiliation cannot be ascertained, to determine which Indian tribes have the strongest claim based on a preponderance of the evidence for such remains.

While possible, it seems very unlikely that a direct lineal relationship can be established between living tribal members and specific Native American human remains discovered on LANL lands, including those that have been previously recovered. Therefore, on LANL lands the ownership of human remains and associated and unassociated objects under NAGPRA will rely heavily on the evidence for cultural affiliation.

The purposes of the cultural affiliation study are (1) to summarize the documentation collected to date for determining potential cultural affiliation for those Native American human remains that may be encountered during ground-disturbing activities at LANL and (2) to make recommendations as to which Indian tribes should have standing with respect to the purpose and intent of NAGPRA.

It is noted that since around 1994, LANL has consistently consulted with five tribes on issues relating to cultural resources management, which includes informing them of proposed construction projects and other issues surrounding cultural resources management at LANL. These include the "Accord Pueblos" of San Ildefonso, Santa Clara, Cochiti, and Jemez, each of which have signed agreements with the Department of Energy (DOE) and LANL, along with the Mescalero Apache Tribe. In addition, the Pueblo of Acoma and the Jicarilla Apache Nation have been recognized as having an active interest in cultural resources management at LANL.

In January 2002, a draft version of the present document was prepared (Masse 2002) and sent by LASO to all New Mexico Pueblos and to the Hopi Tribe in Arizona and Pueblo of Ysleta del Sur in Texas, as well as to the Jicarilla Apache Nation, the Mescalero Apache Tribe, the Navajo Nation, and the Ute Mountain and Southern Ute Tribes. The purpose of this action was to help initiate dialog and government-to-government consultation regarding the draft document and to elicit any recommendations for additions to, or changes in, the document based on oral traditions and other knowledge that might be applicable to the determination of NAGPRA cultural affiliation at LANL. While it is understandably difficult for tribes to share many aspects of their tribal knowledge with federal agencies, organizations, and individuals outside of their own tribe, some general information was passed on to LASO that is reflected in this document and discussed where appropriate.

It is understood that the subject of "cultural affiliation" can be a difficult and sometimes emotional topic for Native American tribes and for the agencies that attempt to define cultural affiliation and apply it to the myriad of laws and situations demanded by federal cultural resources management. It is based on at least partially conflicting principles and goals among the various laws. It forces tribes to categorize and think about their world in ways that do not necessarily mesh with traditional concepts of identity and boundaries. The concept of cultural affiliation does not necessarily remain static and may evolve and change in response to legal challenges and changing paradigms in academic anthropology and archaeology. It may contain social and political implications that can become divisive for the dynamics of tribes and cultural resource managers. And finally, the attempt to deal with cultural affiliation can seem like an unnecessary burden or even a barrier to some tribes and tribal members, particularly when applied inconsistently or poorly, without regard to the participation of all tribes and tribal members who may have opinions and views that should be heard.

There are a number of recently published studies that review the conflicts surrounding the definition and application of "cultural affiliation" and other related legal requirements by federal agencies (e.g., Biolsi and Zimmerman 1997; Ferguson 2004; Fine-Dare 2002; James 2001; Mihesuah 2000; Swidler et al. 1997), but they also provide thoughtful insights as to how to help resolve or avoid the painful aspects of conflicts. Other studies highlight the importance for agencies to work with tribes in order to recognize and preserve traditional cultural landscapes and their features (Feld and Basso 1996; Gulliford 2000; King 2003).

It is noted that this cultural affiliation determination document supports all other NAGPRA-related activities and documents at LANL including the LANL NAGPRA Inadvertent Discovery Plan issued in 2007 (LANL 2007b; LA-UR-06-6712) and any specific NAGPRA Intentional Excavation Agreements that may be prepared due to future mission requirements at LANL.

Definitions

- **Burial site** means *"any natural or prepared physical location, whether originally below, on, or above the surface of the earth, into which, as a part of the death rite or ceremony of a culture, individual human remains were deposited, and includes rock cairns or pyres which do not fall within the ordinary definition of grave site"* [43 C.F.R. 10.2(d)(2)].

- **Cultural affiliation** means *"that there is a relationship of shared group identity which can reasonably be traced historically or prehistorically between members of a present-day Indian tribe…and an identifiable earlier group"* [43 C.F.R. 10.2(e)].

- **Funerary objects** mean *"items that, as a part of the death rite or ceremony of a culture, are reasonably believed to have been placed intentionally at the time of death or later with or near individual human remains. Funerary objects must be identified by a preponderance of evidence as having been removed from a specific burial site of an individual affiliated with a particular Indian tribe…or as being related to specific individuals or families or to known human remains"* [43 C.F.R. 10.2(d)(2)].

- **Sacred objects** mean *"items that are specific ceremonial objects needed by traditional Native American religious leaders for the practice of traditional Native American religions by their present-day adherents. While many items, from ancient pottery sherds to arrowheads, might be imbued with sacredness in the eyes of an individual, these regulations are specifically limited to objects that were devoted to a traditional Native American religious ceremony or ritual and which have religious significance or function in the continued observance or renewal of such ceremony"* [43 C.F.R. 10.2(d)(3)].

- **Objects of cultural patrimony** mean *"items having ongoing historical, traditional, or cultural importance central to the Indian tribe or Native Hawaiian organization itself, rather than property owned by an individual tribal or organization member. These objects are of such central importance that they may not be alienated, appropriated, or conveyed by any individual tribal or organization member. Such objects must have been considered inalienable by the culturally affiliated Indian tribe…at the time the object was separated from the group"* [43 C.F.R. 10.2(d)(4)].

- **Indian tribe** means *"any tribe, band, nation, or other organized group or community of Indians, including any Alaska Native village or corporation as defined in or established by the Alaska Native Claims Settlement Act (43 U.S.C. 1601 et seq.), which is recognized as eligible for the special programs and services provided by the United States to Indians because of their status as Indians"* [43 C.F.R. 10.2(b)(2)].

- **Intentional excavation** means *"the planned archaeological removal of human remains, funerary objects, sacred objects, or objects of cultural patrimony found under or on the surface of Federal or tribal lands pursuant to section 3(c)"* of NAGPRA [43 C.F.R. 10.2(g)(3)].

- **Inadvertent discovery** means *"the unanticipated encounter or detection of human remains, funerary objects, sacred objects, or objects of cultural patrimony found under or on the surface of Federal or tribal lands pursuant to section 3(d)"* of NAGPRA [43 C.F.R. 10.2(g)(4)]. For the purpose of this procedure, inadvertent discoveries are also assumed to include the discovery of potentially intact archaeological deposits in locations not previously identified as archaeological sites. Such deposits must be evaluated for their archaeological significance and for the possibility that they may contain unexposed human remains or NAGPRA-related objects.

- **Isolated remains and cultural objects** are individual human elements and NAGPRA-related cultural objects that when discovered are not located in the context of a burial site.

For the purposes of the C&T Project and other NAGPRA-related activities and planning at LANL:

- **Cultural objects** refer specifically to NAGPRA funerary objects, sacred objects, and objects of cultural patrimony.

- **Archaeological deposits** refer to intact archaeological contexts that require evaluation for their potential to yield human remains and cultural objects.

- **Tribal contacts** mean the designated representatives of the Indian tribes discussed in the section on Cultural Affiliation.

- **Government-to-government consultation** refers to consultation between the federal agency (LASO) and Indian tribes in compliance with federal historic preservation laws and regulations.

- **LASO Cultural Resources Program Manager** is the individual designated by LASO to oversee LASO's compliance with federal historic preservation laws and regulations, the LANL Cultural Resources Management Plan (CRMP), and cultural resources government-to-government consultation between Indian tribes and LASO.

- **LANL Cultural Resources Team (CRT)** refers to the internal organization and associated subject matter experts assigned by the Laboratory Operations Management Contractor to assist LASO with implementation of the LANL CRMP. As of June 2006, the LANL CRT is part of the Ecology and Air Quality Group within the Environmental Protection Division.

- **LANL CRT Native American Consultation Lead** refers to that person on the LANL CRT who is designated by the Team Leader to assist the LASO Cultural Resources Program Manager with facilitating cultural resources government-to-government consultation between LASO and Indian tribes.

- **NAGPRA Intentional Excavation Agreement** is a document prepared in compliance with NAGPRA in support of planned archaeological excavations on federal lands.

NAGPRA Cultural Affiliation Evidence

For convenience, this cultural affiliation documentation and evidence summary is divided into four basic categories: Geography and Historical Evidence; Tribal Knowledge and Oral Tradition; Archaeological Evidence; and Physical Anthropological Evidence. These categories are meant to be inclusive of all the various evidentiary classes noted in the NAGPRA law.

Geography and History

The Pajarito Plateau is a large, southeastward-sloping tableland perched on the eastern margin of the Jemez Mountains in northern New Mexico. It represents the erosional remnant of consolidated ash deposits (tuff) that erupted more than one million years ago from the Valles and Toledo volcanoes. The Pajarito Plateau is bounded by the Jemez Mountains to the west, Cañada de Cochiti to the south, the Rio Chama Valley to the north, and on the east by the Rio Grande. The approximately 27,000 acres within the boundaries of LANL are perched in the virtual center of this peculiar geological formation (Powers and Orcutt 1999b:7–11).

LANL manages three tracts of land, including two parcels that are discontiguous from the large tract situated between Bandelier National Monument and the Los Alamos town site. One of the discontiguous parcels is situated in Rendija Canyon immediately north of the Los Alamos town site. The second is a small parcel situated at Fenton Hill, about 25 miles west of the Los Alamos town site and some 15 miles to the northeast of Jemez Springs. It is noted that in the discussion that follows, the term "LANL" will refer to just the two tracts on the Pajarito Plateau immediately adjacent to the Los Alamos town site (LANL proper and Rendija Canyon).

There are 19 federally recognized tribes whose reservations are situated within 100 miles (160 km) of LANL. Eighteen of these are New Mexico Pueblos whose members speak five different languages that fall into three language groups (Cordell 1994; Hale and Harris 1979). The largest Pueblo language group is the Tanoan, which includes the Tiwa (divided into southern and northern dialects), Tewa, and Towa languages. The second is Keresan (divided into the western and eastern dialects). Zuni is the third Pueblo language group, which is spoken by only a single Pueblo. The remaining New Mexico tribe within 100 miles of LANL is the Jicarilla Apache, who belong to the Apachean family of languages in the overall Athapaskan language group. According to language specialists, there are seven Apachean-speaking tribes in the Southwest (Opler 1983a; Young 1983). In addition to the Jicarilla Apache, there are the Chiricahua, Kiowa-Apache, Lipan, Mescalero, Navajo, and Western Apache. Of these seven groups, the Navajo, Jicarilla, and the Western Apache had the greatest degree of interaction with the Pueblos (Opler 1983a:380).

In terms of proximity to Los Alamos, the 19 New Mexico tribes within 100 miles are the Tewa-speaking Pueblos of San Ildefonso, Santa Clara, and Tesuque; the eastern Keresan-speaking Pueblo of Cochiti; the Tewa-speaking Pueblos of Pojoaque, Nambe, and San Juan; the Towa-speaking Pueblo of Jemez; the eastern Keresan-speaking Pueblos of Santo Domingo, San Felipe, Santa Ana, and Zia; the northern Tiwa-speaking Pueblos of Picuris and Taos, the southern Tiwa-speaking Pueblos of Sandia and Isleta; the western Keresan-speaking Pueblo of Laguna; the Jicarilla Apache; and the western Keresan-speaking Pueblo of Acoma. In addition, there are six tribes (Hopi, Navajo, Mescalero Apache, Ute Mountain Ute, Ysleta del Sur, and Zuni) which, although beyond this 100-mile radius, nevertheless have some historical connections to northern New Mexico.

In the period of 1540 through 1598, at the time of expeditions of Francisco Vásquez de Coronado through that of Juan de Oñate, the geographical configuration and placement of Native American tribes largely approximated that which we see today (Ortiz 1979a), at least for northern New Mexico. This situation is true despite the subsequent depredations of the Spanish explorers and colonists, which resulted in the destruction or relocation of a number of individual Pueblo villages (Snow 1981:366), and despite the impact of more recent Euroamerican influences. Such geographical stability is particularly marked for the Rio Grande in the vicinity of the Pajarito Plateau, in part because the Spanish saw little economic or commercial value in the resources of the Pajarito Plateau.

Among the Native American groups noted in their present locations by these early (1540–1598) explorers were the four pueblos currently sharing accord agreements with LANL and LASO: Cochiti, Jemez, San Ildefonso, and Santa Clara. At least some scholars make a reasonable argument that the Jemez and Tewa Pueblos (including the large Classic period pueblos on the Pajarito Plateau such as Tsirege and Tsankawi) were visited or otherwise noted in 1542 during the Coronado Expedition (e.g., Schaafsma 2002:201–203). Schroeder (1979:250) provides the following general description of the Tewa Pueblos based on Castaño de Sosa's visit in 1590:

> Castaño de Sosa, the next to visit the Tewas, stopped at a small Pueblo (Tesuque), where he noted tortillas, maize, and turkeys. Four other Pueblos, one league apart and two to three stories high, were heavily populated (Cuyamungue, Nambe, Pojoaque, and Jacona). Maize, flour, beans, squash, tortillas, turkeys, and bows and arrows were seen at the second one. Two leagues beyond was large Pueblo (San Ildefonso) with four houseblocks of adobes (apparently coursed adobe), two to three stories high, well whitewashed, with ovens and very large plaza with exits at each corner. In its center was a big round house (kiva), half above and half below ground, containing many idols as in the previous Pueblos, wherein the people gathered on certain occasions to perform ceremonies. A large area was under irrigation, as in the previous Pueblos, and the people dressed the same as at Pecos. Upriver were two more Pueblos (San Juan and Pioge), across the river another (Yunque), one league from which was another (Teewi), and downstream the last of these Pueblos was Santa Clara.

The timing and nature of the entrance of Apachean-speaking groups into the Southwest has been a matter of considerable controversy (Towner 1996a; Vierra 1992a; Wilcox and Masse 1981). They clearly were already present at the time of the initial Spanish explorations in the 16th century (Gunnerson 1979; Opler 1983a; Wilcox 1981). However, in the past most scholars have argued that the Apachean-speaking groups arrived from the Plains only a few years before the Spanish (e.g., Cordell 1997:376–377). More recent archaeological research in northwestern New Mexico (e.g., Brown 1996; Brugge 1992, 1996; Hancock 1992; Winter and Hogan 1992) suggests that at least some Apachean groups were present no later than the middle of the 15th century, and perhaps earlier, although there are some notable dissenters to such early dating (e.g., Schaafsma 1996, 2002).

Also somewhat problematic is the presence of the Southern Numic-speaking Utes, a member of the Numic group of Uto-Aztecan languages shared by most of the Great Basin tribes. The Ute Mountain Utes and the Southern Utes currently live on two reservations on the border between Colorado and New Mexico. During the late prehistoric and early historic periods the Utes were nomads who ranged across much of the northern Colorado Plateau. It is believed that they had arrived in the Four Corners area by no later than the beginning of the 16th century, and perhaps as early as the beginning of the 14th century (Schaafsma 1996:31). A few scholars have argued that at least some of the population dislocation and possible warfare present in the Four Corners during the 12th through 15th centuries was due to the Utes (Cordell 1997:376–377), although the evidence is currently problematic. The San Juan River and the Continental Divide have been identified as the southern and eastern boundaries for the Historic period Utes (Schaafsma 1996:33), but this does not preclude hunting or raiding trips into the area around the northern Jemez Mountains.

The 1680 Pueblo Revolt against the Spanish and a subsequent smaller revolt in 1696 were in part inspired by Tewa-speaking political and religious leaders. These revolts led to a number of changes as individual village members and indeed in some cases whole Pueblo communities fled to the protection of other villages and tribes in the attempt to escape Spanish retaliation. It was at this time that Tewa villagers from the Galisteo Basin near Santa Fe left New Mexico to live among the Hopi of Arizona. Their descendants are still present as the village of Hopi-Tewa at First Mesa on the Hopi Indian Reservation (Dozier 1966; Stanislawski 1979). Likewise, a sizable number of Tiwa-speaking occupants of Isleta Pueblo fled to the vicinity of El Paso, Texas, along with a number of displaced Piro and Tompiro language speakers (now extinct Tiwa-speaking populations that had been along the Rio Grande south of Albuquerque), and a few refugees from Jemez. Most of the Isleta Tiwa-speaking refugees eventually settled at what is now called Ysleta del Sur ("Southern Isleta") Pueblo (Beckett and Corbett 1992; Ellis 1979:353–354).

The movement of individuals and villages in northern New Mexico during and after the Pueblo Revolt is symptomatic of the considerable fluidity between tribes throughout the period of 1540 to 1850 (Lange 1979a). This fluidity seemingly represents in part the Spanish encouragement of regional trade and in part patterns of warfare stemming from conflicts between the Spanish and the French, the latter which played a significant role in encouraging the 18th century raiding by Comanches from the southern Great Plains throughout much of northern New Mexico. The Comanche are a Numic-speaking people closely related to the Utes. The Comanche were among the first Native Americans to adapt the use of horses (introduced by the Spanish during the 16th century) as a key element of their nomadic hunting and raiding lifestyle. The Comanches and Utes together and separately are known to have conducted raids from Pecos to Abiquiu (Towner 1996b:166), an area that would have touched upon the Pajarito Plateau. Indeed, as noted below a Tewa place name in Guaje Canyon just north of LANL commemorates a historic encounter with a Comanche raider.

Ultimately, the Utes and the Jicarillas entered into an alliance against the Comanche and Kiowa. In 1779, a campaign was mounted by the Spanish against the Comanche that included Pueblos, Utes, and Jicarillas as allies against the Comanche (Tiller 1983). However, even this alliance vacillated. In 1786, a treaty between Comanches with the Spanish and Puebloan tribes was used as a device to host a campaign by Comanches, Utes, Navajos, Puebloans, and Jicarillas against the Gila Apache (Western Apache).

It is likely that during this period (the 18th century) the Utes came to view the northern Jemez Mountains to be within the limits of their hunting and raiding excursions, and it was likewise at this time or slightly earlier that the Jicarilla Apache established camping grounds just to the west of San Juan Pueblo and also near Abiquiu, a pattern evident by 1850 (Figure 1 in Tiller 1983). The Jicarillas living in the vicinity of San Juan Pueblo were known as the Olleros (Potters), a band distinct from the Llaneros (Plainsmen) who lived to the east of the Rio Grande. As a matter of practicality, the Jicarilla adopted the material culture of the Plains Indians, including the use of the tipi.

At this time it is appropriate to address the relationship between the Jicarilla and the Mescalero Apache. It is generally thought that the aboriginal range of the Mescalero Apache never extended much to the west of the Rio Grande nor north of Albuquerque (Opler 1983b), and thus seemingly the Mescalero were unlikely to have much of a presence in the Jemez Mountains. However, it is noted that the Mescalero did take part in the Pueblo Revolt, and they did maintain relations with other Apachean groups. The mobility of these groups, particularly during the middle and late 19th century in response to changing climatic conditions and pressures from the U.S. government (e.g., Bourke 1971; Geronimo 1971) suggests that small numbers of Mescaleros and Jicarillas and perhaps even other Apachean groups could have been present on brief occasions in the Jemez Mountains and the Pajarito Plateau.

Navajo history during the period of 1540 through 1850 is largely mingled with that of their Puebloan and Apachean neighbors, which is not surprising given the vast range of Navajo settlement and activities throughout the Four Corners area. According to Brugge (1983:Figure 1), as early as 1600 Cerro Pedernal, at the northern end of the Jemez Mountains, was at the eastern edge of the range of Navajo settlement. By the 1700s, this range had extended along the western flanks of the Jemez Mountains and almost as far to the east as to Abiquiu, but it apparently did not extend to the Pajarito Plateau itself. By the 1800s, the range of Navajo settlement had contracted back further to the west. Although actual Navajo settlement was not documented for the Pajarito Plateau and along the Rio Grande, it is possible that brief raids and hunting trips did occur in the area from time to time. Wilcox (1981:231) also points out that early Navajo may have occupied ancestral Tewa territory in the Piedra Lumbre Valley in the Upper Chama valley, a location near Cerro Pedernal.

Oral Historical Evidence

Ethnographers and archaeologists did not start gathering traditional knowledge from the northern New Mexico tribes until the late 19th and early 20th centuries, in some cases long after Euroamericans had greatly altered the configuration and boundaries of traditional tribal lands. The earliest attempts to gather tribal oral histories regarding the use of the Pajarito Plateau, including the area now occupied by LANL, were those by Adolph Bandelier and Edgar L. Hewett, which were summarized and amplified in John Peabody Harrington's now classic *The Ethnogeography of the Tewa Indians* (1916). Other notable related collections include Robbins et al. (1916) *The Ethnobotany of the Tewa Indians*, Henderson and Harrington's *The Ethnozoology of the Tewa Indians* (1914), and the Hewett et al. (1913) treatise on Rio Grande physiography in relation to Pueblo peoples.

A quote from Hewett (1906:12) provides a good starting point for dealing with oral traditions relating to the Pajarito Plateau:

> The ruins herein described were the ancient habitations of Indian tribes some descendants of which are doubtless now living in the adjacent valley of the Rio Grande and its tributaries, but most of whom are probably dispersed widely over the southwest. In every existing Tewa tribe (San Juan, Santa Clara, San Ildefonso, Nambe, and Tesuque) it is claimed that certain clans may be traced back through one or more migrations to the ruined pueblos and cliff-villages of the Pajarito plateau. The same may be said of the Keres villages (Cochiti, Santo Domingo, San Felipe, Santa Ana, and Zia), while it is known that the earlier Jemez people and their kindred occupied sites farther up the valley well into the historic period.
>
> ....It must be remembered that the foregoing statements refer to the period of continuous residence on the plateau. There have been from time to time in comparatively recent years sporadic reoccupations of these ancient villages by clans from the valley, as that of Puyé by the Santa Clara Indians, and of Kotyiti, or Pueblo Viejo, above the Cañada de Cochiti, by the Keres after the Pueblo rebellion of 1680. These reoccupations were attended with considerable rebuilding and repairing of ancient structures....

In treating the topic of oral traditions, four aspects are considered here. The first includes those traditions relating specifically to the peoples who constructed and used the Ancestral Puebloan remains at and around LANL. The second treats traditions relating to multi-tribal shrines (sacred places) on and near the Pajarito Plateau. The third deals with traditions regarding the migrations and origins of the Tewa and Keresan populations in the vicinity of the Pajarito Plateau, as well as similar traditions by non-Puebloan tribes. The fourth includes statements gathered from various tribes as part of the 1999 Department of Energy Site-Wide Environmental Impact Statement for continued operations at Los Alamos National Laboratory (DOE SWEIS).

LANL/Bandelier National Monument Oral History

It was clear from Harrington's work, which he largely conducted in 1910, that the area now occupied by LANL was considered by the people of San Ildefonso Pueblo to have been a critical part of their aboriginal territory. It is also noted that in 1919, and thus somewhat contemporary with Harrington's study, "*the Board of Indian Commissioners reported that San Ildefonso had probably suffered greater land loss through squatters than had any other Pueblo. In addition, commercial (non-Indian) timber removal on the hills above the Pueblo drastically affected the terrain and watershed*" (Edelman 1979:312). This statement obviously refers to the establishment of Hispanic and Anglo homesteads, beginning in the 1890s, on the Pajarito Plateau in and around the present location of LANL, along with the widespread and wholesale commercial cutting of juniper, the stumps of which are still visible in large numbers throughout the piñon-juniper woodlands at LANL.

In Harrington's study, residents of San Ildefonso Pueblo were able to identify and name a large number of specific places throughout the central Pajarito Plateau between Chupaderos Canyon to the north of the modern Los Alamos town site and Frijoles Canyon to the south in modern Bandelier National Monument (1916:Maps 16, 17). This area encompasses all of LANL, including the DOE property in Rendija Canyon immediately south of Guaje Canyon, with the single exception of the Fenton Hill property near Jemez Springs.

Harrington (1916:Map 14) depicts the southern boundary for Santa Clara Pueblo and thus the northern boundary for San Ildefonso Pueblo as being between Garcia Canyon and Chupaderos Canyon immediately north of Guaje Canyon. The large Classic period (AD 1325–1600) Ancestral Pueblo villages of Puye and Shufinne located in or adjacent to Santa Clara Canyon, along with the cavate structures associated with these villages, are attributed at least in part to the ancestors of Santa Clara village (see also Arnon and Hill 1979:296). However, Harrington (1916:237–238) notes that Frederick Hodge felt that other Tewa Pueblos in addition to Santa Clara also had ancestors at Puye and Shufinne.

The largest known Coalition period (AD 1200–1325) Ancestral Pueblo village site on the Pajarito Plateau, Guaje Pueblo, is presently situated on US Forest Service land on the north side of Guaje Canyon. Although the canyon is within the aboriginal boundaries of San Ildefonso Pueblo, apparently in the early AD 1800s a group of Santa Clara Indians lived in the canyon bottom close to Guaje Pueblo (Harrington 1916:266).

Guaje Pueblo is also situated along a trail that originally was used by the Tewa when traveling to Jemez Pueblo (Harrington 1916:265). Along a tributary wash of Guaje Canyon is the location named "where the Comanche fell down." This spot commemorates the time that a Comanche Indian, pursued by the Tewa, fell over a cliff and died (Harrington 1916:267). On a mesa west of the beginning of Pueblo Canyon is a spot called "mesa where the donkey was killed" (Harrington 1916:269). This spot is said to commemorate the location of where a Tewa donkey, stolen from a corral by a Navajo, fell off of a cliff after the Navajo was pursued by armed Tewa.

Otowi (Potsui'i) is a large Classic period Ancestral Pueblo village that is situated on lands transferred to the Pueblo of San Ildefonso in 2002 as part of the Congressionally mandated C&T Project (Public Law 105-119). Otowi contains five major multistoried roomblocks, with an estimated combined total of around 450 individual ground floor rooms. Archaeological evidence suggests that Otowi was initially founded in the transition between the Coalition and Classic periods (ca. AD 1300–1350). Hewett (1906:20) notes:

> The traditions of Otowi are fairly well preserved. It was the oldest village of Powhoge clans of which they have definite traditions at San Ildefonso. They hold in an indefinite way that before the building of this village they occupied scattered "small house" ruins on the adjacent mesas, and they claim that when the mesa life grew unbearable from lack of water, and removal to the valley became a necessity, a detachment from Otowi founded the pueblo of Perage in the valley on the west side of the Rio Grande about a mile west of their present village site.

The "small house" ruins noted by Hewett is a clear reference to the many Coalition period roomblocks and plaza pueblos scattered throughout the mesa tops within the boundaries of LANL and elsewhere on the Pajarito Plateau.

About two miles southeast of Otowi is Tsankawi (Saeewi'i), another large Classic period Ancestral Pueblo village situated on land now operated by the National Park Service as a noncontiguous parcel of Bandelier National Monument. Harrington notes that he was emphatically told that the people living at Otowi and at Tsankawi were ancestors specifically to the people of San Ildefonso and not to any of the other Tewa villages. Hewett (1938:48) notes that for Tsankawi,

> The inhabitants, it is claimed were Tewa, related to the people of Otowi. They are alleged by some informants to have migrated to the region south of Santa Fe; by others, to have merged with Otowi clans to form the San Ildefonso community.

On LANL property, just west of the town site of White Rock, is the large Classic Ancestral Pueblo period village of Tsirege. Hewett (1938:50) states:

> It was the largest pueblo in the Pajarito district, and with the cliff villages [cavates and associated talus rooms] clustered about it, the largest aboriginal settlement, ancient or modern, in the Pueblo region, of which I have personal knowledge, with the exception of Zuñi. The ruin shows a ground plan of upward of six hundred rooms.... Tsirege is said to have been the last of the villages of Pajarito Park to be abandoned.

Harrington (1916:283) was told by residents of San Ildefonso that, as with Otowi and Tsankawi, only the ancestors of San Ildefonso and not the other Tewa villages lived at Tsirege. Harrington also notes that a Cochiti informant confirmed that the Tewa lived at Tsirege.

Harrington (1916:278) suggests that the ancestral boundary between San Ildefonso Pueblo and Cochiti Pueblo is situated immediately north of Frijoles Canyon near the present southern boundary of LANL. As cited in Powers and Orcutt (1999b:575), the boundary may coincide with Ancho Canyon immediately south of Water Canyon and within the boundaries of LANL. The analysis conducted by Powers and Orcutt (1999b:575–576) suggests that this cultural boundary was "permeable" and may have shifted to the northeast during the Classic period. Recent government-to-government discussion by the LASO Cultural Resources Program Manager and the LANL CRT with cultural specialists from the Pueblos of San Ildefonso and Cochiti suggests that there may be some overlapping tribal claims between Frijoles Canyon to the south and Water Canyon to the north.

Cochiti oral history appears to be very specific in regards to their relationship with the Pajarito Plateau. Lange (1959:7) notes:

> ...some claim to have lived …at Frijoles Cañon 'along with all the other Pueblo Indians.' Although this latter claim is overly inclusive in light of present anthropological research, there does appear to be a general inclination to agree that the Cochití and probably other Keresans (and perhaps other linguistic groups as well?) occupied Frijoles until a few centuries before the advent of the Spanish in 1540...
>
> In the vicinity of the reservation and within the pueblo itself potsherd collections show a sequence extending from the present back to Glaze 1 red and yellow wares, with dates as early as A.D. 1225. Other sites, such as Pueblito, west of Cochití in the Santa Fe National Forest, show pottery types of the period 1050-1250. The Cochití, however, claim no direct association with the majority of these ruins other than those in and adjacent to Frijoles Cañon, including those in association with the well-known Stone Lions of Cochití, and those above and in Cañada de Cochití.

These claims are of interest both from the perspective of the ancestral affiliation that Cochiti shares with the cultural resources of Bandelier National Monument, and with the acknowledgment that other Keresan villages and potentially other language groups (such as the Tewa) occupied areas immediately adjacent to Frijoles Canyon and Cañada de Cochiti on the Pajarito Plateau. Apparently, Santo Domingo viewed their relationship to Frijoles Canyon and surrounding areas in a manner very similar to that of Cochiti (Lange 1979b:379).

Of particular interest are the traditions surrounding the Ancestral Pueblo village site of Kuapa whose ruins are situated in Cañada del Cochiti about five miles north of Cochiti Pueblo. According to Adolph Bandelier, the ancestors of Cochiti Pueblo and San Felipe Pueblo lived in Kuapa as one people sometime before the advent of Coronado expedition in 1540 (Strong

1979:392). Bandelier's version of this tradition is as follows (cited in Haas and Creamer 1992:25):

> [T]he village of Kua-pa was once attacked by the Tehuas [Tewas] and captured. The survivors retreated to the Portrero Viejo; the Tehuas pursued, but their attack upon the lofty cliff signally failed. They were defeated and driven back across the Rio Grande, many of them are said to have perished in that river, and the Tehuas never troubled the Queres [Keresans of Kuapa] again. In consequence of these hostilities, the survivors established themselves on the potrero [high cliff] for a short time, whence they descended to settle where Cochiti stands to-day.

This story and other traditions, including information from current cultural specialists at Cochiti and San Ildefonso, indicate that the approximate location of the boundary between Cochiti and San Ildefonso in the vicinity of Frijoles Canyon and Water Canyon goes back at least as early as the 15th century. However, more recent interviews (e.g., Martinez and Suina 2005) illustrate how difficult it is to draw precise boundaries.

Multi-Tribal Shrines

Shrines are an important part of traditional cultural landscapes (Anschuetz 1998), being associated with trails, cultural boundaries, important resource locations, and the locations of important tribal or clan events.

The Coalition and Classic period resources of the main unit of Bandelier National Monument in and around Frijoles Canyon are attributable to the ancestors of Cochiti Pueblo and perhaps other Keresan Pueblos. Notable, however, is the fact that although Keresan ancestors are said to have constructed the famous shrine of the "stone lions" immediately west of the ruins of Yapashi village, other tribes have also historically come to venerate this particular shrine. For example, Hewett (1938:55) states:

> This was the most important hunting shrine in the entire Pueblo region. Until very recent times it has been visited by Indians from as far away as Zuñi.

It is unclear as to what degree the historic publicity surrounding the Stone Lions, since at least the time of Adolph Bandelier's studies in 1880s, may have contributed to the interest and claims by tribal groups other than Cochiti Pueblo and other Keresan pueblos.

The presence of notable shrines on the Pajarito Plateau and adjacent regions that serviced more than one Pueblo and even perhaps members of different language groups is of considerable interest. There are at least two other known shrines utilized by Tewa speakers that crossed ethnic/linguistic boundaries. One is on Cerro Toledo in the Jemez Mountains. The Cerro Toledo example is a so-called "world quarter" shrine that apparently was used by people from the Pueblos of Taos, San Juan, Santa Clara, San Ildefonso, Cochiti, and Jemez (Douglass 1912). The other multi-tribal shrine is an alleged Keresan "emergence shrine," also seemingly utilized by Tewa-speakers, that was reported along the Rio Caliente some 55 miles north of Santa Fe (Devereux 1986).

Such potential multi-tribal shrines are not known at LANL. It is noted that ongoing consultations will likely identify several locations at LANL that have traditional cultural and/or religious significance for specific pueblos, particularly San Ildefonso, and possibly for specific non-Puebloan tribes as well. However, historic records and the ongoing discussions thus far make it seem unlikely that multi-tribal shrines are present at LANL.

Origin and Migration Traditions

The Tewa Pueblos have a widespread tradition that they migrated to the Pajarito Plateau from the north and west of their present locations along the Rio Grande (e.g., Whitman 1947:4). For some Tewa their original homeland and place of emergence was from a lake in the general region of southern Colorado (Arnon and Hill 1979:296; Ortiz 1979b:278; Parsons 1994). The Tewa were led in this migration by the Hunt chief, a man who had been given supernatural powers and assumed the shape of a mountain lion (Ortiz 1969:14–15):

> [T]he Hunt chief divided the people between the Summer chief and the Winter chief. Those who were to follow the Summer chief would proceed south along the mountains of the west side of the Rio Grande. The Winter chief and his group would proceed along the mountains on the east side of the river. The Summer People, as the former group came to be called, subsisted by agriculture and by gathering wild plant foods, while the Winter People subsisted by hunting. Each group "took twelve steps" (made twelve stops) on this journey, and after each step they built a village....

Although Alfonso Ortiz (1979b:280), a member of San Juan Pueblo and noted 20th century anthropologist, was hesitant to directly link the Tewa with the people who built the spectacular cliff dwellings in the Mesa Verde area of southern Colorado, at least some modern Tewa, including those at San Ildefonso, believe that at one time they indeed lived in vicinity of the Mesa Verde area (Edelman 1979:312). They claim affinity to the cultural resources of the Mesa Verde National Park, a claim recognized by the National Park Service. Archaeologists have long speculated that the large increase in population during the Late Coalition and Classic periods on the Pajarito Plateau is linked with widespread abandonment of the San Juan Basin and the northern San Juan (including both Chaco Canyon and Mesa Verde) during the period of AD 1150–1300 (Cordell 1979; 1997:359–360; Powers and Orcutt 1999b:551–589). Santa Fe Black-on-white, the most prevalent Coalition period decorated pottery type on the Pajarito Plateau, has definite affinities to pottery produced earlier in Chaco Canyon, and, similarly, Galisteo Black-on-white to Mesa Verde.

The Keresan-speaking pueblos, including Cochiti, uniformly consider that they migrated to the Rio Grande from the north, which includes links to both Chaco Canyon and Mesa Verde. For example, the following traditional history issued by the tribal council of San Felipe Pueblo in the late 1960s is typical of the Keresan view of their origin and migrations (cited in Strong 1979:390):

> Age after age the Spirit, the guardian and leader of the Pueblo Indians, took the ancient people across this great continent southward, until they came to settle temporarily in the places of today's National Parks and National Monuments.

> Everything they planted was harvested and was eaten along the route. Maybe to preserve the human race from total annihilation of any attack which may befall them, the Spirit caused the people to migrate in groups in separate directions from these places of historic settlements. He continued to guide each group on their trek until he brought them to a region [the Rio Grande Valley] where they can readily be safe and begin their tribal settlement.

Hewett was one of the early champions of the notion that the Classic period pattern of settlement aggregation and some abandonment on the Pajarito Plateau was due to the depredations of nomads, presumed to be Navajos (1904:658):

> If students of the Navaho will tell us at what time that tribe poured into the intermontane region and commenced to worry the peaceful Pueblos, we can approximately date the construction of the great Pueblos and cliff-villages of Pajarito Park. Tewa traditions tell of long undisturbed peace before the coming of these marauders; after this a tendency to concentration for some time, and then a throwing off of detachments by emigration, amounting at last to a complete abandonment of these sites.

This brings us to a discussion of the Navajo view of their origins and early interactions with Puebloan populations in northwestern New Mexico. One of the more elaborate myths associated with the Navajo creation and events that according to tradition took place early in the present Fifth World, is that of the Great Gambler (Levy 1998:99, 107–109; Matthews 1994:81–87; O'Bryan 1993:48–62; Zolbrod 1984:98–112). In the myth of the Great Gambler, the Navajo are described as being contemporaneous with Pueblo Indians living in Chaco Canyon, including during the time of the 10th and 11th century construction of the Chaco Great Houses, such as Pueblo Bonito.

It is clear that this myth is not a modern fabrication, but rather has some time depth—and certainly before the 20th century concerns regarding competing land claims, and before the creation of Chaco Canyon National Monument in 1906. However, our current archaeological and historic documentary evidence does not support the presence of Navajo before the 15th century. It is possible that this myth had its genesis after the Pueblo Revolt of 1680 during which time there was considerable co-residence and even intermarriage between Puebloan and Navajo populations. The Great Gambler story may reflect a natural blending of Pueblo and Navajo traditions at a period of time during which both groups were experiencing considerable upheaval and turmoil due to Spanish, Comanche, and Ute depredations.

A final point to make about migration stories is the fact that Indian perceptions of time and space within such stories is not necessarily the same thing as the more materialistic view of anthropologists and archaeologists. For example, Tessie Naranjo (1995) from the Pueblo of Santa Clara reminds us that their traditional view of the Tewa migration is really about general aspects such as movement and directional orientation, and is layered with multiple meanings.

DOE SWEIS Statements

In 1999, DOE published a SWEIS for the continued operation of LANL. In order to evaluate the possibility that TCPs as defined by the NHPA are present at LANL, DOE commissioned an ethnographic study, the results of which are included in Appendix E of Volume III, Part B of the SWEIS document (U.S. Department of Energy 1999). The only other TCP study that had been previously conducted for DOE and LANL lands had been that conducted in the early 1990s in Rendija Canyon as part of the then proposed Bason Land Exchange (Peterson and Nightengale 1993). The Rendija Canyon study resulted in seven sites being identified as TCPs by San Ildefonso Pueblo.

The SWEIS ethnographic study involved a review of the extant historic documentary and ethnographic literature, along with letters of inquiry being sent to 24 tribes and Hispanic communities, and meetings being conducted with representatives of those tribes and Hispanic communities wishing to become involved with the study. The information gathered during this process, while of interest here, was insufficient to substantiate claims for specific TCPs at LANL. Therefore, a separate ongoing process has been implemented by DOE specific to the issue of TCPs (U.S. Department of Energy 2000).

The SWEIS study indicated that many tribes considered themselves to be at least loosely affiliated with LANL lands and the Jemez Mountains in general. However, with the exception of the Pueblos of San Ildefonso, Cochiti, Santa Clara, and Jemez, the claims of most other tribes were of such a nature (such as plant gathering resource areas) to suggest that the activities conducted by these other tribes would be unlikely to result in human remains and other items covered by NAGPRA to be present at LANL.

Archaeological and Physical Anthropological Evidence

Two bodies of archaeological evidence are important for our discussion of cultural affiliation at LANL. The first is that of the general archaeological evidence, apart from that at LANL itself, by which to evaluate oral traditions, linguistic reconstructions, and other aspects of culture history bearing on the movements of specific cultural groups. The second is that of the totality of archaeological evidence, as it currently exists from all past and current projects conducted at LANL.

General Archaeological Evidence [Non-LANL]

Ford et al. (1972) published a seminal paper that looked at the question of the archaeological origins of the historically documented Pueblos in the Southwest. Although the three authors exercised their prerogative for debate and disagreement among themselves, their general conclusions still largely stand today as the primary model for historic Pueblo origins (Ford et al. 1972:39):

> Agreement is evident concerning the prehistory of the Jemez extending back in time to the Gallina, Rosa, and Los Pinos phases [ca. AD 1 to 1300] and of the withdrawal of groups in northern Arizona and southern Utah to form the ancestral basis of the Hopi. We concur that the Tiwa developed in the Rio Grande but

> differ on the cause of the two divisions. The Zuni are also viewed as developing in the general area where they are found today, but Peckham feels they were augmented by additions from the Chuska-Chaco area. The Keres are seen occupying prehistoric Mesa Verde and Chaco Canyon; differences emerge when we attempt to trace their movements. The greatest disagreements emerge when the Tewa are examined; after AD 1300 we have no dissent, but before that Ford and Schroeder look to the upper San Juan area for their homeland, while Peckham defends a Rio Grande hearth.

Admittedly, these reconstructions were derived during an era when most archaeologists tended to view named pottery types and their associated cultural sequences as having some kind of a quasi-genetic relationship to specific cultural groups. However, given the broad experience with both archaeology and ethnohistory possessed by these three individuals (Ford, Schroeder, and Peckham), their general conclusions should not be readily dismissed. These conclusions are presented in more detail below. Other classic studies that usefully address Rio Grande and historic Tewa pottery-making include those by Guthe (1925), Chapman (1970), Harlow (1973), and Frank and Harlow (1990). The totality of Puebloan archaeology and related aspects of ethnohistory have been productively reviewed in several recent publications (e.g., Adams and Duff 2004; Adler 1996; Cordell 1994, 1997), including specific treatment of the northern Rio Grande (e.g., Riley 1995, Schlanger 2002), including Bandelier National Monument (Kohler 2004; Kohler et al. 2004; Powers 2005). These together with the earlier overview by Ford, Schroeder, and Peckham form the basis for the following cultural history outline:

By Basketmaker III times (ca. AD 400 to 750), the following distribution of Puebloan cultural groups seem to have been established (Ford et al. 1972:23):

> Hopi speakers occupied southeastern Nevada, southern Utah, and a band across Arizona north of the Colorado River. Zuni speakers inhabited a triangle generally delimited by extreme west-central New Mexico to the drainage of the upper Little Colorado and Puerco (west) rivers. We concur (Schroeder excepted) that the Keres were living in the middle San Juan area south toward the Rio Puerco and Acoma. This leaves the Tanoans as denizens of southern Colorado and New Mexico from the Animas River east to and down the Rio Grande.

Following the Basketmaker III period, there appears to have been a sequence in which the ancestors of the Tewa and Towa lived together in the upper San Juan until around AD 700 to 1000, about which time they began to split. After AD 1000 the Tewa began moving out of the upper San Juan down the Chama and Puerco valleys northwest of Albuquerque, and perhaps in the Galisteo Basin as well. They came into the Española portion of the Rio Grande Valley by no later than AD 1250. The Towa seemingly moved into the areas around Jemez Springs and at Pecos by around AD 1250 to 1300. Meanwhile, the Tiwa as a cultural entity seemingly developed in situ in the Rio Grande Valley. Around AD 950 to 1000 the Tiwa began to split into the southern and northern dialect groups. This split was caused by the advent of the Tewa migrations into the northern Rio Grande around Santa Fe, or alternatively by the in situ development of the Tewa from a local basis in the northern Rio Grande.

The archaeological relationship between Keresan speakers and the Tanoans after AD 1000 is intertwined, confused, and complex. Keresans moved out of Chaco Canyon during the period of AD 1100 to 1200, displacing some Tewa speakers towards the Jemez Mountains and perhaps the middle Rio Grande-Galisteo Basin. The eastern Keresans become recognizable archaeologically at around AD 1300. As noted by Ford et al. (1972:35):

> Schroeder and Ford have the Keres on the Puerco moving into the Salado River valley below Jemez to the Rio Grande, north to Frijoles Canyon, and east to San Marcos in the Galisteo.... This movement, following Schroeder, pushed more Tewa into the Pajarito Plateau and Chama, and displaced the Towa in the Santa Fe area toward Pecos Pueblo. Peckham strongly disagrees. By his model the initial withdrawal from Mesa Verde began in the twelfth century and brought the inhabitants in a southerly direction and expanded with other San Juan Basin migrants in the next century into the Puerco and Rio Grande areas.

The recent large-scale intensive survey conducted at Bandelier National Monument amplifies this picture for this portion of the Pajarito Plateau (Powers and Orcutt 1999b:551–589). Before around AD 1150, there was only limited use of the Bandelier National Monument area by post-Archaic period (after ca. AD 600) populations. At around AD 1150 (the beginning of the Coalition period) there is the start of the use of small, briefly occupied habitation sites that bear strong similarities to the basic habitation unit of the San Juan and Mesa Verde areas. These people were likely attracted to the largely pristine high woodlands by the development of dry farming techniques not previously extensively used along the northern Rio Grande.

Around AD 1200, population begins to aggregate into larger social groups (small hamlets and villages) in the Bandelier National Monument area. A sizable amount of this aggregation appears to be from the arrival of new immigrants. At around AD 1250 to 1300, most of the aggregated sites are abandoned and population drops, possibly a local response to climatic change. Between around AD 1300 to 1325, there is a renewal of aggregation associated with new immigrants, but it seems to be on a smaller scale than that between AD 1200–1250, but with longer life spans of use for individual habitation sites.

During the period of AD 1325–1440, population again declines in the Bandelier National Monument area, but there is a peak in aggregation. By around AD 1350 to 1375 virtually all population had aggregated into just a few large isolated villages such as Yapashi, Tyuonyi, San Miguel, and a few of the cavate complexes. Population in these villages is not stable, but shows periodic fluctuations. Between around AD 1400 to 1440, there is a decrease in the level of aggregation and an increase in the use of cavate rooms as opposed to rooms in the open pueblos, with about 60 percent of the rooms in use being cavates. Agricultural features (fieldhouses and gridded gardens) are also prevalent at this time.

Between AD 1440 and 1600, although population at Bandelier National Monument remains largely aggregated, overall population levels drop. Powers and Orcutt (1999b:586) note that the nearest aggregated settlements during this period to those in Frijoles Canyon were at Kuapa, 14 km to the south, and Tsirege, 6.5 km to the north. A drought during the AD 1570s to the early

1590s resulted in the final abandonment of the large aggregated settlements on the Pajarito Plateau, although the area may have been already largely abandoned by around AD 1550.

The potential of warfare (presumably including Navajo and Ute hostilities as well as internecine Pueblo warfare) at Bandelier National Monument for being a factor in the abandonment process was considered before the survey (Powers and Orcutt 1999b:27–28), but seemingly no evidence for such hostilities was documented. There was evidence, however, for the Puebloan reuse of at least one cavate complex in Frijoles Canyon around the time of the 1680 Pueblo Revolt.

However, it is clear that by at least the end of the 17th century Navajos were utilizing lithic resources in the Jemez Mountains (see Shackley 2005a for a general treatment of the value of obsidian sourcing). For example, Vierra (1995:126) found examples of Jemez Mountain source materials in his analysis of the lithic assemblages from Navajo Pueblito complexes in the Dinetah district of northwestern New Mexico that dated to around 1690–1750. A total of 29 obsidian artifacts were identified from sources in the Jemez volcanic field (Cerro del Medio, Polvadera Peak, Obsidian Ridge, Paliza Canyon), along with two specimens of Pedernal chert from the vicinity of Cerro Pedernal. It is certainly notable that the 21 specimens of Cerro del Medio obsidian would have been collected from Cerro del Medio, a volcanic glass source that is less than 5 km west of Pajarito Peak adjacent to Los Alamos.

Because the Jemez volcanic field lithic sources do not appear to have been controlled by any specific tribe, it is assumed that the Navajo were themselves procuring materials from Cerro del Medio as opposed to simply acquiring the material in trade (Bradley J. Vierra, personal communication 2001). This assumption is supported by the documented presence of Jemez volcanic field lithics (obsidian and chert) as a consistent exotic at many historic period Navajo sites throughout northern New Mexico (Kearns 1996:121–123, 143).

LANL Archaeology

The history of archaeological fieldwork at LANL has been detailed as part of the cultural resource assessment volume prepared in conjunction with the C&T Project (Vierra 2000:4-1 to 4-10).

Briefly summarized, this includes

- Excavations by Edgar Hewett at Otowi and Tsirege between 1900–1904.
- Excavations at Otowi by Lucy Wilson between 1915–1917.
- Surface collections from Tsirege and Otowi (and from Navawi and Tsankawi) by H. P. Mera in the 1920s–1930s. Stabilization work at Otowi and some of the nearby cavates by Robert Lister of the National Park Service in 1939.
- Salvage excavations of a one-room fieldhouse and a Coalition period 10-room pueblo roomblock by J. W. Hendron for the National Park Service in the early 1940s.
- Survey and surface collections in portions of Barrancas, Bayo, Pueblo, Otowi, Los Alamos, Sandia, and Mortandad canyons by John Turney for the National Park Service in 1955.

- General survey and the excavation of two Coalition period pueblo roomblocks (eight-room and a ten-room) at Technical Area 21 and in Los Alamos Canyon by Frederick Worman of the Los Alamos Scientific Laboratory (LASL) during 1950–1971.
- General survey throughout LANL by LASL archaeologist Charlie Steen during 1973–1981.
- Extensive survey and surface collection of artifacts throughout LANL by James Hill of the University of California, Los Angeles Pajarito Archaeological Research Project during 1977–1985.
- Small surveys and one homestead excavation project by LANL contract archaeologist David Snow during 1983–1985.
- Various surveys throughout LANL by LANL archaeologist Beverly Larson during 1986–1997. During this period of time, excavations were also carried out at two pueblo roomblocks, in Technical Area 54 Area L (1990–1991) and Area G (1993), that were threatened by LANL building construction activities (Schmidt 2006; Vierra et al. 2002).
- A cavate survey by LANL employee James Jorgenson during the 1980s.
- Two surveys and site testing by the Museum of New Mexico along State Route 4 and White Rock Y in 1987.
- Additional survey and the testing of 11 sites at White Rock Y by the Museum of New Mexico in 1987.
- Survey by TFA, Inc., of Rendija Canyon for the Bason Land Exchange in 1992.
- Survey by Archaeological Research, Inc., of Rendija Canyon for the Bason Land Exchange along with the testing of 26 sites in 1993 (Peterson and Nightengale 1993).
- Various surveys by the LANL Ecology Group CRT throughout LANL during 1998–2006. This included surveys for the C&T Project, and surveys as part of the Cerro Grande Fire Rehabilitation Project. Also during this period, University of New Mexico graduate student Marit Munson conducted a detailed study of rock art in various locations throughout LANL, including those associated with cavate complexes (Chapter 81, Volume 4).
- The recently finished excavation of more than 40 Archaic period, Ancestral Pueblo Coalition and Classic period, and historic Apachean tipi ring archaeological sites as part of the Congressionally mandated C&T Project.

As of the summer of 2006, approximately 84 percent of LANL had been subjected to intensive and systematic archaeological survey. Although some of the earlier studies (before 1986) remain poorly reported, general conclusions can be reached about the nature of the documented archaeological resources at LANL. The cultural historical sequence at LANL reflects our understanding of the findings at Bandelier National Monument as well as the data from the C&T Project. In addition to the baseline excavation itself, important baseline syntheses by a variety of subject matter experts have been prepared on a wide range of topics such as trails, rock art, faunal remains, agricultural intensification, projectile points, geology, biscuitware ceramics, maize, dendrochronology, pottery temper, geomorphology, and subjects that provide useful information about past peoples on the Pajarito Plateau. The following is a brief summary:

The Paleoindian period (9500 to 5500 BC) is only represented by a single isolated projectile point. It is undetermined if substantive Paleoindian sites are present at LANL.

There are a sizable number of Archaic period (5500 BC to AD 600) sites scattered throughout LANL. Virtually all of these appear to be temporary campsites associated with pine nut collecting, hunting, lithic procurement, and similar limited seasonal activities. Because of the temporary nature of these sites, it is unlikely (although still possible) that burial and associated grave goods dating to this period are present at LANL.

Evidence for Developmental period (AD 600 to 1150) sites is almost completely lacking for LANL. The Developmental sites that have been identified at LANL are distributed into two clusters: a northern cluster near Pajarito Canyon and a southern cluster near Ancho and Water canyons. These sites include artifact scatters, one- to three-room structures, and small roomblocks utilizing jacal construction. The ceramic assemblages are dominated by Kwahe'e Black-on-white, with lesser amounts of Red Mesa Black-on-white and Wingate Black-on-red. It seems likely that this limited occupation reflects an early attempt by agriculturalists to colonize the plateau, but was met with only limited success.

There are large numbers of Coalition period (AD 1150–1325) sites of many different types scattered throughout LANL. These include pueblo roomblocks, plaza pueblos, cavate complexes, rock art, agricultural features such as garden plots and fieldhouses, artifact scatters, and various rock features. Although there are a few trade items (such as ceramics) that obviously came from other Pueblo groups in northern New Mexico and eastern Arizona, there is nothing in the assemblages and sites known to date to the Coalition period that suggests anything other than a Tewa or possibly Keresan affiliation.

There a number of Classic period sites (AD 1325–1600) scattered throughout LANL, but these are far fewer in number than the earlier Coalition period sites. These Classic period sites include a few large aggregated pueblos such as Otowi and Tsirege, along with cavate complexes, agricultural features such as garden plots and fieldhouses, artifact scatters, rock art, and various rock features. And, as with the earlier Coalition period, although there are a few trade items (such as ceramics) that obviously came from other Pueblo groups in northern New Mexico and eastern Arizona, there is nothing in the assemblages and sites known to date to the Classic period that suggests anything other than a Tewa or possibly Keresan affiliation. There is an absence of material culture items that can be attributed to the Navajo, Apache, Utes, or Comanches during the Classic period. It is noted that excavation collections from Otowi and Tsirege, currently housed at the Smithsonian Institution and largely consisting of material culture items likely associated with burials, were briefly examined by members of the LANL CRT. These all appeared consistent with a Tewa affiliation.

The Puebloan reuse of Coalition and Classic period sites after AD 1600 has not yet been definitively documented at LANL, with the exceptions of the use of agricultural fields near Otowi (documented by pollen evidence and radiocarbon dated to the 1700s), and the known reuse of the Late Coalition-Early Classic period standing-wall pueblo of Nake'muu by women and children from San Ildefonso Pueblo during the 1680 Pueblo Revolt. It was this reuse of Nake'muu that likely resulted in the preservation of the site as the only standing-wall open Ancestral Pueblo archaeological site at LANL. Some of the cavate rooms at LANL exhibit what is almost assuredly Historic period use, but it is uncertain how much of this reuse represents the activities of Euroamerican homesteaders as opposed to Native American (presumably Pueblo) activities.

Throughout all of LANL, only two archaeological sites appear to represent the remains of non-Puebloan Native American activities. These two sites are both situated in Rendija Canyon and each contains a single nearly circular alignment of stones that bear reasonable similarities to the remains of known wickiup or tipi rings (e.g., Gunnerson 1979:Figure 6). The two sites are situated less than 150 m apart at the far northern boundary of the Rendija Canyon parcel. Both sites were recorded and tested as part of the Bason Land Exchange Project (Peterson and Nightengale 1993). The rock ring at one of the sites was estimated to have been about 4.5 m in diameter with individual rocks spaced from 40 to 75 cm apart (much of the feature has been destroyed by erosion), while the other ring was about 5.0 meters in diameter with rocks spaced from 40 to 60 cm apart.

Excavation in 2004 of these two stone ring sites as part of the C&T Project indicated there use as likely seasonal habitation by Apacheans for a brief period of time (one or two years) during the 1890s. It seems likely that the occupants were Jicarilla, based on the presence of Jicarilla ceramics, metal artifacts, and moccasin beads. However, due to the mobility of the period, other Apachean groups cannot be ruled out.

Physical Anthropology Evidence

A single recent study (Schillaci and Stojanowski 2005) looked at the physical evidence from actual human remains from the Pajarito Plateau and elsewhere in northern New Mexico in the attempt to identify and understand biosocial aspects of Ancestral Tewa populations. These remains were from Ancestral Pueblo villages of Puye, San Cristobal, Sapawe, Otowi, and Tsankawi.

This study suggested that Puye and Tsankawi were "somewhat isolated from extraregional migration and gene flow, or possibly did not participate in region-wide aggregation, despite comparatively long occupation spans" (Schillaci and Stojanowski 2005:410). This finding is seemingly consistent with the traditional view of Tsankawi as being related to just a single descendant pueblo (San Ildefonso), but may contrast with the previously mentioned view that Puye is ancestral to several different Pueblos and thus would have been expected to reflect a mixture of populations. The opposite case was found for Otowi in that it had a high degree of genetic heterogeneity in its population, but is associated with only a single descendant pueblo (San Ildefonso).

However, it is important to remember that the sample size for this study (128 crania) is relatively small given the length of occupation span and the numbers of people living at these five pueblos. Therefore, these findings should be viewed cautiously in terms of their explanatory value(s).

LANL NAGPRA Cultural Affiliation Determination Conclusions

The combined weight of the evidence outlined above leads to the following conclusions regarding the likely cultural affiliation of Native American human remains at LANL. This refers to all LANL lands with the exception of the small Fenton Hill parcel.

San Ildefonso Pueblo has maintained relative geographical stability since at least the beginning of the 13th century in its relationship to the Pajarito Plateau and LANL lands. During that period of time there may have been some boundary overlap with the Keresan-speaking Pueblo of Cochiti to the south and the neighboring Tewa Pueblo of Santa Clara to the north. Historically, the aboriginal lands of San Ildefonso Pueblo on the Pajarito Plateau were approximately bounded by Ancho Canyon to the south and Guaje or Chupaderos canyons to the north, and the flanks or crest of the Jemez Mountains to the west.

There is evidence for non-sedentary or limited seasonal non-Puebloan Native American use of a portion of LANL/DOE lands (Rendija Canyon), apparently during the 1890s by Jicarilla Apache or other Apachean groups. The remains of two tipi or wickiup rings suggest a brief occupation of the area, but are not indicative of sustained or repeated use of the area by Apacheans. It is unlikely, although possible, that additional similar remains are present in the unsurveyed portions of LANL.

There is little evidence for Developmental period (AD 600–1200) Puebloan archaeological material at LANL, and it seems plausible that such remains, if present, could with a degree of certainty be linked with the Pueblos of San Ildefonso, Cochiti, and perhaps Santa Clara. There is some possibility for Archaic period (5500 BC to AD 600) human remains to be present at LANL, but it would be difficult to directly link such remains to a specific tribe or Pueblo. The preponderance of evidence suggests that early Tanoan speakers (Tewa, Tiwa, Towa) and Keresan speakers occupied the northern Rio Grande region before AD 600, thus all Tanoan and Keresan pueblos should have some affinity to human remains dating to the Archaic period.

Based on these data and conclusions, the following determinations are made in terms of ownership and cultural affiliation as specifically applied to human remains and associated and unassociated objects covered by NAGPRA:

1. The Pueblo of San Ildefonso will be considered to have standing to claim cultural affiliation for all Developmental period through Classic period Ancestral Pueblo Native American human remains and associated material culture items covered by NAGPRA throughout LANL, with the specific exceptions noted below. Consideration of Paleoindian and Archaic period remains is treated separately below.

2. Given the development that has taken place at the LANL Fenton Hill parcel near Jemez Springs, it is unlikely that Puebloan Native American human remains and associations are present. However, in the event that such remains are discovered, Jemez Pueblo will be considered to have sole standing to claim cultural affiliation to these remains.

3. The Jicarilla Apache and the Mescalero Apache are considered to have standing solely for the two wickiup or tipi ring sites in Rendija Canyon. San Ildefonso Pueblo, Santa Clara Pueblo, and other Puebloan groups do not have standing for these specific sites for purpose of NAGPRA. In the unlikely event that additional similar non-Puebloan Native American sites are identified in the remaining unsurveyed portions of LANL, or in the equally unlikely event that intentional excavation or inadvertent discoveries elsewhere at

LANL result in Native American human remains and associated material culture items that may be non-Puebloan based on contextual evidence, then the appropriate non-Puebloan tribe(s) will be considered to have standing for such sites and remains.

4. Both the Pueblo of Cochiti and the Pueblo of San Ildefonso are considered to have standing to claim cultural affiliation for all Ancestral Pueblo Native American human remains and associated material culture items covered by NAGPRA that are located at LANL along the southern escarpment of Water Canyon, but not including Water Canyon itself. It is noted that discussions with each tribe suggest that this determination is satisfactory for both, although neither tribe was willing to commit to such a determination in writing.

5. After lengthy discussions with the Pueblos of Santa Clara and San Ildefonso, it was determined by LASO that both tribes have standing to Ancestral Pueblo NAGPRA remains and cultural objects in Rendija Canyon. A similar finding was made with respect to TCPs in Rendija Canyon in compliance with the NHPA. However, it is recognized that the Pueblo of San Ildefonso is not satisfied with this shared finding in that they view Rendija Canyon as being solely within their aboriginal territory. Although the specific determination for Rendija Canyon expressed here is considered disputatious, it is also understood by all parties that for the purposes of NAGPRA and cultural resources management at LANL, the determination seemingly does not have major consequences in that no NAGPRA remains and cultural objects were actually found during the C&T Project excavations, and the Rendija Canyon parcel is currently scheduled for transfer out of federal jurisdiction before 2012.

6. Because of a variety of historic marriage and kinship relationships along with customary land use, it is possible that individuals at pueblos other than San Ildefonso, Cochiti, Santa Clara, and Jemez feel they have legitimate claims for standing under NAGPRA to the Ancestral Pueblo Native American remains and associations found at LANL, and are likewise concerned with cultural resources management at LANL. While recognizing this likely may be the case, LASO will proceed with the determinations as described above. This approach does not preclude or foreclose on individuals and tribes making independent NAGPRA claim. Were claims to occur, LASO would evaluate on a case-by-case basis.

7. It is unlikely that Paleoindian period human remains and associations will be found at LANL, and it is also somewhat unlikely that Archaic period human remains and associations will be discovered. In the event Paleoindian and Archaic period remains and associations are discovered, standing to claim cultural affiliation should be provided for all New Mexico pueblos along with the Hopi-Tewa of Arizona and Ysleta del Sur in Texas. However, LASO will encourage that the Pueblos of San Ildefonso, Santa Clara, Cochiti, and Jemez take the lead for such a claim on the behalf of the other Pueblos.

8. The detailed scientific study of NAGPRA remains and cultural objects by appropriate professional members of the scientific community, apart from that necessary for initial NAGPRA evaluation and documentation, is permitted under NAGPRA. However, the

legitimacy of such a request for further scientific study and its appropriateness must be demonstrated to LASO and clearly discussed and documented in government-to-government consultation with the appropriate culturally affiliated tribes. The LASO Cultural Resources Program Manager with the assistance of the LANL CRT will determine if such study is warranted, but as a prerequisite it must be demonstrated that such detailed study has a positive value not only for the scientific community but also for the culturally affiliated tribes.

9. In the unlikely event intentional excavation or inadvertent discovery at LANL results in a finding that the discovered Native American human remains and/or their associations are of such character as to not fall under the recommendations listed above, these will be treated in accordance with NAGPRA on a case-by-case basis.

10. Each of the 25 tribes included in the LANL SWEIS (U.S. Department of Energy 1999), along with the Ute Mountain Utes, were provided a copy of the cultural affiliation document for review. It is understood that any of these groups may challenge the above determinations, with the understanding that they must provide enough appropriate documentation to substantiate their claims.

TRADITIONAL CULTURAL PROPERTIES (TCP)

TCPs are defined in National Register Bulletin 38, *Guidelines for Evaluating and Documenting Traditional Cultural Properties*, as places of special heritage value to contemporary communities (often, but not necessarily, Native American groups) because of their association with the cultural practices or beliefs that are rooted in the histories of those communities and are important in maintaining the cultural identity of the communities (DOI 1990). Native American TCPs typically represent what are commonly referred to as "sacred sites." Sacred sites are defined more narrowly in Executive Order (EO) 13007 as discrete locations on federal land identified as sacred by virtue of their religious significance or ceremonial use by Native American religious practitioners and made known to the administering federal agency by an appropriately authoritative representative of a Native American religion.

A difficulty in the process of identifying Native American TCPs on federal land results from the fact that the tribes associated with TCPs historically until recently have often been excluded from visiting such sites. This situation is sometimes due to explicit restrictions such as pertain to the high security areas at LANL, or more commonly result from miscommunication between the agency and the tribe in which the tribe is not aware that the agency would allow visitation if specifically asked by the tribe. There potentially are TCPs at LANL that have not been visited by pertinent tribes (e.g., the Pueblos of San Ildefonso and Cochiti) due to the establishment of the Manhattan Project on the Pajarito Plateau in 1943, and perhaps even to some degree since Anglo and Hispanic homesteads began to be constructed in the 1890s. Thus while a TCP may be present in the general fund of cultural knowledge of a tribe, the exact location may have been obscured or forgotten.

Opportunities for identifying TCPs specific to the C&T Project locations have consisted of several different initiatives conducted during the period of 1992 and 2003. Two of these initiatives were part of consultation associated with two major LANL Environmental Impact Statements (EIS), both released in 1999. The first of these was that of the DOE SWEIS (U.S. DOE 1999a). The second was the EIS for the C&T Project itself, the *Environmental Impact Statement for the Conveyance and Transfer of Certain Land Tracts Administered by the U.S. Department of Energy and Located at Los Alamos National Laboratory, Los Alamos and Santa Fe Counties, New Mexico* (DOE 1999b). The remaining opportunities for TCP identification consisted of studies accompanying the survey and testing of Rendija Canyon archaeological sites in 1992–1993 as part of the then considered Bason Land Exchange (Peterson and Nightengale 1993), during NHPA Section 106 compliance consultation associated with the release of the C&T Project survey report (Hoagland et al. 2000) and that of the C&T Project research design (Vierra et al. 2002), and a 2002 site assessment conducted by the Pueblos of San Ildefonso and Santa Clara in conjunction with the Cerro Grande Rehabilitation Project in response to cultural sites damaged by the May 2000 Cerro Grande fire (San Ildefonso Pueblo/Santa Clara Pueblo 2002).

TCP/sacred sites consultations were extensively attempted for the DOE SWEIS (U.S. DOE 1999a, Appendix D). Twenty-three Native American tribes and two Hispanic communities were contacted, informed of the undertaking, and asked to enter into consultation on issues of traditional and/or spiritual concerns. Of the 23 contacted groups, four did not wish to participate in formal consultations. Virtually all of the consulted groups indicated that they had TCPs present on, or in the vicinity of, LANL.

Although many Native American groups expressed interest in this process, they did not provide sufficient locational information essential for long-term management and protection decisions to LANL. To date only the Pueblos of San Ildefonso and Santa Clara have provided such detailed information, identifying eight locations specific to the C&T Project within the Rendija Tract (Figure 72.2). Seven of these sites—a series of shrines marking a trail leading from the Rio Grande to a specific peak in the Jemez Mountains—were first identified by the Pueblo of San Ildefonso and evaluated in 1992–1993 as part of the earlier considered Bason Land Exchange (Petersen and Nightengale 1993). The eighth site, a cultural boundary shrine, was identified and initially evaluated as part of the cultural site assessment project conducted in 2002 by the Pueblos of San Ildefonso and Santa Clara in conjunction with the Cerro Grande Rehabilitation Project.

Figure 72.2. Members of the Pueblos of Santa Clara and San Ildefonso examine an archaeological site in Rendija Canyon.

These eight locations have been subsequently fenced by LANL for protection from inadvertent damage by vehicular traffic and pedestrian recreational use of Rendija Canyon. Although these parcels (represented by two sets of fences) are within the lands being transferred to Los Alamos County, they will be restricted from future development and visitation access will be provided to the Pueblos of San Ildefonso and Santa Clara.

CONSULTATION AND EDUCATIONAL OUTREACH FIELD AND LABORATORY VISITS

It was determined through consultation with both the Pueblos of San Ildefonso and Santa Clara that neither Pueblo wanted LANL to conduct an active program of outreach and education with the non-Native American public in terms of the C&T Project archaeological excavations. Although LANL archaeologists may have regretted not being able to perform such public outreach, we understood the sensitivity involved.

However, we were pleased to conduct periodic field tours for the Pueblos of San Ildefonso and Santa Clara themselves (Figure 72.3), and for the Jicarilla Apache Nation at the two sites in Rendija Canyon that proved to be culturally affiliated with a late 19th century Apachean occupation (Figure 72.4), as well as to Ancestral Pueblo fieldhouses then being excavated in Rendija Canyon. In addition to these field visits, all three tribes took the opportunity to visit the C&T Project archaeology laboratory and our office building at Technical Area 21.

Figure 72.3. Members of the Pueblo of Santa Clara visiting site LA 135290 during excavation (October 30, 2003).

THE NAGPRA INTENTIONAL EXCAVATION PLAN

Background

The NAGPRA, enacted in 1990 as Public Law 101-601 (25 USC 3001), is designed to develop a systematic process for determining the right of lineal descendants and Indian tribes to certain Native American human remains, funerary objects, sacred objects, or objects of cultural patrimony with which they are affiliated. This law is relevant to cases of intentional excavation and inadvertent discovery on federal lands, such as LANL. The federal agency is required to develop plans and associated comprehensive agreements, in consultation with appropriate affiliated Native American tribes, that detail the manner in which discovered human remains, funerary objects (both associated and unassociated), sacred objects, and objects of cultural patrimony are to be excavated, analyzed, stored, and repatriated, and that lay out a process of dialog and consultation during the recovery, analysis, and disposition of these remains and objects. The plan detailed here is specific to the act of intentional excavation at LANL.

Public Law 105-119, authorized by Congress in 1997, mandated LASO to identify excess lands at LANL for potential conveyance and transfer to the Incorporated County of Los Alamos (the County) and to the Department of Interior in trust for San Ildefonso Pueblo. An EIS was subsequently published that identified 10 tracts for conveyance and transfer (DOE 1999b). The timeline set for the actual conveyance and transfer of excess land was within 10 years of the passage of the law, which is the year 2007, with the transfer being conducted on a tract-by-tract basis. The first intentional excavations specific to Public Law 105-119 were initiated in June 2002, with subsequent field seasons beginning each succeeding May until the fieldwork is complete, which was in calendar year 2006. [NOTE: In 2006, the law was modified to extend the completion of the transfer process until 2012].

The 10 land conveyance and transfer tracts represent a total of approximately 4000 acres to be divided between the County and San Ildefonso Pueblo. An intensive archaeological survey documented a total of 213 cultural resource sites within the project parcels (Hoagland et al. 2000). The survey documented a number of historic homestead features and historic early Laboratory features, as well as Native American archaeological and cultural sites.

Among the resources on lands potentially being transferred to Los Alamos County are three Ancestral Pueblo habitation roomblocks (8 to 10 rooms) dating to the period of around AD 1200 to 1350, one of which has been previously impacted by highway construction as well as being partially excavated many years ago. Other resources include Ancestral Puebloan fieldhouses, agricultural features and artifact scatters dating to the period of around AD 1200 to 1600, and an Archaic period (ca. 5500 BC to AD 600) lithic scatter. These resources are typical of the types of Native American resources anticipated to be involved in any future intentional excavations.

The C&T Project also includes two probable historic non-Puebloan tipi or wickiup rings. It is emphasized that these two tipi or wickiup rings represent the only non-Puebloan Native American resources known to be present on LANL lands. In addition, San Ildefonso Pueblo has previously identified seven archaeological sites in one of the tracts proposed for transfer to the

County as being TCPs, and another site is presently being evaluated as a TCP. LASO and LANL are currently in the process of identifying and evaluating other possible TCPs on LANL lands.

Goals and Assumptions

The primary goal of this LANL NAGPRA Intentional Excavation Comprehensive Agreement is to create a framework for effective compliance with NAGPRA during and after archaeological data recovery fieldwork associated with the conveyance and transfer of lands from federal ownership under Public Law 105-119, and for any other intentional excavation projects that may arise on LANL lands in the future. The LANL NAGPRA Intentional Excavation Plan outlines the process for the identification and treatment of Native American human remains, associated funerary objects, unassociated funerary objects, sacred objects, and items of cultural patrimony encountered during the period from archaeological fieldwork through that of actual repatriation.

An archaeological Data Recovery Plan was prepared by the LANL CRT to help guide the intentional excavation efforts of the C&T Project. The Data Recovery Plan details research issues and the actual methods to be used during fieldwork and laboratory analysis, and addresses the structure of the subsequent report on project findings. Separate Data Recovery Plans will be prepared for all other future intentional excavation projects at LANL. These Data Recovery Plans, including the present one for the C&T Project, will incorporate the most recent updated LANL NAGPRA Intentional Excavation Comprehensive Agreement and any other pertinent agreements reached between LASO and LANL and culturally affiliated Native American tribes.

It is understood that the excavation of archaeological sites is something that the Pueblos of San Ildefonso and Santa Clara and most other Native American tribes do not condone in principle and actively seek to avoid unless absolutely necessary.

Cultural Affiliation

As noted above, based on the combination of geography, past ethnographic studies (including linguistics and collections of oral traditions), historical documents, and past cultural resource surveys and excavations in and around LANL, a set of recommendations was made regarding the likely cultural affiliation of the remains of Native Americans found at LANL (Masse 2002, LANL 2007a). In brief, it is anticipated that nearly all human remains and items covered by NAGPRA that may be found during project fieldwork will relate to Ancestral Puebloans (ca. AD 600 to 1600). San Ildefonso Pueblo has been determined to have primary standing under NAGPRA for the great majority of archaeological contexts throughout LANL. The Pueblos of Cochiti and Santa Clara have also been determined to have standing for portions of LANL, and ongoing consultations may help to further define these areas and relationships. The Pueblo of Jemez only has standing for the small, detached Fenton Hill facility near Jemez Springs.

The only archaeological evidence for a non-Puebloan Native American presence in the immediate vicinity of LANL are two apparent historic Apachean—probably Jicarilla Apache based on excavations conducted in the 2003 field season—temporary structures identified in

Rendija Canyon (Peterson and Nightengale 1993). Although these sites are not anticipated to contain human remains or the type of archaeological materials covered by NAGPRA, the present Intentional Excavation Comprehensive Agreement allows for such a possibility.

There is a slight possibility for Archaic period (5500 BC to AD 600) remains and associated NAGPRA-related objects in the C&T Project area, particularly in the White Rock parcel. If such Archaic period remains and objects are identified, it is assumed that all Tanoan and Keresan-speaking pueblos are potentially culturally affiliated. It is anticipated that despite the large numbers of Pueblos who may be affiliated, the Pueblos of San Ildefonso, Santa Clara, Cochiti, and Jemez would take the lead for any repatriation efforts.

Comprehensive agreements relating to NAGPRA have been sought with each of the culturally affiliated tribes outlined above, specific to the contexts defined above and in the LANL cultural affiliation study (Masse 2002). As of April 2002 the Pueblo of San Ildefonso verbally entered into such an agreement, and by April 2004 both San Ildefonso and Santa Clara have verbally entered into such an agreement. The signing of the present document will formalize these agreements. It is emphasized that in the unlikely event that an intentional excavation reveals the presence of remains or NAGPRA-related objects unquestionably associated with another tribe not involved with that specific intentional excavation project, that tribe will be brought into the overall NAGPRA consultation process for that project. For example, in the very unlikely event intentional excavations at the tipi/wickiup ring sites in Rendija Canyon were to yield burials obviously affiliated with the Tewa rather than Apachean groups, then the Pueblos of San Ildefonso and Santa Clara would be notified and brought into the overall consultation process for these two sites.

All intentional excavation work will be sensitive to the issue of cultural affiliation.

Definitions

- *Human Remains*. “Human remains” include any identifiable human skeletal element, including teeth, regardless of whether or not they are found in an intentional burial site or as an isolated element elsewhere in the archaeological sites.

- *Funerary Objects*. “Funerary objects” represent those items of material culture that are intentionally placed with human remains for inclusion in a burial site. Whole ceramic vessels, items of marine shell, whole projectile points, crystals, turquoise beads, stone pipes, whole manos, and other objects are often variously found in direct association with burials. However, it is noted that burials typically are placed in areas where “trash” has accumulated (such as broken pottery, chipped stone debris, and exhausted and discarded manos and metates), thus part of the job of professional archaeological excavation is to carefully separate the burial and its funerary objects from the surrounding unassociated trash. It is noted that post-burial offerings are sometimes deliberately placed on top of or in the immediate vicinity of the burial pit. The archaeologists will need to work closely with the tribal monitors to evaluate the materials and contexts surrounding burials and burial pits in order to identify, if possible, if such post-burial offerings are present.

- *Unassociated Funerary Objects*. "Unassociated funerary objects" represent special items of material culture whose primary function is to be placed with a burial, but which for some reason is not actually found in recognizable association with a burial. For example, for some Native American groups certain miniature ceramic vessels likely were specifically made to accompany burials. Thus, regardless of where such items are found during intentional excavation (including in a trash deposit), they would be considered to be a part of the objects and human remains covered under NAGPRA, and are thus subject to repatriation.

- *Sacred Objects and Items of Cultural Patrimony*. "Sacred objects" and "objects of cultural patrimony" represent material items that are closely bound with the cultural identity of a specific tribe, and which are also likely to have specific sacred value. Examples might include ceramic and stone images of tribal deities; ceramic vessels with painted images of deities (such as Kachinas); Shaman artifact bundles; and portions of wooden ceremonial masks. As with unassociated funerary objects, sacred objects and objects of cultural patrimony are covered under NAGPRA regardless of where such items are found during intentional excavation (including in a trash deposit). They would be considered to be a part of the objects and human remains subject to repatriation. It is emphasized that ordinary ceramic vessels and sherds, projectile points and other stone tools, animal bones, corncobs, and other items found in "trash" deposits and in habitation and storage contexts are usually not considered sacred objects or objects of cultural patrimony. They would be covered by NAGPRA only in the case of being determined to be a part of an intentional funerary assemblage. As with the case of post-burial offerings discussed above, the tribal monitors will need to work closely with the archaeologists to identify such potential funerary objects.

Stipulated Procedures

Listing of Unassociated Funerary Objects, Sacred Objects, and Items of Cultural Patrimony

1. For unassociated funerary objects, sacred objects, and items of cultural patrimony, a list of such objects will be developed in consultation with the appropriate affiliated tribes before the start of intentional excavation. This will ensure that the field archaeologist will know the proper manner in which to treat such objects if and when found during excavation.

2. Field archaeologists will be instructed to use their professional judgment in encountering unusual items during excavation that while not on the list of NAGPRA-covered objects, nevertheless given their attributes or context appear likely to be of a sacred nature. These will be handled and treated as if they are indeed an unassociated funerary object, sacred object, or object of cultural patrimony, and will be brought to the attention of the appropriate affiliated tribe.

NAGPRA Excavation Procedures

3. Archaeological field crews will be given mandatory training regarding the nature and content of this intentional excavation comprehensive agreement before the beginning of actual excavation.

4. Anytime human remains are encountered during the intentional excavation, they will be treated with the utmost sensitivity and respect. Excavation will be conducted in such a manner as to ensure the successful recovery and careful preservation of the remains, including the careful documentation of the burial context.

5. Typically, a burial is exposed in its entirety before the removal of the individual elements and associated funerary objects. This is done so as to ensure that issues of context and overlapping or multiple interments can be resolved before removal of the burial.

6. Photographs and sketches will be made to provide a documentary record of the burial, and to ensure that funerary objects can be re-associated with the burial at the time of repatriation. It is emphasized that photographs of the human remains will not be included in reports, rather only line drawings will be used.

7. A "Human Burial Feature Form" will be filled out for each set of human remains encountered during the intentional excavation.

8. Individual human elements will be collected separately and wrapped for protection, and will be securely placed into properly labeled bags and containers for transportation and temporary storage. Associated funerary objects, unassociated funerary objects, sacred objects, and objects of cultural patrimony will be provided similar treatment.

9. In the event that the documentation and removal of a burial takes longer than a single day, the burial will be carefully covered and protected at night before its final removal. In order to minimize the possibility that a burial will be left partly exposed over one or more non-working days (such as a weekend), no excavation of a known or suspected burial will be initiated the day before a non-working day.

10. Fences, surveillance cameras, and/or other protective measures will be utilized in excavation areas to minimize the possibility of vandalism of archaeological resources and human remains after work hours. In the unlikely event that vandalism does occur, The Pueblos of San Ildefonso and Santa Clara will be immediately notified and necessary corrective actions will be initiated.

Laboratory Analysis and Documentation of Human Remains

Documentation, or the physical examination of the remains, is an integral part of the repatriation process. It provides one line of evidence used to determine cultural affiliation as required by the law. Biological information on the shape and physical condition of the remains is evaluated, along with archaeological and anthropological information, and traditional knowledge, to help identify Native American groups with whom the remains may be affiliated. Documentation forms part of the permanent record of LASO's compliance with the repatriation mandate, the determination of cultural affiliation, and the arrangements made for transfer of remains to Native representatives. Information assembled and permanently archived as a record of repatriation is available to Native groups for their own records and use.

11. Analysis of human remains recovered from LANL intentional excavation projects will be performed by a professional physical anthropologist, but will be limited to standard non-destructive "metrical analyses" (collecting precise measurements using calipers) and non-metrical analyses for cultural ethnicity as required by NAGPRA.

12. The information will be recorded on appropriate analysis forms and will be summarized in the project report.

13. The documentation may require photography, but such photographs will not be included in reports. However, line drawings of the remains may be included in the report as a way of illustrating pertinent aspects of the analysis.

14. The analysis of all sets of human remains will be performed in a timely manner.

15. Upon completion of this analysis, the remains will be carefully wrapped for protection and placed into clearly labeled containers for short-term storage before repatriation.

16. The location of analyzed and stored human remains will be provided to the appropriate culturally affiliated tribe.

Analysis and Documentation of Funerary Objects, Unassociated Funerary Objects, Sacred Objects, and Items of Cultural Patrimony

17. Funerary objects, unassociated funerary objects, sacred objects, and items of cultural patrimony will be subject to analysis and documentation by photography and line drawings as warranted.

18. The analysis of these objects will be summarized in the project report, with the use of illustrative photographs and line drawings as warranted.

19. There will be no destructive analysis performed on these objects.

20. The analysis of any NAGPRA-related object will be performed in a timely manner.

21. Upon completion of analysis, the remains will be carefully wrapped for protection and placed into clearly labeled containers for short-term storage before repatriation.

22. The location of analyzed and stored NAGPRA-related objects will be provided to the appropriated culturally affiliated tribe.

Temporary Storage of Human Remains, Funerary Objects, Unassociated Funerary Objects, Sacred Objects, and Items of Cultural Patrimony

23. The temporary storage of human remains, funerary objects, unassociated funerary objects, sacred objects, and objects of cultural patrimony, both before and after analysis, will be conducted in a manner respectful of these remains and objects, and in a manner that satisfactorily provides for their security and safekeeping.

24. The location of analyzed and stored human remains and NAGPRA-related objects will be provided to the appropriate culturally affiliated tribe, and the tribe will be granted access to visit and view the remains and object upon request.

Disposition and Repatriation of Human Remains, Funerary Objects, Unassociated Funerary Objects, Sacred Objects, and Items of Cultural Patrimony

25. All Native American human remains, funerary objects, unassociated funerary objects, sacred objects, and objects of cultural patrimony that are recovered from an intentional excavation project must be repatriated to the appropriate affiliated tribe(s) in a timely manner. Unless otherwise agreed upon by LASO and LANL and the appropriate tribe(s), repatriation will take place no later than one year after the end of an excavation field season and its associated concluding formal NAGPRA meeting. At this meeting the tribe will examine the collections and will be presented with detailed lists of human remains, associated funerary objects, unassociated funerary objects, sacred objects, and items of cultural patrimony as defined by NAGPRA.

26. At the formal request of the appropriate tribe(s), LASO and LANL may store these remains and objects for a longer period in the event that the tribe(s) needs more time to adequately prepare to receive the remains. The maximum amount of time that LASO and LANL will store the remains and objects before repatriation will be five years.

Consultations, Notifications, and Monitoring

Depending on the outcome of ongoing consultations regarding NAGPRA cultural affiliation, it is anticipated that San Ildefonso Pueblo will be the primary Native American tribe for standing under NAGPRA for most archaeological contexts on LANL lands that pertain to Ancestral Pueblo occupation (AD 600–1600). Cochiti Pueblo will likely share this standing for resources around and south of Ancho Canyon, and possibly other locations at LANL as formally determined in consultation with LASO. Santa Clara Pueblo will equally share this standing with San Ildefonso Pueblo for resources in Rendija Canyon, and possibly other locations at LANL as formally determined in consultation with LASO. Jemez Pueblo will have sole standing for any NAGPRA-related resources that may be present at the Fenton Hill property, unless it can be demonstrated during the excavation or analysis that these resources are related instead to Apachean or Ute groups. The Navajo Nation, Jicarilla Apache Tribe (and possibly the Mescalero Apache), and the Southern Ute tribe will have standing only for intentional excavation performed on the two tipi/wickiup ring sites in Rendija Canyon, or for other similar non-Puebloan Native American resources that may be encountered on LANL lands. All Tanoan-speaking and Keresan-speaking Pueblos will have standing for Archaic period human remains and NAGPRA-related objects, but as noted above it is anticipated that consultations would be led by San Ildefonso, Santa Clara, Cochiti, and Jemez Pueblos.

Because the Pueblos of San Ildefonso and Santa Clara are presently considered to be the primary tribes to have standing for most archaeological contexts on LANL lands in Rendija Canyon, including those lands going to the County as part of the land conveyance and transfer process, the discussion here for consultation and monitoring is tailored specifically for these two Pueblos. However, similar procedures would be followed with the other NAGPRA culturally affiliated tribes for any intentional excavation that may pertain to them.

27. It is important that there be an open line of communication between LASO, LANL, and the Pueblos of San Ildefonso and Santa Clara during the conduct of intentional excavation fieldwork, during the laboratory analysis period, and through the period until any and all human remains and NAGPRA-related objects are repatriated. Arrangements will be made with the two Pueblos for a monitor from the Pueblos to be present during the intentional excavation fieldwork.

28. In the event that excavations are simultaneously being carried out at two or more widely separated areas within the Rendija Tract, multiple monitors are warranted. Due to a variety of logistical considerations discussed with the Pueblos of San Ildefonso and Santa Clara, the LASO has determined that two full-time monitors from San Ildefonso and one full-time monitor from Santa Clara will be supported during the 2004 excavation field season in Rendija Canyon. It will be up to the Project Director to determine in consultation with the monitors the most satisfactory and efficient manner by which sites will be monitored by the two Pueblos.

29. The purpose of the monitor would be to observe the conduct of the excavations, and to observe the treatment of any human remains, funerary objects, unassociated funerary objects, sacred objects, and objects of cultural patrimony that may be encountered during excavation.

30. The monitor could also be involved in physical aspects of the excavation (as a training tool) at the request of the tribe and with the permission of the LANL intentional excavation Project Director (Figure 72.5).

Figure 72.5. San Ildefonso Tribal Monitors Tim Martinez and Aaron Gonzales.

31. The monitor would not in any way direct the conduct of the excavations. However, the monitor (or other appropriate tribal member) may raise NAGPRA-related issues or pertinent concerns to the LANL Project Director (or his or her designee) at any time during the course of the intentional excavations. If the concerns or issues are not immediately resolved to the satisfaction of the monitor (or appropriate tribal representative), LASO and LANL must provide a formal response to the Pueblos of San Ildefonso and Santa Clara (and/or other culturally affiliated tribe) within three working days after the day that the issue is raised.

32. Regardless of whether or not a Pueblo of San Ildefonso and Santa Clara monitor is available during the intentional excavation fieldwork, the LANL Project Director (or his or her designee) must immediately notify the San Ildefonso's and Santa Clara's Governor's office and the Cultural Resources specialist whenever human remains are found. A status briefing regarding these remains and any funerary objects should be provided to the Cultural Resources specialist no more than five working days after the initial discovery is made.

33. In the event of the discovery of an Archaic Period burial, the LANL Project Director (or his or her designee) must immediately notify the Governors' offices of the four Accord pueblos. Written letters of notification, within 60 calendar days of the initial discovery, will be sent to the other culturally affiliated Pueblos as appropriate.

34. Regardless of the presence of a monitor, the Pueblos of San Ildefonso and Santa Clara may request at any time to allow representatives from the Pueblos to view the intentional excavation fieldwork. This request should be directed to the LANL Project Director (or his or her designee). This procedure would also be appropriate if either Pueblo (or even another Tanoan or Keresan Pueblo) wanted to bring classroom students to view the fieldwork for educational purposes.

35. Should members of the Pueblos of San Ildefonso and Santa Clara wish to take educational photographs, including video coverage, of the field excavations or of the laboratory analysis of excavated materials, this will be coordinated with the LANL Project Director (or his or her designee). Such educational media will be encouraged to the limit practicable without unduly impacting work schedules.

36. The Pueblos of San Ildefonso and Santa Clara may request at any time to allow representatives from the Pueblo to view ongoing laboratory analyses, or to view the storage and security measures in effect for the protection and preservation of human remains, funerary objects, unassociated funerary objects, sacred objects, and objects of cultural patrimony.

Reburial of Human Remains

The reburial of human remains is not a legally mandated federal agency responsibility under NAGPRA. The legal endpoint of the NAGPRA process is that of the repatriation or turning over of human remains and NAGPRA-related objects to the appropriate affiliated tribe(s). However, LASO and LANL recognize that the Pueblos of San Ildefonso and Santa Clara (and possibly other culturally affiliated tribes, as appropriate) may desire the reburial of remains and objects on LANL property so as to be as near as possible to the original interment location. LASO and LANL encourages a timely and frank discussion with the Pueblos of San Ildefonso and Santa Clara of the issues surrounding such a potential reburial scenario. Such a dialogue was begun after the completion of the initial field season, at the formal NAGPRA meeting with the Pueblo of San Ildefonso on April 1, 2003.

In addition to these stipulations, other duties for the tribal monitors became apparent during C&T Project excavations. For example, this included things such as assisting in the drawing and measurement of archaeological features and structures, the mapping of archaeological sites, screening dirt for artifacts, and assistance with the flotation of soil samples at the C&T Project archaeological laboratory. Also, it was decided through discussions between field supervisors and the tribal monitors that at the end of excavations at each individual site, it would be necessary to level the ground surface, including the razing of the masonry walls of roomblocks and fieldhouses, so as to discourage potential future pot-hunting at the sites once the transfers of land had taken place. This was an activity observed and often supervised by the tribal monitors themselves (Figure 72.6).

Figure 72.6. Tim Martinez observing the leveling of LA 135290 after the completion of archaeological site excavations.

NAGPRA REPATRIATION FOR THE C&T PROJECT

On December 14, 2005, the Cultural Resources Program Manager for DOE LASO, Vicki Loucks, met with the Pueblo of San Ildefonso Tribal Monitors, Aaron Gonzales and Timothy Martinez, and members of the LANL CRT, Brad Vierra, Steve Hoagland, Gerald Martinez, and Bruce Masse. The purpose of this meeting was to officially repatriate to the Pueblo of San Ildefonso the three sets of culturally affiliated human remains obtained during the C&T Project archaeological excavations at White Rock in 2003, along with an additional set of remains that had been inadvertently discovered in 2003 within the TA-72 White Rock Y land transfer tract, and subsequently excavated in 2005 due to its precarious situation in an erosional channel.

The repatriation also included 34 additional sets of remains that had been obtained from LANL lands between 1956 and 1993, along with sacred objects and items of cultural patrimony identified through the NAGPRA consultation process as being culturally affiliated with the Pueblo of San Ildefonso. These earlier sets of remains and objects had been curated in the Maxwell Museum at the University of New Mexico in Albuquerque and at the Laboratory of Anthropology in Santa Fe. All of these remains, objects, and items were physically transferred to the Pueblo of San Ildefonso tribal monitors.

As an expression of their gratitude for the successful completion of the NAGPRA repatriation process, the Pueblo of San Ildefonso subsequently hosted a traditional dinner for C&T Project personnel and representatives of LANL and LASO senior management, including LASO Manager Ed Wilmot. Part of the festivities included the bestowing of blankets upon those LANL and LASO representatives who worked most closely with the Pueblo during the C&T Project archaeological excavations and NAGPRA repatriation process (Figure 72.7).

CHAPTER 73
INTRODUCTION TO VOLUME 4

Bradley J. Vierra

The Land Conveyance and Transfer (C&T) Project data recovery program was implemented for seven archaeological sites in the White Rock Tract (A-19), five archaeological sites in the Airport Tracts (A-3, A-7, A-5-1), and 27 archaeological sites in the Rendija Tract (A-14). The results of the four-year excavation project were presented in Volumes 1, 2, and 3. Excavations were conducted from 2002 to 2005; thirty-nine archaeological sites were excavated and approximately 150,000 artifacts were collected. Volume 1 (Baseline Studies) included background information on the geology, geomorphology, and environment of the Pajarito Plateau, as well as on general dating techniques. Volume 2 (Site Excavations) presented the site excavation reports for the White Rock, Airport, and Rendija tracts and the results of site testing for the Technical Area 74 and White Rock Y tracts. Volume 3 (Analyses) provided the detailed results of artifact and sample analyses. This volume (Research and Conclusions) provides various specialized studies and answers to the final project research questions.

The C&T Project data recovery program involved the collection of data necessary to answer a series of detailed research questions as provided in the data recovery plan (Vierra et al. 2002). The data recovery plan presented a set of research contexts that consists of chronometrics, geoarchaeology, paleoenvironment, land-use, community and site organization, subsistence and seasonality, and technology, production, and exchange. These questions laid the ground work that guided the excavation of 39 archaeological sites ranging in age from Early Archaic campsites to Coalition period roomblocks to a Homestead era cabin. Chapter 85 presents the conclusion to this project by addressing the research questions.

As noted in the introduction to Volume 2 (Chapter 13), this project involved the hard work of many individuals. The majority of the field staff was comprised of graduate students, with several members of the project conducting their dissertation research on these data. The results of their research are presented here, in conjunction with several chapters involving project data. Vierra and Balice's chapter (Chapter 82), however, was written as part of the post-Cerro Grande fire archaeological site assessment. It is included here due to the potential effects of wildfires on obsidian hydration dating and includes data from the Rendija Tract. Overall, a wide range of topics are discussed in Volume 4, including Archaic foraging technology, prehistoric and historic ceramic production and exchange, prehistoric agriculture, trail systems, rock art, and the results of the project's site rehabilitation program. The information presented in Volumes 1 through 4 provides the data necessary to summarize and address the project research questions.

Finally, the C&T Project data recovery program involved a close working relationship with the affiliated tribal governments. The Pueblos of San Ildefonso and Santa Clara provided monitors to observe the excavations, identify sacred objects, and supervise the treatment of human remains. These monitors provide their own individual perspectives on the process of excavation, tribal consultation, and repatriation in this volume (Chapter 84). An open and fair dialogue was critical to the success of the project and has led to a strong working relationship between Los

Alamos National Laboratory and the Pueblos. As the Lieutenant Governor of Santa Clara once stated, “our ancestors have always watched over us, now it is our turn to take care of them.”

CHAPTER 74
ARCHAIC FORAGERS OF THE NORTHERN RIO GRANDE VALLEY, NEW MEXICO

Bradley J. Vierra

INTRODUCTION

The Pajarito Plateau is a unique geologic feature situated within the larger northern Rio Grande Valley. Archaic foragers roamed over this ancient landscape while hunting and gathering a variety of plant and animal species. These annual rounds involved a seasonal pattern of movement up and down the valley and between lowland and upland areas. This chapter presents the results of a preliminary study of the possible relationship between changes in climate, resource structure, foraging strategies, and Archaic projectile point technology in the northern Rio Grande Valley.

The northern Rio Grande Valley includes an area from the San Luis Valley and adjacent foothills of the San Juan Mountains to the north to the Santa Fe area and the Jemez Mountains in the south. From tundra and high mountain meadows in the San Juan and Jemez Mountains, to the marshes and grasslands of the San Luis Valley, to the piñon-juniper covered mesa tops, the region contains a diverse array of resources across elevations ranging from about 1600 to 4260 m (5200 to 14,000 ft). Lithic raw materials also abound in the area, including obsidian, fine-grained dacite, chalcedony, chert, and quartzite.

In order to spatially delineate the sample, I divided my study area into three separate zones (Figure 74.1). Zone 1 is located at the southern end of the region and includes the Santa Fe-Abiquiu area; Zone 2 includes the Taos-Tres Piedras area; and Zone 3 consists of the San Luis Valley and the Rio Grande headwaters. Zone 3 was included in a previous study conducted by Vierra et al. (2005) for the Late Paleoindian and Early Archaic time periods. In contrast, this study will focus on the Early, Middle, and Late Archaic periods in Zones 1 and 2. One hundred and thirty-nine Early Archaic, 87 Middle Archaic, and 172 Late Archaic projectile points provide the database used for this study. Figure 74.2 illustrates the frequency distribution across the 10 separate point types identified.

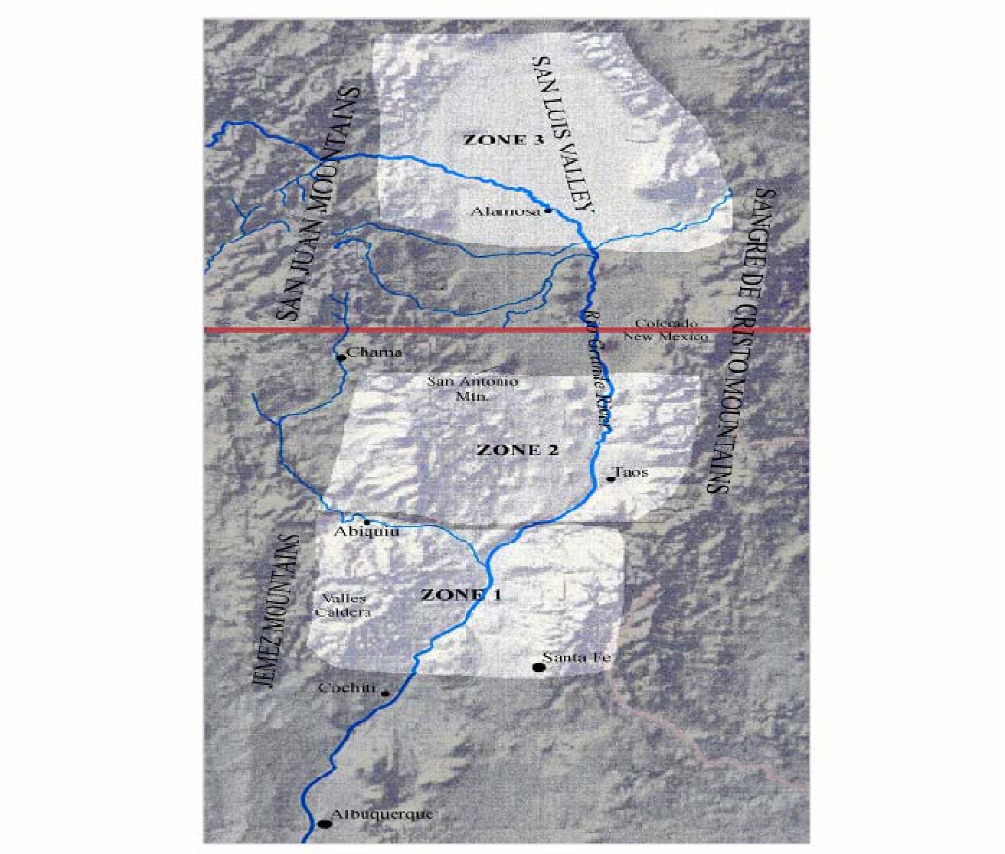

Figure 74.1. Location of study area Zones 1 to 3.

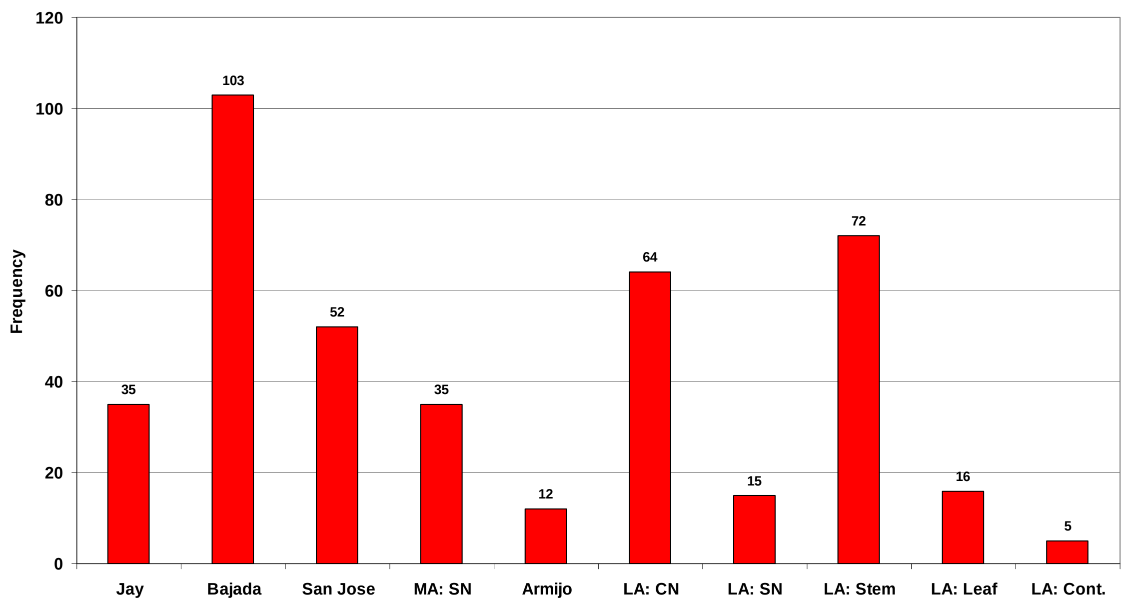

Figure 74.2. Distribution of Archaic point types.

ARCHAIC CHRONOLOGY AND ENVIRONMENT

The projectile point chronology used in this study follows the defined Oshara Tradition sequence (Irwin-Williams 1973). However, I would suggest a date range of circa 8000 to 6000 BP for the Early Archaic, 6000 to 4000 BP for the Middle Archaic, and 4000 to possibly as late as circa 900 BP for the Late Archaic (Vierra and Ford 2007). The Early Archaic includes Jay and Bajada points, the Middle Archaic consists of San Jose and possibly large side-notched points, and the Late Archaic includes Armijo and five other distinctive point types. These latter types consist of corner-notched, side-notched, stemmed, leaf-shaped, and contracting stemmed varieties. The exact temporal placement of these large side-notched points is unclear in this region; however, my review of the literature indicates that the radiocarbon dates, obsidian hydration data, and relative stratigraphic sequence data primarily indicate a Middle Archaic temporal designation (Vierra 1993a) and as such the points will tentatively be assigned to this period.

A review of documents at Eastern New Mexico University indicates that a range of radiocarbon dates were obtained during Irwin-Williams' Anasazi Origins Project near Albuquerque, New Mexico (Vierra 1996). These dates are illustrated in Figure 74.3, with a Late Paleoindian and Early Archaic date cluster between about 9000 to 6000 BP (uncalibrated), followed by a second cluster of Middle Archaic dates between 6000 and 4000 BP, followed by a continuous occupation from Late Archaic through the Ceramic period.

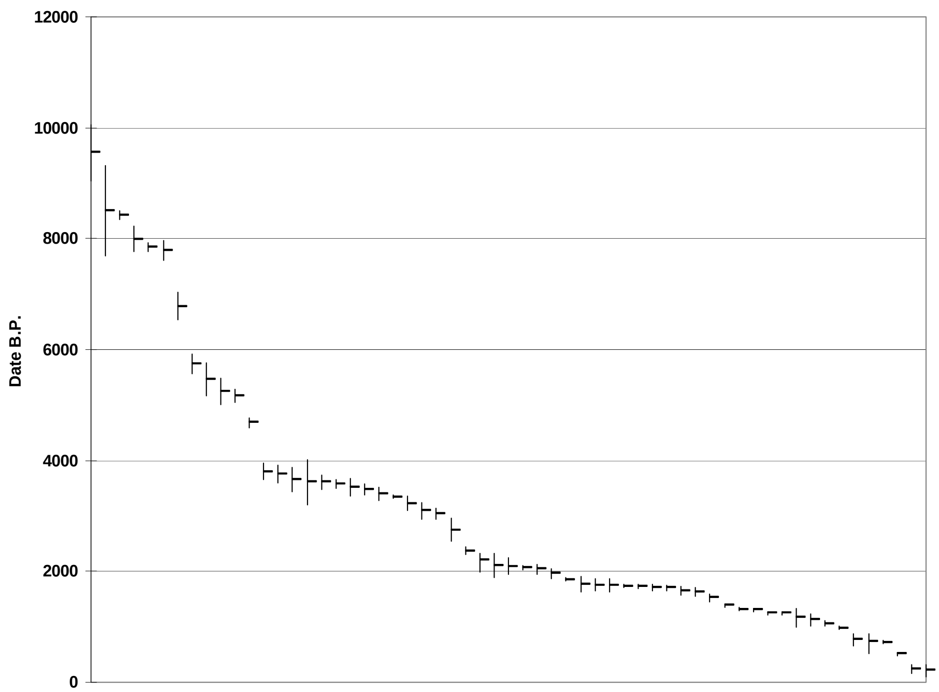

Figure 74.3. Radiocarbon dates from the Anasazi Origins Project.

Recent studies by Scott Anderson (Chapter 5, Volume 1; Anderson et al. 2007; Brunner-Jass 1999) and his students of pollen cores in the Jemez Mountains indicate that these Late Paleoindian and Early Archaic dates are separated by a period of decreased effective moisture when the Chihuahueños Bog had dried up from circa 8000 to 6500 BP. Pollen cores from basin lakes in the San Luis Valley show a similar trend with a decline in lake and creek levels after about 8000 BP and a period of least effective moisture at roughly 6500 BP (Jodry 1999; Jodry and Stanford 1996; Shafer 1989). This obviously had a significant effect on the Early Archaic foragers in the area, with their settlement system shifting to a north-south pattern within the northern Rio Grande Valley (Vierra et al. 2005). A variety of large, medium, and small size game was hunted, including evidence for bison hunting and fishing in the San Luis Valley (Jodry 2006; Vierra and Ford 2007).

There is evidence for moister conditions and the expansion of piñon-juniper woodlands in the northern Rio Grande Valley during the subsequent Middle Archaic (6000 to 4000 BP). This evidence is represented by increased percentages of piñon pollen at circa 4500 BP at Chihuahueños Bog, 4300 BP at Alamo Bog, and 4000 to 3500 at Alta Alamo Bogs (Chapter 5, Volume 1; Anderson et al. 2007; Brunner-Jass 1999; Stearns 1981). However, this pattern is clearly illustrated in a pollen diagram from the Anasazi Origins excavations at Collier Dune near Albuquerque (Figure 74.4). This diagram shows a marked shift from grassland to piñon-dominated pollen at about 4500 BP (Vierra 1997). It may be during the Middle Archaic that fall hunts in the Rio Grande Valley were becoming less successful, so these hunter-gatherers would have shifted their residence to the uplands where they could collect piñon nuts and hunt deer. Rather than dried bison meat, stored piñon nuts might have provided an important source of protein during the winter months (Vierra 2005a).

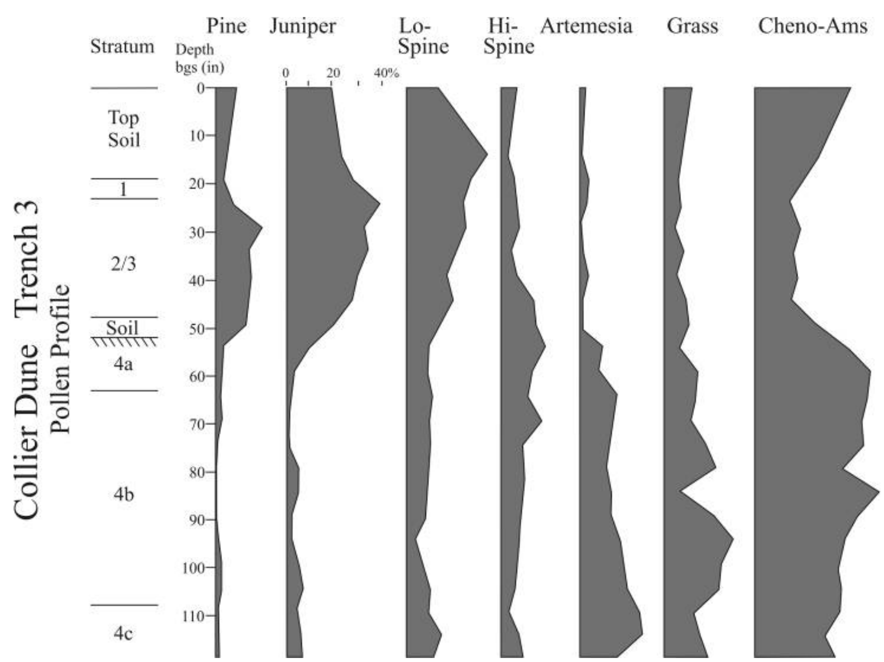

Figure 74.4. Collier Dune pollen profile.

The initial use of maize agriculture is dated to about 3000 BP during a period of increased effective moisture (Smith and McFaul 1997; Vierra and Ford 2006, 2007) (Figure 74.5). These moister conditions continue until about 2200 BP with the onset of drier conditions. The cyclical nature of the rainfall conditions during the subsequent time period has been described in the El Malpais data (Grissino-Mayer 1996). Late Archaic land-use appears to be characterized by a lowland/upland pattern within restricted areas of the Rio Grande Valley. This involved movements from the juniper-savanna in the early summer (Indian ricegrass), to the ponderosa pine/mixed conifer in the mid to late summer (cheno-ams, wild onions, berries, and wild potatoes), and then down to the piñon-juniper woodlands in the fall (pine nuts, acorns, broad leaf yucca, and cacti). Riverine settings also appear to have been used for winter campsites (Vierra 2003, this volume; Vierra and Foxx 2002, this volume).

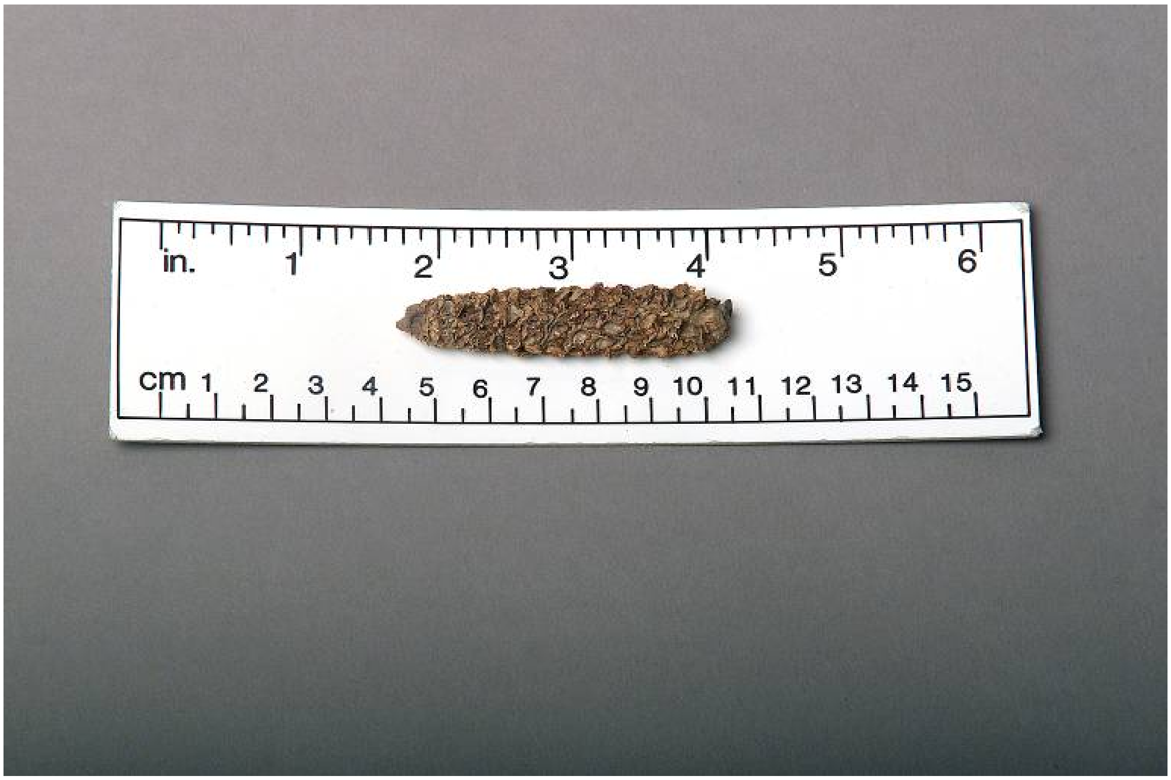

Figure 74.5. Maize cob from Jemez Cave.

ARCHAIC PROJECTILE POINT TYPOLOGY AND TECHNOLOGY

A total of 409 Archaic projectile points provide the database for research conducted for this chapter. Previous systematic studies of Archaic projectile points have identified important changes in point technology through time (e.g., Moore 1994; Moore and Brown 2002). Most notable of these are decreasing stem length, changes in basal morphology, and stem/base modifications (e.g., grinding and thinning).

The Early Archaic points are large stemmed points with long blades, slight shoulders, and a contracting stem (Figure 74.6). Jay points (upper) are generally larger than Bajada points (lower), with the latter exhibiting basal thinning and concave bases, and most of the former having straight or convex bases. These points are made from large biface blanks with a mean thickness of 8.3 mm. The base and/or lateral edges usually exhibit grinding (96%), with blade resharpening and rebasing also being common (86%). Previous studies indicate that Late Paleoindian groups often increased tool use-life by refurbishing the proximal end of broken points, while discarding the smaller base fragments. Early Archaic groups, on the other hand, resharpened the blade in conjunction with refurbishing the base. This may in part reflect a shift from the intercept hunting of large game in open settings to the increasing use of an encounter hunting tactic for medium to small game in wooded settings. This might also explain the shift to smaller-sized Bajada points.

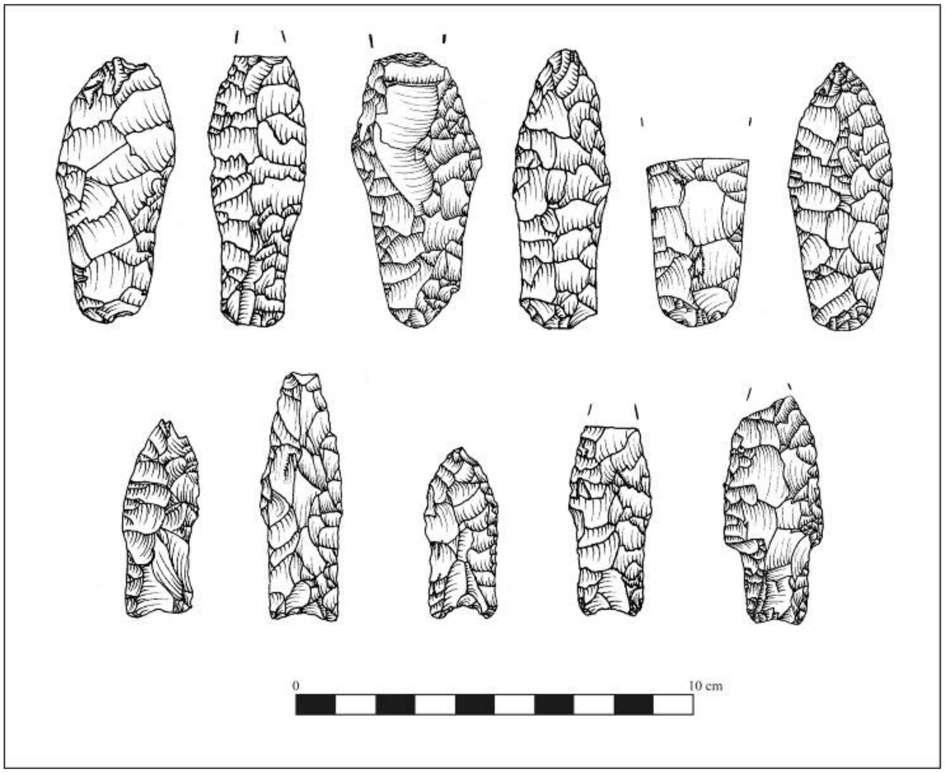

Figure 74.6. Jay (upper) and Bajada (lower) Early Archaic points.

Middle Archaic San Jose style points are characterized by large to medium size stemmed points with shorter blades and stems (Figure 74.7, upper). The blade is serrated with a concave base. The base and/or lateral edges often exhibit grinding (96%); however, the points are rarely rebased, but the blades are often resharpened (66%). They are often discarded when exhausted, with about 50 percent of the points being whole. Again, this point type is made from a large biface blank, with a mean thickness of 6.9 mm. This change in point morphology could have allowed for greater efficiency while encounter hunting in upland wooded environments. This might also explain the presence of serration, which would have increased bleeding and therefore provided a blood trail to follow. In addition, serration might also offset the decreased resharpening potential of the shorter blade by allowing for fewer resharpening events.

In summary, Early and Middle Archaic point technology is designed for a lower tool replacement rate that involves the production of points from biface blanks and heavy blade resharpening (also rebasing during Early Archaic). On the other hand, there is low point diversity, with generalized points being used to hunt various large, medium, and small size game.

Changes in point size and design presumably reflect the increasing importance of hunting medium to small size game in wooded settings.

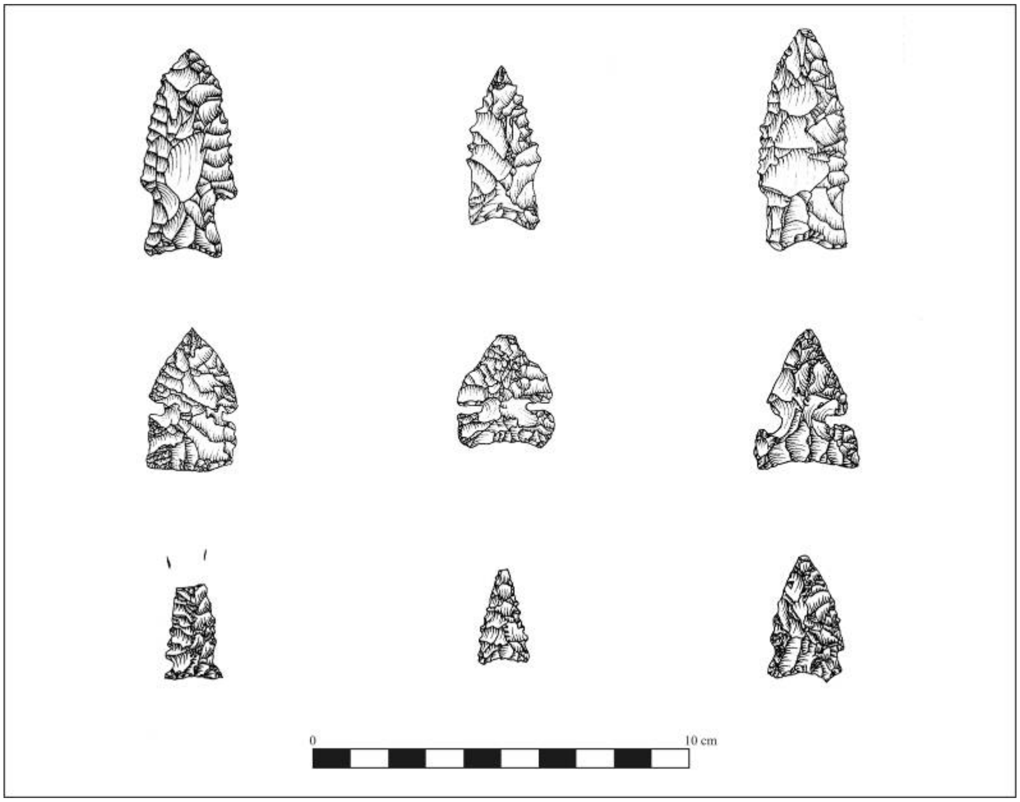

Figure 74.7. San Jose (upper), side-notched (middle), and Armijo (lower) Middle to Late Archaic period points.

On the other hand, if the large side-notched points are roughly contemporaneous with San Jose style points, then two very different technologies were being used at the same time (Figure 74.7, middle). All are made on thinner flake blanks with a mean thickness of 5.0 mm. These points exhibit less blade resharpening (52%) and almost no basal grinding (3%). They are more often being discarded when broken, with only 34 percent being whole.

Late Archaic Armijo points appear to represent a continuation of the San Jose style, with shorter blade and stem and the presence of serration and a concave base (Figure 74.7, bottom). However, there are important differences. These Late Archaic points are also made on thin flake blanks with a mean thickness of 5.1 mm. They also exhibit little resharpening (33%), but usually exhibit basal grinding (75%). Like the large side-notched points, they too are mostly being discarded when broken, with only 33 percent being whole.

The Late Archaic En Medio period is characterized by a shift away from the use of a few generalized point types to a variety of specialized point types. This includes at least five different types: corner-notched (n = 64), side-notched (n = 15), wide and narrow stemmed points with straight and concave bases (n = 72), leaf-shaped points (n = 16), and contracting stemmed points (n = 5) (Figure 74.8). All of these are made on flake blanks with mean thicknesses ranging from 5.4 to 5.9 mm, with evidence of the original ventral surface of the flake and plano-convex cross-section being common. These points are rarely resharpened (0 to 30%), with roughly half of the points being discarded either when broken or whole. They generally do not exhibit basal grinding (0 to 30%), which is especially true for the leaf-shaped points that may have been hafted with mastic. The leaf-shaped and contracting stem points also differ from most other Late Archaic points by being mostly serrated (75% versus 60%, respectively).

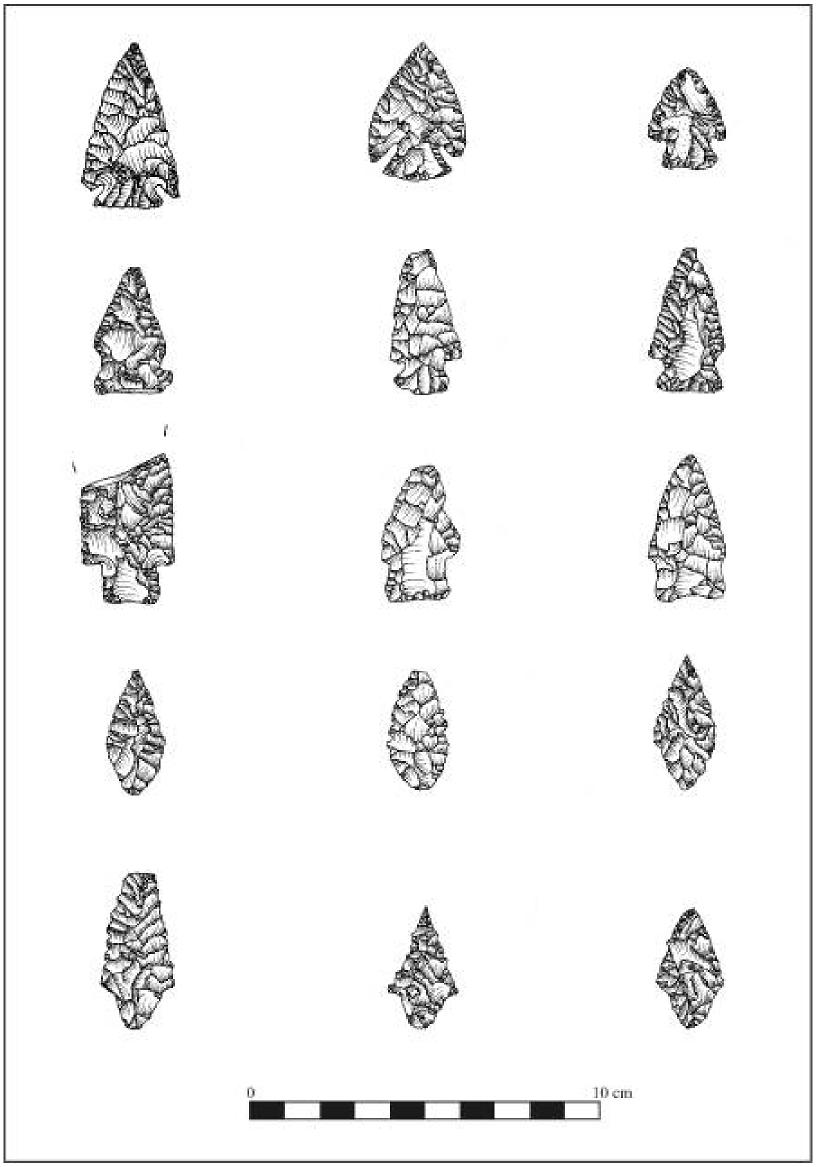

Figure 74.8. Late Archaic point types.

This diversity of Late Archaic point types presumably reflects the implementation of a variety of hunting tactics designed to efficiently procure specific types of game. The use of a few generalized point types, and low tool replacement rates due to resharpening during the Early and Middle Archaic, is now replaced with a diversity of point types and high tool replacement rates, with little blade resharpening to extend tool use-life. Flake blanks could reduce tool production costs and allow for a greater variety of smaller raw materials to be used, something important with restricted mobility. Otherwise, the use of a variety of specialized points sets the stage for the later adoption of the bow and arrow, circa AD 400.

REGIONAL LAND-USE

Distribution of point types across Zones 1 to 3 for Jay and Bajada points, and Zones 1 to 2 for the remaining point types, is provided in Figure 74.9 (left to right). There is an increase in the number of Jay points from south to north, with more Bajada points in the southern zones. The prevalence of Jay points in the San Luis Valley reflects the increased importance of large game hunting in this area, while the later Bajada foragers primarily exploited the wooded terrain in Zones 1 and 2. San Jose points are primarily represented in Zone 1, in contrast to the large side-notched points that are present in Zone 2. If this pattern continued into Zone 3, it might indicate that these side-notched points actually represent foragers entering the Rio Grande Valley from the north with San Jose foragers moving up from the south. There are also more Armijo points in Zone 2, but the sample size is only 12. On the other hand, all the other Late Archaic point types reflect a bias towards Zone 1, especially for the leaf-shaped points.

A variety of lithic raw materials were available to these ancient foragers, and the data indicate that they were very selective in choosing which material fit their tool requirements. The distribution of the three primary lithic raw materials is presented in Figure 74.10. There is a general decrease in the use of basalt from Jay, to Bajada, to San Jose, to large-side notched and Armijo points, with a corresponding increase in the use of obsidian through time. The increasing use of obsidian may in part reflect the increasing use of these upland resources areas, while dacite is primarily situated in lowland settings. Otherwise, very little chert/chalcedony is used for the production of most point types.

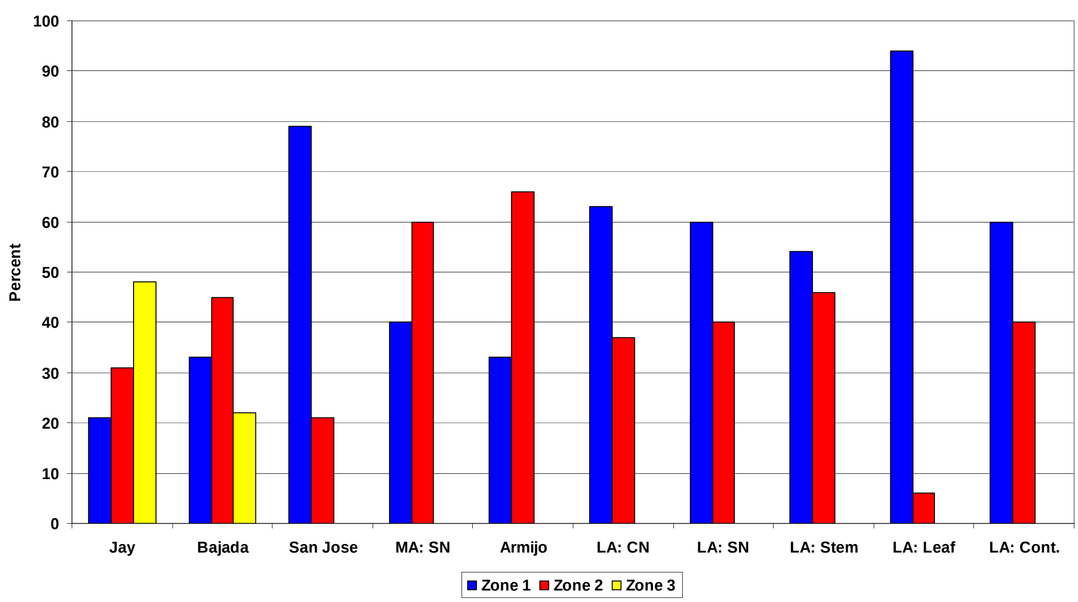

Figure 74.9. Distribution of Archaic point types by zone.

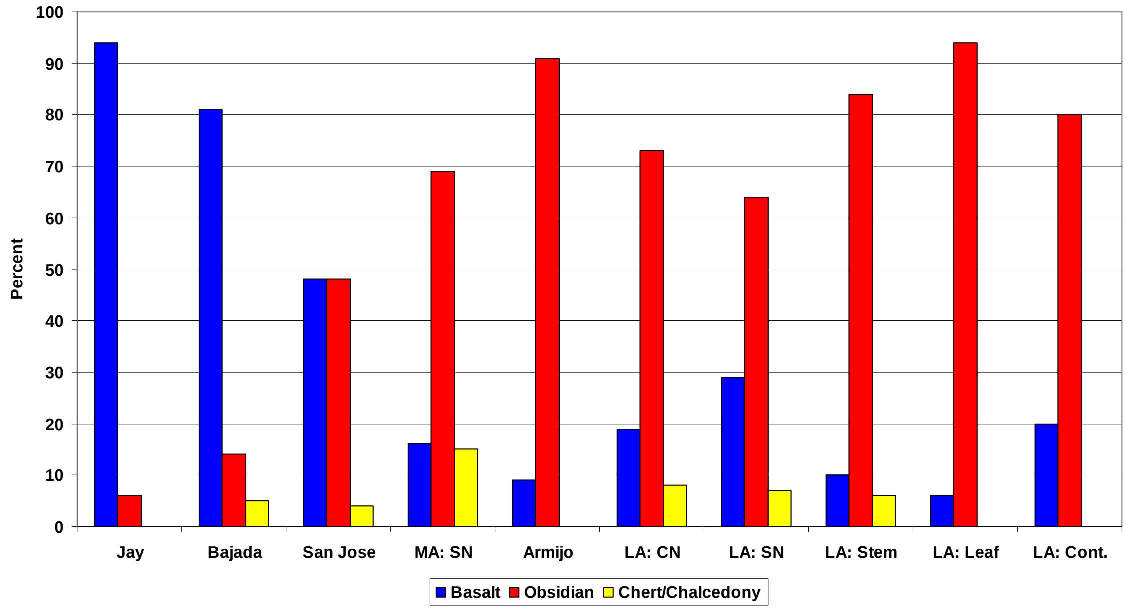

Figure 74.10. Distribution of material types for Archaic point types.

These data were then separated between Zones 1 and 2, with obsidian being visually segregated between the translucent central Jemez Mountains sources and the dusty El Rechuelos source situated at the northern end of the mountains. Figure 74.11 illustrates a similar pattern as observed in Figure 74.10, with the exception that most of the obsidian was derived from the central Jemez Mountains sources (i.e., Valle Grande and Cerro Toledo). In contrast, Figure 74.12 also shows a similar pattern as seen in Figure 74.10, but in this case most of the obsidian was derived from the El Rechuelos source**.** The two exceptions are the San Jose and Armijo style points, which have a mix of Jemez Mountains and El Rechuelos obsidian.

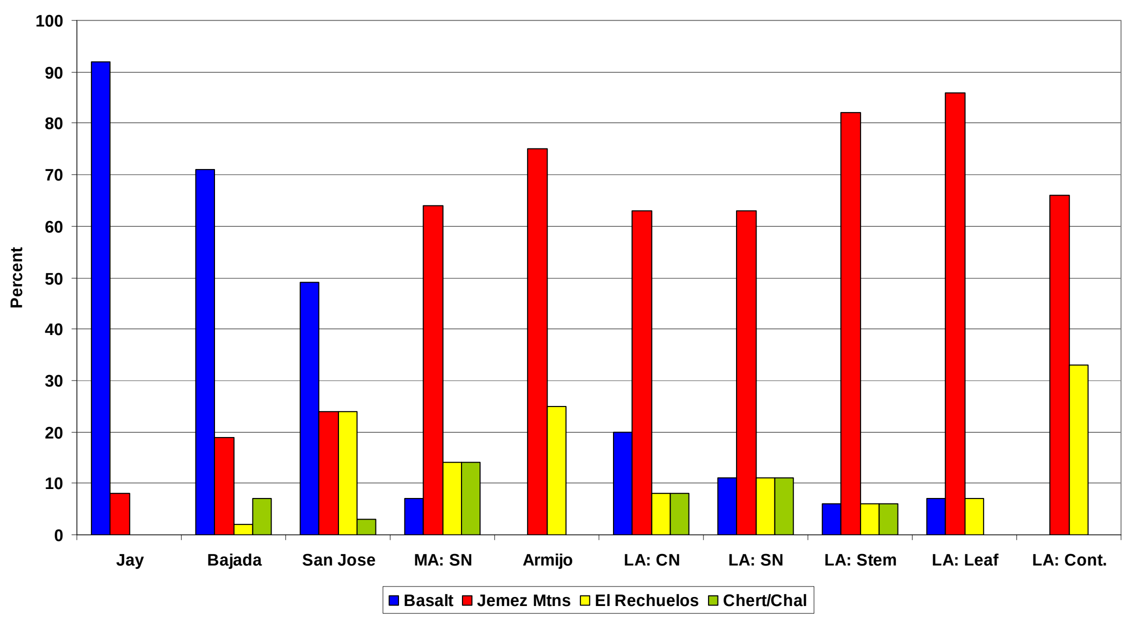

Figure 74.11. Distribution of material types for Archaic points in Zone 1.

An X-ray fluorescence analysis was conducted of a sample of 101 projectile points to further clarify this pattern. This sample consists of 72 obsidian and 29 dacite points. A previous study by Vierra et al. (2005) indicates that these "basalt" artifacts are actually a fine-grained black dacite, with three identified sources: the Cerros del Rio source in Zone 1 at Bandelier National Monument and the San Antonio Mountain and Newman's Dome sources near Tres Piedras in Zone 2.

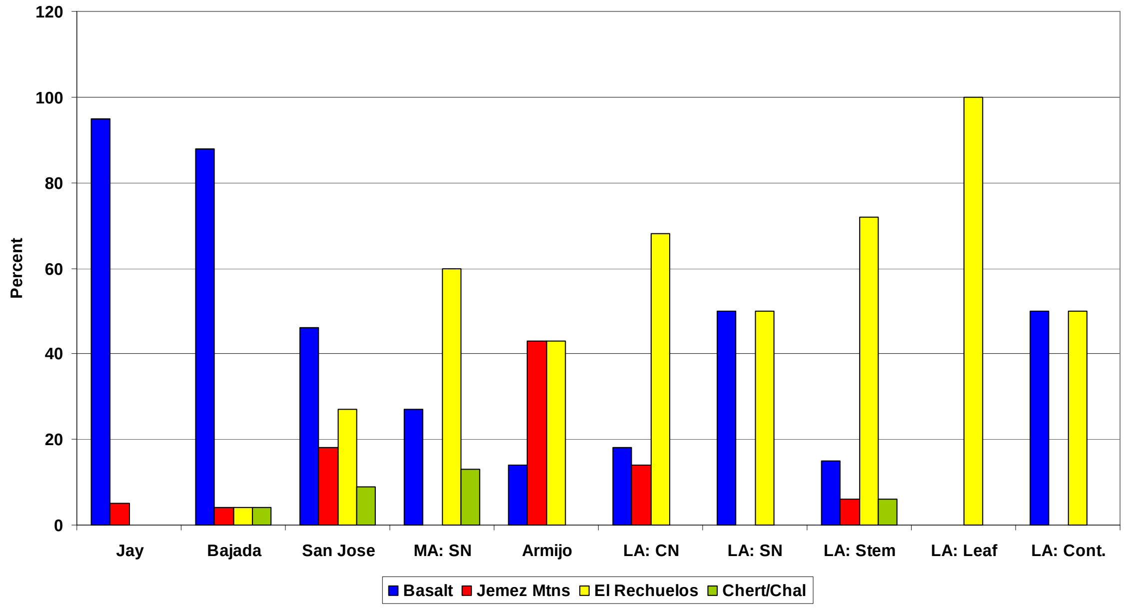

Figure 74.12. Distribution of material types for Archaic points in Zone 2.

Figure 74.13 illustrates the distribution of obsidian types in Zone 1. Due to the small sample sizes and similarities in distribution, the Early and Late Archaic samples have been merged into two single categories. On the other hand, the San Jose and large side-notched points have been kept separate because of important differences in these two distributions. Nonetheless, the central Jemez Mountains sources dominate Zone 1 with mostly Cerro Toledo and Valle Grande obsidian. However, the Early Archaic and San Jose-style points are also represented by obsidian derived from the southern Bear Springs source and a few items from the northern El Rechuelos source. Both San Jose and the large-notched points dominate the Valle Grande source. Since the Valle Grande obsidian source is restricted to the caldera, this pattern provides support for the contention that these Middle Archaic foragers were integrating these upland areas into their summer and fall seasonal rounds and thereby collecting more of this obsidian. This contrasts with the Cerro Toledo source, which is present along the eastern periphery of the caldera and in secondary deposits along the nearby canyons and Rio Grande Valley.

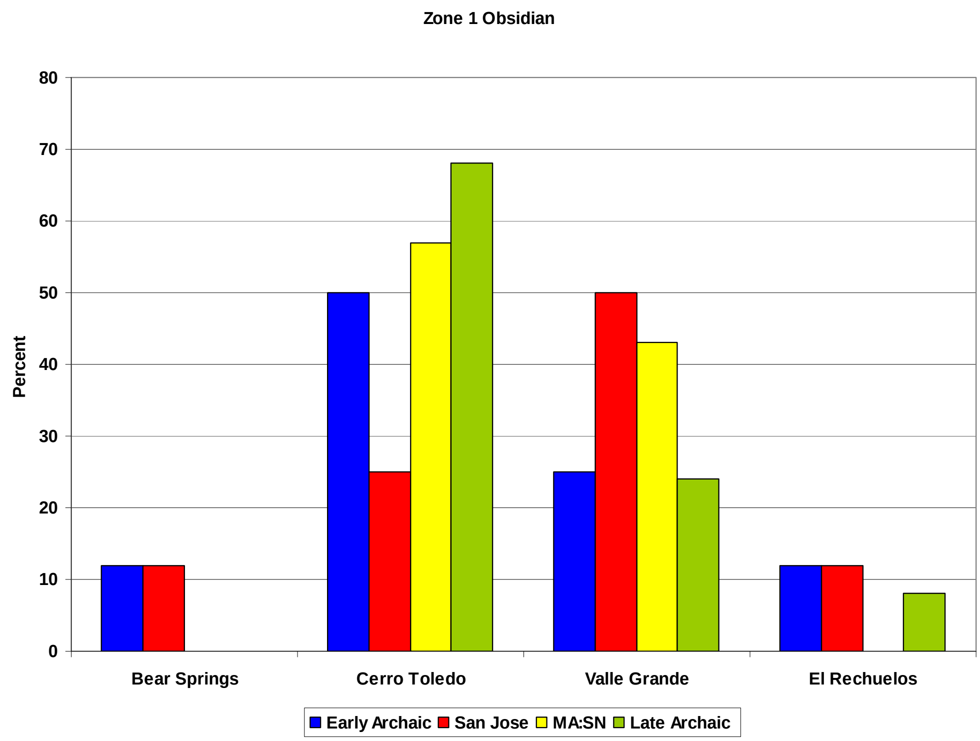

Figure 74.13. Distribution of obsidian types in Zone 1.

Figure 74.14 illustrates the distribution of obsidian types in Zone 2. In this case, most of the points are made of the northern El Rechuelos source. However, the Early Archaic again reflects a north-south pattern with all three central and northern obsidian sources represented. San Jose points continue to reflect the importance of Valle Grande obsidian, but now with El Rechuelos. Lastly, the large side-notched and Late Archaic points are primarily made of El Rechuelos obsidian. Together the obsidian data seem to support a north-south seasonal movement during the Early Archaic, with a more restricted north-south pattern during the Middle Archaic. The large side-notched and Late Archaic points were made on flake blanks with shorter use-lives. In this case, both sets of points are dominated by the most proximate obsidian source. Yet the question is, do these large side-notched points represent foragers moving down the Rio Grande Valley towards the Jemez Mountains and then turning north towards the San Juan Mountains? This contrasts to the Late Archaic, which probably represents an even more restricted pattern of movement that involves a mostly east-west, lowland to upland pattern.

Figure 74.15 illustrates the distribution of dacite in Zone 1. As can be seen, the Early Archaic sample contains examples of all three dacite types that are available in both Zones 1 and 2. In contrast, the later periods are characterized by smaller samples, but lack the San Antonio Mountain source, with some Newman's Dome. This also reflects a clear north-south pattern of movement between Zones 1 and 2 during the Early Archaic period.

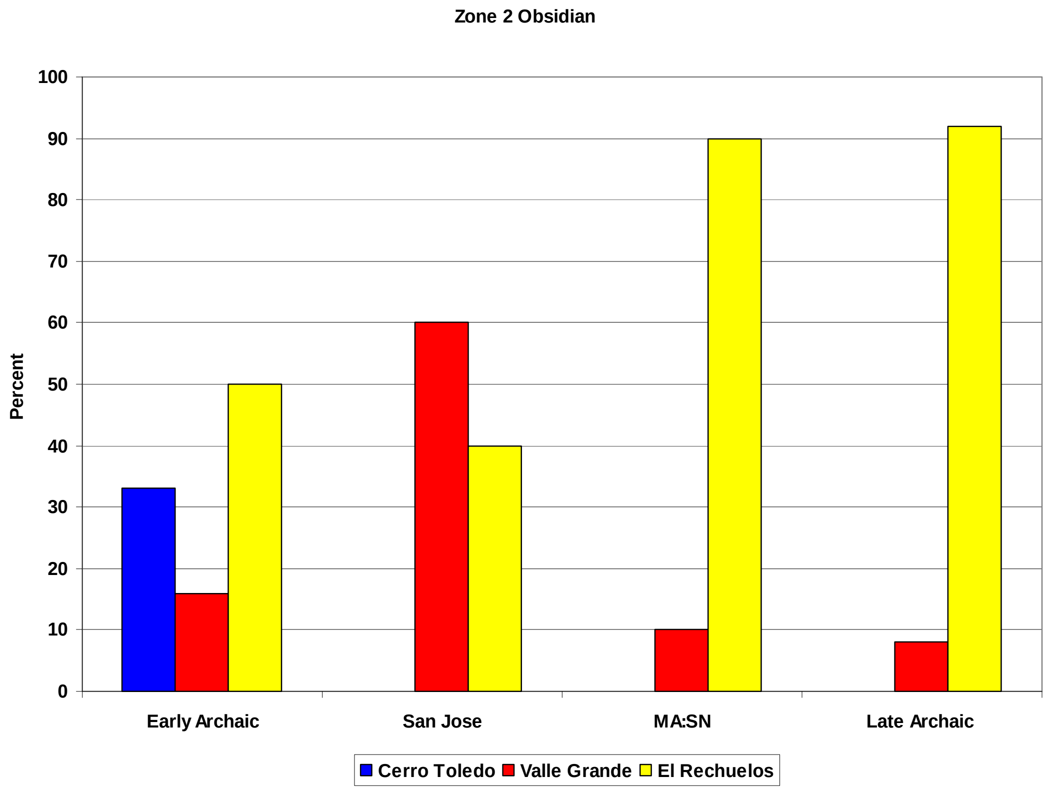

Figure74. 14. Distribution of obsidian types in Zone 2.

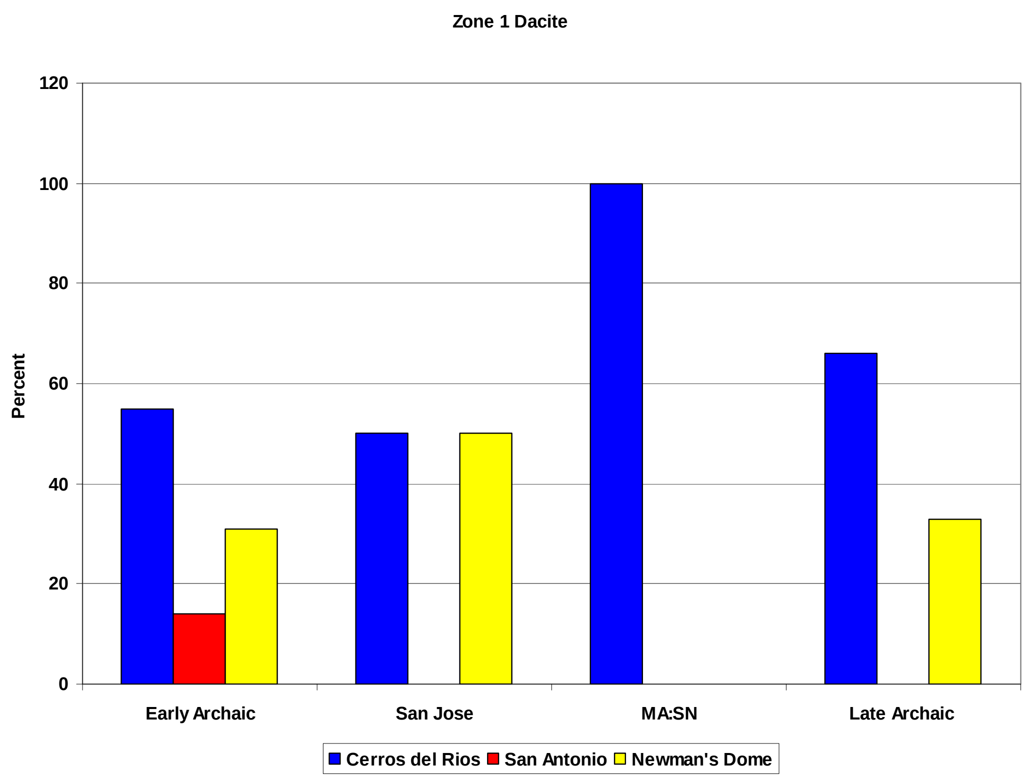

Figure 74.15. Distribution of dacite types in Zone 1.

Figure 74.16 illustrates the distribution of dacite in Zone 2. Again, all three dacite sources are represented in the Early Archaic sample. In contrast, the San Jose points are represented by both local dacite sources, but the large side-notched and Late Archaic points are solely made from the local Newman's Dome source. Presumably this continues to represent a long pattern of decreasing north-south movement from Early to Middle Archaic, with a much more restricted range during the Late Archaic. More data are needed from the San Luis Valley (i.e., Zone 3) to fully clarify the possible relationship with the southern Rocky Mountains for these large side-notched points.

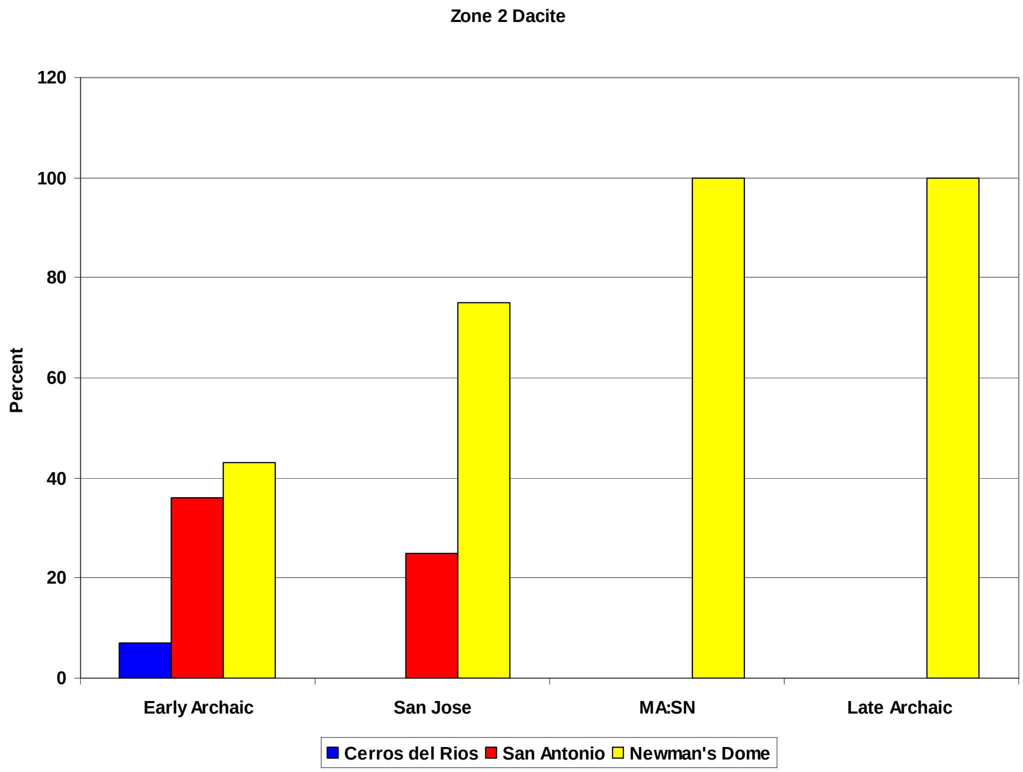

Figure 74.16. Distribution of dacite types in Zone 2.

CONCLUSION

In conclusion, this chapter has taken a preliminary look at the possible relationship between changes in climate, resource structure, foraging strategies, and projectile point technology in the northern Rio Grande Valley. Changes in Early and Middle Archaic period point typology and technology may be associated with the expansion of piñon-juniper woodlands in the region and a shift from hunting large game in open settings to more medium to small sized game in wooded settings. The projectile point technology was characterized by low point diversity and low tool replacement rates. In contrast, the Late Archaic point technology was characterized by high tool replacement rates and high point diversity. Annual movements became more restricted and oriented to a lowland-upland seasonal pattern. The long-term replacement of mostly dacite with obsidian lithic material is presumably associated with the increasing use of these upland resource areas. Overall, these changes in projectile point technology could reflect a "replacement when exhausted" versus a "replacement based on a probability of failure" strategy (Kuhn 1989). That is, Early to Middle Archaic groups were more residentially mobile, with a technology that was continuously being used and maintained. In contrast, Late Archaic groups were becoming more logistically organized while focusing on a greater variety of target species. Therefore, higher tool replacement rates could have been used as a means of increasing tool reliability and hunting success rates (also see Vierra 1992b:104).

CHAPTER 75
ARCHAIC UPLAND RESOURCE USE: THE VIEW FROM THE PAJARITO PLATEAU, NEW MEXICO

Bradley J. Vierra and Teralene Foxx

INTRODUCTION

In 1973, Cynthia Irwin-Williams (1973:5) stated that “two kinds of special activity sites are known outside the [Arroyo Cuervo] region: isolated hunting camps in the Jemez Mountains and repeated quarry workshop camps…” Five years later, one of the first systematic surveys in the Jemez Mountains was conducted along the valley of the Redondo Creek at elevations over 8000 feet (Moore et al. 1978). Although they found numerous lithic scatters, they were neither hunting camps nor quarries, but rather campsites where a range of hunting and gathering activities appeared to have taken place (also see Baker and Winter 1981). However, there has been very little systematic research conducted in these upland settings during the intervening 20 years.

This chapter reviews the archaeological evidence for the Archaic occupation on the central Pajarito Plateau. Recent survey and excavations conducted at Los Alamos National Laboratory (LANL) has identified over 50 Archaic sites and 175 lithic scatters. The survey evidence reveals the systematic and repeated long-term use of these upland resource areas by Archaic foragers. Indeed, several broad occupation zones can be identified. We summarize the ethnobotanical data on possible plant use for each vegetation community and suggest a possible seasonal strategy for exploiting these resource zones during the Late Archaic. Debitage artifact data from recently excavated Late Archaic sites are subsequently used to link lowland habitation to upland campsites to illustrate this complementary land-use strategy.

ARCHAIC LAND-USE AT LOS ALAMOS NATIONAL LABORATORY

LANL occupies the central section of the Pajarito Plateau**.** The plateau covers an area roughly extending from Santa Clara Canyon on the north to the mesas above Cochiti Pueblo on the south to the caldera on the west and the mesas overlooking the Rio Grande Valley to the east. LANL covers approximately 29,000 acres of land on this high mesa, ranging from about 6000 to 8000 feet in elevation. The mesa has been incised with several deep canyons that drain from the mountain country down to the river valley. Balice et al. (1997) have defined four basic vegetation types at LANL: juniper-savanna, piñon-juniper, ponderosa pine, and mixed conifer. Figure 75.1 illustrates the distribution of these vegetation types. As can be seen, most of the area is covered with piñon-juniper woodlands at the lower elevations and ponderosa pine at the higher elevations.

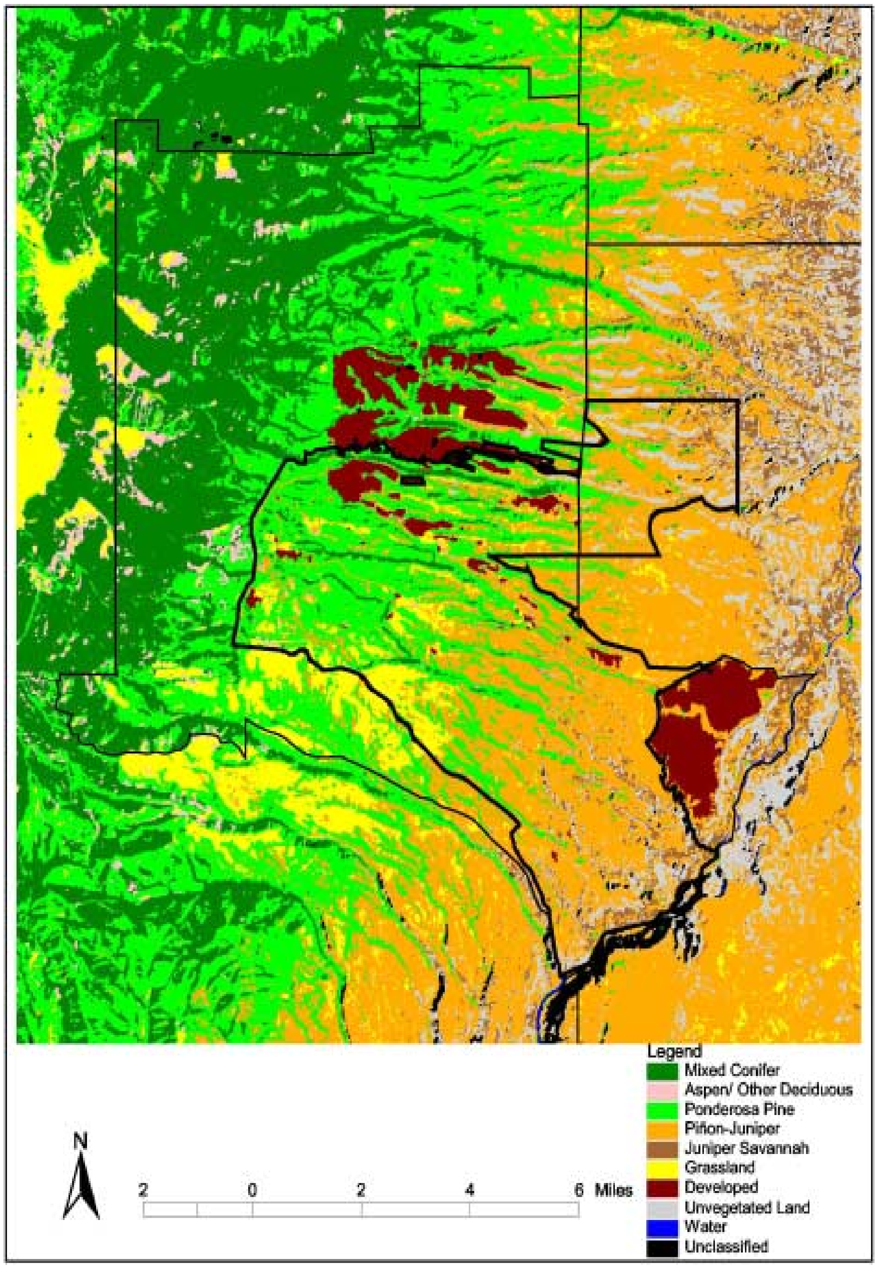

Figure 75.1. Vegetation types at Los Alamos National Laboratory.

A total of 51 Archaic sites have been identified at LANL. These sites are characterized by obsidian lithic scatters ranging from 40 to 140,000 sq m in size. The assemblages emphasize the production/maintenance of bifacial tools, with occasional one-hand manos and millingstones also present. The diagnostic Early, Middle, and Late Archaic projectile point types on the plateau are similar to those defined by Irwin-Williams for the Oshara Tradition (Figure 75.2). Figure 75.3 illustrates the relative percentage of sites by Archaic time period. As can be seen, there are very few Early Archaic sites, somewhat more Middle Archaic sites, and mostly Late Archaic sites represented.

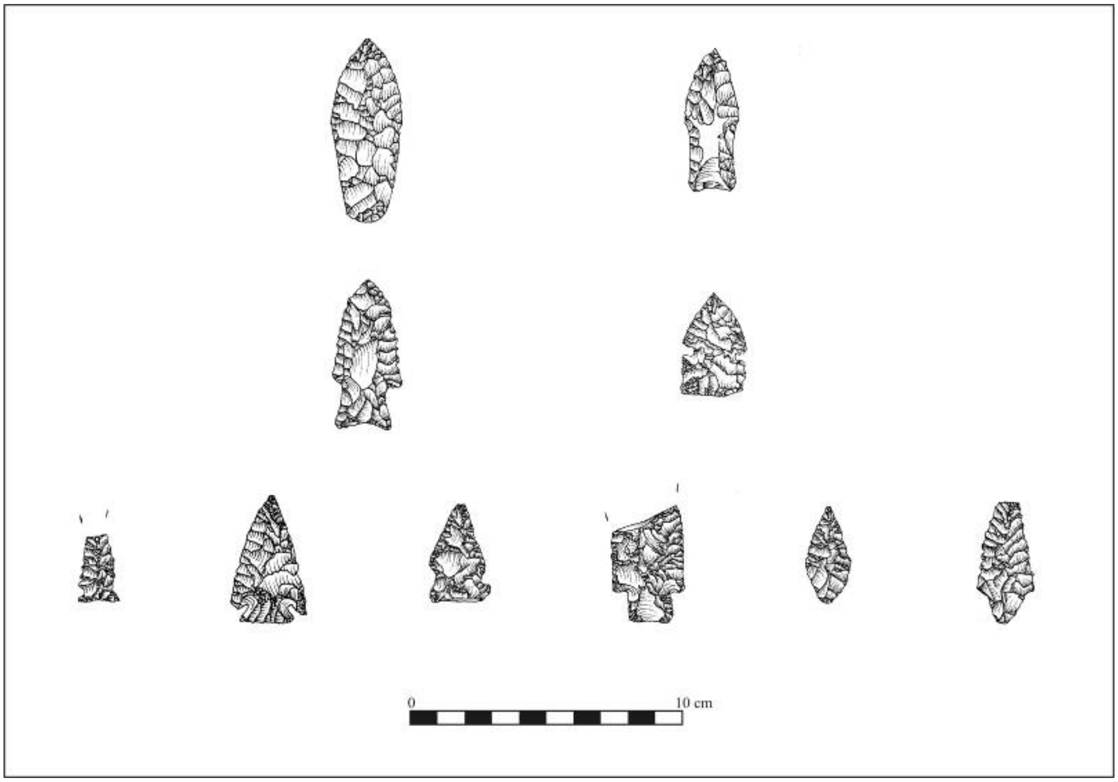

Figure 75.2. Diagnostic Early, Middle, and Late Archaic point types.

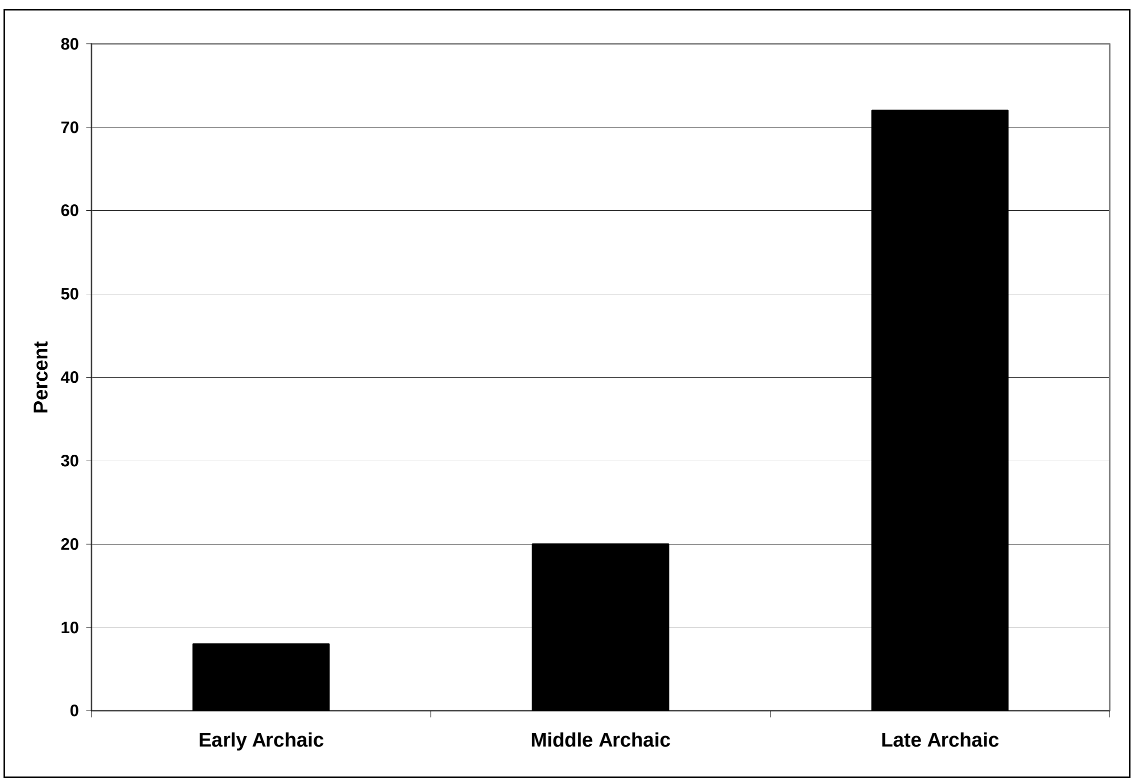

Figure 75.3. Relative frequency of Early, Middle, and Late Archaic sites.

This pattern does not necessarily reflect the increasing use of these upland areas through time, but rather the long-term effects of various geomorphic processes on the archaeological record. For example, although there is a Late Archaic site present on the surface of Mortandad Canyon, a charcoal sample was collected from an 11-m-deep core hole that yielded a date of 7260 BP, indicating that Early and Middle Archaic deposits may be buried within these alluvial settings (Reneau et al. 1996a). This chapter will therefore focus on the Late Archaic, given the number of archaeological sites represented, and the relative similarity in environment over the last 3000 years.

Figure 75.4 illustrates the distribution of Archaic sites at LANL. Since the distribution of sites is sparse, we have combined them with the distribution of all obsidian lithic scatter sites (Figure 75.5). In the latter case, we have used the actual site boundaries and not single points. These assemblages are also dominated by the production/maintenance of obsidian bifacial tools, but lack diagnostic projectile points. Given the previous data, it is likely that most of these sites represent Late Archaic occupations. Nonetheless, both figures illustrate several broad occupation zones: 1) juniper-savanna zone in the Rio Grande Valley, 2) piñon-juniper zone at lower elevations on the plateau, 3) piñon-juniper/ponderosa ecotone at mid-elevations on the plateau, and 4) ponderosa pine/mixed conifer ecotone at the higher elevations. It appears that the ponderosa pine and mixed conifer communities are also important to Late Archaic foragers and not only the piñon-juniper zone as has traditionally been argued.

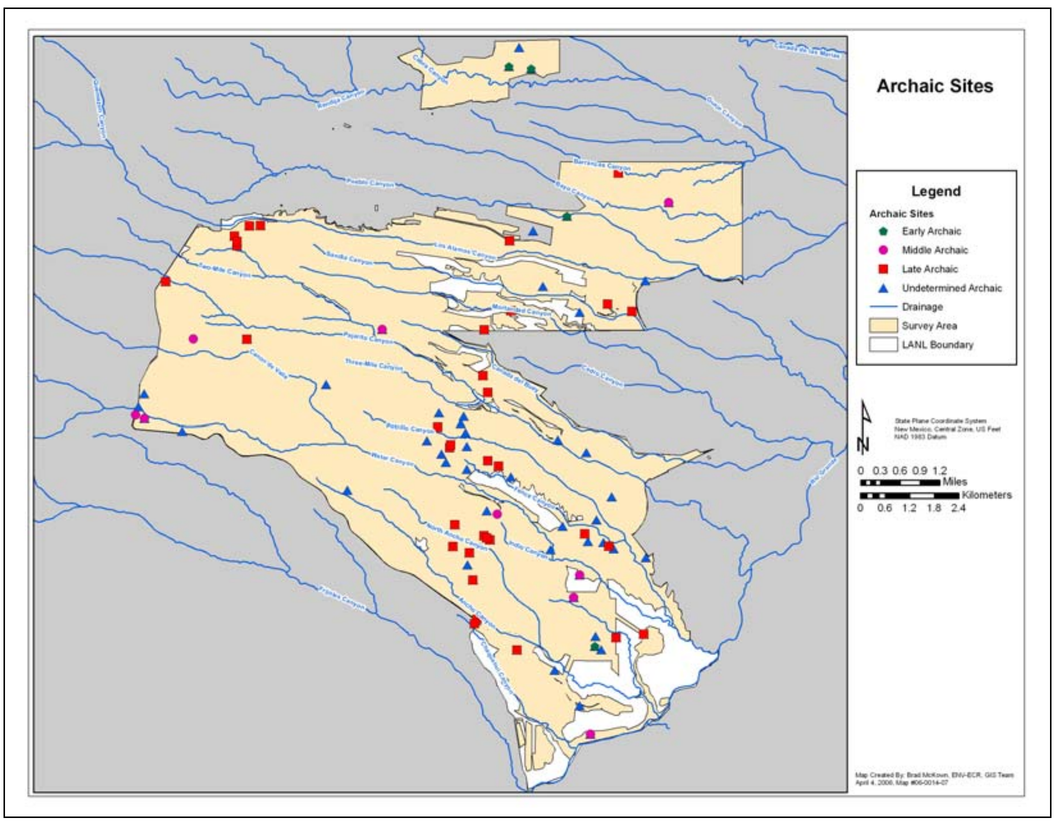

Figure 75.4. Distribution of Archaic sites at LANL.

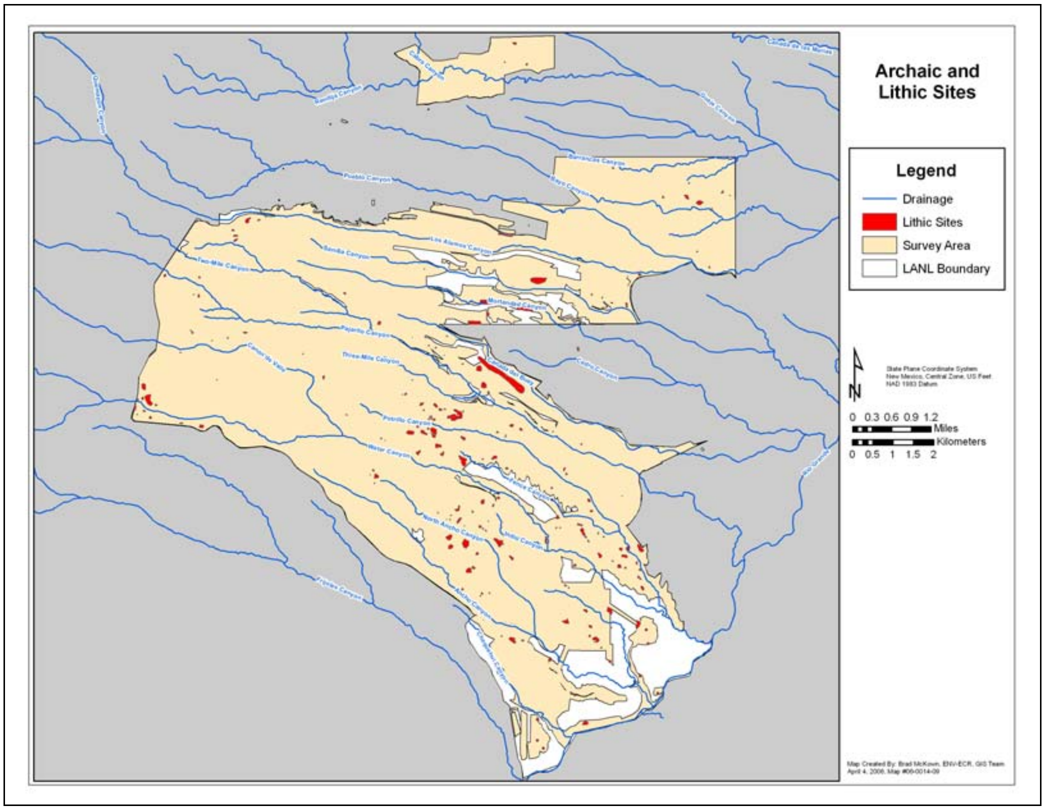

Figure 75.5. Distribution of Archaic and lithic scatter sites.

SEASONAL USE OF UPLAND AREAS

So, how were these Late Archaic foragers using these upland resource areas? A total of 985 plant species were described in Foxx et al.'s (1998) recent *Annotated Checklist of Vascular Plants in the Jemez Mountains*. This checklist provides information on plant locations, occurrence, phenology, and uses. Over 200 of the plants identified for the Jemez Mountains by Foxx et al. (1998) are also identified in Dunmire and Tierney (1995) as having specific ethnobotanical uses such as food, medicine, implements, and many with multiple uses. Using these two references, we constructed tables to analyze the possible plant use by elevation and activity for the Pajarito Plateau and east Jemez Mountains. Table 75.1 summarizes all the uses for the over 200 plants identified. Although many of the plants have multiple uses, we are confining our analysis in this paper to only the108 plants identified as subsistence plants.

Table 75.1. Plant uses by vegetation community.

Activity	**Riparian**	**Jun-Sav***	**PJ***	**Pipo***	**MC***	**Burned**
Medicinal (*n* = 148)	18	82	111	73	35	14
Food (*n* = 108)	23	41	77	56	30	13
Implements (*n* = 28)	4	14	20	15	6	4

Activity	Riparian	Jun-Sav*	PJ*	Pipo*	MC*	Burned
Coloring/Tanning (*n* = 37)	6	19	24	16	6	6
Construction (*n* = 16)	6	7	9	8	4	2
Smoking (*n* = 13)	0	8	11	3	9	1
Cordage (*n* = 6)	2	3	2	2	1	1
Total	**59**	**174**	**254**	**173**	**91**	**41**

*Jun-Sav is juniper-savanna; PJ is piñon-juniper; Pipo is *Pinus ponderosa* or ponderosa pine; MC is mixed conifer.

The plants identified as potential subsistence species are available from a variety of vegetation communities, including from lower to higher elevations: juniper-savanna, piñon-juniper, ponderosa, and mixed conifer. Many species can be found in multiple vegetation communities, but some species are limited to certain habitats within a plant community, or may be more abundant in certain habitats. For example, riparian and water resources are associated with multiple zones and are found within the canyon bottoms, along the Rio Grande, and in areas with springs and flowing water. Some species found near watered sites include wild grape, bee balm, willows, and cottonwoods.

Burned and disturbed areas also provide unique potential collecting sites within the piñon-juniper, ponderosa pine, and mixed-conifer zones. Tree-ring data indicate that there were frequent fires before 1900, particularly in the ponderosa pine zone (Foxx and Potter 1984). Burning enhances the habitat for species such as wild onion and cheno-ams, but also increases the vigor and vitality of these species for a short time, thus making these species more abundant and larger in burned sites (Foxx and Potter 1984). These areas would provide foraging patches within the ponderosa pine or burned areas within other zones. Disturbed areas can be found through all zones and are often associated with Ceramic period habitation sites. Species such as common purslane, wolfberry, and Rocky Mountain beeweed are commonly found in such sites.

To determine the relative potential use of the plant communities and the individual habitats, we took each species and determined which plant community it might occur in, when the plant would most likely be available, and how common it might be. We also looked at other factors that might influence the availability such as the phenology of the plant or habit.

Figure 75.6 illustrates the relative percentage of plant foods by vegetation community. As can be seen, the piñon-juniper community contains the greatest variety of plant foods followed by ponderosa pine zone. Fewer species are found in the juniper-savanna, mixed conifer, and riparian communities. If the five percent burned area species are target collecting sites primarily in the ponderosa pine plant community, then that community becomes an enhanced site for collecting species such as wild onion and cheno-ams. Therefore, the piñon-juniper and ponderosa pine communities are potentially the most productive areas for plant foods.

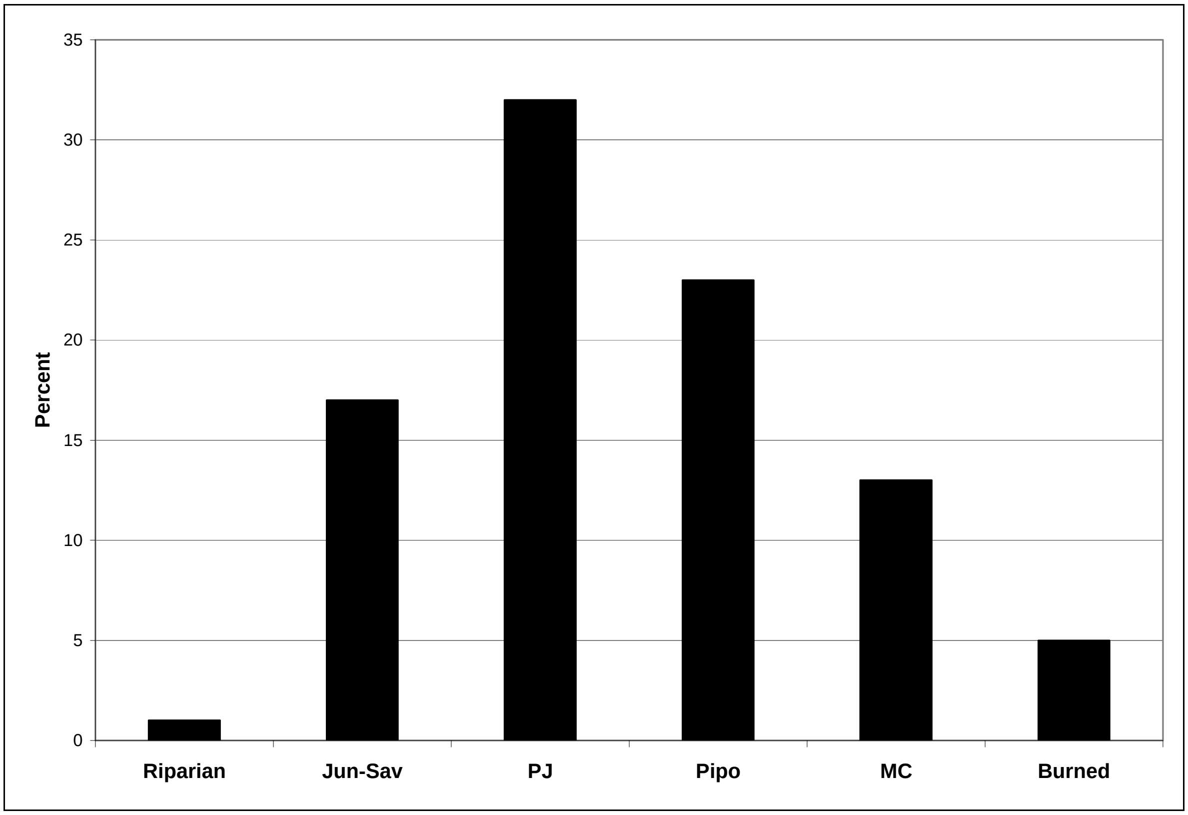

Figure 75.6. Relative percentage of food plants by vegetation community.

Figure 75.7 separates the species by plant group (structure or habit) and vegetation community. There are several important patterns. There is an increase in shrubs with elevation versus a corresponding decrease in annuals with elevation. One factor is the availability of plants as related to the plant structure. Trees, shrubs, and perennial plants will be found in the same locations from year to year because of their long-term longevity. On the other hand, annual plants live only one year and therefore are more dependent on seasonal rainfall patterns and other conditions such as disturbance. Many of the shrubs within the mid-elevation ranges (i.e., piñon-juniper and ponderosa pine) have collectable berries and would be a predictable resource. The increase in diversity of plants within these two zones make the ponderosa pine and piñon-juniper communities more desirable collecting areas.

Figure 75.8 illustrates the seasonal availability of food plant species by vegetation zone. The availability is very dependent on the elevational seasonality. High elevations such as mixed conifer will have a shorter growing season than the lower elevations such as the piñon-juniper woodlands. Warming will begin with the juniper-savannah in early spring providing early-season species such as Indian ricegrass. By May, greening of the mixed conifer and ponderosa pine will begin and species will start to sprout or leaf out. In the fall, the reverse is true. The seasonal cooling begins at high elevations and moves downslope. Therefore, in the fall more species would be available for collecting at lower elevations (i.e., the piñon-juniper woodlands). Overall, there are a variety of plant species available to procure at all elevations and at various seasons.

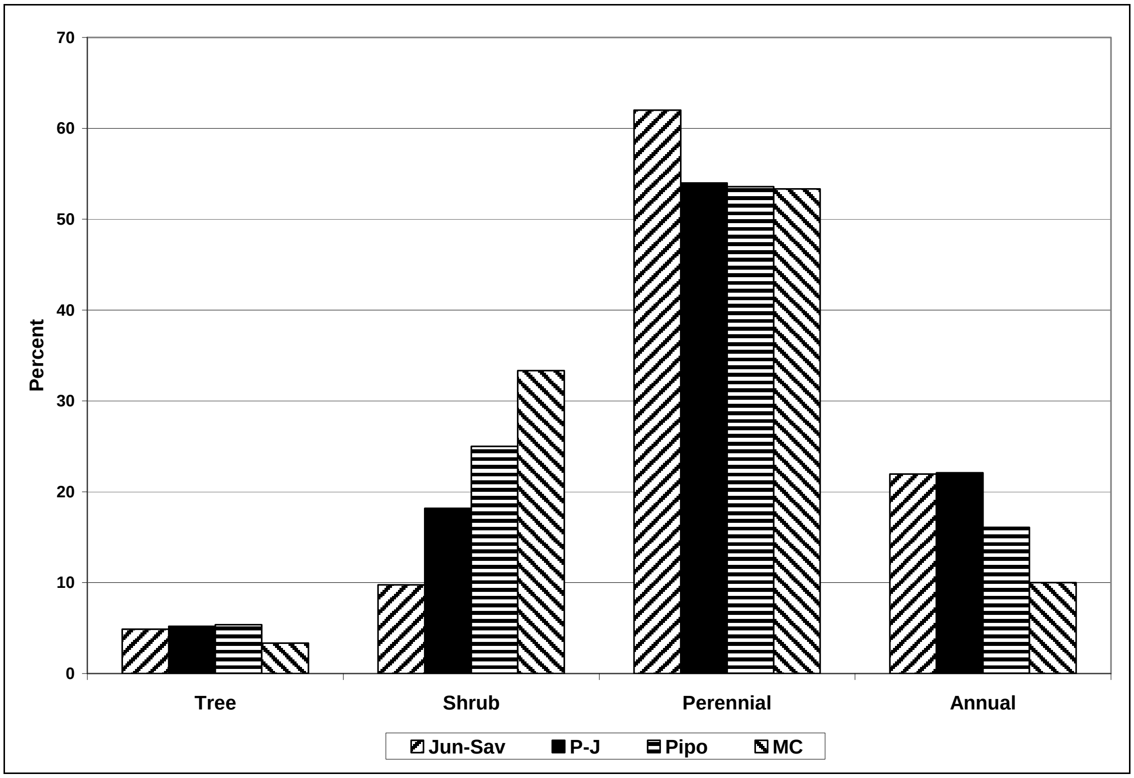

Figure 75.7. Plant groups by vegetation community.

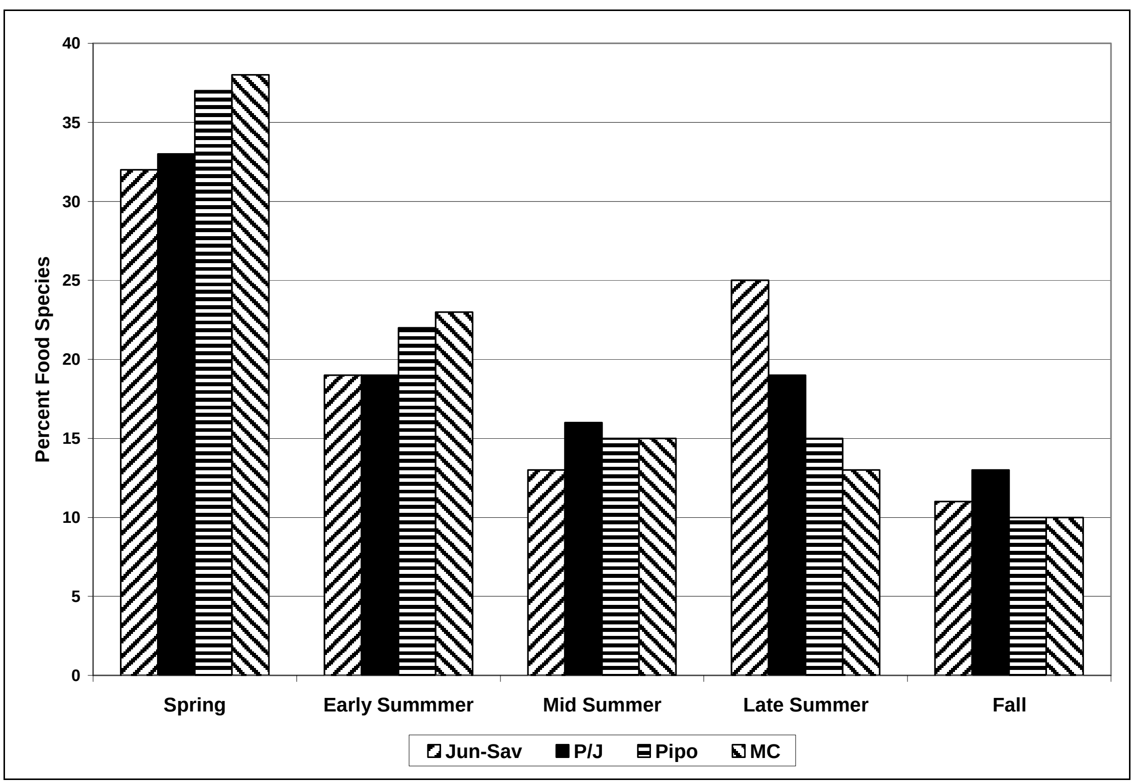

Figure 75.8. Plant seasonality by vegetation zone.

Various portions of a plant can be used at differing times of the year. Many perennial food plants are available for consumption in the springtime and later during the summer. For example, cheno-ams can be used as greens early in the season and seeds harvested later in the summer. Other plants used for the bulb or root crops such as wild onion will be available throughout the growing season. Some plants such as those with nuts and berries will not be used for greens and are therefore most available in mid to late summer or fall.

In this analysis, a number of plants are available in the spring and early summer at higher elevations. The highest number of food species is available during the mid-summer at the higher elevations (mixed conifer and ponderosa pine). In late summer the pattern changes when there is a step-like pattern with decreasing species richness with increasing elevation. In the fall, there are more food plants available in the piñon-juniper community. The drying of soils and south-facing aspect of White Rock Canyon and lack of berry producing shrubs and nut producing trees make the lower juniper-savannah less desirable for collecting except within the riparian zone along the river where berry producing species such as wild grape is found.

However, species richness does not necessarily reflect relative species abundance or evenness. Particular target species within each vegetation zone can be more common and productive than other species. Figure 75.9 provides information related to how common a particular plant is and its availability.

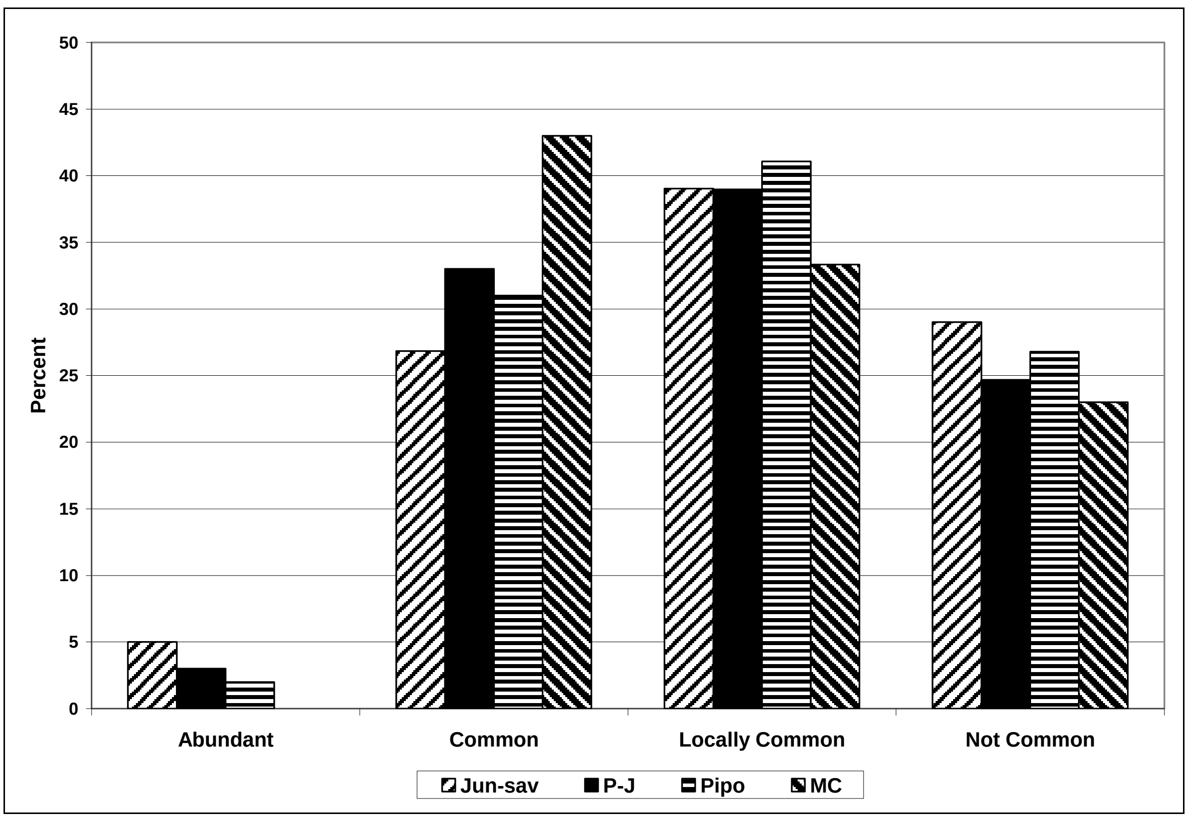

Figure 75.9. Relative plant species abundance by vegetation community.

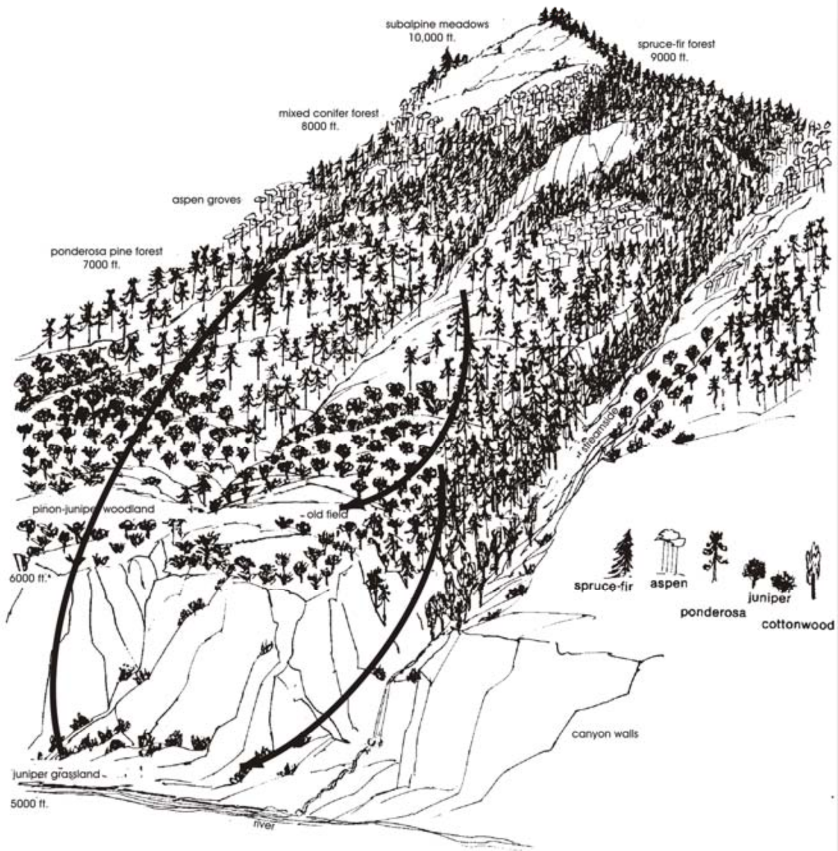
Based on personal experience, plant collections, and botanical texts, we have divided the plants into four categories: common, locally common, not common, and abundant. Species identified as common are those that are seen throughout an area. Locally common means that plants are found in patches or groups. Not common indicates they are seen as single plants, not in patches and not throughout an area. Abundant usually refers to a dominant species of an area such as the piñon pine in the piñon-juniper plant community. As can be seen from this figure, many of the species are locally common. This means perennial plants that are locally common would be found in patches. Therefore, we would expect particular target species to be collected in these areas.

If we identify a few possible target species that are both common and abundant in these various communities, then we can suggest a possible annual cycle for exploiting these resource areas (see Table 75.2). In the juniper-savanna community, cool-season grasses like Indian ricegrass are abundant, having seeds that are available in the early summer. Species used for greens such as cheno-ams can be found in all disturbed and burned contexts, but their resource patches could be found represented in the ponderosa pine zone and lower mixed conifer early in the summer. In addition, wild onions, berries, and wild potatoes are also available in these areas during the mid to late summer time period. In contrast, acorns, pine nuts, broad leaf yucca, and cacti would be available for consumption during the fall in the piñon-juniper zone. Dropseed grasses and cheno-am and saltbush seeds could have also been exploited during the late summer in this zone. If obsidian raw materials were procured while at high-elevation quarries while foraging, then these materials could have been reduced while camping at the lower-elevation campsites. This model of Late Archaic seasonal mobility is graphically illustrated in Figure 75.10.

Table 75.2. Target plant species in vegetation communities.

Vegetation Community	Season			
	Spring	Early Summer	Mid to Late Summer	Fall
Jun-Sav	Greens	Indian ricegrass, wolfberry		Cacti
P-J	Greens		Dropseed, saltbush, cheno-ams, wild potato, purslane	Pine nuts, acorns, broad leaf yucca, cacti
Pipo	Greens		Cheno-ams, wild onions, berries, wild potato	
MC	Greens		Cheno-ams, wild onions, berries	

If we consider that the deep canyons could act as natural travel routes to these upland plateau resource areas, then camping in the piñon-juniper/ponderosa pine ecotone would provide easy access to a wide variety of species within a small catchment area. For example, riparian and some mixed conifer species would be present in the canyon bottoms, ponderosa pine communities along the south-facing canyon slopes, and mixed conifer on the north-facing canyon slopes, and piñon-juniper woodlands on the mesa tops. Indeed, if the typical daily foraging radius around a hunter-gatherer campsite is about 10 km, then almost all of the plateau at LANL would be located within walking distance of a site located in this central zone (Binford 1982; Yellen and Lee 1976).



PLANT COMMUNITIES AND HABITATS

Figure 75.10. Late Archaic seasonal mobility pattern.

Lastly, if these Late Archaic populations were practicing some form of incipient horticulture, then how would this activity have been integrated into the foraging schedule? The evidence from Jemez Cave may help us understand this. Ford (personal communication, 2002) suggests that maize may have been planted in May, and the site abandoned and then reoccupied during September or October to harvest the crop. On occasion, this occurred when the maize was still green, and other times when it was mature. Maize plants were probably grown in the mud flats adjacent to a small lake located behind the Soda Dam. Broad leaf yucca was also procured and used for textiles, and a variety of game species were hunted (e.g., bighorn sheep). The lithic assemblage was dominated by obsidian, with some Pedernal chalcedony/chert. Therefore, some of these early horticulture sites could have been placed in well-watered settings adjacent to piñon-juniper woodlands and fall plant resource areas. This would have reduced any seasonal scheduling conflicts and provided a backup strategy for natural resource shortfalls (e.g., see Minnis 1985).

THE LATE ARCHAIC ARCHAEOLOGICAL RECORD

Seven Late Archaic open-air sites were selected for this study of debitage assemblages. Together, they cover an elevation range from 1700 to 2880 m (5580 to 9450 ft). From lower to higher elevations, this includes a possible winter habitation site near San Ildefonso Pueblo that contains a single structure, with storage pits and an outside activity area (LA 51912; Lent 1991; *n* = 1747). Excavations along Highway 502 at the Los Alamos/Española interchange also identified an extensive Late Archaic site containing multiple hearths and activity areas (LA 65006; Moore et al. 1998; *n* = 5997 for Component 1). Both of these sites were excavated by the Museum of New Mexico and are located in the valley just east and west of the Rio Grande, respectively.

Two sites are situated in the piñon-juniper zone at LANL. LA 12587 (Area 8) is a small lithic scatter situated in the White Rock Tract that was recently excavated by Schmidt (Chapter 15, Volume 2; *n* = 485). Another site is located on Mesita del Buey that was mostly excavated. Although the site consists of an extensive lithic scatter, the sample used for this study included the area around a possible occupation surface (LA 70029; Biella 1992; *n* = 1420). LA 115373 is another lithic scatter site that was recently tested, but is located in the ponderosa pine zone at the upper elevations of LANL (Larson et al. 1997; *n* = 402). Site 03-1172 is an extensive lithic scatter site that was tested by Forest Service archaeologists on Sawyer Mesa near Obsidian Ridge in the higher ponderosa pine zone (Moore 1986; *n* = 1003). Lastly BG-21, is a small lithic scatter located in Redondo Creek Valley along the west side of the Valles Caldera (*n* = 296). It is one of 23 sites excavated by the University of New Mexico (Baker and Winter 1981). All but two of the sites have sample sizes of over 1000 artifacts. However, the remaining two sites have smaller samples of 135 and 402 artifacts. Four of the seven sites were analyzed for this study; whereas, published data were used for the two Museum of New Mexico and the Forest Service sites.

Analysis of the debitage assemblages from these sites indicates that there are some significant differences in the reduction tactics being implemented between riverine versus upland sites. The sites are oriented from left to right, that is, from lower to higher elevations in Figure 75.11. As can be seen, the two riverine sites emphasize core reduction activities with less biface production/maintenance. In contrast, the upland sites emphasize biface production with less core reduction. The exception to this pattern is site 03-1172, which is located within the Cerro Toledo obsidian source area. Here the emphasis is on core reduction activities, which presumably reflects the production of prepared cores and flake blanks for transport to sites at lower-elevation settings. Otherwise, the distinction between core reduction versus biface production appears to reflect differences between lowland habitation versus upland campsites.

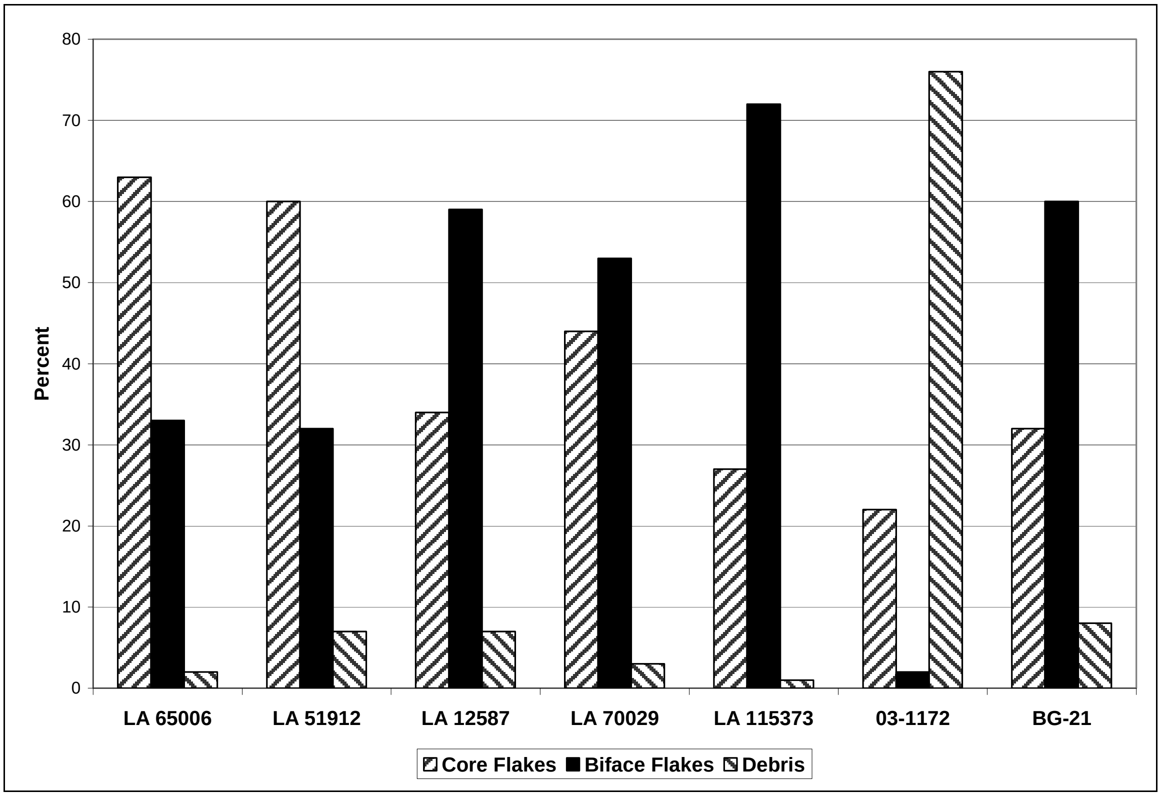


Figure 75.11. Debitage types.

This complementary link between lowland and upland sites is also reflected in the lithic material assemblage. Figure 75.12 illustrates that all the assemblages are dominated by obsidian. However, the four sites situated in the riverine and piñon-juniper settings also contain some chalcedony/chert and other materials. This includes basalt and quartzite in the lowland sites and orthoquartzite at LA 70029. With the exception of the orthoquartzite, these materials are available in gravels along the flanks of the Rio Grande Valley. The presence of waterworn cortex on these materials supports this contention. It is, however, undetermined as to whether the orthoquartzite is also available from this secondary source or was obtained from primary sources to the north near Abiquiu Reservoir. Otherwise, the higher-elevation sites are almost exclusively composed of obsidian that primarily exhibits a natural weathered (i.e., nodular) cortex, indicating that this material was derived from the primary source.

X-ray fluorescence analysis had been conducted on four of the sites identifying the specific obsidian sources utilized by these groups. Samples were analyzed from a lowland habitation site (Lent 1991:40), the LA 12587 and LA 70029 campsites located in the piñon-juniper zone (Chapter 61, Volume 3; Stevenson 1992), and the two higher-elevation sites situated in the ponderosa pine/mixed conifer communities (03-1172: Hughes 1986; BG-21: Sappington and Baker 1981). Three points and four bifaces were analyzed at the lowland habitation site. Four of these artifacts are made of Cerro Toledo, two from Cerro del Medio, and one from El Rechuelos (Polvadera) obsidian. Twenty-six flakes and two retouched tools were analyzed at the piñon-juniper campsites, with 23 made of Cerro Toledo, four from Cerro del Medio, and one from El Rechuelos obsidian. Twenty-one artifacts were analyzed from the campsite located within the

Cerro Toledo obsidian source area, so it is not surprising that 18 of these were derived from this source, with two made of El Rechuelos and one of an undetermined source. Lastly, 100 flakes were analyzed from three sites located in the area of BG-21. All but one of these were derived from the nearby Cerro del Medio source, with a single flake made of El Rechuelos obsidian. Our own analysis indicates that El Rechuelos obsidian was visually identified at both the piñon-juniper campsites and BG-21, in both cases representing 2 percent to 3 percent of the debitage assemblage.

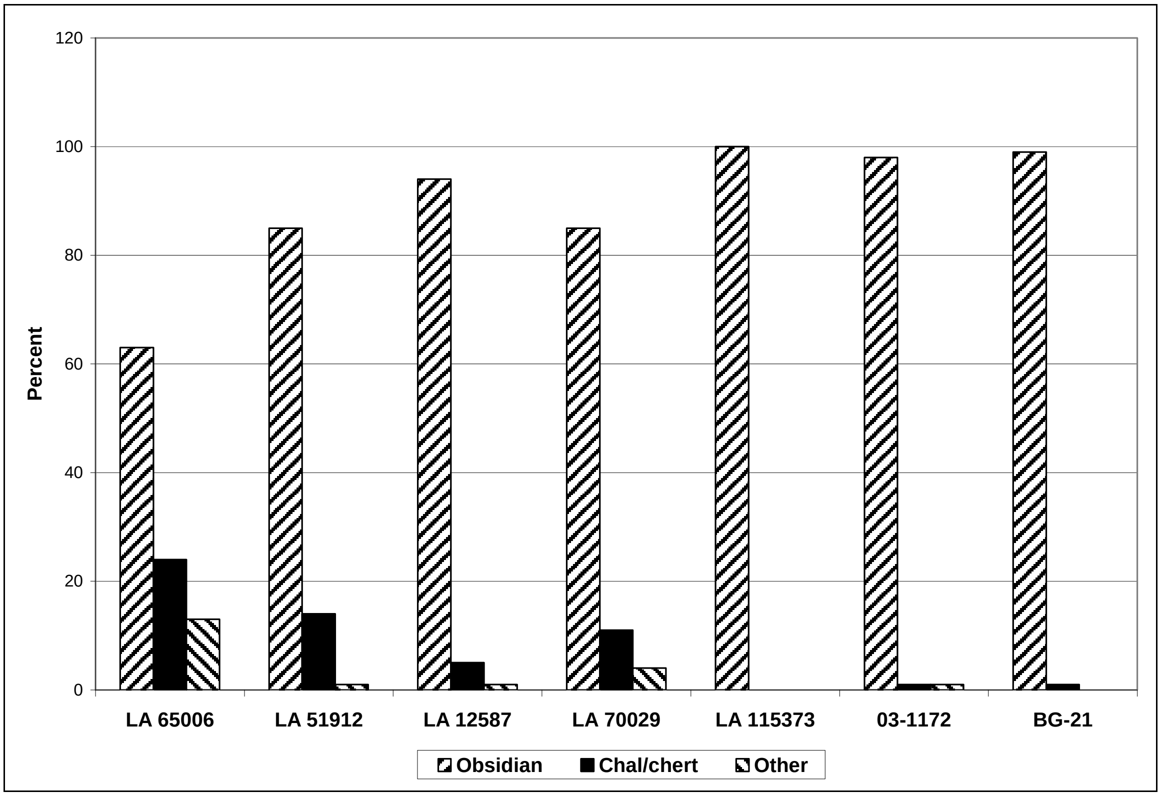

Figure 75.12. Debitage material types.

Overall, we see that the sites in my study are primarily linked to the Cerro Toledo and Cerro del Medio obsidian source areas, with each of the two high-elevation sites being tied to the nearby obsidian source. This supports our contention that obsidian could have been procured at these high-elevation settings during the mid to late summer and later reduced at the lower-elevation sites. The presence of small amounts of El Rechuelos obsidian may also reflect some distant ties to this area further to the north.

SUMMARY AND CONCLUSION

In conclusion, a variety of resources are present as plant foods in all the vegetation communities. Therefore, multiple foraging tactics could have been used by Late Archaic populations depending on seasonal rainfall, plant productivity, and changes in annual resource structure. Nonetheless, we have proposed one possible transhumance pattern, involving seasonal movements from the juniper-savanna to ponderosa pine/mixed conifer and then down to the piñon-juniper zone. It was in the latter community that maize could have also been harvested to reduce seasonal resource shortfalls. Nonetheless, these higher elevation resource settings were critical to Late Archaic foragers, including plant, animal, and obsidian raw material procurement.

The analysis of debitage assemblages from a sample of sites distributed throughout these vegetation zones, indicates that they are all linked by reduction tactic and obsidian procurement patterns. That is, lowland habitation sites are characterized by an emphasis on core reduction while upland campsites are characterized by biface production. Otherwise, obsidian dominated all the lithic assemblages, with sites situated in the juniper-savanna and piñon-juniper communities also containing a small amount of material derived from local river gravels. These data appear to lend some preliminary support to our model of a complementary settlement system that is distributed from river valley to mountaintop.

CHAPTER 76
PAJARITO CULINARY WARE: AN EXAMINATION OF RIM SHERD ATTRIBUTES FROM THREE COALITION AND THREE CLASSIC PERIOD SITES

Diane C. Curewitz

This study of culinary ceramics at six sites on the Pajarito Plateau of north-central New Mexico (Figure 76.1) is part of a larger research program that addresses the role of ritual in effecting changes in ceramic economy, particularly in stimulating increased specialization and value-based exchange during a period of population aggregation and agricultural intensification (Anschuetz 1995; Hill 1998; Hill et al. 1996; Powers and Orcutt 1999a). The overall research program examines five major ceramic types in three sub-regions of the northern Rio Grande: two glazeware types, two biscuitware types, and micaceous culinary ware. Ceramics from the Santa Fe sub-region and the Rio Ojo Caliente area of the Chama sub-region will be analyzed in future studies.

The Pajarito Plateau sites are central to the hypotheses to be tested. This area shows overlapping distribution of contemporaneous but very distinct ceramic wares, thought to denote the pre-contact presence of contemporary ethnic boundaries (Creamer et al. 2002; Futrell 1998; Vint 1999). Creamer (2000) convincingly argues, however, that language groups, commodity exchange networks, and settlement clustering show a variety of possible social boundary configurations. My hypothesis is that these overlapping ceramic distributions show that exchange between sub-regions was essential to the performance of common rituals, including communal feasts, and that the requirements associated with these rituals stimulated specialized production and exchange at the local level.

Analysis of culinary ware is an integral part of the overall research program. While much northern Rio Grande culinary ware shows standardized attributes that may be related to specialist production, micaceous ware is the only culinary ware whose production may be specialized for exchange (Curewitz 2004a). Significant quantities appear in Classic period assemblages at Tyuonyi (Curewitz 2004a; Vint 1999) and Arroyo Hondo (Habicht-Mauche 1993), but was produced only in the Chama-Española area north of Santa Fe (Habicht-Mauche 1993:Table 2; Warren 1981; Vint 1999).

Asymmetry of exchange is apparent between the Chama-Española and Pajarito areas. Little or no sand-tempered or mafic volcanic rock-tempered Pajarito grayware occurs in Chama-Española area assemblages, such as Howiri (Gauthier 1987a:44, Table 7), other sites in the Rio Ojo Caliente valley (Curewitz 2004b), and Te'ewi in the Rio del Oso valley (Gauthier 1987a:45, Table 8; Wendorf 1953). However, micaceous ware most likely produced in these areas occurs at Pajarito sites.

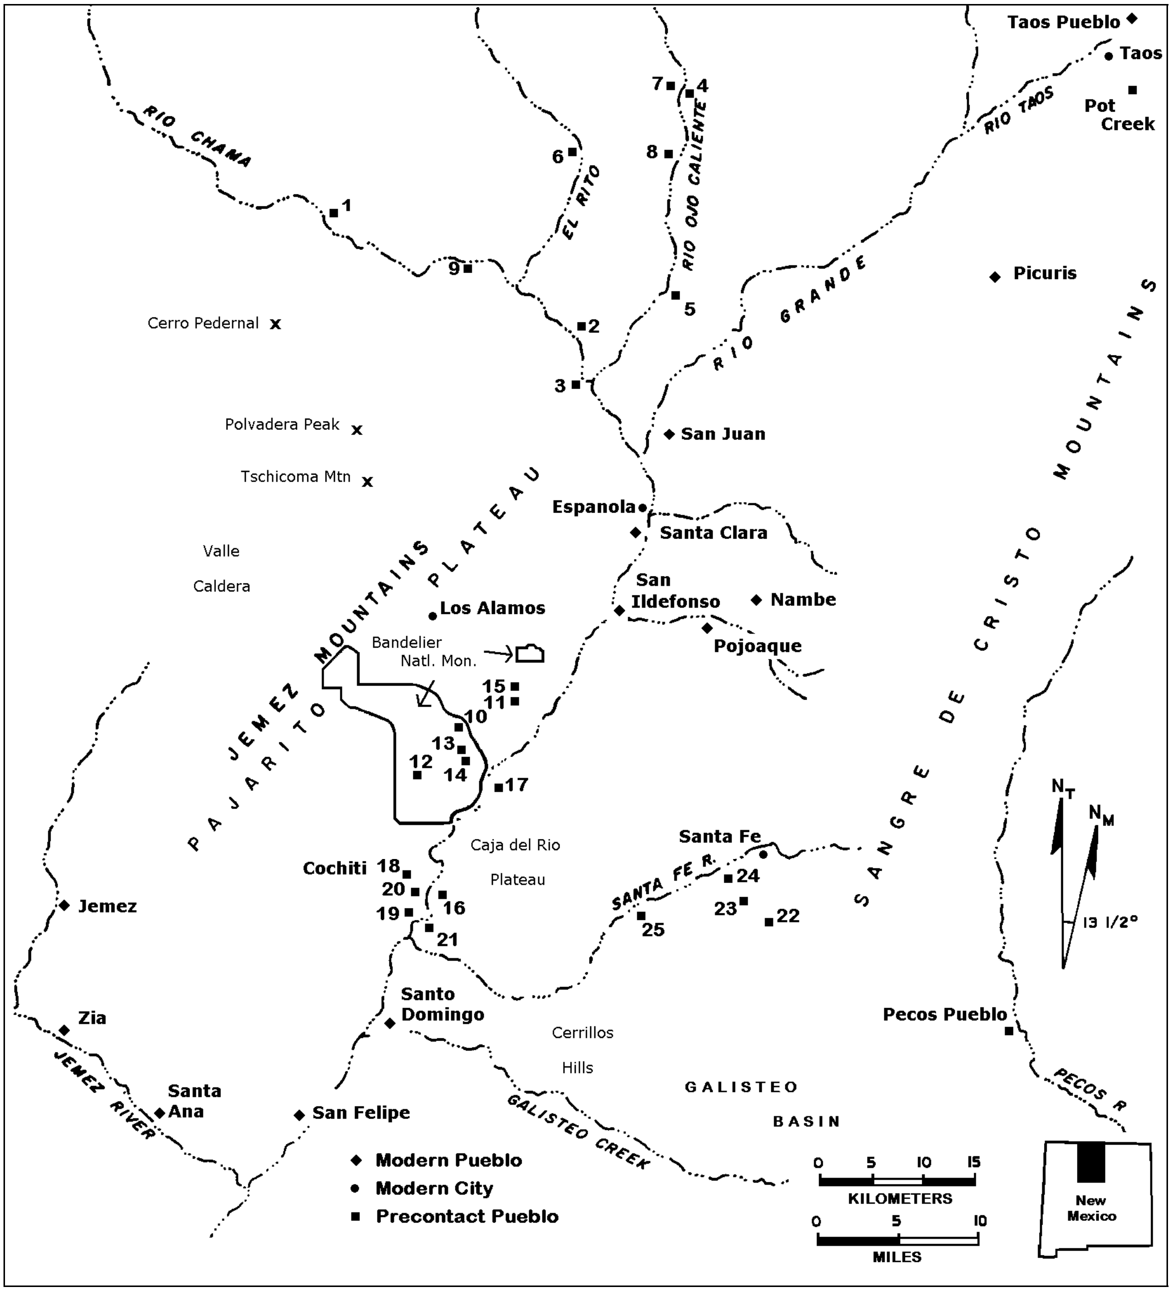

Figure 76.1. Major cities, modern pueblos, and selected archaeological sites of the northern Rio Grande. Precontact sites: 1. Riana (LA 920); 2. Leaf Water (LA 300); 3. Te'ewi (LA 252); 4. Howiri (LA 71); 5. Ponsipa-Akeri (LA 297); 6. Sapawe (LA 306); 7. Hupobi (LA 380); 8. Posi (Pose'uinge) (LA 632); 9. Poshuinge (LA 274); 10. Burnt Mesa (LA 60372.1); 11. White Rock (LA 12587); 12. Shohakka Pueblo (LA 3840); 13. Tyuonyi (LA 82); 14. Tyuonyi Annex (LA 60550); 15. Tsirege (LA 170); 16. Caja del Rio South (LA 5137); 17. Caja del Rio North (LA 174); 18. Cochiti (LA 295); 19. Alfred Herrera (LA 6455); 20. Kuapa (LA 3444); 21. Pueblo del Encierro (LA 70); 22. Arroyo Hondo (LA 12); 23. Pindi (LA 1); 24. Agua Fria Schoolhouse (LA 2); 25. Tzeguma (Cieneguilla) (LA 16). (Adapted from Powers and Van Zandt 1999:Figure 1.6).

Symmetrical, reciprocal exchange of pots is believed to represent reinforcement of existing relationships through gifts, establishment of new relationships through marriage, transportation of resources, circulation during intercommunity gatherings, or all of the above at various times (Zedeño 1998). If pots are associated with different ideological systems, exchange may represent reciprocal gifting between communities practicing similar classes of rituals (i.e., communal feasting), as in the case of biscuitware found at southern Pajarito sites (Mera 1940; Vint 1999). Asymmetrical exchange of relatively standardized undecorated culinary ware, however, may indicate that a barter system is developing.

THE QUESTION OF STANDARDIZATION AND SPECIALIZATION

Research on aspects of northern Rio Grande Classic period production organization using Costin's (1991) parameters (Habicht-Mauche 1993; Vint 1999) suggests that *context* of production was independent. Households continued to produce according to their own perceptions of advantage without control by an elite group. C*oncentration* of production facilities ranged from dispersed to nucleated. Production *scale* was most likely small, kin-based work units, operating in households. *Intensity* of production was probably part-time rather than full-time, since households still needed to produce most of their food. Clark and Parry (1990:320) note that all societies examined in their study of the correlation between craft specialization and cultural complexity, no matter what level of complexity, exhibit some type of craft specialization, usually part-time and independent.

There is little or no direct ceramic production evidence, such as kilns, raw material caches, production debris, and tools, on the Pajarito Plateau and in the northern Rio Grande in general. In this case, comparing attribute variation to arrive at relative standardization is one method of measuring degree of specialization (Arnold and Nieves 1992; Costin 1991, 2001; Crown 1994; Longacre 1999; Roux 2003). Other methods include identifying production sources and defining ceramic distributions (Bishop et al. 1982; Costin and Hagstrum 1995; Shepard 1942; Warren 1979).

Crown (1994:116) and B. Stark (1995:238) use Coefficient of Variation (CV) or Q-test to measure standardization. Based on ethnographic and ethnohistoric research, CVs of 10 percent or less are believed to indicate standardization at a level highly suggestive of specialized production. Stark's (1995:256–257) ethnoarchaeological research suggests that standardization may result when many potters follow customary production methods or a few specialize in production for exchange ("the ratio effect").

Crown's examination of Salado Polychrome production organization (1994:115−122) showed complex, non-repetitive, labor-intensive designs and relatively nonstandard forms for vessels produced for local use. CVs calculated to assess relative vessel height and diameter homogeneity were generally above 10 percent, indicating a low degree of specialization (Crown 1994:Table 7.2). The exception is CVs below 10 percent for height and diameter of very large bowls at one site, suggesting specialized production of vessels for communal feasts.

Schleher (2005) has recently compared the production characteristics of ethnographic ceramic assemblages with those from archaeological sites. In her assessment of whether CVs of 10 percent or less have value as measures of specialization in archaeological assemblages, she notes that time scales, number of producers and production episodes, and sample size variation are not always known for archaeological assemblages, and even when known may not be comparable with ethnographic production parameters.

Hagstrum's (1985) calculation of CV for painted decoration (but not size) of a small sample of Coalition period Santa Fe/Wiyo Black-on-white bowls relative to Classic period Bandelier Black-on-gray (Biscuit B) bowls is the only study to focus on production specialization in the northern Rio Grande. She found more standardized design elements and greater decoration efficiency in the later type, implying an increase in ceramic specialization in decorated service wares.

Motsinger (1997) analyzed the width and placement of framing lines on northern Rio Grande glazeware rim sherds tempered with hornblende latite. He found a decrease in CV for framing line width from early Glaze A through Glaze D and a decrease in CV for distance of the framing line from the vessel lip from late Glaze A through Glaze F. He concluded that earlier glazewares are more specialized than later varieties.

The research reported here represents the first examination of standardization and possible specialization in northern Rio Grande culinary ware production. Vessel thickness and size are used to measure standardization. These are considered production efficiency measures, but may also relate to consumer demand for performance-related functional characteristics (Costin and Hagstrum 1995; Hegmon et al. 1995:35; Rice 1987; Rye 1981; Shepard 1956).

THE PRESENT STUDY

In this study of ceramic attributes, I measured and categorized over 600 culinary jar rim sherds from excavation units at three Coalition period sites and three Classic period sites on the Pajarito Plateau (Figure 76.2). I found changes in surface treatment, temper, size range of jars, ratio of large to small jars, vessel wall thickness, and rim thickness. I found some indications of standardization at Coalition sites and increased standardization between the Coalition (AD 1150 to 1325) and Classic (AD 1325 to 1600) periods.

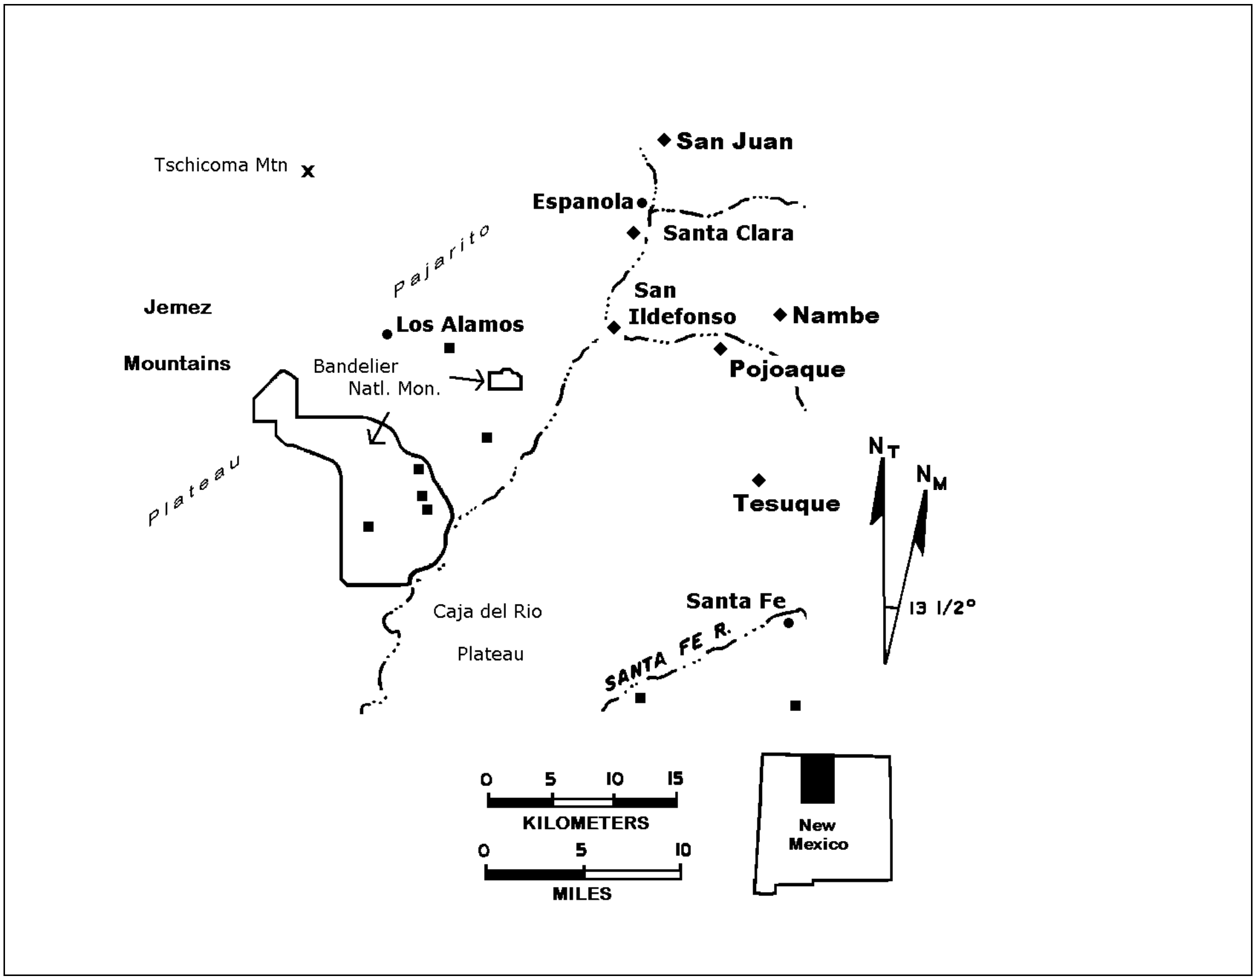

Figure 76.2. Selected archaeological sites on the Pajarito Plateau. A) Shohakka Pueblo (LA 3840); B) Tyuonyi (LA 82); C) Tyuonyi Annex (LA 60555); D) Burnt Mesa Pueblo (LA 60372); E) White Rock (LA 12587); F) Airport (LA 86534).

SITE LOCATION AND DESCRIPTION

Coalition Sites

These sites are presented according to their geographic location from south to north on the Pajarito Plateau (Figure 76.2).

- LA 60372 (Burnt Mesa Pueblo) is a Late Coalition/Early Classic period site located on Burnt Mesa north of Frijoles Canyon at Bandelier National Monument. Area 1 is a plaza pueblo with 65 rooms and a kiva in the plaza. The 93 culinary rims I examined came from a stratified plaza test unit to the west of the kiva (Kohler 1989; Kohler and Root 1992b, 2004). Unit 90S/88E was excavated in 1990 as part of the Bandelier Archaeological Excavation Project and described in Kohler and Root (2004:191–192). A tree-ring date from Stratum 6 of this unit yielded an age of 1271vv, and Kohler and Root

(2004:211) propose that the main construction of Area 1 began in the 1270s or 1280s. Based on tree-ring dates and ceramic assemblage, they estimate the occupation of Area 1 "to have occurred between 1275 and 1325 or slightly later" (Kohler and Root 2004:212).

- LA 12587 (White Rock Site) is a linear roomblock (Vierra et al. 2002:5-2) located just west of the town of White Rock on Mesita del Buey, about 10 km north of LA 60372. One of the 22 rooms is a large room with two hearths that might be a kiva. The 71 culinary rims analyzed came from 60-cm-wide trenches excavated into the midden east of the roomblock. No stratigraphic distinctions were made between levels in these trenches. Wilson and Castro-Reino (2005:1) use ceramics from room and midden units at LA 12587 to date the site "to the early and middle 13th century with some continuation into the 14th century." Radiocarbon dates from hearths in the roomblock suggest that the site was occupied from ca. AD 1180 (870±70 B.P.; two-sigma calibrated result AD 1020–1280; intercept AD 1180; Beta 183747) to ca. AD 1300 (650±40 B.P.; two-sigma calibrated result AD 1280–1400; intercept AD 1300; Beta 183748) (Harmon et al. Volume 2).

- LA 86534 (Airport Site) is located near the Los Alamos Airport and "dates to the early to middle 13th century" (Wilson and Castro-Reino 2005:1; see Vierra et al. 2002:5-1). This site was cut through when NM 502 was built and only eight rooms remain, but one is a kiva cut into the tuff east of the roomblock. The 41 culinary rims analyzed came from the west half of this kiva. Excavators identified rooffall, wallfall, and a post-occupation layer within the kiva. The materials from LA 12587 and LA 86534 studied here constitute samples from different portions of the site than those studied by Wilson and Castro-Reino (2005). Radiocarbon dates from hearths in the roomblock suggest the site was occupied from ca. AD 1190 (860±40 B.P.; 2σ calibrated result AD 1040–1260; intercept AD 1190; Beta 183760) to ca. AD 1280 (730±40 B.P.; 2σ calibrated result AD 1240–1300; intercept AD 1280; Beta 183761) (Schmidt Volume 2).

The three Classic period sites are all located at Bandelier National Monument and are presented here according to geographic location from south to north. No ceramics were examined from Classic sites on the Pajarito Plateau north of Bandelier.

- LA 3840 (Shohakka Pueblo), in Capulin Canyon, about 12 km southwest of Frijoles Canyon, is a horseshoe-shaped roomblock, open to the south, containing about 90 rooms. The plaza contains three kivas. The 63 culinary rims analyzed came from a midden trench excavated south of the roomblock (Kohler 1989; Kohler and Linse 1993; Kohler et al. 2004; Ruscavage-Barz 1999). Tree-ring samples from the site could not be dated. Radiocarbon dates were obtained from beams in Room 1 and Kiva 3 rooffall. An archaeomagnetic date was obtained from the hearth in Room 2. Calibrated ages for these samples, combined with ceramic evidence, yield an occupation range "that begins in the last decade of the 1300s and extends through the first three decades of the 1400s (Linse and Kohler 1993:34). The distribution of ceramics in the midden, which probably contains material deposited over the entire occupation, shows some slight differences with the room and kiva fills, notably a higher proportion of smeared-indented corrugated ware (Kohler and Gray 1993:40–41).

- LA 82 (Tyuonyi) is an enclosed plaza pueblo in Frijoles Canyon with 240 ground floor rooms, three kivas in the northern part of the plaza, and a big kiva to the east. Tree-ring samples from the site date from the 1360s to 1520s. The 293 culinary rims analyzed are from two units excavated in the southern part of the plaza in the early 1970s (Curewitz 2004a; Kohler et al. 2004; Williams and Griggs 1973). These units did not produce any tree-ring or radiocarbon samples, but Mean Ceramic Dates have been calculated (see Curewitz 2004a).

- LA 60550 (called "the unexcavated site" on Park Service maps of Frijoles Canyon) is referred to here as Tyuonyi Annex (Kohler 1989). This 50-room rectangular block is located 60 m southeast of Tyuonyi, between Tyuonyi and the big kiva. The 52 culinary rims analyzed are from a 2- by 2-m unit located about 10 m southeast of the roomblock. The ceramic assemblage suggests occupation relatively late in the Classic sequence, overlapping with the last 75 years of occupation at Tyuonyi (Kohler 1989; Kohler and Linse 1993; Kohler et al. 2004).

WARE AND TYPE DISTRIBUTION CHANGES

Culinary ware makes up 84 percent to 88 percent of the sherds at the Coalition sites (Table 76.1a), but only 61 percent to 72 percent at the Classic period sites (Table 76.1c). Smeared-indented corrugated ware is the dominant culinary type at Coalition period sites, with percentages ranging from 92 to 95 (Table 76.1b). Plain gray is the dominant culinary type at Classic period sites, with percentages ranging from 82 to 90 (Table 76.1d). Micaceous ware makes up a significant proportion of the culinary ware at LA 82 (Tyuonyi), averaging 22 percent in the two excavated units (Table 76.1d). Larger percentages occur in the upper levels of the units (Curewitz 2004a:Table 2). In contrast, only 0.1 percent of the culinary sherds at one Coalition period site (LA 12587) and between 0.6 percent and 1.1 percent at the other two Classic period sites contain any mica (Table 76.1a and 76.1b).

Table 76.1a. Ware and type distribution for selected units at three Coalition period Pajarito sites.

Service ware types also change from the Coalition to Classic periods. Santa Fe Black-on-white and other thin, hard, ash-tempered varieties of the Pajarito Series (Habicht-Mauche 1993:Table 2; 19–26) are the dominant decorated Coalition period service ware types, making up between 93 percent and 97 percent of all decorated wares (Table 76.1b). Glazewares are the dominant Classic period service wares, ranging from 69 percent at LA 82 (Tyuonyi) to 90 percent at LA 3840 (Shohakka) (Table 76.1d). Only one Coalition site (LA 60372) contains any glazeware (Table 76.1a). Kohler and Root (2004:197) consider the two later glaze rim sherds from Unit 90S/88E to represent late reuse of the site rather than late occupation. Biscuitware makes up less than 0.2 percent or less of any Coalition service ware assemblage, but ranges from 4 percent at LA 3840 (Shohakka) to 23 percent at LA 82 (Tyuonyi) (Table 76.1d).

The Sample

Attributes were recorded for a total of 1108 culinary and service ware rim and body sherds from the six Pajarito sites (Tables 76.2a and 76.2b). The culinary ware sample consists of 618 rim sherds (58.6 percent of all Pajarito rim sherds) and 20 body sherds (37.0 percent of all Pajarito body sherds). The discrepancy between the total percentage and the sample percentage of each type is due in part to the smaller number of culinary ware types and tempers to be sampled. It may also relate to better preservation of service ware rims. Rims make up 7 percent to 12 percent of all service ware sherds but only 5 percent to 7 percent of culinary ware. Within culinary ware categories, the ratio of smeared-indented corrugated rims to body sherds is much smaller than for plain gray. Smeared-indented corrugated rims are generally much thinner and more tapered than plain gray, which may affect their preservation rate.

Culinary Ware Type/Temper Associations

Several recent studies have used petrographic analysis to identify the sources of Pajarito Plateau ceramics from the Coalition period. These include a study of ceramics at LA 4624, located west of LA 12587 on Mesita del Buey (Castro-Reino and Lavayen 2002; Curewitz and Harmon 2002), and at LA 135290 (Chapter 25, Volume 2) and LA 4618 (Schmidt 2006) as well as rooms and midden units at LA 12587 and LA 86534 (Chapters 14 and 24, Volume 2; Castro-Reino 2005; Wilson and Castro-Reino 2005).

These studies "support previous observations on the distinct nature and uniformity of Coalition period pottery" (Wilson and Castro-Reino 2005:10). Observation of ceramics from the three Coalition period Pajarito sites with a binocular microscope shows similar results (Table 76.3). The dominant temper type for smeared-indented corrugated and plain gray culinary ware at the three sites is "anthill sand," which consists mainly of coarse feldspar and quartz crystals.

The Coalition to Classic period transition from smeared-indented corrugated to plain gray culinary ware occurs at the same time that the thin, hard, ash-tempered Black-on-white Santa Fe varieties in the Pajarito series are replaced by glazeware and by thicker, softer biscuitware (Tables 76.1a through 76.1d). A change in culinary ware tempering material can be observed while smeared-indented corrugated is still the dominant culinary type (Tables 76.3a and 76.3b).

At the earlier Coalition period sites, LA 12587 and LA 86534, smeared-indented corrugated makes up over 90 percent of the culinary ware, and almost all of it is tempered with coarse anthill sand (Figures 76.3a and 76.3b). The temper change to finer material appears first in smeared-indented corrugated ware at Burnt Mesa (LA 60372), which bridges the Coalition to Classic period transition. Petrographic characterization of a sub-sample of smeared-indented corrugated and plain gray sherds (n = 35) shows similar mineral and lithic content, but differences in grain size and sorting (Appendix AA).

Both varieties of anthill sand temper are dominated by sanidine feldspar and monocrystalline quartz, with minor biotite, oxides, and plagioclase occurring in most sherds. Rare pyroxenes, amphiboles, or olivine may also be present. In the coarser anthill sand temper, 67 percent to 100 percent of the dominant grains are very coarse sand-size quartz (1.0-2.0 mm). Only 33 percent to 67 percent of the secondary grains are very coarse. Sorting is bimodal.

In the finer anthill sand temper, 0 to 40 percent of the dominant grains are very coarse; more are fine (0.125 to 0.25 mm), medium (0.25 to 0.50 mm), or coarse (0.50 to 1.0 mm). It is the secondary temper grains that are larger, more often coarse to very coarse. Sorting is poor, but not strongly bimodal as in the earlier type.

Felsic volcanic rock (rhyolite) is the lithic most often found with both anthill sand tempers. Small quantities of intermediate (andesitic) and mafic (basaltic) volcanic rock are present, sometimes as the dominant lithic type, but more often secondary to the felsic rock. Pumice dominates only one sherd but is found as a secondary lithic in about one-third of all sherds. Two sherds contain glassy pumice.

The above suggests that differences in the tempers may be due to a change in the preparation method for anthill sand temper, possibly sieving and selection of a finer fraction. Almost a fifth of the sherds in the sample are tempered with this finer material.

Most plain gray sherds from Coalition sites (*n* = 5) show three different temper varieties: earlier, coarser anthill sand, later, finer anthill sand; two plain gray sherds from LA 60372 contain fragments of disaggregated intermediate and mafic volcanic rock and very little additional sand. My study of culinary ware at Tyuonyi (Curewitz 2004a) found similar rock temper in plain gray sherds in upper levels of the two excavated units. Non-micaceous culinary sherds from Classic period sites were not sampled for petrographic analysis in this study.

At Classic period Shohakka (LA 3840), 89 percent of the culinary ware is plain gray (see Table 76.1d). Eighty-nine percent of it contains fine, angular to sub-angular felsic material and nine percent contains some mica. The small amount of smeared-indented corrugated present also contains finer, angular to sub-angular felsic material rather than coarse anthill sand crystals.

At Tyuonyi, smeared-indented corrugated makes up between 10 percent and 20 percent of the lower levels, dropping to less than 10 percent in the upper levels (Curewitz 2004a:76, Table 2). Roughly equal percentages are tempered with anthill sand crystals and finer, more angular felsic material, with sparse mica flakes in some (Table 76.3b). Most plain grayware is tempered with the finer, more angular, felsic material.

Micaceous sherds make up about 22 percent of the plain-surfaced ware from the two excavation units (Table 76.3b; Figure 76.3). The five micaceous washboard rim sherds found in Unit B appear to have a micaceous paste or added mica temper.

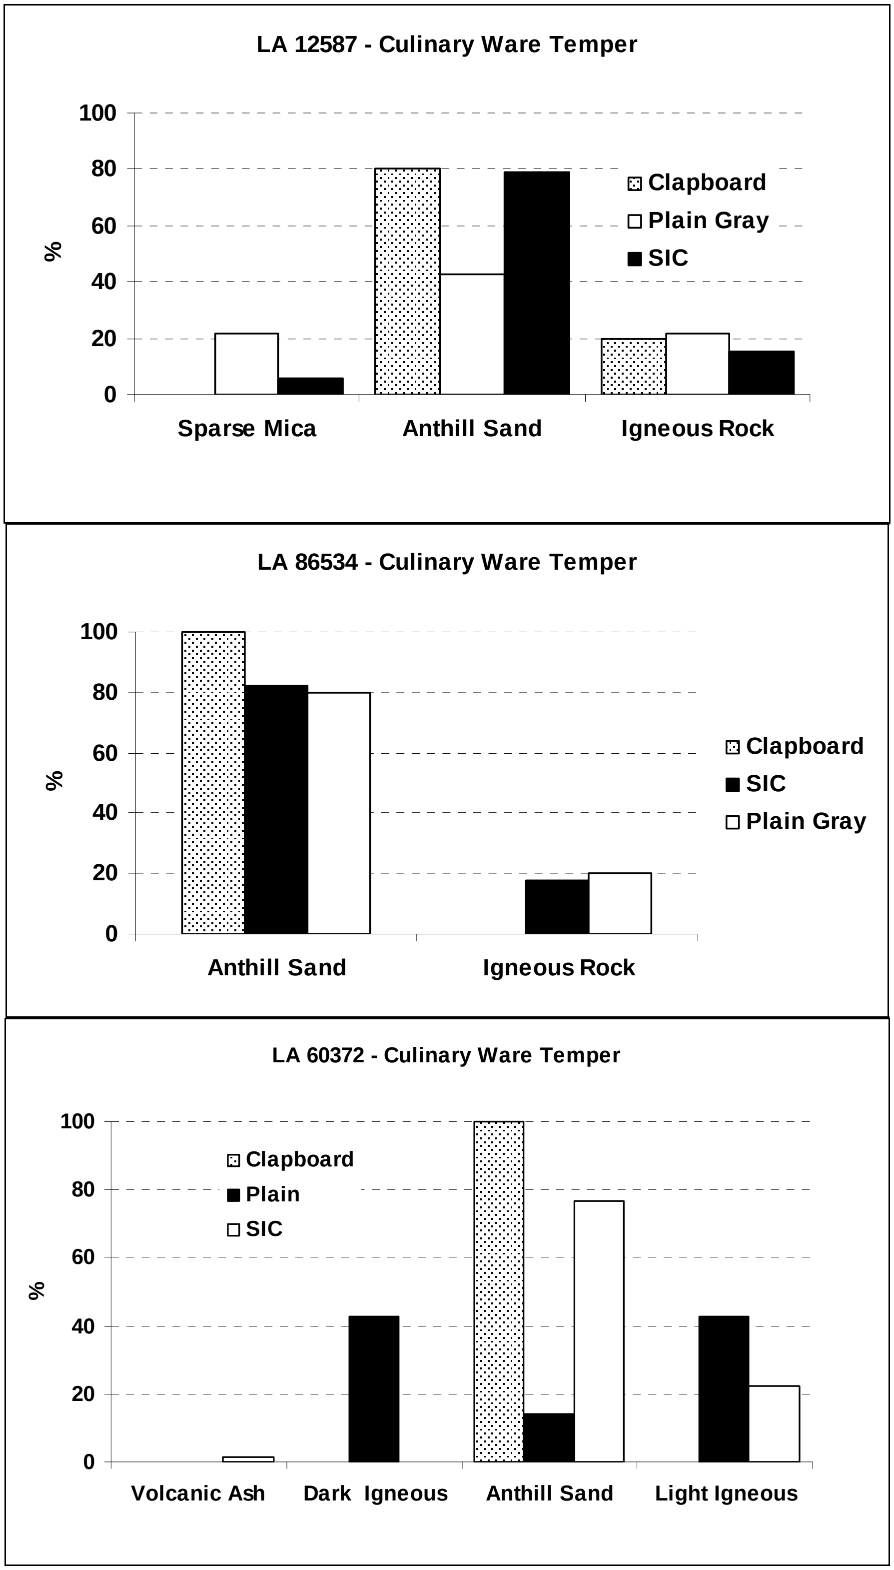

Figure 76.3a. Culinary ware temper at LA 12587 (top), LA 86534 (middle), and LA 60372 (bottom), Coalition period Pajarito sites.

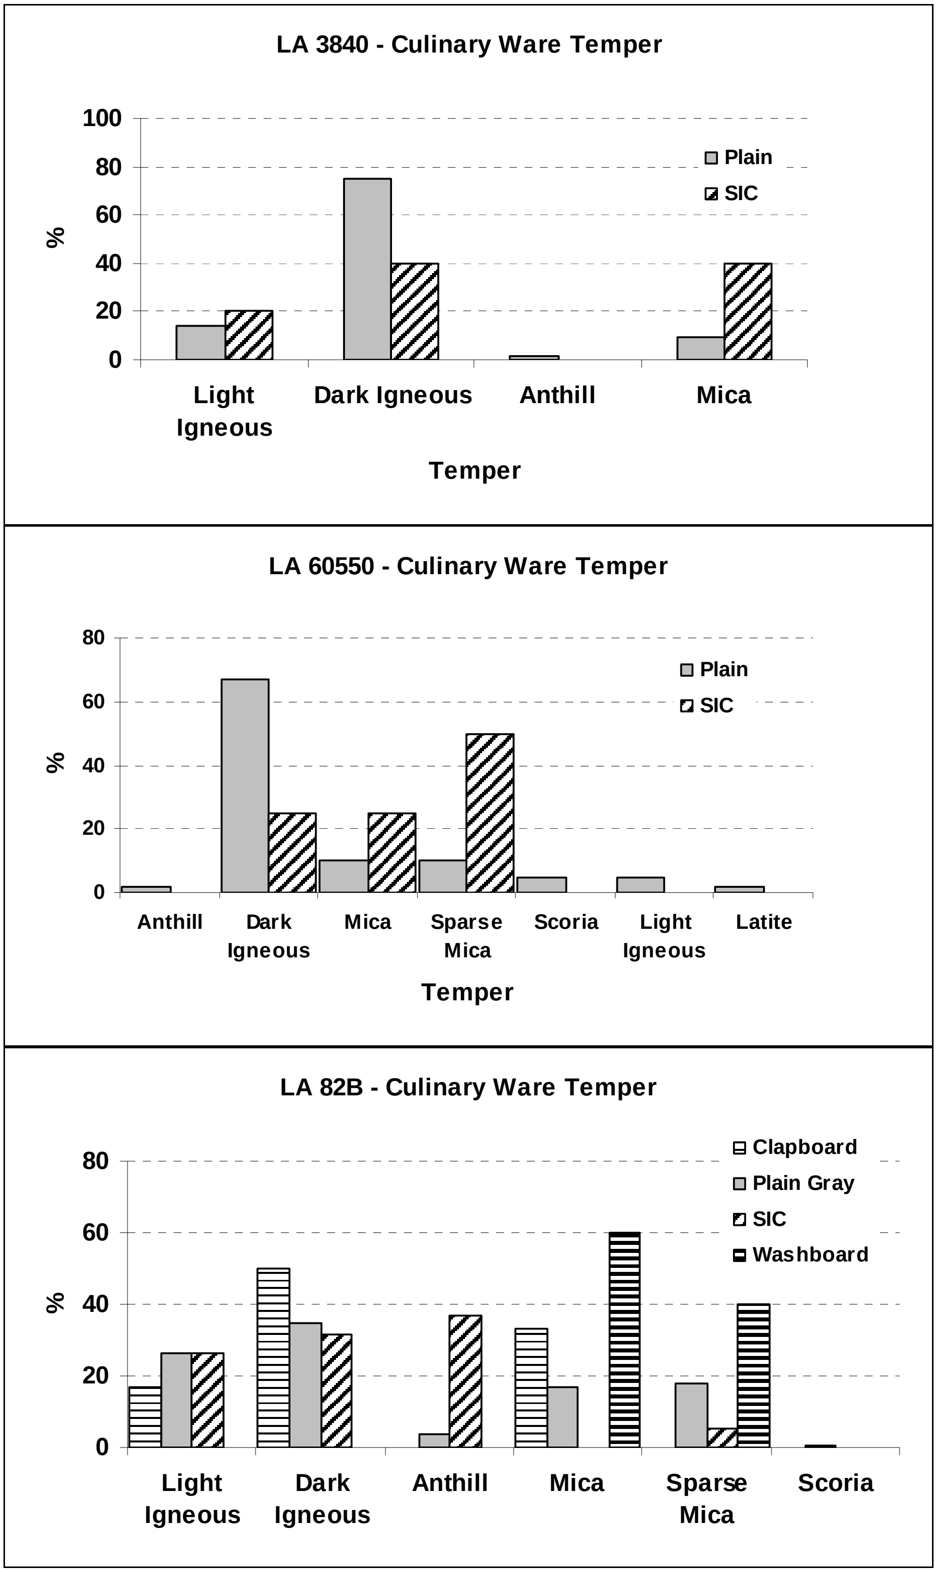

Figure 76.3b. Culinary ware temper at LA 3840 (top), LA 60550, (middle), and LA 82B (bottom), Coalition period Pajarito sites.

The excavation unit at LA 60550, which is contemporaneous with Tyuonyi does not contain any micaceous washboard (Table 76.2b). Ninety percent of the culinary sherds from the excavated midden unit are plain gray (Table 76.1d). Eighty percent contain fine, angular felsic inclusions, and eight percent also contain mica (Table 76.3b). Three of the four smeared-indented corrugated sherds found contain mica. In addition to mica inclusions, one-third of the micaceous sherds are washed with a micaceous solution.

Smeared-indented corrugated sherds containing coarse anthill sand crystals are not found at LA 3840 and LA 60550, nor do these sites contain Santa Fe Black-on-white rims (Table 76.1c). This may relate to the later initial settlement of these sites.

Micaceous Ware on the Pajarito

A small quantity of plain-surfaced micaceous ware, with sparse mica inclusions, is found at LA 12587. Dean Wilson of the Office of Archaeological Studies at the Museum of New Mexico (Blinman and Wilson, OAS workshop notes, December 2001) believes these early micaceous culinary wares first appeared in the Rio Grande along with Red Mesa Black-on-white pottery in the 10th century AD. Mica fragments in the paste may be from granite-derived clays or crushed granitic rock temper.

According to Eric Blinman (Blinman and Wilson, OAS workshop notes, December 2001) true micaceous clays in the northern Rio Grande are weathered from the granites of the Sangre de Cristo Mountains north and east of Santa Fe. Sources of added mica include Rio Grande alluvium, crushed granitic rock, and crushed metamorphic schist. According to Shepard (1956:162), "it may be difficult in some instances to distinguish a residual clay paste [derived from mica granite] from one tempered with sand high in mica, or a mica-bearing rock such as gneiss and schist." She recommends petrographic analysis and precise knowledge of the geology as essential to distinguishing these micaceous pastes. Blinman suggests refiring to distinguish between micaceous clay and added mica temper. Until the distinction can be made with certainty, Shepard (1956:162) recommends that "paste…be described as micaceous rather than as mica-tempered."

Petrographic characterization of micaceous sherds from Coalition period sites is instructive but not conclusive. The three smeared-indented corrugated sherds and one plain gray sherd come from LA 12587 and have similar paste, mineral, and lithic characteristics. The medium to coarse paste has low to moderate birefringence and low grain alignment and void quantity. Paste grains are predominantly monocrystalline quartz with secondary muscovite. Temper is monocrystalline quartz (75%) or microcline. Platy muscovite and biotite are minor minerals. Temper size maximum is very coarse, but most grains are coarse. The lithic type is mica granite containing microcline. There are no volcanic or mica schist (metamorphic) lithic grains present (Appendix BB).

One micaceous smeared-indented corrugated sherd from each Classic period site was examined. The medium-texture paste shows low to moderate birefringence, moderate grain alignment and void quantity. The dominant paste grain is monocrystalline quartz. Two sherds have secondary mica in the paste, and one does not. Each sherd has a different dominant temper mineral:

muscovite, monocrystalline quartz, or microcline feldspar. The two sherds with dominant quartz or feldspar contain minor muscovite and biotite. Grain size maximum is coarse, but most grains are medium size. All lithics are mica granite, with no volcanics or mica schist.

A sub-sample of 42 Classic period micaceous sherds was characterized using a petrographic microscope. The sub-sample consists of plain gray (n = 32), washboard (n = 5), smeared-indented corrugated (n = 3), and clapboard neck (n = 2) sherds. Under the binocular microscope, the sherds initially appeared to have different densities and/or sizes of mica flakes. Two tempers were identified, Type 5, with flakes appearing larger and more numerous, and Type 5-, which appeared to contain sparser concentrations and/or smaller grains. Higher proportions of Type 5- sherds are washed with a mica solution (Table 76.4c).

Type 5 (Dense Mica) sherds at all three sites show high-moderate to high birefringence, moderate to high-moderate alignment and void quantity. Dominant paste grains are 79 percent quartz, 21 percent muscovite. Half the sherds have fine-textured paste. Dominant temper mineral at LA 82 is muscovite 65 percent of the time, whereas none of the sherds at LA 3840 or LA 60550 have muscovite as dominant mineral. Maximum grain size for the dominant mineral ranges up to granule size (>2.0 mm) but most grains are coarse. Mica granite is the dominant lithic type; two have added mica schist and one includes volcanics and mica schist. One sherd contains only mica schist. Paste characteristics of Type 5- sherds (Sparse Mica) are much more variable. There is a wide range of birefringence, but most trend to high-moderate to high. Alignment is moderate to high-moderate, and voids are low-moderate to moderate in quantity. Eighty-seven percent of the sherds have monocrystalline quartz as the dominant grain in the paste. Only 20 percent of sherds have fine paste. Sixty percent of the sherds have monocrystalline quartz as the dominant grain; 26 percent have feldspar (microcline or plagioclase) as the dominant grain; only 13 percent have muscovite as the dominant temper mineral. Maximum grain size for the dominant temper mineral is 40 percent medium and 40 percent coarse sand-size. Secondary and minor muscovite and biotite also tend to fall into the medium to coarse sand size category. Lithic grains in the sherds at LA 3840 (n = 3) are all mica granite. At LA 60550, lithic grains are mica granite plus mica schist. Lithics at LA 82 are both variable and mixed: some are entirely volcanic, while others consist of mica granite or mica schist plus andesite or basalt. Only one sherd consists of mica granite and no other lithic type.

At the Chama-area sites, which are possible sources for these micaceous vessels, 20 percent to 50 percent of dense mica sherds and 46 to 68 percent of sparse mica sherds in excavated units are finished with a mica wash (Table 76.4a). Much of the culinary ware at Chama sites has a washboard exterior surface (Table 76.4b).

Micaceous culinary sherds at Classic period Pajarito sites are mainly plain-surfaced, rather than washboard. The five micaceous washboard sherds found in LA 82 Unit B represent less than three percent of the culinary ware rim sample from both excavation units. The lack of sources for micaceous clay or mica temper on the Pajarito suggests that these vessels were brought to Tyuonyi from the Chama area. Comparison of the paste composition of the sherds at Tyuonyi with those from Chama-area sites should further refine the possible production location of these jars.

CULINARY JAR SIZE

Each jar rim sherd in the sample was measured between the rim and shoulder using a template fitted into the curve of the jar throat. These aperture measurements are recorded as radii in centimeters. Based on the jar aperture size distribution histograms, small jars are defined as less than or equal to 12 cm.

Measurements taken on a small sample (*n* = 11; *n* = 9) of whole Classic period culinary jars excavated from rooms at Tonque Pueblo (LA 240) strongly suggest that vessel aperture may serve as proxy for vessel diameter (Barnett 1969:Table XXV and XXVI) (Tables 76.5a and 76.5b). The scatter plots and associated R^2 values (Figure 76.4) demonstrate that the ratio of aperture diameter to vessel diameter for each defined type of culinary jar but remains constant for both large and small vessels (Barnett 1969:181–185).

Table 76.5a. Rio Grande-style culinary jars from Tonque Pueblo (LA 240): globular with flared rims and rounded bottoms.

Orifice Diameter (inches)	Vessel Diameter (inches)	Vessel Height (inches)	Orifice Diameter (cm)	Radius (cm)
4.75	9.13	6.25	12.1	6
5.50	9.50	7.00	14.0	7
6.75	10.50	8.25	17.1	9
7.00	10.88	7.75	17.8	9
7.25	10.50	8.25	18.4	9
8.25	11.50	8.63	21.0	10
8.50	11.88	9.13	21.6	11
9.00	14.25	9.50	22.9	11
9.50	14.00	11.75	24.1	12
9.75	15.00	12.50	24.8	12
16.25	21.63	20.00	41.3	21

The two smallest vessels have an ovoid shape and lugs at the rim; the largest vessel is an oversized storage vessel.

Table 76.5b. Sankawi-style culinary jars from Tonque (LA 240) with thicker walls and an elongated neck.

Orifice Diameter (inches)	Vessel Diameter (inches)	Vessel Height (inches)		Orifice Diameter (cm)	Radius (cm)
4.25	6.00	5.25	w. handles	10.8	5
6.00	8.25	6.25		15.2	8
7.50	12.13	9.63		19.1	10
8.25	9.75	7.38		21.0	10
9.00	12.50	10.63		22.9	11
9.25	13.75	9.00		23.5	12
9.75	14.75	12.50		24.8	12
11.75	16.75	13.00		29.8	15
12.75	16.75	14.00		32.4	16

The smallest vessel is ovoid with handles

It should be noted that there are few very large jars at Tonque (Figure 76.5) compared with the six Pajarito sites (Figure 76.6a, b, and c). The difference may be that Barnett's sample represents *de facto* or primary refuse, whole vessels abandoned on room floors, rather than the secondary refuse, generally found in middens (Schiffer 1972:161–162). Very large jars may not have been stored in these rooms, or may have been removed before abandonment, especially if they were more difficult to replace.

Coalition Sites

The range of jar sizes and the ratio of small to large jars both change over time (Tables 76.6a and 76.6b) (Figures 76.6a, b, and c). At each of the three Coalition sites, 77 to 80 percent of smeared-indented corrugated jars have aperture radii less than or equal to 12 cm (Table 76.6b).

Table 76.6a. Culinary vessel aperture for selected types at Pajarito sites. Vessel aperture is measured at the throat, below the vessel rim interior.

Type/Size	*n* =	*df* =	*t*	Pr>|t|
SIC–small	7	5	0.04	0.9724
SIC–large	6	4	-0.48	0.6580
Plain Gray–small	7	5	-1.43	0.2128
Plain Gray–large	7	5	1.05	0.3408
Clapboard Neck	4	2	-2.64	0.1182

The size distribution of large jars differs at the three Coalition sites. The maximum radius for any smeared-indented corrugated jar aperture for LA 60372 is 21 cm, 3 cm greater than the 18 cm maximum for LA 12587 (White Rock) and LA 86534 (the Airport) (Table 76.6a). Five of the 18 large smeared-indented corrugated jars at LA 60372 (28 percent) exceed the maximum radius found at the other two sites (see Figures 76.6a through 76.c). T-tests comparing the vessel aperture radius sample means for large and small smeared-indented corrugated and plain gray jars at Coalition and Classic period sites showed no significant differences between large and small vessels, types, or time periods (Table 76.6c).

Coefficients of Variation (CV) are uniformly high for small smeared-indented corrugated jars and noticeably lower for large ones, indicating that while there are fewer large jars, their sizes are more uniform. The CV for large smeared-indented corrugated jars at LA 12587 is 9.5 percent (*n* = 10), suggesting standardized production. The larger size range at LA 60372 affects the CV, which is between 10 percent and 20 percent.

Small plain gray jars at Coalition sites show larger mean radii than small smeared-indented corrugated jars. For large jars, both maximum vessel size (19 cm) and mean radius (17 cm) at LA 12587 are larger than at LA 86534 and LA 60372, with a CV of 11 percent. CVs at or below 10 percent at LA 86534 are for samples of three or fewer rim sherds.

Classic Sites

The Classic period sample of smeared-indented corrugated rims is considerably smaller. Mean aperture radii for small and large jars are similar to those from Coalition sites. CVs are high, particularly for the small jars (Table 76.6a).

The proportion of large jars increases at Classic period sites (Table 76.6b). Ratios of large to small plain gray jars at the two smaller sites, however, are closer to those for smeared-indented corrugated at Coalition sites, with 76 percent and 65 percent small jars, respectively (Table 76.6b). Small jars make up 50 percent of plain gray rims in LA 82 Unit A and 61 percent in Unit B.

Jars are larger overall in the Classic than in the Coalition. The largest jar in the sample has a radius of 20 cm, with a 25 cm outlier at Tyuonyi. CVs are generally higher for small jars. CV for large plain gray jars at LA 60550 (Tyuonyi Annex) (*n* = 13) is 9.6 percent, and for washboard micaceous jars from LA 82 Unit B (*n* = 5) CV = 9.4 percent (Table 76.6a), with the rest between 10 percent and 20 percent.

SHERD THICKNESS

Sherd thickness (Table 76.7a) is the median wall thickness of the four sides of a body sherd or the three non-rim sides of a rim sherd (Rocek 2002). Sherds with no measurable body wall below the rim were not included in the calculation.

Table 76.7a. Univariate statistics: Culinary sherd thickness at Pajarito sites by vessel aperture.

Plain gray jars have a greater mean thickness than smeared-indented corrugated jars, whether at Coalition or Classic period sites (Table 76.7b). Smeared-indented corrugated sherds are thicker at Classic sites, and the mean thickness range overlaps for large plain gray and smeared-indented corrugated. T-tests comparing the sherd thickness sample means for large and small smeared-indented corrugated and plain gray jars at Coalition and Classic period sites showed no significant differences between large and small vessels, types, or time periods. It is very likely, however, that there is a significant difference in mean rim thickness for the small sample of clapboard neck jars ($n = 5$; $df = 3$; $t = 5.69$; $Pr > t = 0.0107$) (Table 76.7c).

With the exception of large plain gray jars at LA 86534 (*n* = 2; CV = 28.3 percent), CVs for Coalition period sherd thickness fall below 20 percent (Table 76.7a). Large smeared-indented corrugated jars at LA 60372 (*n* = 18) have a CV of 10.2 percent, otherwise only small samples of plain gray and clapboard neck fall at or below 10 percent.

Likewise, CVs for sherd thickness at Classic period sites fall at or below 20 percent, with the exception of large smeared-indented corrugated jars at LA 3840 (*n* = 2; CV = 37.5 percent). Only two small samples at LA 82 Unit B fall below 10 percent (Table 76.7a).

RIM THICKNESS

Rim thickness (Table 76.8a) is measured ~2 mm below the vessel lip. Plain gray jars have a greater mean rim thickness than smeared-indented corrugated jars, whether at Coalition or Classic period sites. The upper end of the range for smeared-indented corrugated rims overlaps with the lower end of the plain gray range at Coalition sites, but not at Classic sites (Table 76.8b). The differences in mean rim thickness, however, are not significant. T-tests comparing the rim thickness sample means for large and small smeared-indented corrugated and plain gray jars at Coalition and Classic period sites showed no significant differences between large and small vessels, types, or time periods. There is a small likelihood of a significant difference in mean rim thickness for the small sample of clapboard neck jars (*n* = 5; *df* = 2; *t* = 4.36; *Pr > t* = .0488) (Table 76.8c).

With two exceptions (large smeared-indented corrugated jars at LA 12587 [*n* = 10; CV = 23.0 percent] and large plain gray jars at LA 86534 [*n* = 2; CV = 34.9 percent]), CVs for rim thickness at Coalition sites are below 20 percent. One very small sample of clapboard neck jars at LA 86534 (*n* = 2) has a CV of 7.0 percent. This same sample also has a CV below 10 percent for sherd thickness (Table 76.8a).

With one exception (small smeared-indented corrugated jars at LA 82 Unit A [*n* = 7; CV = 27.4 percent]) all CVs for rim thickness at Classic sites are between 10 percent and 20 percent.

COEFFICIENTS OF VARIATION AND PASTE COMPOSITION

Table 76.9a compares CVs for jar aperture, sherd thickness, and rim thickness at each site for large and small jars by exterior surface treatment (smeared-indented corrugated, plain, clapboard neck, and washboard).

Coalition Sites

Few CVs at Coalition sites are lower than 10 percent for vessel aperture and rim thickness, and these may be the effect of sample size.

Large smeared-indented corrugated jars at LA 12587 (*n* = 10) have a CV of 9.5 percent for aperture. This suggests that these jars may have been produced to certain size specifications. Large smeared-indented corrugated jars at LA 86534 (*n* = 8) and LA 60372 (*n* = 10) are between 10 percent and 20 percent.

Plain gray jars at Coalition sites show a higher degree of standardization, but these samples are quite small. Large plain jars at LA 12587 (*n* = 5) have a CV of 8.1 percent for sherd thickness. Large plain gray jars at LA 86534 (*n* = 3) have a low CV for aperture (CV = 10.0) as do small plain gray jars (*n* = 2; CV = 5.2). The small jars also have low CVs for both sherd thickness (CV = 6.0) and rim thickness (CV = 8.2). Small plain jars at LA 60372 (*n* = 5) have a low CV for sherd thickness (CV = 8.4).

Low CVs for most plain gray and clapboard neck rims at all three Coalition sites may reflect small sample size (Costin 2001; Schleher 2005). Thirteen out of 14 samples (93%) have CVs lower than 20 percent for sherd thickness even in the six cases (43%) when CV for vessel aperture is high.

Classic Sites

Classic period samples initially show very few low CVs. These are for small samples at LA 82 Unit B (large smeared-indented corrugated jars [*n* = 2; CV = 8.1% for sherd thickness]; micaceous washboard jars [*n* = 5; CV = 9.4% for jar aperture]). CVs for all attributes of plain gray jars are higher than 10 percent, but 16 of the 18 values (89%) fall below 20 percent

Micaceous and non-micaceous culinary jars at LA 82 Units A and B were analyzed separately to ascertain whether CV differed based on presumed production locale. The micaceous rim samples at LA 3840 and LA 60550 were too small for a separate analysis. Histograms of plain gray micaceous and non-micaceous samples at Tyuonyi (Figures 76.7a through 76.7c) show a higher breakpoint between large and small vessels for non-micaceous plain gray jars (≤13 ≥14), and an even higher breakpoint for micaceous jars (≤14 ≥15).

There are four times as many non-micaceous smeared-indented corrugated jars at Tyuonyi as micaceous (Tables 76.9b and 76.9c), but the samples are still quite small and CV calculations may be affected by sample size. However, 10 of the 12 jars (83 percent) have aperture radii less than or equal to 13 cm. Five of the six CVs are below 20 percent; two are below 10 percent.

The non-micaceous plain gray sample for both units (*n* = 110) includes 76 jars with aperture radii ≤13 cm (69 percent). CVs are just above 20 percent for aperture and between 10 percent and 20 percent for sherd and rim thickness. For large jars, CVs are between 10 percent and 20 percent. A very small sample of non-micaceous clapboard neck jars has one CV just above 10 percent and one just below (one attribute did not return a CV).

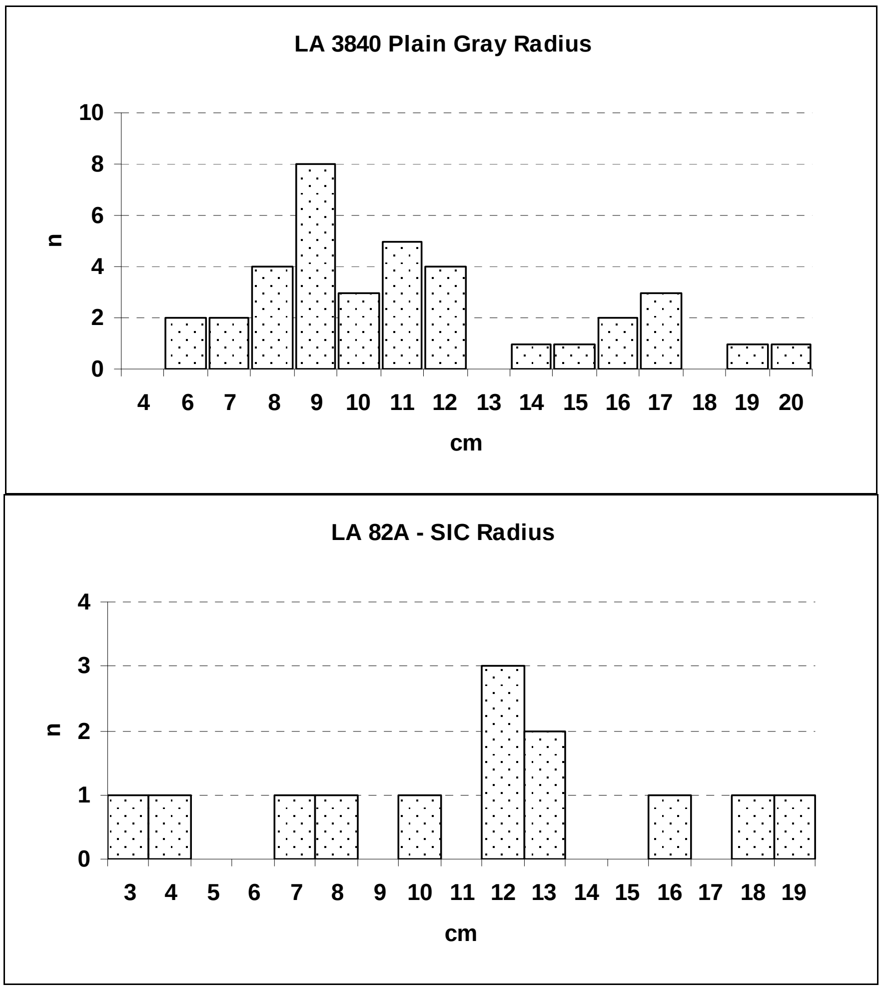

Figure 76.7a. Aperture radii for jars from LA 3840 and LA 82A.

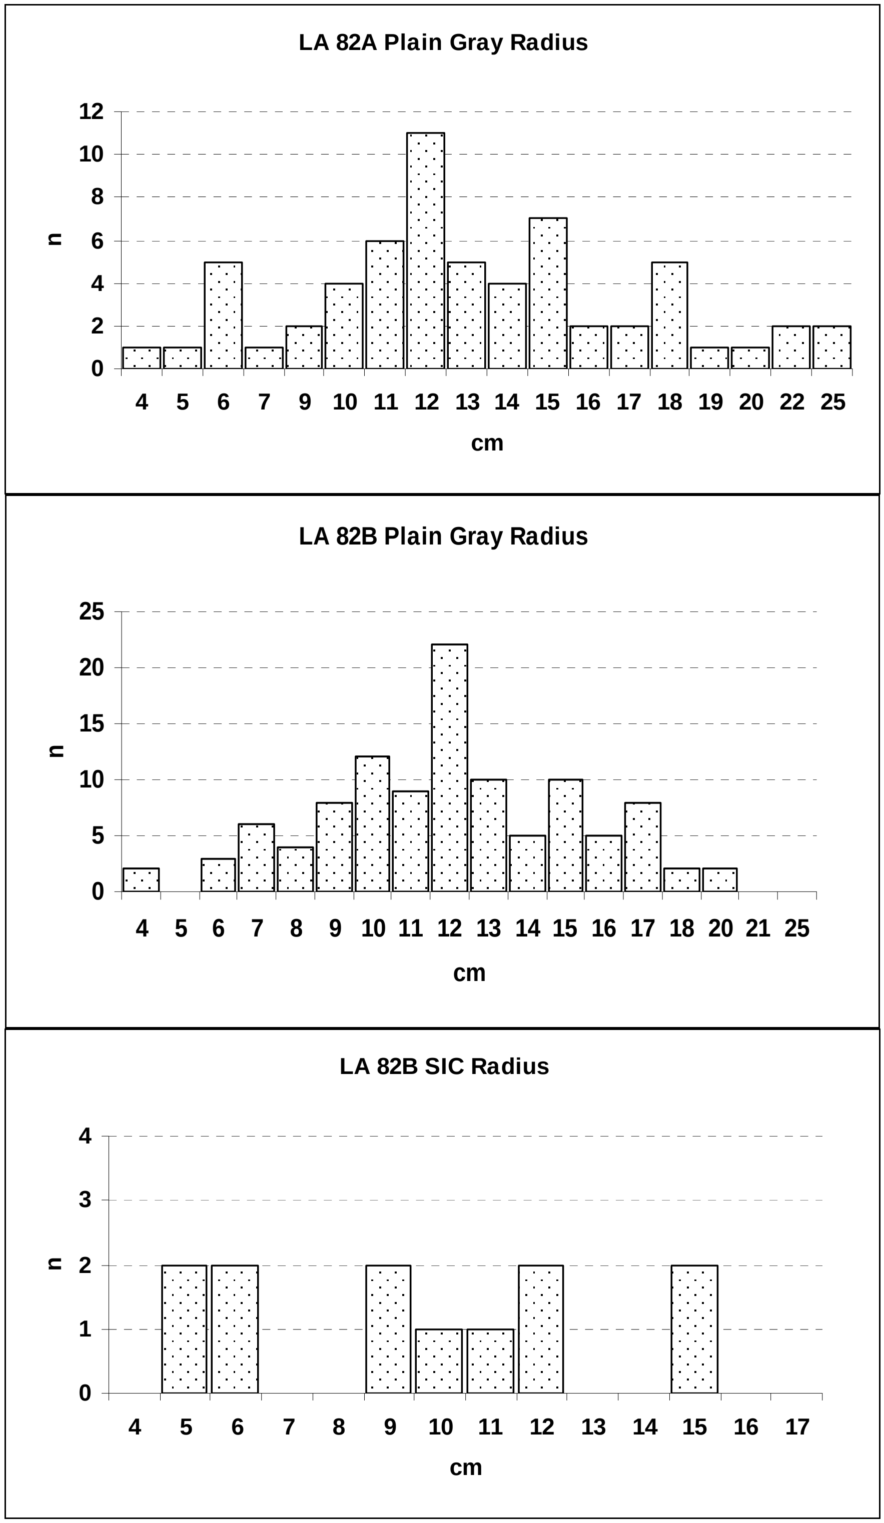

Figure 76.7b. Aperture radii for jars from LA 82A and LA 82B.

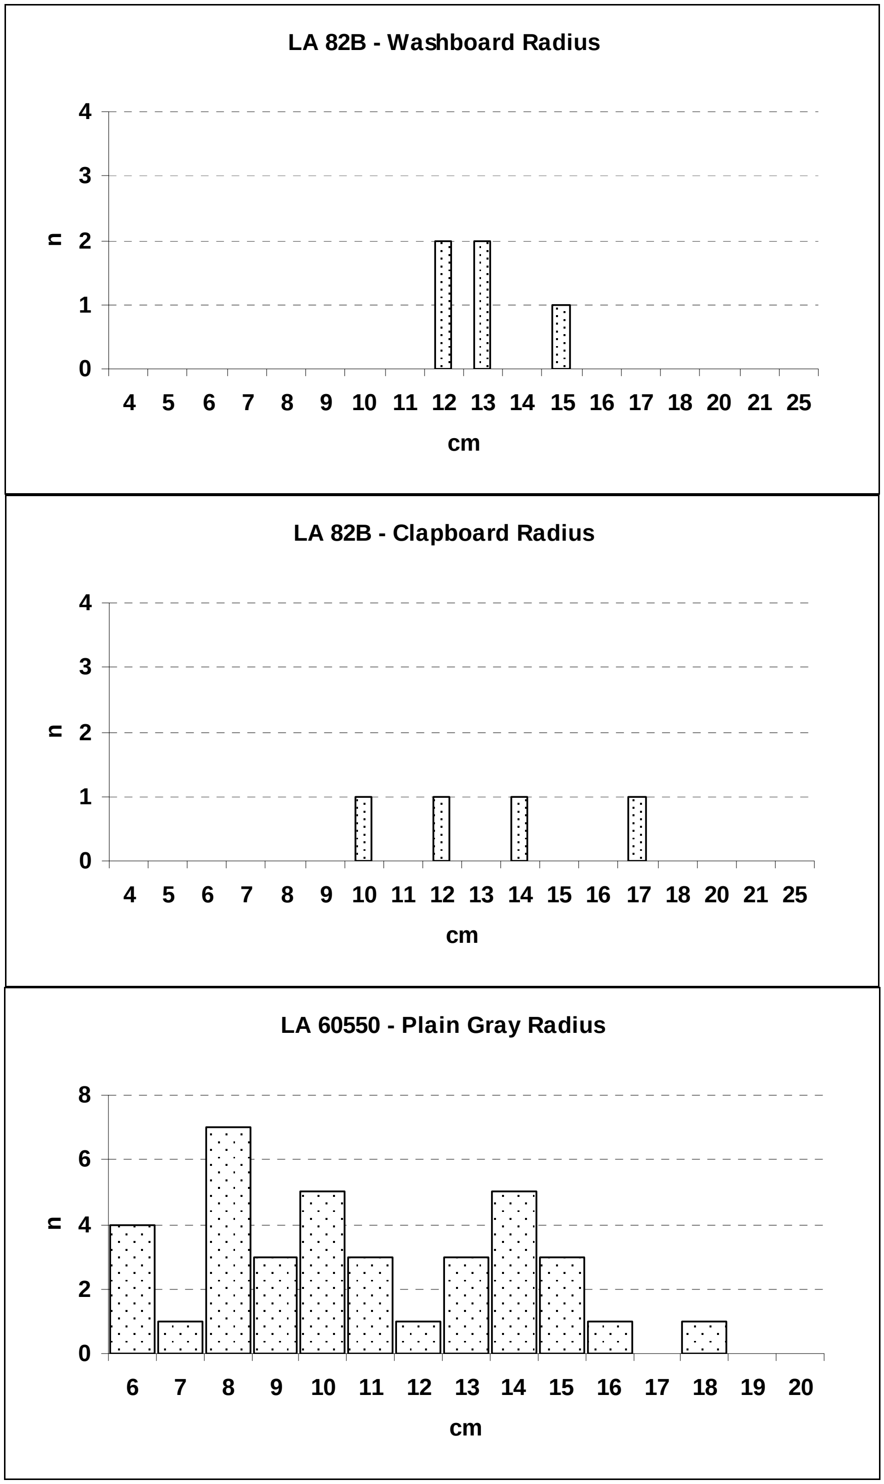

Figure 76.7c. Aperture radii for jars from LA 82B and LA 60550.

The sample of micaceous plain gray jars for both units (n = 54) includes 35 jars with aperture radii ≤14 cm (65 percent). Small micaceous jars, like the non-micaceous jars, have CVs just above 20 percent for aperture radii. In this case, however, CVs for sherd and rim thickness are between 10 percent and 15 percent, slightly lower than for the small non-micaceous plain gray vessels. CVs for large micaceous plain gray jar apertures are below 10 percent, with CVs for sherd and rim thickness between 10 percent and 20 percent, slightly higher than for large non-micaceous plain gray. Micaceous washboard jars return values for small jars only. CVs for aperture and sherd thickness go down slightly for the smaller sample, while CV for rim thickness goes up slightly.

TESTING EQUALITY OF VARIANCE

How reliable are the CVs calculated from these archaeological samples? Sample sizes are relatively small and the samples are not normally distributed. Occupation dates are imprecise and range from ca. 40 years for LA 3840 to ca. 160 years for LA 82. The number of producers, production episodes, and number of vessels produced are unknown. Dividing samples into vessel size classes magnifies the effect of these conditions.

CVs calculated in this study were compared with CVs calculated for controlled ethnoarchaeological and archaeological samples, using an Excel® algorithm provided by Jelmer Eerkens (personal communication, December 2005). The method is discussed fully in Eerkens and Bettinger (2001). It tests the equality of CVs and describes "how far sample CVs lie from the estimate of the overall population CV" (Eerkens and Bettinger 2001:499). A *p*-value less than 0.05 indicates that CVs for two samples are statistically distinct.

The controlled ethnoarchaeological samples are from studies done in the Philippines (Kvamme et al. 1996) and India (Roux 2003). Potters in the village of Dangtalan, Luzon, Philippines, produce meat and vegetable cooking pots (two-*chupa oppaya*) "primarily for household use and restricted exchange" (Kvamme et al. 1996:118). Although these are the least specialized of the potters studied in three Philippine communities, CVs for aperture, circumference, and height are below 10 percent (Kvamme et al. 1996:123; Table 4). Seasonal potters in Andhra Pradesh, India, produce *ralla catti* for cooking lentils and spinach. Each potter produces roughly 6000 vessels per year for barter or trade. Roux (2003:777; Table 4) pooled measurements taken for six individual potters for height, maximum diameter, and vessel aperture.

The archaeological samples are from a study of fine-ware bowl wasters at Tell Leilan, Syria (Blackman et al. 1993) and medium size, globular, Early Matsaki buffware jars from protohistoric Zuni Pueblo villages in New Mexico (Mills 1995). The fine-ware bowl wasters are from a single production episode dating to approximately 2300 BC (Blackman et al. 1993:63). Data are from Table 5 in Blackman et al. (1993:73). The Zuni buffware jars are dated from the 1400s–1500s through "formal and stylistic attributes" (Mills 1993:205–208). Data are from Table 8.5 in Mills (1995:222).

Eerkens' algorithm compares two samples using sample mean, standard deviation, and sample number. In this case, I held sample 1 constant, using one of the four control data sets as sample 1, and used the measurements from each of the 16 Pajarito grayware data sets as sample 2.

Pajarito Gray Ware versus Ethnoarchaeological Samples: Aperture

In the first comparison (Table 76.10a), sample 1 is aperture measurements for Dangtalan *two-chupa oppaya* and sample 2 is aperture measurements for Pajarito gray ware jars. Five samples of Pajarito grayware jars return *p*-values above 0.05. The CVs for these archaeological samples range from 8.9 to 11.3. A second comparison, made with sample 1 equal to aperture measurements for Andhra Pradesh *ralla catti*, returns only three samples with *p*-values above .05. CVs for these samples range from 8.9 to 9.5. The difference between the two ethnoarchaeological samples are 1) a slightly smaller CV for the Andhra Pradesh vessels (7.35 versus 7.47) and 2) a sample size for the Andrha Pradesh vessels, which is three times as large as that from Dangtalan.

Pajarito Grayware versus Archaeological Samples: Aperture

In the second comparison (Table 76.10b), sample 1 consists of aperture measurements for Tell Leilan fine-ware bowl wasters and sample 2 consists of aperture measurements for Pajarito grayware jars. The same five samples, with a CV range of 8.9 percent to 11.3 percent, return *p*-values greater than 0.05. A second comparison, using aperture measurements for Zuni Early buffware jars as sample 1, returns *p*-values greater than 0.05 for the same five samples of Pajarito grayware jars. Comparison of the range of *p*-values for the two sets of calculations shows that *p*-values are much higher in the two cases where sample 1 archaeological samples are used as the basis for comparison.

Pajarito versus Ethnoarchaeological and Archaeological Samples: Thickness

Only the Tell Leilan data include measurements and CVs for vessel thickness. These data and the aperture measurements for the Dangtalan vessels were used to compare CVs for vessel thickness (Table 76.10c). None of the CVs for thickness for the Pajarito Plateau vessels are below 10 percent, however, the first case returned nine *p*-values greater than 0.05. CV values for these samples range from 10.2 to 12.9. The second case returned only three *p*-values greater than 0.05. CV values for these samples range from 10.2 to 10.8. The differences between the two data sets used for sample 1 are 1) the CV for the Dangtalan apertures is lower (7.47 versus 8.14) and 2) there are twice as many vessels in the Dangtalan sample.

Examination of these comparisons indicates that the algorithm is effective in comparing CVs from less precisely controlled Pajarito Plateau archaeological samples and more precisely controlled archaeological and ethnoarchaeological samples. I can reliably report CVs for samples as small as seven vessel rims and expect that the overall population would return a similar result. However, results are affected by control sample size, mean, and standard deviation, and any interpretations should factor these in.

DISCUSSION

Surface Treatment Change

The dominant culinary ware type changes from smeared-indented corrugated at Coalition sites to plain gray at Classic sites, as service ware types are also changing. The proportion of culinary sherds decreases at Classic sites.

Temper Change

Most smeared-indented corrugated sherds contain coarse, subangular feldspar and quartz sand-sized crystals from anthills. About one-fifth of the smeared-indented corrugated at the later Coalition site, LA 60372, appears to have inclusions of finer, more angular feldspar and quartz. The small quantities of smeared-indented corrugated at Classic sites, as well as the plain gray jars that dominate the Classic assemblages, are mainly tempered with this finer material (see also Wilson and Castro-Reino 2005:6).

Micaceous ware, which is rare in any Coalition assemblage, becomes an important part of the ceramic assemblage at LA 82, the largest Classic site, especially in the upper levels of the two excavation units. There is much less micaceous culinary ware at the two smaller Classic sites. Five micaceous washboard jar rims, likely to have come from the Chama-Española area, appear washed with a mica solution. These occur only in one unit at LA 82. This suggests that although micaceous washboard jars may have been brought to Tyuonyi, none were brought to the Annex.

Size Change

More than three-quarters of all jars at Coalition sites are small, with aperture radii less than or equal to 12 cm.

Large smeared-indented jars at LA 12587 show a peak size distribution at 16 cm and have a CV of 9.5 percent, strongly suggesting production by a small number of skilled potters. The large plain gray jars at this site have a CV just above 10 percent. There is some suggestion of short-distance whiteware exchange, based on the composition of the volcanic lithic fragments (Wilson and Castro-Reino 2005:8), but culinary ware temper composition does not differ from other sites on the Pajarito. This would suggest specialized local production of this ware.

The presence of very large smeared-indented corrugated jars at LA 60372, the plaza pueblo, suggests cooking for larger groups, either extended families or communal feasts. The CV for these jars, however, is higher.

The mean size of plain gray jars at Coalition sites is greater than for smeared-indented corrugated. This could indicate a temporal trend toward larger jars. While samples of plain gray are small, several have low CVs, which might represent the work of one potter.

Classic period assemblages have a larger proportion of jars with openings ≥13 cm, and the upper end of the size range is greater. The breakpoint between large and small jars appears to shift upward in the Classic period. Four samples of large jars have low CVs: LA 82 Unit B micaceous washboard (n = 5; CV = 9.4%) and plain micaceous in Unit A (n = 7; CV = 8.9%) and Unit B (n = 12; CV = 9.1%). LA 60550 has 13 large plain gray jar sherds with CV = 9.6 percent.

Thickness

Plain gray jars are always thicker than smeared-indented corrugated. Increased wall thickness would increase resistance to mechanical stress and would transfer heat more slowly, possibly indicating a change in food preparation methods to longer, slower cooking (Skibo 1994). Reduction in breakage might account for the lower proportion of culinary sherds in Classic period assemblages.

Most CVs for Coalition types of both sizes are less than 20 percent. When the Classic period sample is subdivided by type and temper, CVs for both micaceous and non-micaceous plain gray jar sherds and rim thickness are less than 20 percent.

Rim Thickness

Plain gray jar rims are thicker in the Classic than the Coalition, and always have a greater mean rim thickness than smeared-indented corrugated. Rim thickness may be more of a stylistic attribute than a functional attribute, but a thicker rim may add to the strength of the vessel and increase its use-life. Most CVs for rim thickness fall between 10 percent and 20 percent in both the Coalition and Classic periods.

Coefficients of Variation

A large number of CVs for size, body thickness, and rim thickness fall between 10 percent and 20 percent in both the Coalition and the Classic. The number of CVs below 10 percent is greater in the Classic period, especially when the sample is subdivided according to the presence or absence of mica in the paste.

Many Coalition CVs below 10 percent may be an effect of the small sample size. While a small sample with a low CV might indicate the output of a single potter, a larger sample with a low CV could indicate size standardization. The former may be the case at LA 86534, where the sample is small, while the larger sample of large smeared-indented corrugated jars at LA 12587 may indicate the latter. Because corrugations and smearing create additional variability in thickness, smeared-indented corrugated jars show little standardization of this attribute except possibly at LA 60372.

CVs for Classic period jars are mainly between 10 percent and 20 percent, with exceptions for very small samples. However, when the Classic period jars at LA 82 are analyzed based on presence or absence of mica in the paste, the CVs for all attributes are lower. Here many samples are large enough to suggest attribute standardization rather than a lower number of producers.

CONCLUSION

This preliminary examination of Pajarito culinary ware shows changes from the Coalition to the Classic period in surface treatment, inclusions, size range, ratio of large to small vessels, and vessel wall and rim thickness. These changes are not in lock-step; they differ in timing according to settlement size and type and may be part of an overall increase in large-group feasting activities.

The presence of much larger jars at LA 60372 in the Late Coalition may indicate food preparation in larger quantities, suggesting larger family groups or communal feasting. There is evidence of a trend toward standardization at LA 12587 and at LA 60372, which could indicate either specialized production for local exchange at those sites, or trade with specialists from another community. Standardization in the smaller samples may indicate output by a few skilled domestic specialists.

Vessel size range, the proportion of large jars, and the degree of size standardization increases from the Coalition to the Classic period at these Pajarito sites. Production of large jars requires a higher degree of skill, and these may have been made by fewer potters, resulting in a more standardized size range. If large jars were being produced for special functions or events, then size range may have also been prescribed (B. Stark 1995).

Vessel thickness and rim thickness also increase from Coalition period smeared-indented corrugated to Classic period plain gray. This may relate to changes in cuisine, cooking practices, or in fuel available for cooking and/or firing (see Curewitz 2004b for discussion). Thickness of plain versus smeared-indented corrugated may be related to the change in temper material, but may also relate to vessel size.

Micaceous sherds make up 23 percent of the culinary ware at LA 82, but only 0.4 percent and 0.7 percent, respectively of the culinary ware at LA 3840 and LA 60550. These vessels were not produced on the plateau. They clearly show attribute standardization and may have been produced for exchange by specialist potters. The quantities present suggest that they were an important item of exchange for the inhabitants of the large plaza pueblo but not for those of the two smaller Classic period sites.

CHAPTER 77
CERAMIC ANALYSIS AND INTERPRETATION OF CLASSIC PERIOD PUEBLOS ON LOS ALAMOS NATIONAL LABORATORY LAND COLLECTED BY THE PAJARITO ARCHAEOLOGICAL RESEARCH PROJECT

Samuel Duwe

INTRODUCTION

Archaeological questions of identity, technology, and craft specialization have preoccupied researchers over the past 25 years. By understanding the methods and use-life of craft (such as pottery) it becomes possible to delineate interesting patterns in the material record. These can be used to infer group identity and modes of social cohesion, social boundaries, and interactions and relationships at an inter- and intra-site level. This research also is important to descendent communities of prehistoric people whose material culture is being analyzed. These lines of inquiry make it possible to not only understand the presence and location of a prehistoric society in culture historic terms, but also create ways in explaining this behavior.

The above questions are especially pertinent in the American Southwest where a detailed culture history has been devised, making it possible to ask detailed and somewhat abstract questions. The reason for the precision of knowledge of the archaeological record owes much from the over 100 year history of investigation and inquiry. The northern Rio Grande is no exception. In fact, much of the early work in the Southwest was performed near or amongst the modern Rio Grande pueblos. This area was also subject to many ethnographic analyses, which has given researchers the ability to use analogies of Pueblo behavior as an effective middle-range theory in interpreting prehistoric ruins and artifacts.

Even with this excellent knowledge of the archaeological record, as well as a firm base in the ethnographic and ethnohistoric literature, certain large portions of prehistory have yet to be addressed, or if already addressed, more completely understood. This includes Classic period (AD 1325–1600) prehistoric Tewa populations on the Pajarito Plateau. Although a general understanding of their location and material culture are understood, questions of chronology, identity, and the degree of craft specialization and pottery technology have not been successfully answered. Another problem that plagues the entire field of archaeology is the collection of artifacts that remain unanalyzed. This too is true of many collections of northern Rio Grande sites currently housed in museums but never examined to their full potential (or in many cases, not at all).

This report examines ceramics collected from two Classic Period sites on the Pajarito Plateau by the Pajarito Archaeological Research Project (PARP): Otowi (LA 169) and Tsirege (LA 170). These collections have never been fully analyzed and their analysis promises answers to a broad range of questions, including those mentioned above. I will first briefly describe the study area and the history of archaeological research. After laying out a research design for analyzing these collections, I analyze multiple attributes of pottery sherds (both painted and utilitarian wares) including not only basic visual properties but also microscopic temper/paste characteristics and the results of refiring oxidation experiments. These results are interpreted using a theoretical and methodological approach that addresses questions of chronology, identity, technology, and craft specialization.

Of course, ceramics from the surface of two sites can only reveal so much information about regional patterns of exchange, specialization, and identity. Near the end of this report, the results of this analysis are compared with existing data from other pueblos in the northern Rio Grande region to make preliminary hypothesis of regional interaction during the Classic period. Further directions for future research are suggested to fully incorporate these results into the larger culture history of northern New Mexico.

THE PAJARITO PLATEAU NATURAL ENVIRONMENT AND CULTURE HISTORY

The Pajarito Plateau is defined as the high mesas that slope eastward from the Jemez Mountains to the Rio Grande Valley in north-central New Mexico, ranging from Puye ruins on the Santa Clara Pueblo Reservation to the north to Canada de Cochiti near present day Santa Fe in the south (Steen 1977). The magnitude of this area both in size and environmental diversity is represented in the change of elevation: 1590 m (5217 ft) above sea level at the Rio Grande to 3526 m (11,568 ft) at Tschicoma Peak in the Jemez (Allen 2004). Geologically, the landscape is formed by the explosion and collapse of a great volcano (1.4 and 1.1 million years ago), which created the Valles Caldera to the west and whose remnants formed the Jemez Mountains and canyon-dissected tuff plateaus on their eastern flank. The area experiences a semi-arid climate with a mean annual precipitation of 40.7 cm (Allen 2004)—a climate that can reasonably be extended into prehistory (Dean and Robinson 1977). Vegetation ranges from juniper (*Juniperus monosperma*) grasslands in the lowlands, juniper and piñon pine (*Pinus edulis)* woodlands on the raised mesas, and ponderosa pine (*Pinus ponderosa*) in the mountains (Allen 2004).

Although the natural landscape can be separated into three unique and easily identifiable categories, the cultural landscape is more difficult to discern. The earliest human occupants in the region were Paleoindian foragers (9500–5500 BC) who most likely ventured across the plateau during hunting expeditions or raw material procurement endeavors. The evidence lies in projectile points: a Folsom point was found during the Los Alamos National Laboratory (LANL) survey (Steen 1977:7) and Clovis, Folsom, and Plainview points were identified in the general study area (Acklen 1993, 1997; Lent et al. 1986; Traylor et al. 1990; Wiseman 1992).

Archaic period (5500 BC–AD 600) foragers appear to have occupied the plateau at least seasonally, hunting small and large game (rabbits and deer) and procuring nearby lithic materials. Evidence takes the form of projectile points, obsidian lithic tools, and stone chipping debris (Vierra et al. 2002). Summer sites used for pine nut harvesting, hunting, and rock collection were recorded and interpreted (Baker and Winter 1981; Biella 1992; Moore et al. 1998), as were winter sites nearer the Rio Grande in the piñon grasslands (Lent 1991).

The first Pueblo occupation was during the Developmental period (AD 600–1150). Although there are few sites with corresponding diagnostic Kwahe'e Black-on-white ceramics, those that are found are small pithouses and lithic and ceramic scatters (Vierra et al. 2002). Because of this low frequency of sites, it can be interpreted that there was a minor Pueblo presence during the Developmental period and that these people were practicing a mixed subsistence: that of mostly foraging with some maize horticulture.

During the Coalition period (AD 1150–1325), the plateau saw a large increase in the number of sites. Year-round settlement appeared in the uplands and there was an increased reliance on agriculture as evidenced by agricultural features such as check dams and gravel mulch gardens (Vierra et al. 2002). This rapid population growth has been attributed to migration (Wendorf and Reed 1955) or population explosion (Steen 1982).

The Classic period (AD 1325–1600) saw an even greater increase in the reliance on agriculture and populations aggregated into multiple large centers. At these centers were large pueblos with various other corresponding sites such as fieldhouses, shrines, and smaller pueblos. These main pueblos were Tsirege, Tsankawi, and Otowi and are typed by the presence of biscuitware (Vierra et al. 2002). At this time there was also the apparent solidification of a Tewa group, defined by pottery and settlement patterns. To the south, this aggregation had created tightly definable regions as well, especially along traditional cultural lines. This is seen most spectacularly with the change in ceramic assemblage between the northern Pajarito Plateau and pueblos to the south. These pueblos were specializing in the manufacture of Rio Grande glazewares and the Tewa groups were producing their own distinct biscuitware vessels.

HISTORY OF PAST ARCHAEOLOGICAL RESEARCH

Although the area was visited and sites were mentioned by early explorers, the first true archaeological investigation of the Pajarito Plateau was by Adolph Bandelier who collected artifacts from the major sites of Otowi and Tsirege (Bandelier 1892). The first large publications of the major sites were by Edgar Lee Hewett and Lucy Wilson. Hewett (1904, 1905, 1906, 1908a) recorded and sketched some of the largest Classic Pueblo ruins located on LANL property, including Otowi and Tsirege (Figure 77.1). Wilson led excavations at Otowi from 1915 to 1917 and produced information in the northern roomblocks of the site (Wilson 1916a, 1916b, 1917, 1918a, 1918b). Harry Mera surveyed the Plateau in the 1920s and 30s, recording some of the same large Classic period pueblos and collecting ceramics in which he constructed an initial chronology that dated the sites of Tsirege and Otowi to the 14th and 15th centuries (Mere 1932, 1934). Through the mid-part of the century, further work on the plateau was performed by archaeologists working under the auspices of LANL (Steen 1977, 1983; Worman and Steen 1978) and Bandelier National Monument (Turney 1955). These included test excavations and extensive survey projects.

The PARP was the first systematic survey of the region. Conducted from 1977 to 1985, the project was lead by James Hill of the University of California, Los Angeles (UCLA). The survey recorded 935 sites, 445 which were multi-room masonry dwellings ranging from one- to three-room fieldhouses to large multi-storied plaza pueblos (Hill et al. 1996). Small test excavations were performed on the smaller sites, whereas large-scale collection of artifacts was performed on the large Classic period sites (Otowi and Tsirege). Much of this material, including ceramics, remains unanalyzed at the UCLA. The main theoretical framework of the project was the understanding of settlement patterns and demographics of sites to interpret prehistoric people of the plateau's adaptation to environmental and social stress. This included preliminary dating, mapping, and collection at all accessible sites.

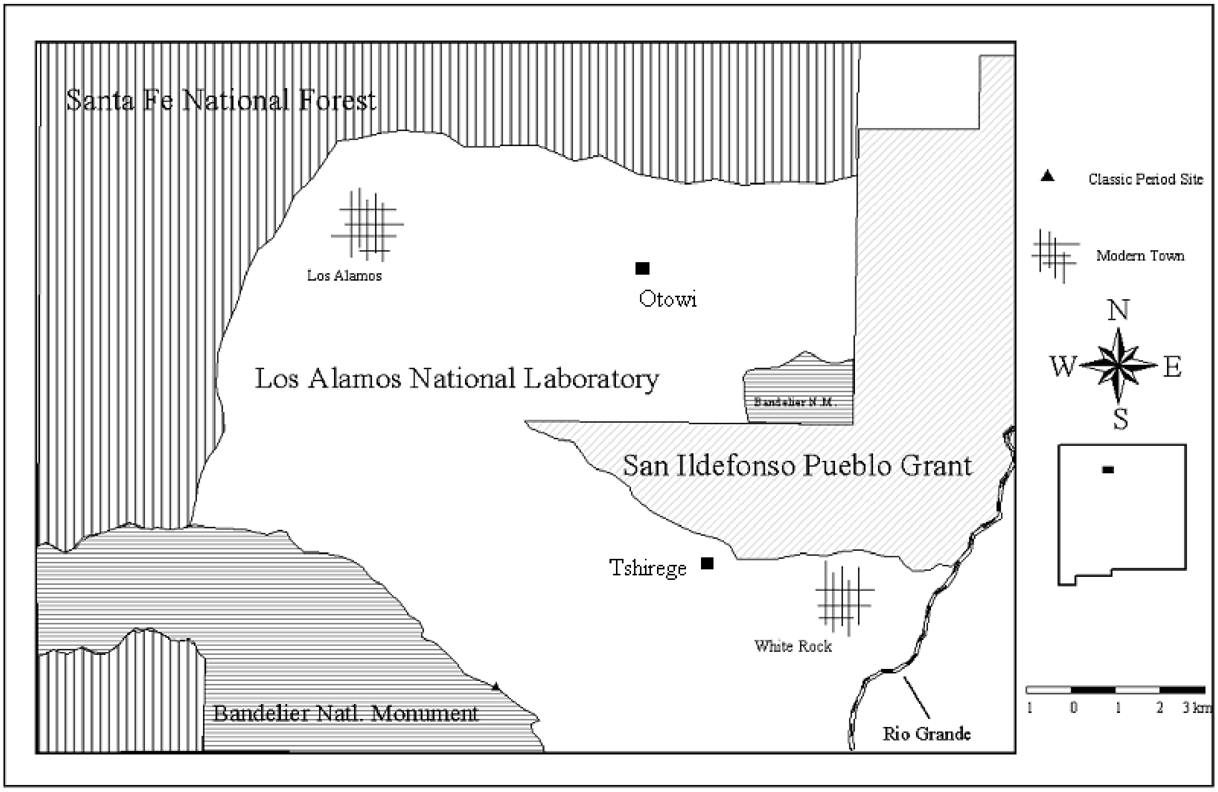

Figure 77.1. Classic period sites at LANL selected for analysis.

Up until the present, various LANL archaeologists have performed culture resource management work across the northern Pajarito Plateau in which LANL (United Stated Department of Energy) owns much of the land. The most important of these projects was the survey and synthesis of LANL data. As of this report, 16,000 acres of LANL lands have been 100 percent surveyed, with another 5,500 acres unsystematically examined. A total of 1595 sites have been recorded (Vierra et al. 2002). Currently, LANL archaeologists are completing the Land Conveyance and Transfer Project in which a multitude of smaller one- to three-room Coalition and Classic period fieldhouses have been excavated. This data will help in understanding chronology, settlement, and subsistence patterns during these periods on the Pajarito Plateau.

STUDY AREA AND SAMPLE

Otowi (LA 169)

Otowi (LA 169) is a very large Classic period pueblo with 700 or more ground floor rooms, including five rubble mounds and several kiva and midden areas. Both tree-ring and ceramic samples have dated the site tentatively to the AD 1400s (see Chapter 7, Volume 1). The pueblo is divided into five roomblocks and seven kivas. The roomblocks are estimated to be two to three stories tall (Hewett 1953). The site was first excavated by Hewett (1906, 1953) and reported by Lucy Wilson (1916a, b), where the first detailed maps and analyses were presented. PARP crews in the 1970s parceled the site into 12 units (A–H and J–M) and surface collected 100 percent of the ceramic assemblage within these units (PARP 1978) (Table 77.1). The site was again revisited in 1999 by LANL archaeologists who performed infield analyses of surface ceramics (LANL 1999) (see Figure 77.2 for a map of the sites as well as the location of collection units from both PARP and LANL analyses).

Table 77.1. PARP collection units at Otowi and their associated sizes and reasons for collection (from PARP 1978).

Unit	Location	Size	Reason Collected
A	Central mound (backdirt?)	3- by 3-m grid square	For midden and backdirt samples (from previous excavations)
B	Primary midden	2- by 2-m grid square	For midden and backdirt samples (from previous excavations)
C	Central mound (backdirt?)	2- by 3-m grid square	For midden and backdirt samples (from previous excavations)
D	Primary midden	2- by 2-m grid square	For midden and backdirt samples (from previous excavations)
E	South of Roomblock A	3- by 3-m grid square	To obtain ceramics from earlier occupations
F	South of Roomblock A	1- by 2-m grid square	Revealed glazeware
G	South of Roomblock A	1- by 1-m grid square	Revealed glazeware
H	Roomblock A	2- by 2-m grid square	As a check to make sure no important components were missed
J	West of Roomblock B	2- by 2-m grid square	As a check to make sure no important components were missed
K	West of Roomblock B	2- by 2-m grid square	To obtain ceramics from earlier occupations
L	Adjacent to Roomblock B	2- by 2-m grid square	As a check to make sure no important components were missed
M	South of Roomblock A	0.5- by 0.5-m grid square	Revealed glazeware

The excavations by Wilson (1916a, b) revealed that Roomblock A was most likely the oldest occupation of the site, which she called the "old pueblo." However, very little information is known on the extent of these excavations as well as by those of Hewett (1906). In fact, there is debate whether the central earthen mound is backdirt from these early excavations (as proposed by PARP crews) or a "burial mound" (Hewett 1906). Most likely it is a mixture of both, although this has been difficult to prove using surface collections alone. This problem points to the complexity of both natural and cultural transformation processes (Schiffer 1976) that affect the composition of ceramic assemblages in surface contexts.

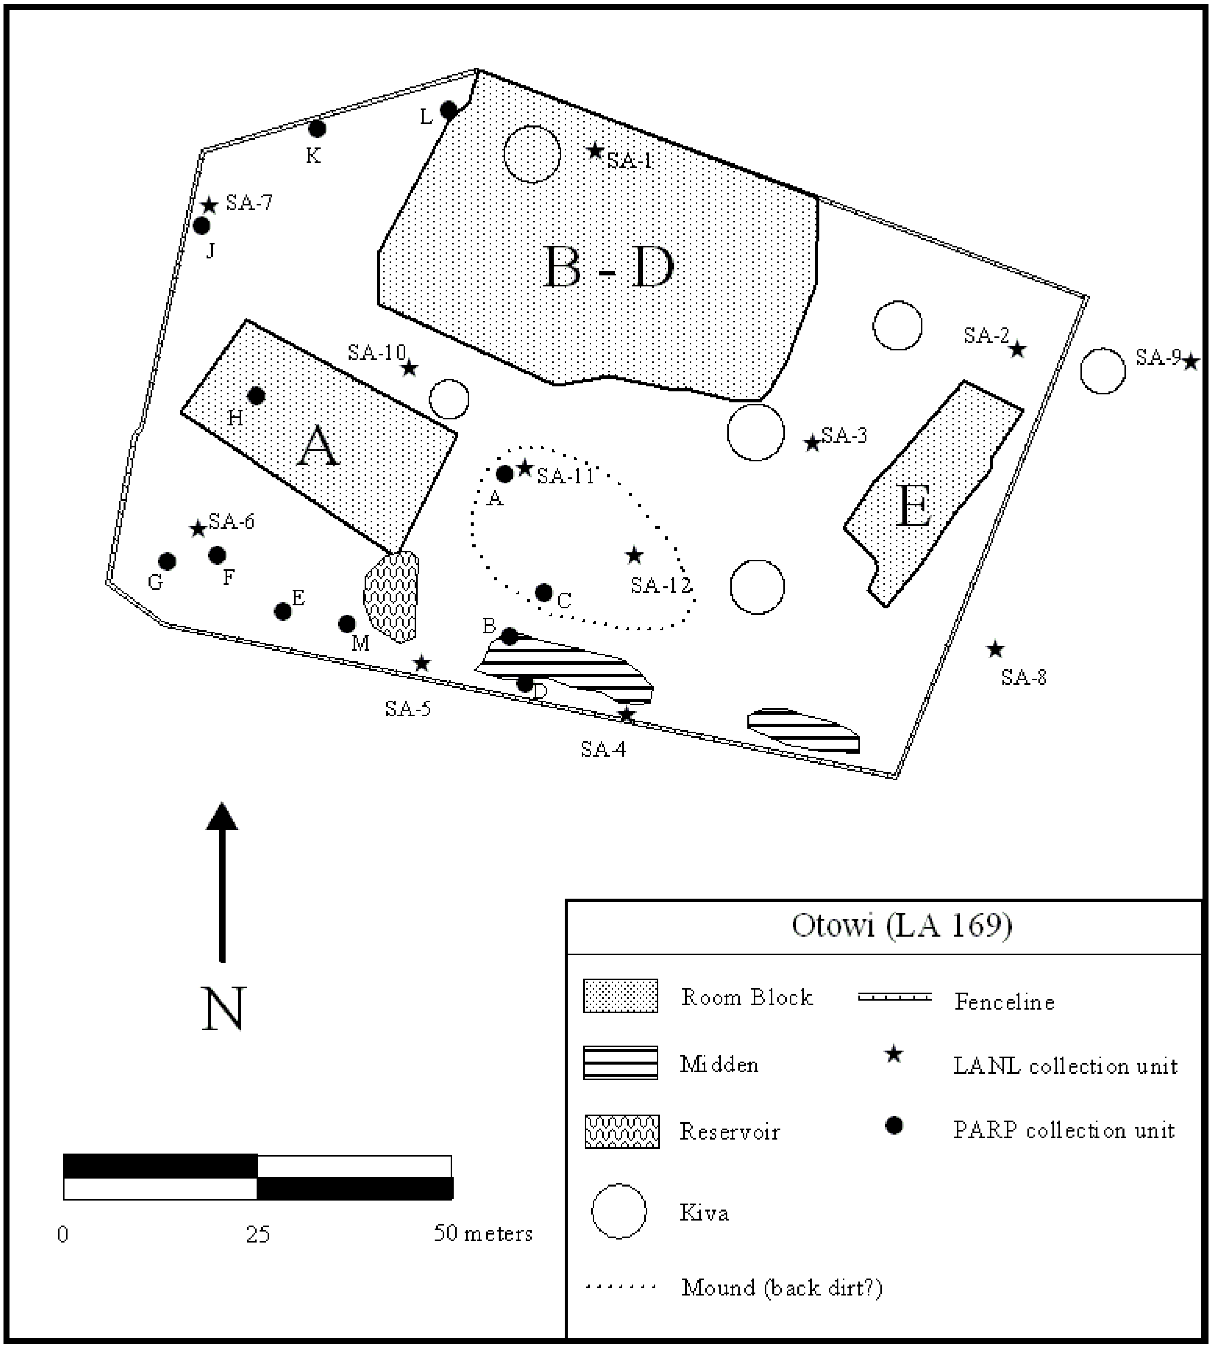

Figure 77.2. Map of Otowi (LA 169) with both PARP and LANL collection units.

Otowi is an important site to many groups for it is claimed as an ancestral home for the modern Pueblo residents of San Ildefonso Pueblo. It also holds a great deal of interest to archaeologists because of its location on the southern edge of the historic Tewa language (and ethnic) area. The analysis of ceramic at the site may aid researchers in understanding the occupational sequence of the site and its relationship with Keres speaking groups to the south, a perennial and still debated question to the nature of this historic ethnic boundary that possibly extended back into prehistory.

Tsirege (LA 170)

Tsirege is a large Classic period site located on the north side of Pajarito Canyon near the modern town of White Rock. Limited tree-ring samples have dated it to the AD 1500s (see Chapter 7, Volume 1), although no ceramic cross-dating has been performed. The site has many large features that include the masonry pueblo, kivas, middens, a reservoir, and numerous small cavates in the surrounding canyon (Hewett 1938). The original excavations were performed by Edgar Hewett in the early 20th century and the site has been studied by LANL archaeologists since mid-century. PARP crews sectioned the pueblo into six horizontal spatial units (A-F) and collected each (Figure 77.3). Tsirege has the largest ceramic assemblage of the sites collected by PARP (Table 77.2).

Table 77.2. PARP collection units at Tsirege and their associated sizes and reasons for collection (from PARP 1979).

Unit	Location	Size	Reason for Collection
A	Southeast of east roomblock, near (or part of) midden	7- by 5-m grid square	Representative of east roomblock
B	South of Plaza 1 in primary midden	5- by 5-m grid square	Representative of west roomblock
C	Center of Plaza 1	5- by 5-m grid square	Representative of main plaza
D	North of north roomblock in midden	5- by 5-m grid square	Representative of north roomblock
E	Near primary midden	1- by 1-m grid square	Pothunter's cache
F	Southeast of east roomblock	1- by 1-m grid square	Pothunter's cache
G	Southeast of east roomblock	1- by 1-m grid square	Pothunter's cache
H	Southern portion of east roomblock	1- by 1-m grid square	Pothunter's cache
J	Plaza 2	5- by 5-m grid square	Representative of Plaza 2
K	East roomblock	1- by 1-m grid square	Pothunter's cache
L	Plaza 1	1- by 1-m grid square	Pothunter's cache
M	East roomblock midden	1- by 1-m grid square	not specified
N	Near east roomblock midden	1- by 1-m grid square	not specified
O	Southwestern corner of west roomblock	1- by 1-m grid square	not specified
P	Northwest of north roomblock (near reservoir)	1- by 1-m grid square	not specified
Q	Northwest of north roomblock (near reservoir)	1- by 1-m grid square	not specified

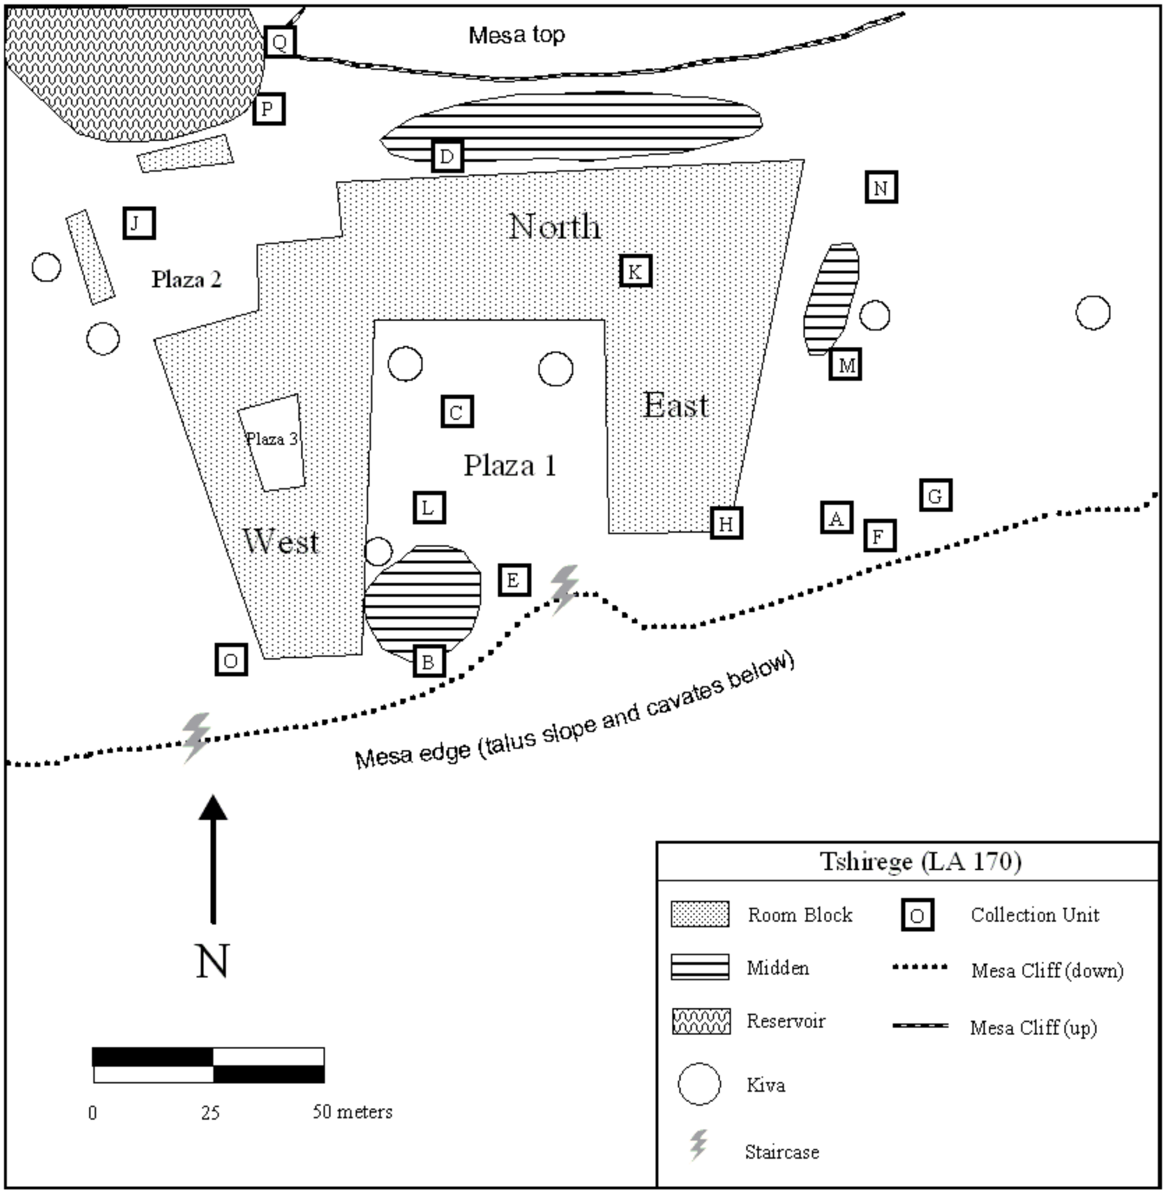

Figure 77.3. Map of Tsirege (LA 170) and PARP collection units.

Tsirege consists of three large connected roomblocks (described in this analysis as the Eastern, Western, and Northern roomblocks) surrounding a main plaza. Each roomblock has an associated midden that was the focus of testing for much of the PARP collection units. In the northeastern portion of the site, there are two small roomblocks with a plaza and two associated kivas. Although no official midden is documented, the plaza contains a great deal of sheet trash (PARP 1979). It is likely that this area represents an older (or first) occupation of the site, a question that will be tested in this subsequent analysis.

Tsirege is an important site because, like Otowi, it is regarded as an ancestral home to the residents of San Ildefonso Pueblo. It also holds a great deal of interest to archaeological researchers for it is regarded as a Late Classic period site near the border of the traditional Tewa/Keres boundary. It is also a pueblo that was likely recorded by early Spanish explorers associated with Coronado's exploration up the Rio Grande (Schroeder and Matson 1965).

THE NORTHERN RIO GRANDE CERAMIC ASSEMBLAGE

Tewa Series

The Pajarito Plateau has traditionally been classified as part of the "biscuitware" area that also includes the Chama drainage to the north. The region correlates with the spatial extent of historic Pueblo linguistic groups; the Tewa pueblos are most likely the descendants of these archaeological communities. The area is unique from other regions in the northern Rio Grande for while areas to the south began to produce glaze-painted pottery, a black-on-white ceramic tradition continued and evolved. The first systematic study of ceramics from the region was by A. V. Kidder (1915) who later chronologically seriated the entire region's pottery from ceramics found in the deeply stratified contexts of Pecos Pueblo (1936). Formal names were given to these types in Kidder's monograph (1936) as well as in the seminal work by H. P. Mera (1932, 1935). Numerous other syntheses and chronological reevaluations took place mid-century (see Wendorf and Reed 1955) but in an important work, Harlow (1973) laid out the general date ranges for the ceramics from the biscuitware pueblos, also known as the Tewa series. In the past 30 years, several periods of refinement have come to bare, and the dating that is used in this report is described in Table 77.3.

Table 77.3. Types of Tewa Series pottery and associated date ranges.

Kwahe'e Black-on-White

Dating from the 11th and 12th centuries, Kwahe'e Black-on-white was the dominant ware across the Rio Grande region. This also includes the Taos Region to the north and east, which has a local variety termed Taos Black-on-white (Fowles 2004). It appears to be an indigenous phenomenon that marks the beginning of a long tradition of black-on-white painted pottery production unique to the region (Habicht-Mauche 1993:15). Although the paste is similar to the succeeding Santa Fe Black-on-white ceramics (quartz sand and volcanic ash), the paint is mineral based versus the carbon (organic) based paints of later traditions (Habicht-Mauche 1993). Ending at the end of the 12th century, the type correlates with the later part of the Developmental period (AD 600–1150), although the type is found among the surface contexts (rarely) of Coalition period sites on the Pajarito Plateau (de Barros 1981).

Santa Fe Black-on-White

During the 13th century, this ware spread rapidly over the entire northern Rio Grande region, dominating the ceramic assemblage of all sites through the 14th century. The type is easily distinguished by its carbon paint and distinctive blue-gray paste (Mera 1935). Santa Fe Black-on-white has been described as remarkably uniform in both color and texture (Habicht-Mauche 1993:20), although recent petrographic work suggests that regional variations in tempering material exist (Wilson and Castro-Reino 2005). Regardless, it appears that the type was made locally by potters across a wide region who probably shared in some sort of regional identity (Futrell 1998; Graves and Eckert 1998). Although it is believed that this type was replaced by Wiyo Black-on-white (and later Abiquiu Black-on-gray) by the beginning of the 15th century, Habicht-Mauche (1993:19) argues that there is evidence (both tree-ring and archaeomagnetic) that Santa Fe Black-on-white was being produced up through the first quarter of the 1400s, at least after AD 1410.

Wiyo Black-on-White

Compared to its predecessor, Santa Fe Black-on-white, Wiyo Black-on-white has a limited geographic area restricted to the Tewa region (lower Chama River drainage, Espanola, Valley, and the northern Pajarito Plateau). The type has a dark black organic paint on a polished (sometimes slipped) surface with design elements that resemble the earlier Santa Fe Black-on-white ceramics. The real difference that distinguishes this type is the clay body composition, with a trend toward fine-grained tuff and smaller amounts of sand/silt inclusions. It is this quality that caused both Kidder and Amsden (1931) and Mera (1935) to call this type "biscuitoid." Wiyo Black-on-white is widely believed to be the predecessor of the later biscuitwares. The type is associated with Late Coalition/Early Classic period sites.

Abiquiu Black-on-Gray (Biscuit A)

Also referred to as Biscuit A, Abiquiu Black-on-white ceramics have thick walls and fine textures and light paste, hence looking like unfired porcelain, or *bisque*. This type is restricted almost entirely to bowl forms where the exterior is rough and unpolished and the interior is polished, often slipped, and has striking dark organic paint painted in broad lines. The production area for these wares appears to be centered on the Española and Chama Valleys, and perhaps the northern Pajarito Plateau, although this has not been substantially tested (Habicht-Mauche 1993:26). The distinguishing features of the biscuitwares are their thick, porous, and light clay body and paste. Previous analyses have indicated that these wares are untempered, with fine tuff paste. Abiquiu Black-on-white sherds from Arroyo Hondo, however, had 20 percent of the sherds with quartz sand inclusions (Habicht-Mauche 1993). Clearly, the range of diversity in both temper material and paste has yet to be fully explored. Technologically, it appears that the clay used to manufacture the biscuitwares is difficult to work and fire (Shepard 1936), thus raising some interesting technological questions of procurement and production. The wares were traded in moderate quantities to the glazeware producing areas to the south (Kidder 1936).

Bandelier Black-on-Gray (Biscuit B)

This type is nearly identical to Abiquiu Black-on-white in terms of technological considerations of paste and temper, although Shepard (1936) identified through oxidation experiments differences in clay procurement between the two types. Bandelier Black-on-gray, unlike Abiquiu Black-on-gray, was made as both bowls and jars. Bowls are polished and sometimes slipped on both sides. Design elements are similar to that of Abiquiu Black-on-gray with dark organic paints painted in broad lines, although the painting appears to be less exact (Kidder 1936). This type, although overlapping with Abiquiu Black-on-white, is generally believed to have been produced later in time, until the middle part of the 16th century.

Cuyamungue Black-on-Tan (Biscuit C)

Cuyamungue Black-on-white is described by Harlow (1973) as a third type of biscuitware, postdating Bandelier Black-on-white, ending near the turn of the 17th century. It is generally tan in color versus the white-gray of the earlier biscuitwares, with a more upright, square rim form. The design elements are generally less precise than Bandelier Black-on-white.

Sankawi Black-on-Cream

Sankawi Black-on-cream is the next in the Tewa Series and was produced in the same area and replacing the biscuitwares. Produced as both bowls and jars, vessels are generally tan in color with thin, hard walls (Wendorf 1953). Bowls are polished and slipped on both sides, and jars are polished and slipped on the exterior, with smoothed interiors. Paint is organic and uses the same design elements as the biscuitwares, although line width is thinner and less complex (Harlow 1973).

Potsuwi'i Incised

Potsuwi'i Incised is technically an utilityware that dates from AD 1450–1550 (Jeancon 1923; Mera 1932). Although unpainted, the surface is incised with rectangular geometric designs. Vessel forms are predominantly jars or ollas; bowls are rare. The type is thought to be produced somewhere in the Tewa area, most likely at Classic period sites in the Rio Chama drainage. The temper and consistency of paste most resembles that of Sankawi Black-on-cream with both tuff and quartz sand inclusions.

Glaze Series

The classification of the Rio Grande Glaze Series is based on Mera's (1933) revision of Nelson's (1914) and Kidder and Kidder's (1917) analyses of rim form and surface treatments from stratified, datable contexts. Six types (A–F) that seriate through time have been securely established by petrographic analyses (Shepard 1942; Warren 1979). Rio Grande glazeware was produced widely across the region from the southern portion of the Pajarito Plateau south to Socorro. Unlike the whiteware tradition of the Tewa area, during the Late Coalition/Early Glaze periods, glazeware replaced earlier traditions. Becoming widespread across the Rio Grande Valley and beyond, it appears that the ware was produced in many different localities, with each large Pueblo producing and exchanging glaze pottery (Habicht-Mauche 1993). Interestingly, although biscuitware and later ceramics were imported from the Tewa area, very low percentages of glazewares were imported north into the region. Glazewares vary across time, but a unifying characteristic is glaze paint (mineral-based paint with the addition of a flux, such as galena [Habicht-Mauche et al. 2000]) on a red or yellow clay body.

The current project examines two large Classic period pueblos that most likely span a large time period. Therefore, all Glaze Series types are relevant, from early Glaze A to later, historic Glaze F. The dates of each type and their associated characteristics are listed in Table 77.4. Kidder's (1936) rim seriation used in typing is displayed in Figure 77.4.

Table 77.4. Types of Rio Grande Glaze Series pottery and associated date ranges.

Glaze Series	Type	Characteristics	Dates	References
Glaze A	Agua Fria	Direct parallel-sided rimes, red surfaces inside and out, design elements simple, crushed sherd or rock temper	1315–1425	Schaafsma 2002:195; Vint 1999:391,
	Cienegulla	Same but polychrome, with glaze outline by red matte design elements		
Glaze B	Largo	Thickened expanded rim, crushed rock temper, cream or white slip on both sides, can be polychrome	1415–1450	Schaafsma 2002:195
Glaze C	Espinoso	Shorted everted or beveled rim, crushed rock temper, polychrome	1450–1500	Schaafsma 2002:195
Glaze D	San Lazaro	Long thickened rims (everted), crushed rock temper, polychrome	1490–1525	Schaafsma 2002:195
Glaze E	Puaray	Long thickened rims, crushed rock temper, polychrome, late types have runny paints	1515–1625	Vint 1999:391; Schaafsma 2002:195
Glaze F	Kotyiti	Long parallel sided rims, runny glaze paint	1625–1700	Harlow and Lanmon 2003:32; Schaafsma 2002:195

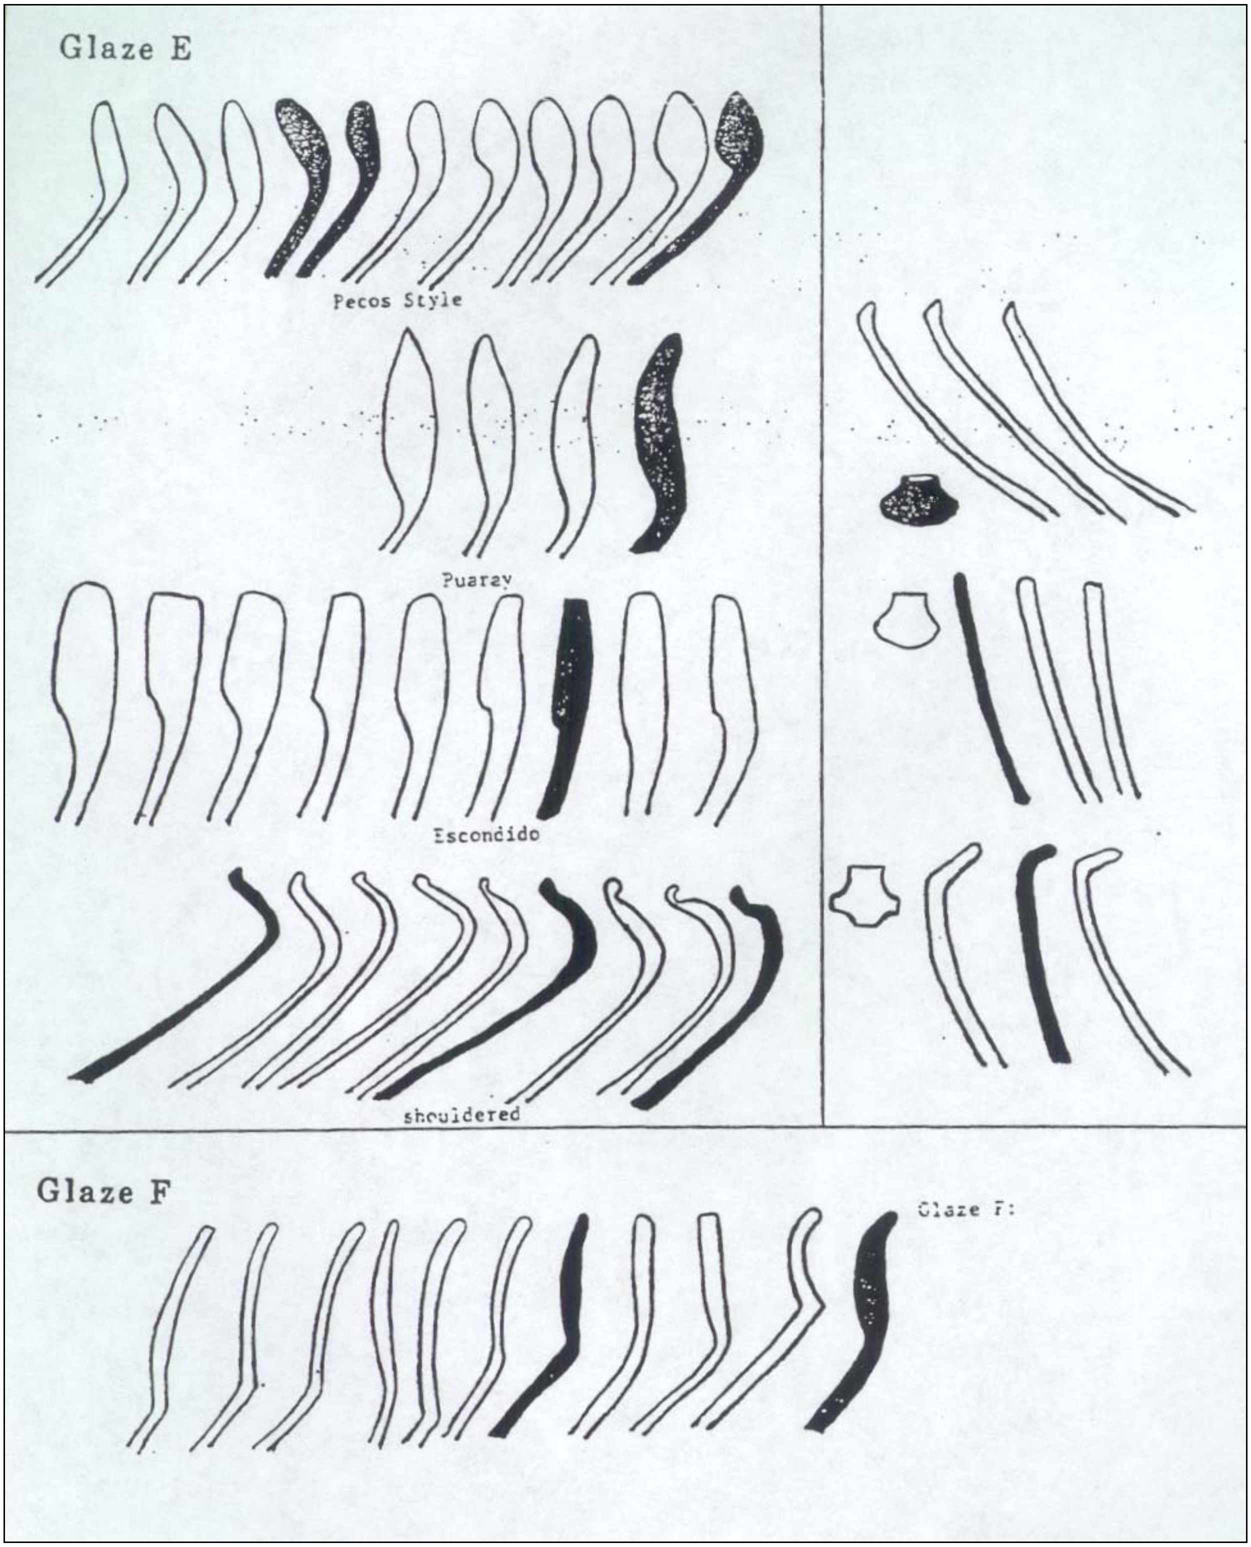

Figure 77.4. Kidder's (1936) Glaze Series rim seriation chart.

Utilitywares

As for vessel function, ethnographic and archaeological evidence has shown that painted ceramic vessels were mostly used as serving vessels and articles for gifts and exchange. Unpainted utilitywares are generally considered to have fulfilled the role of cooking and storage of food products. In the Tewa area generally and on the Pajarito Plateau more specifically, these ceramics took the form of graywares.

The literature dealing with these wares is frustratingly silent and ambiguous. Throughout time and depending on who was publishing the data, the grayware from the Pajarito Plateau has taken on a variety of names based on surface treatment (plain, indented corrugated, smeared-indented corrugated, obliterated corrugated) and presence of mica. Some researchers have been splitters creating many different types, whereas other have been lumpers. For this project, a middle ground is taken in which two general types of grayware are defined and whose primary distinguishing feature is the presence/absence of a mica slipped exterior. Although many more attributes were recorded (see full data table), these two categories appear to be most faithful to past research and the present ceramic assemblage (Table 77.5).

Table 77.5. Types of Utility grayware and associated date ranges.

Type	Dates	References
Tesuque Gray	1250–1500	Habicht-Mauche 1993; McKenna and Powers 1986; Mera 1935
Sapawe Washboard	1425–1600	McKenna and Powers 1986; Mera 1935
Potsuwi'i Incised	1550–1650	Harlow 1973
Kapo Black	1680–1760	Mera 1939:14; Harlow 1973:40; Schaafsma 2002:150

Besides sherds that fall into other categories such as plain and clapboard surface treatment, two major types were delineated amongst the Pajarito Plateau graywares. Tesuque grayware is a general description of smeared-indented corrugated ware that can have either the presence or absence of micaceous inclusions (Habicht-Mauche 1993; McKenna and Powers 1986; Mera 1935). It has been proposed that the Tesuque grayware samples with mica inclusions date later than pots with no mica, although this is highly untested (National Park Service 1991). From personal observations this type can and does vary tremendously across a single large pot, with the neck being clapboard and the body alternating between smeared and obliterated indentations.

Sapawe Washboard is a type of this smeared to obliterated corrugated construction, with thin walls and a mica wash or slip creating a brilliant gold color. Dating from AD 1425–1600, it has been widely thought to have originated and possibly produced in the Chama River valley north of the Pajarito Plateau (McKenna and Powers 1986; Mera 1935). It is also thought to be a later ware than the Tesuque Gray although there is a large chronological overlap in contemporaneity.

Historic Wares

Tewa Red/Polychrome

Tewa Red/Polychome, a historic ware produced between the mid-16th and mid-17th centuries (Harlow 1973; Schaafsma 2002:149), has an orange-tan paste slipped with either red or red and white (on polychrome) and is decorated with a black organic paint. Both bowls and jars are present. Both the red and polychrome varieties are combined in this analysis because the ceramics are in surface contexts and are small; a polychrome vessel may produce sherds that appear to be only black-on-red. Paste and temper resembles other types in the Tewa series with fine tuff and few sand grains. It is believed that this type was produced exclusively at the Tewa Pueblos along the northern Rio Grande.

Kapo Black

Kapo Black is a historic utilityware that was manufactured in the Tewa area from the late 17th century to the middle of the 18th century (both before and after the Pueblo Revolt of 1680) (Harlow 1973:40; Mera 1939:14; Schaafsma 2002:150). Generally, a dark black color that results from sooting in a reduced atmosphere, the ware is smoothed and polished with no additional decoration. The paste is similar to earlier Tewa wares, which consists of a fine tuff with little to no sand inclusions. Both bowls and jars were produced.

Imported Wares

White Mountain Redware

A small percentage of non-painted redware that, based on microscopic temper analysis, was neither glazeware or Tewa Red/Polychrome. Temper was sand and sherd based, leading to the interpretation of these unidentifiable ceramics as belonging to the White Mountain Redware category. Early varieties of the ware (St. Johns Polychrome) were found at Arroyo Hondo (Habicht-Mauche 1993) and Pecos Pueblo (Kidder 1936), and later ones were found at Classic period sites in the Chama such as Te'ewi (Wendorf 1953) and Howiri (Fallon and Wening 1987). White Mountain Redware was produced in east-central Arizona and it is not unlikely that interaction (as seen by pot mobility) occurred between the Rio Grande and Western pueblos.

CERAMIC ANALYSIS METHODOLOGY

All ceramics collected by PARP crews from Otowi and Tsirege (n = 8457) were sorted into previously described types. The descriptions by Kidder and Amsden (1931) and Habicht-Mauche (1993) proved most helpful, although the ceramic guide from Bandelier National Monument (National Park Service 1991) was also consulted. Understanding and dealing with the diversity of both biscuitware types and corrugated ceramics was greatly aided by discussions with archaeologists currently working in the northern Rio Grande (Kurt Anscheutz, Jim Vint, Richard Ford, Diane Curewitz; personal communications), as was an afternoon at the Laboratory of Anthropology in Santa Fe examining the Mera type collection.

Following Gauthier's (1987a) suggestion, one previously discussed Tewa Series type, Cuyamungue Black-on-tan, was not sorted for. The type is described by Harlow (1973) as being differentiated from Bandelier Black-on-gray by a tan paste and a "square" shaped rim. Gauthier (1987a) found that rim type and paste/slip color are not correlated and that classifying sherds in this category has the potential to cause serious errors in subsequent analyses.

To ensure data compatibility when the data from this project is evaluated in terms of previous analyses performed by LANL and the Laboratory of Anthropology at the Museum of New Mexico, the Museum's ceramic analyses framework was used to structure a methodology that measures multiple facets of prehistoric pottery. This includes sorting by pottery ware and type, vessel form, pigment type, interior and exterior modifications, temper and paste composition, rim sherd size and diameter, sherd weight, and vessel wall thickness. The only exception to the above traits measured is with the corrugated utilityware (n = 2612), in which vessel wall thickness was not measured due to time constraints (see Appendix CC).

Although the type of inclusions for all sherds was analyzed, a detailed examination was performed on the biscuitwares (Abiquiu Black-on gray and Bandelier Black-on-gray) to understand the range of diversity. This analysis will support any interpretations based on the aforementioned theoretical framework.

The subsequent statistical and spatial analyses were performed on all sherds that could reasonably be typed into one of the described categories. Unidentified sherds or ones that were incompletely coded (e.g., undifferentiated whiteware, undifferentiated biscuitware) were excluded from these analyses, although the data have been provided with this report.

Clay oxidation analysis using the refiring technique were conducted on multiple sherds (n = 335) of both Abiquiu Black-on-gray and Bandelier Black-on-gray bowls. The former were analyzed from surface units at both sites with substantial amounts of each ware and encompass the full range of temper and paste characteristics. The latter were taken from a unit at Tsirege that had a large amount of both ceramic types that included both micaceous and non-micaceous varieties. Clay oxidation does not provide the detailed provenance information of petrographic and chemical composition, but it does provide an inexpensive and expedient method of assessing the relationships between raw materials (clay) and the finished pottery found in archaeological contexts (Bubemyre and Mills 1991). Refiring sherds drives out organic impurities and chemically changes major components in the clay body. The most important of these is iron, which is converted to a reddish shade. Paste color results from firing conditions, atmosphere (oxidized or reducing), maximum temperature, duration of firing, and most importantly, clay composition (Mills 1987:186). Simply put, the more iron in the sample, the redder (darker) the color. Experiments by Shepard (1936, 1971) have shown that the ideal temperature to refire sherds for this intended purposed is at 950 degrees C (1750 degrees F) for 30 minutes. The resulting color was then measured with a Munsell® color chart.

The underlying assumption is that within both the biscuitwares and corrugated ceramics different clay sources were used, indicating change of procurement strategies over time or pot mobility. Because no raw material analyses (clay sources) were analyzed for this project, the former possibility is most easily testable. This analysis will help to lend interpretative strength to arguments about chronology, technology, identity, and craft specialization.

THE OTOWI (LA 169) CERAMIC ASSEMBLAGE

Tewa Series

Kwahe'e Black-on-White

As is to be expected for the surface assemblage of a large Classic period site, no sherds of this type were found. This does not negate the fact that a possible Coalition period occupation directly under the Classic period architecture contained some Kwahe'e Black-on-white; however, it is apparent that the site was densely and intensely occupied during the Late Coalition and Early Classic periods, if not later (Table 77.6).

Table 77.6. Percentages of decorated ceramic types by PARP collection in the Otowi surface assemblage.

Unit	Santa Fe B/w	Wiyo B/w	Biscuit A	Biscuit B	Sankawi B/c	Potsuwi'i	Glaze	Imported	Historic
A (*n* = 208)	1%	7%	30%	41%	14%	2%	4%	0	0
B (*n* = 150)	5%	17%	13%	45%	9%	3%	4%	0	3%
C (*n* = 369)	5%	16%	11%	44%	17%	3%	4%	<1%	<1%
D (*n* = 72)	6%	0%	28%	44%	11%	3%	8%	0	0
E (*n* = 441)	3%	6%	29%	41%	15%	2%	4%	0	0
F (*n* = 109)	14%	17%	19%	27%	17%	1%	6%	0	0
G (*n* = 42)	2%	0	12%	55%	17%	0	14%	0	0

M (*n* = 38)	5%	8%	16%	42%	8%	5%	11%	5%	0
Total (*n* = 1605)	5%	9%	22%	41%	15%	2%	5%	<1%	<1%

Santa Fe Black-on-White

Santa Fe Black-on-white occurred infrequently in the entire surface assemblage of Otowi, with only 78 sherds (5%) being reliably typed. This is probably not too surprising given that the site has traditionally been dated to the Early Classic period whereas Santa Fe Black-on-white is generally considered a Coalition period ceramic type. However, the analysis of the type at Arroyo Hondo placed later varieties into the first quarter of the 15th century (Habicht-Mauche 1993), allowing for the possibility of Santa Fe Black-on-white being present in larger quantities. Because this is a surface assemblage without stratigraphic cross-dating, the small amount of this type can be interpreted two ways: either Santa Fe Black-on-white is not being produced in great quantities at Early Classic period sites on the northern Pajarito Plateau, or Otowi dates around to or later than AD 1425. Although it is not possible to disprove the latter, the former proposition appears to be more favorable due to the large amounts of biscuitware and Sankawi Black-on-cream in the ceramic assemblage. With early 20th century excavations and pot hunting activity over the past century, the surface assemblages are far from representing a pristine abandonment context. These events surely mixed earlier and later pottery types thus allowing for Santa Fe Black-on-white to coexist among Sankawi Black-on-cream sherds.

Santa Fe Black-on-white was present in nearly every surface unit collected except for Unit H, which has a relatively small sample size (*n* = 51). The type dominates in two units: F and K. Unit F is located in the midden area of Roomblock A of what Wilson (1916a) described as the "old pueblo," or the original roomblock in the building sequence of the site. Subsequent surface analysis by LANL teams also arrived at this conclusion based on the predominance of early ceramics (LANL 1999). Unit K is located to the east of Roomblock B and was collected by PARP crews, "to obtain ceramics from earlier occupations" (PARP 1978). Although there is no indication of what these early occupation could have been based on, notes and maps created by these crews suggest it is likely the remains of a prior Coalition period site that sits below the Classic period architecture at Otowi.

Wiyo Black-on-White

Wiyo Black-on-white ceramics were found at approximately half of the units collected, with 9 percent (*n* = 147) reasonably typed. This type was found at Arroyo Hondo until AD 1475 and appears to occur with Abiquiu Black-on-gray, although it appears to have ended somewhat earlier and can be dated as an earlier type (Habicht-Mauche 1993). Units G, H, J, K, and L all had sherds present, and due to their location (spread out in all collected areas and nearby units with Wiyo Black-on-white was present) this can possibly be explained based on a small sample size.

Three collected units (B, C, and F) had a large amount (>15%) of Wiyo Black-on-white present. Units B and C are located to the south of the main plaza. Unit C is located on top of the mound that was recorded by PARP crews as "possible backdirt" from the excavations of Hewett and Wilson. Although as discussed above, this description is possibly incorrect. Unit C is adjacent to the central midden in which Unit B was collected. Both units are probably the result of mixing of the ceramic assemblages of the entire site. As such, there appears to be a middle 15th century occupation of Otowi, which would fit its definition as an Early Classic period pueblo.

Unit F is located in the midden of Roomblock A, which has been described as the oldest architecture of the site. This unit also had a large amount of Santa Fe Black-on-white ceramics, thus lending support that this was probably the earliest portion of the site to be occupied.

Abiquiu Black-on-Gray (Biscuit A)

Abiquiu-Black-on-gray has been dated from the late 14th century through possibly the middle of the 16th (Habicht-Mauche 1993), although it is considered a 15th century type. The type accounts for 22 percent (*n* = 346) of the ceramic assemblage at Otowi. Every unit collected on the site had Abiquiu Black-on-gray ceramics of relatively similar quantities (11% to 30%), which were considerably smaller compared to the amounts of Bandelier Black-on-gray sherds. Areas of low concentration (Units B and C) were located in the central midden and appear to have a mixed context of all ceramic types found at the site. Although these small amounts are puzzling, it appears that this was a result of sampling error as both of these contexts had high amounts of both Wiyo Black-on-white and Bandelier Black-on-gray, two types that bracket Abiquiu Black-on-gray in time.

For this project, samples of both Abiquiu Black-on-gray and Bandelier Black-on-gray bowl sherds were analyzed from Otowi and Tsirege to understand the degree of variability within and between sites and types. Five temper types were classified: primarily tuff, tuff and quartz sand, tuff and quartz sand and volcanics, tuff and quartz sand and plutonics, and a type with all the above inclusions.

Traditionally, the biscuitwares were thought to have been tempered (or self tempered) primarily with volcanic tuff (Mera 1932). Additional inclusions, either accidental or intentional, have been seen as the exception rather than the rule. However, when examining Abiquiu Black-on-gray vessels from Arroyo Hondo, Habicht-Mauche (1993) found that approximately 20 percent of the biscuitware sherds were tempered with quartz and other inclusions. Similar results are seen in the analysis of Abiquiu Black-on-gray sherds from Otowi, although the average from sample units with large quantities of the type are larger, averaging approximately 30 percent (Table 77.7). The majority of these tempered sherds have only quartz inclusions, and judging from the edges of the grains under 40x magnification, these are most likely sand. Whether this sand was intentionally added to the paste cannot be concluded at this time without analyses of the clay procurement areas, for sand may be naturally occurring and not separated from the raw clay used for pottery building.

Two other types of temper categories were discovered in this analysis: tuff with quartz sand and volcanics and tuff with quartz sand and plutonics. The first has dark igneous volcanic rock inclusions while the second has plutonic rocks such as granite. Although not well-represented in the Otowi Abiquiu Black-on-gray assemblage, these temper types may indicate non-local ceramic provenance, or perhaps differing raw material sources. This is especially the case for the plutonics. Because the traditional area of Tewa pottery is geologically volcanic, these inclusions could point toward ceramic mobility into the pueblo. Units (with substantial sample size, or greater than 40 sherds) with a small sample of plutonic tempered ceramics are Units C and A, with Unit A having a relatively larger amount (10%). Unfortunately, these two units are located on the earthen mound in the central plaza of Otowi making any spatial analysis void, for these ceramics could be associated with any of the roomblocks from the pueblo. However, the fact that these different tempers exist leads to further research questions about ceramic mobility and technology, as will be discussed in a later section of this report.

Table 77.7. Percentages of temper types by unit for Abiquiu Black-on-gray bowl sherds from Otowi.

Unit	Temper			
	Tuff	Tuff w/ sand	Tuff w/ sand + volc.	Tuff w/ sand + plut.
A (*n* = 62)	76%	21%	2%	2%
B (*n* = 20)	45%	50%	0%	5%
C (*n* = 41)	63%	22%	5%	10%
D (*n* = 18)	78%	11%	0	11%
E (*n* = 128)	70%	27%	3%	0
F (*n* = 20)	85%	15%	0%	0
G (*n* = 5)	20%	40%	20%	20%
H (*n* = 11)	27%	55%	9%	9%
J (*n* = 7)	29%	71%	0	0
K (*n* = 19)	68%	11%	11%	11%
L (*n* = 7)	86%	14%	0	0
M (*n* = 6)	100%	0	0	0
Total (*n* = 344)	70%	52%	30%	30%

Bandelier Black-on-Gray (Biscuit B)

Bandelier Black-on-gray is the predominant ware found at Otowi with 41 percent (*n* = 664) collected. The type has been dated from the early part of the 15th century through the middle of the 16th. Every unit collected had a large majority of this type. Using language that was in vogue in the early part of last century, this truly is a "Biscuit B pueblo."

Interestingly, two of the PARP units that had smaller amounts (<30%) of Bandelier Black-on-gray were the units of F and K, both of which had the largest amounts of Santa Fe Black-on-white pottery. Unit F is located in the midden of Roomblock A and Unit K is located to the west of Roomblock A. Both of these areas represent the earliest areas of occupation, with unit K in a possible Coalition period occupation and Unit F representing the first and oldest roomblock architecture.

The same sorts of temper categories that existed in Abiquiu Black-on-gray bowls are also present in bowl sherds of Bandelier Black-on-gray (Table 77.8). Units with substantial sample sizes encompassed the full range of this variability. Interestingly, the number of samples with plutonic inclusions outweighed those with volcanic temper (average of 1% versus 5%). This raises questions about where Bandelier Black-on-gray as manufactured and how it was brought into the site assemblage. This will be further discussed in a later section.

Table 77.8. Percentages of temper types by unit for Bandelier Black-on-gray bowl sherds from Otowi.

Unit	Temper			
	Tuff	Tuff w/ sand	Tuff w/ sand + volc.	Tuff w/ sand + plut.
A (*n* = 79)	65%	32%	1%	3%
B (*n* = 58)	60%	31%	2%	7%
C (*n* = 124)	81%	13%	1%	5%
D (*n* = 35)	57%	14%	26%	3%
E (*n* = 164)	71%	25%	1%	3%
F (*n* = 23)	70%	22%	9%	0
G (*n* = 18)	61%	39%	0	0
H (*n* = 25)	44%	48%	4%	4%
J (*n* = 15)	67%	13%	7%	13%
K (*n* = 12)	92%	8%	0	0
L (*n* = 12)	25%	33%	25%	17%
M (*n* = 15)	60%	27%	0	13%
Total (*n* = 665)	59%	21%	3%	4%

Sankawi Black-on-Cream

Sankawi Black-on-cream dates to the middle of the 16th to the middle of the 17th century (Harlow 1973), postdating all of the biscuitwares. The type is less prone to error in typing due to its distinguishing features (color, hardness, width) so its presence is securely recorded. The type was recorded in every collection unit at similar frequencies of 8 percent to 18 percent. The one exception was Unit J, which contained 30 percent in its assemblage. The unit is located to the far western portion of the site, and although it is intriguing to think that this could have been representative of a later occupation of the site, the sample size is too small (*n* = 36) to make any firm interpretations. Although Sankawi Black-on-cream is securely represented across Otowi, it is unlikely that this type was being used during the maximum occupation of the site, although it does suggest that we can evaluate the Bandelier Black-on-gray dating as weighing to the later end of its chronology.

Potsuwi'i Incised

Potsuwi'i Incised, which dates to AD 1550–1650 (Harlow 1973), can be seen as representing some of the latest occupation of the site. Although only present in two percent of the site assemblage (excluding the gray utilitywares), it is present in all units except for Unit G, which is located in the midden context of Roomblock A (the old pueblo). The percentage of Potsuwi'i Incised is nearly constant from 1 percent to 4 percent, making spatial analysis useless. The presence of this ware suggests that the site was occupied until the mid-16th century.

Glaze Series

Only three rim sherds with diagnostic characteristics were found to securely type into the Rio Grande glaze series. These samples are San Lazaro polychrome sherds that have been dated to

AD 1490–1525 (Schaafsma 2002:195), or more generically, Glaze D. Two sherds were found in Unit C on top of the earthen mound, and another was found in Unit E, located to the south of Roomblock A. Although the sample size voids any meaningful interpretations, it appears that the site was occupied through the first part of the 16th century. This is also substantiated by the amount of Sankawi Black-on-cream found in the assemblage.

Unidentified glazeware sherds were found in all units collected, although Units G and M had substantial amounts (>10%). Both are located in the midden area of Roomblock A, which is believed to be the oldest portion of the pueblo. It appears that the early occupation of the Otowi exchanged regularly with glazeware-making potters to the south.

Utilitywares

Overall, the grayware assemblage at Otowi was dominated by smeared-indented corrugated, both with (27%) and without (34%) mica inclusions (Table 77.9). The other large portion was Sapawe washboard (23%) although there was a small amount (11%) of indented corrugated ceramics found in surface contexts. Although the Bandelier Ceramic Guide (National Park Service 1991) tentatively puts micaceous smeared-indented corrugated chronologically later than the same type without mica, this cannot be tested due to mixed midden contexts. The highest concentration of Sapawe washboard (51%) was found in Unit A, located on the central mound in the main plaza. The type is dated to AD 1425–1600 (McKenna and Powers 1986; Mera 1935), making this deposit one of the latest of the site. This seems to fit well with other ceramic counts of the painted wares.

Table 77.9. Percentages of utility ceramic types by PARP collection in the Otowi surface assemblage.

Unit	Plain	Indented Corrugated	Smeared-Indented Corrugated	Plain Mica	Mica Smeared-Indented Corrugated	Sapawe Washboard	Striated	Clapboard
A (*n* = 105)	0	3%	12%	1%	30%	51%	0	3%
B (*n* = 54)	0	13%	30%	0	57%	0	0	0
C (*n* = 113)	7%	4%	26%	4%	31%	27%	0	1%
G (*n* = 42)	0	0	55%	0	43%	2%	0	0
H (*n* = 40)	5%	18%	0	0	48%	30%	0	0
J (*n* = 19)	0	32%	0	0	63%	5%	0	0
K (*n* = 102)	0	12%	39%	5%	19%	25%	0	0
L (*n* = 38)	0	0	53%	0	47%	0	0	0
M (*n* = 18)	0	100%	0	0	0	0	0	0
Total (*n* = 531)	2%	11%	27%	2%	34%	23%	0	1%

Historic Wares

Only five historic sherds were found at the site. All were unpainted redware with fine tuff temper and were typed as Tewa Red/Polychrome. This type dates from the middle of the 17th century to the early part of the 18th century. Four sherds (3%) were found in Unit B, located in the midden south of the main plaza and one sherd (<1%) was in Unit C located on the mound. Due to the lack of any sizable amount of historic wares at the site, it can be reasonably argued that there was no historic reoccupation of the site.

Imported Wares

Only three imported sherds were found in the surface collections from Otowi. All three were unpainted redwares with sherd and sand temper, thus typed as White Mountain Redware. One sherd (<1%) was found in Unit C, located on the mound south of the main plaza, and two others (5%) in Unit M in the midden area of Roomblock A.

Refiring Experiments

Refiring analysis was performed on 176 samples of both Abiquiu and Bandelier Black-on-gray bowls from Otowi, sampling to allow a full representation of all temper types classified. The results are listed in Table 77.10. It appears that there is variation between samples based on clay type, which, using a Munsell© color chart, were grouped into five main color groups: brownish yellow, reddish yellow, pink, brown, and yellowish red.

Table 77.10. Percentages of refiring colors in the clay oxidation experiments for both Abiquiu and Bandelier Black-on-gray bowl sherds from Otowi.

Abiquiu Black-on-Gray Bowl						Bandelier Black-on-Gray Bowl					
Unit	Brownish Yellow	Reddish Yellow	Pink	Brown	Yellowish Red	Unit	Brownish Yellow	Reddish Yellow	Pink	Brown	Yellowish Red
A	54%	38%	0	4%	4%	A	30%	55%	0	10%	5%
B	11%	72%	6%	11%	0	B	38%	54%	4%	4%	0
C	24%	62%	5%	10%	0	C	21%	75%	4%	0	0
E	41%	50%	0	9%	0	E	15%	59%	7%	15%	4%

All of the different clay types that the refiring experiment illuminated were present amongst both wares. It appears that brownish yellow and reddish yellow clay were the predominate types, with much smaller quantities of the others. There were no appreciable differences in spatial analysis aside from Unit E, which had a larger portion of Bandelier Black-on-gray bowls with reddish yellow versus brownish yellow. Because Unit E is located in the midden of Roomblock

E (the old pueblo) this raises an interesting question: do clay types seriate (or at least change somewhat) through time?

When comparing the Abiquiu and Bandelier Black-on-gray samples, it does not look as if there is a noticeable change of clay location between the two ceramic types. Brownish yellow and reddish yellow are the dominant color categories and both pottery types have similar amounts of the other colors as well.

Still another question remains: what can be made of the additional clay color categories? Do these represent additional ceramic provenances and hence ceramic mobility? Or are these rather the result of different clay procurement strategies across the pueblo, and time? Possible interpretations will be further elucidated by comparing the results of the refiring experiments with those of the temper analysis.

The refiring data were compared to that of the temper analysis (Table 77.11). It appears that there is no correlation of the two variables with the samples of both Abiquiu and Bandelier Black-on-gray bowl sherds with their associated temper types. The only interesting association is that the brown and yellowish red sherd samples were only associated with tuff and tuff and quartz sand tempered pottery. The same is true for the sherds that were pink in color aside from samples of Bandelier Black-on-gray pottery with volcanic inclusions.

Table 77.11. Percentages of samples of temper type by refiring color from biscuitwares at Otowi.

Unit A	**Temper**	**Refire Color**				
Abiquiu B/g		Brownish yellow	Reddish yellow	Pink	Brown	Yellowish red
	Tuff	30%	60%	0	10%	0%
	Tuff w/ sand	50%	40%	0	0	10%
Bandelier B/g		Brownish yellow	Reddish yellow	Pink	Brown	Yellowish red
	Tuff	30%	60%	0	10%	0%
	Tuff w/ sand	30%	50%	0	10%	10%
Unit B	Temper	Refire Color				
Abiquiu B/g		Brownish yellow	Reddish yellow	Pink	Brown	Yellowish red
	Tuff	10%	50%	10%	20%	0
	Tuff w/ sand	13%	88%	0	0	0
	Tuff w/ sand + plut..	0	100%	0	0	0
Bandelier B/g		Brownish yellow	Reddish yellow	Pink	Brown	Yellowish red
	Tuff	40%	50%	0	10%	0
	Tuff w/ sand	30%	60%	10%	0	0
	Tuff w/ sand + plut..	50%	50%	0	0	0

Unit C	Temper	Refire Color				
Abiquiu B/g		Brownish yellow	Reddish yellow	Pink	Brown	Yellowish red
	Tuff	20%	60%	10%	10%	0
	Tuff w/ sand	14%	71%	0	14%	0
	Tuff w/ sand + plut.	50%	50%	0	0	0
Bandelier B/g		Brownish yellow	Reddish yellow	Pink	Brown	Yellowish red
	Tuff	10%	90%	0	0	0
	Tuff w/ sand	33%	56%	11%	0	0
	Tuff w/ sand + plut..	20%	80%	0	0	0
Unit E	Temper	Refire Color				
Abiquiu B/g		Brownish yellow	Reddish yellow	Pink	Brown	Yellowish red
	Tuff	50%	40%	0%	10%	0
	Tuff w/ sand	44%	44%	0	11%	0
	Tuff w/ sand + volc	0	100%	0	0	0
Bandelier B/g		Brownish yellow	Reddish yellow	Pink	Brown	Yellowish red
	Tuff	20%	40%	0	30%	10%
	Tuff w/ sand	10%	70%	10%	10%	0
	Tuff w/ sand + volc	0	75%	25%	0	0
	Tuff w/ sand + plut.	33%	67%	0	0	0

Few interpretations can be made with this limited analysis. However, some plausible scenarios can be considered. Although it is possible that both the refiring and temper data exhibit the full range of technological variability for locally made pots, this is unlikely due to the specialization of biscuitware pottery shown by stylistic analysis (Hagstrum 1985). Because we have no data on local clay and temper sources this cannot be established. If different clay sources are being exploited, how do these relate to the variation of tempered samples? The question becomes: what's local? And which line of evidence most likely represents local versus non-local pottery? This will be further discussed in a later section of this report.

Comparison with LANL Collections

LANL crews revisited Otowi in 1999 (LANL 1999) and performed infield analyses of both ceramic and lithic artifacts in 12 units across the site. Of these units six corresponded with similar locations of the PARP collection unit locations (Table 77.12).

Table 77.12. Correlation of PARP and LANL testing units at Otowi.

PARP Unit	LANL Unit
A	11
C	12
D	4
G	6
J	7
M	5

Although the LANL analyses only included rim sherds, the sample sizes were big enough to compare to the ware and type counts made in this analysis (Table 77.13). On the whole, both the PARP and LANL analyses correlated well with the proportions of ceramics within 10 percent. Notable exceptions (in bold type font) are that some units contained Abiquiu Black-on-gray, Bandelier Black-on-white, and Sankawi Black-on-cream. These differences could be the result of many different kinds of phenomena, such as weathering and erosions (that covered or uncovered artifacts) during the 25-year duration between analyses, or illegal artifact collection. Other possibilities include the nearby but not perfect spatial comparison of PARP and LANL units or sampling error and lack of consistency in ceramic analysis by multiple persons. Most likely this is the result of a sample bias; PARP crews collected all ceramics and LANL crews only examined rim sherds. This explains the higher proportion of ceramic types in the PARP analysis.

Table 77.13. Comparison of percentages of decorated ceramics from both PARP and LANL analyses at Otowi.

Project	Unit	Santa Fe B/w	Wiyo B/w	Abiquiu B/g	Bandelier B/g	Sankawi B/c	Potsuwi'i	Glaze
PARP	A (*n* = 306)	1%	5%	20%	28%	10%	2%	3%
LANL	11 (*n* = 52)	0	2%	6%	21%	12%	4%	6%
PARP	C (*n* = 461)	4%	13%	9%	35%	13%	2%	3%
LANL	12 (*n* = 82)	1%	0%	13%	43%	7%	0	0
PARP	D (*n* = 72)	6%	0	**28%**	44%	11%	3%	8%
LANL	4 (*n* = 390)	0	1%	**12%**	39%	7%	0	2%
PARP	G (*n* = 84)	1%	0%	6%	27%	8%	0	7%
LANL	6 (*n* = 524)	2%	2%	16%	26%	5%	0	2%
PARP	J (*n* = 50)	2%	0	16%	**30%**	**22%**	2%	2%
LANL	7 (*n* = 82)	1%	0	13%	**43%**	**7%**	0	0
PARP	M (*n* = 36)	6%	8%	17%	**44%**	8%	6%	11%
LANL	5 (*n* = 256)	1%	3%	16%	**27%**	5%	1%	2%

Seriation and Chronology

Due to their location and size of ceramic assemblage, five units (Units H, E, G, A, and B) were selected to help understand the occupational sequence of Otowi. Unit H is located on top of Roomblock A (the old pueblo) and Units E and G are located in the roomblocks midden. Units

A and B are located on the earthen mound in the main plaza and the primary midden, respectively. Using the interpretations that were made for each ceramic type described above as well as the proportions of ceramic types and their associated dates, a table was constructed that dates these units from earliest to latest (Table 77.14).

Table 77.14. Selected units used to build site chronology from Otowi.

Unit	Santa Fe B/w	Wiyo B/w	Abiquiu B/g	Bandelier B/g	Sankawi B/c	Potsuwi'i	Glaze	Smeared IC	Mica SIC	Sapawe Wash.
H	0	0	12%	32%	11%	2%	5%	0	23%	15%
E	3%	6%	29%	41%	15%	2%	4%	NA	NA	NA
G	<1%	0	6%	27%	8%	0	7%	27%	21%	1%
A	<1%	2%	11%	15%	5%	1%	1%	5%	9%	50%
B	4%	13%	10%	35%	7%	3%	3%	8%	16%	0

Units H, E, and G are the oldest units and are associated with Roomblock A, which has traditionally been interpreted as the oldest portion of the site. Units A and B are associated with the rest of the site's architecture. To understand the relative dating of occupation at Otowi, a map was constructed (Figure 77.5). Roomblock A has been substantiated to be the oldest occupation, and Roomblocks B through E are chronologically later. Although there is no data to further understand this sequence and whether the whole site or just portions were occupied at the same time, it looks as if the pueblo grew from west to east, expanding from a small roomblock with one kiva to a large village pueblo with multiple kivas and a central plaza.

THE TSIREGE (LA 170) CERAMIC ASSEMBLAGE

Tewa Series

Kwahe'e Black-on-White

Like Otowi, no sherds of this type were found at the site, indicating a primarily Coalition period or later occupational sequence, at least for the upper strata of the site (Table 77.15).

Santa Fe Black-on-White

Santa Fe Black-on-white occurred infrequently in the Tsirege surface assemblage and was collected in half of the units in small quantities (>6%). This is not surprising due to the fact that even if the type was manufactured up until AD 1425, Tsirege has traditionally been dated to the Late Classic period.

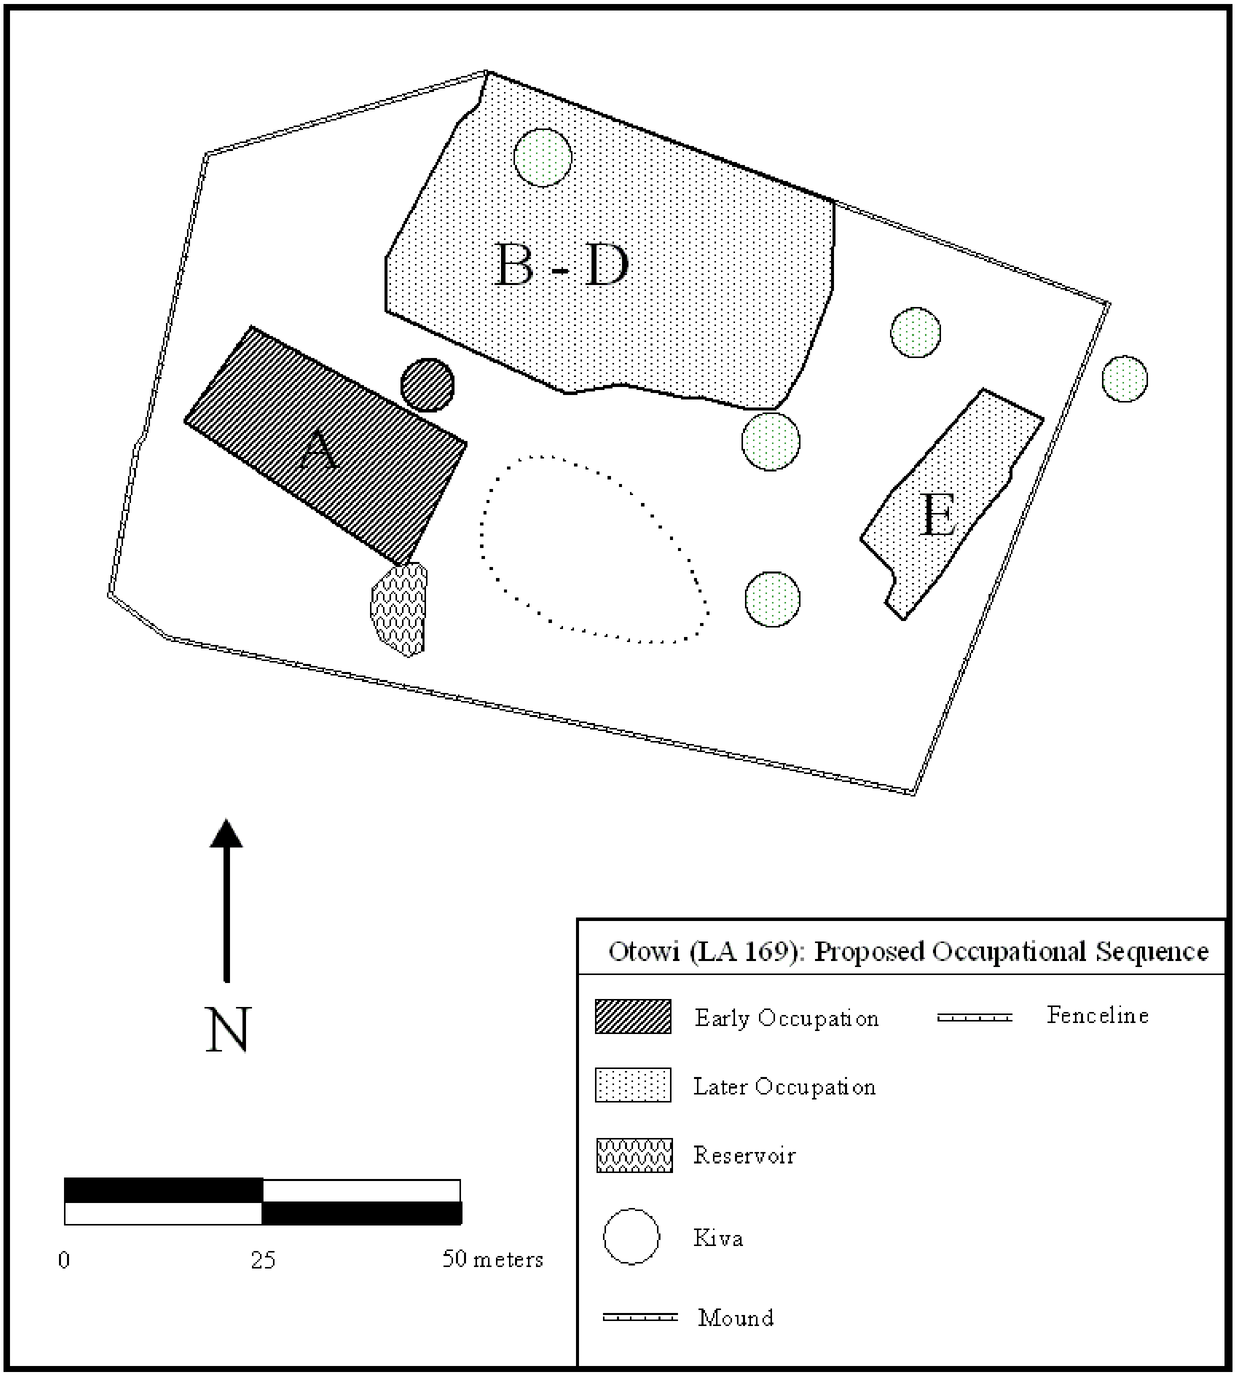

Figure 77.5. Proposed occupational sequence at Otowi.

Table 77.15. Percentages of decorated ceramic types by PARP collection in the Tsirege surface assemblage.

Unit	Santa Fe B/w	Wiyo B/w	Biscuit A	Biscuit B	Sankawi B/c	Potsuwi'i	Glaze	Imported	Historic
A (*n* = 805)	0	1%	2%	52%	28%	2%	12%	1%	1%
B (*n* = 1126)	1%	2%	12%	39%	34%	1%	9%	2%	1%
C (*n* = 59)	0	5%	3%	75%	8%	0	8%	0	0
D (*n* = 956)	0	<1%	2%	39%	43%	0	13%	<1%	2%
E (*n* = 7)	0	0	0	71%	29%	0	0	0	0
F (*n* = 33)	0	0	0	79%	9%	0	12%	0	0
G (*n* = 37)	3%	3%	11%	38%	35%	0	11%	0	0
H (*n* = 33)	0	0	3%	0	94%	0	3%	0	0
J (*n* = 156)	6%	2%	26%	19%	20%	1%	21%	1%	3%
K (*n* = 28)	0	4%	0	32%	50%	0	7%	0	7%

N (*n* = 164)	5%	8%	7%	32%	32%	1%	11%	1%	2%
O (*n* = 26)	4%	0%	8%	77%	12%	0%	0%	0%	0%
P (*n* = 10)	0%	10%	0%	80%	10%	0%	0%	0%	0%
Q (*n* = 359)	2%	0	6%	35%	36%	1%	18%	2%	1%
Total (*n* = 4037)	1%	1%	7%	41%	35%	1%	12%	1%	1%

Although all of the units had small amounts of Santa Fe Black-on-white, two of the PARP units (J and N) had 5 percent or greater. Unit J is located in the middle of Plaza 2 in the northwest portion of the site. The plaza is surrounded by two small roomblocks that are much smaller than the main architecture of the site and may be the remains of a Coalition period occupation. Unit N is located at the extreme northeastern section of the site. Although it is not affiliated with any mapped feature, the unit may also represent an earlier phase of occupation at the site. It is not uncommon in ancestral Tewa archaeology for earlier sites being dwarfed by Classic period building events, as demonstrated by the excavations at Te'ewi (Wendorf 1953).

Wiyo Black-on-White

Wiyo Black-on-white also occurred infrequently across the site being collected in small quantities (less than or equal to 10%) at most units. This type was found at Arroyo Hondo until AD 1475 and appears to coincide with Abiquiu Black-on-gray, albeit it appears to have ended somewhat earlier and can be dated as an earlier type (Habicht-Mauche 1993). Only Units E, F, and H did not have any sherds of this type collected most likely due to a small sample size. Two units had higher quantities of Wiyo Black-on-white present, although Unit P can be ignored due to its low total sample size (n = 10). Unit N had 8 percent (n = 13) of the sherds in its assemblage. Interestingly, this is also the unit with higher concentrations of Santa Fe Black-on-white ceramics, giving support that this unit represents an earlier occupation of the site (probably Coalition period) although there are no affiliated features.

Abiquiu Black-on-Gray (Biscuit A)

Abiquiu-Black-on-gray has been dated from the late 14th century through possibly the middle of the 16th (Habicht-Mauche 1993), although it is securely settled as a 15th century type. The degree of variation within these samples is shown in Figure 77.6.

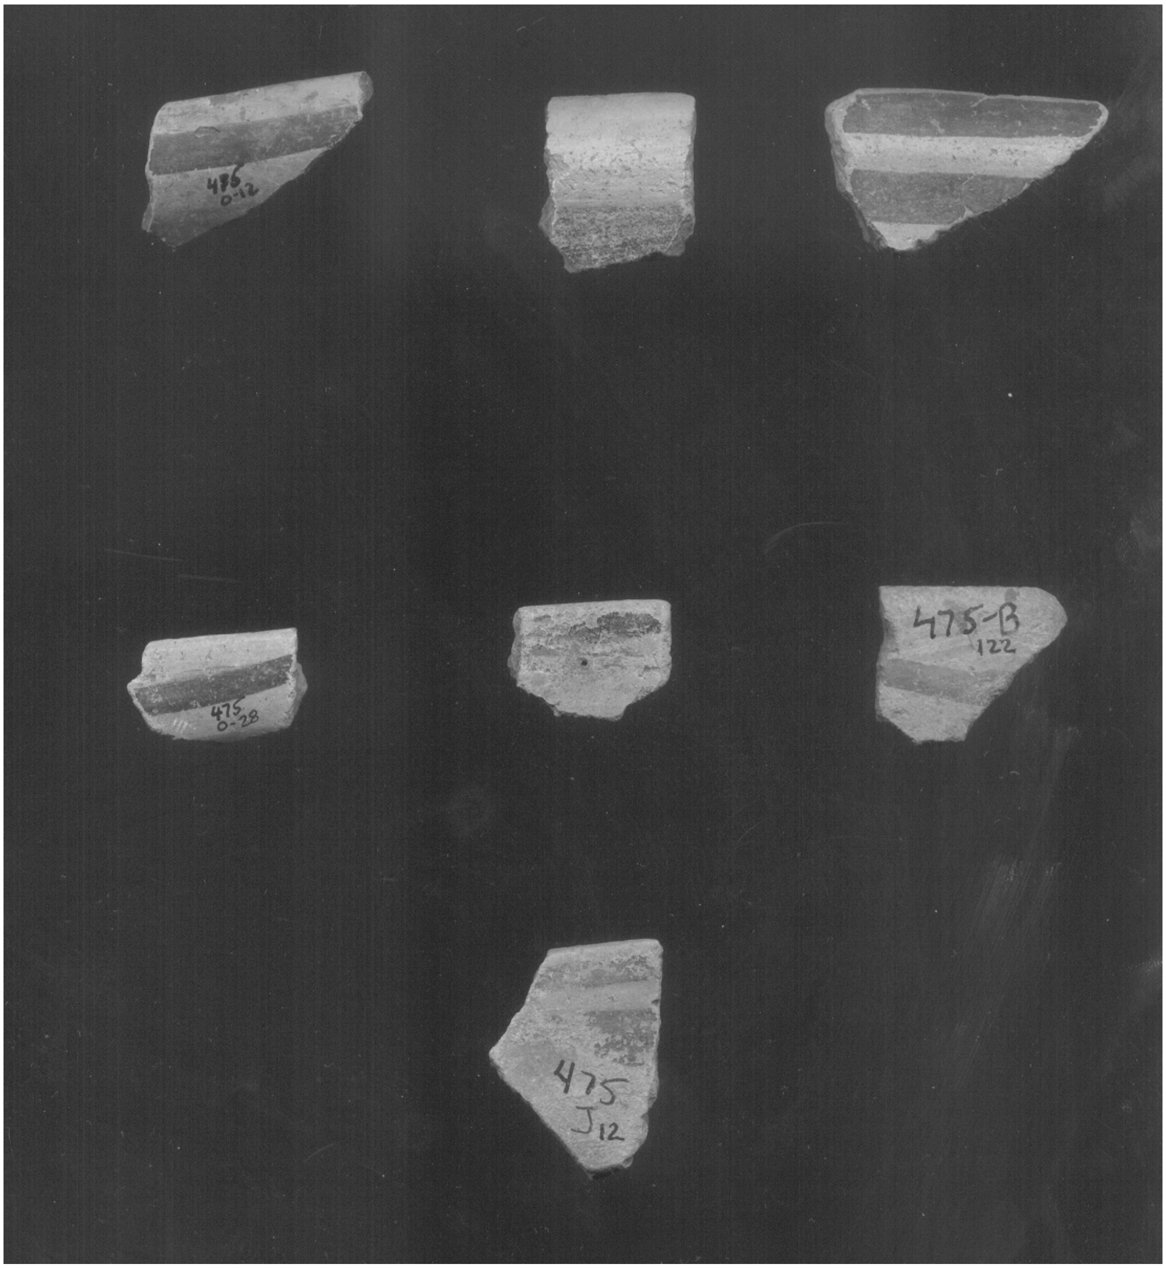

Figure 77.6. Abiquiu Black-on-gray bowl rim sherds from Tsirege.

The type is present at nearly every unit at Tsirege aside from Units E, F, and K, which have very small sample sizes. However, in the units where the type is present the concentrations are relatively low compared to later varieties of Tewa Series ceramics, ranging from 2 percent to 12 percent. The one exception is Unit J with 41 sherds (26%). This unit is located in the middle of Plaza 2 and is associated with two small roomblocks. The unit also had a relatively larger concentration of Santa Fe Black-on-white sherds, giving weight to the fact that although it appears that this was an early occupation, this area of the pueblo was occupied through the 15th century.

Unlike Otowi, the ceramic assemblage of Tsirege had much fewer samples of Abiquiu Black-on-gray bowls, which is understandable due to its later dates of occupation. However, like the samples from Otowi, the sherds broke down into four main categories during microscopic analysis (Table 77.16). Tuff was the dominant tempering material, with tuff and quartz sand being the second most common. However, unlike Otowi there were much fewer samples with plutonic inclusions. This could indicate differential access to resources or exchange networks, a question that will be addressed in a later section of this report.

Table 77.16. Percentages of temper types by unit for Abiquiu Black-on-gray bowl sherds from Tsirege.

Unit	Temper			
	Tuff	Tuff w/ sand	Tuff w/ sand + volc.	Tuff w/ sand + plut.
A (*n* = 20)	50%	40%	10%	0%
B (*n* = 136)	60%	27%	11%	1%
C (*n* = 0)	0	0	0	0
D (*n* = 17)	94%	0	6%	0
F (*n* = 0)	0	0	0	0
G (*n* = 4)	100%	0	0	0
J (*n* = 41)	41%	49%	10%	0
K (*n* = 0)	0	0	0	0
M (*n* = 12)	83%	8%	8%	0
N (*n* = 12)	92%	8%	0	0
O (*n* = 0)	0	0	0	0
P (*n* = 0)	0	0	0	0
Q (*n* = 19)	32%	53%	11%	5%

Bandelier Black-on-Gray (Biscuit B)

Bandelier Black-on-gray was found in nearly every unit collected (aside from Unit H that had a small sample size [*n* = 33]). The type has been dated from the early part of the 15th century through the middle of the 16th. The unit with the largest percentage of the type recovered from a collection with a substantial sample size (>100 sherds) was in Unit A, with 52 percent (*n* = 415). This unit is located in the midden area on the east side of the site and represents the ceramic assemblage of the Eastern Roomblock. At least this portion of the site can be considered a "Biscuit B" roomblock, dating somewhere in the 15th to middle of the 16th centuries. The degree of variation within the samples found at the site is illustrated in Figure 77.7.

Figure 77.7. Bandelier Black-on-gray bowl rim sherds from Tsirege.

Microscopic analysis has shown that the proportions of tuff versus tuff and quartz sand inclusions are well weighted toward tuff (Table 77.17). However, compared to Otowi the percentages of quartz-tempered Bandelier Black-on-gray pottery are smaller. All temper types were found at the site but with much smaller quantities of ceramic samples with plutonic inclusions. One exception to this is Unit N (18% plutonic-tempered samples) located in the northeastern portion of the site near Eastern Roomblock. Is this indicative of non-local pottery? The answer to this question can be aided by evaluating the clay oxidation analysis data.

Table 77.17. Percentages of temper types by unit for Bandelier Black-on-gray bowl sherds from Tsirege.

Unit	Temper			
	Tuff	Tuff w/ sand	Tuff w/ sand + volc.	Tuff w/ sand + plut.
A (*n* = 390)	62%	23%	15%	1%
B (*n* = 372)	57%	24%	16%	3%
C (*n* = 44)	68%	25%	7%	0
D (*n* = 347)	79%	17%	4%	0
F (*n* = 24)	71%	21%	8%	0
G (*n* = 5)	60%	40%	0	0
J (*n* = 12)	83%	8%	8%	0
K (*n* = 7)	71%	29%	0	0
M (*n* = 67)	82%	10%	7%	0
N (*n* = 39)	49%	33%	0	18%
O (*n* = 20)	75%	10%	15%	0
P (*n* = 8)	75%	13%	13%	0
Q (*n* = 112)	61%	32%	4%	3%

Sankawi Black-on-Cream

Sankawi Black-on-cream dates to the middle of the 16th to the middle of the 17th century (Harlow 1973), post-dating all of the biscuitwares. The type is present in all collected units, ranging from 8 percent to 94 percent. The degree of variation is shown in Figure 77.8. Of the units with a substantial sample size (>100 sherds), Units D and M had the greatest concentrations. Four-hundred-twelve Sankawi Black-on-cream sherds (43%) were recovered in Unit D, which is located in the large midden area north of the northern roomblock, and 102 sherds (43%) were recovered from Unit M, which is located in the midden area east of the eastern roomblock. Both of these units likely represent their respective roomblock. It can be interpreted that both the Northern and Eastern Roomblocks were the latest occupied areas of the pueblo.

Potsuwi'i Incised

Potsuwi'i Incised, which dates to AD 1550–1650 (Harlow 1973), represents some of the latest occupation of the site. The type is only found in the Tsirege ceramic assemblage in very small quantities (1%) in about half of the collected units. Because these units are distributed over all major features of the site, a spatial analysis was not possible. However, it appears that some Potsuwi'i Incised was used at the site, possibly in its later occupations. The proportions of the pottery type are lower than that of Otowi, which is surprising because of the larger proportions of later ceramics (Sankawi Black-on-cream and Glaze E and F). These problems will be discussed later in this report.

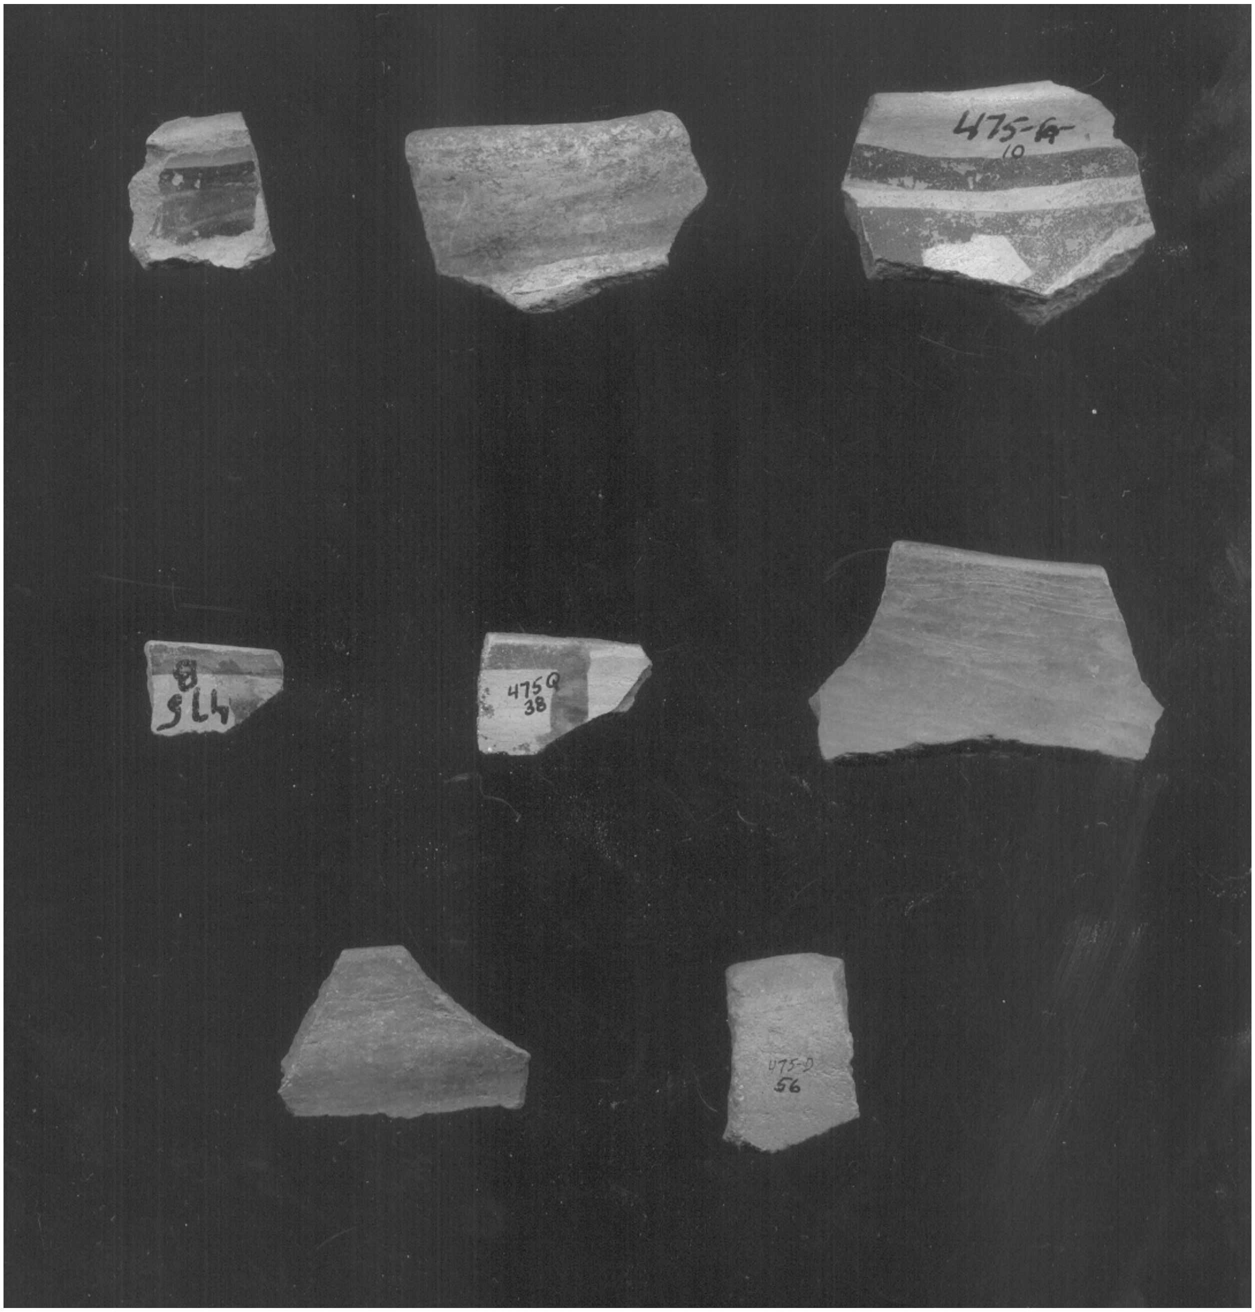

Figure 77.8. Sankawi Black-on-cream bowl rim sherds from Tsirege.

Glaze Series

The full range of Rio Grande glazewares were present on the surface context of Tsirege in all collected units. Although the glazeware counts are much higher than those of rim sherds (see

Table 77.18 for percentages of glazeware totals per unit), rim sherds provide a unique sample that allows for typing a vessel using only a small portion. Many of the units had only small amounts of glaze series rim sherds in their assemblages. However, three units (B, C, and Q) had substantial quantities (>10 sherds). Both Units B and C are located in the main plaza of the pueblo, with Unit B located in the midden (possibly more associated with the Western Roomblock?) and Unit C in the center of the plaza directly between the Eastern and Western Roomblocks. Unit Q is located in the northwestern portion of the site near the two small roomblocks. Interestingly, Unit Q is dominated by Glaze A ceramics, which date to AD 1315–1425 (Schaafsma 2002:195; Vint 1999:391). This further substantiates the fact that the small roomblocks in Plaza 2 represent the oldest visible occupation of the site. Units B and C are both dominated by Glaze D ceramics that have been dated to AD 1490–1525 (Schaafsma 2002:195). Although only very few sherds of Glaze E (AD 1515–1625) and F (AD 1625–1700) ceramics are present on the site, they are best represented in Units A and D, located in the midden areas of the Eastern and Northern roomblock, respectively. These two roomblocks appear to be the last occupied areas of the pueblo and could possibly extend the occupation of the pueblo into the 17th century.

Table 77.18. Percentages of glazeware rim sherd type by unit from Tsirege.

Unit	Glaze Series Type						
	Glaze A	Glaze B	Glaze C	Glaze D	Glaze E (early)	Glaze E (late)	Glaze F
A (*n* = 6)	17%	17%	0	33%	0	17%	17%
B (*n* = 13)	15%	15%	8%	38%	8%	15%	0
C (*n* = 17)	12%	29%	0	35%	6%	12%	6%
D (*n* = 4)	0	0	0	0	25%	50%	25%
G (*n* = 2)	0.5	0	0.5	0	0	0	0
M (*n* = 1)	0	0	1	0	0	0	0
N (*n* = 1)	0	0	1	0	0	0	0
Q (*n* = 12)	42%	0	33%	17%	8%	0	0

Utilitywares

Tesuque Grayware is the predominant utilityware found at the site (Table 77.19). Although it dates from AD 1250–1500 (Habicht-Mauche 1993; McKenna and Powers 1986; Mera 1935), the ending date has been largely untested. There is a dominance of the no-mica smeared-indented corrugated variety (62%), although 11 percent of the assemblage had mica-based Tesuque Gray as well. This causes doubt whether the mica inclusions really signify chronological change (the proportions are similar to the earlier site of Otowi) and whether these mica samples are the result of ceramic mobility.

Sapawe Washboard pottery was found in every context of the PARP surface collections and represents 23 percent of the utilityware assemblage. Of the units that are not classified as “pot hunters’ cache” and with substantial sample size, Unit A has the highest proportion of this ware.

Not surprisingly, this is in the midden of the Eastern Roomblock, which is thought to be part of the latest occupation of the site.

Table 77.19. Percentages of utility ceramic types by PARP collection in the Tsirege surface assemblage.

Unit	Plain	Indented Corrugated	Smeared Indented Corrugated	Plain Mica	Mica Smeared Indented Corrugated	Sapawe Wash.	Striated	Clapboard
A (*n* = 375)	2%	0	38%	0	27%	33%	0%	0
B (*n* = 331)	2%	2%	59%	2%	17%	17%	2%	1%
C (*n* = 257)	5%	2%	70%	0	4%	18%	0	1%
D (*n* = 736)	1%	<1%	78%	0	4%	16%	0	0
E (*n* = 5)	0	0	60%	0	0	40%	0	0
H (*n* = 82)	0	0	0	0	0	100%	0	0
J (*n* = 217)	5%	2%	65%	2%	11%	13%	1%	0
K (*n* = 10)	0	0	10%	0	40%	50%	0	0
Total (*n* = 2013)	2%	1%	62%	1%	11%	23%	<1%	<1%

Historic Wares

Only a small amount of historic sherds were found at the site (51 sherds, 1%). All were unpainted redwares with fine tuff temper and were typed as Tewa Red/Polychrome. This type dates from the middle of the 17th century to the early part of the 18th century. Tewa Red/ Polychrome ceramics were found in half of the PARP units, although in small percentage (1 to 2%) and were spread evenly across the site. It appears that, although these sherds were not part of the original occupation, they may represent a later reoccupation or visitation of the site in the 17th or 18th centuries.

Imported Wares

Forty-nine imported sherds were found in the surface collections from Tsirege. All were unpainted redwares with sherd and sand temper, thus typed as White Mountain Redware. These sherds, while present in very small quantities in seven of the 12 PARP collection units, were most abundant in Units A (10 sherds) and B (23 sherds). These units represent the Eastern and Western Roomblocks, respectively, indicating that exchange with distant regions likely happened throughout the occupational sequence of the pueblo.

Refiring Experiments

The clay oxidation refiring experiments performed on both Abiquiu and Bandelier Black-on-gray bowl sherds showed a much more limited degree of variability than those of Otowi (Table 77.20). No sherds were recorded as "pink" and only a very small amount of Bandelier Black-on-gray were classified as "brown." Dominant colors for both ceramic types were reddish yellow, brownish yellow, and yellowish red. There does not appear to be any spatial significance to the location of certain clay groups compared to others. When the two pottery types are compared there appears to be many more samples of yellowish red clay paste in Abiquiu Black-on-gray bowls, which possibly could be a function of changing clay procurement strategies or exchange interactions through time.

Table 77.20. Percentages of refiring colors in the clay oxidation experiments for both Abiquiu and Bandelier Black-on-gray bowl sherds from Tsirege.

Abiquiu B/g Bowl					Bandelier B/g Bowl				
Unit	Brownish yellow	Reddish yellow	Brown	Yellowish red	Unit	Brownish yellow	Reddish yellow	Brown	Yellowish red
A	0	38%	0	10%	A	0%	52%	0	48%
B	20%	55%	0	5%	B	15%	80%	3%	3%
D	8%	35%	0	0	D	31%	65%	0	4%

Like the analysis of Abiquiu and Bandelier Black-on-gray bowl sherds from Otowi, the results of the refiring analysis were compared to the temper data generated through microscopic analysis (Table 77.21). Because of the small amount of samples that were recorded as "brown" these samples were combined with the "brownish yellow" category.

Table 77.21. Percentages of samples of temper type by refiring color from biscuitwares at Otowi.

Unit A	**Temper**	**Refire Color**		
Abiquiu B/g		Brownish yellow	Reddish yellow	Yellowish red
	Tuff	0%	70%	30%
	Tuff w/ sand	0%	88%	13%
	Tuff w/ sand + vol.	0%	100%	0%
Bandelier B/g		Brownish yellow	Reddish yellow	Yellowish red
	Tuff	0%	50%	50%
	Tuff w/ sand	0%	30%	70%
	Tuff w/ sand + vol.	0%	30%	70%
	Tuff w/ sand + plut.	0%	75%	25%
Unit B	**Temper**	**Refire Color**		
Abiquiu B/g		Brownish yellow	Reddish yellow	Yellowish red
	Tuff	40%	40%	20%

Unit A	**Temper**	**Refire Color**		
	Tuff w/ sand	30%	70%	0%
	Tuff w/ sand + vol.	10%	90%	0%
	Tuff w/ sand + plut.	0%	100%	0%
Bandelier B/g	Tuff	10%	90%	0%
	Tuff w/ sand	0%	100%	0%
	Tuff w/ sand + vol.	33%	67%	0%
	Tuff w/ sand + plut.	22%	78%	0%
Unit D	**Temper**	**Refire Color**		
Abiquiu B/g		Brownish yellow	Reddish yellow	Yellowish red
	Tuff	20%	80%	0%
	Tuff w/ sand	0%	0%	0%
	Tuff w/ sand + vol.	0%	100%	0%
	Tuff w/ sand + plut.	0%	0%	0%
Bandelier B/g	Tuff	20%	80%	0%
	Tuff w/ sand	30%	60%	10%
	Tuff w/ sand + vol.	43%	43%	14%
	Tuff w/ sand + plut.	0%	0%	0%

Like the samples from Otowi there does not appear to be any correlation between temper type and refiring (oxidation) color. Possible reasons and interpretations of these two sets of data (provenance and technology) will be discussed in the next section.

Seriation and Chronology

Due to location and size of ceramic assemblage, four units were selected to help understand the occupational sequence of Tsirege in combination with the distribution of individual ceramic types described previously. The units and their ware count proportions are listed in Table 77.22 from latest to earliest occupation. Figure 77.9 is a map showing a reconstruction of possible occupation across the site.

Table 77.22. Selected units used to build site chronology from Tsirege.

Unit	**Santa Fe B/w**	**Wiyo B/w**	**Biscuit A**	**Biscuit B**	**Sankawi B/c**	**Potsuwi'i**	**Glaze**	**Smeared IC**	**Mica SIC**	**Sapawe Wash.**
A	0	1%	2%	36%	20%	1%	8%	12%	9%	11%
D	0	<1%	1%	22%	25%	<1%	8%	35%	2%	7%
B	0	1%	10%	32%	27%	1%	7%	14%	4%	4%
J	3%	<1%	12%	9%	9%	<1%	10%	41%	7%	8%

Units A and D are located in the midden contexts of the Eastern and Northern Roomblocks, respectively. The ware counts in Table 77.15 are similar, and the individual ceramic type/ware analysis indicates that the occupation for each of the roomblocks is contemporaneous (at least at the resolution of this analysis). Unit B is located in the midden for the Western Roomblock, which appears to date slightly earlier than the eastern and northern architecture. Unit J, located near the small roomblocks and kiva in Plaza 2, is obviously the earliest occupation of the site based on the number of Glaze A ceramics and the presence of Santa Fe Black-on-white pottery.

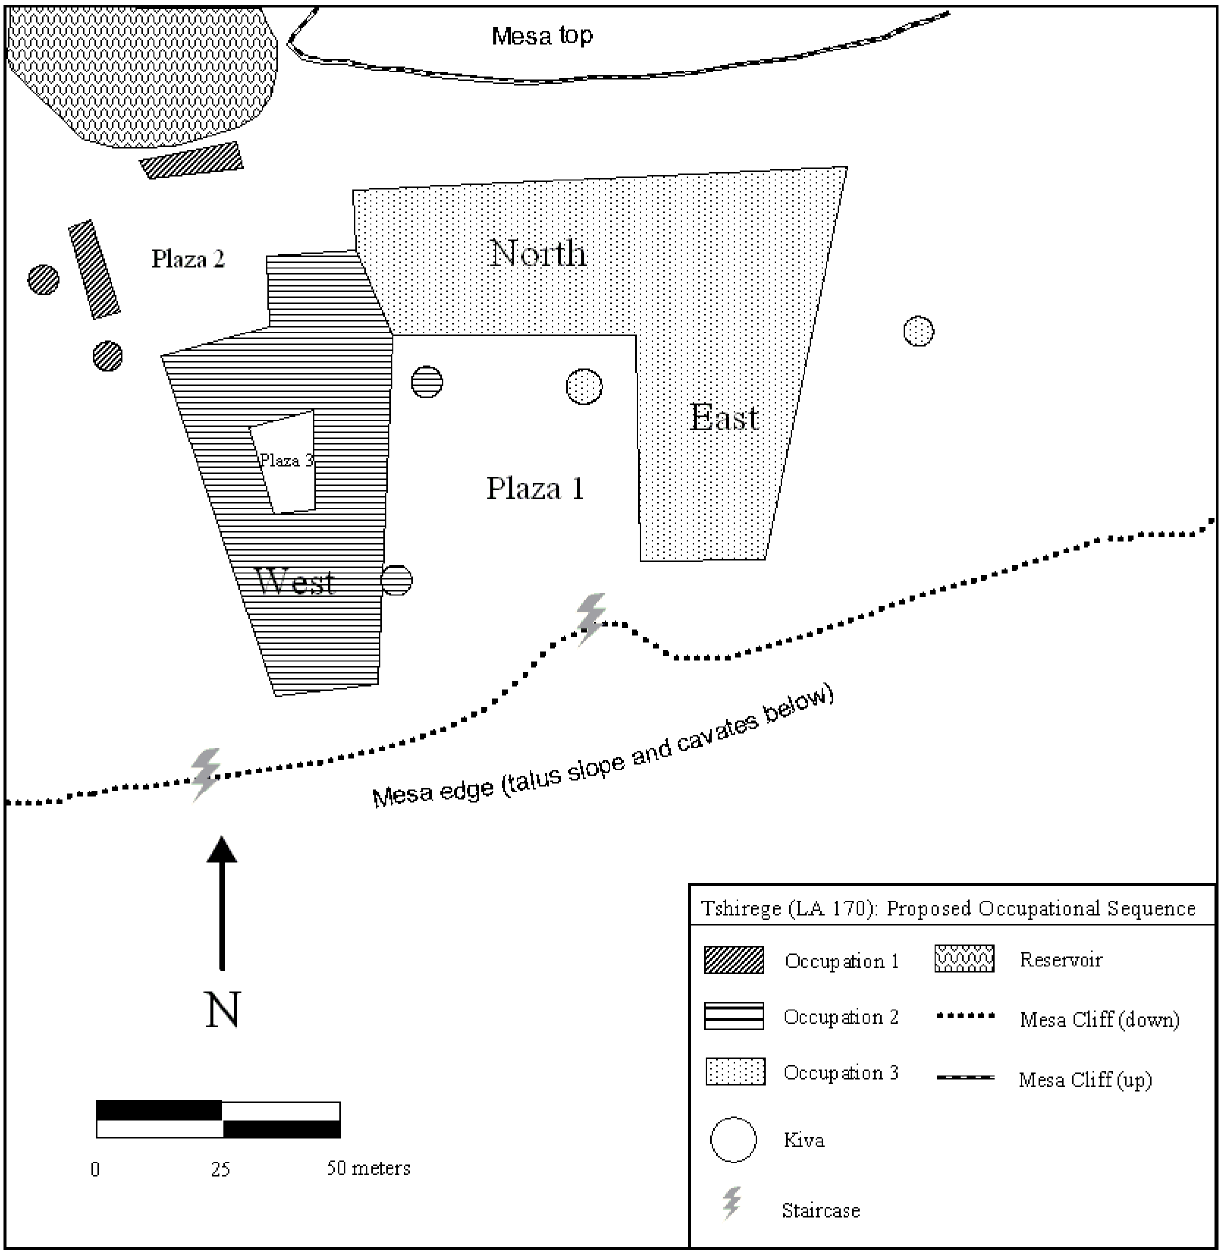

Figure 77.9. Proposed occupational sequence at Tsirege.

It is likely that the two small roomblocks represent the earliest phase of occupation of the pueblo (perhaps extending back into the Coalition period?). During the middle- to- late Classic period, the pueblo underwent a series of expansion events with first the Western and then the Eastern and Northern Roomblocks being built. At this point with limited analysis, it remains impossible to understand which architecture was being occupied contemporaneously, although it is likely that the entire pueblo of Tsirege was not being lived in at any one time.

DISCUSSION

Chronology

Wendorf and Reed (1955) formulated the regional chronology of the northern Rio Grande, a guide that is still relevant today. However, the assigning of specific dates to sites on the Pajarito Plateau has undergone multiple revisions and still appears to require work at a finer scale. Establishing and trusting a good chronology is inherently important in interpreting every question of prehistoric Tewa life on the plateau. This section describes previous research and proposes how this project will serve to clarify some unresolved issues.

Aside from rough approximations based on the presence of biscuitware and its correlation to the chronology presented by Wendorf and Reed (1955), there has been little work on the Pajarito Plateau to understand accurate dating of the Tewa pueblos. This, of course, is due in part to limited excavations and that PARP collections were primarily surface based. This is the case for the two large Classic period sites that this report has analyzed. After limited collections, de Barros (1981) performed microseriation analysis on the collections part of the PARP sites, including Otowi, which he tentatively dated to AD 1325/1350 to 1550/1575. LANL surveys have proposed that the end date be moved to AD 1600, or the end of the Classic period (LANL 1999). The other site, Tsirege (LA 170), remained undated for unknown reasons, perhaps being that not enough surface collection had been performed by the time of the analysis.

Although provenience is not well understood, the Laboratory of Tree-Ring Research (LTRR) at the University of Arizona has dated multiple samples that have yielded dendrochronological dates for the large pueblos of Tsirege and Otowi (see Chapter 7, Volume 1). Stallings' (1933) excavations of Tsirege procured 59 samples from the site. Of these, there were three cutting dates that range from AD 1559–1581, with overall occupation taking place primarily during the AD 1570–1600 time frame. Although Wilson (1916a) excavated Otowi with no collection of ancient wood (these excavations took place well before the advent of dendrochronology), tree-ring samples were collected by Stallings and submitted to the LTRR (see Chapter 7, Volume 1). Of these, five samples were dated, with one cutting data at AD 1414 and the rest suggesting occupation nearly a century of occupation in the AD 1400s.

Although the PARP surface collections do pose problems, such as the fact that these large pueblos were probably occupied over multiple centuries and this time span cannot be accurately recorded using surface collections alone, using relative frequencies of ceramics can inform researchers of general chronological trends. For this project it is important to compare the relative dates of occupation between Otowi and Tsirege, as well as construct an occupational sequence for each site.

Because of the mixed and unreliable contexts of the surface assemblages, as well as the known ceramic chronology with very large temporal time spans (some ceramic types are present for almost two centuries), the use of microseriation or mean ceramic dating (South 1977) seems inappropriate. This is compounded with the fact that the latter dates of the Tewa Series pottery is suspect, with the terminal dates ending with the assumed abandonment of Tewa sites not along the Rio Grande by the mid-16th century (Richard Ford, personal communication).

Both Otowi and Tsirege have small quantities of Santa Fe Black-on-white, which dates the early occupation of the site to at least the first part of the 15th century. The presence of this type is isolated to specific sections of both pueblos, which this report argues is evidence for the growth of the pueblo over time. No earlier Kwahe'e Black-on-white sherds were found at either Otowi or Tsirege, and the percentages of Santa Fe Black-on-white were relatively small. However, this does not refute the possibility that an earlier Coalition period occupation was dwarfed by later Classic period building and living events, as seen at other pueblos in the region (Wendorf 1953).

When compared to each other, and in concert with the available tree-ring dates (see Chapter 7, Volume 1), it does appear that Tsirege was occupied later than Otowi. The tree-ring dates for Otowi suggest that the site was occupied through the 15th century, but the small but present quantity of Sankawi Black-on-cream (15%) on the surface context suggests that the site was inhabited into the 16th century, most likely in Roomblocks B through E.

One tree-ring cutting date at Tsirege dates to AD 1581, suggesting that the site was most likely occupied through the end of the 16th century. This is supported by the large amount of Sankawi Black-on-cream pottery (35%). There is reason to believe that the pueblo may have been occupied into the 17th century, with the presence (although small) of Glaze E and F pottery found in the midden contexts of the Northern and Eastern Roomblocks. The very small quantities of historic ceramics do not suggest a reoccupation of the site, but rather a revisitation by later Pueblo people.

Although questions of identity, craft production, and socio-political structure are inherently important in understanding northern Rio Grande prehistory, a firm knowledge of the time-space systematics of the region are not only a desired, but a required, first step. Further research into this area could take the form of direct dating of the pottery itself as was conducted by Ramenofsky and Feathers (2002) to understand dates of abandonment of pueblos along the Rio Chama drainage.

Identity

Social identity has been described as "the ways in which individuals and collectives are distinguished in their social relations with other individuals and collectives" (Jenkins 1996:4). It is based on relativity: simply put, a group cannot have an identity without a comparison to another group of individuals, or using Jenkin's term, collective. The archaeological characterization of identity is important in understanding prehistory at a multi-scalar level, for it provides the researcher insight into migration, use of the physical landscape, and relationships with the larger world. As Mills (2002) points out, each turning point of Southwestern prehistory involved a restructuring and alteration of group identity. This is especially true for the northern Rio Grande in the Classic period where site aggregation rapidly consolidated populations with differing backgrounds and worldviews (Adams and Duff 2004).

The study of identity is the study of similarities and differences between groups of individuals. Although social boundaries have been notoriously difficult to delineate (see papers in Stark 1998) and are often permeable and "fuzzy," using a multi-scalar approach to understand identity such as that of Duff (2002), creates quantifiable tests to social boundedness. Social identity may be studied at the regional (Duff 2002), the community (Herbich 1989), and even at the intra-site level (Duwe 2006; Duwe and Neff 2006) using a variety of methodologies that attempt to record meaningful patterns in the material record. Social identity is important for two main reasons: the first is that some sort of measure of the group is necessary to facilitate archaeological comparisons between populations in both time and space, especially without the use of classic culture areas; and second, that social identity is fundamentally important to modern descendant communities who have a large stake in Native American Graves Protection and Repatriation Act-legislated cultural affiliation studies.

To qualify and quantify identity, researchers take measurements in material culture that reflect the day-to-day interactions between people. This testing of identity has taken many shapes over the past decade. Recently, it has relied on technological aspects of practice frameworks, using the ideas of *habitus* (Bourdieu 1977) that states that the ways of making material culture can be measured archaeologically and used to infer social identity. The ways in which this is done will be described in the next section. It can also be measured indirectly through interpreting the configuration and scale of craft production, specifically that of craft specialization. As will be illustrated below, craft production and identity are often interrelated in meaningful ways.

There is a very real cultural division across the Pajarito Plateau that was recorded into the historic period, and continues to exist in the modern era (Harrington 1916; Kidder 1936). The ethnohistoric record documents Tewa speaking people in the north and Keres speaking populations in the south, with the line drawn somewhere around east to west on the southern portion of the Pajarito Plateau near Frijoles Canyon (Harrington 1916). The earliest archaeological ceramic research verified this dichotomy with biscuitware producers in the north and glazewares to the south (Kidder 1915). Not only were the ceramic assemblages from prehistoric sites dominated by one class of ware or the other, it was stated as fact early on that this correlated to differences in production areas, with the Tewa pueblos not participating in the procurement and use of glazes and their dedication to the biscuitwares. This conclusion was later verified by Shepard (1936) in her technological analyses of pottery from Pecos Pueblo and surrounding regions.

Although modern researchers try to avoid the "pots as people" hypothesis without sound evidence, it appears that the "Tewa area," defined by the Tewa-Keres line in the south upwards into the Chama River basin and including the five modern pueblos of San Ildefonso, Santa Clara, San Juan, Tesuque, and Nambe (Harrington 1916), correlates well with what Mera (1935) called the "Biscuitware Pueblos." Recent research by Graves and Eckert (1998) and Futrell (1998) further support the argument that the apparent division of biscuitware producers to the north and glazeware producers to the south delineate Tewa and Keres ethnic boundaries, respectively. In addition, from ceramic counts given from preliminary PARP ceramic data and LANL infield analysis (LANL 1999), glazewares account for only 1 to 25 percent of the ceramic assemblage. This contrasts with the large amounts of biscuitware produced in the Tewa area and exported, with the most famous case being that of Pecos Pueblo where Kidder found the Keres pueblo to have 20 percent in the assemblage (Kidder 1936). Interestingly, these ceramic analyses contrast with studies of rock art on the Pajarito Plateau, in which there appears to be no striking difference between the northern and southern halves of the region (Munson 2002). This begs the questions: what was being traded for biscuitwares, and what sorts of economic relationships were happening between the Chama and the greater northern and central Rio Grande region? Do these reflect social or political networks? And most important to this proposal, what does this say about Tewa identity? Is the historic Tewa-Keres boundary really in such correspondence with pottery production and distribution? Are pots actually representing the relationships and identity of people? And finally, how do changes in ceramic production and exchange vary through time, specifically looking at the two sites of Otowi and Tsirege?

This project can only start to answer the above questions in small ways. Interestingly, although there is only a small amount of glazeware at Otowi there are much greater frequencies at Tsirege. Tsirege has been classified as a Tewa pueblo as it is located on the northern part of the Pajarito Plateau and has an abundance of prehistoric Tewa series pottery (biscuitware, Sankawi Black-on-cream) in its assemblage. If the above-mentioned assumptions are used to hypothesize the amount of glazeware at the site this should be very low (<5%) as is the case for other Tewa pueblos (Futrell 1998; Gauthier 1987a; Graves and Eckert 1998; Wendorf 1953). Interestingly, this is not the case. Tsirege has 8 percent glazeware in the site's overall ceramic assemblage and 12 percent among the decorated pottery. The question arises: what do these higher frequencies mean?

Perhaps the proposed ethnic Tewa/Keres boundary did exist in prehistory, although it was more permeable than previously thought. If this was the case, then a Tewa pueblo located near the boundary would likely have greater percentages of glazeware than those to the north. The proposed boundary based on ethnic identity could still have existed, although it is likely that there was much more interaction between groups near the Frijoles Canyon border. Future research could explore this boundary more fully, examining architectural and lithic evidence to further understand the degree and meaning of this proposed permeability.

Technological Considerations

Pfaffenberger (1992) argues that the study of technology in material culture "may significantly alter the way anthropologists analyze everyday life, cultural reproduction, and human evolution" (Pfaffenberger 1992:491). In the past three decades, archaeologists have become increasingly interested in style, specifically that of technology. Technological style has been defined by Rice (1987:201) as "a combination of experience and custom resulting in a body of information and practice governing the manufacture of material culture, which leads to a characteristic product with a unique range of properties." Many attributes of technological style can be seen only during the production phase of an artifact's life; therefore, the most likely way that these attributes could be precisely copied would be first-hand observation, such as a teacher-student relationship. This has a distinct advantage over other overt forms of style, such as painted designs, for archaeologists interested in understanding knowledge transmission. In short, there are many things about creating a pot, a point, a sandal, or any other object that cannot be mimicked by examining the finished product, but rather is learned in the process of knowledge transmission through forming communities of practice.

Many artifacts carry inherent messages about social identity not intended by their producers (Hegmon 1998). Stark (1998, 2005) discusses the theory of learning frameworks and *habitus* (*sensu* Bordeiu 1977), which is defined as culturally specific ways of doing things that are generally unconscious actions (Dietler and Herbich 1998). In essence, although there may be many ways to express oneself in the creation of objects such as pottery, many of the skills and ways of "doing things" are learned early in one's career and are perpetuated throughout life. Although specific technical choices are affected by multiple factors such as environmental constraints and behavioral decisions, the work of archaeologists (Crown 2001, 2002) and ethnoarchaeologists (Wallaert-Pêtre 2001) show that many aspects of technology (examined as technological style) remain relatively stable when passed down through apprenticeship relationships along social identity lines.

These arguments are also supported by ethnographic and ethnoarchaeological studies in the learning of motor skills, which are taught and not manipulated consciously by the student (Arnold 1985:235-237; Gosselain 1998). This is the basic assumption of the study of technological style and how it is used as a methodology for studying socially complex ideas of communities of practice and ancient apprenticeship.

Besides their ubiquity in the archaeological record, ceramics are also unique in the amount of data they carry about the technical choices of prehistoric potters. Because of this, pottery has become the primary material class in studying technological style and applying it to learning frameworks and communities of practice theory. Ethnoarchaeological studies are especially helpful in testing assumptions about the way in which knowledge is transferred. Herbich (1989) explains that the Luo of Kenya have specific "micro-styles," or distinctive combinations of technological, formal, and decorative features characteristic of different potting communities between separate villages. These communities pass knowledge of how to manufacture a pot from older to younger members. Kramer (1997) also describes ceramic knowledge transfer in an Indian study area of Rajasthan as that of mother-daughter learning.

Not surprisingly, prehistoric pottery has been a perennial focus for the analysis of technological style in the archaeological record. Clay preparation techniques (Gosselain 1998), temper types (Goodby 1998), vessel size and shape and wall thickness (Chilton 1998), and vessel forming techniques (Gosselain and Smith 1995; Miller 1985; Welsh and Terrell 1998) have all been examined as ways that covert, sometimes unconscious information is transmitted with the teaching and learning of how to create a pot. Even the painting style itself has been uniquely studied, such as the patterning of brush stroke sequences on White Mountain Redware in east-central Arizona (Van Keuren 1999, 2001, 2005).

In summary, by studying how a pot is made through its technological characteristics it is possible to make inferences about group identity at both a micro and macro scale and to understand the boundedness and interactions between these groups.

In recent years, the analyses of the technological aspects of artifacts have gained prominence in the archaeological literature, with talk of technological style affecting many of the anthropological theories currently being used by Southwestern researchers, including those of "communities of practice" and other models of knowledge transmission. This section details how analyzing the technological aspects of pottery from Classic period sites on the Pajarito Plateau will both help to understand social identity at a macro and micro level, and also help to answer basic unresolved questions of procurement and manufacture of northern Rio Grande ceramics.

As stated earlier, measuring the technological style of pottery, or the unconscious and non-signaling aspects of a pot's design, can be used to infer group identity. In short, in the American Southwest where ethnohistoric documents inform researchers that society was matrilineal and matrilocal, pottery was performed and instructed and learned by women. Therefore, certain "ways of doing" in the form of procuring raw materials (locations or in their mixtures), shaping a pot, mixing pigments, painting the design, and firing the final product will be similar within communities of practice, or what has become known as "potting communities" (Fenn et al. 2006). These special technological characteristics have been identified and measured in many ways. This project has focused on four characteristics: vessel wall thickness, vessel size and shape, temper type, and paste composition (on a crude scale by 20x microscope and paste color via Munsell© color classification). Samples were also selected for future compositional analyses of both chemical (using inductively coupled plasma-mass spectrometry) and mineralogical (using petrographic analysis).

The analysis of the technology of ceramics in the American Southwest is nothing new. Anna Shepard pioneered the use of optical petrography in understanding the provenance and material properties of pots in the first half of the 20th century. One of her most famous early studies was the analysis of pottery excavated at Pecos Pueblo by A.V. Kidder in the 1920s and 1930s. Her study (1936) examined not only ceramics produced at the site, but also those that were imported from other areas. She focused on the biscuitware series, and attempted to not only source the production area of the pottery, but also the technological steps that must have gone into making the pot, ideas that could fit under the rubric of *chaînes opératoires*. Interestingly, her study appeared so thorough that little if nothing has been written in succeeding years about the technology of the biscuitwares. These ideas have been applied to earlier periods on the Pajarito Plateau, however. Wilson and Castro-Reino (2005) used both the microscopic and petrographic analyses described above to understand differences or similarities in potting style amongst Santa Fe Black-on-white ceramics from Coalition period sites. They successfully interpreted the use of unique geologic resources from four sites as indicating local production, even in the face of a widely used regional painted tradition. These same problems have also been addressed across the entire Pajarito Plateau using a combination of microscopic and painted style analyses (Ruscavage-Barz 1999, 2002).

As noted by Mera (1932) and others, the biscuitwares were produced with a unique dark paste that fired to a light gray color and were tempered with volcanic tuff. On further petrographic examination, Shepard (1936:487) found this to be almost entirely true, with few other inclusions apart from quartz or feldspar grains, which she attributes to be naturally occurring in the clay. Other petrographic analyses revealed that the paste was unusually hard and had a preponderance of voids leaving the ceramics weighing less per volume than paste from contemporary wares. Refiring suggested that the pots were fired in an oxidizing (but not fully) environment at approximately 800°C.

Using her understanding of the geology of the northern Rio Grande, Shepard concluded that both the clay and temper used to make biscuitware originated in the Chama District, and hence were the product of local potters. The amounts of the ware found at Pecos were almost 20 percent of the assemblage (Kidder 1936) and were thus traded extensively to the south.

Most importantly, Shepard was able to reconstruct the technological processes of which the biscuitwares were made. Shepard (1936:491) discovered that the ware was unusually standardized in vessel form and design style. This has implications that will be discussed below. One of her main research questions was: what makes the paste so light and porous? Was it the kind of tempering material, the quality of the clay, the method of firing, or a combination of all three? And why would potters want these types of properties?

When examining local clay and temper from the Chama District, Shepard (1936:496) found that the firing temperature was unimportant to the porous nature of the ceramic, and that certain local clays and tempers were responsible for these properties. These tempers occurred in volcanic tuff outcroppings throughout the district, and the local clays that were believed to be procured for ceramic production were composed of high quantities of tuff. Using workability tests, Shepard also found that the clays necessary to make biscuitwares were extremely difficult to use, and based on this she made the inference that these clays were selected not for their ease of use in potting, but for their fired characteristics. But why use these types of clays and tempers? Shepard (1936:497) proposed that these materials, when fired, allowed for a dark gray paste that extenuated the black mineral paint well, creating an appearance unlike any other black painted pottery. In essence, the product's quality and visual appearance compensated for its difficulty in manufacture, perhaps giving worth to the vessel due to the skill and effort invested by the potter.

I have found no technological analyses of any of the other Classic period wares in the Tewa area, including the Pajarito Plateau that is as in-depth as Shepard's (1936) study of the biscuitwares. What is known about Potsuwi'i Incised and the micaceous and corrugated wares has been already stated in overviews by Mera (1932) and Wendorf (1953), as well as a recent study by Curewitz (2004a).

Basic technological understanding of the process of manufacture is imperative in understanding communities of practice and hence identity, as well as the mode and nature of craft production. Because no researchers have made any overall synthetic inferences on the ceramic technology from the Tewa area since the 1930s, the analyses in this report have attempted to add to the understanding of the nature and changes of biscuitware technology. Due to time and money constraints, as well as the limited scope of this project, the synthetic overview that is so needed is not produced here. Rather some interesting trends and characteristics were observed that will help future researchers to better understand the technological considerations of northern Rio Grande pottery. Data on temper and refiring oxidation experiments are summarized below. Although the interpretations may be misguided or faulty, the hope is that the data will be of some use.

The recording of temper attributes can assist in the inference of many archaeological problems, including craft production and specialization, prehistoric economics, and ceramic technology. However, one important observation is immediate before any future statistical and spatial analyses: temper inclusions in the biscuitwares are *extremely* variable. This high degree of variability is not stressed in many past writings (Kidder 1936; Mera 1932, 1935; Wendorf 1953), but has been described in more recent publications (Gauthier 1987a; Habicht-Mauche 1993). From the analysis of both Abiquiu and Bandelier Black-on-gray ceramics from both Otowi and Tsirege, one thing is striking: there is much more than tuff included in the paste. This includes quartz sand, but also to a lesser degree, volcanic and plutonic inclusions. Perhaps the sand was part of the raw clay material and was sorted out by some potters but not others? Or perhaps this is a function of time? Or maybe this is indicative of pottery made in other places and imported into sites on the Pajarito Plateau. Based on surface contexts with no established chronological control, these questions are impossible to answer, although it is likely that this technological aspect of making biscuitware pottery is socially meaningful. As for the additional inclusions of volcanic and plutonic material, this is likely indicative of pottery with provenance outside of the immediate area of the two studied pueblos. This is especially the case with the plutonic inclusions, although this will be further resolved with petrographic and chemical analyses.

To understand the provenance of the clay material itself, clay oxidation (refiring) analysis were performed on both Abiquiu and Bandelier Black-on-gray bowl sherds from both sites. This analysis was built on the work of Gauthier (1987a) who proposed that from refiring experiments from Bandelier Black-on-gray from Howiri, a large Classic period pueblo along the Rio Ojo Caliente (a tributary to the Rio Chama and one of the northernmost prehistoric Tewa pueblos), clay sources changed through time. He describes a general trend that was also observed by Shepard (1936) that clay sources gradually changed from light yellow clay to a darker yellow.

Of course, the surface contexts from Otowi and Tsirege do not have the luxury of chronologically controlled stratigraphy. However, when Gauthier's color chronology is applied to Bandelier Black-on-gray bowls from Tsirege, where this report has interpreted that the eastern and northern roomblocks were the latest occupied architecture at the site with the western roomblock slightly earlier, it does not hold up (Table 77.23). Perhaps this is due to the mixed contexts of these surface assemblages, or maybe (and most likely) that the potters on the Pajarito Plateau have access to different clay sources than their contemporaries to the north.

Table 77.23. The application of Gauthier's (1987a) clay oxidation color chronology based on Bandelier Black-on-gray ceramics at Tsirege.

Unit	Occupation	Roomblock	5YR (later)	7.5YR (earlier)
A (*n* = 34)	Later	Eastern	97%	3%
D (*n* = 26)	Later	Northern	42%	58%
B (*n* = 40)	Earlier	Western	60%	40%

The clay oxidation colors stated earlier in this report are representative of different clay sources, as the color reflects the amount of iron and hence the source's geological signature. There is a great deal of variability within the said analysis, and although no interpretations of provenance can be made until clay sources are evaluated, there was probably biscuitware being produced in multiple pueblos in the Tewa area and not just at one locale. The same is true with the variability in temper sources, and although there is no clear correlation between temper type and oxidation color, these data suggest that there is a great deal of potential in understanding which pueblos are producing pottery, the nature of exchange relationships and pottery mobility, and what technology can tell us about group identity.

Craft Specialization

Craft specialization is part of the larger method and theory addressing craft production, which "are a fundamental part of archaeological inquiry in that they are central to the reconstruction of ancient lifeways and the explication of sociocultural evolution" (Costin 2002). If the record of prehistoric peoples is inherently materialistic, then understanding how these artifacts are made and distributed can illuminate not only the actions of the craftspeople, but also those of their societies in general. The ways in which craft production has been characterized and analyzed has a long history in the field, but generally focuses on typologies, modes of production, parameters of variation, and specialization. Costin's (1991, 2002) view that studying a production system as an integrated whole that accounts for all actions and variables between craftspeople, technology, artifacts, exchange, and distribution is regarded as completely appropriate for this study, hence the heavy emphasis on technology. However, to address the more specific problems of identity and areas and intensity of production based on the ceramic assemblage, I focus here on craft specialization.

In essence, specialization of craft production means that "fewer people make a class of objects than use it" (Costin 2002:276). Although traditionally specialization has been used to explain and interpret cultural complexity, it has more recently been used in small-scale societies to infer ritual specialization and group identity and cohesiveness (Mills and Crown 1995). Costin (1991) has formulated four parameters in which to view craft production, in which specialization can be analyzed. The first is the *context* of production, which reflects the nature of the demand for a particular good. The second is *concentration* of production, which describes the spatial relationship between producers and consumers. The third is *constitution* of the production unit, which describes the group size and social relations of those individuals who regularly cooperate to produce a recognized corpus of goods (Costin and Hagstrum 1995). This is a continuum with one end being the household group and the other being the workshop. And the fourth parameter is the *intensity* of production, which describes the relative amount of time workers put into craft production in relation to other economic tasks.

These four parameters can be measured in various ways to understand the context, nature, and scale of craft specialization, which are often contextual to the artifact assemblage. The main advantage of a holistic approach to production is that is accounts for many kinds of variation and does not measure whether there is a presence or absence of specialization, but rather what kind of specialized production and by whom. After these questions are answered it is possible to infer what these newly found answers can tell us about social and technological identity.

As stated above, the study of ceramic craft specialization is helpful in understanding group identity and social boundaries. Prior work on the Pajarito Plateau used measurements of standardization and efficiency in pottery decoration. Melissa Hagstrum (1985) analyzed 12 Classic period Biscuit B bowls from Otowi (LA 169) and concluded that due to brush-stroke sequences used on the bowls, the painting style was increasingly standardized and more efficient than prior pottery. She uses this evidence to propose increasing ceramic specialization into the Classic period, which is concurrent with observations made by Kidder (1917), Shepard (1936), and Mera (1932, 1935).

Hagstrum's study used whole vessels from Otowi to present an accurate, yet minimal analysis of standardization and specialization of Classic period pottery. For comparison with Hagstrum's data and due to a large sample size of rim sherds, Bandelier Black-on-gray bowl rim sherds were compared between Otowi and Tsirege. Two measurements were used in this comparison: vessel size (the diameter of the bowl opening) and interior framing line width.

Vessel size and standardization differed between the two sites (Figure 77.10). In general, the mean size of Bandelier Black-on-gray bowls from Otowi was smaller than those from Tsirege (Table 77.24). Also, Tsirege had a much smaller standard deviation of bowl size than Otowi. If consistency of pottery is a sign of standardization, Tsirege is producing more standardized vessels, which could be interpreted as a higher degree of craft specialization.

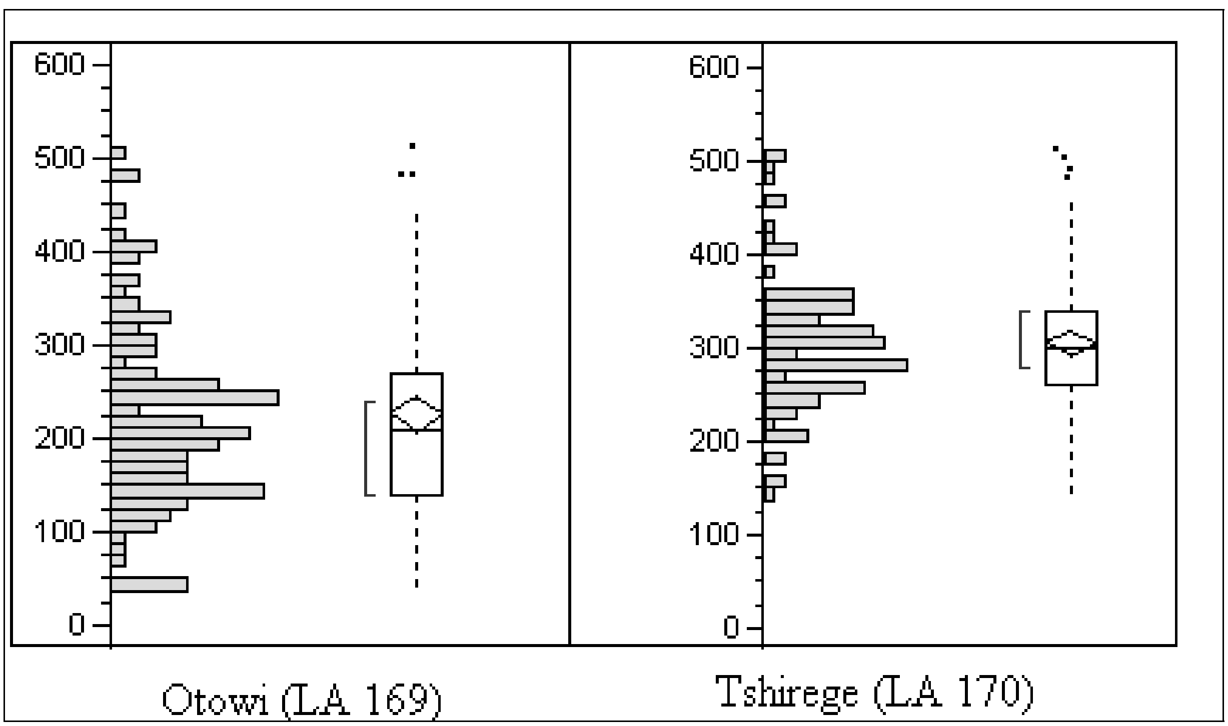

Figure 77.10. Distribution of rim diameter of Bandelier Black-on-gray bowls between Otowi and Tsirege.

Table 77.24. Statistics of the distribution of rim diameter of Bandelier Black-on-gray bowls between Otowi and Tsirege.

Site	# of Samples	Mean	Std. Dev.	Std. Err. Mean	upper 95% Mean	lower 95% Mean
Otowi	119	226.05	109.52	10.04	245.93	206.17
Tsirege	99	305.05	72.38	7.27	319.49	290.61

The same sorts of relationships between Otowi and Tsirege were also seen when comparing the width of the interior framing line between the sites (Figure 77.11). The standard deviation of framing line width was much smaller than that of Otowi, also suggesting specialization of pottery production (Table 77.25).

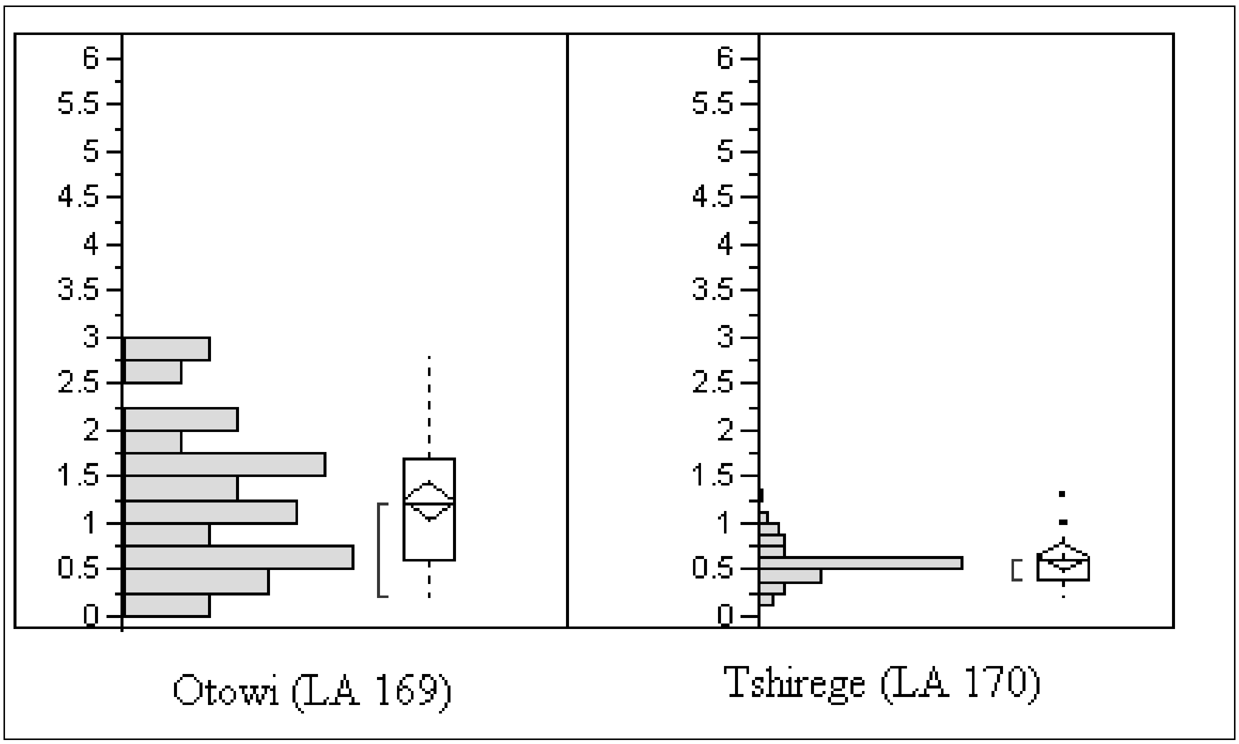

Figure 77.11. Distribution of interior framing line width of Bandelier Black-on-gray bowls between Otowi and Tsirege.

Table 77.25. Statistics of the distribution of interior framing line width of Bandelier Black-on-gray bowls between Otowi and Tsirege.

Site	# of samples	Mean	Std. Dev.	Std. Err. Mean	upper 95% Mean	lower 95% Mean
Otowi	47	1.24	0.75	0.11	1.46	1.02
Tsirege	76	0.65	0.65	0.07	0.80	0.50

With the limited context of this study it is not possible to address all of Costin's (2001) parameters of specialization. However, it does appear that Tsirege is producing standardized

Bandelier Black-on-gray pottery not unlike what was observed by Hagstrum (1985), at least compared to the Bandelier Black-on-gray pottery from Otowi. This argument is bolstered by the fact that there appears to be less variability in clay sources, as well as temper types, in the Tsirege assemblage as seen in the results of the clay oxidation experiments and microscopic analysis described earlier in this report.

Perhaps the degree of variation in the measured attributes of biscuitware pottery from Otowi results in regional exchange of ceramics whereas Tsirege is producing much of its own pottery, and probably much of the pottery for the northern Pajarito Plateau. Although this report cannot account for technological changes through time, it is most likely that there are real differences between biscuitware at the two contemporary Classic period pueblos. The importance of Tsirege as a central pueblo is also suggested by the larger rim diameter of the vessels found at the site, which is indicative of feasting events. These events brought people from the entire region together for social and most likely ritual purposes.

The importance of Tsirege as a central, large, and chronologically late occupied pueblo appears to be a fruitful research topic for future studies. The site is described multiple times in many Tewa oral traditions (Parsons 1994 [1926]). This research will aid researchers in understanding the scale and logistics of prehistoric Tewa social organization.

CONCLUSIONS

This project has sought to analyze and interpret both decorated and utility ceramics from two Classic period sites on the northern Pajarito Plateau. For the first time, the ceramic collections made by the PARP have been fully analyzed and the data made available to interested researchers. Interpretations have been made on the occupational sequences of both Otowi (LA 169) and Tsirege (LA 170), as well as their approximate dates of occupation in comparison to the northern Rio Grande chronology. Additionally, data have been generated relating to technological aspects of this pottery in which tentative interpretations have been made dealing with social identity, ceramic technology, and craft specialization of prehistoric Tewa potters from two large and understudied pueblos.

The following points summarize the findings and interpretations of this report:

1. Using relative frequencies of ceramics from surface contexts, the occupational sequence of both Otowi and Tsirege has been proposed.

2. Using these same frequencies, both Otowi and Tsirege have been situated chronologically within the culture history of the northern Rio Grande region.

3. Due to higher than expected frequencies of glazeware ceramics found at Tsirege, a new model of boundary permeability has been proposed for the prehistoric Tewa/Keres ethnic division across the Pajarito Plateau.

4. Both microscopic temper and clay oxidation experiments on biscuitware from Otowi and Tsirege suggest high variability in use of materials and technology of production, suggesting that these wares were being produced by many potters across the Tewa pueblos.

5. When comparing ceramic attributes of rim diameter and framing line width, as well as variability in the use of clay sources between Otowi and Tsirege, it appears that Tsirege produced much more standardized vessels. This suggests that the pueblo was an important producer of pottery for the region.

6. The rim diameters of Bandelier Black-on-gray pottery from Tsirege was larger than that of Otowi, suggesting that Tsirege was a pueblo of central importance in the region as evidence of feasting events.

This project has raised more questions than it has answered (the sign of interesting data) and it is hoped that these data will be helpful for future research in understanding how Classic period sites on the northern Pajarito Plateau interacted between and within themselves and with the larger Rio Grande region.

CHAPTER 78
AN ANAYLSIS OF MICACEOUS POTTERY FROM THE PAJARITO PLATEAU

B. Sunday Eiselt

INTRODUCTION

The current study is based on examination of 107 sherds representing 22 vessels distributed among four sites dating to the early Historic and Homestead periods at Los Alamos National Laboratory (LANL). This count includes nine sherds from the Serna Homestead (LA 85407), eight from the McDougall Homestead (LA 131237), four from one Apache campsite (LA 85864), and seven from a second Apache campsite (LA 85869). Seventy-seven sherds representing one isolated pot drop were also analyzed. With the exception of one likely commercial terracotta vessel, all ceramics were locally made and represent well-defined and dated northern Río Grande ceramic types attributed to Pueblo, Jicarilla Apache, and Hispanic potters. Examination of 164 clay fragments recovered from LA 131237 indicates that all of these pieces represent burned and unburned adobe plaster.

CERAMIC TYPE IDENTIFICATIONS

Ceramic analysis included examination of each sherd using a 40x Zoom microscope and standard measurement charts and templates. Sherds were classified according to form and origin of production through observations on shape, color, paste, and surface finish. Microscopic analysis was used to identify paste and surface characteristics. Tewa and Hispanic plainwares were identified based on typologies developed by Olinger (1992) and others (Carrillo 1986, 1997; Levine 1990, 2004). Micaceous sherd type identifications were based on descriptions provided in Carrillo (1997), Dick (1965a, 1968), Gunnerson (1969), Lang (1997), and Warren (1981). The characteristics used to define micaceous and plain paste ceramics are indicated in Tables 78.1 through 78.3, and additional descriptions may be found in Eiselt (2005, 2006).

Twenty-four historic ceramic types are currently defined for the northern Rio Grande region. These include plainware, decorated, and micaceous ceramics made by Pueblo, Jicarilla Apache, and Hispanic potters. Plainware types include Tewa and Hispanic redwares (17^{th} century to present), San Juan Red-on-tan (AD 1700 to present), Casitas Red-on-brown and Casitas Red-on-brown smudged (Hispanic: pre-AD 1672 to 1890), Kapo Black (Santa Clara Pueblo: 17^{th} century), Tewa and Hispanic polished blackwares (17^{th} century to present), and Carnué Plain (Hispanic: AD 1700 to 1895). Decorated wares include Tewa, Pojoaque, Ogapoge, Powhoge, and Nambé Polychrome and Powhoge Black-on-red. Micaceous types encompass residual paste and slipped varieties including Cimarron Micaceous (Jicarilla Apache: AD 1730 to present) and Ocate Micaceous (Jicarilla Apache AD ~1550 [1600]–1730), Taos Micaceous (AD ~1550 [1730] to present); Peñasco Micaceous and Vadito Micaceous (Picurís: ~1550 [1690] to present), Tewa Micaceous and Micaceous Slipped (17^{th} century to present), and Petaca Micaceous and El Rito Micaceous Slipped (Hispanic: AD 1690–1890).

Table 78.1. Distinguishing characteristics of Pueblo and Hispanic plainwares (from Carrillo 1997; Dick 1968; Levine 1990, 2004; Olinger 2004).

Ceramic Type	Forms	Surface Treatment	Paste Characteristics
Tewa Red and San Juan Red-on-tan	Large water and storage jars (unslipped, unpolished interiors). Bowls and soup plates also present. Flanged plates with well-defined flanges	Slip on exterior does not extend over rim and on to interior. Slip band below rim at shoulder; above band is polished not slipped (usually redware). Applied with a brush, producing a fine line with an even edge	Vitric tuff temper, often with pumice and/or fine sand mixed in. Soft paste with thicker walls (fired at lower temperatures?)
Casitas Red-on-brown and smudged	Bowls and soup plates dominate but larger jars also present. Flanged plates with poorly defined flanges	Thin slip not highly polished (streaky appearance), unevenly applied (with a rag?) leaving uneven edges between the band and the polished surface. Bowls: slipped on interior, slip extends to a narrow band on the exterior. Jars: narrow band of slip on exterior extends over the rim and to the interior. Decorations also include occasional scrolls, circles, and bulls-eyes on bowl interior	Vitric tuff temper, often with pumice and/or fine sand mixed in. Soft paste with thicker walls (fired at lower temperatures?)
Tewa polished blackwares	Large water and storage jars (unslipped unpolished interiors). Bowls and soup plates also present. Flanged plates with well-defined flanges	Thick slip, well-polished on exterior and interior of bowls with some crazing and cracking evident on the surface of thick slip pieces	Fine to medium sand temper, occasionally a very small amount of tuff or pumice. Friable but glassy paste (fired at higher temperatures?)
Hispanic polished blackwares	Bowls and soup plates dominate but larger jars also present. Flanged plates with poorly defined flanges	Thin slipped not highly polished (streaky appearance), unevenly applied leaving uneven edges between the band and the polished surface. Bowls: slipped on interior, slip extends to a narrow band on the exterior. Jars: narrow band of slip on exterior extends over the rim and to the interior	Vitric tuff temper, often with pumice and/or fine sand mixed in. Soft paste with thicker walls (fired at lower temperatures?)

Table 78.2. Distinguishing characteristics of micaceous slipped pottery (from Dick 1968; Eiselt 2005; Olinger 1992).

Characteristics	**Vadito Micaceous**	**Tewa Micaceous Slipped (Santa Clara, San Ildefonso)**	**Tewa Micaceous Slipped (San Juan)**	**Tewa Micaceous Slipped (Nambe/ Pojoaque/ Tesuque**	**El Rito Micaceous Slipped**
Forms	Large and medium-sized bowls and jars, storage vessels	Large and medium-sized bowls and jars, storage vessels	Large and medium-sized bowls and jars, storage vessels	Large and medium-sized bowls and jars, storage vessels	Large and medium-sized bowls and jars, storage vessels
Interior Surface finish/color	Sanded and polished raw clay (characteristic shimmering appearance). Reduced	Thick to thin reduced Santa Fe formation clay slip, highly polished. Dark brown to black in color (no mica)	Thick to thin reduced Santa Fe formation clay slip, highly polished. Dark brown to black in color (mica rare to common)	Thin oxidized plain clay slip. Mica content much greater than San Juan, Santa Clara, and San Ildefonso	Thick to thick reduced Santa Fe formation clay slip, highly polished. Dark brown to black in color (mica rare to common)
Exterior Surface finish/color	Fine silvery muscovite mica wash (reduced)	Golden yellow, orange, or gray primary micaceous clay slip (oxidized and reduced)	Golden yellow, orange, or gray primary micaceous clay slip (oxidized and reduced)	Distinctive salmon-pink to salmon-orange primary micaceous clay slip (oxidized)	Primary micaceous clay slip
Clay Paste	Muscovite mica, quartz mica schist	Plain (Santa Fe formation) with vitric tuff, pumice, and glass sherds that are easily mistaken for mica. Fine rounded sands common	Plain (Santa Fe formation) with moderate amounts of muscovite mica (biotite rare). Variably sized arkosic sands dominant.	Plain (Santa Fe formation) with abundant muscovite and biotite. Poorly sorted arkosic sands present	Plain (Santa Fe formation) with abundant arkosic sands (tuff, pumice and glass rare)
Core	Black to dark gray, laminated and coarse	Gray and dense (to ropey) or slightly granular with rounded aplastics	Black to burnt umber, granular and friable paste	Gray to light gray granular and friable paste	?

Table 78.3. Distinguishing characteristics of micaceous pottery (from Eiselt 2005).

Characteristics	Petaca Micaceous	Peñasco Micaceous	Taos Micaceous	Tewa Micaceous	Cimarron Micaceous
Vessel Forms	Small atole cups, jars, and bowls common, medium to large storage vessels and jars present but rare, pinch pots, candlestick holders, comales	Small bowls and jars, large storage vessels and jars, pitchers, figurines	Small and large bowls and jars frequently with multiple appliqués and spouts, pitchers, figurines	Small bowls and jars common, pitchers, figurines	Small and large bowls and jars, bag-shaped jars, medicine bowls, pitchers, pipes, pinch pots, figurines, appliqués common at neck and shoulder
Rim and Neck Forms	Everted (acute) on small vessels, gently everted on large vessels. Occasionally thickened neck wall below rim, inverted rim bowls common	Everted (acute) on small vessels, gently everted on large vessels, inverted rim bowls common	Gently everted to straight, inverted rim bowls common	Gently everted to straight, inverted rim bowls common	Gently everted to straight bowls and jars
Rim Margin	Undulating (uneven) and fluted/crenulated	Undulating (uneven) and fluted/crenulated	Undulating (uneven) and fluted/crenulated, indentations common	Undulating (uneven) and fluted/crenulated	Cut and straight (common). Occasionally fluted or crenulated (accompanied by y-shaped lip profile)
Lip Profile	Round (occasionally bulbous and thickened) and subangular	Round to tapered	Round to subangular with parallel-sided neck below rim	Tapered, round, subangular	Flat (square), expanding (keeled and y-shaped), sanded lip face,

Characteristics	Petaca Micaceous	Peñasco Micaceous	Taos Micaceous	Tewa Micaceous	Cimarron Micaceous
					occasional corn-cob indentations
Base Configuration	Rounded to flat	Conical to subangular, flat	Conical to subangular with occasional acute concave center	Rounded to flat	Conical to subangular with occasional slight concave center
Corn-cob Scrape Marks	Occasional, obliterated	Occasional, obliterated	Occasional, obliterated	Rare to absent, obliterated	Pronounced on interior and exterior necks and rims, partially obliterated through application of slip and/or slurry
Sanding	Heavily sanded and unslipped on some interiors, otherwise rarely sanded	Light sanding especially at interior and exterior rims	Light sanding especially on interior bowls, otherwise sanding rare	Light sanding especially at interior and exterior rims, occasionally highly sanded with mixed clays	Light sanding especially at interior and exterior rims
Slip/Slurry	Thick and uneven slurry on interior and exterior (slurry covers protruding aplastics or thin watery slurry that is prone to cracking and erosion)	Fine "silvery" muscovite mica wash (characteristic shimmering appearance)	Usually thick, even application	Rare with occasional presence of ochre	Usually thick, even application, with occasional presence of ochre
Buff/Polish	Light buffing only on some pieces. Wipe marks are present and pronounced on most pieces	Light buffing	Light buffing with a tendency towards high gloss finish on later pieces (20th century)	Light buffing	Moderate buffing especially on interior and exterior neck and rim

Characteristics	Petaca Micaceous	Peñasco Micaceous	Taos Micaceous	Tewa Micaceous	Cimarron Micaceous
Surface Compaction	Slight to none with most pieces rough to the touch	Slight to none with most pieces rough to the touch. Occasionally compacted through polishing	Slight to none with most pieces rough to the touch. Occasionally compacted through polishing	Slight to none with most pieces rough to touch. Occasionally compacted through polishing on interior bowls	Highly compacted and smooth to the touch with 'waxy' appearance
Smudging	Common to rare on interiors and exteriors	Common on interiors and exteriors	Common on interiors and exteriors	Rare with light gray to salmon-colored or orange oxidized clay	Common to rare on interiors and exteriors
Aplastic Size and Sorting	Coarse paste with large aplastics and poorly sorted aplastics (poorly cleaned clay). Aplastics range from 0.5 to 3.0 mm with large aplastics common in small, thin-walled vessels	Fine paste with small well-sorted aplastics (screened?). Mica "spalling" common on surfaces of some pieces	Fine paste with small well-sorted aplastics (screened?). Mica "spalling" common on surfaces of some pieces	Fine paste with small well-sorted aplastics (screened?). Occasional dense gray paste (evidence of clay mixing)	Generally well-sorted. Aplastic size varies with the size of the vessel
Aplastic Constituents	Quartz, muscovite mica, micaceous schist, Vadito group accessory minerals with hematite common	Quartz, muscovite mica, micaceous schist, Vadito group accessory minerals with garnet and feldspars common	Quartz, muscovite mica, micaceous schist, Vadito group accessory minerals with garnet and feldspars common	Quartz, muscovite mica, micaceous schist, Vadito group accessory minerals with biotite common	Quartz, muscovite mica, micaceous schist, Vadito group accessory minerals
Clay Constituents	Primary micaceous clay (no evidence of mixing)	Primary micaceous clay (evidence of mixing rare)	Primary micaceous clay (mixing rare)	Primary micaceous clay with some evidence of mixing w/ plain clays	Primary micaceous clay (evidence of mixing rare)

The ceramics identified for this project represent a limited but representative subset of these types including Cimarron Micaceous, Tewa and El Rito Micaceous Slipped, Tewa and Hispanic polished blackwares, and one prehistoric black-on-white sherd. Several indeterminate body sherds also were tentatively assigned to community based on similarities with known types. Nearly 91 percent of the total assemblage ($n = 96$ or 59 percent of the minimal vessel count) are ceramics made from primary micaceous clays or ceramics slipped with mica clay. Eight percent ($n = 9$ or 41 percent of the minimal vessel count) represent plain paste varieties.

SOURCE PROVENANCE DETERMINATIONS

Source provenance determinations for the LANL ceramics are based on visual examination of ceramic cross-sections and published descriptions of ceramics. Plain paste and micaceous ceramics may be assigned to producer community based on clay and temper identifications and ethnographic references to clay source utilization. Olinger (1992, 2004) has described the characteristics of plain paste temper that separate ceramics by Tewa Pueblo with a major axis of difference between Pueblos east of the Río Grande and those to the west. San Juan, Pojoaque, and Tesuque ceramics contain higher abundances of finely divided muscovite and biotite mica as a natural constituent of the Santa Fe Group clays used in ceramic production. These clays border a portion of the Sangre de Cristo Range that contains Precambrian mica-schist outcrops (as discussed below). Santa Clara and San Ildefonso ceramics are made from Santa Fe Group clays that rarely contain mica but instead are mixed with Tertiary volcanic sources to the west.

Pueblo plainwares are typically tempered with vitric tuff with smaller amounts of pumice, glass, and/or fine sand. These elements also occur as natural constituents of clays. Hispanic plainwares, in contrast, have fine to medium sand temper with occasional tuff or pumice (Carrillo 1997; Levine 1990; Olinger 1992). Pueblo pottery also is softer and the pastes are not as glassy as Hispanic types. Olinger attributes differences in paste fabrics to firing practices with higher temperatures achieved in Hispanic kilns (see also Carrillo 1997). D. Levine (2004:167) states, however, that the pastes of Hispanic wares are generally more friable than the tuff-tempered Tewa wares due to higher amounts of coarse sand temper. Geochemical analysis nonetheless suggests that Hispanic and Pueblo plainwares were made with the same geologic clays (Olinger 2004:137). Differences in paste related to Pueblo and Hispanic plainwares also extend to mica-slipped varieties, which can be further distinguished based on the color and aplastic constituents of the slip.

The micaceous clays of the northern Río Grande are located in the Sangre de Cristo Mountain Range and southern San Juan Mountains. Specifically, they occur in several Precambrian-cored topographic uplifts including the Brazos (Tusas Range), the Sangre de Cristo (Taos, Picurís, Truchas, and Santa Fe Ranges), and the Río Mora Uplifts (Rincon Range and El Oro Mountains) (Figure 78.1). The Precambrian complex is composed of metamorphic schists, quartzites, and other metarhyolites and metasedimentary rocks. Muscovite is the most common mica type found in these formations, occurring in pegmatite dikes and in quartz-muscovite schists (Austin et al. 1990). The largest deposits are associated with a middle Precambrian rock sequence called the Vadito Group, which contains an average of 38 percent to 50 percent muscovite by weight (Bauer 1988; Beckman 1982:37; Gresens and Stensrud 1974). Translucent and iron-stained quartz, feldspar, and quartz-mica schist account for 40 percent to 60 percent. Accessory minerals occur in trace amounts and include magnetite, biotite, hematite, rosy quartz, white quartz, and garnet primarily. Micaceous clay source districts and source areas are defined by regional variations in Vadito Group lithologies including trace element geochemistry of clay (Eiselt 2006). Figure 78.1 shows the locations of clay source districts and sampled source areas for comparison to LANL ceramics. Table 78.4 identifies major differences in trace mineral and rock abundances and other characteristics of micaceous clay that distinguish major source districts (Petaca, Picuris, Cordova-Truchas, and Mora) based on visual examination alone. These characteristics may be compared to ceramic pastes to determine source provenance of finished pottery. Source determinations, in turn, may be related to ethnographic accounts of clay harvesting practices by pottery producing community (Table 78.5).

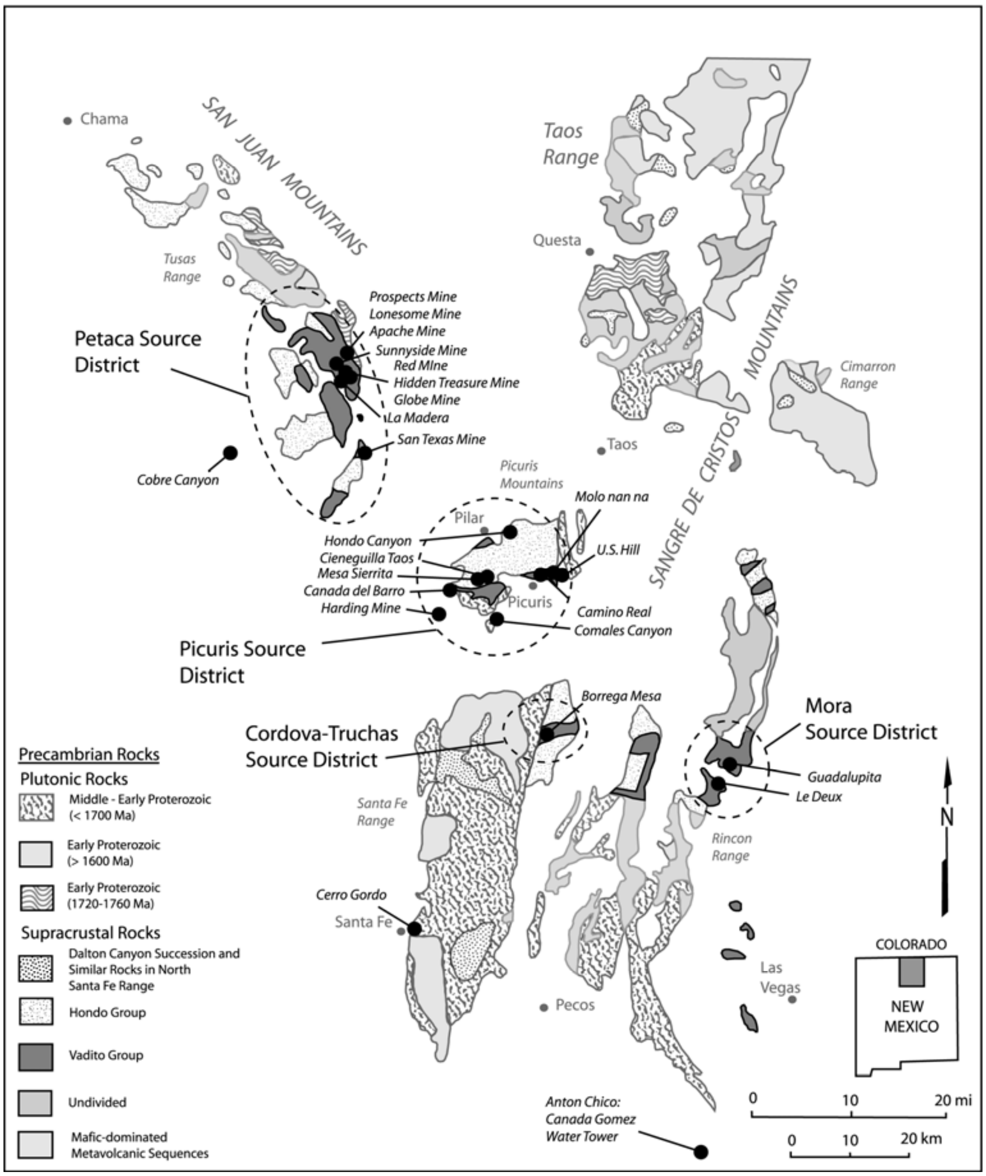

Figure 78.1. Map showing locations of predefined source districts and source areas (Redrawn from Bauer and Williams 1989).

Table 78.4. Summary of diagnostic traits for source districts (from Eiselt 2006).

High Abundance	Low Abundance	Other Characteristics	District
Quartz-mica schist (dominant). Hematite (large, common). Rosy quartz	White quartz. Booked biotite. Garnet	Medium-fine texture (mica and aplastics). Poorly sorted, angular aplastics. Red to pink muscovite	Petaca
Magnetite (dominant). Biotite (common). Garnet. Hematite (small, rare)	Quartz mica schist. Rosy quartz. White quartz (none).	Fine texture (mica and aplastics). Subangular to round aplastics. White to green muscovite	Picuris
Biotite (dominant). Magnetite. Booked biotite.	Quartz-mica schist (none). Garnet (none). Hematite.	Coarse texture (mica and aplastics). Poorly sorted, angular aplastics	Cordova-Truchas
Magnetite (dominant). Biotite. Quartz-mica schist.	Garnet (none). Booked biotite.	Coarse texture (mica and aplastics). Poorly sorted, angular aplastics	Mora

RESEARCH QUESTIONS

Ceramic analysis focused on answering several research questions related to dating historic sites and establishing the cultural affiliations of pottery. Specifically, the relative abundances of ceramics of different types were examined to investigate the timing of homestead and tipi ring occupations and the nature of ceramic exchange between site occupants and neighboring communities.

Temporal changes in the relative abundances of plain, decorated, and micaceous wares have been noted by several researchers working in the northern Rio Grande. Moore (1996) relates these changes to two factors: style and economy. The use of locally produced pottery varied as access to imported cooking, serving, and storage vessels changed after the colonial period. Tewa polychromes replaced glazewares by the late 1700s. Similarly, polished redwares comprise a large percentage of early colonial period assemblages by comparison to blackwares and decorated wares. Redwares waned in popularity through time, while blackwares increased until they were the most common types in the Santa Fe Trail and Railroad periods (ca. 1820s to 1890s). The use of decorated wares also decreased significantly during this time (D. Levine 1990, 2004; Moore 1996:149). Work by Carrillo (1997) and Levine (1990) in the Abiquiu area suggest that increases in blackwares may be explained, in part, by increased ceramic production in Hispanic villages during the 19th century.

Micaceous wares followed a similar trajectory to that of the blackwares, becoming the second most common category of ceramics by the 1820s. Carrillo (1997:131) relates the popularity of micaceous pottery to preferences associated with the cooking qualities of micaceous wares, and Eiselt (2006) additionally attributes the proliferation of mica pottery to the presence of Jicarilla Apache potters in the Chama after the 1840s. The removal of the Apaches to the Dulce Reservation and the increased availability of commercial cooking and serving wares after the 1890s led to significant declines in local pottery manufacturing, including plainware and micaceous ceramics.

Relative abundances of plain, decorated, and micaceous ceramics thus may be used to date archaeological assemblages to major periods including the early colonial (ca. 1590 to 1700), the late colonial (ca. 1700 to 1821), the Mexican and U.S. Territorial periods (roughly 1821 to 1890), and the pre-New Mexico statehood period (ca. 1890–1912).

Ceramic assemblages also may be related to patterns of economic exchange and interethnic relations including village-based specialization and trade in subsistence and ceramic goods between women (Brody and Colberg 1966; Carrillo 1997; Dickey 1949:90–91; Eiselt and Ford 2007; Ford 1972; Levine 2004; G. Schroeder 1964:46–47; Swadesh 1974:41; Thomas et al. 1992). Hispanics were primary consumers of Indian-made ceramics, although several villages in the northern Río Grande also produced and traded their own pottery (Carrillo 1997). Hispanic assemblages thus provide direct evidence for the organization of ceramic distribution and the scale of production and trade by pottery community during the Historic period. Village assemblages are typically dominated by Pueblo and Jicarilla pottery with lesser amounts of Hispanic wares (Eiselt and Darling 2007). The homestead sites on LANL present an excellent opportunity to examine patterns of exchange in the more remote areas of the plateau, particularly as this relates to ceramic trade with the Jicarilla and San Ildefonso Pueblo.

CERAMIC DESCRIPTIONS

Ceramic type identifications by site are provided below along with brief interpretations of assemblage characteristics at the end of each section.

McDougall Homestead (LA 131237)

The McDougall Homestead, occupied from around 1907 or 1908 to 1942 or 1943, was owned by Hispanic and Anglo families sequentially for relatively short periods of time (McGehee et al. 2006). The ceramic assemblage is likewise attenuated but is indicative of this multi-cultural occupation. A total of eight sherds representing six vessels were recovered (Table 78.6). Sherds are attributed to Hispanic, Jicarilla, and Pueblo potters, and a single terracotta fragment likely represents a commercially manufactured vessel of unknown origin dating to the Anglo occupation. Complete descriptions are provided below along with type identifications and probable source determinations where appropriate.

Table 78.6. LA 131237 ceramic counts.

Ceramic Type	Ceramic Form	Total Sherd Count	Minimum Vessel Count
Cimarron Micaceous	Medium- to large-sized jar (24 cm orifice diameter)	1	1
Cimarron Micaceous	Small- to medium-sized jar (unknown diameter)	3	1
Hispanic Blackware	Small- to medium-sized jar (unknown diameter)	1	1
Peñasco/Tewa Micaceous	Bowl/jar	1	1
Indeterminate Micaceous	Unknown	1	1
Terracotta (Commercial)	Unknown	2	1
Total		**9**	**6**

Ceramic Descriptions

Field Specimen (FS) 179 represents a definite Cimarron Micaceous ceramic rim sherd. Diagnostic characteristics include rim form and surface finish. The vessel displays a nicely finished expanding rim profile with squared edges and slight keeling to the exterior. Vessel walls have been smoothed (either with the hands or a rough stone) and then slipped with a relatively thick micaceous slurry that was subsequently rag polished to a mat luster on the interior. Polish extends on to the lip face. The vessel appears to represent a medium to large cook pot with an orifice diameter in excess of 24 cm. The dominant minerals in the paste include angular and poorly sorted translucent yellow quartz, quartz mica-schist, and muscovite mica. Accessory minerals include some garnet and possibly magnetite. The specific array of minerals combined with particle sizes, sorting, and angularity suggest that the clay for this vessel came from the Petaca source district.

The FS 432 sample represents a definite Cimarron Micaceous vessel. This sample includes one rim, a neck, and a body fragment that all appear to be part of the same small- to medium-sized cook pot or olla. The lip of the rim is flanged or crenulated. The margins of the rim are subangular, with a slightly squared and expanding profile. The lip face displays a slight, longitudinal finger groove, which is diagnostic for Cimarron Micaceous. Vessel surfaces are smooth and nicely compacted but are not sanded or polished. A thin micaceous wash has been applied to the surface. Wipe-marks are visible as faint striations. Corn cob scrape marks are absent. The interior portion of the neck fragment contains a dark encrustation or film that is likely carbonized food residue, which typically builds up on vessel bases and necks through repeated use. The dominant minerals in the paste include subangular sand-sized quartz and feldspars and muscovite mica. Inclusions are relatively well-sorted and fine. Accessory minerals include garnet, hematite, and minor amounts of biotite. These minerals are apparent in cross-sections and on the surfaces of pieces. Hematite fragments are visible in cross-section as dark black (reduced) areas that also have diffuse margins. The specific array of minerals combined with particle sizes, sorting, and angularity suggest that the clay for this vessel came from the Picuris source district. The general lack of quartz-mica schist further eliminates Petaca as a likely source, and the lack of white quartz and abundant biotite likewise eliminates Cordova-Truchas.

FS 84 represents a likely Hispanic rim sherd. Diagnostic characteristics include surface finish and paste characteristics. The vessel is reduced and a slip has been applied to the exterior. This slip extends over the rim and to the interior. The slip is thin and poorly polished, and the margin of the interior band is irregular, suggesting application with a rag as described by Levine (1990) and Carrillo (1997). The vessel appears to represent a small- to medium-sized jar with an unknown orifice diameter. The dominant minerals in the paste include fine, sub-angular to rounded translucent quartz and feldspars with minor amounts of microscopic glass fragments. Paste and surface finish characteristics are consistent with Hispanic blackwares dating to the Territorial period in Hispanic sites near Abiquiu (e.g., see Carrillo 1997; Levine 1990).

FS 430 is a micaceous rim sherd that contains ambiguous diagnostic traits that prevent a good identification. Most of the characteristics are consistent with Picurís pottery, but Tewa manufacture cannot be ruled out. Vessel form could not be determined. The rim profile is rounded and slightly bulbous, and a thin micaceous wash has been applied to the surface but is not polished. Paste texture and aplastic constituents also are most similar to Picuris district clays. The paste texture is fine, laminated, and well-sorted. Dominant plastics include angular to sub-rounded quartz and muscovite mica. Accessory minerals include feldspar, garnet, and possibly magnetite. Biotite is absent and this rules out the Cordova-Truchas clay district as a possible source for the clay. The general lack of quartz-mica schist and hematite also seems to eliminate Petaca. However, the vessel has not been greatly reduced in firing, which is a good characteristic for Peñasco Micaceous, and the mica content is low relative to typical Peñasco sherds. Round rims and oxidized firings are common features of Tewa micaceous ceramics. Tewa Micaceous cannot be ruled out as a result.

The FS 190 micaceous body sherd also contains ambiguous diagnostic traits that prevent a good identification. Clay paste is similar to FS 430 and may be from the Picuris district, but this cannot be confirmed. Vessel surfaces are smooth and compacted. A micaceous slip has been applied to interior and exterior surfaces, but is not polished.

The two FS 190 terracotta body sherds are likely commercially made and date to the Anglo occupation of the site. The form of the vessel cannot be determined but may represent portions of a flower pot.

Summary

The LA131237 ceramic assemblage, although small, is relatively diverse with input from Jicarilla, Hispanic, and Tewa or Picuris potters. Locally made ceramics likely date to the Hispanic occupation of the site, whereas the terracotta fragments were probably deposited during the later Anglo occupation. The earlier Hispanic assemblage is consistent with other Chama Valley homestead sites dating to the U.S. Territorial period, which typically include a diversity of ceramics attributed to Jicarilla, Pueblo, and Hispanic potters. The Hispanic blackware vessel may have been made at the homestead or it was procured from one of the known pottery-producing Hispanic villages in the Chama such as Abiquiú.

Although the historic documents indicate that the McDougall Homestead was established in 1907 or 1908, the ceramic assemblage suggests that the area may have been occupied at a slightly earlier date. The presence of Cimarron Micaceous, in particular, suggests a pre-1895 occupation that may overlap with nearby Jicarilla campsites (LA 85864 and LA 85869). However, the Jicarillas did continue to produce and use micaceous pottery at Dulce as late as 1909 to 1920 and individual families also regularly left the reservation covertly up to the 1920s. These off-reservation forays included hunting, clay harvesting, trade, and visiting friends or family members who were adopted or married into Hispanic and Pueblo households, particularly at Taos, Picuris, Abiquiu, and La Madera and La Petaca. These visits seem to have dropped off significantly after the 1920s, once the government improved conditions on the reservation, including the introduction of sheep in 1918 and the establishment of better health and educational facilities. There are no documented cases of Jicarillas visiting homesteads on the LANL, although the Jemez district was one of the favored fall hunting grounds of the Olleros from the 1850s to the turn of the last century. Cimarron Micaceous vessels therefore may have been obtained by the Hispanic residents of the site through trade with Apache visitors some time between 1895 and 1920. The possible presence of Peñasco Micaceous ceramics also may be attributed to Jicarilla trade. According to Schroeder (1964:46–47), the Jicarilla Apaches traded pottery from San Juan and Picurís Pueblos to Hispanics living near the Chama and upper San Juan Rivers during the 19th century.

The general characteristics of the McDougall ceramic assemblage are consistent with 19th and early 20th century patterns of interethnic exchange in ceramics reported by Carrillo (1997), Moore (1996), Eiselt (2006), and Eiselt and Ford (2007). All of the vessels identifiable to form represent jars and cooking vessels. Ceramic types and proportions, particularly the prevalence of micaceous and blackware ceramics, can be attributed to the Hispanic occupation of the site some time before 1920 and possibly as early as the late 19th century. The terracotta vessel post-dates this occupation.

The Serna Homestead (LA 85407)

The Serna Homestead was occupied at a slightly later date than the McDougall homestead and this is reflected in the ceramic assemblage. The post-1913 date for the Serna Homestead is associated with a general lack of residual micaceous pottery (particularly Cimarron or Peñasco

Micaceous) and the nearly exclusive presence of mica slipped and plainware ceramics made by Tewa potters. A total of 10 sherds representing nine vessels were recovered (Table 78.7). A total of 164 fragments of burned and unburned adobe plaster also were recovered from the Area 1 cabin and the Feature 1 horno. Complete descriptions are provided below along with type identifications and probable source determinations where appropriate.

Table 78.7. LA 85407 ceramic counts.

Ceramic Type	Ceramic Form	Total Sherd Count	Minimum Vessel Count
Tewa Blackware (San Ildefonso, Santa Clara)	Unknown	2	2
Tewa Micaceous Slipped (San Ildefonso, Santa Clara)	Large storage vessel?	2	1
Tewa Micaceous Slipped (Nambe, Tesuque, Pojoaque)	Unknown	2	2
Hispanic/Tewa buff/plain	Unknown	4	4

Ceramic Descriptions

FS 377-2 is a Tewa Blackware sherd likely originating in Santa Clara or San Ildefonso. Ceramic cross-sections reveal a fine but friable clay paste. The dominant constituents of the clay include vitric tuff, pumice, and fine sand temper. Interior and exterior surfaces are sanded, slipped, and polished. The exterior surface is a deep glossy black. The interior is polished to a lesser degree and is partially oxidized. Vessel form cannot be determined.

FS 346 is a Tewa Blackware sherd likely originating in Santa Clara or San Ildefonso. Ceramic cross-sections reveal a fine but friable clay paste. The dominant constituents of the clay include vitric tuff, pumice, and fine sand temper. Interior and exterior surfaces are sanded, slipped, and polished. Minor amounts of microscopic muscovite mica are visible on the exterior slip surface. Vessel form cannot be determined.

The FS 324 and FS 337 ceramics represent two Tewa Micaceous slipped body sherds likely belonging to the same vessel. Surface finish, wall thickness, and paste characteristics are identical. The form of the vessel cannot be determined, but it was likely a relatively large jar based on the wall thickness of the body sherds (7 mm). The pieces may represent portions of a storage vessel. Ceramic cross-sections reveal a fine but friable clay paste. The dominant constituents of the clay include rounded stream sands and microscopic glass fragments with minor amounts of vitric tuff and pumice. The interior of the vessel is sanded, polished to a mat finish, and reduced, but is not slipped. The exterior is slipped with a thin micaceous wash that contains an abundance of muscovite mica and no biotite. Paste characteristics indicate that the vessel was produced either in San Ildefonso or Santa Clara using local clay and temper sources.

The FS 117 body sherd represents a Tewa Micaceous slipped jar or bowl. Ceramic cross-sections reveal a relatively coarse and friable clay paste. The dominant constituents of the clay include subangular to rounded and poorly sorted stream sands and minor amounts of muscovite mica. The interior of the vessel is sanded, slipped with a thin slurry of plain clay, polished to a mat finish, and reduced. The exterior is slipped with a relatively thick micaceous slurry containing muscovite and biotite mica. Paste characteristics and surface finish indicate that the vessel was produced at San Juan, Nambe, Pojoaque, or Tesuque using local clay and temper sources.

The FS 305 body sherd is nearly identical to FS 117. Paste and surface finish are the same with the notable exception that biotite is not present in the micaceous slip of the FS 305 sherd. Paste characteristics and surface finish indicate that the vessel was produced at San Juan, Nambe, Pojoaque, or Tesuque using local clay and temper sources.

Four body sherds (FS 116, FS 135, FS 377-1, and FS 402) likely represent separate vessels but are otherwise very similar in appearance. Each is tempered with medium to fine and subangular arkosic sands. Interior and exterior surfaces are not slipped. Clay color is a light buff to brown. The general lack of tuff, pumice, glass, and mica suggests that the sherds may be Hispanic in origin, but the small size of the sherds prevents a definite identification. Vessel form cannot be determined.

Adobe Plaster

A total of 164 fragments of burned and unburned adobe plaster were recovered from LA 85407. Nearly all of them (n = 163) came from the Area 1 cabin, with the majority encountered in the Stratum 2 post-occupational fill. Plaster was present in most of the interior grid units but was concentrated primarily in Room 1. One fragment was recovered from the horno (Feature 1) in Area 3. There are no visible differences between the plaster from the cabin and the horno.

A number of characteristics separate adobe plaster from fired ceramics. The adobe paste consists of a fine, granular clay paste containing moderate amounts of rounded quartz and fine arkosic sands. Tuff and pumice aplastics are present but rare in most cases. Unburned fragments are buff to gray in color. Interior sides show signs of being attached to an adobe floor or wall substrate. Aplastics are exposed at the roughened contact surface. Exterior surfaces were buffed with a soft cloth, wool, or chamois. Striations are visible, the surfaces are compact, and some crazing is evident on the fine clay float or film. None of the pieces show any signs of sanding, polishing, or firing consistent with pottery and only a few display slight curvature. Several of the unburned pieces also contain fragments of a possible whitewash or paint, further suggesting wall plaster. In general, the adobe plaster is compact but not fused or vitrified through firing. Burned pieces also break easily and were likely baked in one or more of the post-occupational fires that destroyed the structure. The context, distribution, and physical characteristics of the plaster indicate that portions of the walls within the cabin were finished with adobe, possibly in the area of an interior wood burning stove or hearth in Room 1. Plaster from the area of the horno may have come from the interior or exterior of this feature.

Summary

The LA 85407 ceramic assemblage indicates that residents of the Serna Homestead obtained locally produced ceramics from the Tewa Pueblos almost exclusively. Vessels consist of blackware and micaceous slipped vessels, some of which may represent large storage vessels. Four of the sherds (40% of the total assemblage) appear to be Hispanic in origin, but this could not be verified. Despite the lack of diagnostic pumice, tuff, or glass in the temper, these unidentifiable fragments could represent Tewa vessels. Sixty-seven percent of the identifiable assemblage (n = 4, or 3 out of 5 vessels) originated either in Santa Clara or San Ildefonso, including both of the Tewa blackwares and one of the Tewa Micaceous slipped fragments. Thirty-three percent of the identifiable assemblage (n = 2, or 2 out of 5 vessels) originated east of the Rio Grande at Nambe, Pojoaque, San Juan, or Tesuque. Both of these vessels are Tewa Micaceous slipped fragments.

Ceramics were recovered from three features including the Area 1 cabin, the Area 4 circular rock alignment (Feature 2), and the Area 6 corral (Feature 3). All of the Santa Clara/San Ildefonso ceramics were associated with the cabin and all of the ceramics from Nambe, Pojoaque, San Juan, or Tesuque were associated with the circular rock alignment. Both features also contained unidentifiable Hispanic/Tewa buffwares and one unidentifiable buffware also was associated with the corral. Unfortunately, ceramic distributions do not contribute to a better interpretation of the circular rock alignment function, although it is interesting that all of the east-side Tewa ceramics were associated with this feature. The presence of ceramics in the feature, however, suggests that it may have functioned as a storage facility or outdoor food service or cooking area. The presence of adobe fragments indicates that portions of the cabin interior were prepared or finished with plaster.

The prevalence of Tewa ceramics and general lack of Jicarilla ceramics is consistent with the post-1920s occupation of the site. Residents interviewed as part of ongoing LANL research indicate that members of nearby Pueblos continued to use the mesa areas on the plateau for gathering, hunting, and religious activities. In particular, homestead farmers hired local Pueblo men to help with plowing and harvesting, and homesteaders also sold cane syrup and exchanged crop seed and information about medicinal plants with nearby Pueblos, especially San Ildefonso (Vierra et al. 2006:223–224). The LA 85407 excavations demonstrate that ceramics also were part of this exchange system. Ceramics from the Serna Homestead may be contrasted with the McDougall Homestead assemblage, which shows significant input from Apaches and likely represents a pre-1920s rather than post-1920s Hispanic occupation.

Apache Campsite: LA 85864

LA 85864 includes a rock ring alignment likely representing the remains of a wickiup or tipi foundation. Three micaceous sherds representing two vessels were recovered from this structure. Unfortunately, all three of the fragments represent small body sherds and could not be definitively identified to maker, but they were likely produced or used by the Jicarillas. A single Biscuit A fragment also was recovered from the site. Complete descriptions are provided below along with type identifications and probable source determinations where appropriate.

Both of the sherds from FS 575 likely came from the same vessel based on paste and surface finish characteristics. This vessel displays characteristics most similar to Cimarron Micaceous. Sherds contain only a moderate amount of mica. Rosy quartz and possible magnetite are present but rare and may indicate a Cordova-Truchas Source District origin for the clay. Exterior and interior sherd surfaces are burnished and compacted, unlike Tewa vessels. No corncob striations are present.

The FS 572 sherd appears to be made from an alluvial clay containing mica rather than primary micaceous clay. Mica fragments are silt- to clay-sized and larger fragments are rare. Aplastics are subangular to subrounded. The origin of the clays used to make this ceramic is unknown, although alluvial micaceous clays are present north of Abiquiu. Surface slip or float does not appear to be micaceous. Ethnic affiliation also is unknown.

The FS 574 fragment represents a small Biscuit A body sherd.

Apache Campsite: LA 85869

LA 85869 includes two rock ring alignments likely representing the remains of wickiup or tipi foundations. A total of six micaceous sherds representing two vessels were recovered along with a possible Tewa buffware fragment. The micaceous fragments represent small body sherds and could not be definitively identified to maker, but they were likely produced or used by the Jicarillas. Complete descriptions are provided below along with type identifications and probable source determinations where appropriate.

Both of the FS 309 sherds likely came from the same vessel based on paste and surface finish characteristics. This vessel displays characteristics most similar to Cimarron Micaceous. The ceramic paste contains abundant muscovite mica in a gradient of sizes. Biotite and booked biotite also are common. Aplastics include translucent to white quartz (dominant) and magnetite (rare). The abundance of booked biotite in combination with the presence of magnetite and white quartz indicate a Cordova-Truchas Source District origin for the clay. A micaceous float (slurry) was applied to the exterior surface. Exterior and interior sherd surfaces are burnished and compacted, unlike Tewa vessels. No corn cob striations are present.

All four of the FS 328 sherds likely came from the same vessel based on paste and surface finish characteristics. This vessel displays characteristics most similar to Cimarron Micaceous. Ceramic pastes contain abundant muscovite in a gradient of sizes. Quartz mica-schist also is common, and iron-stained quartz and magnetite are present. One small fragment of hematite was noted. The abundance of quartz-mica schist and the presence of iron-stained quartz and hematite strongly suggests a Petaca Source District origin for the clay. Vessel interiors are smudged. Interior and exterior surfaces are compacted by sanding and burnishing, but some wipe-marks also are visible.

FS 325 represents a probable Tewa buffware body sherd of unknown origin.

Summary

The small ceramic assemblages recovered from LA 85864 and LA85869 are consistent with other sherd assemblages found at 19th century Jicarilla Apache sites in the Chama District and elsewhere. Although type identifications are tentative, all of the micaceous sherds likely represent Cimarron Micaceous vessels based on paste characteristics and surface finish. The Petaca and Cordova-Truchas source districts are represented and these two districts were used extensively by the Jicarillas (Eiselt 2006). Vessel surfaces also are highly compacted through burnishing and polishing; traits that are likewise commonly found on 19th century Cimarron Micaceous sherds (Eiselt 2005). The Biscuit A sherd from LA 85864 may represent an earlier component at the site. The probable Tewa buffware sherd at LA 85869 was probably brought to the site by Apaches.

Isolated Pot Drop

The isolated pot drop is an excellent example of a medium-sized Cimarron Micaceous long-necked olla or cook pot with an orifice diameter of around 26 cm. The 77 recovered fragments include five rim sherds, three neck sherds, and 69 body fragments. Base sherds are not evident, suggesting that the vessel had a conical or rounded bottom. The neck is long and gently everted with vertical corn cob scrape marks on the exterior and horizontal corn cob scrape marks on the exterior. Interior and exterior surfaces have been lightly sanded and rag burnished. The rim is sharply keeled and expanding and shows evidence of being sanded and burnished. The paste includes residual micaceous clay that contains abundant quartz, feldspars, and mica-schist. Minor amounts of magnetite also are present. Paste texture is fine and laminated. A general lack of accessory minerals prevents a definite determination of source district, but Petaca or Picuris are likely candidates. The vessel likely dates from around 1850 to 1880 or 1890 based on similarities with dated types in the Río del Oso Valley (Eiselt 2006).

DISCUSSION

Summary counts and percentages from each of the four sites and the isolated pot drop are listed in Table 78.8. Cimarron Micaceous is the most numerous ceramic type in the overall assemblage and this type occurs at three of the four sites examined as part of this study. Ceramics originating in the Tewa Pueblos are the next most numerous categories and are associated with the homestead sites primarily.

Table 78.8. Ceramic summary counts.

Ceramic Type	Total Sherd Count	Minimum Vessel Count
Cimarron Micaceous	89 (83.2)	6 (27.3)
Indeterminate Micaceous (Cimarron?)	1 (0.9)	1 (4.5)
Peñasco/Tewa Micaceous	1 (0.9)	1 (4.5)
Indeterminate Micaceous	1 (0.9)	1 (4.5)
Tewa Micaceous Slipped (Nambe, Tesuque, Pojoaque)	2 (1.9)	2 (9.1)
Tewa Micaceous Slipped (San Ildefonso, Santa Clara)	2 (1.9)	1 (4.5)
Tewa Blackware (San Ildefonso, Santa Clara)	2 (1.9)	2 (9.1)
Hispanic Blackware	1 (0.9)	1 (4.5)

Ceramic Type	Total Sherd Count	Minimum Vessel Count
Hispanic/Tewa buff/plain	5 (4.7)	5 (22.7)
Prehistoric Biscuit A	1 (0.9)	1 (4.5)
Terracotta (Commercial)	2 (1.9)	1 (4.5)
Total	107 (100.0)	22 (100)

The content and diversity of the McDougall Homestead ceramic assemblage are characteristic of 19th century assemblages elsewhere in the Chama. These assemblages contain a mixture of Pueblo, Jicarilla Apache, and Hispanic ceramics with blackwares and micaceous wares being dominant up to the 1890s. Occupation of the McDougall Homestead may therefore pre-date the 1906 to 1907 patent by a few years. Some of the ceramics could represent heirloom pieces or micaceous tradewares produced by the Apaches after their removal to Dulce, but the overall assemblage composition is characteristic of 19th century ceramic production and exchange economies in the Chama (Carrillo 1997; Eiselt 2006; Moore 1996).

In contrast, the Serna Homestead site assemblage is consistent with a post-1920s occupation. Nearly all of the ceramics are attributed to the Tewa. Hispanic and Jicarilla Apache ceramics are lacking, and this can be attributed to a general decline of pottery making by these two groups after the 1890s. The Serna assemblage likewise reflects general trends in Chama Valley economies and trade relationships after the turn of the last century. These trade relationships involved the exchange of clay and pottery between Hispanic and Tewa villagers. For example, mica clay was obtained by San Juan potters from their Hispanic neighbors at Abiquiu (Schroeder 1964:46–47). Hill and Lange (1982:83) also note that Santa Clara potters obtained micaceous clays from neighboring Spanish-Americans (probably from Cordova or Abiquiu) who came to the pueblo to trade. Picuris and Taos likewise traded mica pottery to San Juan, Santa Clara, and San Ildefonso Pueblos to pay for curing ceremonies during the 20th century (Ford 1972:37–39), and Nambe produced cooking ware for trade with other Pueblos and Hispanics (Ford 1972:40).

Ceramic analysis and oral history testimony on the LANL demonstrate that these trade relationships also extended to the plateau and included neighboring homestead grants and Pueblos. Most of the Pueblo ceramics in both homestead assemblages came from neighboring San Ildefonso or Santa Clara Pueblos and Jicarilla Apaches, but Tewa Pueblos east of the Rio Grande are also represented. Although oral testimony makes no mention of exchange between women, they were undoubtedly involved in trading ceramics.

The presence of several Jicarilla Apache sites and abundant Cimarron Micaceous ceramics in the LANL assemblage is not surprising. During the 19th century, the Jicarilla traded their own ceramics in addition to pottery from San Juan and Picuris to Hispanic villagers living near the Chama and upper San Juan Rivers (Schroeder 1964:46–47). The Jemez Mountains were sacred to the Olleros, and Jicarilla hunting camps were located near Los Alamos according to oral testimony gathered by ethnographers and ethnohistorians during the 20th century (Goddard 1911:206; A. Schroeder 1974a:128, 1974b:445). Also, nearly 200 Olleros also stayed at San Ildefonso for several months in 1884 while they negotiated a permanent reservation (Tiller 1983:92–93). The archaeological sites and ceramics on the LANL thus may be attributed to the Ollero band of the Jicarilla as part of their occupation of the Española Basin. Specifically, they may belong to the *Saitinde* local group who regularly hunted the Jemez Mountains and Pajarito Plateau, but the *Dachizhozhin* cannot be eliminated.

By the 1850s, nearly all of the Olleros were living in the Lower Chama Valley from Canjilon to Española. The total population was around 300 people or six extended families divided into two local groups. The *Dachizhozhin* maintained their headquarters in the Petaca and El Rito areas, and the *Saitinde* took up residence near Española and Abiquiu. The favored hunting grounds of the *Dachizhozhin* included the Tusas and San Juan Mountains as far north as Colorado. The favored hunting grounds for the *Saitinde* were the Jemez Mountains. The 1869 census for the *Saitinde* lists a total of 170 people distributed among three extended families. One family occupied the Rio Puerco near Coyote, and the second lived in the lower reaches of the Rio del Oso (Opler 1971b:317). The third may have lived part time at Coyote and part time in the vicinity of Petaca. The headwaters of the Rio del Oso was a favored camping place for all of the *Saitinde* families moving into the Jemez Mountains for the communal fall hunts during the 1860s (Anonymous 1974:207). At the headwaters, these families traded ceramics and other items with Hispanic homesteaders at Los Rechuelos and San Lorenzo (Eiselt 2006).

The identification of Cimarron Micaceous sherds at the two tipi ring sites and at the McDougall homestead is important for two reasons. First it suggests that the Jicarilla continued to trade with Hispanic settlers as they moved in and around the Jemez Mountains and Pajarito Plateau during the communal fall hunts. Second, it reveals the itinerate nature of Jicarilla Apache pottery exchange, which involved villages and Pueblos along the Rio Grande in addition to individual homesteads in the mountains and plateaus surrounding the Española Basin.

CONCLUSION

Ceramics from the four LANL sites function as temporal and cultural indicators. The McDougall site assemblage reflects late 19th century patterns of ceramic exchange, with Jicarilla, Hispanic, and Pueblo sherds represented. The Serna site assemblage is consistent with the early 20th century date for this homestead and reflects a general decline in the diversity of ceramic production and ethnic communities producing ceramics after the 1890s. Nearly all of the sherds at the Serna Homestead are Tewa in origin, with most originating either at San Ildefonso or Santa Clara. The Serna assemblage also shows that trade between homesteaders on the plateau and neighboring Pueblo groups also included ceramics in addition to food, labor, and medicinal plants. The two tipi ring sites are attributed to the Jicarilla based on site features and ceramics. Historic documents suggest that they likely represent *Saitinde* seasonal hunting camps dating from the 1840s to the 1880s or 1890s. While on the plateau, Jicarillas interacted with local residents through the exchange of pottery.

CHAPTER 79
SETTLEMENT CHANGE AND DEMOGRAPHY ON THE PAJARITO PLATEAU

Brandon M. Gabler

PUEBLO AGGREGATIONS: A PERENNIAL PROBLEM IN PREHISTORY

Between AD 1250 and 1300, the social organization of Native American communities on the Pajarito Plateau underwent a profound shift known to archaeologists as "pueblo aggregation," in which large aggregated residential structures replaced smaller, more numerous, and widely dispersed households. Understanding aggregation and related processes is critical to southwestern archaeology, and these have been addressed through innumerable approaches for decades (Cordell et al. 1994; Orcutt 1991; see chapters in Adams and Duff 2004; Adler 1996; Cordell and Gumerman 1989; Kohler 2004; Neitzel 1999). These arguments have not yet developed a unified understanding of aggregation as an adaptive strategy by prehistoric populations throughout the U.S. Southwest. Sheer population growth could lead to increased density of small settlements. Instead, a new form of village settlement appeared (the large complex pueblo), likely coupled with a new form of social organization (Cordell et al. 1994). A possible ecological framework for this innovative qualitative change is offered by ecologist C. S. Holling's (Holling and Gunderson 2002; Holling et al. 2002) model of adaptive cycles. Holling's model proposes a fundamental relationship between growth and structural change, and so offers a candidate explanation. But testing the fit of the adaptive cycle model requires empirical data on paleoenvironmental change changes in farming and settlement patterns, and an analytical model that captures the essence of Holling's qualitative predictions.

The Ancestral Puebloan Pajarito Plateau is a dynamically coupled socio-ecological system (SES), in which migrant Puebloans from desiccated landscapes elsewhere on the Colorado Plateau (i.e., San Juan Basin) encountered local peoples during the last half of the Coalition period (AD 1250–1325; Cordell 1979b; Hill and Trierweiler 1986; Hill et al. 1996; Vierra et al. 2006:192; Wendorf and Reed 1955). The migrants brought with them alternate ideas of social structure, agriculture, tools, and the rituals and behaviors associated with these lifeways. Additionally, their arrival caused an increase in population unachievable by local reproduction alone, adding additional stress to an environment already under the pressure of the Great Drought (AD 1276–1299). There exist two narratives, elaborately intertwined, but potentially separable in order to understand the whole in more detail. The two stories are as follows: 1) the social institutions that allowed the application, development, and evolution of intensified agriculture on the Pajarito Plateau, and 2) the ensuing adaptation to changing climatic conditions, culminating in drastic reformation of settlement pattern into aggregated pueblos. The second story, which is the primary focus of this research, is the ecological half of the Pajarito SES. It is necessary to understand both stories independently for the purposes of modeling the SES as a whole—such is the nature of the study complex adaptive systems (CAS; see Lansing 2003 for a discussion of complex adaptive systems and emergent behavior). Any misunderstanding of the details of the parts will obviously lead to a gross misunderstanding of the sum of those parts, since the larger Pajarito system as a whole is—as with all CAS—greater than the sum of its parts. This study attempts to investigate several hypotheses that have been proposed for the

Pajarito Plateau, specifically, and the U.S. Southwest broadly.

The first hypothesis is that there is a significant, observable change in geographic location through time, specifically an increase in elevation, of agricultural (fieldhouses) structures (Preucel 1986; Hill and Trierweiler 1986; Vierra et al. 2006:202–203). The second is that population peaked during the Late Coalition period and declined again during the Classic period (Preucel 1986; Hill et al. 1996; Orcutt 1999). Finally, returning to the heuristic adaptive cycle model, the last hypothesis is that the patterns of population migration, expansion, aggregation, and eventual relocation off of the Pajarito Plateau fit a regional pattern of nested adaptive cycles on the Colorado Plateau (Crown et al. 1996; Holling and Gunderson 2002).

Understanding the ecological narrative is linked directly to the understanding of settlement pattern and location throughout the Coalition and Classic periods (Table 79.1). There exists a developing set of ecological theories revolving around ideas of resilience and complexity, with conceptual models based on Holling's heuristic models of nested adaptive cycles (Holling and Gunderson 2002). In the confines of this project, the information revealed by the first two hypotheses above is employed to test the adaptive cycle models as productive means for exploring and describing the complex SES of the central Pajarito Plateau. Finally, future work is discussed as a direct result of the inability to fully center the Pajarito Ancestral Puebloan system within the framework of adaptive cycles.

Table 79.1. Ancestral Puebloan chronology for the Pajarito Plateau.

Period	Dates
Early Developmental	AD 600 to 900
Late Developmental	AD 900 to 1150
Early Coalition	AD 1150 to 1250
Late Coalition	AD 1250 to 1325
Early Classic	AD 1325 to 1400
Middle Classic	AD 1400 to 1550
Late Classic	AD 1550 to 1600

The Pajarito Plateau is a series of interconnected mesas, and as such is a relatively bounded system of high- and low-elevation flat lands, amenable to agriculture but subject to annual climate fluctuation. The region covers approximately 700 square km (270 square miles) and ranges in elevation from 1500 to 3000 meters (4920 to 9840 feet). It is bounded by Santa Clara Canyon to the north, Cochiti Canyon to the south, the Jemez Mountains to the west, and the Rio Grande to the east (Vierra et al. 2002:195). The Pajarito Plateau, as a geographically bounded system, provides an ideal opportunity to examine local pueblo aggregation as well as the functioning of adaptive cycles. Events such as initial occupation and abandonment—critical to panarchy, or nested adaptive cycles—are apparent from the material record. It is essential to test the Pajarito Plateau data against a heuristic model of adaptive cycles at multiple scales, following Holling et al. (2002). The patterns of aggregation throughout northern New Mexico and southern Colorado suggest that at a super-regional level, aggregation may have been cyclic with migration serving as the destruction/reorganization phases of Holling's adaptive cycle discussed below.

METHODS AND THEORY

The key challenge for models of resilience and adaptation in the Southwest is to determine the scale at which to view cycles of agricultural intensification, aggregation, demographic change, and migration to eliminate noise but capture the system as a whole. Pueblo aggregation cannot be understood by simply assessing the movement of individual households. Detail of individual households will likely be necessary, but it is the system as a whole that develops aggregation, in turn causing changes in population size, agricultural strategies, and migration. The entire plateau region must be addressed to understand the processes driving the formation of large pueblos throughout the Rio Grande Classic period.

Testing Pueblo Aggregation

This research builds on the work of Schiffer (1976) and Reid et al. (1975) who developed principles of behavioral archaeology to frame the material record of the past in terms of past and present human behavior and its impact on the environment. Cordell et al. (1994) and Orcutt (1991) proposed that settlement relocation and aggregation at the end of the Coalition period was, at least in part, due to decreased precipitation, because the events coincide in time. Strategies 1 and 3 of the four behavioral archaeology strategies are of importance here, because they deal with the use of past material culture to understand past (Strategy 1) and present (Strategy 3) human behavior. Strategy 1 of behavioral archaeology properly addresses Cordell et al. (1994) and Orcutt's (1991) formulation of these assumptions that dictate the change in settlement patterns. While their conclusion may be appropriate and logical, there could be other driving factors as well. Models of aggregation and the processes driving it in the Southwest will be useful for analyzing aggregation or similar settlement patterns in other archaeological systems. Thus Strategy 3 becomes important to the question of aggregation, for through the analysis of the Pajarito populations in terms of adaptive cycles, the research uses the material record about the past to make statements of wider applicability throughout various systems in the past and present. Like other questions posed and addressed through Strategy 3 (Reid et al. 1975:865), general processes of aggregation may exist with the potential to be identified through the study of individual instances. Those with high data resolution, like the case on the Pajarito Plateau, provide the most promise for developing general laws about aggregation.

Panarchy: Adaptive Cycles for an Ecological Perspective

Within archaeological research, there is a growing concern with connecting the behaviors of people in the past to those in today's world. Holling (1973) and Gunderson and Holling's (2002) theory of nested adaptive cycles, or *panarchy*, seeks to explain resilience of natural ecosystems. The adaptive cycle is divided into four phases: exploitation or rapid growth (r), conservation (K), release or destruction (Ω), and reorganization (α). Panarchy is applied to socio-ecological systems (Carpenter et al. 2001; Holling et al. 2002; Westley et al. 2002) to explain resilience of human systems to ecological disturbance and vice versa. Though the adaptive cycles likely will not *explain* the variation observed through time on the Pajarito Plateau, they may provide a framework within which patterns may be observed to fit, or not fit, the expected cyclic patterns.

The long time-depth of archaeological systems combined with the high-resolution data on the Pajarito Plateau makes these Ancestral Puebloans ideal for testing against the panarchy model, especially as they operate at and across multiple scales (Levin 1992). If fitted to a panarchy, the Pajarito Plateau story (Figures 79.1 and 79.2) may appear as follows. Exploitation is a phase of economic optimization, and where the adaptive cycle would have "flipped" into a mode of agricultural production in the prehistoric Southwest. On the Pajarito Plateau, agricultural groups are moving toward the conservation phase by AD 1150. During this phase, small pueblo sites develop at low- and high-elevation mesas, capitalizing on widespread precipitation and varying levels of soil nutrients. Populations reach carrying capacity during this phase, and beginning around AD 1250 or 1275, a brief release phase occurs, potentially at the hands of the Great Drought (AD 1276–1299). Immediately, the Puebloans would begin a phase of restructuring. It is within this phase that aggregation occurs, as a response to either the massive release of resources during the Great Drought, or more likely the immense immigration of Puebloans from the San Juan Basin to an already depleted Pajarito Plateau resource area.

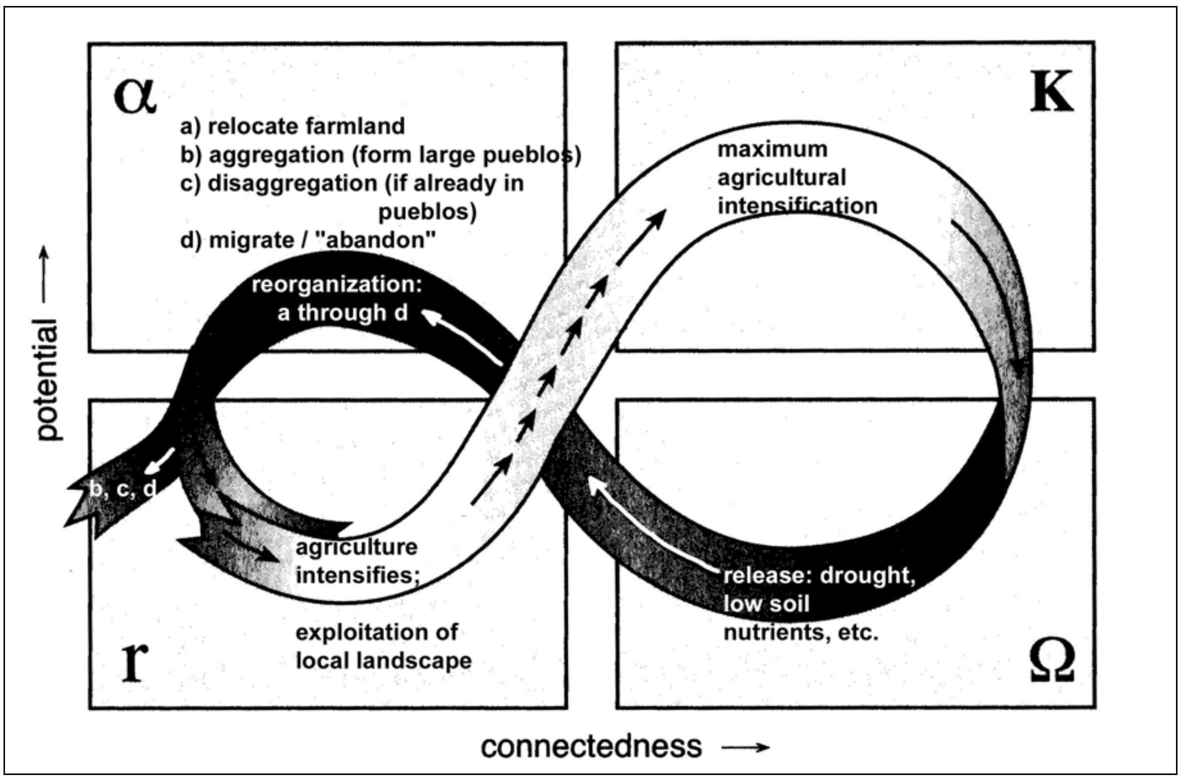

Figure 79.1. Adaptive cycle for village farming societies in the U.S. Southwest (adapted from Holling and Gunderson 2002:34, Figure 2-1).

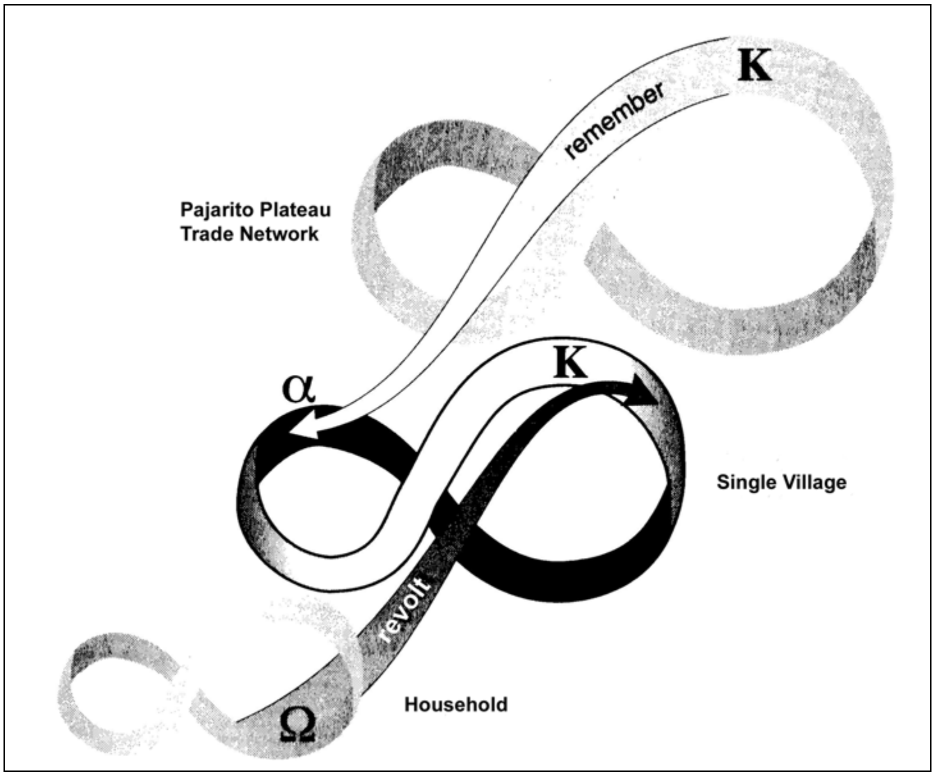

Figure 79.2. A panarchy representing the multiple levels of adaptive cycles for the pre-aggregated Pajarito Plateau (adapted from Holling et al. 2002:75, Figure 3-10).

The questions raised by an adaptive cycle relate to causes of change at the end of each phase and to the potential lack of a second cycle on the Pajarito Plateau. Cordell (1989) and Orcutt (1991) argue for a reorganization of massive pueblos at low elevations during the AD 1300s as a direct result of climate change. However, there is evidence for an aggrading environment (AD 1295–1330; see Chapter 7, Volume 1) following the Great Drought, suggesting that social factors must have influenced the continued organization into aggregated pueblos—one such idea is that of populations migrating out of southern Colorado and western New Mexico, where Puebloans had established cliff dwellings and large pueblos before abandoning them by AD 1300.

The Pajarito Plateau archaeological environment provides data rich with potential for testing the emergence and dissolution or migration of an agricultural society against the assumptions included in framing the system within Holling's adaptive cycles. Single households, villages, trade networks, and migration patterns may serve as the multiple spatial scales necessary to test the cyclic nature of human behavior, while growing seasons, generations, and settlement relocation in pre-state agricultural societies of the Southwest should provide the multiple temporal scales.

Holling's adaptive cycle model will be tested through the analysis of settlement patterns and change through time as the Pajarito farmers develop aggregation. As shown in Figures 79.1 and 79.2, there are multiple processes operating at each stage of the cycle, and various cycles occurring at different scales. To disconfirm the adaptive cycle model, it may be necessary to show that the cycle does not repeat, and therefore is not a cycle at all, rather a trajectory.

Additionally, it may be possible to show that the Great Drought did not constitute a great enough drain of resources to influence the reorganization phase. If this is the case, then it is social, not ecological, properties driving reorganization into aggregated pueblos, suggesting that the Pajarito system follows some other adaptive process uncaptured by Holling's model.

Data, Resolution, and Application

Agriculture on the Pajarito Plateau began between AD 900 and 1150 as small-scale horticulture, and was thoroughly established by AD 1150 at the start of the Coalition period. Throughout this time, population growth steadily increased followed by decreased precipitation during the mid to late 1200s culminating in the 'Great Drought' throughout the region. This period is also when the plateau experiences its greatest population growth rate and the beginning of major pueblo aggregation. By AD 1325, the beginning of the Classic period, nearly all agriculturalists occupying the plateau lived in a few large (>300 room) pueblos, as opposed to the more abundant smaller roomblocks (8 to 30 rooms, with a maximum around 100 until the large, 200- to 250-room structures appeared during the latest Coalition period) consistent throughout the Coalition period (Vierra et al. 2002). Through high-resolution LANL data, it is possible to test ideas relating to adaptation and resilience in the prehistoric American Southwest.

Cultural Resource Information

The research presented here uses existing field survey and excavation data as well as various sources of climate and landscape information for the Pajarito Plateau. The Conveyance and Transfer (C&T) Project involved excavation of nearly 30 fieldhouses, several pueblo roomblocks, and field survey and site recording on several thousand acres of land on the Pajarito Plateau. These sites comprised agricultural period artifacts and structural materials, much from the Coalition (AD 1150–1325) and Classic (AD 1325–1600) periods. The fieldhouses and pueblo roomblocks are a large portion of the current investigation of settlement pattern on the plateau to determine causes of aggregation and provide glimpses into the daily lives of village farmers. Grid gardens and check dams provide useful information about where the Ancestral Puebloans were routinely farming and where they may have avoided with relative consistency. The C&T Project added to an existing substantial database generated by past archaeological research on the plateau. These investigations include those before LANL by Hewett (1904, 1905, 1906, 1908a) and Wilson (1916, 1917, 1918b); and the LANL-era investigations conducted by Steen (1977, 1982), Worman and Steen (1978), and the Pajarito Archaeological Research Project (PARP) led by Hill (Hill et al. 1996). Additional investigations on the Department of Energy’s LANL property have been conducted until the present under the supervision of various LANL archaeologists (Vierra et al. 2002; Vierra et al. 2006). The cultural resource database lists sites by their standard attributes (location, area, survey name, eligibility) as well as classifies each by type (Table 79.2) and likely affiliation (Table 79.3).

Table 79.2. Archaeological site type categories present at LANL and used in this research (Vierra et al. 2006:183–185).

Type	Description
Cavate	Isolated, multi-roomed contiguous, or adjacent groups of rooms that are carved into cliff faces within the Bandelier Tuff geological formation.
Complex or plaza pueblo	One or more pueblo roomblocks enclosing a plaza; generally (but not always) larger than pueblo roomblocks.
Pueblo roomblocks	Contiguous, multi-roomed habitation structures of more than four rooms, lacking a plaza, and constructed of adobe, jacal, or masonry.
One- to three-room structures	Small surface structures, consisting of rectangular or D-shaped rock alignments, no more than three rooms, and constructed of unshaped dacite cobbles or shaped and unshaped tuff blocks. Often referred to as "fieldhouses."

Table 79.3. Temporal affiliation categories assigned to LANL archaeological sites (Vierra et al. 2006:180).

Affiliation	Dates	Comments
Coalition	AD 1150–1325	The majority of LANL Ancestral Puebloan sites fall within this period; first widespread agricultural success, beginning of aggregation at end of 1200s.
Late Coalition/ Early Classic	AD 1250–1400	Overlaps Coalition and Classic periods, generally used for sites that are confirmed multi-component after excavation, or whose surface deposits are deemed to span both periods based on survey (i.e., presence of multiple painted wares, especially Wiyo Black-on-white [see Chapter 76, this volume]).
Classic	AD 1325–1600	Major settlement reorganization during this period, when aggregation into a few large plaza pueblos occurred.

Ecological Information

The data pertinent to this project include elevation (LIDAR data as a digital elevation model at a cell resolution of 16 feet), paleoclimate (annual precipitation reconstructed from tree-ring indices for AD 680 through 2002; see Chapter 7, Volume 1; Dean and Robinson 1977) soil samples and types across the plateau, hydrology, and vegetation/land cover. Department of Energy/LANL owns the majority of the central Pajarito Plateau (north of Frijoles Canyon), which is the area of interest for this research.

Methodological Applications

The open source GRASS geographic information system (GIS) program (GRASS Development Team 2006) is used to operationalize the data and analyze potential settlement patterns within the Pajarito system. These localized interpretations are available for multiple regions in the Southwest, providing insights into cross-cultural similarities in pueblo social organization, response to changing climate, and population dynamics. The GIS framework of settlement pattern analysis will become the foundation for building an agent-based model of individual household interaction (Box 2002; Kohler et al. 2005; Lim et al. 2002). An agent-based model applied in this fashion will allow for intensive experiments with control over agent behavior, landscape change (i.e., erosion or modification by humans), and climate factors, while providing the possibility for emergent properties of the archaeological system as a complex adaptive system (Lansing 1991, 2003).

Humans adapt not only to their perception of the environment, but also to the cultural system in which they live. Puebloan society transforms due in part to climate response and in part to the growing complexity of society through pueblo interactions, religious beliefs, and changing community dynamics of cooperation and trade. Societies generally only adapt to the extent that is necessary based on changing conditions (Trigger 1995:450), and what they leave behind forms the archaeological record, which anthropologists must make sense of to determine the extent of adaptation required by the past populations.

Data Shortcomings

It is critical to bring to the forefront two issues with the archaeological data used in conducting statistical tests and creating models throughout this research. First, archaeological sites lacking a constrained chronological period are not included in the analyses. Table 79.1 contains the broadest scale chronological information deemed acceptable for inclusion. Various sites in the LANL database have been coded as “Undetermined Prehistoric” or “Undetermined Anasazi” and as such are not useful to the present analyses. Second, there seems to be some difficulty in ascribing chronological time ranges of Coalition or Classic period based on surface surveys using ceramic seriation, considering the abnormally long ranges of painted wares such as Santa Fe Black-on-white. This ceramic type, for example, spans 200+ years and overlaps the Coalition and Classic periods considerably, causing considerable haze during the Late Coalition/Early Classic transition, especially if other ceramic types were not sufficiently visible on the surface. Included in future work for this project will be a return to the original field notes of the Steen, PARP, and other LANL surveys to attempt to bring further chronological control to some of the sites, particularly those currently defined as undetermined thus far.

Geographic Location and Culture Change

As stated above, it has been proposed through past research on the Pajarito Plateau (Crown et al. 1996; Hill and Trierweiler 1986; Hill et al. 1996; Vierra et al. 2006) that the mean elevation of agricultural structures increases through time. Specifically, Preucel (1986) suggests that there is an observable shift to higher elevations during the Classic period, potentially suggesting movement into the uplands to aid in capturing moisture for agricultural purposes.

Using the LANL cultural resources database within GRASS, sites were separated into different files based on the site type and affiliation classifications (see Tables 79.2 and 79.3). Only those sites with assigned cultural affiliation were used for these analyses. Out of a total of 823 sites meeting these criteria, 422 are Coalition period roomblocks or cavates with more than three rooms (Figure 79.3), 146 are Coalition period one- to three-room structures (Figure 79.4), 53 are Late Coalition/Early Classic structures with more than three rooms (Figure 79.5), 46 are Late Coalition/Early Classic one- to three-room structures (Figure 79.6), 37 are Classic period structures with more than three rooms (Figure 79.7), and 98 are Classic period one- to three-room structures (Figure 79.8). These data and the other site types are summarized in Table 79.4. For purposes of calculations, sites are grouped as either large sites (those with four or more rooms, including all types of pueblos and cavates that have been identified as contiguous) or small sites (those with one to three rooms). These categories are intended to avoid bias between functionality of sites as well as differences in the actual occupants of sites; therefore, all rooms are equal in the initial assumptions, as in Orcutt's momentary population calculations (1999).

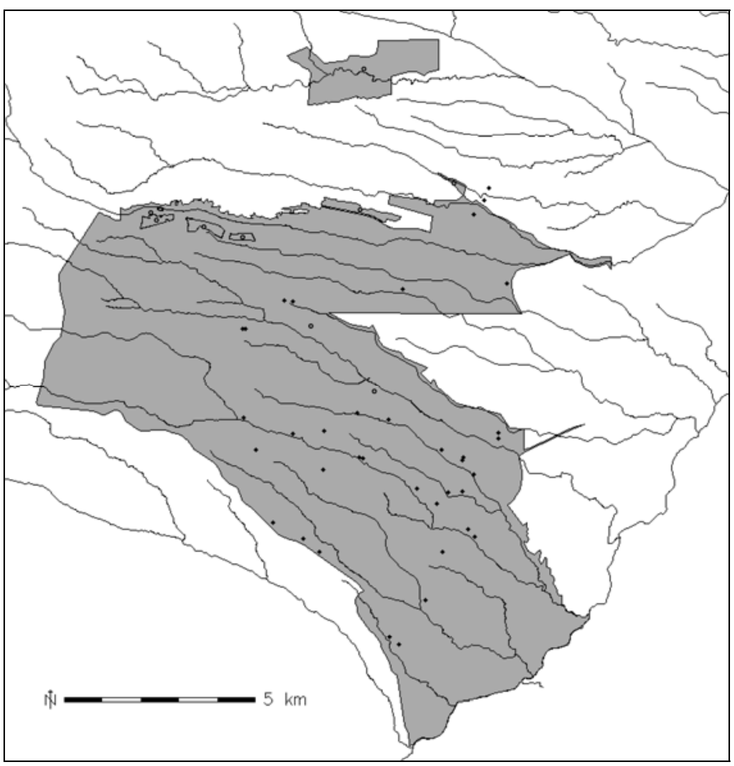

Figure 79.7. Classic period pueblos with more than three rooms.

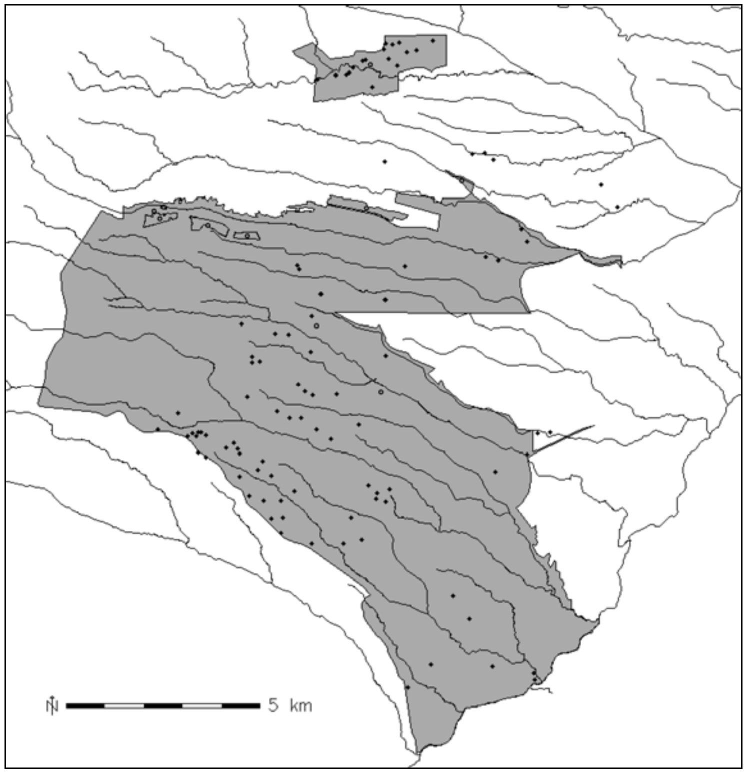

Figure 79.8. Classic period small (one- to three-room) structures.

Table 79.4. Relevant categories and summary statistics of identified archaeological sites.

Period	Type	Sites (*n*)	Mean Elevation (ft)	Number of Rooms (number of sites with estimates)
Coalition	Small (1 to 3 rooms)	146	6864	261 (n = 146)
	Large (>3 rooms)	422	6778	5159 (n = 293)
Late Coalition/ Early Classic	Small (1 to 3 rooms)	46	6865	69 (n = 46)
	Large (>3 rooms)	53	6773	1104 (n = 33)
Classic	Small (1 to 3 rooms)	98	6898	164 (n = 98)
	Large (>3 rooms)	37	6694	1706 (n = 10)

Testing the Change in Agricultural Site Elevation

After computing the mean elevation for each individual site (due to the fine grid resolution of the digital elevation model), it was possible to test Preucel's observation of a change in elevation through time on the Pajarito Plateau. Table 79.5 presents a summary of the frequency of archaeological sites in the same elevation zone categories as in Hill and Trierweiler (1986:Table 7), using the current archaeological site database of categories and types. Brief visual inspection of the table suggests that there is a slight shift in number of sites to higher elevations, but this is based on the assignment of categories with intervals of 350 feet and somewhat arbitrary breaks.

Table 79.5. Frequency of sites by elevation and period, using elevation categories from Hill and Trierweiler 1986:Table 7 and Vierra et al. 2006:Table 9.4). Includes water control and grid garden sites (*n* = 21).

Elevation (m)	Coalition	Late Coalition/ Early Classic	Classic	Elevation (ft)
2400+	0	0	0	7900+
2300–2400	0	0	0	7550–7900
2200–2300	41	5	13	7220–7550
2100–2200	189	38	61	6900–7220
2000–2100	207	37	34	6550–6900
1900–2000	142	22	29	6200–6550
below 1900	2	0	3	below 6200
TOTAL	581	102	140	--

Given the large number of sites within each category, it was determined that formal hypothesis testing should result in the ability to say whether or not the mean elevation of sites actually changed between the Coalition and Classic periods. Two hypotheses were interpreted from the prior hypotheses of Hill and Trierweiler (1986), and they are as follows:

> Null hypothesis 1: The mean elevation of all Coalition period sites (μ_1) is equal to the mean elevation of all Classic period sites (μ_2).
> Alternative hypothesis 1: $\mu_1 \neq \mu_2$
>
> Null hypothesis 2: The mean elevation of Coalition period small sites (one- to three-room structures; μ_3) is equal to the mean elevation of Classic period small sites (μ_4)
> Alternative hypothesis 2: $\mu_3 \neq \mu_4$

Table 79.6 provides a summary of the means, sample sizes, and results of the independent sample tests. In each of these cases, the independent samples test failed to produce a significant result, meaning that currently there is not enough evidence to suggest a change in elevation between the Coalition and Classic periods on the Pajarito Plateau (see also Figures 79.9 and 79.10). It is even more important to note that a misleading feature of Table 79.5 (constructed using the same categories as Hill and Trierweiler 1986:Table 7) is that the observable elevation shift may be due to the fact that the mean elevation for small fieldhouse sites is 6898 feet, and the table breaks elevation at exactly 6900 feet.

Table 79.6. Statistical results of hypothesis testing for mean elevation change of agricultural sites between the Coalition and Classic periods.

Hypothesis	Period	*N* (sites)	Mean Elev. (ft)	St. Dev.	*t*-value	*p*-value
1) All sites	Coalition	581	6798.56	284.86	-1.278	0.202
	Classic	140	6833.96	329.95		
2) Small sites	Coalition	146	6863.94	325.00	-0.803	0.423
	Classic	98	6898.70	340.98		

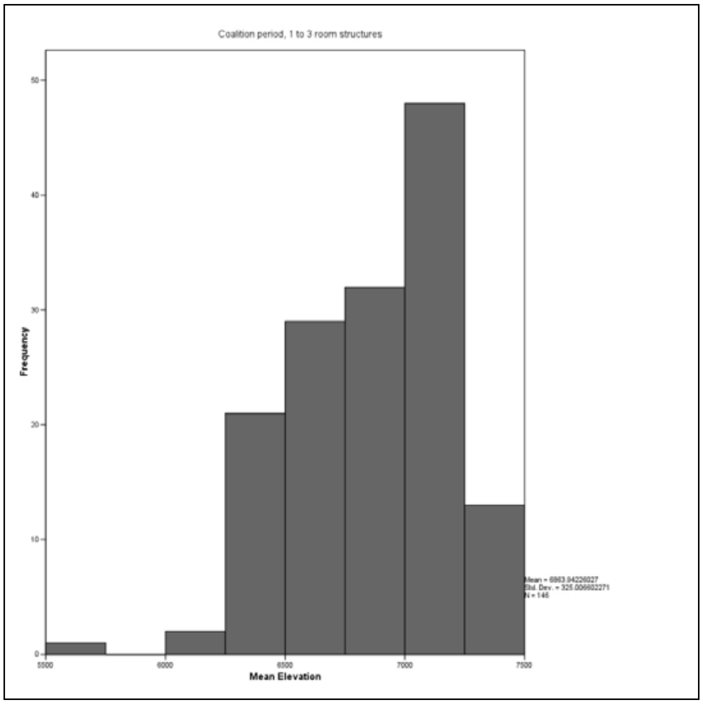

Figure 79.9. Distribution of Coalition period one- to three-room structures with respect to elevation.

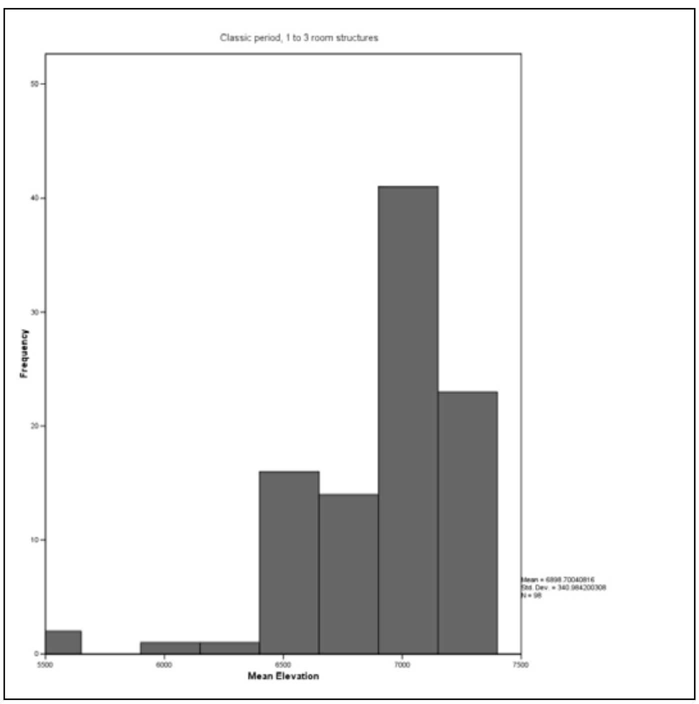

Figure 79.10. Distribution of Classic period one- to three-room structures with respect to elevation.

One may question the ability to reject outright the claims of elevation change in the Classic period, and there certainly may be evidence of an increase in elevation *during* the Classic period, but the chronological resolution for the majority of surveyed sites does not allow the assessment of a more refined chronology than that presented in Table 79.2. Perhaps most important is to note that these tests merely refute the claim that central Pajarito farmers relocated to higher elevations through time *on the central Pajarito Plateau*. The section on population modeling, discussed below, reiterates Crown et al. (1996:195–197) and Orcutt (1999) in showing that population declines sharply on the central Pajarito, with approximately 85 percent of its population moving to the southern Pajarito and, therefore, to lower elevations.

Exploring Other Geographical Features of the Pajarito System

Due to the failure to accept alternative hypotheses about changing elevation through time, it became necessary to conduct a series of exploratory statistical tests so that other features of the landscape that potentially correlate with cultural adaptation were not overlooked based on prior hypotheses.

These tests include two other strictly geographical relationships on the landscape: the geographic distance of each site to the nearest major drainage, and the average slope (degrees) of each site. Hypotheses similar to those for elevation were constructed for each of these variables, resulting in, again, no significant relationship between time and the geographic distance to the nearest drainage. Multiple reasons for a lack of relationship exist. First is the possibility that there truly is no change in the distance of sites to the nearest drainage. Alternatively, since direct Euclidean distance was used for these calculations, it is possible that the landscape has not been accounted for properly regarding cost to travel into, and back out of, canyons to carry water.

A comparison of slope, however, suggests a very strong significant decrease ($t = -6.37$, $p<0.001$) from the Coalition to the Classic periods for the location of sites larger than three rooms. The cultural significance of this change has not yet been investigated, and the substantial difference in number of sites (Coalition = 422, Classic = 37) generates some cause for concern, because the cavate rooms during the Coalition period are outliers (cavates are located in places with the highest slopes) but during the Classic period, they are not. However, Levine's statistic confirms that equal variance in the means can be assumed, given the distribution of the slopes for the two periods. Even without the assumption of equal variance, the test statistic remains significant. To confirm this, a Mann-Whitney test and a Kolmogorov-Smirnov test were conducted, both resulting in significant ($p<0.001$ in both cases) differences between the Coalition and Classic period slopes. As these tests were not originally part of the hypotheses under consideration, they are not explored in more detail here for cultural significance, but they do produce a thought-provoking argument that site location choice shifted at the end of the Coalition period, perhaps in connection with increasing population density and a more stressed environment. On the contrary, the difference could simply be a relic of the small number of large sites during the Classic period. Understanding the relationship between elevation, slope, and distance to major year-round water sources is inherently conjoined with the concept of aggregation on the Pajarito and throughout the U.S. Southwest.

The final missing piece, which is substantial in relation to the tests conducted on large sites, but not so much in connection with those on small sites, is the lack of Tsankawi in the current database, as it is a large Classic period pueblo on the northern Pajarito Plateau but is part of Bandelier National Monument, not LANL. The data for the northern portion of Bandelier have recently been acquired and will be recoded and entered into these tests. However, as the location is on the eastern end of the plateau, the lack of significance between agricultural sites and increased elevation is not likely to change.

Demographic Models of the Northern Pajarito Plateau

Following Orcutt (1999) and Newcomb (1999), it was desirable to subject the current LANL database of sites to the same population estimate models to which the PARP data had been subjected (Orcutt 1999). Past investigators of LANL sites estimated room counts while surveying, and excavated sites have complete counts provided in the field reports. However, the majority of sites recorded in the LANL database lack estimates of room counts; therefore, it was first necessary to develop a methodology for converting site size (generally, the mound size created by structural rubble) into number of rooms (the primary statistic used by both Orcutt and Newcomb for estimating population in the Southwest).

Average mound size, where available, for excavated sites on LANL property was calculated and then compared with the total number of rooms discovered on the site. Additionally, the average room size including wall width for a number of excavated sites, where this information had been documented, was calculated. The numbers are, of course, rough estimates and should not be used to determine specific numbers of rooms for individual sites, except to then calculate regional room counts. Most variation in mound size and room size will be accounted for at the regional scale. On average, it was determined that there is approximately 1.5 m of extra mound in each direction, so that amount was subtracted from mound length/width measurements before dividing total area by the average room size of 9.6 m^2. This was tested with acceptable accuracy on sites with known room counts, and therefore applied to the rest of the sites in the database that had either site maps or mound size estimates in the field notes or Laboratory of Anthropology site files. In total, it was possible to add room counts for 625 of the 802 sites with identified chronological periods.

Orcutt (1999:220–230) used population models to reconstruct room counts and population from the PARP data (Hill and Trierweiler 1986; Preucel 1986). This involved dividing the chronology of the Pajarito into five periods: Early Coalition (AD 1150–1250), Late Coalition (AD 1250–1325), Early Classic (AD 1325–1400), Middle Classic (AD 1400–1550), and Late Classic (AD 1550–1600). Orcutt standardized the number of rooms per period in order to distribute rooms from sites evenly through time. Figure 79.11 reproduces the chart from the PARP data with respect to roomblock area. Reproducing Orcutt's methods as described for number of rooms (1999:224–225), the shape of the curve remains nearly identical (Figure 79.12) even with the addition of hundreds of sites to the database since the PARP. (The sites with room counts in the current database now cover approximately 48% of LANL land. This is lower than the actual amount of LANL land that has been subjected to archaeological investigation, because room counts for 30% of the pueblos are not available at present.)

Figure 79.11. Roomblock area for PARP survey (after Orcutt 1999:Figure 5.1).

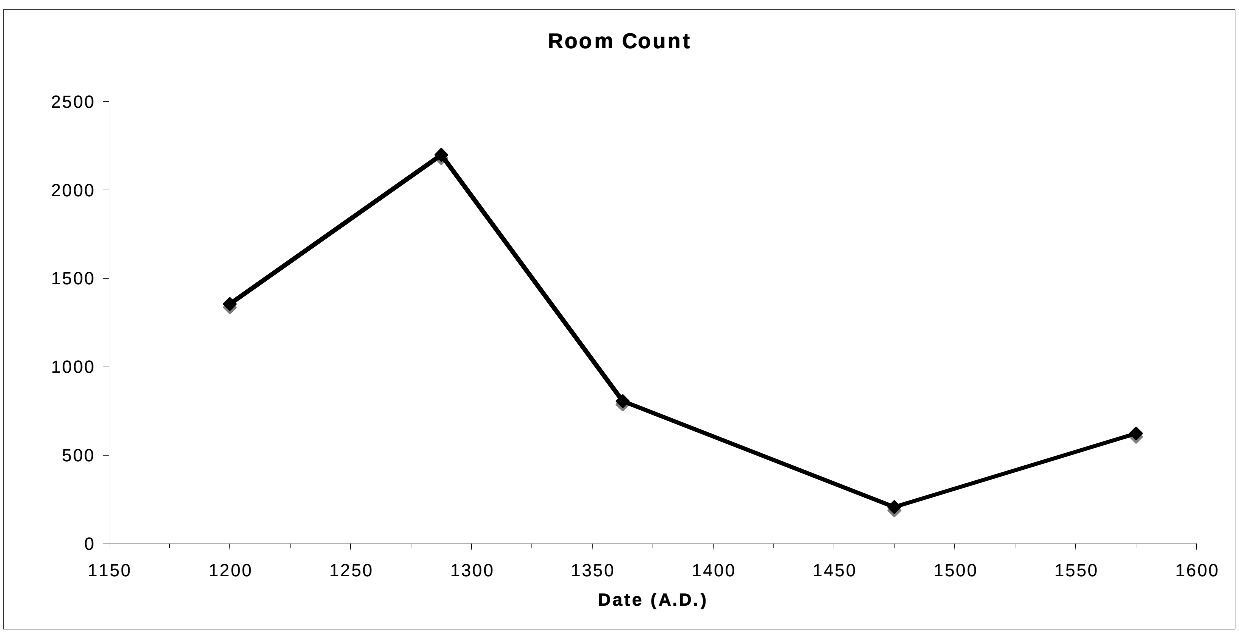

Figure 79.12. Room count on LANL region based on Orcutt (1999) room distribution methodology.

Various methods exist for estimating momentary population from room counts (Newcomb 1999; Orcutt 1999; Plog 1974; Preucel 1990). Following Orcutt (1999:225–229), use-lives of 15, 35, and 50 years were used for the Coalition, Late Coalition/Early Classic, and Classic periods, respectively. Occupancy rates, or the percentage of rooms in use during each specific period, were estimated at 100 percent, 80 percent, and 50 percent for the same respective periods. These numbers were justified by Orcutt (1999:226) as the result of archaeological testing throughout the Southwest. Orcutt lists alternate use-lives and occupancy rates for calculating minimum and maximum populations, but these are not applied at present, given the desire of strictly testing the robustness of the PARP population estimates. Following Kintigh (1985:105) and Schlanger (1988:783), the equation for calculating momentary population is

$$\text{momentary population} = \frac{(\text{num. rooms x occupancy rate) x use - life}}{\text{length of period}} \text{ x people per room} \qquad (1)$$

Five different curves were generated for the LANL Pajarito Plateau, one using Orcutt's five periods (Figure 79.13) and four using the following methodology described by Newcomb (1999; Figure 79.14), all with the same equation (1). The projected population in Figure 79.13 is based on dividing momentary population by 0.48, the approximate percent of surveyed LANL property with room count estimates.

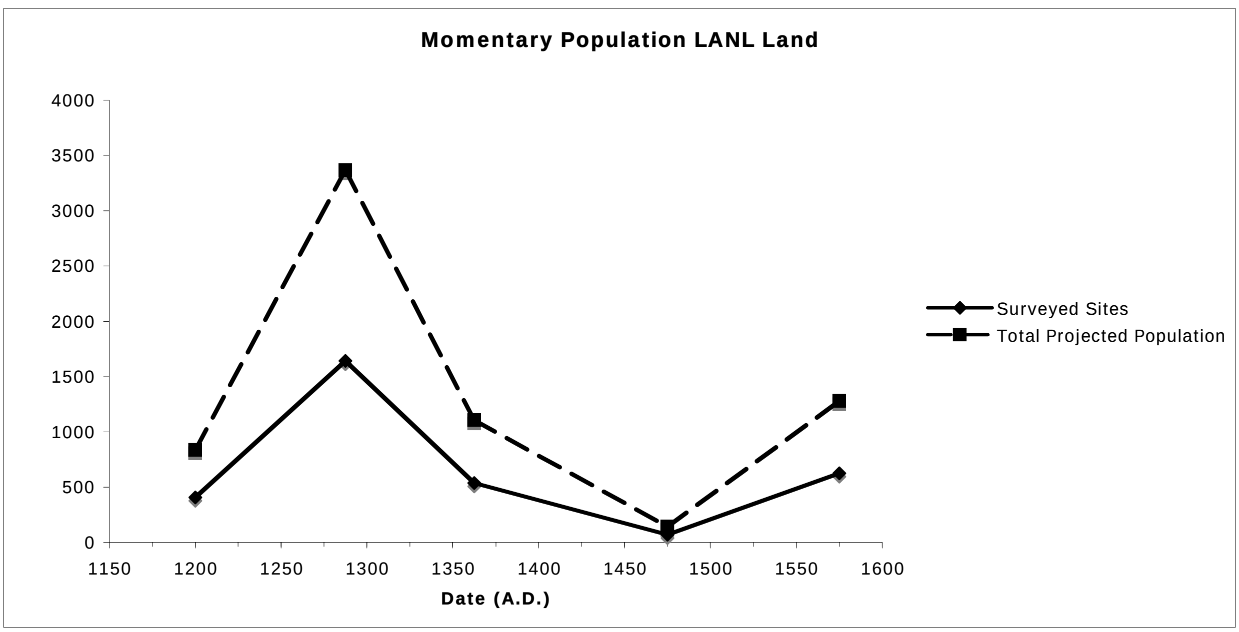

Figure 79.13. Momentary population estimates for LANL region using Orcutt's (1999) methodology

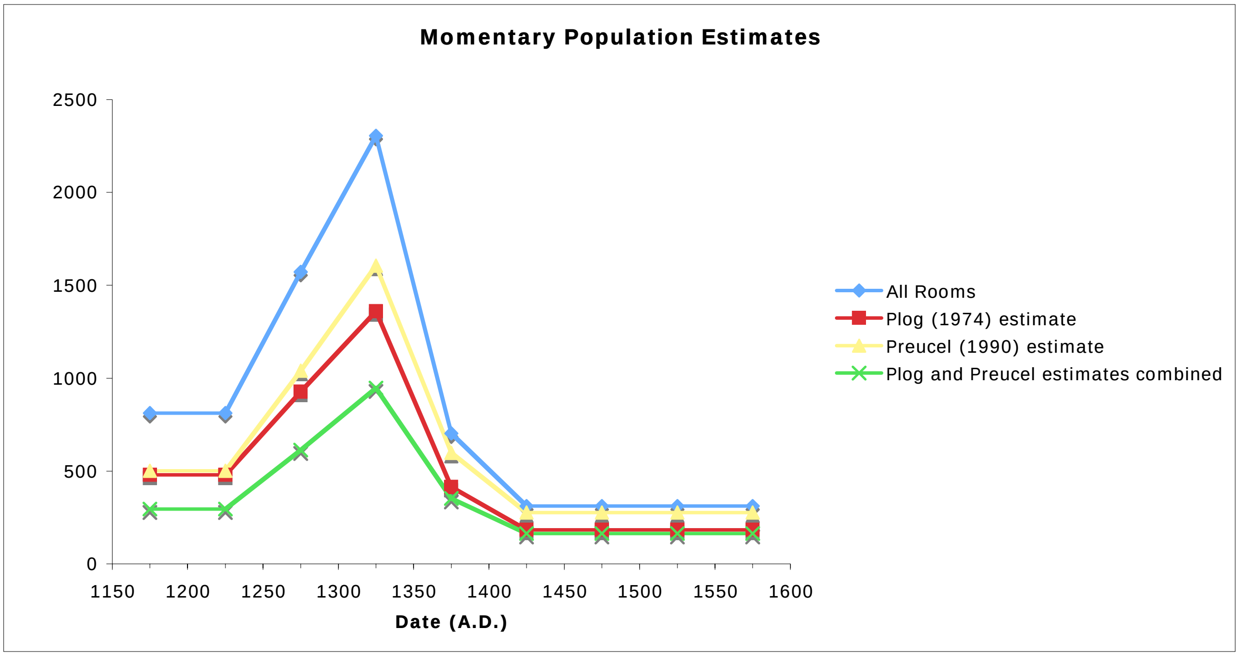

Figure 79.14. Momentary population estimates for LANL region using various strategies: 1) based on all rooms in region; 2) based on removal of 41 percent of rooms (Plog 1974); 3) based on removal of sites smaller than four rooms per period (Preucel 1990); 4) combination of Plog (1974) and Preucel (1990).

Rather than divide the time scale into the five unequal periods of culture chronology, Newcomb advocates dividing the entire span into equal 50-year intervals, and dividing the number of rooms for each site evenly across the periods. For example, a site defined as Coalition period with 40 rooms would result in 10 rooms in each range of 50 years (from AD 1150–1200, 1200–1250, 1250–1300, and 1300–1350). A site defined as Late Coalition/Early Classic with 60 rooms would result in 20 rooms each from AD 1250–1300, 1300–1350, and 1350–1400. The use-lives and occupancy rates remain consistent with Orcutt's, and people per room in all cases is constant at two, again consistent with Orcutt's assessment for the Pajarito Plateau (Orcutt 1999:226).

The variation in population estimates based on Newcomb's calculations is due to several realizations and corrections of assumptions (Newcomb 1999:40–41). First, it is highly unlikely that throughout the study region there was year-round occupation of all rooms every year. Second, seasonal occupation of small sites, such as the extremely large number of one- to three-room structures, has the potential to nearly double the population during the Early and Late Coalition, and make the population appear 10 percent to 15 percent larger throughout the Classic period. Finally, Orcutt's initial population reconstruction, and the curve based on it in this study (see Figure 79.13), assumes that all rooms are habitation rooms.

Plog (1974) and Newcomb (1999:43–44) proposed that after AD 1150, 41 percent of rooms should be subtracted from the total, to account for seasonality, storage, and manufacturing rooms. Doing so produces the second curve in the legend of Figure 79.14. Preucel (1990:165) suggests that small sites may act as territorial markers rather than habitation sites, and Newcomb

(1999:44-45) also argues that the removal of small sites (less than four rooms per 50-year period), especially after aggregation occurs, may help to account for this. The third curve in Figure 79.14 reflects the removal of small sites. Combining the propositions by Plog and Preucel, the fourth population curve is produced, which greatly reduces the overall population, but also reduces the drastic increase at AD 1325, and subsequent sharp decline post-1325. Figure 79.15 shows the momentary population of the entire LANL region, divided by the 48 percent survey value. Figure 79.16 shows the same line, but smoothed.

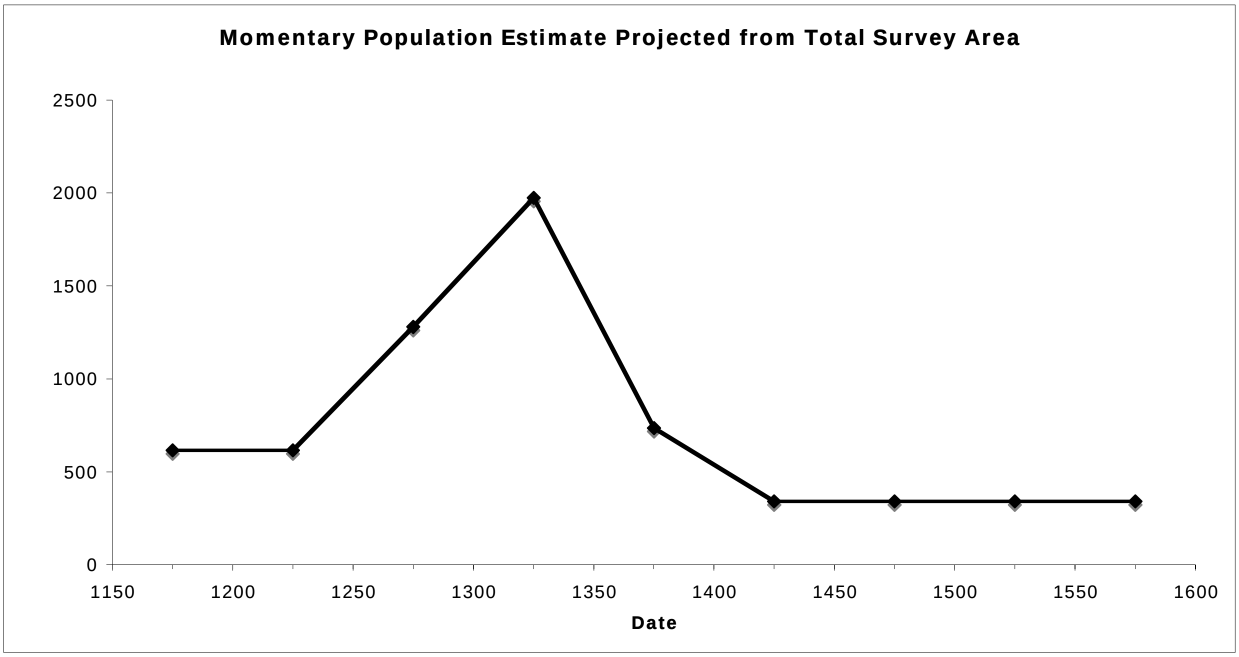

Figure 79.15. Momentary population estimate for LANL region, projected for the entire LANL-owned property, both surveyed and unsurveyed, based on the combined Plog (1974) and Preucel (1990) population estimate method.

All of the curves reflect the same basic population trajectory; it should be noted that the population of the Classic period should be adjusted upward to account for Tsankawi—as noted above, the sites in the Tsankawi member of Bandelier National Monument will be added to the database in the near future. The importance of determining accurate representations of momentary population enters the picture as the intended models based on these data become more complex. Once the methods for reconstructing population are proven to be robust, they can be used within later modeling techniques to distribute agents on the landscape. Additionally, the amount of space "leftover" from the total number of rooms available provides a starting point for determining if there is enough storage and activity space available for populations of the projected size. Obviously, these numbers will be in constant flux; as number of occupied rooms increases, the number of observed storage rooms decreases even though it is a fact that the amount of storage space should necessarily increase as well.

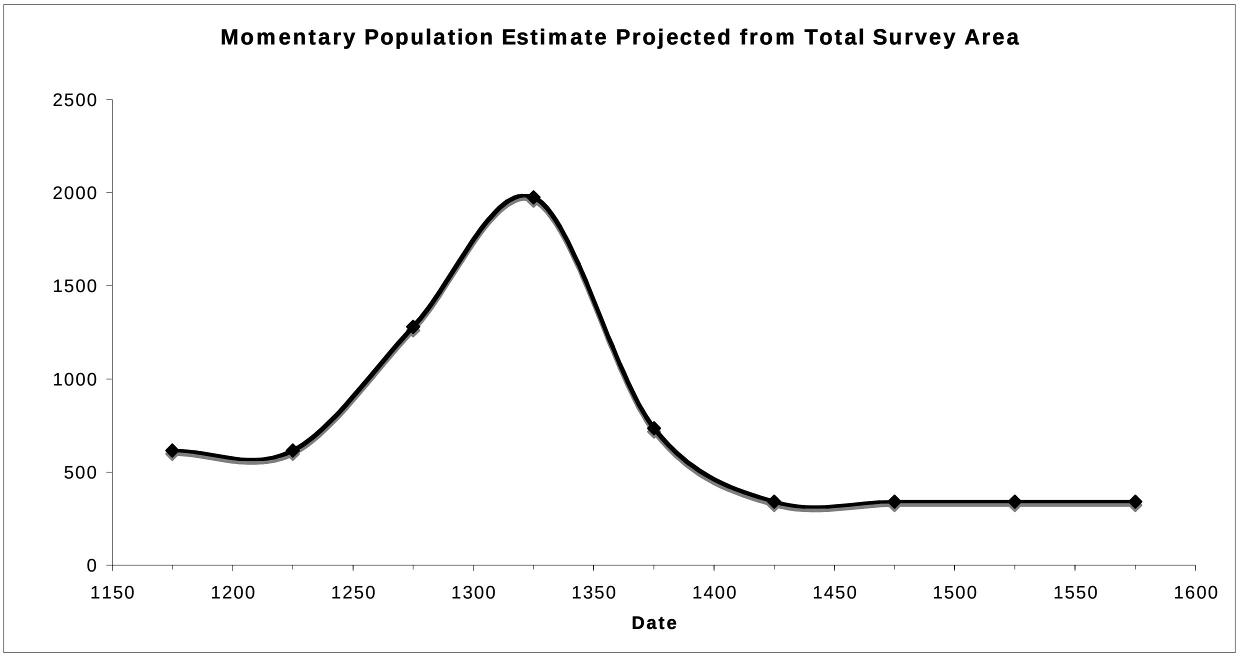

Figure 79.16. Momentary population from Figure 79.15, smoothed through time.

A final note about the room count and population estimates must be stated. There is reassurance of sound information based on the much smaller PARP sample sizes. The curves, though slightly varying, are generally equivalent in trajectory. This is good news for the usual 8 percent to 10 percent surveys that are conducted in most areas.

What Can Adaptive Cycles Reveal about Pueblo Adaptation?

Incorporating these data into the adaptive cycle heuristic model is largely theoretical, but may provide a framework for understanding change on the Pajarito Plateau as more than simple responses to climate change via relocation. The story of the Pajarito system from the Archaic through the Developmental periods (until AD 1150), and likely even through AD 1230–1250, is one of expansion, adaptation, and resource specialization—the r phase of the adaptive cycle (see Figure 79.1). This is known as the period of exploitation, where the species in a given ecosystem are not yet packed. Those occupants—in this case, including Ancestral Puebloans—continue to expand their ecological niche, and in many cases begin to specialize.

However, as this population is, on its own, reaching the K, or conservation, phase, the Great Drought begins *and* there is a migration of the San Juan Basin people to the Pajarito Plateau. This influx of peoples is well-represented by the K phase, given the immediate and widespread impact on the Pajarito environment. This occurs at the same time as the other half of the SES, the environment, is in a period of drought—a LFP (low-frequency process) that is of lower magnitude than droughts that pre- and post-date it; however, the timing of this drought with an influx of people—and therefore an increased stress on wild food resources in addition to resources stored in the soil for agriculture—provided the unfortunate combination of circumstances that caused a rapid release phase (Ω; see Figure 79.1; Figure 79.17; Dean 1988:26–36).

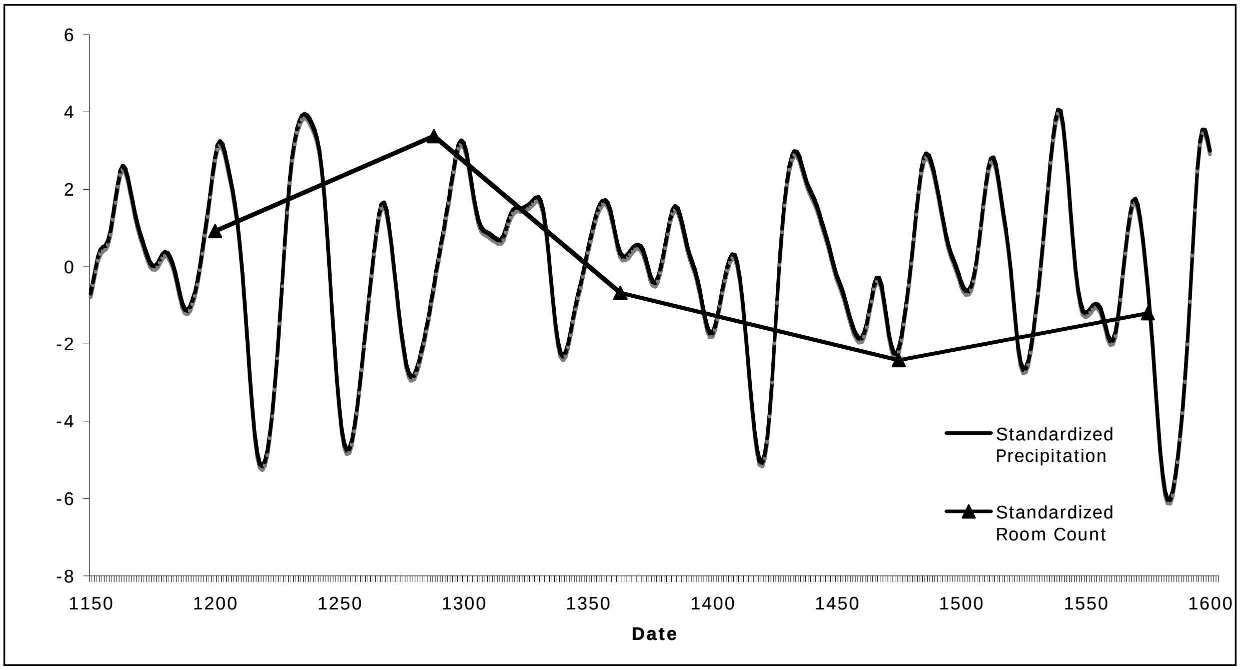

Figure 79.17. Room count for LANL region matched against precipitation reconstructed from tree-ring indices (20-year spline; Chapter 7, Volume 1) shows the greatest population increase for the region during the middle of the Great Drought (AD 1276–1299).

Why did population drop, and so rapidly, after AD 1325? Newton's infamous Third Law proposes that every action is responded to by an equal and opposite reaction—the influx of too many people + a strained environment = one of two things: 1) a decrease of population through out-migration, or 2) at worst, conflict over resources resulting in the death of many people, possibly simply through starvation.

The rapid release, though, also causes an immediate reorganization phase, and the potential for leaving one cycle and entering another. The migrants arrived on the Pajarito Plateau, began building large aggregated communities. After the release, this structure continued to develop, expand, produce more crops, add to storage and surplus when possible, and likely become more selective about where to plant and live each season. The development of more complex social systems of hierarchy, property ownership, common law, and ceremonial activity would have been inevitable.

DISCUSSION

Future work will involve an attempt to piece together this story, especially the bit discussed immediately above. Analysis within the GIS framework using spatial logistic regression models should be able to reveal more descriptive settlement patterns. A major goal will be to identify whether later settlements occupied a more refined, selective subset of the previous Coalition period's wide range of occupied elevation, soil types, geologic landforms, and vegetation communities (Vierra et al. 2006:226).

Would the Puebloans have responded the same under different environmental conditions? Or in a region with very different topography from the undulating finger mesas of the Pajarito Plateau? Agent-based modeling using the GIS framework will reveal much of this information. The understanding of the Pajarito Plateau Puebloan communities as complex systems will aid in developing an understanding of aggregation as a potential, but not necessarily, emergent property.

CONCLUSION

The Pajarito Plateau archaeological study area is a data-rich test area for the analysis of pueblo aggregation against the adaptive cycle model. The time-depth of the archaeological past, combined with the high-resolution nature of archaeological and chronological data in northern New Mexico, provides the essential combination necessary for testing traditional hypotheses of processes driving prehistoric aggregation.

It has been argued that previous hypotheses about changing elevation on the Pajarito Plateau through time are not supported by the current data. The implications of this conclusion are potentially far-reaching, for the continuous occupation of similar elevations creates more questions than it answers. This research also suggests that mean slope of site locations changes through time, and this may or may not be significant to the past cultural behavior; further investigation will inform this idea.

Further models revealing the full range of ecological habitat selection on the central Pajarito are under construction, taking into account regional vegetation, soils, hydrological features, geological formations, reconstructed precipitation, and social variables (including distance to contemporaneous sites and prehistoric trail locations). Models of population size and trajectory are robust and can be confidently used in the next generation of models of Puebloan communities in this region. The demographic models support population trends proposed by PARP (Hill and Trierweiler 1986) data.

Utilizing the demography models within an agent-based model ensures that population is not under- or overestimated differently in each period. With the support of data and models of the Pajarito Plateau system, long-term cross-cultural comparisons should be possible. There are many separate pueblo groups in prehistory that may have been driven to large, aggregated structures by similar processes to those on the plateau, but until these models are formed, tested, and applied elsewhere, the problem will remain unsolved. Additionally, there are various native groups still occupying different niches in the modern Southwest, and these models will lead to a detailed understanding of the scales and processes on which their behavior operates.

CHAPTER 80
ELK REMAINS AT ARCHAEOLOGICAL SITES IN THE SOUTHWESTERN UNITED STAES

Kari M. Schmidt

At archaeological sites throughout the American Southwest, elk (*Cervus elaphus*) remains are often less abundant (or non-existent) relative to other artiodactyl remains (e.g., pronghorn, deer, and bighorn sheep) in faunal assemblages (see Table 80.1). In xeric areas of the Southwest (i.e., lowland areas), this is to be expected given the lack of suitable grassland habitat for elk populations. In more mesic areas (i.e., upland areas), such as is found in the Jemez Mountains and on the Pajarito Plateau, the prehistoric absence of elk is purported to be anomalous since research suggests that habitat composition may have been just as, if not more, favorable to supporting and sustaining elk populations. Some researchers in the northern Rio Grande area have argued that elk were not indigenous to the area, and that they were a recent introduction (Allen 1996, 2004; Bryant and Maser 1982; Eberhardt et al. 1996; Kay 1994; Truett 1996; White et al. 1998).

To address the apparent dichotomy between the expected and observed occurrences of elk at archaeological sites, I conducted an extensive review of the archaeological literature from all areas of the Southwest to see if and where elk remains were recovered in archaeological faunal assemblages. I present the data recovered in the literature review, which show that elk remains were recovered at a number of archaeological sites (Table 80.1), including in areas of the Pajarito Plateau and Jemez Mountains. Elk were identified in a variety of areas in Arizona, New Mexico, Colorado, and Utah. Additionally, occurrences of elk are also noted in both open lowland areas (e.g., the Donaldson site in the Cienega Valley, Arizona, University Indian Ruin in the Tucson Basin, and Bat Cave in New Mexico) and more wooded upland areas (e.g., Mogollon Village in New Mexico, McEuen Cave in Arizona, and many sites in the Mesa Verde/Mancos area of Colorado). Finally, elk were identified in assemblages that span over 9000 years from Early Archaic sites in Colorado to the original Tucson Town Site (1890–1914) in Pima County, Arizona.

Table 80.1. Elk remains at archaeological sites in the southwestern United States.

CHAPTER 81
ANCESTRAL PUEBLO TRAILS OF THE PAJARITO PLATEAU: A SUMMARY OF RECENT RESEARCH

James E. Snead

Old-time trails across the rock
Knee-deep nearly, sheerly worn
Here converge and interlock
Old when Babylon was born

- From "Tsan-Ka-Wi," by John H. Underwood; *El Palacio* 1916 4(3):9

INTRODUCTION

The Ancestral Pueblo trails of the Pajarito Plateau have been a source of curiosity and contemplation since Euro-American explorers first entered the region in the late 19th century. Thoroughly photographed, described in letters, articles, even poems, as the excerpt above, referring to trails near the pueblo now called Tsankawi, indicates, these features have nonetheless confounded archaeological analysis. Hard to follow, difficult to date, enigmatic in design, trails (or paths) are difficult to understand through standard approaches. They also subvert our traditional categories, since they are not truly *places*; no one lived on a trail, or grew their crops in its ruts, or made tools there, except perhaps, in passing. Instead, trails represent the linkages *between* places. They are thus the physical embodiment of immaterial processes such as movement and relationships, things incompletely captured by pottery, stone, and bone. Only recently have archaeologists realized that these connections are of equal value to the places that they join together, and that, in certain, favorable conditions, we can study such relationships through the traces of the process itself.

The Pajarito is one of the rare regions where such evidence is preserved for the archaeologist. The consolidated, pyroclastic ash flows that represent the foundation of the plateau are sufficiently erosive so that the passage of foot traffic over time wears a groove directly into the rock. The soft surface can also be intentionally carved and shaped, a phenomenon that gave rise to the famous cave dwellings of the vicinity but which also means that stairways and even trails themselves could be pecked out by hand. These circumstances, and the fact that the mesas and portreros of the region were relatively isolated throughout most of the post-Columbian period, mean that in the present day it is possible to literally walk in the footsteps of the ancestors.

The archaeological challenge presented by this pattern is to sort out the evidence of the trails created and used by the Ancestral Pueblo people of the Pajarito, but to also unravel their meaning. The Pajarito Trails Project (PTP) was created with that purpose in mind; this report collates three seasons of fieldwork (1991, 1999, and 2001) with scattered records from other projects that have recorded trails in the region. As with most archaeological efforts it is a work in progress, part method, part data, with a few tentative conclusions. The extraordinary cultural landscape of the Pajarito provides a great opportunity for archaeology: trails, while merely one element of this complex whole, represent one way to draw us into that world, and to let us see it through other eyes.

METHOD

The study of ancient trails and paths is in its infancy. Archaeologists have made a sharp distinction between these features, argued to be informal and ephemeral, and *roads*, which, by virtue of their greater formality, are more visible and present fewer problems of method (Trombold 1991:3). Their functional implications and labor requirements have meant that roads are also considered a hallmark of complex social systems, long a subject of archaeological interest (cf. Earle 1991). Thus, while a number of substantive studies of ancient roads have been published (Hererra and Cardale de Schrimpff 2002; Hyslop 1984; Laurence 1999; Vermuelen and Hageman 2001), issues of evidence and preconceptions about the "significance" of trails have hindered research.

In the absence of formal roads, discussion of movement through the landscape has traditionally adopted a large scale and emphasized *routes*, rational patterns of travel mandated by topography. Archaeologists are familiar with maps that feature lines and arrows "documenting" directions of trade and interaction, often based upon the watercourses, passes, and similar features of terrain that make such movement possible. Physical evidence for the use of such routes is often sought in the distribution of artifacts and raw materials across space, rather than in documentation of the process of movement itself. Such an approach is unsatisfactory on several counts, among which are the vast scale at which such models must be structured and the multitude of natural/cultural factors which can account for artifact distribution. By emphasizing exchange, this approach also emphasizes only one of the many different types of movement that would have occurred along such routes, skewing our perception of those doing the traveling.

In some cases, evidence for routes of transit is sought in historical records. In the mid-20th century, considerable effort was devoted to combing documentary sources for information about Native American trails in colonial North America (cf. Ayres 1940; J. Davis 1963; Hindes 1959; Myer 1929; Sample 1950). In most cases no physical evidence for any of these routes was available. Even in cases where eyewitness descriptions of trails were relatively recent, identifying them "on the ground" proved challenging, as the experience of a 1960s project to find the historically documented "Comanche War Trail" in southwest Texas suggests. "We found many abandoned roads and numerous animal trails, but nothing identifiable as a Comanche trail. As a matter of fact, we found no artifacts that could be identified with the Comanche" (Campbell and Feld 1968:140).

It is evident, however, that in some cases material evidence for trails and paths *is* preserved in the archaeological record. This is particularly true in arid locations. Several studies in the Mohave and Colorado deserts, for instance, have documented long-distance trails with clear pre-Columbian associations (Campbell 1931; Harner 1957; F. Johnson and Johnson 1957; Rogers 1966:47; Von Werlhof 1988). Trails associated with springs and water catchments were recorded in the Great Basin (Ives 1946) and the Southwest (Britt 1973), while evidence for trails in the Great Plains has also been recorded (Blakeslee and Blasing 1988). With the urging of Carling Malouf (1961, 1980), a number of studies were conducted on trails in the northern Rockies, culminating in an entire issue of *Archaeology in Montana* [21:3] devoted to the archaeology of trails (1980).

Failure to incorporate data for trails into our interpretations of the past can thus be more a question of research bias than of evidence, per se. With increasingly detailed recording of archaeological data, trails and related features are now commonly noted in archaeological reports (e.g., Boyer et al. 2002; Van Zandt 1999). Systematic analysis remains uncommon, however, and the discussion of movement continues to emphasize routes and roads. Recent literature on the Chaco period in the greater San Juan Basin of New Mexico, for instance, features a flourishing discussion of the formally constructed Chaco "roads" (cf. Hurst et al. 1993; Kanter 1997; Marshall 1997; Mathien 1991; Roney 1992; Severance 1999; Vivian 1997a, b; Windes 1991). References to the network of trails that must also have been a component of the Chacoan landscape, in contrast, are scarce. The fact that 148 stairways or sets of steps were documented in the course of the Chaco surveys (Pattison 1985:63), most of which would necessarily have been associated with local trail systems rather than the roads themselves, is an indication that when such data appeared they were relegated to the back pages of reports.

In addition to the fact that "evidence" for trails is increasingly difficult to ignore, the body of ethnographic and theoretical discussions of these features increasingly makes the case for their importance. Indigenous perceptions of pathways are much more elaborate than previously credited; more than expedient means to get back and forth, trails are complex, tangible metaphors of interaction and association (cf. Ballard 1994; Laird 1976; Parmentier 1987; Weiner 1991). Recent reports on trails in the Southwest have also emphasized this ethnographic dimension (e.g., Hart and Othole 1993; Stoffle et al. 1977). Finally, "paths" are an important part of the evolving theoretical discussion of landscape, space, and place in archaeology (see Barrett 1994:141; Ingold 1993:167; Thomas 1996:90; Tilley 1994:31; Zedeño and Stouffle 2003).

It is within this increasingly productive context for the archaeological study of paths and trails that recent field research in the Southwest has developed. Consideration of trails at Hopi (Zedeño 1997), Hohokam "roads" (Motsinger 1997), and Navajo pathways at Cañon de Chelly (Jett 2001) all point to the importance of understanding how people of the southwestern past moved through their landscape. My own work, published (Snead 2002a, c) and unpublished (Snead 2000, 2001b), has made use of the optimal preservation conditions for trails on the Pajarito Plateau to develop ideas about the history of settlement in the region, political interaction, and the human role in the structuring of the landscape. From this expanding body of work it is evident that the traditional distinction between *roads* and *trails* is no longer tenable. Both serve, in the words of one author, as "paths of political control, of social rhythms, military tactics, religious observances, and economic endeavors" (Darnell 2002: 114). The complexity of paths and trails as categories of information should not interfere with our acknowledgment of their importance, but instead spur us to find new and creative ways to redress the limits of our methods.

Recording Strategies

All of the archaeologists that work with trails and paths grapple with three linked problems of evidence:

A. Chronology. Trails are very difficult to date directly, since almost by definition they are worn down rather than built up. Does a trail across the mesa top date to the Ancestral Pueblo period, or is it a 19th century stockmen's route?

B. Association. Since the use of a trail may leave very little evidence beyond footprints, linking trail-related activity with other evidence from the surrounding area is particularly complicated. A cairn may mark the course of a trail, but does it date to the era when the trail was initially blazed, or is it a more recent addition?

C. Contiguity. Because trail preservation is a factor of local geology, topography, and ground cover, it is rarely possible to estimate their true extent and interrelationships. Does this trail climbing out of a canyon relate to the small fieldhouse on top, or did it eventually connect with the major trail running along the mesa? Or both?

There is obviously no simple answer to these problems, but they figure heavily in limiting the amount of research on trails that has been conducted in the Southwest. In a case from the early stages of the recent Bandelier Archaeological Survey (BAS), a major Ancestral Pueblo trail and staircase entering Frijoles Canyon was initially recorded as an "isolated occurrence" from which minimal information was collected. The recording protocol had no category for such a feature, which was of uncertain extent, and, regardless, couldn't be dated directly. Ultimately it was re-recorded, but the dilemma facing the crew that first encountered it is real.

The critical approach to analyzing trails in the archaeological record concerns establishing *context*. Trails in isolation appear as enigmatic fragments, but trails in context with other trails and the surrounding cultural landscape become much more comprehensible. In this way it is possible to compare trails with each other to identify salient characteristics, shared and different. It also becomes possible to more clearly identify nodes and places linked by particular trails; since those features are often more "datable" than the trails themselves, they introduce a more specific chronology. It is certainly true that some trails, once established, will remain in use for centuries or millennia. Patterns of human movement do change over time, however, and trails, like the places they connect, may not only go out of use, but also undergo structural change as the nature of use shifts. In a simple example, the routes taken by the US interstate highway system parallel, but do not entirely obliterate, earlier roads, which were built for different types of traffic and often go in slightly different directions. Trails function in similar ways, and in many cases the resultant differences can be seen archaeologically.

Trails as a category of archaeological information are a poor fit for the traditional idea of the "site." Sites are usually contiguous or closely proximate clusters of features and artifacts, distributed across finite space. We use this concept to divide a complex body of information into units that are manageable and can be compared with each other. Trails, in contrast, are "anti-sites," being the tangible connection *between* sites. They may go on for miles, but are usually intermittent, and also will intersect with other trails that, at least in theory, extend throughout a region. They are understandable only in a landscape context, in which they exist in various relationships with an array of other features across an unbounded space.

In practice, I have approached trails as assemblages of different but related types of evidence. A recording protocol developed in the course of the Pajarito research (Snead 2000) and under continual revision, goes some way toward addressing these concerns, and has three basic components:

A. Recording of trail features as <u>segments</u>. It is increasingly standard practice among archaeologists working on trails and roads to record them as segments of a potentially larger feature (e.g., Marshall 1991). Segments, of which an infinite number are possible, can be distinguished by visibility, surrounding terrain, or any other characteristic that distinguishes parts from the whole. Decisions as to what this "whole" may consist of (and whether it should be classified as a "site") are thus left in abeyance until later in the analysis.

B. Consideration of <u>trail structure</u>. This includes both the *fabric* of the trail itself, the characteristics (width, depth, steps/stairs, etc.) of the feature underfoot, but also *associated features* (cairns, walls, etc.). Not all elements of trail structure need be contemporary, but all are functionally related to the trail itself. Treating this array of features collectively allows for the complexity of the trail to be accurately portrayed.

C. Evaluation of the <u>trail network</u>. The spatial organization of an array of trails, both as they potentially connect with each other and as they articulate with other nodes in the landscape, provides critical evidence regarding the context of the entire system. In this case neither trails nor their destinations are treated generically, but instead as aspects of a larger, interconnected landscape.

These approaches are sufficiently general to be adaptive to different circumstances; my application of them to the Pajarito case is outlined below. In principle, however, they provide a way for us to bring a fresh perspective to the archaeological study of paths and trails. This potential is seen in a wave of recent studies on the subject, ranging from using remote sensing to study trails buried by volcanic ash deposits in Costa Rica (Sheets and Sever 1991), historical records to augment fieldwork on indigenous Hawaiian trails (P. Mills 2002), and geographic information system analysis to identify routes of local travel in prehistoric Europe (Bell and Lock 2000; Bell et al. 2002). As the roads/trails dichotomy breaks down, the greater potential for developing an archaeology of human movement is realized, enriching our knowledge of the cultural landscape.

BACKGROUND

Natural and Cultural Setting

The Pajarito Plateau is a region of north-central New Mexico bounded by the Jemez Mountains to the west and the Rio Grande to the east, extending from roughly Santa Clara creek on the north side to the Rio Chiquito on the south. The plateau itself consists of a basalt substrate overlain by consolidated pyroclastic flows of Pleistocene date (Ross et al. 1961). Erosion of this friable material has created a topography of flat-topped mesas and "portreros" separated by sheer-walled canyons. Permanent water flows in a small number of these streams; the lower elevations of the plateau along the Rio Grande are dominated by piñon pine and juniper, with ponderosa more prevalent towards the Jemez further west.

Ownership of the Pajarito is divided up several ways. Most of the southern plateau falls within Bandelier National Monument, while the central plateau is under the jurisdiction of Los Alamos National Laboratory (LANL), with sizable acreage also governed by San Ildefonso Pueblo. Smaller tracts include substantial private land around the town of White Rock and the Tsankawi Unit of Bandelier National Monument. Much of the northern plateau is part of the Española Ranger District of the Santa Fe National Forest, with Santa Clara Pueblo owning land along Santa Clara creek. The diverse ownership of land on the Pajarito Plateau has had a demonstrative affect on trail archaeology in the region, as will be seen below. From a preservation perspective, however, the significant level of public ownership and the relative remoteness of the area (until recently) has provided remarkable protection for local archaeological resources.

This evidence suggests that Archaic period hunter-gatherers were the first inhabitants of the Pajarito, but the primary Ancestral Pueblo occupation of the area began during the AD 1100s. During the Coalition (AD 1150–1325) and subsequent Classic (AD 1325–1550) periods, the region was home to a significant human population, who farmed the canyon bottoms and mesa tops (for an overview, see Powers 2005; Powers and Orcutt 1999b). An initial pattern of dispersed small residences close to the fields evolved into one characterized by a few large "community houses" surrounded by hinterlands with seasonally occupied fieldhouses. The most prominent of these are (from north to south) Puyé, Otowi, Tsankawi, Navawi, Tsirege, Tyuonyi, and Yapashi, although dozens of smaller pueblos as well as extensive cliffside cavate pueblos are preserved. Other elements of a diverse cultural landscape include petroglyphs, reservoirs, field systems, shrines, and trails. The permanent population of the plateau appears to have declined over the course of the late pre-Columbian period, and by the early 1600s it seems to have been used largely as a seasonal hunting ground. Descendant populations of the Pajarito inhabitants are to be found in the Tewa pueblos of Santa Clara and San Ildefonso as well as the Keres pueblo of Cochiti.

Previous Research

The first recorded mention of the Ancestral Pueblo trails of the Pajarito Plateau comes from Col. James Stevenson of the Smithsonian's Bureau of Ethnology, who mentioned trails at the Pueblo of Puye in 1880 (J. Stevenson to J. W. Powell, 27 October 1880:BAE). Adolph Bandelier's

Cochiti guides took him along the old trails further south on the Pajarito during the same period (Bandelier 1892:147), routes used by many others over the subsequent decades (cf. Prince 1903). A typical experience was recorded by J. A. Jeancon, reporting to Edgar Lee Hewett about a visit to Tsankawi. "The trail leading across the solid stone is worn in some places to a depth of three feet," he wrote. "This is most remarkable when one stops to consider that the Indians wore only moccasins or went barefoot" (89ELH.081; LOA). Hewett's own work contains numerous references to trails, including several published photographs (cf. 1909:437; 1953). Although he described plans to publish a report focusing on trails (1908b:18), it was never completed. Related ethnographic information was collected by J. P. Harrington, whose *Ethnogeography of the Tewa* contains descriptions of 17 different trails, including several on the Pajarito (1916:412).

Trails make only rare appearances in discussions of Pajarito archaeology over the next two generations, circumstances that I have argued reflect the dominance of a "chronological perspective" in Southwest archaeology for which landscape features were largely irrelevant (Snead 2002b). It wasn't until the 1970s, when surveys of lands associated with LANL were begun, that interest in the archaeological potential of trails reemerged. Charlie Steen (1977) documented several individual trails in the central plateau, which although lacking in detail provided a baseline for future research.

A new and more systematic approach for Pajarito archaeology was inaugurated in the late 1970s with the Pajarito Archaeological Research Project (PARP), which conducted intensive surveys to test hypotheses concerning the response of the Ancestral Pueblo population to environmental stress. In the process, more than 800 sites were recorded from all parts of the plateau, including numerous trails (see Hill and Trierweiler 1986; Hill et al. 1996). Despite the processual strategy and the more rigorous fieldwork, however, the PARP analysis was similar to more traditional research in its concentration on chronological information and residential sites. Landscape features such as trails were recorded, but did not play a substantive part of the discussion. A more holistic strategy was adopted by the BAS in the 1980s; over five years more than 3000 sites of 50+ types were recorded within the national monument. The discussion of trails in the project's final report was brief but substantive, notable in view of the extraordinary quantity of archaeological data that had been generated (Van Zandt 1999).

As of the early 1990s the Ancestral Pueblo trails of the Pajarito were thus widely known among archaeologists but had never been systematically documented. The considerable information provided by the PARP and BAS field crews, however, had generated a detailed landscape within which the trails could be placed. Attempts to use existing information to evaluate the trail networks themselves, however (Snead 1991) were problematic, largely because of the methodological issues discussed in the introduction. It was often impossible to tell from existing site records, for instance, whether trails on adjacent sites were actually different segments of the same larger-scale feature or were entirely unrelated. On another level, the different jurisdictions on the plateau created obstacles for trail recording, since they rarely stopped at modern boundaries. If the Pajarito trails were to contribute to our understanding of the Ancestral Pueblo world, then a new project would have to be developed to address the issue directly.

The Pajarito Trails Project

The PTP began in 1991 as an exploratory survey of land belonging to San Ildefonso Pueblo in the vicinity of the Navawi community house (Snead 2002c). Working with a permit from the pueblo, I spent two weeks documenting a series of trails and related features associated with Navawi and other habitation sites in the area. This work produced substantial new information, particularly since the area had not been the scene of archaeological work for decades; but the level of documentation was uneven, particularly since it was only after beginning that I became aware of many of the complexities of trail recording.

The PTP was revived in 1999, when an opportunity for fieldwork in both Bandelier and Los Alamos lands opened up. In the meantime a number of new theoretical approaches to space and landscape had also been developed, making the work timely in a way that it had not been eight years before. Accordingly, three weeks in 1999 and one week in 2001 were devoted to the recording of trails in the central and southern portions of the plateau.

The methodology of the project developed largely along the lines discussed above. Rather than survey entirely new areas, the project focused on the re-recording of trail sites that had already been identified. Seven areas, containing 32 recorded trail sites, were emphasized. These include: Frijoles Canyon (Bandelier), White Rock Canyon (Bandelier), Lummis Canyon (Bandelier), Yapashi (Bandelier), Capulin Canyon (Bandelier), Tsankawi (Bandelier), and Otowi/Sandia Canyon (LANL).

The characteristics of trail structure (Table 81.1) were derived from existing records and modified in the field. Since many of the terms developed at the time will appear in the following section, I will reproduce them here:

A. Fabric

1. Cleared talus. Cleared talus indicates construction of a trail by moving larger stones and cobbles from its path (Figure 81.1).

2. Wearing. Wearing, also called "incision," "erosion," etc., refers to areas where the trail has been worn into the bedrock surface by friction caused by foot traffic, leaving a tangible imprint (Figure 81.2). Trail wearing can range from a faint "shadow" on the ground to deep worn segments a meter or more in depth.

3. Construction. Construction indicates formal excavation of trail into the ground or physical modification of the trail surface by means other than gradual erosion (i.e., wearing). It is assumed that this means pecking or grinding through the use of tools made of basalt or other hard stone (Figure 81.3). Construction is considered to reflect a formal process of trailbuilding. Construction must also be argued rather than assumed, since it is difficult in most cases to distinguish wearing from construction. The dilemma is illustrated in Van Zandt's summary of BAS trail data, which lists nine "pecked" trails, 20 "excavated" trails, 32 "worn" trails, and nine considered to represent a "mixture" of fabrics (41). These categories reflect the assessment of field teams, rather than any standard measure. Steps and similar features, while more clearly evidence for formal construction, are covered by their own category, below.

Table 81.1. Characteristics of trail structure developed for the recording of Pajarito trails (modified after Table 1 in Snead 2000).

Trail Structure (Pajarito)	
Fabric	**Associated Features**
Wearing	Berms
Cleared Talus	Flanking Walls
Construction	Shoring
Braiding	Cairns
Switchbacks	Trail Markers
Hand and Toe Holds	Architecture
Steps (One-foot, Two-foot, and Basin)	
Stairs	
Ramps	

Figure 81.1. LA 134901 as it descends from the Portero del Rito into White Rock Canyon, illustrating cleared talus trail construction.

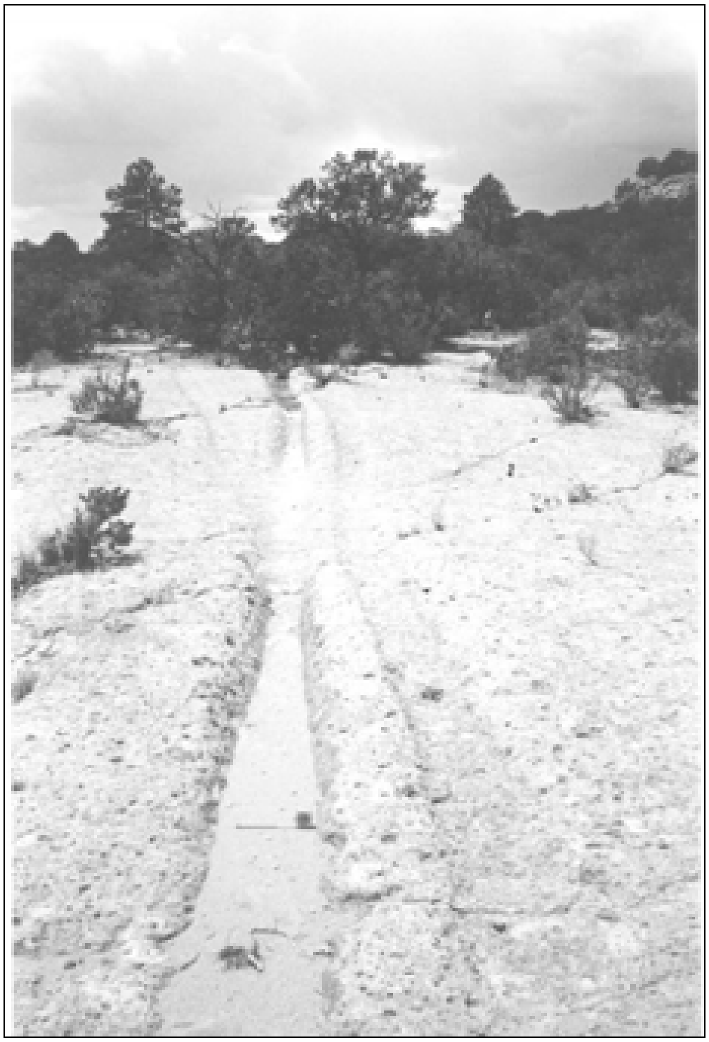

Figure 81.2. LA 66885, the Sandia Canyon Trail Network (Segment 03), illustrating wearing and braiding (10 cm scale).

4. Braiding. Braiding, also called "multiple routes," is the duplication of a trail into parallel and often interwined paths within a relatively restricted area. Operationally, braided trails are usually no more than 10 m apart, or they were considered separate (if possibly related) segments (see Figures 81.4 to 81.6). It should be noted that braiding can be both informal (a product of slight modifications in a trail's route over a period of time) and formal (the intentional re-alignment or re-construction of a trail). Distinguishing the two is not straightforward and has been done inconsistently by the PTP. The trail depicted in Figure 81.2 illustrates braiding as an informal process, while the braided trails in Figures 81.7 and 81.8 show evidence of more formal construction.

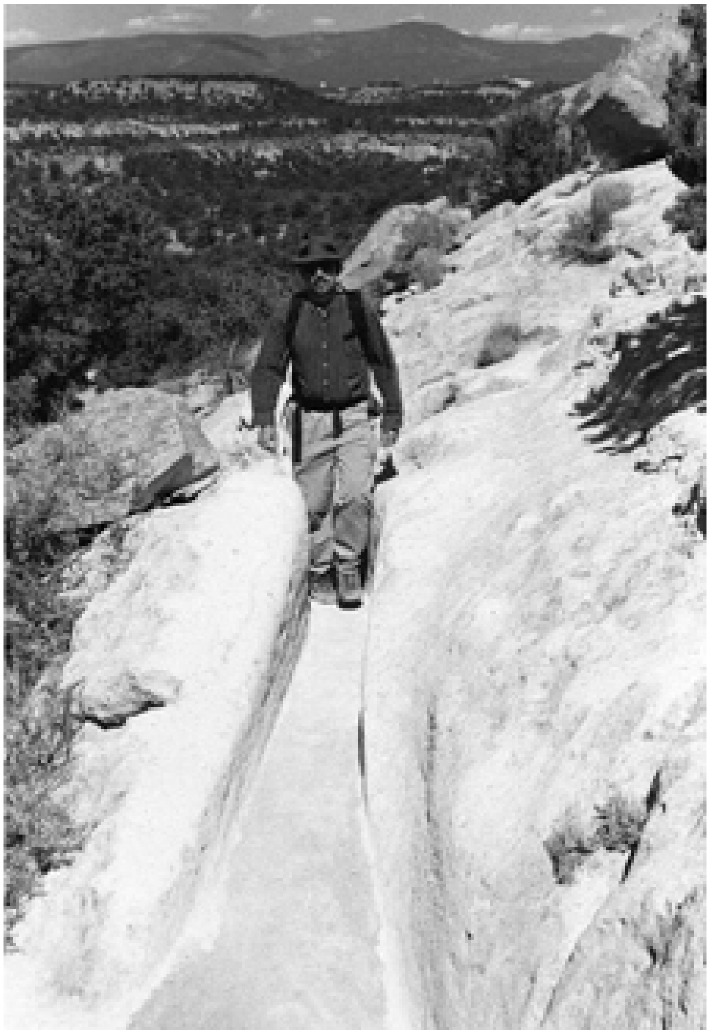

Figure 81.3. LA 70989, the Tsankawi Mesa Trail network (Segment 01), illustrating wearing and probable construction. J. Snead in photo.

5. Switchbacks. Switchbacks refer to trails that angle back and forth across a slope. Switchbacks are sometimes thought of as a Euro-American introduction, but also appear on trails that are clearly associated with the Ancestral Pueblo period.

6. Hand and toe holds. Hand and toe holds are modifications of the tuff surface designed to facilitate climbing up steep boulder/cliff faces. Hand and toe holds usually consist of shallow "cups" pecked into the rock surface and demonstrate a minimum of effort. In some cases hand holds are found in association with steps.

7. Steps. Steps are modifications of the trail surface designed to facilitate climbing moderate slopes. They are generally larger and wider than hand and toe holds. Three general morphological characteristics of steps have been noted:

Figure 81.4. "One-foot" steps on Tsankawi Mesa. 1 m scale.

Figure 81.5. LA 77779, illustrating "basin steps." 10 cm scale, view from above.

Figure 81.6. LA 70989, the Tsankawi Mesa trail network, illustrating worn segment and associated steps. 1 m scale.

a. one-foot steps. These are steps large enough for a single foot. Unlike hand and toe holds, they have been cut straight down into the rock surface and are thus "open" at the top (Figure 81.4).

b. two-foot steps. Steps large enough for two feet side by side.

c. Basin steps. These are large steps that by design or subsequent erosion have a concave profile (Figure 81.5).

8. Stairs. Stairs are aligned sets of steps. Operationally, a set of five or more steps is here suggested to define "stairs" in relation to "steps." The term "staircase" is used for stairs that are qualitatively distinct (Figures 81.14 to 81.17).

9. Ramps. A ramp is a constructed or modified inclined plane by which a trail ascends or descends a section of slope. A ramp may be a section of bedrock that has been shaped to facilitate foot traffic down a short drop.

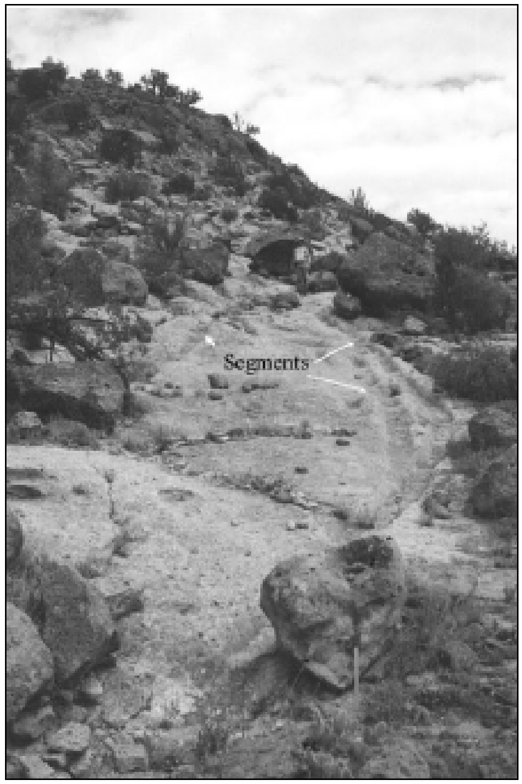

Figure 81.7. LA 65581, illustrating braiding associated with the Capulin Staircase.

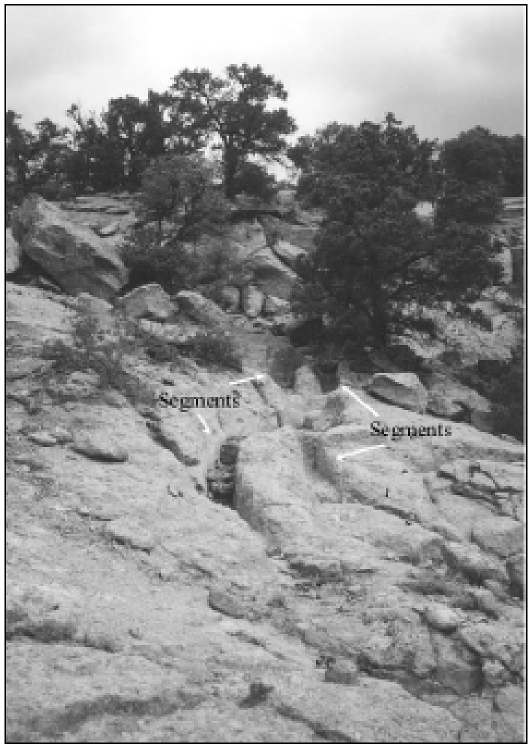

Figure 81.8. LA 66885, the Sandia Canyon trail network, illustrating braiding on Segment 6.

B. Associated Features

1. <u>Berms</u>. Berms are linear mounds of stacked cobbles and boulders found along trail margins parallel to the trails themselves. Typically, berms function to bound a trail's downhill side (Figure 81.13). Berms are another feature of possible Euro-American introduction, although in at least one case—LA 90799, associated with the Caja del Rio North community house—large piñon and juniper trees growing in the path suggest that the construction of the associated berm is of some antiquity. This trail is also quite distinct from an obviously historic example nearby, making a credible case that the berms at LA 90799 are Ancestral Pueblo in origin.

2. <u>Flanking walls</u>. Walls of stacked shaped/unshaped cobbles set perpendicular to the course of a trail. Flanking walls are typically found at mesa rims and appear to have been designed to limit access to the mesa tops by people traveling on the trail (Figure 81.9).

Figure 81.9. LA 125383, illustrating Segment 1 with flanking walls.

3. Shoring. Shoring refers to the stacking of cobbles or other construction material to level the downslope side of a trail.

4. Cairns. Cairns are piles of unshaped cobbles placed alongside trails to mark their routes. Dating is a particular challenge regarding associated features of these types. Most are associated with Historic period trail construction, but are present in sufficient numbers on trails that otherwise are clearly associated with the Ancestral Pueblo period that each must be considered on its own merits (Figure 81.10).

Figure 81.10. LA 84137, illustrating associated cairns of possible Ancestral Pueblo date.

5. Trail markers. Trail markers consist of petroglyph panels or isolated elements that mark trail routes. While some trails may lead to or pass near larger petroglyph panels, trail markers are directly associated with trails themselves (Figure 81.11).

6. Gametraps. Gametraps are pits excavated into the tuff bedrock that are believed to have been used in the hunting of deer. Several gametraps have been found in direct association with Ancestral Pueblo trails (Figure 81.12). My interpretation of these features, following Steen (1977:29), is that they date from the colonial or early modern eras, and were used by Pueblo hunting parties who came up on the plateau when the full-time residential population had largely departed. Otherwise they would have represented a dangerous obstacle for people using the trails.

It should be evident from this list that the Pajarito trails can be complex and quite variable, since some major trails included most of these aspects of trail structure. The results of the project were documented in three reports (Snead 2000, 2001b) and one publication (Snead 2002a) that focused on the trail segments of the southern plateau.

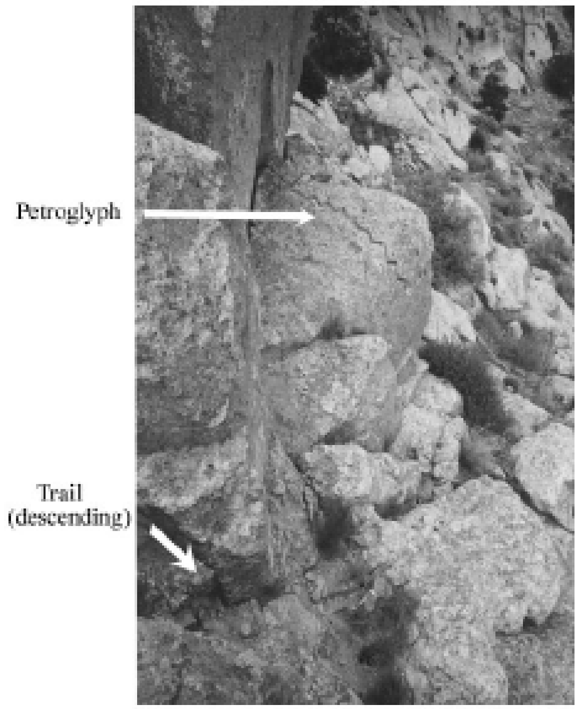

Figure 81.11. LA 21602, the Kwage Mesa trail network, illustrating Segment 4 with petroglyph trail marker.

ANCESTRAL PUEBLO TRAILS

In the following three sections I provide an overview of recorded Ancestral Pueblo trails of the Pajarito Plateau. They are the *Northern Pajarito*, defined as the area between Guaje and Santa Clara canyons; *Central Pajarito*, between Ancho and Guaje canyons; and *Southern Pajarito*, from Ancho Canyon south to the Rio Chiquito.

For several reasons, I do not provide a figure for the total number of sites recorded as trails in the Pajarito region. Detailed field checking has failed to confirm the presence of some of these features. Since many trails have been recorded as secondary features associated with residential sites, it is also often difficult to pick them out of site forms or databases. Hand and toe holds, for instance, are present at many sites but receive little or no mention. This would suggest that the number of sites that include trails or trail features is actually larger. In contrast, many of the more visible trails have been re-recorded or assigned different site numbers at different points along their length, as they pass near other features. In my own work, for instance, I have suggested that site numbers be assigned to particular, functionally interrelated trails, which would often subsume several different numbers. Numbers of trail sites thus reflects dueling strategies of record-keeping that only distantly approximate “real” conditions on the ground.

In the spirit of the "landscape" perspective towards archaeological trails that I advocate, however, recorded features presented below are divided into two categories. These are a) *local trails*, which appear to have had significance only to people living in the immediate vicinity, and *trail networks*, which either ran for longer distances or where multiple segments appear to have been functionally interlinked. Typically the local trails are identified by the LA number that has been assigned to them or another associated feature. They are listed in the associated table. I will list the LA numbers associated with the trail networks as well, but will also refer to them by names that represent the collective whole and will discuss them in the text.

The methodological difficulties described above will make it challenging to present trail data with any consistency until they are all re-recorded. This is particularly true since I am suggesting that some of the Pajarito trails have been erroneously recorded under different LA numbers, and that these should be consolidated. Thus in the case of trails and trail networks recorded by PTP, I indicate the LA numbers originally associated with the trail, the number under which I recommend that this information be consolidated, and the suggested name of the network. In cases where trails haven't been formally re-recorded but for which other information suggests that they form a network, I will list the relevant LA numbers and suggest a name for the network itself.

Northern Pajarito

Despite the fact that the Ancestral Pueblo trails of the northern Pajarito Plateau were the first to be noted by archaeologists, at present they are the least well-documented. This is in part because of the vagaries of land ownership and recent research; the area around Puyé (LA 47) has not been archaeologically examined in recent decades, and although numerous sites in Garcia, Chupaderos, and Guaje canyons were recorded by PARP, their sample transect strategy was ill-suited to the identification of trails. There is considerable anecdotal evidence for local trail networks throughout these canyons but formal documentation is almost entirely absent. Steen describes two sets of formal staircases associated with the Guaje Mesa site (LA 12900), both of which had been destroyed in recent rockfalls: "[t]he stairs were approximately 1.5 m wide and had fairly uniform risers of about 20 cm and treads of about 30 cm" (1977:30).

The only two trails that have been formally recorded in the area, LA 21444 and LA 21460, indicate the potential for further research. These trails are closely associated, running east (LA 21444) and west (LA 21460) from a prominent saddle on Chupaderos Mesa, the portrero separating Garcia and Chupaderos canyons. The saddle may be a node in the major north-south axis connecting more southerly areas with the vicinity of Puyé, with which these trails are closely articulated. A substantial Coalition community is present on Chupaderos Mesa (LA 21605), to which LA 21460 provides access from the west and north.

Another important northern Pajarito trail that has never been formally recorded is what I call the "Garcia staircase." The stair, located on a saddle between Garcia and Corral canyons, was originally noted by Hewett, who described the associated trail as "worn hip-deep in the rock by the attrition of human feet" (1906:16). A photograph of the stair was published in a subsequent report (Hewett 1908b:11). The Garcia staircase is a compact set of formal, constructed, braided steps climbing the west side of the canyon, not as long as many of the other Pajarito staircases but perhaps the most elaborate. Numerous minor trails/stairs are associated with the mesa top community to the west. The unique character of the Garcia staircase and its location roughly opposite the saddle associated with LA 21444 and LA 21460 suggests that it is probably related to the same north-south axis.

Central Pajarito

Research at the prominent community houses of the central Pajarito by Hewett and others in the early 20th century meant that attention was also paid to the associated trails. Photographs of the trails at several of the sites were published (cf. Hewett 1908b, 1909), and they appear on site maps (cf. Hewett 1906). These references, plus the recording of trail features by Steen, PARP, BAS, and LANL, have created a vastly larger body of data than is present for areas further north. This information was augmented by PTP work, first on San Ildefonso land in 1991 (see below), and subsequently on National Park Service (NPS) and LANL jurisdiction in 1999 and 2001.

Table 81.2 lists the different LA numbers associated with trails on the central plateau. Trails associated with Otowi, Tsankawi, and Sandia Canyon are described in greater detail in the relevant PTP reports (Snead 2000, 2001a). The list includes 129 trail segments grouped into 32 sites with LA numbers, representing four local trails, one major trail, and six trail networks. Trails in the San Ildefonso sacred area, which have not been assigned LA numbers, are treated separately.

Table 81.2. Ancestral Pueblo trails on the central Pajarito Plateau, listing alternative numbers and suggested names. The underlined LA number is that recommended for use when the different segments of a trail network are "consolidated."

Segs = number of recorded trail segments; L = local (minor) trail; M = part of major (regional) trail; N = network of related trails

LA 12609. LA 12609 is the Sandia Pueblo trail network and is a series of stairs and trails leading up the north side of Mortandad Canyon to the mesa top community house. These trails have not been recorded in any substantive way. There is evidence that Sandia Pueblo is linked to the Sandia Canyon trail network (LA 66885), but this has not been confirmed by fieldwork.

LA 16803. LA 16803 is an unnamed trail on the north side of Mortandad Canyon that was initially noted in the 1970s and subsequently re-recorded by LANL. This trail appeared to be isolated, implying to Steen that it was of local significance, despite the fact that it is “deeply cut” (Steen 1982:7). The fact that LA 30639 was subsequently recorded nearby, however, makes it possible that the two formed part of a larger network, perhaps a major east-west trail ultimately linking up with the North Mesa trail (see below).

LA 21585. LA 21585 is the Otowi Mesa trail network. It is a series of 11 trail segments that consists of the Bayo staircase, which climbs out of Bayo Canyon north of Otowi (LA 169), a segment descending the north side of the mesa into Barrancas Canyon, and associated trail features to the east and west along the mesa top. LA 21585 was originally assigned to a set of hand and toe holds climbing up the south face of the mesa west of the Bayo staircase recorded by PARP; subsequent LANL fieldwork applied the number to other trail features on the mesa (Hoagland et al. 2000:7–81), while the segment entering Barrancas Canyon was added by PTP in 1999.

LA 21602. LA 21602 is the Kwage Mesa trail network. PARP recorded three segments of this trail ascending the toe of Kwage Mesa west of Otowi. These segments were re-recorded by PTP in 1999 with several additional segments recorded on the south-facing cliff of the mesa, where a possible rock-art shrine is present (Snead and Munson 2001). The total number of segments is

11. Since Kwage Mesa is not continuous to the west, these trails appear to be of local significance.

LA 21624. This trail is a short, deeply worn trail segment recorded by PARP and that crosses a narrow mesa neck south of Tsirege. The topographic location of this trail and the apparent depth of wearing evident suggests that this trail may have been a segment of a major north-south network.

LA 21629. This is a short trail that was recorded by PARP but not re-located by PTP. The original site form suggests that it is a local trail providing access to a mesa top summit north of Sandia Canyon; it is probable that this is actually Segments 5 and 6 of LA 66885 (see below).

LA 21632. See LA 66885.

LA 21634. See LA 66885.

LA 21635. See LA 66885.

LA 30639. This is a short trail segment recorded by LANL on Sigma Mesa north of Mortandad Canyon. There is a circular feature of unknown association at the toe of the mesa above the trail, suggesting that the trail may have provided local access to this feature; the proximity of LA 16803, however, suggests the possibility that the two trail segments may have been part of a trail network supporting east-west movement along the mesa tops.

LA 50976. See LA 70989.

LA 65661. See LA 70989.

LA 65683. Part of the suggested North Mesa trail network; see LA 65738.

LA 65687. Part of the suggested North Mesa trail network; see LA 65838.

LA 65714. See LA 70989.

LA 65716. See LA 70989.

LA 65738. LA 65738 is the North Mesa trail network. This series of a minimum of eight segments recorded under five LA numbers (65683, 65687, 65738, 75740, and 65741) represents access to the summit of Tsankawi North Mesa and travel along it to the east and west. These segments were visited in 2001 but not formally re-recorded, so that their definition as a trail network is incomplete.

LA 65740. Part of the suggested North Mesa trail network; see LA 65738.

LA 65741. Part of the suggested North Mesa trail network; see LA 65738.

LA 65743. This is a related set of minor trails associated with a group of cavates on a lower level near the west end of North Mesa. The articulation of these trails with the North Mesa Trail Network is unclear.

LA 65752. See LA 70989.

LA 65753. See LA 70989.

LA 64754. See LA 70989.

LA 65755. See LA 70989.

LA 65756. See LA 70989.

LA 65757. See LA 70989.

LA 66885. LA 66885 is the Sandia Canyon trail network. This series of nine trail segments recorded under five LA numbers (21632, 21634, 21635, poss. 21629, and 66885) represent a major route onto the mesa between Sandia and Los Alamos canyons and along it to the west. The recording of these segments has a complex history; see Larson (1987:11) and Snead (2001b) for further details. It is likely that these segments were originally a part of the North Mesa trail (see below), and also articulate closely with the Tsankawi Mesa trail network.

LA 70956. See LA 70989.

LA 70989. LA 70989 is the Tsankawi Mesa Trail Network. As defined in 2001, this network consists of 74 distinct trail segments associated with LA 214 (Tsankawi Pueblo), and was originally recorded under 12 LA numbers (50976, 65661, 65714, 65716, 65752-57, 70956, and 70989). The network includes features on the top and flanks of the mesas as well as stairways connecting the mesa top with the surrounding valleys. This is the most intricate trail network on the Pajarito, with a total measured length of 7.62 km (4.73 mi). The Tsankawi Mesa trail network connects both to the Sandia Canyon trail network to the west and the proposed North Mesa trail network to the north.

LA 70993. This is a minor trail running along the north flank of North Mesa, apparently below the upper cliff. No other associations noted in the site report.

LA 125383. This is a minor trail providing access to the top of “fence mesa” or “south mesa” immediately south of Tsankawi Mesa. Trail is notable for the flanking walls that restrict access to the mesa summit and between which the trail passes.

LA 127693. LA 127693 is the Otowi East trail network. As defined in 2001, this network consists of a minimum of four trail segments associated with the small mesa east of Otowi (LA 169), all of which serve to provide access to the mesa summit. Rough terrain inhibits movement further east.

Sacred Area Trails

In the summer of 1991, I spent two weeks undertaking reconnaissance survey of portions of the San Ildefonso Sacred Area, located on the Central Pajarito Plateau. This area is critical for an understanding of Ancestral Pueblo settlement in the region, since it includes much of the terrain between Pajarito and Sandia canyons and, in particular, the Classic period community house of Navawi (LA 214). Restricted access to this property means that knowledge of sites in this area is several decades old; my examination of these early records, however, suggested that trails were an important part of the archaeological record in the Navawi area. I accordingly applied to the Office of the Governor at San Ildefonso Pueblo for a permit to make a preliminary assessment of trails and related sites therein, which was granted with the proviso that respect be shown to any locations of a probable sacred nature. The informal nature of the project also meant that no reports were filed with the New Mexico Historic Preservation Division, nor were LA numbers assigned to the sites encountered.

The brevity of the project, the large area covered and the fact that I conducted the work by myself on all but a few days meant that the data were recorded in haste. This was also several years before I devoted much thought to developing a recording protocol for trail features. The result is a body of information that is incomplete and not directly comparable to records collected by the BAS or, later, by PTP. It is, however, suggestive of the full extent of the trail system on the central Pajarito, and fills an important spatial gap between the major communities. Further research in the vicinity, particularly with the advent of geographic positioning system recording of archaeological sites, is a high priority.

Of the 34 sites noted in the course of the Sacred Area survey, 17 were trail features, for a total estimated length of 1.61 km (1 mi). Several of these included multiple segments, as presently defined. All of the characteristics of trail fabric and structure noted elsewhere on the Plateau were present, with some segments worn or constructed to nearly 0.66 meters in depth. Cairns and berms were also noted. Minor trails linking mesa tops to canyon bottoms were distinguished in four cases; seven others can be collectively considered to form a Navawi Mesa trail network, linking the Navawi community house with the surrounding countryside. Among these can be included a series of four braided trails with associated stairs/steps at the mesa neck northwest of Navawi that is also the location of the famous "game trap" mentioned by Steen (1977:29). This seems to be the major "gateway" to Navawi itself. Several of the associated trails are highly formal. Another element of the Navawi Mesa trail network is a parallel set of stairs descending into the canyon due east of the community house, illustrating the redundant character of stairs known from other Pajarito examples.

One of the most significant aspects of the Sacred Area survey was the recording of five trail segments that represent long-distance travel across the central plateau. In particular, these link both the larger Coalition period settlements in the area and the three large community houses (Tsankawi, Navawi, and Tsirege) that dominate the settlement pattern in the subsequent Classic period. One major route is visible for a considerable distance traveling along the mesa top northwest of Navawi, passing directly through a substantial Coalition settlement before descending into Sandia Canyon close to New Mexico Highway 4. At this point, travel onwards towards Tsankawi, visible to the north, would pass through valley bottoms, but a route towards the Coalition site of Sandia Pueblo (LA 12609) to the northwest is equally plausible (and, since the mesa top trends in that direction, may be preserved archaeologically).

Between Navawi and Tsirege the route runs across the lay of the land and is largely visible where it crosses saddles on the low mesitas. To the southwest one of these segments ascends from the Cañada del Buey, only a short distance beyond Tsirege, while to the northeast the trail enters Mortandad Canyon directly west of the gametrap/trail complex on Navawi Mesa. These trail segments are uniformly short and widely separated but often deeply worn, showing signs both of construction and of long-term use. In this they are analogous to LA 21624, which may represent a similar major trail headed south from Tsirege. Perhaps the most dramatic trail recorded in the Sacred Area survey is on North Mesa at Tsankawi on the San Ildefonso side of the fence east of the monument boundary. Here a worn trail, sometimes divided into two clearly parallel routes, heads down the mesa in the direction of the Rio Grande, with recognizable segments extending to over one km in length. Associated stairways, including one formal feature that descends north into Los Alamos Canyon, indicate the importance of this route, which is clearly a continuation of the North Mesa trail network. In each of these cases the presence of worn trail segments far from the larger centers of habitation indicates frequent use over long periods of time (see below).

Southern Pajarito

Sites and trail network names recorded in the Southern Pajarito are listed in Table 81.3. This area has seen the most recent and intensive survey, and there is a correspondingly greater number of trail features recorded. The BAS recorded 49 trail features in the main section of the monument, of which several are otherwise clearly "historic." Table 81.4 includes lists of these latter sites as well as historic trails that have been recorded elsewhere on the plateau. In addition, some of the BAS trails could not be re-located in 1999 and should be considered questionable (see Table 81.5). An additional 27 sites were recorded as trails by BAS but were not re-recorded. The current list of recently documented trails thus includes 47 trail segments grouped into 15 sites with LA numbers, representing five local and 10 major trails. Further information on most of these trails can be found in Snead (2000).

Table 81.3. Ancestral Pueblo trails on the southern Pajarito Plateau, listing alternative numbers and suggested names.

LA #	BAS IO	PTP	Name	Segments	Type
60442			Portrero del Rito Trail		M
60494			Old Pajarito Trail	4	M
60495			Old Pajarito Trail	3	M
60496			Portrero del Rito Trail		M

LA 71036	Trail of uncertain associations along branch of Hondo Canyon
LA 71044	Major trail running down mesa south of Yapashi
LA 77707	Trail of uncertain associations on the upper Portrero del Alamo
LA 77762	Trail of uncertain associations on the Portrero del Alamo

LA 60442. LA 60442 is a major trail and is part of the Portrero del Rito trail (see below), which runs along the Portrero del Rito south of Frijoles Canyon. The site is associated with LA 60496 and LA 134901.

LA 60494. This is a major trail that is part of the Old Pajarito trail (see below). It consists of four recorded segments that climb the south side of Frijoles Canyon across the creek from the modern horse corral. It is associated with LA 60495. Some worn areas are evident, although the slope itself consists largely of loose talus.

LA 60495. LA 60495 is a major trail that is part of the Old Pajarito trail (see below). It runs parallel to LA 60494 but is less formal in its attributes. Three segments of the trail were recorded. Cairns associated with both of these trails are of uncertain association, particularly since modern travel is apparent on the trail.

LA 60496. This site is a major trail that is part of the Portrero del Rito trail (see below). It is associated with LA 60442 and LA 134901. Both LA 60496 and LA 60442 were quite ephemeral when originally recorded. Neither of the trails could be re-located in 1999, despite the identification of other features associated with these "sites," suggesting that the ongoing watershed restoration in the vicinity had impacted their visibility.

LA 60522. This is a minor trail that consists of six recorded segments climbing the east side of Capulin Canyon.

LA 65581. LA 65581 is a major trail that is part of the Portrero de las Vacas trail (see below). This site consists of five recorded segments that climb the east side of Capulin Canyon. This trail provides access from points to the south and west to the mesa top and ultimately, Yapashi (LA 250); it has been designated the "Capulin Staircase" because of deeply worn/constructed segments, braiding, and sets of stairs.

LA 65610. This is a minor trail that consists of six short recorded segments that are largely sets of steps. The area is notable for a petroglyph trail marker at the point where the trail meets the mesa rim.

LA 65846. This is a possible major trail of five segments that leads south from Yapashi (LA 250). This trail may be the initial stretch of the Portrero de las Vacas trail (see below) and link up with the Capulin Staircase (LA 65581), but it is also possible that it only went as far as a small mesa top summit that may have been the location of a shrine. This is the only recorded trail directly associated with Yapashi, which suggests that further survey in the vicinity would be valuable.

LA 70821. This is probably an historic trail northwest of Yapashi.

LA 77721. LA 77721 is an historic trail in Frijoles Canyon that is a possible former interpretation loop.

LA 77731. This is an historic trail in Frijoles Canyon that is a possible former interpretation loop.

LA 84901. This is probably an historic trail in Frijoles Canyon that is of uncertain association.

LA 110141. This is the Mattie Brook Trail located in DP and Los Alamos canyons (Hoagland et al. 2000:7-2).

LA 127624. LA 127624 is the Los Alamos Bench Trail that runs along the north rim of Los Alamos Canyon (Hoagland et al. 2000:7-3).

LA 127699. This site is the Camp Hamilton Trail, which is on the mesa south of Pueblo Canyon (Hoagland et al. 2000:7-149).

LA 138092. This is an historic trail that climbs the west side of Hondo Canyon. This route possibly intersects with that used by LA 65581, which was also used historically (Gauthier, personal communication, 2003).

LA 77779. LA 77779 is a major trail that is part of the Portrero del Alamo Trail (see below). It consists of five segments running from the mesa top down the west slope of a tributary drainage, ultimately leading toward the Rio Grande. LA 77779 is highly formal, with several step/stair segments and cairns of various dates. Large parts of the route are in view of the LA 12579 community house, which is across the river.

LA 84137. This site consists of a major trail of three segments linking the Portrero del Rito with the bottom of Lummis Canyon. Berms and cairns are present and the site is closely associated with LA 84138. This may be one of the primary routes associated with the Old Pajarito trail (see below), but further definition is required.

LA 84138. This is a minor trail of a single segment that provides access to a mesa top shrine overlooking the confluence of Lummis Canyon and the Rio Grande. LA 84137 is only a few meters distant.

LA 90799. LA 90799 is a major trail located on the east side of the Rio Grande across from the mouth of the Rito de los Frijoles. The site is associated both with LA 174, the Caja del Rio North community house, and LA 134901, which represents the easternmost extension of the Portrero del Rito trail (see below).

LA 134910. This is a minor trail that consists of a single recorded segment that descends into White Rock Canyon from the Portrero del Rito several hundred meters south of LA 134901. This trail is comparatively ephemeral and does not link to any previously documented routes.

LA 134111. This site consists of a major trail and is part of the Old Pajarito Trail (see below). It contains five recorded segments that climb up the east side of Frijoles Canyon. This highly formal feature, with stairs, braiding, and deeply worn sections, is also called the "Frijoles Staircase."

LA 134091. LA 134091 is a major trail that is part of the Portrero del Rito Trail (see below). It contains four recorded segments that descend into White Rock Canyon from the southeastern end of the portrero. Flanking walls are present where this trail crosses the canyon rim, and it is evident that this is the major route into the Frijoles area referred to by Hewett (1909:437) and Bandelier (1982:146–147).

LA 138059. This is a major trail that climbs the mesa in lower Hondo Canyon. The site was recorded by NPS in 2002.

DISCUSSION

There are several interesting points of comparison between the recorded trails from the Central and Southern Pajarito. Figure 81.18 depicts the general distribution of sites recorded since the early 1990s, either by the PTP, LANL, or post-BAS research within Bandelier (for clarity, sites recorded earlier have been omitted). Most evident is the impact of different survey regimes in different jurisdictions on the plateau, with the absence of recent work on the northern plateau creating an obvious and artificial gap in the record.

There is, however, an obvious pattern in the distribution of trails in the different defined categories. Although minor trails are distributed relatively evenly, trail networks are confined entirely to the central plateau. In contrast, segments of major trails dominate in the south but appear to be less common further north. Once again, this pattern appears to be less a product of human action and more attributable to geology and the parameters of modern land ownership. All of the trail networks on the central plateau are found on the relatively low, flat mesas of the area, where wide exposures of tuff are common. Such conditions favor the preservation of even relatively ephemeral trails. With the exception of Otowi, all of the Classic period community houses on the central plateau are located on such mesa tops, meaning that the dense patterns of activity associated with such sites have remained visible.

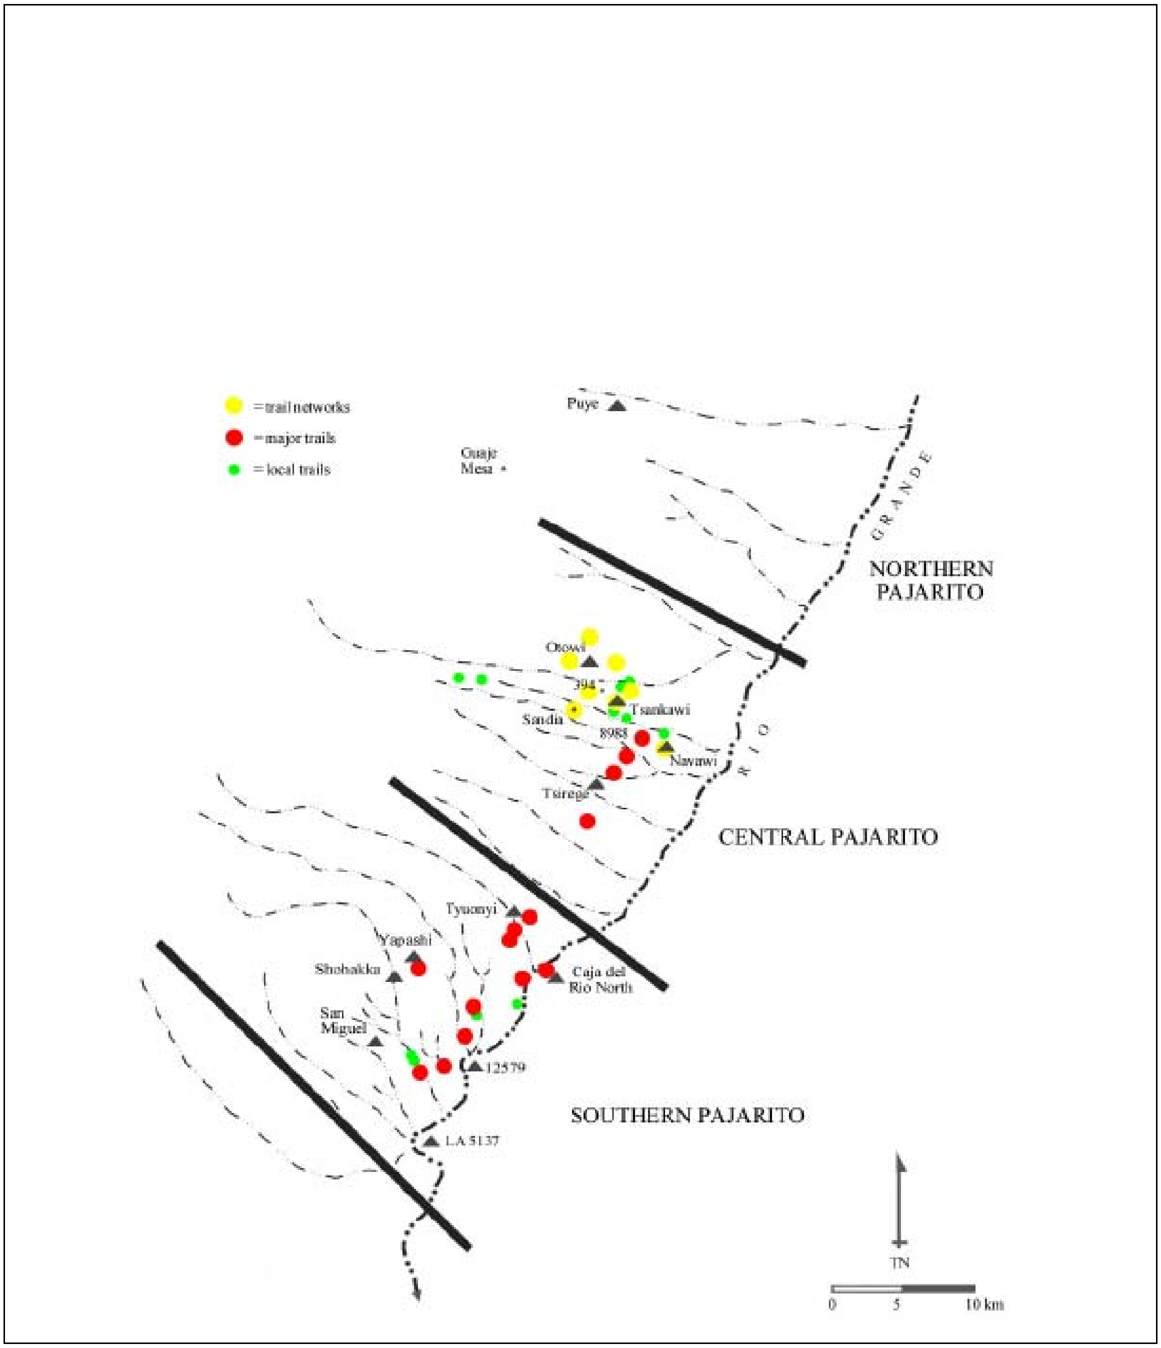

Figure 81.18. Ancestral Pueblo trails of the Pajarito recorded by PTP or other recent projects, along with other sites mentioned in the text.

In contrast, the community houses of the southern plateau are located either on tops of broad portreros (e.g., Caja del Rio North, Yapashi, and San Miguel) or in the canyon bottoms (e.g., Tyuonyi, Shohakka, LA 12579, and LA 56137), both locations where topsoil is relatively well-preserved. Such circumstances are not conducive to the preservation of trail networks as exist further north. Indeed, trails appear most clearly along the canyon rims, in some cases far from the community houses themselves. The cluster of major trails along the Rio Grande does reflect important patterns of movement, which will be taken up below, but the analogous terrain on the central plateau is presently unavailable for survey. Lastly, several of the trail networks of the central plateau are not directly associated with the community houses but instead represent major trails with associated alternate routes and feeder trails, rendered different in appearance to those further south by the vagaries of preservation but conceptually analogous.

In essence, we have yet to reach a point in the recording of Pajarito Plateau trails where the sort of broad spatial trends implied by Figure 81.18 can actually be relied upon. There remain, however, several areas of useful discussion.

Trail Names

The complexities of trail data that are hinted by Tables 80.2 and 80.3, in which minor trails, major trails, trail networks, and their constituent segments mesh uneasily with different site-numbering systems, are quickly becoming an impediment to understanding the data itself. My suggestion is that the nomenclature used here be expanded to incorporate the most spatially extensive scale of the trail system, thereby providing frames of reference more in keeping with the actual structure of the landscape and less entrapped by archaeological convention. This system is essentially hierarchical. The minimal units are aspects of trail fabric and features associated with particular trail segments. If necessary, closely related groups of segments can still be considered "sites," designated as either local trails or major trails by applying the criteria outlined above. More widespread use of the trail network concept, and consolidating them under one LA number, will result in a smaller number of sites being designated and thus streamline the process, but this will not be relevant in all cases.

At the maximal level, groups of related sites (or networks) should be linked together into "named trails" that reflect movement across the landscape at a large scale. Those names should be derived from traditional toponyms to reflect the relationship between trails and the surrounding terrain. Naming dozens of local trails would be as confusing as referring to them by LA number, but the data suggest that the numbers of major trails are relatively few. I suggest the following named trails, from south to north:

Portrero de las Vacas Trail. This would refer to all trails heading towards Yapashi from lower Capulin and, possibly, Hondo canyons, presently represented by LA 65581, the Capulin Staircase.

Portrero del Alamo Trail. This would refer to all trails leading north/northwest up the portrero between Alamo and Lummis canyons, presently represented by LA 77779.

Portrero del Rito Trail. This would refer to all trails heading north/northwest up the portrero south of Frijoles Canyon, presently represented by LA 60442, LA 60496, LA 134901, and, possibly, LA 90799, which although it is on the east side of the Rio Grande clearly articulates with LA 134901.

North Mesa Trail. This would refer to all trails headed east-west on the series of mesitas immediately north of Tsankawi, in particular the North Mesa trail network and the Sandia Canyon trail network. Note that not all of the potentially relevant major trails/trail networks listed in Tables 81.2 and 81.3 are covered by these names, since some spatial associations and relationships are less clear than others. All of those named here, however, represent long-distance, roughly east-west routes linking the Rio Grande with points close to the Jemez or San Miguel Mountains.

A final, and perhaps more controversial, trail designation is what I am calling the *Old Pajarito Trail*, which represents a north-south route that spanned the entire Pajarito Plateau. Identifying such a feature is challenging, since moving across the southeast/northwest-trending portreros might leave less evidence than following the terrain. It would seem to be just such a route that the early explorers followed, however, and physical evidence that such a major thoroughfare once existed is also accumulating. At present I would include LA 60494, LA 60495, LA 134111 (the Frijoles Staircase), LA 21624, several deeply worn trail segments on San Ildefonso land between Tsirege and Mortandad Canyon, LA 21585 (the Bayo Staircase), and the Garcia Staircase, with the trail ultimately coming to an end first at Shufinne (LA 795), and in subsequent centuries further east at Puyé. LA 81437, which descends from the Portrero del Alamo into Lummis Canyon near its confluence with the Rio Grande, may represent the point where the Old Pajarito Trail finally descends and begins to follow the river bottom towards Cochiti.

There is some logic to the terrain that such a route would have followed. From the top of the Bayo Staircase, for instance, the viewer looks through a gap in the north side of Barrancas Canyon, making for relatively unobstructed travel as far as Guaje Canyon. On a reconnaissance along that section of the Guaje Canyon rim in 2001, I located an old cairn that marked a likely spot for just such a trail to have descended. This is obviously ephemeral data, but my expectations are that when fieldwork is extended to parts of the plateau that are currently under-documented, such as the zone between Frijoles and Pajarito canyons and that between Guaje and Garcia canyons, more evidence for the Old Pajarito Trail will be forthcoming.

Dates and Routes

Dating the Pajarito trail system is largely a process of defining the association between the trails and other, more chronologically sensitive, features, so it is only with reference to the extensive databases established by the various Pajarito projects that any progress can be made on this issue. As empirical evidence for the extent of the trail system increases, the subtleties of these associations become clearer. There do appear to be morphological aspects of trail structure that pertain to different time periods, and some associated features, such as petroglyphs, contribute relevant information.

It can be assumed that the local trails were the products of patterns of movement through the landscape that may have been quite brief. LA 65610, for instance, is closely associated with a fieldhouse on the portrero east of Capulin Canyon, and it is logical to associate the relatively ephemeral trail with the use of that structure over only a few generations. A single Agua Fria

Glaze-on-red sherd found at the fieldhouse would thus suggest an Early Classic date for the entire complex. The associated trail marker, a single petroglyph of the outline of a human head adorned by a feather (see Snead 2002a:763), enforces the image of a pattern of use that was restricted in time and pertained to a particular circumstance.

A relative chronology can also be established for several of the major trails. In cases where a comparison between the trail system and the Coalition/Classic settlement pattern can be made, the Coalition sites appear to represent a better “fit.” This is particularly clear on the central plateau, where the trail from Navawi to Tsankawi intersects a clustered Coalition settlement (LA 8988), and the North Mesa trail appears to pass through LA 394 before merging with the Sandia Canyon trail network. The associated trail segments, including one continuing southwest towards Sandia Pueblo, are all heavily worn. In contrast, a branch of the trail that heads back east toward Tsankawi, is relatively ephemeral.

It is also interesting to note that the major trail represented by the Frijoles Staircase (LA 134111) and LA 60494/LA 60495, passes through Frijoles Canyon 800 meters south of the center of Classic period population in the canyon (e.g., Tyuonyi and Long House). This is despite the fact that, as demonstrated by the modern Frey trail, it is possible to descend the canyon’s north cliff much closer to Tyuonyi.

It thus appears that the major axes of movement on the Pajarito Plateau date to the Coalition period, suggesting that they were established during the early period of settlement on the plateau. When the settlement pattern shifted during the Classic period, short “feeder routes” developed that linked the new community houses more closely to the regional trail system. When these communities were abandoned, however, the traditional network appears to have resumed its original importance, with evidence suggesting use well into the Historic period.

Guard Pueblos

The concept of guard pueblos, which are small residential facilities established as outliers of community houses to provide warning or defense in case of attack, is widespread in southwestern ethnography (cf. Connelly 1979:540), and has recently been inferred to explain the distribution of sites in Frijoles Canyon (Snead et al. 2004). It is also closely correlated with trail systems, since it is the regional trail system that would bring outsiders into a community.

Identifying some of the smaller residential structures on the Pajarito as guard pueblos would be an important step in understanding the settlement pattern, and the relationship between these sites and the trail network would be important evidence of such a function. This close correlation exists in three cases; Duchess Castle (LA 42), Navawi Long House (LA 214), and Rainbow House (LA 217). Each of these sites can be considered a “satellite” of a nearby larger community house (Tsankawi, Navawi, and Tyuonyi, respectively), and each is directly associated with a major trail that passes near, but not directly through, the community house itself. Travelers from particular directions would only have access to the community core after passing the guard pueblo. The fact that Caja del Rio North commands a clear view of Tyuonyi several kilometers to the northwest and also sits on the trail leading to it suggests that it may have had a similar function.

Guard pueblos appear to have been a relatively late development, coming only with the 14^{th} century AD. It isn't clear whether this is due largely to the reorganization of settlement associated with the rise of the community houses, or whether some added constraint, such as increasing conflict, played a role. It does seem likely, however, that they are a reflection of an increased need to keep watch on the trails, a need taken to the greatest extreme in Frijoles Canyon, where Frijolito (LA 78) and the House of the Water People (LA 10942) in addition to Rainbow House may have created a formidable perimeter.

Labor Investment

The final point of discussion here is the issue of relative investment in trails. It was clear from the outset that not all trails were constructed in the same fashion, and the original designations "local" and "major" reflected more than function. Although both trail fabric and associated features provide evidence for levels of investment, fabric is more reliable since it is in that area that Ancestral Pueblo "style" is most distinctive.

It is typically argued that investment of labor in trails relates to increasing efficiency. It could thus be expected that more elaborate trails would be present in places where traffic was high and terrain difficult. This is to a certain extent true in the Pajarito case, since several of the more elaborate trails are found at topographic "choke points" or places where obstacles must be crossed. Pajarito archaeologists have frequently noted, however, that explaining the more labor-intensive trails in terms of "efficiency" is not always adequate. In many cases steps are pecked out to an extent that far exceeds functional requirements, and indeed makes climbing more difficult. Some sets of steps are also located on relatively gentle slopes where it is almost easier to walk beside them than in them.

It is increasingly clear that the Pajarito trails include some symbolic content that is expressed not only in the form of petroglyph trail markers but in the structure of the trails themselves. The most visible manifestation of such "meaning" are the remarkably elaborate staircases. The most prominent cases recorded to date, the Bayo, Capulin, Frijoles, and Tsankawi North staircases (Figures 81.14 through 81.17), are remarkable examples of the investment of labor in trails. Each of these cases includes sections of formal stairs, sometimes extending for more than 10 meters, with additional features such as hand holds also present. Braiding is also a recurrent feature of Pajarito staircases; all of those recorded are characterized by multiple routes, sometimes tightly interwoven, sometimes forming distinct parallel stairs up the sides of the canyon.

It is difficult to construct a functional explanation for the high level of formality in staircases. At the Frijoles Staircase, for instance, it is possible to walk up the slope alongside the most formal stair segment almost as easily as it would be to use the stair itself. There also seems to be only one such highly formalized staircase in association with particular sites; although there are numerous stairs in association with the Tsankawi Mesa trail network, the Tsankawi North Staircase is qualitatively distinct. The same holds true for Otowi, where despite the presence of trails and steps associated with travel east and west (the Kwage Mesa trail network, and the Otowi east trail network), neither approaches the high formality of the Bayo staircase. The nature of braiding at these sites is also distinct. Since the stairs are actually constructed, it is difficult to account for the existence of parallel routes as a simple factor of shifts in traffic over time. Parallel sets of stairs were intentionally constructed, and while it can be argued in some cases that such efforts would be necessary when some steps became too worn to be used efficiently, this is clearly not the case in all examples.

I have argued that these elaborate staircases represented formally designed entrances to the major communities, a feature I call "gateway trails" (Snead 2002c:763). As such, they are intended to symbolically inform the traveler that they were entering a new space, one directly associated with a community house and its residents. They would thus be a different iteration of a trail marker, in which the investment of labor in the trail itself would signify ownership, identity, or some related concept. In their original form, together with the cairns, berms, and other associated features that are now largely absent, such approaches would have been visually impressive symbols of community.

The issue of braiding/parallel routes may pertain to a related but distinct process. Within Pueblo society, repetition is a key component of ritual; such actions can involve the process of construction as well, such as the repetitive plastering of the inner walls of kivas and other ceremonial spaces. Watson Smith tabulated numerous archaeological sites where kivas had been plastered on multiple occasions, up to as many as 63 at Hawikuh; one of the kivas in his survey that featured 20 replasterings was in Frijoles Canyon (cf. W. Smith 1952:17). The construction and dismantling of altars for ritual practices in many of the pueblos also seems to reflect a similar process (see Parsons 1996 [1933]. In the case of gateway trails, the repetitive re-construction of trails may represent a formal renewal of the relationship between the community and the route, possibly conducted at particular intervals or at points of social/political transition. Under such circumstances, the establishment of parallel routes may not have reflected a need to speed up traffic or bypass an obstacle, but instead a desire to reestablish a ritual relationship between the community or some of its members and the trail itself.

Another intriguing possibility regarding trail symbolism concerns duality. In several cases, stairways are structured as two parallel and distinct routes in close proximity. The best example is the Bayo Staircase, where two stairways climb much of the distance to the mesa top 10 to 20 meters apart. This is echoed in a pair of stairs at Navawi, segments 7 to 8 of the Sandia Mesa trail network (and possibly segment 4; Snead 2001a:map 2), and perhaps in the Tsankawi North Staircase as well (segments 71 and 69), where two different stair segments can be distinguished on the exposed tuff. Such patterning may also be present in other trails on the central plateau; two braided routes are evident in the North Mesa trail east of the NPS boundary, and two clear, parallel routes are evident in segments 3 (Figure 81.3) and 6 (Figure 81.8) of the Sandia Mesa trail network. This pattern is not evident on the southern plateau, although further study may prove otherwise.

The consistent appearance of twinned routes on major trails and stairways of the central plateau present several intriguing possibilities. One is simply that the trails were established at different times, and, following the logic described for gateway trails, reflect different episodes of symbolic labor investment. If rebuilding one stairway was an important act, it is conceivable that building a new, parallel stair was an extension of the same practice. It is also possible that the different stairs reflect the presence of different users. If the Ancestral Pueblo occupants of Tsankawi, Navawi, and surrounding communities were organized into moieties like their Tewa descendants, their use of separate but aligned pathways is conceivable. The fact that only some of the stairs and trails show evidence of such a pattern suggests that such formality was not part of everyday life in the community houses, but instead linked to specific ritual practices. Just as repetitive construction of stairways may have been a symbolic act, so the use of those stairs at particular times may have been linked to specific ceremonial practices, and thus reflective of the internal structures of the community itself

Archaeological evidence from elsewhere in the Southwest suggests that some of the patterns documented for the Pajarito trails are not unique. Some twinned or parallel stairways are evident at Chaco Canyon; W. H. Jackson's photo of the famous Jackson staircase depicts an example of this (see Powers 1984:53). The anomalous presence of stairways in "relatively flat terrain," implying that they had other than functional significance, has also been documented (Pattison 1985:71). Mike Marshall describes a widespread pattern of parallel roads and paths in the Chaco region, for which he finds ample ethnographic documentation, including for the Tewa, where "double roads" leading south from the place of emergence are described over which the Tewan moieties diverged and rejoined in the ancestral journey to Ojo Caliente" (1997:69; see also Vivian 1997a, b).

Regarding the idea that twinned trails may be symbolically associated with ancestral migration and pilgrimage, it is interesting to note that many of the twinned segments documented here are associated with the North Mesa trail. This route, which appears to have run from the Rio Grande all the way to the Jemez, passes right through the center of Ancestral Pueblo settlement on the central Pajarito. Although it surely had extensive functional uses, it is intriguing to think that it served as a ceremonial route as well. It is, of course, difficult to determine whether these different patterns of movement would have been associated with the trail from the beginning, or whether they evolved over time. To return to Marshall, "[p]ilgrimage down these divergent corridors into parallel paths may have the reactualized and validated the origin myths and opened cosmological channels over which spiritual energy was conducted" (1997:69). It may be that the trail accrued symbolic importance over time, and that it could have been until the Historic period when this role became dominant. The likelihood that the twinned stairs were constructed when the community houses were occupied suggests that such a pattern had deep historical routes, but its longevity remains to be investigated.

CONCLUSIONS

Work on the Pajarito trails since the 1990s has been enormously productive. The insights of earlier generations of scholars, who saw great potential in studying the trails, were correct, and we are thus gaining a greater appreciation both for the complexity of the cultural landscape of the Pajarito and for the Ancestral Pueblo people for whom the trail network was an intrinsic part of their everyday lives.

Several contributions can be identified. The first is that the diverse morphology of the Pajarito trails is increasingly well-understood. Trail fabric and associated features are now thoroughly documented, providing scope for further analysis. The general parameters of the overall network are also coming into focus. The chronological approaches that will ultimately allow us to link changes in the settlements to shifting patterns of movement across the plateau are getting better. We also have a greatly improved sense of the role that the trail system played in politics, economics, and ritual in the Ancestral Pueblo world.

The preliminary nature of this research must nonetheless be emphasized. Less than half of the Pajarito trails for which some documentation exists have been re-recorded. Adequate documentation of the elaborate trail networks is time-consuming. Re-examination of areas that have been the subject of recent systematic survey has turned up new trail sites, suggesting that trails are elusive even when up-to-date field methods are applied. Large portions of the Pajarito have yet to be surveyed at all, including zones that lie between the major nodes of Ancestral Pueblo settlement. Administrative barriers remain, and the continuing physical remoteness of some parts of the Pajarito present considerable logistical difficulties.

The first priority for further research is completion of the re-documentation process. Revisiting known trails is an efficient and cost-effective means of expanding the body of available information, and ensures that all trails are recorded to a similar standard. New survey is, of course, also highly desirable. Given that the administration of large parts of the plateau are currently being reorganized, efforts to survey lands that will no longer be in the public domain (strictly speaking) are particularly vital. Recent work in TA-71 (Hoagland et al. 2000; Snead 2001a) is an example of what such targeted efforts can accomplish. Similar approaches need to be employed elsewhere, particularly on the northern plateau, where the baseline survey information is less accurate and the resources of the administrative agent less plentiful.

Priorities for further survey should also include detailed analyses of trail networks associated with the remaining community houses of the central plateau for which these have not yet been conducted. Tsirege is the most prominent example, since our knowledge of the trails associated with that site has not appreciably expanded for a hundred years. Another priority is Sandia Pueblo, particularly since a close examination of the site and associated lands along Mortandad Canyon will assist in determining the age of the trail network in that area. Finally, a targeted plan of research in the region south of Tsirege should be developed, since is in that area that evidence for an Old Pajarito Trail linking Frijoles Canyon with points farther north should be available.

In addition to providing a window on the Pajarito trails, the study of roads and trails present a unique opportunity for the archaeological study of trails in general. By breaking down the roads/trails dichotomy, we make further progress in understanding the relationship between movement and landscape in human societies. It is no longer possible to see trails as functional reflections of economic processes without either symbolic or political significance. Taking a serious look at trails has proved to be a major step forward in expanding archaeological perspectives on the past; the value of taking this study and related studies to new levels requires no further argument.

CHAPTER 82
ROCK ART OF LOS ALAMOS NATIONAL LABORATORY

Marit Munson

INTRODUCTION

This chapter discusses the rock art of Los Alamos National Laboratory (LANL), set within the broader context of relevant information from the Pajarito Plateau and the northern Rio Grande region. The chapter begins with a discussion of previous rock art research on the Pajarito, from the curiosity of late 19th century explorers to regional syntheses and systematic recording for management purposes. It then continues with a discussion of rock art styles generally applicable to northern New Mexico; these widely used style designations provide a broad regional chronology, yet they overlook significant variation within the Rio Grande Valley. Recent research has resulted in a more realistic stylistic chronology for Coalition and Classic period rock art of the Pajarito Plateau. The next section describes the dating methods in brief, then discusses the stylistic traits characteristic of each period.

The focus then shifts to spatial variation on two different scales. First, dramatic differences in the immediate context of Coalition and Classic rock art are discussed, as the images shifted from private functions to more public significance. The following section expands the geographic scale to consider variation across the Pajarito Plateau, specifically addressing the issue of boundaries between Keres and Tewa ancestors. The data collected in Munson's dissertation work (2002) indicate that the boundary is not visible in the rock art; instead, rock art imagery varies relative to specific communities, including an Otowi-Tsankawi community and a Tsirege community. Small-scale variations in more detail, highlighting issues specific to the rock art of LANL are then discussed. Finally, the chapter concludes with brief recommendations for rock art recording procedures and management issues.

PAST RESEARCH

Early Interest (1890s–1930s)

The prehistory of the Pajarito Plateau was not well known to the Anglo world until the late 19th century, when the area's proximity to Santa Fe encouraged the attention of explorers and the general public (Snead 2001b). Adolph Bandelier, a Swiss-born businessman and self-taught scholar, began a survey of the Southwest in 1880, under the auspices of the Archaeological Institute of America. Led by guides from the Keres pueblo of Cochiti, Bandelier traveled throughout the Pajarito Plateau, documenting sites and writing about the Pueblo inhabitants of the northern Rio Grande (Lange and Riley 1966). Although Bandelier occasionally noted rock art sites, his interest in the imagery was minor. Other than a brief note that "there are pictographs" in Frijoles Canyon (1892:143), he mentions just a single site on the entire Pajarito Plateau. Describing Painted Cave, located in Bandelier National Monument, he lists images at the site as including "clouds, sheet lightning, the sun, dancing-shields, and male and female dancers" (1892:156), then adds some information from his Cochiti guide:

> I was informed that in former times, whenever a pueblo was abandoned, it was customary to paint a series of such symbols in some secluded spot near the site of the village. Whether this is true or not, I do not know (Bandelier 1892:157, note 1).

In a later discussion of rock art in the Abo area, Bandelier again mentioned the information about Painted Cave, saying that "such records of the Cachina were usually executed whenever a pueblo was to be forever abandoned" (1892:278).

In 1896, Edgar Lee Hewett began an archaeological survey of the Pajarito Plateau and adjoining areas in the northern Rio Grande. Although Hewett worked throughout the Jemez Plateau (Hewett 1906), he was particularly enamored of the Pajarito; seeking to preserve it as his own personal fiefdom, he simultaneously limited other researchers' access and lobbied for the creation of a national park (Rothman 1992). Throughout the first decade of the 20th century, Hewett excavated at major pueblos across the southern and central Pajarito Plateau, including Yapashi, San Miguel, and Otowi. He ran several School of American Archaeology field schools in Frijoles Canyon, aided by a Tewa crew from San Ildefonso pueblo.

Hewett's perspective on Pajarito prehistory, and especially the relationship between modern pueblos and the prehistoric sites, was often contradictory (Snead 2001b:130–131). Initially, his interest in rock art on the Pajarito Plateau was rooted in his hope that "while some of these [images] represent nothing more than idle picture-making, perhaps most of them are of serious totemic, legendary, and religious significance" (1906:11). Thirty years later, however, Hewett simply illustrated a few examples of the more interesting rock art, writing that rock art from Puye was "far inferior to... the pottery designs" (1938:115). Comparing the imagery to kiva murals, "does not," he added, "give the impression that the Puye rock pictures were intended to be ceremonial or mythological records....They are a much less serious form of art, merely suggestive of the play of fancy that characterized the Indian mind throughout the Southwest, which reflected, to some extent, their attitude toward nature and life" (Hewett 1938:115). His disappointment that the rock art "had little function in recording facts" (Hewett 1938:115) is evident. Hewett had come to believe that there was a significant disconnect between prehistoric imagery in all media and early 20th century Pueblo designs, a break "so radical that it can only be accounted for on the ground of strong new elements intruding from an outside source" (Hewett 1938:104).

During Hewett's tenure on the Pajarito Plateau, a network of scholars, artists, and public figures developed that ultimately not only influenced research on the Pajarito, but shaped the course of Pueblo arts in the early 20th century as well. Intrigued by the "graphic art of the cave dwellers" (K. Chapman 1916), artists from Santa Fe often joined Hewett in the field. Kenneth Chapman, in particular, spent two field seasons recording images inside cavate rooms, concerned that the "picture writing" was "in danger of being obliterated both by the elements and by mutilation at the hands of vandal tourists whose activity was everywhere manifest" (K. Chapman 1917:1). Chapman's overviews of the rock art, published as part of Hewett's reports (K. Chapman 1916, 1917, 1938), were the first to speculate on the dates of the images, noting the potential temporal significance of soot blackening and plastering over the rock art (1938:142).

Chapman also mentioned that Hewett's Pueblo workers, who used some cavates as living quarters while in the field, produced designs of their own on the cavate walls, noting that "many of these might have been confused with the work of the ancient Pajaritans were it not for the freshness of their appearance" (K. Chapman 1917). The workers' exposure to prehistoric arts during the Pajarito fieldwork is often cited as a significant influence on the work of early 20th century Pueblo artists, including Crescencio Martinez (Brody 1997:22–24). Gustave Baumann, a well-known German-American artist, also drew inspiration from Hewett's fieldwork, eventually producing a series of woodcuts representing the images inside Pajarito cavates (Baumann 1939).

Defining Styles (1960s–1990s)

Research on the rock art of the Pajarito Plateau did not begin in earnest until the 1960s, when Charlie Steen and Polly Schaafsma both worked on defining temporally significant styles. Steen's work with Los Alamos rock art in the 1970s resulted in the definition of two distinct rock art styles (1977, 1979): the Frijoles Style and the Mortandad Style. He defined the Mortandad Style, using the Mortandad Cave Kiva (at LA 12609) as the type "site," as large, rough anthropomorphic figures pecked[1] into the walls and ceilings of densely sooted cavates (Steen 1979). Steen seldom mentioned exterior rock art, focusing instead on interior imagery that he felt was "of a religious nature" (1977:17). He believed that cavates with interior imagery served as kivas or, in the case of the smallest isolated and heavily soot-blackened rooms, "quiet retreats for individuals--small caves for prayer" (Steen 1977:17). Thus defined, the Mortandad Style appears to be confined to a handful of cavates in Mortandad, Ancho, and Sandia canyons. Although subsequent researchers sometimes refer to the Mortandad Style (H. Toll 1995:196–197), its limited geographic distribution makes its utility questionable and it has not been widely adopted.

Steen's Frijoles Style, defined in contrast to the Mortandad Style, is similarly problematic. The Frijoles Style consists of images incised into the plaster walls of cavates, including geometric patterns, realistic figures, and "life forms" (Steen 1979), or, the figures illustrated by Chapman (1938) (Figure 82.1). These interior scratched figures are often divided into prehistoric and historic categories, based entirely on subject matter. Images of hunters, dancers, kachinas, and various animals, for example, are often accepted as prehistoric (e.g., H. Toll 1995:196; Wellman 1979:93–96), while associated images of people on horseback or wearing broad-brimmed hats are classified as historic (Chapman 1938:141; Wellman 1979:96; see Liebmann 2002:136–138 for a more extreme example). However, the suite of scratched interior images appears stylistically consistent; given the depiction of horses and other historic subject matter, it is likely that this distinct scratched style is entirely historic, an idea given support by Chapman's (1938:141) accounts of Pueblo workmen producing images in the cavates during Hewett's excavations at Frijoles. As with the Mortandad Style, this Frijoles Style is geographically

[1] Steen uses the term incised, but inspections of the Cave Kiva and of his illustrations indicate that the images were almost certainly pecked.

limited; it is most common within Frijoles Canyon, with scattered examples from the north-central Pajarito.

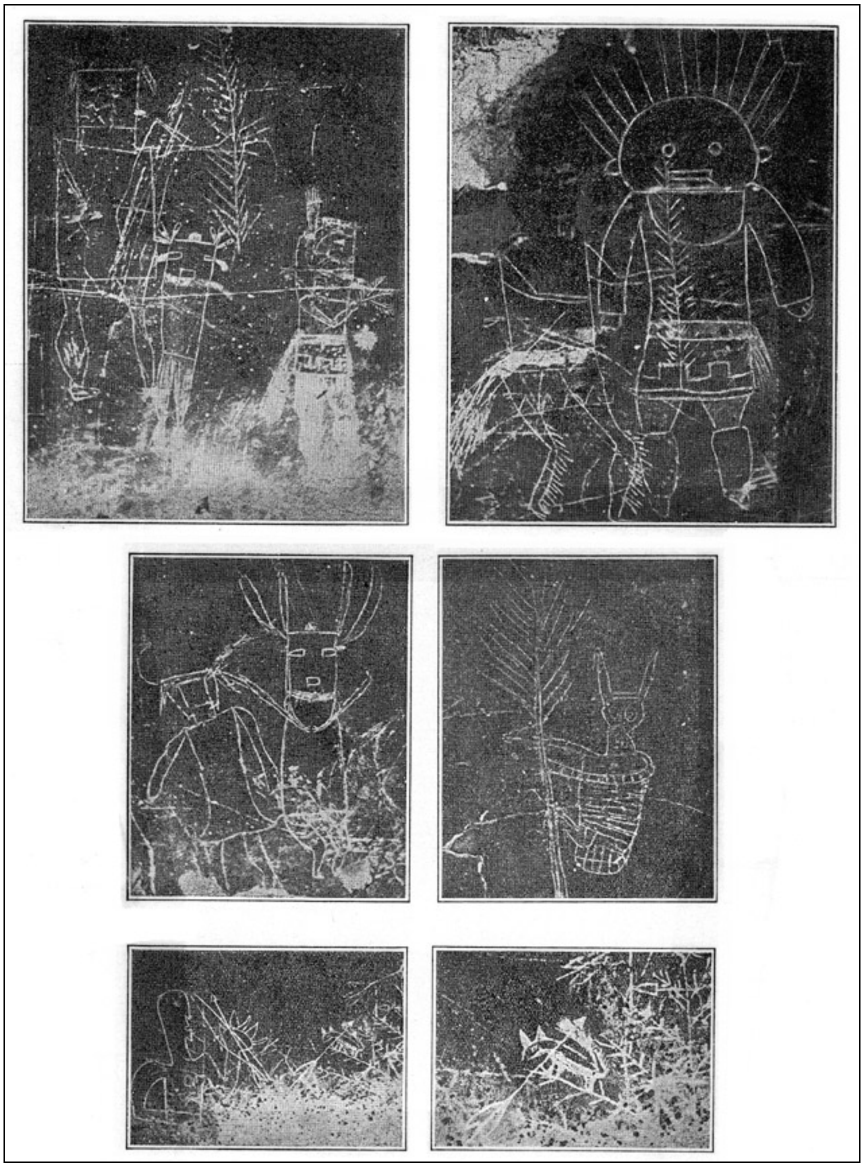

Figure 82.1. Historic incised or scratched rock art, as illustrated by Chapman (1938).

Schaafsma's broader classification of Rio Grande Valley rock art is much more widely accepted. Beginning with a 1966 rock art survey associated with the Cochiti Dam project, P. Schaafsma (1975) began to sketch in the rough outlines of a chronological sequence for Rio Grande rock art. By 1972, Schaafsma had defined the Rio Grande Style, which encompassed post-AD 1325 rock art within the Rio Grande Valley. Although she believed that all of this rock art "can be considered a single entity" stylistically (P. Schaafsma 1980:275), she also acknowledged distinct geographic differences, dividing the Rio Grande Style into five distinct provinces corresponding to the distribution of historic linguistic groups (P. Schaafsma 1972, 1992:87–113). The Rio

Grande Style is discussed in greater detail below, with specific attention to the Keres and Tewa provinces, which include the Pajarito Plateau.

Schaafsma's general outline of the prehistory of northern Rio Grande rock art, in which the distribution of motifs parallels the ethnic and linguistic boundaries visible in ceramics and ethnohistoric accounts, is widely accepted for the Pajarito Plateau. She proposes that the distinctions between the various provinces of the Rio Grande style are related to "variations in mythology, religious emphases, and values" (1992:113) throughout the Rio Grande Valley. For example, she suggests that the emphasis on themes of war and conflict in the Galisteo Basin reflects the presence of warrior societies to the east of the Pajarito, prompted by conflict with Plains tribes, while the lesser frequency of war iconography in other Rio Grande rock art may reflect competition among the pueblos. She also suggests that the steady decrease in the number and complexity of rock art masks from south to north along the Rio Grande reflects the "marginal nature" of the kachina religion in the northern Tewa pueblos (P. Schaafsma 1992:115).

Numerous other researchers have adopted Schaafsma's general chronological outline wholeheartedly, using it as support for studies of ethnic boundaries on the Pajarito Plateau. In their work on northern Rio Grande ceramics, for example, Graves and Eckert (1998) use Schaafsma's distinction of rock art provinces in support of their argument that differences in the color and iconography of decorated wares reflect the presence of different ideological systems. Nevertheless, it should be noted that Schaafsma herself recognized a certain continuity in style and content between the Keres and the Tewa provinces on the Pajarito Plateau (1992:111).

Site-Specific Research (1980s–1990s)

In 1989, Arthur Rohn published a general-interest book on the rock art of Bandelier National Monument. In it, he illustrates numerous rock art sites that are accessible to the public, setting them within the context of a brief prehistory of the Pajarito Plateau. He believes that the rock art is uniformly religious imagery, created during dances and ceremonies as a means of declaring clan or lineage membership (Rohn 1989). Although the book contains little analysis or support for these statements, its conclusions are widely cited.

Rohn's students at Wichita State University have since conducted a series of studies focused on the rock art of individual sites in the central Pajarito. Loy Neff (1990), for example, documented the rock art of Tsirege Pueblo in exhaustive detail, analyzing the layout of the images relative to clusters of rooms within the cavate pueblo. Cynthia Orr (1996) carried out a similar study at Tsankawi, although her recording was more limited and perhaps less accurate than Neff's work at Tsirege. In Neff's thesis, he concluded that Tsirege rock art is mostly related to marking sacred places and providing symbolic protection; imagery within the cavate pueblo, for example, marks different clan groups, while other images are placed in locations where they serve as protection for stairs and trails, as in the Awanyu at the main stairway. He proposes that more isolated rock art images provide protection to the village in general; such images include a series of large shields pecked on boulders that rest on the valley floor in front of the cavate pueblo. Neff briefly notes a variety of differences in the frequency, placement, and presumed function of motifs at

Tsirege compared to Frijoles Canyon, suggesting that the differences indicate belief systems that have diverged from a common antecedent, perhaps related to the Keres/Tewa boundary.

Broad Research Agendas (1990s–Present)

The most intensive research on Pajarito rock art has been focused on Bandelier National Monument. In Toll's (1995) study of variability in cavate architecture, he briefly discusses rock art within the cavates, partly refuting the notion that the presence of rock art indicates that cavates served as kivas. He attributes differences in the rock art of Frijoles Canyon and Tsankawi to differential preservation of the cliffs themselves (also see Crowder 1995). In addition, crews systematically noted rock art during the Bandelier Archaeological Survey (BAS), and several volunteers addressed the rock art directly (Crowder 1995; N. Olsen 1995, 1997). Olsen, in particular, launched an ambitious study of all of the rock art identified during the BAS. Focusing on patterning in the distribution of rock art motifs relative to a variety of geographic and archaeological features, she sought to demonstrate that rock art was a form of symbolic communication. Although some of the descriptive material may be useful, the multivariate statistical methods that she applied are inappropriate for the data, calling her conclusions into question. Crowder's work (1995), more limited in scope, provides a summary of the motifs present at various sites in Frijoles Canyon and within the Tsankawi unit of Bandelier National Monument.

Information from the northern plateau is less comprehensive; major projects, such as the Pajarito Archaeological Research Project, seldom recorded rock art, and data from LANL and the Santa Fe National Forest have never been incorporated into a broader study. Instead, most of the discussions of geographic variation in Pajarito rock art compare data from the entire bulk of Bandelier south of Frijoles Canyon against a few sites from the Tsankawi Unit, or compare extensive field data with more limited published accounts from elsewhere. Munson's dissertation (2002) sought to address this issue, examining rock art sites from across the Pajarito Plateau; the discussion below summarizes her findings.

Recording and Management (1990s–Present)

In addition to ongoing professional recording for management purposes at LANL, Bandelier, and the Santa Fe National Forest, two major projects have used volunteers to record and monitor the rock art of the Pajarito Plateau.

In Los Alamos County, two volunteers, Betty Lilienthal and Dorothy Hoard, have done extensive recording of the vast concentration of images near springs and other natural features along the Rio Grande; their publication (see Lilienthal and Hoard 1995) also includes some photographs of sites on tuff within Sandia Canyon and adjacent canyons. Their records, on file at the Laboratory of Anthropology, ultimately culminated in a National Register listing for the petroglyphs of White Rock Canyon. Their recording of the rock art is detailed and thorough, although it sometimes neglects archaeological remains associated with the petroglyphs.

In addition, Mike Bremer and other US Forest Service archaeologists have led a Passport in Time work program on the northern Pajarito for many years (e.g., Baldwin and Bremer 1999). This project, which uses volunteers from around the country to record archaeological resources on Forest Service land, has focused on sites in Garcia Canyon. Although the primary aim has been to record cavate pueblos, the crews have been diligent about recording associated rock art.

TEMPORAL VARIATION IN ROCK ART STYLES

Temporal control has always been a difficult issue where rock art is concerned. Although various direct dating methods are currently being developed (e.g., Rowe 2001), they are not yet practical for widespread use. Most rock art research still relies upon the definition of temporally significant styles (Francis 2001), defined through standard methods of relative dating (Keyser 2001; P. Schaafsma 1985:241–244). In the Rio Grande Valley, P. Schaafsma's (1980, 1992) decades of work have resulted in the following general classification of rock art styles through time.

Archaic and Developmental Period Rock Art

Archaic and Developmental rock art are little documented and poorly understood in northern New Mexico. Early rock art in New Mexico is referred to as the Abstract Style, loosely classified through the presence of heavy patination and stylistic similarities to early rock art elsewhere in the arid west. In fact, the style is sometimes known as the Great Basin Abstract Style, after its resemblance to Archaic rock art documented by Steward (1929) and Heizer and Baumhoff (1962). With a few exceptions, such as the array of petroglyphs dated through partial excavation at Glorieta Pass, the Abstract Style in the Southwest has never been properly dated; in the northern Rio Grande region, Abstract Style is believed to encompass petroglyphs from the Archaic through Basketmaker II, and perhaps even into later periods (P. Schaafsma 1980:77).

The Abstract Style (Figure 82.2) is characterized by zigzags that are either single or in parallel sets, straight and curved lines, rows of dots, curvilinear meandering lines, spirals, circles that are bisected, conjoined, concentric, with central dots, or with rays like sunbursts, rectilinear patterns such as "ladders," "nets," rakes, grid patterns, or rectilinear meandering lines, or representational figures, which are less common, but include stick-figure anthropomorphs, simple animals, and tracks.

Abstract Style petroglyphs usually occur on all sides of a boulder or cliff face, sometimes tucked into narrow cracks or formed to fit the shape of the boulder (Figure 82.3). Elements are often repeated in long rows (P. Schaafsma 1992:83).

Figure 82.2. Abstract style petroglyphs (from P. Schaafsma 1992:85).

Although poorly documented in the Rio Grande Valley, the Abstract Style is present at an array of sites in the northern Rio Grande. Black Mesa, near Leiden, includes boulders covered with completely repatinated abstract petroglyphs that probably date to the Archaic or Developmental periods (Boyd and Ferguson 1988). Heavily patinated petroglyphs at Arroyo Hondo are superimposed by Coalition period images (P. Schaafsma 1980:47), while Abstract Style imagery at other sites north of Arroyo Hondo is associated with a Basketmaker II site (P. Schaafsma 1980:47, 47). Pitted boulders occur in Arroyo Hondo, in the Galisteo Basin, and along the Rio Grande north of Cochiti (P. Schaafsma 1992:83); similar completely repatinated boulders in the Great Basin have been suggested to date between 5000 and 3000 BC (Heizer and Baumhoff 1962:234–235). Other Abstract Style petroglyphs are known from West Mesa (Albuquerque) and the Socorro area (P. Schaafsma 1992:83) and along the San Jose River (P. Schaafsma 1980:47).

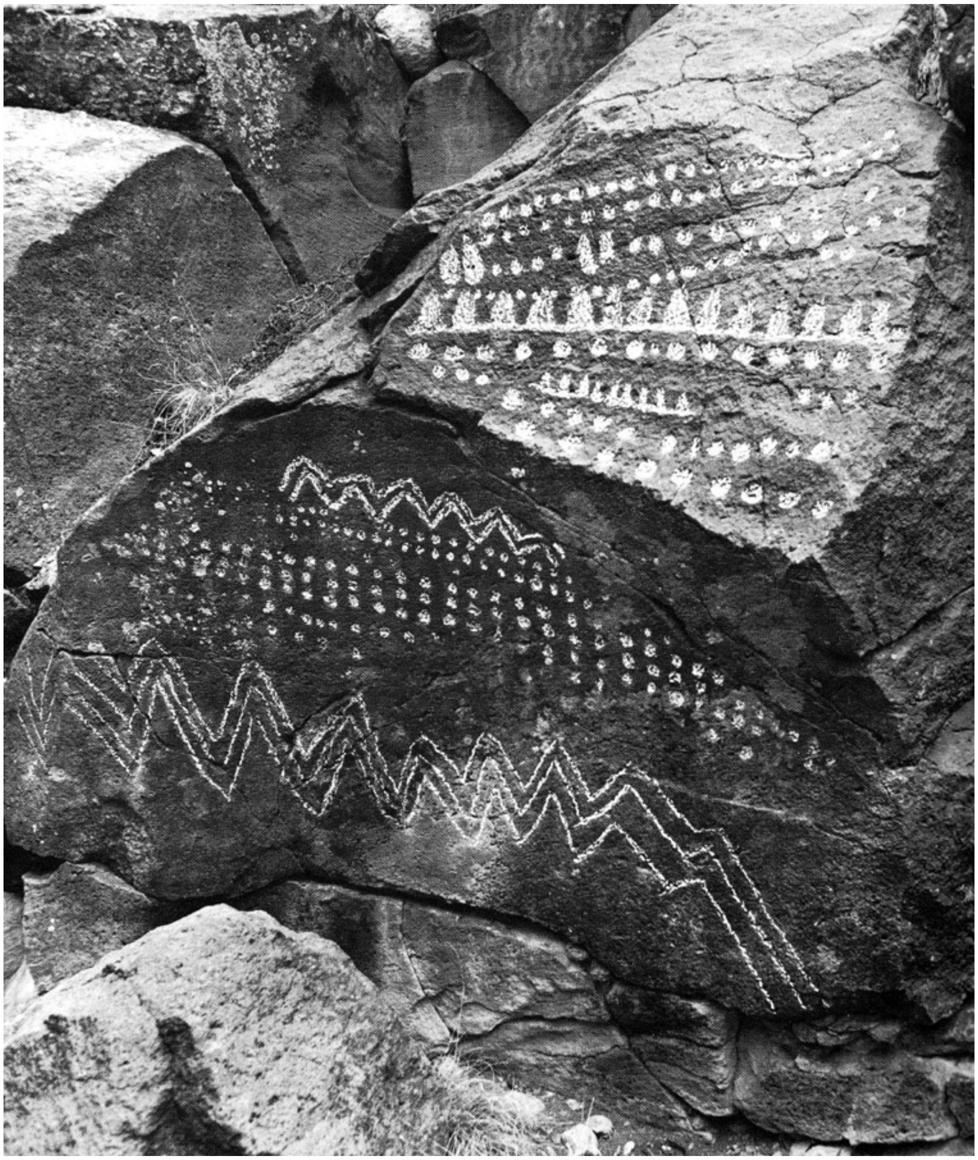

Figure 82.3. Abstract style petroglyphs, showing typical layout of elements (from P. Schaafsma 1992:84).

It should be noted that all of the northern Rio Grande rock art that is believed to predate the Coalition period is in the form of pecked images on basalt boulders; neither Abstract Style paintings nor petroglyphs on tuff have been identified on the Pajarito Plateau. There are several possible explanations. First, Abstract Style rock art is rare throughout northern New Mexico; low population levels on the Pajarito Plateau during the Archaic and Developmental periods make it unlikely that there was much associated rock art from these periods. Second, Archaic or Developmental rock art produced on the soft tuff available on the Pajarito Plateau may have eroded so heavily that it can no longer be recognized. Rock art on basalt has better resistance to erosion, but relatively little survey has been carried out in basalt-rich areas of the Pajarito Plateau. Finally, the Abstract Style is generally completely repatinated and usually lacks representational imagery; its subtlety makes it easy to overlook. Even in extensively recorded areas such as White Rock Canyon (Lilienthal and Hoard 1995), the Abstract Style may be unnoticed or simply neglected in favor of the more recent, visually dynamic work.

Coalition Period Rock Art

Schaafsma believes that most pre-14th century rock art in the Rio Grande Valley dates to the Pueblo III period, coinciding with a major population increase. She describes Pueblo III period rock art as generally similar to that of the Colorado Plateau, although it shows "considerable variability in style, content, and ... relationships to rock art in adjacent regions" (P. Schaafsma 1992:85).

In general, Pueblo III style rock art includes (Figure 82.4) solidly pecked life-forms including birds, deer, lizards, mountain sheep, and tracks; stick figures; flute players; human figures with oversized hands and feet, and scenes involving copulation are common in the northern Rio Grande (P. Schaafsma 1992:86); complicated geometric designs, similar to textile and pottery motifs; spirals and concentric circles; meandering lines, lines of dots, zigzags, and bisected and conjoined circles, elements that are typical of the Abstract Style but were also produced in Pueblo III rock art (P. Schaafsma 1992:87). The specifics of Coalition style rock art on the Pajarito Plateau are discussed in greater detail in the following section.

Classic Period Rock Art

Classic period rock art is usually discussed as part of a widespread fluorescence of visual arts in Puebloan society, beginning in the early 14th century (Brody 1991; P. Schaafsma 1992). The Rio Grande Style of the Classic period (P. Schaafsma 1992:91) is widespread and well known for its visually dynamic qualities and detailed representational imagery. The Classic Rio Grande Style (Figure 82.5) includes highly stylized outlined figures with considerable decorative detail and the human figures are often drawn with boxy bodies, large feet, knobby knees, and well-developed calves; masks and/or faces; mammals, birds, snakes, and horned serpents; shield bearers and shields; and cloud terraces, four-pointed stars, and crosses.

Schaafsma describes regional variation in the Rio Grande Style relative to historic linguistic groups, including the Keres and Tewa pueblos associated with the Pajarito Plateau. The southern Pajarito Plateau, up to Frijoles Canyon, is included in Schaafsma's Keres province. She describes Keres rock art as including simple faces, often consisting of a basic circular or square outline, "very simple headgear" (1992:106), and plain dots for facial features. Square masks are especially common north of Cochiti Pueblo, although some of these may have been made recently. Full anthropomorphs are depicted with stylized boxy bodies, often with an X across the torso. Fluteplayers are common, while shield bearers and shields are less notable. Lines of heads or masks on rectangular blanket-type designs are primarily found in the Keres province (P. Schaafsma 1980:275). Mountain lions are "emphasized" by their large size and prominence (P. Schaafsma 1992:108); portrayals of snakes and horned serpents are common, although they are less "dramatic" than in the northern and southern Tewa provinces (P. Schaafsma 1992:108). Spotted fawns, skunks, and other animals are also represented (P. Schaafsma 1992:105–108).

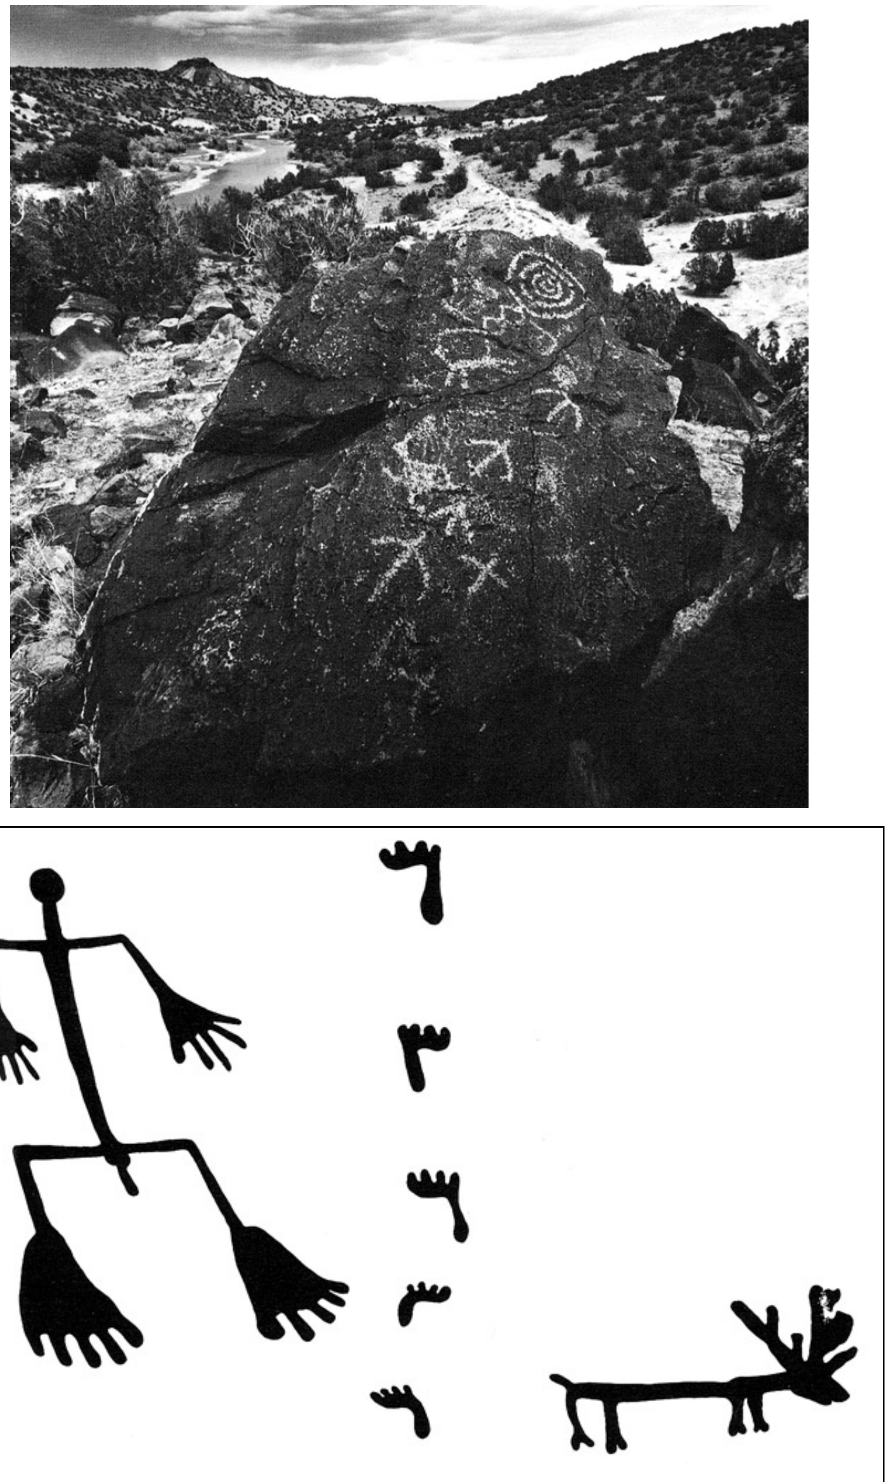

Figure 82.4. Typical Pueblo III rock art. Upper: Rio Grande Valley, north of Santa Fe (from P. Schaafsma 1992:87). Lower: Petrified Forest National Monument, Arizona (from P. Schaafsma 1980:157).

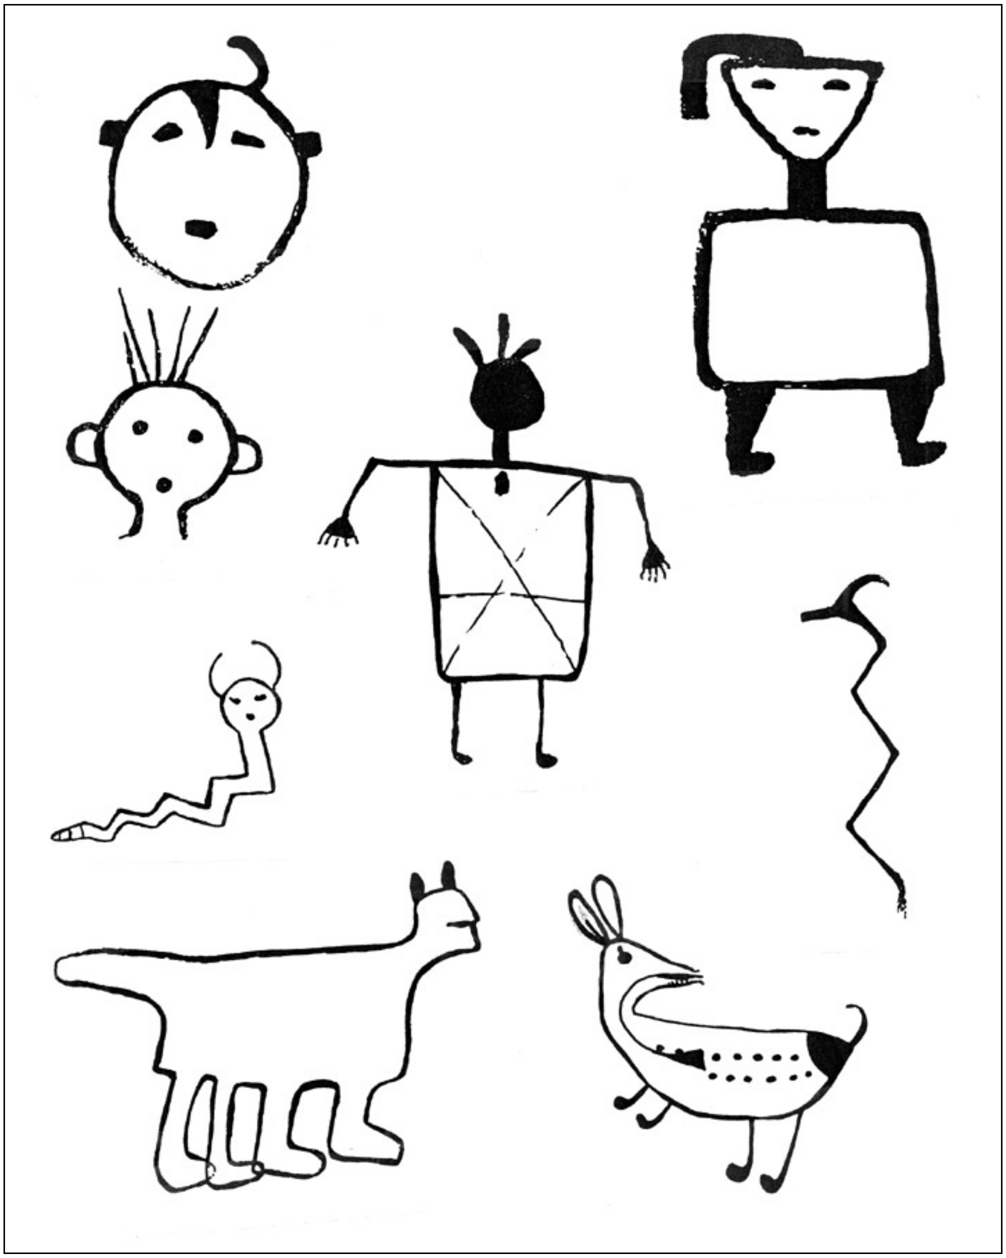

Figure 82.5. Rio Grande style petroglyphs, post-AD 1325 (from P. Schaafsma 1992).

The northern Pajarito Plateau, in contrast, is included in the northern Tewa province. Masks and human figures are less common than in other Rio Grande provinces, decreasing in frequency as one moves north along the Rio Grande (Boyd and Ferguson 1988; P. Schaafsma 1980:286). Instead, the images emphasize flute players, lightning arrows, birds, cloud terraces, and "fertility motifs" (Schaafsma 1980:286, 1992:111). Depictions of shields increase in size and detail (Schaafsma 1992:112). Horned serpents from the Northern Tewa area are depicted with horns pointing backwards; the horned serpent from Tsirege (LA 170) provides a classic example. Spirals and concentric circles are common elements. The specifics of Classic style rock art on the Pajarito Plateau are discussed in the following section.

Dating Pajarito Rock Art: Coalition and Classic Periods

Although Schaafsma's chronology is generally accurate, it has two major problems. First, it focuses almost exclusively on Classic period rock art. As P. Schaafsma puts it, rock art before AD 1300 is "overshadowed by the proliferation of petroglyphs in the [Classic] Rio Grande Style" (1980:160). Second, detailed studies have documented that her broad classification obscures significant geographic and temporal variation on the Pajarito Plateau.

Munson's dissertation (2002), the first project to focus on dating rock art on the Pajarito Plateau, dated the imagery in two distinct stages. First, association, superpositioning, and other relative methods were used to distinguish between rock art elements directly associated with the primary occupation of each site and those that post-date occupation. Then the primary elements were used as the foundation for stylistic seriation of rock art elements through correspondence analysis, an exploratory multivariate statistical method. Analyses indicated that there are few differences in the depictions of animals and in the use of geometrics through time; human figures change dramatically between the Coalition and Classic periods.

Seriation of human figures using correspondence analysis shows the relationship between the style of human figures and the sites at which they are located; a plot of the first two dimensions of the correspondence analysis has the characteristic horseshoe-shaped plot that indicates a linear relationship between the variables (Baxter 1994:119–120). This linearity could potentially be a function of any number of temporal, spatial, or functional patterns. Assessing its temporal significance must be accomplished by cross-referencing the independent dates, based on ceramic chronologies that are available for 22 sites dated by previous research projects (see Munson 2002). When the sites are arranged according to their values along Dimension 1, the independent dates are in chronological order, indicating that Dimension 1 orders the sites temporally. The most recent sites are indicated by negative values on Dimension 1, while the oldest sites have positive values. The array of stylistic traits in the correspondence analysis documents stylistic trends in the representation of humans through time. In general, this analysis indicates that there was a shift from naturalistic depictions during the Coalition period to increasing detail and iconicity during the Classic and into the Historic period.

Coalition Period: Naturalistic Figures

Coalition figures are often solidly pecked and are characterized by simple naturalistic bodies, necks, feet, legs, and arms (Figure 82.6). The majority of the human figures are shown in frontal view, as they are from all periods on the Pajarito Plateau. Only about 10 percent of the figures have facial features, in part because they are difficult to depict on solidly pecked heads. Depictions of male genitalia, common in Coalition figures, almost always take the form of an erect phallus from a figure shown in profile; although most common on Coalition period flute players, other individuals are also shown with penises. Ambiguous "lizard-men" that may be men with long penises or lizards with tails are also a part of this tradition. Female genitalia are usually not depicted; the two occurrences are of complex figures with solid or bisected ovals inside the outline of the body, at the base of the torso.

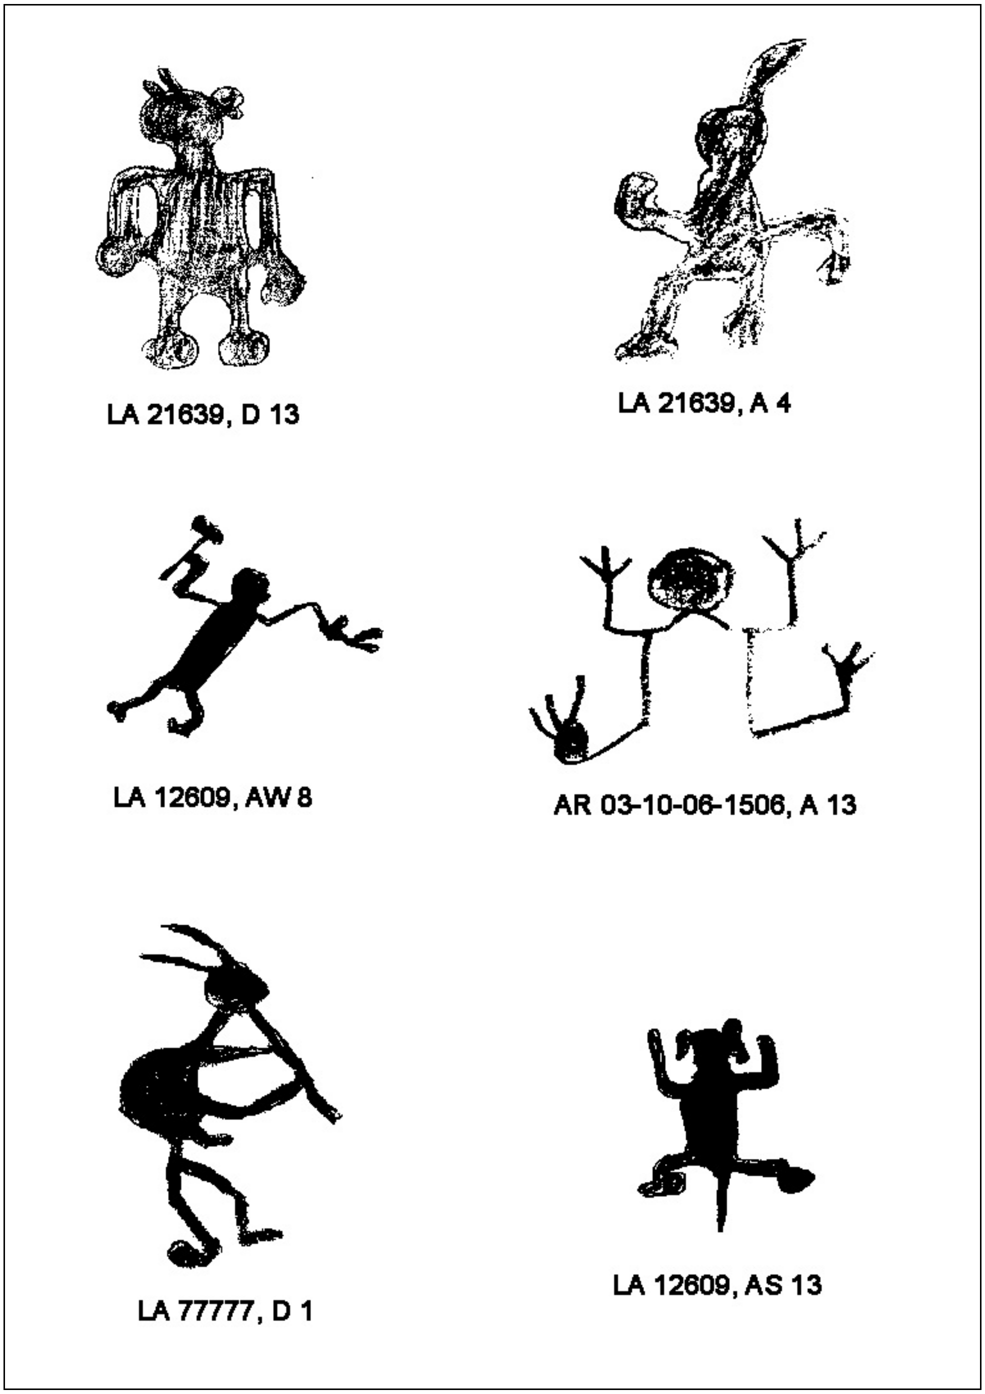

Figure 82.6. Coalition style human figures from the Pajarito Plateau.

In general, Coalition figures lack complex decoration, although some figures do have simple additions to their heads. Feathers are the most common; on individuals shown in profile (especially flute players), they are often just a single thick line, raking back from the head. In frontal view, they are usually shown in pairs, angling slightly outward, almost like antennae. A few individuals have short pairs of lines, often curved, emanating from the upper sides of the head; these are believed to represent horns. Projections from the sides of the head more often take the form of small circles, representing ears, or perhaps hair whorls; more distinct representations of hair whorls take the form of a stemmed "butterfly." Other possible depictions of headdresses are shown on an individual with horns with balls on the tips and a figure with thick straight lines from the top of the head, like rabbit ears.

Solidly pecked flute players, shown in profile, are quite common (Figure 82.7). Most have straight, downward-pointing flutes and humped backs, and are shown with bent legs, as if they are seated. These images are not only characteristic of the Coalition period on the Pajarito (P. Schaafsma 1980:160), but they are also typical of Pueblo II-III rock art on the Colorado Plateau (P. Schaafsma 1992:86).

Figure 82.7. Coalition style flute players from the Pajarito Plateau.

Classic Period: Geometric Figures

During the transition from the Coalition to the Classic, a new, geometric form of human representation was introduced (Figure 82.8). Although some figures that date to the Classic period are similar to the naturalistic Coalition style, the proportion of naturalistic portrayals of humans decreased rapidly; by the Classic period per se, 85 percent of the human figures were depicted with strict geometric shapes. This rectilinear style of representation is most noticeable in the shapes of bodies, heads, and necks. Almost a third of the Classic figures have rigidly rectangular bodies, and another 10 percent have square or triangular bodies. Figures are often depicted with a distinct "hollow" neck consisting of open, parallel lines; when no neck is shown, the base of the head usually opens directly into the body, indicating that the configuration of the shoulders and upper body was produced with the head shape in mind. Just half of the figures have rounded, naturalistic heads; the remainder are strict geometric shapes, such as squares, drawn with precise right angles. Downward pointing triangular heads, flat-topped heads (rounded along the bottom and sides but truncated with a straight flat line across the top), and tapered trapezoidal heads are also predominantly Classic.

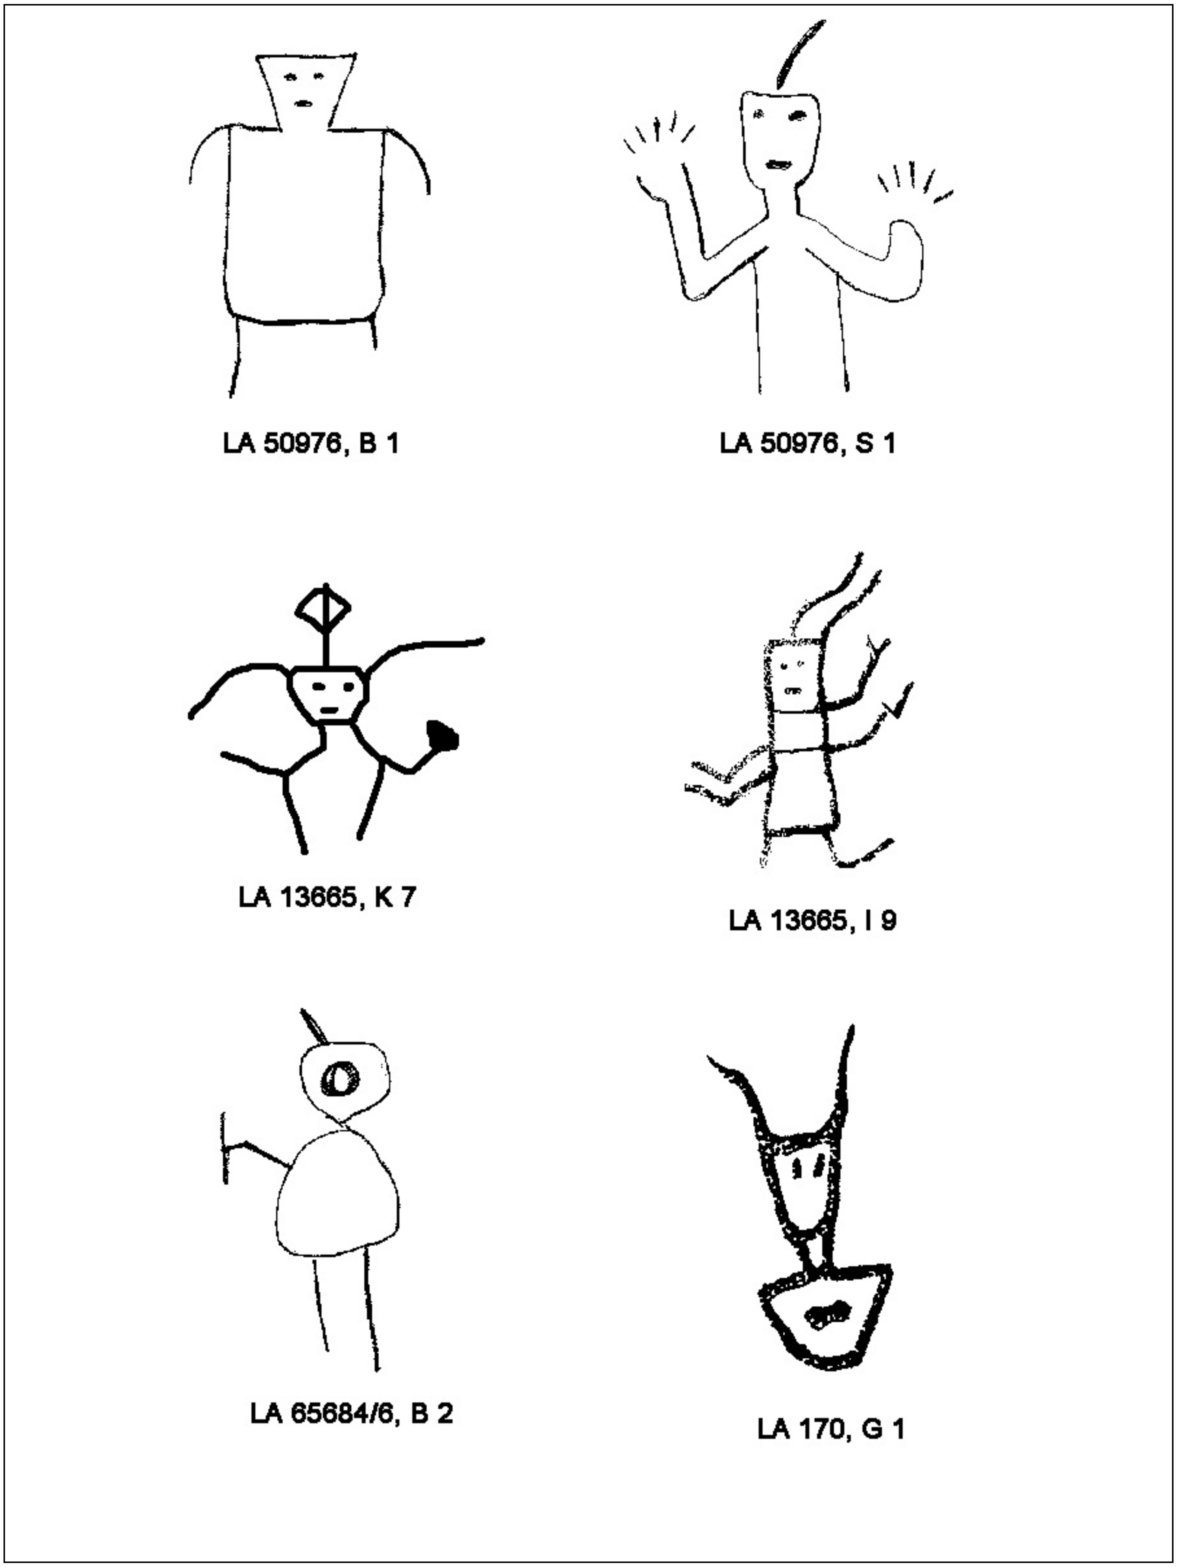

Figure 82.8. Classic style humans from the Pajarito Plateau.

In contrast to the largely geometric bodies and heads, other body parts are represented in an increasingly realistic fashion; almost two-thirds of Classic humans are shown with details such as fingers and facial features. Eyes are usually shown as simple dots or short horizontal lines, and mouths are seldom more than a straight horizontal line. Most forms of decoration are more complex than in Coalition period figures, although ears or hair whorls are rarer and less distinct in the Classic; the small circles on either side of the head are present in low frequencies, but clear depictions of hair whorls are rare. Feathers, although occasionally shown in the Coalition single-line style, are usually depicted as a series of long parallel lines, while more complex headdresses are shown in a wide range of forms. Some individuals have decorated torsos, such as chevrons, Vs, Xs, and diagonal lines, although they are relatively rare.

The proportion of figures that are outlined increases dramatically from the Coalition-Classic transition (slightly more than half) through the Classic (around 90%). Most of the depictions of female genitalia are from the Classic period. They take the form of individuals shown in frontal view, with a loop or two short parallel lines pendant from the base of the body, between the legs. Males are rarely indicated in the Classic period; like the females, they are usually depicted in frontal view. In the Coalition period, many of the male individuals are flute players; in the Classic period, only a single flute player is phallic. In addition, Classic period flute players are rendered in looping lines, completely unlike previous figures (Figure 82.9).

Historic Period: Elaborate Geometric Figures

Historic period rock art shows little change from that of the late Classic, although most of the trends in the Classic are somewhat strengthened (Figure 82.10). Less than 10 percent of human figures are naturalistic; rectilinear figures dominate. Rectangular heads are more typical of this late imagery. Details such as fingers, mouths, and eyes are increasingly common, reaching almost 75 percent. Almost two-thirds of these late figures lack arms and/or legs. The fact that prevalence within an assemblage is the main distinction between Classic and historic styles makes it difficult to distinguish between the two periods without specific historic imagery at the later sites.

However, the latest imagery includes various elaborations rarely seen in earlier imagery, such as legs drawn with bulging calves. Individuals may have Xs across the torso or carefully delineated belts, complete with tassels. Noses are indicated by a short vertical line at the forehead. Other figures are shown with elaborate hairstyles, such as "butterfly" whorls, plaits, and asymmetrical hair, or pointed caps. These decorative traits have strong similarities to ethnohistorically documented Pueblo paraphernalia, such as bandoliers (Strong 1979), hair whorls, and the pointed cap worn by warriors.

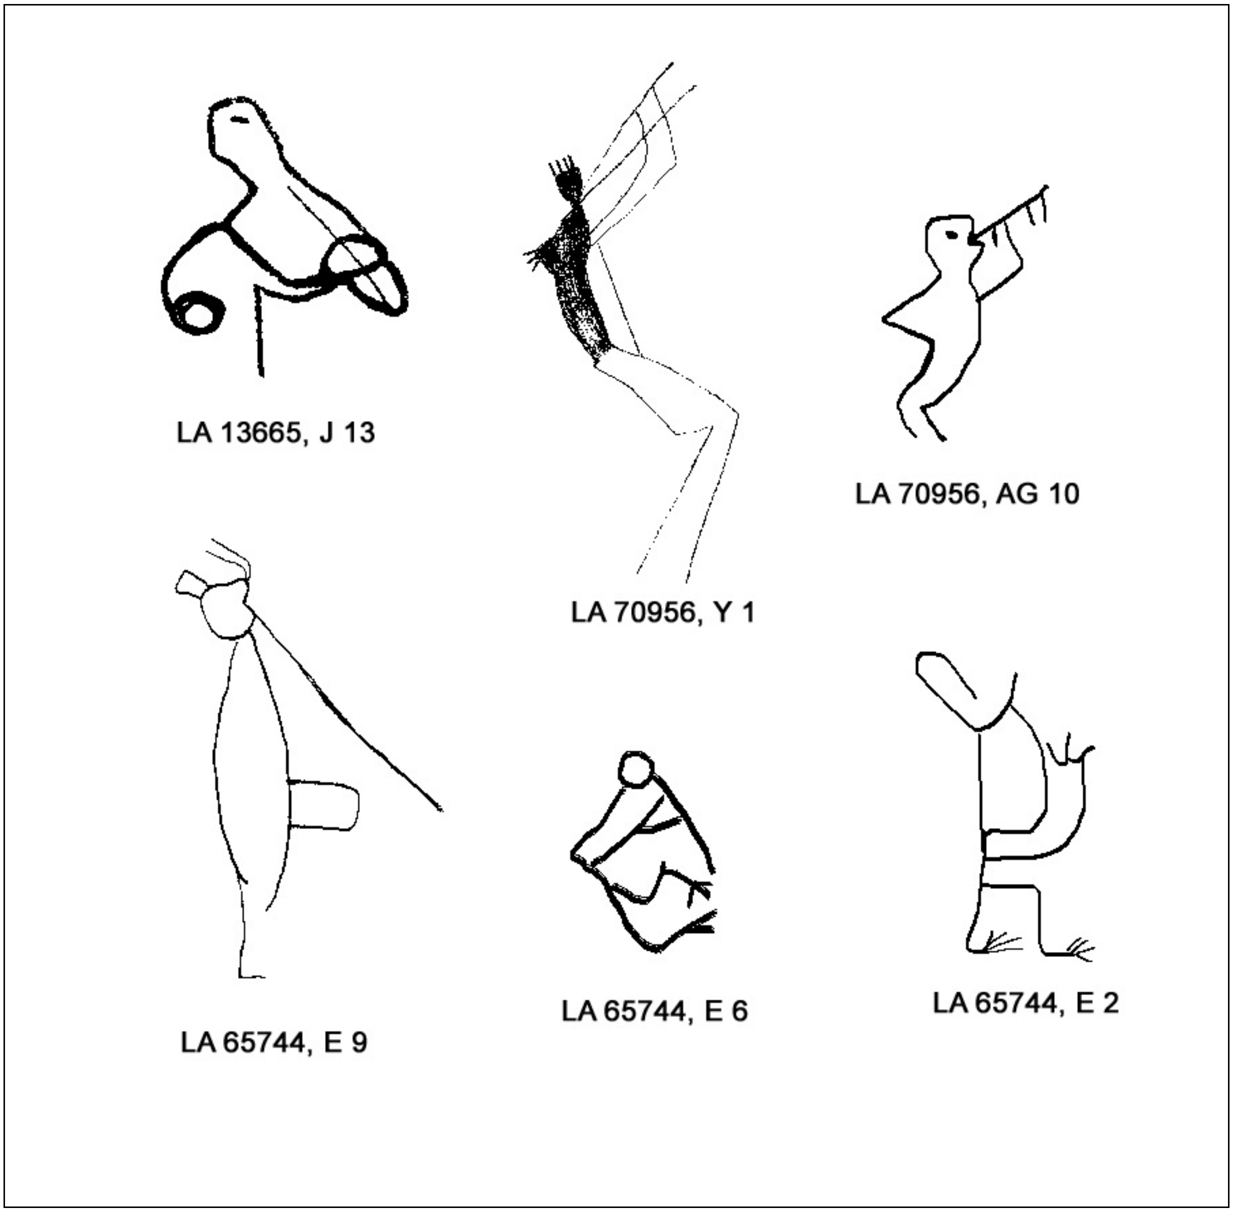

Figure 82.9. Classic style flute players from the Pajarito Plateau.

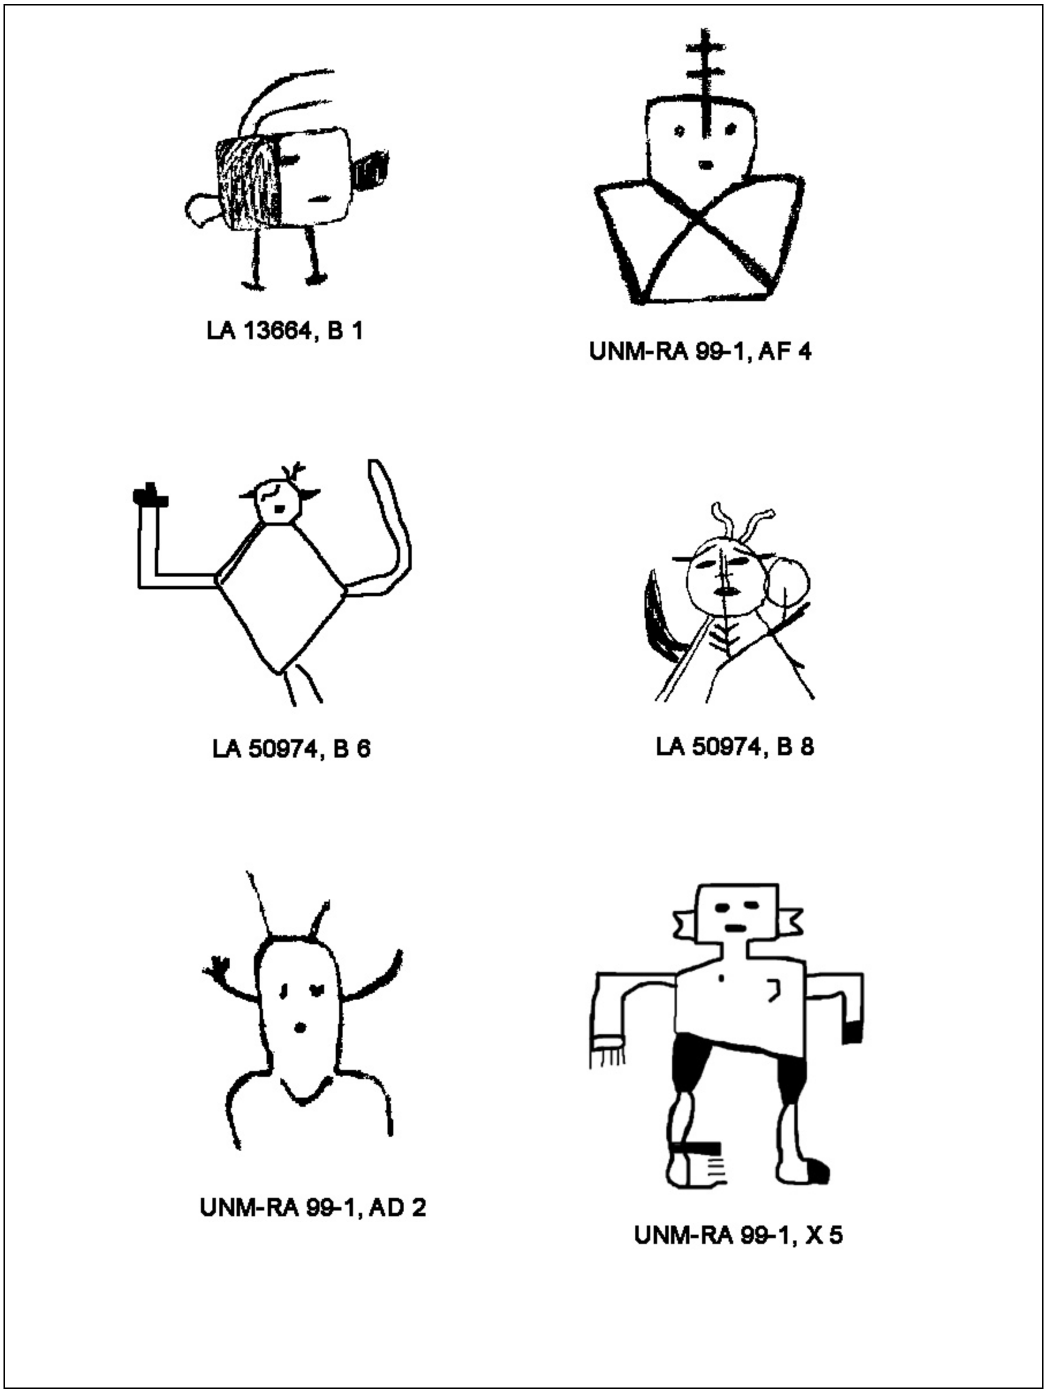

Figure 82.10. Historic style human figures from the Pajarito Plateau.

Depictions of Animals

Attempts to seriate depictions of animals were unsuccessful; correspondence analysis fails to show any linear relationship between the stylistic traits of animals and the sites at which the depictions occur. This result is rather surprising; given the range of variation observed in the field, it was anticipated that Classic period animals would show greater complexity and detail than those at Coalition sites. Classic birds, for example, seemed to be shown with feathered wings and precise fan shaped or feathered tails, while rare depictions of claws on quadrupeds or of rattles on snakes date to the Classic period or later (Figure 82.11).

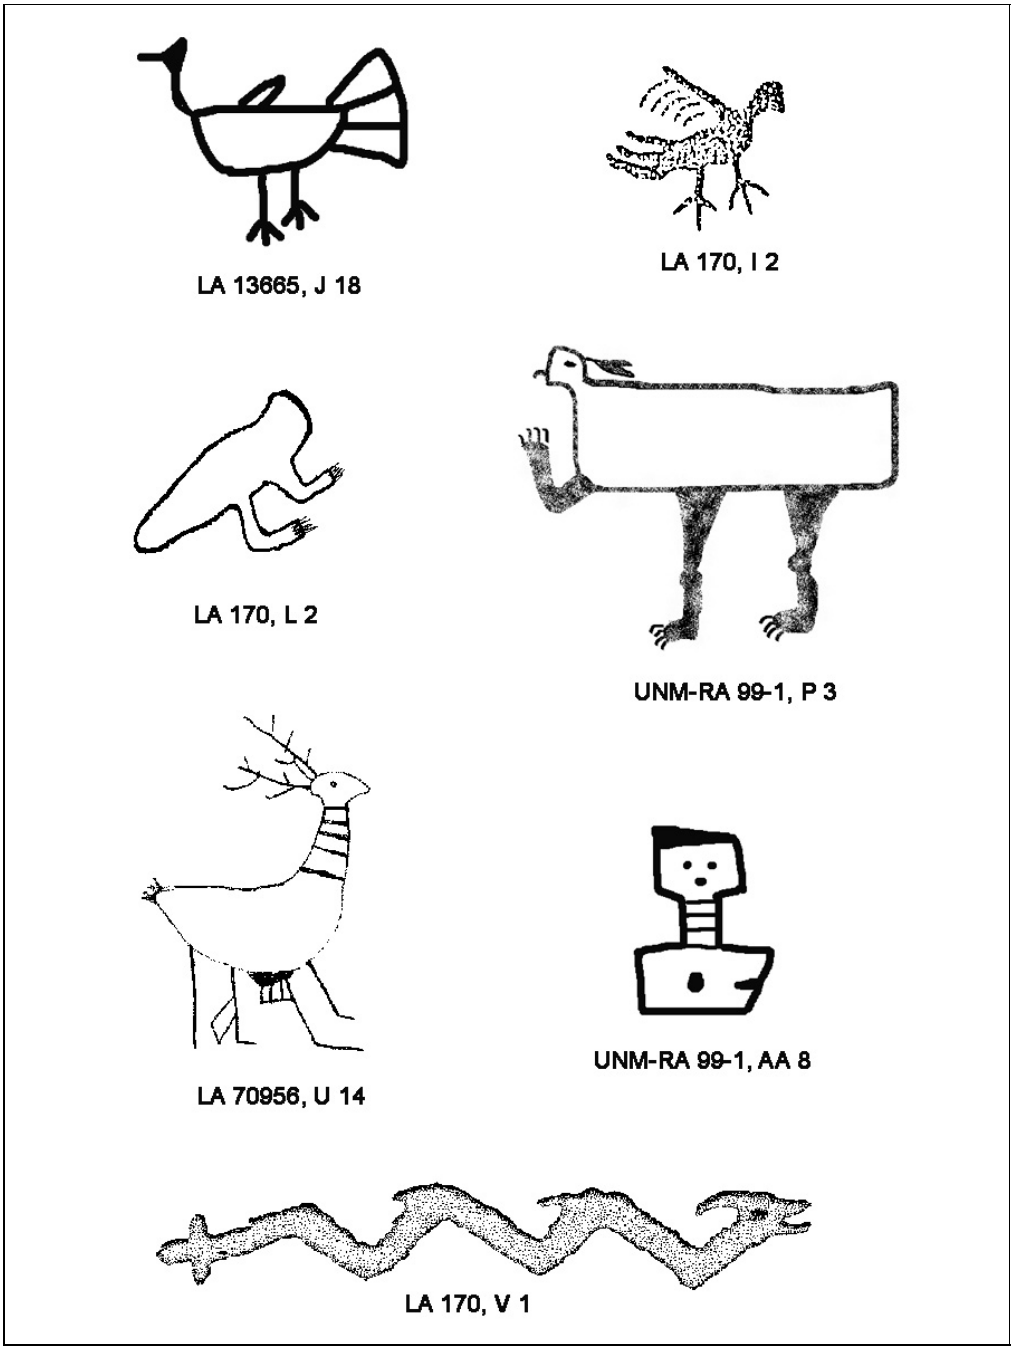

Figure 82.11. Detailed animals from the Pajarito Plateau. Most of the figures date to the Classic period; the mountain lion (UNM-RA 99-1, P 3) is from a historic site. The rectilinear human with striped neck (UNM-RA 99-1, AA 8) is also historic; it is provided as comparison to the deer with striped neck (adjacent).

A closer look at the data provides a partial explanation. For one thing, traits such as body shape may be determined more by the specific animal being depicted than by stylistic concerns. An artist is limited by the need to choose an appropriate combination of traits in order for the depiction to be understood (B. Smith 1998). For example, mountain lions in Puebloan imagery are often shown with long narrow bodies, a long tail stretched straight out, and short limbs and neck. The proportions of the tail, legs, and neck relative to the body are essentially fixed; lengthening the neck or changing the tail leads to ambiguity, such as that visible in the composite animals from LA 127636 (Figure 82.12).

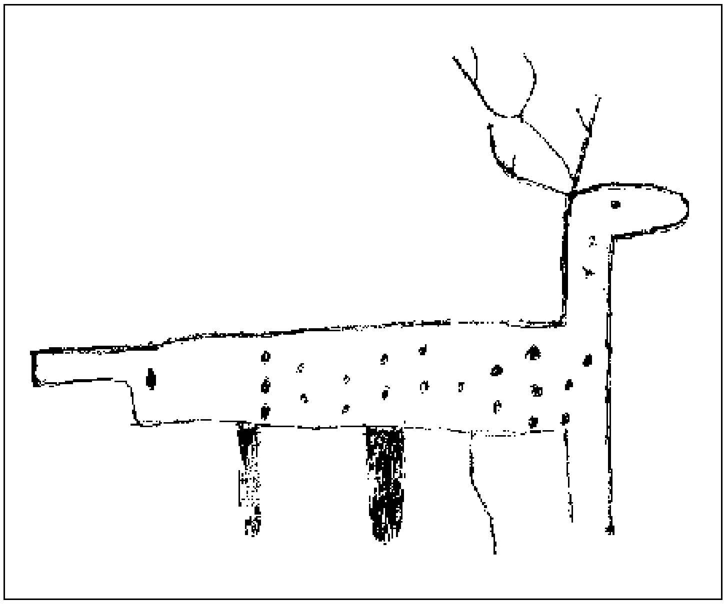

Figure 82.12. A composite animal from LA 127636, combining characteristics of a mountain lion and deer.

CONTEXTUAL DIFFERENCES THROUGH TIME

Context of Coalition Period Rock Art

In addition to dramatic shifts in style, Coalition and Classic period rock art also differ greatly in context. Coalition rock art is overwhelmingly found in private contexts. Of the images dating to the Coalition period, a full 80 percent are inside cavates carved into cliff faces. Some of these rooms are entirely enclosed by the rock, while others have openings in the front that were filled in with stone and mortar; all are small, enclosed spaces. They vary in size and quality of construction, but most are relatively small, with low ceilings. Some of the rooms have features such as niches, vents, and loom anchors, which are typical of cavates on the Pajarito (H. Toll 1995; Vierra et al. 2000).

Although in-depth analysis of cavates and cavate features is not the focus of this report, the cavates recorded during field work (Munson 2002) supported previous observations regarding the variability of features and finishes in cavate rooms (e.g., H. Toll 1995). Cavates with rock art are larger and have more features than those without; cavates with imagery average 5.1 square meters in size, and contain 5.0 features, while plain rooms average 2.7 square meters in size, with 2.2 features each. Rock art also tends to occur in rooms that are more formally prepared; 85 percent occur in cavates with a tan plaster dado on the lower walls and/or a thick coat of soot on the upper walls and ceiling. Most of the rock art is pecked or cut through the soot, exposing the light gray tuff below and creating high-contrast images (Figure 82.13).

Figure 82.13. High-contrast imagery inside a cavate at LA 12609.

Previous researchers have interpreted this interior Coalition period rock art as an indication that the rooms served as kivas (Rohn 1989; Steen 1977, 1979). Indeed, a few cavates are so distinctive in the amount of imagery, the relatively large size of the room, and the density of the features that they are likely ceremonial rooms. The Mortandad Cave Kiva, for example, is dramatically different from most cavates. One of the largest cavates on the Pajarito, the room is well-formed and has numerous features, including multiple niches, a firepit, a double doorway, and vent holes. The densely packed rock art crowded together on the cavate walls includes three times more imagery than any other cavate, and the combined scale, density, and iconography of the images is visually overwhelming (Figure 82.14). There is no coherent overall layout, but several of the images are integrated into small "scenes" of interacting figures. On the west wall, a person swings a club at a humped arrow swallower; on the east, two canids are shown muzzle to muzzle. Between and above the two doors is the dominant image, which is a large shield bearer with a feathered shield. The shield bearer holds a club in one hand and a horned serpent in the other. In addition, an arrangement on the wall opposite the doors pairs spotted mountain lion-type animals with two horned serpents; the serpents' bodies merge into a large arc over all four figures. Their symmetrical arrangement around a niche behind the fire pit is reminiscent of some northern Rio Grande kiva layouts (Smith 1990).

Nevertheless, most cavates with rock art are considerably simpler and are unlikely to have had primarily ceremonial functions. For example, of the 24 other Mortandad cavates with rock art, only five have even a fifth the number of images of the Cave Kiva; most have fewer than three scattered images and low to moderate numbers of features. The images could have been produced and viewed only by people with access to the rooms, whether inhabitants, kin, neighbors, or invited artists. The small size of the rooms effectively limited the audience to less than a dozen people, all sanctioned by the inhabitants of the room. The interior location of the rock art implies direct individual or family control over the imagery and its use. It is unlikely that these cavates were the functional equivalent of standard kivas (see H. Toll 1995:213–215).

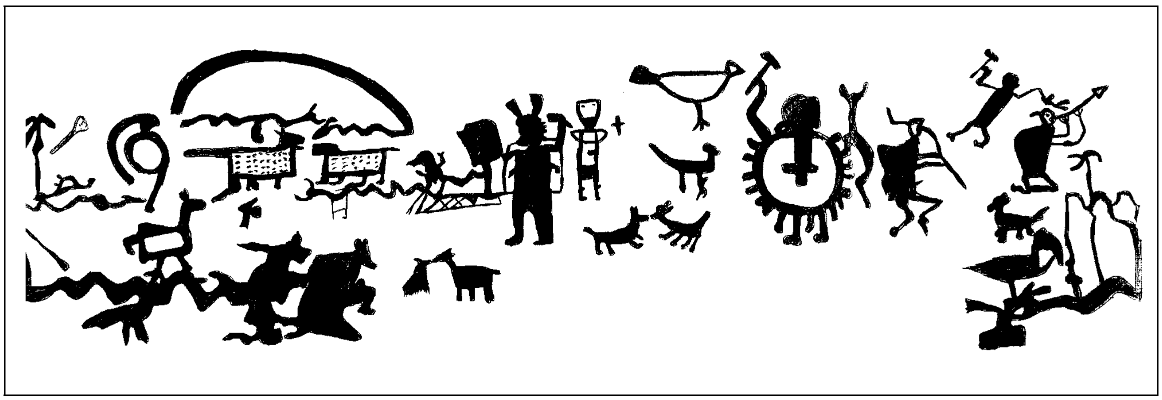

Figure 82.14. Interior petroglyphs from the Mortandad Cave Kiva.

Coalition rock art does occur in exterior contexts, but it is seldom directly associated with cavates. The Mortandad site, for example, has an unusually high proportion of exterior rock art: 18 of the 23 panels are on the cliff face. However, only a single element is actually on the lower level of the cliffs, directly associated with the cavates; the remaining 78 elements are on the caprock at the top of the mesa, linked to the cavate pueblo only by a trail and stairway leading to the masonry pueblo on the mesa above. Similarly, only three elements of the 348 at the Kwage cavates (LA 35003) are on an exterior panel. The only significant exterior rock art in the vicinity is at LA 21602, a single panel of fewer than a dozen images that is located high above the Kwage site, just below the top of the mesa (Snead and Munson 2001).

Informal field observations suggest a general division of Coalition period rock art between intensive imagery inside rooms at cavate pueblos and small quantities of exterior rock art scattered along upper cliffs away from habitation sites. The north side of Bayo Canyon, for example, consists of a long, steep talus slope topped by a series of cliff faces, one of which includes a number of cavates. At the top of the cliff is a sloping section of eroded bedrock and boulders, leading up to a second, shorter outcrop at the top of the mesa; this cliff is scattered with numerous small panels of rock art (Figure 82.15). The pattern of small rock art panels located in the vicinity of small Coalition period cavate pueblos is repeated in Sandia Canyon and along the Mesita del Buey, near Tsirege (Vierra et al. 2000). These panels have not yet been dated stylistically and they lack the close association with habitation sites that would allow them to be dated securely. These scattered panels, often too small to be documented as full-fledged sites, are probably under-reported in the literature; it they do indeed date to the Coalition period, they raise the possibility that Coalition rock art may also be under-reported.

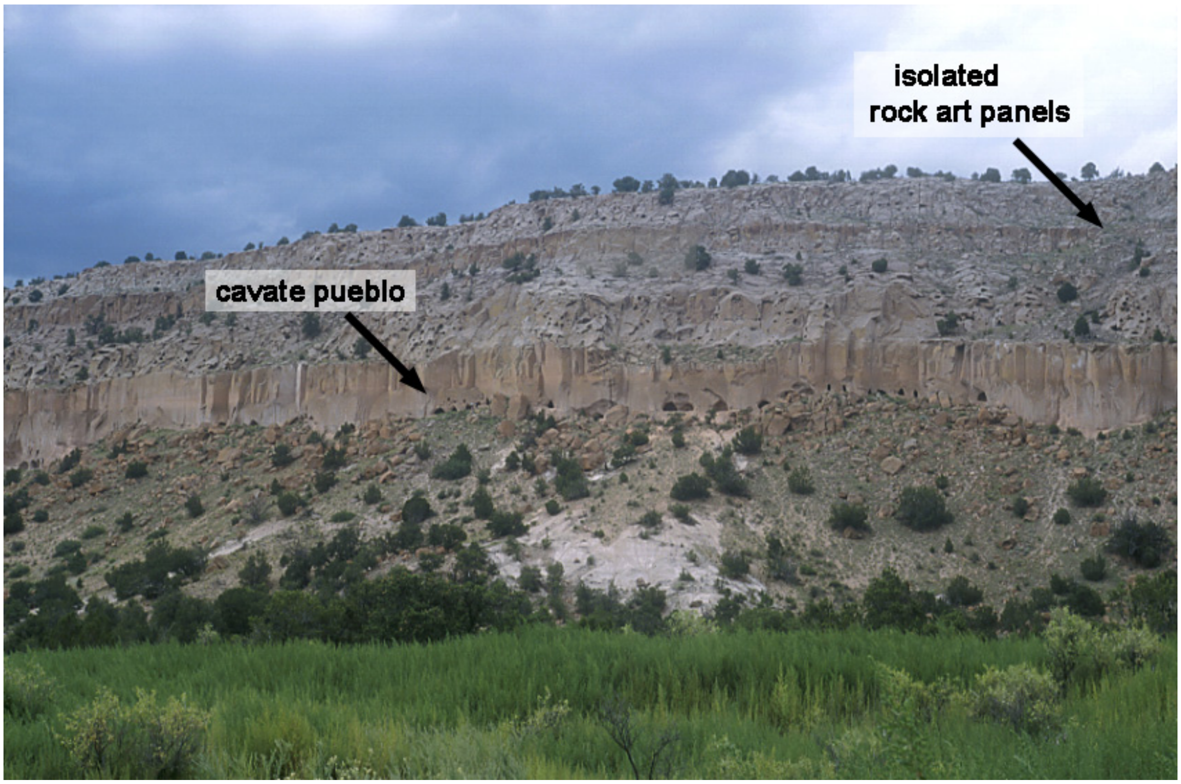

Figure 82.15. Location of isolated rock art panels relative to cavate pueblos in Bayo Canyon. The photograph was taken from Otowi Pueblo.

In the absence of additional information, however, the distribution of these panels relative to Coalition and Classic period sites provisionally suggests that this scattered rock art may be contemporaneous with small Coalition pueblos. If so, the dichotomy between dense interior rock art and scattered, distant exterior rock art indicates that each context had different audiences. The exterior rock art is relatively open, without physical barriers that would restrict its production or viewing, yet much of it is far enough afield that the images are less likely to have been seen frequently. The presence of trails leading from most of the Coalition cavate pueblos to the mesa tops (Snead 2002a) would have facilitated access to the rock art on the upper cliffs, but direct associations between trails and rock art are unusual (Snead and Munson 2001). At the Mortandad site, for example, the central stairs lead individuals within view of the most concentrated rock art, but not directly to it (Figure 82.16). Similarly, a major stairway at the east end of the mesa along Bayo Canyon provides access to the same level as the rock art, but only a single panel with a few elements is actually visible from the trail.

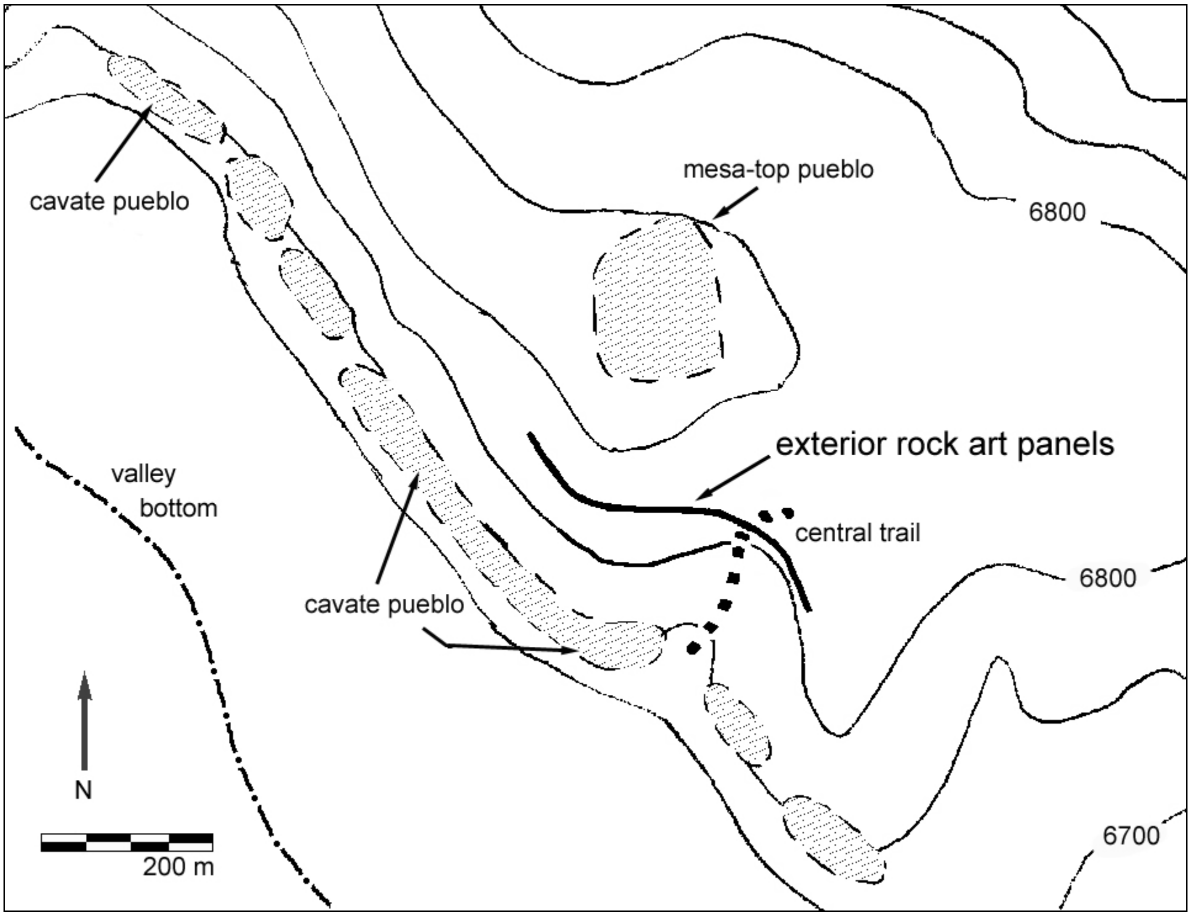

Figure 82.16. A plan map of the Mortandad site, showing the relationship of exterior rock art panels to other features.

Context of Classic Rock Art

While Coalition rock art is almost entirely in private contexts, 85 percent of Classic rock art in this study is located on exterior surfaces. Rock art on cliff faces is, of course, a logical accompaniment for the multi-story cavate pueblos that were common in the Classic period (Van Zandt 1999:387), as the very fabric of the cavate pueblos provided an expanse of cliff and walls suitable for rock art. However, many Coalition period sites, like the Kwage and Mortandad sites or smaller cavate pueblos like LA 21639, have ample cliff faces that were completely ignored by artists. There is no indication that Coalition period rock art was crowded onto insufficient space; more than 80 percent of the panels from both periods have light or moderate use of space, and only a small, uniform proportion of the panels have heavy use that might indicate crowding. In addition, the increase in large cavate pueblos in the Classic period would have provided ample interior space for rock art, space that these artists seldom used. The dramatic jump in exterior rock art, then, indicates a new emphasis in the Classic period on public locations for imagery.

Although the exterior rock art is large enough to be potentially visible from a moderate distance, only a small percentage is in the prominent locations visible to individuals approaching a site.

The primary audience for most of the external rock art was the inhabitants of each cavate pueblo, or at times individuals living within a segment of a pueblo (Figure 82.17). Closer examination of the distribution of Classic rock art highlights the existence of special-purpose locales, involving small platforms surrounded by extensive rock art imagery. These alcoves, visible from villages but somewhat removed from the traffic of daily life, are locations where small groups of individuals gathered periodically for rituals centered on the production of rock art.

Figure 82.17. The horned serpent at Tsirege (vertical panel at center of photo) is located along the main stairs leading to the mesa top pueblo. Although it would have been seen by anyone entering the site using this stairway, it is not readily visible to strangers at a distance.

GEOGRAPHIC VARIATION IN PAJARITO ROCK ART

Purported Differences in Northern and Southern Pajarito

As discussed earlier, much research on Pajarito rock art has relied upon Schaafsma's stylistic distinctions relative to historic Keres and Tewa boundaries. In broad outline, the geographic distribution of elements fits within P. Schaafsma's (1992) delineation of conflict-related Tewa rock art in the north and religious Keres rock art in the south. Rock art from the northern plateau, for example, includes most of the imagery with war-like connotations, such as shield bearers, weapons, arrow swallowers, thunderbirds, and mountain lions. Depictions of possible kachinas, in turn, are most common in or south of Frijoles Canyon.

Nonetheless, close examination of the distribution of rock art elements indicates that the greatest variability is actually among clusters of neighboring sites: those in Garcia Canyon, in the Otowi-Tsankawi area, the Tsirege area, Frijoles Canyon, and the southern Pajarito around San Miguel. For example, although flute players are numerically most common in the north, 90 percent of all flute players in the Pajarito sample are found in the Otowi-Tsankawi area. Similarly, the predominance of shield bearers in the north results from the fact that 88 percent of all shield bearers in the sample are limited to the Otowi-Tsankawi area. Weapons, thunderbirds, and arrow swallowers, limited almost entirely to sites on Tsankawi and north mesas, are even more restricted in distribution. In turn, the Otowi-Tsankawi area largely lacks elements such as individuals with torso Xs, possible kachinas, and the pointed-cap being, all of which are common at Tsirege and in Frijoles Canyon. Tsirege and the Frijoles sites also have numerous shields and concentric circles, but completely lack the shield bearers of the Otowi-Tsankawi area. The Frijoles Canyon sites are distinguished from Tsirege by their numerous faces and plain circles. The sites in Garcia Canyon, with large numbers of spirals and plants, are unusual enough that they were difficult to date stylistically, while the rock art on the far south Pajarito is also quite distinct from other locations. The imagery in the San Miguel area includes many pictographs, the unique star ceiling, and numerous faces pecked around corners. The following section describes the characteristic rock art of each of these geographic areas in greater detail.

The Northern Pajarito

The northern Pajarito rock art in Munson's dissertation consists entirely of Coalition period imagery from sites in Garcia Canyon. Although this sample is not an ideal representation of the northern plateau, it is sufficient to point out certain differences between Garcia Canyon imagery and the remainder of the Pajarito. The assemblage is dominated by spirals and zigzags. Animals and anthropomorphs are uncommon; the latter are often incomplete, as in the case of isolated legs and feet. The unique representations of plants are notable; the rare depictions of plants elsewhere on the Pajarito lack the rounded circles at the tips of the stems that make the northern depictions of plants resemble sunflowers. The sole shield is also unusual, with a lobed interior and a central face.

The North-Central Pajarito

The rock art of the north-central Pajarito Plateau is dominated by transitional Coalition-Classic elements and Classic period imagery. The areas around Otowi and Tsankawi, in particular, are mixed temporally, while the rock art at Tsirege is primarily limited to the Classic period. In addition to their temporal differences, these two areas within the north-central Pajarito have overlapping but different rock art motifs.

Compared to the rest of the Pajarito, the Otowi-Tsankawi area has the vast majority of the images relating to hunting or warfare, including most of the shield bearers and virtually all of the images of weapons. In the Coalition period, representations of weaponry are mostly bows and arrows, often with individuals using them to shoot quadrupeds, although sometimes as individual objects. A few human figures hold possible spears. Transitional Coalition-Classic weapons are entirely held by single individuals, including some shield bearers. In the Classic period, weapons are represented as isolated bows and arrows, a single object that appears to be a projectile point, and a shield bearer holding a possible spear. The Otowi-Tsankawi area also contains most of the arrow swallowers in the sample. These individuals are represented in profile and often look much like flute players. The earliest, from the Coalition period, is inside the Cave Kiva at Mortandad; the latest is a Classic period figure in Frijoles Canyon. The majority of these images, though, are Coalition-Classic transitional and are located at the Tsankawi Trail site.

Birds and unidentified quadrupeds constitute more than two-thirds of the animals in the Otowi-Tsankawi area. Canids are found in all periods, while depictions of deer or possible elk are limited to the Coalition and transitional Coalition-Classic. Mountain lions are common in the Coalition period, while transitional sites include the sole dragonfly and almost all of the thunderbirds in the sample. Horned serpents are common in the Otowi-Tsankawi area in the Coalition rock art, along with numerous zigzags that resemble snakes; although short or excessively meandering zigzags bear little resemblance to local conventions for depicting snakes, the long horizontal zigzags that encircle cavates are similar to the form of more direct depictions of serpents. Such "cavate snakes" are common in Coalition and Classic period cavates on the north-central Pajarito.

At Tsirege, in contrast, simple passive figures and simple faces dominate, each constituting about 30 percent of all human images. Elaborate humans are evenly split between active and passive forms. Two of the anthropomorphs represent a person with a pointed cap being and a beaked masked figure. Animals, as is typical of the Pajarito, are mostly birds and unidentified quadrupeds. Numerous canids are present at Tsirege, as is the only Classic mountain lion in the northern Pajarito sample. Horned serpents are unusually common, comprising more than 10 percent of the animals, while plain snakes are relatively rare; this is hardly surprising, given the presence of the Awanyu and other dramatic horned serpents. Only a single plant is present. Shields are common at Tsirege, including some that bear elaborate designs similar to historic pueblo shields (Wright 1976, 1992) and others that are decorated with concentric circles, lobes, or feathers. Large plain concentric circles, more common at Tsirege than in any other dated rock art site on the Pajarito Plateau, probably also represent shields, although this should not be assumed of all concentrics.

Frijoles Canyon

The most numerous, and most visually prominent, shields in the sample are from Classic and late sites in Frijoles Canyon. Long House, in particular, has 10 shields, and a careful examination of the canyon shows that most of the major cavate pueblos have at least one large shield prominently placed on the cliff face high above. Large concentric circles that may also represent shields are fairly common in Frijoles Canyon.[2] Single circles, which are quite common, could potentially evoke shields, although judging from their small size they might simply be incomplete or heavily weathered faces. As at Tsirege, Frijoles sites lack shield bearers and weapons of any kind.

[2] Cavate Groups A and M, for example, have large shield-like concentrics that are visible from the canyon bottom with binoculars.

Virtually all of the human imagery consists of faces; most are simple, but a few have sufficient detail that they could represent masks. The infrequent full human figures are mostly elaborate and active; they include a being with a pointed cap, a possible representation of Shalako, and the only arrow swallower outside the Otowi-Tsankawi area. Birds are by far the most common animal (35% of animals), followed closely by snakes and horned serpents (16% each). Unidentified animals and quadrupeds constitute only one-fifth of the animals, which represents a sharp break from other Pajarito Plateau rock art. A sole plant is the southernmost such image in the study. Though rare overall, terraces and sets of concentric arcs are more common in Frijoles Canyon than in other parts of the Pajarito.

The Southern Pajarito

The distribution of rock art in the sample makes it difficult to fully address variation across the southern Pajarito Plateau. The vast majority of the rock art in the south is from the vicinity of San Miguel. This southernmost rock art is almost half human figures, which is a full 25 percent more than any other area. About 30 percent of the humans are elaborate, including multiple representations of specific individuals. Nine of the human figures have a pointed cap and claw-like hands, two are Shalako, and three have a combined head and body. The only shield bearer outside the Otowi-Tsankawi area is a late figure in Capulin Canyon, although Painted Cave, which was not recorded, also includes some of the figures (Rohn 1989). The only exceptions in the distribution of weaponry in the Otowi-Tsankawi area are two late individuals on the far southern Pajarito, one with an arrow coming from the top of its head, another holding a possible spear.

The most elaborate depictions of humans are in the late sites of the far southern Pajarito. Some detailed faces are probably representations of masks, while particularly elaborate humans may be kachinas or supernatural beings, such as mudheads, the pointed cap being, Shalako, and ogres. Most of the human figures on the southern Pajarito are passive. Handprints, though infrequent, are almost entirely from the San Miguel area, probably due to the greater proportion of pictographs in the southern Pajarito. Simple faces are usually pecked around corners, a trait typical of Keres rock art (P. Schaafsma 1980:275).

Animals are quite rare, forming only 13 percent of the southern rock art. Horned serpents, zigzags, and snakes are correspondingly rare, although when they do occur it is often in complex forms, such as the serpent at the San Miguel Site that has a body of interlocking diamonds. Most of the clear depictions of mountain lions occur in this southern area, as do most of the weasel-like animals. The far southern plateau also includes the only thunderbird outside the north-central Pajarito. Dots and + signs are quite common, due entirely to the presence of the star ceiling at the San Miguel Site. Only a single terrace was recorded on far southern Pajarito, but anthropomorphized terraces are also present at Painted Cave (see Rohn 1989:112).

Taken in concert, this evidence suggests that the content of the rock art varies on a finer geographic scale than previously recognized. The relative size of this spatial distribution is in keeping with the imagery's apparent audience, the occupants of individual communities. These geographic differences also appear to persist through time. The weaponry depicted in the Otowi-

Tsankawi area, initially present in Coalition hunting scenes, is common at transitional Coalition to Classic sites, as well as in later Classic sites. Shield bearers, likewise, are found at a few Coalition sites in the area, then increase in number, particularly during the transition to the Classic period. Similarly, the Late Coalition images of detailed humans in the far south are predated by related Classic period depictions.

Geographic Factors Related to LANL Rock Art

Two specific issues relating to geographic variation are pertinent to the rock art of Los Alamos. First, the palimpsest effect in the Otowi-Tsankawi area is a potentially serious problem. Most sites were established in the Late Coalition period, with major occupation in the Classic period, and the whole area was intensively used prehistorically. Individual rock art sites or panels may have imagery with a wide range of dates, and differences in patination or style may not be great enough to distinguish Late Coalition period rock art from that of the Classic period. At best, much of the rock art within the Otowi-Tsankawi area may have to be designated as transitional in nature, rather than definitively assigned to a specific time period. This is particularly true of the small clusters of panels common on isolated cliffs not directly associated with habitation sites (discussed above relative to the context of Coalition images).

Second, there are considerable differences between rock art on tuff and that on basalt. Some of these differences are simply due to the nature of the material; it is impossible to create the same kind of fine detail on the soft, coarse tuff as on basalt. In general, petroglyphs on tuff are larger in scale and/or include less detail. Petroglyphs on basalt may have greater detail and are less likely to be solidly pecked, given the amount of labor required to work the surface of the hard basalt. As a result, the stylistic dating outlined above is not always sufficient to date rock art sites exclusively on basalt.

LA 49948, a petroglyph site located in Water Canyon, is a prime example of this problem. The site consists of small petroglyph panels scattered along talus slope boulders and low, broken cliffs of basalt on the north side of Water Canyon. With the exception of two small concentrations on the upper cliff, the panels are isolated spatially and do not seem to have been placed relative to each other or to any discernible feature of the landscape. The petroglyphs themselves include concentric circles, lobed figures and curvilinear meanders, small Xs, a lizard-like figure, and a few simple humans. The rock art at LA 49948 is closely related to that at LA 49944, LA 49945, LA 49946, and LA 49947, which are single panel rock art sites located just upstream on basalt boulders and cliffs. These elements strongly resemble Abstract Style rock art traditions (P. Schaafsma 1992), but the lack of heavy patination at the site argues against a date that old. Some elements have also been modified with historic scratching.

Rock art from White Rock Canyon, as recorded by Lilienthal and Hoard (1995), and from the Cochiti Dam area, as recorded by Schaafsma (1975), includes many similar elements that are cryptic in date, along with large, detailed images that are stylistically similar to historic Pueblo drawings. Petroglyphs on basalt should therefore be dated with great caution, relying heavily on patination and superpositioning (when available).

RECORDING AND MANAGEMENT ISSUES

Recommended Recording Procedures

In addition to standard archaeological recording procedures, there are several recommended procedures for recording rock art sites. A separate rock art sheet is desirable to ensure that the necessary information is collected without adding much time to the overall site recording process.

First priority, for quick recording:

• A photograph, with scale and date, of each panel. They provide a record of the exact condition of rock art at a given point in time, which is useful for monitoring changes in condition.

• A listing of all elements present. The terms used to describe the elements should be standardized in a field manual, with verbal descriptions as well as example illustrations. It is important that these categories are as explicit as possible, as one person's idea of a corn plant may be someone else's dance wand or prayer stick. If the elements categories are organized as a brief check list, the recorders can simply check to indicate which elements are present at a site.

• An estimate of the number of elements present. Again, this could be done with check boxes listing ranges of numbers (<10, 10 to 25, 26 to 50, 51 to 100, >100). This number is useful for determining how extensive the rock art is at a given site, should more detailed recording be desired at a later date.

• An indication of the techniques present at the site (pecking, incising, grinding, painting, combinations).

• An indication of the possible date of the imagery, the basis for the judgment, and/or the potential for dating. This would include check boxes for superpositioning, patination (including sooting or plaster in cavates), subject matter, stylistic variation, and comparison with other media. A comments field would help provide further details.

• A list of potential threats and/or management issues, including check boxes for erosion, plant growth, vandalism, heavy visitation, and other threats.

Second priority, for more detailed recording:

• All elements should also be drawn whenever possible, as field observations often show details that cannot be seen in photographs. Drawings should attempt to represent what can be seen as objectively as possible, without embellishment. If it is desirable to extrapolate from what can readily be seen (as is often useful for making sense of eroded pictographs), the reconstructed image should be clearly labeled as such.

• Each element should be given an identifying number or letter.

• Dating information should be recorded in detail for each image.

Superpositioning relationships should be stated clearly, in a form such as "X lies under (is older than) Y." If the relationship cannot be determined, that should be stated explicitly. Relative patination should be noted using standardized terms (such as complete, heavy, medium, light).

Dating petroglyphs within cavates is particularly important; the rock art within cavates in the central Pajarito Plateau appears to be a mixture of imagery contemporaneous with occupation and images post-dating occupation. When dealing with interior rock art it is important to remember that the rock art may be contemporaneous with the primary occupation of the site, or it may be more recent. Rock art on different panels within a site, or different elements within a single cavate may not be contemporaneous. Previous projects have typically failed to record information necessary to distinguish between the two. This can be addressed by explicitly recording information that may help in dating; specifically, photograph and document in writing:

• any indication of sooting, including an estimate of percent sooted, from 0 to 100 percent blackened,
• any superpositioning of plaster layers over images or parts of images,
• any differences in the color of the tuff itself. Color differences can be very subtle, and may differ depending on lighting. Recording the color of pecked areas and the background color of the tuff with a Munsell color chart may help identify color differences that could distinguish between fresh, modern images and earlier petroglyphs.

Erosion and Other Natural Damage

The volcanic tuff of the Pajarito Plateau, which is the substrate for the majority of the rock art, is generally soft and highly susceptible to weathering and erosion. However, tuff forms a hard weathering rind through time, and it appears that erosion from wind and water is not a major problem for most Pajarito rock art (Vierra et al. 2000). Likewise, growth of lichens and other plants also does not seem to pose a significant threat to most Pajarito rock art. Peeling plaster within cavates is a more serious threat, particularly to fine-line scratched historic images and inscriptions. Forrest's Master’s thesis in historic preservation (2001) may provide information useful for assessing the threat of plaster loss. Photographs are a useful means of monitoring changes in the condition of elements through time.

Vandalism

The major threat to Pajarito rock art is from human action. Field observation suggests that vandalism has not been a great problem in recent years. In some cases, this is due to the inaccessibility of sites; there is a sharp decrease in dated graffiti at a former party site on Kwage Mesa (LA 35003) following the construction of the sewage treatment plant directly below it. The cages on significant cavates in Mortandad and Sandia canyons, though visually disruptive, are highly effective in preventing vandalism. Less drastic measures, such as the warning signs posted at the entrance to the trail to the Mortandad site, also appear effective. The greatest potential threat is probably from unintentional damage. Visitors love to view rock art; most will touch the images. This should be discouraged as much as possible, especially for rock art on tuff. Rubbings, castings, moldings, and the addition of chalk or any other substance should never be permitted.

CHAPTER 83
FUEL LOADS AND WILDFIRE EFFECTS ON ARCHAEOLOGICAL SITES AT LOS ALAMOS NATIONAL LABORATORY

Bradley J. Vierra and Randy G. Balice

INTRODUCTION

Los Alamos National Laboratory (LANL) is located on the Pajarito Plateau in north-central New Mexico. Archeological surveys have recorded over 1000 archeological sites at LANL. The majority of these sites are located in the lower elevations and in areas dominated by piñon-juniper vegetation. The question is, what types of archaeological sites are at greatest risk to wildfires? Since most of the heavy forest fuel loads at LANL are at higher elevations, there is an inverse relationship between site density and fuel loads. Wildfires therefore pose the greatest risk to archaeological sites situated at higher elevations (e.g., temporary campsites and fieldhouses). However, several factors can affect wildfire behavior, with the potential of severe damage occurring to any archeological site. This chapter will present our research on the relationship between archaeological site distribution and fuel loads at LANL. A comparison will then be made between these data and the information collected on archaeological sites within the Cerro Grande fire burn area, including the Rendija Tract.

DISTRIBUTION OF ARCHAEOLOGICAL SITES

LANL occupies the central section of the Pajarito Plateau. The plateau covers an area roughly extending from Santa Clara Canyon on the north, to the mesas above Cochiti Pueblo on the south, to the caldera on the west, and to the mesas overlooking the Rio Grande Valley to the east. LANL covers approximately 29,000 acres of land on this high mesa, ranging from about 1829 to 2438 m (6000 to 8000 ft) in elevation and covered with stands of piñon-juniper and ponderosa pine. The mesa has been incised with several deep canyons that drain from the mountain country down to the river valley. Balice (1998) has defined six basic vegetation and land cover types for LANL: unvegetated, grassland, juniper savanna, piñon-juniper, ponderosa pine and mixed conifer. Figure 83.1 illustrates the distribution of these vegetation types across LANL. Most of LANL is covered with piñon-juniper woodlands at the lower elevations and ponderosa pine at the higher elevations.

As of 2001, approximately 15,700 acres, or about 50 percent of LANL, had been intensively surveyed, with a total of 1025 archeological sites recorded. This reflects an average density of 1 site per 15 acres. The archaeological record of the plateau is rich and diverse, representing over 8000 years of human occupation. The recorded sites span a period from Archaic times to the Cold War era. However, the majority of these sites date to the Coalition period, ca. AD 1200–1325, with a large number of undetermined prehistoric sites (e.g., artifact scatters, fieldhouses, cavates, or rock art sites).

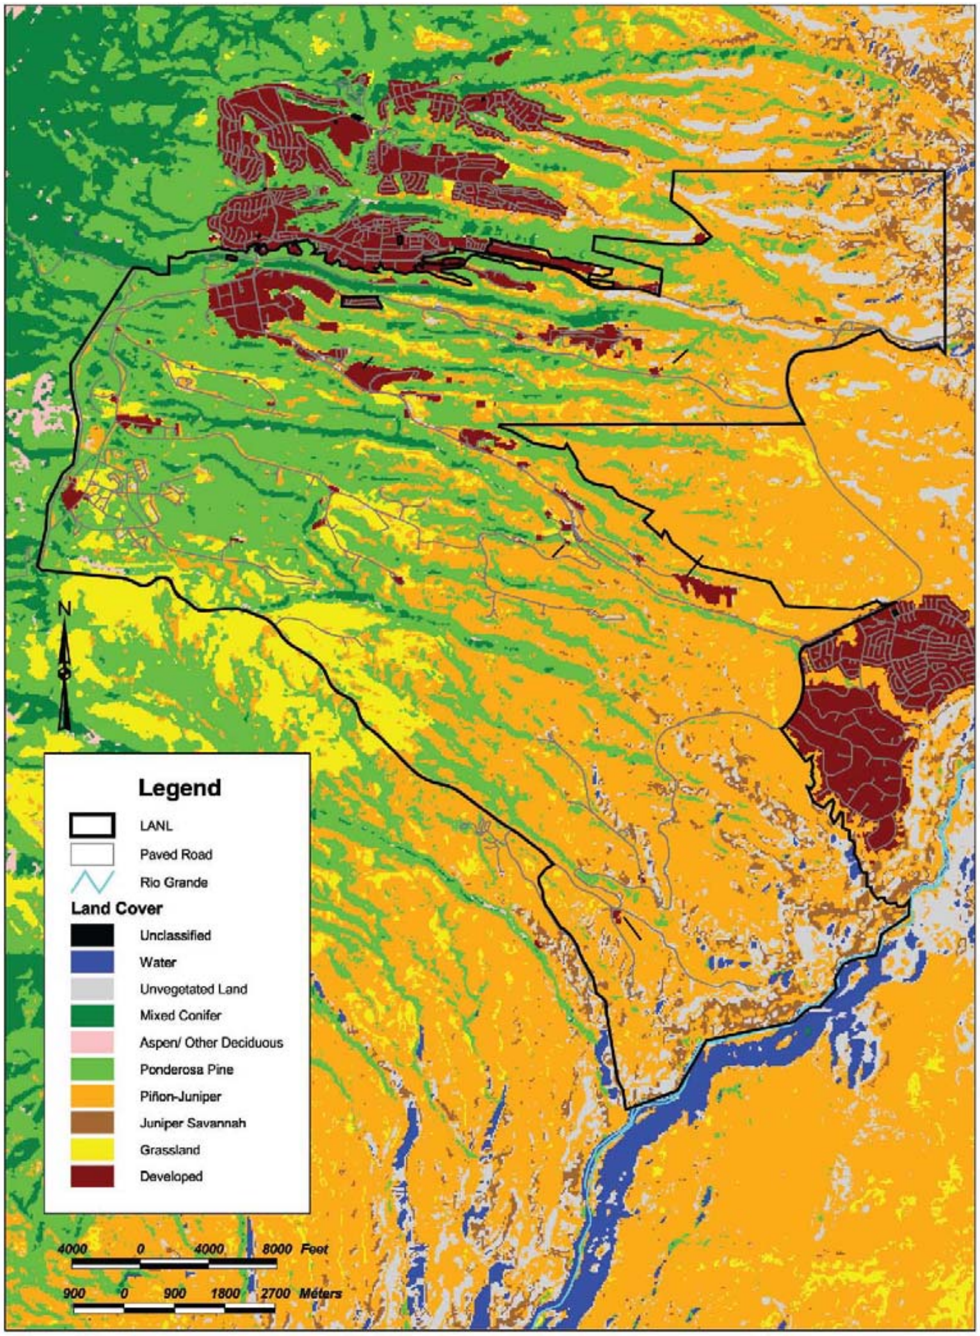

Figure 83.1. Vegetation types at Los Alamos National Laboratory.

Site distribution maps reveal obvious differences in the patterning of sites over time (see Vierra and Schmidt 2006). These differences presumably reflect important changes in past upland land-use strategies. For example, Archaic campsites are distributed across both piñon-juniper and ponderosa pine zones**.** Undetermined lithic scatter sites exhibit a similar distribution and presumably reflect Archaic campsites lacking diagnostic artifacts**.** However, these patterns stand in mark contrast to the distribution of Ceramic period habitation sites. Coalition period habitation sites are confined to the piñon-juniper zone**,** as are Classic period sites**.** Most of the

Coalition period fieldhouses are also located in the piñon-juniper zone, with a few situated at higher elevations in the ponderosa pine. This contrasts with the Classic period fieldhouses, which show a marked increase in the use of the ponderosa pine zone, most notably the area of Rendija Canyon.

Piñon-juniper and ponderosa pine cover the majority of the area surveyed. Table 83.1 presents the information on site density by vegetation type. Site densities range from a high of one site per 10 acres in the piñon-juniper woodlands, to a low of one site per 585 acres in mixed conifer forest. If we assume a 1000-acre survey was conducted in the piñon-juniper, ponderosa pine, and mixed conifer, we would see an inverse relationship between site density and elevation, with an expected 100 sites recorded in the piñon-juniper, 38 sites in the ponderosa pine, and only two sites in the mixed conifer. The latter may be an underestimation based on the small sample size.

Table 83.1. Density of archaeological sites by vegetation type.

Vegetation Type	Total Sites	Total Acres	Site per Acre
Unvegetated	88	2049	1:23
Grassland	14	1277	1:91
Juniper Savanna	2	442	1:221
Piñon-Juniper	556	6041	1:10
Ponderosa Pine	203	5373	1:26
Mixed Conifer	1	585	1:585

A chi-square analysis of archaeological sites by vegetation type for piñon-juniper and ponderosa pine (Table 83.2) indicates some significant differences (*chi-sq* = 10.9, *df* = 4, *p* = 0.27). Adjusted residuals were therefore calculated to determine which of the cells were contributing to the significant chi-square value. The results confirm the patterns observed in the distribution maps; there is no significant difference in the distribution of Archaic sites, lithic scatters, or Coalition period fieldhouses between the two vegetation types. However, there are significantly more Coalition period habitation sites in the piñon-juniper and Classic period fieldhouses in the ponderosa pine. Classic period habitation sites were excluded from the analysis because only four of these were represented.

Table 83.2. Archaeological site by vegetation type. Top number is the frequency and bottom number is adjusted residual. Adjusted residuals in bold are significant at the 0.05 level.

Site	Piñon-Juniper	Ponderosa Pine	Total
Archaic	36 -0.5	9 0.5	45
Lithic Scatter	7 -1.1	3 1.1	10
Coalition Habitation	102 **2.5**	12 -2.5	114
Coalition Fieldhouse	54 0.1	11 -0.1	65

Site	Piñon-Juniper	Ponderosa Pine	Total
Classic Fieldhouse	25 -2.6	12 **2.6**	37

Chi-square = 10.9, *df* = 4, *p* = 0.027

In summary, there is an inverse relationship between site density and elevation, with most sites being located in the piñon-juniper woodland. Overall, there are relatively more Archaic campsites with some Classic period fieldhouses situated in the ponderosa pine forest, versus more Coalition period habitation sites in the piñon-juniper woodland.

FUEL LOADING AT LOS ALAMOS NATIONAL LABORATORY

Information on fuel inventories conducted in 1997 has been adopted from Balice et al. (1999), as supported by additional data collected in 1998 and 1999 (Balice et al. 2000). The results of these analyses are presented in Table 83.3. The table presents information on fuels inventory summaries and the results of their multivariate analyses. Data are organized by the independent variables: vegetation type (Veg) and by topographic characteristic (Topo). The vegetation types are as follows: PJ = piñon-juniper woodland, Pipo = ponderosa pine forest, and MC = mixed conifer forest. The dependent variables in the top row include 1-hr fuels (0 to ¼"), 10-hr fuels (¼ to 1"), 100-hr fuels (1 to 3"), 1000-hr-sound fuels (>3"), 1000-hr-rotten fuels, duff (decomposed litter), litter (surface pine needles), herbaceous vegetation like shrubs and grasses (Veg), trees per acre that are less than 8" DBH (T/A<8), and trees per acre that are greater than or equal to 8" DBH (T/A≥8). The values for the down woody fuels and ground fuels are in tons per acre. Values in bold type are significantly different from other values in the same column ($p \leq 0.05$). As can be seen, the mixed conifer vegetation type consistently exhibits the highest fuel loads in both canyon and mountain settings. On the other hand, the ponderosa pine also exhibits significantly more 10 hr fuels (i.e., ¼ to 1" size) in both canyon and mesa settings, and a greater number of the larger trees per acre on mesa tops. These smaller fuels can act as ladder fuels to start crown fires in the higher-elevation forests. In contrast, the piñon-juniper woodlands contain significantly more fuel as ground shrubs, grasses, and forbs in both canyon and mesa settings. These fuels are less likely to create severe wildfires.

Table 83.3. Fuels inventory summaries and results of multivariate analyses. Significant values are in bold.

Veg-Topo Class	1 hr	10 hr	100 hr	1K hr S	1K hr R	Duff	Litter	Veg	T/A <8	T/A≥8
PJ-Canyon	0.3	1.2	0.7	0.5	2.9	3.4	0.8	**0.03**	46.4	25.9
PJ-Mesa	0.3	1.6	0.9	1.6	2.9	3.6	1.7	**0.03**	68.7	33.1
Pipo-Canyon	0.2	**1.9**	0.7	0.4	4.4	9.7	0.6	0.01	34.0	42.3
Pipo-Mesa	0.2	**2.3**	0.9	1.3	6.7	8.5	0.9	0.01	52.5	**91.0**
MC-Canyon	**0.9**	**3.1**	**2.5**	1.2	**14.2**	**12.5**	1.4	0.01	**227.9**	**78.7**
MC-Mountain	**0.6**	**2.0**	**3.4**	**3.2**	**28.6**	9.1	0.7	0.01	**222.1**	**121.8**

In summary, there are increasing fuel loads with elevation. We would therefore expect increasing levels of burn severity in these forests. As a consequence of this burn severity, steeper slopes and greater rainfall, we would also expect an increase in the potential for soil erosion at these higher elevations.

THE EFFECTS OF THE CERRO GRANDE FIRE ON ARCHAEOLOGICAL SITES AT LOS ALAMOS NATIONAL LABORATORY

Although the Cerro Grande fire burned a total of approximately 40,000 acres, only about 8000 acres were burned within LANL. This occurred under extreme weather conditions with excessively high winds. As previously discussed by Nisengard et al. (2002), a post-fire assessment was made on all the archaeological sites within the LANL burn area. A total of 384 sites were revisited during the field assessments. Of these, 369 were assessed for burn severity. Burn severity was defined as follows:

1. Low: duff partially consumed, none to little ladder fuels burned, no canopy burned.
2. Moderate: duff consumed, ladder fuel burned, isolated crown burn or torching.
3. High: duff, ladder, and crown completely burned.

Table 83.4 presents the information on burn severity by vegetation type for field-assessed archaeological sites. Overall, about 60 percent of the burned area at LANL is comprised of ponderosa pine. However, about 88 percent of the LANL area that burned did so with low severity, 11 percent with moderate severity, and about 1 percent with high severity. An additional 455 acres were burned in Rendija Canyon on Department of Energy lands. This area is situated within a ponderosa pine setting, with 355 acres of low-burn severity and 110 acres of high-burn severity. Archaeological data from this area are also included in our analysis.

Table 83.4. Burn severity by vegetation type for field-assessed archaeological sites within the Cerro Grande fire burn area at LANL.

Vegetation Type	Total Acres	*Total Archaeological Sites by Burn Severity*		
		Low	Moderate	High
Unvegetated	293	2	0	1
Grassland	814	80	18	2
Juniper Savanna	15	0	0	0
Piñon-Juniper	1394	85	8	11
Ponderosa Pine	4941	61	54	38
Mixed Conifer	624	3	2	2
Total	8081	231	82	54

Based on our previous discussion, we would expect significantly more severely burned sites in the ponderosa pine forest, and that relatively more temporary campsites and fieldhouses would be more severely burned.

So, are there significantly more severely burned sites located in the ponderosa pine forest versus the piñon-juniper woodland? The answer to this question is yes. An analysis of a contingency table of burn severity by vegetation type for field assessed archaeological sites indicates a significant difference in the distribution of sites across piñon-juniper and ponderosa pine zones (Table 83.5) (*chi-sq* = 4.25, *df* = 2, *p*≤001). A review of the adjusted residuals indicates that there are significantly more low severity sites in the piñon-juniper woodlands, and relatively more moderate- and high-severity burned sites in the ponderosa pine forest.

Table 83.5. Burn severity by vegetation type for field-assessed archaeological sites within the Cerro Grande fire burn area at LANL. Top number is the frequency and bottom number is the adjusted residual. Adjusted residuals in bold are significant at the 0.05 level.

Vegetation Type	***Total Archaeological Sites by Burn Severity***		
	Low	**Moderate**	**High**
Piñon-Juniper	85 **6.6**	8 -5.1	11 -2.9
Ponderosa Pine	61 -6.6	54 **5.1**	38 **2.9**
Total	146	62	49

Chi-square = 4.25, df = 2, p≤001

Second, are there significantly more severely burned temporary campsites and fieldhouses in the ponderosa pine versus the piñon-juniper? Table 83.6 presents the information on archaeological site type by burn severity. However, the sample sizes are too small to run a chi-square analysis. Nonetheless, 11 of the 15 (73%) severely burned sites are located in the ponderosa pine, with only four situated in the piñon-juniper. The sites in the ponderosa pine consist of temporary campsites and fieldhouses. Most of the moderately burned sites are also located in the ponderosa pine. That is, 13 of the 19 (68%) sites are situated in the ponderosa pine, with two in the piñon-juniper and four in grassland settings. Given the weather conditions associated with the Cerro Grande fire, patches of moderate- and high-severity burn areas are also present within the piñon-juniper woodlands.

Table 83.6. Archaeological site by field-assessed burn severity.

Site	***Burn Severity***		
	Low	**Moderate**	**High**
Archaic	14	4	3
Lithic Scatter	7	3	0
Coalition Habitation	43	7	1
Coalition Fieldhouse	21	3	2
Classic Fieldhouse	25	1	9

CONCLUSIONS

At the beginning of this chapter, we asked the question "what types of archaeological sites are at greatest risk to wildfires" at LANL. Our archaeological site distribution and fuel inventory studies indicate that those sites situated at higher elevations were potentially at greater risk for burn severity (Table 83.7). This mostly includes Archaic campsites and Ceramic period fieldhouses in the ponderosa pine forest. The evidence from the Cerro Grande Fire provides empirical support for these propositions.

Table 83.7. Burn severity by topographic setting for field-assessed archaeological sites within the Cerro Grande burn area at LANL. Top number is the frequency and bottom number is the adjusted residual. Adjusted residuals in bold are significant at the 0.05 level.

Topographic Setting	***Total Archaeological Sites by Burn Severity***		
	Low	**Moderate**	**High**
Canyon	43 -1.9	15 -0.7	21 **3.5**
Mesa	195 1.9	67 0.7	33 -3.5

Chi-square = 11.95, *df* = 2, *p* = 0.003

CHAPTER 84
THE LAND CONVEYANCE AND TRANSFER PROJECT ARCHAEOLOGICAL SITE RESTORATION PROGRAM

Samuel Loftin

INTRODUCTION

Several archaeological sites were excavated in association with the Land Conveyance and Transfer (C&T) Project. The process of excavating a site removes much of the vegetation and disturbs the soils. Although the sites are relatively small, there is a risk of accelerated soil erosion, site degradation, and impacts to surface water quality. Once the excavation activities have been completed, we have a responsibility to stabilize and restore the integrity of these sites. Because the budget and staff available for site restoration were limited, we decided to use relatively low-tech treatments that could be implemented quickly and easily. Information gained from successful treatments can be used to design future restoration projects.

Following excavation activities, the sites were back filled and graded. Sites were then broadcast seeded by hand with a native grass seed mixture developed for the C&T Project. The seed mix included native grass species such as blue grama (*Bouteloua gracilis*), little bluestem (*Schizachyrium scoparium*), and dropseed (*Sporobolus cryptandrus*). Broadcast seeding alone can result in very low rates of seedling establishment due to inadequate conditions for germination, coupled with high seed predation by birds and insects. This is particularly true for arid and semiarid areas. Northern New Mexico has been experiencing drought conditions for the past eight to ten years. Annual precipitation has been alternating between average to above average one year to below average the next. These conditions can severely reduce the success of seed germination and establishment but are not uncommon for this region. For these reasons, it is beneficial to combine the seeding with some form of mulching treatment. The White Rock and Airport sites were seeded and mulched with straw. The Rendija Canyon sites were seeded and partially covered with piñon and juniper slash mulch to protect the seedbed and to improve establishment.

WHITE ROCK TRACT

The White Rock Tract is partially situated at the eastern tip of Mesita del Buey and within the Cañada del Buey floodplain (Figure 84.1). The area is covered by a piñon-juniper woodland at an elevation ranging from 2133 to 2186 m (6400 to 6560 ft).

LA 12587

The White Rock Tract rehab activities at this site were conducted in the winter of 2003. Seed and straw mulch was surface broadcast by hand. No slash mulch was used at this site. At the time the original photographs were taken, most of the straw mulch had blown off the site (Figure 84.2). By August 2007, the site was dominated by early successional species, primarily purple aster (*Machaeranthera bigelovii*), with scattered individuals of pale trumpet (*Ipomopsis longiflora*), snakeweed (*Gutierrezia sarothrae*), and Russian thistle (*Salsola kali*). Some seeded grasses are present but at low abundance. Although vegetation cover is relatively low (around 15%), there is no visible evidence of soil erosion.

Figure 84.1. Overview of the White Rock Tract showing important landmarks.

Figure 84.2. LA 12587 with extensive bare soils (top) with much of the straw mulch blown off the site. Bottom photo shows establishment of early successional weedy plant species two years later.

AIRPORT TRACT

The Airport Tract is located near the eastern end of the mesa, which is situated between Pueblo and DP canyons (Figure 84.3). It ranges in elevation from 2153 to 2196 m (7060 to 7200 ft) and is primarily covered by a piñon-juniper woodland with areas of ponderosa pine.

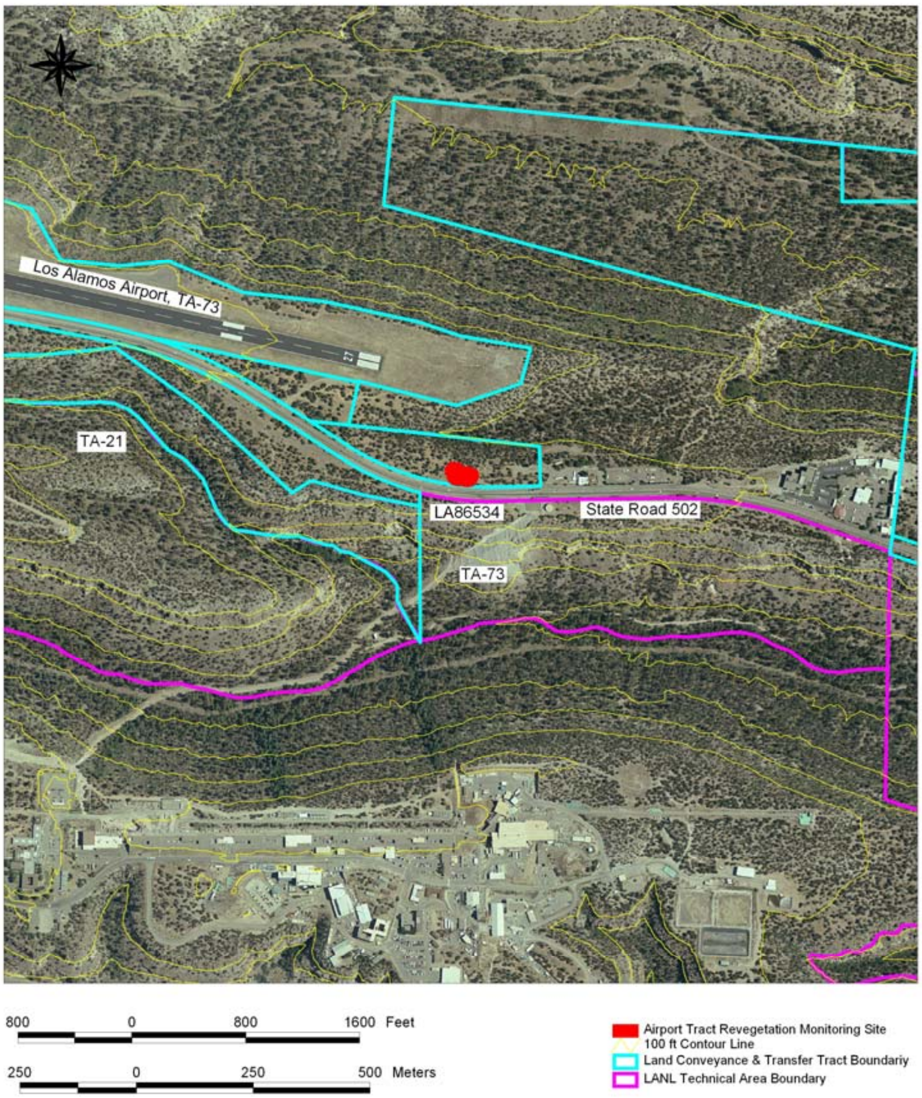

Figure 84.3. Overview of the Airport Tract showing important landmarks.

LA 86534

Archaeological activities at LA 86534 were completed in October 2002. The site was broadcast seeded by hand and then straw mulch was applied. No slash mulch was used at this site. The early photograph show that most of the straw mulch has blown off the site (Figures 84.4 and 84.5). The photos also show a nice stand of early successional plants, mostly lambsquarters (*Chenopodium album*). By August 2007 there had been a distinct change in vegetation. The site is dominated by grasses, mostly native perennials bottlebrush squirreltail (*Elymus elymoides*) and needle and thread grass (*Stipa comata*). There is also substantial cheatgrass (*Bromus techtorum*) cover, a non-native annual grass species. Other incidental plant species include blue aster and snakeweed. Average cover at the site is around 50 percent and there is no visible sign of soil erosion.

Figure 84.4. LA 86534 in the first growing season following seeding treatment; most of the understory plants are early successional weedy plant species.

Figure 84.5. LA 86534 in August of 2007 shows fewer weedy plants and more grasses. Note that the mature piñons have died and been removed from the site. A small piñon tree can be seen in foreground of both photos.

RENDIJA TRACT

The Rendija Tract contains portions of Rendija and Cabra canyons and ranges in elevation from 2293 to 4226 m (6880 to 7280 ft) (Figure 84.6). The lower canyon area is covered by a ponderosa pine forest, whereas, the mesa top areas are covered by a piñon-juniper woodland. The following sites were all located in these mesa top settings.

LA 85408

Rehab treatments on this site were conducted in summer 2005. The treatment included broadcast seeding by hand and then lightly covering with slash mulch that was scavenged from the trees that had been cut to clear the site. Figure 84.7 shows bare, loose, rocky soils with a light slash mulch, and how the same locale looked in August 2007 when grass cover averages around 50 percent. The vegetation is dominated by blue grama with some little bluestem. Another locale at the site (Figure 84.8) shows less vegetation cover (15% to 20%) but more surface rock to protect the soil from erosion. Neither locale at the site shows any visible evidence of soil erosion.

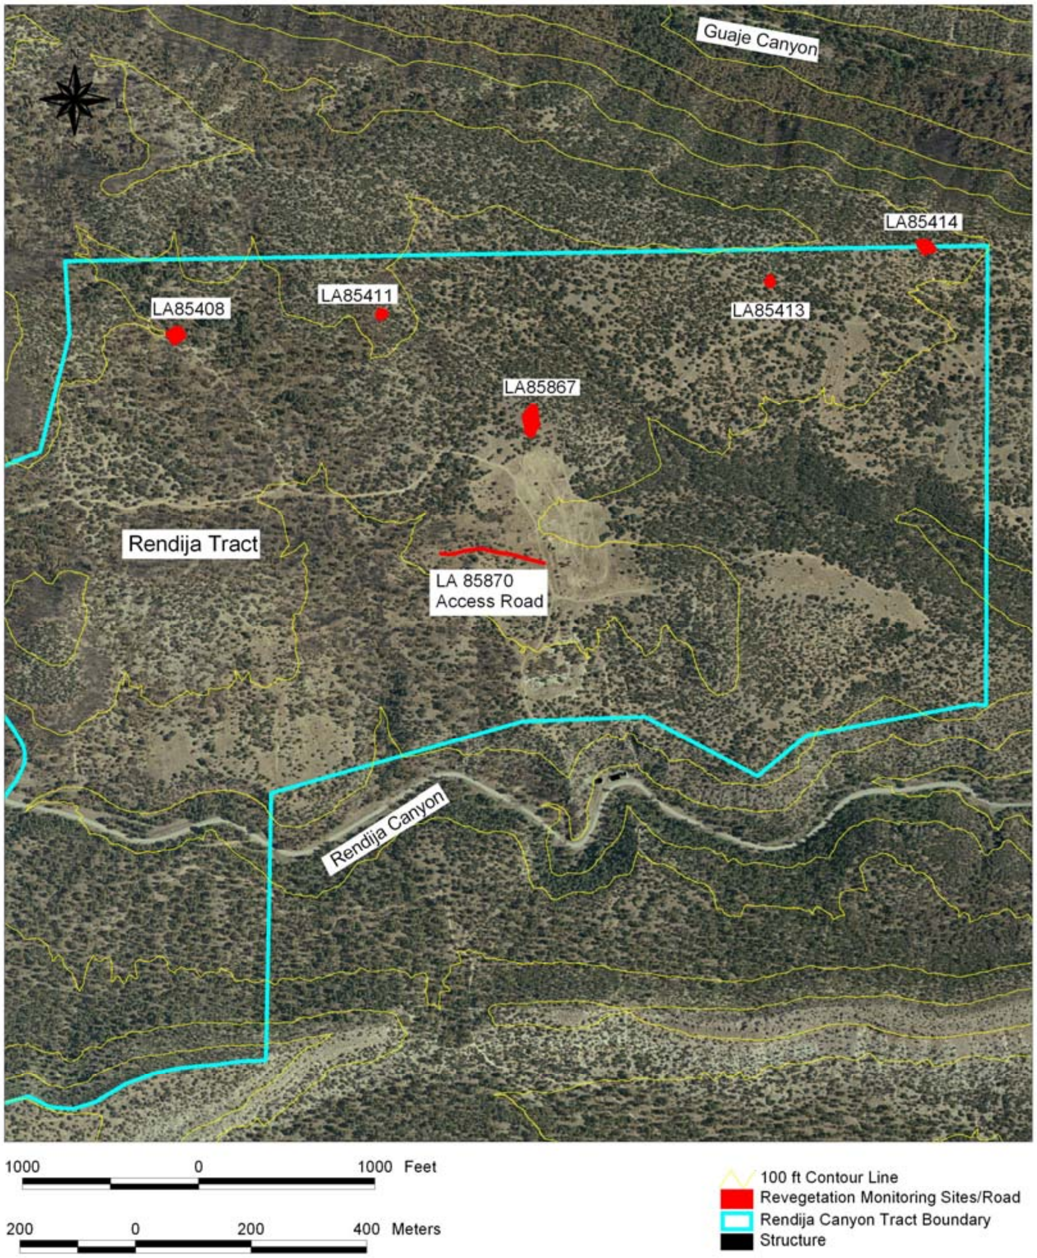

Figure 84.6. Overview of the Rendija Tract showing important landmarks.

Figure 84.7. Top photo shows one locale at LA 85408 shortly after seed and mulch were applied in the summer of 2005. The bottom photo shows the response after two years when the site is dominated by blue grama and soils are well stabilized.

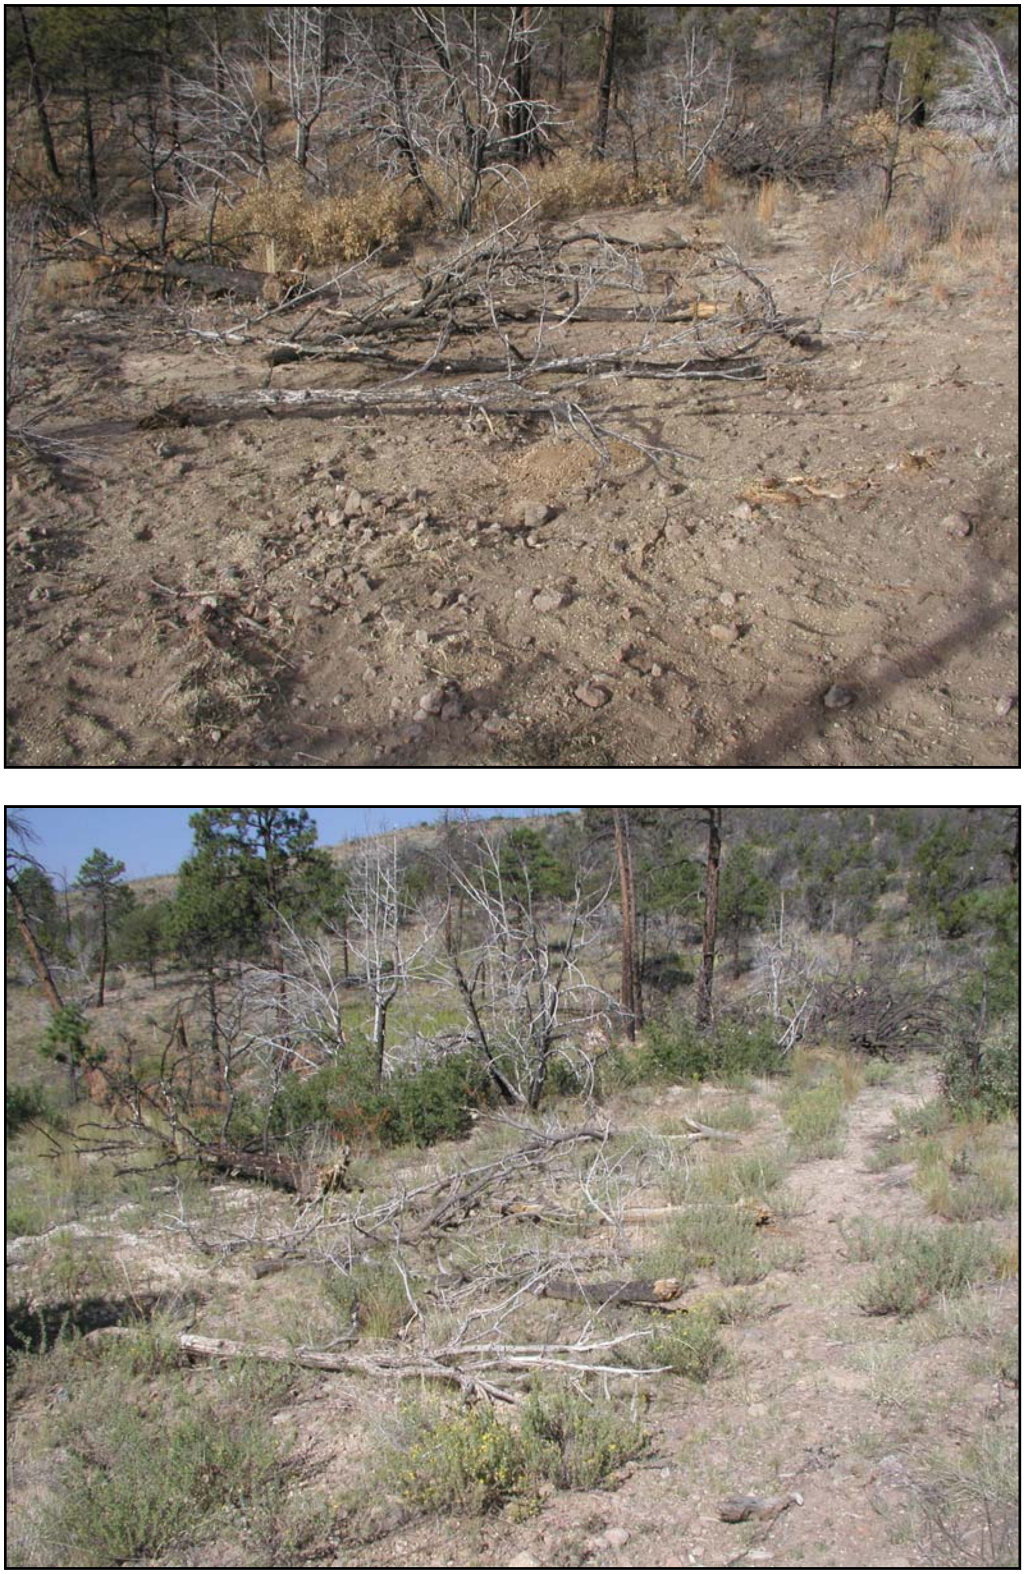

Figure 84.8. Adjacent to the locale shown in Figure 84.7, this locale has less establishment by seeded grass and better establishment from resident plants. Top is shown in summer of 2005 and bottom is summer of 2007.

LA 85411

Rehab treatments on this site were conducted in summer 2005. The treatment included broadcast seeding by hand and then lightly covering with slash mulch that was scavenged from the trees that had been cut to clear the site. The original photograph (top) shows loose bare soils with slash mulch (Figure 84.9). The later photo (bottom) shows substantial vegetation cover. There is good establishment of blue grama, particularly around the perimeter of the site. There appears to be some gopher activity in the center of the site, which is dominated by blue aster and other weedy species. There is a lot of dead plant litter on the site from past growing seasons and there are several resprouting oaks. There is no visible evidence of erosion on the site.

LA 85413

Rehab treatments on this site were conducted in summer 2005. The treatment included broadcast seeding by hand and then lightly covering with slash mulch that was scavenged from the trees that had been cut to clear the site. The original photograph shows loose bare soils with slash mulch. By August of 2007 there is a thick stand of blue grama on the site (see Figure 84.10), with few other plant species present. The blue grama cover averages 70 percent to 80 percent and is adequate to control soil erosion at the site.

LA 85867

Rehab treatments on this site were conducted in summer 2005. The treatment included broadcast seeding by hand and then lightly covering with slash mulch that was scavenged from the trees that had been cut to clear the site. The original photos show loose bare soils with slash mulch and some tracks left by the heavy equipment used to prep the site. The August 2007 photograph shows good vegetation cover on the site. Again, the blue grama has successfully established throughout the site, particularly under or around the slash (see Figure 84.11). The site appears stable with no visible evidence of erosion.

LA 85414

Rehab treatments on this site were conducted in summer 2005. The treatment included broadcast seeding by hand and then lightly covering with slash mulch that was scavenged from the trees that had been cut to clear the site. The original photograph shows loose bare soils with slash mulch (Figure 84.12). The August 2007 photo shows an excellent stand of blue grama (70 to 75% cover), substantially better than in surrounding undisturbed areas. Few other plant species are present on the site. Even with a slope of around 20 percent, there is no visible evidence of soil erosion at this site.

Figure 84.9. Top photo shows LA 85411 shortly after seed and mulch were applied in summer 2005. Bottom photo shows vegetation response after two years. This site still has a substantial weedy plant component along with some seeded blue grama. Judging by the amount of dead plant material on the site, there has been a substantial crop of weedy plants on the site over the past two years.

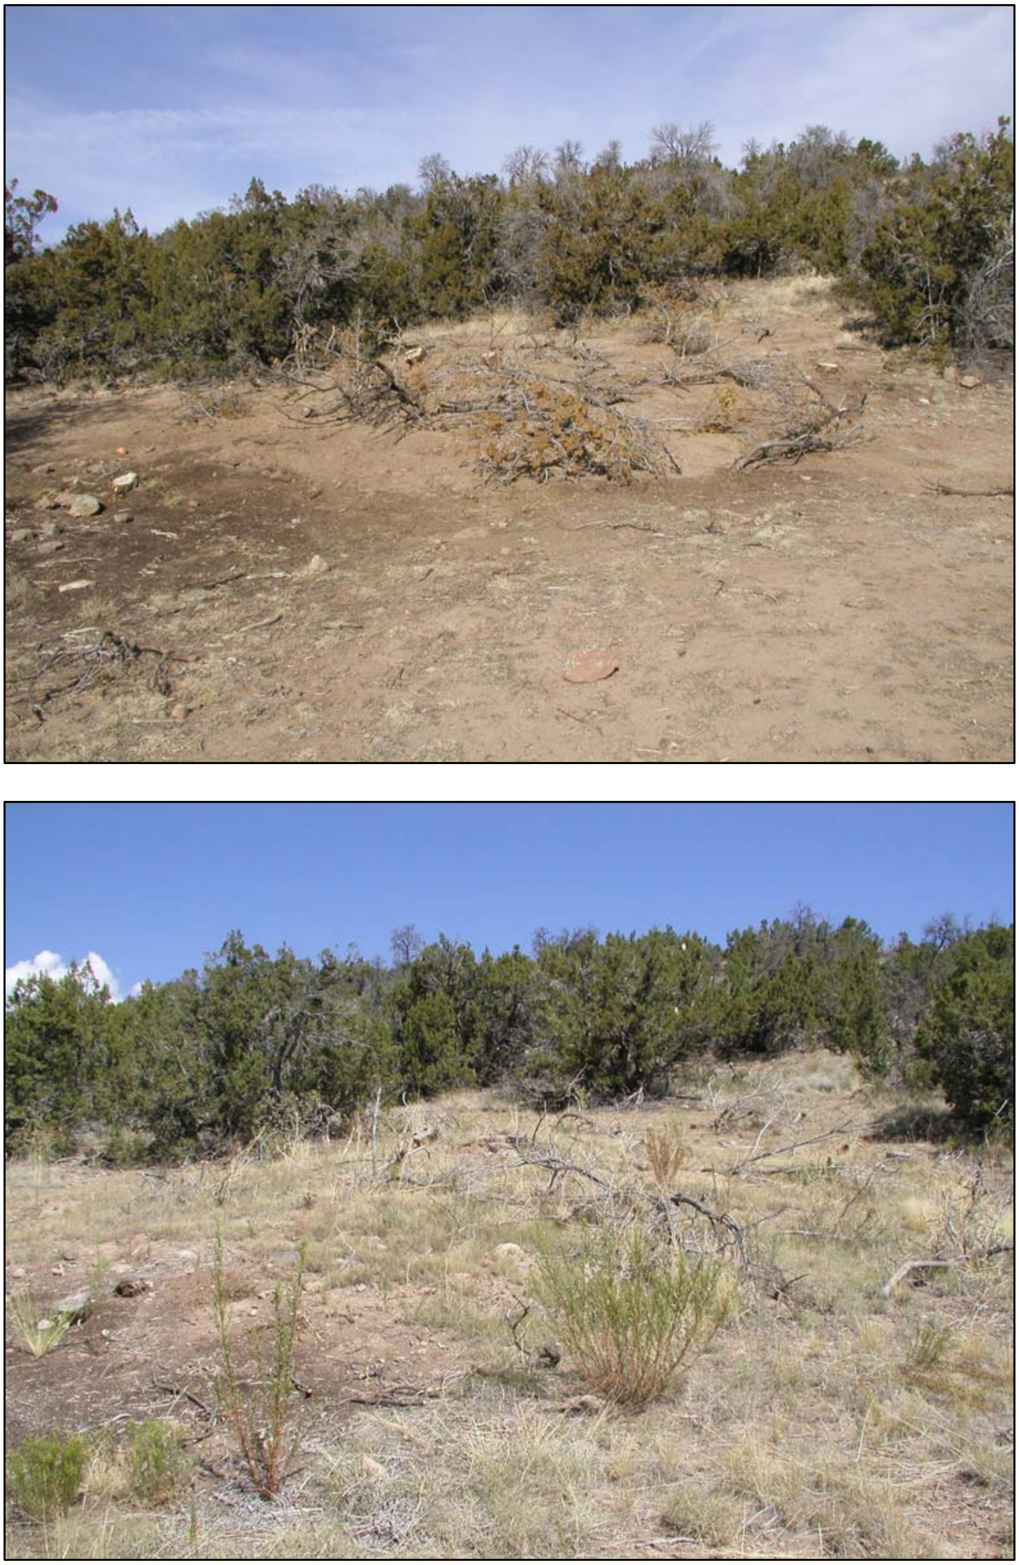

Figure 84.10. Top photo shows LA 85413 shortly after seed and mulch were applied in summer 2005. Bottom photo shows vegetation response after two years. Vegetation on this site is almost exclusively blue grama.

Figure 84.11. Top photo shows LA 85867 shortly after seed and mulch were applied in summer 2005. Bottom photo shows vegetation response after two years. Vegetation on this site is almost exclusively blue grama.

Figure 84.12. Top photo shows LA 85414 shortly after seed and mulch were applied in summer 2005. Bottom photo shows vegetation response after two years. Again, vegetation on this site is almost exclusively blue grama.

Road to LA 85417

This site is a road section that was constructed for access to LA 85417. Rehabilitation treatments were conducted in summer 2005. The treatment included broadcast seeding by hand with no mulch application. After two years, some vegetation (mostly blue grama) was re-established on site mostly in the tracks where water collects (Figure 84.13). The site has little slope and does not appear to be overly impacted by vehicular traffic. There is no visible evidence of erosion.

Figure 84.13. Top photo shows LA 85414 shortly after seed was applied in summer 2005. Bottom photo shows vegetation response after two years. Resident species have resprouted in the road median and there is some vegetation growing in the tracks.

CONCLUSIONS

Despite less than desirable precipitation during the project period, all the sites are stable with no evidence of soil erosion. The Airport and White Rock sites (LA 12587 and LA 86534) are dominated by weedy plants but this is a typical response for disturbed areas and native perennial plants should establish in time. The best seeded vegetation establishment was observed at the Rendija Canyon sites where we used a slash mulch to protect the seedbed (Figure 84.14). Interestingly, blue grama was the only grass from seed mix to successfully establish at these sites. For comparison, we photographed one of the Jicarilla tipi ring sites that received no rehabilitation treatments. The site is still bare with little vegetation cover (Figure 84.15).

Figure 84.14. Photo of juniper slash with blue grama established under and around the protective cover of the dead limbs. Slash improves microsite conditions for seed germination and establishment and provides some physical protection.

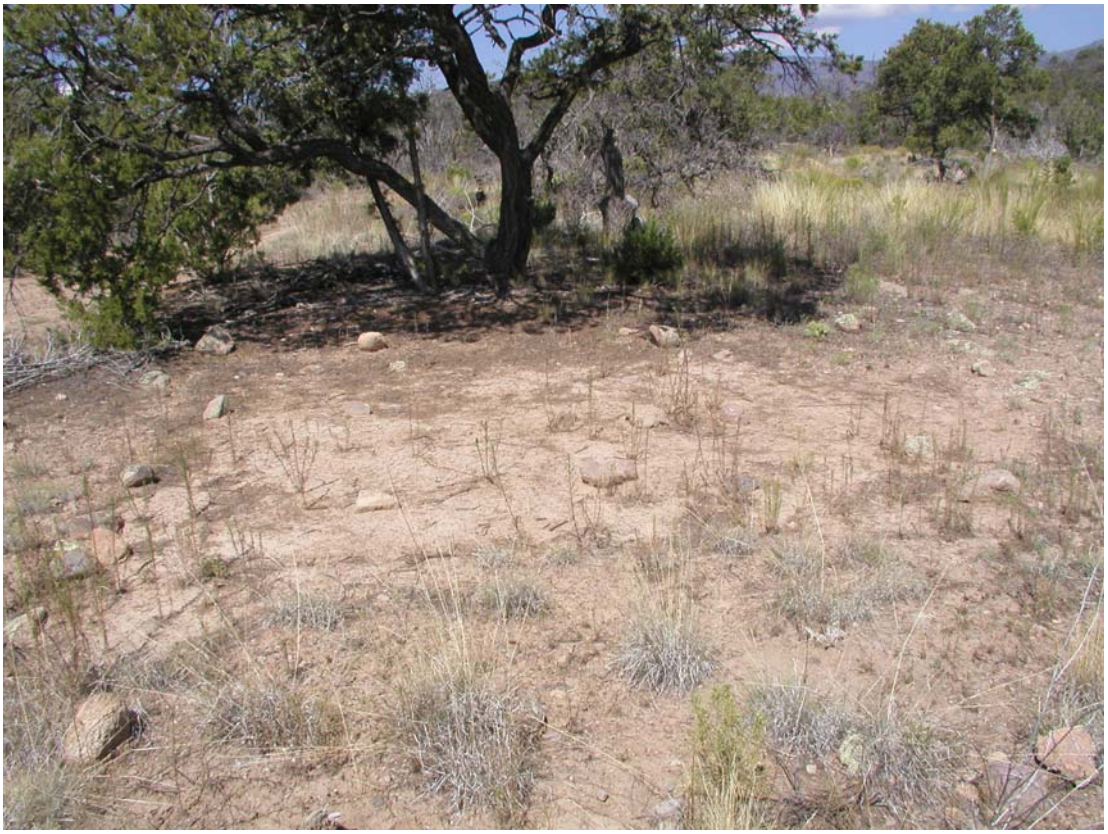

Figure 84.15. Photo of site with no rehab treatments. Although this site is relatively small, after two years the soils remain mostly bare with little vegetation reestablishment.

The results of this project suggest the importance of protective microsites for seed germination and seedling establishment. Broadcast seeding with a slash mulch performed better than other treatments. A surface straw mulch can be helpful, but if there is nothing holding it down it will often blow off the site. I would still recommend using a seed mix with several species. It may have been the case that the climatic factors following these treatments were optimal for blue grama grass. Other years may favor other grass species so it is best to hedge our bets when we can.

CHAPTER 85
PERSONAL PERSPECTIVES ON THE NATIVE AMERICAN GRAVES PROTECTION AND REPATRIATION ACT TRIBAL MONITOR PROGRAM OF THE PUEBLOS OF SAN ILDEFONSO AND SANTA CLARA

Timothy Martinez, Jeremy Yepa, Aaron Gonzales

Los Alamos National Laboratory (LANL) is situated on lands considered to be affiliated with San Ildefonso and Santa Clara Pueblos. A Tribal Monitor Program was set up for the Conveyance and Transfer (C&T) Project archaeological excavations as part of the initial 2002 Intentional Excavation Agreement in compliance with NAGPRA—the Native American Graves Protection and Repatriation Act (see Chapter 72, Volume 3).

San Ildefonso and Santa Clara Pueblos provided tribal monitors who were responsible for observing the excavations, identifying any sacred objects, and supervising the treatment of human remains. During the first two field seasons, Aaron Gonzales and Timothy Martinez served as monitors for the Pueblo of San Ildefonso. Beginning in 2004, they were joined by a monitor from the Pueblo of Santa Clara for all work conducted in Rendija Canyon. Michael Chavarria, Sr., served as the Pueblo of Santa Clara monitor in Rendija Canyon for the 2004 field season. He was replaced in 2005 first by Paul Baca and then by Jeremy Yepa. This chapter presents the views of Martinez, Yepa, and Gonzales (Figure 85.1).

Figure 85.1. Tribal Monitors Aaron Gonzales, Jeremy Yepa, and Timothy Martinez.

STATEMENT OF TIMOTHY MARTINEZ – PUEBLO OF SAN ILDEFONSO

***Powhoge Oweenge* "Where the water cuts through"**

The Pajarito Plateau is the traditional setting of the Pueblo of San Ildefonso. These lands continue to be acknowledged in the songs and prayers of our Tewa people.

I was hired by Los Alamos National Laboratory as the Pueblo of San Ildefonso Tribal Monitor from 2002 through 2006 for the Intentional Archeological Excavation, pursuant to lands managed by the Los Alamos National Laboratory in the Northern New Mexico for the U.S. Department of Energy, in order to create a framework for effective compliance with the Conveyance and Transfer of Lands from Federal Ownership under P.L. 105.119, as well as the Native American Graves Protection and Repatriation Act (NAGPRA), enacted in 1990.

The Excavation and Repatriation Process

As a tribal monitor, I observed the conduct of the excavations as well as treatment of any human remains, funerary objects, unassociated funerary objects, sacred objects, and objects of cultural patrimony that were encountered during the excavations (Figure 85.2).

Figure 85.2. Tim Martinez observing artifact collecting at LA 86534.

Training

Training for the job of monitor included taking the annual CPR, First Aid, Defensive Driving, Substance Abuse Awareness, Computer Security, Annual Security Refresher, and Ordinance Training courses, as well as reading the Environmental Management Awareness System (EMS), Archaeology Excavation, and Lab Safety training manuals.

Excavation

Project work included excavations from four major periods: (1) Archaic, 6000 BC to AD 500; (2) Coalition, AD 1100 to 1325; (3) Classic, AD 1325 to 1600; and (4) Homestead, 1890 to 1943. Excavated site types included lithic scatters, artifact scatters, fieldhouses, roomblocks, garden plots, water control features, tipi/wickiup rings, a homestead, a corral, and a wagon road. Over 40 sites were excavated in three separate C&T parcels: the Airport Tract, the White Rock Tract, and the Rendija Tract.

Laboratory and Field Work

Laboratory and field work activities consisted of flotation, mapping, monitoring access gates, counting, cleaning, washing and re-bagging artifacts, organizing the lab, printing labels, labeling boxes, organizing equipment, and conducting inventory (Figures 85.3 and 85.4).

Figure 85.3. Timothy Martinez screening at one of the sites in the White Rock tract.

Figure 85.4. Bettina Kuru'es and Tim Martinez processing flotation samples.

Meetings

A wide variety of meetings touched upon the C&T archaeological excavations. These included monthly group meetings, weekly team meetings, Resource Council meetings, Tribal Consultation, LANL NAGPRA meetings, and the Trails Working Group meetings.

Repatriation

In December of 2005, I oversaw repatriation and interment of 34 remains from the Maxwell Museum in Albuquerque, one ceremonial object from the Laboratory of Anthropology, three remains from the White Rock site, and one inadvertent discovery from TA-72.

Recommendations

Consultation is the key requirement of any Intentional Archeological Excavation. Museum and Federal agencies must consult with Indian Tribes prior to making decisions. Consultation is a process involving open discussion and joint deliberation with respect to potential issues, changes, or actions. Consultations regarding activities that affect tribal trust resources or property must be carried out on a government-to-government basis.

Unclaimed Native American human remains and objects shall be disposed of in accordance with regulations. Native American groups and representatives of museums should be consulted. Initiate consultation on the inadvertent discovery if human remains must be excavated or removed. Enter into agreement with the consent of culturally affiliated tribe or organization as to the disposition of, or control of, specific items.

Consultation must seek to identify traditional religious leaders who would also be consulted to identify where applicable lineal descendents and Indian Tribes (Pueblo) affiliated with the human remains, funerary objects, sacred objects, or objects of cultural patrimony.

Conclusion

Archaeology is not only about digging up the past, it's about history and education. It's about learning how our ancestors lived, what plants they grew, what they ate, how they built their home. It's also about working with a group of people of various backgrounds, and personalities, and working as a team. The excavations of all the sites were done with the utmost respect by the field crew through communication, protocol, enforcement, and compliance (Figure 85.5).

Figure 85.5. Completion of excavations at LA 127635.

STATEMENT OF JEREMY YEPA – PUEBLO OF SANTA CLARA

My name is Jeremy Yepa. I worked as the tribal monitor for the Pueblo of Santa Clara from 2005 to the end of the C&T Project. Since coming to work with the Cultural Resources Team, I observed and participated in many of the excavations of sites in Cabra and Rendija canyons located north of Barranca Mesa. I monitored the excavations for human remains and burial and sacred artifacts to ensure that the NAGPRA guidelines were followed and proper repatriation to the respective pueblo would be assured. This experience was very educational as both a student and a tribal member. The C&T Project set up a framework for communication between DOE, LANL, and the four accord Pueblos and was a model for any relations between tribes and the government (Figure 85.6).

Figure 85.6. Tim Martinez and Jeremy Yepa discussing issues in Rendija Canyon.

I began working as a Santa Clara tribal monitor in the latter part of August 2005. I hired on as a full time undergraduate student. Employed through the UGS program, I came on board on June 5. At the start of my employment, Paul Baca was the Santa Clara Pueblo Monitor. Due to personal issues he was unable to continue his work with the Cultural Resources Team. With the agreement of Vicki Loucks, Brad Vierra, Bruce Masse, and Santa Clara Pueblo officials, I became the interim monitor until a replacement for Mr. Baca was found. At the end of August and not having found a suitable replacement, Santa Clara Pueblo and LANL selected me to continue as the Santa Clara tribal monitor for the duration of the C&T Project.

Through the course of my employment at LANL, I observed and excavated many sites throughout Cabra and Rendija canyons. These sites included prehistoric fieldhouses, artifact scatters, agricultural plots, water diversion formations, tipi/wikiup rings, traditional cultural properties (observed but not excavated), and the historic Serna Homestead (Figure 85.7). As an undergraduate student, I excavated at each site. It was a new and gratifying experience. I learned so much about archaeology through my employment at LANL. I learned about stratigraphic distinctions, recording excavation unit elevations, measurements, and artifacts, and sweeping the site for clues to its history and its inhabitants such as pollen samples, dendrochronology, charcoal/macrobotanical samples, flotation samples, and the condition of artifacts as they come out of the site. I definitely learned that there is more to archaeology than just digging. It taught me a lot more about my culture, my ancestors, and where we came from. Because one of my majors is computer science, I was given the opportunity to work with the GPS unit. For a project for Santa Clara Pueblo, Brian Harmon, a full time archaeological contractor with LANL, mentored me in plotting out a Traditional Cultural Property (TCP) and then I aided him in superimposing the GPS points onto a topographical map. The invaluable experience and knowledge that I have developed through my time working here will greatly help me to achieve my goals and to better help my people.

Figure 85.7. Jeremy Yepa excavating a fieldhouse in Rendija Canyon.

In addition to my duties as an undergraduate student employee, I was also the tribal monitor for Santa Clara Pueblo. I was trained on NAGPRA guidelines and other issues that are currently a concern for DOE, LANL, and Santa Clara and San Ildefonso Pueblos. I also obtained on the job training on excavating, recording data in the field, screening artifacts (Figure 85.8), and site profiling. As monitor, my duties were screening buckets excavated from the site and identifying NAGPRA defined funerary and sacred artifacts, as well as, non-NAGPRA related artifacts.

Figure 85.8. Jeremy Yepa screening excavation fill at a site in Rendija Canyon.

As a LANL liaison to Santa Clara and DOE, I coordinated negotiations between DOE, LANL, the Santa Clara Tribal Council, and the Santa Clara Environmental Department that resulted with the Santa Clara Pueblo being able to claim two sites located in Rendija Canyon as Traditional Cultural Properties (TCPs). By claiming a site a TCP, the site will be protected from development and Pueblo members will be able to access the site once the Los Alamos County takes over. I also advised the tribe to register the site for the New Mexico Historic Preservation Department's Cultural Properties Review. By being on the list, the tribe can receive assistance for protecting, restoring, and cleanup of the site. The negotiations happened over several meetings that occurred in Santa Clara Pueblo and at LANL with myself, Brad Vierra, Bruce Masse, Vicki Loucks, members of the Santa Clara Tribal Council, and the Santa Clara Environmental Department. In addition to the consultation meetings we had with the tribe, we also provided several tours for Tribal Council members, elders, and department administrators of the sites in the Rendija Canyon. I feel, in addition to the training I received with LANL, that I also have had beneficial experience dealing with my pueblo's Environmental Department, Office of Land Claims and the Tribal Council. It will set up a basis for future employment or consultation opportunities. This experience will directly help me achieve my goals of assisting my tribe to better ourselves.

Overall, the project, in my opinion, was successful. I think that it is a model for future relations between tribes and the government. This project sets precedence for future attempts at a working relationship between these two entities. The bond that was once nonexistent now extends strong from the accord pueblos to the lab, strengthening as we move forward. However, I think that involving the youth, in addition to the elders and tribal representatives of the tribes, may be even more beneficial to the tribes and their futures. Decisions cannot be made without knowing the past. It is imperative that the youth, our future leaders, learn where we come from and who we are so that they are better prepared to lead us in the right direction. It would also be more beneficial to the tribe to involve the whole community by offering presentations at centralized community centers of what is being done. In the end, it was a rewarding experience. I learned the various aspects of archaeology, more history of my people, and helped my pueblo.

STATEMENT OF AARON GONZALES – PUEBLO OF SAN ILDEFONSO

My name is Aaron Gonzales; I am one of two Tribal Monitors from San Ildefonso Pueblo for the Los Alamos National Laboratory's (LANL) Land Conveyance and Transfer Project (Figure 85.9). I am the San Ildefonso Tribal Sheriff's assistant and a member of the Tribal council as well. I was born and raised at the Pueblo. I have been working for LANL, monitoring the archaeological excavations that are part of the C&T Project since May 2002. It has been a great honor to participate in the consultation process with LANL. In addition to being a great learning experience, I feel that having tribal monitors work with archaeologists on their projects is something that is long overdue. Only recently has San Ildefonso been invited to participate actively with the DOE and LANL. We hope that the C&T Project will be a stepping stone to a better working relationship with the Pueblo of San Ildefonso as well as a model for future projects.

Traditionally, the people of San Ildefonso have not condoned excavations of any ancestral sites situated on tribal lands. However, we are excited to have an opportunity to share our perspectives about culturally significant sites situated on LANL lands with archaeologists and other LANL and DOE officials after all this time. Many sites, situated on LANL property, have been excavated since the inception of both entities. To my knowledge, some of these excavations have not been properly documented, thus presenting the Pueblo of San Ildefonso with many unanswered questions regarding where some cultural, ceremonial, and human remains originated.

I feel that this project has been a huge step for LANL in the sense that it is finally seeking the advice from the Native People who once called the Pajarito Plateau home. We no longer reside on the plateau, but our spiritual ties will be with us forever. I hope that this project is only a stepping-stone to a good working relationship with our tribe for the future. There are a lot of other archaeological sites on Laboratory property. As Tribal Monitors, I hope we will be asked to help or give guidance to LANL when the need arises. As long as there are sites being disturbed on LANL land, there will most likely be NAGPRA issues. I hope that DOE and LANL will work with San Ildefonso Pueblo to create a "NAGPRA Excavation/Testing Agreement" where monitors from the San Ildefonso Pueblo will observe and give advice during any future archeological excavations. As a monitor and tribal official, I feel that the tribe has much to learn from DOE/LANL, and vice versa, if only we are all given the opportunity.

Figure 85.9. Aaron Gonzales and Tim Martinez, San Ildefonso Tribal Monitors.

As a Tribal monitor for San Ildefonso Pueblo, I have come to realize that while we do not condone the excavations of any ancestral site, the C&T excavations had to occur in accordance with federal law. I feel that the project has opened a lot of doors for the Pueblo of San Ildefonso and is the first to be referred to the Pueblo. The Pueblo had a impact on "WHAT" was excavated, and most importantly "HOW" sites were excavated. Although LANL is one of our closest neighbors, the dialogue between our communities has been difficult and sometimes questionable. I feel that C&T marked the beginning of a great and positive relationship between our two entities.

I have expressed several concerns, questions, and comments regarding the Draft Comprehensive Agreement. Since then, we had several meetings about Tim Martinez's and my concerns to correct or adjust the 2002 Draft Comprehensive Agreement. I feel that this document should remain a draft so that it can be open to modification if the need arises. During the 2003 field season, we did not encounter any NAGPRA related items, so it was not necessary to consult the agreement or follow the protocol established in the 2002 document. Several Jicarilla Apache tribal elders visited the tipi ring sites. The tribal elders were able to see their ancestral site and provide us with some information about the kinds of things we might expect to find. We also had several site visits by members of San Ildefonso and Santa Clara Pueblos.

A monitor's job description is detailed in the Comprehensive Agreement between DOE/LANL and San Ildefonso Pueblo (see Chapter 72, Volume 3), and was a great learning experience. Not only was I a monitor, but I was also given the opportunity to be an active member of the field and laboratory crews and I am grateful for that (Figure 85.10). I helped with screening for artifacts, washed artifacts and processed flotation samples, and in early 2004 I began illustrating artifacts we found during the C&T Project. Examples of my illustrations are included in Volumes 2 and 3. These illustrations took a considerable amount of time and I took great pride in doing them.

Figure 85.10. Aaron Gonzales, processing flotation samples.

I have learned a lot about what is out there on our ancestral lands and from now on, I will look at things differently. I now know about rock alignments, one- to three-room structures/fieldhouses, grid gardens, artifact scatters, and other features and artifacts. Throughout this project, I have seen things and been a part of things I never would have known about otherwise. I wish that more of the people from San Ildefonso could be given the same opportunities as I have had.

There are three highlights from my time here at LANL with the Cultural Resources Team. One of the highlights was the trip the Trails Assessment Working group took to Mortandad Cave Kiva. I have lived in northern New Mexico all my life and have sat on the San Ildefonso side of the fence facing Mortandad Cave Kiva many times, but I had never been across the fence because of all the ‘No Trespassing’ signs. To some of the people who came to hike the Mortandad trail it was just a little trip we took, but to me it was something more and I will always remember it.

The second highlight was when I visited Nake'muu. Just to be there at the site and to know that it is still right there, smack in the middle of LANL is just amazing. There must be some strong spirits there. A lot of times when I see places like that, I contemplate things like, what is in store for the rest of us? What is our mission in life? Why did this place last for so long? My life is only a passing wind to a place like that. It was there before my time and it will be there long after I am gone. If only I can make such a lasting impression on this world.

The third highlight of my time here at LANL was the repatriation of the remains and sacred objects that had been removed from their original resting places. I am very proud to have been a part of the repatriation.

Finally, I am proud of the artifact illustrations and other designs I have done during the C&T Project. I feel that I have made a small, but lasting contribution to the project. I come from a long line of artists and I have them to thank for my talent.

I hope that the C&T project will just be the beginning of a long relationship between LANL/DOE and San Ildefonso. I also hope that if any other projects arise, then LANL would first consult with San Ildefonso and other affiliated Pueblos. I feel that too many years and too many decisions have been made without consulting with the Pueblo people who were on these lands first.

CHAPTER 86
RESEARCH QUESTIONS AND CONCLUSIONS

Bradley J. Vierra

INTRODUCTION

Approximately 10,000 years of human occupation are represented on the Pajarito Plateau. This includes the initial use of the area by Clovis hunter-gatherers and, more recently, the nuclear research conducted by the Manhattan Project. During this long history, the plateau has witnessed various periods of sporadic and intense occupation. Most notable of these are the Coalition and Classic periods (ca. AD 1200–1600), during which many of the archaeological sites on the plateau were constructed, occupied, and later abandoned. Nonetheless, the region was also visited on a seasonal basis by Archaic foragers, and groups of Navajos and Apaches. But it was not until the turn of the 20th century that the plateau would again witness a return to more permanent residences with Homestead cabins and the founding of Los Alamos National Laboratory (LANL).

Although the plateau has witnessed almost 100 years of archaeological research, very little of this work has been published in synthetic reports. Most notable of these is the work of Hewett and Wilson at the large Classic period sites of Otowi and Tsirege (Hewett 1906, 1938; Wilson 1916a, 1916b, 1918a, 1918b). Not until the 1950s to 1970s would there be a resurgence in the excavation of sites on the plateau by Worman, Steen, and the Los Alamos Archaeological Society; however, little of this work has been fully published (Fretwell 1954, 1959; Maxon 1969; Poore 1981; Steen 1974, 1977, 1982; Worman 1967; Worman and Steen 1978; Young 1954). More recently, three major survey projects have been conducted on the plateau. The Pajarito Archaeological Research Project (PARP) (Hill and Trierweiler 1986; Hill et al. 1996), the Bandelier Archaeological Survey (BAS) (Powers and Orcutt 1999a, 1999b), and the Land Conveyance and Transfer (C&T) Project (Hoagland et al. 2000). In the latter two cases, detailed reports presenting the results of these surveys were completed. Reports were also done for small-scale excavations conducted by Washington State University in conjunction with the BAS Project (Kohler 1989, 1990; Kohler and Linse 1993; Kohler and Root 1992b). However, only a series of theses and dissertations and a single summary article were ever written for the PARP. All of this underscores the general lack of data currently available on the archaeology of the Pajarito Plateau.

A total of 39 archaeological sites were excavated as part of the Data Recovery Program for the C&T Project. A series of research contexts have already been proposed in the Cultural Resource Management Plan for Los Alamos National Laboratory and provided in the project data recovery plan (Vierra et al. 2002; Vierra and Schmidt 2006). These contexts consist of chronometrics, geoarchaeology, paleoenvironment, land-use, community and site organization, subsistence and seasonality, and technology, production, and exchange. These research domains provide the framework for identifying specific research questions that can be used to help determine the potential eligibility of sites for inclusion to the National Register of Historic Places. Here, they provide a research design to guide the excavation and analysis of data obtained from the sites located within the C&T Project area. This chapter addresses the results of the project excavations in respect to a series of detailed research questions that were provided in the original data recovery plan (Vierra et al. 2002).

CHRONOMETRIC DATING RESEARCH QUESTIONS

1. **What period do the sites date to, and is there evidence of multiple occupational episodes?**

Harmon and Vierra (Chapter 69, Volume 3) reviewed the chronometric information on the excavated sites and presented a coherent sequence for these. Four sites were assigned to the Archaic period: LA 85859, LA 99396, LA 99397, and Area 8 at LA 12587. Three charcoal dates were submitted from the lower levels of LA 85859 providing a calibrated intercept range from 5300 to 4860 BC. This site presumably dates to the Early Archaic period. LA 99396 and LA 99397 can be tentatively assigned to the Middle to Late Archaic period. The Archaic component consists of a surface lithic scatter with possible Middle to Late Archaic points. Obsidian hydration dates indicate a possible Middle to Late Archaic period occupation. Lastly, LA 99397 is a surface scatter with subsurface deposits. Two charcoal dates from the upper levels provided calibrated intercepts of 380 and 160 BC, with obsidian hydration dates ranging from Middle- to-Late Archaic. A single possible Late Archaic site was identified in the White Rock Tract. LA 12587 (Area 8) contains Late Archaic projectile points. Late Archaic points were also recovered at several multi-component surface scatters: LA 86533, LA 86637, and LA 139418.

Table 86.1 summarizes the Ancestral Pueblo temporal sequence for the sites. It has been separated into nine categories: Indeterminate Pueblo, Indeterminate Coalition, Coalition 1, Coalition 2, Coalition2/Classic 1, Indeterminate Classic, and Classic 1, Classic 2, and Classic 3 based on the chronometric and ceramic dates. LA 4618 and LA 4619 were not excavated during the C&T Project, but are included since they are located near the White Rock Tract on Mesita del Buey (Hoagland 2007; Schmidt 2006). The Coalition period sequence includes both roomblocks and fieldhouses, whereas the Classic period sequence solely includes fieldhouses. The temporal sequence for the Coalition roomblock sites consists of LA 86534, LA 135290, LA 4618, LA 12587, and LA 4619.

Architectural remodeling was solely identified at the Coalition period roomblock site of LA 135290. At least three occupation episodes were identified, including multiple floors and features. One hearth was remodeled at LA 86534 and consisted of two use-events. However, three separate components were found at LA 12587. The first component consists of a Late Coalition roomblock, the second component is an unfinished linear roomblock that also dates to the Late Coalition period, and the third component is a Classic period fieldhouse with multiple agricultural features. In addition, at least one fieldhouse in Rendija Canyon may have been reused. The hearth at LA 127635 was radiocarbon dated to the 13th century, however, the ceramic assemblage appears to represent a later 14th century occupation.

Table 86.1. Ancestral Pueblo site temporal sequence from the C&T Project.

Ind. Pueblo	Ind. Coalition	Coalition 1	Coalition 2	Coalition/ Classic	Ind. Classic	Classic 1	Classic 2	Classic 3
86531	85404+?	85417	4618	4619	85861	85404	70025	15116
127633?	86606	86533-	12587		127625	85411	85411?	85403
	86607	86534	85861+		128803	85413	86637	85408
		99396			139418	85414		86605
		127635+			141505	85867		86606?
		135290				127631		87430
						127635		110126
						135291		110130
								127627?
								127634
								128804
								128805
								135292

In addition to the prehistoric sites, three historic sites were also excavated. LA 85864 and LA 85869 are turn-of-the-20th-century Jicarilla Apache tipi ring sites. Five radiocarbon samples were submitted from the latter site; however, only one returned a date that is clearly associated with the occupation. The 260±40 BP date has several calibrated two-sigma ranges, starting at AD 1520 and ending at AD 1950. A single micaceous sherd did yield a luminescence date of AD 1859±13. The historic bead, metal, and ceramic artifacts also indicate a late 19th or early 20th century occupation at the site.

LA 85407 is the Serna Homestead site in Rendija Canyon. Eight wood construction elements from the cabin and corral were submitted to the Dendrochronology Laboratory at the University of Arizona for tree-ring dating. All the samples were ponderosa pine, with five of the eight yielding dates. However, none provided cutting dates due to the poor preservation of the outside rings, leading to a couple of interpretations. The simplest is that the entire structure was built sometime after 1900, based on the 1900+vv date from Room 2. The historic metal and glass artifacts indicate a late 19th to early 20th century occupation and the ceramics a post-1913 date. This corresponds with oral interviews that indicate the homestead was occupied in the early 1900s.

2. **Do the recovered projectile points resemble types described for the Oshara Tradition? If so, do the associated chronometric dates place them within the time range as defined by Irwin-Williams?**

Very few Archaic projectile points were recovered during the C&T Project excavations. Most of these were found in surface contexts, with no clearly associated chronometric dates. They include Middle and Late Archaic points, with one San Jose point recovered from a Classic period fieldhouse (LA 85411). Figures 86.1 through 86.3 provide examples of Early, Middle and Late Archaic point types from the area.

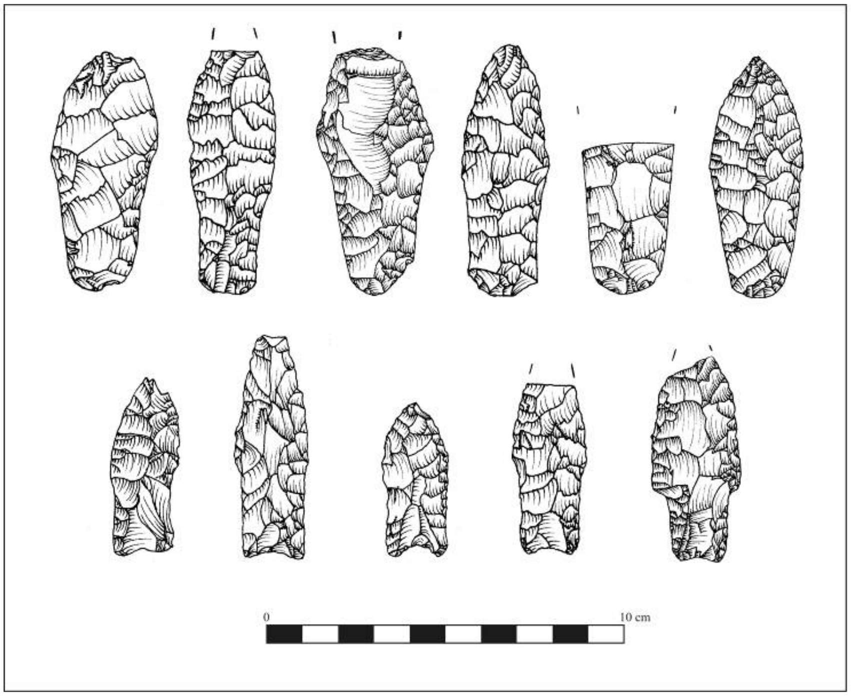

Figure 86.1. Early Archaic points (Jay: upper; Bajada: lower).

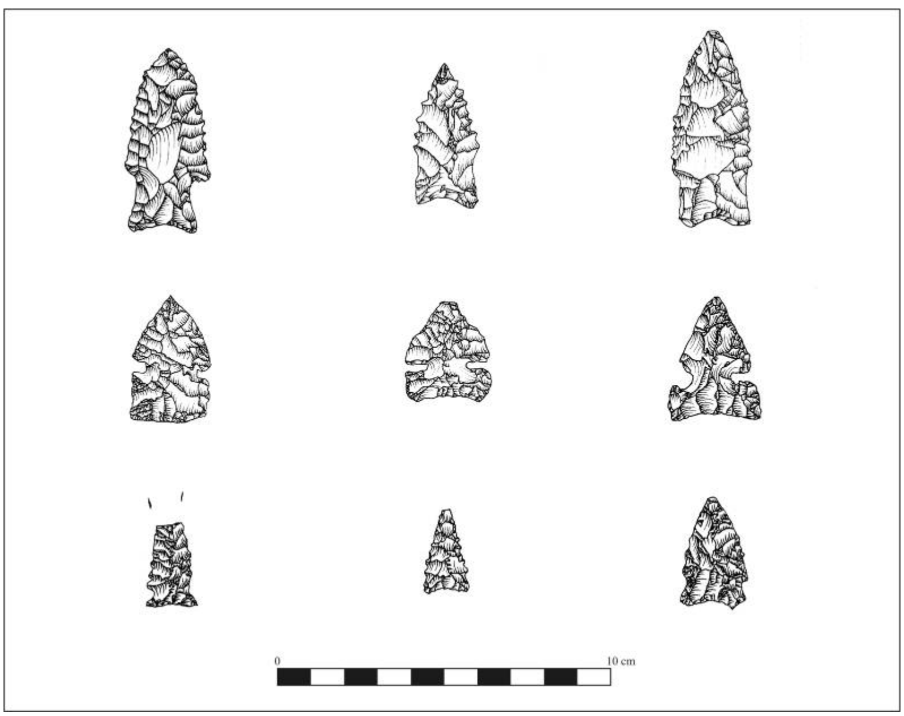

Figure 86.2. Middle and Late Archaic points (San Jose: upper; Large side-notched: middle; Armijo: lower).

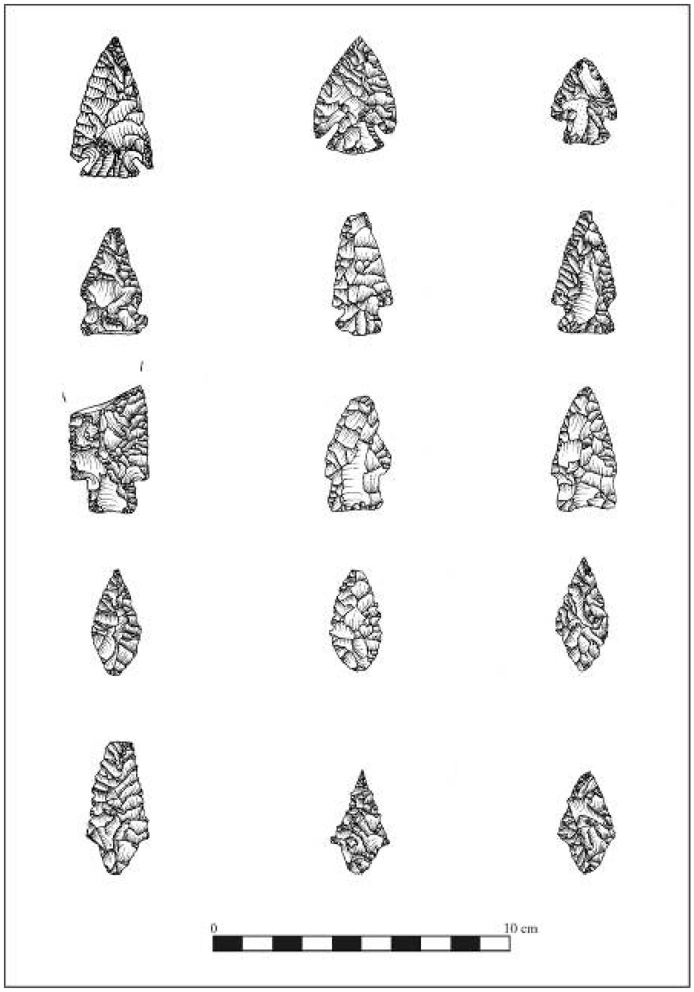

Figure 86.3. Late Archaic points (top to bottom: corner-notched, side-notched, stemmed, leaf-shaped, and contracting stem).

3. **How do the projectile points compare in morphology and temporal range to the sequence defined by Turnbow (1997)?**

There is no temporal information to clarify the relative ages of the projectile point sequence. However, the point types illustrated in Figures 86.1 through 86.3 do fit the variability described by Turnbow (1997). This includes Jay, Bajada, San Jose, large side-notched points (Sudden, Northern or San Rafael types), Armijo, and five other Late Archaic point types. The latter consists of corner-notched, side-notched, stemmed, leaf-shaped, and contracting stem points.

4. **Given the problems with the obsidian hydration dating of Early and Middle Archaic obsidian artifacts, do projectile points from LA 85859 and LA 99396 also follow the pattern of dating to the Late Archaic? Or, were some of these point types actually used (reused) during later times?**

Harmon et al. (Chapter 71, Volume 3) discussed the problems with obsidian hydration dating for this project. Most of the artifacts recovered from both Archaic and Ancestral Pueblo contexts actually dated to the Archaic period. It therefore seems likely that Archaic surface scatters were used as a source of raw materials by the later occupants of the plateau. There were no Early Archaic points recovered from LA 85859, and several possible Middle to Late Archaic point bases were found at LA 99396. Obsidian artifacts from LA 85859 provided a date range of circa 6000 to 2000 BC, with a later surface component dating to the AD period, whereas, LA 99396 provides an unbroken sequence of obsidian dates from about 6000 BC to the first few centuries AD. This indicates that the sites may represent multiple occupation episodes.

Given that obsidian debitage appears to have been scavenged and reused by the later Pueblo site occupants, the question is, did they also scavenge Archaic projectile points. Certainly, Archaic-style dart points were recovered from Ancestral Pueblo contexts. As previously noted, this included a San Jose point from a Classic period fieldhouse and other possible Late Archaic points from Coalition period contexts. However, it is unclear as to whether these latter points actually date to the Archaic or represent Pueblo lance or dart points. A pilot study was conducted on four arrow points and four lance/dart points recovered from a Late Coalition roomblock site (LA 4618) (Figure 86.4). The points were submitted for obsidian hydration dating and the results are presented in Table 86.2. One arrow point could not be dated (Field Specimen [FS] 348), but the remaining six points exhibit hydration rims ranging from 2 to 4 microns, with one outlier of about 7 microns. The larger points do exhibit slightly thicker rims (3.59 to 4.36) and the smaller points have thinner rims (1.94 to 2.13), however, the dates do overlap. Presumably these arrow and lance/dart points are roughly contemporaneous, versus the single dart point, which appears to be Archaic in age. This dart point also exhibits more resharpening than the other points. It therefore seems likely that at least some large points continued to be manufactured and used during the later Ceramic period.

Table 86.2. Obsidian hydration data for the projectile points from LA 4618.

FS #	Type	Rim (*um*)	Age	*sd*
8	Lance/dart	3.59	AD 1650	17
31	Lance/dart	4.36	AD 1431	24
179	Lance/dart	3.71	AD 1619	18
282	Arrow	2.07	AD 1447	50
443	Arrow	1.94	AD 1547	43
466	Arrow	2.13	AD 1828	12
781	Lance/Dart	6.91	3258 BC	152

5. **Can obsidian hydration analysis distinguish between Archaic and later Ceramic period occupations (i.e., Coalition and Classic periods)?**

As previously noted, most of the obsidian artifacts recovered from Ceramic period occupations dated to the Archaic. Therefore, it is presumed that most of these were in fact scavenged from these older sites. Obsidian hydration dating did not clearly distinguish between Coalition and Classic period occupations.

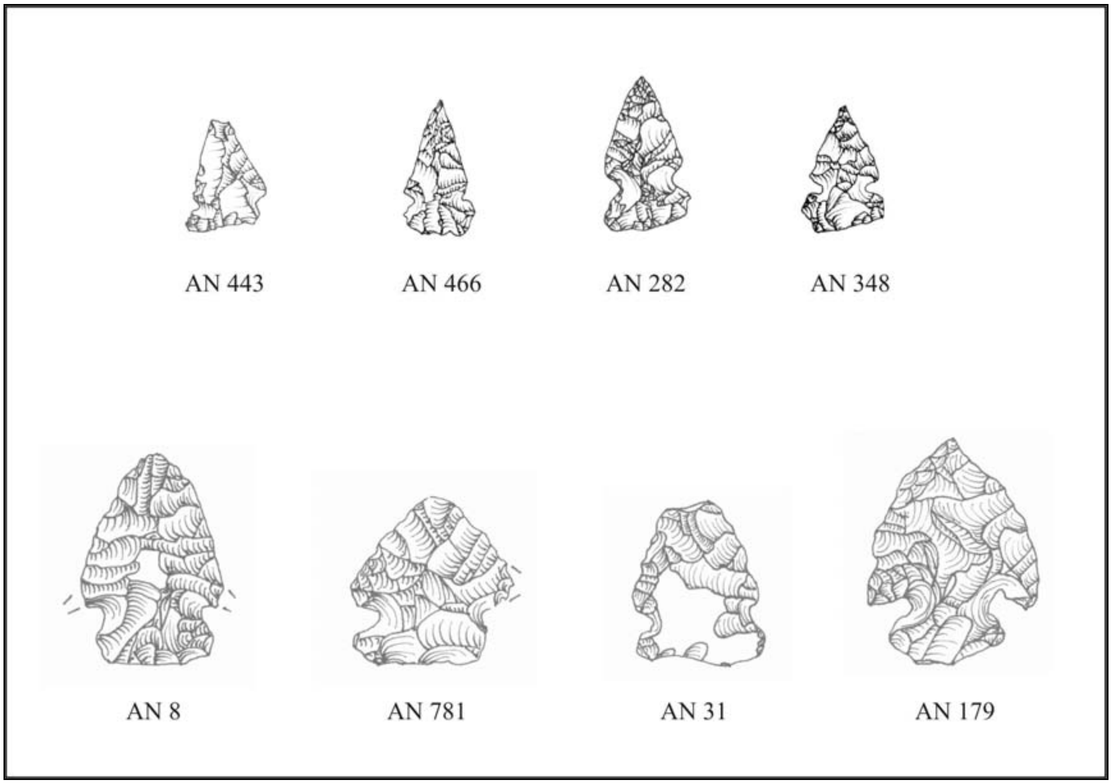

Figure 86.4. Arrow (top) and lance/dart (bottom) points from LA 4618.

6. **How do the ceramics compare with the type descriptions and date spans as provided by McKenna and Miles (1991)?**

Dean (Chapter 58, Volume 3) described Santa Fe Black-on-white as having relatively thin and straight vessel walls and being similar in shape and thickness to Kwahe'e Black-on-white. Pastes are often fairly dense, hard, and can be vitreous. They are usually very fine in texture and fracture along an even plane. Paste color is usually light gray to blue-gray. Surfaces are moderately to well polished, often slipped, and range from white, light-gray, greenish, to tan in color. Decorated surfaces are usually polished and often slipped. Bowls are by far the dominant vessel form in this type. Undecorated exterior bowl surfaces are often unslipped and unpolished and may occasionally display unobliterated coils, striation, or basket impressions. Tempering materials include finely crushed volcanic rock, fine sand, and, in some cases, sherd temper (Habicht-Mauche 1993; Stubbs and Stallings 1953).

Painted decorations are executed in organic pigment, which is sometimes faded and translucent. Paint color ranges from dark gray, bluish-black, to black. Rims are usually tapered and undecorated, while ticked rims, similar to those noted in contemporaneous pottery from regions on the Colorado Plateau, are extremely rare. In bowls, decoration is oriented in a band on the interior surfaces. Decoration consists of banded panels on bowl interiors and the upper portions of jars. These banded panels are often framed by a pair of single lines that are separated by very short spaces between the line and the top and bottom of the panels. Similar lines are also directly incorporated into the top and bottom edges of the panels. These designs are occasionally framed by a series of similar-sized parallel lines or a combination of thick and thin lines. Santa Fe Black-on-white is thought to have first been produced during the middle to late 1100s and continued to dominate assemblages until the middle 1300s and may occur as late as the early 1400s (Habicht-Mauche 1993; Stubbs and Stallings 1953; Sundt 1987). Indeed, a very small percentage of Santa Fe Black-on-white sherds are often represented at Early Classic period fieldhouse sites indicating that it could have been produced during the 14th century. In addition, although smeared-indented corrugated dominates the Coalition period utilityware assemblages, this pottery type also continues into the Early Classic period.

7. **What are the most temporally sensitive attributes for the ceramic types? Can Santa Fe Black-on-white be subdivided into earlier and later varieties?**

Dean's (Chapter 58, Volume 3) ceramic analysis indicates that Santa Fe Black-on-white does not appear to exhibit any significant stylistic changes during the Coalition period. However, there does appear to be some noteworthy long-term changes in temper and paste characteristics. Most of the Santa Fe Black-on-white ceramics appear to be tempered with a fine tuff, although LA 135290 exhibits more of a fine tuff with clay fragments. Nonetheless, this is a variable group that presumably reflects the use of multiple local sources. Miksa's (Chapter 59, Volume 3) petrographic analysis identified five temper groups: anthill sand, anthill/clay, granitic, Tuff 1, and Tuff 2. Anthill sand seems to be more prevalent in the earlier varieties of Santa Fe Black-on-white, while Tuff 2 is more prevalent in the later varieties. Tuff 2 is a natural occurring material that is highly variable and was probably used without alteration. In contrast, Tuff 1 has a more uniform grain sorting, with a finer grain size. It was used primarily for the production of biscuitwares and represents a more selective use of this tempering material. As Dean notes, these changes are first reflected in some of the pastes at the Late Coalition period site of LA 12587 and then are more dramatically represented at LA 4618. As a result, a shift to the use of crushed tuff temper, common during the Classic period, may have first occurred during the Late Coalition period. Therefore, changes in temper and paste appear to be more sensitive than stylistic changes for distinguishing earlier versus later varieties of Santa Fe Black-on-white.

8. **How do Santa Fe and Wiyo Black-on-white compare with similar types that were produced in the Rio Grande Valley (e.g., Pindi and Poge Black-on-white) and later biscuitware types from the plateau?**

Dean (Chapter 58, Volume 3) notes that the styles and manipulations noted in Santa Fe Black-on-white are similar to contemporary whitewares found on sites in other areas of the Rio Grande region including the Albuquerque area, Santa Domingo Basin, Puerco Valley, Pecos Valley, Santa Fe Valley, Tewa Basin, Chama Valley, and Galisteo Basin. Otherwise, any differences are primarily restricted to the use of local paste and tempering materials; however, unlike areas to the west, local Santa Fe Black-on-white ceramics are dominated by bowl vessel forms with the almost complete absence of kiva jars and ladles.

Some of the sherds classified as Santa Fe Black-on-white during the Early Classic period might actually be classified as Pindi Black-on-white. Dean (Chapter 58, Volume 3) states that this type may be distinguished from earlier varieties of Santa Fe Black-on-white by the presence of added vitric temper with distinctive paste and slip clays. Therefore, some of these sherds may have been imported from the nearby valley or represent a local variant of Santa Fe Black-on-white that was produced at the same time as the biscuitwares. In contrast to Santa Fe Black-on-white, the sample size for the later biscuitwares was too small for a detailed stylistic analysis.

9. How do the dated ceramic assemblages compare with Orcutt's seriation sequence?

Harmon and Vierra (Chapter 69, Volume 3) conducted a detailed chronological study of the project dating methods and associated ceramic types. A direct comparison with Orcutt's seriation sequence could not be conducted due to the small ceramic sample sizes. Nonetheless, their preliminary cluster analysis was able to distinguish six distinct ceramic type clusters: 1) Santa Fe Black-on-white and smeared-indented corrugated; 2) smeared plain corrugated; 3) undetermined biscuitware and plain gray; 4) mixed decorated wares and smeared-indented corrugated; 5) Biscuit B or Biscuit C and Sapawe Micaceous, and 6) Biscuit A and Sapawe Micaceous.

10. Is there a difference in accuracy between archaeomagnetic samples taken from tuff versus clay-lined features or burned soil?

All the archaeomagnetic samples were taken from burned adobe or clay-lined features. None were taken from burned tuff. However, a set of archaeomagnetic dates was obtained from two clay-lined features: Feature 20 at LA 12587 and Feature 2 at 127635. Neither of the samples from Feature 20 or Feature 2 returned exactly the same dates, although in both cases there is considerable overlap, particularly with the Wolfman Curve dates.

11. How do the results of the dendrochronology, radiocarbon, archaeomagnetic, obsidian hydration, and luminescence dating techniques compare with each other? Which are the more accurate techniques?

Harmon et al. (Chapter 71, Volume 3) conducted a detailed comparison of the chronometric methods used to date sites on the project. Since tree-ring samples were only obtained at the Serna Homestead, the other four dating techniques were contrasted in this study. In general, the obsidian hydration dates from Ancestral Pueblo sites are much earlier than expected, whereas, the Archaic site dates appear to be accurate, but very imprecise. As previously suggested, it may be that the later inhabitants were scavenging obsidian from these older surface sites.

The radiocarbon and archaeomagnetic dates are generally in agreement indicating that both methods are accurate. Of the two methods, archaeomagnetic dating is often more precise, with a resolution of 20 to 40 years possible for a given sample. Accelerator mass spectroscopy dating also appears to be more precise than the standard radiocarbon dating method. However, between about AD 1460 and AD 1640, the radiocarbon calibration curve flattens out. At two sigma, any radiocarbon date with an AD 1440 to 1600 intercept is almost indistinguishable from any other.

When luminescence dates are compared with other dating methods, they either agree with the other dates or are too early. A similar result was obtained by Dykeman et al. (2002), although late luminescence dates are not unknown (e.g., Ramenofsky and Feathers 2002). In summary, radiocarbon and archaeomagnetic dating techniques appear to be the most accurate and precise.

12. Which suite of historic artifacts provide the most accurate dating mechanism for the homestead site?

Haecker (Chapter 32, Volume 2) conducted the historic artifact analysis for the Serna Homestead. He considers that food cans appear to provide the most useful information for dating because they are more time sensitive due to changes in manufacturing techniques (i.e., lead solder to sanitary seal) and because of the encouragement of the Canning Trade Association to standardize can dimensions (i.e., height and diameter) during the circa 1900 to 1930 time period. In fact, this information could yield the year of introduction and sometimes the year of discontinuation for a particular can dimension. In addition, since canned foods are not curated items like tools, jewelry, or buttons, they can reflect the purchase, use, and discard sequence within a short period of time. Thus, an estimated date range of all cans found on a site would accurately reflect the time period of occupation.

GEOARCHAEOLOGY RESEARCH QUESTIONS

1. What is the geomorphic context of the sites?

Drakos and Reneau (Chapters 3 and 57, Volumes 1 and 3) provide a detailed description of the geomorphic context of each tract and excavated archaeological site. All the tracts are situated in differing topographic and geomorphic settings. Each context has a differing effect on the depositional history of the site area. The highest potential for site preservation exists along small drainage channels on mesas, on alluvial fans, and in canyon bottoms, where net deposition of alluvium and colluvium has occurred during the Holocene, and on the more stable parts of mesa tops where erosion has been minimal or where deposition of eolian sediment has occurred.

In canyon settings, early to middle Holocene deposits are less extensively preserved, except in some canyon bottoms, recording net erosion during the Holocene across most of the landscape. Late Pleistocene soils are truncated, indicating erosion some time during the Holocene, before deposition of the late Holocene colluvium. In Rendija Canyon, the development of shallow hillslope drainages and their subsequent filling is recorded by the ca 1 to 2 ka and ca 6 to 7 ka swale fill deposits. Valley bottoms preserve 1.5- to 2-m-thick mid to late Holocene colluvial deposits and an unknown thickness of underlying early Holocene and/or late Pleistocene deposits. Pre-Coalition period colluvial deposits are apparently preserved over a larger part of the Cañada del Buey landscape, but are apparently very poorly preserved in Pueblo Canyon within the TA-74 South Tract. Use of soil stratigraphic characteristics to differentiate between Coalition and Classic period sites in hillslope settings has not been as reliable as has been found for mesa top sites. This may indicate that the main pulse of recent colluvial deposition has occurred later than the AD 1250–1325 eolian event, likely after AD 1500.

2. Which sites have been affected by sediment deposition or erosion, and how have these processes affected the integrity of the sites?

Archaeological sites examined by Drakos and Reneau (Chapter 57, Volume 3) are situated on mesa top, colluvial slope, fluvial terrace, valley bottom, and ridge top settings. The record of eolian and colluvial deposition on mesa tops and within canyons indicates periods of widespread deposition during the latest Holocene (generally <1 ka deposits) and during the late Pleistocene to early Holocene. Middle Holocene (approximately 6 to 8 ka) and late Holocene (approximately 1 to 2 ka) colluvial deposits are less extensively preserved. Similarly, early Holocene (9 to 10 ka), middle Holocene (approximately 4 to 6 ka), and late Holocene (approximately 2 to 3 ka) eolian deposits are less extensively preserved than late Pleistocene and latest Holocene deposits.

Preliminary regional correlation of eolian stratigraphic units has been developed during investigation of sites located on mesa top settings in the Airport Tract and White Rock Tract, and by comparison with the stratigraphic record exposed in paleoseismic trenches on Pajarito Mesa. A post-Puebloan age eolian deposit is present in each of the mesa top locations; therefore Ancestral Pueblo sites are typically buried and are generally in good archaeological context. It is inferred that 15 to 20 cm of eolian deposition occurred some time after the Middle Coalition period but before the Classic period (i.e., ca AD 1250–1325), and in many cases Coalition and Classic period sites can be differentiated based on soil stratigraphic relationships. The timing of this eolian event corresponds to "The Great Drought" of AD 1276 to 1299 and a locally drier period from AD 1250 to 1255, inferred from tree ring data, and a major regional event associated with the abandonment of Mesa Verde (Rose et al. 1981; also see Chapter 7, Volume 1). A second, more recent eolian event occurred after abandonment of the Early Classic (?) period sites, resulting in deposition of an additional 5 to 10 cm of fine-grained sediment in mesa top settings since approximately AD 1500. Up to 4 cm of eolian deposition has occurred since the mid to late 1800s at one site.

The general processes of erosion versus deposition are best illustrated at the Rendija Canyon Archaic sites. Abandoned roomblock sites act as effective traps to catch soil. They are partially buried by colluvium that is in part derived by the erosion of the roomblock. In addition, the rubble mound acts to catch silty eolian sediment and short-distance colluvium. Whereas, the site area may have exhibited little deposition before the construction of the roomblock, soil deposition increases during the post-occupational period. This process provided an excellent niche for agriculture during the later Classic period.

In contrast, middle to late Holocene deposits are less extensively preserved. Therefore, the older Archaic sites in Rendija Canyon are primarily found in secondary context. For example, at LA 85859 the upper hillslope was eroded during the early to middle Holocene and then deposited in a concave part of the lower hillslope. Then, a second period of erosion likely occurred during the late Holocene, when the upper hillslope was stripped to bedrock and the middle Holocene soils on the lower slope were truncated. These soils were subsequently buried by a thin late Holocene colluvial deposit. Although artifacts were recovered from both the middle and late Holocene colluvium, the highest artifact concentration was located in the middle Holocene deposit, with artifacts present in the late Holocene deposit being supplied by bioturbation.

PALEOENVIRONMENTAL RESEARCH QUESTIONS

1. **What evidence do the tree-ring measurements, and the pollen and floral remains provide for past environmental conditions at the sites?**

Towner (Chapter 7, Volume 1) provides a detailed paleoclimate reconstruction based on the tree-ring sequence from the Jemez Mountains. This sequence is graphically illustrated in Figure 86.5. Agriculturalists colonized the plateau circa AD 1150 during a period of above average rainfall following the Chaco drought. This is followed by two droughts during the 13th century (including the Great Drought) and then a period of increased effective moisture during the 14th century. This period correlates with the Classic period occupation of the plateau. The 15th through 17th centuries are bounded by two droughts, with intervening above average rainfall. It is the megadrought of the 1580s that causes the eventual termination of year-round occupation of the Pajarito Plateau.

The two Middle Coalition period roomblocks (LA 86534 and LA 135290) date to circa AD 1160 to 1270. This time range is bounded by two periods of increased effective moisture with about 35 cm of rainfall, separated by a drought. The two Late Coalition period roomblocks (LA 4618 and 12587) were occupied circa AD 1275 to 1325, also during a period of above average rainfall with about 35 cm.

The 14th through 16th centuries were generally characterized by increased effective moisture (30-40 cm), with a drought circa AD 1420. The Classic period fieldhouses span this time period, although there does appear to be a bimodal distribution with most of the sites dating to earlier and later temporal segments. Smith's study (Chapter 63, Volume 3) does show a marked decrease in the amount of pollen present in the Early-Middle Classic period fieldhouses, which could reflect the early 15th century drought.

The Serna Homestead was occupied during a period of above average rainfall (35 to 40 cm) from circa AD 1910 to 1950. This would have been an excellent time for the rainfall farming of beans.

A pilot paleoenvironmental study was initiated by collecting pollen from geologic contexts, however, the study only met with limited success. That is, only 40 percent of the 41 total samples collected yielded sufficient pollen to describe the spectra. Smith (Chapter 6, Volume 1) identified four major trends in this dataset: 1) pollen concentrations drop dramatically from the A to B horizon and continue to decline with depth; 2) this decrease is in part due to increased amounts of degraded pollen that is unidentifiable; 3) pine pollen decreases with depth; and 4) cheno-am pollen tends to increase with depth. Otherwise, the archaeological pollen indicates an environment similar to today during the Ancestral Pueblo and Historic periods; however, these data do not provide sufficient detail to allow time-specific descriptions of potential changes in vegetation structure. For example, was it open or park-like with more grass, closed, or deforested?

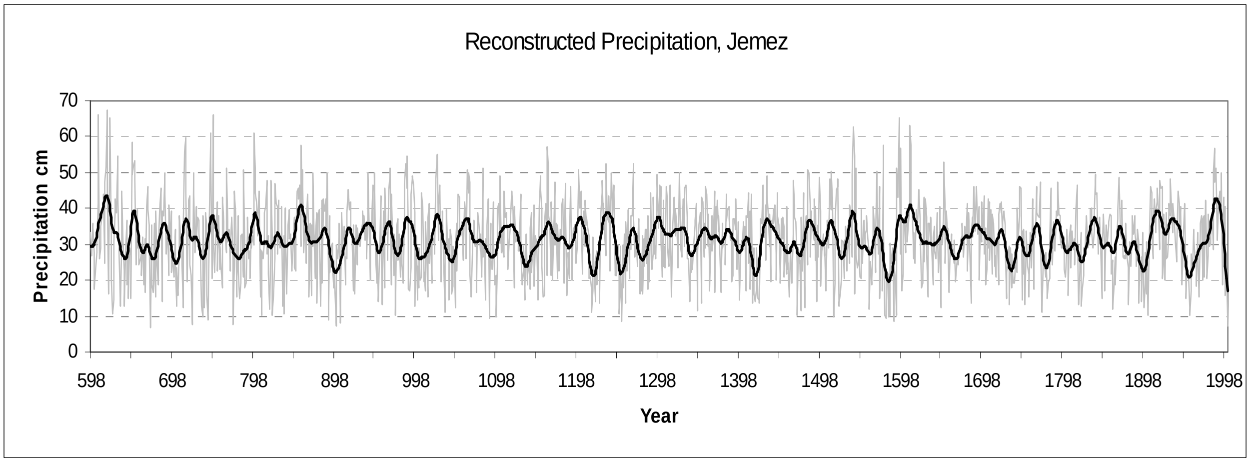

Figure 86.5. Reconstructed precipitation for the Jemez Mountains tree-ring chronology.

McBride's (Chapter 62, Volume 3) fuel wood study indicated that local materials were collected during the Coalition and Classic periods, consisting mostly of piñon, juniper, and ponderosa pine. Although the macrobotanical evidence does not support widespread deforestation, there are indications that some lower-elevation conifers (e.g., juniper) may have been depleted and subsequently replaced with the use of higher-elevation woods during the Late Coalition period.

2. **Are there differences between the Early and Late Archaic period sites versus the Ancestral Pueblo and Historic periods that could reflect changes in past vegetation communities?**

The pollen record provides some excellent baseline environmental data for understanding the changing vegetation setting during the Archaic. Recent studies by Scott Anderson and his students (Chapter 5, Volume 1; Anderson et al. 2007) of pollen cores in the Jemez Mountains indicate that the Late Paleoindian and Early Archaic transition is separated by a period of decreased effective moisture when the Chihuahueños bog had dried up from circa 8000 to 6500 BP. This obviously had a significant effect on the Early Archaic foragers in the area, with their settlement system shifting to a north-south pattern within the northern Rio Grande Valley (Vierra et al. 2005; Chapter 74, Volume 4).

Then during the subsequent Middle Archaic period (6000 to 4000 BP), there is evidence for moister conditions and the expansion of piñon-juniper woodlands in the northern Rio Grande Valley. This evidence is represented by increased percentages of piñon pollen at circa 4500 BP at Chihuahueños Bog, 4300 BP at Alamo Bog, and 4000 to 3500 at Alta Alamo Bog (Chapter 5, Volume 1; Anderson et al. 2007; Brunner-Jass 1999; Stearns 1981). It may be during the Middle Archaic that fall hunts in the Rio Grande Valley were becoming less successful, so these hunter-gatherers would have shifted their residence to the uplands where they could collect piñon nuts and hunt deer (Vierra 2005a; Chapter 75, Volume 4).

The initial use of maize agriculture is dated to about 3000 BP during a period of increased effective moisture (Smith and McFaul 1997; Vierra and Ford 2006). These moister conditions continue until about 2200 BP with the onset of drier conditions. The cyclical nature of the rainfall conditions during the subsequent time period has been described in the El Malpais data (Grissino-Mayer 1996). Late Archaic land-use appears to be characterized by a lowland/upland pattern within restricted areas of the Rio Grande Valley (Vierra 2003, Chapter 75, Volume 4; Vierra and Foxx 2002; Chapter 75, Volume 4).

As previously noted, the pollen record provides little detailed information on long-term structural changes in the local vegetation communities; however, the archaeobotanical evidence does indicate that the juniper population may have been depleted and replaced with the use of ponderosa pine from higher elevations during the Late Coalition period.

LAND-USE, COMMUNITY, AND SITE ORGANIZATION QUESTIONS

1. **Can site structure studies identify the internal organization of the Archaic campsites? If so, what evidence is there for identifying the occupying group size, structure, and site occupational history?**

The answer to this question appears to be no. Four sites were assigned to the Archaic period: LA 85859, LA 99396, LA 99397, and Area 8 at LA 12587. All of the Archaic sites are situated in secondary contexts. A spatial analysis of LA 99396 did identify two artifact clusters (Chapter 71, Volume 3); however, these appear to be the result of both natural and cultural factors. There is no difference in respect to lithic debitage between the two areas, but there are some minor differences in respect to chipped stone tools. That is, the northern cluster primarily contains bifaces and the southern cluster contains a variety of tools. This may in part reflect a mixture of Archaic and Ceramic period components in the northern cluster versus mostly Archaic material in the southern cluster.

2. **Is there any evidence of structures or features on the Archaic campsites?**

No Archaic age features were identified during the excavations.

3. **How do these Archaic campsites contrast with the Late Archaic winter habitation site excavated near San Ildefonso Pueblo?**

Vierra (2003, Chapter 75, Volume 4) did a comparative analysis of Late Archaic lithic assemblages across the various vegetation zones. These zones covered the elevational gradient from river valley to piñon-juniper to ponderosa pine to mixed conifer. In doing so, he determined that these debitage assemblages are all linked by reduction tactic and obsidian procurement patterns. That is, lowland habitation sites are characterized by an emphasis on core reduction while upland campsites are characterized by biface production. Otherwise, obsidian dominated all the lithic assemblages, with sites situated in the lowland juniper-savanna and nearby upland piñon-juniper communities also containing a small amount of material derived from local river gravels.

LA 85859 is an Early Archaic site that emphasizes the reduction of bifacial cores and biface blanks using obsidian derived from the nearby caldera. The Late Archaic site of LA 12587

(Area 8) is also dominated by the production/maintenance of bifacial tools. However, the Middle to Late Archaic sites of LA 99396 and LA 99397 are characterized by a mix of core reduction and biface production/maintenance activities. The implication of Vierra's (2003, Chapter 75, Volume 4) argument was that sites containing a mix of core and biface flakes presumably reflect habitation sites versus temporary campsites with mostly biface flakes. If so, LA 85859 and LA 12587 (Area 8) reflect temporary campsites, whereas LA 99396 and LA 99397 may be habitations. It is, however, unclear whether the Ceramic period component at LA 99396 is contributing to the increased amount of core reduction at this site.

4. **What is the general layout of the Coalition period habitation sites?**

Most Coalition period habitation sites are linear, north-south-oriented roomblocks that are two to three rooms deep, and have a single or multiple kivas located along the eastern side of the pueblo (Steen 1977, 1982; Worman 1967; Worman and Steen 1978) (Figure 86.6).

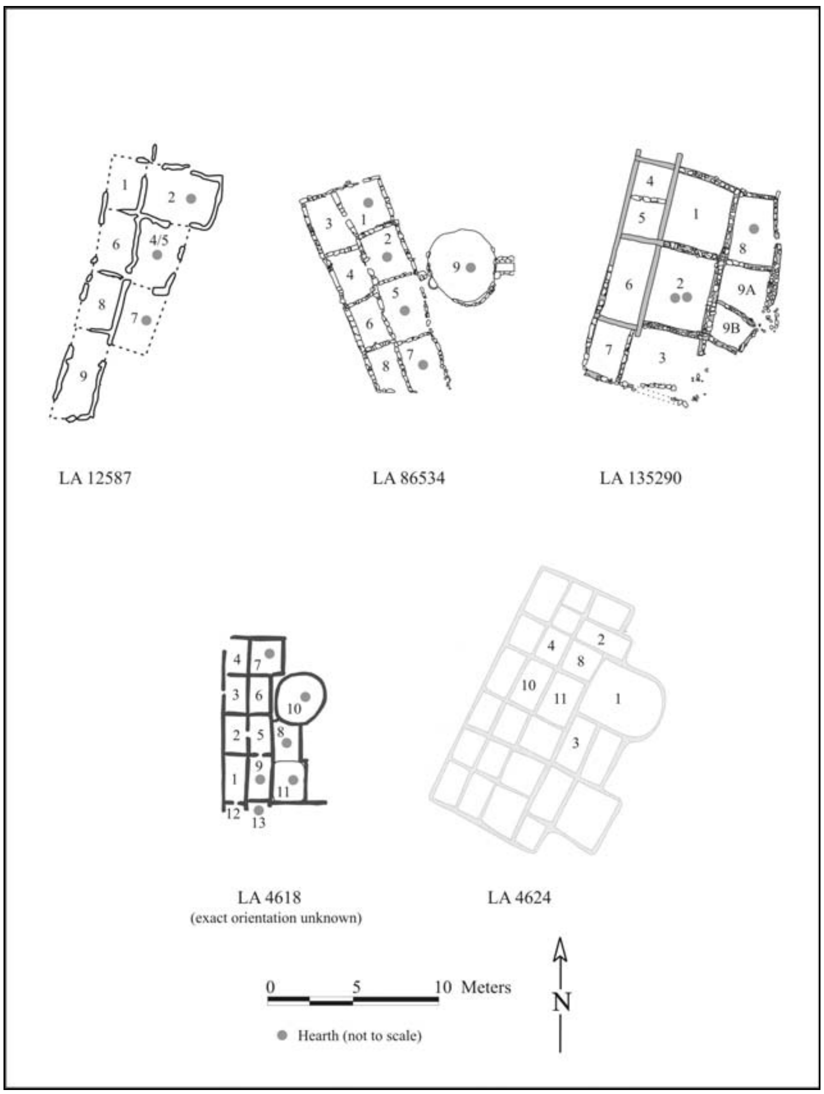

Figure 86.6. Roomblock ground plans.

The three Coalition roomblocks excavated during the C&T Project are quite similar (Figure 86.6). LA 12587, LA 86534, and LA 135290 are all composed of two linear sets of rooms (front and back); however, LA 135290 does contain three plaza-oriented rooms that could represent ramadas and not a fully enclosed space (Chapter 71, Volume 3). Of the three sites, only LA 86534 contains a kiva (Chapter 24, Volume 2). This makes it more similar to LA 4618 and LA 4624 where the roomblocks are three or more rows deep, including both circular and rectangular kivas (Schmidt 2006; Vierra et al. 2002). The roomblocks are generally oriented north-south, with three being slightly tilted towards the northeast and one to the northwest (LA 86534). The kivas are all situated along the east facing (front) of the roomblocks.

5. **Can habitation versus storage rooms be identified and are there kivas (or communal rooms) present?**

Coalition period habitation rooms typically contain hearths and are located along the eastern (front) side of the pueblo, while storage rooms are typically located on the west (rear) side of the pueblo and may contain storage or milling bins. Communal rooms (i.e., kivas) are generally larger in size than the habitation and storage rooms and can be round, square, or D-shaped. In addition, the habitation rooms also tend to be larger than the storage rooms.

Most of the front rooms at LA 12587, LA 86534, and LA 135290 contain hearths; whereas, only a single rear room at LA 86534 contained evidence of a milling bin. The architecture at LA 135290 did differ between front and back rooms, with the front rooms being constructed of masonry and the back rooms of adobe. The fact that the back rooms were consistently burned during the three occupations indicates that these were probably storage rooms that were being hardened to protect stored foods.

The pollen information as provided by Smith (Chapter 63, Volume 3) is variable by room location and site. For example, there is a greater diversity of plant pollen in the front rooms at LA 135290, with similar amounts of maize pollen in both front and back rooms. This would appear to support the contention of the front rooms being used as domestic space and the back rooms as storage. However, the pollen spectra are similar for both front and back rooms at LA 86534 and vary between front and back rooms at LA 12587. That is, the front rooms at LA 12587 contain relatively more maize and beeweed pollen while the back rooms contain more cheno-am, grass, sage, and pine pollen. Overall, cultigen abundance can be high in the front or back rooms; however, prickly pear pollen tends to be associated with the front rooms, with beeweed and cheno-am pollen usually being higher in back rooms.

The single kiva at LA 86534 is circular-shaped, with an east-oriented ventilator shaft, deflector, ash pit, hearth, and sipapu. It appears that the entrance was through the back wall into an adjacent room and not through the roof (Chapter 24, Volume 2). Maize, cholla, prickly pear, and sunflower pollen were all identified on the kiva floor.

A study by Harmon et al. (Chapter 71, Volume 3) indicates some important differences in room size and function for LA 4618, LA 86534, LA 12587, and LA 135290 (Figure 86.7). It appears that the sites without kivas tend to have larger rooms (both front and back); whereas, the sites with kivas have a large ceremonial room, but the other rooms tend to be smaller. Nonetheless, habitation rooms with hearths are generally larger than the rear storage rooms at all the sites. In addition, McBride (Chapter 62, Volume 3) notes that maize is more ubiquitous in samples from the non-kiva versus the sites with kivas. The occupation of these non-kiva sites may therefore have involved a greater emphasis on agriculture.

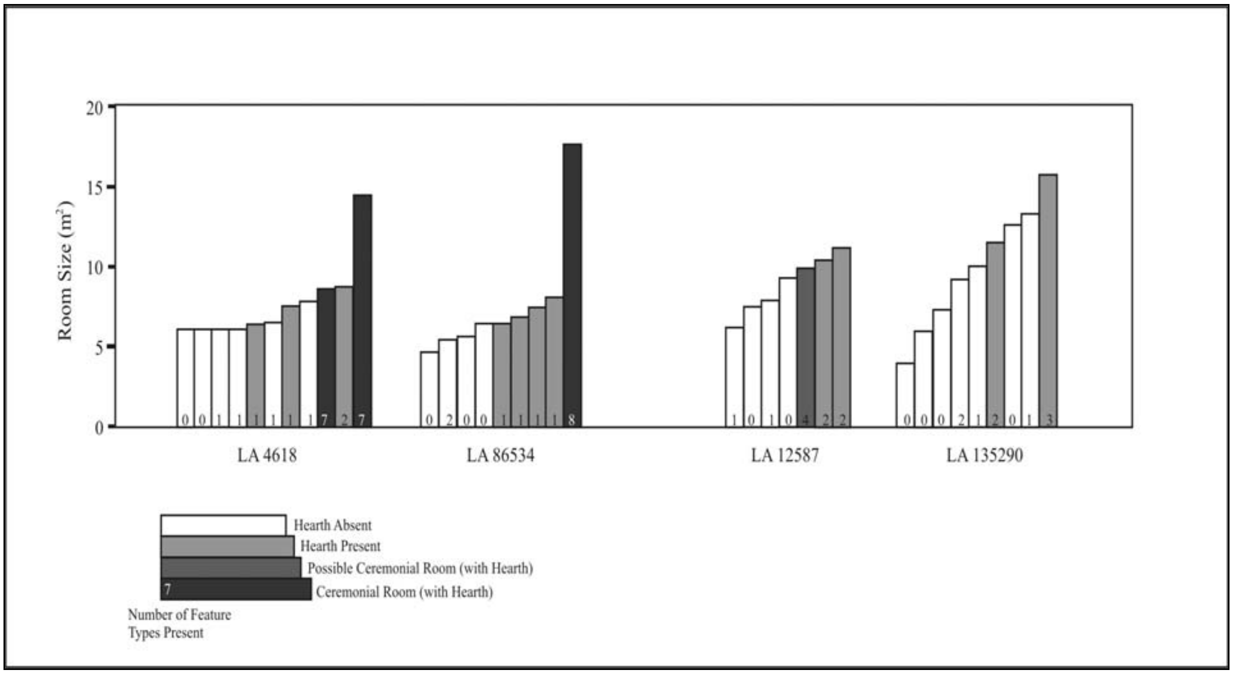

Figure 86.7. Room size at Coalition period roomblocks.

6. **Is there an outside midden area located to the east of the roomblocks?**

A light surface scatter of artifacts was identified to the east of the Middle Coalition roomblocks at LA 86534 and LA 135290, however, no clear evidence of a midden was identified. On the other hand, a 50-cm-thick midden deposit was exposed at the Late Coalition period site of LA 12587. It appears that this latter site was occupied for a longer period of time, with several burials being interred at this location.

7. **Are there exterior activity areas present adjacent to the roomblocks?**

There was no obvious evidence of an exterior activity area present adjacent to the roomblock at LA 86534. In contrast, the front rooms at LA 135290 may represent ramadas that could have been used for outside activities. In addition, there is a possible agricultural feature situated to the immediate east of the roomblock, but it is undetermined as to whether it is associated with the roomblock or a later occupation.

Although no clear activity areas were defined at LA 12587, an exterior cist was present along the east wall of the structure and a large tuff mortar was recovered from the back hoe excavations to the immediate east of the structure. The following charred botanical remains were identified from the contents of the cist: pigweed, sagebrush, saltbush/greasewood, goosefoot, cheno-ams, bugseed, unknown conifer, juniper, unidentified pine, piñon pine, ponderosa pine, prickly pear, cottonwood/willow, and maize.

8. What architectural style was used in the construction of the walls?

A variety of architectural styles were used in the construction of the walls at LA 12587, LA 86534, and LA 135290. As previously noted, the front rooms at LA 135290 were constructed of shaped and unshaped tuff block masonry and the back rooms of adobe. Given that the back room walls and floors were consistently burned, it appears that this area was used for storage. Nonetheless, the masonry walls also differed across the site. Some walls were multiple layers of tuff blocks with adobe mortar; whereas, other walls contain larger tuff blocks or upright blocks along the basal sections of the walls, with rows of smaller tuff blocks in the upper section. Lastly, it appears that the rear adobe walls were also capped with masonry.

A diversity of styles is also represented at LA 12587. These walls are built of shaped and unshaped tuff blocks, adobe mortar, and chinking stones. Additionally, dacite cobbles are occasionally used as masonry and one adobe block was encountered during excavation. Most basal courses consist of large tuff uprights set into adobe and/or sunk beneath the floor surface. In one wall these uprights are covered with multiple layers of adobe (turtlebacks) forming a thick platform upon which the overlying course is laid. In several walls the basal course consists of core and veneer segments separated by upright tuff blocks that are perpendicular to the length of the wall. The veneer consists of a thick layer of adobe set with small tuff stones, whereas, the core consists of sediment and rubble. The basal course of one wall consists of two parallel rows of upright tabular tuff blocks, with sediment and rubble probably filling the space between these uprights. The few upper courses still present consist of shaped and unshaped tuff blocks set in adobe and reinforced with chinking stones.

In contrast to the other two sites, the masonry at LA 86534 is consistently made of shaped and unshaped tuff blocks, which are a single course wide, and set into adobe mortar with chinking stones. The one difference is that the kiva was constructed by cutting a pit directly into the bedrock with some tuff block masonry being present at ground level.

9. What is the construction history of the roomblock? Is it similar to the plan used at Nake'muu?

Nake'muu is the only standing-walled pueblo at LANL. Although the final configuration of the site is a plaza-oriented pueblo, this was not the initial site layout. The initial site layout consisted of two separate sets of linear roomblocks with front and back rooms. In each case, the smaller back rooms were built as a single unit and then the larger front rooms bonded to this central wall. In this case, site construction was characterized by rows, rather than blocks of rooms (Nordby et al. 1998; 2003; Vierra and Foxx Chapter 75, Volume 4).

The construction history of LA 135290 follows a similar pattern. That is, the back rooms (Rooms 4 to 6) were constructed first and the front rooms (Rooms 1 and 2) bonded to the back room walls. Room 8 (plaza room) was also constructed during this time. This involved the initial construction of the north-south back wall, the addition of the east-west walls in the back rooms, followed by the central north-south wall and then the front rooms. Later, Room 3 (front) and Room 7 (back) were added on to the southern end of the roomblock and Room 9 as another plaza room. A similar pattern is represented at LA 86534. However, in this case it appears that the central north-south wall was built first, with the wall between back Rooms 6 and 8 built at the same time. The east-west walls in the back rooms were then built, followed by the back north-south wall. It then appears that the front rooms were abutted on to the central north-south wall. Again, a similar pattern is evident at LA 12587. Many of the room corners of the pueblo were in poor condition, thereby making bonding versus abutment determinations quite difficult. Nonetheless, it appears that the central north-south wall was built first and that the other front/back rooms added to it. It could not be determined whether the front or back rooms were the first to be added on to the central wall. Room 9 appears to represent a later back room addition to the south end of the pueblo.

10. Is there any evidence of remodeling in the roomblocks?

LA 135290 contains the greatest evidence of remodeling for the three excavated pueblos. At least three separate occupations are represented by multiple floors in the back rooms. In addition, the hearth in Room 8 was remodeled with two use-events, and there is a temporal sequence of three hearth features present in Room 2. Lastly, Rooms 3 (front), 7 (back), and 9 (plaza) reflect later additions to the southern end of pueblo. On the other hand, LA 86534 contains no evidence for the remodeling of any walls. The only evidence of remodeling is the hearth in Room 1 that represents two use-events. The nature of the standing architecture is difficult to determine given the poor condition of the walls at LA 12587; however, Room 9 (back) certainly represents a later addition to the southern end of the pueblo. Again, hearths in Rooms 4/5 and 7 appear to have been remodeled with two use-events.

11. Do the fieldhouses represent short-term residences, or is there any evidence that they might have been used as long-term habitations?

Harmon et al. (Chapter 71, Volume 3) describe the variability represented by the fieldhouses. In this chapter, Lockard notes that 20 of the Rendija Canyon fieldhouses consist of a single room, with only one having two rooms. Seventeen of the one-room fieldhouses are rectangular in form and one is circular. The form of the two remaining one-room fieldhouses could not be determined due to extensive disturbance of their wall foundations. The estimated masonry wall height for the fieldhouses ranges from 0.94 to 1.63 m, with an average of 1.17 m. Based on the burned remains from LA 85417, the upper structure was presumably built of wattle and daub. Only six of the fieldhouses contained hearths, whereas, both rooms at the two-room structure contained hearths. The number of artifacts recovered from the fieldhouses ranges from 9 to 772, with an average of 253. An above average number of artifacts were recovered from all six of the sites that contained hearths. On the other hand, sites without hearths contained fewer artifacts. This indicates that the sites with hearths were more intensively occupied than sites without hearths. The two-room structure (LA 85411) contains two rectangular-shaped rooms with hearths and an exterior wing wall that encloses a small plaza area. A total of about 430 artifacts were recovered during the site excavation, indicating that it represents one of the longer occupied structures.

12. How does the architecture at the fieldhouses compare to Coalition and Classic period roomblock sites?

Again, Lockard (Harmon et al., Chapter 71, Volume 3) provides information on fieldhouse architecture. The wall foundations of the Rendija Canyon fieldhouses are generally constructed of dacite cobbles and/or slabs. In the case of 17 of the fieldhouses, the entire wall masonry consists of only dacite cobbles. The remaining fieldhouses have masonry that consists of a mix of dacite cobbles, tuff cobbles, and/or shaped blocks. This generally depends on the availability of local building materials. As previously noted the estimated masonry wall height for the fieldhouses ranges from 0.94 to 1.63 m, with an average of 1.17 m. Based on the burned remains from LA 85417, the upper structure was presumably built of wattle and daub. Overall, the construction of these temporary structures is quite different from that exhibited at the Coalition and Classic period pueblos. The pueblos have full height masonry walls that are primarily composed of small to medium versus large tuff blocks at the Coalition and Classic period sites, respectively. Although a Classic period fieldhouse in the area of White Rock was observed with large shaped tuff block masonry, the other excavated Classic period fieldhouses in the White Rock Tract are composed of one to three courses of small- to medium-size tuff block masonry, including both shaped and unshaped pieces of building stone. This building material could have been scavenged from the nearby Coalition period site of LA 12587.

13. What construction techniques were used for agricultural features?

Three sets of Classic period grid gardens were excavated at LA 12587, LA 128803, and LA 139418 (Figure 86.8). Feature 22 at LA 12587 consists of three east-west-running berms of unshaped tuff blocks. The berms are 4 to 5 m long, 0.5 to 1.5 m wide, and 0.15 to 0.20 m high. A few rocks on the west side of the feature created a rough boundary that could form an "E" shape to the feature. If so, the feature is set at an oblique angle to the direction of the slope. The tuff blocks making up the feature are loosely placed together and stacked no more than three high. The A horizon (sandy loam) is somewhat deeper inside the feature, indicating that some of this dirt was intentionally placed inside the berms.

The grid garden at LA 128805 was constructed of local basalt cobbles. The feature consists of two U-shaped grids with a connecting wall that measures 4 by 6 m in size. The opening of each grid is perpendicular to the slope of the hill. Presumably the water drained over the side walls and was caught within the grid. It appears that the native clayey soil was removed from inside the grids and replaced with a more arable mixture of silty loam soil.

The grid garden at LA 139418 consists of a central grid with two partial grids on either side, measuring 3 by 7 m in size. The grids are situated parallel to the slope, allowing the water to flow into the open end of the northern grid. The basal portion of the north and south walls of the central grid were constructed with thin and wide pieces of tuff that were overlain with narrow and larger blocks. On the other hand, the east and west walls were built of a single course of tuff blocks that were mostly situated in an upright position. In contrast, the outside grids were constructed with a single course of shaped and unshaped tuff blocks. Again, the geomorphic study indicates that the grids were filled with a loose, unconsolidated silty loam with small rocks and gravel that appears to be culturally modified.

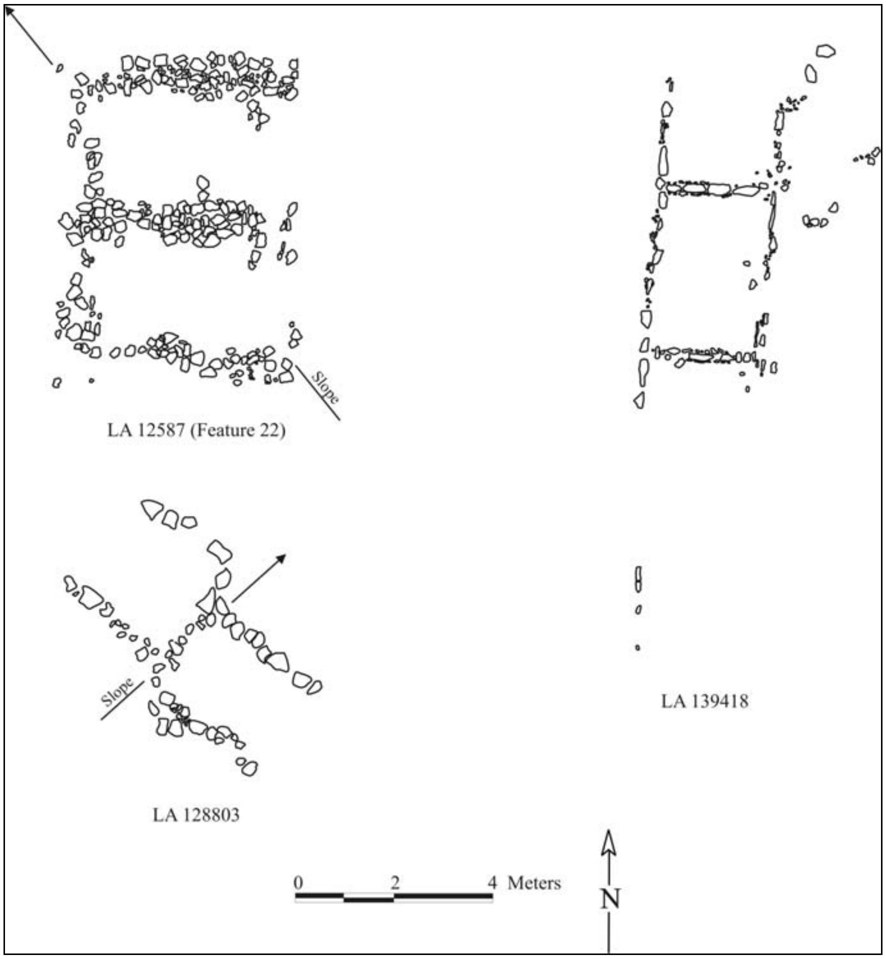

Figure 86.8. Grid gardens at LA 12587, LA 128803, and LA 139418.

14. Can site structure studies identify the internal organization of Ceramic period artifact scatters? If so, what evidence is there for identifying the occupying group size, structure, and site occupational history?

Multi-component lithic and ceramic scatters were present at LA 86637 and LA 127625 in the White Rock Tract. Both of these are situated in secondary context and contain potential Archaic and Ceramic period components. Therefore, the site lacks site structural integrity. LA 86533 and LA 139418 also contain Archaic and Ceramic period components on sites located in the Airport Tract. LA 86533 is a very diffuse artifact scatter; however, LA 139418 exhibited two primary surface artifact clusters in the eastern (Area 2) and southern (Area 3) sections of the site. Most of these artifacts included the by-products of lithic reduction activities, although a few ceramics were present. Nonetheless, the lithic assemblage was dominated by chalcedony core reduction activities, which are more likely to represent a Ceramic period versus Archaic period occupation. Detailed site structure information is lacking, but both Coalition and Classic period occupations appear to be represented.

15. Do LA 85864 and LA 85869 represent Athabaskan campsites?

Both sites appear to represent Jicarilla Apache tipi ring sites that were occupied circa the turn of the 20th century. LA 85864 contains a single rock ring and LA 85869 contains two rock rings. Small charcoal concentrations were present within both tipi rings at LA 85869, indicating the presence of a warming hearth, but no in situ fire. Artifacts recovered from LA 85869 include a .50-caliber unalloyed lead ball, *coscojos* fragments, possible cone tinkler fragments, a pony bead, and numerous seed beads. Seven micaceous sherds that represent two jars and one non-micaceous plainware sherd were also found. One of the vessels can be attributed to Taos, Picuris, or Jicarilla makers, whereas the other vessel was probably made by Jicarilla Apaches and is of the Cimarron Micaceous type. A single micaceous sherd was submitted for luminescence dating, providing a date of AD 1859±13. The lithic assemblage contains a mix of core reduction and tool production /maintenance activities, with an exterior lithic reduction area being located adjacent to one of the tipi rings. Otherwise, most of the worked obsidian appears to have been derived from the nearby Valle Grande caldera source.

16. Given that the Serna Homestead appears to have been sporadically occupied during the growing season, how does the organization of this site contrast with the Romero Homestead that was occupied continuously during the growing season?

Recent excavations were conducted at the McDougall Homestead site located adjacent to the Romero Homestead (McGehee et al. 2006). Comparisons will therefore be made between the McDougall and Serna Homesteads because both of the historic artifact collections were analyzed by Charles Haecker (Chapter 32, Volume 2; McGehee et al. 2006). Comparison of the Serna and McDougall homesteads indicate not-surprising idiosyncratic differences between the daily routines of the two households. As examples, the McDougall household indulged in alcoholic beverages and tobacco, whereas these indulgences were virtually absent at the Serna Homestead. Extensive food can refuse is present at the McDougall Homestead, but significantly fewer cans are present at the Serna Homestead. This difference is presumably due to the Sernas occupying their homestead on a seasonal basis, in contrast, to the McDougalls who lived on their homestead year-round. The McDougall residence also contains a basement where household items and food could have been stored. This too indicates a longer period of occupation. Otherwise, most of the artifact assemblage is similar between the two sites, with the exception of more canning jars being present at the McDougall Homestead. Again, this would stress the importance of stored foods and a longer period of site occupation. Nonetheless, an horno and a corral are present at the Serna Homestead, with a masonry-lined cistern being present at the McDougall Homestead.

SUBSISTENCE AND SEASONALITY RESEARCH QUESTIONS

1. What subsistence foods were exploited by Archaic peoples on the plateau?

No direct evidence of subsistence items were recovered from any of the Archaic sites. The presence of projectile points, bifaces, and ground stone indicate that hunting and gathering activities were occurring.

2. **During what season(s) of the year were Archaic peoples occupying the plateau?**

There is no direct evidence for season(s) of occupation from any of the Archaic sites.

3. **Are there differences in foods and season(s) of occupations between the Early and Late Archaic occupations?**

There is no direct evidence for subsistence or season(s) of occupation from any of the Archaic sites.

4. **Are there differences in foods and season(s) of occupations between Archaic sites in the piñon-juniper versus the ponderosa pine zone?**

There is no direct evidence for subsistence or season(s) of occupation from any of the Archaic sites.

5. **What subsistence foods are represented at the Coalition period habitation sites?**

A variety of botanical remains were recovered during the excavation of the Coalition period habitation sites. The potential economic species identified during McBride's (Chapter 62, Volume 3) analysis consist of maize, beans, squash, beeweed, cheno-am seeds, dropseed grass, four-wing saltbush, goosefoot, ground cherry, mint, pigweed, prickly pear, piñon nuts, purslane, ricegrass, sunflower, and tobacco. Maize cobs included 8- to 14-rowed varieties.

A diverse array of pollen remains were also identified during Smith's (Chapter 63, Volume 3) analysis of the soil samples from the Coalition period roomblocks. The potential economic species include maize, beeweed, cholla, prickly pear, squash, cotton, cheno-am, sunflower, lily family (e.g., yucca), purslane, and rose family.

The remains of various animal species identified at these sites includes turkey, jackrabbit, cottontail, rock squirrel, gray fox, coyote, domestic dog, pronghorn, mule deer, and several different birds (Chapter 64, Volume 3). Elk remains are absent from these assemblages, but they have been identified at other sites in the northern Rio Grande region (Chapter 80, Volume 4). There do, however, seem to be some differences in the relative abundance of certain species through time. For example, mule deer remains are more abundant at the Middle Coalition sites versus turkey and large bird remains at the Late Coalition sites. It appears that mule deer are actually more abundant than rabbit at each site, which is unusual for Southwestern archaeological faunal assemblages. This is presumably due to the upland setting of these sites versus the lowland setting for most Southwestern sites. At any rate, the increased abundance of turkey during the Late Coalition period corresponds with the increased abundance of maize at these sites. Both appear to be indicators of subsistence intensification during this later time period. Lastly, two varieties of turkey were identified. The smaller variety was recovered from midden contexts and the larger variety from room and kiva contexts. These differences in size and context could reflect wild versus domesticated turkeys.

6. Were the Coalition period habitation sites occupied seasonally or throughout the year?

LA 86534 contains a kiva and LA 12587 a midden, with both sites containing domestic and storage rooms. Indeed, burned maize cobs were stored in one of the rooms at LA 12587. Overall, the evidence would seem to indicate that these sites were occupied throughout the year. Nonetheless, as McBride (Chapter 62, Volume 3) points out, the habitation sites without kivas appear to exhibit a stronger focus on agricultural activities than those sites with kivas (including LA 4618). The pollen evidence also indicates a strong agricultural focus for LA 135290. This site contains back storage rooms that were built of adobe and then burned to harden the floor areas. This activity was repeated during the subsequent two periods of occupation. On the other hand, the lack of a midden deposit indicates that this site experienced a much lower occupational intensity than the non-kiva site at LA 12587, but a similar occupational intensity as the nearby kiva site at LA 86534. So, the variability exhibited by the excavated Coalition period roomblocks indicates a range in site function and occupational histories. Presumably LA 86534, LA 12587, and LA 4618 were all occupied throughout the year; however, it is unclear as to whether LA 135290 was occupied on a seasonal basis or throughout the year. It is possible that the site was occupied for part of the year, with the back rooms being used for storage without the occupants residing there; however, this would seem unlikely.

Smith (Chapter 63, Volume 3) discusses the issue of seasonality and notes that the pollen results cannot determine whether roomblocks were occupied year-round, but there are seasonal signals in the data. The overwhelming evidence for maize agriculture indicates spring through early fall occupation. The interpretation of the use of cholla as a cultigen at the pueblos supports an interpretation of late spring activities, as most cacti species flower between late April and June. Lily family encompasses both early spring plants (e.g., wild onion) and late spring and early summer resources, such as yucca. The prickly pear fruits or tunas are harvested later in the summer and into the early fall months. Beeweed, several cheno-am, and sunflower family taxa are late summer through early fall resources.

7. What subsistence foods are represented at fieldhouses?

Very few botanical remains were recovered from the Coalition period fieldhouses, with most of the evidence having been derived from the Classic period sites. These economic species include maize, beans, squash, beeweed, bugseed, cheno-am, goosefoot, pigweed, purslane, and tobacco (Chapter 62, Volume 3).

The fieldhouses also contained much less evidence of pollen remains when compared with the habitation sites (Chapter 63, Volume 3). A comparison of floor samples indicates lower pollen concentrations (2069 versus 4677) and a lower mean number of economic species (1.8 versus 3.1), respectively. Economic pollen present at the fieldhouse locations includes maize, squash, pea family, prickly pear, beeweed, sunflower, lily family, purslane, and cholla.

Very few faunal remains were recovered from the fieldhouses (Chapter 64, Volume 3). Taxa identified in the fieldhouses included mule deer, cottontail, pocket gopher, and elk (modern surface remain). Small-medium and medium-large sized mammal remains were also identified.

8. What season(s) were fieldhouses occupied?

Given the economic species identified in Question 7 and the seasonality data presented in Question 6, it would appear that the fieldhouses could have been occupied from spring to fall. Nonetheless, as previously noted, several of the fieldhouses did contain internal hearths. It is therefore possible that at least some of these structures were also occupied during the winter while hunting in the area. Grooved abraders were recovered from LA 85861 and LA 85414, however, an internal hearth was only present at LA 85861.

9. Are there differences in subsistence items and season(s) of occupation between Coalition and Classic period fieldhouses?

As McBride (Chapter 62, Volume 3) notes, the meager non-wood cultural plant material from Coalition period fieldhouses consists of burned cheno-am and purslane seeds, grass stems, and immature piñon nuts. Although lacking the diversity of taxa from Classic fieldhouses, the assemblage from one of the Coalition fieldhouses (LA 85861) resembles those of several Classic period fieldhouses in that beeweed seeds were recovered in two samples from the hearth. The increased plant species diversity represented at the Classic period fieldhouses may indicate an increase in the number of species being cultivated (or collected), that they were occupied for a longer part of the growing season, and/or that differential preservation is a factor.

Smith (Chapter 63, Volume 3) also identified a similar pattern with Classic period fieldhouses exhibiting a higher representation of maize than Coalition period fieldhouses. Of the 39 floor samples collected from 16 Classic period fieldhouses, 12 (33%) produced maize pollen as compared to 2 of 9 floor samples (22%) with maize pollen from five Coalition period sites. Only three Classic sites did not produce any maize pollen, but two of the Coalition sites lack maize. The pollen samples collected from LA 85413 produced the highest maize and beeweed concentrations of all the Rendija Tract fieldhouses.

10. What crops were grown in the agricultural features (e.g., grid gardens)?

As previously noted, three sets of Classic period grid gardens were excavated at LA 12587, LA 128803, and LA 139418. Very few botanical remains were recovered from the grid gardens, however, these include carbonized maize cupules, goosefoot, and cheno-am seeds and wood charcoal (Chapter 62, Volume 3). Otherwise, most of the botanical evidence was derived from the pollen remains (Chapter 63, Volume 3). Most of the pollen identified in the grid gardens consists of cheno-ams, sunflower, and piñon. However, pollen representation from these features is intermediate between fieldhouses and pueblos. That is, cheno-am percentages from gardens are moderate, and piñon and juniper values tend to be higher than observed within structures. This pattern makes sense, as gardens were open to atmospheric pollen deposition; thus tree pollen input drives the conifer percentages higher. The feature sampled at LA 12587 is an exception among the gardens, with pollen concentrations and cheno-am percentages comparable to the LA 12587 roomblock. Otherwise, maize is represented in all three features, with its abundance being greatest at LA 12587 (93%), with less at LA 128803 (44%), and the least at LA 139418 (15%). Cotton pollen was also documented at LA 12587 and LA 128803.

Lastly, although cholla and prickly pear pollen were identified in all of the features, their relative abundance is significantly greater at LA 12587, indicating that they may have been cultivated.

11. What subsistence foods were exploited at the possible Athabaskan campsites?

Very few botanical remains were recovered from the two Jicarilla Apache sites, however, charred goosefoot and a possible wheat seed were identified. Otherwise, beeweed and sunflower pollen were the only other potential economic plant species identified.

12. During what season(s) were the possible Athabaskan campsites occupied?

The presence of goosefoot and sunflower could indicate a late summer or early fall occupation. Given the presence of warming hearths within the tipi rings, it seems likely that the occupation was during the fall when the nights were becoming cooler.

13. What subsistence foods are represented at the Serna Homestead? What relative contribution did hunting, gathering, agricultural produce, herding, and store-bought foods provide for the diet?

The plant remains of several cultigens were recovered from the site including maize, bean, grape, and peach. On the other hand, maize pollen was the only domesticated plant pollen identified at the homestead. Prickly pear, beeweed, and sunflower pollen was also present, but it is not known whether these were environmentally or culturally introduced. The paucity of plant remains is surprising given that informants state that 40 acres of beans, corn, wheat, pumpkins, and various vegetables were cultivated at the homestead. In addition, only 27 pieces of bone were recovered from the site, including cow, goat, deer, elk, and blue grouse. The latter three species were presumably hunted in the area.

Haecker (Chapter 32, Volume 2) states that the measurable cans indicate that the homestead inhabitants depended on canned fruits, juices, vegetables, and baked beans. Sardine cans were also present, but represented less than 3 percent of the total number of food cans. In addition, coffee, condensed milk, and lard cans were also identified. Canned meats likely were not a regular item on the menu, and neither were home-canned foods. An informant recalled that his family regularly ate fresh beef (Peterson and Nightengale 1993:66), which would explain the virtual absence of meat cans and the presence of cow bone. Glass containers that once held food or condiments are also present, including canning jars. It is likely that, at least during the harvest season, the Sernas were consuming some of what they were harvesting (e.g., onions, beans, squash, chili, and corn).

14. What evidence for season(s) of occupation is represented at the Serna Homestead?

Informants state that the Serna Homestead was used as a seasonal farm, with the family traveling to the rancho three times during the year: in the spring for planting, the summer to weed and clean the fields, and in September/October to harvest the crops. They stayed about two weeks at a time and brought milk, cows, chickens, and all the supplies and tools they needed (Peterson and González-Peterson 1993). Even though 40 acres of beans, corn, wheat, pumpkins, and various vegetables were cultivated, the archaeological evidence is limited to corn and beans. The limited archaeobotanical evidence could be interpreted as reflecting an occupation during the spring to fall growing season, however, the oral history information refutes this interpretation.

15. How does the subsistence and seasonality information recovered from the Serna Homestead contrast with that recovered from the Romero and Vigil y Montoya Homesteads?

In contrast to the Serna Homestead, the Romero Homestead appears to have been occupied most or all the time from April to November. An informant stated that the Romero family moved to the homestead in "the first part of spring, usually in late April, and stayed until cold weather set in at about the middle of November" (Foxx and Tierney 1999:15). They also brought some chickens and pigs to the rancho in a horse-drawn wagon. Beans were the main crop, with some squash, pumpkins, peas, and corn; whereas, melons, watermelons, and chile were mainly grown in the Rio Grande Valley. A kitchen garden contained peas, pumpkins, sweet corn, and melons, and peach trees were also present on the homestead. Archaeological excavations at the Romero Homestead yielded evidence of cheno-ams, watermelon, squash, sunflower, piñon pine nuts, apricot, wild and domestic plum, domestic cherry, peach, chokecherry, acorn, and maize. Many of the seeds were obtained from deposits adjacent to the cabin where a lean-to had been attached (Foxx and Tierney 1999). Obviously, a much wider variety of plant remains were recovered from the excavations conducted at the Romero Homestead, including several structures and trash dumps. In contrast, very little was recovered from the excavations of the McDougall cabin, including amaranth, goosefoot, grape, and peach seeds (McBride 2006). This paucity could be due to the cabin having burned and the lack of trash deposits at the site. These deposits solely consisted of a surface concentration of cans.

16. How do these data on subsistence and seasonality reflect changes in the long-term use of the plateau from Archaic through Homestead Era times?

Vierra (2003, 2007; Vierra and Foxx 2002; Chapter 75, Volume 4) suggests a changing pattern of land-use from Early to Middle to Late Archaic times. These long-term patterns reflect the increasing use of upland areas like the Pajarito Plateau. However, this interpretation is based on a limited amount of subsistence information. In fact, direct subsistence information is lacking from the excavated Archaic sites on the plateau. Information is solely available from the excavation of two Late Archaic sites situated in the Rio Grande Valley near San Ildefonso Pueblo. The botanical remains recovered from these sites include chenopodium, prickly pear, and squawberry seeds. These sites have been interpreted as representing habitation sites (winter?) based on the lithic assemblages and the presence of a structure and storage facilities at one of the sites, whereby the upland sites are assumed to represent limited campsites (Vierra 2003; Vierra and Foxx Chapter 75, Volume 4). On the other hand, a variety of plant and animal species have been identified from the excavations conducted at Jemez Cave. The botanical remains include maize, yucca, pumpkins, prickly pear, piñon pine, and cotton. The faunal remains include turkey, grouse, crane, bison, ground squirrel, prairie dog, porcupine, black bear, mountain lion, jackrabbit, cottontail, bobcat, skunk, mountain sheep, mule deer, fox, and badger. Not all of these were necessarily introduced by the site occupants, and not all of these are associated with the Archaic occupation of the rockshelter (Alexander and Reiter 1935).

Nonetheless, Ford (1975) suggests that Late Archaic people occupied the rockshelter from late spring to summer based on the growing of maize near the site. Overall, the Late Archaic land-use pattern appears to be characterized by a lowland/upland pattern within restricted areas of the Rio Grande Valley. This may have involved movements from the juniper-savanna in the early summer (Indian ricegrass), to the ponderosa pine/mixed conifer in the mid to late summer (cheno-ams, wild onions, berries, and wild potatoes), and then down to the piñon-juniper woodlands in the fall (acorns, pine nuts, yucca, and cacti). As previously noted, the riverine settings also appear to have been used for winter campsites (Vierra 2003; Vierra and Foxx 2002, Chapter 75, Volume 4).

It seems likely that Archaic foragers continued to seasonally occupy the Pajarito Plateau until the 12th century when agriculturalists began to move into the area as full-time residents. Although a few Developmental period sites are present on the central plateau, these are mostly situated at lower elevations and presumably reflect the first attempt to occupy the plateau by agriculturalists; however, it was probably not productive to implement a year-round strategy until 12- to 14-rowed varieties of maize could be planted in these upland settings (Vierra and Ford 2006, 2007).

Not until the 12th century was the Pajarito Plateau occupied on a year-round basis as reflected by the immigration of Coalition period agriculturalists into the area. Most of these early sites consist of 10- to 20-room pueblos; however, excavations conducted by this project indicate that a variety of floor plans and architectural styles were used in the construction of these roomblocks. As previously noted, it seems likely that LA 12587, LA 86534, and LA 4618 were all occupied throughout the year; however, it is unclear as to whether LA 135290 was occupied seasonally and/or on a year-round basis. A variety of wild and domesticated plants and animals are represented at the sites, but a general lack of remodeling presumably indicates that these sites were occupied for 10 to 15 years and then abandoned once the local resources were exhausted. The roof beams appear to have been removed and subsequently integrated into the new structure. The presence of middens and evidence for subsistence intensification reflects that these Late Coalition period pueblos were occupied for longer periods of time than their Early-Middle Coalition period counterparts.

This evidence of subsistence intensification is also represented in the expansion of farming plots into higher elevation settings during the Late Coalition period. However, as pointed out by Gabler (Chapter 79, Volume 4), there does not appear to be significant difference in the distribution of Coalition versus Classic period fieldhouses in respect to elevation. Nonetheless, comparisons of Late Coalition versus Classic period fieldhouses in Rendija Canyon indicate that the latter were more intensively occupied. This is of course associated with a marked increase in the number of Classic period fieldhouses present in the Rendija Tract, but fieldhouses and grid gardens are also present in the Airport and White Rock tracts during this time period. Overall, these fieldhouses appear to have been occupied during the growing season, with some possibly being used for hunting during the winter months.

Eventually a series of droughts during the 1580s forced the Ancestral Pueblo occupants of the plateau down to the Rio Grande Valley for year-round habitation. Nonetheless, these peoples continued to seasonally use these upland settings for agriculture and hunting and gathering activities. Evidence from test excavations at the Otowi grid gardens indicates that the features continued to be used during the 18th century, with both squash and maize pollen being recovered (Chapter 55, Volume 2). In addition, Steen (1977) suggests that the various game pits situated along deer trails were used from the 17th through the early 19th centuries.

Eventually the plateau was occupied on a seasonal basis by Jicarilla Apaches at the turn of the 20th century. During this time, Apaches roamed this area of the northern Rio Grande prior to the designation of a reservation near Dulce. In addition, the Homestead Act opened up the plateau to mostly Hispanics who filed for patent claims during the 1890s to early 1900s. As previously noted, this was a period of above average rainfall that provided the moisture necessary for dry land farming. The rainfall farming of mostly beans provided a cash crop to the residents who seasonally occupied the plateau during the growing season. Otherwise, their primary residences were located in the nearby Rio Grande Valley. With the exception of the Los Alamos Boys Ranch, it was not until the arrival of the Manhattan Project during the 1940s that the plateau would again witness a year-round occupation.

TECHNOLOGY, PRODUCTION, AND EXCHANGE RESEARCH QUESTIONS

1. **Are the Archaic lithic assemblages dominated by the production and maintenance of bifacial tools?**

The answer to this question is obviously yes, however, it is much more complicated than that. Figure 86.9 illustrates the relationship between core flakes, biface flakes, and angular debris for Archaic (n = 3), Coalition period roomblocks (n = 5), Classic period fieldhouses (n = 2), and Jicarilla Apache (n = 1) sites. As can be seen, the Archaic sites form a cluster with a greater emphasis on bifacial cores and tools and the Coalition period roomblocks another cluster emphasizing core reduction. There are three sites situated between these two groups, including an Archaic site, a fieldhouse, and the Jicarilla Apache site. Nonetheless, significant changes in biface technology were occurring during the Archaic (Chapter 74, Volume 4). The lithic assemblage at LA 85859 indicates that the Early Archaic site occupants were gearing up with bifacial cores at the nearby caldera obsidian source. These cores were then being reduced and used to produce biface blanks for dart points. A similar situation is represented at the La Bajada site (LA 9500), except that the Early Archaic occupants of this site were using dacite instead of obsidian. Figure 86.10 presents an example of bifacial cores and biface blanks from the La Bajada site. This pattern of using bifacial cores and biface blanks for the production of dart points continues during the Middle Archaic period as is represented by the San Jose point technology; however, it changes during the Late Archaic period when flake blanks replace biface blanks for the production of dart points. Analyses of biface flake platform angles at LA 85859 and LA 99397 (Middle-Late Archaic) indicates that the early to middle stage bifacial cores and biface blanks were being reduced at LA 85859 versus early, middle, and late stage bifaces including bifacial knives and points at LA 99397. Therefore, the former site probably represents a temporary campsite and the latter a habitation site (e.g., see Vierra 2003)

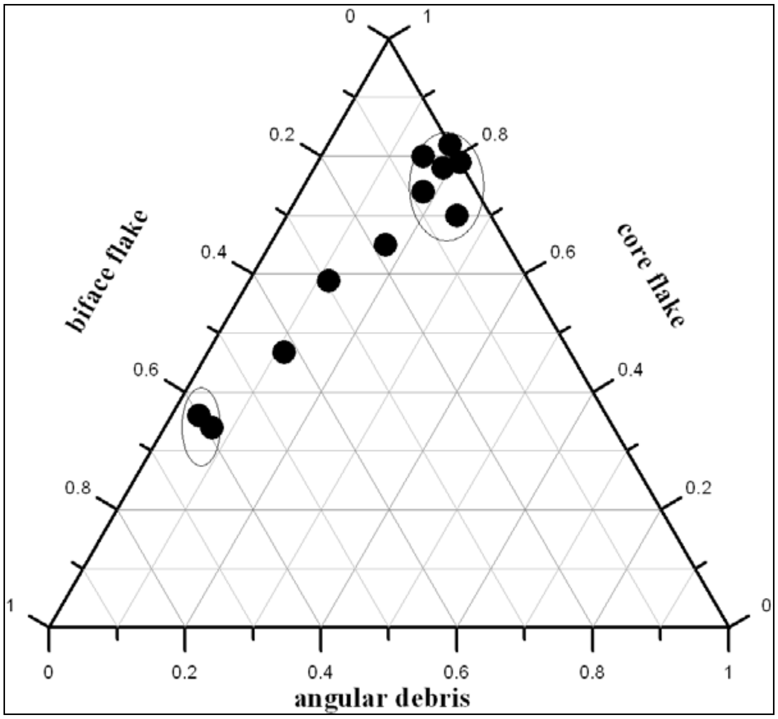

Figure 86.9. The relative distribution of debitage types for Archaic, Ancestral Pueblo, and Jicarilla Apache sites.

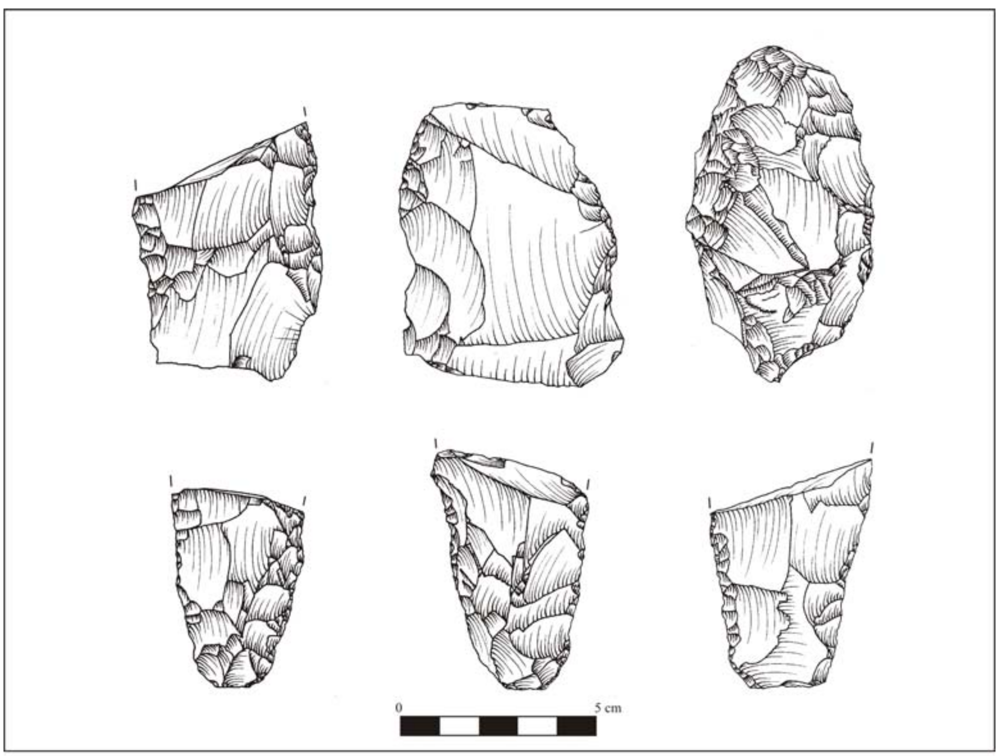

Figure 86.10. Early Archaic bifacial cores (upper) and biface blanks (lower) from the La Bajada site.

2. What nonlocal lithic materials are present on the Archaic sites, in what form were these items brought to the sites, and what artifacts were being produced on these materials?

Figure 86.11 illustrates the distribution of obsidian, chalcedony/chert, and basalt for Archaic, Ancestral Pueblo, and Jicarilla Apache sites. As can be seen, the Archaic and Jicarilla sites form a cluster that is dominated by obsidian, the Ancestral Pueblo sites by chalcedony/chert, and a single fieldhouse by both obsidian and chalcedony/chert. However, the obsidian was obtained from several different sources. Larger cobbles were available from the Valles Caldera (Valle Grande) and the Rabbit Mountain/Obsidian Ridge (Cerro Toledo) source areas; however, small nodules were also scattered in surface lag gravels on the mesa at Rendija Canyon (Cerro Toledo). Nonetheless, it appears that the primary sources were mostly used by the Archaic inhabitants. Larger nodule sizes would have been critical to the production of large biface and flake blanks for the production of dart points and bifacial knives. As previously noted, both bifacial cores and platform cores were being brought to campsites on the plateau for further reduction and tool production. At least some artifacts made of El Rechuelos obsidian were also identified. Given the lack (or paucity) of this material in nearby gravels, it is assumed that most of the material used for the production of these items was obtained to the north near the Abiquiu source area.

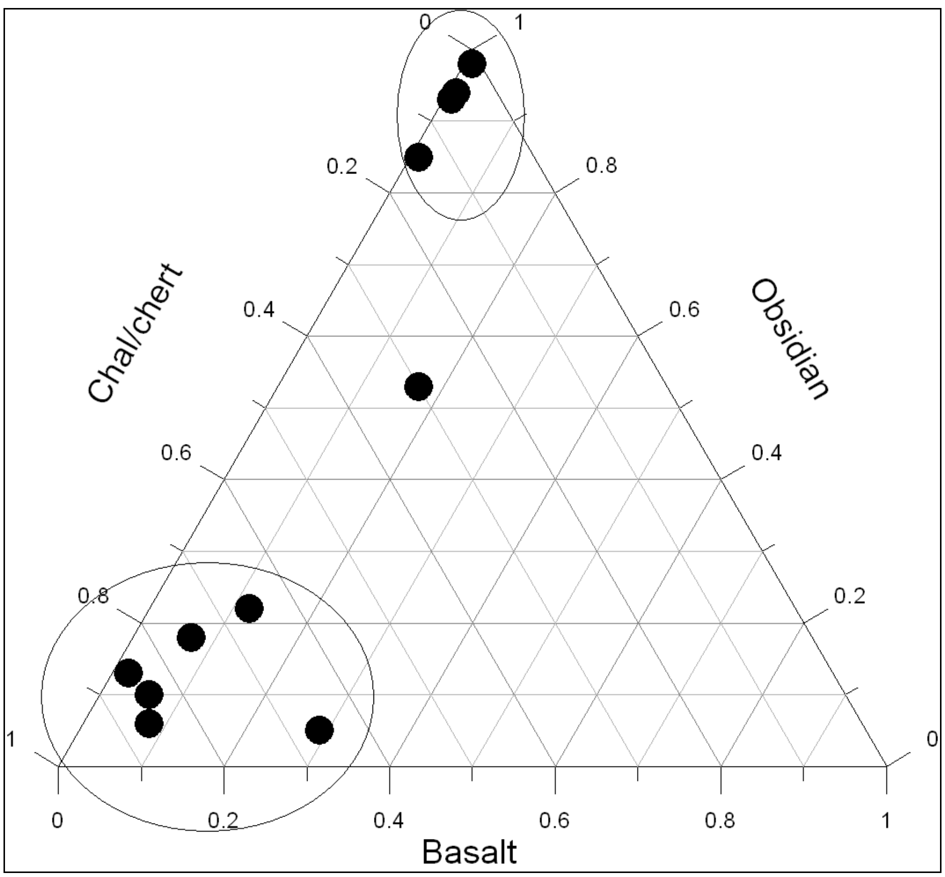

Figure 86.11. The relative distribution of debitage material types for Archaic, Ancestral Pueblo and Jicarilla Apache sites.

3. **What information do these nonlocal materials provide concerning possible Archaic mobility patterns?**

Vierra (2007, Chapter 75, Volume 4; Vierra et al. 2005) presents a potential model for long-term changes in Archaic mobility patterns. This study was based on the X-ray fluorescence (XRF) sourcing of projectile points made of both obsidian and dacite, which are available in the Jemez Mountains (Zone 1) and San Antonio Mountain (Zone 2) areas. It appears that the central Jemez Mountains sources dominate Zone 1 with mostly Cerro Toledo and Valle Grande obsidian; however, the Early Archaic and San Jose points are also represented by obsidian derived from the southern Bear Springs source and a few items from the northern El Rechuelos source. On the other hand, the San Jose points are dominated by the Valle Grande source. Since the Valle Grande obsidian source is restricted to the caldera, this pattern provides support for the contention that these Middle Archaic foragers were integrating these upland resource areas into their summer and fall seasonal rounds, and thereby collecting more of this obsidian. This contrasts with the Cerro Toledo source, which is present along the eastern periphery of the caldera and in secondary deposits along the nearby canyon and Rio Grande Valley.

In contrast, most of the Archaic points are made of El Rechuelos obsidian in Zone 2. However, the Early Archaic reflects a north-south pattern with all three central and northern obsidian sources being represented. San Jose points continue to reflect the importance of Valle Grande obsidian, but now with El Rechuelos. Together, the obsidian data seem to support a north-south seasonal pattern of movement during the Early Archaic period, with a more restricted north-south pattern during the Middle Archaic period. On the other hand, the Late Archaic points were made on flake blanks with shorter tool use-lives. In this case, these points are dominated by the most proximate obsidian source. That is, the central Jemez Mountains sources in Zone 1 and the El Rechuelos source in Zone 2.

The dacite sourcing study corroborates the obsidian study. That is, the Early Archaic points contain examples of dacite derived from all three southern and northern sources. In contrast, the later periods are mostly characterized by the increasing use of local dacite.

4. **Are there significant differences between Early and Late Archaic period stone tool technology, and, if so, what are the implications of these differences for understanding changes in past land-use strategies?**

As Vierra (2007, Chapter 75, Volume 4) points out, changes in Early and Middle Archaic period point technology may be associated with the expansion of piñon-juniper woodlands in the region and a shift from hunting large game in open settings to more medium to small game in wooded settings. This projectile point technology was characterized by low point diversity and low tool replacement rates. In contrast, the Late Archaic period point technology was characterized by high tool replacement rates and high point diversity. Overall, these changing patterns could reflect a "replacement when exhausted" versus a "replacement based on probability of failure" strategy (Kuhn 1989). That is, Early and Middle Archaic groups were residentially mobile, with a technology that was continuously used and maintained; whereas, Late Archaic groups were becoming more logistically organized, while focusing on specific target-species. Higher tool replacement rates would be used as a means of increasing tool reliability (also see Vierra 1992a:104). The changing emphasis on lowland versus upland resource use is reflected in the long-term pattern of using mostly dacite from lowland sources to obsidian derived from upland sources from the Early to Late Archaic period.

5. **Do Ceramic period lithic assemblages emphasize core reduction activities?**

The answer to this question is yes, as illustrated by the cluster of sites emphasizing core reduction in Figure 86.9. All of the Coalition period roomblocks and most of the fieldhouses emphasize core reduction activities; however, one Classic period fieldhouse does exhibit a mix of core reduction and biface production/maintenance activities (LA 128805). This fieldhouse is situated in the White Rock Tract and contains both a one-room structure and associated artifact scatter that dates to the Middle Classic period (15^{th} century). Most of the biface flakes are made of obsidian, with only two obsidian artifacts dating to the Classic period; whereas, the remaining eight artifacts date to the Archaic period. Therefore, at least some of the evidence for biface production could be associated with an older Archaic component.

6. **What nonlocal lithic materials are present on the Ceramic period sites, in what form were these items brought to the sites, and what artifacts were being produced on the materials?**

Obsidian is the only potential nonlocal lithic raw material that appears to have been brought onto the Ceramic period sites. Overall, about 11 percent to 15 percent of the total flake assemblages from roomblock and fieldhouse sites exhibit cortical platforms, indicating that cobble raw materials were being brought to the sites for reduction. On the other hand, most of the flakes exhibit single-faceted platforms (52% to 56%), indicating the reduction of platform (or flake) cores was also important. Obsidian comprises about 5 percent to 10 percent of the Early-Middle Coalition period roomblocks and increases to 17 percent to 22 percent at the Late Coalition and Classic period fieldhouses. Most of these fieldhouses are located in Rendija Canyon where small obsidian nodules were present in surface lag gravels situated on the mesa top. Bipolar reduction was one technique used to reduce these small pebbles. Nonetheless, some of the obsidian present at these sites was also derived from the Valle Grande source located in the nearby caldera. On the other hand, both Cerro Toledo and Valle Grande sources were exploited by the occupants of the Coalition period roomblocks. About 8 percent of the flakes on these sites exhibit cortical platforms, with 34 percent being single-faceted, and 33 percent being crushed. Therefore, both nodules and prepared cores (or flakes) appear to have been brought to the roomblock and fieldhouse sites for reduction.

A total of four prepared cores and a single tested obsidian nodule were identified at the Coalition roomblock sites, whereas, one prepared core and four tested obsidian nodules were recovered from the fieldhouses. The relative increase in tested nodules at the fieldhouses presumably reflects the use of local lag gravels. In contrast, the obsidian materials used at the roomblocks were probably obtained from the original source areas. For example, a large obsidian flake was observed at a Late Coalition period cavate site along Mesita del Buey near the White Rock Tract. The flake is 18.5 cm long and weighs 1274 g. The dorsal surface is covered with nodular cortex, indicating that it represents a large primary flake removed from a very large nodule. XRF analysis indicates that the item was obtained at the Valle Grande source. A similar procurement tactic was employed by Pueblo groups in the Flagstaff area while collecting obsidian from the Government Mountain source (Vierra 1993a).

7. What is the nature of the Ceramic period ground stone assemblages?

The Coalition roomblock sites contain mostly one-hand manos, but two-hand manos are represented as well (Figure 86.12). The percentage of two-hand manos actually increases slightly from the Early/Middle Coalition period to the Late Coalition period at the roomblock sites, but is highest at the Late Coalition period fieldhouses. Slab metates are also present at the roomblock sites, but no trough metates being identified. The fieldhouses contain both one- and two-hand manos, with some grinding slabs and undetermined metate fragments.

The sample sizes vary greatly when attempting to compare mean mano lengths; that is, Early/Middle Coalition roomblock (*n* = 11), Late Coalition roomblocks (*n* = 38), Late Coalition fieldhouses (*n* = 3), and Classic fieldhouses (*n* = 13). These comparisons are also difficult given that two-hand manos tend to be discarded when broken and cannot therefore provide overall length measurements. Nonetheless, there is a similar pattern with smaller mean lengths for Early/Middle Coalition (mean = 133 mm, *std* = 44.9) and Late Coalition roomblocks (mean = 120 mm, *std* = 48.2) versus larger lengths for Late Coalition period fieldhouses (mean = 176.6 mm, *std* = 52.5) and Classic period fieldhouses (mean = 151, *std* = 57.6). This again emphasizes the general importance of smaller-size manos at the roomblock sites.

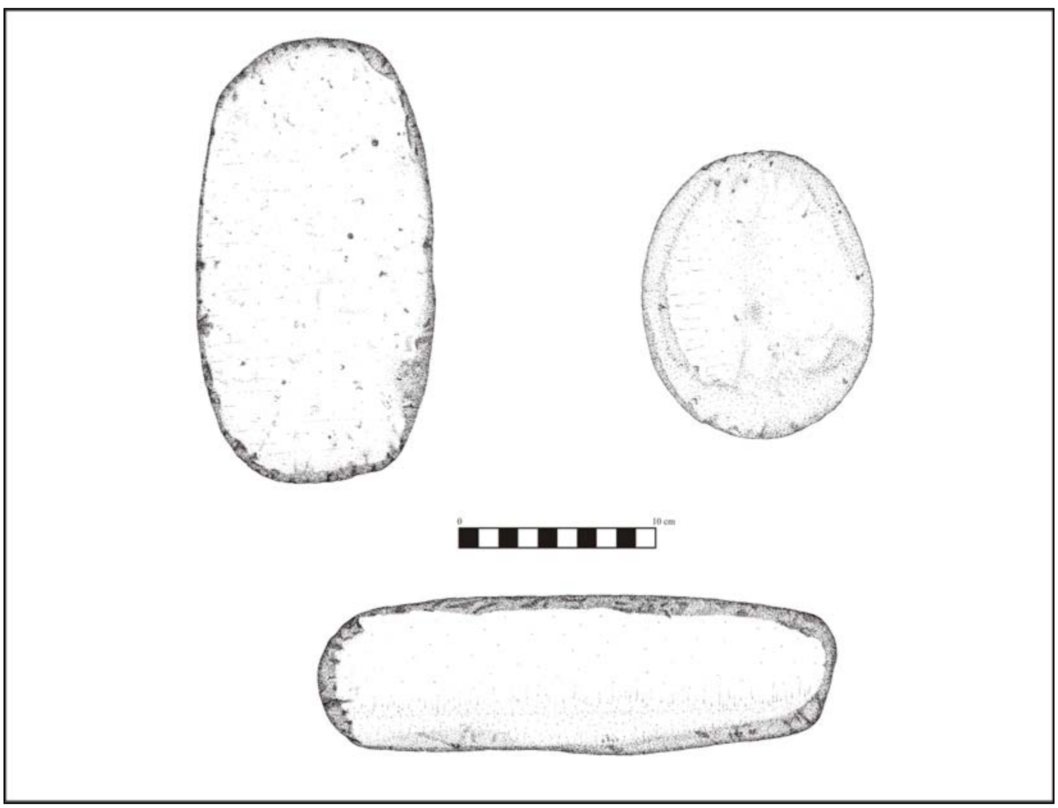

Figure 86.12. One- and two-hand manos.

8. How do the Ceramic period site types differ in respect to chipped and ground stone assemblage composition?

This question has partially been addressed by Questions 5, 6, and 7. That is, both roomblock sites and fieldhouses emphasize chalcedony core reduction activities. Although a single fieldhouse does deviate from this pattern, the increased proportion of biface flakes may actually represent an older Archaic component. Cortical:noncortical flake ratios do vary with somewhat lower ratios at the fieldhouses (0.24 and 0.29) versus higher ratios at the roomblocks (0.35 and 0.38). Given the small assemblage size at most of the fieldhouses, this probably indicates that prepared cores were often being brought to these sites for reduction. However, a closer inspection of cortical platforms by material types also reveals some subtle differences. Cortical platforms make up a minor portion of the flake platform types in all the assemblages, reflecting an emphasis on reducing platform cores at these sites. Nonetheless, the Classic period fieldhouses contain some obsidian (11%) and chalcedony (8%) cortical platforms, but no basalt cortical platforms. In contrast, the Early-Middle Coalition period roomblock assemblages contain obsidian (10%), chalcedony (13%), and basalt (9%) cortical platforms. Lastly, the Late Coalition period roomblock assemblages contain obsidian (9%), chalcedony (26%), and basalt (9%) cortical platforms. This indicates that some local obsidian pebbles and chalcedony cobbles were being brought to the fieldhouses for reduction, with a notable increase in the presence of basalt nodules at the roomblock sites and a marked increase in the reduction of chalcedony cobbles at the Late Coalition period roomblocks. Several cobble unifaces and tested nodules were recovered from the fieldhouses (n = 8). All of the latter are obsidian pebbles. In contrast, only two cobble bifaces and three tested nodules were actually found at the roomblocks. These consist of chalcedony, pedernal chert, basalt, and obsidian materials.

In respect to the ground stone assemblages, both roomblocks and fieldhouses contain mostly one-hand manos with fewer two-hand manos. The Late Coalition period roomblock manos tend to be more heavily used than either the Early-Middle Coalition period or fieldhouse sites; however, the large loaf-shaped two-hand manos were only identified at fieldhouse sites in Rendija Canyon. Lastly, formal slab metates were identified at the roomblock sites versus grinding slabs and undetermined metate fragments at the fieldhouses. Nonetheless, the presence of larger two-hand manos at some fieldhouses indicates that slab metates must have been present at some time.

9. What types of tools are present on Ceramic period agricultural sites?

A single hoe was the only agricultural tool recovered from the three grid garden sites at LA 12587, LA 128803, and LA 139418. It consists of a thin oval-shaped quartzite cobble with notches along either side (Figure 86.13) from LA 128803. Hoes that were presumably used for maintaining their agricultural fields and axes for construction or possibly clearing forested land for field plots were also recovered from fieldhouses.

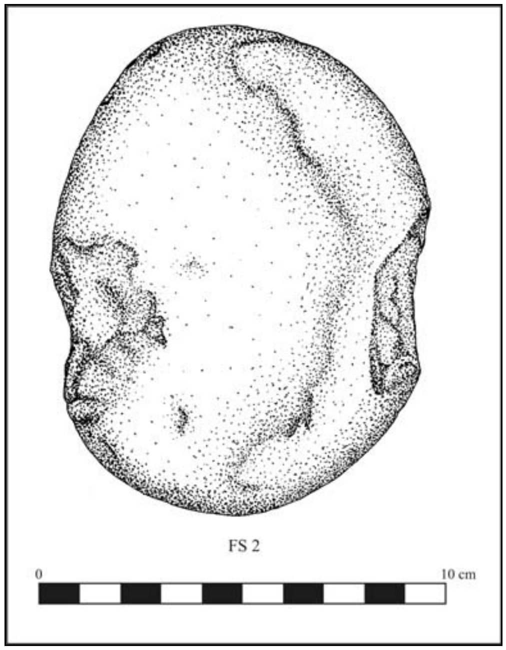

Figure 86.13. Hoe from LA 128803.

10. Can compositional studies of clay and temper sources identify distinctive signatures that can then be used to evaluate long-term changes in ceramic production and exchange on the plateau?

Miksa's (Chapter 59, Volume 3) petrographic study identified five basic temper groups. These groups consist of anthill sand, anthill sand with clay lumps, granitic, Tuff 1, and Tuff 2. Although source samples were taken from local alluvial sands, these were not sufficiently distinct to separate from the anthill. Santa Fe Black-on-white exhibits the greatest degree of variability including all but the granitic temper types. Overall, there appears to be a temporal trend with anthill tempers generally occurring earlier and tuff tempers later in time. This includes more Tuff 2 and less Tuff 1. The majority of the corrugated wares are tempered with anthill sand, although three sherds did contain granitic temper. All the biscuitware sherds are tempered with tuff, although there is more Tuff 1 represented than Tuff 2. Sapawe Micaceous is always tempered with granitic material, whereas most of the plainware pottery is tempered with anthill sand and a few with granitic temper.

11. Can compositional studies of paste and temper identify different sources for these materials? If so, which of these sources are local versus nonlocal?

Miksa's (Chapter 59, Volume 3) petrographic study identified five basic temper types. Four of these appear to be from local sources, consisting of anthill sand, anthill sand with clay lumps, Tuff 1, and Tuff 2; whereas, ceramics with granitic temper were presumably obtained from nearby villages in the Rio Grande Valley. The latter includes all of the Sapawe Micaceous, and a few of the plainware sherds. In addition, three corrugated sherds also exhibited granitic temper. These consist of two smeared-indented corrugated sherds that were recovered from Classic period fieldhouses and an indented corrugated sherd that was obtained from the Coalition period roomblock site at LA 4624. Otherwise, all the Santa Fe Black-on-white and biscuitware sherds appear to have been locally made. However, Curewitz and Harmon (2002) and Dean (2006) note the presence of igneous and sand, and granite and sand temper in several Santa Fe Black-on-white sherds from excavated Coalition period roomblocks on Mesita de Buey near the White Rock Tract. In addition, Dean (Chapter 58, Volume 3) also identified about 50 sherds with granite and sand temper from LA 12587, LA 86534, and LA 135290. These items presumably represent nonlocal trade wares.

12. Can refiring and tensile strength studies help us understand past ceramic production techniques?

Sam Duwe conducted a tensile strength study of Coalition and Classic period ceramics. In his preliminary test, it appears that ceramic strength, and hence durability, remained relatively consistent through the entire Pajarito whiteware chronology (Table 86.3). In fact, tensile strength may have actually *increased* with the advent of biscuitware technology. This is likely due to the average increased width of vessel walls, which likely compensated for the use of a softer and more porous paste.

From this analysis of tensile strength, it appears that although potters in the Classic period were changing the construction techniques and material sources of their pottery, these changes in ceramic technology allowed for the maintenance of vital performance characteristics, such as durability. This would have been important for the pottery to endure both domestic and ceremonial use and also long-distance exchange. Whatever the reasons for the transition to biscuitware technology, certain performance characteristics were inherent in all types of Pajarito whiteware through prehistoric occupation on the northern Pajarito Plateau.

Table 86.3. Results of the Pajarito whiteware ceramic tensile strength analysis.

Type	Date	Site	Unit	Thickness (mm)	Mean Thickness (mm)	Load (lbs)	Mean Load (lbs)

13. What nonlocal ceramics are present during the Coalition period? Besides the Red Mountain whitewares, is there evidence for the presence of nonlocal Santa Fe Black-on-white or other intra-regional painted wares? What are the implications of these data for understanding regional trade networks?

Nonlocal ceramics are very rare at Coalition period sites (Chapter 58, Volume 3). The Early-Middle Coalition sites of LA 86534 and LA 135290 contain eight Chupadero Black-on-white and three Reserve Smudged sherds, which indicate ties with the Jornada Mogollon to the south; whereas, a Gallup Black-on-white, a Socorro Black-on-white, and two Cibola whiteware sherds reflect ties to the west and to the San Juan Basin. Lastly, two White Mountain redwares also represent long-distance trade relationships to the west into east-central Arizona. The petrographic analysis indicates that all the sampled Santa Fe Black-on-white sherds were locally made (Chapter 59, Volume 3). The presence of Mogollon and Cibola ceramics may reflect ancestral ties by immigrants from the lower Rio Grande Valley and San Juan Basin to the Pajarito Plateau. In contrast, the White Mountain redwares reflect a region-wide Pueblo III exchange network that links many of these upland communities.

The Late Coalition site of LA 12587 contains a single Chupadero Black-on-white and three Reserve Smudged sherds, which indicate continuing ties to the south; however, the absence of any Jornada Mogollon ceramics at LA 4618 also reflects that these ties were more restricted (or terminated) near the latter part of the Coalition period. On the other hand, the presence of a Tularosa Black-on-white and six Cibola sherds reflects continuing ties to the San Juan Basin, and seven White Mountain redware, and four St. Johns Black-on-red and St. Johns Polychrome sherds to the regional Pueblo III trade network. On the other hand, two Gallina Black-on-white and four Mesa Verde Black-on-white sherds were also recovered from both sites, again reflecting subtle changes in regional contacts (recent immigrants?) during the latter part of the Coalition period. Gabler's (Chapter 79, Volume 4) study does identify peak population levels on the central plateau at about AD 1300 to 1350. This peak could reflect a second immigration into the area, this time from the four-corners region. Nonetheless, Duwe's (Chapter 77, Volume 4) analysis of the ceramic assemblage from Otowi, which includes Late Coalition and Early Classic period components, failed to identify any non-local Pueblo III ceramics (with the exception of three Red Mountain redware sherds). Two of these sherds were recovered from the older Late Coalition period component situated at Roomblock A. Overall, the ceramic evidence indicates that there was only a limited amount of regional interaction between the residents of the Pajarito Plateau and their neighbors during the Coalition period, although the effects of immigration into the area are still poorly understood.

14. What nonlocal ceramics are present during the Classic period? Besides the glazewares, is there evidence for the presence of nonlocal biscuitwares and utilitywares? What are the implications of these data for understanding regional trade networks?

The limited evidence of regional interaction that characterizes the Coalition period changed dramatically during the Classic period. There is a marked increase in the trade relationships between the occupants of the Pajarito Plateau and their Tewa neighbors in the nearby Rio Grande Valley. This is best illustrated by the presence of Sapawe Micaceous at the Classic period fieldhouses. Duwe's (Chapter 77, Volume 4) study at Otowi and Tsirege determined that micaceous ceramics composed 59 percent and 35 percent of the utilitywares, respectively. In addition, a locally produced micaceous slipped pottery was also identified at the Classic period fieldhouses, which appears to mimic the nonlocal type. Curewitz's (Chapter 76, Volume 4) study also identified that vessel size range, the proportion of large jars, and the degree of size standardization increases for utilitywares from the Coalition to the Classic period at sites on the Pajarito Plateau. The production of large jars requires a higher degree of skill, and these may have been made by fewer potters, resulting in a more standardized size range. However, it is unclear as to whether these Classic period jars were being exchanged with communities in the nearby valley.

Small amounts of nonlocal glazeware sherds are represented at the Classic period fieldhouses (3 to 8%). Otherwise, the petrographic analysis indicates that Sapawe Micaceous and a few plainware and corrugated sherds were obtained from villages in the nearby Rio Grande Valley. In contrast, all the sampled biscuitwares were produced using local tuff temper (Chapter 59, Volume 3).

Glazewares compose 5 percent to 12 percent of the decorated ware assemblages at Otowi and Tsirege, respectively (Chapter 77, Volume 4). Larson et al. (1986) determined that most of the glazewares in their sample from Tsirege were being produced on the Pajarito Plateau, with some from Cochiti and the Galisteo Basin. In addition, about 6 percent of the biscuitwares at Tsirege were obtained from the Chama Valley area. Larson et al. (1986) consider that there was more trade among the biscuitware sites than between the biscuitware and glazeware producing sites. On the other hand, Duwe (Chapter 77, Volume 4) suggests that the increase in glazewares at Tsirege may reflect increasing exchange relationships with Keres populations to the south.

Munson's (Chapter 82, Volume 4) rock art study could not identify a clear cut border between Tewa and Keres social boundaries. In fact, the majority of the conflict-related glyphs (e.g., shields) were observed in the area of Otowi and Tsankawi, which is north of the proposed Tewa-Keres boundary along Ancho Canyon. Snead's (Chapter 81, Volume 4) trail study denotes several major east-west trails from the Rio Grande Valley into the Jemez Mountains; however, he also defines an important north-south trail that spanned the entire Pajarito Plateau (the Old Pajarito Trail). This trail includes segments in the area between Tsirege and Mortandad Canyon and the Bayo Staircase near Otowi.

15. **Is there any evidence of ceramic production on the Ceramic period sites? Or, is there any evidence that a lithic and ceramic scatter site could reflect a kiln(s) used in pottery production?**

Petrographic analyses indicate that most of the decorated ceramics were produced using local tuff tempers, whereas, anthill sand was used for the utilitywares (Chapter 59, Volume 3). There seems little doubt that the majority of the Coalition period ceramics and much of the Classic period ceramics were produced by the residents of the Pajarito Plateau. However, no direct evidence of kilns or any other ceramic production features were identified during the excavations. The lithic and ceramic scatters appear to represent limited activity areas or temporary campsites, but not pottery production locales.

16. Is there evidence of ceramic craft specialists during the Classic period, and if so, what are they producing for exchange?

As previously noted, Curewitz's (Chapter 76, Volume 4) study identified that vessel size range, the proportion of large jars, and the degree of size standardization increases for utilitywares from the Coalition to the Classic period at sites on the Pajarito Plateau. The production of large jars requires a higher degree of skill, and these may have been made by fewer potters, resulting in a more standardized size range. However, it is unclear as to whether these Classic period jars were being exchanged with communities in the nearby valley. The biscuitwares are also represented by a marked increase in the proportion of jar forms when contrasted with decorated bowls during the Coalition period.

Duwe's (Chapter 77, Volume 4) study of biscuitwares from Otowi and Tsirege revealed that vessel size and standardization differed between the two sites. In general, the mean size of the Biscuit B bowls recovered from Otowi were smaller than those from Tsirege. Also, Tsirege had a much smaller standard deviation for bowl size than that from Otowi. If consistency of pottery is a sign of standardization, Tsirege is producing more standardized vessels, which could be interpreted as a higher degree of craft specialization. The same sort of relationships between Otowi and Tsirege was also identified when comparing the width of the interior framing line. That is, the standard deviation of framing line width was much smaller at Tsirege when compared with that of Otowi, also indicating increasing craft specialization in pottery production.

Lastly, Miksa (Chapter 59, Volume 3) suggests that the shift from sand and tuff temper sources for the production of Santa Fe Black-on-white to tuff temper sources for the production of biscuitwares represents a "much more controlled selection of materials and possibly much better control of production technology." This also presumably reflects a shift from household production to ceramic specialists.

17. What evidence is there for domestic versus agricultural activities at the Serna Homestead site?

A variety of domestic artifacts were identified at the Serna Homestead, including food cans, commercial food jars, canning jars, medicine bottles, whiteware and stoneware ceramics, kerosene lamp, lard pails, tools, and personal possessions. The latter consists of glass beads, a brooch fragment, a harmonica fragment, a clasp knife fragment, a pocket compass fragment, shirt and blouse fragments, jacket buttons, shoe and boot fragments, a comb, and a cold cream jar. In addition, various tools were also recovered including metal files, scissors, a wrench, and a hacksaw blade. Lastly, a Mexican-style slab metate and one-hand mano were also found near the cabin.

Four horseshoes and one horseshoe nail were identified in the collection, as were fragments of what is believed to be a leather harness. The presence of several fence staples in the collection indicates that the homestead included a wire fence. Strands of barbed wire were also present, with several fence posts still remaining around the periphery of the compound. With the exception of a shovel blade, no other agricultural implements were recovered from the site. Several large pieces of sheet metal with multiple holes punched in them may have been used to wash or clean the beans.

18. Were any manufactured items recycled into other tools?

The only example of a manufactured item being recycled into another tool appears to the use of sheet metal as bean sieves. Multiple holes were punched into large sheets of sheet metal and presumably used to wash or clean the beans.

19. Are there any historic Pueblo ceramics or other artifacts that would indicate interaction between Hispanic homesteaders and local Pueblos?

A total of 10 sherds representing nine historic Pueblo vessels were identified during Eiselt's (Chapter 78, Volume 4) analysis of the Serna Homestead. These consist of two Tewa Blackware sherds, four Tewa Micaceous slipped sherds, and four Hispanic/Tewa Buff sherds. Two of the Tewa Micaceous sherds could have been derived from a vessel produced at nearby San Ildefonso or Santa Clara Pueblos, while the other two sherds could have been derived from a vessel produced at Nambe, Tesuque, or Pojoaque. In addition, an isolated pot drop was recovered from near the Serna Homestead. It is an excellent example of a medium-sized Cimarron Micaceous long-necked olla or cook pot with an orifice diameter of around 26 cm. The 77 recovered fragments include five rim sherds, three neck sherds, and 69 body fragments. The vessel likely dates from around 1850 to 1880 or 1890 based on similarities with dated Jicarilla Apache types in the Río del Oso Valley (Eiselt 2006). In addition, a total of seven micaceous sherds were recovered during the excavations of the McDougall Homestead site west of the White Rock Tract. The ceramic assemblage is small, but relatively diverse with input from Jicarilla Apache, Hispanic, and Tewa or Picurís potters. These sherds were identified as Cimarron Micaceous (n = 4), Hispanic Blackware (n = 1), Peñasco/Tewa Micaceous (n = 1), and indeterminate micaceous (n = 1).

APPENDICES

APPENDIX A
PROGRAMMATIC AGREEMENT

AMONG THE UNITED STATES DEPARTMENT OF ENERGY, THE ADVISORY COUNCIL ON HISTORIC PRESERVATION, THE NEW MEXICO STATE HISTORIC PRESERVATION OFFICER AND THE INCORPORATED COUNTY OF LOS ALAMOS, NEW MEXICO, CONCERNING THE CONVEYANCE OF CERTAIN PARCELS OF LAND TO LOS ALAMOS COUNTY, NEW MEXICO

WHEREAS:

1. Section 632 of Public Law 105-119 (Public Law 105-119) directs the Secretary of Energy to convey to the Incorporated County of Los Alamos, New Mexico (County), or its designee, and to transfer to the Secretary of the Interior in trust for the Pueblo of San Ildefonso (Pueblo), certain parcels of federal land under the administrative control of the Secretary of Energy in the vicinity of Los Alamos National Laboratory.

2. The Department of Energy (DOE) has determined that the conveyance of certain parcels pursuant to Public Law 105-119 to the County may have adverse effects on properties that are eligible for inclusion in the National Register of Historic Places (Historic Properties), and has entered into consultation with the New Mexico State Historic Preservation Officer (SHPO) and the Advisory Council on Historic. Preservation (Council) in accordance with Section 106 of the National Historic Preservation Act, 16 U.S.C.470 et. seq. (Act), its implementing regulations (36 CFR Part 800). DOE, the SHPO, the Council and the County may also be referred to in this Programmatic Agreement (PA) collectively as "the Parties" or "the Consulting Parties" and individually as a "Party."

3. The DOE has identified ten parcels of real property for conveyance, and has performed historic property identification surveys for the ten parcels. All potential historic properties have been evaluated for eligibility to the National Register of Historic Places (Register). SHPO has concurred with these eligibility determinations. It has been determined that historic properties are located in the following eight Parcels: TA-74, DP Road, White Rock Y, White Rock, Airport, LAAO, Manhattan Monument, and Rendija Canyon (Historic Parcels).

4. The *Final Environmental Impact Statement for the Conveyance and Transfer of Certain Land Parcels Administered by the U.* S. *Department of Energy and Located at Los Alamos National Laboratory, Los Alamos and Santa Fe Counties, New Mexico,* 1998, (DOE/EIS-0293) describes the contemplated land use by the County for the White Rock, Airport, LAAO, and Rendija parcels as economic development, and the contemplated land use for the TA-74 and White Rock Y parcels to include cultural preservation, natural areas, transportation, and utilities.

5. The Pueblo and the Bureau of Indian Affairs have participated in the consultation, and have been invited to concur in this PA.

6. The Consulting Parties have agreed that the schedule of the activities associated with the

conveyance of Parcels is set forth in the Conveyance Agreement (Attachment C [draft to be completed]). Environmental restoration and conveyance activities are likely to affect Historic Properties. It is appropriate for the DOE in this PA to set forth processes for the treatment and management of historic properties identified in the *Cultural Resources Assessment for the Department of Energy Conveyance and Transfer Project,* LA-CP-00-179, and the *Historic Building Assessment for the Department of Energy Conveyance and Transfer Project,* LA-UR-OO-I03.

7. The Consulting Parties have considered the applicable requirements of the Act, the American Indian Religious Freedom Act, 42 U.S.C. 1996 et. seq. (AIRFA), Executive Order 13007, Native American Sacred Sites (EO 13007), the Native American Graves Protection and Repatriation Act (NAGPRA), New Mexico Unmarked Burial Statute (18-6-11.2, NMSA 1978), the Archeological Resources Protection Act, 16 U.S.C. 470aa et. seq. (ARPA) and Public Law 105-119 in the course of consultation.

NOW, THEREFORE, the parties agree that they will act in accordance with the following stipulations in order to take into account the effect of the land conveyance activities and plan on Historic Properties in accordance with the Act, AIRFA, EO 13007, NAGPRA, the New Mexico Unmarked Burial Statute (18-6-11.2, NMSA 1978), and ARPA.

STIPULATIONS

I. Transfer to Other Federal Agencies

Notwithstanding any other provision of this PA, it is understood that should the DOE transfer any portion of the parcels to the Bureau of Indian Affairs in trust for the Pueblo, the DOE will implement such transfers through the development of a separate Memorandum of Understanding between the participating parties.

II. The Manhattan Monument, the Department of Energy Los Alamos Area Office buildings (TA-43-39, 41), LANL Archives (TA-21-1001, 1002), and the Incinerator Building (TA-73-2) located on the Airport Parcel.

1. The Manhattan Monument is a contributing element to the National Historic Landmark District (NHL) that includes the Fuller Lodge and the Bathtub Row residences. The Manhattan Monument will be transferred in accordance with the requirements of the NHL designation.

2. The SHPO has concurred with the Register eligibility under criteria A and C for the Department of Energy Los Alamos Area Office Buildings (TA-43-39, 41), the LANL Archives (TA-21-1001-1002), and the eligibility of the incinerator building (TA-73-2 located at the Los Alamos County Airport. The Parties understand that these properties may be demolished after transfer to the County. Therefore, the DOE will ensure that any adverse effects to these eligible historic buildings will be resolved by implementing the proposed treatment of effects presented below (see Attachment D for expanded version of treatment of

effects agreement):

a. Documentation will be carried out according to standards of the Historic American Building Survey/Historic American Engineering Record (HABS/HAER), Level Two, with original LANL construction drawings substituted for new drawings, and medium format black and white photographs substituted for large format photography.
b. Prior to demolition, the interiors and exteriors of the four buildings will be photographed. Archival quality, medium format black and white photographs will be produced in accordance with the standards set forth in the Secretary of the Interior's Guidelines for Architectural and Engineering Documentation.
c. A complete set of LANL drawings for each property will be compiled. Available drawings and technical schematic plans will be submitted depicting the significant instrumentation historically housed in each property. Additionally, at each technical area, the overall site will be documented so that there will be a permanent archival record of the history and appearance of the area. Documentation will include maps showing the location of the TA-21, TA-43, and TA-73 properties relative to the entire Laboratory. Site maps will also be generated depicting, at a sufficient scale, the footprint of each eligible and non-eligible building or structure as they appear today. Additional overlays will be produced depicting the historic properties at each technical area and any previously removed properties that would have been associated with significant missions during the Cold War.
d. A written history will be prepared and will include a use history of the properties supplemented with information from oral interviews. This use history will include a discussion of each property's role at LANL, its historical significance, and a comparison of the administrative, security, and support missions carried out at these technical areas with similar missions historically conducted at other DOE Cold War facilities. A description of any specialized instrumentation housed in the properties and an evaluation of how this instrumentation contributed to the Cold War effort at Los Alamos will also be included.
e. Decontamination and decommissioning activities will commence only after drawings have been compiled and medium format photographs have been produced. A final report will be submitted to the SHPO after the decontamination and decommissioning phase is complete.
f. Copies of all documentation, including historical and architectural information, will be provided to the New Mexico SHPO. The New Mexico Archaeological Records Repository (ARMS) will be the designated repository. Original negatives will be curated at LANL's photographic archives.

3. Implement the proposed treatment of effects, including completing the historic building documentation, prior to the transfer of TA-43-39, 41, TA-211001-1002, and TA-73-2 to the County. Any revision to this PA will be recorded in accordance with Stipulation VIII.

4. Should it not be feasible to transfer the properties subject to Stipulation 11.2., the DOE will take the lead in consultation with the SHPO, the Council, and the County to ensure appropriate historic preservation measures are taken with regard to TA-43-39, 41, TA-21-

11O-1002, and TA-73-2 to resolve the adverse effects of the transfer. Any revision to this PA will be recorded in accordance with Stipulation VIII.

III. Land Conveyance Parcels TA-74 and White Rock Y

1. The portions of Parcels TA-74 and White Rock Y that contain Historic Properties will be nominated by DOE to the New Mexico State Register of Cultural Properties before conveyance to the County or its designee.

2. In the portions of Parcels TA-74 and White Rock Y that are to be conveyed to the County, or its designee, the DOE will undertake such conveyance in consultation with the SHPO, the County, the Pueblo, and other interested parties as relating to the following issues:
    a. Archaeological sites in Parcel TA-74 associated with the Ancestral Puebloan culture and identified as Register-eligible in the *Cultural Resource Assessment for the Department of Energy Conveyance* and *Transfer Project,* LA-CP-OO179 and concurred with by the SHPO in July, 2000, will be identified in the transfer documents as three.(3) archaeological preservation districts. The three archeological preservation districts are defined by the distribution of large, complex Ancestral Puebloan sites and made the subject of three (3) preservation easements as set forth in the sample document, Attachment A, and Figure A-I. These preservation easements will be included in the conveyance instrument pertaining to the real property containing the sites, developed in consultation with the County, and recorded in the real estate records of Santa Fe County, State of New Mexico, for the conveyance of such real property.
    b. Other archaeological Historic Properties in the TA-74 and White Rock Y Parcels that are not included in the archaeological preservation districts will be subject to New Mexico State Historic Preservation Laws and Regulations. Any objection regarding the development of such districts raised by a party to the DOE decision shall be resolved as specified in Stipulation X.

3. Should any traditional cultural property or cultural landscape of value to an Indian tribe or other social group be determined eligible for inclusion in the Register, through the DOE ongoing Traditional Cultural Properties consultation, the DOE will consult further with the SHPO, the Council, and the Indian Tribe(s), the County and others who ascribe value to the property, in accordance with 36 CFR 800.5(e), the requirements of the AIRFA and EO 13007, if applicable. If through this consultation process, the property is determined not to be Register eligible, the DOE may convey such property without further consultation with the Council and SHPO, but will consult further with the applicable Indian Tribe in accordance with AIRFA.

4. The DOE will evaluate any archaeological site or other possible Historic Property that has not already been evaluated, prior to conveying such site or property to a non-federal entity. If after consultation with the SHPO, the property is determined eligible for inclusion in the Register, the DOE will comply with 36 CFR 800, with respect to such property. If the property is determined not eligible on its own merits and is not a contributing element of a National Register of Historic Places District or Landmark, the DOE may transfer such

property without further consideration.

IV. Land Conveyance Parcels: Airport, White Rock, Rendija

The County portions of the parcels designated the Airport Tract, the White Rock Tract, and the Rendija Tract, described in the *Final Environmental Impact Statement for the Conveyance and Transfer of Certain Land Parcels Administered by the U.* S. *Department of Energy and Located at Los Alamos National Laboratory, Los Alamos and Santa Fe Counties, New Mexico,* 1998 (DOE/EIS-0293), as having the intended use of economic development, will be treated in the following manner:

1. DOE shall propose a representative sample of Historic Properties that will be subjected to archaeological data recovery prior to conveyance, in accordance with a scope of work developed in consultation with the SHPO, the County, Indian Tribes, and other interested parties, in accordance with the schedule set forth in this PA, and meeting the standards set forth in Attachment B.

2. Should any traditional cultural property or cultural landscape of value to an Indian tribe or other social group be determined eligible for inclusion in the Register, as stated in Stipulation III.3 above, the DOE will consult further with the SHPO, the Council, the Indian Tribe(s), the County and others who ascribe value to the property, in accordance with 36 CFR 800.5(e), giving particular attention to the requirements of the AIRFA and EO 13007, if applicable and Public Law 105-119. If the property is determined not eligible, the DOE may transfer such property without further consultation with the Council and SHPO, but will consult further with the applicable Indian Tribe and take such actions as are feasible and prudent to advance the purpose of the AIRFA.

3. If the DOE proposes to convey to the County any archaeological site or other possible Historic Property that has not yet been evaluated, the DOE will ensure that it is so evaluated in consultation with the SHPO. If the property is determined eligible for inclusion in the Register, the DOE will comply with 36 CFR 800, with respect to such property. If the property is determined to not be eligible on its own merits and is not a contributing element of a National Register District or Landmark, the DOE may transfer such property without further consideration.

V. Interim Protection of Historic Properties

While the property remains in DOE ownership, the DOE will comply with 36 CFR 800 with respect to any undertaking it proposes to carry out on the parcels.

VI. Reporting

The DOE shall ensure that reports on all activities carried out pursuant to this PA are provided to the Parties, in so far as such disclosure is not in violation of the Archaeological Resources Protection Act (ARPA) of 1979, 16 D.S.C. Section 470 hh.

VII. Qualification of Personnel

The DOE shall ensure that all archaeological surveys and Historic Property data recovery work pursuant to this agreement are carried out by or under the direct supervision of a person or persons meeting, at a minimum, the requirements for Archaeologist set for that Appendix C-l of DOE Regulation 420-40; also that any studies of traditional cultural properties are carried out by or under the direct supervision of a person or persons trained in cultural anthropology at a minimum consistent with the requirements of Appendix C-6 of DOE Regulation 420-40.

VIII. Amendments

1. The Parties may amend this PA, and any attachment hereto by signing an amendment document.

2. The DOE will ask any of the concurring parties to this PA whose interests may be affected by an amendment, to concur in such amendment.

3. Upon execution of the amendment, each Party will attach a copy of the fully executed amendment document to that Party's copy of this PA, and will enter the amendment number and date on the upper-right-hand corner of the first page of this PA.

IX. Scheduled Consultation

1. Implementation plans developed in accordance with this PA that have received final approval, shall be final for all purposes and shall not be subject to further revision or consultation except in accordance with the express provisions of this PA. Upon completion of the activities and treatments required by this PA, the Parties shall have taken into account the effect of the land conveyance activities and plans on historic properties in accordance with applicable law. No further activity or treatment shall be required prior to the conveyance of the properties in accordance with the conveyance agreement between the DOE and the County.

2. Twelve (12) months after this PA and annually thereafter until the Historic Parcels have been transferred in accordance with this PA, the DOE will invite the Parties to review implementation of this PA and to determine whether revisions are needed. If revisions are needed, the Parties will consult in accordance with 36 CFR Part 800 to make such revisions.

X. Dispute Resolution

1. Should any party object within 30 days to any plans or other documents provided by the DOE or others for review pursuant to this agreement or to any actions proposed or initiated by the DOE that may pertain to the terms of this agreement, the DOE shall consult with the objecting party to resolve the objection. If the DOE determines that the objection cannot be resolved, the DOE shall forward all documents relevant to the dispute to the Council. Within 30 days after receipt of all pertinent documents, the Council will either:
    a. Provide the DOE with recommendations, which the DOE will take into account in

reaching a final decision regarding the dispute; or

b. Notify the DOE that it will comment pursuant to 36 CFR 800.6(b), and proceed to comment. Any council comment provided in response to such a request will be taken into account by the DOE in accordance with 36 CFR 800.6(C)(2) with reference to the subject of the dispute.

2. Any recommendation or comment provided by the Council pursuant to Stipulation X.l will be understood to pertain only to the subject of the dispute; the DOE's responsibility to carry out all actions under this PA that are not the subject of the dispute will remain unchanged.

3. At any time during development of implementation plans for measures stipulated in this PA, should an objection to any such measure or its manner of implementation be raised by a member of the public, the DOE shall take the objection into account and consult as needed with the objecting party, the SHPO, other pertinent parties, and the Council to resolve the objection.

Execution and implementation of this PA evidences that the DOE has afforded the Council a reasonable opportunity to comment on the disposal of the Parcels, and that DOE has taken into account the effect of the undertaking on historic properties.

ATTACHMENT A:
STANDARD PRESERVATION EASEMENT FOR ARCHAEOLOGICAL SITES

Sample Document Subject to Change

In consideration of the conveyance of the real property that includes the [name of archaeological sites] located in the County of Santa Fe, State of New Mexico, which is more fully described as: [Insert legal description of Archaeological Districts.] [Name of property recipient] hereby agrees (?) on behalf of [himself/herself/itself], [his/her/its] heirs, successors, and assigns at all times to the [name of agency of organization] and the New Mexico State Historic Preservation Officer to maintain and preserve the [name of archaeological site] as follows:

1. No disturbance of the ground surface or any other thing shall be undertaken or permitted to be undertaken on [name or archaeological site] that would affect the physical integrity of the [name of archaeological site] without the express prior written permission of the [name of agency or organization], signed by a fully authorized representative thereof. The [name of agency or organization] may require, as a condition of the granting of such permission, that the [name of recipient] conduct archaeological data recovery operations or other activities designed to mitigate the adverse effect of the proposed activity on the [name of archaeological site]. In the event that such a requirement is made, the [name of recipient] shall at [his/her/its] own expense conduct such activities in accordance with the Secretary of the Interior's Standards and Guidelines for Archaeological Documentation (48 FR 44734-37) and such standards and guidelines as the [name of agency or organization] specify. Standards and guidelines may include but will not be limited to those with research design, conduct of field work, conduct of analysis, preparation and dissemination of reports, disposition of artifacts and other materials, consultation with Native American or other organizations, and reinterment of human remains.

2. [Name of recipient] shall make every reasonable effort to prohibit any person from vandalizing or otherwise disturbing the [name of archaeological site], and shall promptly report any such disturbance to the [name of agency or organization].

3. The [name of agency or organization] shall be permitted at all reasonable times to inspect [name of archaeological site] in order to ascertain if the above conditions are being observed.

4. In the event of a violation of this easement, and in addition to any remedy now or hereafter provided by law, the [name of agency or organization] will take all feasible steps to remedy the violation in a timely manner, and may, follow reasonable notice to [name of recipient], institute suit to enjoin said violation in a timely manner, and may, following reasonable notice to [name of recipient], institute suit to enjoin said violation or to require the restoration of [name of archaeological site]. The [name of agency or organization] if successful shall be entitled to recover all costs or expenses incurred in connection with such a suit, including all court costs and attorney's fees.

5. [Name of recipient] agrees that the [name of agency or organization] may at his discretion, without prior notice to [name of recipient], convey and assign all or part of its rights and responsibilities contained herein to a third party.

6. This easement is binding on [name of recipient], [his/her/its] heirs, successors, and assign in perpetuity. Restrictions, stipulations, and easements contained herein shall be inserted by [name of recipient] verbatim or by express reference in any deed or other legal instrument by which [he/she/it] divests [himself/herself/itself] of either the fee simple title or any other lesser estate in [name of archaeological site] or any part thereof.

7. The failure of [name of agency or organization] to exercise any right or remedy granted under this instrument shall not have the effect of waiving or limiting the exercise of any other right or remedy or the use of such right or remedy at any other time.

8. This easement is granted pursuant to the New Mexico Cultural Properties Preservation Easement Act, ss 47-12.A-l et seq., NMSA 1978

The easement shall be a binding servitude upon the real property that includes the [name of archaeological site] and shall be deemed to run with the land. Execution of this easement shall constitute conclusive evidence that [name of recipient] agrees to be bound by the foregoing conditions and restrictions and to perform to obligations herein set forth.

ATTACHMENT B: DATA RECOVERY STANDARDS

1. Archaeological data recovery shall be carried out in accordance with a data recovery plan developed in consultation with the New Mexico SHPO, the County, and any Indian tribe(s) that ascribe cultural value to the site. The data recovery plan shall be consistent with the Secretary of the Interior's Standards and Guidelines for Archaeological Documentation (48 FR 44734-37) and pertinent standards and guidelines of the New Mexico SHPO, and shall take into account the Council's publication, Treatment of Archaeological Properties, subject to any pertinent revisions the Council may make in the publications prior to completion of the data recovery plan. The plan shall specify, at a minimum:
    a. The property, properties, or portions where data recovery is to be carried out;
    b. Any property, properties, or portions of properties that will be transferred without data recovery, and the rationale for doing so;
    c. The research questions to be addressed through the data recovery, with an explanation of their relevance and importance;
    d. The field work methods to be used, with an explanation of their relevance to the research questions;
    e. The methods to be used in analysis, with an explanation of their relevance to the research questions;
    f. The methods to be used in data management and dissemination of data. including a schedule;
    g. The manner in which recovered materials will be disposed of. shall be in a manner consistent with Federal law regarding disposition of archeological materials and recovered human remains;
    h. The manner in which field notes and other records of field work and analysis will be preserved and disposed of;
    i. The methods to be used to involve the interested public in the data recovery;
    j. The methods to be used in disseminating results of the work to the interested public;
    k. The methods by which any Indian tribe that ascribes cultural value to the site, the County, and other parties with special interests in the property, if any, will be kept informed of the work and afforded the opportunity to participate; and
    l. The schedule for the submission of progress reports and final reports to the New Mexico SHPO, the County and others.

2. Records of data recovery field work and analysis shall be retained in an archive or other curatorial facility approved by the New Mexico SHPO and disseminated as appropriate to facilitate research and management without unduly endangering historic properties.

3. Material recovered from data recovery projects shall be curated in accordance with 36 CFR Part 79, except that human remains and artifacts associated with graves shall be treated in conformance with the Native American Graves Protection and Repatriation Act (NAGPRA) of 1990.

ATTACHMENT D

Memorandum of Agreement Between The Department of Energy and The New Mexico Historic Preservation Division Regarding the Transfer of Buildings 1001 and 1002, Technical Area 21; Buildings 39 and 41, Technical Area 43; and Building 2, Technical Area 73, Los Alamos National Laboratory

WHEREAS, the U.S. Department of Energy, Office of Los Alamos Site Operations (DOE/OLASO), proposes to transfer four early Cold War era properties at Technical Areas (TAs) 21, 43, and 73, Los Alamos National Laboratory, Los Alamos, New Mexico, to the County of Los Alamos; and

WHEREAS, the DOE/OLASO has determined that the proposal constitutes an undertaking, as described in Section 106 of the National Historic Preservation Act (16 V.S.C. 4701); and

WHEREAS, the DOE/OLASO has determined that the undertaking will have an adverse effect upon properties that are eligible for inclusion in the National Register of Historic Places; and

WHEREAS, in accordance with Section V.G. of the Programmatic Agreement for the Management of Historic Properties at Los Alamos National Laboratory, (MOD DEGM32-00AL 77152), the DOE/OLASO has consulted with the New Mexico Historic Preservation Division and its representative, the State Historic Preservation Officer (SHPO), concerning this undertaking; and

WHEREAS, the DOE/OLASO intends to use the provisions of this Memorandum of Agreement to address applicable requirements of Section 110(b) of the National Historic Preservation Act.

NOW, THEREFORE, DOE/OLASO and the SHPO agree that, upon DOE/OLASO's decision to proceed with the property transfer, the undertaking shall be implemented in accordance with the following stipulations in order to take into account the effects of the undertaking on historic properties.

Stipulations

DOE/OLASO will ensure that any adverse effects to these eligible historic buildings will be resolved by implementing the proposed treatment of effects presented below. Documentation conducted under stipulations 1 and 2 will be carried out according to standards of the Historic American Building Survey/Historic American Engineering Record (HABS/HAER), Level Two, with original LANL construction drawings substituted for new drawings, and medium format black and white photographs substituted for large format, when appropriate.

1. Prior to demolition, the interiors and exteriors of the four buildings will be photographed. Archival quality, medium format black and white photographs will be produced in accordance with the standards set forth in the Secretary of the Interior's Guidelines for Architectural and Engineering Documentation.

2. A complete set of LANL drawings for each property will be compiled. Available drawings

and technical schematic plans will be submitted depicting the significant instrumentation historically housed in each property. Additionally, at each technical area, the overall site will be documented so that there will be a permanent archival record of the history and appearance of the area. Documentation will include maps showing the location of the TA-21, TA-43, and TA-73 properties relative to the entire Laboratory. Site maps will also be generated depicting, at a sufficient scale, the footprint of each eligible and non-eligible building or structure as they appear today. Additional overlays will be produced depicting the historic properties at each technical area and any previously removed properties that would have been associated with significant missions during the Cold War.

3. A written history will be prepared and will include a use history of the properties supplemented with information from oral interviews. This use history will include a discussion of each property's role at LANL, its historical significance, and a comparison of the administrative, security, and support missions carried out at these technical areas with similar missions historically conducted at other DOE Cold War facilities. A description of any specialized instrumentation housed in the properties and an evaluation of how this instrumentation contributed to the Cold War effort at Los Alamos will also be included.

4. Decontamination and decommissioning activities will commence only after drawings have been compiled and medium format photographs have been produced. A final report will be submitted to the SHPO after the decontamination and decommissioning phase is complete.

5. Copies of all documentation, including historical and architectural information, will be provided to the New Mexico SHPO. The New Mexico Archaeological Records Repository (ARMS) will be the designated repository. Original negatives will be curated at LANL's photographic archives.

Execution of this Memorandum of Agreement between DOE/OLASO and the New Mexico SHPO will verify that DOE/OLASO has considered the effects of the property transfer on these historic properties and implemented the proposed treatment of effects.

Elmo Baca, SHPO

Amendment 1 to Stipulation IV.1 of the Programmatic Agreement among the United States Department of Energy, the Advisory Council on Historic Preservation, the New Mexico State Historic Preservation Officer and the Incorporated County of Los Alamos, New Mexico, concerning the conveyance of certain parcels of land to Los Alamos County, New Mexico.

It is agreed by the undersigned parties that in the event that the archaeological data recovery (excavation) activities being conducted by DOE/NNSA cannot be completed by the proposed transfer dates for the Airport, White Rock, and Rendija Parcels, the parcels shall be transferred to the Incorporated County of Los Alamos and DOE/NNSA will continue the data recovery activities to completion. DOE/NNSA shall provide written notice to the parties of completion of the excavations which is anticipated by the end of calendar 2002. During this time period, all archaeological sites under investigation shall be subject to the full protection of Section 106 of the Act.

APPENDIX B

MODERN POLLEN ANALOG STUDY: PLANT SPECIES LISTS AND SITE DESCRIPTION NOTES

Teralene Foxx

All visits were made on June 12, 2002. Field personnel included Susie Smith, Brad Vierra, David Barsanti, and Teralene Foxx. The purpose for the site visits was to collect elevation gradient pollen samples.

SITE 1

Plant Community: Piñon-Juniper

Location: Off State Route 4 to the east side of the road, south of White Rock and Pajarito Acres

GPS: RO 612 16A

General Characteristics: The site is about 50 percent juniper (*Juniperus monosperma*) and Colorado Piñon (*Pinus edulis*). After months of drought plants are showing a great deal of stress: shrubs have not leafed. Cover is approximately 5 percent grass with bare ground 80 percent. Only about 15 percent cover of tree canopy.

Soils: Shallow soils, sandy, with exposed Bandelier tuff.

Plants

Trees
One-seed Juniper (*Juniperus monosperma*)
Colorado piñon (*Pinus edulis*)
Forbs:
Prickly pear cactus (*Opuntia spp*.)
Golden weed *(Heterotheca sp*p.)
Scarlet gilia (*Ipomopsis aggregata*)
Antelope sage (*Eriogonum jamesii*)
Thymeleaf spurge (*Euphorbia seryllifolia*)
Wormwood *Artemisia ludoviciana*
False terragon *(Artemisia dracunculus)*

Grass
Little bluestem (*Schizachyrium scoparius*)
Blue grama (*Bouteloua gracilis*)

Shrubs
Mountain mahogany (*Cercocarpus montanus*)
Apache plume (*Fallugia paradoxa*)
Lemonadeberry (*Rhus trilobata*)
Broadleaf yucca (*Yucca baccata*)
Scrub oak (*Quercus* spp.)

SITE 2: PL2

Plant Community: Disturbance: old fields, old road, other activities

Location: Off State Route 4 to the east side of the road, across from TA-39

GPS: RO 612 17A

General Characteristics: This site is part of a canyon bottom floodplain with the perimeter of ponderosa pine and some juniper. North facing slope. Gophers.

Soils: Sandy soils

Plants

Trees
Ponderosa pine
One-seed juniper

Forbs
Sweetclover (*Melilotus* spp.)
Summercyperus (*Kochia scoparia*)
Blazingstar (*Mentzelia* spp.)
Lupine (*Lupinus caudatus*)
False terragon
Wormwood (*Artemisia carruthii*)
Mullein (*Verbascum thapsus*)
Penstemon (*Penstemon* spp.)
Ponymint (*Monarda pectinata*)
Wild buckwheat (*Eriogonum cernuum*)
Wild buckwheat (*Eriogonum racemosum*)

Grass
Sand dropseed (*Sporobolus* spp.)

Shrubs
Chamisa (*Chrysothamnus nauseosus*)

SITE 3: PL3

Plant Community: Piñon-juniper west of the Bandelier entrance and south of the road.

Location: West of the Bandelier entrance and south of the road

GPS: RO 612 17b

General Characteristics: Deep soils, Juniper 10 percent and Piñon 80 percent; Cover 65 percent trees, grasses are 25 percent of the understory

Soils: Deep soils

Plants:

Trees
One seed juniper
Colorado piñon

Forbs
False terragon
Wormwood
Purple owlclover (*Orthocarpus purpureo-albus*)
Bitterweed (*Hymenoxys richardsoni*)
Snake weed (*Gutierrezia sarothrae*)

Grass
Bluegrass (*Poa fendleriana*)
Bluegramma

Shrubs
Lemonadeberry

SITE 4: PL4

Plant Community: Ponderosa Pine

Location: Pond outside of fence at TA-16

GPS: RO 612 18A

General Characteristics: This pond was associated with the ice house. It presently is dry and was affected by a flood after the Cerro Grande Fire. The pond is filled with wheatgrass and rimmed by Ponderosa pine.

Cerro Grande Fire took place May 5-15, 2000. There were floods from the watershed in July after the monsoon rains.

Soils: Deep soils

Plants

Trees
Ponderosa pine
Aspen (*Populus tremuloides* sprout)

Forbs
wild onion (*Allium cernuum*)
Mullein
Cinquefoil (*Potentilla* spp.)
Bitterweed
Groundsel (*Senecio* spp.)
Yarrow (*Achillea lanulosa*)
Horseweed (*Conyza canadensis*)
Domestic iris
Fleabane daisy (*Erigeron divergens*)
Cinquefoil (*Potentilla* spp.)

Grass
Little bluestem
June grass (*Koleria cristata*)
Mountain muhly (*Muhlenbergia montanus*)
Squirreltail (*Sitanion hystrix*)
Western wheatgrass (*Agropyron smithii*)
Brome (*Bromus* spp.)
Fendler barberry (*Berberis fendleri*)

Shrubs
New Mexico locust (*Robinia neomexicana*)
Gambel oak (*Quercus gambelii*)
Wild rose (*Rosa* spp.)
Common juniper (*Juniperus communis*)

SITE 5: PL5

Plant Community: Ponderosa Pine

Location: Near Pond outside of fence at TA-16

GPS: RO 612 18b

General Characteristics: The area has both rotten low cut and high cut stumps. The low cut stumps may stem from thinning done after the 1977 La Mesa Fire. High cut stumps for homestead days. There is a thick layer of needs on the ground. The ponderosa pine cover is approximately 70 percent.

Cerro Grande Fire took place May 5-15, 2000. There were floods from the watershed in July after the monsoon rains.

Soils: Deep soils, thick layer of needles on ground.

Plants

Trees
Ponderosa pine

Forbs:
Pussytoes (*Antennaria parviflora*)

Grass
Junegrass
Mountain muhly
Squirreltail

Shrubs
Gambel oak
Fendler barberry
Buckbrush (*Ceaonothus fendleri*)

SITE 6: PL6

Plant Community: Ponderosa Pine, burned

Location: Intersection of St R. 502 and Ski hill road

GPS: RO 612 19a

General Characteristics. Area previously thinned.

Cerro Grande Fire took place May 5-15, 2000. There were floods from the watershed in July after the monsoon rains.

Soils: Deep soils, thick layer of needles on ground.

Plants

Trees
Ponderosa Pine (cover 50%)
Russian olive is about ¼ mile upslope

Forbs
Summer cypress
Aster spp.
Goldenrod (*Solidago* spp.)
Pussytoes
Bitterweed

Grass
June grass
Little bluestem
Mountain muhly

Shrub
New Mexico locust
Lemonade berry
Gambel oak

SITE 7: PL 7

Plant Community: Limber pine site

Location: Up ski hill road

GPS: RO 612 20 A

General Characteristics. Rocky south facing slope with 30 percent Limber pine, 40 percent Ponderosa pine, 10 percent Douglas fir

Soils: Rocky with tuff bedrock, sandy grus-like soils

Plants

Trees
Limber pine (*Pinus flexlis*)
Ponderosa pine
Douglas fir (*Psuedotsuga menzieii*)

Forbs
Penstemon spp.

Wild geranium (*Geranium* spp. Probably Caespitosum)

Grass
Mountain muhly
June grass
Pinedropseed (*Blepharoneuron tricholepis*)

Shrubs
Gambel oak
New Mexico locust
Mountain's lover (*Pachystima myrsinites*)
Bearberry (*Archtostaphylos uva-ursi*)

SITE 8: PL8

Plant Community: Mixed Conifer

Location: Up ski hill road

GPS: RO 612

General Characteristics: Just above the ski lodge off road to the left, before going up road to Camp May. Dense stand of aspen, Douglas fir and white fir: Douglas fir 75 percent, White fir 1 percent, Aspen 10 percent.

Plants

Trees
Aspen (*Populus tremuloides*)
Douglas fir
White fir (*Abies concolor*)
Rocky Mountain maple (*Acer glabrum*)

Forbs
Geranium spp.
American vetch (*Vicia americana*)
Wild strawberry (*Fragaria americana*)
Wild onion
Canadian violet (*Viola canadensis*)
Violet (*Viola* (blue) spp.
Cinquefoil (*Potentilla* spp.)
Meadowrue (*Thalictrum fendleri*)
Yarrow
Dandelion (*Taraxicum officinale*)
Shooting star (*Dodecatheon* spp.)

Bedstraw (*Galium* spp.)
Bluntseed sweet cicely (*Osmorhiza obtuse*)
Golden pea (*Thermopsis pinetorum*)

Grass
Brome (*Bromus* spp.)
Sedges

Shrubs
Baneberry (*Actaea arguta*)

SITE 9: PL9

Plant Community: High elevation meadows

Location: Up ski hill road, Camp May

GPS: RO 612 20 c

General Characteristics: Open meadow overgrown by meadow grasses

Plants

Trees
Blue spruce (*Picea engelmanni*)
Douglas fir
Aspen

Forbs
Potentilla spp.
Louisiana wormwood (*Artemisia ludoviciana*)
Mountain parsley (*Psuedocymoptris montanus*)
Dandelion
Thistle (*Cirsium* spp.)
Blue flag *(Iris missouriensis*)
Bracken fern

Grass
Timber oatgrass (*Danthonia intermedia*)

Shrubs
Elderberry (*Sambucus microbothrys*)
Raspberry (*Rubus strigosus*)

SITE 10: PL 10

Plant Community: Pueblo Canyon Sewage Effluent area

Location: Pueblo Canyon road

GPS: RO 612 21A

General Characteristics: Sewage effluent area was dry and no cattails although historically there had been cattails along the area.

Plants

Trees
Ponderosa pine
Piñon
Juniper
Russian Olive

Forbs
Mullein
False terragon

Grass
Orchard grass (*Dactylis glomerulata*)

Shrubs
Lemonade berry
Big sagebrush (*Artemisia tridentata*)
New Mexico olive (*Forestierra neomexicana*)
Chamisa

Site 11: PL11

Plant Community: Piñon juniper, ponderosa pine

Location: Pueblo Canyon

GPS: RO 612

General Characteristics: Open meadow overgrown by meadow grasses. 40 percent juniper, 20 percent piñon, 10 percent Ponderosa pine

Plants

Trees
Piñon
Juniper
Ponderosa pine

Forbs
Prickly pear cactus (*Opuntia* spp.)
False terragon

Grass
Blue grama
Littleseed ricegrass (*Oryzopsis micrantha*)
Ring muhly (*Muhlenbergia torreyi*)

Shrubs
Lemonade berry
Big sagebrush

SITE 12: PL12

Plant Community: Riparian zone

Location: Los Alamos Canyon upstream from the Ice Skating Rink

GPS: RO 612

General: Dense stand of mixed conifer next to stream. Stream is dry at this time but usually flows in wetter years.

Plants

Trees
Douglas Fir
Birch (*Betula*) or Alder (*Alnus*)
Ponderosa pine
Narrowleaf cottonwood (*Populus angustifolia*)
New Mexico Maple

Forbs
Dandelion
Thistle

Grass
Mountain muhly
Brome (*Bromus* spp.)
Sand dropseed

Vines
Virginia creeper (*Parthenocissus inserta*)
Clematis (*Clematis pseudoalpina*)

Shrubs
Wild rose (*Rosa* spp.)
Gambel oak
Fendler barberry
Jamesia Americana
Wax currant (*Ribes cernuum*)
Mock orange (*Philadelphus microphyllus*)
Willow (*Salix* spp.)
New Mexico locust
