Title

THE LAND CONVEYANCE AND TRANSFER DATA RECOVERY PROJECT: 7000 YEARS OF LAND USE ON THE PAJARITO PLATEAU

Volume 1: Baseline Studies

Cultural Resources Report No. 273

Prepared for

U.S. Department of Energy
National Nuclear Security Administration
Los Alamos Site Office

Prepared by

Bradley J. Vierra, Ecology and Air Quality Group
Kari M. Schmidt, Ecology and Air Quality Group

Los Alamos National Laboratory
Los Alamos, New Mexico 87545

June 2008

This report is dedicated to the memory of Charlie Steen.

Contents

Chapter 1: The Land Conveyance and Transfer Data Recovery Project: 7000 Years of Land Use on the Pajarito Plateau, by Bradley J. Vierra and Steven R. Hoagland ... 1

Chapter 2: The Geology of Los Alamos National Laboratory as a Backdrop for Archaeological Studies on the Pajarito Plateau, by David E. Broxton, Fraser Goff, and Kenneth Wohletz ... 7
- Introduction ... 7
- General Geologic Setting ... 7
- Stratigraphy ... 10
- Geologic Structure ... 30

Chapter 3: Overview of Pajarito Plateau Geomorphology, by Steven L. Reneau and Paul G. Drakos ... 31
- Introduction ... 31
- Geomorphic Processes ... 31
- Nomenclature for Geologic Deposits, Soils, and Surface Processes ... 33
- Divisions of Geologic Time ... 35
- Soil Development and Geomorphic History ... 41
- Geomorphic Setting of Land Transfer Parcels ... 42

Chapter 4: Ecosystems of the Pajarito Plateau and East Jemez Mountains: Linking Land and People, by Teralene S. Foxx ... 45
- Introduction ... 45
- Los Alamos National Laboratory and the Pajarito Plateau ... 45
- Plants and Animals as Indicators of Past Land Use and Change ... 64
- Methods for Plant Surveys ... 77

Chapter 5: Paleoenvironments of the Southern Rocky Mountains of Colorado and New Mexico: A Summary from Lake and Bog Sediments, by R. Scott Anderson ... 81
- Introduction ... 81
- New Records from the Jemez Mountains ... 83
- Summary ... 96

Chapter 6: Modern Pollen Analog Study, Los Alamos National Laboratory, by Susan J. Smith ... 97
- Introduction ... 97
- Modern Environment ... 97
- Pollen Stations ... 108
- Methods ... 111
- Results ... 113
- Conclusions ... 121

Chapter 7: The Current Status of Archaeological Dendrochronology and Dendroclimatology of the Pajarito Plateau, New Mexico, by Ronald H. Towner 123
Introduction........ 123
A Brief History of Dendrochronology 124
Methods and Techniques of Dendrochronology........ 126
Previous Archaeological Dendrochronology on the Pajarito Plateau........ 136
A Summary of Dendroarchaeological Data from the Pajarito Plateau 168
Dendroclimatology and Past Environmental Variability in the Pajarito Plateau Area ... 173
Recommendations and Conclusions 179
Conclusions........ 184

Chapter 8: Dendroclimatic Reconstructions in the Northern Rio Grande, by Ronald H. Towner and Mathew W. Salzer 185
Introduction........ 185
Background and Previous Research........ 185
The Pajarito Dendroclimatic Research Design........ 189
Methods and Procedures........ 190
Results 202
Comparing the Jemez and Chama Reconstructions: Spatial Differences in Pajarito Area Precipitation 218
Discussion........ 237

Chapter 9: A Context for the Interpretation of Archaeomagnetic Dating Results from the Pajarito Plateau, by Eric Blinman and Jeffrey Royce Cox 239
Introduction........ 239
Principles of Archaeomagnetic Dating 240
Sampling and Measurement Practice........ 241
Curve Performance Evaluation........ 248
Archaeomagnetic Results from the Northern Rio Grande Region 288
Conclusions........ 298

Chapter 10: Archaeological Obsidian and Secondary Depositional Effects in the Jemez Mountains and the Sierra de los Valles, Northern New Mexico, by M. Steven Shackley........ 299
Introduction........ 299
Bedrock and Alluvial Deposition of the Sierra de los Valles........ 301
Secondary Deposition and Prehistoric Procurement in Northern New Mexico........ 302
Collection Localities 305
Magmatic Relationship between the Glass Sources 315
The LANL Study 316
The Dacite Study........ 320

Chapter 11: Obsidian Hydration Dating by Infared Spectroscopy, by Christopher M. Stevenson........ 325
Introduction........ 325
Previous Obsidian Hydration Studies in New Mexico........ 325

Conclusions.. 337

Chapter 12: Luminescence Dating in Archaeology, by James Feathers....................... 341
Introduction.. 341
Physical Background.. 341
Radioactivity... 344
Measurements... 345
Dating Ceramics and Lithics 350
Dating Sediments.. 351
Sample Collection... 352

CHAPTER 1
THE LAND CONVEYANCE AND TRANSFER DATA RECOVERY PROJECT: 7000 YEARS OF LAND USE ON THE PAJARITO PLATEAU

Bradley J. Vierra and Steven R. Hoagland

The Department of Energy (DOE), National Nuclear Security Administration, Los Alamos Site Office and Los Alamos National Laboratory (LANL) are located in north-central New Mexico approximately 100 km north-northeast of Albuquerque and 40 km northwest of Santa Fe (Figure 1.1). The DOE is scheduled to convey properties at or in the vicinity of LANL to the County of Los Alamos, New Mexico, or its designee and to transfer properties to the Secretary of the Interior in trust for the Pueblo of San Ildefonso. The Land Conveyance and Transfer (C&T) Project is directed by Section 632 of PL 105-119, the *Departments of Commerce, Justice, and State, the Judiciary, and Related Agencies Appropriations Act, 1998*, which was passed by Congress on November 26, 1997.

The *Final Environmental Impact Statement (EIS) for the Conveyance and Transfer of Certain Land Parcels Administered by the U.S. Department of Energy and Located at Los Alamos National Laboratory, Los Alamos and Santa Fe, Counties, New Mexico*, 1998, describes the contemplated land use by the County of Los Alamos for the White Rock (A-19), Airport East (A-3), Airport Central (A-7), Airport South (A-5-1), and Rendija Canyon (A-14) tracts as economic development. The mitigation measures involved minimizing impacts to cultural resources by preparing tract-specific Historic Properties Treatment Plans that include provisions for a data recovery program for National Register of Historic Places (NRHP)-eligible archaeological resources that cannot be avoided.

The DOE examined 10 tracts of land (1942 ha; 4796 ac) proposed for the C&T Project (Figure 1.2). As a result of this examination, a July 2002 report entitled *Cultural Resource Assessment for the Department of Energy Conveyance and Transfer Project* (Hoagland et al. 2000a) was produced and submitted by DOE to the New Mexico State Historic Preservation Officer (SHPO) for comments. SHPO concurrence with the recommended NRHP eligibility for the 213 documented archaeological sites was issued on October 6, 2000. One hundred eighty of the sites are eligible or have an undetermined eligibility (i.e., potentially eligible).

The White Rock Tract (A-19) is located directly north of the community of White Rock and State Road 4. The western boundary runs northward from the State Road 4 and Pajarito Road intersection. The tract includes the southern tip of Mesita del Buey and portions of the Cañada del Buey floodplain.

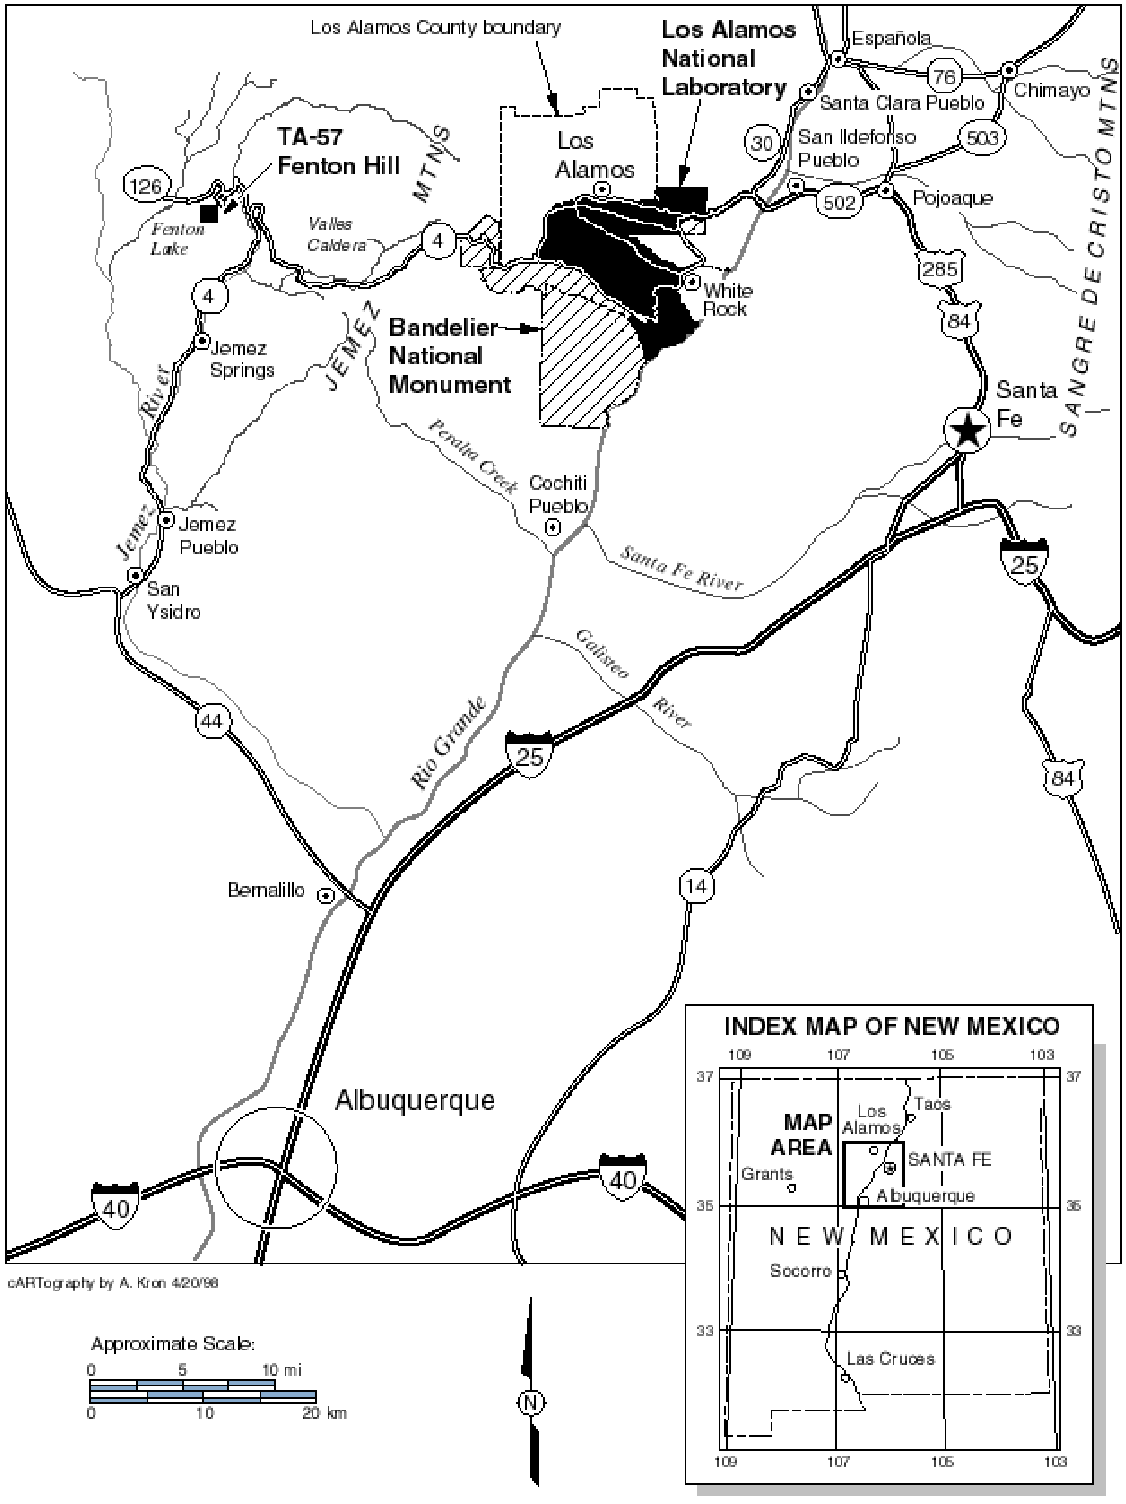

Figure 1.1. Location of Los Alamos National Laboratory (LANL).

Figure 1.2. The location of the Land Conveyance and Transfer (C&T) Project tracts.

The Airport Tracts are located east of the Los Alamos town site. The Airport East (A-3) and Airport Central (A-7) tracts are situated along the north side of State Road 502 (East Road) and the Airport South Tract (A-5-1) on the south side of the road a short distance west of the East Gate Business Park. These tracts are located on the mesa between Pueblo and DP canyons (see Figure 1.2).

The Rendija Tract (A-14) is located north of the Los Alamos town site's Barranca Mesa residential subdivision. The tract is situated within Rendija Canyon and Cabra Canyon. Barranca Mesa forms the southern boundary of the tract and Guaje Mountain forms most of the northern boundary. The Rendija Tract is bounded by U.S. Forest Service property to the north, east, and west and by Los Alamos County lands to the south.

The White Rock Tract (A-19) contains 10 archaeological sites, nine of which are NHRP eligible. Two eligible sites, approximately 80 percent of a third eligible site, and the single non-eligible site are situated on a small portion of land to be transferred to San Ildefonso Pueblo. The remaining six sites and approximately 20 percent of another are within the section to be conveyed to Los Alamos County. The Airport Tract parcels (A-3, A-7, and A-5-1) contain five archaeological sites that are all NRHP eligible. The Rendija Tract (A-14) contains 61 archaeological sites, 49 of which are eligible to the NRHP or have an undetermined eligibility. Nine of these sites have been identified as Traditional Cultural Properties (TCPs) by San

Ildefonso and Santa Clara pueblos and are therefore considered eligible to the NRHP. All of the remaining sites have been deemed eligible or potentially eligible under Criterion D of the NRHP, meaning that they are likely to yield information important to prehistory and/or history of New Mexico.

Land transferred to the Department of the Interior to hold in trust for San Ildefonso Pueblo is not an "undertaking" under the National Historic Preservation Act. Therefore, no further compliance is required for the properties that will be transferred to San Ildefonso Pueblo. This includes their ancestral home of Otowi, which is located within Technical Area (TA) 74. However, under 36 CFR 800.5(vii), the conveyance of lands to Los Alamos County is considered an adverse effect to historic properties, if adequate and legally enforceable restrictions or conditions to ensure the long-term preservation of these properties' historic significance are not established. For example, TA-74 is located east of the Los Alamos town site and below the mesa upon which the town site was built. The southern portion of TA-74 is dominated by Pueblo Canyon, the central portion of Bayo Canyon, and the northern portion of Barrancas Canyon. A total of 98 archaeological sites are situated within this technical area. Portions of the land were transferred to San Ildefonso Pueblo. Limited testing was conducted at nine archaeological sites within TA-74 (A-18a) and two sites within the nearby White Rock Y (C-2) tracts to determine potential eligibility.

A Programmatic Agreement (PA) was entered into by the DOE, Advisory Council for Historic Preservation, New Mexico SHPO, and the County of Los Alamos in order to implement the mitigation measures as specified in the EIS (Appendix A). As previously noted, PL 105-119 provides lands to Los Alamos County for economic development. As a result, the County intends to develop portions, if not all, of the Airport Tract parcels (A-3, A-7, and A-5-1), the Rendija Tract (A-14), and their section of the White Rock Tract (A-19), constituting an adverse effect to the historic properties within. Section IV of the PA (see Appendix A) details the actions to be taken in respect to these parcels. In addition, Attachment B of Appendix A describes the required data recovery standards. In order to resolve this adverse effect, DOE has developed a data recovery strategy for those properties that will be unavoidably destroyed or impacted through development. A data recovery plan entitled *Department of Energy Land Conveyance Data Recovery Plan and Research Design for the Excavation of Archaeological Sites Located within Selected Parcels to be Conveyed to the Incorporated County of Los Alamos, New Mexico* (Vierra et al. 2002a) was submitted by DOE to the SHPO and concurred with on May 5, 2002.

The data recovery plan provides a research design to guide the excavation and analysis of data obtained from the sites to be excavated within the tracts being conveyed to Los Alamos County. A series of research contexts consisting of chronometrics, geoarchaeology, paleoenvironment, settlement patterns, subsistence and seasonality, and technology and interaction are proposed. A total of 68 detailed research questions are presented within these contexts by time period and site type. In addition, the field excavation and laboratory procedures used to collect the data necessary to answering these questions are provided.

This data recovery program was implemented for seven archaeological sites within the White Rock Tract (A-19), five archaeological sites within the Airport Tract parcels (A-3, A-7, and A-5-1), and 27 archaeological sites within the Rendija Tract (A-14) (see Table 1.1). The reduced number of sites within the latter tract relates to the identification of nine TCPs and the selection of a sample of 10 fieldhouses that were excluded from excavation. In addition, two sites could not be relocated (LA 86553 and LA 70026). The results of the four-year excavation project are presented within this four-volume set. Excavations were conducted from 2002 to 2005. A total of 39 sites were excavated and approximately 150,000 artifacts were collected. Volume 1 (Baseline Studies) provides background information on geology, geomorphology, environment, and dating techniques. Volume 2 (Site Excavations) presents the excavation reports for the sites excavated in the White Rock, Airport, and Rendija tracts, as well as the results of site testing for the TA-74 and White Rock Y tracts. Volume 3 (Artifact and Sample Analyses) provides the detailed results of artifact and sample analyses, and Volume 4 (Research Design) presents various specialized studies and results of the project research questions.

Table 1.1. List of excavated and tested sites.

Tract	LA Number	Year of Excavation	Site Type	Period of Occupation
White Rock (A-19)	LA 12587	2002	Roomblock and fieldhouse	Late Coalition; Classic

CHAPTER 2
THE GEOLOGY OF LOS ALAMOS NATIONAL LABORATORY AS A BACKDROP FOR ARCHAEOLOGICAL STUDIES ON THE PAJARITO PLATEAU

David E. Broxton, Fraser Goff, and Kenneth Wohletz

INTRODUCTION

The geology of the Pajarito Plateau exerted a significant influence on the cultural development of prehistoric inhabitants. The local landscape provided the raw materials for buildings, pottery, tools, and other artifacts. This chapter provides a geologic overview of the Pajarito Plateau with emphasis on bedrock geologic units that were important sources of raw materials for the early inhabitants of the area.

GENERAL GEOLOGIC SETTING

The Los Alamos National Laboratory (LANL) is situated on the Pajarito Plateau, an east-sloping, dissected tableland bounded on the west by the eastern Jemez Mountains (Sierra de los Valles) and on the east by White Rock Canyon of the Rio Grande (Figure 2.1). The geology of the Pajarito Plateau reflects the interplay of volcanism in the Jemez Mountains and surrounding areas with the development of the Rio Grande rift, a series of north-south-trending fault troughs extending from southern Colorado to southern New Mexico (Figure 2.1).

Volcanism over the last 13 million years built up the highlands area of the Jemez Mountains, while contemporaneous tectonic rifting resulted in subsidence of the area extending from the eastern margin of the Jemez Mountains to the western margin of the Sangre de Cristo Mountains. This area of subsidence, locally termed the Española basin of the Rio Grande rift, is a graben between two larger basins—the Albuquerque basin to the south and San Luis basin to the north (Kelley 1978). During this interplay of volcanism and rifting, erosion removed materials from the highlands areas to the west and deposited them downslope to the east into the rifted lowlands, which were contemporaneously receiving sediments from other sources. The Pajarito Plateau developed in and now occupies the western part of the Española basin (Figure 2.2).

The gently east-sloping Bandelier Tuff covers the Pajarito Plateau. Deep canyons are incised into the Bandelier Tuff and expose it to depths of up to several hundred feet below the general level of the Pajarito Plateau. From west to east, these canyons cut progressively deeper into the Bandelier Tuff and, near the Rio Grande, some of the deeper canyons expose older lavas and sedimentary rocks. Figure 2.3 is a geologic cross-section that shows the distribution of rock units beneath the plateau. Volcanic rocks of the Tschicoma Formation and their derivative sediments (fanglomerate facies of the Puye Formation) extend eastward under the plateau where they interfinger with Santa Fe Group rocks and basaltic rocks of the Cerros del Rio volcanic field (also called "basaltic rocks of Chino Mesa").

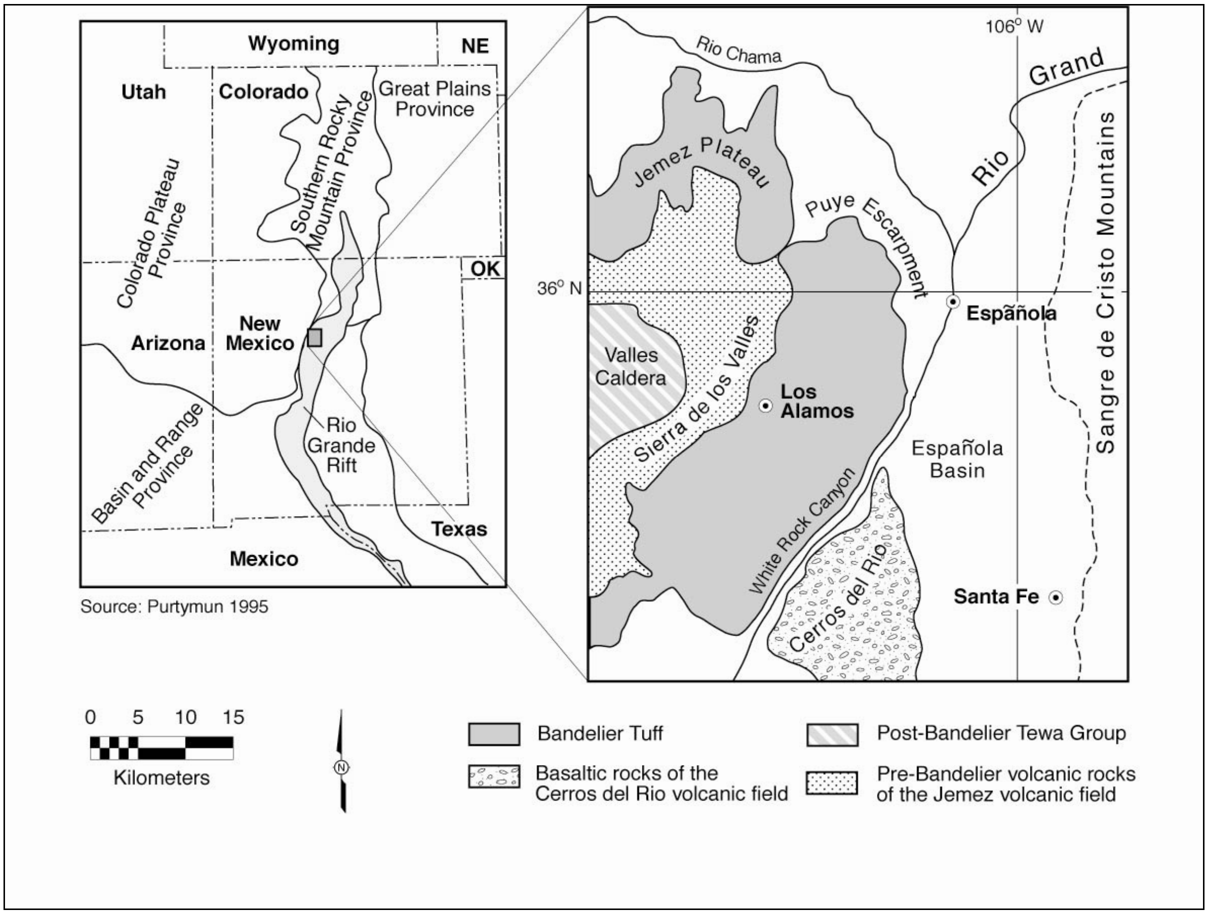

Figure 2.1. Regional setting of the Pajarito Plateau.

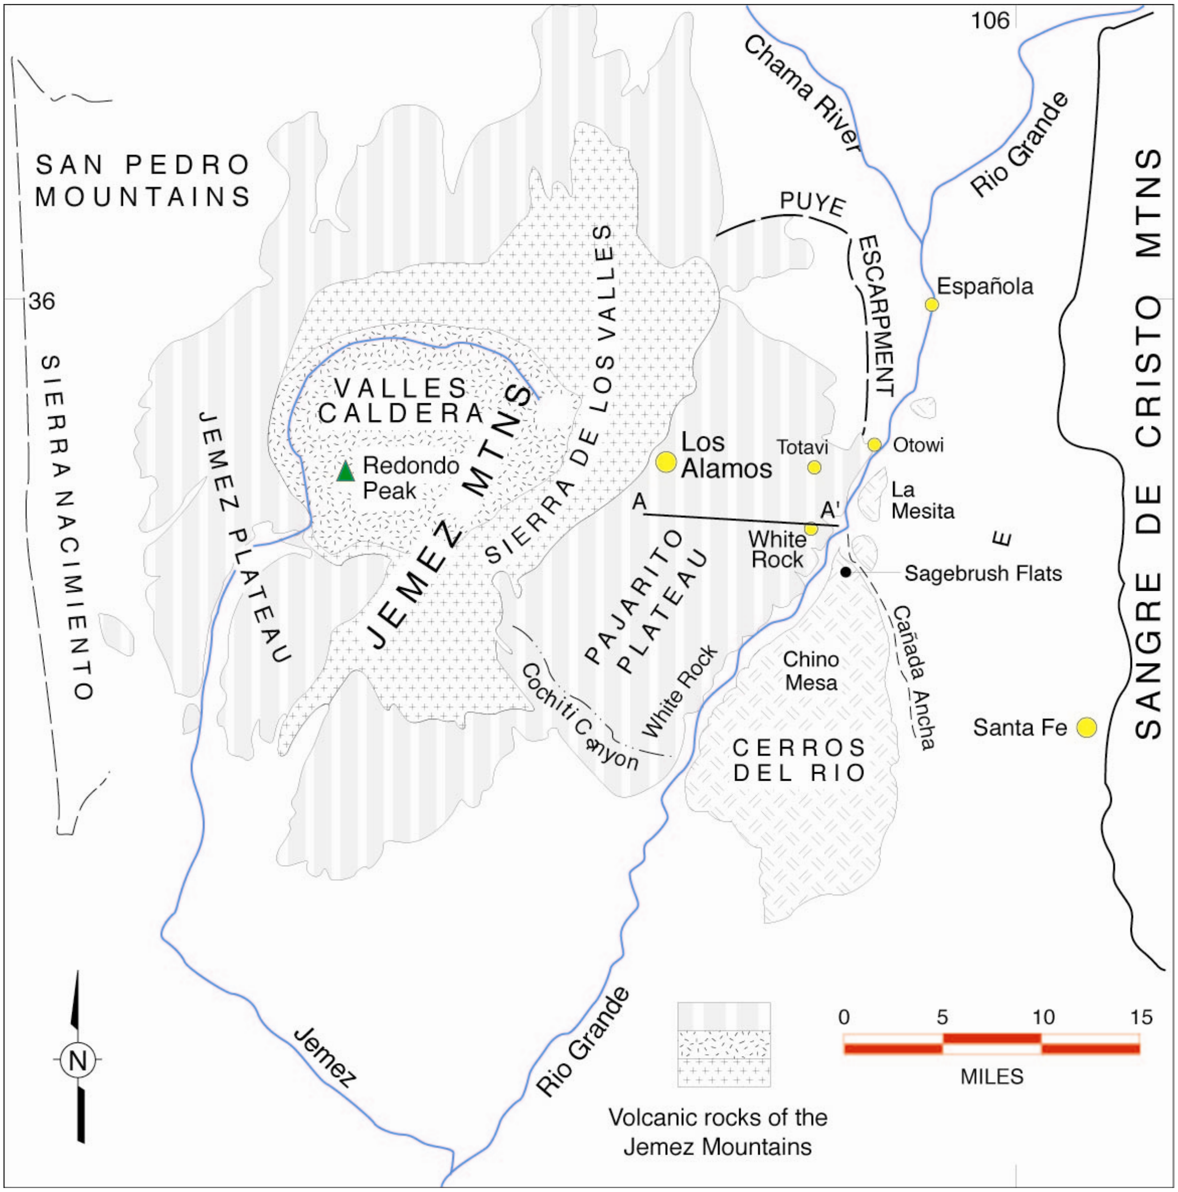

Figure 2.2. Geologic and geographic features of the Pajarito Plateau and surrounding areas. A-A1 is the location of the geologic cross-section in Figure 2.3.

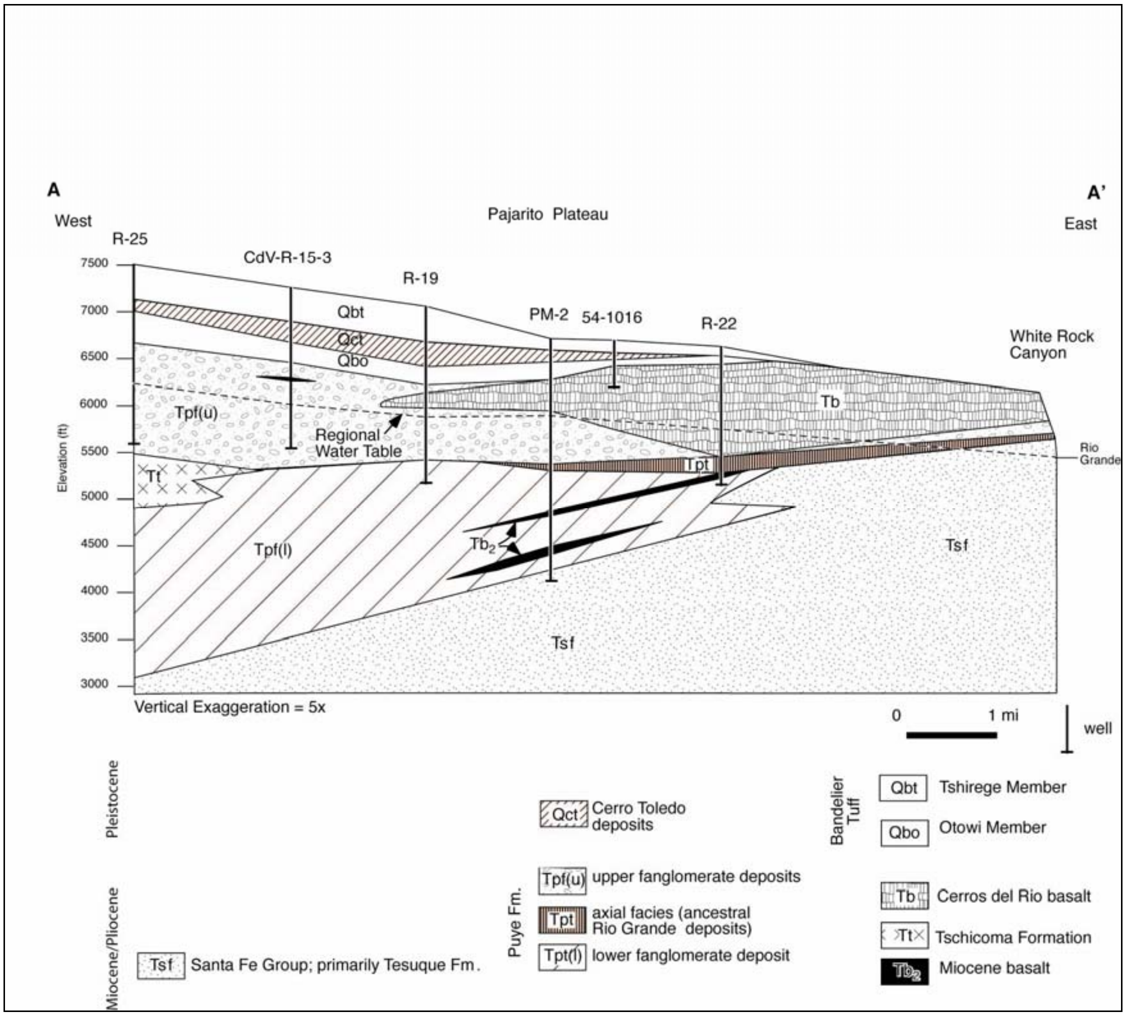

Figure 2.3. East-west cross-section showing stratigraphic relations for geologic units of the Pajarito Plateau; see Figure 2.2 for location of cross-section.

STRATIGRAPHY

A generalized stratigraphic chart for the Jemez volcanic field is shown in Figure 2.4. The following descriptions focus on those rock units that are exposed on or near LANL, starting with the oldest (deepest) and proceeding to the youngest (topmost). Fossil evidence, stratigraphic correlations, and radiometric measurements provide the approximate ages of most of the bedrock units. The bedrock units and their ranges of approximate radiometric ages are listed below in ascending order.

1. Santa Fe Group: 4 to 21 Ma (Manley 1979)
2. Tschicoma Formation: 2.0 to <7.4 Ma (Gardner and Goff 1984; Loeffler et al. 1988; WoldeGabriel 2001, personal communication)
3. Puye Formation: 1.7 to 4 Ma (Spell et al. 1990; Turbeville et al. 1989), which includes a fanglomerate facies, an axial facies (Manley 1979; Turbeville et al. 1989), and a lacustrine facies

4. Basaltic rocks of the Cerros del Rio volcanic field (also known as “basaltic rocks of Chino Mesa”) (2 to 3 Ma) (WoldeGabriel 2001, personal communication; WoldeGabriel et al. 1996)
5. Otowi Member of the Bandelier Tuff: 1.61 Ma (Izett and Obradovich 1994; Spell et al. 1996)
6. Volcaniclastic sediments and tephra of the Cerro Toledo interval: the age of this unit is bracketed by the ages of the underlying Otowi Member (1.61 Ma) and the overlying Tshirege Member (1.22 Ma) of the Bandelier Tuff
7. Tshirege Member of the Bandelier Tuff: 1.22 Ma (Izett and Obradovich 1994; Spell et al. 1990, 1996)
8. Valles Rhyolite: <1.133 Ma (Spell and Harrison 1993) to 50 to 60 Ka (thousand years) (Reneau et al. 1996a; Toyoda et al. 1995)

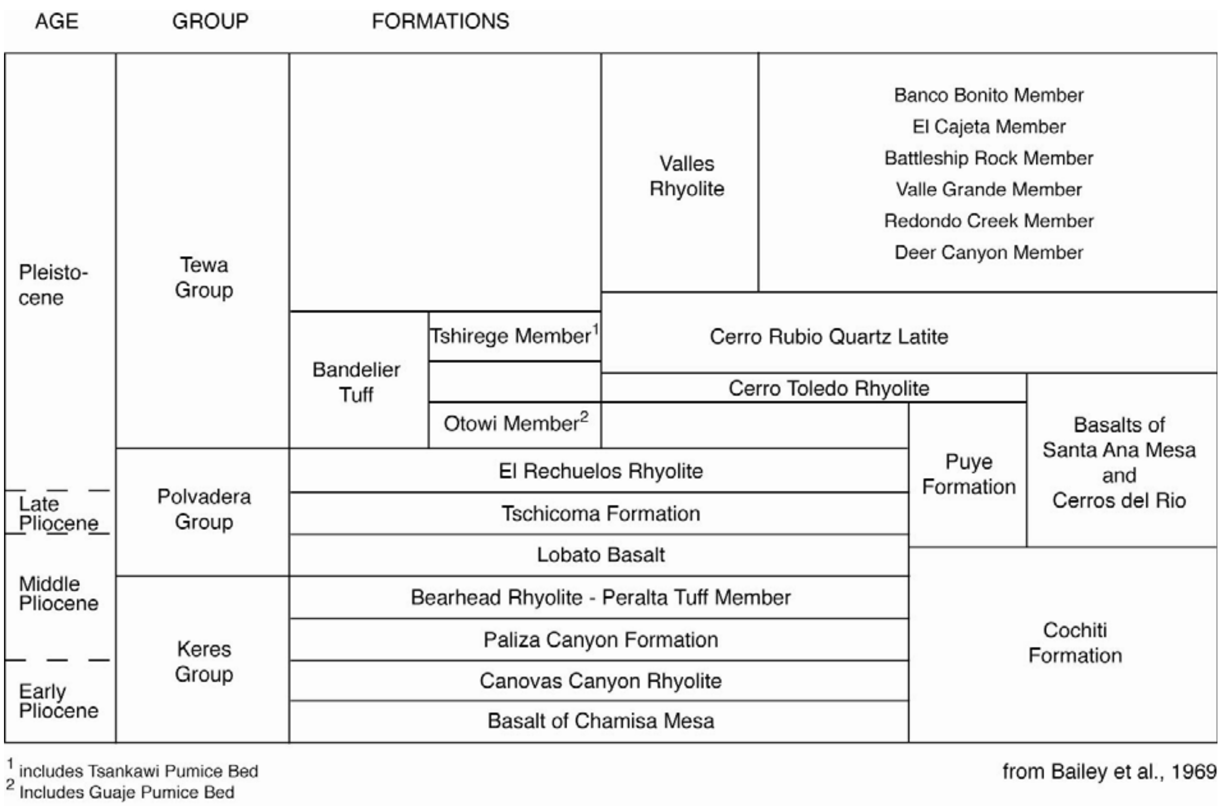

Figure 2.4. Stratigraphic nomenclature for major rock units of the Jemez volcanic field.

A geological map published by R. Smith et al. (1970) shows the distribution of these bedrock units across the Pajarito Plateau. Other general geological maps covering this area are those by Griggs (1964), Kelley (1978), and Goff et al. (1990). More detailed geological maps covering portions of LANL include those by Baltz et al. (1963), Rogers (1995), Vaniman and Wohletz (1990), Reneau et al. (1995), Goff (1995), Goff et al. (2002), Lewis et al. (2002), and Lavine et al. (2003). Figure 2.5 schematically portrays the complex interfingering of volcanic rocks and sediments that occurs below the Pajarito Plateau.

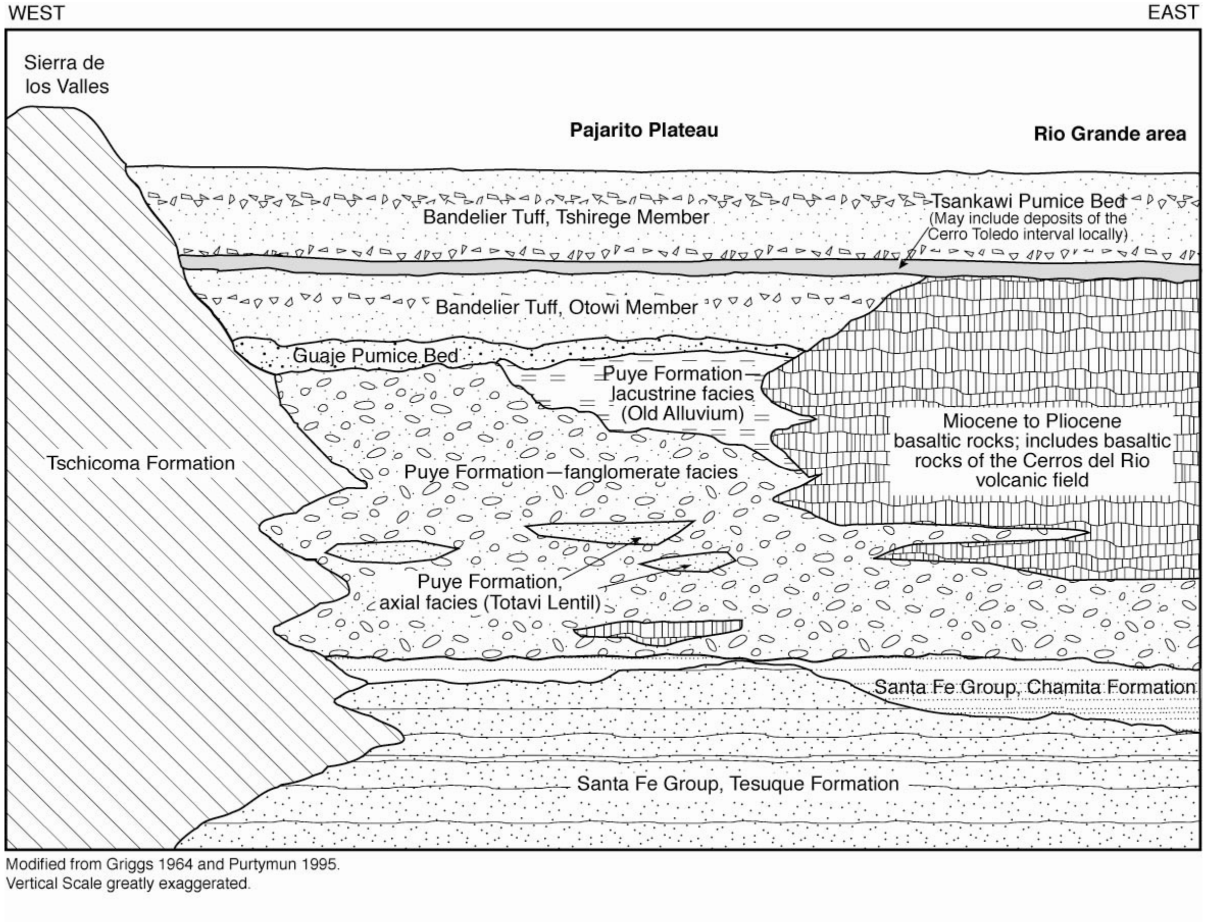

Figure 2.5. Schematic cross-section showing interfingering stratigraphic relationship across the Pajarito Plateau; thicknesses are approximate.

Santa Fe Group

Rocks of the Santa Fe Group crop out in lower Los Alamos Canyon, near the mouth of Guaje Canyon, and along the margins of the Rio Grande from Otowi Bridge south to White Rock. Galusha and Blick (1971) subdivided the Santa Fe Group into formations and members based on geologic mapping and fossil assemblages of late Tertiary mammals. Manley (1979) refined the stratigraphy with additional mapping and dates of interbedded volcanic ash layers, lava flows, and dikes. In the vicinity of the Pajarito Plateau, the stratigraphy and geochronology of the Santa Fe Group is poorly understood because of the near continuous blanket of Bandelier Tuff. Based on exposures near the Rio Grande, the Santa Fe Group beneath the Pajarito Plateau is believed to include, in ascending order, the Tesuque Formation and the Chamita Formation.

Tesuque Formation

The Tesuque Formation is a massive, thick sedimentary deposit consisting of arkosic sediments, derived primarily from Precambrian basement and Tertiary volcanic sources to the east and northeast of the Española basin. This unit is a light pink-to-buff siltstone and silty sandstone with a few lenses of pebbly conglomerate and clay (Figure 2.6). It is poorly to moderately consolidated and has an age range of about 7 to 21 Ma (Cavazza 1989; Manley 1979). Spiegel and Baldwin (1963) describe the Tesuque Formation at the southern end of the Española basin, including the exposures in the vicinity of Otowi Bridge and along White Rock Canyon. This formation exists in deep well boreholes under the Pajarito Plateau and is the primary aquifer for municipal and industrial water supply in Los Alamos County.

Figure 2.6. The Santa Fe Group was shed into the subsiding Española basin from highlands located to the east and northeast. This figure shows the Tesuque formation, which is typically made up of light pink-to-buff siltstone and silty sandstone with lenses of pebbly conglomerate and clay.

Chamita Formation

The Chamita Formation overlies and interfingers with the Tesuque Formation. It consists of arkosic siltstones, sandstones, and pebbly conglomerate and includes two prominent beds of white ash. This formation is thickest in the northern part of the Española basin and thins to less than 9.1 m (30 ft) or is absent under most of LANL property. Aldrich and Dethier (1990) suggest that the Chamita Formation north of the Pajarito Plateau may be as old as 12 Ma. However, paleomagnetic data in the area indicate an age range of 4.5 to 6 Ma (MacFadden 1977), and tephra dates by Manley (1979) support a younger age of about 5 Ma for at least part of the formation.

Tschicoma Formation

The Tschicoma Formation of the Polvadera Group makes up the rugged Sierra de los Valles highlands west of Los Alamos, and it crops out in the headwaters of the larger canyons that cut the Pajarito Plateau. Deep boreholes along the western perimeter of the Laboratory intersect this unit at depths of several hundred feet or more, but the Tschicoma Formation is generally absent in boreholes penetrating the central and eastern parts of LANL.

The Tschicoma Formation consists of numerous thick lava flows that erupted from large overlapping dome complexes. Fragmental deposits of ash and lava debris occur in the distal parts of the formation. It has a variable thickness due to the lenticular shape of its lava flows, and is at least 762 m (2,500 ft) thick in the Sierra de los Valles. The Tschicoma Formation thins eastward under the Pajarito Plateau where it interfingers with the Puye Formation. The lower parts of the Tschicoma Formation may interfinger with rocks of the upper Santa Fe Group.

The Tschicoma Formation ranges in composition from dacite to rhyolite, but dacites are the predominant rock type. The rocks are mainly gray to purplish gray, but in places they are reddish brown. These flows display pronounced jointing and have tops and bottoms commonly marked by blocky breccia. Flow interiors are commonly devitrified to microcrystalline groundmass minerals giving the rocks a stony appearance. Chilled volcanic glass is some times preserved in flow tops and bottoms.

Dated volcanic domes making up the Sierra de los Valles range in age between 2.91 and 5.03 Ma (WoldeGabriel 2001, personal communication). Turbeville et al. (1989) report an age of 2.53 Ma for a Tschicoma ignimbrite within the Puye Formation. In the northern part of the Jemez volcanic field, the Tschicoma Formation is bracketed in age by the underlying Lobato Basalt (7.4 Ma) and the overlying El Rechuelos Rhyolite (2.0 Ma) (Loeffler et al. 1988).

Puye Formation

The Puye Formation is a large apron of overlapping alluvial fans that were shed eastward from the Jemez volcanic field into the Española basin, covering the Santa Fe Group rocks west of and along the Rio Grande. The Puye Formation is intersected by most deep wells on the Pajarito

Plateau (Purtymun 1995), and it crops out in lower Los Alamos Canyon and in canyons to the north. Turbeville et al. (1989) estimated its areal distribution at 200 km^2 (518 mi^2) and its volume at approximately 15 km^3 (3.6 mi^3). Because its primary sources were Tschicoma domes in the Sierra de los Valles, the Puye Formation overlaps and post-dates the Tschicoma Formation in age.

The lithology of the Puye Formation is dominated by conglomerates and gravels consisting of subangular to subrounded dacitic and andesitic lava clasts in a sandy matrix (Figure 2.7).

Figure 2.7. The Puye formation consists of deposits formed by coalescing alluvial fans shed eastward from Tschicoma volcanic centers in the Sierra de los Valles. These deposits of cobbles, gravels, and sand are exposed in canyons in the northern part of the Pajarito Plateau and along the Rio Grande.

At least 25 ash beds of dacitic to rhyolitic composition are interbedded with the conglomerates and gravels (Turbeville et al. 1989), and basaltic ash and lacustrine layers are present along the eastern margins of this formation. Because of its deposition as alluvial fans, the Puye Formation shows considerable vertical and lateral lithological variability. The formation reaches a maximum thickness of approximately 333 m (>1093 ft) in well R-25 on the western side of LANL but thins to 15 m (50 ft) in areas north of the Pajarito Plateau (Dethier and Manley 1985). In the central and eastern portions of LANL, it is approximately 183 m (600 ft) thick and is interbedded with basaltic lavas of the Cerros del Rio volcanic field.

The Puye Formation as defined by Griggs (1964) originally included three units, in ascending order: an axial facies (called the "Totavi Lentil" by Griggs), a fanglomerate facies, and a lacustrine facies (called "older alluvium" by Griggs).

Axial Facies of the Puye Formation

The axial facies of the Puye Formation (also called "Totavi Lentil" or "Totavi Formation") overlies the Santa Fe Group and crops out at Totavi in Los Alamos Canyon and along the east side of the Pajarito Plateau (Griggs 1964). It is generally approximately 15 m (50 ft) thick near the Rio Grande but thickens in a northwest direction. It consists of coarse, poorly consolidated conglomerate containing cobbles and boulders of silicic to intermediate volcanic rocks and Precambrian quartzite, granite, and pegmatite (Figure 2.8). These rocks probably represent axial-channel deposits of the ancestral Rio Grande. The axial facies forms the oldest deposits in the Puye Formation in many areas, but it also interfingers with the lower part of the fanglomerate facies. The age of the axial facies is poorly constrained.

Fanglomerate Facies of the Puye Formation

The fanglomerate facies is the dominant unit of the Puye Formation beneath most of LANL property. Fanglomerate is a general term meaning a rock unit composed of conglomerates deposited in an alluvial fan setting. The fanglomerate facies contains angular to subangular cobbles and boulders of latite, quartz latite, dacite, rhyolite, and tuff in a matrix of silts, clays, and sands. Lenses of silt, clay, and pumice are common. It is interbedded with basaltic rocks of the Cerros del Rio volcanic field in the eastern and central part of LANL. The fanglomerate facies is widespread beneath the Pajarito Plateau and caps the prominent cliffs (Puye Escarpment) along the Rio Grande north of Otowi Bridge.

Lacustrine Facies of the Puye Formation

Griggs (1964) included clay-rich lake beds (the lacustrine facies) as the uppermost part of the Puye Formation. He differentiated them from the fanglomerate facies based on the presence of lake siltstones and ancient stream gravels that fill channels cut into the fanglomerates. Basaltic rocks of the Cerros del Rio volcanic field are also found in these channels (Griggs 1964). The lacustrine facies is present in lower Los Alamos Canyon and extends both northward and southward in discontinuous outcrops for several miles. However, it is apparently of limited extent beneath the Pajarito Plateau, being reported only in boreholes near the eastern edge of the plateau. Most likely, these lake beds were one source of clay used for making pottery.

Figure 2.8. The Totavi Lentil is made of sands, gravels, and cobbles, which were deposited by the ancestral Rio Grande. The deposit contains subangular to subrounded clasts from local sources such as the Jemez volcanic field and rounded Precambrian granitic and metamorphic rocks derived from highlands to the north of the Española basin.

Basaltic Rocks of the Cerros del Rio Volcanic Field

The basaltic rocks of the Cerros del Rio volcanic field crop out primarily on the eastern side of the Rio Grande (Griggs 1964; R. Smith et al. 1970) and occur in the subsurface below much of the Pajarito Plateau (Broxton and Reneau 1996; Dransfield and Gardner 1985). Outcrops within LANL property occur in most canyons along the southern and eastern margins of the plateau. The stratigraphic nomenclature for these basalts has varied with different workers (Aubele 1978; Galusha and Blick 1971; Griggs 1964; Kelley 1978; R. Smith et al. 1970). Kelley (1978) mapped four different units of the Cerros del Rio Basalts, one of which (the Cubero Basalts) includes the five units of the basaltic rocks of Chino Mesa (Griggs 1964). Some of the older basalt flows that have been included in this formation may belong to the Santa Fe Group.

The basaltic rocks of the Cerros del Rio volcanic field form thick lava flows separated by interflow breccia, scoria, and ash (Figure 2.9). The lavas were erupted from numerous vents both east and west of the Rio Grande. In the vicinity of the Pajarito Plateau, these basalts form a north-south-trending highland (now buried by the Bandelier Tuff) extending from the western edge of White Rock to the confluence of Los Alamos and Pueblo canyons (Broxton and Reneau 1996). These basalts are interbedded with the upper part of the Puye Formation.

The basaltic rocks of the Cerros del Rio volcanic field include buried remnants of maar volcanoes in White Rock Canyon (Aubele 1978; Heiken et al. 1986). The aprons of fragmental debris surrounding these buried craters consist of thin layers of basaltic ash and sediments. The maar deposits resulted from steam explosions that occurred where basalt erupted through an aquifer or standing body of water.

Figure 2.9. The 2- to 3-Ma Cerros del Rio basalt consists of a thick sequence of massive lava flows separated by beds of breccia, cinder, and sedimentary deposits. The upper photo shows thick Cerros del Rio basalt flows overlain by the Tshirege Member of the Bandelier Tuff. The lower photo shows Cerros del Rio basalt overlain by the Guaje Pumice bed near the confluence of Pueblo and Los Alamos canyons.

Bandelier Tuff

The Bandelier Tuff consists of the Otowi and Tshirege Members, which are stratigraphically separated in many places by the tephra and volcaniclastic sediments of the Cerro Toledo interval (Figure 2.10). The Bandelier Tuff was erupted from the Valles Caldera complex between 1.61 and 1.22 Ma ago. It is perhaps one of the best studied tuff units in the world, and it has been the subject of numerous geological studies since the early 1960s. The tuff is composed of pumice, minor rock fragments, and crystals supported in an ashy matrix. It is a prominent cliff-forming unit because of its generally strong consolidation. In the Tshirege Member, this consolidation is largely due to compaction and welding at high temperatures after the tuff was emplaced. Its light brown, orange brown, purplish, and white cliffs have numerous, mostly vertical fractures (called joints) that show average spacing of between several feet and several tens of feet. The Tshirege Member includes thin but distinctive layers of bedded sand-sized particles, called surge deposits, which demark separate flow units within the tuff.

Most archaeological sites on the Pajarito Plateau are located on the Bandelier Tuff. Archaeological sites include cavates excavated in soft portions of the tuff as well as a variety of structures (e.g., roomblocks, fieldhouses, dams, and terraces) constructed from tuff blocks. Tools such as manos and metates were shaped from tuff blocks. Because the Bandelier Tuff was such an important source of raw material, its detailed stratigraphy is of considerable importance and is discussed further below.

Otowi Member

The Otowi Member crops out in several canyons but is most extensive in Los Alamos Canyon and in canyons to the north. Griggs (1964), R. Smith and Bailey (1966), Bailey et al. (1969), and R. Smith et al. (1970) are important references describing the nature and extent of the Otowi Member. It consists of moderately consolidated (indurated), porous, and non-welded vitric ash-flow tuff (ignimbrite) that forms gentle, colluvium-covered slopes along the base of canyon walls. The Otowi ignimbrites contain light gray to orange pumice supported in a white to tan ashy matrix of glass shards, broken pumice, crystals, and rock fragments (Broxton et al. 1995; Goff 1995).

The Guaje Pumice Bed occurs at the base of the Otowi Member, making it a significant and extensive marker horizon in many boreholes. The Guaje Pumice Bed (Bailey et al. 1969; Self et al. 1986) contains layers of well-sorted pumice fragments whose mean size varies between 2.0 and 4.1 cm (0.8 and 1.6 in.). It has an average thickness of approximately 8.5 m (28 ft) over much of the plateau with local areas of thickening and thinning. The Guaje Pumice Bed's distinctive white color and stratified bedding make it easily identifiable in outcrops.

Figure 2.10. Two major volcanic eruptions from the Valles Caldera complex in the Jemez Mountains produced the widespread and voluminous ash flow sheets of the Otowi and Tshirege Members of the Bandelier Tuff. The Cerro Toledo interval, an interbedded sequence of rhyolitic tephras and sediments, commonly occurs between the two members of the Bandelier Tuff. The upper photograph shows the subunits of the Tshirege Member overlying deposits of the Cerro Toledo interval. The bottom photographs show Otowi Member ash-flow tuffs (left) and a close up of pumices in fall deposits making up the basal Guaje Pumice Bed (right).

Tephra and Volcaniclastic Sediments of the Cerro Toledo Interval

The Cerro Toledo interval is an informal name given to a sequence of volcaniclastic sediments and tephra of mixed provenance that separates the Otowi and Tshirege Members of the Bandelier Tuff on the Pajarito Plateau (Broxton and Reneau 1995; Broxton et al. 1995; Goff 1995). The unit contains primary and reworked rhyolite tephra normally assigned to the Cerro Toledo Rhyolite as described by R. Smith et al. (1970), as well as dacite-rich sediments derived from the Sierra de los Valles. Although it is intercalated between the two members of the Bandelier Tuff, the Cerro Toledo Rhyolite (and the Cerro Toledo interval on the Pajarito Plateau) is not considered part of that formation (see Figure 2.4; Bailey et al. 1969). Outcrops of the Cerro Toledo interval generally occur wherever the top of the Otowi Member appears in Los Alamos Canyon and in canyons to the north. The occurrence of the Cerro Toledo interval is widespread; however, its thickness is variable ranging from several feet to 81 m (266 ft).

The predominant rock types in the Cerro Toledo interval are rhyolitic tuffaceous sediments and tephra (Broxton et al. 1995; Goff 1995; Heiken et al. 1986; Stix et al. 1988). The tuffaceous sediments are the reworked equivalents of Cerro Toledo Rhyolite tephra that erupted from the Cerro Toledo and Rabbit Mountain rhyolite domes located in the Sierra de los Valles. Primary pumice-fall and ash-fall deposits occur in some locations. Cerro Toledo rhyolite, particularly at Rabbit Mountain, was an important source of archaeological obsidian. Although small amounts of obsidian clasts are present in Cerro Toledo deposits on the plateau, these clasts are generally too small to have been a significant source of archaeological obsidian.

Clast-supported gravel, cobble, and boulder deposits made up of porphyritic dacite derived from the Tschicoma Formation are interbedded with the tuffaceous rocks, and in some deposits, the dacitic detritus is volumetrically more important than rhyolitic detritus. These coarse dacitic deposits commonly define the axial portions of paleochannels.

Tshirege Member

The Tshirege Member is the upper member of the Bandelier Tuff and is the most widely exposed bedrock unit of the Pajarito Plateau (Bailey et al. 1969; Griggs 1964; R. Smith and Bailey 1966; R. Smith et al. 1970). Emplacement of this unit occurred during eruptions of the Valles Caldera 1.22 Ma ago (Izett and Obradovich 1994; Spell et al. 1996). The Tshirege Member is a multiple-flow, ash-and-pumice sheet that forms the prominent cliffs in most of the canyons on the Pajarito Plateau. It also underlies the canyon floor in all but the middle and lower reaches of Los Alamos Canyon and in canyons to the north. The Tshirege Member is generally over 61 m (200 ft) thick in the north-central part of LANL and is over 183 m (600 ft) thick near the southern edge of LANL at Technical Area (TA) 49 (Broxton and Reneau 1996).

The Tshirege Member differs from the Otowi Member most notably in its generally greater degree of welding compaction. Time breaks between the successive emplacement of flow units caused the tuff to cool as several distinct cooling units. For this reason, the Tshirege Member is a compound cooling unit, consisting of at least four cooling subunits that display variable physical properties vertically and horizontally (Broxton and Reneau 1995; Crowe et al. 1978; R. Smith and Bailey 1966). These variations in physical properties reflect zonal patterns of varying degree of welding and glass crystallization that accompanies welding (R. Smith 1960a, 1960b). The welding and crystallization variabilities in the Tshirege Member produce recognizable vertical variations in its properties such as density, porosity, hardness, composition, color, and surface weathering patterns. The degree of welding in each of the cooling units generally decreases from west to east, reflecting the higher emplacement temperatures closer to the Valles Caldera.

The Tsankawi Pumice Bed forms the base of the Tshirege Member. Where exposed, it is commonly 51 to 76 cm (20 to 30 in.) thick. This pumice-fall deposit contains moderately well-sorted pumice lapilli (diameters reaching about 6.4 cm [2.5 in.]) in a crystal-rich matrix. Several thin ash beds are interbedded with the pumice-fall deposits.

Qbt 1g is the lowermost subunit of the thick ignimbrite sheet overlying the Tsankawi Pumice Bed (Figure 2.10). It consists of porous, non-welded, and poorly sorted ash flow tuffs. The “g” in this designation stands for “glass” because none of the glass in ash shards and pumices shows crystallization by devitrification or vapor-phase alteration. This unit is poorly indurated but nonetheless forms steep cliffs because of a resistant bench near the top of the unit that forms a harder, protective cap over the softer underlying tuffs. A thin (10- to 25-cm [4- to 10-in.]), pumice-poor, surge deposit commonly occurs at the base of this unit.

Qbt 1v forms alternating cliff-like and sloping outcrops composed of porous, non-welded, but crystallized tuffs. The “v” stands for vapor-phase crystallization, which together with *in situ* crystallization (devitrification), converted much of the glass in shards and pumices into microcrystalline aggregates. The base of this unit is a thin, horizontal zone of preferential weathering that marks the abrupt transition from glassy tuffs below to crystallized tuffs above. This feature forms a widespread mappable marker horizon (locally termed the vapor-phase notch) throughout the Pajarito Plateau, which is readily visible in many canyon walls. In some locations the transition is marked by a prominent bench developed on top of the glassy tuff (Figure 2.10). The lower part of Qbt 1v is a colonnade tuff that is orange brown, is resistant to weathering, and has distinctive columnar (vertical) joints. The upper part of Qbt 1v consists of white, variably indurated, alternating cliff- and slope-forming tuffs. The tuffs of Qbt 1v are commonly non-welded (pumices and shards retain their initial equant shapes) and have an open, porous structure.

Qbt 2 forms a distinctive, medium brown, vertical cliff that stands out in marked contrast to the slope-forming, lighter colored tuffs above and below (Figure 2.10). A series of surge beds commonly mark its base in the eastern part of LANL, and it displays the greatest degree of welding in the Tshirege Member. It is typically nonporous and has low permeability relative to the other units of the Tshirege Member. Vapor-phase crystallization of flattened shards and pumices is extensive in this unit.

Qbt 3 is a non-welded to partially welded, vapor-phase altered tuff, which forms many of the upper cliffs in the mid to lower reaches of canyons on the Pajarito Plateau (Figure 2.10). Its base consists of a purple gray, unconsolidated, porous, and crystal-rich non-welded tuff that underlies a broad, gently sloping bench developed on top of Qbt 2. This basal, non-welded portion forms relatively soft outcrops that weather into low, rounded mounds with a white color, which contrast with the cliffs of partially welded tuff in the middle and upper portions of Qbt 3. In the western part of LANL, an additional subunit, Qbt 3t, is present above Qbt 3 (Gardner et al. 2001). Qbt 3t is a moderately to densely welded ashflow tuff that has petrographic and geochemical characteristics that are transitional between Qbt 3 and Qbt 4.

Qbt 4 is a partially welded to densely welded ignimbrite characterized by small, sparse pumices and numerous intercalated surge deposits. This unit caps mesas in the western part of LANL, but it is absent from mesa tops over the middle to eastern portions of the Pajarito Plateau. Devitrification and vapor-phase alteration are typical in this unit, but thin zones of vitric ignimbrite occur within this unit in the western part of LANL.

Valles Rhyolite

The Valles Rhyolite includes rhyolites and associated pyroclastic rocks erupted within the Valles Caldera after its collapse. The Valles Rhyolite is comprised of, in ascending order, the Deer Canyon, Redondo Creek, Valle Grande, Battleship, El Cajete, and Banco Bonito Members (see Figure 2.4). The Valle Grande Member of the Valles Rhyolite is of particular interest because the Cerro del Medio dome complex in the northeast part of the Valles Caldera was an important source of archaeological obsidian. Cerro del Medio is the oldest of the Valle Grande domes that erupted on the floor of the Valles Caldera (1.133 ± 0.011 Ma; Spell and Harrison 1993). Other dome complexes include Del Abrigo, Santa Rosa, Seco, San Luis, San Antonio, South Mountain, and La Jara. Within the Valle Grande Member, Cerro del Medio is the primary source of aphyric to sparsely porphyritic high-silica rhyolite obsidian. Other rocks of the Valle Grande Member were less favorable sources of archaeological obsidian because of their higher phenocryst contents (16% to 35%). Assignment of archaeological obsidian to the Valle Grande Member is facilitated by the unique chemistry of these domes. Selected chemical data for the Valle Grande Member are summarized in Figures 2.11 and 2.12.

Although vents for the Valles Rhyolite are confined to the Valles Caldera, fall deposits and reworked tephra from Deer Canyon, Cerro del Medio, and El Cajete eruptions overlie the Tshirege Member at several locations on the Pajarito Plateau (Figure 2.13). Prevailing winds at the time of these eruptions deposited ash and pumice eastward over the Sierra de los Valles and Pajarito Plateau. Deposited as ash and pumice falls, these tephra were quickly washed from the eastern slopes of the Sierra de los Valles and redeposited as sheets of reworked tephra up to 6 m (20 ft) thick in the western part of the Pajarito Plateau before canyon incision. The interbedded nature of primary fall deposits and volcaniclastic sediments indicates that volcanism and reworking of the tephra was penecontemporaneous. At some locations, the fall deposits and reworked tephra are interbedded with early Pleistocene dacite-bearing alluvial fan deposits.

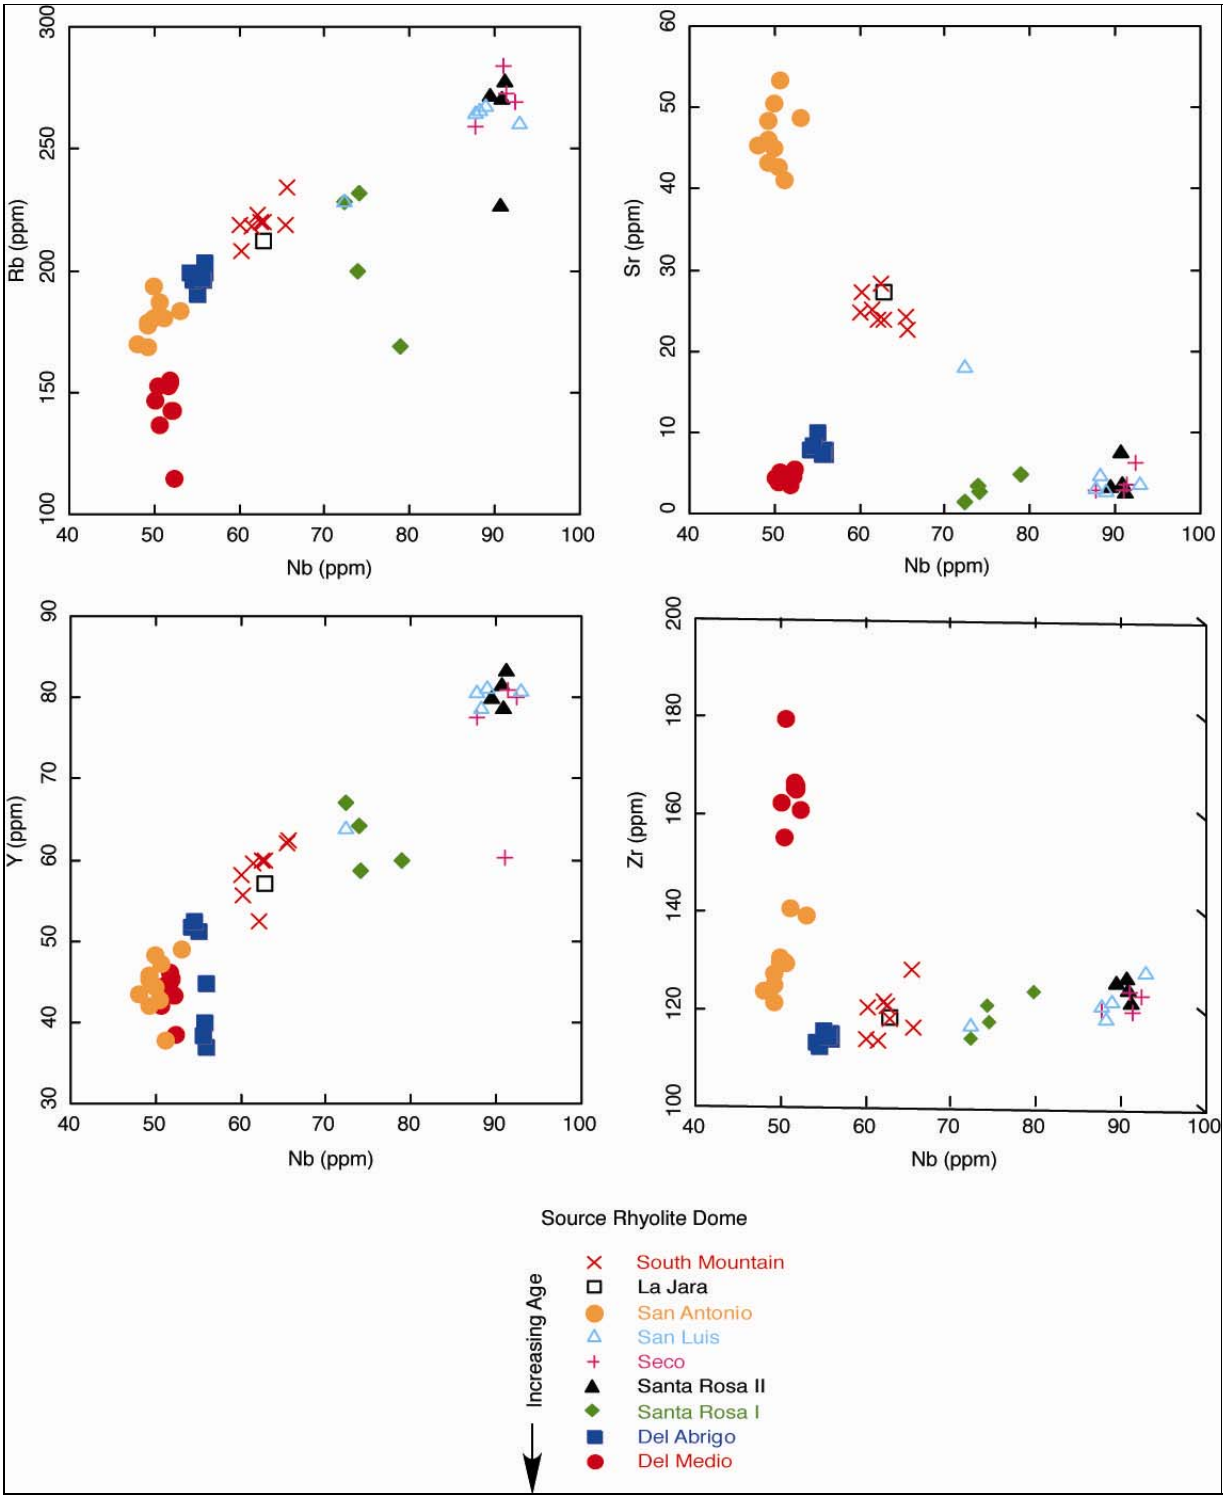

Figure 2.11. Plots of Nd versus Rb, Sr, Y, and Zr for whole rock samples collected from the source domes of Valle Grande Member of the Valles Rhyolite in the Valles Caldera. Data are X-ray fluorescence analyses from Spell (1987).

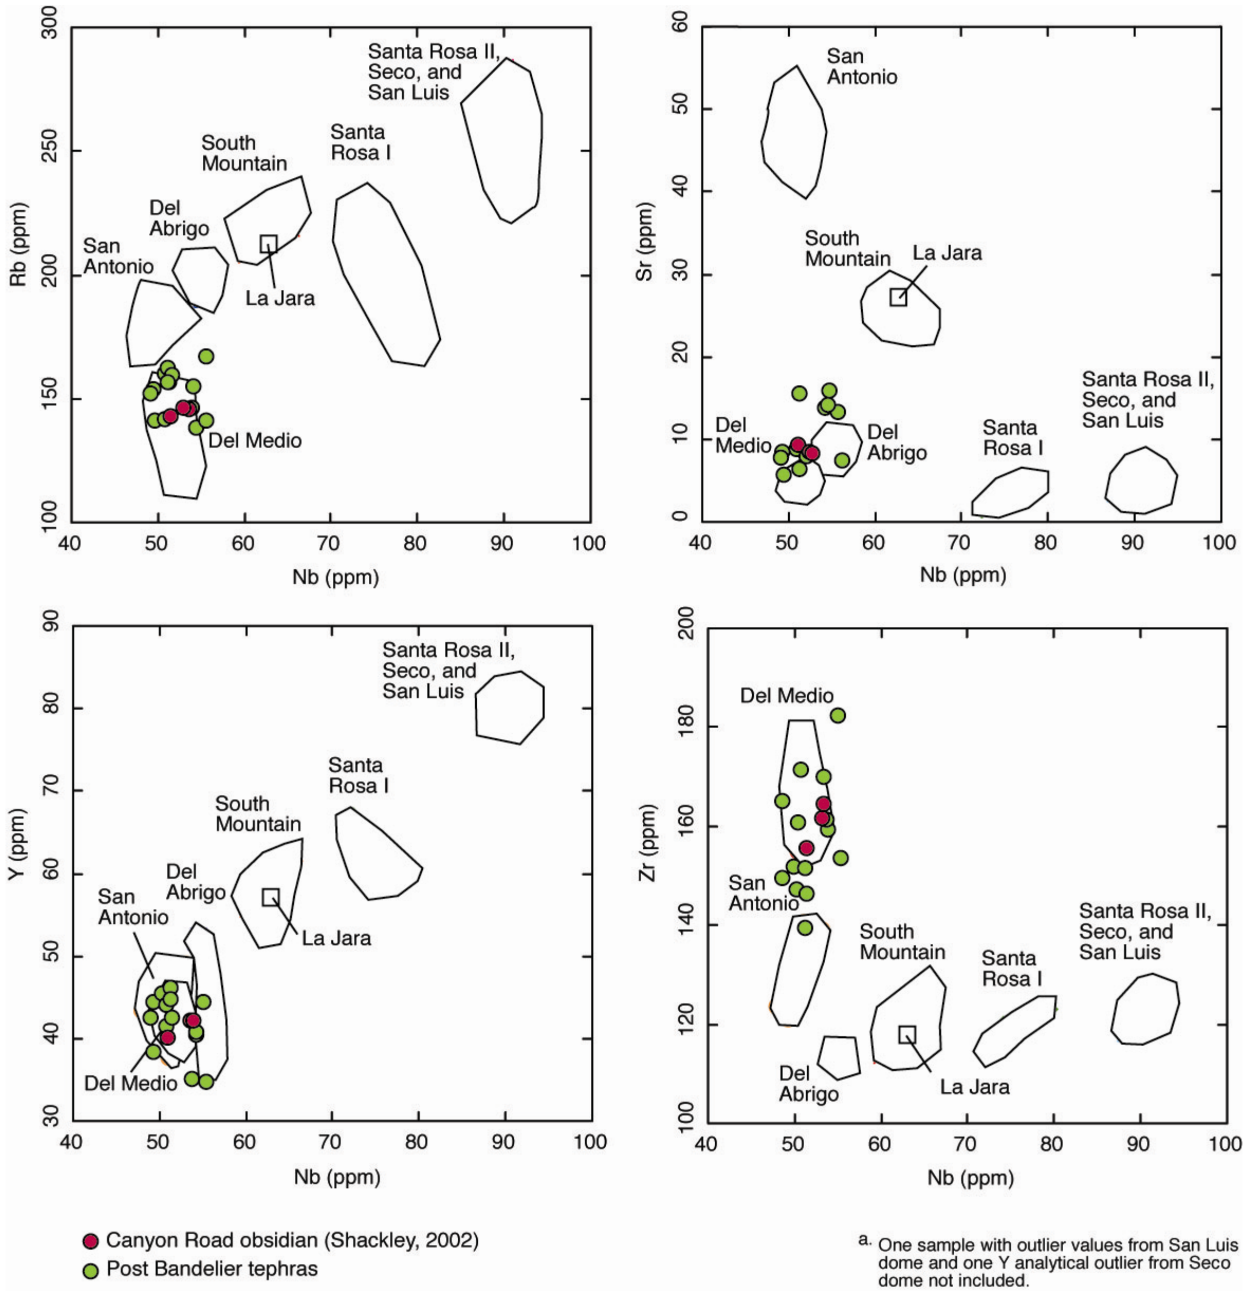

Figure 2.12. Plots of Nd versus Rb, Sr, Y, and Zr for Cerro del Medio tephras collected on the Pajarito Plateau. These data are compared to analyses of source domes (circled areas—see Figure 2.11 for individual analyses; data from Spell [1987]). The tephra data are unpublished X-ray fluorescence analyses (in green) and X-ray fluorescence analyses of obsidian clasts from the Caballo Peaks Apartment site (in red; Shackley 2002).

Figure 2.13. Locations where post-Bandelier fall deposits and reworked tephras have been recently recognized on the Pajarito Plateau.

Deer Canyon (?) deposits are the earliest post-Tshirege tephra recognized on the Pajarito Plateau. The best examples of these deposits are found within the Ponderosa Estates subdivision of Los Alamos near Guaje Pines Cemetery. The correlation of these tephra to the Deer Canyon Member is tentative because there is little published information about the chemical and petrographic characteristics of Deer Canyon source areas. Bailey et al. (1969) describe the Deer Canyon Member as petrographically distinct, containing abundant phenocrysts of quartz and sanidine and lacking visible ferromagnesium minerals. The fall deposits and reworked tephra exposed in the Ponderosa Estates subdivision also contain abundant phenocrysts of quartz and sanidine, but also contain visible pyroxenes. These tephra contain 250 to 350 ppm Zr and 90 to 150 ppm Rb, which distinguish them from the rhyolites of the Valle Grande Member (see Figure 2.12), but are similar to analyses for Deer Canyon lavas collected in the southwest part of Valles Caldera (100 to 130 ppm Rb and 236 to 267 ppm Zr; Broxton, unpublished analyses). More work is needed to test the correlation between these tephra and the Deer Canyon Member.

Cerro del Medio fall deposits and reworked tephra overlie the Tshirege Member at a number of locations on the Pajarito Plateau. Good exposures of these deposits occur along Canyon Road on the north side of Caballo Peak Apartments, on the north end of the Los Alamos Canyon landfill, and along Diamond Drive adjacent to the Los Alamos County golf course. Deposits are typically well-bedded and include both primary fall deposits and volcaniclastic sediments made up of aphyric pumice, obsidian and stony rhyolite clasts, and ash (Figure 2.14). Obsidian clasts within these deposits are generally less than 1 cm in diameter and probably were not important sources of archaeological obsidian. Correlation with the Cerro del Medio Member is based on stratigraphic position, the crystal-poor nature of these deposits, and the chemistry of pumices and obsidian clasts, which are similar to the lavas of Cerro del Medio (see Figure 2.12).

El Cajete pumice is widespread in the southwest part of the Pajarito Plateau (see Figure 2.3). Deposits consist of up to 1.5 m of primary fallout pumice with minimal reworking. Pumice clasts are 3 to 5 cm in diameter and are characterized a dense, poorly vesicular structure. El Cajete pumice are easily recognized by their lack of significant weathering, low phenocryst content (<5%), and salt and pepper appearance due to presence of small ferromagnesium phenocrysts.

Alluvium

Discontinuous Quaternary alluvial units overlie Bandelier Tuff as thin deposits on mesa tops and as stream deposits in canyons. Alluvial fans made up of dacite debris are interbedded with, and overlie, Valles Rhyolite tephra in the western part of LANL. Dacite cobbles occur with sandy to gravelly alluvium in canyon-floor sediments of the major drainages crossing the Pajarito Plateau. These alluvial deposits probably served as local sources for dacite cobbles found at some archaeological sites.

Figure 2.14. Cerro del Medio tephra exposed in north parking lot of Caballo Peak Apartments and along Canyon Road. These deposits consist of primary ash and pumice falls and reworked tephras. Lower photograph is a detailed view of deposit and shows white angular pumice, clasts of medium-gray stony rhyolite, and clasts of dark gray and black obsidian; quarter included for scale.

GEOLOGIC STRUCTURE

The Pajarito Plateau is on the western margin of the Española basin of the Rio Grande rift, a tectonically active region. The Pajarito fault system is the major border fault on the west side of the basin, and it delineates the boundary between the eastern Sierra de Los Valles and the western part of the plateau (Gardner et al. 2001). Continuing displacement along this fault system is reflected by Holocene movement and historic seismicity (Gardner and House 1987; Gardner et al. 1990). The Pajarito fault system is characterized by northerly trending normal faults that intertwine along their traces. Down-to-the-east displacement across the fault system produced the series of prominent fault scarps west of LANL. Post-Bandelier vertical throw on this fault system is over several hundred feet south and west of LANL but decreases north of Los Alamos Canyon where the fault system is less prominent.

In addition to the main traces of the Pajarito fault system, other faults cut the Pajarito Plateau. The Rendija Canyon fault is a normal fault trending north-south in the west-central part of the plateau; it crosses Pueblo Canyon near its confluence with Acid Canyon and Los Alamos Canyon near TA-41 but does not have clear surface expression south of Sandia Canyon. The Guaje Mountain fault parallels the Rendija Canyon fault and is projected to cross Los Alamos Canyon near TA-2 although there is no clear offset of the Tshirege Member south of North Mesa. North of LANL both of these faults have down-to-the-west movement and zones of gouge and breccia up to several meters wide and produce visible offset of stratigraphic horizons and recognizable scarps.

CHAPTER 3
OVERVIEW OF PAJARITO PLATEAU GEOMORPHOLOGY

Steven L. Reneau and Paul G. Drakos

INTRODUCTION

Los Alamos National Laboratory (LANL) is located on the Pajarito Plateau in the eastern part of the Jemez volcanic field in northern New Mexico, within the Española basin section of the Rio Grande rift tectonic province (Keller and Cather 1994) (Figure 3.1). The Jemez volcanic field lies along the Jemez lineament, a southwest-to-northeast-trending zone of structural weakness defined by a series of northeast-trending faults and volcanic centers extending from the Springerville volcanic field in Arizona to the Taos Plateau volcanic field and Capulin volcano in northern New Mexico (Laughlin et al. 1982).

The Pajarito Plateau is a dissected landscape of alternating mesas and canyons that is located between the east flank of the Jemez Mountains (the Sierra de los Valles) and White Rock Canyon of the Rio Grande (Reneau and McDonald 1996) (Figure 3.2). The Pajarito Plateau is underlain by the Tshirege Member of the Bandelier Tuff, a massive series of ignimbrites erupted from the Jemez Mountains at ca. 1.22 Ma (million years) and associated with development of the Valles Caldera (Broxton et al., this volume; Izett and Obradovich 1994; Reneau and McDonald 1996; R. Smith and Bailey 1966). The evolution of drainages since the eruption of Tshirege Member of the Bandelier Tuff has produced a landscape with a variety of landforms including gently sloping mesa tops, steep canyon walls, and canyon bottoms. This chapter provides an introduction to the geomorphologic nomenclature, history, and setting for the Pajarito Plateau at LANL.

GEOMORPHIC PROCESSES

Geomorphic processes, or physical processes acting on the earth's surface, play an integral role in determining the nature of the land surface at any point in time, how the land can be used, and whether archaeological sites will be preserved at the surface, eroded, or buried. Changes in climate, including changes in the amount, intensity, and seasonal distribution of precipitation, have strongly affected geomorphic processes and therefore the stability of the land surface (Bull 1991). The nature and density of vegetation are also affected by short-term and long-term changes in climate and by the geomorphic processes acting under that climate. In turn, geomorphic processes are affected by vegetation through their influence on surface runoff and erosion, resulting in complex interrelationships. Results of numerous investigations at LANL and in adjacent areas on the Pajarito Plateau have demonstrated that significant geomorphic changes have occurred in this area over the time period relevant for archaeological investigations, resulting in extensive sediment deposition in some areas and erosion in others (e.g., Reneau and McDonald 1996; Reneau et al. 1996a). Archaeological sites from any time period may thus be either buried or removed by erosion depending on the landscape position.

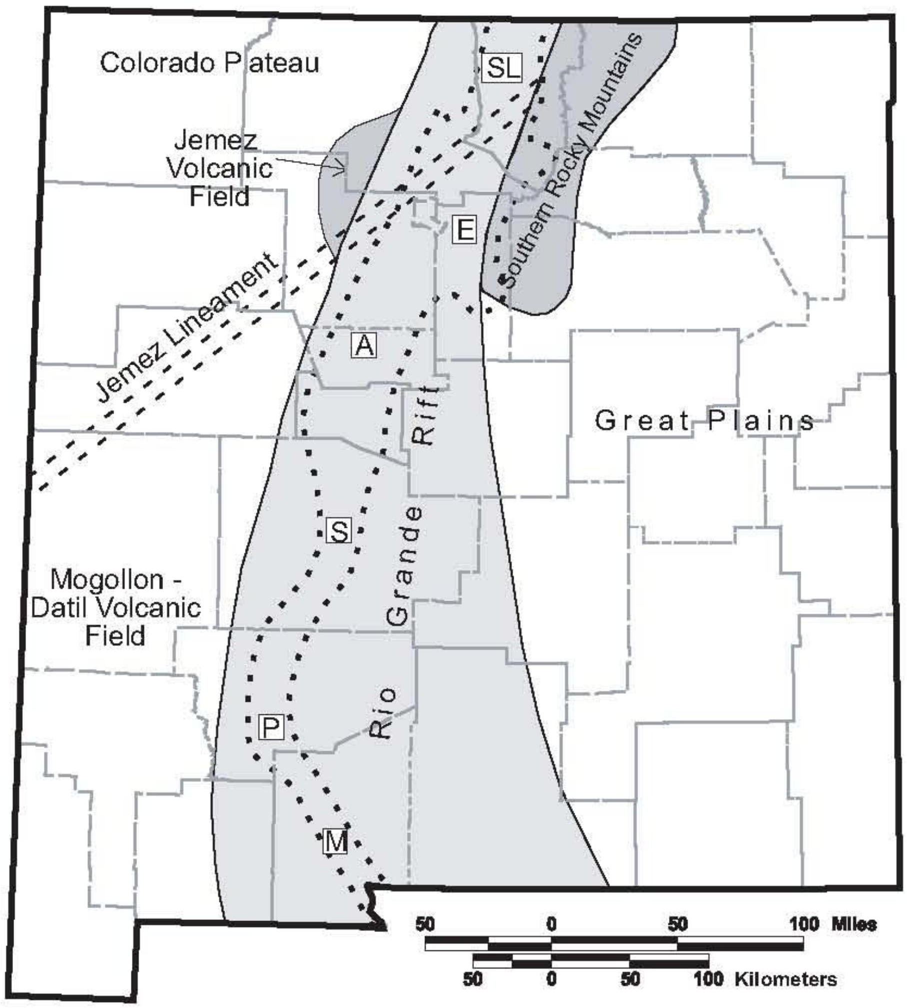

Figure 3.1. Schematic map of New Mexico showing the approximate limits of various physiographic provinces and geographic features. Major basins in the Rio Grande rift from north to south are SL = San Luis, E = Española, A = Albuquerque, S = Socorro, P = Palomas, M = Mimbres. (Modified from Keller and Cather 1994).

NOMENCLATURE FOR GEOLOGIC DEPOSITS, SOILS, AND SURFACE PROCESSES

Several basic terms are used in this section for geologic deposits and related surficial materials such as soils and for relevant surface processes. General definitions of geologic terms can be found in Jackson (1997), and the specific usage in this section is discussed below.

Sediment particle size classes have been defined differently in different professions and here we use the basic divisions utilized by geologists and soil scientists. Higher-level subdivisions include "gravel" (particles >2 mm in size), "sand" (0.0625 to 2 mm), "silt" (0.002 to 0.0625 mm), and "clay" (<0.002 mm or <2 μm). Each of these size classes is further subdivided (e.g., very coarse, coarse, medium, fine, and very fine sand). These terms can apply to either individual sediment particles or to sedimentary deposits that are dominated by particles of certain sizes (e.g., sandy gravel or silty sand).

"Alluvium," "alluvial deposit," or "fluvial deposit" refer to deposits from streams or rivers and include a range of sediment texture from gravel to silt. "Channel deposit" refers to alluvium deposited in the active stream channel at any time and is typically relatively coarse-grained. "Floodplain deposit" refers to alluvium deposited outside the active channel by floods that overtop stream banks and is typically relatively fine-grained. "Stream terrace deposit" refers to alluvium that is older than modern channel and floodplain deposits and generally occurs above the modern channel, underlying surfaces ("stream terraces") that represent channels, or floodplains abandoned following stream incision. "Alluvial fan" refers to generally cone-shaped landforms produced by the deposition of alluvium where streams become unconfined and spread out onto gentler surfaces.

"Colluvium" or "colluvial deposit" refers to generally poorly sorted deposits on hillslopes and includes material with varied origin and grain size. Colluvial deposits can be produced from rockfalls or other forms of mass wasting, such as landslides, and can contain abundant boulders. Colluvial deposits can also be produced by less dramatic processes such as the downslope movement of material on slopes following dislodgment by animals or toppling of trees. As used here, colluvium also includes deposits from shallow, dispersed surface runoff, called "slope wash" or "sheet wash." Note that in this context the distinction between "colluvium" and "alluvium" can be somewhat arbitrary because of a gradual change from dispersed runoff to channelized flow, and stratification resulting from deposition by running water can be locally found on hillslopes.

"Eolian deposit" refers to sediment deposited by wind and is generally in the silt to very fine sand range on the Pajarito Plateau. Eolian deposits dominated by silt are often referred to as "loess." Note that it can be difficult to distinguish thin and/or discontinuous eolian deposits from eolian material that has been locally reworked by surface water, and some deposits with an eolian origin may be included with "colluvium" or "alluvium" for simplicity. Also note that eolian material can be incorporated into soils without producing distinct deposits, and much of the silt, clay, and carbonate in many Pajarito Plateau soils may be supplied by wind (Eberly et al. 1996; McDonald et al. 1996; McFadden et al. 1996; Reneau and McDonald 1996; Reneau et al. 1995).

"Lacustrine deposit" refers to sediment deposited in lakes. Lacustrine deposits are commonly fine-grained and well-laminated, although coarse deposits can also occur near the margins of lakes where coarser sediment is supplied by streams.

"Bioturbation" is a process by which soils and sediments are mixed by biological agents. One common process is animal burrowing, which creates both subsurface tunnels and surficial deposits adjacent to entrances to burrows. The term "krotovina" is commonly used for filled animal burrows. The ingestion and excretion of soil by earthworms is another effective means of bioturbation at smaller scales. The toppling of trees also disrupts soils and sediment, creating "pit and mound" microtopography that gets smoothed over time (Denny and Goodlett 1956). Collectively, these processes can both obscure original sedimentary layers and result in the mixing of material from various depths, affecting the ability to decipher geologic and archaeological records. The effects of bioturbation are most pronounced near the ground surface and become more important over time. Note that some eolian or alluvial deposits on the Pajarito Plateau may be lumped with "colluvium" because bioturbation has created a poorly sorted deposit resembling colluvium whose origin can no longer be determined with certainty.

"Soil" is a term for material at the earth's surface consisting of layers or "horizons" that differ from the parent materials as the result of "pedogenic" or soil-forming processes (Birkeland 1999). At LANL, soils form on a variety of parent materials, including alluvial, colluvial, eolian, and lacustrine deposits. General subdivisions of soil profiles include "A," "B," and "C" horizons, and these horizons can be further subdivided associated with vertical variations in soil properties. "A horizons" are the uppermost soil layers and are characterized by maximum additions of organic matter and often by loss of some material to deeper horizons. "B horizons" are subsurface layers that have generally accumulated clay, iron oxides, or other material translocated from overlying horizons. "C horizons" are deeper layers consisting of generally unweathered parent material. Soil properties change over time, and older deposits have better-developed soils than younger deposits (Birkeland 1999). Soil profiles on the Pajarito Plateau can be complex, reflecting variations in geomorphic processes at the surface (Longmire et al. 1996; McDonald et al. 1996; McFadden et al. 1996; Reneau and McDonald 1996). "Buried soils" are created when significant layers of sediment cover relatively stable surfaces and at some sites several distinct soil profiles can be stacked on top of each other, recording episodic deposition. "Stripped soils" are created by erosion of the upper parts of soil profiles, for example exposing B horizons at the surface. "Cumulative soils" are formed at sites experiencing relatively slow deposition, creating relatively weak but relatively thick A and B horizons. Identification of buried soils and stripped surfaces is integral to identification of occupation surfaces, correlation between sites, and evaluation of relative age of sites based on soil-stratigraphic relationships.

DIVISIONS OF GEOLOGIC TIME

Several general divisions of geologic time are relevant for this discussion. At the highest level, the last 1.8 million years are referred to as the Quaternary period (Van Couvering 1997), which is subdivided into the Pleistocene and Holocene epochs. The term "late Quaternary" includes the late Pleistocene and the Holocene, which is the time period relevant for archaeological investigations in North America. The Pleistocene-Holocene boundary is commonly placed at 10,000 radiocarbon years before present (^{14}C yr BP) (Hopkins 1975), although this is an arbitrarily chosen date within a period of transitional climate and may be subject to change (Morrison 1991). However, 10 ^{14}C ka (ka = thousands of years BP) roughly corresponds to a time of major geomorphic changes on the Pajarito Plateau and is an appropriate boundary for this discussion. When calibrated to a dendrochronological time scale (to correct for variations in the $^{14}C/^{12}C$ ratio in the atmosphere over time), 10 ^{14}C ka is equivalent to about 11.35 to 11.55 cal (calibrated) ka or about 9400 to 9600 cal BC. (A recent calibration of the radiocarbon time scale is presented in Stuiver et al. 1998, and we use their conversions here.) The Holocene has no formal subdivisions, and here we use the general terms "early," "middle," and "late" to refer to roughly the first third, second third, and last third of the Holocene.

Geomorphic History

In this section we discuss the geomorphic history of the Pajarito Plateau since about 15 ^{14}C ka (ca. 17.4 cal ka), or since the latest Pleistocene, based on available studies. Emphasis is given to dated deposits and soils from different periods and in different landscape positions and their implications for variations in environmental conditions since 15 ^{14}C ka.

This section uses radiocarbon ages in reference to the geomorphic history of the area because this dating method has provided the most abundant age control for prehistoric deposits on the Pajarito Plateau and in nearby areas. Also, because radiocarbon calibration has changed over time and because many studies utilizing radiocarbon dating have not provided calibrated dates, direct reference to radiocarbon dates allows easier comparison between studies.

Latest Pleistocene

The period between 15 and 10 ^{14}C ka was a time of transitional climate after the peak of the late Wisconsin glaciations in North America and before establishment of the more modern Holocene climate. Paleoenvironmental records in the region, including the record of lake level changes in the Estancia basin (B. Allen 1991), indicate a generally moister climate than at present with significant climatic fluctuations. Deposits dating to the period between 15 and 10 ^{14}C ka on the Pajarito Plateau indicate significantly different geomorphic conditions than during the Holocene that were probably associated with the unique climatic conditions at that time.

Relatively few latest Pleistocene radiocarbon dates have been obtained from the Pajarito Plateau, and available information suggests that the landscape was relatively stable. Some evidence of colluvial deposition has been found, but there was apparently minimal sediment deposition or incision along stream channels. Out of a total of 55 alluvial deposits that had been dated by 1996, only a single site had yielded a date in this range (Reneau and McDonald 1996). This date, 11.6 ^{14}C ka, was obtained from a drill hole sample at a depth of 6.1 m (20 ft) beneath the bottom of the north fork of Ancho Canyon in LANL Technical Area (TA) 39 (Figure 6A of Reneau et al. 1996a). It is similarly expected that in many canyons on the Pajarito Plateau, alluvium of this age, if present, would also be deeply buried.

Dates very close to the Pleistocene-Holocene boundary have been obtained from buried soils at several sites on the Pajarito Plateau and provide evidence for a relatively stable landscape at about 10 ^{14}C ka. Examples include a buried floodplain soil beneath the north fork of Ancho Canyon (9.9 ^{14}C ka, Reneau et al. 1996a, Figure 6A); a buried, organic-rich deposit within a shallow tributary drainage to Cañada del Buey in TA-54 (9.7 and 10.1 ^{14}C ka, Reneau et al. 1996a, Figure 7); an extensive buried soil in a shallow mesa top drainage south of Frijoles Canyon in Bandelier National Monument (10.3 ^{14}C ka, Reneau and McDonald 1996); and a buried soil beneath an alluvial fan at the western margin of LANL in TA-69, between Pajarito Canyon and Two Mile Canyon (10.1 ^{14}C ka, Reneau et al. 2002). McFaul and Doering (1993) report a radiocarbon date of 9.4 ^{14}C ka from humate in a buried soil south of Water Canyon in TA-70, and their sample site is inferred to be analogous to the sites mentioned above.

Slightly older colluvial deposits, dating to the period between 15 and 10 ^{14}C ka, have been identified at several sites on the eastern Pajarito Plateau beneath the buried soils discussed above and suggest at least local deposition of colluvium during this period. One site is along the north wall of Fence Canyon in TA-70, where a 12.3 ^{14}C ka date has been obtained from the upper part of a buried colluvial deposit (Reneau and McDonald 1996, Figure 1-22). Analogous late Pleistocene units on mesa tops may be recorded by deposits studied by McFaul and Doering (1993) north and south of Water Canyon in TA-70 that are bracketed by dates on humate in buried soils of 9.4 and 15.7 to 16.0 ^{14}C ka (see also Reneau and McDonald 1996:58–60). Additional dates of 11.5 to 13.8 ^{14}C ka have been obtained from buried soils and colluvium in Rendija Canyon and on Pajarito Mesa at TA-67 (McDonald et al. 1996; Reneau et al. 1995), indicating local preservation of colluvium of this age at sites farther west on the plateau.

In contrast to the apparent complacency of geomorphic processes during the latest Pleistocene on the Pajarito Plateau, data from White Rock Canyon indicate a very dynamic landscape along the Rio Grande. In particular, the presence of lacustrine deposits demonstrate that large lakes formed at least three times between ca. 13.7 and 12.4 ^{14}C ka, produced by the damming of the river by landslides (Reneau and Dethier 1996). Unique ecological conditions would have existed along the Rio Grande at these times.

Early to Middle Holocene

Extensive deposits of early to middle Holocene age exist on the Pajarito Plateau in a variety of landscape settings, including alluvial, colluvial, and eolian material. These deposits document a substantial flux of sediment that was apparently derived from extensive erosion in upland areas and on slopes. This sediment supply exceeded the capacity of local transport processes acting under the Holocene climate, resulting in widespread aggradation of canyon bottoms and associated deposition along tributary drainages and on slopes, burying latest Pleistocene soils and stream channels. Significant eolian deposition also apparently occurred at this time. There is also some evidence that larger floods occurred during this period than in the latest Pleistocene, causing relatively high rates of stream incision into bedrock in some canyons.

Channels with drainage areas that range from the smallest first-order basins on mesa tops to the largest watersheds draining the Jemez Mountains have provided evidence for significant sediment deposition in the early to middle Holocene, indicating regional controls on erosion and sedimentation that affected a variety of vegetation communities and terrain (Drakos et al. 1996; Reneau and McDonald 1996; Reneau et al. 1996a). In Frijoles Canyon in Bandelier National Monument, up to 13 m (43 ft) of coarse alluvium was deposited before 6.2 ^{14}C ka, deposits which have now been exposed following stream incision (Reneau 2000). In Mortandad Canyon in TA-5, samples from drill holes indicate that 10 to 12 m (33 to 39 ft) of alluvium has been deposited since 7.2 to 7.8 ^{14}C ka (Reneau et al. 1996a; Figure 6B), and the base of the Holocene section is likely deeper. In Los Alamos Canyon, drill hole data show that alluvial deposits bury El Cajete pumice and indicate that 10 m (33 ft) of aggradation has occurred since ca. 50 to 60 ka (Broxton et al. 1994; Drakos et al. 1996). On the western margin of LANL in TA-69 between Pajarito Canyon and Two Mile Canyon, a trench through a small alluvial fan deposited along a drainage off the Pajarito fault escarpment provided excellent constraints on the timing of initial Holocene aggradation, exposing alluvial deposits at a depth of 2 to 2.5 m that were dated at 9.4 ^{14}C ka, overlying a buried soil dated at 10.1 ^{14}C ka (Reneau et al. 2002). North of Water Canyon, on another alluvial fan at the base of the Pajarito fault escarpment, similar dates of 9.4 to 9.6 ^{14}C ka were obtained from near the top of a 6-m- (20-ft-) thick deposit, providing additional support for significant deposition at the very beginning of the Holocene (Gardner et al. 2001). Significant early Holocene deposition has also been found along first-order drainages on mesa tops farther east on the Pajarito Plateau, including a location in TA-73 near the Los Alamos town site where deposition began some time before 7.9 to 8.1 ^{14}C ka, burying a shallow channel on bedrock (Longmire et al. 1996; Reneau et al. 1996a:Figure 3). Roughly contemporaneous deposition in White Rock Canyon is documented by a date of 10.0 ^{14}C ka from the lower part of a small alluvial fan above a late Pleistocene Rio Grande terrace (Reneau and Dethier 1996).

Significant deposition of slopewash colluvium in the early to middle Holocene has been documented at several sites. At a borrow pit exposure on the north wall of Fence Canyon in TA-70, about 2.7 m (9 ft) of slopewash material accumulated between 7.9 and ~4 ^{14}C ka (Reneau and McDonald 1996:Figure 1-22). Notably, an Archaic hearth dated at 4.7 ^{14}C ka was exposed nearby within the slopewash deposits, demonstrating prehistoric use of this geomorphic setting and the potential for site preservation by burial (Reneau and McDonald 1996:Figure 1-23). On the mesa south of Frijoles Canyon in Bandelier National Monument, a similar chronology has been obtained, with dates of 8.6 to 8.7 ^{14}C ka obtained from the lower part of a 1.6-m-thick slopewash deposit above a buried soil that yielded a 10.3 ^{14}C ka date (Reneau and McDonald 1996). Early Holocene slopewash deposits dated at 7.0 ^{14}C ka also overlie a buried, organic-rich deposit within a shallow tributary drainage to Cañada del Buey in TA-54 (Reneau et al. 1996a:Figure 7). Although early to middle Holocene deposits are present at several locations, such deposits are typically buried by younger deposits. Early to middle Holocene deposits are likely discontinuously preserved and may be absent from many locations on the Pajarito Plateau.

Evidence for eolian deposition in the early Holocene has been found in one area, where trenches excavated on Pajarito Mesa in TA-67 exposed fine-grained deposits that yielded dates of 9.3 to 9.5 ^{14}C ka overlying older soils (Kolbe et al. 1994; Reneau et al. 1995, 1996a). The texture and the stratigraphic setting of these deposits both argue for an eolian source for the material, and it is expected that similar deposits occur on other mesas. Two of the dated sites on Pajarito Mesa were locations with oxidized tuff clasts that were interpreted as Paleoindian fire pits constructed during a period of mesa top aggradation (e.g., see Figure 2A of Reneau et al. 1996a), indicating the potential preservation of similar sites elsewhere on the Pajarito Plateau.

Evidence for the occurrence of significantly larger floods on the Pajarito Plateau in the early and middle Holocene than in the late Pleistocene is provided by stream terrace sequences in Rendija Canyon and Frijoles Canyon. Stacked Holocene terraces in each canyon record periods of channel stability and lateral cutting that alternate with incision into bedrock. Average Holocene incision rates have been an order of magnitude higher than Pleistocene rates, suggesting recurring large floods capable of stripping gravel from the streambeds and leading to deeper incision (Reneau 2000; Reneau and McDonald 1996).

Late Holocene

Late Holocene deposits on the Pajarito Plateau are generally similar to early and middle Holocene deposits, suggesting similar geomorphic processes, although evidence from several sites indicates that rates of overall sediment deposition may have decreased in the late Holocene, locally replaced by erosion.

Late Holocene alluvium is widespread in canyons on the Pajarito Plateau, including the lower terraces in Rendija and Frijoles canyons, although in both of these canyons the thickest and/or widest terrace deposits were deposited in the early or middle Holocene (McDonald et al. 1996; Reneau 2000; Reneau and McDonald 1996). Progressive aggradation through the late Holocene is indicated in several canyons that head on the Pajarito Plateau. In Sandia Canyon in TA-53, 4 m (13 ft) of alluvium has been deposited since 2.8 ^{14}C ka (Reneau and McDonald 1996; Figure 1-10), and in Cabra Canyon 4 m (13 ft) has been deposited since about 3.7 ^{14}C ka (Gardner et al. 1990, 2003; Reneau and McDonald 1996:Figure 2-31). The late Holocene section is apparently thinner in other canyons, such as Ancho Canyon in TA-39 where 1.6 m (5 ft) of alluvium has been deposited since 3.0 ^{14}C ka (Reneau and McDonald 1996: Figure 1-29), and the north fork of Ancho Canyon, where a date of 2.9 ^{14}C ka was obtained from a depth of 0.9 m (3 ft) (Reneau et al. 1996a: Figure 6A).

Late Holocene colluvium is present in many areas, including along canyon walls and at the margins of floodplains, demonstrating active erosion and transport of material off hillslopes. Examples include Los Alamos Canyon in TA-62, where 1.4 m (5 ft) of colluvium has accumulated since 3.1 ^{14}C ka (Longmire et al. 1996), and Cañon de Valle in TA-16, where up to 1.9 m (6.2 ft) of colluvium has accumulated since 3.8 ^{14}C ka (Gardner et al. 2001). In other areas, however, colluvial deposits from the early and middle Holocene have been dissected, and erosion has predominated instead of deposition. At the site in Fence Canyon in TA-70 discussed previously, deposition apparently stopped some time after 4.4 ^{14}C ka, and about 4 m (13.1 ft) of incision has subsequently occurred (Reneau and McDonald 1996). Many areas with colluvial soils on the eastern Pajarito Plateau are currently experiencing rapid erosion, including an intensively studied mesa top drainage basin south of Frijoles Canyon in Bandelier National Monument (Wilcox et al. 1996a, 1996b). Erosion is impacting archaeological resources in some of these areas, and 1 liter of potsherds and lithic fragments were collected at a sediment trap in the study area mentioned above after a single runoff event in 1995. Erosion was also apparently active during occupation of some ancestral Puebloan sites, as apparent prehistoric check dams have been seen within a gullied area north of the Tsirege ruins in the Cañada del Buey basin (Reneau and McDonald 1996:54–56).

Late Holocene eolian deposits have been observed at several locations on the Pajarito Plateau. The trenches excavated on Pajarito Mesa at TA-67 provided evidence for thin but extensive late Holocene eolian deposits, averaging about 20 cm thick on the mesa (Kolbe et al. 1994; Reneau et al. 1995, 1996). These deposits date to 0.7 ^{14}C ka or less and cover a series of subsurface archaeological sites near ancestral Puebloan ruins (Reneau et al. 1996a:Figure 2b). Similar thin, discontinuous post-Puebloan age deposits not greater than 20 to 30 cm thick were noted during archaeological excavations on the Mesita del Buey mesa top (Steen 1982). This evidence for young deposition contrasts with evidence for erosion elsewhere on mesa tops, particularly near their margins where tuff bedrock is commonly exposed, and illustrates some of the great variability of surface processes on the Pajarito Plateau.

Late Holocene deposits also occur in White Rock Canyon, in part representing significantly different environments than are found on the Pajarito Plateau. For example, at one location along the Rio Grande 2.1 to 2.6 m (6.8 to 8.5 ft) of fine-grained sediment has been deposited since 2.9 ^{14}C ka directly above a gravel bar along the Rio Grande and may represent Rio Grande floodplain deposits or eolian deposits (Reneau and Dethier 1996; Reneau and McDonald 1996:30). The dated material was in association with fire-cracked stones and indicates burial of an Archaic campsite along the river.

Implications for Site Preservation

Geomorphic processes since the latest Pleistocene on the Pajarito Plateau have resulted in spatially and temporally complex patterns of erosion and deposition that provide abundant opportunities for preservation of archaeological sites of a variety of ages in a range of landscape positions and that also results in destruction of sites by erosion.

The highest potential for site preservation exists along small drainage channels on mesas, on alluvial fans, and in canyon bottoms, where net deposition of alluvium and colluvium has occurred during the Holocene, and on the more stable parts of mesa tops where erosion has been minimal or where deposition of eolian sediment has occurred. Stable parts of fluvial terrace surfaces that have experienced net deposition of colluvium or eolian sediment also have excellent site preservation potential. In contrast, mesa margins have the lowest potential for site preservation due to surface runoff that has eroded soils and exposed bedrock in many areas, and any artifacts in these areas may either have been transported to the site or left as a lag following erosion of associated deposits. Colluvial slopes have variable site preservation potential that is controlled by local geomorphic factors, including slope aspect, relative site position on a particular hillslope, sediment supply, and slope gradient above and below a particular site.

The common presence of a buried soil dating to near the Pleistocene-Holocene boundary beneath early Holocene alluvium or colluvium indicates the potential preservation of Paleoindian sites in many areas, although in canyon bottoms strata of this age may be buried beneath many meters of sediment. The potential for preservation of Paleoindian sites on mesa tops has been demonstrated in an area where apparent fire pits dating to 9.3 to 9.5 ^{14}C ka were found within deposits of inferred eolian material. However, available exposures have indicated great variability in the nature and age of deposits on mesa tops that makes it difficult to predict where sites of a given age might be found. In addition, mesa tops and other relatively stable geomorphic settings where deposition rates are low should be most prone to the mixing of soil and associated artifacts by bioturbation, helping to obscure the archaeological record. This problem should be most severe at older sites that are at or near the ground surface.

The local occurrence of middle and late Holocene alluvial and colluvial deposits also indicates potential preservation of Archaic sites in a range of settings. Buried Archaic sites have been found in colluvial deposits along the margins of canyon bottoms, although these are also commonly areas experiencing erosion in the latest Holocene, contributing to the loss of older sites and preventing burial of younger sites. In comparison to Paleoindian sites, Archaic sites could be much less deeply buried in areas of deposition and less affected by bioturbation near the surface, although the same caveats apply.

Widespread late Holocene deposits that are contemporaneous with or that post-date Puebloan occupation of the area are more areally extensive than earlier Holocene deposits, providing greater opportunity for site preservation following burial. Significant deposits from this period are in the bottoms of major canyons, and the potential for burial should be highest on late Holocene floodplains and near the base of slopes where late Holocene colluvium has been deposited. Additional deposition has occurred on mesa tops where eolian sediment has accumulated, providing local opportunities for preservation of Puebloan sites. Some colluvial slopes below ridge tops and at slope breaks between steeper slopes above and shallower slopes below have also experienced late Holocene deposition and offer good potential for site preservation. Of interest is the apparent use of some areas by Pueblo people during periods of erosion and landscape dissection, and some sites in eroded areas may provide evidence of how they adapted to and utilized an eroding landscape.

SOIL DEVELOPMENT AND GEOMORPHIC HISTORY

The nature of soils and surficial deposits are controlled by environmental conditions acting during their development, and they can therefore provide various kinds of paleoenvironmental information relevant for archaeological investigations.

The characteristics of surface and buried soils provide primary information about the stability or instability of the land surface at various times and can provide supplemental information about climate and/or vegetation. For example, a strongly developed buried soil indicates an extended period of land surface stability followed by some environmental change that caused sediment deposition at that site. Alternatively, a weakly developed soil or a thickened (cumulative) soil indicates a briefer period of stability or gradual sediment accumulation, respectively. Certain soil characteristics, such as gleying or mottling, can indicate the presence of prolonged periods of saturation or fluctuating water levels and, conversely, the absence of these characteristics can indicate that unsaturated conditions prevailed during soil development (Birkeland 1999). Certain soil properties are some times associated with specific vegetation conditions, and their presence may provide ecological information. For example, mollisols are a type of soil with thick dark surface horizons that generally form under grasslands, whereas other soil types such as alfisols, may form under forest cover. Such lines of evidence have been used to infer changes from forest to grassland at some sites with stacked soils with different characteristics (McFaul and Doering 1993). Weakly developed soils that are likely formed in late Holocene deposits burying Ancestral Puebloan sites are likely entisols or inceptisols. Better-developed soils burying Archaic or Paleoindian sites on the Pajarito Plateau have formed during a predominantly semi-arid climate regime, often have carbonate B horizons, and are likely aridisols.

The characteristics of surficial deposits provide primary information about geomorphic processes during their deposition, and in some circumstances can provide supplemental inferences about other aspects of the environment. For example, particle size and sedimentary characteristics of associated deposits can indicate whether an archaeological site was in or near an active alluvial or colluvial setting or at a location subject to eolian deposition, or was alternatively at a relatively stable or eroding site on the landscape. Geomorphic processes can be affected by climatic variables that are too short in duration to be preserved in other paleoenvironmental records, such as tree rings, and the record of geomorphic changes may thus provide unique insight into some important environmental characteristics. For example, while tree rings record variations in annual precipitation, particularly precipitation during the winter months, major environmental changes such as channel incision or arroyo cutting can be caused by changes in the intensity of summer thunderstorms that might not be detected in the tree ring record (Leopold 1951).

GEOMORPHIC SETTING OF LAND TRANSFER PARCELS

Five land conveyance parcels located on the Pajarito Plateau at LANL have been the focus of this investigation. Fieldwork was conducted within the Airport (A-3, A-7, and A-5-1), White Rock (A-19), TA-74 (A-18-a), White Rock Y (C-2), and Rendija (A-14) land transfer parcels (Figure 3.2). Geomorphic maps, detailed descriptions of surficial geology, soils, and the geomorphic history of each tract are presented in Reneau and Drakos (Chapter 57, Volume 3). The following is a brief introduction to the geomorphic setting of each tract.

The White Rock Tract is within the Cañada del Buey watershed (Figure 3.2) and includes part of the active stream channel and adjacent floodplains, colluvial slopes, and alluvial fans. Colluvium throughout most of the parcel overlies basalt of the Cerros del Rio volcanic field, and some areas of the parcel comprise stripped basalt bedrock. The Tshirege Member of the Bandelier Tuff, which overlies the Cerros del Rio basalt, is present as an isolated mesa in the western part of the parcel.

The Airport Tract includes a gently east-sloping mesa between a tributary to Pueblo Canyon on the north and DP Canyon, a tributary to Los Alamos Canyon, on the south (Figure 3.2). Bedrock beneath the mesa consists of the Tshirege Member of the Bandelier Tuff. The mesa is capped by eolian sediments and colluvium that thins to exposed bedrock near the mesa edge.

The Rendija Tract is located within the Rendija Canyon watershed and includes part of the active stream channel and adjacent floodplains, tributary drainages, fluvial terraces, colluvial slopes, ridge crests, and mesitas. Rendija Canyon possesses what may be the most extensive and best preserved set of stream terraces on the Pajarito Plateau, locally including at least five Pleistocene surfaces and four Holocene surfaces (McDonald et al. 1996; Reneau and McDonald 1996). The terrace sequence is well-preserved in the central and western part of the tract, whereas the eastern part of the tract includes colluvial slopes below high ridges leading to tributary drainages to Rendija Canyon with narrow strips of young alluvium and relatively poor preservation of terraces. Rendija Canyon has incised below the Tshirege Member of the Bandelier Tuff, and surficial deposits are underlain by Tschicoma Formation dacite lavas Puye Formation fanglomerates, Cerro Toledo interval (unit Qct) pumice beds and alluvium, and non-welded tuff and pumice beds of the Otowi Member of the Bandelier Tuff.

The TA-74 South Tract is located in a relatively broad part of lower Pueblo Canyon (Figure 3.2). TA-74 South Tract geomorphic features include the active stream channel and adjacent floodplains of Pueblo Canyon, higher stream terraces of Holocene and Pleistocene age, and areas of colluvium and alluvial fans on the side slopes and along tributary drainages. The part of Pueblo Canyon comprising the TA-74 South Tract has incised below the Tshirege Member of the Bandelier Tuff, and surficial deposits are underlain by Pliocene fanglomerates of the Puye Formation and non-welded tuff and pumice beds of the Otowi Member of the Bandelier Tuff.

The White Rock Y Tract is located in Los Alamos Canyon and includes the confluence with Pueblo Canyon (Figure 3.2). White Rock Y Tract geomorphic features include the channel of Los Alamos Canyon, incised into basalt bedrock, and an adjacent stream terrace that is overlain by colluvium derived from a higher, Pleistocene-age terrace. The higher terrace is bordered on the south by colluvial slopes that lead up to a Bandelier Tuff-capped mesa south of the tract. Approximately 15-m- (49.2-ft-) high basalt cliffs border the modern stream channel east of the confluence with Pueblo Canyon.

CHAPTER 4
ECOSYSTEMS OF THE PAJARITO PLATEAU AND EAST JEMEZ MOUNTAINS: LINKING LAND AND PEOPLE

Teralene S. Foxx

INTRODUCTION

After the volcanic eruptions in the Jemez Mountains over a million years ago, development of vegetation on the ash-hewn Pajarito Plateau and in the remnant mountains was influenced by relief and climate and, more recently, by human interaction. Volcanism and erosion influenced the development of the soil through factors like rainfall, vegetation, topography, and time. Geofloras were influenced by drying climate and mountain building. Conversely, the developing soils influenced vegetation through chemical make-up, texture, and water availability (Dick-Peddie 1993). As the environment of the Pajarito Plateau and the Jemez Mountains underwent geologic change, various plant communities became established with woodlands at lower, drier elevations and forests at higher, cooler locales (Figure 4.1).

The erosive power of water developed watercourses that incised deep canyons into the plateau. Riparian zones developed in canyon bottoms, dominated by water-loving species that grew within the area mediated by water flowing permanently or ephemerally through the canyons. Throughout the centuries, before humans inhabited the area, a dynamic process of change took place. Fire, windfalls, floods, and changing weather patterns influenced ecosystems—some times within a microhabitat or within the vast landscape. Some 10,000 years ago, humans entered into the ecosystem for the first time. Although their impact was gradual and largely unnoticed until about 1000 years ago, they did bring change. As people aggregated on the land and began to use it more intensively, the landscape was modified. Using data from ethnobotanical, ethnozoological, and archaeological studies, this chapter describes the ways people used the Pajarito Plateau and the adjacent Jemez Mountains and looks at how they impacted their environments.

LOS ALAMOS NATIONAL LABORATORY AND THE PAJARITO PLATEAU

Los Alamos National Laboratory (LANL) is situated on the Pajarito Plateau. The Pajarito Plateau consists of a series of narrow mesas and deep canyons that trend east-southeast from the Jemez Mountains to the Rio Grande. The defining feature of the plateau is the Tshirege Member of the Bandelier Tuff, a massive series of ignimbrites or "ash-flow tuffs" that erupted from the Jemez Mountains caldera. The Tshirege Member buried most of the former topography between the Jemez Mountains and the Rio Grande thereby creating a new landscape. The subsequent erosion of this formation has resulted in the distinctive topography of the Pajarito Plateau and LANL (Broxton et al., this volume; LASL 1976:4–6; Reneau and McDonald 1996:3).

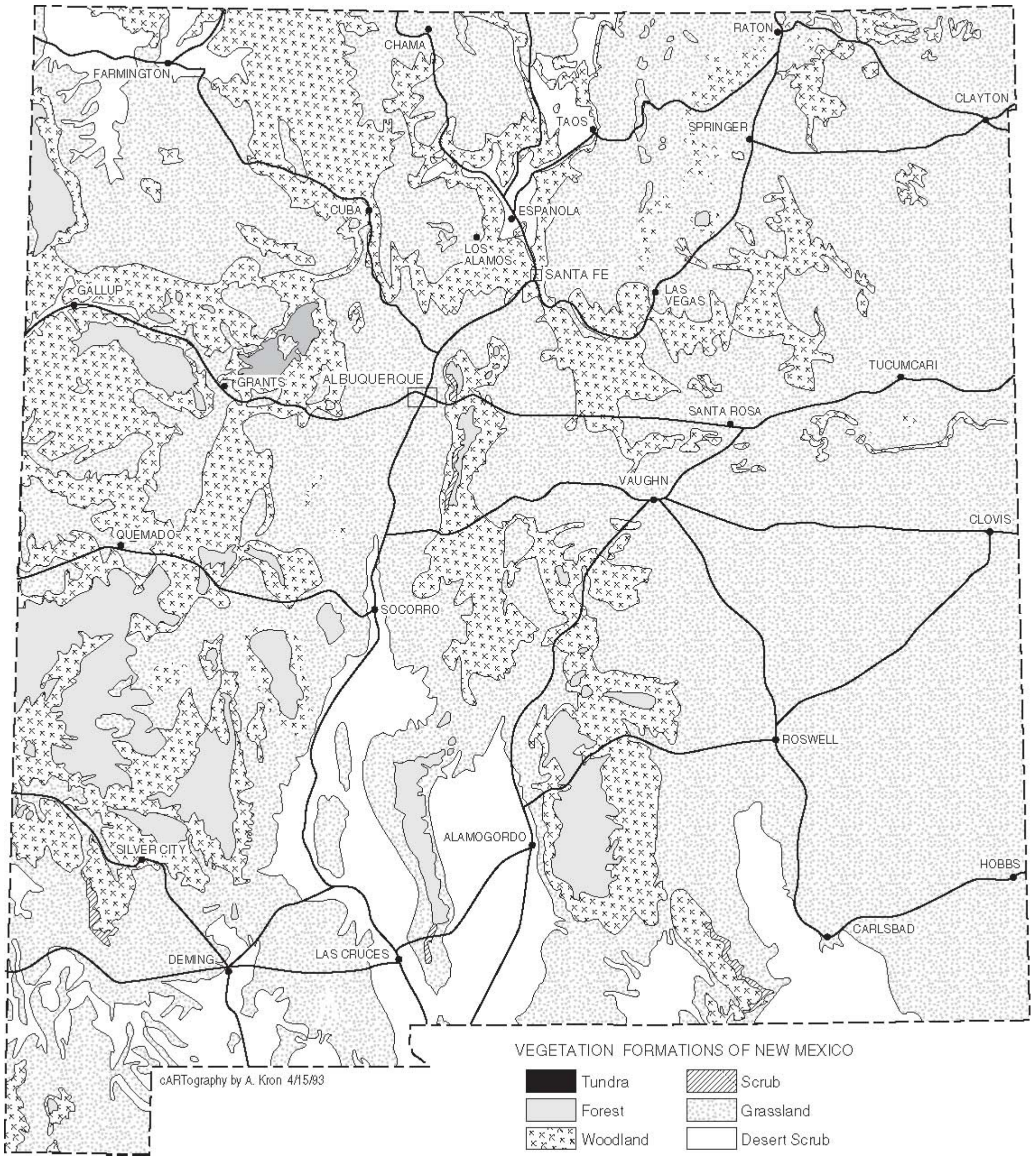

Figure 4.1. Established vegetation types of the Los Alamos area in relation to the rest of New Mexico.

LANL contains several distinct environmental zones. The elevation gradient at LANL is approximately 800 m (2400 ft), ranging from the Rio Grande Valley (1620 m; 5400 ft) to the base of the Jemez Mountains (2340 m; 7800 ft). This elevation change and a complex geologic history have created several different climatic zones, soil types, vegetative zones, and animal habitats within the confines of LANL (Balice et al. 1997:4–6; LASL 1976:2–6; Reneau and McDonald 1996:1–3). Topography is typically rugged and undulating and contains a number of mesa tops and canyon bottoms and their associated steep talus slopes and cliffs. Soils in the canyon bottoms and on the mesa tops of the south and southeastern part of LANL are mostly aridisols and entisols, with an abundance of alluvium on the steep slopes, large tuff rock outcrops, volcanic rock outcrops, talus slopes, and gravelly and sandy loams. Mesa tops are generally associated with areas of high agricultural potential.

Climate of the Pajarito Plateau

Los Alamos has a semiarid, temperate mountain climate. Mean temperatures vary with altitude and average 5°F higher in and near the Rio Grande Valley (1980 m; 6500 ft) and 5°F to 10°F lower in the nearby Jemez Mountains (2600 to 3050 m; 8500 to 10,000 ft) (Bowen 1990:3–17). Mean precipitation values for the Pajarito Plateau over the last 30 years show that higher elevations near Los Alamos receive approximately 48 cm (19 in.) of rain per year, while lower elevations in the piñon-juniper zone near White Rock receive approximately 34 cm (13.5 in.).

Winter temperatures on the Pajarito Plateau range from 15°F to 25°F at night and 30°F to 50°F during the day. Cold Arctic air masses occasionally invade the Los Alamos area from the north and east, but often the shallow layer of coldest air is dammed to the east by the Sangre de Cristo Mountains. Temperatures in the Los Alamos area occasionally will drop to 0°F or below. The freeze-free growing season of 157 days in Los Alamos is relatively short, while the normal growing season in White Rock is even shorter at 145 days. Above 2743 m (9000 ft), frosts can occur during any time throughout the year (Bowen 1990:3–17; Reneau and McDonald 1996:2–3). Summer temperatures are in the 70s and 80s (Bowen 1990, Table 7). Climatic information for the County of Los Alamos extends back to 1910, while that for the community of Española dates back to 1895, and to 1924 for Bandelier National Monument (Bowen 1990; Scurlock 1998).

The normal annual precipitation around Los Alamos, including rainfall and snowfall, totals approximately 46 cm (18 in.). Annual precipitation decreases rapidly toward the Rio Grande Valley, with the normal White Rock precipitation falling somewhere around 33 cm (13 in.). Annual precipitation at higher elevations in the Jemez Mountains is normally around 51 cm (20 in.). In general, the precipitation patterns of the Pajarito Plateau region are characteristic of a semiarid climate where precipitation amounts vary considerably from year to year. Over a 69-year period, the annual precipitation extremes ranged from 17.77 to 77.06 cm (16.08 to 30.34 in.) (Balice et al. 1997:1–12; Bowen 1990:3–17).

Monsoon season on the Pajarito Plateau spans the months of July and August. Convection of warm air over the Jemez Mountains causes thundershowers to develop during the afternoons and early evenings, and these drift over the plateau and cause brief, but intense, rains (Bowen 1990:3–17). Westerly winds push the thunderstorms above the Jemez Mountains towards Los Alamos. The large-scale atmospheric flows transport moisture from the Gulf of Mexico during the summer monsoons, and from the Pacific Ocean during the winter, spring, and fall. Nearly 40 percent of the annual precipitation falls during the monsoon months. Although summer precipitation is heavily weighted toward the monsoons, winter precipitation falls primarily as snow. Accumulations usually approach upwards of 130 cm (51 in.) seasonally, but snowfall levels vary considerably from year to year.

Water Resources

Water is one of the most important elements for permanent habitation. The Pajarito Plateau has both permanent and ephemeral streams and some springs. Few of the canyons of the Pajarito

Plateau have perennial water. Large settlements are associated with canyons that have perennial water (e.g., Frijoles Canyon, Santa Clara Canyon) or springs (e.g., Pajarito Canyon). Pajarito Canyon has a perched aquifer where the water emerges to the surface. Throughout the plateau, there are areas where inhabitants also used water-collecting devices (Steen 1977).

In addition to the permanent and ephemeral streams on the Pajarito Plateau, there are 27 springs that discharge from formations in White Rock Canyon (Purtymun et al. 1980). These springs are habitats for various obligatory and facultative wetland species (Foxx and Tierney 1980), including the giant helleborine orchid (*Epipactis gigantea*).

Water resources and riparian zones are important habitats for many plants and animals. Various plant species were important to the Pueblo and Hispanic residents. Wetland plants were indicators of water; some wetland taxa were used for food and medicine, while others provided building material (e.g., cattail) (Table 4.1). Additionally, wetland and riparian areas attracted greater quantities of game.

Table 4.1. Wetland plants used by Pueblo and Hispanic residents.

Scientific Name	Common Name	Occurrence	Spring	Summer	Habit	Wetland*
Acer glabrum	Rocky Mountain maple	locally common	x		tree	FACW, FAC
Acer negundo	boxelder maple	locally common	x		tree	FAC, FACW
Alnus tenufolia	alder	locally common	x		tree	FACW
Berula erecta	water parsnip	not common		x	perennial	OBW
Betula occidentalis	western water-birch	locally common		x	tree/shrub	FACW
Cyperus aristatus	flatsedge	locally abundant			Perennial	FACW
Equisetum laevigatum	smooth horsetail	locally common			Perennial	FAC, FACW
Forestiera neomexicana	New Mexico olive	common	x		shrub	FAC+
Iris missouriensis	Rocky Mountain iris	locally common	x		perennial	FACW, OBW
Juncus spp.	rush	locally common		x	perennial	FACW, OBW
Mentha arvensis						FACW
Mimulus glabratus	monkeyflower	not common	x		perennial	OBW
Phragmites communis	common reed	occasional			perennial	OBW
Plantago major						FACW

Scientific Name	Common Name	Occurrence	Spring	Summer	Habit	Wetland*
Populus angustifolia	narrowleaf cottonwood	locally common	x		tree	FACW
Populus fremontii	Fremont cottonwood	locally common	x		tree	FACW
Prunus virginiana	chokecherry	locally common	x		shrub	FAC
Rorippa sinuata	yellow cress	locally common	x		perennial	FACW
Rudbeckia lacinata	coneflower	locally common		x	perennial	FACW
Rumex crispus	wild buckwheat					FACW
Salix sp.	willow	locally common	x		shrub	FACW
Scripus sp.	bulrush				perennial	
Typha latifolia	broadleaf cattail	locally common	x		perennial	OBW
Urtica dioca-procera	nettle					FACW

OBW = obligate wetland species; occurs almost always (99%) in wetlands; FACW = Usually occurs in wetlands (67% to 99% of time) but occasionally found in nonwetlands; FAC = Equally likely to occur in wetlands or nonwetlands (34% to 66% of the time).

Plant Communities of the Pajarito Plateau

Mapping and classification of the Jemez Mountains have been done by the US Forest Service for the Santa Fe National Forest (Moir and Ludwig 1979), by Allen (1984, 1989) for Bandelier National Monument, by Potter and Foxx (1981) for the Cerro Grande, by Barnes (1983) for the piñon-juniper woodlands, and by Balice et al. (1997) for LANL and adjacent areas. In the late 1990s, Koch et al. (1996) and Balice et al. (1997) developed a land cover map for the Pajarito Plateau and adjacent east Jemez Mountains. The classification included 10 categories ranging from open water to spruce-fir forests. These classes correspond to the cover types for the land classification map presented in Figure 4.2 (Balice et at. 1997; Koch et al. 1996).

The major cover types were defined by dominant tree species and structural characteristics as follows: juniper savanna, piñon-juniper woodland, ponderosa pine forest, mixed conifer forest, and spruce-fir forest. The relationship between these cover types and elevation is show in Figure 4.3 (Foxx and Hoard 1984). The other cover types—grassland, shrubland, open water, and unvegetated land—are not influenced by topography.

Figures 4.4 through 4.21 show each of the major cover types discussed in Balice et al. (1997), and each are discussed briefly. Additional information concerning plant species that occur in these cover types can be obtained from Foxx and Hoard (1984), Foxx and Tierney (1980), Foxx et al. (1998), and Jacobs (1989).

Open Water, Wetlands, and Riparian Zones

In the arid Southwest, water is essential for survival. On the Pajarito Plateau, springs, perennial and intermittent streams, and the Rio Grande provide life-giving water (Figures 4.4 through 4.9). This cover type includes all land that is periodically flooded (intermittent streams) or is open water (rivers, perennial streams, and ponds). Wetlands are defined as areas with hydric soil and wetland species that either always require water (obligatory wetland species) or must have water part of the time (facultative wetland species). Cattails (*Carex* spp.) are an example of obligatory wetland species and can be found in marshes. Willow and various sedges are examples of facultative wetland species. These species are found on drier sites, sandbars, and mudflats and grass/sedge meadows. Narrow strips along permanent and intermittent rivers and streams are called riparian zones.

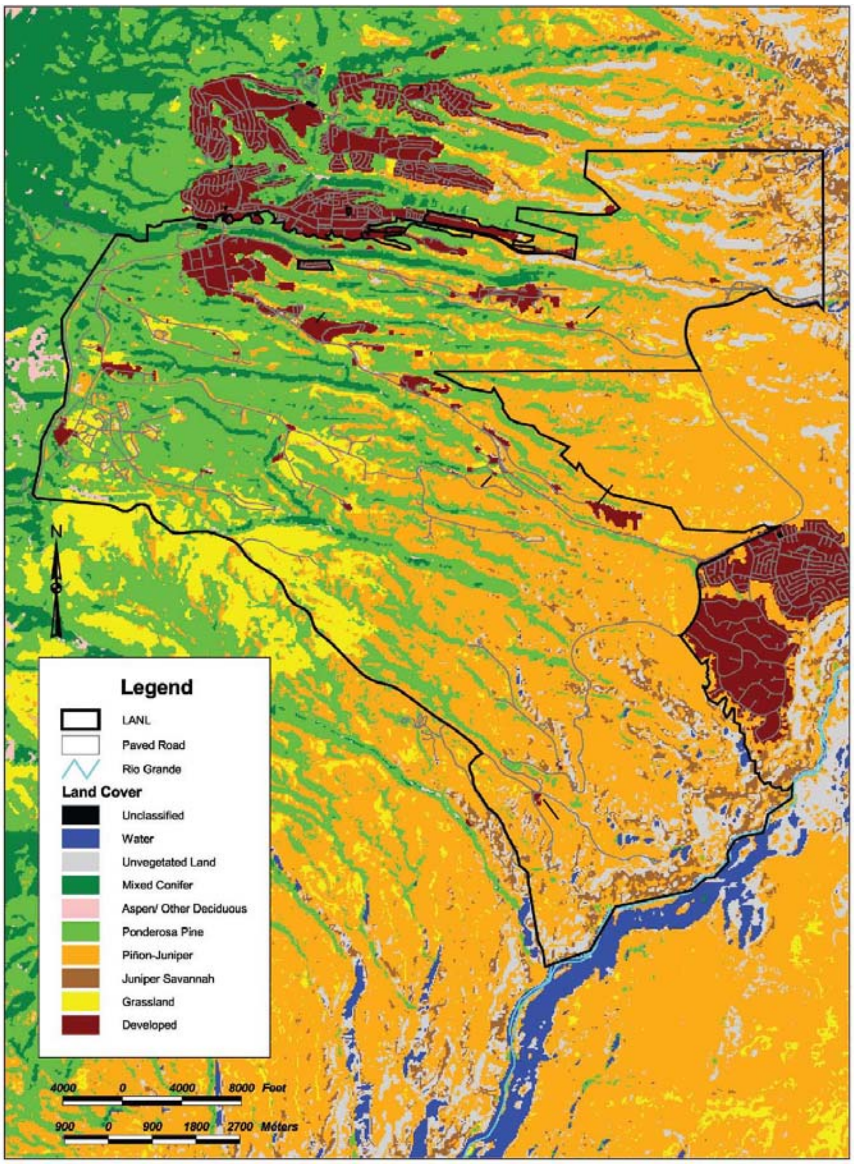

Figure 4.2. Land cover map for LANL and vicinity before the Cerro Grande fire.

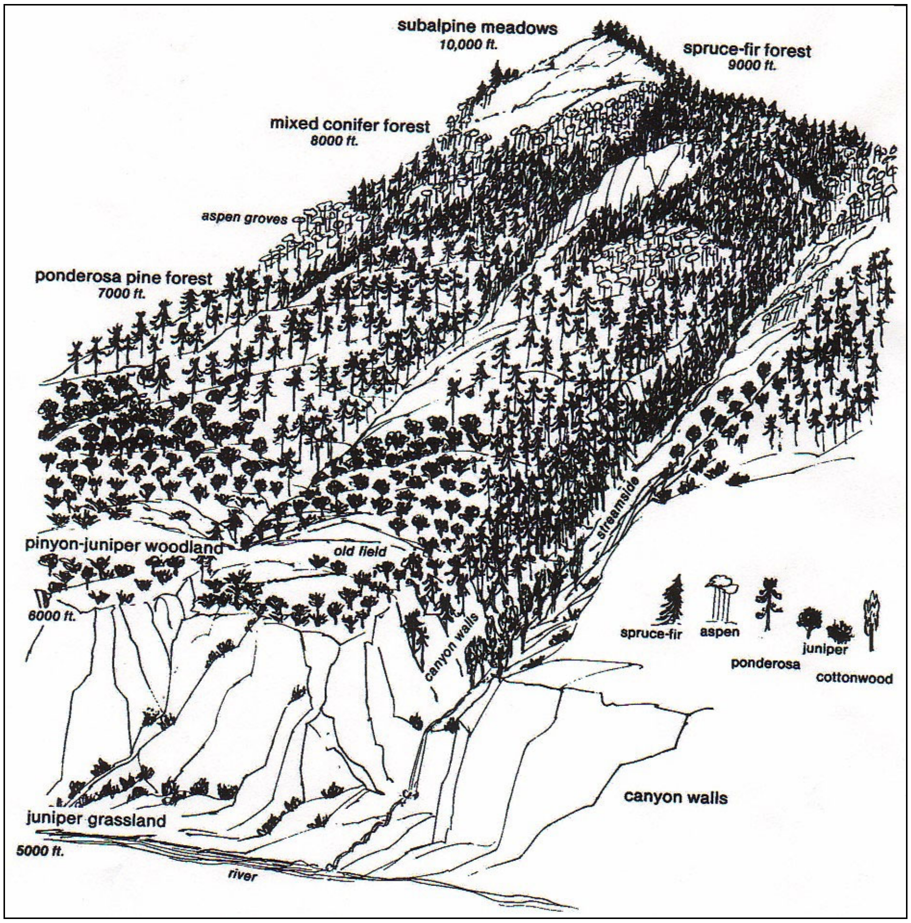

Figure 4.3. Cover types by elevation.

Species within the riparian zones of perennial streams (e.g., Frijoles) include cottonwood (*Populus* spp.) and boxelder (*Acer negundo*). Along the Rio Grande in the vicinity of Bandelier and LANL, tree species have been flooded but were present before construction of Cochiti Dam. Exotic species such as tamarisk (*Tamarix* spp.) and Russian olive (*Elaeagnus angustifolia*) have increased along the Rio Grande, replacing native cottonwoods.

Unvegetated Lands

The unvegetated lands include tuffaceous cliffs, cliff faces, basal cliffs, basalt talus slopes, and felsenmeers. These sites generally have less than 7 percent vegetation, and even though there is not much vegetation, the tuffaceous cliffs and cliff faces were important habitat sites for prehistoric inhabitants. The soft tuff was worked into cavates, and houses and storage areas extended from cliff faces. At lower elevations, the basalt caves provided areas for storage and safekeeping, and petroglyphs are common on the large basalt boulders. Figures 4.10 and 4.11 provide pictures of the tuffaceous and basaltic cliffs around LANL.

Figure 4.9. The Rio Grande with native willow along the bank.

Figure 4.10. Tuffaceous cliffs in Ancho Canyon.

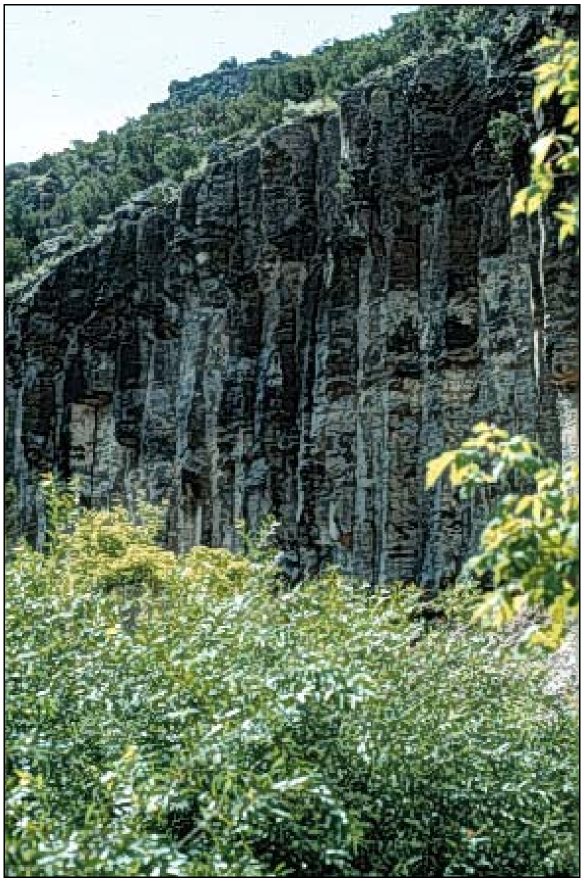

Figure 4.11. Basaltic cliffs in Ancho Canyon.

Juniper Savanna

The juniper savanna is an open grassland that is dominated by one-seed juniper (*Juniperus monosperma*) (Figure 4.12). Land cover in the juniper savanna is between 10 percent and 30 percent. Understory species in this cover type include sideoats grama (*Bouteloua curtipendula*), blue grama (*B. gracilis*), and hairy grama (*B. hirsuta*). The juniper savanna is the primary upland vegetation along the Rio Grande and ranges from 1634 m (5360 ft) to 1951 m (6400 ft) in elevation. There is little evidence of human habitation within this cover type, but evidence of ancient fields and historic animal pens have been found along the upland reaches of the Rio Grande.

Figure 4.12. Juniper savanna in White Rock Canyon.

Piñon-Juniper Woodland

The piñon-juniper woodland consists of open or closed low trees. The dominant tree species are one-seed juniper (*Juniperus monosperma*) and piñon (*Pinus edulis*) (Figure 4.13). One-seed juniper is more abundant at lower elevations, while piñon is more abundant at higher elevations within the zone. These woodlands are between 1890 and 2195 m (6200 and 7200 ft) within the canyons. On the mesa tops these species dominate between 1890 m (6200 ft) and 2195 m (7200 ft). Depending on the altitude, the following species can be found in the understory: blue grama (*Bouteloua gracilis*), Indian ricegrass (*Oryzopsis hymenoides*), and sand dropseed (*Sporobolus cryptandrus*). At higher elevations, mountain muhly (*Muhlenbergia montanus*) is some times present. Most of the habitation sites found on the plateau are located within the piñon-juniper woodland, but many of the homestead sites were located at the ecotone between this type and the ponderosa pine forest.

Figure 4.13. Piñon-juniper woodland.

Ponderosa Pine Forest

This cover type is either a closed or open forest (Figures 4.14 and 4.15). Ponderosa pine (*Pinus ponderosa*) is the dominant species with a cover greater than 7 percent; one-seed juniper and piñon may also be present, but they make up less than 7 percent of the cover.

Figure 4.14. Open ponderosa pine forest.

The ponderosa pine forests can be found at elevations as low as 1890 m (6200 ft) in some protected canyons on the plateau. In more open canyons, ponderosa pine is generally not found below 1921 m (6300 ft). On the mesa tops and lower slopes of the Sierra de los Valles, for example, ponderosa pine forests extend to 2378 m (7800 ft) in elevation.

Understory species in the ponderosa pine forest include blue grama, mountain muhly, mutton grass (*Poa fendleriana*), and little bluestem (*Schizachrium scoparium*). Gambel oak is a common shrub species. A number of fieldhouses and historic homestead sites have been identified in the ponderosa pine forest. Much of the community of Los Alamos and the upper portions of LANL are within this cover type.

Figure 4.15. Closed ponderosa pine forest.

Mixed Conifer/Spruce Fir

Mixed conifer forests typically appear at higher elevations in the mountains and consist of trees that are at least 5 m (16 ft) tall. Douglas fir *(Pseudotsuga menziesii*) and white fir (*Abies concolor*) are the dominant overstory species, although other species such as ponderosa pine may be present in the overstory or midstory (Figure 4.16 and Figure 4.17).

.

Figure 4.16. Mixed conifer forest with Douglas fir and white fir.

Mixed conifer forest intergrades with ponderosa pine communities and as “stringers-on” in north aspects of the canyons and on the canyon bottoms above 2104 m (6900 ft) in elevation. These communities continue to 2591 m (8500 ft) on eastern exposures and on flat areas. Shrubs include ninebark (*Physocarpus monogynous*), wild rose (*Rosa woodsii*), cliffbush (*Jamesia americana*), and dwarf juniper (*Juniperus communis*).

Figure 4.17. Engelmann spruce and white fir dominate high elevations.

Aspen Forest

This cover type occurs in montane and upper montane landscape positions. Trees that are greater than or equal to 5 m (16 ft) tall with coverage greater than or equal to 13 percent are present. Aspen (*Populus tremuloides*) is present in the overstory with at least 20 percent cover (Figure 4.18).

Figure 4.18. Aspen groves are found throughout higher elevations indicating past fire.

Some combination of Douglas fir, ponderosa pine, white fir, or Engelmann spruce (*Picea engelmanni)* are also present but does not dominate the overstory. Aspen communities are common at mid-elevations in the mountains, ranging from approximately 2700 to 3030 m (8900 to 9950 ft). Below 2820 m (9250 ft) aspen stands occupy north and northeast aspects, whereas at upper elevations they are found on the southeast- to southwest-facing positions

Shrublands

Shrublands are identified by the presence of shrub species greater than 0.46 m (1.5 ft) in height with at least 15 percent cover (Figure 4.19 and Figure 4.20). Trees are generally not present or, if they are present, they make up less than 10 percent of the cover. Shrubs include fourwing saltbush *(Atriplex canescans)*, which is often an indicator of prehistoric dwellings, chamisa *(Chrysothamnus nauseosus*), which is often found along roadsides and drainages, New Mexico locust (*Robinia neomexicana)*, which is a common species in burned and/or disturbed areas, and Gambel oak, which is common in ponderosa pine forests and burned areas.

Figure 4.19. Sagebrush (*Artemisia tridentata*) shrubland in White Rock Canyon.

Figure 4.20. Oak shrubland and grassland from the La Mesa fire.

Grasslands and Disturbed Areas

Grasslands are dominated by grasses and grass-like plant species. If shrubs or trees are present in this cover type, then the total percent cover is less than 10. Grasslands can be found on hillslopes in White Rock Canyon or other open sites (Figure 4.21). At the crest of the Sierra de los Valles, subalpine grasslands are conspicuous. They occur at 2743 m (9000 ft) on steep southerly and southwesterly slopes. Montane meadows are found in the mixed conifer and spruce-fir zone. Disturbed areas are found throughout and are recognized by the prevalence of weedy species including Russian thistle, summer cypress (*Kochia scoparia*), snakeweed (*Gutierrezia* spp.), and dandelion (*Taraxacum* spp.).

Figure 4.21. Subalpine grasslands on mountain peaks.

Water Canyon Elevation Gradient

The survey of Water Canyon shows that plant diversity is quite high on the Pajarito Plateau. Almost 300 plant species have been identified (LASL 1976:23). Species diversity among all plants except grasses is elevated at higher elevations (Table 4.2).

Table 4.2. Floral distribution by community type along an elevation gradient.

Overstory-Vegetation Type	Elevation (m)	Numbers of Families	Number of Species*
Fir-spruce	2865	18	28
Subalpine grassland	2865	10	24
Mixed conifer	2560	9	22
Ponderosa pine	2255	12	25
Piñon-juniper	1950	8	17
Juniper-grassland	1645	8	11

*Does not include grasses

A maximum of 18 taxonomic families and 28 non-grass species were recorded in the subalpine grassland (LASL 1976). Members of the composite (Compositae) and grass (Gramineae) families occur with the highest frequency and comprise the highest percentage of ground cover at all elevational sites. Total ground cover reaches a maximum of nearly 100 percent at the higher elevations and decreases steadily to a minimum of 15 percent in the juniper woodland community. As with plant communities, animal communities on the plateau are affected by differences in elevation.

Animal Communities on the Pajarito Plateau

Several invertebrates and vertebrate animal communities are represented at LANL. Many species of small mammals such as deer mice (*Peromyscus* sp.), woodrats (*Neotoma* sp.), moles (*Microtus* sp.), squirrels (Sciuridae), and chipmunks (*Eutamias* sp.) occur in the area, some of which are specific to certain elevation gradients. Other small mammals, such as bats (Chiroptera), are present within the Laboratory boundaries as well, and consist of at least 15 different species (Biggs et al. 1997:1–3; LASL 1976:24–27). The area also contains mule deer (*Odocoileus hemionus*) and elk (*Cervus elaphus*). Little is known about other large and medium size mammals of the area, but based on observations and current studies, a minimum of 12 species of carnivores are present. Among these are black bear (*Ursus arctos*), mountain lion (*Felis concolor*), bobcat (*Felis rufus*), gray fox (*Urocyon cineroargenteus*), and coyote (*Canis latrans*) (Biggs et al. 1997:1–3; LASL 1976:24–27).

Cold-blooded animals in the area include several species of fish found in the Rio Grande. The carp (*Ctenopharyngodon* sp.), chub (*Gila pandora*), and white sucker (*Catostomus commersoni*) are abundant in the waters of the Rio Grande on the eastern boundary of LANL. There are a few brown trout found in the area but not enough to represent a significant population, probably due to the turbidity of the river (LASL 1976:25).

There are approximately nine species of reptiles in the LANL area including small lizards and king snakes (*Lamprapeltis getula*), bull/gopher snakes (*Pituophis melanoleucus*), garter snakes (*Thamnophius* sp.), and rattlesnakes (Crotalidae). The Jemez Mountains salamander (*Plethodon neomexicanus*) is a rare amphibian that is found in the area (LASL 1976:25).

There are some 187 bird species from 44 families reported in the area, some of which are permanent residents and some of which are transient populations. Observed permanent residents include the common raven (*Corvus corax*), pygmy nuthatch (*Sitta pygmaea*), western bluebird (*Sialia mexicana*), gray-headed junco (*Junco caniceps*), and rufus-sided towhee (*Pipilo erythrophthalmus*). Summer birds include the turkey vulture (*Cathartes aura*), red-tailed hawk (*Buteo jamaicensis*), American kestrel (*Falco sparverius*), peregrine falcon (*Falco peregrinus*), chipping sparrow (*Spizella passerina*), and violet-green swallow (*Tachycineta thalassina*) (LASL 1976:25).

The ecological relationships to the topography are interesting. Animals in the lower elevation zone (1700 to 2000 m; 5610 to 6600 ft) include coyote, rattlesnake, bobcat, gray fox, red-tailed hawk, spiny lizard (*Sceloporus magister*), mule deer, deer mouse, and the cottontail (*Sylvilagus* sp.). Animals in the middle elevation zone (2000 to 2400 m; 6600 to 7920 ft), especially in the canyons, include coyote, raccoon (*Procyon lotor*), mountain lion, American black bear, turkey vulture, American kestrel, golden eagle (*Aquila chrysaetos*), gopher snake, rock squirrel (*Spermophilus variegatus*), and mule deer. Animals from the same elevation zone that inhabit the mesa tops include American black bear, mountain lion, common raven, pygmy nuthatch, Colorado chipmunk (*Tamias quadrivittatus*), pine squirrels (*Tamiasciurus* sp.), and mule deer. Animals in the highest elevations (2400 to 3200 m; 7920 to 10,560 ft) include the American black bear, mountain lion, green-tailed towhee, hairy woodpecker (*Picoides villosus*), Rocky Mountain elk, mule deer, western bluebird, and gray-headed junco (LASL 1976:24–26).

PLANTS AND ANIMALS AS INDICATORS OF PAST LAND USE AND CHANGE

Plants

The Pajarito Plateau has a long history of use by different groups of peoples. Archaeological evidence shows that humans were in the area by at least 10,000 years ago (Steen 1977; Vierra 2005a). Agriculture was a common practice on the Pajarito Plateau by about 1000 years ago. Since the 18^{th} century, the plateau has been logged, grazed, and dry-land farmed. Laboratory activities (disposal sites, roads, building) and fires have affected plant and animal communities in the last 50 years. Disturbances, of whatever kind, typically have a general pattern of plant succession after a given period of time: weedy annuals, replacement of annuals with perennial forbs and grass, and invasion of woody species. Plants known as colonizers are usually the first species to grow on disturbed sites since they out-compete the natural species of the original community after the disturbance (Clements 1928; Foxx et al. 1998).

Prehistoric and historic dwellings, agricultural areas, and the surrounding landscape can provide information about past use and activities (Foxx and Tierney 1984, 1999; Foxx et al. 1998). The remains of vegetal and faunal remains within the hearths at an archaeological site can provide information about possible plant and animal uses. Also, the dwellings themselves and the immediate surroundings can provide information about past use and activities. Habitats that had natural or human disturbance are atypical of the surrounding, undisturbed area. These areas of disturbance often have an abundance of plants that were introduced by human activity (Housely 1974; Yarnell 1958). Various categories of these colonizing plants are useful in determining changes in the environment. There are three categories of species often found in association with natural or human disturbance: invasive weeds (often called pioneer plants), noxious weeds, and camp followers.

Invasive Weeds (Pioneer Plants)

Invasive weeds can be defined as plants that favor an open habitat and thrive in any disturbed area, ancient or contemporary (Lee 1999; Tierney 1973). These plants are called pioneer plants because they are the first arrivals on sites that have been disturbed by human habitation or types of disturbed soils. Most of these species have been introduced from outside the area (e.g., Europe, Africa, or other places within North America) since the time of the European entry into the Southwest and are not native to the landscape. Some species were purposely brought as medicinal or food plants, but others were accidental introductions by seeds clinging to animals or clothing or in goods. Some recent introductions were used as ornamentals (e.g., iris [*Iris missourriensis*]), for repairing spoiled land (e.g., crested wheatgrass [*Agropyron cristatum*]), and landscaping (e.g., Russian olive [*Elaeagnus angustifolia*]). Many of these plants have become naturalized, or have become a common part of the flora of areas in disturbed sites such as archaeological sites, along roadsides, and within floodplains.

Noxious Weeds

Noxious weeds, or a plant that has a negative impact on the environment or the economy, is used in this chapter as defined by the Cooperative Extension Service (Lee 1999). Noxious weeds displace native vegetation, increase soil erosion, and reduce opportunities for land use. In recent years, areas that have been denuded by vegetation after catastrophic wildfires have become prime locations for the growth of noxious weeds such as Canada thistle (*Cirsium arvense*). These weeds are often recent introductions to an ecosystem, and eliminating infestations are important (Lee 1999).

The difference between noxious weeds and invasive weeds is subtle. As the plant becomes common in the environment it may change in its classification. Species such as Russian thistle (*Salsola kali*) have become a common part of the landscape and, although widespread on disturbed soil, is not included in the list of weeds that are noxious in New Mexico. In a Santa Fe New Mexican article dated September 16, 1897, Russian thistle was first reported in the Santa Fe Valley and called a noxious weed. Today, Russian thistle can be found in abundance on some archaeological sites (e.g., Otowi), along roadsides, and in other disturbed sites where subsurface excavation occurred (Yarnell 1958). Since Otowi was excavated in the early 20th century, their presence is to be expected. Unexcavated archaeological sites, however, usually do not have plants like Russian thistle in abundance.

Camp Followers

Camp followers are tolerant of disturbed areas surrounding human activity and, in turn, are tolerated or even encouraged by humans because of their economic or aesthetic value (Tierney 1973). Camp followers have proven to be useful indicators of human activity (Housely 1974; Tierney 1973; Yarnell 1958). They are generally non-native species that were brought along for a utilitarian use such as food, medicine, or ceremony (e.g., wolfberry [*Lycium pallidum*] and sacred datura [*Datura meteloides*]). Indicator species may be native or non-native species that thrive in the disturbance of habitation sites (e.g., walkingstick cactus [*Opuntia imbricata*], four-wing saltbush [*Atriplex canescans*], and lambs quarters [*Chenopodium* spp.]). Prehistoric agricultural areas can often be located by rock alignments and some times by an anomaly in the existing vegetation, even after 400 years of abandonment. Thus, marks of earlier activities as evidenced by existing vegetation are a legacy of the past.

Floral introductions have occurred since people entered into the environments of the Pajarito Plateau. The presence of introduced species (invasive weeds, noxious weeds, and camp followers) indicates use, changing environments, or accidental introductions. The earliest introductions were probably camp followers brought as people migrated to the plateau. Later introductions may have been purposeful or accidental. Scurlock (1998) listed plants introduced since the entry of the Spanish into the middle Rio Grande Valley with approximate dates. Using Scurlock's list as a starting point, we compared that list of introduced plants with Foxx et al. (1998). Those plants that were found in the Jemez were noted. The list of introduced plants for the Jemez was further extended by other references, including Agricultural Research Service (1971), Crockett (1977), Curtin (1965), Lee (1999), Martin and Hutchins (1980), Phillips Petroleum Company (1957, 1960), Stubbendieck et al. (1989), Tierney (1973), Tierney and Hughes (1983). This list includes primarily "wild" species and does not concentrate on domestic species introduced by the Spanish such as wheat, barley, onions, oats, lettuce, watermelon, or fruit trees, or crops introduced by the Spanish such as tomatoes, chilies, cultivated tobacco, and new varieties of corn and beans (Wozniak 1995).

Animals

Introduction of domestic animals (cows, sheep, goats, pigs, horses, and other species) by the Europeans has had a profound impact on the land and peoples of the Southwest. Migratory societies could move when drought occurred and sedentary groups did not have to depend so much on wild foods. The result was that more trading and raiding was possible. Peace fairs such as those held at Taos in the 18th century between Pueblos, Apaches, Comanches, and the Spanish provided a means to distribute goods (Simmons 1991).

As time passed, some animals were no longer necessary for domestic life. For example, in the mid 20th century, burros were no longer needed for the economy as beasts of burden. Many were released and became feral in Bandelier National Monument and the Santa Fe National Forest. In the mid 1970s and early 1980s, the impacts of these animals on the ecosystem and archaeological sites were addressed in Bandelier National Monument. The animals were removed or exterminated. In recent years there has been one feral burro at LANL.

There have been introductions, extirpations, and extinctions of animal species that have changed the nature of the food chains. One example is the introduction of non-native fish, including brown and cutthroat trout. These fish have reduced the numbers of native fish species (Allen 1989) and make it difficult to determine the use of such groups by early peoples.

Prehistoric Land Use

The landscape of the Pajarito Plateau and east Jemez Mountains remained mostly untouched by human influence until approximately 10,000 years ago when small groups of Paleoindian hunter-gatherers followed game animals up and down the Rio Grande and took trips onto the plateau and into the Jemez Mountains to collect obsidian and other subsistence resources. These people moved often to take advantage of the various resources, and as edible plants became available, the consumers would reposition themselves (Tainter and Tainter 1996). These patterns meant that these hunter-gatherers might be at low elevations for gathering spring greens and at higher elevations for collecting summer and fall berries (Tainter and Tainter 1996; Vierra and Foxx 2002; Vierra 2005a).

From those first few people who wandered the mesas and canyons, the use of the area increased slowly. Archaic hunter-gatherer groups relied on small game such as grouse, as well as various plant species. Later, as maize horticulture became established, agriculturalists used the area for foraging. As the population density increased on the Pajarito Plateau, familiar landscapes were modified. Lands were cleared for agriculture, and every piece of wood within walking distance and that was useful for construction, cooking, or heating was quickly collected. The distribution and abundance of native plants and animal species within that area were altered in a short time. Vegetation communities were influenced by introduced and extirpated plants (Tainter and Tainter 1996).

By the Coalition period (AD 1150 to 1325), humans occupied the Pajarito Plateau on a year-round basis, and environmental impacts were, by extension, greater. During the Coalition and Classic (AD 1325 to 1600) periods, population and associated settlement increased, large, aggregated pueblos were developed, and agriculture, particularly in the lower elevations within the piñon-juniper woodland and juniper savanna, increased into all available arable lands. Though virtually abandoned by the late 1500s because of an extensive period of drought, the plateau continued to be used for foraging and hunting by the occupants who remained to take advantage of the plant and animal resources. In general, human activities on the Pajarito Plateau were closely associated with topography; middle elevations were used primarily for habitation, while upper and lower elevations were used for hunting, foraging, grazing, agriculture, and historic recreational activities.

Plant Resources

The Pueblo people used various plants and animals for daily living, including food, clothing, recreation, and ceremony. Use can be determined in three ways: from literature about ethnobotanical or ethnozoological studies, from surveys of sites to determine availability and camp followers, and from the study of macrobotanical and faunal material from archaeological excavations.

Knowledge of early plant and animal uses has been defined by early ethnologists and, more recently, by interviewers of tribal members. During the early 1900s, interviewed persons from the Keres, Tiwa, and Tewa language groups and Athabascans (the Apache and Navajo) related folklore about plants and plant usage. Researchers included Castetter (1935), Castetter and Opler (1936), Cook (1930), Elmore (1943), Jones (1931), Robbins et al. (1916), M. Stevenson (1912, 1915), and Swank (1932). Henderson and Harrington (1914) interviewed tribal members about animal uses. These studies have been a basis for much of the understanding about early plant and animal use. Additional information was obtained through excavations and the recovery of plant and animal remains, and from surveys of sites (Ford 1968; Foxx 1982; Lang 1986; Matthews 1990, 1992; Tierney 1977a, b, 1979; Trierweiler 1990, 1992).

Dunmire and Tierney (1995) summarized much of the ethnographic literature and also conducted personal interviews with tribal members of various pueblos. They identified 304 plants known to have uses for food, medicine, cordage, construction, implements, and tanning within the Pueblo Province. The categories they found and percentages of plants within each use category for the Jemez are found in Table 4.3.

Using the list compiled by Dunmire and Tierney, Vierra and Foxx (2002) identified 215 of the 305 species as being present in the Jemez Mountains flora. Of the 215 species, many had multiple uses. Table 4.4 shows the groups of species most commonly used by various groups. Vierra and Foxx (2002) also analyzed the list to determine the plant community where plants used for food and beverages are most likely to occur (Table 4.5).

Table 4.3. Percentage of plants used for different activities (from Dunmire and Tierney 1995).

Activity	Percent
Food and Beverage	42.0
Medicine	59.0
Smoking or Chewing	5.0
Construction	5.0
Coloring, Tanning, Soap, Art, Crafts	12.0
Cordage, Fiber, Fine Matting	3.0
Implements	11.0
Total Number of Identified Plants	**304**

Table 4.4. Plant uses and numbers of plant species used from plant communities.

Activity	Riparian	Juniper Savanna	Piñon Juniper	Ponderosa forest	Mixed Conifer
Medicinal (*n* = 148)	18	82	111	73	35
Food (*n* = 108)	23	41	77	56	30
Implements (*n* = 28)	4	14	20	15	6
Coloring/Tanning (*n* = 37)	6	19	24	16	6
Construction (*n* = 16)	6	7	9	8	4
Smoking (*n* = 13)	0	8	11	3	9
Cordage (*n* = 6)	2	3	2	2	1

Additional information has been gleaned from macrobotanical analysis of remains recovered from archaeological excavations. Information discussed here is limited to two sources (Foxx 1982; Matthews 1990). Foxx (1982) identified macrobotanical material from sites excavated in the Cochiti flood pool, while Matthews (1990) examined materials recovered from Burnt Mesa Pueblo and Casa del Rito. Both charred and uncharred seeds were recovered from flotation samples.

Table 4.5. Species of plants used by multiple Native American cultures of New Mexico.

Plant	Common Name	Number Groups
Achillea lanulosa	yarrow	3
Alnus tenuifolia	alder	3
Amaranthus graezans	pigweed	3
Amaranthus retroflexus	amaranth	6
Artemisia filifolia	sand sage	4
Artemisia frigida	wormwood	3
Artemisia tridentate	big sagebrush	2
Atriplex canescens	four-wing saltbush	7
Croton texensis	doveweed	5
Fallugia paradoxa	Apache plume	4
Hedeoma nana	false pennyroyal	3
Ipomopsis aggregata	scarlet gilia	3
Juniperus monosperma	one-seed juniper	4
Lycium pallidum	wolfberry	4
Mirabilis multiflora	showy four o'clock	3
Monarda menthaefolia	beebalm	4
Cleome serrulata	Rocky Mountain beeplant	8
Pectis angustifolia	lemoncillo	4
Penstemon barbatus	scarlet bugler	3
Pinus edulis	piñon pine	4
Portulaca oleraceae	verdolaga	5
Quercus gambelii	Gambel oak	3
Rhus trilobata	lemonade berry	7
Ribes inebrians	gooseberry	3
Rosa woodsii	wild rose	3
Solanum elaeagnifolium	bullnettle	5
Solanum jamesii	wild potato	4
Yucca spp.	yucca	8

Animal Resources

Compared to plant use, there is far less ethnographic information available for animals. Most of the current knowledge regarding animals comes from analyses of animal remains found in archaeological excavations, from mythology and folk story collections, and through ceremonial uses. Henderson and Harrington (1914) published a comprehensive work on animals of the

Tewa province in the early 20th century. Their work provides one of the earliest listings of animals found in the area and also includes the Tewa names for animals. The purpose of the study was to determine the use and presence of various animal species found in, or that had previously been found, in the areas of El Rito de los Frijoles, the Valle Grande, and Painted Cave in 1910. Their identifications provide a glimpse of species that were common in the area early in the 20th century. Some of these species were extirpated or became extinct since the late 1800s (e.g., bighorn sheep, elk, and wolf). Henderson and Harrington's study was also conducted to help identify various bone fragments that were recovered from archaeological excavations in the Frijoles Canyon area. The taxa identified as a result of their study included deer, rabbit, fox, coyote, wolf, dog, raccoon, badger, wildcat, beaver, small birds, turkey, eagle, hawk, and owl.

Of the 48 mammals Harrington and Henderson (1914) identified, only 15 species were found to have a specific use as food, in ceremony, or within the mythology of the Tewa. Of the 46 bird species noted, only 10 species were used as food, in ceremony, or within the mythology of the Tewa. No reptiles or amphibians were used for food, and only turtles were used for ceremonial purposes. Insects had little importance as a food source, but Henderson and Harrington (1914) identify a number of species referred to by the Tewa.

Extensive excavations for Bandelier were conducted within the Cochiti Lake flood pool in the 1970s. The excavated sites included large multi-room sites, one- and two-room masonry sites, and caves. Guthrie (1982a, b) surveyed the area for present fauna and then identified the various animal remains within the sites. Guthrie determined that many of the faunal remains belong to species that may have used the rocky sites after abandonment by humans and were not used for food or implements. Only a few designated species had charring or knife cuts. Guthrie notes that the bones of other species were a normal part of the fauna of the Rio Grande or were migrants along the river.

During the Bandelier Survey, Trierweiler (1990, 1992) identified the non-human bone assemblages from Burnt Mesa Pueblo (LA 60372) and Casa del Rito (LA 3852), two sites hat were excavated within Bandelier National Monument. Trierweiler identified 16 taxa, including 14 mammal and two bird species. He also noted that although charring on the bones might indicate food preparation, edible species such as antelope, bison, prairie dog, blue grouse, porcupine, skunk, and mule deer did not always contain evidence for burning. Trierweiler identified 10 bone tools made from turkey and mule deer bones.

Faunal assemblages can inform about a number of aspects regarding animal use. The primary result tells of the use of animal resources by people. Another piece of information they can tell about is the occupation or use of a site by an animal after abandonment by humans. And, although a taxon may not be identified in an archaeological faunal assemblage, this does not indicate lack of use by humans. Trading of some remains such as pelts, bones, antlers, and horns may account for some discrepancies.

The list compiled from Henderson and Harrington (1914), and the excavation data were compared to a species list created for the Pajarito Plateau by Biggs et al. (1997) and habitat information by Findley (1987). The kit fox (*Vulpes velox*; reported by Trierweiler 1992) has not been reported for the Pajarito Plateau and because of their habitat requirements they may never have inhabited areas of the plateau or Jemez Mountains. Similarly, jackrabbits are not presently found in the area. Allen has tabulated the use of various species in 45 different excavations for the Jemez Mountains. Table 4.6 shows the species found in the various ruins and the numbers of faunal remains in descending order.

Table 4.6. Animal species identified from archaeological sites and the numbers of remains in descending order (after Allen 2004).

Common Name	Scientific Name	Number
Turkey	*Meleagris gallopavo*	531
Cottontail	*Sylvilagus audubonii*	460
Jackrabbit	*Lepus californicus*	317
Mule deer	*Odocoileus hemionus*	155
Prairie dog	*Cynomys ludovicianus*	81
Sheep/goat	*Ovis/Capra*	79
Cow	*Bos taurus*	75
Fish	Osteichthyes	53
Quail	*Callipepla/Lophyortyx* sp.	45
Sandhill crane	*Grus canadensis*	33
Bighorn	*Ovis canadensis*	24
Pronghorn	*Antilocapra americana*	24
Kangaroo rat	*Dipodomys* sp.	24
Toad	Bufonidae	10
Bear	*Ursus* sp.	9
Horse/burro	*Equus* sp.	8
Bison	*Bison bison*	7
Owl	Strigidae	5
Elk	*Cervus elaphus*	3
Frog	Ranidae	3
Beaver	*Castor canadensis*	2
Bobcat	*Felix rufus*	2
Pig	*Sus scrofa*	2
Ringtail	*Bassariscus astutus*	2
Dog/coyote	*Canis familiaris/latrans*	2
Sheep	*Ovis aries*	1
Goat	*Capra hircus*	1
Burro	*Equus asinus*	1

Kohler (1990) notes that faunal assemblages from sites excavated in the 1989 and 1990 seasons did not contain elk. Allen (1996) compiled ungulate (hoofed mammals) faunal remains from 45 archaeological sites in the Jemez Mountains. Of the 218 ungulate individuals (based on a total of 646 bones), he found that other ungulate remains—bighorn, pronghorn, and bison—exceeded elk, indicating low population numbers from 1200 to 1500 AD (Allen 1996). It should be noted that elk do not like densely forested sites and generally are found in open meadows like those of the Valle Grande. The last Merriam elk (*Cervus elaphus merriami*) were noted in the Jemez in the late 1800s. Rocky Mountain elk (*Cervus elaphus nelsoni*) were introduced in 1948 with 28 elk from herds in Jackson Hole, Wyoming; the herds now number into the thousands. The general patterns of movement of elk before the La Mesa fire were different than today and might more closely reflect the migration patterns at the time of prehistoric habitation of the Pajarito Plateau. The elk would summer in the Valle Grande when calving and nursing, and would move down in elevations to the upper mesas (e.g., Burnt and Escobas Mesas) during the winter months (White 1981). The patterns of migration have changed since the La Mesa, Dome, and Cerro Grande fires (Allen 1996; Biggs et al. 1999).

Fire on the Pajarito Plateau

The plant and animal communities discussed in this chapter represent elements of the environment that prehistoric and historic peoples have used and lived in for thousands of years. In the past 20 years there have been several major fires that substantially changed the nature of the plateau landscape:

- The La Mesa fire (1977) burned primarily ponderosa pine forest and some piñon-juniper woodland in Bandelier National Monument, Santa Fe National Forest, and LANL. Areas that were severely burned are now mostly grassland or shrubland; these areas were historically in ponderosa pine forests.

- The Dome fire (1996) burned higher-elevation ponderosa pine and mixed conifer forests in Bandelier National Monument and the Santa Fe National Forest.

- The Oso fire (1997) burned areas within Santa Clara Pueblo land and in the Santa Fe National Forest.

- The Cerro Grande fire (2000) burned much of the ponderosa pine and mixed conifer in the Santa Fe National Forest above 2438 m (8000 ft) behind the town of Los Alamos and Santa Clara Pueblo land. It also burned within LANL between about 2132 and 2438 m (7000 and 8000 ft); these areas were predominantly located within the community of Los Alamos. Much of the area was burned by a medium to low-intensity fire, which changed the overstory from ponderosa pine and mixed conifer to shrubland and aspen stands.

The number of fires on the Pajarito Plateau has been influenced by recent droughts. Table 4.7 shows the droughts in the Historic period in New Mexico. Year numbers in red in Table 4.7 represent fire scar years on tree ring samples collected by Foxx and Potter (1984). The year numbers in green represent recent large fires in the east Jemez Mountains and Pajarito Plateau that are not represented by tree ring sampling, and the year numbers in blue represent the 20 largest fires listed from a regional fire time series developed by Swetnam and Baisan (1996).

Table 4.7. Historic New Mexico droughts, 1542 to 1989 (Scurlock 1998).

16th and 17th Centuries	18th Century	19th Century	20th Century	21st Century
1542	1700 to 1709	1801 to 1803 1801, 1804 1801	1900 to 1904 1900	2000 to 2002 (2000)

	1787 to 1790	1886 to 1890	1989	
	1793; 1797; 1798	1892 Summer 1896 1893, 1896		
		1898 to 1900 1897	(1996, 1998)	

Hunter-gatherer populations actively manipulated vegetation to increase production of useable resources (Pyne 1999). Historically, there is no specific evidence that the native peoples of the upper Rio Grande deliberately set fires for the purposes of attracting game or foraging. There is evidence, however, that fire was used in the Southwest by certain Indian groups. The first Spaniard to enter the region, Cabeza de Vaca, recorded fire practices of the Indians in Texas. Pyne (1999) notes that Bernard DeVoto records that one of the first American columns into the Southwest during the Mexican War found that fire on the mountain was a Southwestern tradition. As their successors learned, it was a fire regime controlled equally by natural and cultural history.

The Apache used broadcast fire as did many tribes living within grasslands. They used smoke signals, burned to cover trails, and burned as an inducement for rain. W. A. Bell noted in 1870 that, “the Apaches also have a very destructive habit … of firing forests of their enemies.” Fire frequencies changed after the Apaches were subdued (Pyne 1999). The specific use of fire by

Puebloan peoples has not been recorded. There is some indirect evidence of use of fire through ethnobotanical studies. Lemonade berry (*Rhus trilobata*) has been used in historic Southwestern Indian basketry (M. Stevenson 1915). The branches however are not straight switches and thus ethnobotanists were puzzled by their use for basketry. However, ethnobotanist Vorsilla Bohrer (1983) observed the shrub in a burned area of the Navajo reservation regenerating with vigorous straight new shoots following a fire. She states,

> If ancient hunters were in the habit of burning vegetation to secure raw material for their offerings, they may have served themselves in another way. The burned patches of vegetation would foster increased abundance of game and annual plants like sunflower (*Helianthus*) and bugseed (*Corisperumum*).

Although there is no evidence that peoples of the area specifically set fire for the purposes of hunting or gathering, there is an attitude of understanding the rejuvenating aspects of fire mythology and ritual. At Zuni, fire is used in the rabbit hunt; at Cochiti, Nambe, Zuni, and Isleta, fire has taken the form of fostering new life and growth. Bohrer (1983) states,

> Although, our knowledge of formalized burning practices among Pueblo agriculturalists has been preserved erratically, an attitude toward fire as a fertile force still persists in ritual contexts.

Indeed, fire has a regenerating effect. Almost immediately after fire, shrubs sprout and plant species that have roots or underground stems regenerate quickly. Large game such as elk and deer are attracted to burned areas (Foxx 2001; Whelan 1995).

From fire scar data, it is shown that small and regional fires are correlated with times of drought. Between 1975 and 1977, Foxx and Potter collected 18 fire scarred ponderosa pine samples and calculated the fire frequency for samples dating from the early 1700s. Additionally, Swetnam and Baisan (1996) have extended fire scar data for the New Mexico and Arizona region. From 1709 through 1900 all 20 of the large regional fires identified were in drought years (Tables 4.7 and 4.8).

Because of the regenerating nature of burned areas, Foxx and Potter (1984) speculated that fire could be a source of food items in subsistence cultures. For example, wild onion, known to be collected for food and medicine by most or all Pueblos (Dunmire and Tierney 1995), generally is found as a single plant throughout forested areas. However, after fire large patches can be found within the ponderosa pine zone. Many shrubs are sprouters meaning that young straight shoots would be available (Table 4.9).

Table 4.8. Cross-section from a representative tree on Escobas Mesa sampled after the La Mesa fire (dates courtesy of Craig Allen).

Date	Drought Year	One of 20 Highest Fire Years
1637 Center	Yes	
1725	No	Yes
1737	Yes	

Date	Drought Year	One of 20 Highest Fire Years
1748	Yes	Yes
1757	No	
1763	No	Yes
1773	Yes	Yes
1797 (6)	Yes	
1801 (1)	Yes	Yes
1806 (5)	Yes	Yes
1814 (3)	Year after drought	
1833 (3)	No	
1842 (6)	Yes	Yes
1851	Yes	Yes
1858 (4)	No	
1878 (7)	Yes	
1893 (5)	Yes	
1965	No	
1977	Very early fire season	1977 La Mesa

Information is from one tree with fire scars from 1725 through 1977. Numbers in parenthesis () represent the number out of the other 18 fire scar trees sampled by Foxx and Potter and summarized in Foxx (1982). Column 2 represents those years that correspond to drought years on Table 4.7. Column 3 represents those years determined by Swetnam and Baisan (1996) to be the largest regional fires in New Mexico and Arizona.

Hill and Trierweiler (1986) discuss food stress and drought (Table 4.10). Although fire scar data for the most part is only from trees that were 350 years old (Allen et al. n.d.), extrapolating from available information, it is conceivable that burned areas may have been a source of some species when food stores were dwindling because of drought. Vierra and Foxx (2002) compared the listing of plants used for food, medicine, and other uses with information gained through succession studies after fire. From fire ecology studies we know that before 1900 there were frequent small fires within the ponderosa pine zone (see Table 4.9). We also know from observations and studies (White 1981) that these burned areas attract large game animals like elk and deer and small game animals such as turkey because of new and nutrient-rich forage. Although it presently cannot be proven, there is evidence of the usefulness burned areas might have been to subsistence peoples.

Table 4.9. Early succession plants in burned areas that may have been plant resources for early peoples.

Scientific Name	Common Name	Habitat	Primary Plant Community*				
			MC	PIPO	PJ	JS	Uses

*Each year listed is the third (or later) sequential year of drought when food stores would have been exhausted.

Summary of Fire on the Pajarito Plateau

Today, as when the plateau was first inhabited, fire is a part of the natural cycle. Although the most recent fires (e.g., the Cerro Grande fire) have been caused by human activities, most fires in the mountainous west are caused by lightning. Over a 21-year period in the Santa Fe National Forest, officials recorded 68 lightning-caused fires per year. However, many of these fires remained as ground fires because crown fires only occur when forest and weather conditions are right for fires to get out of control. Studies show that fire was a frequent occurrence before the turn of the 20th century; trees were scarred by fire every five to ten years. The changes resulting from human settlement on, and use of, the Pajarito Plateau in the late 1800s caused suppression of fire, and today many places in the area have not had a fire in over 100 years.

Studies indicate that the last major fire in the 19th century on the Pajarito Plateau was in 1893. Through the ensuing years, without the cleansing of frequent low-intensity fires, forests of the plateau became heavily overgrown. In 1977, environmental and meterological conditions were right for the ignition of a wildfire, and this resulted in the La Mesa fire. This was the first large-scale wildfire on the Pajarito Plateau in the 20th century and burned over 15,000 acres of predominantly ponderosa pine forest. Twenty years later, the Dome fire burned 16,000 acres, and in 1998, the Oso fire burned another 5,000 acres. In May 2000, the Cerro Grande fire burned over 43,000 acres of the eastern slope of the Jemez Mountains. In total, over 80,000 acres of forested landscape on the Pajarito Plateau and in the east Jemez Mountains have been burned by wildfires in the last 23 years; some of these fires have been the result of human activities while others have resulted from natural processes.

METHODS FOR PLANT SURVEYS

During the summers of 2002 and 2003, surveys for the presence of plants within various elevation zones and transfer tracts were conducted for two reasons: 1) to provide plant community information for the archaeological excavations and 2) to provide modern plant information for the pollen identification from the excavated sites. Personnel collected pollen samples in an elevation transect from White Rock to the Pajarito Ski Hill. Photographs were taken at each pollen-collecting site and the major plants recorded. Additionally, the plant communities of the major excavation sites within the land transfer tracts were examined. The plant identification was checked in Foxx and Hoard (1993) and Martin and Hutchins (1984). Since the period of the survey was after the Cerro Grande fire, some areas were within the burn perimeter. A deepening drought in 2002 and 2003 caused many plants to be stunted (or not fully leafed). Additionally, much of the area was ravaged by the bark beetle and many piñons were dead and dying. These conditions made the diversity of plants normally in the various plant communities stressed and in some cases plants that would have been there were not blooming at the time of year we surveyed. Therefore a general description is based on the present survey information and historic survey information that may be pertinent to each area.

Results of the Plant Surveys for the Conveyance and Transfer Land Tracts

Airport Tract

The Airport Tract (A-3, A-7, and A-5-a) is located at the eastern end of the Los Alamos Airport. It is within the piñon juniper zone and generally has an understory of blue grama. Average rainfall is 12 to 14 inches. The site is relatively narrow and has limited vegetation that includes piñon pine and one-seed juniper with an understory of blue grama. Forbs included bitterweed, snakeweed, and cacti.

White Rock Tract

The White Rock Tract (A-19) is in the piñon-juniper woodland and has an understory of blue grama. The average annual precipitation at this elevation is 12 to 14 inches. The greatest number of edible plants has been found within this zone (Foxx and Tierney 1984; Vierra and Foxx 2002). The tract parallels State Route 4 and is directly across from the town of White Rock. The site is within the vicinity of Tsirege and is within lower Pajarito Canyon. An ephemeral stream flows through the canyon and springs likely provided water for the residents of Tsirege and a watering area for livestock. This tract, when examined, had been particularly hard hit by the bark beetle. Few piñons were still alive. Without an overstory cover the drought had taken a toll on the understory vegetation.

A cereal grain was noted in the vicinity of the site. The plant was most likely sorghum or another cereal grain but was not maize. In addition, some garden sunflowers were identified. Both sorghum and sunflower seeds are common in bird feeders. Scrub jays raid bird feeders for sunflower seeds. They carry the seeds to other trees and seeds also pass through their digestive system. The seeds probably lay dormant until rains provided conditions for sprouting. The thinning and death of so many trees in the area has opened up the tree canopy and such species can grow. There was very little understory vegetation due to the drought and opening of the canopy. To provide a more accurate indication of the plants within the canyon, studies by Foxx and Tierney (1980, 1984) were consulted. These sources also indicate the diversity of plant life when drought is not a factor.

Technical Area 74 Tract

The Technical Area 74 tract is primarily within Pueblo Canyon. The vegetation within this canyon is primarily piñon juniper with some ponderosa pine. There is a wetland area created from the effluent from the Los Alamos County sewage plant. In June of 2002, we noted plant habitats within Pueblo Canyon.

Rendija Tract

The Rendija Tract (A-14) is on the north side of Los Alamos County above Rendija Canyon. The sites were visited in July of 2003. Photographs were taken and plants were noted at both the Archaic and homestead sites. The homestead site had a large quantity of tomatillo, which usually indicates disturbance and is common on archaeological sites. Tomatillo is considered a camp follower taxon and is often found associated with archaeological sites. The cover found on homesteads within Rendija Canyon and near the pumice mine were used to supplement data collected during the survey (Foxx et al. 1997).

CHAPTER 5
PALEOENVIRONMENTS OF THE SOUTHERN ROCKY MOUNTAINS OF COLORADO AND NEW MEXICO: A SUMMARY FROM LAKE AND BOG SEDIMENTS

R. Scott Anderson

INTRODUCTION

Interest in the long-term history of climate, vegetation, and forest disturbance of northern New Mexico, and specifically the Jemez Mountains/Bandelier National Monument area, has grown steadily over the last decade. This may be due to several important events that have impacted the local area since the late 1990s. One of these—the creation of the Valles Caldera National Preserve (VCNP)—established a focus on preservation and study of a ca. 36,000-ha (88,900-ac) property, formerly part of the privately held Baca Ranch. Bills appropriating funding for, and establishing the boundaries of, the Preserve were passed in 1999 and 2000. Establishment of the Preserve has allowed land managers and scientists to craft management plans that provide for a significant research component in an area that previously existed in private hands.

A second event that focused interest on the region was the Cerro Grande fire, which burned as much as 19,400 ha (48,000 ac) within and near Los Alamos, New Mexico, in May 2000. The effects of this high-severity fire were devastating on ponderosa pine and mixed conifer stands primarily west of Los Alamos and east of the VCNP and focused attention on the history of forest disturbance and its effect on vegetation within the area. A third characteristic bearing directly on the local environmental history is the long record of human habitation within the region (see chapters in Vierra 2005b; Kohler 2004). Therefore, the juxtaposition of interest in understanding local environments and processes that have created those environments, with the history of human habitation and exploitation of this landscape, suggests that the Jemez Mountains may be an ideal location for investigation of the relationship between climate change, human habitation, and forest disturbance.

Former environments and climates can be deduced using a variety of proxies, including pollen and plant macrofossils from lakes, bogs, or meadows; plant macrofossils and pollen from packrat (*Neotoma*) middens; and the tree-ring record of live and dead trees. Each of these proxies has been used primarily to determine climate conditions and/or former vegetation types. Many other proxies exist that are equally as important in determining former environments, including geomorphic and alluvial histories, isotopic analysis of sediments and cave deposits, and the archaeological record of human activities and habitations, among others.

No one proxy can tell the entire story of environmental change; each has its advantages and limitations, and an integration of as many proxy records as possible provides us the best chance to determine the entire picture of former environments. For example, analysis of tree-ring series allows us to determine year-to-year variations of climate (e.g., temperature and precipitation) as well as fire histories for a site. Most often, the record from tree-rings is limited to a few hundreds of years, less often to several millennia (Grissino-Mayer 1996). Packrat midden deposits provide abundant plant macrofossils that allow us to determine—often to species level—the precise composition of the local flora (Betancourt et al. 1990). Addition of pollen analysis from middens allows for determining characteristics of the regional flora as well (Anderson and Van Devender 1991). But these glimpses of vegetation are most often separated by large blocks of time and are limited to the rocky substrate surrounding the site, as packrats primarily collect within several tens of meters from their nest only. Pollen and plant macrofossils from sedimentary deposits provide a longer, more continuous record than other proxies, but the source area for the pollen is often unclear, especially in areas of high relief (Markgraf 1980).

This chapter explores the history of vegetation change in north-central New Mexico and southern Colorado, centering primarily on the research that has been accomplished in the Jemez Mountains. The data proxies for reconstruction come primarily from analyses of sedimentary deposits that have accumulated in meadows, wetlands, bogs, and lakes over the last 15,000 years. These records document a series of vegetation and environmental changes that span a particularly intriguing time in southwestern North America, including the waning of the last great Laurentide and Cordilleran ice sheets in the northern hemisphere, the establishment of the warmer climates of the present interglacial (the Holocene), and the introduction of *Homo sapiens* into the continent. While the complete picture of paleoenvironmental change in this part of the southern Rockies has yet to emerge, the geographic distribution of sites for reconstructions has rapidly increased. Even so, most of this research on northern New Mexico exists today in the "gray" literature (e.g., project reports, master's theses, and conference abstracts and presentations).

For the general region of interest, Hall (1985) and Brunner-Jass (1999) summarized the paleoecological records from the Southwest and, more specifically, from northern New Mexico and southern Colorado before 2000 (ages presented in calendar years Before Present). A cluster of sites occurred in northwestern New Mexico, including the Chaco Canyon region (Hall 1977, 1985; Betancourt and Van Devender 1981), and the Chuska Mountains (Dead Man Lake region; Bent and Wright 1963; Wright et al. 1973). Other pollen records to the northwest come primarily from archaeological sites, and are of limited temporal extent. Additional sites had been analyzed from the San Juan Mountains of southwest Colorado, including Hurricane Basin (Andrews et al. 1975), Lake Emma (Carrara et al. 1984), Molas Lake (Maher 1963), Twin Lakes (Petersen and Mehringer 1976), and several sites in Mesa Verde (Martin and Byers 1965; Wyckoff 1977). By 1999, virtually nothing was known about the vegetation history of the southern Sangre de Cristo Mountains in New Mexico and Colorado.

From the Valles Caldera itself, a long pollen stratigraphy was recovered from the Valle Grande by Sears and Clisby (1952), which was presumed to be a pre-Wisconsin vegetation record. More recently, a second core was taken from this location, with radioisotope and paleoemagnetic stratigraphies documenting a ca. 50,000-year record spanning the OIS13–OIS14 transition (Fawcett et al. 2005). Closer to the present, Ensey (1997) produced two pollen records of the latest Holocene from Laguna de los Piños and Laguna de la Grulla, of which only the first was included in the report. Brunner-Jass (1999) undertook analysis of a sediment core from Alamo Bog in Alamo Canyon (western portion of the present Preserve), and from Chihuahueños Bog (immediately north of the Preserve in the Santa Fe National Forest). These records have proven to be the most detailed analysis of vegetation and fire histories for the region to date.

Since 2000 the number of sites within this region has increased substantially. For instance, new records have been produced for the San Juan Mountains (Toney 2004; Toney and Anderson 2006) and the southern Sangre de Cristo range (Armour et al. 2002; Bair 2004), as well as numerous sites stretching northward in highlands west of the Rio Grande (Anderson et al. 2004, 2005). Additional research has been completed on the original Chihuahueños Bog core, while new cores were taken and analyzed from Alamo and Valle Santa Rosa Bogs within the Preserve. With the exception of the last two, most of these records span the entire post-glacial period.

The present chapter is presented in two parts. In Part I, two new records from the Jemez Mountains are presented. These records document Holocene changes in vegetation and fire. Part II presents a summary of the paleoenvironmental data, primarily pollen, macrofossils, and charcoal particles from sediment cores in the Southern Rocky Mountains.

NEW RECORDS FROM THE JEMEZ MOUNTAINS

Alto Alamo Bog

Alamo Bog occurs along Alamo Creek within Alamo Canyon, which is a prominent feature of the western Jemez Mountains of the VCNP. Over the last three decades, several significant research projects have focused on the region, including archaeological investigations (the Baca Geothermal Anthropological Project [Baker 1981]), and an initial study of the vegetation and fire history of the region (Brunner-Jass 1999). The wetland that composes the central core of the bog is located at the intersection of Alamo Creek and an unnamed creek flowing north, at an elevation of 2630 m (8628 ft; location in Figure 5.1).

In 2000 an additional core was obtained from a section of the bog further upstream along Alamo Creek, named Alto Alamo Bog (AAB). Our reasoning for obtaining a second core location was to substantiate and validate the original Alamo Bog record, which suffered from potential problems in sediment dating. This is important because of the long history of human habitation of the region and the potential for human manipulation of the mixed conifer forest there. It was hoped that the AAB core would not be affected by the problems discovered at the site of the original study.

AAB is located at 2658 m (8720 ft) elevation, latitude 35^{o} 54’ 45” N, longitude 106^{o} 34’ 45” W on the Valle San Antonio 7.5’USGS Quad. Vegetation at AAB is much the same as at Alamo Bog proper. The bog surface is dominated by grasses (Poaceae) and sedges (Cyperaceae). Slopes surrounding both bogs are forested and strongly affected by aspect. On north-facing slopes, mixed conifer forests predominate, with Douglas-fir (*Pseudotsuga mensiezii*), white fir (*Abies concolor*), quaking aspen (*Populus tremuloides*), Colorado blue spruce (*Picea pungens*), and southwestern white pine (*Pinus strobiformis*). On xeric south-facing slopes, particularly around Alamo Bog, ponderosa pine (*P. ponderosa*) and Gambel oak (*Quercus gambelii*) dominates with lesser amounts of the more mesic common juniper (*Juniperus communis*) and many herbaceous species. Terminology follows Martin and Hutchins (1980).

Two Livingstone sediment cores (Wright 1991) were taken from AAB in 2001. Core 1, which was intensively analyzed, yielded a 3.75-m record. Each drive section was described in the lab, noting stratigraphy, sedimentary and organic content, and Munsell color under fluorescent light. Magnetic susceptibility measurements were made using a Bartington MS2E meter at 5-mm intervals. Magnetic susceptibility readings are reported as electromagnetic units per cubic centimeter (emu/cc).

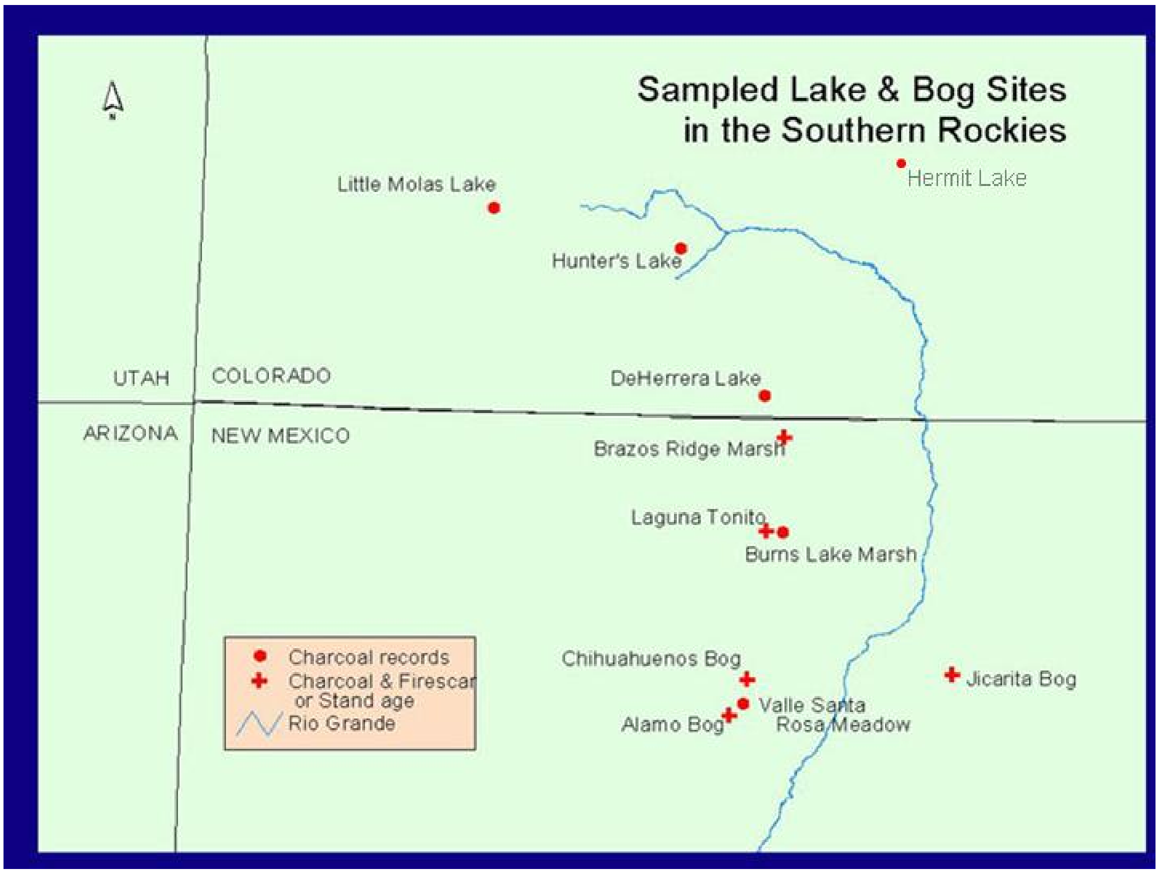

Figure 5.1. Sampled lake and bog sites in the southern Rockies.

Pollen was extracted from the sediments using standard methods (Fægri et al. 1989), including suspension in KOH, HCl, and HF. After acetolysis, pollen residues were stained and suspended in silicone oil. Many of the core samples required a 9-µ sieving step to remove additional clay and fine organics. Pollen counts per sample consisted of a minimum 300 non-Cyperaceae/non-Poaceae grains and a minimum of 50 non-*Pinus* terrestrial grains. *Pinus* grains were identified to subgeneric level when possible (Jacobs 1985a). Wetland (bog/riparian) types, excluding Poaceae, are graphed outside the pollen sum. Plant macrofossil samples for each core were recovered by washing the sample through stacked soil sieves. Macrofossils were also tallied during charcoal analysis (see below). Pollen types and macrofossils were identified using the comparative collection and manuals in the Laboratory of Paleoecology (LOP) at Northern Arizona University. Pollen data were plotted using Tilia View (Grimm 1992).

For the high-resolution sedimentary charcoal analysis we extracted a 0.5-cc sample from each linear cm of the core length. Sediment samples were sieved into 125-μm and 250-μm fractions. Charcoal particles were identified under a binocular microscope at 10x to 70x. Charcoal was identified by a uniformly black color, an iridescent sheen, and the presence of cellular structure. Macroscopic charcoal counts were standardized to 1-cc volume.

Radiometric ages for this core came from a combination of ^{210}Pb, ^{137}Cs, and ^{14}C analyses. Older sediments (below 42.5 cm depth) were dated by accelerator mass spectroscopy analysis of small sediment samples. ^{14}C ages were converted to calendar ages using CALIB 5.0 (Stuiver et al. 1998). To date the uppermost sediments we used both ^{210}Pb and ^{137}Cs (Appleby et al. 1979; Crusius and Anderson 1995). ^{210}Pb is suitable for dating the most recent 150 years, since its half-life is 22.26 ± 0.22 years (Blais et al. 1995; Olsson 1986). ^{137}Cs has a half-life of ca. 30 years and was produced in great abundance during nuclear atmospheric testing beginning in 1945 (Olsson 1986). The first pronounced increase of ^{137}Cs in sediment dates to AD 1954, with a maximum occurring in AD 1963 to 1964 and a decline by AD 1965.

The Sedimentary Record

The AAB record extends back in time to about 4750 calendar years ago (Figures 5.2 and 5.3), with continuous sedimentation to the present. The sediments consist primarily of silty peats (i.e., colluvium) for most of the record (Figure 5.3), except for a section of sand and pebbles near the core bottom and peat in the upper ca. one meter of the core. Although the sand and pebbles have been graphed as being deposited over several hundred years, this deposit is in all likelihood a nearly instantaneously deposited unit.

The dominant pollen types are pine (*Pinus*) and grass (Poaceae) throughout the record (Figure 5.2), but occurrence of other conifers, especially spruce (*Picea*), fir (*Abies*), Douglas fir (*Pseudotsuga*), and juniper (*Juniperus*) suggests that a rich mixed conifer forest existed adjacent to a grassy meadow for the entire record. The dominant pines were probably ponderosa pine (*Pinus ponderosa*) and southwestern white or limber pine (*Pinus strobiformis* or *P. flexilis*), as shown by macrofossil analysis (Figure 5.3), but macro-remains of spruce and Douglas fir also attest to their local presence. The occurrence of pollen from Colorado piñon (*P. edulis*) and oak (*Quercus*) suggests that these trees may have been present locally as well, or at least were important tree species within the general region, much as they are today.

Small changes in the pollen assemblages suggest that subtle differences in the vegetation history of AAB can be recognized. For instance, before 2200 years ago, herbs were more abundant in the record, including grasses, ferns, and members of the mustard family (Brassicaceae), as well as sedges (Cyperaceae) and meadow-rue (*Thalictrum*) (Figure 5.2). Pollen of spruce and Douglas fir was more common, while pollen of pine (including ponderosa pine) and fir was less abundant than in later time periods. After 2200 years ago, spruce and herb species declined, while pollen of ponderosa pine and fir increased.

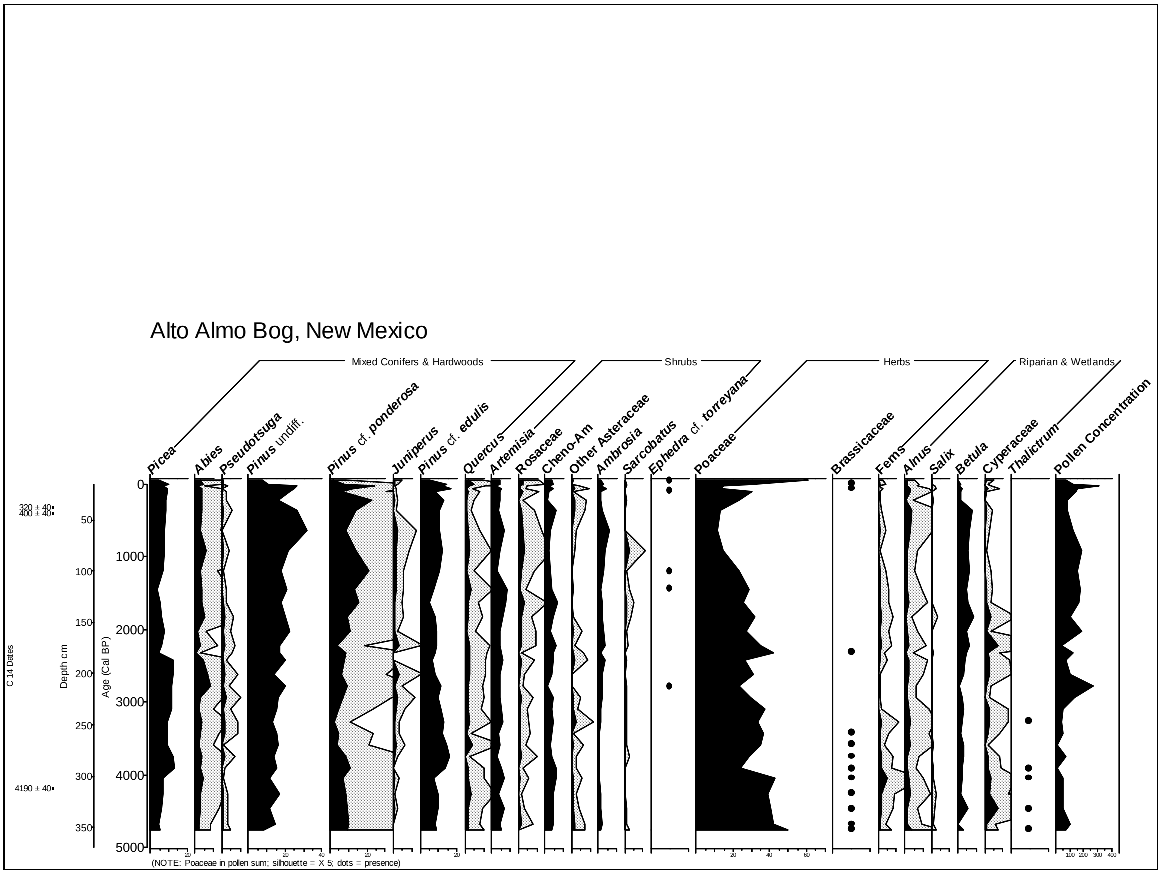

Figure 5.2. Pollen types at the Alto Alamo Bog, New Mexico.

Shrubby taxa, such as members of the rose family (Rosaceae), ragweed (*Ambrosia*), greasewood (*Sarcobatus*), and joint-fir (*Ephedra*) increased after 2200 years ago. Most other taxa do not vary significantly over this transition. Of interest from a biogeographic viewpoint is the occurrence during this period of birch (*Betula*), which is probably bog birch (*B. glandulosa*), whose only known occurrence during the Holocene is here in Alamo Canyon. Pollen changes in the uppermost levels of the core—the Historic period—include declines in pine pollen (especially noted in ponderosa pine) and birch, with increased in grass pollen percentages.

The charcoal stratigraphy (Figure 5.3) approximates the fire history of the site. Abundant charcoal was retrieved from sediments deposited before ca. 4000 years ago, but the amount of charcoal declines substantially between 4000 and 2200 years ago. Subsequently, charcoal concentration increases between ca. 2200 and 400 years ago and declines considerably. Sediments deposited during the 20th century contain virtually no charcoal (Figure 5.3).

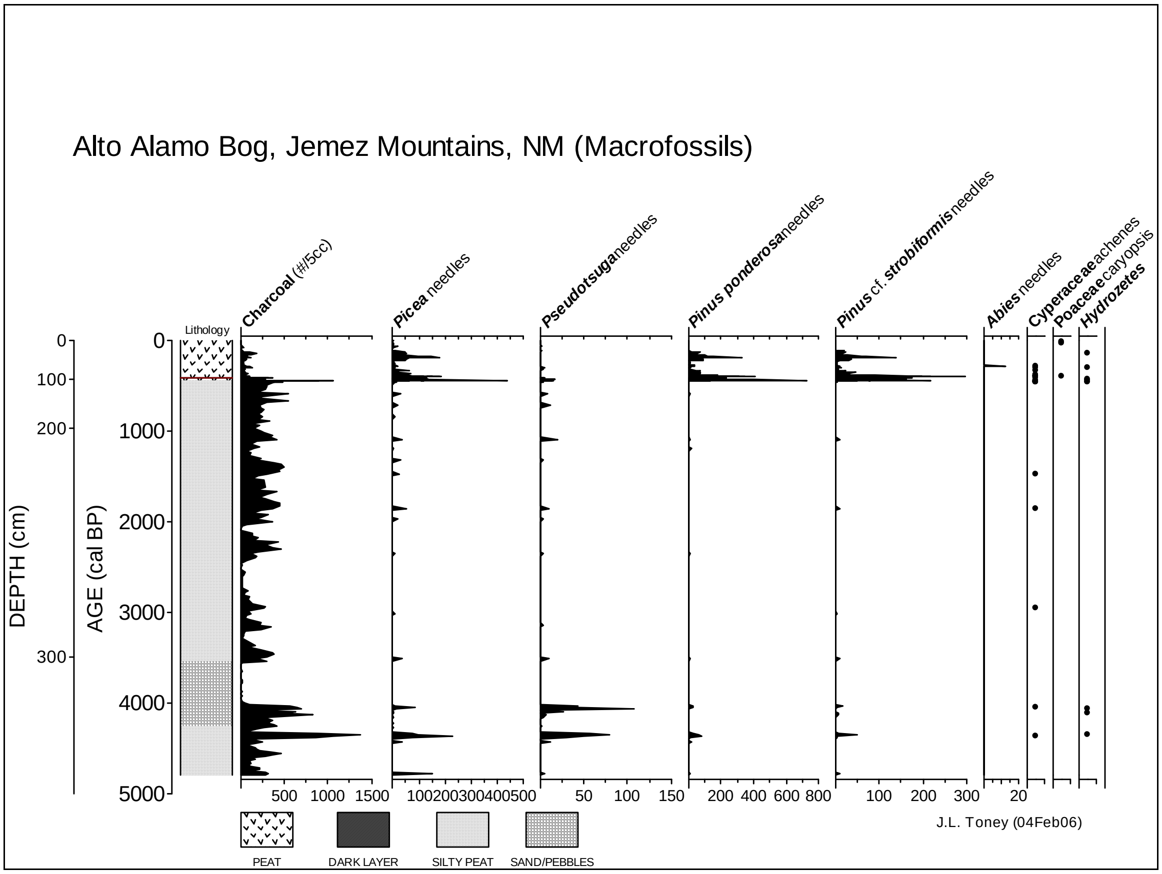

Figure 5.3. Charcoal stratigraphy from the Alto Alamo Bog, New Mexico.

Pollen and charcoal stratigraphies are consistent with an interpretation of occurrence of a mixed conifer forest surrounding an open meadow-like wetland, with frequent fire over the last 4750 years. Before 2200 years ago, however, the local environment may have been moister than subsequently, as shown by the greater abundance of spruce and wetland herbs, such as sedge. The fire record is also consistent with this interpretation for the early part of the record, with smaller concentrations of charcoal, except for the lowermost samples deposited before 4000 years ago. Beginning by 2200 years ago, however, an increase in ponderosa pine in the record, along with an increase in charcoal concentrations, suggests drier conditions with perhaps more frequent fire, at least in portions of the drainage basin. Further support for this comes from the increase in shrubs, although it is unclear if species like greasewood and joint-fir grew locally, or if these types represent long-distance transport of pollen from locations to the west of Alamo Canyon. The Historic period is seen in samples of both pollen and charcoal stratigraphies, with a decline in ponderosa pine pollen—probably due to logging locally—and an increase in grass pollen, which may be due to introduction of exotic grasses due to grazing.

Valle Santa Rosa Bog

A second new study in the VCNP comes from Valle Santa Rosa Bog (VSRB), located in Valle Santa Rosa near its confluence with Valle San Antonio in the northern portion of the VCNP (location in Figure 5.1). The coring site is located at 2590 m (8500 ft), latitude 35° 57' 45" N, and longitude 106° 31' 00" W, also on the Valle San Antonio 7.5' USGS Quad. Uplands around the bog are fairly open, but common trees include *Picea* sp., quaking aspen (*Populus tremuloides*), and ponderosa pine, with common juniper (*Juniperus communis*) as groundcover. The bog itself is covered by sedges and grasses. On the drier marginal meadow grow blue flag (*Iris missouriensis*), cinquefoil (*Potentilla* sp.), shrubby cinquefoil (*P. fruticosa*), dandelion (*Taraxacum officianale*), yarrow (*Achillea lanulosa*), pussytoes (*Antennaria* sp.), clover (*Trifolium* sp.), buttercup (*Ranunculus* sp.), and members of the pink family (Caryophyllaceae) (terminology after Martin and Hutchins 1980).

Two sediment cores were taken with a Livingstone corer in 2001 on the western margin of the Bog. Core 2 was selected for study and measures 1.8 m long. Our reasoning for studying this site was to obtain a record from the northern portion of the VCNP that could be compared with the Alamo Canyon records.

Essentially the same procedures were followed for analysis of VSRB sediments as for AAB. These included description of core stratigraphy, sedimentary and organic content, and Munsell color, as well as magnetic susceptibility. Pollen and charcoal particle stratigraphy methodology followed the same procedures as for AAB as well (see above). Radiometric ages for this core also came from a combination of ^{210}Pb, ^{137}Cs, and ^{14}C analyses. Older sediments (below ca. 62 cm depth) were dated by accelerator mass spectroscopy analysis of small sediment samples. ^{14}C ages were converted to calendar ages using CALIB 5.0 (Stuiver et al. 1998). ^{210}Pb and ^{137}Cs ages determined the upper 39 cm of the core.

The Sedimentary Record

According to our chronology accepting the bottommost age of the core, the VSRB record extends back in time to over 9000 calendar years ago (Figure 5.4). The upper 8.5 cm of the core is dark brown peat. Below the peat, to ca. 125 cm depth is organic silts (colluvium) alternating with sand layers. Sand units increase below 125 cm, but primarily return to organic silts to the core bottom. Unlike the AAB record, however, sedimentation at this site has not been continuous, and a number of unconformities, or periods of severe drying, are apparent in the pollen record. The most extensive unconformity occurs between 125 and 140 cm depth, encompassing perhaps 1375 to 8500 years ago, or most of the record. Thus, the VSRB pollen record includes only a short period in the late Holocene and one in the early Holocene. Each of these will be treated separately.

As at AAB, the dominant tree pollen type at VSRB is pine (*Pinus*) throughout the record. Unlike AAB however, grass (Poaceae) is not as abundant anywhere in the record. Early Holocene pollen spectra include spruce (*Picea*), ponderosa pine (*Pinus ponderosa*), and other pines, as well as some fir (*Abies*). Shrubs are dominated by sagebrush (*Artemisia*), saltbush-type (*Atriplex*; cheno-am), and other members of the aster family (Asteraceae). Riparian plants, such as willow (*Salix*), carrot family (Apiaceae), and meadow-rue (*Thalictrum*) are most important in this period, suggesting the site may have been a streamside location during the early Holocene.

Pollen deposited during the most recent 1375 years shows that pines, spruce, and fir continued to be important here, and Douglas fir (*Pseudotsuga*) increased in importance during this time (Figure 5.4). Sediments in the upper 40 cm show an increase in juniper (*Juniperus*) and oak (*Quercus*). In addition, pollen indicators of local land clearance and cattle ranching are evidenced here, beginning with the occurrence of introduced species associated with grazing (filaree, *Erodium*; dock, *Rumex*), followed by increased grass (Poaceae) pollen, perhaps a result of non-native introductions. In the uppermost sediments, pine pollen declines although the proportion of ponderosa pine pollen does not. At the same time, an increase is seen in sedge (Cyperaceae) pollen, suggesting higher groundwater tables in the most recent century.

The preliminary charcoal record shows generally highest concentrations of charcoal in the early Holocene section of the core (Figure 5.5). Charcoal concentrations trend to zero during the period encompassing the unconformity, then rebounds in the late Holocene to amounts not exceeding those from the early Holocene. Charcoal declines about 33-cm depth, and falls to zero above 16-cm depth.

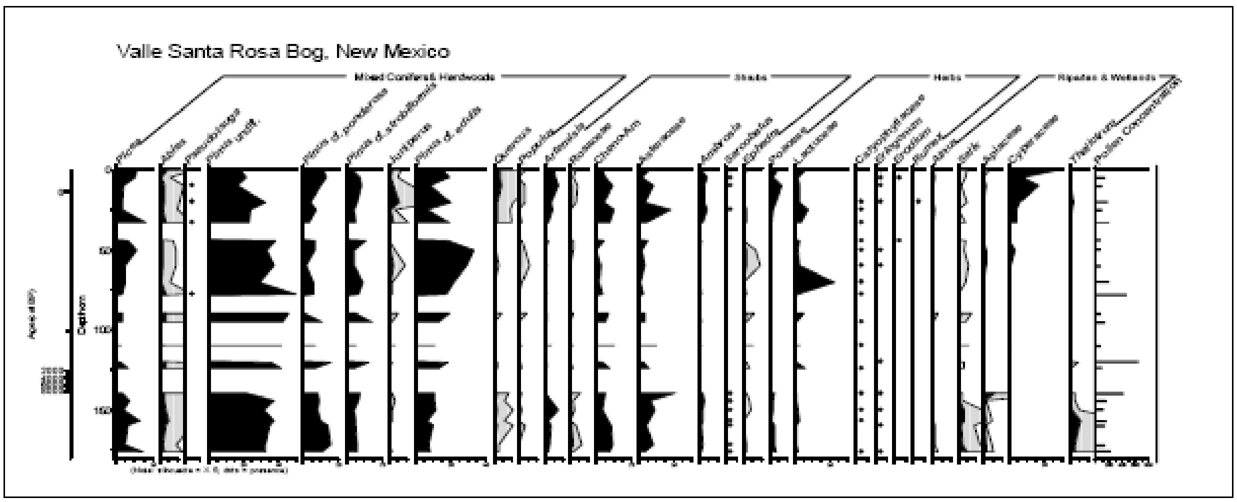

Figure 5.4. Pollen cores from the Valle Santa Rosa Bog, New Mexico.

Pollen and charcoal stratigraphies are considerably more difficult to interpret from VSRB than from AAB due to the considerable portion of the record that is missing. Still, the overall pollen record suggests a similar mixed conifer forest surrounding an open meadow-like wetland for both the early and late Holocene. One major difference between the two sites is the general paucity of grass in the VSRB record compared to the AAB record. This is a little puzzling, since the Valle Santa Rosa today is primarily a grassland, with open forest on the upper-side slopes. The fire history records of the two sites are generally similar, however, with similar amounts of charcoal (on a /cc basis) and a declining amount of charcoal deposited during the 20th century fire suppression period.

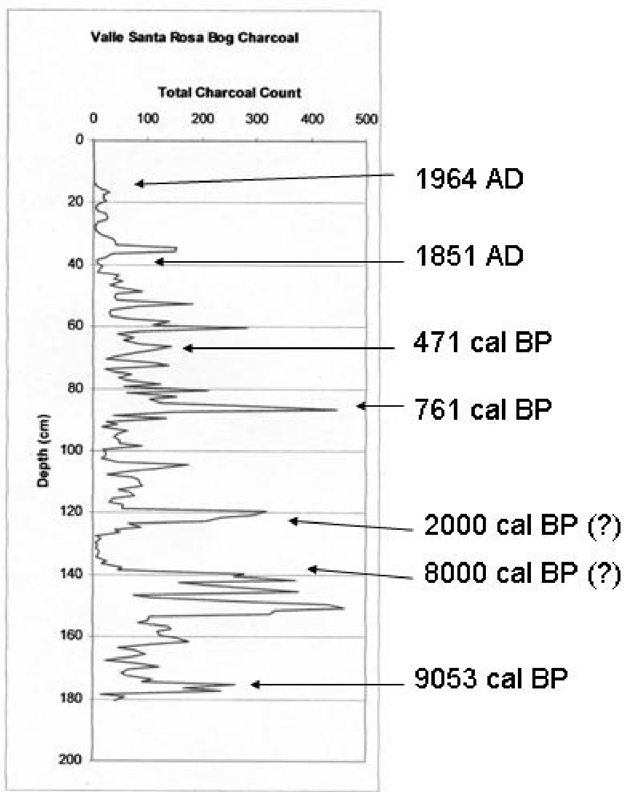

Figure 5.5. The charcoal record from the Valle Santa Rosa Bog, New Mexico.

Vegetation Change in the Southern Rockies

As discussed in the introduction above, our knowledge of the post-glacial paleoenvironmental history of the southern Rockies—including the San Juan and Sangre de Cristo ranges—is meager, but recent efforts have begun to tackle the temporal and spatial history of vegetation change there. Study has tended to concentrate around several themes, including the 1) characteristics of vegetation and climate change during deglaciation in the highlands, 2) understanding the development of the southwestern monsoon and its influence on vegetation, 3) the characteristics of the late Holocene, a time of particular interest in the archaeological record, and 4) fire histories of the present interglacial, among others. In reality, each of these individual subjects is part of a continuum of change that has occurred over the course of the last ca. 15,000 years.

Full- and late-glacial paleoecological studies from the southern Rocky Mountains indicate that treeline was up to 500 m lower during the Pinedale glaciation (Legg and Baker 1980; Maher 1963; Markgraf and Scott 1981). Highest-elevation sites were glaciated, while alpine vegetation found above 3300 m today occupied areas around 2800 m elevation (Legg and Baker 1980). Similarly, subalpine forests found between 2700 and 3300 m elevation today occupied sites below 2300 m elevation (Markgraf and Scott 1981). High-elevation sites reflect late-glacial conditions with cold winters and increased winter precipitation and drier than present summers (Vierling 1998) and enhanced winter storms originating in the Pacific Ocean (Markgraf and Scott 1981). Models suggest summer precipitation was at a minimum during this period (COHMAP 1988; Kutzbach et al. 1998).

The Late Glacial and Younger Dryas

The southern Rocky Mountains were extensively glaciated during the Pleistocene (Pierce 2004). However, the timing of deglaciation varies from place to place. For instance, in the Park Ranges of northern Colorado, insect assemblages suggest deglaciation before 16,440 cal BP (13,800 yr BP) (Elias 1996), which also suggest mean annual temperatures were only 3 to 4°C cooler than present, but mean winter temperatures were considerably colder (ca. 19 to 21°C cooler than present). Similar evidence (Elias 1996) suggests the Front Range of Colorado underwent deglaciation before ca. 13,860 cal BP (12,000 yr BP) (Elias 1996; Menounos and Reasoner 1997). Deglaciation in the San Juan range may have been somewhat later. Elias et al. (1991) reported ^{14}C basal dates suggesting that deglaciation was complete there by 11,480 cal BP (10,000 yr BP). This was recently confirmed at Little Molas Lake with deglaciation by 11,200 cal BP (Toney and Anderson 2006). In the southern Sangre de Cristo range, near Jicarita Peak, Bair (2004) suggested a much earlier deglaciation, by ca. 15,300 cal BP.

Of great interest has been recent research confirming that the environments of the Southwest were affected by events centered in the North Atlantic during deglaciation. The Younger Dryas stadial (YD; ca. 13,000 to 11,600 cal BP) was a brief period of climatic deterioration in the overall warming of the post-glacial (Yu and Wright 2000). While effects centered primarily on both sides of the North Atlantic, recent evidences suggests that the YD oscillation resulted in rapid vegetation responses at high-altitude sites in the southern Rockies as well. For instance Armour et al. (2002) documented periglacial activity during the YD in the Winsor Creek Basin of the southern Sangre de Cristo Mountains, New Mexico. Nearby at Jicarita Bog on Jicarita Peak, Bair (2004) documented minor vegetation changes associated with cooler conditions at that time. In Colorado at the Sky Pond site, glacio-lacustrine sediments probably associated with a glacial re-advance characterize the YD there (Menounos and Reasoner 1997). Reasoner and Jodry (2000) compared the Sky Pond record with that from Black Mountain Lake in the San Juan Mountains of Colorado and found major vegetation boundaries corresponding with onset and termination of the YD.

The Early to Middle Holocene and Development of the Arizona Monsoon

Subsequent to the YD cooling, extensive warming of climate commenced at the beginning of the present interglacial—the Holocene. The number of sites covering the transition to the Holocene is becoming substantial. Along the Front Range of Colorado, change to organic gyttja deposition with terrestrial macrofossils overlying the YD clastic sediments at Sky Pond signifies elevated biological activity within the lake and increased vegetation cover on land (Menounos and Reasoner 1997). The fossil insect record indicates that the postglacial warming maximum occurred between 12,930 and 10,180 cal BP (11,000 and 9000 yr BP) in the Rocky Mountains. At the La Poudre Pass, Colorado site, the warmest mean July temperatures occurred at 11,255 cal BP (9850 yr BP), and were 3.7 to 6.7°C warmer than present (Elias 1983, 1996). Four sites above 3000-m elevation in the Front Range show an early Holocene warming between ca. 10,180 to 7830 cal BP (9000 to 7000 yr BP), based on ratios of forest species to tundra species, and the presence of conifer macrofossils (Elias 1985).

In central Colorado, Fall (1997) examined a pollen record from Cottonwood Pass Pond (3670 m), presently above the treeline. However, sediments dating between 9840 and 4480 cal BP (8800 and 4000 yr BP) contains conifer macrofossils and high percentages of *Picea* and *Abies* pollen, indicating a subalpine forest grew at the location then. Climate reconstructions based on modern lapse rates and using an estimated treeline rise of 270 m suggest mean July and mean annual temperatures were ca. 1.9°C and 1.6°C warmer than present, respectively. In south-central Colorado, Anderson et al. (2004) demonstrated establishment of post-glacial, subalpine forests at Hunter's Lake (Wiminuche Wilderness Area, north of Pagosa Springs) by ca. 12,500 cal BP, and at DeHerrera Lake (south-central Colorado) by ca. 13,000 cal BP.

In the San Juan Mountains, Maher (1963) documented fluctuations in pollen ratios of high-elevation conifers—*Picea* and *Pinus*—that suggested higher treeline in the early Holocene at Molas Lake. This was a period of warmer, dry conditions favorable to the upslope migration of trees. Elias et al. (1991) also observed *Picea* and *Abies* krummholz fragments identified by their small size and contorted annual-ring pattern in Lake Emma, Colorado. Sediments indicate that the krummholz vegetation was at least 70 m higher than today throughout much of the early and middle Holocene (Elias et al. 1991), while Toney (2004) and Toney and Anderson (2006) documented early Holocene establishment of spruce forest at Little Molas Lake.

In northern New Mexico, the record from Chihuahueños Bog (north of the VCNP) spans the last ca. 15,000 years (Anderson et al. 2004). Unlike other sites in the region, this area was not glaciated during the late Pleistocene, since it was well below the elevational limit for permanent ice (2925 m). An open spruce forest grew around a small pond until ca. 11,500 cal BP when ponderosa pine became established. Further to the southeast, at Jicarita Bog in the Sangre de Cristo range of New Mexico, warming commenced by 12,000 cal BP and intensified after ca. 11,700 cal BP. Warmest and driest conditions probably existed from ca. 9000 to 4400 cal BP there.

Several studies have documented the establishment of the Arizona Monsoon by the opening of the Holocene. The monsoon is important since it brings moisture to the Southwest during the driest part of the growing season. Anderson (1989) suggested the establishment of ponderosa pine across the southern Colorado Plateau signified expansion of the Arizona Monsoon, since today ponderosa pine is found in locations where summer precipitation is important. Using deuterium (δD) of wood cellulose at Lake Emma, Friedman et al. (1988) suggested that summer monsoonal precipitation dominated in the San Juan Mountains in the early Holocene, but shifted to a greater mix of Pacific frontal storms and monsoons after 4400 cal BP (Carrara et al. 1991). Changes in δD indicate changes in moisture source, the seasonality of precipitation, or a combination of both. Precipitation from air masses originating over the Gulf of California reach the San Juan Mountains without first passing over high mountains; higher D level are expected relative to those originating in the Pacific Ocean that must travel over high mountain ranges before reaching the southern Rocky Mountains. Models suggest that summer radiation decreased from 9000 years ago to the present (COHMAP 1988; Kutzbach et al. 1998). Because the summer monsoons are driven by heating of land masses, a corresponding decrease in monsoon activity was predicted for the remainder of the Holocene.

Though the early Holocene was warm enough to drive the intensification of the Arizona Monsoon, at least one study from New Mexico suggests that the transition between the early and middle Holocene was particularly dry. Chihuahueños Bog dried out completely between ca. 8500 and 6200 cal BP, as groundwater tables fell in response to warm and dry climates (Anderson et al. 2004). Few other sites have shown such a drastic response to climatic drying. One such site is VSRB (this report), which also shows a lack of sediment accumulation beginning about 8500 years ago. However, the VSRB record does not resume until about 1375 years ago, with most of the Holocene record missing. At Little Molas Lake in the San Juan Mountains, warm conditions prevailed from 10,570 to 6700 cal BP, culminating in a shallow lake phase from 6230 to 5900 cal BP. This falls within the mid-Holocene period of higher treeline documented by Elias et al. (1991).

A site nearby to the Chihuahueños and VSRB—Alamo Bog—also within the VCNP, spans the last 9000 years, but shows a continuous record during this period (Brunner-Jass 1999). Apparently this site had sufficient soil moisture to remain wet during the entire Holocene. The pollen spectra of the entire record is dominated by mixed conifer species, with alder (*Alnus*), sedge (Cyperaceae) and *Spagnum* growing locally on and around the bog.

The Middle to Late Holocene

The middle to late Holocene period is one of substantial transition within the Southwest, and indeed, worldwide. This period is characterized by a general cooling trend relative to the early Holocene, with an increase in effective moisture. Even so, the late Holocene is punctuated by substantial droughts, both recognized in the sedimentary record as well as the tree-ring record.

Physical evidence for effectively cooler conditions is shown in the Winsor Creek Basin cores of northern New Mexico (Armour et al. 2002). The cores document four episodes of magnetic susceptibility spikes congruent with increases in clastic sediment deposition, interpreted as indicative of periglacial activity. These events occur at ca. 5640, 4390, 2870, and 130 cal BP (4900, 3945, 2770, and 120 yr BP, respectively) (Armour et al. 2002).

Palynological evidence of cooling is ubiquitous, but the actual period of transition differs between locations. For instance, effectively more moist conditions occur at Chihuahueños Bog by 6000 to 5000 years ago, as shown by the increase in fir (*Abies*), followed by piñon (*Pinus edulis*) pollen. Moist meadow conditions prevailed at Jicarita Bog, New Mexico, after 5000 years ago, with the development of a sedge meadow at the site. Sediments at Brazos Ridge Marsh (northern New Mexico, 3222 m) did not begin to accumulate in the shallow basin until 5000 years ago, presumably due to lower groundwater tables before that time. At Alamo Bog, grass (Poaceae) expanded at the expense of all other pollen types by ca. 4800 years ago. We interpret this as an expansion of the wet meadow—also due to rising groundwater tables—forcing the mixed conifer forest to grow further away from the middle of the bog as increasingly wetter conditions prevailed. In central Colorado, both the lower treeline (controlled by precipitation) and the upper treeline (controlled by temperature) contracted after ca. 4990 cal BP

(4400 yr BP) (Fall 1997; Markgraf and Scott 1981). And warmer and drier climates than today transition to effectively moister climates at Little Molas Lake in the San Juan Mountains by ca. 4100 years ago. Timberline lowering around Lake Emma in the San Juan range reflected presumed cooling after ~3100 cal BP (Elias et al. 1991). These data document that sites respond to climate changes individualistically, depending upon the sensitivity of sites, and to a lesser extent, the accuracy of the chronology.

Some sites not only document broadscale changes in vegetation and climate during the late Holocene, but the records can be interpreted as being sensitive enough to register drier and wetter periods internal to the long-term late Holocene trend toward cooler conditions. For instance, summer and annual precipitation decreased after 2800 cal BP at Beef Pasture and Twin Lakes in the La Plata Mountains, as indicated by a decrease in *P. edulis* and a narrowing of the *Picea* zone, respectively (Petersen 1981). From 2500 to 1500 cal BP the Twin Lakes data indicate cooler temperatures, but drier summers (Petersen 1981). The upward shift of *Picea* to modern elevations due to warming occurs in the Lost Park record after 1800 cal BP, as higher sagebrush (*Artemisia*) and lower goosefoot (cf. *Atriplex*; Cheno-am) pollen percentages indicate drier summers (Vierling 1998). Modern climate and vegetation conditions were established at Jicarita Bog by 1700 years ago (Bair 2004). Additional evidence for a variable climate during the late Holocene comes from studies of fire histories, as documented below.

Undoubtedly the most detailed tree-ring series published to date for northern New Mexico comes from El Malpais National Monument. Grissino-Mayer (1996) constructed a 2129-year record based on long-lived live and dead Douglas fir (*Pseudotsuga menziesii*) and ponderosa pine (*Pinus ponderosa*) trees in this habitat that was largely protected from grazing and lumbering. Grissino-Mayer's analysis for the last 1900 years documents at least seven major long-term trends in rainfall. Above normal rainfall occurred during the periods AD 81–257, 521–660, 1024–1398, and 1791–1992, while below normal rainfall occurred during AD 258–520, 661–1023, and 1399–1790. The most intense drought during this time period was during AD 258-520. The precision of these data are unmatched by any of the pollen records obtained to date in the Southwest.

Fire Occurrence During the Holocene

Until recently, little was known about the long-term (Holocene-length) fire history of high elevation forests in the Southwest. Anderson et al. (2004, 2005) has reported on a fire history reconstructions from lake and bog sediments from seven sites in southern Colorado and northern New Mexico, which includes data on Little Molas Lake (Toney 2004) and Jicarita Bog (Bair 2004). More recently, Toney and Anderson (2006) have compared the long-term fire history records from Little Molas Lake with several from California to examine sub-continental patterns of burning during the Holocene.

High-resolution sampling—usually every 0.5 to 1.0 cm of linear core—is conducted to deduce the temporal patterns of fire at an individual site. This allows the investigator to construct the raw charcoal record (usually in particles/unit volume). Using the CHAPS program (Long et al. 1998) allows for calculation of charcoal deposition rates (CHAR), and separation of local fires (peaks) from non-local fires (background). This allows for calculation of a metric relating fire occurrence to time, often number of fires/1000 years. For high-elevation spruce-fir forest types, fire event frequency is usually measured in multiple decades to centuries (Alington 1998; Kipmueller and Baker 2000; Sherriff et al. 2001; Veblen et al. 1994), while for mixed conifer and ponderosa pine forest types it is years to decades (Swetnam and Baisan 1996).

Presently long-term data for the entire Holocene exist for Little Molas Lake, Hunter's Lake, and DeHerrera Lake in southern Colorado and from Jicarita Bog and Chihuahueños Bog in northern New Mexico. Shorter records have been analyzed for Brazos Ridge Marsh, Alamo Bog, and VSRB in northern New Mexico. Two time periods occur in these records where fire event frequency is higher than the Holocene average. Four sites—Little Molas, Hunter's, and DeHerrera Lakes, and Chihuahueños Bog—show higher fire event frequency between ca. 10,000 and 12,000 years ago (Anderson et al. 2004, 2005). The peak in fire activity for Jicarita Bog is displaced to ca. 12,000 to 14,000 years ago. We believe that there are two explanations for this. First, this was the time of highest post-glacial summer insolation, as modeled by Kutzbach and Guetter (1986) and others. This led to much warmer summers, with perhaps 7 percent to 8 percent greater insolation than today. With the initiation of the summer monsoon at this time came an ignition source as well—lightning. Second, this was also a period of rapidly changing vegetation, with the replacement of spruce woodland by spruce-fir forest or of spruce-fir forest by mixed conifer forest. Theoretically, the landscape would have contained abundant dead wood and other necromass for burning, assuming an ignition source was present.

The second period that witnessed a greater than average fire event frequency was during the late Holocene, between ca. 2000 and 1000 years ago. This pattern is present at Hunter's Lake, Brazos Ridge Marsh, and Chihuahueños Bog, with Alamo Bog showing higher fire event frequencies somewhat earlier at ca. 2500 years ago. Several explanations can be advanced for this (Anderson et al. 2004, 2005). First, Mayewski et al. (2004) demonstrated numerous records worldwide that document rapid climate changes as being more frequent during the late Holocene than before. Rapid fluctuations in climate may have placed additional stresses on plant communities that were not as apparent earlier in the record. It is likely that the late Holocene witnessed greater drought frequency. Within the limits of our dating, this late Holocene period is nearly contemporaneous with the AD 258–520 drought period documented from tree-rings at El Malpais (Grissino-Mayer 1996), which also documents additional extended periods of drought in the area during the most recent 2000 years. Second, most of the pollen evidence presented above suggests that mid- to high-elevation forest development reached its maximum extent during the late Holocene. This may have been a result of increased late Holocene winter precipitation, a result of the strengthening of El Niño over the last ca. 5000 years (Anderson and Smith 1997; McGlone et al. 1992; Menking and Anderson 2003; Rodbell et al. 1999). A climatic linkage between drought and climate for the Southwest has been established by Swetnam and Baisan (1996) who clearly showed from tree-ring evidence that the largest fire years are also those with the deepest drought, as measured by the Palmer Drought Severity Index. Therefore, we might expect with increased biomass, periods of drought would witness more frequent fire.

SUMMARY

The number of paleoecological sites with pollen and charcoal data within the southern Rocky Mountains of Colorado and New Mexico has grown considerably in the last decade. Research in this region has been driven by the desires of land managers to understand the history of vegetation change and long-term fire history. For most of the post-glacial period, climate has been the driver of vegetation and fire histories. However, human activities have had an increasingly important impact on the landscape of the region, as shown by the results of the Cerro Grande fire of 2000.

Two new records of vegetation and fire in the Jemez Mountains include AAB and VSRB. Although the record from VSRB is of limited use, the AAB record spans most of the late Holocene, a period of considerable interest to land managers and archaeologists. Pollen and macrofossil evidence demonstrate that forest of this elevation was one of mixed conifers throughout the period, but the characteristics of the forest transitioned about 2200 years ago to one including more ponderosa pine, with greater fire. It is unclear whether an increase in fire frequency allowed for greater ponderosa pine, or vice versa, from these data. It is also unknown at this time whether this change was driven by climatic or human causes. Further investigation is warranted on these issues.

Much of our knowledge of the long-term history of the region remains unpublished, or is found in “gray” literature publications. However, this may soon change, as the numbers of articles from a large USGS-BRD study become published (e.g., Toney and Anderson, 2006). Of great interest to paleoecologists is the occurrence of definitive evidence of a major cooling event—the YD—in the Southwest in several studies. Research has also demonstrated that the Arizona Monsoon developed by the early Holocene and may have been instrumental in providing the ignition source (i.e., lightning) that caused higher fire event frequencies during the major vegetation changes of the early Holocene. At several locations, the late to middle Holocene was the driest time of the record, when lake levels were lower and bogs dried out completely. This phenomenon was not universal, however, and probably depended upon the reliability of sufficient groundwater to maintain moisture in the basin center. Generally cooler climates of the late Holocene allowed an increase in biomass in mid- to high-elevation forests, and favored the expansion of low- (e.g., *Pinus edulis*) and high- (*Abies*) elevation conifers. Climate change during the late Holocene was not unidirectional, though, as the period was punctuated by numerous droughts of centennial duration.

Evidence of human modification of vegetation and fire regimes in the southern Rockies is not obvious until the late 19th and early 20th century. The establishment of grazing is shown at several locations by increases in grasses and introduced herbaceous species. Similarly, the effect of fire suppression is shown at most sites by the cessation of sedimentary charcoal deposition. Paleoecologists continue to examine the record for the impact of native populations on the forests of the southern Rockies, but, with our present understanding of the history of the region, climate appears to be the primary driving force on southwestern forests until the most recent centuries.

CHAPTER 6
MODERN POLLEN ANALOG STUDY, LOS ALAMOS NATIONAL LABORATORY

Susan J. Smith

INTRODUCTION

This report documents the results of a modern pollen study in Los Alamos National Laboratory (LANL). The main goal of this research is to develop an analog that can be used to study archaeological sites. Archaeological pollen data can be compared to natural pollen spectra and unique separated signatures that might reflect cultural activities. The analog is constructed from bulk sediment samples collected during June 2002 from 20 sites arrayed along a vegetation gradient from mixed conifer forests above 9000 ft to piñon and juniper below 7000 ft.

Archaeological sites at LANL are concentrated in transition zone ponderosa pine and piñon-juniper forests, where most of the sites date to the Coalition period (ca. AD 1150–1325) (Vierra et al. 2002a:6–29). The extent and persistence of agriculture on the Pajarito Plateau is impressive and is not limited to the prehistoric period. During the AD 1900s, there were about 35 homesteads on the plateau (Foxx et al. 1997:7). The homesteaders were grazing stock and farming grain, beans, orchards, and vegetables. An important research theme for the modern pollen study is to explore the pollen nature of disturbance. Can past agriculture be recognized from unique pollen assemblages or any key indicator types? A special class of disturbance is created by wildfire, and large tracts of forest have burned in the last 100 years, notably the 2000 Cerro Grande fire. Are there distinct pollen signatures in burned and unburned plots from different forest types? Do pollen spectra from burned sites share any traits with disturbed sites?

MODERN ENVIRONMENT

Detailed information about LANL vegetation is documented in geographic information system databases (Balice et al. 1997; Balice et al. 2000) and a botanical inventory (Foxx and Tierney 1984). LANL is sited on approximately 50,000 ac on the Pajarito Plateau, a broad piedmont off the east slope of the Jemez Mountains characterized by east-west-trending canyons and intervening mesas. The Sierra de los Valles, with three mountain peaks greater than 10,000 ft high, form a dramatic landscape west of Los Alamos and the Rio Grande Valley lies to the east. The elevation gradient from the crest of the Sierra to the Rio Grande (5350 ft elevation) is greater than 5000 ft over a horizontal distance of less than 15 miles.

The regional elevation gradient and diverse local physiography generate a variety of microclimate niches. The corresponding modern vegetation is a complex mosaic that Balice et al. (1997) have categorized into the following five main (Level 1) cover types: juniper savannah, piñon-juniper woodlands, ponderosa pine forests, mixed conifer forests, and spruce-fir forests. Figure 6.1 is a generalized model of the elevation range of the main vegetation types (Balice et al. 1997:13). The boundaries between vegetation communities are diffuse transition zones, moderated by slope aspect and the many canyons that carry linear stringers of higher-elevation species through lower-elevation communities.

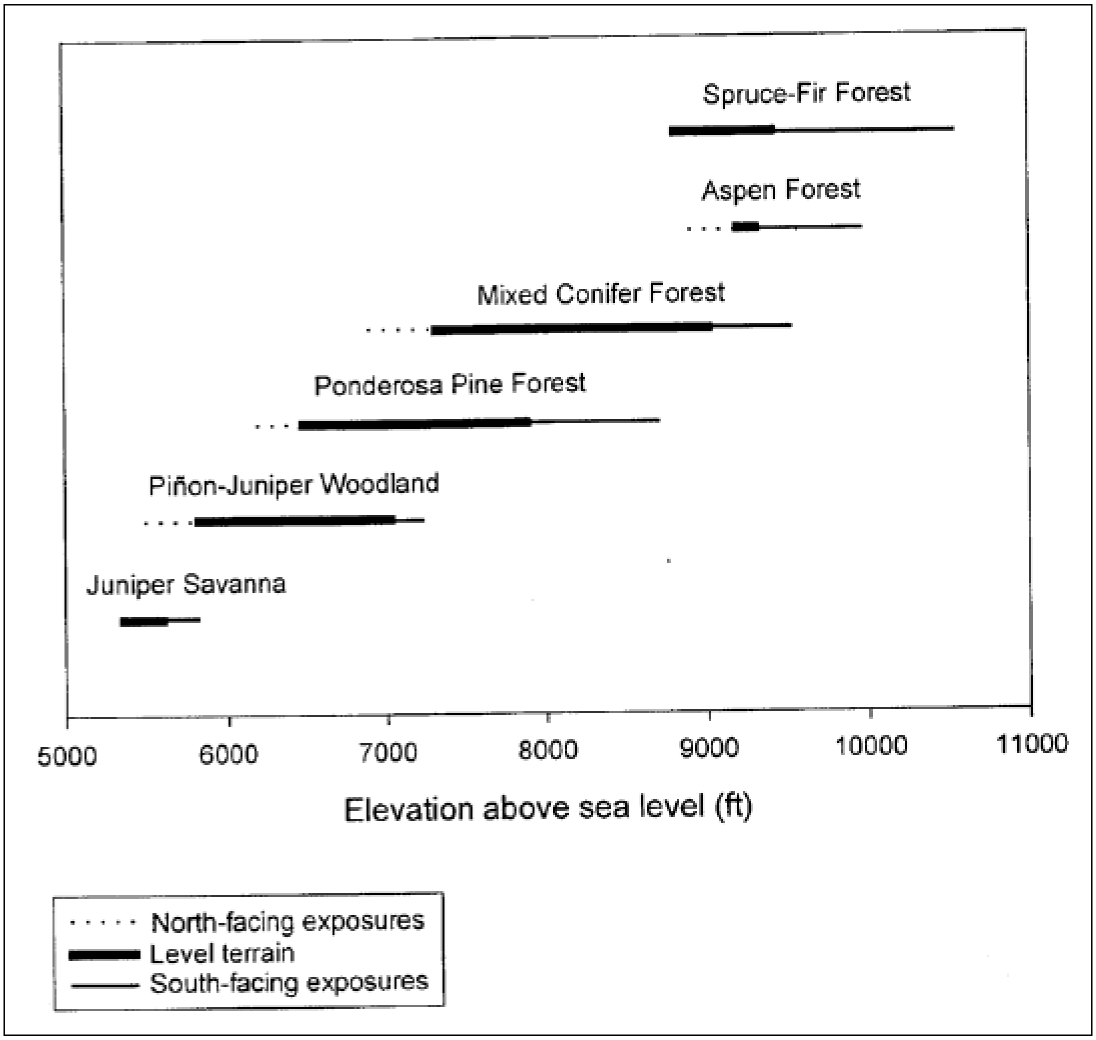

Figure 6.1. Elevational range of main vegetation types (Figure 4 in Balice et al. 1997:13).

During the June 2002 field work, Teralene Foxx identified plant species in the field at 12 of the 20 pollen stations, which is a feat that only an experienced Los Alamos botanist could attempt in the record-breaking drought year of 2002. Several of the herb and forb species were recognized by a stub of stem and a dry piece of curled leaf picked from the soil around the plant base. The plant species identified at each station are listed in Table 6.1. The detailed lists, station descriptions, and pictures for 11 of the stations are documented in Appendix B. A list of all the plant species identified and frequency as a percent of the 20 stations is presented in Table 6.2. A total of 114 plant species were documented, which included 14 species of trees, 25 shrubs, 54 herbs and forbs, 17 grasses, three aquatic species, and one fern. The variety of plants would undoubtedly have been higher, but for the extreme 2002 drought conditions.

Table 6.1. Plant species list for the Los Alamos pollen stations (June 12 to 14, 2002).

POLLEN STATIONS

The modern pollen analog is constructed from 20 stations that sample the main vegetation types, examples of disturbance, meadow and riparian sites, and paired stations in burned and unburned plots from the 2000 Cerro Grande fire. Station descriptions are listed in Table 6.3, organized generally by elevation and vegetation type. The estimated percent cover of three overstory layers (trees, shrubs, and grasses and herbs) and the dominant tree species are included in Table 6.3. Stations selected to represent a burned forest stand, disturbed or riparian site, or meadow are viewed as openings within forest. This perspective is particularly relevant to pollen studies in forests, because conifer trees produce literally tons of wind-dispersed pollen (Fægri et al. 1989:14) that dominate the regional pollen rain. Thus, at the coarsest level, the stations occur in four vegetation types: mixed conifer (*n* = 4), ponderosa pine (*n* = 5), transition ponderosa pine and piñon-juniper (*n* = 5), or piñon-juniper (*n* = 3).

Table 6.3. Modern pollen sampling stations.

Pollen Station (S No.)		Vegetation Type	Description	Elevation		Percent Cover			Ranked Dominant Trees & Plant Taxa Richness[a]

a. Ranked dominant trees lists all the trees identified at a station in the order of abundance. Plant taxa richness from Appendix B is the number of plant species identified at each station.

Subdivisions within the forest types follow. Stations 11 and 12 represent canyon bottoms characterized by mixed forests, and station 9 is an example of a high-elevation meadow within a mixed conifer forest. There are four examples of disturbance: a road shoulder (S 26), an area of mechanical disturbance (S 18), a possible historic field (S 2), and an historic (ca. AD 1900s) bean field (S 29) at the Romero homestead. The Romero homestead was the subject of a field succession study and archaeobotanical study (Foxx and Tierney 1999; McGehee et al. 2006). There are two sets of paired sites (four stations) sampling the Cerro Grande fire: one pair from burned and unburned ponderosa pine (S 27 and 28) and one set in piñon and juniper (S 17 and 19). Examples of riparian environments were sampled at stations 4, 10, 12, and 25.

METHODS

One to three separate bulk sediment samples were collected at each station by taking 15 to 20 pinches of soil from the top 1.0 to 0.5 cm of soil across an approximately 50- by 50-m area (Adam and Mehringer 1975). The vegetation at each station was characterized by estimating the percent cover of the dominant trees, shrubs, and ground cover. Although only one of the multiple samples from each station was processed and analyzed, the analog could be expanded in future studies to examine the degree of variability between multiple samples.

In the laboratory, subsamples (20 cc volume) were taken from the sample bags, weighed, and spiked with a known concentration (25,084 grains) of tracers (*Lycopodium* spores). Addition of tracers allows pollen concentration to be calculated, which estimates the raw number of pollen grains in a sample. The samples were processed with acids (overnight hydrochloric and hydrofluoric), followed by a heavy liquid gravity separation (zinc bromide 1.9 specific gravity) and acetolysis, which reduces organics. The extracted samples are stored in glycerol.

Pollen assemblages were identified by counting slides from the processed samples on a Reichert, Microstar IV microscope. Entire slides were examined by counting transects at 400x magnification to a 300-grain pollen sum, then scanning remaining transects at 100x magnification to record additional taxa. Pollen aggregates (clumps of grains of the same taxon) were included in the pollen sum as one grain per occurrence and a separate tally made of the number of grains within each aggregate. The occurrence of pollen aggregates in modern surface samples is generally ignored in ecological studies, but is a useful class of data in archaeological pollen studies (e.g., Gish 1991).

Another type of data documented from the slides is the percent cover of background charcoal particles. Trends in microscopic charcoal abundance from lake core samples have been used to infer fire history. However, the micro charcoal data are generally useful only for long-term regional patterns (MacDonald et al. 1991; Patterson et al. 1987). Pollen extraction procedures filter the possible size range of charcoal to dust or smoke size particles (approximately 200 to <10 µm), which can be blown into a site. Macroscopic charcoal from sediment profiles is a better proxy for local fire history. The purpose in examining the micro charcoal matrix in the LANL samples is to test for any differences at burned and unburned paired sites.

Pollen identifications were made to the lowest taxonomic level possible based on comparison to the Northern Arizona University, Laboratory of Paleoecology pollen reference collection and published references (Faegri et al. 1989; Kapp 2000; P. Moore et al. 1991). The separation between piñon pine and other pines was based primarily on size measurements (Jacobs 1985b). Piñon pine was found to be the least reliable predictor of vegetation in the LANL pollen assemblages. There is significant overlap in the size gradient between small ponderosa pine grains and larger piñon pine (Martin 1963:20–21), and it is likely that there are misidentified grains in both pine categories. Haploxylon pine grains greater than 70 µm were also documented, and these probably represent limber pine (*Pinus flexilis*), a rare conifer growing at higher elevation.

The broad sunflower family group was separated into seven types: sagebrush (*Artemisia*), thistle (*Cirsium*), chicory tribe (Liguliflorae), sunflower family (Asteraceae or Compositae Hi-Spine), the ragweed/bursage type (*Ambrosia* or Low-Spine Compositae), Long Spine, and Broad Spine. The separation between the high and low spine Compositae categories was based on the height of spines, using 2 µm as a cutoff (Hevly et al. 1965). The Long Spine and Broad Spine are unique categories in this analysis.

The Long Spine type is defined as a grain with spines greater than 3.0 µm and a tricolporate aperture system with pores aligned transverse to furrows. The Long Spine probably represents sunflower (*Helianthus*), but other northern Colorado Plateau genera with the same grain morphology include *Layia*, fetid marigold (*Pectus*), coneflower (*Rudbeckia*), marigold (*Tagetes*), crown-beard (*Verbesina*), and *Viguiera*. The broad spine grain morphology is similar to ragweed/bursage, but the spines are distinct with bases twice as wide as long. A possible candidate for the broad spine is *Dicoria*; however, this genus is not listed in Foxx and Tierney (1984), and some other sunflower family member may be represented.

Three numerical parameters were calculated from the pollen counts: taxa richness, pollen percentages, and pollen concentration. Taxa richness is the number of different pollen types identified in each sample. Pollen percentages are a smoothing transformation that represent the relative importance of each taxon in a sample ([pollen counted/pollen sum]*100). Percentages are the main parameter used to discriminate trends in the LANL modern pollen samples.

Pollen concentration is a measure of the absolute number of grains or the density of pollen grains in a sample. Concentration was calculated for each sample by taking the ratio of the pollen count to the tracer count and multiplying by the initial tracer concentration. Dividing this result by the sample weight yields the number of pollen grains per gram of sample sediment, abbreviated gr/g. Concentration may also be calculated by volume—both sample weight and volume are documented in Appendix C. Pollen concentrations can be used to gauge several processes. In natural settings, concentrations can reflect sediment accumulation rates, and in cultural contexts, concentrations can relate to the amount of plant material handled.

RESULTS

All of the pollen data are documented in Appendix C. A total of 43 pollen types were identified, and these are listed in Table 6.4 by common and taxa name and organized into two main categories, trees and shrubs and the ground cover plants (forbs, herbs, grasses, and weeds). The sample frequency for each pollen type is also included. The results are presented in two parts. First, the correspondence between pollen spectra and the main forest types is analyzed, and second, the disturbance, riparian, burned sites, and other unique locations are discussed.

Pollen Correspondence to Forest Composition

The stations are grouped by the main forest types: mixed conifer, ponderosa pine, transition forests of mixed piñon-juniper and ponderosa pine, and piñon-juniper. Three stations are grouped separately (S 25, 26, and 29) as unique, primarily disturbed sites. Station 12, a riparian site in Los Alamos Canyon at 2217 m (7276 ft), was listed with the high-elevation mixed conifer sites because the dominant tree is Douglas fir. Station 12 is an example of the more mesic environments created in canyons.

One pattern in the LANL pollen data is the trend for more diverse assemblages at higher elevations, especially in the mixed conifer and ponderosa pine forests. Pollen taxa richness ranges between 15 to 20 pollen types above 2133 m (7000 ft) and less than 15 taxa in the transition and piñon-juniper forests. The exceptions are either high-elevation transition zone sites (S 17, 18, and 19) or unique situations (S 2, 4, 25, 26). This pattern is not evident in the plant species richness at each site (Table 6.1 and Table 6.2), except for a greater number of species from the high-elevation mixed conifer stations. However, the variety of taxa identified in the field is probably low due to the 2002 drought.

The mixed conifer stations produced distinct pollen assemblages, with high values of fir (4% to 34%), high taxa richness (15 to 20), and presence of some rare types, such as honeysuckle, birch, and maple. Low percentages of Douglas fir and limber pine are associated with the mixed conifer stations. Spruce pollen surprisingly was not a good indicator of the higher-elevation stations. Spruce was identified in 11 of the 20 samples analyzed, including S 1 in piñon-juniper.

There is no significant pattern in pollen concentrations, except for low pollen abundance at two disturbed sites (S 26 and 29) and the high-elevation meadow (S 9). Pollen concentration in surface soil is sensitive to the dynamic influx of pollen and sediment. Pollen deposition increases concentration and sediment deposition dilutes pollen density. Generally, pollen concentration is high in the analog samples, which reflects the abundant production from the wind-pollinated conifers.

The distribution of pollen aggregates was not diagnostic of vegetation types. Aggregates from most pollen taxa were rare occurring in only one to three samples, except for pine (Appendix C). Aggregates of pine occurred at 11 of the 20 stations. Oak pollen aggregates were documented at two sites (S 18 and 19), and, at S 18, oak was the primary tree.

The pollen types sensitive to forest composition are fir, pine, and juniper. Piñon pine is included in the summary diagram (Figure 6.2), but this type is not diagnostic, even in the piñon and juniper forest. Disturbed sites and small meadows are generally characterized by high representation of grass or cheno-am, sunflower family, and herb types. The best summary measure of forest types is a ratio between pine (excludes piñon) and juniper. In Figure 6.2, the pine/juniper ratio is highest (19 to 60) from stations in the ponderosa pine forests. Juniper frequencies rise at stations from the transition forests and are highest in the piñon and juniper forests, which is reflected by the minimum pine/juniper ratio of 1. The pine/juniper ratio is suppressed at the high-elevation mixed conifer sites because pine is not the dominant tree at these stations. Pollen taxa that are not particularly good indicator pollen types, with a few exceptions, are oak, rose family, cliffrose/mountain mahogany type, sagebrush, and grass.

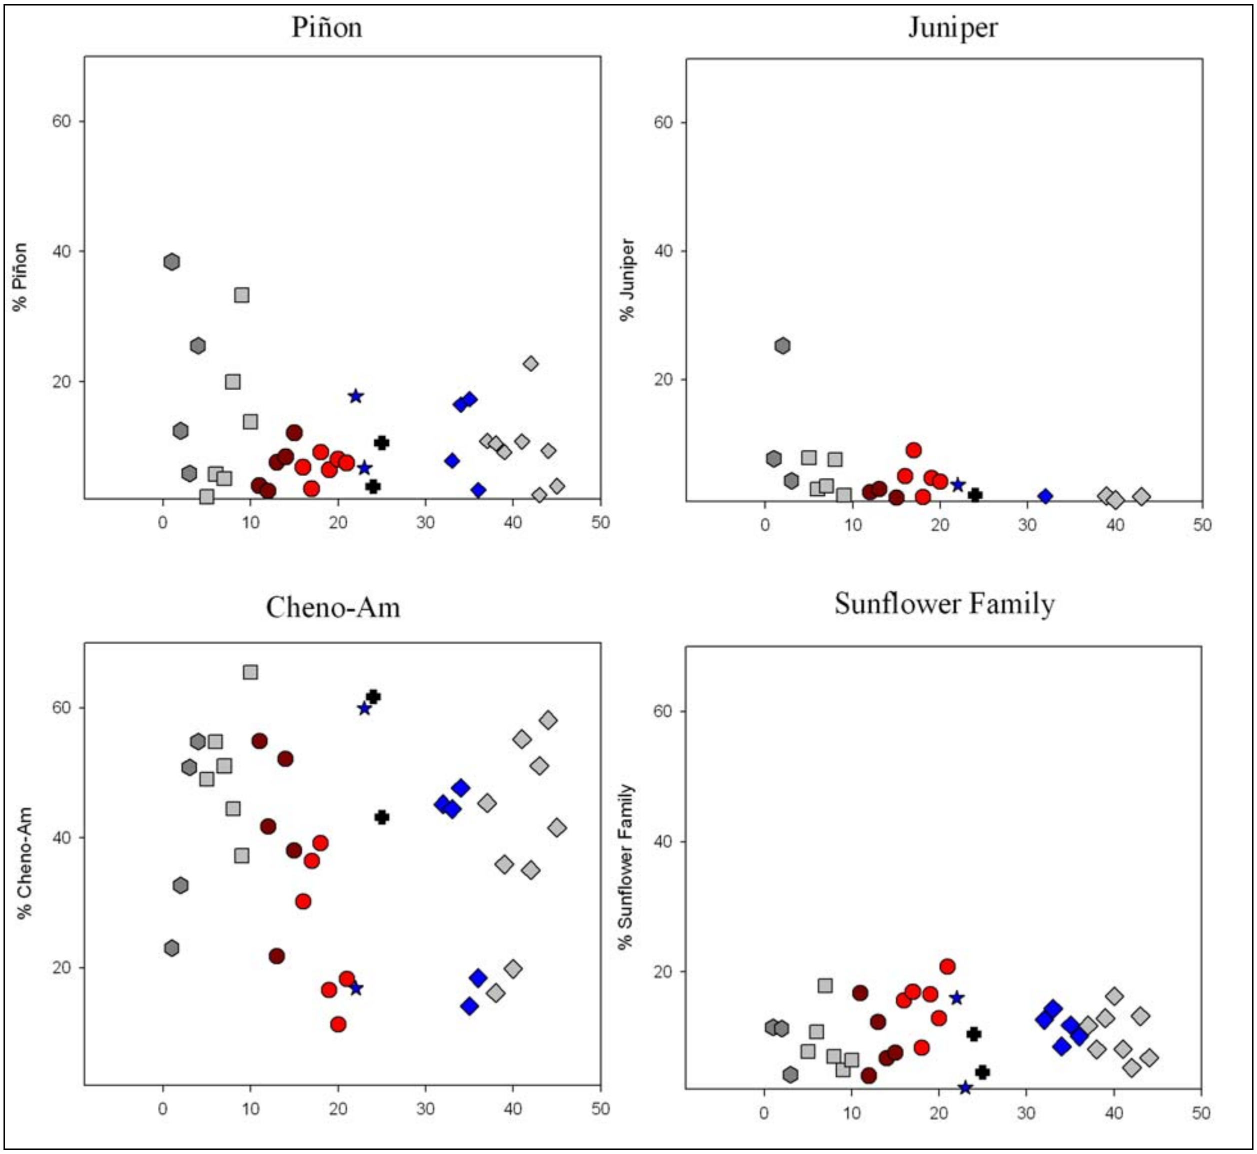

Figure 6.2. Modern pollen analog summary percentage diagram.

Pollen Indicator Types at Disturbance and Riparian Sites

In this section, patterns are discussed that discriminate subdivisions within the main forest types. Summary data for each station are listed in Table 6.5, including general station descriptions, plant taxa richness, pollen concentration, pollen taxa richness, and other key variables.

a. Micro Charcoal is an estimate of the percent cover of microscopic charcoal in the background matrix of slides made from the processed pollen samples; b. Percent all trees is the sum of pollen percentages from the following trees: Pine, Piñon, Juniper, Douglas Fir, Fir, and Spruce.

Disturbed Sites: Road Shoulder (S 26), Fields (S 2, 29), and Mechanical Disturbance (S 18)

An important research theme explored in this study is the sensitivity of pollen to vegetation changes due to disturbance, which typically occurs in small (1 to 100 acre) areas that have been cleared of trees. Homestead era agriculture during the AD 1900s and modern development at LANL have created a wide range of disturbed sites to choose from. The historic Romero field (S 29) on Pajarito Mesa, a possible historic field (S 2) on the floodplain in Ancho Canyon, a bulldozed area (S 18) on Pajarito Mesa, and a road shoulder (S 26) were sampled. Except for the Romero field (S 29), each disturbed site is matched with samples from adjacent undisturbed forests. Foxx and Tierney (1999) have intensively studied the botany of the old Romero Homestead, including a field succession study in the old bean field. Field succession botany has also been studied at eight other historic fallow fields in the LANL region (Foxx et al. 1997), and these studies provide invaluable information about historic land use and vegetation response to disturbance.

Three of the pollen stations produced pollen signatures distinct from matching samples in surrounding forest. The two field sites (S 2 and S 29) and the road shoulder (S 26) are characterized by the project maximum percentages of cheno-am and sunflower family pollen (combined values 18% to 40%) and the lowest frequencies of tree pollen (all tree taxa combined range from 38% to 40%). The cheno-am and sunflower family encompass a broad range of weedy plant species, and the high representation from disturbed sites is probably related to opportunistic weeds colonizing new habitat.

The variety of pollen types is also high at disturbed sites; taxa richness ranges from 17 to 22 at stations 2, 18, 26, and 29. This diversity is due to a higher representation of herbs and forbs in open areas, compared to the sparse ground cover plants under forest canopies. Pollen from weedy plants, such as thistle and sunflower (Long Spine *Helianthus* type), is documented more frequently from the disturbed sites. At the Romero field site (S 29), sagebrush pollen was over 20 percent of the pollen count. Two sage plant species, carruth sage and false tarragon (*Artemisia carruthii* and *A. dracunculus*), were identified as good indicators of disturbance in the field succession study completed by Foxx et al. (1997), and both sages are also abundant in the Romero field (Foxx and Tierney 1999). Broad spine, another unknown type from the sunflower family, is more frequent at the disturbed sites than forest sites.

Station 18, the one example of mechanical disturbance, did not produce a pollen assemblage distinct from adjacent forest (S 17 and 19). Station 18 is a small, less-than-one-acre opening in burned piñon-juniper forest that is also within the transition ponderosa pine to piñon-juniper zone. Shrub size oaks that root-sprouted after the Cerro Grande fire killed the piñon and juniper trees common around S 18, and oak pollen is high at S 18 and S 17, which are separated by less than 300 feet. High pollen concentration (greater than 150,000 gr/g) and high percentages of conifer pollen (63% combined from all conifers) indicate the small opening is an efficient collector of abundant pine pollen. Acre-scale clearings will capture more wind-blown conifer pollen than ground inside a forest due to the dynamics between pollen dispersal and wind (Faegri et al. 1989:14–15; Jackson and Smith 1994:191).

Riparian Sites, Stations 4, 10, 12, and 26

Four sites were selected to sample riparian situations; however, wet sites are rare at LANL. The two best examples are the Pajarito Canyon wetland (S 25) and a riparian site in Los Alamos Canyon (S 12). The other two riparian sites are historic wetlands—a pond (S 4) that is now dry and an area in Pueblo Canyon that was a sewage effluent wetland (S 10), but now is dry. The reclaimed water in Pueblo Canyon has been diverted to the golf course.

The pollen assemblage from the dry pond at S 4 did not correspond to the site vegetation. Western wheatgrass was the dominant plant in the old pond site, but grass pollen was only three percent of the pollen assemblage. Pine pollen from the surrounding ponderosa pine forest overwhelmed the assemblage. Sheetwash sediments from burned forest stands upslope of S 4 filled the depression, and the collected pollen sample is probably not representative of pond sediments. Willow trees grow around S 4 and willow pollen was documented from S 5, which represents the pine forest surrounding S 4. The Pueblo Canyon site (S 10) is now a meadow area. The pollen assemblage from S 10 is dominated by tree pollen (69% combined conifers), but there is a component of grass pollen (7%) and cheno-am and sunflower family (10% combined values) that correlate with the wet meadow environment.

The water indicators were cattail and willow pollen recovered from S 25, the Pajarito Canyon wetland. This site is a perennial wetland with bulrush, cattails, and willow. Pine pollen was high from S 25, which reflects the surrounding pine forest in the canyon. No riparian pollen types were identified from S 26, the road shoulder site that is within 100 feet of the Pajarito Canyon wetland. The limited occurrence of cattail pollen is consistent with other research that has shown that, although a wind-pollinated plant, cattail pollen is not dispersed far from source plants (Hevly 1974; Krattinger 1975).

2000 Cerro Grande Fire Paired Pollen Stations

Two pairs of stations were sampled within the Cerro Grande burn, an intense wildfire that burned several thousand acres around Los Alamos in 2000. Stations 27 and 28 are in Rendija Canyon near the gun club and represent burned (S 27) and unburned (S 28) stands of ponderosa pine forest. The fire burned hot in Rendija Canyon, although at S 27, the fire was a ground fire and the trees were not killed. The tree composition and cover are comparable between S 27 and 28, and the main vegetation difference is greater cover of grasses and weeds at the burned site. Stations 17 and 19 represent burned (S 17) and unburned (S 19) transition ponderosa pine to piñon and juniper. The tree canopy was killed at S 17 and there is a greater contrast in the vegetation cover between the two stations (Table 6.3). Shrub size oaks, probably root-sprouted from fire-killed trees, yucca, and grasses and herbs characterize S 17, compared to 70 percent pine, piñon, and juniper tree cover at S 19.

The pollen results from the paired stations show some weak patterns (Table 6.5) that are related to the different plant composition and architecture at the two sites. The percentage of pine pollen was 10 percent less at the burned ponderosa pine S 27 compared to the unburned S 28, but the combined cheno-am and sunflower family percentages were higher at the unburned site S 28, compared to S 27. There is a greater contrast between S 17 and S 19, which is a more mixed forest (Table 6.2). Low percentages of pine and high frequencies of cheno-am and sunflower family were calculated from the burned site (S 17), compared to high pine and juniper values and lower cheno-am and sunflower family at the unburned site (S 19). Oaks are the dominant tree at S 17 and oak pollen was high at 8 percent in the S 17 sample and aggregates of oak pollen were recovered, whereas oak was low (2%) at S 19.

The percent of microscopic charcoal (ca. 200 to less than 10 μm long) in slide preparations was estimated in all 20 LANL modern analog samples to test whether samples from burns had higher amounts of charcoal than unburned sites. The estimated charcoal cover is listed in Table 6.5. Microscopic charcoal was present in all 20 samples at a minimum of less than 10 percent of the background matrix. The maximum percent cover was 30 percent to 40 percent in the sample from S 10, the Pueblo Canyon meadow. Four samples produced charcoal values of 20 percent to 30 percent: S 4 (disturbed pond), S 25 (Pajarito Canyon wetland), and the paired samples S 27 (burned ponderosa pine forest) and S 28 (unburned forest). The samples from S 17 and S 19, the burned and unburned pair in piñon and juniper forest, were characterized by less than 10 percent charcoal. No definitive relationship is interpreted from these data, although there is some indication that charcoal is concentrated in alluvial and sheetwash sediments (S 4, 10, and 25).

CONCLUSIONS

The modern vegetation at LANL is a mosaic that has been modified by a long history of cultural use including prehistoric settlement and agriculture, historic grazing and timber harvest, AD 1900s homesteaders, and modern development and land management practices, such as burning, thinning, and manipulation of water resources. Wildfire is also a significant natural architect of vegetation, as evidenced by the catastrophic effects of recent forest fires. The LANL modern pollen analog developed in this study contributes important baseline information for interpreting pollen data from fossil and archaeological sites. The constructed pollen spectra are sensitive to the natural elevation and vegetation gradient at LANL and to finer-scale compositions that reflect the local site history. However, there is no formula of values that can be applied to filter unique pollen signatures from generic sites—archaeological or natural. The potential for high-resolution pollen analysis can be realized by using the analog to compare to pollen results from specific study sites.

The different forests are characterized by relative differences in fir, pine, and juniper pollen. Cheno-am, sunflower family, and sagebrush (*Artemisia* spp.) characterize old fields. Cheno-am, sunflower family, and grass pollen distinguished the two meadows sampled (S 8 and 10). Riparian sites are rare at LANL, but the only station where cattail was growing (S 25) yielded the only cattail pollen recovered in the study. Other potential indicator pollen types are Douglas fir and cf. limber pine from mixed conifer forests, maple and birch from mesic sites, willow from riparian environments, and sagebrush, thistle, and long spine (cf. sunflower type) from disturbed sites.

CHAPTER 7
THE CURRENT STATUS OF ARCHAEOLOGICAL DENDROCHRONOLOGY AND DENDROCLIMATOLOGY OF THE PAJARITO PLATEAU, NEW MEXICO

Ronald H. Towner

INTRODUCTION

Dendrochronology, or tree-ring dating, has played a significant role in the development of archaeology in the U.S. Southwest; it has also provided important information regarding past environmental variability in the area. This document discusses two subfields of dendrochronology—dendroarchaeology and dendroclimatology—in terms of their impact of studies of human use of the Pajarito Plateau and past environments in the same area. It should be viewed as a summary of what has been accomplished and as a potential guide for further elucidation of human/environment interaction.

Dendrochronology, the science of tree-ring dating, is the most accurate and precise non-documentary dating method available to researchers studying the recent past. Tree-ring dates are accurate and precise to the year, and some times to the season, and have no associated statistical uncertainty or standard error. Other prominent archaeological dating techniques that use natural materials (e.g., radiocarbon, archaeomagnetism, etc.) have been calibrated using dendrochronological samples. It is this precision and accuracy that has allowed archaeologists working in the U.S. Southwest to construct the most detailed chronologies in the world and to explore a plethora of environmental, social, and behavioral questions regarding the past human adaptation to the region.

Dendroarchaeology is the use of tree-ring data from archaeological contexts to provide Christian-calendar dates for archaeological phenomena such as rooms, sites, and cultures, to delineate aspects of past human behavior, such as tool use, wood harvesting and modification practices, and the social strategies used to exploit past wood resources, and to illuminate aspects of past environments, such as species composition of past landscapes and past precipitation and temperature regimes (Dean 1996a; Towner et al. 2001). Dendroclimatology is the use of tree-ring data from living and dead trees—including archaeological timbers—to examine past climate fluctuations and patterns in terms of precipitation and temperature at various temporal and spatial scales (Bradley 1999).

This overview has three main objectives. First, it is a synthesis of all archaeological tree-ring data derived from historic and prehistoric sites on the Pajarito Plateau. Although many of the dates have been published elsewhere (Robinson et al. 1972), this is the most extensive compilation and interpretation of the tree-ring data (not simply dates) from the Pajarito Plateau. Second, it is a synthesis of the existing dendroclimatic data relevant to the area. Such data are not point-specific or constrained by political boundaries and, therefore, the discussion encompasses much of the northern Rio Grande area, not simply the Pajarito Plateau. Finally, the syntheses will be used to suggest possible avenues for future research in the area using both fields. Therefore, this document will be important both as a detailed summary of the existing data and as a guide for future dendroarchaeological and dendroclimatological research.

A BRIEF HISTORY OF DENDROCHRONOLOGY

Andrew Ellicott Douglass is considered the founder of dendrochronology. Trained as an astronomer, Douglass immigrated to Flagstaff, Arizona, in the late 19th century to develop Percival Lowell's observatory that was designed to explore the possibility of canals on Mars (Webb 1983). Douglass, however, was interested in chronicling sunspot activity as a method to document past and predict future climate. The historical climate records in the Flagstaff area were virtually nonexistent (about 20 years in length), so Douglass searched for some proxy measure of climate with which to compare sunspot cycles. At that time, the great ponderosa pine forests of the Flagstaff area were being actively logged. By examining the stumps, and some times cross-sections, of ponderosa pine trees, Douglass identified the "Flagstaff signature" ring series that contained small rings at specific years in the late 1880s, 1890s, and early 1900s. The first test of Douglass's method occurred in 1904 when he deduced that a tree was cut 10 years previously, in 1894; Douglass checked his deduction with the farmer who had cut the log, who confirmed its cutting date (Towner 2000; Webb 1983).

Douglass continued to develop his chronology from living trees, but in 1914 his research attracted the attention of archaeologists working in the Southwest (Nash 1999). Subsequently, archaeological samples collected by Douglass and others from sites such as Pueblo Bonito in Chaco Canyon and Aztec Ruin on the Animas were cross-dated to form a "floating" or relative chronology some 585 years in length (Douglass 1921). Unfortunately, this chronology did not overlap in time with Douglass' modern tree specimens, and therefore, even though the temporal relationships between the sites were known in annual terms, they were not yet known in terms of the Christian calendar. Archaeologists had learned that Aztec Ruin was approximately 45 years younger than Pueblo Bonito, but whether both sites were built 1,000, 2,000, or 3,000 years ago was still undetermined (Nash 1997, 1999; Webb 1983).

During the 1920s, archaeologists and the dendrochronologist (Douglass) were working to solve the problem of the "gap" between the live-tree and floating chronologies (Haury 1962). Fortunately, archaeologists in the Southwest had developed a pottery seriation based on historic and prehistoric period sites (Colton and Hargrave 1937). Thus, the archaeologists knew the relative temporal position of many sites, if not their absolute ages. Throughout the decade, numerous "beam" expeditions traveled to the Colorado Plateau and Rio Grande area to collect archaeological specimens to further Douglass' tree-ring research (Nash 1999). Using the pottery seriation, these expeditions focused on specific sites thought to represent occupations during the "gap" between the chronologies. Finally, on June 22, 1929, a burned beam (HH-39) from the Whipple Ruin allowed Douglass to combine the two chronologies into a single master record more than 1000 years in length (Haury 1962). After "the gap" was bridged in 1929, dendrochronology experienced a brief florescence with research laboratories established in Tucson, Flagstaff, and Globe, Arizona, and Santa Fe, New Mexico; additional research was conducted on the High Plains in Kansas and North Dakota, in the southeastern United States, and in Alaska.

Dendrohistory in the Northern Rio Grande

As Douglass developed his living tree and archaeological ring sequences for the Four Corners area and Colorado Plateau, he soon realized that the northern Rio Grande area contained a different climatic signal (Douglass letter to Judd date June 24, 1927; cited in Nash 1999:185). Under Douglass' direction, Jeançon and Ricketson collected Rio Grande samples, including some from San Idlefonso, as part of the first Beam Expedition (*El Palacio* 1923a, 1923b). Douglass had worked with samples from Pecos Pueblo excavated by Alfred Kidder, but was unsure of their chronological position. Indeed, the omission of any Rio Grande site, including the famous Pecos Ruin, from his seminal article "The Secret of the Southwest Solved by Talkative Tree-Rings" (Douglass 1929) was glaring (Nash 1999).

After the "gap" in the Central Pueblo chronology was bridged, the most pressing problem in Southwestern dendrochronology became dating the Rio Grande archaeological sequence. Eager to move quickly on the problem, the newly formed Laboratory of Anthropology (LAH) established a tree-ring dating program and Jesse Nusbaum, director of LAH, hired a young Douglass student, W. S. Stallings, to direct it in 1931 (Nash 1999).

Stallings had already collected samples from the area and immediately spent four months in the field collecting living-tree, dead wood, and archaeological tree-ring samples; many of the archaeological samples came from sites on the Pajarito Plateau, such as Puyé, Tsankawi, and Tyuonyi (see below). By the end of 1931, Stallings had collected more than 300 wood and charcoal specimens and by early 1932 had dated the Palace of the Governors and several other historic structures and established a chronology for the Jemez Mountains and Pajarito Plateau back to the early 1500s. Paralleling Douglass' research design, Stallings used the Rio Grande ceramic glazeware sequence established by H. P. Mera (1939) to target specific sites for sampling (Nash 1999).

By the end of 1932, Stallings had developed a ring sequence—predominantly using ponderosa pine—that extended back to AD 1200 and in the process dated Pecos Pueblo for Kidder (Stallings 1933, 1937). In 1934, Stallings and Stanley Stubbs collected numerous samples from Pindi Pueblo that extended the chronology to AD 1100 (Stallings 1934). By 1935, Stallings had established dates for some of the Glaze Wares of the upper Rio Grande and dated numerous historic and prehistoric period sites (Stallings 1937). Thus, within a span of only five short years, Stallings had developed the Rio Grande ring sequence back to AD 1100 and provided Christian-calendar dates for sites and artifact sequence.

This promising beginning, however, soon faltered. Nusbaum's move to Mesa Verde, Stallings' desire to complete his Ph.D. and subsequent military service, and a lack of institutional support resulted in the abrupt decline of tree-ring dating in the northern Rio Grande area. Although additional samples were collected by Stubbs, and E. T. Hall dated many samples from Awatovi, and Stallings even dated some samples for the Taylor Museum in Colorado Springs, dendrochronology at the LAH simply "faded away" in the early 1940s (Nash 1999). Every other tree-ring laboratory in the country except the Tucson Laboratory of Tree-Ring Research (LTRR) facility suffered this same fate. Fortunately, through the foresight of Terah Smiley, the LTRR acquired the LAH collection and accompanying documentation in the early 1950s. Just as importantly, a young scholar used the collection for his first major dendrochronology project, reanalyzed the samples, and published the Rio Grande chronological sequence—an unfinished goal of Stallings (Bannister, personal communication, 2002; Smiley et al. 1953). All samples collected in the area since the 1950s (see below) have been analyzed and are curated at the LTRR in Tucson, and thus there is a coherent collection available for additional research.

The transfer of collections and expansion of the LTRR in the 1960s resulted in significant advances in dendrochronology and southwestern archaeology (and other fields). Bannister refined the dating of several of the larger ruins in Chaco Canyon and developed theoretical approaches to dendroarchaeology (Bannister 1962, 1965); Robinson began using tree-ring data to examine past human behavior by delineating the impact of stone ax use on Basketmaker III (AD 600-750) society and wood-use practices, and initiated dendroclimatic research using archaeological samples (Robinson 1967; Dean and Robinson 1977). Other researchers examined the dendroarchaeological remains of other southwestern cultural groups (Towner 1996, 1997), refined the theoretical basis of dendroarchaeology (Ahlstrom 1985, 1997) and studied the impact of the field on American archaeology in the 20th century (Nash 1997, 1999).

Jeffrey S. Dean, however, has conducted the most significant research in archaeological dendrochronology in the past few decades. His research on Kayenta Anasazi cliff dwellings used dendrochronological and archaeological data to posit testable hypotheses about the nature of prehistoric social organization and adaptation to southwestern environments (Dean 1969). His 1978 article, "Independent Dating in Archaeological Analysis," elucidated the theoretical basis of various dating techniques and their application to the interpretation of past human events (Dean 1978). Finally, he described three types of information that can be gleaned from tree-ring data: chronological, behavioral, and environmental (see below) (Dean 1996a).

METHODS AND TECHNIQUES OF DENDROCHRONOLOGY

Dendrochronology is based on the fact that many trees, particularly in temperate and high-latitude zones, produce an annual growth layer (cambium). This cambial layer is typically composed of two visually distinct parts—early wood and latewood (Figure 7.1). Early wood consists of large, open, thin-walled trachial cells that appear light in cross-section. Early wood is produced during the first part of the growing season (which varies by species), when the factors that limit growth, such as moisture, temperature, nutrients, and growth hormones are at their optimal levels. Latewood, on the other hand, is comprised of progressively smaller, thicker-walled, trachial cells that appear dark in cross-section. At the end of the growing season, the tree becomes dormant and ceases to produce cambium; a distinct boundary between the previous year's latewood and the current year's early wood is clearly visible, particularly in conifers.

The variability of annual ring width reflects variation in some climatic variable (e.g., precipitation, temperature). In low-elevation conifers, precipitation is the factor most responsible for ring-wide variability. In dry years, trees produce thin cambial layers, but in wet years water ceases to limit growth and a thicker cambial layer is produced. It is this variability in ring width that is the basis of crossdating and dendrochronology. False rings, also known as intra-annual growth bands, result from a water deficit during the growing season that causes the tree to produce latewood-like cells. If the water deficit is ameliorated, such as by summer monsoon moisture in the Southwest, the tree again produces early wood-like cells until near the end of the growing season. Micro-rings occur in drought years when the tree produces cambium on only specific areas; if samples are taken from areas that lack the cambial layer, the rings appear locally absent or "missing." Crossdating tree-rings, assigning specific years to individual growth rings, accounts for both missing and false rings, and thus is fundamentally different from merely counting rings.

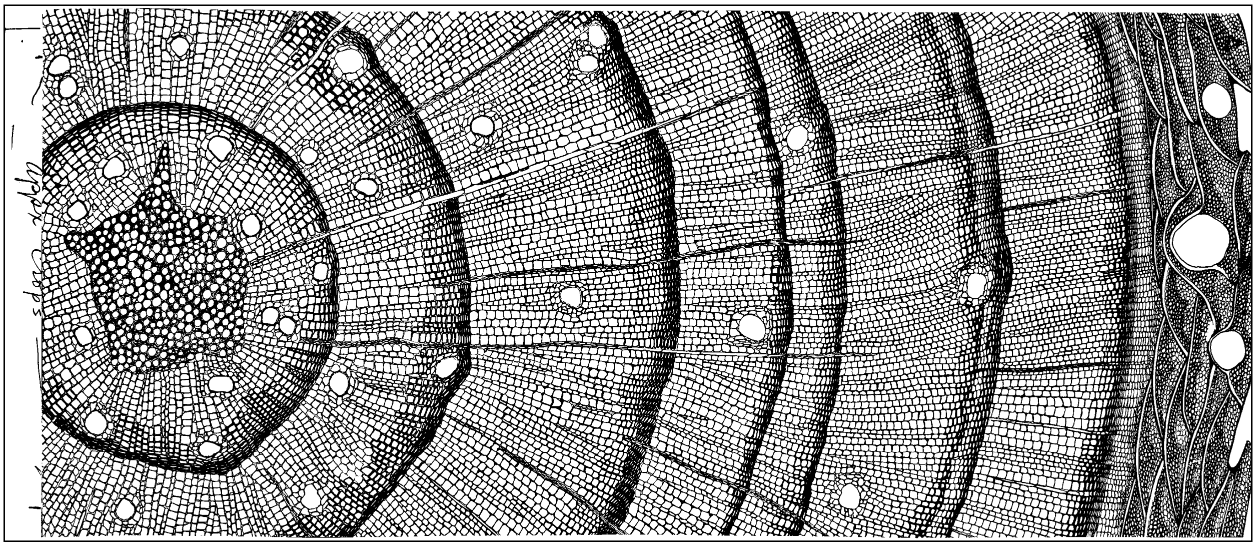

Figure 7.1. Schematic of conifer tree rings.

Crossdating is the most fundamental principle of dendrochronology. If samples do not cross date, temporal control is lost and any interpretations of the tree-ring data become mere estimates. The most common crossdating method used in American archaeology is skeleton plotting. Skeleton plotting is a visual analog technique wherein each ring on a sample is represented by a line on a piece of 1-mm graph paper. The small rings on a sample are noted by drawing a vertical line on the graph paper at the appropriate ring number; the smaller the ring—relative to the surrounding rings—the longer the vertical line drawn on the graph paper. Thus, the skeleton plot visually represents the pattern and "narrowness" of the small rings on a sample. Drawn lines do not represent large and “average” rings. By precisely matching the small-ring pattern between samples, each ring can be assigned to a specific calendar year. Although similar ring-wide patterns have occurred in the past, a sample of 50 to 100 years is usually sufficient for crossdating in the Southwestern United States. An interactive computer crossdating program can be viewed at http://tree.ltrr.arizona.edu/skeletonplot/introcrossdate.htm.

Tree-ring chronologies are built using live trees, dead snags, remnant wood, and archaeological specimens (Figure 7.2). Starting from a known point in time (usually the present), dendrochronologists precisely match and overlap ring-width patterns from successively older samples to create a year-by-year chronology. Typically, chronologies are initiated with a sample of at least 40 increment cores from 20 trees and strengthened with additional specimens and by comparison with other chronologies in the area. When sample depth for any chronology drops below 10 trees, the dating is considered tentative. The spatial extent of tree-ring chronologies varies according to factors such as topography, elevation, and dominant climatic pattern. For example, extant chronologies from many areas of the Colorado Plateau crossdate with each other even though they are separated by more than 100 miles. In contrast, a chronology from Rayado Creek in the eastern foothills of the Sangre de Cristo Mountains does not crossdate with the Taos chronology less than 30 miles away on the other side of the mountains (Towner 2000). In this case, different climate patterns in each area have resulted in different ring-width patterns in trees on different sides of the mountains.

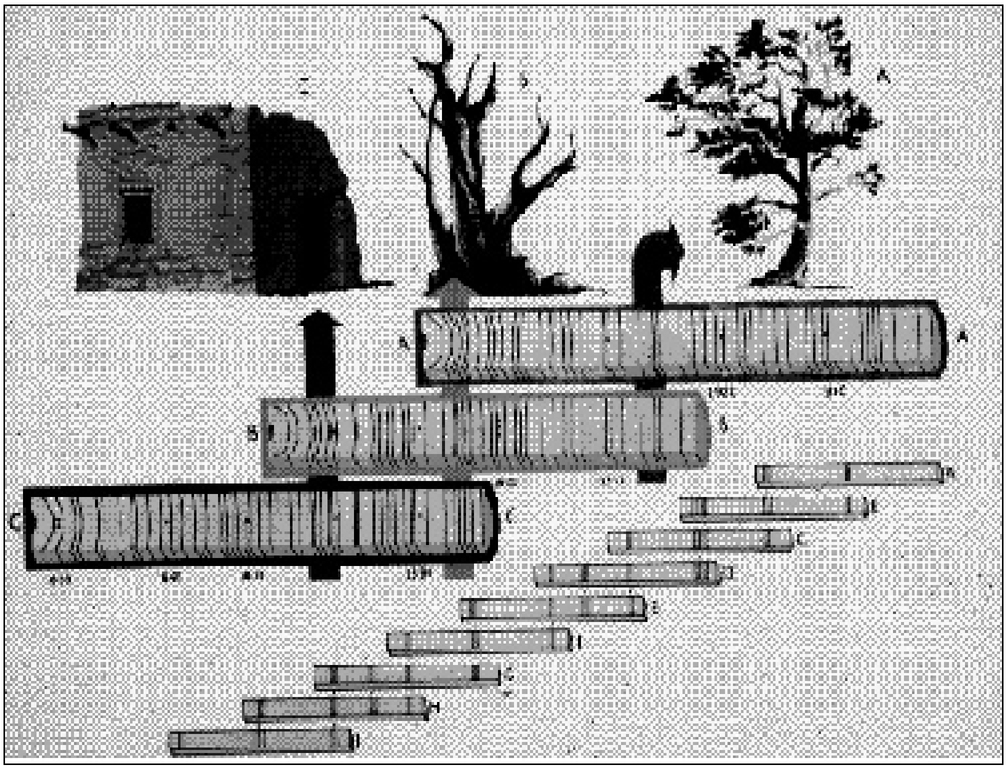

Figure 7.2. Schematic of chronology building with tree rings.

Tree-Ring Requirements

Trees must exhibit four attributes in order to be dendrochronologically useful. First, they must produce distinguishable annual growth layers (rings). Second, an individual ring must grow in a uniform manner around the bole of the tree, or branch (i.e., it must exhibit circuit uniformity). Third, the rings must exhibit some type of annual variability (e.g., ring width, ring density). Finally, a sample must contain a sufficient number of rings to permit the identification of variability patterns; in southwestern conifers, 50 to 100 rings are usually sufficient, but in some areas and with other species like European oak, 200+ rings may be necessary.

Dendrochronology is probably best known as a technique that provides absolute Christian calendar dates for archaeological sites in the American Southwest. The most fundamental principle of dendrochronology is crossdating—matching patterns of annual variability among local or regional tree populations. In the Southwest, the skeleton plot method of crossdating has been used successfully for decades. If the variability patterns on a sample do not exactly match the tree population, the sample does not crossdate and cannot be used in dendrochronology. In this fundamental respect, crossdating is significantly different than simply counting rings or estimating tree age.

Crossdating allows dendrochronologists to assign a single calendar year to each and every ring on a sample. Unfortunately, not all trees or archaeological samples, even in the Southwest, produce dates. Some trees produce cambium in response to microenvironmental factors that are not reflected in the overall tree population; others respond to non-climatic factors such as nutrient availability, and still others do not produce annual rings.

In order to construct a chronology, the skeleton plotted samples from living trees, standing snags, remnant wood, and archaeological samples are combined into a master skeleton plot. By overlapping the plots of individual specimens, the chronology can be extended backwards in time until a lack of sample depth precludes crossdating. Specific small "marker rings" that occur on a large proportion (usually >75%) of samples in a collection help establish the basic pattern, which is then tested against additional samples and other nearby chronologies. In addition to small size, marker rings may be identified by internal features such as frost-damaged cells, false or double rings, unusually wide or narrow latewood bands, or other microscopically visible attributes.

Collecting and Analyzing Archaeological Tree-Ring Samples

As discussed below, past human behavior is the most significant factor affecting archaeological tree-ring dates. Past people did not select wood for its dendrochronological properties, and not all archaeological specimens will produce dates. Some samples will exhibit little ring-width variability (complacent ring series) and some will show extreme variability outside the range of the normal tree population (erratic ring series) (Stokes and Smiley 1968). Archaeologists and dendrochronologists can mitigate these factors by collecting all samples that display any potential for dating, or, which are the appropriate species and contain 50+ rings (Towner 2000). Even experienced dendrochronologists cannot date samples in the field, however, so selecting only the "best" samples is often self-defeating.

Samples can be collected using several different methods. Live trees are sampled using a Swedish Increment Borer that removes a small pencil-shaped core from the tree (Figure 7.3). Depending on the specific site circumstances, archaeological samples are collected as cross-sections sawn from beams, cores extracted from beams using a specially adapted hole saw, or as charcoal; approximately 80 percent of the 4000 samples annually processed by the LTRR are charcoal from excavated contexts.

Figure 7.3. Photograph of A. E. Douglass collecting a live-tree core near Pinedale, Arizona.

Sample preparation in the laboratory differs depending on the type of material collected. Wood samples, either cores or cross-sections, are sanded with fine-grit sandpaper until the individual cells are visible under a binocular microscope at 10x to 50x magnification. Charcoal is not sanded, but broken to expose a fresh surface. Each sample is then examined under the microscope and the ring series is skeleton plotted on graph paper. The skeleton plots are compared to each other to identify internal crossdating between samples and compared to local and regional master chronologies to determine Christian calendar dates. Discrepancies among samples are resolved using the wood (or charcoal) as the basic unit of analysis; the paper skeleton plots are only representations of the sample ring series. As the only repository of archaeological tree-ring samples in the western United States, the 300,000 samples and 70,000 dated specimens housed at the LTRR provide an unmatched comparative research collection.

Attributes of Archaeological Tree-Ring Dates

Even when samples produce dates, they must still be interpreted, and not all archaeological tree-ring dates are the same. Because archaeological tree-ring samples are the result of past human behaviors, specific sample attributes and the archaeological context must be considered in any interpretation of the chronological materials. Sample attributes can be used to identify cutting, near cutting, and noncutting tree-ring dates.

Cutting dates, also known as tree death dates, retain the last cambial layer grown by the tree and indicate that the tree was cut in a specific year (assuming tree death resulted from human harvesting). Evidence on the sample that it is a cutting date includes the presence of bark, beetle galleries, a shiny patina, or a continuous ring around the sample (denoted by B, G, L, c, or r in LTRR reports) (e.g., Robinson et al. 1972); a sample can also be considered a cutting date if the symbol "v" accompanies the date—noting that in the opinion of the analyst, the last ring on the sample is the last ring grown by the tree (Ahlstrom 1985). Samples that retain the last cambial layer can also be assigned a cutting (death) season. Samples that exhibit a terminal ring with a full complement of latewood were cut after that growing season for that particular year ended; samples that show only early wood cells were cut during the growing season. Because different tree species have different growing seasons, cutting dates in a structure in the same year from different species can define construction of a building or room to relatively short time period, as little as 4 to 6 weeks in some cases (Dean and Warren 1983; Towner and Dean 1992).

Samples that yield near cutting dates also retain the last ring grown by the tree; however, these particular samples may (or may not) contain a locally absent or missing ring near the end of the sample ring sequence, and are denoted by a "+" symbol (Towner 1997). For example, a sample that dates 1630 to 1748+B retains bark that indicates no exterior ring loss. However, AD 1748 was one of the driest years in the Southwest and the 1748 ring is locally absent on many samples throughout the region. This hypothetical sample may crossdate from AD 1630 to 1744 and contain four additional rings after its last small "marker ring" of 1744. Because 1748 is typically small and often locally absent on other samples, it may also be missing from this hypothetical sample; therefore the last cambial layer on the sample may have actually grown in AD 1749, but there is no way to verify the absence (or presence) of the AD 1748 ring because the ring sequence does not extend far enough beyond AD 1748 to determine if it is locally absent or simply not small on this particular sample. Near cutting dates, therefore, should be considered within a year or two of tree death dates.

Noncutting dates result from two different processes: exterior ring loss or ring counts near the outside of the sample ring sequence (and are denoted by "vv" or "++," respectively). Samples that do not retain the last ring grown by the tree (vv dates) have suffered exterior ring loss either through natural processes, such as erosion, or cultural processes, such as beam shaping. Thus, a sample dated AD 790 to 957vv could not have been cut before AD 957, but because it may be missing one, 10, or even 100 exterior rings, the harvesting date cannot be determined with any degree of confidence, unless a specific heartwood-sapwood ratio has been developed for a particular species in a particular area (Dean and Ravesloot 1993; Nash 1997). Partially ring counted specimens (++ dates) result from a lack of crossdating on the sample beyond a specific year. Consider again our hypothetical AD 1630 to 1748 specimen. If it cross-dates from 1630 to 1720, it can be dated, but there are an additional 28 rings on the sample that do not match the master ring sequence. In addition to the typically small 1748 ring, many other typically small rings, including 1722, 1724, 1729, 1733, 1735, 1737, 1739, and 1744 may also be missing from the sample. Therefore, it would be labeled 1630 to 1748++B and considered a noncutting date. If all of these rings are missing, the sample would date to at least 1756, but there is no way to determine if all, some, or none of these rings is absent. Ahlstrom (1985) suggests that "++" dates may indicate deadwood use. Such an inference is tenable because as trees die a slow natural death, they respond less and less to macroenvironmental conditions and produce more sporadic cambial growth layers. Noncutting dates (both vv and ++) provide only a *terminus post quem*, a date before which tree death could not have occurred; a noncutting date may predate the actual use of a beam by years, decades, or even centuries.

Deriving Chronological Information from Tree-Rings

The key to interpreting archaeological tree-ring dates is the identification of anomalous dates. Anomalous dates are defined as those dates that do not date the event of interest and are therefore dependent upon the archaeological context and research question (Dean 1978). The tree-ring dates themselves are precise and accurate; they date the last ring on the sample, but may not date the event of interest. For example, if one is interested in dating the construction of Spruce Tree House, the most visited cliff dwelling in the world, the 1932 cutting dates from Kiva C are clearly anomalous. If on the other hand, the event of interest is dating the stabilization work, the 100+ dates in the AD 1200s are considered anomalous. Obviously, dates are only anomalous within a context, and all dates may be anomalous in different contexts.

Identifying anomalous dates requires (a) an adequate sample of dates and (b) defining date clusters. An adequate number of dates is a relative term that depends on the number of samples available for collection, the number of samples collected, and the number of dates derived. A large number of dates certainly increases the probability of identifying date clusters, but may actually increase the difficulty of interpreting them—it will also make the process much more interesting. Ahlstrom (1985) has defined a date cluster as "three or more dates falling in a brief time interval," but definitions vary among researchers and from collection to collection. Ahlstrom has adapted the stem-and-leaf technique to plotting tree-ring dates in order to provide a detailed visual representation of each date in a distribution. Applying the technique to archaeological tree-ring dates, he identified an "ideal" date distribution as a single line on the plot consisting of entirely cutting dates in the same year (Ahlstrom 1985). I enlarged this concept (Towner 1997, 2000) and proposed that different date distributions could be used to identify different wood use behaviors. Although stem-and-leaf plots separate the dates from their archaeological contexts, they delineate the temporal attributes of samples and allow an initial assessment of the relationships among them. Because the stem-and-leaf technique ignores the archaeological context of tree-ring dates, however, it does not always adequately explain past human behavior.

Deriving Environmental Information from Archaeological Tree-Ring Samples

The precise chronological data provided by tree-ring dates—even well-provenienced cutting date clusters—illuminate more than simply the temporal aspects of an occupation. Embedded in the samples and their interrelationships is also important environmental information. Environmental information can be derived from archaeological tree-ring samples in at least two ways. First, the tree species exploited by past peoples may indicate aspects of local species availability and, thus, environmental composition. Second, archaeological tree-ring samples can be used to reconstruct past precipitation and/or temperature regimes and identify past "extreme" climatic events (see below).

The tree species present in archaeological tree-ring collections are the result of several factors. First, site occupants often exploited the most available species; thus, archaeological samples can be used to assess past species distributions and forest composition (at least at the genus level). For example, the Black Mesa Archaeological Project (BMAP) in northern Arizona collected more than 5000 tree-ring samples from Navajo archaeological sites that were occupied between AD 1800 and 1972. The modern vegetation community of Black Mesa consists predominantly of piñon-juniper forest, isolated stands of ponderosa pine and Douglas fir, and various undatable non-coniferous species. The Navajo BMAP dendroarchaeological samples mirror this distribution both in terms of species availability and spatial distribution (e.g., in areas with higher concentrations of one species, that species is most often used in structure construction; Dean and Russell 1978). These data indicate little ecological change in the composition of Black Mesa forests over the past 200 years.

Species distributions in archaeological collections are affected by more than species availability, however. Human social and economic systems also impact the presence and proportions of species in collections. For example, copious research concerning the Chacoan use of timbers in the Great Houses in Chaco Canyon demonstrates that people may have expended tremendous amounts of labor and energy to acquire and use specific trees for specific structures and functions (Dean and Warren 1983; English et al. 2001).

Deriving Behavioral Information from Archaeological Tree-Ring Data

That chronological and environmental information is present in archaeological tree-ring samples is usually obvious; behavioral information, however, is often overlooked. Data concerning how past people treated wood as a resource by selecting specific tree species or sizes of trees, choosing specific harvesting and beam modification techniques, or using deadwood, stockpiling or reusing beams all reflect how, and some times why, past populations adapted to their physical and social environments.

The behavioral information inherent in archaeological tree-ring samples is directly impacted by two major factors: the behavior of past peoples and the behavior of archaeologists and dendrochronologists. Past peoples must have (a) used wood as a resource for building structures, making artifacts, and as fuel; (b) they must have exploited species that are appropriate for dendrochronological analysis; and (c) they must have used wood in ways that insured its preservation in the archaeological record. Archaeologists influence tree-ring data by (a) selecting sites for study that contain dendrochronological materials, (b) precisely recording the provenience and surface attributes of samples, and (c) properly collecting and submitting the samples for analysis. Dendrochronologists must correctly date the samples and describe their microscopic attributes (e.g., terminal ring characteristics, false and micro-rings).

Certainly, the above-described species selection and economic procurement systems represent past human behaviors. It is at the individual beam, room, structure, and site level, however, that most detailed human behaviors can be identified. Such behaviors include species selection preferences, deadwood use, beam stockpiling, beam reuse, structure repair and remodeling, structure abandonment, and beam harvesting, preparation, and modification. When data from many beams, rooms, and sites are combined, broad-scale patterns of how specific groups treated wood as a resource can be delineated.

This is one area where dendroarchaeology differs from other subfields of dendrochronology. Single samples or site collections are related to specific past human activities and may not contain information relative to larger spatial and temporal issues. For example, the collection and analysis of 130 high-altitude bristlecone pine specimens from the San Francisco Peaks (SFP) of northern Arizona has had important ramifications for reconstructing temperature variability in the entire Southwest and across western North America for the past 2000 years (Salzer 2000a). In contrast, the collection of 1121 archaeological samples from Long House Ruin in Mesa Verde informs us about the activities of a specific group of people in a specific time. Simply put, archaeological tree-ring specimens are part of a specific human behavioral context that may (or may not) be directly related to broader patterns.

The first level of analysis for deriving information about past human behavior is at the individual beam or sample level. Precise provenience and sample attribute information can reveal aspects of beam function, procurement, and preparation (Dean 1969; Towner et al. 2001; Windes and Ford 1996). Beam function includes information about the architectural element and its use (e.g., is the roof beam a primary or secondary beam, a door lintel, or jamb). As in the Chaco case cited above and others, specific species and sizes may have been preferred for specific architectural elements (Windes and McKenna 2001). Beam procurement methods include cutting with a stone or various types of metal axes or saws, breaking, or burning. Noting the procurement method evident on a sample may indicate the use of deadwood (e.g., breaking, burning) or provide a temporal framework for undated samples (e.g., different saw marks relate to technological innovations in saw technology). Beam preparation may include removing limbs, bark, shaping a beam, and preparing the beam ends using various tools. Tools commonly used in beam preparation include various types of axes and saws as well as draw knives, adzes, and grinding tools. Identifying the types of tools used to procure and prepare timbers may have implications for interpreting anomalous dates, distinguishing technological traditions, or recognizing cultural interaction. Other attributes of individual beams that should be recorded, if appropriate, include the degree of sooting or blackening to recognize potentially reused beams, charring as a potential aid in determining room, structure, or site abandonment mode, the presence of twisted grain or root flares to aid in identifying deadwood use, and any other noticeable attributes.

At the room and structure level, it is necessary to document the architecture as completely as possible. Such characteristics as the bond-abut relationships of walls, changes in wall construction materials or plastering, changes in room function denoted by sealed doorways or covered hearths, and other architectural attributes can help in determining when the room was built (as opposed to when the beams were harvested) and provide clues to the nature of the occupation. When combined with beam attributes and dates, such information can help to identify anomalous dates, the use of deadwood, the reuse of older beams from other rooms or sites, the stockpiling of beams, the repair and remodeling of rooms and structures, and can yield information relative to the duration of occupation and mode of abandonment of a room or structure (Ahlstrom 1997; Dean 1969). Finally, these combined data can help illuminate aspects of human social organization, such as the use of a room or structure by a family or supra-family group; they may also contribute to understanding the dynamics of that group through time, such as changing structure use in response to generational changes in family size, the immigration of new families into a settlement, and many others.

At the site and regional levels, tree-ring data provide the temporal control necessary to delineate broad patterns of human behavior. At the site level, the initial founding of a site can often be determined through tree-ring analysis, and the duration of the occupation may also be delineated. An excellent example of the former is Douglass' dating of the Mesa Verde cliff dwellings. Before the advent of dendrochronology, archaeologists debated whether the structures were hundreds or thousands of years old. Douglass' precise dating of these ruins to the 13th century had profound implications for archaeological and anthropological theories of the rate of human cultural development in the New World (Nash 1999). Similarly, before large-scale sampling efforts and detailed analysis documented the duration of occupation of the Kayenta Anasazi cliff dwelling of Betatakin at less than 40 years, many people assumed such structures had been occupied for hundreds of years. Again, such temporal compression has required anthropologists to reexamine their theories of cultural evolution and has forced archaeologists to consider the importance of settlement mobility patterns in interpretations of population demographics and history.

At the regional level, tree-ring data contribute to understanding population dynamics, culture change, and interaction in a variety of ways. For example, recent dendroarchaeological analysis of several Navajo pueblito structures in Palluche Canyon, New Mexico, reveals very similar initial construction, remodeling, and abandonment dates (Ababneh et al. 2000). These small three- to five-room structures were all apparently constructed, temporarily abandoned, reoccupied, and finally abandoned within a period of about 20 years. The archaeological and dendrochronological data suggest all the sites were occupied by the same extended family group, and this inference is supported by ethnographic data and Navajo oral traditions. Thus, these sites have become much more than simply interesting ruins on the landscape; they can now be related to a specific period in Navajo history, a specific form of social organization, and perhaps to a particular descendent group of Navajos (Ababneh et al. 2000).

On an even larger scale, dendroarchaeological data have been used to illuminate aspects of significant migrations both during the prehistoric period and during the early historic period. As discussed above, the archaeological and climatic information indicate a climatic gradient that may have influenced the timing and direction of the Mesa Verde Anasazi movements out of the Four Corners area and into the Rio Grande Valley (Ahlstrom et al. 1995). More recently, I have suggested that the Navajo emigration out of their Dinétah homeland in northwest New Mexico and into northeastern Arizona during the late 1800s was a social and economic process unrelated to the single-year drought of 1748 (Towner 1997). These large databases enable archaeologists and dendrochronologists to investigate important questions concerning how humans—as individuals, families, and supra-family groups—colonized landscapes, exploited their environments, interacted with their neighbors, and responded to changes in their physical, social, and technological environments.

PREVIOUS ARCHAEOLOGICAL DENDROCHRONOLOGY ON THE PAJARITO PLATEAU

The results of almost 80 years of archaeological tree-ring research on the Pajarito Plateau are presented below. A summary of the dated sites is presented in Table 7.1 and all samples from Pajarito Plateau sites are listed in Appendix D. Before they are discussed, however, a couple of caveats must be offered along with the interpretations. If the two most important factors in a dendroarchaeological date distribution are (a) the behavior of past site occupants and (b) the behavior of archaeologists and dendrochronologists (Dean 1996a; Towner 2000), it is clear that the latter has had a profound influence on the Pajarito Plateau database. Certainly the site occupants' choices of tree species for construction and fuel have helped shape the database. More important, however, has been the research interests, excavation of specific structures and site, and species-specific collection strategies of archaeologists and dendrochronologists, particularly before about 1980.

The interpretations of individual rooms and sites offered below are based on the dendroarchaeological data and minimal provenience information. No site maps or detailed notes are located in the LTRR files, and may not exist for some sites. Because of the limited nature of the accompanying provenience information and site description, however, any such interpretations should be tested against the archaeological and documentary record. Only by placing the tree-ring dates in their archaeological contexts (cf. Towner et al. 2001) can anomalous dates (Dean 1978) be identified and true behavioral events, such as construction, repair, and remodeling, be delineated.

The site presentation is organized in accordance with the LTRR site file system. All sites on the Pajarito Plateau are in the New Mexico "I" quadrangle—a one-degree by one-degree geographic unit, in this case from 35 to 36 degrees N and 106 to 107 degrees W—although the Pajarito Plateau does not encompass this entire range. The archaeological sites included in the synthesis are bounded on the north by Santa Clara Creek, on the south by Borrego Canyon, on the east by the Rio Grande, and on the west by the crest of the Jemez Mountains (Figure 7.4). If known and identified in the LTRR files, sites are also noted by names and LA numbers. Collections with a large number of dates are also shown as stem and leaf plots (Ahlstrom 1985), where the three-digit column on the left indicates the decade (128 indicates the 1280s, for example) and the numbers on the right indicate individual years.

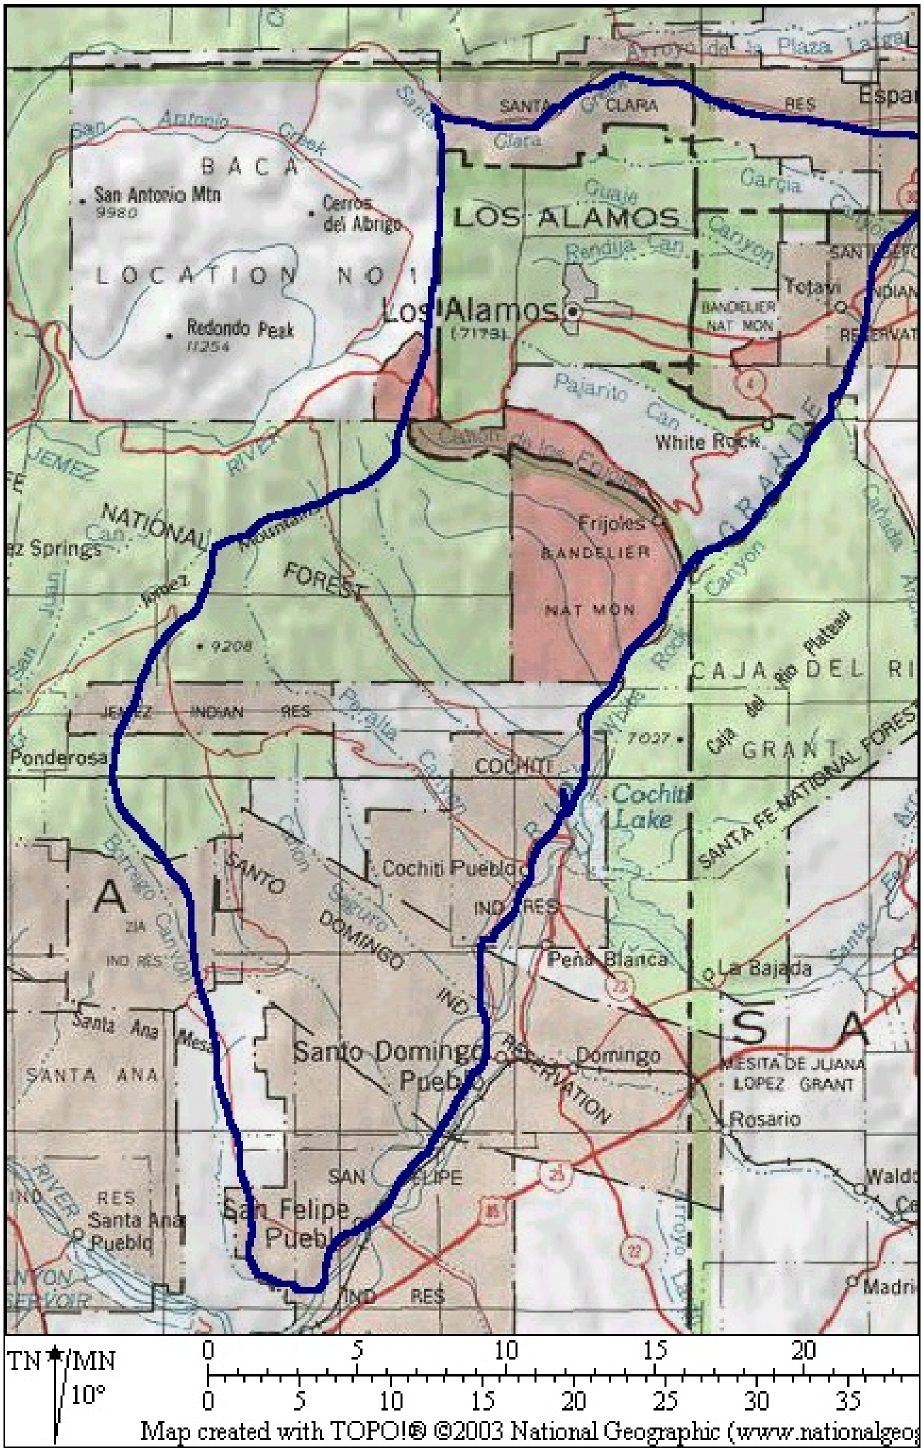

Figure 7.4. Map of the Pajarito Plateau and project area.

Table 7.1. Summary of tree-ring data from all archaeological sites on the Pajarito Plateau.

LTRR NM-I-2, Puyé (LA 47)

A total of 71 samples have been collected from Puyé (Table 7.1; Appendix D), predominantly as a result of Reuter's excavations at the site in the 1930s (Smiley et al. 1953). The samples were initially analyzed by W. S. Stallings at the LAH and dating confirmed by the LTRR in the 1960s. All of the samples are charcoal or wood pieces from excavated contexts. Ponderosa pine (n = 57) dominates the collection, followed by Douglas fir (n = 10), and piñon pine (n = 3). Such dominance by ponderosa (80%) undoubtedly reflects a species preference on the part of the site occupants; selection biases on the part of the collectors, however, may contribute to the species differences, particularly the absence of juniper in the collection.

Forty samples yielded dates, a success rate of 58.6 percent. Douglas fir specimens yielded the highest ratio (9/10), followed by piñon pine (3/4), and ponderosa (29/57). Cutting dates were derived from only eight of the samples; three yielded near cutting dates, and 30 produced noncutting dates. The terminal ring attributes indicate that most tree harvesting occurred in early to mid summer. The mixture of complete and incomplete Douglas fir terminal rings indicates harvesting some time between early May and late June; the ponderosa pine growing season is somewhat later in the summer, but the combination suggests mostly early-season tree procurement (Fritts 1991), although construction may have occurred at any time during the year.

The overall date distribution (Figure 7.5) suggests a site occupation from the late 1400s through the 1570s, although the cutting dates span only 1526 to 1577. The stem-and-leaf plot notes the prefix with year date (e.g., 141 36, represents 1413, 1416). At such a large site, however, the relatively small sample of tree-ring dates probably does not represent the true duration or intensity of the occupation. Although the provenience information for the samples is minimal, if viewed in their archaeological contexts (Towner et al. 2001), the dates suggest the following. First, an initial occupation some time in the late 1400s based on noncutting dates from "the E, S, and W sides of the ruin" (RG-327-12), the "S House 5th N-S line of Rooms from W" (RG-545), the "fill of Deric's Room" (RG-546-3, 15, 22, 23 and RG-547-1, 2), and unprovenienced samples (RG-49, 328, and 625-627). Second, there is a weak cluster of unprovenienced noncutting dates in the 1520s (RG-546-4, 5, RG-653, RG-5306) supported by a 1529v cutting date (RG-48). In addition, a single 1526v cutting date (RG-551) from the "8th N-S line of rooms, 2nd from W," three noncutting dates (1521vv, 1526vv, 1528vv) from the "Fill of Deric's Room," and two noncutting dates (1525vv, 1526vv) from the "E, S, and W sides of Ruin," support the possibility of site expansion in the 1520s. Four areas (E, S, and W sides of Ruin, Fill of Deric's Room, dump, and unprovenienced) contain 1530s noncutting dates—and a 1536+r near cutting date—that indicate a possible site expansion in the 1530s. The mid-1540s are represented by five dates, including three cutting dates from the "dump" (Appendix D), which indicate some activity at the site during that decade. The 1550s and 1560s are represented by single noncutting (1554++vv) and near cutting (1562+v inc) dates, respectively. Five dates, including two cutting and one near cutting date fall in the 1570s. The different proveniences of the samples (E, S, and W sides of Ruin, Fill of Deric's Room, and Dump) suggest tree-cutting activities occurred in several areas of the site in the 1570s.

Figure 7.5. Stem-and-leaf plot of dates from Puyé (underline indicates cutting or near cutting date).

The small sample size relative to the size of the site, meager provenience information, and paucity of cutting dates make interpretation of the Puyé tree-ring data difficult. Nonetheless, it is probable that (a) the site occupants preferred ponderosa pine for construction, (b) they occupied the site at least as early as the late 1400s, (c) they conducted major expansion of the site between the 1520s and the 1540s, (d) there was little construction in the 1550s and 1560s, and (e) major site expansion occurred in the 1570s. If Walpi Pueblo can be used as a model of wood use at a long-lived pueblo (Ahlstrom et al. 1991), such interpretations would change dramatically with the addition of more tree-ring samples from known proveniences.

LTRR NM-I-3, Tsirege (LA 170)

The tree-ring collection from Tsirege was procured by Stallings in the early 1930s (Smiley et al. 1953). Some provenience information accompanied the samples when they were transferred to Tucson, but it is extremely limited considering the size and complexity of the site. Stallings collected a total of 59 samples from the site, including seven duplicates (Table 7.1; Appendix D); one sample for which there are notes was lost in the transfer of the collection to the LTRR. Thus, 44 independent samples are available from the site. The species distribution includes ponderosa pine (*n* = 24), Douglas fir (*n* = 18), and white fir (*n* = 2). Certainly, Stallings selection bias influenced the species distribution, but the relatively large number of Douglas fir and presence of white fir probably reflect at least some prehistoric selection preferences. It may be important to identify the nearest modern stand of white fir as an estimate of procurement distance.

The 44 samples produced 30 dates, but only three cutting dates (Figure 7.6). The date range is 1411+vv to 1581vv and the cutting date range is 1559r inc to 1581v inc. The overall distribution suggests that there may have been some occupation in the early 1400s (seven noncutting dates before 1427), and additional activity in the 1510s (four noncutting dates 1514 to 1516). The few cutting dates, however, suggest that the occupation was predominately during the 1570s to 1600 timeframe. Other data, such as ceramics and architecture, indicate that the site was occupied for much longer than 30 years. Clearly, sampling in only one area of the site biased the dating toward the end of the occupation.

Figure 7.6. Stem-and-leaf plot of dates from Tsirege (underline indicates cutting or near cutting date).

LTRR NM-I-4, Fulton's 190 (LA 8681)

Fifty charcoal samples were collected from Fulton's Site 190 during excavations in the 1950s by the Los Alamos Archaeological Society (Table 7.1; Appendix D). There are no duplicates in the collection. The species exploited include piñon (n = 42), juniper (n = 5), Douglas fir (n = 2), and ponderosa pine (n = 1). The almost total lack of ponderosas makes Fulton's 190 different than most other sites on the Pajarito Plateau, but it may be a result of collection bias. Only the piñon samples yielded dates.

The samples yielded 20 dates, but no cutting dates, and range from 1060vv to 1218+vv. The date distribution (Figure 7.7) shows weak clusters in the 1090s (n = 2), 1160s (n = 3), 1180s (n = 2), 1190s (n = 4) and 1200s (n = 2) that indicate the possibility of a 140+ year occupation. It is most likely, however, that the site was constructed and occupied in the late 1100s until some time in the 1220s. The only date cluster—three noncutting dates of 1190vv, 1191vv, and

1191vv—that supports a late 12th century occupation is from Room 5. No other single provenience contains more than two non-cutting dates within a five-year time span.

Figure 7.7. Stem-and-leaf plot of dates from Fulton's 190 (underline indicates cutting or near cutting date).

LTRR NM-I-9, San Ildefonso

Only two samples have been collected from San Ildefonso. Both are ponderosa pine cross-sections collected by the First Beam Expedition in 1923 (Nash 1999). Only one sample provided a noncutting date (1661p-1787vv) (Smiley et al. 1953) (Appendix D). Although the sample fits with the known occupation, it is completely inadequate for assessing the occupation of this large, extensive pueblo.

LTRR NM-I-18, Cochiti Church (LA 295)

Two ponderosa pine samples were collected as cross-sections from Cochiti Church by George Kubler of the Taylor Museum in Colorado Springs (Smiley et al. 1953). Both samples dated (1697vv and 1745vv) (Appendix D), but neither yielded a cutting date, probably because they were adzed and missing outside rings. They offer little interpretive value other than that they were not used before the 18th century.

LTRR NM-I-25, Kotyiti (LA 84)

A total of 42 samples, including one duplicate, were collected by Stallings in the 1930s (Table 7.1; Appendix D). All but one of the samples is charcoal; 37 are ponderosa pine, four are

Douglas fir, and the single wood fragment is a juniper specimen. None of the samples is provenienced beyond the site level. Thirty-two of the samples (76%) dated, but only four yielded cutting or near cutting dates. The overall date range is 1547vv to 1691vv, and the cutting date range is 1684r comp to 1690rB inc. Most of the dates, including all of the cutting and near cutting dates, cluster in the 1680s and early 1690s. Obviously, the area of the site where the specimens were collected dates shortly after the Pueblo Revolt but before the Spanish Reconquest.

LTRR NM-I-30, Water Canyon Ruin (LA 545)

Twenty-eight charcoal samples were collected from the site by W.S. Stallings in the 1930s (Smiley et al. 1953). There are eight duplicates in the collection, and thus 20 independent samples (Table 7.1; Appendix D). All but two of the samples were collected from the "Northeast Side of the Court," and the other two were collected from the "Southwest Corner of the Court." The species present include 17 ponderosa pine and three Douglas fir specimens.

The 20 samples yielded 14 dates, including five cutting dates. The dates range from 1165vv to 1447v, and the cutting dates range from 1302rB to 1447v. It is possible, given the small sample size and limited provenience information, that the site was occupied for 150+ years. The current tree-ring data, however, suggest two separate occupational episodes. The first, 1302 to 1303, is denoted by four cutting and one noncutting dates; the second, in 1447, is indicated by a single cutting date and two early 15^{th} century noncutting dates. Such a small, unrepresentative sample, however, makes any inferences somewhat tentative. The mid-1400s activities appear to have been contemporaneous with events at Frijolito.

LTRR NM-I-39, Navawi (LA 257)

A single ponderosa pine sample was collected from Navawi by W. S. Stallings in the early 1930s. The sample did not date (Table 7.1; Appendix D).

LTRR NM-I-40, Los Alamos School (LA 708)

Sixteen charcoal fragments were collected from the site by W. S. Stallings in the 1930s. All but one of the samples is ponderosa pine and the other is a Douglas fir specimen (Table 7.1; Appendix D). None of the samples dated because all contain too few rings for crossdating.

LTRR NM-I-44, Bandelier Group M

Five wood fragment samples were collected from Rooms 1, 2, and 5 of the site by Hendron of the National Park Service (NPS) during stabilization work in the 1930s (Smiley et al. 1953). All the samples are ponderosa pine and only one yielded a date (1352p to 1494rG comp) (Table 7.1;

Appendix D). The date indicates tree procurement in the fall/winter of 1494, but offers little other information about the site occupation.

LTRR NM-I-45, Tyuonyi (LA 82)

The tree-ring collection from Tyuonyi was procured by Stallings, but apparently derived from either Hewett's School of American Research excavations or Hendron's NPS stabilization work in the 1930s and 1940s (Smiley et al. 1953). All of the material was transferred to the LTRR in the 1950s, but one sample (TYU-80) was lost in the transfer.

A total of 125 samples, including only two duplicates, was collected from the site. The 122 independent samples include 97 ponderosas, 16 Douglas firs, five junipers, two *Populus*, and single specimens of piñon and oak (Table 7.1; Appendix D). The species distribution clearly reflects Stallings' collection goals of developing a Rio Grande chronology,

The samples yielded 55 dates, a 45 percent success rate; 20 of the dates are cutting or near cutting dates. The date range is 1327vv to 1521vv and the cutting date range is 1369+r inc to 1521r comp. The date distribution (Figure 7.8) suggests that the site was founded some time in the late 1300s, probably in the 1380s and occupied until the 1520s; most construction appears to have occurred in the 1420 to 1430 period, with repair or remodeling in the 1330s, 1460s, and first two decades of the 1500s.

Figure 7.8. Stem-and-leaf plot of dates from Tyuonyi (underline indicates cutting or near cutting date).

Samples were collected from 20 different areas, only four of which did not produce dates (Tier 4, Tier 5, Tier 6, and Trench 1). If the earliest cutting date or cutting date cluster and latest date from each provenience are taken as guides, the following sequence can be inferred. Tier 13, dated 1369+r inc, may be the earliest area sampled. Other areas with their latest (noncutting) dates in the 1300s include Tier 7 (1385vv) and Tier 11 (1386vv), but they probably date to the early 1400s. Several areas indicate construction in the second or third decades of the 15th century, including Tier 12 (1415+vv), Tier 14 (1415+B inc to 1457vv), Tier 10 (1421v to 1496vv), Tier 16 (1419+r comp to 1469vv), Tier 17 (1422+r comp), Tier 18 (1422+r comp), Tier 8 (1431v inc), and Tier 9 (1427r inc to 1451vv). Although not all the areas are supported by cutting dates, it is clear that the 1420s were a period of major site expansion. The 1440s may have also seen some site expansion, particularly in Tier 1 (1443vv), Tier 2 (1442+v), and Tier 3 (1442r comp to 1458vv). Sector C contained a 1466r comp date that indicates activities in the 1460s, contemporaneous with activities in Tier 16 (1466v, 1467r, 1469vv). There may have been some construction at the site in the 1490s, as evidence by a 1496vv date from Tier 10 and a 1494vv date from the site surface. The latest construction at the site was apparently in Tier 15 (1509v inc) and Sector B (1521r comp). It is apparent from both the date distribution and the provenience of different dated timbers that the site was occupied for more than 100 years. Additional samples from different proveniences can be expected to strengthen the existing date clusters and possibly extend evidence of the occupation further.

LTRR NM-I-46, Rainbow House (LA 217)

A total of 34 charcoal samples, including 14 duplicates, was collected from Rainbow House by Worman/NPS in the 1930s (Table 7.1; Appendix D). Nineteen of the independent samples are ponderosa pine and one is Douglas fir, undoubtedly a reflection of the collection bias of the time. One sample is unprovenienced and two were collected from Kiva 1; the remaining 17 samples were excavated from Room 1-18.

Eighteen of the samples yielded dates, including nine cutting dates. The single date from Kiva 1 (1458v) is the latest date from the site. The strong cluster of 1451 cutting dates leaves no doubt that Room 1-18 was built in that year. In addition, the mixture of complete (n = 4) and incomplete (n = 2) terminal rings on the piñon specimens indicates that the structure was built in the late summer/fall of 1451 when some trees had stopped growing and others had not. The subsequent noncutting dates of 1453vv and 1454vv probably represent repair beams procured at the same time Kiva 1 was built (1458). The small cluster of 1420s dates, including two near cutting dates (1422+v and 1427+v) probably represent beams reused from other proveniences or sites. Rainbow House, or at least Room 1-18, appears to be one of the shortest occupations on the plateau and may contribute significantly to ceramic seriation and other studies (Montgomery and Reid 1990).

LTRR NM-I-47, Frijolito (LA 78)

Thirteen ponderosa pine charcoal samples were collected from Frijolito by W. S. Stallings in the early 1930s (Table 7.1; Appendix D); no duplicates were identified in the collection. Five of the samples were collected from a room on the north side of the pueblo, but the remaining samples are unprovenienced. Twelve of the samples dated and six yielded cutting dates. The dates range from 1385vv to 1460r; the cutting dates range from 1426r to 1460r. The distribution of dates suggests some construction in 1426, 1447, 1452 to 1454, and 1460. The limited provenience information suggests that the room on the north side was built in 1447 and repaired in 1460, or built in 1460s with at least one reused timber. Interestingly, all of the dates, except those in 1447, indicate fall/winter tree harvesting. Frijolito was apparently occupied for a relatively brief time—approximately 35 to 40 years (one or two generations), and thus may be an important site for determining ceramic relationships among plateau assemblages. It also appears to be at least partially contemporaneous with the late occupation of Water Canyon Ruin (LA 545).

LTRR NM-I-48, Otowi (LA 169)

Eleven charcoal samples have been collected from Otowi. The site was excavated by L. W. W. Wilson for the Philadelphia Commercial Museum between 1915 and 1917, but the samples were apparently collected by Stallings in the early 1930s. Unfortunately, the data from Otowi are scant and insufficient to asses the internal site dynamics. Five of the samples are duplicates, leaving five independent samples. Four of the samples are ponderosa pine and one is Douglas fir (Table 7.1; Appendix D). Four of the samples yielded dates, including a cutting date of 1414r comp. Although completely inadequate to assess the occupation of such a large complex site, the cutting date of 1409r and noncutting date of 1491vv suggest almost a century of occupation. Additional samples would undoubtedly contribute significantly to understanding the site occupation and external relationships.

LTRR NM-I-49, Hewett's Ruin 12 (LA 42)

The tree-ring laboratory currently curates seven ponderosa pine charcoal samples from Hewett's Ruin 12 that were apparently collected by Stallings in the 1930s. None of the samples is provenienced beyond the site level and two did not date (Table 7.1; Appendix D). The five dated samples yielded four noncutting dates (1830vv to 1871vv) and one cutting date (1867v). Obviously, the samples do not date the prehistoric occupation and there is some suggestion that they came from the "Blumenthal modern house;" they indicate some building activity at the house in the late 19th century (Robinson et al. 1972).

LTRR NM-I-50, Tsankawi (LA 211)

Stallings collected four ponderosa pine charcoal samples from Tsankawi in the 1930s. None of the samples are provenienced beyond the site level and only two dated (Table 7.1; Appendix D).

The two noncutting dates of 1436vv and 1439vv suggest activities in the mid-15th century, but are inadequate for assessing this large pueblo.

LTRR NM-I-51

LA 3852

Three charcoal samples were collected from two structures at the site by NPS (Carlson and Kohler 1989a; Table 7.1, Appendix D). Neither the ponderosa nor the piñon pine sample from Room 6 area 1 dated. A piñon sample (BNM-84) from Pit structure Area 4 yielded a noncutting date of 1006 to 1085+vv and indicates some activity at the site after 1085.

Burnt Mesa Pueblo (LA 60372)

A total of 25 samples, 22 charcoal fragments and three wood fragments, was collected from the site (Kohler 1989; Kohler and Root 1992a, 1992b) (Table 7.1; Appendix D); no duplicates were identified. The majority of the samples are ponderosa pine (n = 16), followed by Douglas fir (n = 7), and piñon (n = 2). It is probable that this species distribution approximates the prehistoric occupants' selection preferences.

The samples yielded 13 dates, including three cutting dates. The overall date range is 1189vv to 1317B inc, and the cutting date range is 1250B inc to 1317B inc. If the dates are combined with their provenience data, the following sequence is inferred. Room 2 appears to be the earliest with a 1250 cutting date; however, other data may indicate this single date is anomalous. Room 1 was constructed some time in the mid-1270s and Room 10 is probably contemporaneous with it. The three noncutting dates from Room 4 only indicate it was occupied some time after 1207; again, archaeological and architectural data may refine the temporal placement of the room. Interestingly, Pit Structure 1, built in 1317, is the latest construction on the site. The dendroarchaeological and provenience data suggest that two separate occupations occurred at the site, one in the mid-1270s and the other approximately 40 years later.

LA 53148

Three wood cross-section samples were collected from the surface of Cavate 1 by NPS. All the samples are ponderosa pine, but none dated (Table 7.1; Appendix D).

LA 71155

A single wood cross-section sample of ponderosa pine was collected from this rockshelter site by the NPS in 1994. It did not date (Table 7.1; Appendix D).

LA 71090

Three wood fragment samples were collected from this cavate and camp site by the NPS in 1994. Two of the samples are juniper and one is ponderosa pine, but none dated (Table 7.1; Appendix D).

LA 84067

A single wood fragment sample of ponderosa pine was collected from a "bedrock pit" at the site by the NPS in 1994. It did not date (Table 7.1; Appendix D).

LA 71081

A single wood charcoal fragment of ponderosa pine was collected from this small surface structure by the NPS in 1994. It did not date (Table 7.1; Appendix D).

Saltbush Pueblo (LA 4497)

Four piñon pine charcoal samples were collected from the site by D. Snow of Museum of New Mexico (Table 7.1; Appendix D). One sample from the "trash" did not date; a sample from the "general fill" dated 1241vv, a sample from the kiva dated 1194vv, and a sample from the kiva floor dated 1215vv. The three noncutting dates indicate activity in the early to mid-thirteenth century, but are inadequate for gleaning any additional temporal information.

LA 2987

A single charcoal sample of piñon pine was collected from the general surface of this site by the NPS or Museum of New Mexico. It did not date (Table 7.1; Appendix D).

LA 2990

A single charcoal sample of *Populus* spp. (probably cottonwood) was collected from this site by the NPS or Museum of New Mexico. It did not date (Table 7.1; Appendix D).

LA 2994

A single charcoal sample of juniper was collected from this site by the NPS or Museum of New Mexico. It did not date (Table 7.1; Appendix D).

LA 2998

A single charcoal sample of *Populus* spp. (probably cottonwood) was collected at this site by the NPS or Museum of New Mexico. It did not date (Table 7.1; Appendix D).

LA 3852

A single charcoal sample of piñon pine was collected from the general surface of this site by Washington State University. It did not date (Table 7.1; Appendix D).

Cavate M 77 (LA 50972)

A single charcoal sample of piñon pine was collected from the general surface of this site by Washington State University (Carlson and Kohler 1989b). It did not date (Table 7.1; Appendix D).

LTRR NM-I-52

Pueblo del Encierro (LA 70)

Pueblo del Encierro was excavated as part of the Cochiti Dam Project by Lange (Table 7.1; Appendix D) and the samples were submitted to the LTRR in the 1960s (Snow 1976). All of the samples are charcoal fragments and all but two are associated with features. A total of 222 samples was collected, including nine duplicates. The 213 independent samples include 94 Douglas fir, 68 ponderosa pine, 39 piñon, seven juniper, three *Populus*, and two non-coniferous specimens that could not be identified to the species level. The species distribution probably reflects prehistoric selection preferences and may indicate some nonlocal procurement of Douglas fir beams. All of the dates were derived from the Douglas fir, ponderosa, and piñon beams; none of the juniper, cottonwood, or other nonconiferous specimens dated.

The 213 samples yielded 163 dates (77%), including 114 cutting dates. The overall date range is 1292vv to 1787vv and the cutting date range is 1401r inc to 1520r inc. The site was certainly not continuously occupied from the late 1200s through the end of the 1700s, but different areas of the site undoubtedly were used at different times. The date distribution (Figure 7.9) suggests that the site was founded in the early 1400s, possibly in the first decade of the century. Major construction began almost immediately in the 1410s and 1420s. Although there is a slight drop in the number of cutting dates in the 1430s, tree harvesting remained relatively constant from the 1440s through the 1480s. The late 15th and early 16th centuries show little activity, but major timber procurement again marked the 1510s until the summer of 1520. The site was probably disused shortly after 1520, and the few, scattered noncutting dates in the 1600s and 1700s may relate to some use in the late 18th century.

Figure 7.9. Stem-and-leaf plot of dates from Pueblo del Encierro (underline indicates cutting or near cutting date).

Tree-ring samples were collected from 41 features and one non-feature area. Samples from 17 of the features did not yield any dates, including Features 29, 33, 42, 62, 78, 79, 90, 93, 100, 107, 123, 140, 167, 179, 181, 229, and 280. Several features yielded single noncutting "vv" dates that may or may not be applicable to construction events. Several potentially early, but poorly dated, features are Feature 92 (1341vv), Feature 87 (1345vv), Feature 213 (1346vv), Feature 223 (1327++vv and 1350vv), Feature 29 (1364vv), and Feature 101 (1381vv); these features may indicate occupation during the 14th century, but the tree-ring evidence is equivocal. By the 15th century, several features contained cutting dates or small date clusters that indicate occupation, including Features 200 (1402+vv), 25 (1416v), 136 (1425+r) , 132 (1427r), 169 (1428vv), 130 (1441r), 292 (1446vv), and 2 (1458vv). Three other features contain disparate cutting dates that are not easily interpreted. Feature 69 contains three dates (1411r, 1423r, and 1427r) from the general fill; they may represent occupation in the 1410s and 1420s, but the earlier beams may have been reused as well. Feature 80 contains four dates (1374vv, 1428r, 1439r, and 1469r) from the general fill; it is unlikely the feature was used for 40+ years, but identifying a construction or repair episode is impossible. Finally, Feature 83 yielded five dates (1388vv, 1406+r, 1412r, 1415r, and 1494r) from the floor fill and general fill; the feature may have been used in the 1410s, but the 1494r date is from the floor fill and may date some repair activity, but it is unlikely that the feature was used for more than 80 years.

Four features contain abundant cutting dates and date clusters and illustrate complex wood use behaviors. Feature 152 yielded 19 dates (Figure 7.10), including 13 cutting dates. The most parsimonious explanation for the date distribution is that CDP-164 (1414r) and CDP-154 (1422r) are reused beams, that the feature was constructed in 1445 using one new and several stockpiled timbers, and that the feature was repaired or remodeled in the summer of 1451 using freshly cut and stockpiled beams. Other interpretations are possible, including construction in 1451 with new, stockpiled, and reused beams and construction over a multi-year period in the 1440s.

Figure 7.10. Stem-and-leaf plot of tree-ring dates from Feature 152 at Pueblo del Encierro (underline indicates cutting or near cutting date).

Feature 186 yielded 18 dates, including 14 cutting dates (Figure 7.11). The most parsimonious explanation for the date distribution is that CDP-190 (1455v) is a reused beam, that the feature was constructed in the summer of 1480 using freshly cut timbers and at least seven beams stockpiled from the previous year, and that it was repaired or remodeled in 1486. Alternatively, the structure may have been built in 1486 with mostly reused beams, but it seems unlikely.

Figure 7.11. Stem-and-leaf plot of tree-ring dates from Feature 186, Pueblo del Encierro.

Feature 128 yielded the abundant dates (n = 31) and many cutting dates (n = 27), yet is the most complex dating situation at the site. The date distribution (Figure 7.12) suggests at least two major construction episodes with several minor repairs as well. The feature may have been constructed as early as 1401, but initial construction in 1424 with reused (1401, 1409, 1413) beams, stockpiled timbers (1420, 1421, 1422, 1423), and freshly cut trees (1424) is considered most likely. Repairs were apparently performed in 1428 and again in 1435. A major rebuilding episode occurred in the 1460s, probably in the fall of 1469; freshly cut, stockpiled, and reused beams from other proveniences were apparently used in the remodeling. Additional repairs were then performed in 1513 and some time in the 1520s. Feature 128 is one of the longest-lived individual structures on the Pajarito Plateau with an occupation of quite possibly more than 100 years. Alternative interpretations of the tree-ring data are possible, such as an extended construction time in the 1460s with mostly reused beams, construction earlier than 1424, or even construction in 1513, although the latter is considered extremely unlikely.

Figure 7.12. Stem-and-leaf plot of tree-ring dates from Feature 128, Pueblo del Encierro (underline indicates cutting or near cutting date).

Feature 279 was one of the latest construction episodes during the prehistoric occupation of the site. It also yielded the most dates and most cutting dates of any feature on the site (see Table 7.1). Unlike Feature 128, however, the interpretations of Feature 279 are relatively straight-forward. The 1507r cutting date is probably a reused beam. The large number of timbers that date to the summer of 1515 (n = 27) were probably procured and stockpiled for construction in 1516 when and additional six trees were cut. The feature apparently needed minor repairs in the summer of 1518, as evidence by CDP-214. Again, an alternative interpretation of the dates is possible, including a multi-year construction period.

Two other features also date to the early 1500s. Feature 124 contained a single roof beam dated 1515rB inc, and Feature 183 contained a single near cutting date of 1518+r. Both of these features appear to be contemporaneous with Features 128 and 279.

Finally, eight samples from Feature 129 and two samples from the doorway between Features 129/123 date to the late 1780s or 1790s. These are the latest dates from the site and none are cutting dates. Certainly they indicate post-abandonment activities at the site, but their significance remains problematic.

LA 34

A single Douglas fir charcoal fragment was collected from FE 13 of the site by Lange. It did not date (Table 7.1; Appendix D).

LA 272

Six charcoal samples were collected from Feature 1 (CDP-2) and Feature 2 (CDP-3-7) by Lange. Four of the samples are *Populus* spp. (probably cottonwood) and two are ponderosa pine. None of the samples dated (Table 7.1; Appendix D).

LA 3446

Five charcoal samples were collected from Squares 7, 8, 9, 10 or 11, and 13 by Lange. Four of the samples are juniper and one is a ponderosa pine (Table 7.1; Appendix D), but none dated.

LA 6178

A single juniper wood fragment was collected from Feature 21 by Lange. It did not date because it contained too few rings for crossdating (Table 7.1; Appendix D).

Alfred Herrera Site (LA 6455)

The Alfred Herrera Site samples were collected as part of the Cochiti Dam project by Lange (Table 7.1; Appendix D). All of the samples are charcoal collected during the excavations, but some lack detailed provenience information. A total of 137 samples, including 72 duplicates, was collected. The species present include ponderosa (*n* = 27), piñon (*n* = 21), Douglas fir (*n* = 12), juniper (*n* = 2), *Populus* (*n* = 2), and one unidentified specimen. The species distribution may reflect prehistoric selection preferences.

The 65 independent samples yielded 28 dates, including five cutting dates (Figure 7.13). The date range is 1281vv to 1497r inc, but the cutting date range is much shorter (1457v to 1497r inc). Thirteen features were sampled, but none of the samples from Features 1, 14, 23, 28, 33, and 59 yielded dates. Likewise, none of the samples from Feature 68 dated, but one is a duplicate of RG-4734, which dates to 1469rB inc. Feature 10 yielded a single noncutting date of 1318vv as did Feature 17, but it is not the same sample. The only date from Feature 24 is 1342vv. The majority of samples and dates were derived from Feature 52, including from rooffall, floor contact, general fill, and floor fill contexts. The latest date, and only cutting date from the floor fill context, is 1457v; there are no dates from the floor contact, but several samples are part of RG-4734, which dates to 1469rB inc. Feature 52 rooffall includes cutting dates in 1469, 1470, 1496, and 1497; it is probable that the roof was constructed in 1469 to 1470 and repaired almost 30 years later. The latest date from Feature 54 is 1478vv and the latest date from Feature 251 is 1382vv.

In general, the dates and proveniences suggest that the entire site was built in the 1470s, possibly as early as 1457, and remodeled or repaired in the late 1490s; the occupation was probably continuous during that time. The weak cluster of noncutting dates in the 1340s, however, suggests that there may have been an earlier occupation. If the cutting dates are used as a guide, the site occupation was approximately 40 years in duration.

Figure 7.13. Stem-and-leaf plot of dates from the Alfred Herrera Site (underline indicates cutting date).

Red Snake Hill Site (LA 6461)

Five charcoals samples, all juniper, were collected from the general fill of Feature 3 at the site by Bussey (1968a; Table 7.1, Appendix D). None of the samples dated and all exhibited erratic ring-growth patterns.

North Bank Site (LA 6462)

The North Bank Site collection was procured as part of the Cochiti Dam Project (Bussey 1968b; Lange 1968a) and contains 258 samples, 37 of which were duplicates (Table 7.1; Appendix D). All of the samples are charcoal fragments and all have at least some provenience information. The species present in the collection include piñon (n = 92), ponderosa (n = 56), juniper (n = 42), *Populus* (cottonwood) (n = 24), Douglas fir (n = 4), two unidentified specimens, and one *Atriplex* spp. (possible saltbush) specimen. The species distribution probably reflects prehistoric selection preferences and local species availability. The paucity of Douglas fir and abundance of both juniper and cottonwood are a result of procurement of low-elevation, local timbers.

The 221 independent samples yielded 98 dates (44%), including 63 cutting or near cutting dates. No dates were derived from Douglas fir, cottonwood, unidentified, or *Atriplex* specimens, and only one juniper sample dated. The low proportion of juniper dates may be related to species growth patterns that create erratic ring series and/or prehistoric selection of small timbers with too few rings for dating.

The overall date range is 1109vv to 1280vv and the cutting date range is 1128r comp to 1280rB inc, approximately a 150-year occupation. The date distribution (Figure 7.14) suggests several episodes of tree harvesting, and probably construction, at the site. The site may have been founded in the late 1120s or 1130 (three cutting dates). There are a few cutting dates in the 1140 to 1174 period that may indicate construction, or they may be reused beams. The first decade of the 13th century saw some construction as evidenced by three 1206 cutting dates and two noncutting dates in 1209. The next significant date cluster occurs in the 1240s and includes cutting dates in 1244, 1246 (*n* = 2), and 1247. The few cutting dates between 1248 and 1277 may indicate construction, but they are probably reused beams. The largest and tightest date cluster contains 47 cutting dates and two noncutting dates between 1277 and 1280; it clearly indicates construction in 1280 with freshly cut and stockpiled beams. The mixture of complete and incomplete terminal rings in 1280 indicates fall procurement. This large terminal date cluster is not followed by any other dates and thus may indicate abandonment of those areas of the site within a decade of 1280 and almost certainly by 1300.

Tree-ring samples were collected from 24 features at the site and 15 features yielded dates. Samples from Features 21, 27, 30, 33, 41, 43, 87, 88, and 109 did not date. Features 37 and 38 are the earliest features, dating to 1130v and 1128r, respectively; Feature 37 also exhibits some activity in 1146. Six samples from Feature 103 dated, including cutting dates in 1140, 1148, and 1174. Feature 85 produced two dates, the latest date and only cutting date is 1165v. These features, 37, 38, 85, and 103 are the only features that indicate a 12th century occupation, although Feature 84 and Feature 12 yielded noncutting dates of 1118vv and 1191vv, respectively.

The remaining features all date to the 13th century. Feature 106 is relatively well dated with three 1206 cutting dates; the terminal rings (two complete, one incomplete) indicate construction in the fall of 1206. Feature 108 is not well dated, but the latest date is 1223+vv from the general fill. Feature 1 yielded only two noncutting dates, the latest of which is 1239vv. It may be associated with Feature 34, which yielded a single cutting date of 1244rB inc, Feature 10 which yielded a single cutting date of 1246r comp, and Feature 20 which yielded three noncutting dates, the latest of which is 1248vv; the 1246 to 1247 cutting dates from Feature 37 may be part of this same building episode. Feature 99 was apparently built in the 1260s, as evidenced by two cutting and one noncutting date. Feature 65 may be contemporaneous, it contains a single noncutting date of 1275vv, or it may relate to the large construction event in Feature 45. Feature 45 is the best-dated feature with 46 cutting and five noncutting dates. The largest cluster is in 1280 with smaller cutting date clusters in 1277 and 1278. The feature was clearly built in 1280 with freshly cut and stockpiled timbers; the terminal rings indicate it was built in the late summer/early fall of 1280.

Figure 7.14. Stem-and-leaf plot of dates from the North Bank Site (underline indicates cutting date).

LA 9139

Five charcoal samples, including one duplicate, were collected from Feature 1 of the site by the Office of Contract Archaeology (Table 7.1; Appendix D). Four of the samples are ponderosa and one is piñon. Two of the samples dated, but yielded only noncutting dates of 1675vv and 1767vv, respectively. The duplicate sample from the rooffall of the feature replicates the 1675vv date. The dates suggest some use of the feature in the late 1700s.

LTRR NM-I-56, Bandelier Big Kiva

The Bandelier Big Kiva samples were collected as part of Hewett's excavations and the stabilization of the site by Hendron of the NPS in the 1930s. Initially analyzed by Stallings as part of the Rio Grande chronology, they were transferred to the LTRR in the 1950s. All of the samples are charcoal from the excavations, but some (presumably Hewett's) lack detailed provenience information. A total of 105 samples was submitted, 68 of which are duplicates (Table 7.1; Appendix D). Interestingly, some of the duplicate samples, such as RG-5156 and RG-223, were collected from different proveniences (the west entrance and south fill, respectively); a detailed map of the excavations may indicate the significance (if any) of the duplicates (e.g., multiple uses of the same timber). The species used in the kiva include ponderosa pine (22 independent samples that yielded 8 dates), Douglas fir (14 samples that yielded 7 dates), and one unidentified specimen (that did not date). Other species were probably present, but were not collected.

The 37 independent samples yielded 15 dates, including six cutting or near cutting dates (Table 7.1; Appendix D). The dates range from 1383vv to 1525+vv; the cutting and near cutting dates are slightly more restricted and span 1505+r to 1525r. Eleven of the dates, and all but one of the cutting or near cutting dates, were procured from the "south fill" of the kiva. The Frijoles Canyon (Hewett?) and "Project 1 West Entrance" samples all yielded "vv" dates that do not date construction episodes. The 1505+r date (RG-5165) from the "West Entrance" may indicate construction, but it may also be a reused beam or piece of dead wood. The dates from the "south fill of the kiva" form a relatively tight cluster in the early 1520s. Based on the terminal cluster, it is most likely that the kiva was built in the fall/winter of 1525, with some freshly cut beams (RG-5191) and timbers that had been stockpiled in 1522 (RG-5178), 1523 (RG-5173, 5206), and 1524 (RG-5193). Another possibility, however, is that the structure was built during three to four consecutive winters, much like Kiva I at Long House in Mesa Verde (Street 2001).

LTRR NM-I-61

Alamo Canyon Group

LA 12121

Seventeen piñon pine samples have been collected from the three different rooms on the site, including charcoal samples and wood cross-sections. Fourteen of the samples yielded dates, including seven cutting dates (Table 7.1; Appendix D). Clearly, Room 4 was built during the growing season of 1177 as indicated by five cutting dates with incomplete terminal rings for that year. The 1162r cutting date probably represents a reused beam and the 1180 noncutting date from the fill indicates that the room was occupied for at least three years. Room 3 was probably constructed in 1150 as indicated by the 1150+v cutting date and three 1149 noncutting dates; the 1154 noncutting date suggests the room was used for a least four years. The only date from Room 2, 1148vv, suggests it may be contemporary with Room 3. It is probable that the site was continuously occupied from 1150 until at least 1180, but it is also possible that there are two separate occupations represented in these rooms. The apparently short-lived nature of the occupation (30+ years) may be important for ceramic seriation and other studies.

LA 13659

Two ponderosa pine charcoal fragments were collected from this cavate site by NPS. Neither sample yielded a date (Table 7.1; Appendix D).

LA 12119

A total of 36 charcoal samples were collected from the site by NPS; four of the samples are duplicates, leaving 32 independent samples from the site (Table 7.1; Appendix D). The species represented include piñon pine (*n* = 18), juniper (*n* = 11), ponderosa pine (*n* = 2), and Douglas fir (*n* = 1). The preponderance of piñon pine and paucity of ponderosa is somewhat unusual. Only five of the samples dated (three piñons, one juniper, and one ponderosa), and all yielded noncutting dates. The range of dates (1191+vv to 1419vv), lack of cutting dates or date clustering, and different proveniences documented makes interpretation difficult. It is probable, but rather speculative, that both Kiva 1 and Kiva 2 were occupied in the 15th century or later. Room 14 may date somewhat earlier, but the single noncutting date of 1203vv is scant evidence for such an inference.

LA 12578

A single piñon pine wood fragment was collected from the surface of this site by NPS. It did not date (Table 7.1; Appendix D).

LA 12567

A single oak (probably Gambel oak) charcoal fragment was collected from this site by NPS. It did not date (Table 7.1; Appendix D) and has not been curated for future analysis.

LA 12581

A single juniper charcoal fragment was collected from Room 1 of this site by NPS. It did not date (Table 7.1; Appendix D).

LTRR NM-I-70

Pajarito Group

This group of samples consists of those submitted by J. Hill of the University of California, Los Angeles (UCLA) in the 1970s. Limited provenience information is available for the samples and the interpretations are relatively weak.

Cavate East Mesa

A single cross-section of ponderosa pine was collected from this cavate site by UCLA. It yielded a date of 1628p to 1674vv (Table 7.1; Appendix D). Although this is limited chronological information, it indicates use of the structure in the 17th or 18th centuries.

Site 118 Kiva 1

A single ponderosa wood fragment was collected from this cavate site by UCLA. It yielded a cutting date of 1792 to 1830r (Table 7.1; Appendix D). Without detailed provenience information or additional knowledge of the site configuration, interpretation of the date is not possible.

Cavate Site 127

Two ponderosa charcoal fragments were collected from this cavate site by UCLA. Neither sample yielded a date (Table 7.1; Appendix D).

Cavate Site 128

A single cross-section of piñon pine was collected from this cavate site by UCLA. It did not date (Table 7.1; Appendix D).

Site 252

Twelve samples, including three charcoal fragments, four wood fragments, and five wood cross-sections were collected from the site by UCLA. The species represented include five juniper, three *Populus* spp., two fir, and two ponderosa pines (Table 7.1; Appendix D). Only one of the ponderosa samples yielded a noncutting date (1797p to 1844++vv).

LTRR NM-I-71, La Mesa Fire Site

Three ponderosa charcoal fragments were collected from this site by the NPS. Two samples, both "north of Room 1," yielded noncutting dates of 1401+vv and 1412+vv, respectively (Table 7.1; Appendix D). This small sample size suggests some use of the site in the early 15th century.

LTRR NM-I-74, LA 3824

Seven charcoal samples, including four Douglas fir and three ponderosa specimens, were collected from this site by David Snow of the Museum of New Mexico. None of the samples yielded a date (Table 7.1; Appendix D).

LTRR NM-I-77

Los Alamos Cabins

The Los Alamos Cabins samples were collected by LANL archaeologists in 1981, 1990, and 2002. There was apparently some confusion of site names and numbers for the Romero Homestead and two separate LTRR designations were assigned to the site (NM-I-77 and NM-I-79). The entire site is discussed here under the designation NM-I-79.

Gomez Homestead (LA 86643)

Eight juniper samples were collected from the site by LANL archaeologists (Table 7.1; Appendix D). Seven samples are cross-sections and one is a beam end that exhibits metal-ax cut marks. The samples were apparently collected from the same structure, with the exception of LAC-31, which was a fence post. None of the samples dated.

Anchor Ranch (LA 16808)

Ten independent samples were collected from the site by LANL archaeologists (Table 7.1; Appendix D). All of the samples are ponderosa wood cross-sections. Five samples dated and four are cutting dates. The Ice House was undoubtedly built in the fall/winter of 1933 as indicated by three 1933 cutting dates with complete terminal rings. Sample LAC-57, which dates 1896++LGB, is probably a piece of dead wood; sample LAC-53, which dates 1896++LGB, is a duplicate of LAC-34 from the Homestead Bridge and may have been reused in that structure as a piece of dead wood. The only date from Structure 1, 1929GB comp, indicates tree felling in the fall/winter of 1929. Additional archaeological and tree-ring data are necessary to determine if it represents the building of Structure 1, however.

Vigil y Montoya Homestead (LA 70028)

A total of 20 samples, including one duplicate, was collected as wood cross-sections or beam ends from the site by LANL archaeologists (Table 7.1; Appendix D). The 19 independent samples include 16 ponderosas, one juniper, one piñon, and one Douglas fir specimen. Only five of the samples (four ponderosas and one piñon) yielded dates, all of which are noncutting dates. The latest date from the site, 1963++G, may indicate activity at the site in the 1960s, but its provenience "near the loaf pan" and "++" designation suggest it is a piece of dead wood that may not date the occupation. The 1911++G date from Feature 4 may indicate construction in the 1910s, but again a single, noncutting (possibly dead wood) date is not strong evidence for inferring an occupation of the site. Likewise, the earlier noncutting dates (1720vv, 1830vv, 1855+vv) contribute little to the site interpretation. More samples are needed to delineate the parameters of the Vigil y Montoya site history.

Homestead Bridge (LA 89826)

Three ponderosa wood cross-sections from the Homestead Bridge were collected by LANL archaeologists (Table 7.1; Appendix D). Two of the samples did not date because they contained too few rings (LAC-32) or exhibited erratic growth patterns (LAC-33). Sample LAC-34 yielded a near cutting date of 1783p to 1899+rLGB. Interestingly, the sample is a duplicate of LAC-53, a door lintel in the Ice House at Anchor Ranch (see above). Because the Ice House dates to 1933, there are two alternative interpretations of the bridge. First, it may have been built in 1899 (or 1900) and part of it used to build the Ice House 30 years later. Alternatively, the date may not apply to the bridge, but to some other structure; in which case the bridge and Ice House may have been built in 1933 with a piece of reused or dead wood.

Homestead Fence (LA 89770)

Nine ponderosa samples were collected from the boundary fence by LANL archaeologists. Eight of the samples are beam ends and one is a cross-section. Three samples did not date because they contained too few rings or lacked ring-width variability (Table 7.1; Appendix D). The six dated samples all yielded noncutting dates because exterior rings have eroded from the samples. The noncutting dates do not form any sort of terminal cluster, so the most parsimonious explanation is that the fence was constructed some time after 1890.

Montoya Homestead (LA 21334)

A total of eight samples, including one duplicate, was collected from the site by LANL archaeologists (Table 7.1; Appendix D). Six of the independent samples are ponderosas and one is piñon; all were collected as wood cross-sections or beam ends. Five samples dated, but none yielded cutting dates. The latest sample (LAC-38) dates 1915++vv and may date the occupation to the 1910s or later. The samples collected from the Canyon Fence provide little data with which to interpret construction other than that the homestead was built some time after 1915.

Serna Homestead (LA 85407)

Four samples, all ponderosa pine, were collected from the site by LANL archaeologists (Table 7.1; Appendix D). Three of the samples are beam ends (one charred) and the other is a wood cross-section. Two samples were collected from the wood pile, one from a structure, and one from a fence. All samples dated, but all yielded noncutting dates that resulted from erosion of exterior rings; indeed, no sapwood rings are present on any of the samples. The noncutting dates indicate construction at the site some time after 1826 and the lack of sapwood rings suggests that the trees were cut some time in the late 1800s or early 1900s.

LTRR NM-I-79, Romero Cabin and Homestead (LA 16806 and 16808B)

The Romero Homestead is the best-dated site on the Pajarito Plateau. A total of 105 samples, including two duplicates, was collected from the site by LANL archaeologists over the past 20 years (Table 7.1; Appendix D). The majority of the samples are wood cross-sections, although a few half-inch cores and charcoal fragments were collected as well. Ninety-nine of the samples are ponderosa pine, three are Douglas fir, and one (a fence post) is juniper. The species distribution clearly reflects (a) preferences by the site occupants and (b) local species availability.

A remarkable 96 percent (n = 94) of the samples dated and 65 samples yielded cutting dates. The overall date range is 1853vv to 1966rB comp and the cutting date range is 1894r inc to 1966rB comp. The date ranges, however, are much less important than the combination of dates and provenience data. Five different proveniences have been sampled: Feature 4, a fence post east of the corral, the corral, the hog pen, and the cabin. The only sample from Feature 4 yielded a noncutting date of 1906vv and the fence post east of the corral yielded a noncutting date of 1894vv. Neither date accurately dates activities at the site.

There are eight dated samples from the corral (Figure 7.15). Although only two are cutting dates, the strong terminal cluster indicates that the structure was built in 1908. Incomplete terminal rings on the two 1908 cutting dates indicate that the corral was built during the ponderosa pine growing season (summer) of 1908.

188	34
189	88
190	6688888

Figure 7.15. Stem-and-leaf plot of dates from the corral at the Romero Homestead (underline indicates cutting or near cutting date).

There are 31 samples from the hog pen, 27 of which dated. The total includes 23 cutting dates (Figure 7.16). The large cluster of cutting dates in 1912 (*n* = 18) leaves little doubt that the hog pen was built in that year. The mixture of complete (*n* = 3) and incomplete (*n* = 15) terminal rings indicates that the structure was built in the late summer/early fall of 1912 when some trees had ceased growth for the year but others had not. The earlier cutting dates in 1894, 1895, 1906, 1908, and 1910 indicate tree harvesting in the area before construction of the hog pen, but do not date the structure itself. The two later noncutting dates (1922++vv, 1933vv) are evidence of structure repair, probably in conjunction with the construction of the cabin (see below).

192	2
193	1

Figure 7.16. Stem-and-leaf plot of dates from the hog pen at the Romero Homestead (underline indicates cutting or near cutting date).

Sixty-one samples have been collected from the cabin, 56 of which dated; fifty-one of the samples yielded cutting or near cutting dates (Figure 7.17). The dates indicate a major construction episode followed by four repair or remodeling events. The single 1913G cutting date is undoubtedly a beam reused from another structure. The cabin was built early in the ponderosa growing season (spring) of 1934. The two 1933 cutting dates exhibit complete terminal rings indicating that they were cut after the 1933 growing season but before the initiation of growth in 1934. All of the 1934 dates, however, exhibit incomplete terminal rings, indicating growing season procurement. The 1935 to 1938 cutting dates (*n* = 4) suggest a repair episode probably in the summer of 1938; additional provenience and attribute information is necessary to determine if there was one or more repair episodes. The cabin was apparently abandoned for a period of more than 20 years before a reoccupation occurred in the 1960s. Minor repairs were conducted in 1960 to 1961; because all the 1960 and 1961 dates are near cutting "+" dates, it is possible, indeed probable, that these beams were procured during the growing season of 1961. The nine 1966 cutting dates all exhibit complete terminal rings and indicate a major remodeling episode in the fall/winter of 1966.

Interestingly, the three well-dated structures at the Romero Homestead date to different years. Although there are several cutting dates that indicate tree felling in the 1890s and early 1900s, construction occurred only in 1908, 1912, and 1934—and the cabin was the last structure built. Where people were living before construction of the cabin should be investigated using archaeological and documentary sources. Repairs to the cabin in 1938 suggest the occupation lasted more than five years, but the precise duration cannot be determined from the tree-ring data. The 1960s repair and remodeling episodes indicate reuse of the cabin, but not necessarily reuse of the site as an economic entity. Additional tree-ring data from other features may contribute to understanding the internal site dynamics of the Romero Homestead, but more detailed archaeological and historical data are needed as well.

LTRR NM-I-83, Archaic Site (LA 51912)

Eight charcoal samples, six juniper and two piñon, were collected from the site by Steve Lent of MNM in 1988. Features 1, 12, 14, and 18 were sampled, but none of the specimens dated.

LTRR NM-I-84, Kuapa (LA 3444)

Two ponderosa pine charcoal samples were collected from the site by Haas. Neither sample yielded a date (Table 7.1; Appendix D).

LTRR NM-I-93

Shohakka Pueblo (LA 3840)

Two ponderosa charcoal samples were collected from Feature 3, Area 1 of the site by Ruscavage-Barz of NPS. One sample yielded a noncutting date of 1387 to 1441vv and the other sample did not date (Table 7.1; Appendix D).

LA 118345

Two ponderosa pine charcoal samples were collected from FE 1 Area 1 of the site by Ruscavage-Barz of NPS. Neither sample yielded a date (Table 7.1; Appendix D).

A SUMMARY OF DENDROARCHAEOLOGICAL DATA FROM THE PAJARITO PLATEAU

Tree-ring samples have been collected from archaeological sites on the Pajarito Plateau for almost 80 years and the results are presented below. Before they are discussed, however, a couple of caveats must be offered along with the interpretations. As mentioned above, the two most important factors in any dendroarchaeological date distribution are (a) the behaviors of past site occupants and (b) the behaviors of archaeologists and dendrochronologists (Dean 1996a, 1996b; Towner 2000). It is clear that the latter has had a profound impact on the structure of the Pajarito Plateau dendroarchaeological database.

Certainly the site occupants' choices of different tree species for construction and fuel have helped structure the distribution. We need only examine the species differences between the Romero Homestead, where ponderosa pine was used almost exclusively and the North Bank Site, where there is a mixture of piñon, juniper, ponderosa, Douglas fir, and even cottonwood, to see that the site occupants influenced the date distribution. It is abundantly clear, however, that, particularly for the large prehistoric pueblos that were sampled before the Cochiti Dam Project, the species-specific collection strategies and minimal recording efforts of the archaeologists and dendrochronologists have structured the data far more than the site occupants' behaviors. Therefore, the summaries presented below should be viewed as preliminary and subject to testing with archaeological, documentary, and other data.

A total of 1528 samples have been collected from Pajarito Plateau archaeological sites, including 238 duplicates (Table 7.1; Appendix D). The 1290 independent samples include 678 ponderosa, 253 piñon, 197 Douglas fir, 108 juniper, 40 cottonwood, and many fewer oak ($n = 2$), fir ($n = 2$), white fir ($n = 2$), undifferentiated non-coniferous species ($n = 2$), unidentified species ($n = 5$), and a single *Atriplex* spp. specimen. Only the Douglas fir, piñon, ponderosa, juniper, and white fir yielded dates. The Douglas fir had the highest ratio of dates/samples (68.9%), followed by the piñon (65.4%), ponderosa (59.7%), white fir (50%, but $n = 2$), and juniper (1.8%). Most of the lack of dating in the pines and Douglas fir is probably a result of samples with too few rings for crossdating. The extremely low proportion of juniper dates, however, is probably a result of small samples with too few rings and erratic growth patterns. As discussed below, however, a more carefully designed research and sampling strategy should enable us to delineate the juniper growth patterns and date many more samples. In many other areas of the Southwest, juniper dates well and in some cases the proportion of juniper dates exceeds that of ponderosa (cf. Towner 1997).

Figure 7.18 presents all the dates, cutting and noncutting, derived from Pajarito Plateau archaeological samples. The distribution of cutting and near cutting dates (see below) certainly can be used to infer tree-harvesting activities. The overall date distribution, however, provides additional information concerning the use of the area.

Figure 7.18. Stem-and-leaf plot of all Pajarito Plateau tree-ring dates (underline indicates cutting or near cutting date).

Although there are a few dates in the AD 1000s, the first dendroarchaeological evidence of pueblo construction is in the early to mid-1100s. A small "bulge" in the distribution between approximately 1130 and 1210 supports this inference. A large peak in the 1260 to 1280 period indicates significant construction in the area; whether this peak is related to the immigration of people into the area (cf. Ahlstrom et al. 1995), or is an artifact of sampling bias, is an archaeological question.

The low number of dates in the 1281 to 1380 period (*n* = 37, or one date every three years) indicates little tree harvesting activity. The tree-ring data certainly do not support the concept of a large immigration of people onto the Pajarito Plateau immediately following the depopulation of the Four Corners area (cf. Ahlstrom et al. 1995).

The tree-ring data indicate that the major occupation of pueblos on the Pajarito Plateau began in the late 1300s and continued at least until the 1540s. The majority of dates fall between the late 1300s and early 1540s and suggest major construction and expansion of pueblos. The slight drop in the number of dates between ca. 1480 and 1510 may indicate a slowing of site expansion, but is not an indication of depopulation or abandonment of the area.

With the exception of a small peak in the 1570s, the period from 1545 to 1680 shows very few tree harvesting episodes. The paucity of dates in the early part of the period, perhaps 1545 to 1610, may be a result of epidemic disease inhibiting new construction (Dobyns 1983; Ramenofsky 1987; Reff 1991); the low level of activity during the latter era—speculatively 1610 to 1680—may be a result of the Spaniards' demands for tribute and labor from the pueblos (Kessell 1979; Scholes 1937).

The sharp peak in the 1680 to 1690 period is probably related to the Pueblo Revolt of 1680 and Spaniards' reconquest the following decade. The low number of dates in the 1700s and early 1800s indicates a cessation of construction and probable depopulation of many sites in the area.

The next peak in the dendroarchaeological data relates to the Hispanic expansion onto the Pajarito Plateau in the 1890s. Interestingly, after significant activities ca. 1890 to 1913, there is apparently a 20-year gap in the data until the early 1930s. Similarly, more than 20 years passed before additional dates indicate activities in the early to mid-1960s. The tree-ring data for the Hispanic occupation indicate that individual families, not larger corporate groups, exploited the area during the 20th century.

The distribution of cutting dates from the Pajarito Plateau (Figure 7.19) shows similar, but more restricted, trends. The earliest cutting date is 1128 and the tree-ring data cannot be used to infer an earlier occupation of the area. Minor levels of tree cutting in the early to mid-1100s suggest that the area was initially settled at that time. There is no substantial increase until the 1170s. The 1170s tree-cutting episodes were followed by almost 30 years of no activity; likewise, the three trees cut in 1206 were followed by an almost 40-year gap in the distribution. Thus, with the possible exception of the 1170s and 1206, the dendroarchaeological evidence suggests small, discontinuous use of the Pajarito Plateau from the early 1100s until the 1270s. The distribution shows a major expansion of tree felling activities in the late 1270s and 1280, but it should be remembered that those cutting dates were derived from a single feature at the North Bank Site. After 1280, there are only eight cutting dates until the turn of the 15th century. This extremely low number of tree-harvesting events—an average of one every 15 years—indicates that there was not a major influx of people onto the Pajarito Plateau during the 1300s.

Figure 7.19. Stem-and-leaf plot of all Pajarito Plateau cutting and near cutting dates.

The major prehistoric occupation of the area was clearly during the 1400s and early 1500s. Beginning in the first decade of the 15th century, tree cutting reached substantial levels in every decade of the century, except the 1430s. The lower level of activity in the 1430s may be a result of sampling bias, a pause in site founding or growth, or some other factor; it is an archaeological issue that deserves further scrutiny. The end of the 1400s witnessed a slow decline in tree harvesting that may be related to out-migration, a lack of site expansion, or both. The large "bulge" in the distribution in the 1510s and 1520s indicate significant tree harvesting in the early 16th century. This bulge, unlike the 1280s one, includes a number of large sites, including Puyé, Tsirege, Tyuonyi, Pueblo del Encierro, and the Bandelier Big Kiva.

The low number of dates from 1530 to 1870 (*n* = 18, or 1 every 14 years), indicates limited occupation and/or use of the area. There may have been a minor resurgence in the 1570s and reuse of the area in the 1680s in response to the Pueblo Revolt, but in general the area appears to have been little used until the Hispanic occupation of the 20th century.

The Hispanic occupation was fundamentally different, however. These single-family groups selected different tree species, mostly ponderosa pine, and constructed different types of structures to accomplish different economic goals (e.g., the hog pen). The 20-year gap between the different structures at the Romero Homestead (and some of the other sites) should be investigated with documentary and oral history sources. Perhaps the most interesting aspect of the Hispanic tree-ring data are the cutting date clusters in the 1960s, after the area became restricted due to LANL priorities. How, who, and why the Romero Homestead was remodeled are interesting questions.

DENDROCLIMATOLOGY AND PAST ENVIRONMENTAL VARIABILITY IN THE PAJARITO PLATEAU AREA

Dendroclimatology is the use of tree-ring data to retrodict past climate patterns. The subfield has a long history within dendrochronology, but has grown exponentially in the past few decades. In part because of Douglass' interest in sunspot activity, tree-rings and climate have been linked since the beginning of dendrochronology. Indeed, one of the obstacles to "bridging the gap" was the severe drought of the late 1200s on the Colorado Plateau. Douglass (1935) was the first scientist to suggest a connection between the "Great Drought" and the Anasazi abandonment of the Four Corners area, a question that is still debated in southwestern archaeology. Schulman (1956) was actually the first dendrochronologist to develop a climate reconstruction, but it was not until Fritts' (1976, 1991) efforts that dendroclimatology became a quantitative endeavor. It was not until the 1970s, however, that dendroclimatology was used in the northern Rio Grande region.

A dendroclimatic reconstruction involves developing a mathematical model of the relationship between the environment and the cambial growth of trees (LaMarche 1974; Schulman 1954, 1956). Trees are natural archives of information about past environments, and because many are older than the oldest historical documents, they can be used to illuminate aspects of prehistoric climate (Dean 1988; Swetnam and Betancourt 1998). Such archives, however, contain information on a number of different aspects of the environment, and it is necessary to isolate the variables one wishes to study. Specific field collection, laboratory analysis, and statistical procedures are designed to eliminate the "noise" in the tree-ring series and highlight the environmental "signal of interest" (Fritts 1991; Salzer 2000a). In some instances, the signal of interest is long-term trends in precipitation, in others it is long-term temperature variability, and in still others it is the short-term spatial differences and identification of extreme events, such as floods or very dry years in specific areas (Graybill 1989). For detailed discussions of the methods and techniques of dendroclimatology, see Fritts (1976, 1991).

Dendroclimatic reconstructions can provide annual estimates of various climatic variables and are the most precise method for doing so. Dendroclimatology, however, is not without its limitations. First, the technique can only be used for those time periods encompassed by the tree-ring samples; in the Southwest, the time frame is limited to the past two and one-half millennia. Climate variation before about 2600 years ago must be examined using other methods. Second, dendroclimatic reconstructions tend to underestimate the extreme values of particular years. Tree rings tend to underestimate the magnitude of high-precipitation (wet) years because in those years water ceases to become the most limiting factor in cambial growth (Fritts 1991). In other words, trees have an adequate supply of water, but some other factor (e.g., temperature, nutrient supply, genetics) prevents uncontrolled cell division and cambial growth (Fritts 1976). In extremely dry years, something of the opposite problem occurs in the Southwest. If a tree does not receive adequate moisture to initiate growth, the result is a locally absent or "missing" ring. The tree, in effect, has recorded "0" moisture for that year even if some precipitation may have fallen. Another potential problem is the 'short-segment' curse (Cook et al. 1995; Sheppard et al. 1997). In some instances, it appears that trees have adapted their growth patterns to "short-term" climatic norms, that is, conditions prevalent during their lifetimes. Thus, it is best to collect extremely long-lived trees (Grissino-Mayer 1996; Salzer 2000a), but that strategy is not always possible. In many cases, including the northern Rio Grande region, archaeological chronologies have been combined with live-tree chronologies to extend the dendroclimatic record into the first millennium AD (Rose et al. 1981). Despite these caveats, tree-ring based reconstructions of climate are the most accurate and precise methods available for examining the past climate variability of the Pajarito Plateau during the past two millennia.

Reconstructions of Precipitation in the Northern Rio Grande

The first dendroclimatic reconstruction in the Southwest was developed by Dean and Robinson in 1977. As a dendroclimatic reconstruction for the Colorado Plateau, this early work is not a reconstruction of annual temperature or precipitation. It is a reconstruction of decadal departures from mean ring-widths for 25 specific tree-ring stations, including the Jemez Mountain chronology. The modern and archaeological tree-ring data used span the period AD 623 to 1978, and have been used predominantly to reconstruct relative variability in annual ring-width on a decadal scale (Appendix E). No climate data were used in this qualitative reconstruction. The reconstruction was certainly adequate for its time and purpose. The qualitative nature of the reconstruction was based on the relative change in decadal ring-width averages; thus, it indicated that tree-growth at the Jemez Mountain locality in the AD 960s, for example, was 1.3 standard deviations greater (Figure 7.20) than the mean and that growth in the AD 1420s was 1.2 standard deviations below the mean at the same site (Figure 7.21).

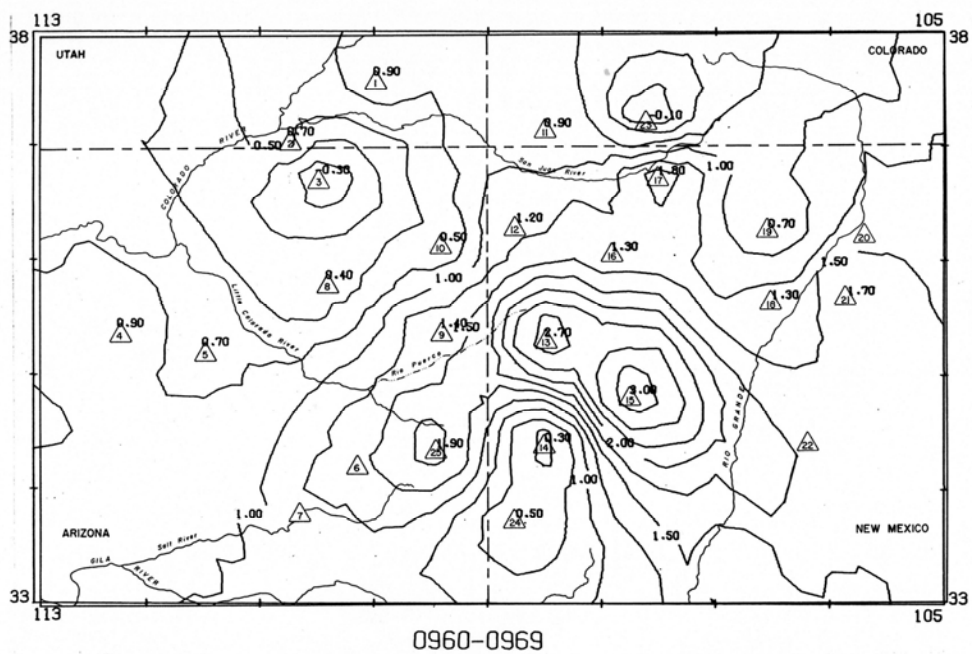

Figure 7.20. Isopleth of growth anomalies in the 960s (from Dean and Robinson 1977).

It did not, however, estimate the environmental factors responsible for the growth departures. Certainly, precipitation is major component of growth in southwestern conifers, but it is by no means the only factor in tree growth (Fritts 1991). The decadal summaries, based on Christian calendar decades, undoubtedly smoothed some between-decade variation and minimized high-frequency annual values. Thus, Dean and Robinson's (1977) research illuminated broad temporal and spatial patterns of ring-width change, but provided no quantitative data concerning annual precipitations or temperature responsible for those changes.

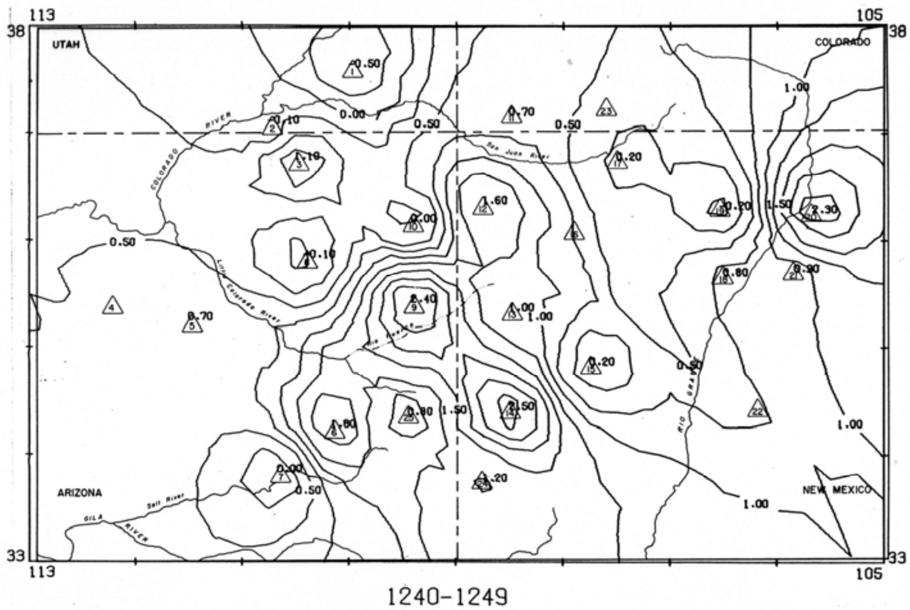

Figure 7.21. Isopleth of growth anomalies in the 1420s (from Dean and Robinson 1977).

Shortly thereafter, Rose et al. (1981) produced a quantitative reconstruction in the northern Rio Grande that extended back to AD 985. Rose and his colleagues used live piñon samples from Glorieta Mesa and archaeological samples from Arroyo Hondo and other sites to reconstruct both annual and spring (March-June) precipitation in the area. Because of the uncertainty as to whether the living trees and archaeological specimens reflected the same climatic variables (e.g., were derived from the same population), Rose et al. (1981) conducted extensive statistical analyses to demonstrate the coherence of the database.

The resulting reconstructions (Appendices F and G) indicate important aspects of precipitation in the area as well as illuminate trends over long time scales. The Arroyo Hondo analysis indicates that the mean annual precipitation for the area is 13.337 inches and the standard deviation is 2.16; the spring mean is 4.21 and spring standard deviation is 1.81. Probably most importantly, their analysis of both the tree-ring and modern climate data indicates that spring precipitation is more variable than annual precipitation. In short, the late-summer (monsoonal) and early-winter precipitation is somewhat consistent—and therefore predictable over the long term—but spring precipitation varies from year to year, decade to decade, and probably century to century. Thus, spring precipitation typically accounts for approximately one-third of the annual rainfall. As they state, "spring is the period of seed germination of traditional Pueblo crops.... And if late summer rainfall is stable as suggested, germination may have been the controlling factor in successful farming..."(Rose et al. 1981:106).

The period from AD 990 to 1430 was characterized by high-amplitude and high-frequency changes in both spring and annual precipitation. Such a trend may have facilitated adaptational strategies such as storage, trade, and "alliance formation" as mechanisms to mitigate the effects of rapid and severe fluctuations in rainfall. The period from AD 1430 to 1735 was somewhat the opposite with low frequency, low amplitude fluctuations; and the period from AD 1735 to 1970 exhibited low frequency changes of somewhat moderate amplitude.

On a more detailed level, the 1295 to 1335 period was consistently above average and 1335 to 1400 was variable with high amplitude in 1335 and 1370 but low amplitude in 1365 and 1380. Consistently high precipitation characterized the 1400 to 1415 years, but there was a very low point in 1420. The early 1500s were consistently high, with a low in 1520, and a return to high precipitation until about 1560. The "mega drought" of the late 1500s was particularly severe. Low precipitation characterized the early Hispanic period, 1875 to 1900, but consistently high precipitation persisted from about 1900 to 1950. The 1950s drought was severe in the northern Rio Grande, but not as severe as in the south.

Although the Dean and Robinson (1977) qualitative reconstruction included a spatial component (see above), it was not until the 1990s that an extensive, quantitative precipitation reconstruction of the spatial and temporal variability within the Southwest was developed. Dean and Funkhouser (1995) used 27 tree-ring chronologies spread from the Grand Canyon to the Pecos River and central Utah to the Gila River to characterize precipitation over the past 1400+ years. They identified two spatially discrete principal components, predominantly to the north and west and the other to the south and east (Figure 7.22). This configuration resembles the modern precipitation regime whereby the north and west is characterized by bimodal distribution with both winter and summer precipitation, and the southeast area exhibits a unimodal, summer-dominant precipitation pattern. The same pattern characterizes much of the prehistoric period, except the 1250 to 1450 period when the northwest area experienced "a totally aberrant" pattern. "The only stable characteristic of this period is the persistence of the southeastern component" (Dean and Funkhouser 1995:94), which includes the Pajarito Plateau. The relationship of this aberrant climatic pattern on the Puebloan peoples of the Colorado Plateau and Rio Grande area has not yet been delineated.

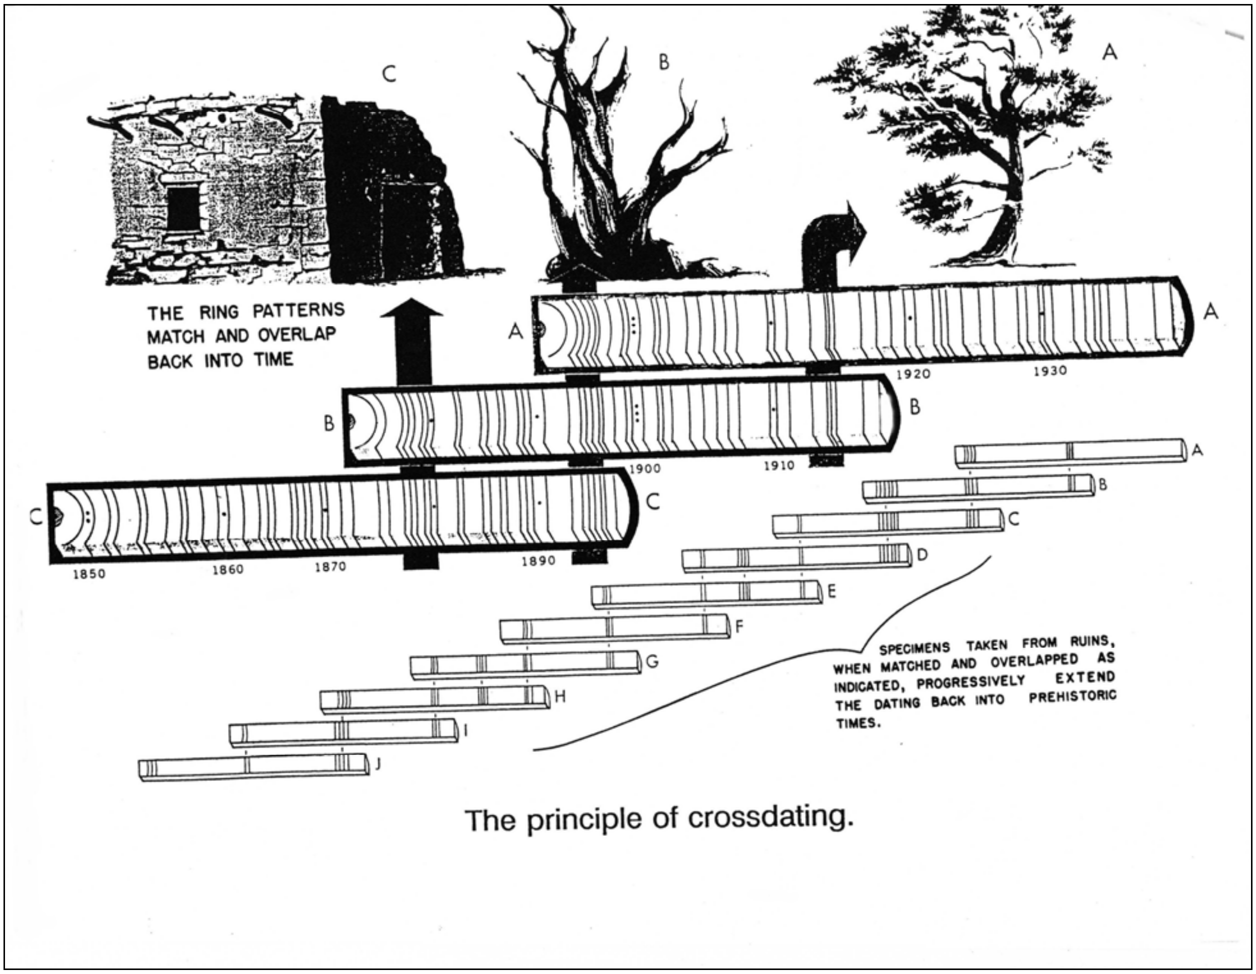

Figure 7.22. Map showing principal components of southwestern precipitation (from Dean and Funkhouser 1995).

Reconstructions of Temperature in the Southwest

Salzer (2000a) had developed the only tree-ring based, quantified temperature reconstruction currently available in the Southwest. Using high-altitude bristlecone pine trees from the SFP in northern Arizona, he retrodicted monthly mean-maximum annual temperature from 663 BC to AD 1997; only the AD 660 to 1997 period is used herein. Details of the reconstruction methods and results can be found in Salzer (2000a) and subsequent articles (Salzer 2000b).

A few comments about Salzer's reconstruction are necessary, however. As mentioned above, relative temperature is more or less uniform across the Colorado Plateau, although extremely local micro-environments may be exceptions to the trends. The Rio Grande and other areas east of the Continental Divide undoubtedly have different temperature influences, so the Colorado Plateau temperature record may only weakly reflect conditions in the northern Rio Grande. Temperature also varies with elevation. The SFP reconstructed temperature values represent temperatures at 2240 m above sea level. Using modern temperature data from several different climate stations and published regression equations, Salzer (2000a) suggests an adjustment of 2 degrees centigrade per 305 m change in elevation. Finally, mean-maximum temperature is an indicator of daily high temperatures. Salzer's (2000a) analysis indicates that the highest correlation of temperature with tree growth is during January to December of the year before the growth year (Year t-1). Thus, a lag of t-1 was used in his reconstruction.

Temperature may be a very important variable to reconstruct in terms of understanding the adaptation of agriculturalists to the Pajarito Plateau. Particularly, if a seasonal (spring) temperature signal can be obtained, we may be able to elucidate more clearly the maize growing season in specific years and over longer time spans.

RECOMMENDATIONS AND CONCLUSIONS

Dendroarchaeology

Dendroarchaeology has made significant contributions to the understanding of past human behavior, occupation, and adaptation to the Pajarito Plateau environment. The dendroarchaeological resources can continue to contribute important information concerning past human/environment interaction in the area if various types of data collection and research are targeted toward specific goals. The information contained in dendroarchaeological samples is a non-renewable resource that is at risk from natural threats, such as fire and erosion of exterior rings, and cultural impacts, such as vandalism and illegal collecting. The following recommendations provide a strategy for more fully exploiting the dendroarchaeological resources of the Pajarito Plateau.

First, all available tree-ring samples from previously excavated and unexcavated contexts should be submitted for analysis. Samples may exist in archaeological collections curated at various museums around the country, and analyzing the samples may yield new information without any additional fieldwork or impact to the resources. Such a strategy was recently used by the field Museum of Natural History in reassessing their Paul S. Martin Collection, and the reanalysis resulted in the dating of previously undated sites and a substantial increase in the number of data and other information from the samples. Many different institutions and individuals have been involved in archaeological excavations on the Pajarito Plateau over the past 100+ years, and it is unlikely that all of the wood or charcoal specimens collected have been submitted for analysis. Analyzing these "old" samples, therefore, may have tremendous benefits.

Second, all newly collected samples should be submitted for analysis. Whether through research projects or Cultural Resource Management-mandated testing and excavation, <u>all</u> such samples need to be analyzed. Pre-selection of samples in the field (e.g., choosing those that "look best") is often a self-defeating exercise. Although trained dendrochronologists <u>may</u> be able to tell if a sample dates in the field, not even they can be certain if a sample will not date. All such samples should be treated as cultural artifacts, which they are, and recorded properly, including precise provenience information, assumed function, size, and tool marks present. The LTRR requires that specific information accompany the samples (Figure 7.23) and additional information (Figure 7.24) is critical for properly interpreting the samples.

Third, a concerted effort should be made to more adequately develop the juniper ring sequence in the area. Traditionally, juniper was not collected because it was difficult to crossdate and not valuable for dendroclimatic purposes. Indeed, the low proportion of dates (2/113) from Pajarito Plateau juniper samples attests to its difficult nature. Many of those samples, however, were collected in the 1960s when the ring sequences had not been intensively analyzed. In other areas, new juniper chronologies are contributing important chronometric data to understanding the past. The development of juniper chronologies and reanalysis of samples from Long House in Mesa Verde, for example, has resulted in a more than threefold increase in the number of dates from that structure (Street 2001). Certainly, such a task will not be easy or quick, but the dividends will be substantial.

Fourth, a serious effort should be made to exploit the "arboreal" dendroarchaeological record. Isolated cultural features, such as ax-cut limbs and stumps, peeled trees, and intentionally burned stumps have been used elsewhere (Montorano 1988; Swetnam 1983; Towner et al. 1998) to date past human activities, even in the absence of high-quality architectural samples. The inhabitants of the Pajarito Plateau, both prehistoric and historic, have exploited the wood resources of the area in various ways. Sampling such features (Figure 7.25) will have at least two benefits (a) it will increase the number of juniper samples and aid in the development of a juniper ring sequence and (b) it will help date land-use patterns through time by the different occupants of the area.

Figure 7.25. An axe-cut juniper limb in the Rio Puerco Valley.

Finally, samples should be collected from all extant historic and prehistoric structures and features exposed to the elements. Such samples can be collected as half-inch or five-eighth-inch cores with minimal impacts to the resource. The wood in these structures is seriously threatened by natural erosion of the outer rings, fire, vandalism, insect infestations, and a variety of other natural and cultural factors. As a non-renewable resource, the information contained in these wood samples is in danger of being lost forever if action is not taken to preserve it.

Dendroclimatology

Dendroclimatology has been used for more than 20 years to characterize past precipitation on the Pajarito Plateau and throughout the northern Southwest. Live-tree and archaeological samples have been combined in various ways to delineate (a) patterns of annual precipitation for more than 1000 years, (b) patterns of spring precipitation in the northern Rio Grande for more than 1000 years, and (c) changes in the spatial distribution of precipitation for almost 1500 years. Reconstructing temperature, on the other hand, has been much more difficult. Only a single temperature reconstruction, albeit 2600 years long, exists for the entire Southwest. Unlike archaeological tree-ring data, dendroclimatological samples do not reflect "points" on the landscape, they reflect broad-scale patterns. Therefore, the recommendations for future research below extend beyond LANL and the Pajarito Plateau.

The most pressing need in southwestern dendroclimatology is another temperature reconstruction with which to compare Salzer's (2000a) SFP reconstruction. Certainly, temperature is more spatially coherent than precipitation, but the SFP are located west of the Continental Divide in the northwest part of the Colorado Plateau and therefore may not accurately reflect temperature trends in the Rio Grande area. Trees that contain a temperature signal, however, are unlikely to be found in the Jemez Mountains or LANL lands. The most likely area to search for such trees is at extreme timberline in the Sangre de Cristo Mountains east of the Rio Grande.

A second important issue for archaeological and other research is more adequately delineating the seasonal patterns of precipitation on the Pajarito Plateau. Annual precipitation patterns have been well documented and Rose et al. (1981) identified spring precipitation variability. Identifying additional seasonal variability in precipitation will aid not only archaeological research, but other fields as well. One possible way to accomplish this goal is to (a) reassess the dendroarchaeological collections for suitable samples and (b) develop chronologies from different tree species along an elevational gradient from the Rio Grande to the crest of the Jemez or Sangre de Cristo Mountains. If appropriate trees are located, we may be able to reconstruct variables such as winter snowpack, as has been done elsewhere (Woodhouse 2002).

Finally, one task that has not been accomplished, but which had important implications for human use of the area, past, present, and future, is the reconstruction of stream flow for rivers in the area. Stream flow depends on many factors (Stockton 1990), but can be modeled using tree-ring data. Three rivers in the area might be amenable to stream flow reconstructions: the Jemez, the Chama, and the Rio Grande. The Jemez may be the easiest to reconstruct because it has a limited watershed with few major tributaries. The Rio Chama, although larger, may be amenable to reconstructions if trees in the upper portions of the watershed and its tributaries can be located. Stream flow in the upper Rio Grande would be the most difficult to model because of the length and numerous climatic factors that influence its flow—trees from the San Juan and Sangre de Cristo Mountains in Colorado, as well as those in New Mexico would be needed to develop such a reconstruction.

Tree-ring reconstructions of various climatic parameters—precipitation, temperature, snowpack, stream flow-- can contribute significantly to archaeological research on LANL properties, the Pajarito Plateau, and the northern Rio Grande in general. As noted above, however, dendroclimatological data are not point data and they have broad interdisciplinary applicability. It is unrealistic, therefore, to expect archaeological or Cultural Resource Management-related projects to fund such research. A broad coalition of pubic and private interest groups is needed to identify the variability in climate that has and will continue to impact the human and non-human populations of the Pajarito Plateau.

CONCLUSIONS

Dendrochronology has a long and distinguished history on the Pajarito Plateau. Beginning with the 1st Beam Expedition and Stallings' development of the Rio Grande chronology, tree-ring data have helped date many archaeological sites and cultural phenomena. Beginning in the 1970s, archaeological and live-tree samples have been used to illuminate various aspects of past climate variability. Pan-southwestern tree-ring data have helped identify aspects of past population movements and adaptations to local and regional environments, as well as help us understand past climate variability over the past two millennia.

Despite the successes of the past 80 years, much work remains to be done. The reanalysis of previously collected archaeological samples, more detailed documentation of new samples, development of an adequate juniper chronology, and collection of non-architectural samples will materially enhance our understanding of the human use of the Pajarito Plateau landscape. New, geographically dispersed live-tree collections, combined with carefully selected archaeological samples will help us document past seasonal precipitation patterns, snowpack amounts, temperature fluctuations, and stream flow in the rivers of the area. These are ambitious goals, but they can be accomplished with dedicated researchers, adequate public and private funding, and continued institutional support.

CHAPTER 8
DENDROCLIMATIC RECONSTRUCTIONS IN THE NORTHERN RIO GRANDE

Ronald H. Towner and Mathew W. Salzer

INTRODUCTION

One of the goals of archaeology is to provide a long-term perspective on human/environment interaction. Humans, like all other species, live in and interact with the environment, and these interactions involve the extraction of both biotic and abiotic resources and respective adaptations to them. The environment—both biotic and abiotic—is constantly changing and does so at many difference scales (e.g., day, month, year, decade, century, and millennium). Through the medium of culture, humans have the ability to modify their environment, but they must also cope with both long- and short-term trends and perturbations in that environment. Thus, understanding past environments helps us understand how past human groups adapted to the ever-changing environment using technology, social organization, and even ideology. This chapter uses recent data to develop new paleoclimatic reconstructions for the Pajarito Plateau in an effort to better understand prehistoric interactions between Pajaritans and their environment (Figure 8.1).

Understanding the past environment of the area is critical for comprehending the adaptations of the past inhabitants to their physical environment. This chapter examines only one aspect (precipitation) of past environments on the Pajarito Plateau. The data and interpretations presented herein have important implications for understanding the Ancestral Puebloan, Puebloan, Hispanic, and Anglo occupations of the area. They may also help illuminate aspects of the AD 700–1100 period when few people lived in the area and will provide insights into the modern climate variability as well. The dendroclimatic reconstruction data presented here are only one component of the human/environment interaction matrix, and it is hoped that it will spur other researchers to investigate other aspects of the matrix.

BACKGROUND AND PREVIOUS RESEARCH

Dendroclimatology was chosen as the method to examine paleoclimate in the project area for several reasons. First, the project area is part of the vast piñon-juniper forest of the Colorado Plateau and Rio Grande (Figures 8.2 and 8.3). In addition, the appropriate tree species such as ponderosa pine (*Pinus ponderosa*), Douglas fir (*Pseudotsuga menziesii*), piñon pine (*Pinus edulis*), and Southwestern white pine (*Pinus reflexa*) are plentiful in the project area, and are excellent natural archives of past environmental and climatic information. Thus, the wood resources are available for many kinds of analysis. Second, dendroclimatology, the study of climate based on annual growth rings in trees, is the most precise and accurate method of reconstructing climate in the prehistoric period. Dendroclimatic reconstructions provide statistically reliable estimates of annual precipitation and/or temperature for each and every year in the study. No other method of studying long-term climate variability can make such a claim.

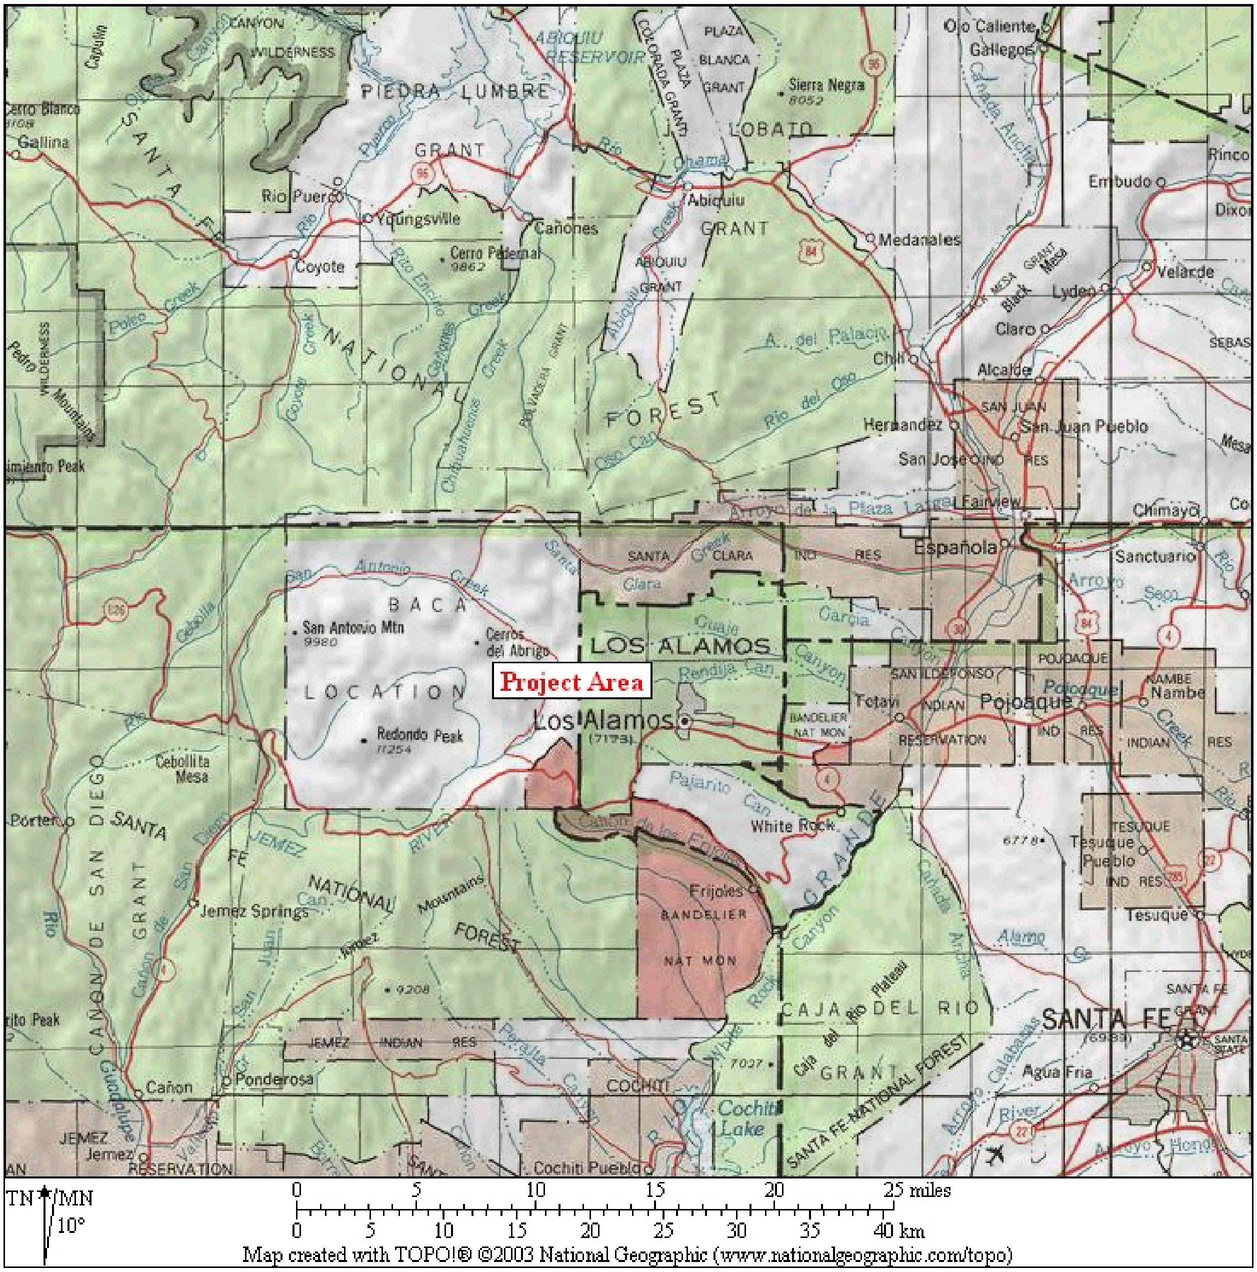

Figure 8.1. Map of the project area.

Figure 8.2. Photo of project area.

The trees of the project area have proven to be quite useful in dendrochronology (tree-ring dating) because they add a single annual layer of cambium (a tree ring) that varies in width depending on climatic conditions in a particular year. The presence of these environmentally sensitive tree species in both the modern vegetation mosaic and archaeological record of the area enables us to use dendroclimatology to examine aspects of past precipitation variation. This study will significantly enhance understanding of past climatic change in the project area and allow archaeologists to better incorporate climatic variations into their interpretations of past cultural adaptations.

A dendroclimatic reconstruction involves developing a mathematical model of the relationship between the environment and the cambial growth of trees (LaMarche 1974; Schulman 1956). Trees are natural archives of information about past environments, and because many are older than the oldest historical documents, they can be used to illuminate aspects of prehistoric climate (Dean 1988; Swetnam and Betancourt 1998). Such archives, however, contain information on a number of different aspects of the environment, and it is necessary to isolate the variables one wishes to study. The specific field collection, laboratory analysis, and statistical procedures described below are designed to eliminate the "noise" in the tree-ring series and highlight the "signal of interest." In some instances, the signal of interest is long-term trends in precipitation, in others it is long-term temperature variability, and in still others it is the short-term spatial differences and identification of extreme events, such as floods or very dry years in specific areas.

Figure 8.3. Photo of project area.

Dendroclimatic reconstructions can provide annual estimates of various climatic variables and are the most precise method for doing so. Dendroclimatology, however, is not without its limitations. First, the technique can only be used for those time periods encompassed by the tree-ring samples; in the Southwest, the time frame is limited to the past two and one-half millennia (Salzer 2000a). Climate variation before about 2600 years ago must be examined using other methods. Second, dendroclimatic reconstructions tend to underestimate the extreme values of particular years. Tree rings tend to underestimate the magnitude of high precipitation (wet) years because in those years water ceases to become the most limiting factor in cambial growth (Fritts 1991). In other words, trees have an adequate supply of water, but some other factor (temperature, nutrient supply, genetics, etc.) prevents uncontrolled cell division and cambial growth (Fritts 1976). In extremely dry years, something of the opposite problem occurs in the Southwest. If a tree does not receive adequate moisture to initiate growth, the result is a locally absent or "missing" ring. The tree, in effect, has recorded "0" moisture for that year even if some precipitation may have fallen. Despite these caveats, tree-ring based reconstructions of climate are the most accurate and precise methods available for examining the past climate variability of the Rio Grande and Colorado Plateau during the past two millennia (Grissino-Meyer 1996; Salzer 2000b).

Dendroclimatology has been used for more than 20 years to characterize past precipitation throughout the northern Southwest (see Chapter 7, this volume for a detailed discussion of past efforts in the northern Rio Grande). On a local and archaeologically oriented level, Orcutt (1999) used many of the previously collected data to retrodict the Palmer Drought Severity Index (PDSI) in the Bandelier area as part of the Bandelier Archaeological Survey. Although not strictly a dendroclimatic reconstruction, Orcutt's detailed examination of the AD 1150–1610 period and use of proxy paleoclimate data have been a major contribution to studies of human/environment interaction in the northern Rio Grande. Orcutt's Agricultural Risk Model is discussed in more detail below.

The following are reasons why a new climate reconstruction was needed:

1. Both the tree-ring and climate data for the previous reconstructions end in the late 1970s (Dean and Robinson 1977; Rose et al. 1981). The addition of 30 years of both tree-ring and climate data resulted in an almost 20 percent increase in the period of overlap needed to calibrate the tree-ring/climate relationship. This longer period of overlap is critical and resulted in much stronger correlation coefficients and increased our confidence in the results significantly.
2. By using climate data from individual stations, instead of divisional data, the reconstruction much better reflects the conditions in the local project area.
3. Using these climate station data and new tree-ring chronologies also enabled us to document spatial variability within the project area.

THE PAJARITO DENDROCLIMATIC RESEARCH DESIGN

Developing new chronologies and retrodictions of past precipitation were the bases of this project. Certainly, other aspects of past climate, such as temperature, played a role in human use of the Pajarito Plateau. Precipitation, however, is the most direct measure available and was probably the most important for prehistoric and historic period agriculturalists.

This project had four specific goals for elucidating past aspects of human/environment interaction through the retrodiction of past precipitation: low-frequency variation, high-frequency variation, spatial variability, and evaluating agricultural risk. We wanted to

1. Examine the low-frequency variability in the precipitation signal. Low-frequency variation is important because it is the climatic condition adapted to by human groups;
2. Examine high-frequency variation in the dendroclimatic record. High-frequency variation is important because it contains the signal of extreme events that may have seriously impacted local populations on a short-term basis;
3. Document the spatial variability in precipitation within the project area. For example, we wish to examine geographic areas that were affected differently than others;

4. Evaluate the climatic variability aspects of the Agricultural Risk Model developed for the area by Orcutt (1999).

METHODS AND PROCEDURES

Field Research and Methods

An important component of this project was to collect samples from living trees in the project area. Initially, our goals were to collect long-lived trees throughout the project area in order to provide data relevant to both past temporal and spatial retrodictions of two climate parameters: precipitation and temperature. As we conducted the field work, however, it became clear that we would have to modify our goals.

Our first problem is that there are very few long-lived trees in the area; most trees are less than 500 years old. We observed few trees that exhibit characteristics of old age, such as stripped bark, spiral grain, and spiked tops (cf. Schulman 1954). Indeed many of the trees in the area appear to have germinated in the early 1600s following a massive die-off during the mega-drought of the 1560s to 1590s (Swetnam and Betancourt 1998). This pattern, massive die-off in the late 1500s and extensive tree recruitment in the early 1600s, has been documented in many areas of the Southwest (Allen et al. 1998; Betancourt et al. 1993; Savage et al. 1996).

Second, the lack of high-altitude temperature-sensitive trees prevents us from retrodicting Pajarito temperature variability. Salzer's (2000b) San Francisco Peaks, Arizona, retrodiction may be relevant, but a Rio Grande area temperature retrodiction is badly needed.

Field Methods

The field work component of the project included extracting 318 cores and cross-sections from 166 climatically sensitive old trees at 11 sites (Table 8.1).

Table 8.1. Description of live-tree collections.

Collection Site	Species	Trees	Cores	Date Range	Measured?	Previous Chronology	Old Measurements?	Used in Reconstruction

Pine Springs Resample	PP	17	34	1767–2005	Y	Y	Y	YES
Totals		**166**	**318**					

No juniper trees were sampled as part of this project because they exhibit more variability within individual rings and are much more difficult to measure accurately. Using a Swedish increment borer (Figure 8.4), cores were taken from the lowest practical location on the tree bole in order to maximize the number of rings available for analysis.

Figure 8.4. Photo of sampling with increment borer.

When possible, two cores were collected from each tree in order to minimize the within-tree variation in ring width; likewise, multiple trees were sampled at a single site (always more than 10 trees if possible) in order to reduce the between-tree variation in growth. These sampling strategies help ensure that the resulting site-specific ring sequences reflect a common growth parameter, in our particular case, precipitation, and that other "noise" is averaged out of the chronologies (Fritts 1976).

Collected during November 2005, our samples are distributed on and around the Pajarito Plateau (Figure 8.5). Six of the live-tree sites have been collected previously but the data were never used due to funding shortages; the data, however, existed in paper form at the Laboratory of Tree-Ring Research (LTRR) and were entered into a computer database for use during this project. Our re-sampling at these sites was designed to update the ring sequences and provide an additional 30 years of ring-width data against which to calibrate the precipitation data.

Our five new chronologies were distributed throughout the project area, although four species-specific chronologies are all located on Mesa Alta; the only new chronology on the Pajarito Plateau is Upper Los Alamos. Table 8.1 presents some descriptive data for these chronologies and merits additional explication. Although we attempted to collect two cores per tree, some cores were unsuitable because of breakage, interior heartwood rot, pitch pockets, or other idiosyncratic abnormalities. The table also illustrates that trees greater than 500 years old are difficult, if not impossible, to locate in the project area. In addition, the Caja del Rio live tree site could not be adequately re-sampled because the trees died during the recent drought and beetle infestation.

Laboratory Research and Methods

After the end of field work, the first step in chronology development and climatic reconstruction is cross-dating each of the live-tree samples. Each of the chronologies used in the reconstruction was developed completely independently of the others; thus, each can be considered an independent test of the cross-dating method. By cross-dating the cores against each other and the "New Mexico I" master chronology (Robinson et al. 1972), we were able to determine the year each and every ring grew. Although different cross-dating methods are used in different parts of the world, the LTRR uses the ‘skeleton plot’ method of cross-dating (Stokes and Smiley 1968). Skeleton plotting is an analog method of representing the narrow rings on a sample using graph paper (Figure 8.6). By comparing skeleton plots of many different samples, a master skeleton plot can be developed that extends further back in time and contains more information than any single sample. Area l master plots are developed and extended further back into the past by overlapping samples from living trees, dead snags, and archaeological specimens (Figure 8.7).

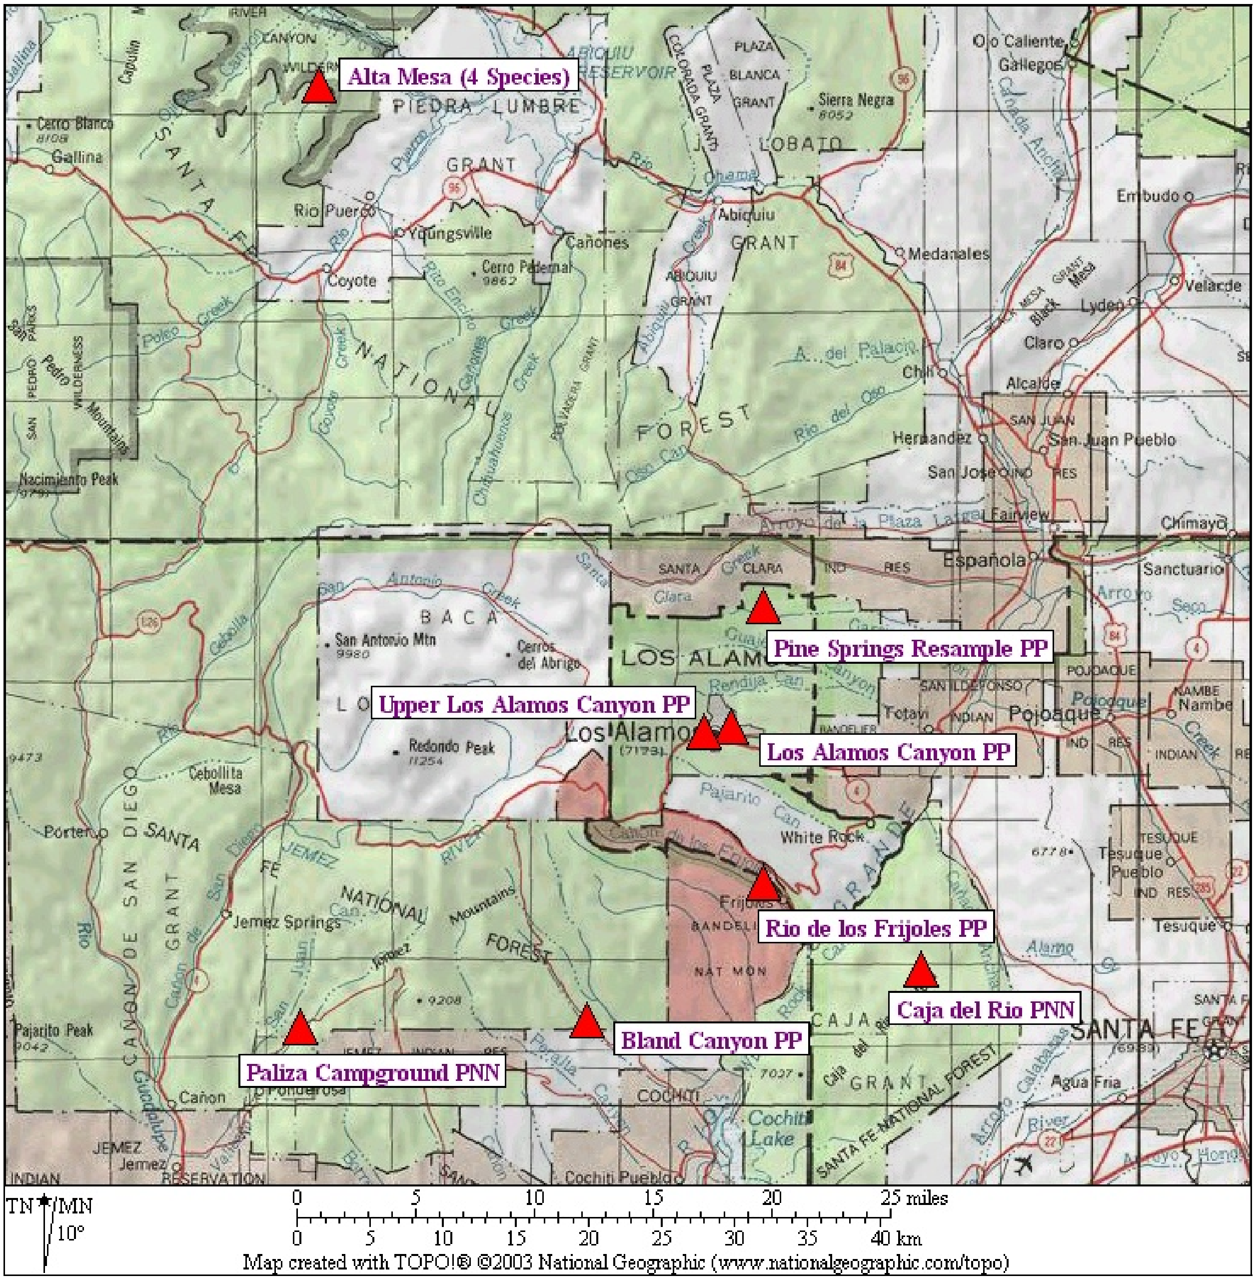

Figure 8.5. Map of live-tree sample locations.

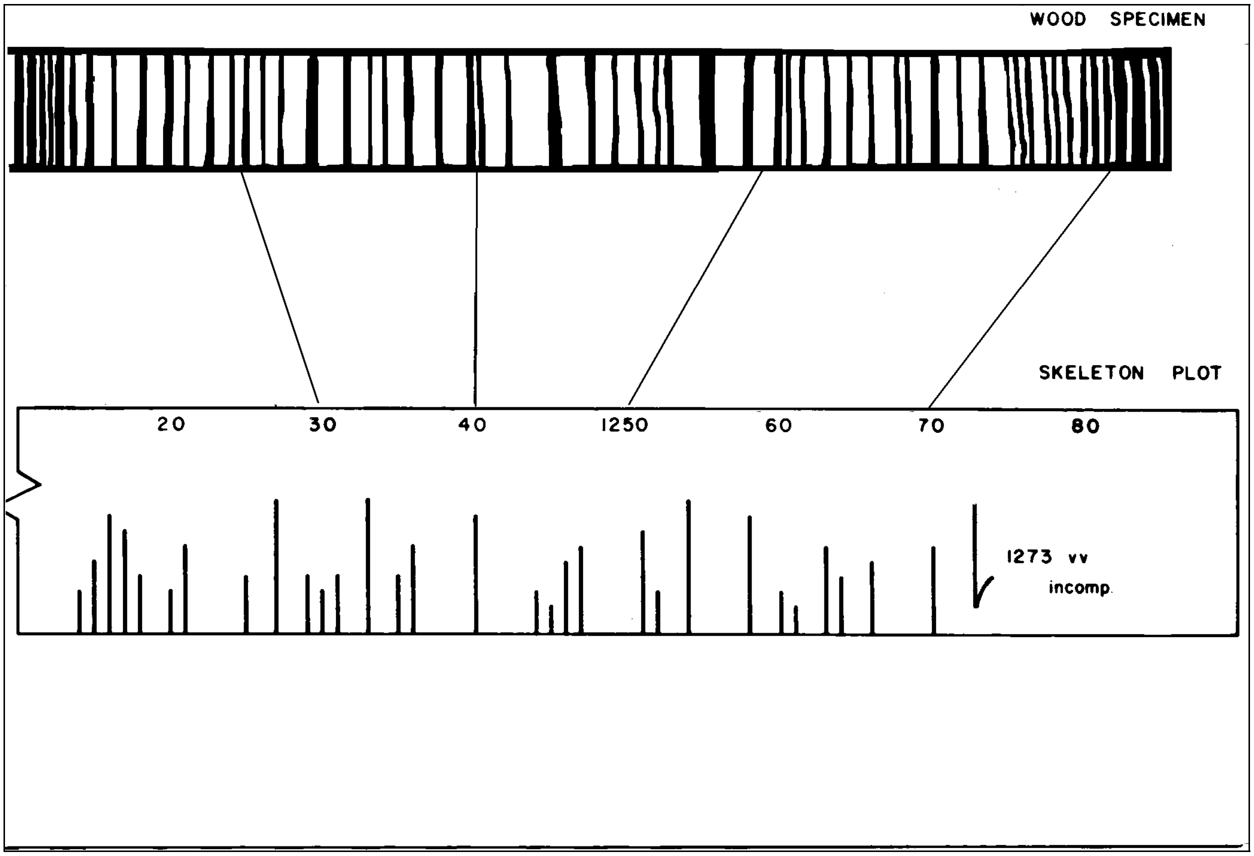

Figure 8.6. Skeleton plotting technique.

Statistical Methods: Building Quantitative Tree-Ring Chronologies

A master skeleton plot is not a tree-ring chronology, however; it is simply a graphical representation of relative ring widths—very useful for dating, but less useful for reconstructing climate. In order to develop a quantitative chronology of the cross-dated ring series, each ring on each sample must be measured to the nearest 0.01 mm. The LTRR uses a Velmax microscopic measuring system (Figure 8.8) that automatically inputs the measurements onto a computer disk. For this project, we measured 33,004 individual rings from the live-tree samples (Table 8.2); other samples used in the reconstruction (see below) had been measured previously.

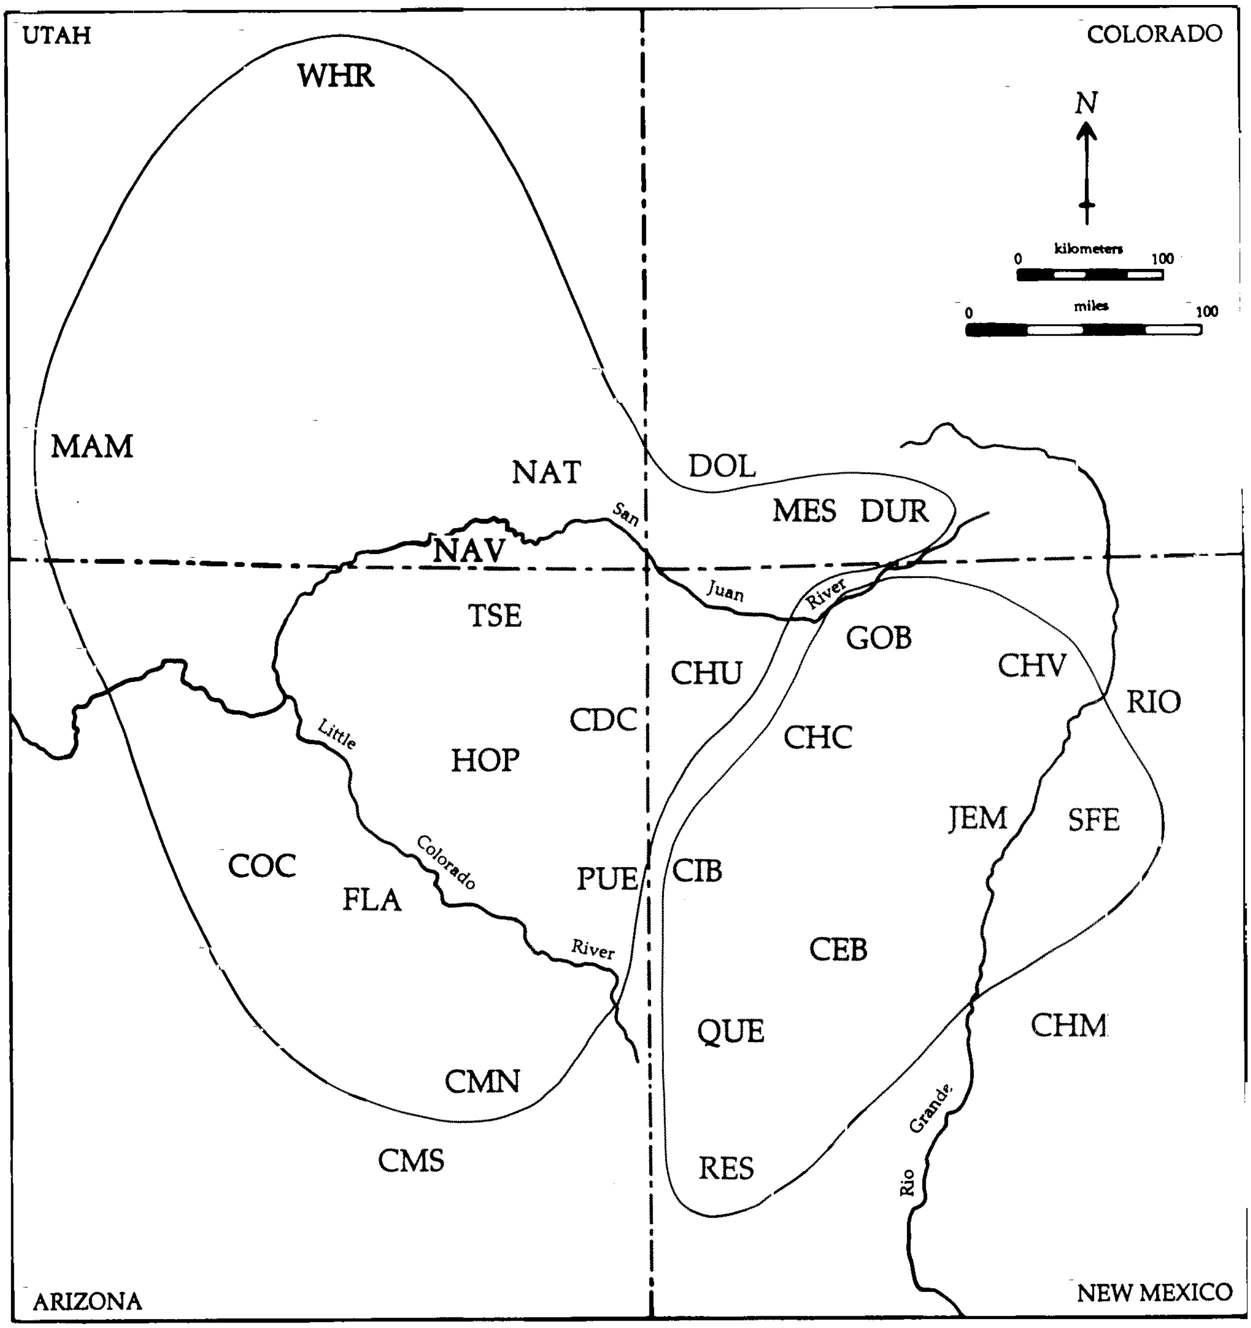

Figure 8.7. Chronology building process.

Measuring the samples provides more information than simply ring width. By using the computer program COFECHA we were are able to evaluate the accuracy of our cross-dating and determine the strength of our chronologies (Holmes 1983). The computer program also enables us to measure the within- and between-tree variation, and compare the mathematical correspondence of each of our chronologies.

Table 8.2 shows the descriptive quantitative data that guided our sample and chronology selection. The variables shown in the last three columns of the table show the utility of the chronologies for dendroclimatic purposes. The series intercorrelation is a measure of how much variability in individually dated rings exists in the chronology (i.e., how much variability is seen in the AD 1729 ring among the trees at the same site). Simply put, the series intercorrelation indicates how much ring-width variation in the series is common to all trees—and presumably due to climate. Therefore, the higher the series intercorrelation, the stronger the climate signal in our chronologies. The correlations are similar, but the Alta Mesa Douglas-firs show the highest correlation.

Mean sensitivity is a statistic developed in dendrochronology that considers the frequency of missing rings, series intercorrelation, and other factors. In theory, mean sensitivity can vary between "0" and "2." A mean sensitivity of "0" indicates no ring-width variability meaning that all rings are exactly the same size. Conversely, a means sensitivity of "2" indicates that every other ring in the series is missing (50% missing rings). In practice, neither of these extremes is reached because such samples cannot be cross-dated—the "0" series because there is no variability and the "2" series because there is too much variability. Typically, mean sensitivity varies between 0.25 and 0.75, depending on the species, tree age, and site location. Again, our chronologies are similar, although the Pine Springs chronology is the most sensitive.

The percent of missing rings is also a general indicator of site growing conditions and contributes to mean sensitivity. Whereas Upper Los Alamos, Los Alamos Canyon, and Alta Mesa are relatively mesic sites, Pine Springs and Paliza Campground are relatively arid and the trees are subject to more water stress. Finally, Douglas-firs tend to have fewer missing rings than other tree species. This attribute of Douglas-firs is important because it allows us to cross-date more samples and verify the cross-dating of samples with more missing rings. After initial evaluation using COFECHA, some trees and cores were deemed unsuitable for quantitative analysis and were not included in the reconstruction.

Standardization

The next step in the reconstruction process is to standardize each ring series and create tree-ring indices for the samples. Standardization is accomplished using a curve-fitting equation and results in all series having a mean of "0" and a standard deviation of "1." This process eliminates the size- and age-related ring-width variability (i.e., rings near the pith are larger than those near the outside of the tree), retains the climate signal, and makes the ring series comparable. In the initial chronology building procedure, we standardized the ring series using the computer program ARSTAN. All measured ring-width series were standardized conservatively through the fitting of a modified negative exponential curve, a straight line, or a negatively sloped line to the series. This process removes the age/size related growth trend and transforms the ring-width measurement values into ring-width index values for each individual ring in each series (Fritts 1976). By averaging the annual standardized indices of tree growth, we created mean site chronologies for each site. In general, these conservative standardization techniques and the use of long series preserve low-frequency information in the resulting chronologies (Cook et al. 1994). This process resulted in six independent, quantitative tree-ring chronologies that could be selected for the climate reconstructions**.**

Calibration of the Tree-ring/Climate Relationship

The next step in the reconstruction is calibrating the tree rings against modern climate data and assessing the strength of that relationship. This step necessitates (a) testing the association between the modern part of the chronology and instrumental climate data to determine the strength and seasonality of the climatic influence on tree growth with correlation analysis; (b) calibrating the climate data and the tree-ring chronology using a statistical scaling technique; and (c) retrodicting past climate for the length of the tree-ring chronologies. See Fritts (1976) for more details on developing dendroclimatic reconstructions. Two calibrated and verified reconstructions of wet-season (previous October through June) precipitation were developed from the tree-ring chronologies—one for the northern region (Chama) and one for the southern region (Jemez Springs). Each of these reconstructed time-series of past precipitation was then smoothed using a 20-year cubic smoothing spline. The final products are four time series: two for the northern part of the study area (one to emphasize high-frequency [annual] variability and one to emphasize low-frequency variability) and two for the southern part of the study area (similarly, one high frequency [annual] and one low frequency).

We compared the tree-ring indices for the modern period with instrumental precipitation data from the United States Historical Climatology Network (USHCN). These data are part of a quality-controlled network and are considered highly reliable. In the southern section, we compared four tree-ring series to USHCN data from Jemez Springs, New Mexico. In the northern section, we compared USHCN data from Chama, New Mexico, to the two tree-ring series. In both cases, correlation analysis showed a strong positive correlation between wet-season (previous October through June) precipitation and tree-ring index. There is negligible correlation between summer precipitation and tree growth. This is consistent with other tree-ring based precipitation reconstruction studies in the U.S. Southwest ((D'Arrigo and Jacoby 1991). For each "year" the precipitation amounts for previous October to June were totaled. These amounts form the basis for the calibration with the tree-ring data.

Growth processes of lower-elevation trees in the Southwest often are limited by climatic conditions during a period before the actual growing season (Fritts 1976). Ring-width variability can reflect changes in precipitation amounts from the fall/winter seasons before the trees' growing season through the growing season of ring formation. The period from the previous October through June of the growing season is the seasonal climatic interval most highly correlated with annual tree-ring width and was determined to be the interval when precipitation had the greatest effect on tree growth. Monthly values for this period were summed for the individual years to create the final climate series used in the reconstructions. Consequently, the variable being reconstructed is prior-October through current June precipitation.

In total, there are six new (seven modern living-tree) and two archaeological tree-ring series used in the reconstructions. Because of the absence of long-lived trees in the project area, previously measured ring-width series of beams from archaeological sites (LTRR files) were appended to the earlier portions of measured series from living trees near the sites in order to substantially lengthen the records. In both the northern and southern portions of the study area, the archaeological chronologies are shown to be consistent with the modern living-tree chronologies used in the calibration (Figures 8.9 and 8.10). This is an important point and suggests that the new living-tree chronologies are an adequate analog for what occurred in the past—the earlier portion of the reconstructions. The southern and northern chronologies were lengthened in the following manner.

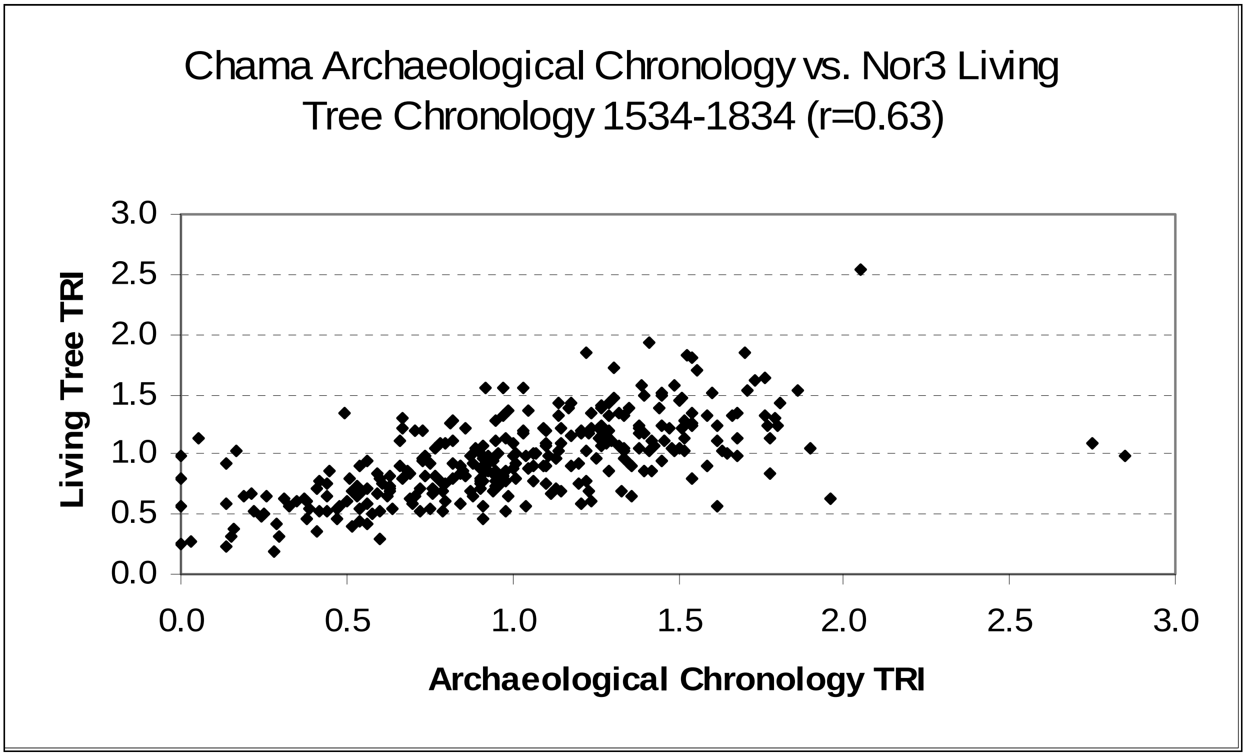

Figure 8.9. Correlation of archaeological and living tree samples from Chama.

At Jemez, we took an average of the tree-ring indices from four new sites: Paliza Campground (piñon), Upper Los Alamos, Los Alamos Canyon, and Pine Springs (all ponderosa pine). This process of combining or compositing several chronologies into a single series reduces non-climatic "noise" in the tree-ring data and strengthens the climatic signal. The new tree-ring average chronology extends back to AD 1645 and correlates very well with the Jemez Springs USHCN previous October to June precipitation series (r = 0.78, 1911–2002). Before AD 1645 (AD 598–1644), the Jemez archaeological chronology was used.

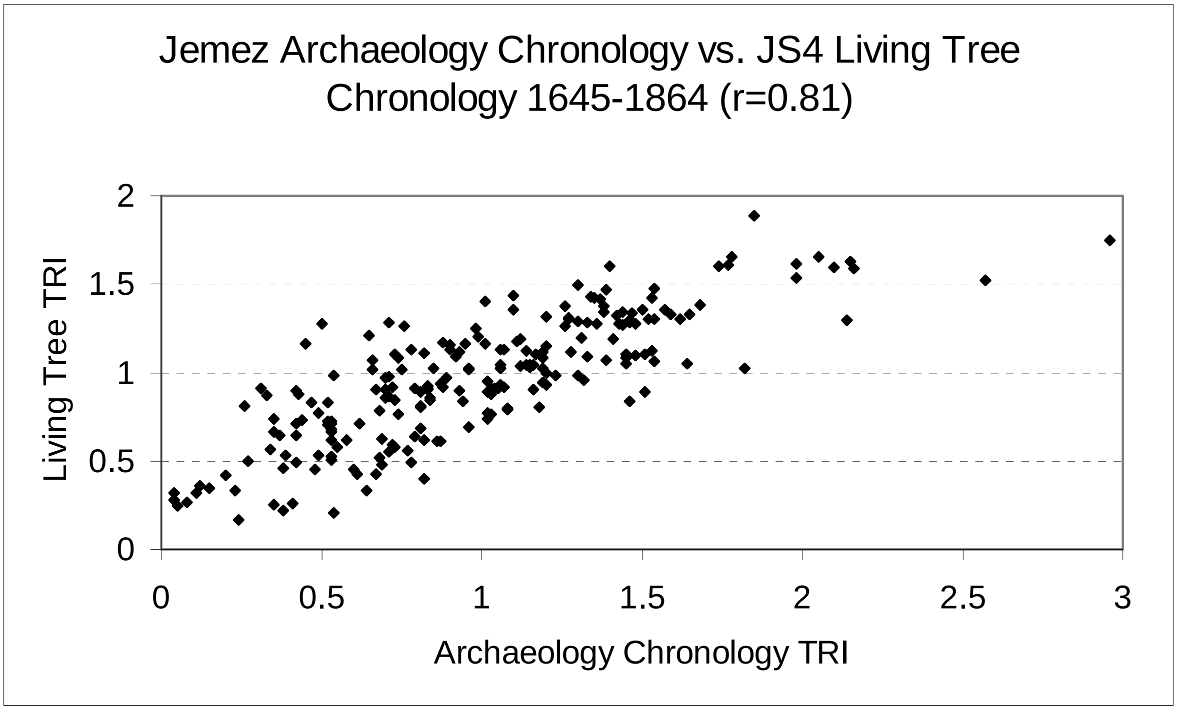

Figure 8.10. Correlation of archaeological and living tree samples from the Jemez.

For the northern reconstruction at Chama, we used two new tree-ring chronologies, both from Alta Mesa, New Mexico (Douglas-fir and piñon). These extend back to AD 1534 and correlate well with modern USHCN precipitation data from Chama (r = 0.66, 1889–2002). The tree-ring series used in the northern reconstruction is a more complicated composite than that used in the southern reconstruction. In the earliest part, AD 759–1361, it consists only of the Chama archaeological chronology (LTRR files); from 1362 to 1533, it is the archaeological chronology combined with the Echo Amphitheatre living tree chronology collected in the 1970s (Dean and Robinson 1977); from 1534 to 1834 it is an average of the new Alta Mesa chronologies and the Chama/Echo chronologies; from 1835 to 1972 it is an average of the Alta Mesa and Echo chronologies without any archaeological wood; and from 1973–2002 only the new Alta Mesa average was used.

For both Jemez and Chama, we scaled the tree-ring width index values to the previous October to June precipitation instrumental data for the period of record to equate their means and standard deviations (Figures 8.11 and 8.12). Scaling in this manner has been used as a calibration device in some recent multi-proxy reconstructions of past temperature (Moberg et al. 2005). This type of calibration, as opposed to regression techniques, tends to maintain rather than suppress amplitudes. It is clear that the ring-width variability and reconstructed precipitation anomalies co-vary in both their interannual and decadal-scale frequencies.

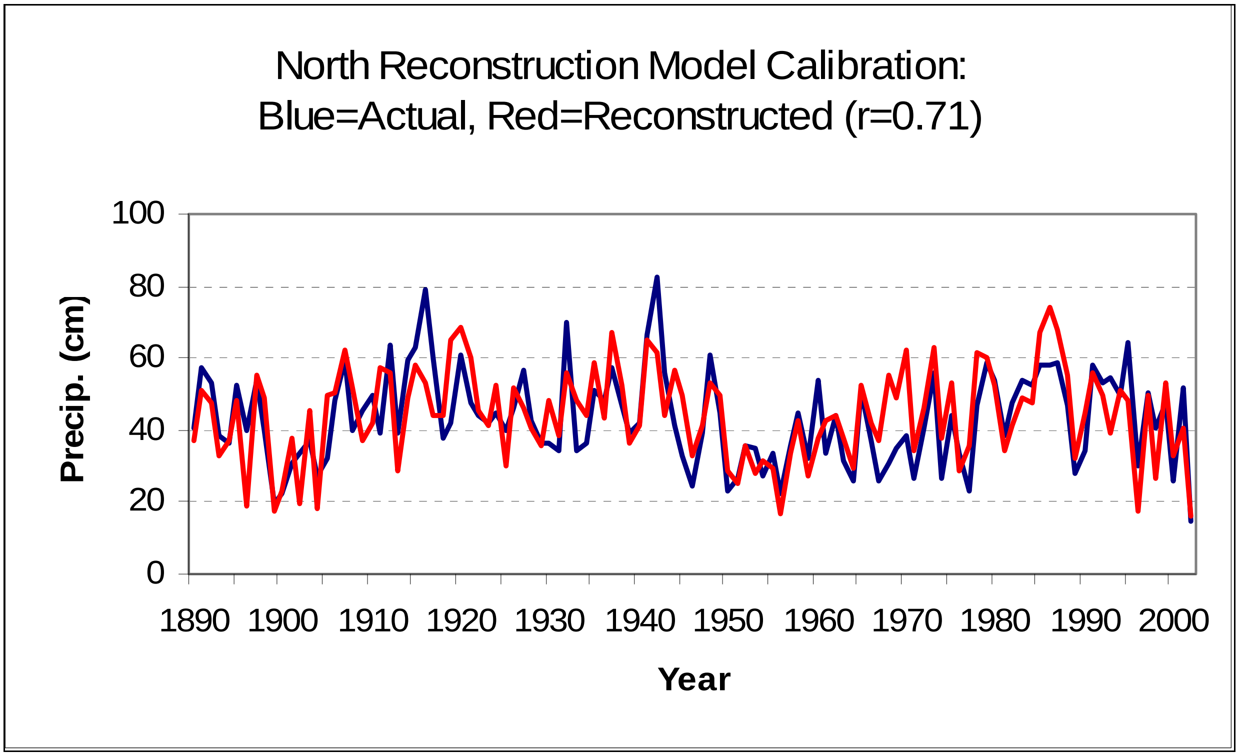

Figure 8.11. Calibration period comparison of Chama tree growth and historical data.

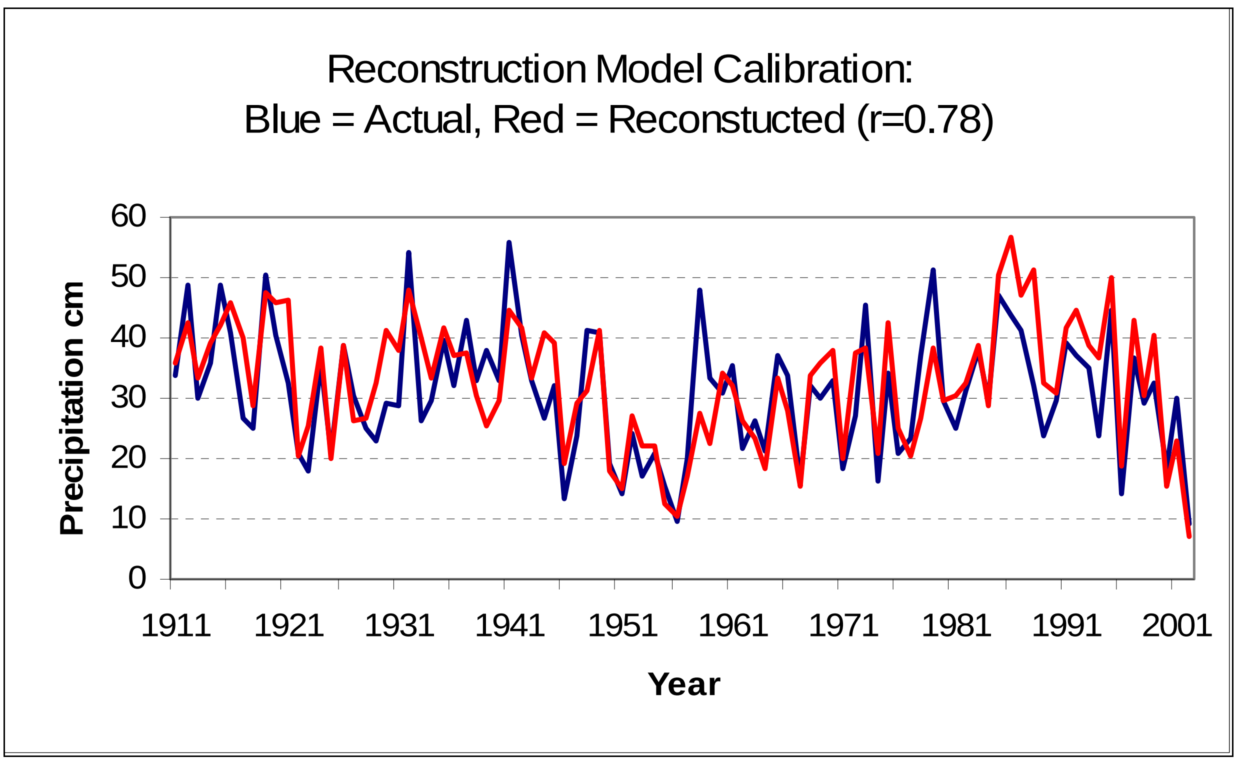

Figure 8.12. Calibration period comparison of Jemez tree growth and historical data.

The calibration followed Moberg et al. (2005) and can be formally expressed as follows:

$$P(t) = f \cdot R(t) + c ,$$

where P is the instrumental precipitation data, R is the ring-width index chronology, f is a variance scaling factor, c is a constant that adjusts the mean, and t is time. The factor f and constant c are derived by:

$$f = S_P/S_R \qquad \text{and} \qquad c = P_{(mean)} - f \cdot R_{(mean)}$$

where S_P and S_R are the respective standard deviations of the instrumental precipitation data and the ring-width index chronology in the overlapping interval and $P_{(mean)}$ and $R_{(mean)}$ are the corresponding means. The long Jemez and Chama tree-ring chronologies were scaled in this manner to produce the southern (Jemez) and northern (Chama) precipitation reconstructions (see below).

RESULTS

Jemez Chronology: Long-Term, Low-Frequency Precipitation Trends

The Jemez reconstruction of low- and high-frequency trends in precipitation in the Pajarito Plateau area is shown in Figure 8.13; the raw data are presented in Appendix H. The long-term precipitation mean for the area is 31.32 cm per tree-year, and the standard deviation is 10.49 cm per year. For any substantial period of time (100+ years) over the course of the reconstruction, the mean changes very little. Several aspects of the reconstruction merit detailed discussion.

First, overall, Figure 8.13 shows the most variable precipitation between AD 600 and approximately AD 900; the extremes are both higher and lower during this period than during most other periods. Another period of significant variability is the late 1400s through the early 1600s. Extreme highs in the early and late 1500s are contrasted with deep lows in the mid to late 1500s. In contrast, periods of generally low variability include the late 1200s through the early 1400s and the 1700s and early 1800s.

If variability is measured in overlapping 20-year increments, however, a different picture emerges. The AD 600 to 900 period shows variability, but most of the fluctuations are near or above the mean. Beginning in the late 800s, a significant decline in precipitation lasts through the early 10th century. Temporal variability changes about AD 1000 and lasts until the beginning of the 15th century. The peaks and valleys of the graph are farther apart, indicating precipitation was variable at longer time scales, even if mean precipitation was lower. This low-frequency variation is typically the type of change to which human societies adapt (Doyel and Dean 2006; Dean et al. 1994). The period from about 1500 though the late 1800s is characterized by higher frequency changes, particularly after AD 1700. Lower-frequency changes returned in the 20th century.

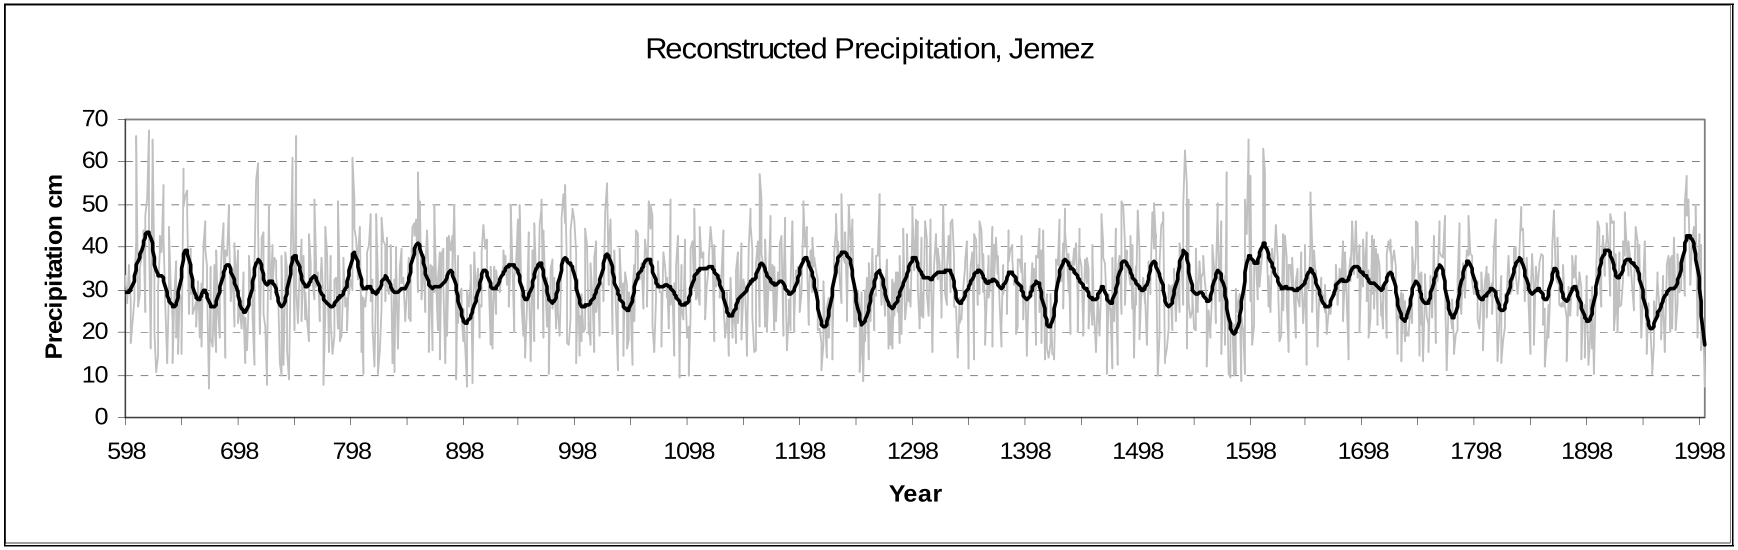

Figure 8.13. Annual and splined precipitation graph for the Jemez chronology.

In terms of absolute precipitation, high precipitation periods tend to be slightly more common in the early part of the reconstruction and low precipitation periods more common after AD 1200. Notable droughts are centered on the late 800s, the late 1000s to early 1100s, the late 1200s, the early 1400s, the late 1500s, the late 1800s, and the mid-1900s. Wetter intervals include the early 600s, the late 700s, the mid-800s, the early 1200s, the early 1400s, the early 1600s, the early 1900s, and the late 1900s.

Jemez Chronology: High-Frequency Variation

By statistical definition, any year within one standard deviation of the mean (e.g., between 20.83 and 41.81 cm of precipitation per year) would be considered normal. Embedded in the annual precipitation values is information concerning high-frequency variation and extreme years that may have significantly impacted human groups in the Pajarito area. If a year with a precipitation value within a single standard deviation of the mean is considered normal, those outside of the range can be considered extreme to some degree. Towner (1997) suggests that "Good" and "Bad" years can be defined as more than one standard deviation from the mean and "Very Good" and "Very Bad" years defined as two standard deviations above or below the mean, respectively.

Most century-long periods exhibit similar numbers of extremely good and extremely bad years. This pattern is an illustration of the variability and short-term unpredictability of precipitation on the Colorado Plateau (cf. Euler et al. 1979). Indeed, over the length of the reconstruction, slightly more than 30 percent of the annual values are more than one standard deviation from the long-term mean. In human terms, these data indicate that almost one in every three years was either ‘Good,’ ‘Bad,’ ‘Very Good,’ or ‘Very Bad.’ Given the human propensity for remembering stressful times, it is not surprising, therefore, that historical documents and even oral traditions have recorded more "drought" times than times of plenty (Reeve 1958, 1959).

It is instructive to examine extreme years on a century by century basis (Table 8.3) keeping in mind that the century designation are an artificial division based on the Christian calendar. Several centuries stand out as unusual.

Table 8.3. Extreme years by century, Jemez chronology.

Century	Century Mean	Very Good	Good	Average	Bad	Very Bad
600–699	32.62	7	12	62	18	1
700–799	30.42	5	8	67	16	4
800–899	32.43	3	12	69	13	3
900–999	31.82	2	15	62	18	3
1000–1099	30.24	1	11	66	20	2
1100–1199	31.47	1	10	72	17	0
1200–1299	30.83	1	14	67	17	1
1300–1399	32.27	0	13	77	10	0
1400–1499	30.89	0	11	69	19	1
1500–1599	30.83	**6**	**13**	**59**	**17**	**5**
1600–1699	32.34	3	4	82	11	0
1700–1799	30.27	0	8	77	17	0

Century	Century Mean	Very Good	Good	Average	Bad	Very Bad
1800–1899	29.77	0	6	81	13	0
1900–1999	32.69	1	14	69	16	0
2000–2002	n/a	0	0	1	1	1
Total		**30**	**151**	**980**	**223**	**21**

The 600s exhibited the second highest century mean and had equal numbers of extreme years. The high number of 'Very Good' years (n = 7) were all concentrated in the first 52 years of the century. Strings of consecutive 'Good' years occurred in 616–619 and 649–653, and only one consecutive string of 'Bad' years occurred (627–628).

The 700s were below the long-term precipitation average and experienced 20 'Bad' or 'Very Bad' years and five 'Very Good' years (all in the first half of the century). Consecutive 'Good' years occurred in 714–716 and there was never a string of three consecutive 'Bad' years. Thus, the last half of the AD 700s were certainly not optimal for rainfall-dependent agriculturalists. We leave it to Pajarito area archaeologists to discuss the potential cultural adaptations to this extremely dry period.

The following century (AD 800s) is notable for a return to higher precipitation values, and a "normal" number of extreme years. 'Good,' 'Bad,' 'Very Good,' and 'Very Bad' years occurred in almost the same frequency and were more or less evenly distributed throughout the century. Three 'Good' years (AD 800–802) started the century and is the only three-year period of either extreme.

The AD 900s had a relatively high number of extreme years (n = 38) and slightly above average precipitation. Consecutive extreme years occurred three times, all late in the century (AD 966–968, AD 986–989, and AD 994–997). In general, the century was drier early and wetter late.

The AD 1000s were, on average, the driest century in the reconstruction period, and contained 34 extreme years; there were only two 'Very Bad' years, but 20 'Bad' years. All but one of the 'Good' years occurred before AD 1067, but there were two 'Good' consecutive-year periods (AD 1024–1026 and AD 1063–1066). In general, the latter half of the century was drier than the first half.

The AD 1100s exhibit near mean precipitation and slightly fewer extreme years; no consecutive-year extremes were noted in the century. The mid-1130s were dry. Six of the 10 years in the decade were 'Bad,' but in general, extreme years were distributed more or less evenly throughout the century. This period coincides with the "Chaco drought" farther west, but does not appear to have been extreme in the northern Rio Grande area

The AD 1200s exhibited below average precipitation, some extreme years (n = 33), but positive and negative departures from the mean were more or less equal. The only string of 'Good' years occurred in AD 1216–1218, and no bad strings were identified. In general, the AD 1230–1250 period was wet, as was the AD 1290–1299 period, but the middle of the century was dry. The Great Drought (AD 1276–1299) of the Four Corners area appears to have been much shorter and less severe in the Pajarito area

The AD 1300s present a very different story. They were one of the wettest centuries in the reconstruction, had the most average years, and contained no 'Very Good' or 'Very Bad' years; nor were there any consecutive three-year periods of extreme precipitation. In short, the AD 1300s were relatively wet and consistent. Extreme years, 'Good' or 'Bad,' were distributed more or less evenly and never occurred for long periods of time.

The AD 1400s were much drier and experienced more 'Bad' years than 'Good' and there were two multi-year extreme periods (AD 1418–1420 and AD 1422–1424). In particular, the early part of the century was much drier than normal, and wet years occurred only infrequently.

The AD 1500s were also quite dry, but contained the highest frequency of extreme years in the entire reconstruction (n = 41). 'Very Good' years were offset by 'Very Bad' years. Consecutive multi-year 'Good' periods include AD 1519–1521, AD 1539–1541, and AD 1594–1597; 'Bad' periods include AD 1522–1524 and AD 1579–1561. It is interesting to note that some of the wettest years in the entire reconstruction occurred when Coronado was encamped in New Mexico (AD 1539–41) and just before Oñate's colonization of the Rio Grande (AD 1594–1597). The megadrought of the AD 1570s–1590s noted elsewhere appears to have been shorter (AD 1573–1593) and less severe in the Pajarito area; it contained six 'Bad' and three 'Very Bad' years that were only partially mitigated by one 'Very Good' year. Because the annual means were consistently low, even if not extreme, the dry years probably had a more deleterious effect on the local environment.

The AD 1600s contained fewer extreme years than any other century in the reconstruction and there were no three-year extreme periods. The latter half of the century was certainly more variable than the early part, but exhibited many 'Good' years. The idea that a drought played a major role in the Pueblo Revolt of 1680 is not supported by the dendroclimatic data. The year of the revolt (AD 1680) was an average year (41.55 cm) in the Pajarito area, and no 'Bad' years occurred between AD 1676 and AD 1684. Historical references to drought, therefore, are probably better interpreted as food shortages caused by severe disruptions in trade, labor, scheduling, and tribute responsibilities of the Rio Grande pueblos. Clearly, the causes of the Pueblo Revolt lie in the social and economic policies of the Spanish Colony, not in environmental perturbations

The AD 1700s were relatively dry; mean precipitation was 30.27 cm, but the century contained neither 'Very Good' nor 'Very Bad' years. 'Bad' years (n = 17) far outnumber 'Good' years (n = 8), and there were two strings of 'Bad' years (AD 1737–1739 and AD 1779–1782), but no strings of 'Good' years. The latter half of the century was probably drier than the first half, but some wet years did occur.

The AD 1800s were the driest century in the reconstruction (mean precipitation 29.77 cm), but contained neither 'Very Good' nor 'Very Bad' years. The only consecutive string of extreme years was the AD 1839–1841 dry period.

The AD 1900s are notable for two trends. The century mean is the highest in the reconstruction (32.69 cm), and there was significant variability. The first few years of the AD 1900s were marked by drought as were the mid-1950s. In contrast, the late 1910s and mid-1980s were wet.

Jemez Chronology: Extreme Events

Extreme events can have serious impacts on human societies. Extreme droughts may lead to crop failures, changes in storage technologies and agricultural strategies, site abandonments and migrations, and many other sociological and technological changes. Likewise, high precipitation years or events may lead to flooding and crop failure, increased erosion and arroyo cutting, and even such phenomenon as increased disease-carrying rodent populations (e.g., hantavirus).

Table 8.4 presents the 25 highest and 25 lowest precipitation years in the Jemez reconstruction. The range of precipitation is quite impressive, ranging from a low of 6.91 cm in AD 672 to a high of 67.42 in AD 618. Nine of the driest years and eight of the wettest years fall within the Bandelier chronology periods defined by Orcutt (1999; see below).

Table 8.4. Twenty-five wettest and driest years in the Jemez reconstruction.

Jemez		Jemez	
Year	**Driest**	**Year**	**Wettest**
672	6.91	618	67.42
901	7.15	608	66.20
2002	7.15	749	65.96
723	7.89	622	65.47
774	7.89	1596	65.47
907	8.13	621	63.27
1254	8.62	1610	63.03
1590	8.62	1540	62.79
743	9.11	800	61.08
892	9.11	746	60.83
1580	9.35	715	59.61
1090	9.59	649	58.64
736	9.84	858	57.66
1099	9.84	1611	57.66
1516	9.84	1577	57.42
1583	9.84	1162	57.17
823	10.08	1599	56.93
975	10.08	1986	56.64
1585	10.08	714	55.95
1904	10.32	1026	54.98
809	10.33	989	54.73
1471	10.33	631	54.49
1579	10.33	1541	54.49

Jemez		Jemez	
Year	Driest	Year	Wettest
1593	10.33	1597	53.76
1956	10.43	652	53.27

In terms of centuries, the AD 1500s stand out as unique with seven of the 25 driest years as well as six of the 25 wettest years. Such variability almost certainly was a challenge for the Puebloan occupants of the area. However, the centuries from AD 800–1500 were relatively free of these extreme years; particularly the period from AD 1100–1500, which experienced two extremely dry years and a single extremely wet year. As noted above, critical years of the Spanish exploration and colonization of New Mexico were quite favorable. Coronado experienced two wet years in AD 1540 and AD 1541; Oñate marched up the Rio Grande on the heels of wet years in AD 1596 and AD 1587 and experienced a wet year in AD 1599; later, he moved the capital during the two wettest years, AD 1610–1611, of the 17th century. We present the raw data in Appendix H so that Pajarito area archaeologists may explore any possible relationships between extreme events and cultural changes.

Jemez Chronology: The Bandelier Archaeological Periods

Orcutt (1999) developed an archaeological chronology of the Bandelier area based primarily on seriation of ceramics. Because we are interested in the entire human occupation of the area, we added several periods to the Orcutt chronology (see below). These periods are defined based on political events in New Mexico history and may or may not correlate with the archaeological or climatic records.

Period 1 (AD 1150–1190)

This period is defined as the Early Coalition and represents the initial settlement of the Bandelier area (Orcutt 1999). The period has a mean of 31.91 cm and standard deviation of 11.26 cm, both of which are greater than their long-term counterparts. ‘Bad’ years outnumber ‘Good’ years and there is only one ‘Very Good’ year (AD 1162), which ranks as the 16th wettest year in the chronology. ‘Good’ and ‘Bad’ years are distributed about evenly throughout the period and there are no consecutive strings of extreme years. In general, the period was slightly wetter than normal, but had more variable precipitation than normal as well.

Period 2 (AD 1190–1220)

This period remains part of the Early Coalition in Orcutt’s (1999) archaeological chronology. It has a period mean of 31.24 cm and standard deviation of 9.85 cm, both of which are lower than the long-term values. The only consecutive string of extreme years is the AD 1216–1218 period; however, the initial years of the 13th century (AD 1200–1203) include three ‘Good’ years and a normal year, but the AD 1214–1218 period includes four ‘Bad’ years and one normal year. The period was slightly drier than normal and exhibited less variability than normal.

Period 3 (AD 1220–1235)

This short period is still part of the Early Coalition. It has a mean of 31.05 cm, slightly lower than the long-term mean and a standard deviation of 11.63 cm, which is substantially higher than the long-term standard deviation. 'Good' years and 'Bad' years were equal in frequency and there were no signs of extreme years. In general, the period was slightly drier than normal, but had a wider variation in precipitation. With such a short period, however, these statistics may not be very meaningful.

Period 4 (AD 1235–1250)

This period brings the Early Coalition to a close. It has a mean of 35.40 cm and a standard deviation of 10.48. There were no 'Bad,' 'Very Bad,' or 'Very Good' years, and four 'Good' years, but not in a consecutive string. All four 'Good' years occurred before AD 1245, however. The period appears to have been the wettest period in the reconstruction, but its small size makes such an inference uncertain.

Period 5 (AD 1250–1290)

This is the first period in the Late Coalition (Orcutt 1999). It has a mean of 28.15 cm and a standard deviation of 9.52, both of which are substantially lower than their long-term values. 'Bad' and 'Very Bad' years outnumber 'Good' and 'Very Good' years 11 to 2, but there are no consecutive strings of extreme years. The early part of the period (AD 1251–1258) had four 'Bad,' one 'Very Bad,' and three normal years (all of which were low precipitation years); the 'Very Bad' year (AD 1254) ranks as the seventh driest year in the chronology. The late part of the period encompasses much of the Great Drought (AD 1276–1299) and contains five 'Bad' years. In general, the period was dry and not variable.

Period 6 (AD 1290–1325)

This period represents the end of the Late Coalition. It has a mean of 34.43 cm and a standard deviation of 9.97. 'Good' years far outnumber 'Bad,' but there are neither 'Very Good' nor 'Very Bad' years, nor are there any consecutive strings of extreme years. The early portion of the period, AD 1290–1302, contained six 'Good' years and seven normal years, but the remainder of the period was mostly within the normal range of variation. The period was wet and not extremely variable.

Period 7 (AD 1325–1375)

This period encompasses much of the Early Classic (Orcutt 1999). It has a mean of 32.26, higher than the long-term mean, and a standard deviation of 9.15, lower than the long-term value. The frequency of 'Good' and 'Bad' years is about equal, and there are no 'Very Good' or 'Very Bad' years; neither are there any consecutive strings of extreme years. The period was slightly wetter than normal with less variability, but the measures are not extreme.

Period 8 (AD 1375–1400)

This short period marks the end of the Early Classic period of the archaeological chronology. It has a mean of 30.23 cm and a standard deviation of 8.57, both of which are substantially lower than the long-term values. There are four 'Bad' years and one 'Good' year, but no consecutive strings of 'Very Good/Very Bad' years. The period was apparently dry with little variability, but the short duration of the period makes such measures suspect.

Period 9 (AD 1400–1440)

This period is the early part of the Middle Classic period. It has a mean of 29.90 cm and a standard deviation of 10.27, both of which are lower than the long-term values. 'Bad' years (n = 10) outnumber 'Good' (n = 5) and there were two strings of 'Bad' years, AD 1418–1420 and AD 1422–1424; indeed, the AD 1415–1424 period contained seven 'Bad' years and three normal years (all of which were below the period mean). The period was generally dry and not very variable.

Period 10 (AD 1440–1525)

This is a large portion of the Middle Classic period in the archaeological chronology. It has a mean of 31.44 cm and a standard deviation of 10.54, both of which are very close to the long-term values. There are only two consecutive strings, both near the end of the period; AD 1519–1521 was 'Good,' but AD 1522–1525 was 'Bad.' In general, the early two-thirds of the period was dry or normal, and only the AD 1510–1521 period was wet. One of the 'Very Bad' years (AD 1516) ranks as the 15th driest year in the chronology.

Period 11 (AD 1525–1610)

This period encompasses the end of the Late Classic period and beyond in the archaeological chronology. It has a mean of 30.46 cm, substantially lower than the long-term mean, and a standard deviation of 13.07 cm, significantly greater than the long-term value. The period is notable for the greatest frequency of 'Very Good' and 'Very Bad' years of any period in the chronology. Consecutive 'Good' years occurred in AD 1539–1541 and AD 1594–1597, and consecutive 'Bad' years occurred in AD 1579–1581. All six 'Very Bad' years in this period (AD 1579, AD 1580, AD 1583, AD 1585, AD 1590, and AD 1593) rank in the top 25 driest years in the chronology, and likewise, all six 'Very Good' years (AD 1540, AD 1541, AD 1577, AD 1596, AD 1597, AD 1599, and AD 1610) rank in the top 25 wettest years in the chronology. In general, the period was dry but highly variable.

Period 12 (AD 1610–1680)

This period is defined by the founding of the Spanish capital in Santa Fe and ends with the Pueblo Revolt. As such, it encompasses much of the early Spanish colonization era. The precipitation mean for the period is 32.11 cm, which differs from the long-term mean by +0.79 cm, and the period standard deviation is 9.11, which differs from the long-term standard deviation by –1.38. There are no three-year strings of extreme years (see Table 8.4). The first two years of the period (AD 1610–1611) were 'Very Good,' however, and may have facilitated the Spaniards' move to Santa Fe. Indeed, both AD 1610 and AD 1611 rank in the top 14 wettest years in the chronology. Two two-year periods (AD 1624–1625 and AD 1666–1667) were 'Bad,' but in general much of the period experienced normal amounts of precipitation. 'Bad' years were distributed relatively evenly throughout the period. Notably, AD 1680 was relatively wet (41.55 cm), but is not classified as a 'Good' year (41.71 cm); in addition, none of the 12 years before AD 1680 was 'Bad.' Thus, a precipitation deficit probably had little to do with the Pueblo Revolt.

Period 13 (AD 1680–1692)

This short period is defined by the Pueblo Revolt and ends with the Spaniards' return to the north. The period mean is 33.94 cm, compared to the long-term mean of 31.32, and the period standard deviation is 8.95, compared to the long-term standard deviation of 10.49. There was only one 'Bad' year (AD 1685) and two 'Good' years (AD 1689 and AD 1692). The later good year may have impacted de Vargas' return to New Mexico in some fashion.

Period 14 (AD 1693–1753)

This period is defined by the Reconquest and ends with the rise of Ute and Comanche threats in the north and the attack on Abiquiu. The period mean is 30.0 cm, compared to the long-term mean of 31.32, and the period standard deviation is 8.97 compared to the long-term standard deviation of 10.49. There is one period of consecutive extreme years, the 'Bad' years of AD 1737–1739; in addition, the AD 1729–1739 period included six 'Bad' and five normal years. Thus, the period was generally drier and less variable than normal.

Period 15 (AD 1754–1821)

This period is defined by the rise of the Ute/Comanche threat and ends with Mexican independence. The period mean is 30.29 cm and standard deviation is 8.63; both measures are below their long-term counterparts. There is only one string of extreme years—the 'Bad' years of AD 1779–1782. There were no 'Very Good' or 'Very Bad' years, and 'Good' and 'Bad' years are distributed throughout the period. In general, the period was dry and not very variable.

Period 16 (AD 1822–1849)

This is the period from Mexican independence until the U.S. acquisition of New Mexico. The period mean is 31.49 cm, slightly above the long-term mean, and the standard deviation is 8.65, significantly below the long-term measure. There is only one consecutive string of extreme years—the 'Good' years of AD 1839–1841; the first two years of the period (AD 1822–1823) were 'Bad' years.

Period 17 (AD 1850–1912)

This period is defined by the US acquisition of New Mexico and ends with Statehood. The period mean is 29.43 cm , significantly lower than the long-term mean, and the standard deviation is 9.00, also below the long-term measure. There were no consecutive strings of extreme years, but 'Bad' years (*n* = 11) outnumbered 'Good' (*n* = 4), and most of the 'Bad' years occurred between AD 1861–64 (three 'Bad' and one normal) and between AD 1893–1904 (six 'Bad' years and six normal years). The 'Very Bad' year of AD 1904 ranks as the 20th driest year in the chronology.

Period 18 (AD 1913–2002)

This period is defined by New Mexico statehood and ends with the end of the reconstruction. The period mean is 32.45 cm and the standard deviation is 10.40. There were two 'Good' strings (AD 1919–1921 and AD 1985–1988) and one 'Very Bad' string (AD 1955–1957). The 1950s included five 'Very Bad' and five normal years. In general, the period was normal or wet until the 1950s, dry from the 1950s through early 1970s, and wet throughout the remainder of the 20th century. The drought of the 2000s has included two 'Very Bad' years (AD 2000 and AD 2002). Two 'Very Bad' years (1956 and 2002) and one 'Very Good' year (1986) rank in the top 25 driest and wettest years, respectively (Table 8.5).

Table 8.5. Extreme years in the Bandelier archaeological periods, Jemez reconstruction.

Chama Chronology: Long-Term, Low-Frequency Precipitation Trends

The Chama reconstruction of low- and high-frequency trends in precipitation in the northern area is shown in Figure 8.14; the raw data are presented in Appendix I. The long-term precipitation mean for the area is 43.34 cm per tree-year, and the standard deviation is 11.42 cm inches per year. For any substantial period of time (100+ years) over the course of the reconstruction, the mean changes very little. Although the Chama mean is substantially higher than the Jemez mean, the trends in the two chronologies are similar—as one would expect. There are however, some important differences that are discussed below.

The Chama reconstruction shows relatively consistent variability (i.e., the low-variability and high-variability periods are usually short). High-variability predominates in the late 800s and early 900s, and again in the late 1400s to early 1500s, whereas low variability is typical in the mid-1300s and late 1500s/early 1600s periods.

Using 20-year overlapping periods, however, shows a different trend. From the beginning of the chronology through the late 900s, variability over this longer term is relatively low. A period of high variability begins about AD 1000 and continues until the early 1100s. Low long-term variability again predominates from about AD 1150 through the mid-1400s. High variability typifies the period from the 1700s to the present.

In terms of absolute precipitation, there are several periods of high and low precipitation. High precipitation periods occur in the early 1000s, mid-1000s, mid-1300s, early 1600s, and throughout much of the 20th century. Low periods include late 1000s, early and mid-1200s, mid-1400s, late 1500s, and mid-1900s. Several well-known periods are different in the Chama area. For example, the “Chaco drought” of the mid to late 1100s shows low variability, but mostly average precipitation. The “Great Drought” of the late 1200s was neither lengthy nor severe in the Chama area. The most prolonged downturn in rainfall occurred during the 1400s—a drought that was long, but not extremely severe and extremely favorable precipitation dominated in the 1600s, a factor which may have aided the Spaniards colonization of northern New Mexico. Likewise, with the exception of the 1950s, which was the most severe drought in the

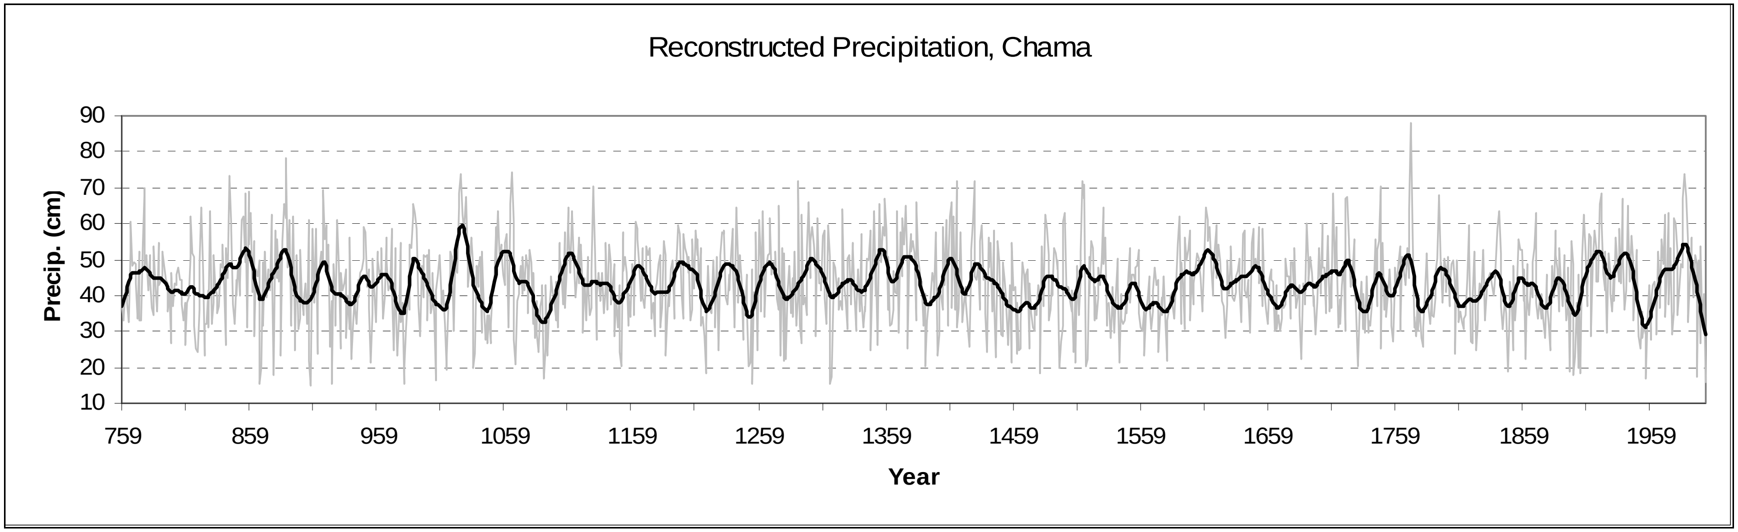

Figure 8.14. Annual and splined precipitation graph for the Chama chronology.

reconstruction, the 20th century shows high precipitation that many Anglos have come to regard as "normal" conditions.

Chama Chronology: High-Frequency Variation

Examining the Chama chronology in terms of individual centuries yields additional interesting results (Table 8.6). Because the reconstruction does not begin until AD 759, however, the AD 700s are not included in the discussion.

Table 8.6. Extreme years per century, Chama reconstruction.

Century	Century Mean	Very Good	Good	Average	Bad	Very Bad
600–699	--	n/a	n/a	n/a	n/a	n/a
759–799	--	0	2	37	1	0
800–899	44.63	4	17	61	15	3
900–999	42.48	1	15	69	12	3
1000–1099	43.04	4	11	68	13	4
1100–1199	44.16	1	14	75	9	1
1200–1299	43.40	1	16	67	14	2
1300–1399	44.98	1	23	63	10	3
1400–1499	42.54	2	17	60	19	2
1500–1599	41.09	3	6	76	14	1
1600–1699	44.01	0	12	80	8	0
1700–1799	43.58	6	9	68	16	1
1800–1899	41.07	0	7	81	10	2
1900–1999	45.17	5	15	64	12	4
2000–2002	--	0	0	2	0	1
Total		**28**	**164**	**871**	**153**	**27**

In terms of individual years, the AD 800s are the second-most variable century in the Chama reconstruction; they also have a relatively high century mean. The AD 840s to AD 860s period was wet, as was the AD 880s, although the only consecutive string of above average years was AD 885–888. Below average years were spread more or less evenly throughout the century and the only string of bad years was AD 816–818; the AD 867–870 period, however, included two 'Very Bad,' an average, and a 'Bad' year.

The AD 900s have a relatively low century mean and about an average number of extreme years. After a string of 'Good' years (AD 917–919), most of the century was relatively dry, including the 'Very Bad'/'Bad' string of AD 980–982—until the upturn of four 'Good' years in AD 987–990.

The AD 1000s may be the most "average" century in the reconstruction. The century average (43.04 cm) is very close to the long-term mean and the number of extreme years (n = 32) is about average. The only consecutive strings of extreme years are both 'Good' (AD 1063–1066) and include the longest and wettest series of years in the entire reconstruction (AD 1023–1029).

After AD 1066, however, there were no 'Good' years, seven 'Bad' years, and one 'Very Bad' year. Thus, the first two-thirds of the century were wet, but the last three decades were either "normal" or dry.

The 1100s also had a relatively high century mean (44.16 cm) and a relatively low number of extreme years (*n* = 25). 'Good' years (*n* = 14) outnumber 'Bad' (*n* = 9), although 'Very Good' and 'Very Bad' years are equal. The only three-consecutive year strings were both wet (AD 1162–1164 and AD 1195–1197), although the AD 1146–1151 period includes three 'Bad,' two average, and one 'Very Bad' year. The first half of the century was mostly average or 'Good,' the middle average or 'Bad,' and the end was average or 'Good.'

The 1200s had a low century mean (43.40 cm) and 33 extreme years—about evenly split between 'Very Good/Good' (*n* = 17) and 'Bad/Very Bad' (*n* = 16). The only consecutive string of extreme years was wet (AD 1230–1232). The first half of the century was above average with the exception of the AD 1214–1217 period, which had a 'Bad,' average, 'Bad,' and 'Very Bad' string of years. The early AD 1250s were 'Bad,' but most of the rest of the century was average or 'Good.' This reconstruction is notable because the Great Drought (AD 1276–1299) of the Colorado Plateau does not appear to have seriously impacted the Chama area.

The 1300s had the second-highest century mean and third-highest number of extreme years in the reconstruction. The century had the highest number of 'Good' years (n = 23) of any century in the reconstruction, but only one 'Very Good' year. The only string of consecutive extreme years was AD 1356–1359, which included three 'Good' and one 'Very Good' year. Importantly, AD 1353 and AD 1354 were also 'Good' years, and AD 1355 was an average year. In short, the AD 1350s were wet. There were no consecutive strings of 'Bad' years. Overall, the AD 1300s experienced several average and 'Good' periods and no serious downturns in precipitation.

The AD 1400s exhibited the most variability of any century; only 60 years were classified as "normal." The mean is somewhat low, but not extremely so. 'Good' (*n* = 17) and 'Very Good' (*n* = 2) years almost equal the number of 'Bad/Very Bad' years (*n* = 21). The only consecutive string of extreme years is the AD 1495–1497 'Bad' period. The AD 1404–1414 period, however, includes six 'Good,' one 'Very Good,' three normal, and only one 'Bad' year; on the other hand, the AD 1449–1464 period includes seven 'Bad' years, eight normal years, and one 'Good' year. In general, the early part of the century was relatively wet and the last half was much drier.

The AD 1500s had a low century mean and relatively few extreme years. 'Bad' years (*n* = 14) outnumber 'Good' (*n* = 6), but 'Very Good' years (*n* = 3) outnumber 'Very Bad' (*n* = 1) years. The only consecutive string of extreme years is the AD 1513–1515 period when all three years were 'Very Good.' The first 30 years of the century were relatively wet or normal, but the AD 1532–1588 period contains only normal or 'Bad' years. The mega-drought of the late AD 1500s may have affected the area, but probably not as severely as areas farther south.

The AD 1600s had a high century mean and neither 'Very Good' nor 'Very Bad' years; indeed, the century was the second least variable in the reconstruction in terms of extreme years (*n* = 20). The only consecutive string of extreme years was the AD 1610–1613 wet period. In general, extreme years were somewhat evenly distributed throughout the century with neither prolonged wet or dry periods.

The AD 1700s had a century mean near the long-term mean, but had the highest number of 'Very Good' (*n* = 6) years in the reconstruction. The only consecutive strings of extreme years were the AD 1720–1722 and AD 1770–1772 periods; dry periods include the AD 1733–1739 period with four 'Bad' and three normal years, and the AD 1773–1781 period with six 'Bad' and three normal years. The early part of the century was somewhat wet, but after AD 1729, most years were either normal or 'Bad' with a couple of exceptions.

The AD 1800s had the lowest century mean in the reconstruction. They also had the highest number of normal years (*n* = 81); 'Bad' (*n* = 10) and 'Very Bad' (*n* = 2) years outnumber 'Good' (*n* = 7) and 'Very Good' years (*n* = 0). No strings of consecutive extreme years were identified.

The AD 1900s had the highest century mean in the reconstruction (45.17) and a relatively high number of extreme years (*n* = 36). Extremely wet periods include 1919–1921 and 1985–1988 (three 'Very Good' and one 'Good' year); only one string of 'Bad' years was identified (1954–1956). In general, the 1905–1950 period was wet or normal, the 1950s with six 'Bad,' one 'Very Bad,' and three normal years were extremely dry, and the last 40 years of the century were relatively wet or normal.

Little can be said about the 2000s, except that 2002 was an extremely dry year.

Chama Chronology: Extreme Events

The 25 most extreme years (Table 8.7) show an impressive range of precipitation from a low of 14.70 cm in AD 907 to a high of 88.11 cm in AD 1771. In terms of centuries, the AD 1900s and AD 1000s both contain four of the driest and four of the wettest years. The AD 800s also contained a high number of these extreme years. Interestingly, the AD 1100–1600 period of the most intense Puebloan occupation of the area contains only six of the wettest and six of the driest extreme years. In historical terms, the only significant correlation is the very wet year of AD 1793, which may have aided de Vargas' reconquest of New Mexico.

Table 8.7. Twenty-five wettest and driest years in the Chama reconstruction.

Year	Driest	Year	Wettest
907	14.70	1771	88.11
867	15.28	888	78.29
924	15.57	1065	74.53
980	15.57	1986	74.04
1254	15.57	1025	73.66
1315	15.57	843	73.37
2002	15.81	1290	71.93
1005	16.15	1414	71.93
1956	16.82	1428	71.64

Year	Driest	Year	Wettest
1090	17.01	1513	71.64
1996	17.29	1515	70.77
1316	17.59	1747	70.29
1899	17.76	1129	70.19
878	17.88	776	69.90
1217	18.17	917	69.62
1480	18.17	858	68.75
1904	18.23	856	68.46

1896	19.02	1710	68.26
1013	19.32	1920	68.24
1902	19.75	1793	67.93
868	19.90	1987	67.52
981	19.90	1721	67.38
1035	19.90	1029	67.30
1495	19.90	1937	67.13

COMPARING THE JEMEZ AND CHAMA RECONSTRUCTIONS: SPATIAL DIFFERENCES IN PAJARITO AREA PRECIPITATION

One of the goals of this project was to explore the possible spatial differences in precipitation in the Pajarito area. Such differences may help archaeologists elucidate differences in settlement and subsistence patterns in different areas at different times and address issues such as mobility and migration. By using the chronologies and correlating them with the Chama and Jemez Springs weather stations, respectively, we are able to provide estimates for past precipitation in both the northern and southern portions of the project area (Figure 8.15).

There are several ways to examine and compare the two reconstructions, including by annual values, smoothed annual values, frequency and severity of extreme events, and Z-scores. Appendices H and I present the annual and smoothed basis for every common year in both chronologies. The reconstruction graphs typically track each other very well—when it is wet/dry in Chama, it is wet/dry in Jemez and vice versa. The Chama area typically received about 10 cm more precipitation than the Jemez area (Figure 8.15) on an annual basis. This difference is certainly real, although the magnitude of the difference may be impacted by our use of the Chama modern data in the calibration. Chama is farther north than our tree collection sites, but the live-tree sites are approximately 1000 ft higher in elevation than the weather station. Both of these factors may inflate the absolute quantities for the northern Pajarito area, but we believe they represent increased precipitation in the north and that the trends are accurate. One interesting aspect of Figure 8.15 is those years when the Jemez area shows higher absolute values than the Chama reconstruction. Given that Puebloan societies developed a three-year storage strategy (Schlanger 1985), such single-year discontinuities probably had little effect on long-term adaptive strategies. It would be interesting, however, to determine whether or not hunting, gathering, trading, or raiding changed during those years.

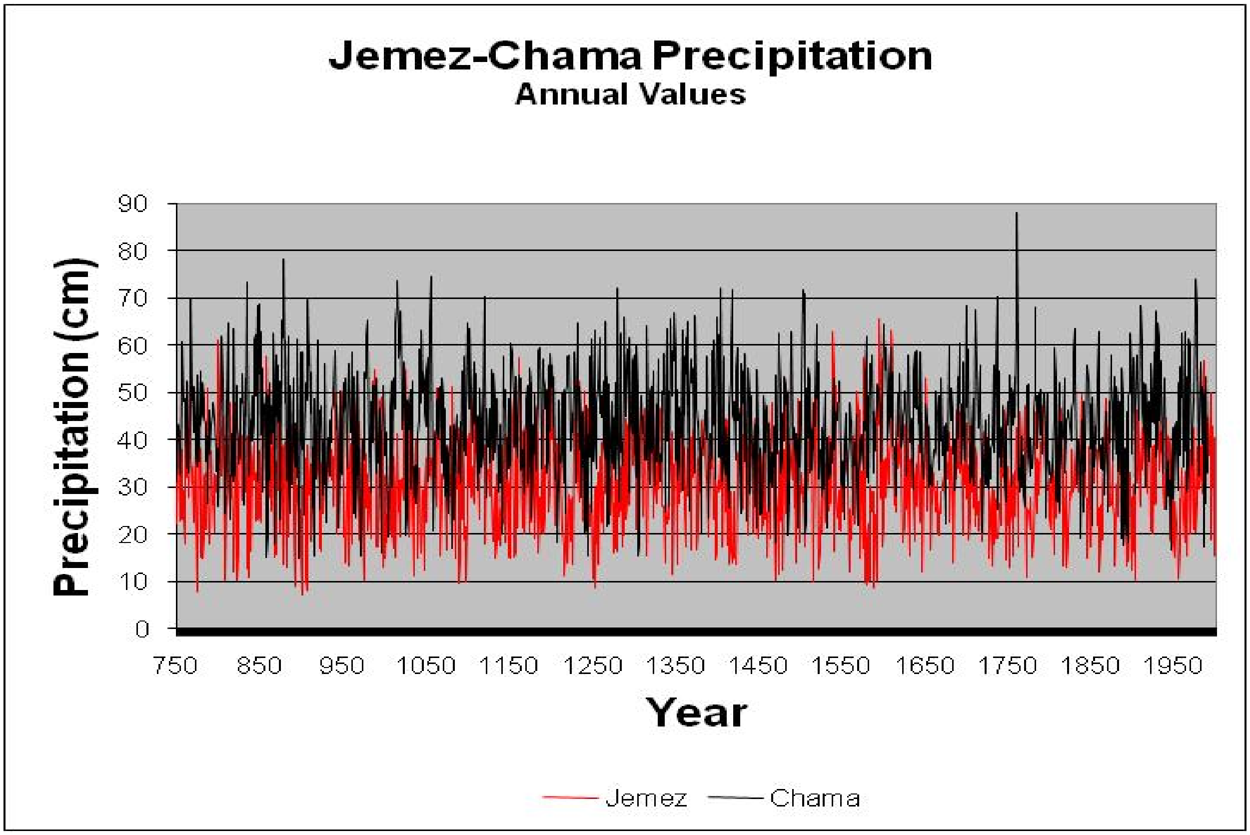

Figure 8.15. Annual precipitation values for both Jemez and Chama chronologies.

Another way to compare the two reconstructions is by plotting the 20-year smoothed absolute values for each year (Figure 8.16). This approach helps remove the individual annual variation in each reconstruction. The Chama reconstruction almost always retrodicts higher precipitation values than the Jemez reconstruction using the 20-year spline. There is one short span in the entire 1241 years of both reconstructions when the Jemez was more well-watered than the Chama area. The AD 1538–1542 period shows the Jemez with absolutely more precipitation than the Chama; in addition, during AD 1543–1544 the two areas are nearly equal. Significantly, this trend is not due to droughts when both areas were dry and the Jemez simply less arid. Included in the 25 wettest years of the Jemez reconstruction are AD 1540, AD 1541, and AD 1543 (see below); none of the years between AD 1530–1550 in the Chama area was unusually wet. As shown in Figure 8.17, even the absolute differences are highest during this time period. From this perspective, Coronado's trip from Hawikuh and sojourn in the Rio Grande Valley could not have come at a better time for the Spaniards.

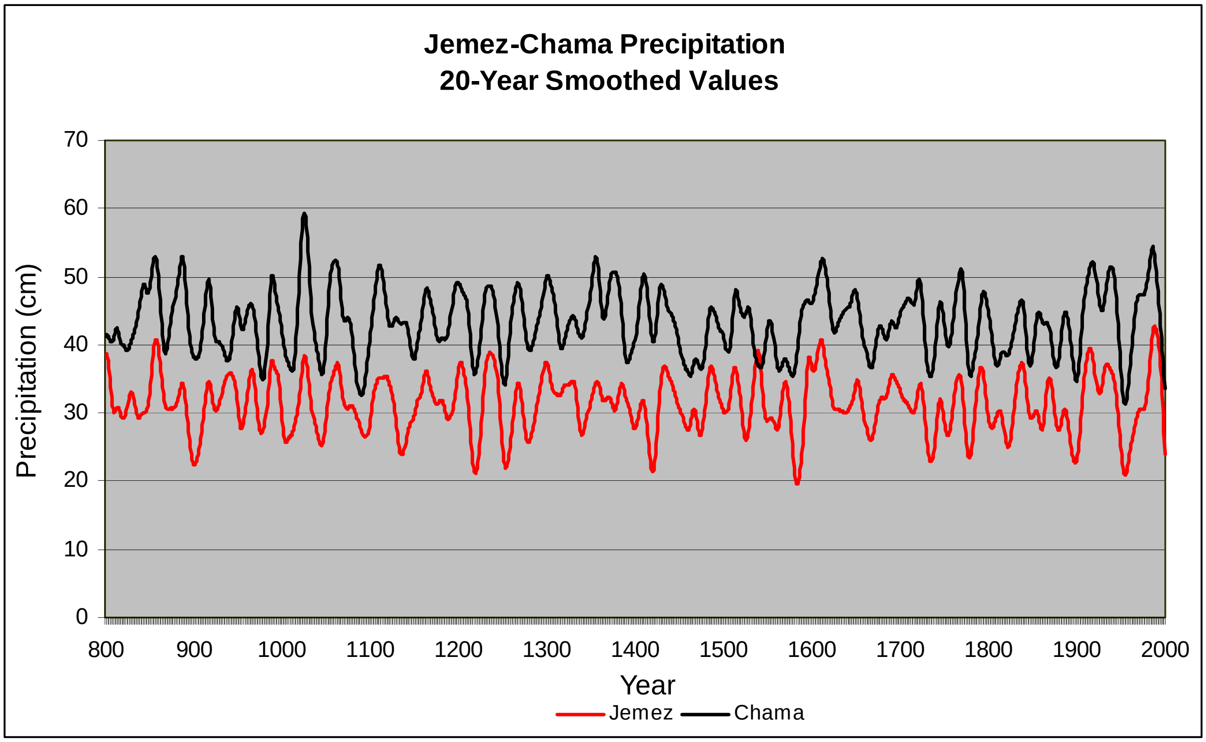

Figure 8.16. Splined precipitation values for both Jemez and Chama chronologies.

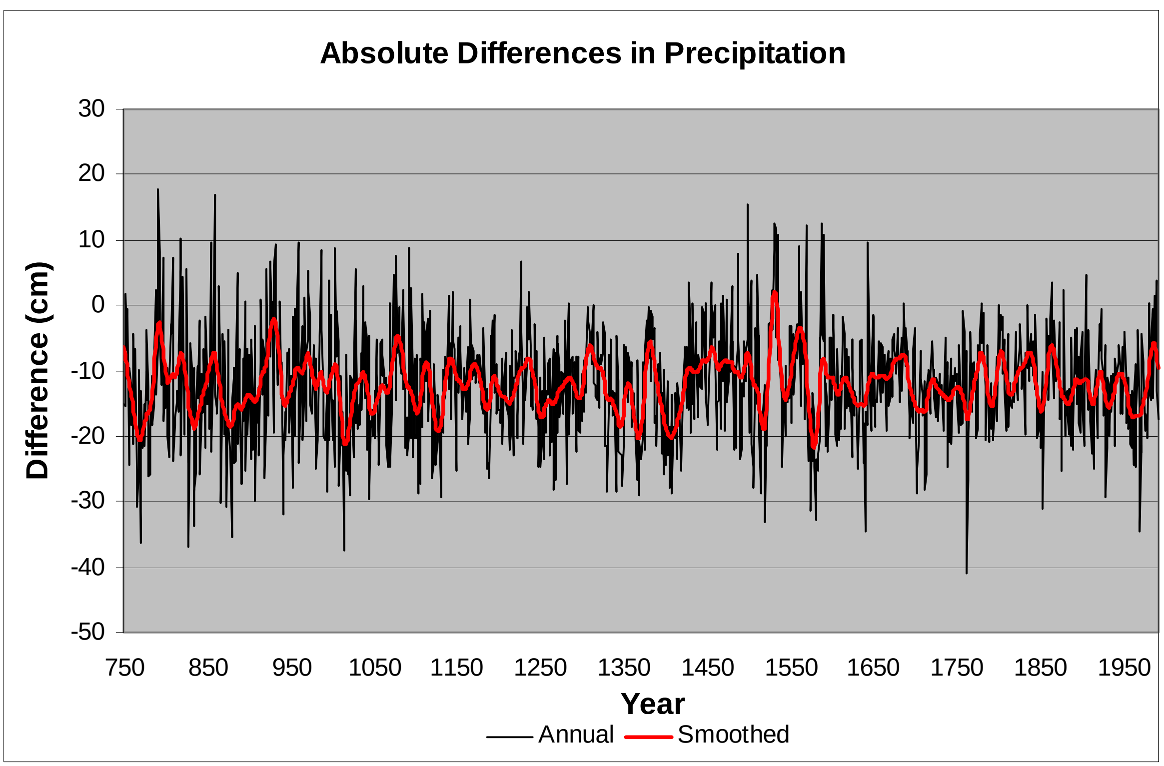

Figure 8.17. Graph of precipitation value absolute differences, both chronologies.

Extreme Events

Another factor that may have been important in land-use strategies of the area is the frequency and magnitude of extreme events. The chronology-specific extreme events have been discussed above, but here we examine the temporal relationships in each area.

Table 8.8 presents the extreme (very good, good, bad, and very bad) years in each reconstruction. These classifications are based on each chronology's mean and standard deviation; thus, a 'Bad' year in Chama may not necessarily be a 'Bad' year in Jemez and vice-versa. Because the Chama retrodiction is shorter, only the 9th to 20th centuries are compared.

Table 8.8. Comparison of extreme years in each reconstruction.

Century	Jemez Very Good	Chama Very Good	Jemez Good	Chama Good	Jemez Average	Chama Average	Jemez Bad	Chama Bad	Jemez Very Bad	Chama Very Bad
800–899	3	4	12	17	69	61	13	15	3	3
900–999	2	1	15	15	62	69	18	12	3	3
1000–1099	1	4	11	11	66	68	20	13	2	4
1100–1199	1	1	10	14	72	75	17	9	0	1
1200–1299	1	1	14	16	67	67	17	14	1	2
1300–1399	0	1	13	23	77	63	10	10	0	3
1400–1499	0	2	11	17	69	60	19	19	1	2
1500–1599	6	3	13	6	59	76	17	14	5	1
1600–1699	3	0	4	12	82	80	11	8	0	0
1700–1799	0	6	8	9	77	68	17	16	0	1
1800–1899	0	0	6	7	81	81	13	10	0	2
1900–1999	1	5	14	15	69	64	16	12	0	4

In general, the frequency of extreme years are similar in the two areas through time. The Jemez area has experienced fewer 'Very Bad,' 'Very Good,' and 'Good' years, but more 'Bad' years. Most centuries were similar in that most had an equivalent number of normal years, but there were exceptions.

In the AD 800s, the Chama area experienced more 'Good' years; in the AD 900s, the Jemez area suffered through more 'Bad' years; in the AD 1300s, the Chama area had more 'Good' years, but also more 'Very Bad' years; in the AD 1400s, the Chama area also had more 'Good' and 'Very Good' years. The AD 1500s were unusual in that the Jemez area had more 'Very Good' and 'Good' years, but also more 'Bad' and 'Very Bad' years—obviously, precipitation was more variable in that area at that time. The AD 1900s were also somewhat unusual in that the Chama area experienced more 'Very Good,' 'Good,' and 'Bad' years, but also more 'Very Bad' years.

These data suggest that differences in extreme years most often, but not always, were the result of wetter years in the north. The impacts of these inferences on past human settlement and land-use practices remain to be explored by area archaeologists.

Z-Scores

Perhaps the most efficient way of comparing the two retrodictions on both short- and long- term time scales is by transforming the data into Z-scores. This transformation allows us to compare the chronologies using the same quantitative and temporal scales regardless of the absolute values. Table 8.9 summarizes these differences for each century in the reconstructions. It should be remembered, however, that the absolute values in the reconstruction are estimates with associated statistical errors and that they should not be interpreted as absolutely measured precipitation amounts.

Table 8.9. Comparison of Z-scores.

Time Period	Jemez	Chama	Comments
770–790	decreasing	increasing	Values moving in opposite directions; possibly related to sample size (?)
795–807	increasing	flat	Jemez wetter, Chama relatively flat just below mean
836–848	flat	increasing	Chama wetter, Jemez flat around mean
875–893	increasing	increasing	Both wet; Chama much wetter
895–910	decreasing	decreasing	Both dry; Jemez much drier
929–945	increasing	decreasing	Values moving in opposite directions; Chama much drier
972–984	decreasing	decreasing	Both dry; Chama drier
1019–1033	increasing	increasing	Both wet; Chama much wetter
1078–1096	decreasing	decreasing	Both dry; Chama drier
1107–1114	increasing	increasing	Both wet; Chama wetter
1128–1152	decreasing	decreasing	Both dry; Jemez drier; Chama offset 1133–1157
1211–1227	decreasing	decreasing	Both dry; Jemez drier
1230–1244	increasing	increasing	Both wet; Jemez wetter
1311–1325	increasing	decreasing	Jemez wet above mean; Chama dry
1349–1361	increasing	increasing	Both wet; Chama wetter
1372–1383	flat	increasing	Chama wet; Jemez at mean
1386–1402	decreasing	decreasing	Both dry; Jemez offset 1393–1406
1411–1426	decreasing	decreasing	Both dry; Jemez much drier; Chama offset 1417–1424
1480–1497	increasing	increasing	Both wet; Jemez wetter
1525–1530	decreasing	increasing	Jemez dry; Chama around mean
1533–1545	increasing	decreasing	Chama dry; Jemez much wetter
1566–1574	increasing	decreasing	Chama dry; Jemez wetter
1579–1592	decreasing	decreasing	Both dry; Jemez much drier
1593–1622	increasing	increasing	Both wet; 1593–1613 Jemez wetter

Time Period	Jemez	Chama	Comments
1676–1698	increasing	decreasing	Jemez wet; Chama dry
1710–1717	decreasing	increasing	Jemez average; Chama wet
1806–1813	decreasing	decreasing	Chama dry; Jemez not as dry
1830–1844	increasing	increasing	Both wet; Jemez wetter
1845–1854	decreasing	decreasing	Both dry; Chama drier
1866–1871	decreasing	decreasing	Both dry; Chama drier

Figure 8.18 shows the smoothed Z-scores for the common years in both chronologies. As can be seen, both chronologies track each other relatively well—again, not surprising. During periods such as the AD 850s, mid-900s to mid-1000s, mid-1100s to early 1300s, and much of the post-1700 era, the chronologies are very similar in terms of trends, if not magnitudes of change. Certainly there were more severe droughts and more precipitation in one area or another, but the changes were, for the most part, synchronous.

The most interesting periods, on the other hand, are those that are asynchronous—drought in one area offset by wetter conditions in the other. Table 8.9 describes the graph in detail and the raw data are presented in Appendix J. Again, the most dramatic difference between the two areas occurs in the AD 1530s and early 1540s when Jemez was wet and Chama dry.

Finally, we have also developed quantitative methods for comparing the periodicity of the two time series (Cook and Peters 1981; Johnson 1994; Salzer 2000a). We use these techniques to characterize each reconstruction and compare the high and low precipitation periods in each area.

The quantitative method involves several steps. First, a 10-year smoothing spline was applied to the reconstructed precipitation values (Cook and Peters 1981); the spline functions as a low-pass filter and preserves the high-frequency variation in the data. Second, the original and splined data were converted to Z-scores, which quantified the deviations from the long-term mean. Third, we used the splined (Z-score) data to identify periods that deviated from long-term mean conditions by at least 1.1 standard deviations, the value proposed by Dean (1988) as significant in influencing past human adaptive behavior. The initial and terminal years of each period were defined using non-smoothed data because the splined data are influenced by preceding and succeeding amounts. The minimum length for any period was defined as five years. Finally, the beginning of a period was defined as the year when the reconstructed value first substantially deviated from mean conditions (<0.5 sad or >0.5 sad), and the end of a period was defined as that point when conditions returned for two consecutive years.

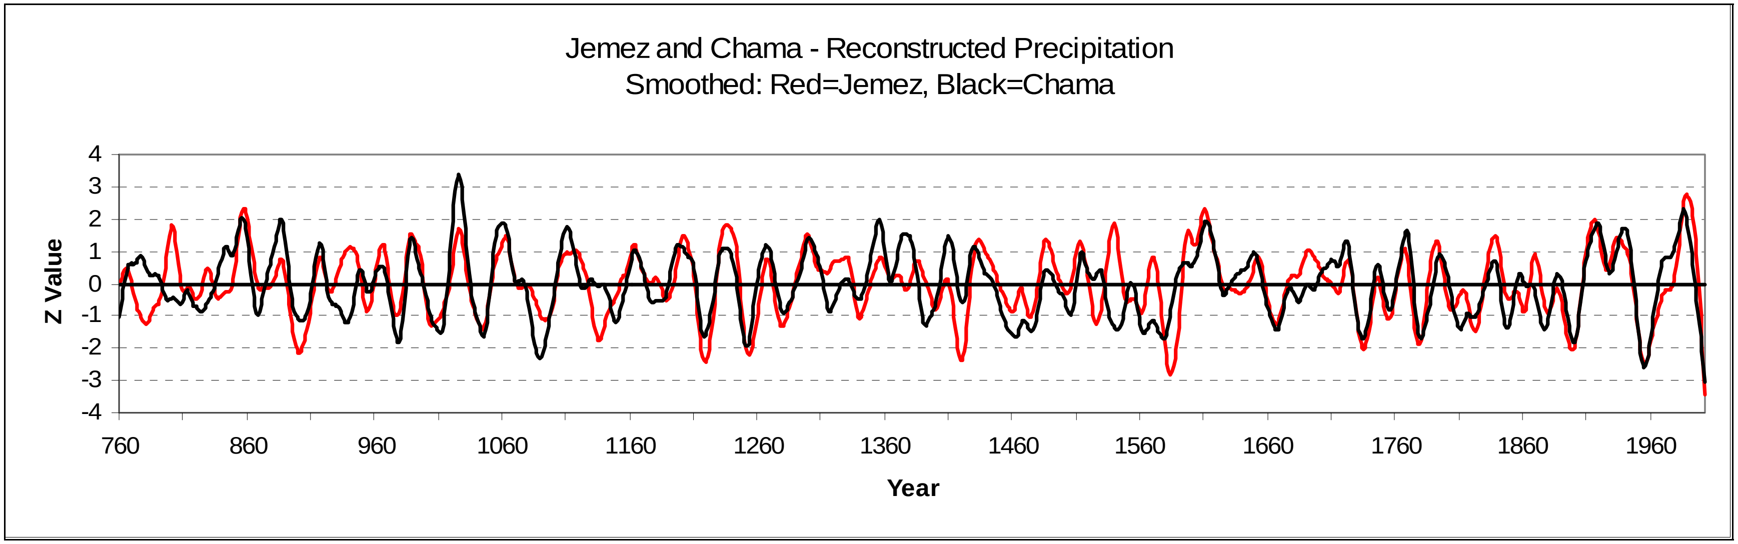

Figure 8.18. Z-scores of both chronologies.

Table 8.10 lists the wet and dry periods for both areas using quantitative criteria. There are several interesting aspects of these data. First, the only absolutely contemporaneous dry periods in both chronologies are near the recent end—the 1899–1904 drought, the 1950s drought, and the current drought. Conversely, four absolutely contemporaneous wet periods all occurred before AD 1302. Six wet periods overlap substantially, but are offset by a year or more; three occurred before AD 1029 and three occurred after AD 1608. There are also seven near-contemporaneous dry periods—three occurred before AD 1000 and three occurred after AD 1664. These short differences in periodicity may be the result of the use of different tree species in various parts of the chronologies and deserves additional research. The distribution of these periods in different centuries may also be important; there were no wet periods in the 1800s in either chronology, no dry periods in the 1300s at Chama, and no wet periods in the 1500s at Chama.

Table 8.10. Quantitative comparison of wet/dry periods in each reconstruction.

1930–1937	--	--	--
1983–1988	--	--	--

Also of interest may be those near-sequential periods with similar conditions. For example, the Jemez wet period of AD 1200–1204 was followed shortly thereafter by a Chama wet period from AD 1207–1213; other wet sequences include AD 1377–1384 (Chama) and AD 1383–1387 (Jemez), and AD 1646–1651 (Chama) and AD 1651–1655 (Jemez). There are only two near-sequential dry periods in the reconstructions; AD 1455–1461 (Jemez) and AD 1461–1465 (Chama), and AD 1573–1581 (Chama) and AD 1579–1587 (Jemez). Although few in number, these near-sequential periods may have influenced land-use patterns on the Pajarito Plateau and in surrounding areas. All but the latest wet episode in the mid-1600s occurred during the Bandelier archaeological periods and may be amenable to archaeological research using those data.

It is probable that the differences between the Chama and Jemez, particularly on a seasonal basis, are related to the fluctuating, sinuous line that separates two different climatic regimes in the Southwest (Ahlstrom et al. 1995; Dean and Funkhouser 1995). North and west of the line, precipitation has generally been unimodal; that is, winter snow pack has been the major component of annual precipitation. South and east of the line, a bimodal regime of winter rains and summer monsoons has predominated. Over the centuries, this fluctuating pattern has moved back and forth between the New Mexico-Colorado border and approximately the northern Chama Valley area (Dean 1996b; Dean and Funkhouser 1995), except during the chaotic period of ca. AD 1225–1450. Therefore, combined with the archaeological record of the area, the Pajarito area is an ideal locale to investigate the impacts of changing seasonal precipitation patterns on the cultural adaptations of subsistence agriculturalists, hunter-gatherers, and pastoralists.

Evaluation of the Agricultural Risk Model

Orcutt (1999) developed a detailed model of agricultural risk in the Bandelier area in order to explain such archaeological phenomena as mobility, aggregation, and the degree of commitment to agriculture during the AD 1150–1610 period. Orcutt's detailed study used the July PDSI (Palmer 1965) and exhaustive archaeological data (Powers and Orcutt 1999b) to elucidate many aspects of the prehistoric and protohistoric occupation of the area. The PDSI data were derived using the Rose et al. (1981) Arroyo Hondo tree-ring reconstruction of precipitation.

One of the major goals of this study was to evaluate the climatic aspects of the model; we are not reevaluating or using the archaeological data. This evaluation should in no way be construed as a criticism of Orcutt's efforts. We have developed new databases and used previously collected data that were not available at the time of her study.

The basic theoretical underpinnings of the Orcutt model are sound and we use them here. The mean and variability of moisture during each archaeological period are critically important to the success of argriculturalists in the Southwest. We use these same measures, but in different ways, to compare all three data sets: the Jemez reconstruction, the Chama reconstruction, and the Orcutt model.

The Jemez Reconstruction

Table 8.11 presents the precipitation mean and standard deviation for each period in the Bandelier chronology. It also lists the period deviation from the long-term mean and standard deviation (columns 4 and 6); Figure 8.19 summarizes these data using box-and-whisker plots.

Table 8.11. Jemez reconstruction wet/dry periods compared to Bandelier archaeological chronology (non-overlapping).

Period	Years	Mean	Deviation from Long-Term Mean	St Dev	Deviation from Long-Term Value
1	1150–1190	31.91	0.59	11.26	0.77
2	1190–1220	31.24	-0.08	9.85	-0.64
3	1220–1235	31.05	-0.27	11.63	1.14
4	1235–1250	35.40	4.08	10.48	-0.01
5	1250–1290	28.15	-3.17	9.52	-0.97
6	1290–1325	34.43	3.11	9.97	-0.52
7	1325–1375	32.26	0.94	9.15	-1.34
8	1375–1400	30.23	-1.09	8.57	-1.92
9	1400–1440	29.90	-1.42	10.27	-0.22
10	1440–1525	31.44	0.12	10.54	0.05
11	1525–1600	30.46	-0.86	13.07	2.58

Long-term mean = 31.32; standard deviation = 10.49

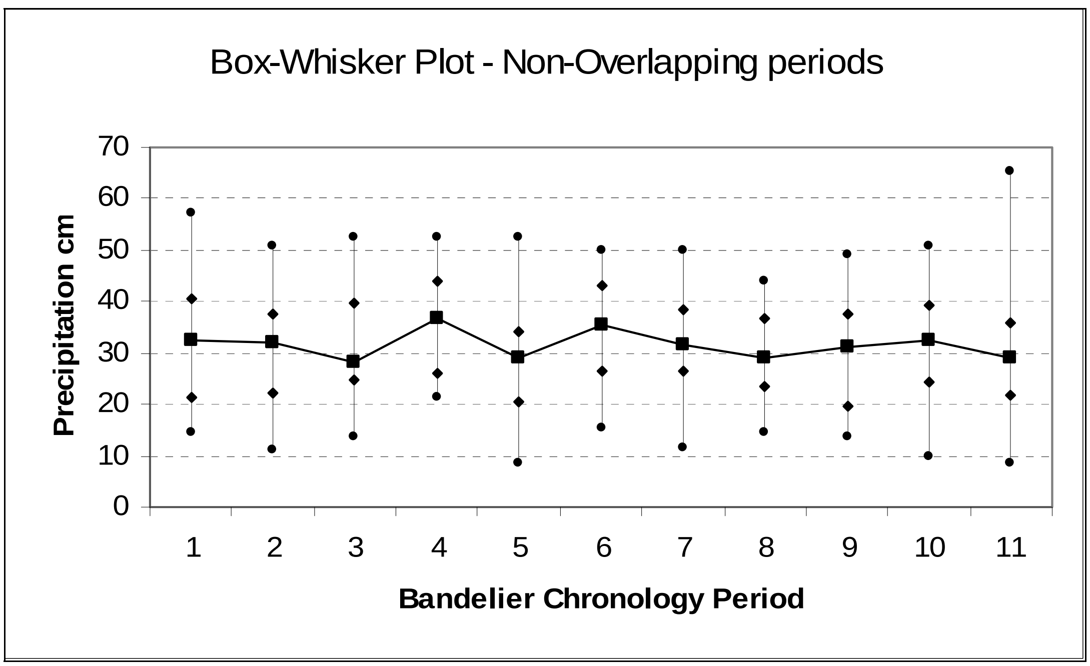

Figure 8.19. Jemez box-and-whisker plot of Bandelier chronology (non-overlapping).

Most of the periods exhibit similar precipitation means and standard deviations. Periods 4, 5, 6, and 9, however, are clearly different. Periods 4 and 6 had much higher mean precipitation than other periods, and Period 5 was much lower. Period 9 was also dry, but not as dry as Period 5. The dramatic differences, or alternations, between Period 4, 5, and 6 may have had important impacts on the area occupants. We leave such interpretations to Pajarito archaeologists.

The standard deviations within each period are also informative. Periods 3, 7, 8, and 11 have the highest standard deviations, although Period 5 could also be considered somewhat high. We believe it important that the "alternating" Periods 4, 5, and 6, which have very different precipitation means, have relatively low standard deviations. It may also be important that the highest standard deviation is in Period 11, which exhibits a relatively low mean precipitation. How this precipitation regime impacted the Puebloan and Spanish populations in the area remains an important question.

Orcutt uses 10-year overlaps for each period because the period boundaries are uncertain and because there is usually a lag between environmental stress and human behavior (Orcutt 1999:231). Table 8.12 presents the 10-year overlapped Jemez data and Figure 8.20 shows these data graphically.

Table 8.12. Jemez reconstruction wet/dry periods compared to Bandelier archaeological chronology (overlapping).

Period	Years	Mean	Deviation from Long-Term Mean	St Dev	Deviation from Long-Term Value
1	1140–1200	31.57	0.25	10.36	-0.13
2	1180–1230	30.59	-0.73	10.32	-0.17
3	1210–1245	31.80	0.48	11.14	0.65
4	1225–1260	31.36	0.04	11.41	0.92
5	1240–1300	30.32	-1.00	10.18	-0.31
6	1280–1335	33.29	1.97	9.56	-0.93
7	1315–1385	31.92	0.60	9.12	-1.37
8	1365–1410	31.71	0.39	8.26	-2.23
9	1390–1450	30.15	-1.17	9.88	-0.61
10	1430–1535	31.64	0.32	10.03	-0.46
11	1515–1610	30.95	-0.37	13.39	2.90

Long-term mean = 31.32; standard deviation = 10.49

Examining the data in this way indicates that only Periods 5, 6, and 9 were different from the long-term mean in any meaningful way. Period 4, which is the most different period in the non-overlapped analysis, is very close to the long-term mean. Period 9 also stands out in both analyses as below the mean. If we examine the overlapped periods in terms of standard deviations, Periods 7, 8, 11, and possibly 6 are clearly different. Period 11 was clearly more variable, as well as relatively dry.

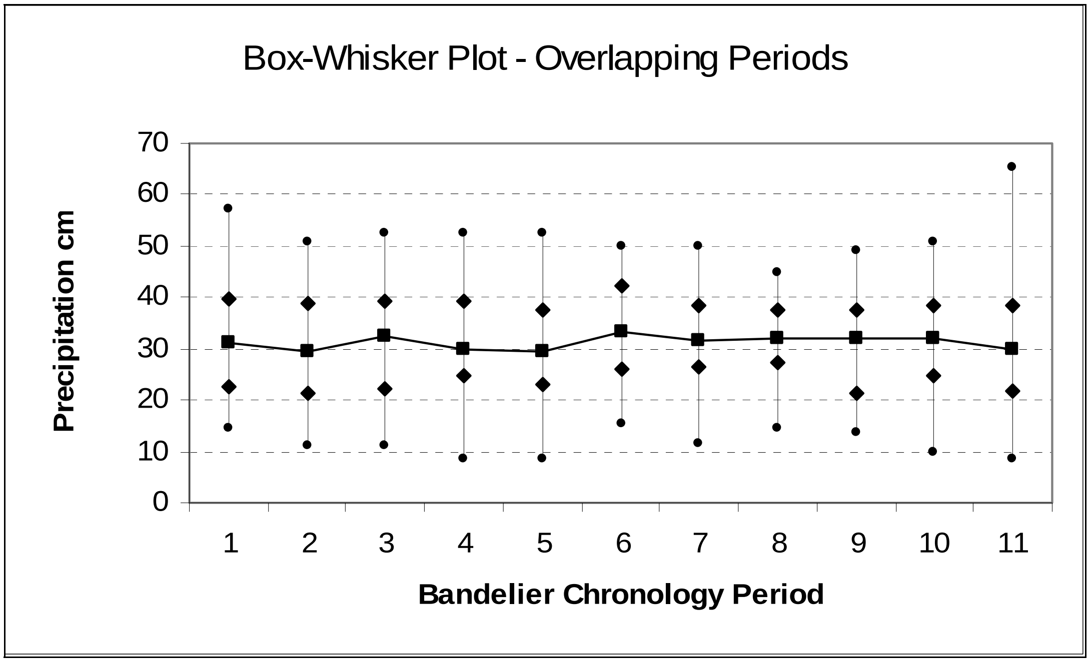

Figure 8.20. Jemez box-and-whisker plot of Bandelier chronology (overlapping).

The Chama Reconstruction

Table 8.13 presents the Chama precipitation mean and standard deviation for each period in the Bandelier chronology. It also lists the period deviation from the long-term mean and standard deviation (columns 4 and 6); Figure 8.21 summarizes these data using box-and-whisker plots.

Table 8.13. Chama reconstruction wet/dry periods compared to Bandelier archaeological chronology (non-overlapping).

Period	Years	Mean	Deviation from Long-term Mean	S.D.	Deviation from Long-term S.D.
1	1150–1190	42.79	-0.55	10.16	-1.26
2	1190–1220	44.68	1.34	10.73	-.69
3	1220–1235	43.57	0.23	10.25	-1.17
4	1235–1250	44.45	1.11	9.81	-1.61
5	1250–1290	42.39	-0.95	13.43	2.01
6	1290–1325	45.22	1.88	13.29	1.87
7	1325–1375	46.58	3.24	11.85	.43
8	1375–1400	42.39	-0.95	11.30	.12
9	1400–1440	45.47	2.13	12.56	1.14
10	1440–1525	41.18	-2.16	12.15	.73
11	1525–1600	40.55	-2.79	9.01	-2.41

Long-term mean = 43.33731; standard deviation = 11.42

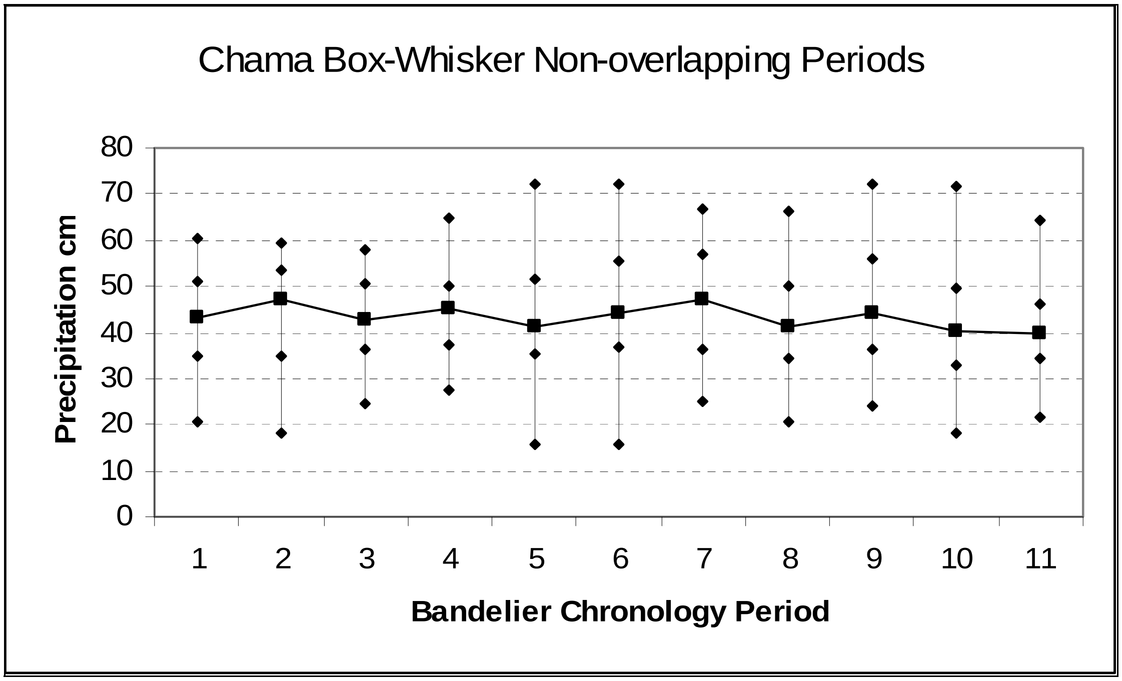

Figure 8.21. Chama box-and-whisker plot of Bandelier chronology (non-overlapping).

The Chama reconstruction period means present an interesting pattern. After below-average precipitation in the AD 1150–1190 period, there was above-average precipitation in Periods 2 to 4, from AD 1190–1250. After low precipitation from AD 1250–1290 (Period 5), above average precipitation prevailed throughout Periods 6 and 7 (AD 1290–1375). Periods 8 and 9 alternated between below and above-average precipitation, but the final two periods (10 and 11) experience the lowest precipitation means in the reconstruction. In short, the archaeological chronology begins dry, is somewhat wet for 60 years, drier for 40 years, wetter for 85 years, drier for 25 years, wetter for 40 years, and finally drier for the last 160 years of the chronology.

The Chama period standard deviations also present an interesting pattern. The first four periods (AD 1150–1250) experienced variability below the long-term average; the next six periods were all above the long-term standard deviation, and the final period (AD 1525–1610) was the least variable in the entire archaeological chronology.

Viewing the Chama chronology using 10-year overlapped periods (Table 8.14; Figure 8.22) changes the interpretation slightly.

Table 8.14. Chama reconstruction wet/dry periods compared to Bandelier archaeological chronology (overlapping).

Period	Years	Mean	Deviation from Long-term Mean	S.D.	Deviation from Long term S.D.
1	1140–1200	43.32	-0.02	9.94	-1.48
2	1180–1230	43.53	0.19	10.58	-.84
3	1210–1245	43.68	0.34	10.94	-.48

Period	Years	Mean	Deviation from Long-term Mean	S.D.	Deviation from Long term S.D.
4	1225–1260	42.83	-0.51	12.59	1.17
5	1240–1300	42.92	-0.42	12.89	1.47
6	1280–1335	43.70	0.36	12.00	.58
7	1315–1385	45.49	2.15	12.20	.78
8	1365–1410	45.53	2.19	11.90	.48
9	1390–1450	43.76	0.42	12.47	1.05
10	1430–1535	41.83	-1.51	11.92	.5
11	1515–1610	41.57	-1.77	9.94	-1.48

Long-term mean = 43.33731; Standard deviation = 11.42

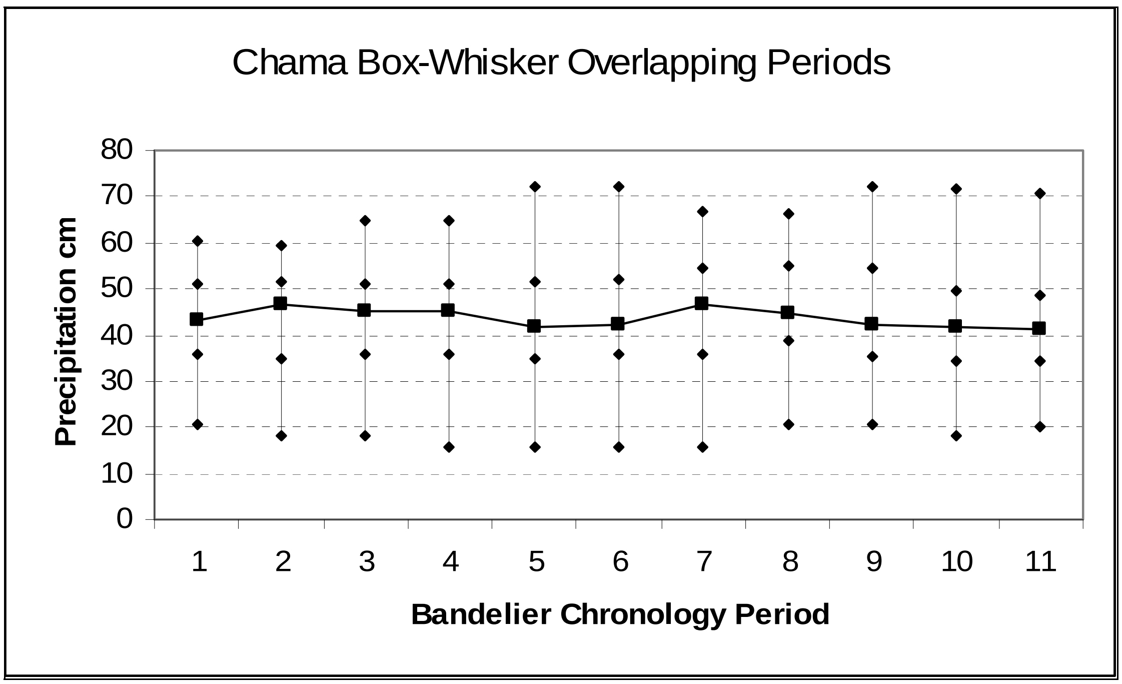

Figure 8.22. Chama box-and-whisker plot of Bandelier chronology (overlapping).

In terms of mean precipitation, Period 4 (AD 1225–1260) is below average and Period 8 (AD 1365–1410) is now above average; the other periods change in terms of absolute values, but not whether or not they are above or below the long-term mean. In terms of standard deviations, only Period 4 changes from less variable to above the long-term standard deviation.

The Jemez and Chama reconstructions and the Orcutt model provide three different views of past moisture availability in the Pajarito Plateau area between AD 1150–1610. There are, of course, differences. This project retrodicted precipitation using tree-ring data and Orcutt retrodicted soil moisture based on different tree-ring data. There are also spatial differences in these approaches—our Jemez retrodiction is calibrated on the Jemez Springs HCN data, our Chama retrodiction is based on the Chama station data, and the Orcutt model is ultimately based on the

Arroyo Hondo tree-ring series. Nevertheless, we believe the different reconstructions are broadly comparable.

Orcutt developed a matrix that partitioned her period data into four possible moisture and variability combinations: high mean/high variation, high mean/low variation, low mean/high variation, and low mean/low variation. She then plotted each archaeological period in the matrix (Figure 8.23) and posited behavioral responses to these variables that should be visible in the archaeological record.

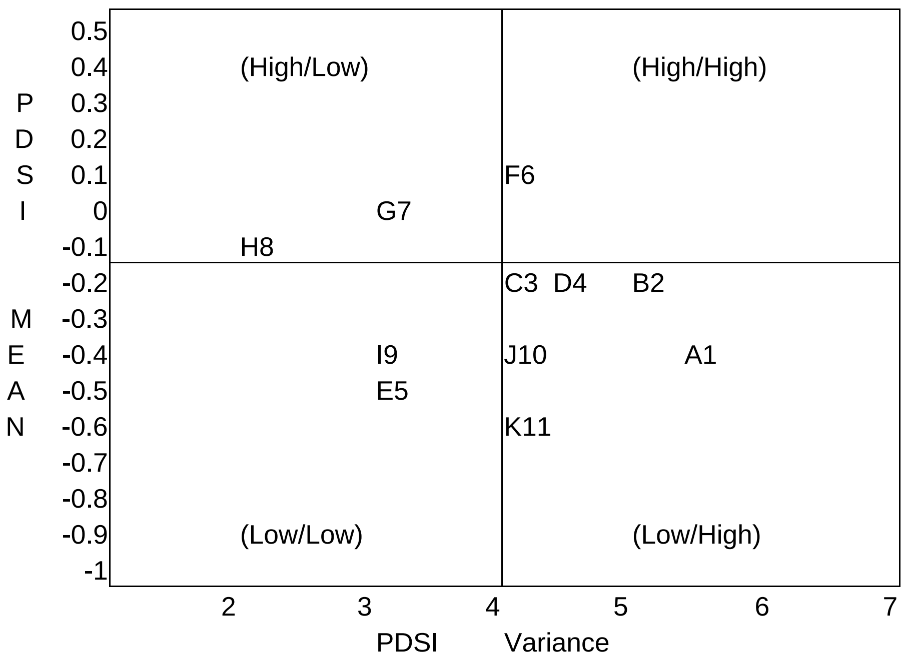

Figure 8.23. Orcutt's quadrats of precipitation variability.

As a comparative exercise, we have partitioned the Jemez and Chama data into similar combinations and plotted them (Figures 8.24 and 8.25). When we compare all three models (Table 8.15), there are important similarities and differences.

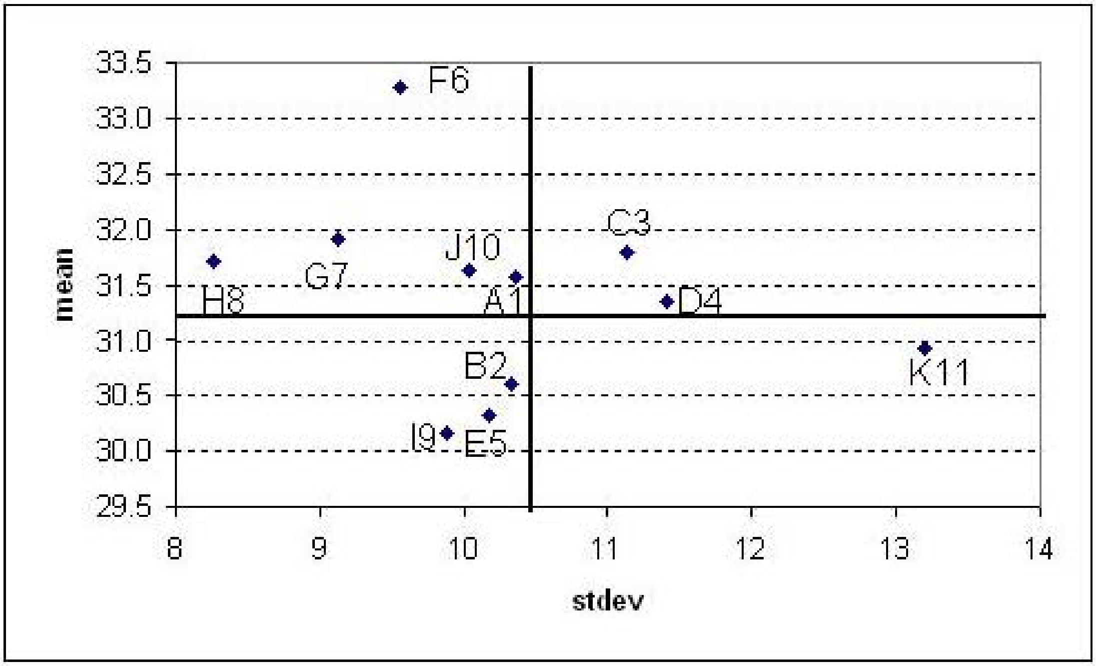

Figure 8.24. Jemez chronology quadrats of precipitation variability.

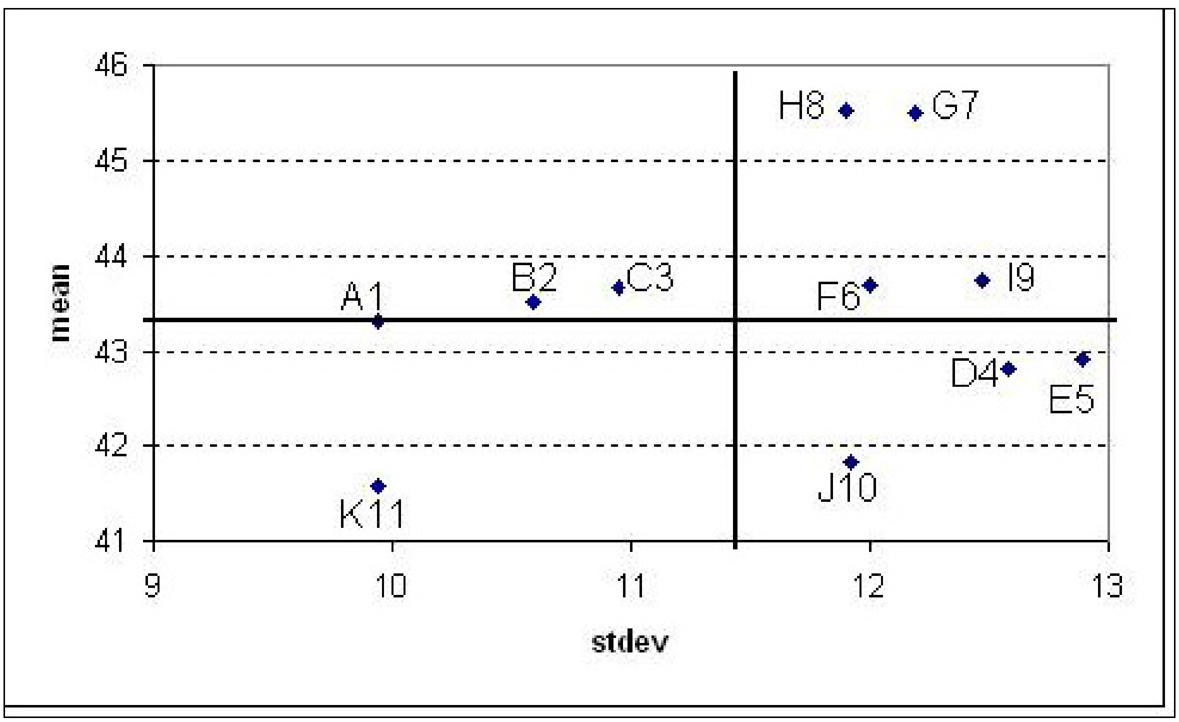

Figure 8.25. Chama chronology quadrats of precipitation variability.

Table 8.15. Comparison of three models' mean and variance.

Period	Orcutt Model		Jemez		Chama

10	L	H	H	L	L	H
11	L	H	L	H	L	L

Interestingly, there are no periods in which all three models agree on both variables. Sometimes they all agree on one variable, and some times two reconstructions agree on both, but disagree with the other model. The possible reasons for these similarities and differences are explored below.

In Period 1 (AD 1150–1190), the Jemez and Chama datasets agree (High mean/Low standard deviation) and are opposite of the Orcutt model (Low/High). These differences may be more perceived than real. The Jemez and Chama High means are only slightly above their long-term values, and the Jemez standard deviation is only slightly below its long-term value. Clearly, however, the Chama and Orcutt variability value are much different.

During Period 2 (AD 1190–1220), all three reconstructions are different: Orcutt is Low/High, Jemez is Low/Low, and Chama is High/Low. Again, the absolute values may be important—the Chama mean is only slightly above the long-term average, the Orcutt mean is slightly below, and the Jemez standard deviation is slightly below. Thus, the major differences between the Orcutt model variance and Chama standard deviation.

All three reconstructions show different results in Period 3. The Jemez (High/High) and Chama (High/Low) agree about above-average precipitation, and the Orcutt model (Low/High) and Jemez agree about above-average variability. A closer look at the plots, however, shows that all three reconstructions place the period near both central axes of the quadrants; thus, the differences are simply not great.

Period 4 (AD 1235–1250) shows significant agreement in that all three models indicate high variability; the Orcutt model and Chama also indicate low mean moisture availability. Like the previous periods, however, the mean values are all very near the long-term value and the differences are probably not behaviorally important. The period obviously experienced highly variable conditions as indicated by all three datasets.

With only one exception, Period 5 (AD 1250–1290) is characterized as Low mean/Low variability; the Chama reconstructions recorded very high variability. The period was clearly dry throughout the northern Rio Grande, but the Chama area was less arid and experienced more wet years. The implications of this difference deserve more scrutiny by area archaeologists.

Conditions changed significantly during Period 6 (AD 1290–1325). All three models indicate high mean moisture, and the Orcutt and Chama data indicate high variability as well. The Orcutt and Jemez data suggest that this period had the highest mean precipitation during the archaeological chronology. Apparently, the Jemez/Bandelier area was wet and somewhat variable; the Chama area was only slightly above average and somewhat more variable. All in all, Period 6 should have been very productive throughout the northern Rio Grande area.

The good times continued during Period 7 (AD 1325–1375) with high means and low variability, except in the Chama area which also experienced high variability. The high variability in the Chama area was probably offset by one of the highest means in the entire reconstruction.

Period 8 (AD 1375–1400) is identical to Period 7 in terms of the category classifications; Orcutt and Jemez (High/Low) and Chama (High/High). The high means in all three reconstructions are very similar and the variability is lower in all three models than in Period 7. Indeed, Period 8 may have been the most optimal period in the entire archaeological chronology.

Things changed dramatically in Period 9 (AD 1400–1440). Mean moisture availability was low in both the Orcutt and Jemez models, but slightly above average in the Chama dataset. Variability was low in the Jemez/Bandelier area, but still high in the Chama area. These spatial differences may have had important implications for settlement and subsistence throughout the area and should be explored by area archaeologists.

The Orcutt and Chama reconstructions agree that Period 10 (AD 1440–1525) experienced low mean/high variability; the Jemez, on the other hand, indicates high mean/low variability. Examination of the raw data, however, indicates that the Jemez High/Low configuration is a result of classification; the mean is only slightly above the long-term value and the standard deviation is only slightly below the long-term value. Thus, all three models are telling similar stories—times were not great.

The final archaeological period (AD 1525–1610) continued to be relatively poor. The Orcutt and Jemez models indicate Low mean and High variability, and the Chama data indicate Low mean and Low variability.

Finally, we also used quantitative methods to evaluate precipitation periodicity during the years of the Bandelier archaeological chronology. Our methods are similar to those used above to identify wet/dry periods in each reconstruction. In this evaluation, however, every year's value was forced into a wet/dry category based on its relationship to the long-term mean and splined values around it. In this way, the method is similar to those of a PDSI analysis.

Table 8.16 presents our wet/dry years, the Bandelier periods, and comments regarding the precipitation during those periods. Only two periods, Period 1 (AD 1150–1190) and Period 6

(AD 1290–1325), did not experience changes in the precipitation regime. Interestingly, both Periods 1 and 6 experienced above-average precipitation. All the other archaeological periods experienced at least one, and some times more, shifts from wet or dry conditions to the opposite.

Table 8.16. Quantitative evaluation of precipitation periodicity compared to Bandelier archaeological periods.

Years	Condition	Bandelier Period	Bandelier Years	Comments on Period Precipitation
1131–1151	DRY	--	--	n/a
1152–1213	WET	1	1150–1190	wet all period
1214–1227	DRY	2	1190–1220	wet early, dry late period
1228–1245	WET	3	1220–1235	dry early, wet late period
1246–1264	DRY	4	1235–1250	wet early, dry (very) late period
1265–1275	WET	5	1250–1290	dry early, wet middle, dry late period
1276–1289	DRY	5	1250–1290	dry early, wet middle, dry late period
1290–1334	WET	6	1290–1325	wet all period
1335–1350	DRY	7	1325–1375	wet early, dry middle, wet late period
1351–1388	WET	7	1325–1375	wet early, dry middle, wet late period
1389–1403	DRY	8	1375–1400	wet early, dry late period
1404–1414	WET	9	1400–1440	dry (very) early, wet early, dry middle, wet late period
1415–1425	DRY	9	1400–1440	dry (very) early, wet early, dry middle, wet late period
1426–1448	WET	9	1400–1440	dry (very) early, wet early, dry middle, wet late period
1449–1483	DRY	10	1440–1525	wet (very) early, dry early middle, wet late middle, dry early late, wet late period
1484–1494	WET	10	1440–1525	wet (very) early, dry early middle, wet late middle, dry early late, wet late period
1495–1510	DRY	10	1440–1525	wet (very) early, dry early middle, wet late middle, dry early late, wet late period
1511–1541	WET	11	1525–1610	wet early, dry middle, wet late period
1542–1593	DRY	11	1525–1610	wet early, dry middle, wet late period
1594–1655	WET	11	1525–1610	wet early, dry middle, wet late period

DISCUSSION

The three models all provide important data regarding precipitation and the availability of moisture during the AD 1150–1610 period. One of the major problems with using the quadrant classification system, however, is that it ignores the range of data. Several periods in all three models cluster near the quadrant axes, and slight changes in one variable would change their classification. For example, the long-term standard deviation of the Jemez reconstruction is 10.49; the standard deviation for the smoothed Period A1 data is 10.36—a difference of only 0.13. Likewise, the Period A1 mean is 31.57 and the long-term mean is 31.32. Thus, the Jemez period A1 is classified as High/Low, but with minor adjustments—either in the real precipitation or in analysis techniques, could just as easily be classified as High/High, Low/High, or even Low/Low.

In the Jemez reconstruction, five, and maybe more, of the periods could be subject to change due to minor variations (A1, B2, C3, D4, and J10); only Periods E5, F6, K11, and G7 appear to be truly different than the others. In the Chama reconstruction, Periods G7, H8, J10, and K11 appear different, although others could be included as well. In the Orcutt model, all the periods cluster more tightly near the central axes, but Periods F6, H8, G7, K11 and possibly some others appear different.

The quantitative evaluation of precipitation during the Bandelier archaeological periods suggests little correlation between precipitation amounts and variability and cultural sites. This is not to imply that precipitation had no impact on cultural trajectories on the Pajarito Plateau; it most certainly did on both long and short time scales. What we infer is that precipitation was but one factor in the decisions of people to settle, use, and depopulate the plateau over the centuries.

We are not suggesting that there has been no variability between the archaeological periods; clearly other data in this chapter indicate that precipitation has varied over time and across space during the prehistoric and protohistoric occupation of the northern Rio Grande. We do question whether this variability coincides with the Bandelier archaeological periods and if the human responses to the variability are reflected in the archaeological record at such fine temporal scales. In general, we believe the archaeological periods, particularly if overlapped, are too short to capture either the climatic or cultural variation.

CHAPTER 9
A CONTEXT FOR THE INTERPRETATION OF ARCHAEOMAGNETIC DATING RESULTS FROM THE PAJARITO PLATEAU

Eric Blinman and Jeffrey Royce Cox

INTRODUCTION

Archaeomagnetic dating is one of several dating techniques that can be applied to the development of detailed archaeological chronologies. In the context of archaeological investigations on the Pajarito Plateau, the alternate tools include tree-ring dating, radiocarbon dating, ceramic dating, and a variety of luminescence techniques. This summary of archaeomagnetic dating was requested in order to accomplish three goals. The first was to provide an explanatory guide to the theoretical and practical foundations of archaeomagnetic dating. The second was to evaluate existing archaeomagnetic curves that are relevant to the dating interpretation of Pajarito Plateau samples, specifically looking at the strengths and weaknesses of the curves as revealed using sample results from Dr. Robert DuBois, University of Oklahoma. The third was to catalog the archaeomagnetic results from the northern Rio Grande region that can be used for comparison with results from the Pajarito Plateau.

The basic elements of archaeomagnetic dating were developed in the 1930s by Emile Thellier and his students (Wolfman 1990). Despite this early start, research and development have proceeded sporadically compared with other dating techniques in the face of theoretical and practical limitations (Eighmy 1991). Progress has been greater in the Southwestern United States than elsewhere in North America, but archaeomagnetic dating remains of secondary importance to archaeologists compared with other natural science techniques such as dendrochronology and radiocarbon assays. Luminescence dating techniques (Feathers 2000) are showing promise as well, although confidence in its strengths and weaknesses will be dependent on additional case studies (e.g., Dykeman et al. 2002).

The ambiguous position of archaeomagnetic dating is due to a mixture of advantages and disadvantages. Archaeomagnetic dating records the time of the last exposure of archaeological features to a source of heat. Archaeomagnetic dating is most effective when the feature is heated above 580 to 680° C (the Curie points for the most common magnetic materials in soils), but lower temperatures can also produce datable samples (Smith 1990). For features such as hearths or burned structures, archaeomagnetic dating is one of only two techniques that can provide last-use or abandonment dates as opposed to construction dates (luminescence dating can also provide last-use dates in some contexts). Another advantage is that since archaeomagnetic dating is based on geophysical properties (Sternberg 1990) rather than cultural behavior, dating results can be more reliable in some contexts. This is particularly true when dead wood is harvested for fuel or building material, skewing radiocarbon or tree-ring samples toward dates that are too old (Smiley 1985). Finally, when high-quality samples are available, and for some time periods when dating curves are robust, archaeomagnetic dating accuracy and precision can be excellent, falling within the range of 20 to 40 years.

Disadvantages of archaeomagnetic dating are both methodological and contextual. The underlying basis for the technique is the year-to-year variation in the geographic position and strength of the earth's geomagnetic field. There is no theoretical model that can accurately describe geomagnetic field variation, and calibrated virtual geomagnetic polar curves for dating purposes must be developed from paleo- and archaeological samples (or from historic records). The pole positions of these samples and often their calibrating dates are measured with error, and the uncertainties result in archaeomagnetic dating curves that are tentative approximations of the true curve. Also, curves follow an overlapping path, resulting in the possibility of multiple date interpretations for a single sample result. In this respect, final date interpretations are often dependent on the expectations of the archaeologist, reducing the independence of archaeomagnetic dating's contribution to the resulting cultural chronologies. Finally, sample quality can be affected by both systematic and idiosyncratic factors of sampling technique and local magnetic anomalies, resulting in either imprecision or inaccuracy in individual cases.

PRINCIPLES OF ARCHAEOMAGNETIC DATING

The underlying basis for archaeomagnetic dating is the year-to-year variation in the geographic position and strength of the earth's geomagnetic field (Sternberg 1990). This field consists of a dipole component that is usually oriented near the rotational axis of the earth and non-dipole components that are regional and local in nature. At any given point on the earth's surface, these components combine to create an apparent or virtual geomagnetic pole (VGP) location. As the strength and orientation of the dipole and non-dipole fields vary through time, the VGP location changes, describing a VGP curve. Because of the influence of non-dipole fields, VGP curves will not be the same from region to region, although there are greater similarities between regions that are adjacent east-west than north-south (Sternberg 1990:9–10).

Magnetic material in soil (primarily magnetite and hematite) is affected by the prevailing geomagnetic field. When this magnetic material is heated to and above its Curie point (580° C for magnetite and 680° C for hematite), it acquires a field direction that is influenced by the orientation of the earth's field as the material cools. This is known as the thermal remnant magnetism, or TRM. Although subsequent events can weaken or alter this TRM, such as a nearby lightning strike, in most cases the TRM orientation persists until the soil is subjected to another heating episode that exceeds the previous temperature or the Curie point.

An archaeomagnetic sample usually consists of a set of up to 12 specimens collected from the soil lining a hearth, kiln, oven, or other type of burned feature. Fired rocks, such as sandstone, can also be sampled if care is taken during collection. The orientation of each specimen is carefully measured, and magnetic properties of each specimen are subsequently measured in the laboratory. Measurement usually includes progressive alternating field (AF) demagnetization to reduce the influence of any secondary magnetic components that might have been acquired since the feature was last fired. Results of the individual specimen measurements are compared, and data from the best specimens are combined to characterize the earth's magnetic field at the time the feature was burned. The mean orientation of the specimens is the estimate of the VGP location, and the dispersion of the specimen orientations provides an error term that is expressed as an ellipse or oval of confidence (two standard deviations) around the VGP center point.

Inconsistent specimen orientations result in samples with large ellipses, reflecting greater uncertainty about the true VGP location.

Date interpretations are made by comparing each sample plot with a regional VGP curve (also called a secular variation curve). Points of intersection of the ellipse with the curve determine the beginning and end points of the date range. Since the calibration curve is only an approximation of the real curve, when a sample centerpoint falls off of the curve, a common convention is to move the centerpoint to the nearest point on the curve for the calculation of the date range. Where the ellipse intersects more than one segment of the calibration curve, the centerpoint is moved in turn to the closest point of each segment, resulting in as many date range estimates as the number of curve segments that fall within the original ellipse.

Because of the influence of non-dipole components on the geomagnetic field, calibration curves must be established for each region of the earth's surface. The U.S. Southwest curves have been developed for a relatively large region of 500 to 1000 miles in diameter. For this reason, the calibration curves are best thought of as bands within which the true curve lies, varying slightly depending upon the location of the project area within the region. As an arbitrary compensation for this additional uncertainty, date range estimates are usually rounded five years beyond either end of the points where the ellipse intersects the curve.

For regions or time periods where a calibration curve does not exist, sample results can be used to construct a curve. In the absence of independent dates for samples, seriation principles can be used to develop a first approximation of the true curve. Where independent dates are available, they can serve both to validate the direction of the curve and to calibrate the curve to the modern time scale. For regions and time periods where calibration curves have been established, sample results are used not only to produce date estimates but also to validate and refine the existing approximation of the true curve.

SAMPLING AND MEASUREMENT PRACTICE

Burned sediments are collected as carefully oriented specimens approximating the volume of a sugar cube. Ideally, specimens are cut from portions of the feature that are well burned, show no erosion, and show no evidence of cracking or slumpage. Ideal sampling material is rare due to the actions of roots, insects, small mammals, mass slumpage, and repeated exposure to wetting and drying. To the extent that disruptive agents cause small random reorientations of the material, the ultimate sample result will be less precise but still accurate. To the extent that slumpage causes the systematic reorientation of large blocks of the material to be sampled, results may be precise but may be inaccurate. Most of these sources of error can be detected and avoided or minimized during specimen collection. Where cracked and potentially displaced material must be sampled (as in many Pajarito Plateau fire hearths where hearth lining material has cracked), field judgments must identify the most stable material. Where there is ambiguity in the integrity of any particular block of burned sediment, multiple specimens from multiple blocks are necessary to evaluate the potential effects of slumpage on the orientations. A sample or set usually consists of eight to 12 specimens. Fewer than eight weakens the statistical confidence measure of the result. More than eight specimens do not materially improve the statistical precision, but more than eight may be required to cope with sample quality issues that are noted during the collection process.

When columns of burned material have been isolated, they are enclosed within high-precision brass or aluminum molds. The molds are set on bases of modeling clay, which both seal the bottom of the mold to the burned feature and allow the mold to be precisely leveled. After leveling, the mold is filled with a fast-setting plaster, and the contemporary magnetic orientation of the mold is measured with a vetted Brunton compass. Vetting is necessary because of inherent imprecision in the compass manufacturing process; up to seven of every 12 compasses are rejected for inaccuracies that are greater than is acceptable for archaeomagnetic sampling. When the plaster has set, the mold and contents are detached from the feature, the ends of the specimen are trimmed, the base is capped with plaster, and the specimen is labeled so that the mold orientation can be associated with the specimen during measurement.

After collection, samples are transported to the measurement laboratory. At the Archaeomagnetic Dating Laboratory (ADL) at the Museum of New Mexico in Santa Fe, samples are stored under shielded conditions and are measured within Helmholtz coils that are adjusted to create a zero magnetic field around the spinner magnetometer. Storage within a zero field allows weak viscous contaminating magnetic components to dissipate before measurement. Under conditions of a zero magnetic field, measurement accuracy and precision are increased, especially for weak samples. Samples are assigned sequential laboratory numbers. Declinations are assigned to each sample based on the date of collection and the latitude and longitude of the site using either maps of geomagnetic declination or the MagCalc program (1993). The declination allows the magnetic specimen orientation taken during sampling to be translated into an azimuth relative to true north.

Magnetic orientation and strength are first measured for samples (sets of specimens) at their natural remnant magnetism (NRM). The NRM is a combination of the TRM vector of interest and any other vectors that may be present. “Contaminating” vectors can include magnetized pebbles whose size precluded reorientation on heating and viscous magnetic fields that are slowly subject to reorientation by the prevailing earth’s magnetic field. In an effort to remove these contaminating vectors, the specimens are remeasured after progressive AF demagnetization steps. Standard demagnetization and remeasurement are carried out at the following intervals: 50, 100, 150, 200, and 300 Oe (Oersteds). Demagnetization effectively eliminates weakly held magnetic components, from both the TRM and other sources. These secondary components are generally not random and therefore affect both the apparent direction of magnetization and the dispersion of the specimen directions, influencing both the accuracy and precision of pole locations and date estimates. Under ideal conditions, the TRM of interest is the strongest contributor to NRM, and demagnetization eliminates the unwanted components, leaving a residual component that accurately reflects the orientation of the earth's magnetic field at the time of cooling. Under poor conditions (usually extremely weak samples), demagnetization can eliminate the TRM as well as any secondary components before a defensibly “best” orientation is identified.

Since the magnetic history of a sample is unknown and since the strength of spurious magnetic components can vary widely, selection of the "best" demagnetization level for an individual sample can't be predicted in advance. The best demagnetization level for a sample is identified by the analyst when the direction and dispersion measurements of a specimen suite stabilize, and when the analyst is confident that the direction is appropriate for a TRM result. The latter criterion inserts an undesirable but unavoidable subjectivity into the archaeomagnetic dating process. Since the TRM vector of interest must by definition be a point on the VGP curve, demagnetization results that move the centerpoint toward the curve are judged more likely to accurately reflect the TRM than are results that move the centerpoint away from the curve. The field archaeologist's expectations of sample age influence the archaeomagnetic technician's decisions, as do the currently accepted version of the VGP curve. In the absence of any theoretical model that can distinguish the non-TRM vector contributions to the overall result, the judgment, experience, and biases of the technician are a necessary part of the measurement and dating process.

In some instances, individual specimen measurements deviate markedly from the other specimens of the sample. These outliers are usually defined as specimens that fall beyond two standard deviations of the sample mean. Outliers can be caused simply by sampling error, by unwanted heterogeneity in the specimens (such as magnetized pebbles), or by mistakes in field collection and documentation. The usual procedure is to use Fisher statistics to identify outliers and to progressively eliminate outliers from the set result until the results of the remaining specimens fall within two standard deviations of the new sample mean. If only sampling error were contributing to the dispersion of specimen vectors, 1 out of 20 samples would have a result where a single specimen was eliminated. In practice, more samples than expected have one or more specimens dropped from the final result, reflecting the presence of more potential sources of error than simply the measurement process.

Mean vector direction (recorded as the inclination and declination of the sample) and the dispersion (recorded as an angular expression of alpha 95 or α_{95}) are used to calculate a VGP for the selected sample result and an oval of confidence around the VGP centerpoint. Where the α_{95} dispersion value exceeds 4.0°, the confidence oval is so large that its overlap with dating curve segments generally yields large date ranges that are not useful for the archaeologist. Also, as the α_{95} exceeds 4.0°, there is less and less confidence that the result is exclusively representative of the TRM as opposed to other sources of a magnetic orientation. Although results with α_{95} values of more than 4.0° can be interpreted, the ADL does not routinely assign date ranges to those results. As α_{95} values decrease, precision of the VGP location increases. A "good" result generally has an α_{95} of less than 2.0° and an excellent result has an α_{95} of 1.0° or less. However, measurement precision applies to the estimate of the sample VGP location only, and its extension to a subsequent dating interpretation is dependent on all of the assumptions of the dating technique being correct.

Calibration Curves

Archaeomagnetic dates are estimated by comparing sample results with a calibration or VGP or dating curve. However, as discussed above, VGP curves are approximations since there is no theoretical model for polar movement. We can assume that the true curve is continuous, it can change in its rate of movement, it can turn abruptly or slowly, and it can loop back upon itself in either short or long time periods. Any attempt to derive a true curve with these qualities from ancient records faces three problems. First is the degree to which the material being sampled is continuously recording the changing VGP and that the material will support a sampling interval that is fine enough that all significant inflection points of the curve are represented in the dataset. Second, since VGPs are measured with error, sample density at each time point must be high enough that a mean VGP location is a valid representation of the curve position. Third, the independent chronology of the samples must be sufficiently robust that samples are not mis-sequenced or mis-dated.

Lake or ocean sediment cores can provide a relatively continuous record of polar movement through detrital remnant magnetism, in which minute magnetized particles are influenced by the prevailing earth's magnetic field as the particles fall through water (Sternberg 1990:18). The particle orientations are set as the sediment gels and compacts, and the sediment sequence becomes a continuous record of secular field variation. Such records would be ideal for VGP curve development, but the theoretical potential runs into practical limitations. Even small variations in sedimentation rates stretch and shrink the record, limiting the simple use of depth as a proxy for an interval or ratio time scale. The physical process of core collection is challenging, and it is difficult to maintain core orientation precisely. Relative declination variation within a core is generally reliable, but the absolute orientation of a core to the modern geomagnetic field is only an approximation. Rapid sedimentation rates are ideal, but core lengths are limited (generally 2 to 3 m), so that long records must be collected by multiple overlapping cores, introducing the problem of core matching, both in a stratigraphic sense and in the sense of consistent specimen orientation. Dating calibration is limited to radiocarbon assays of the organic constituents of the sediments, with the inherent ambiguities of the calibration process (Stuiver and Reimer 1983) and the expense of having to submit multiple and close interval samples to calibrate changes in deposition rates as well as to establish age. Also, detrital magnetism studies have been limited in number, and their geographic positions have been peripheral to the Southwest (e.g., Verosub et al. 1986). Similarities with the Southwestern archaeological VGP curves have been used to validate the detrital curves, rather than the opposite.

At the present time, approximations of the Southwestern VGP curve must be built from large numbers of results from archaeological contexts, using independent sources of dating both to establish the relative sequence of pole positions and the calibration of the resulting curve to the modern time scale. This task is not simple, either in theory or in practice. Archaeological samples are dependent on cultural burning events and on the archaeologists' decisions of what sites will be excavated. There is no guarantee that the cultural burning events are sampling the entire sequence of VGP variation with the same richness, and of the universe of culturally burned sediments, only a small portion has been excavated let alone sampled for archaeomagnetic information. Independent chronological control can be highly variable, from the precision of tree-ring dates to the ambiguity of radiocarbon assays to the generality of phase or ceramic period assignments. Given these limitations, it is remarkable and gratifying that the calibration curves that have been proposed through the years by Robert DuBois, Jeffrey Eighmy, Robert Sternberg, and Daniel Wolfman have been so robust and effective, despite their status as approximations and despite their differences.

Two contrasting approaches have been used for constructing VGP curves in the Southwest (Sternberg and McGuire 1990a, b; Eighmy 1991). One is a moving-window averaging technique. In this method, sample results are arranged by estimated archaeological age (based on independent judgments of the excavators). A weighted average is calculated of the sample results that fall or could fall within a given range of years, and that average is used to define the calibration point for the midpoint of the range. The "window" is advanced by an interval (such as one-half the length of the time window), and another average is calculated and plotted. The calibration curve is then constructed by joining these points.

The second method is a visual or freehand approach. In this method, sample centerpoints are placed on a polar plot, including both independently dated and undated samples. A freehand approach is then used to sketch in a curve, assuming that all samples, whether independently dated or not, should be on or near the curve. Independently dated samples are used to confirm the direction of the curve, to differentiate crossover points and loops, and to calibrate the curve to the modern time scale. Knowledge of the behavior of calibration curves in adjacent regions can also be applied to develop the curve in time periods where sample points are thin or trends are ambiguous.

Both techniques have strengths and limitations. The moving-window approach is replicable and explicit, and it is amenable to computer manipulation so that revised curves are easily constructed as additional calibration data become available. Weaknesses are a reduced sample size, susceptibility to error in archaeological date assignment, and artificial smoothing of variation. Smoothing poses two related problems. Window lengths are set arbitrarily, usually in the range of 40 to 100 years, or can be variable based on data density (Sternberg and McGuire 1990; Eighmy and Klein 1990). VGP variation that occurs at time scales below the window size and interval is effectively lost. In most instances this is inconsequential due to the size of most error ellipses, but it also partially explains the disconcerting consequence that an unusually large number of excellent results $\acute{\alpha}_{95}$s of 1.0° or less) fall off of the resulting curve. The second and more important problem is that changes in the direction of VGP movement are artificially foreshortened, with the magnitude of the effect proportional to the abruptness of the direction change. Foreshortening is a mathematical consequence of the averaging technique, and the degree and significance was first demonstrated by Cox and Blinman (1999) and then confirmed by Lengyel (1999). The moving window average technique is also susceptible to distortion if archaeologists have misinterpreted the chronology of the calibration samples or if inaccurate VGPs are included in the calibration dataset.

Subjectivity is the principal weakness of the freehand approach to calibration. Because paleomagnetic curves commonly contain loops and intersections, sample results that are not independently dated can be interpreted based on preconceptions of curve direction. Also, familiarity with individual samples or suites of samples can lead to over-interpretation of small (<2°) curve features such as loops and kinks. As a result, two researchers given the same data are unlikely to produce precisely the same curve. Strengths of the technique are that it makes use of a large amount of data and that it need not systematically dampen variation. The large number of data points has the potential to increase the resolution of the curve, especially if there are cultural factors that reduce the number of independently dated samples for specific time periods. Perhaps more important is that there is no systematic foreshortening bias built into the technique, so that there is an opportunity for more accurate representation of loops and short term deflections of the curve. However, due to the subjectivity of curve construction, there is no internal standard against which the accuracy of the curve can be measured.

Three calibration curves are currently available for the interpretation of dates from Southwestern sample results (Figure 9.1). Robert DuBois' Southwest curve (1989) is a freehand compilation based on four decades of research on Southwestern archaeomagnetic dating. His curve is unique in including a pre-AD 600 component, but its calibration is more general than the other curves, and it is rarely used by other researchers for date interpretation except in the pre-AD 600 period. Stacey Lengyel and Jeffrey Eighmy's SWCV2000 curve is the latest revision of a long series of moving average-based curves produced by Eighmy's Archaeometric Laboratory at Colorado State University (Eighmy 1991; Eighmy and Klein 1990; LaBelle and Eighmy 1995). The Eighmy curves have generally superceded the curves developed by Robert Sternberg (1990) using the same averaging technique. The SWCV2000 curve is a methodological departure in that it incorporates modifications to the moving average results. Simulations were used to estimate and correct for the magnitude and direction of foreshortening at inflection points, and non-calibration data were used to modify the location of the curve in the AD 900 to 1025 segment. Daniel Wolfman's curve is a freehand compilation based on his interpretation of his own data. He lacked data to improve on the various Eighmy curves or on the DuBois curve for the AD 400 to 1000 and post-AD 1450 time periods. Wolfman's curve has been in use for some time (Windes 1991:297–304), but formal publication of the curve was posthumous (Cox and Blinman 1999). The data Wolfman used to construct the curve have never been completely reconstructed.

Differences between the three curves are both minor and dramatic, depending on the time period. This reflects the tentative nature of our understanding of the Southwest VGP curve as well as the different methodological approaches to curve construction. Small discrepancies in both path and calibration characterize the AD 400–1150 period segments of the three curves, but the discrepancies by and large have little effect on date interpretations. In contrast, there are large and significant differences in the AD 1150–1800 period, and in particular the AD 1150–1400 period. The DuBois and Wolfman freehand curves are similar, but the more explicitly developed SWCV2000 differs markedly. These differences are incompatible with the magnitude of many sample error terms, resulting in an inordinately large number of precise results (α_{95}s of 2.0° or less) that fall significantly off of one or more of the curves. These differences have also been evident in a number of incorrect date interpretations, where demonstrably post-AD 1150 samples were being given pre-AD 1150 date assignments, and vice versa. Since only one true curve exists, portions or all of each of the three extant curve models are probably incorrect for the AD 1150–1400 time period.

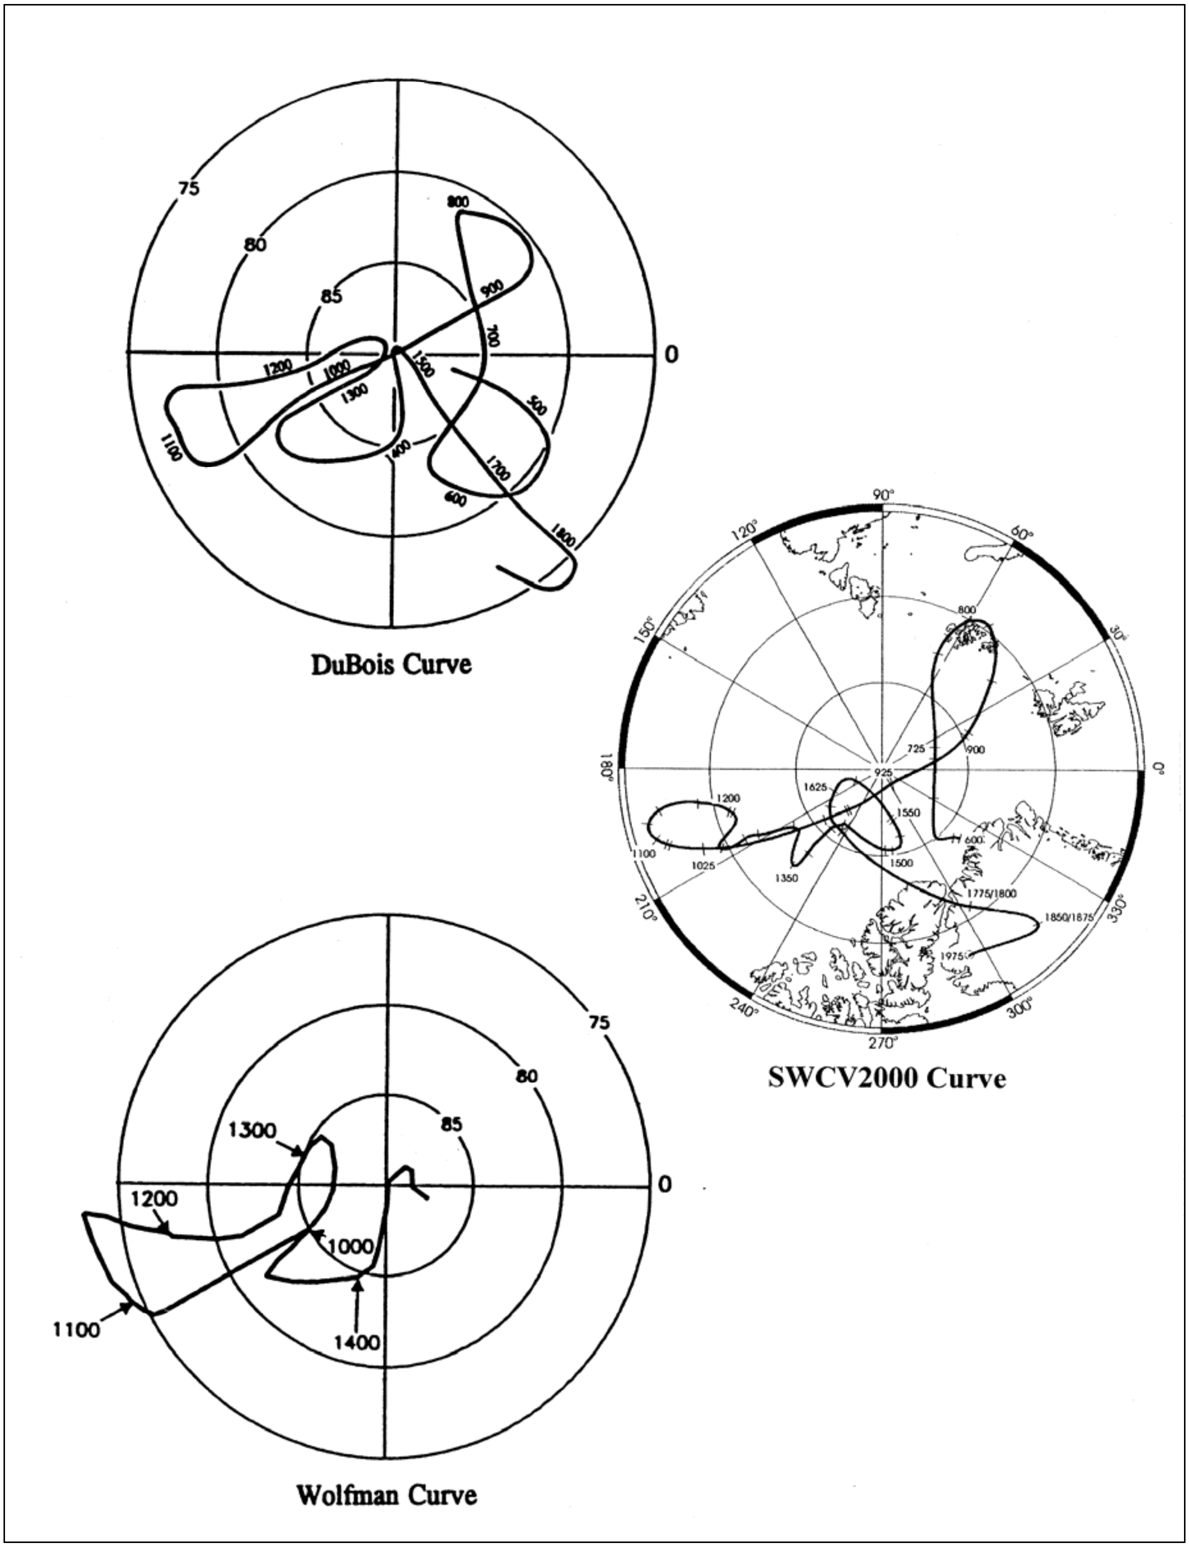

Figure 9.1. Current archaeomagnetic dating curves for the Southwestern United States. The DuBois curve is adapted from DuBois (1989), the SWCV2000 curve is from Lengyel and Eighmy (2002), and the Wolfman Curve is from Cox and Blinman (1999).

This significant weakness in the calibration curves for archaeomagnetic dating coincides, unfortunately, with the period of interest in Pajarito Plateau chronology (Vierra et al. 2002a). The initiation of the Coalition period is placed around AD 1150 (Vierra et al. 2002a) or AD 1200 (Powers and Van Zandt 1999). Trajectories of population growth and aggregation are demonstrable through the Coalition period, but the dynamics of those trajectories are still poorly understood for lack of a robust chronology through the 13th and 14th centuries. Significant regional changes in population aggregation (nucleation) define the onset of the Classic period at AD 1325, and large pueblo-based or village-based settlement patterns persist until the onset of the Spanish Colonial period at AD 1600.

CURVE PERFORMANCE EVALUATION

Ambiguities surrounding the AD 1150–1400 VGP curve segments can be explored with a performance evaluation of the proposed curves. The template for this approach was developed in an evaluation of the AD 650–950 portion of the SWCV590 curve (Cox and Blinman 1999). The underlying assumption is that archaeomagnetic results are all valid "samples" of the true curve position. Each will reflect a location of the earth's geomagnetic pole at the time of cooling, with an error that stems principally (although not entirely) from measurement uncertainties. Additional sources of error may be present, and those must be considered during data interpretation. The method of curve evaluation is most easily characterized as a study of residuals. Samples are reviewed for relevance to a particular curve segment. Sample centerpoints are plotted in relation to the curve, residual distances are calculated between the centerpoints and the curve, and the magnitude and sign of the residuals are evaluated for the presence of any systematic patterns. If the curve is a valid approximation of the true curve, residuals should be randomly distributed around the curve, and most sample error terms (α_{95}s) should overlap with the curve. In the AD 650–950 curve evaluation, we were able to demonstrate that the moving average technique used to develop the SWCV590 curve systematically biased the curve at its inflection points (Cox and Blinman 1999), resulting in confirmation of our conclusions with a simulation approach (Lengyel 1999), and revision of the Eighmy curve to begin to correct the problem (Lengyel and Eighmy 2002).

The original residual study was conducted by hand using graphic techniques (Cox and Blinman 1999). The steps have now been automated using the capabilities of Surfer and custom programs written in C++. The steps in the analysis consist of 1) rendering the curve to be evaluated as a "string of pearls," 2) development of a dataset of relevant (or possibly relevant) archaeomagnetic results, 3) residual calculation, and 4) data analysis and interpretation.

Curve rendering was accomplished by digitizing a proposed curve and replacing the table of digitized points with points that are evenly distributed along the path of the curve (a "string of pearls"). The calibration points (dates) proposed by the curve authors were added to the table at the appropriate points along the curve, and intervening dates were interpolated for each point. As the most widely used curve in the interpretation of contemporary archaeomagnetic results, the SWCV2000 curve was used for segment definition. Arbitrary break points were defined along the curve, each representing both a discrete period of time and a distinctive feature of the curve. The segment definitions are provided in Table 9.1.

Table 9.1. Segment definitions for curve performance evaluation.

Segment number	Beginning date (AD)	Ending date (AD)
1	NA	400
2	400	600
3	600	800
4	800	950
5	950	1125
6	1125	1225
7	1225	1300
8	1300	1400
9	1400	1500
10	1500	1600
11	1600	1900

The datasets chosen for comparison with the curve segments in this study come from data provided by Robert DuBois. These archaeomagnetic results were not used in producing either the SWCV2000 or the Wolfman Curve, and therefore they can be viewed as independent comparative information. Only results with $ά_{95}$ values of 3.0° or less were selected for use in the comparison. Independent chronological information for many of the results is sketchy, but most samples could be assigned to one or more segments after researching site notes and interviewing archaeologists. We expect that additional research will improve the precision in the assignments of individual samples to the segments. Segments 5 through 9 are most relevant to the culture history of the Pajarito Plateau, and only those segments are treated in the following discussion.

AD 950–1125 (Segment 5)

Segment 5 of both the SWCV2000 and Wolfman Curves are generally similar in path location and pace (Figure 9.2). The Wolfman Curve begins at AD 1000 rather than 950, explaining part of the apparent discrepancy at the early end of the curves. The most significant difference is the extension of the Wolfman Curve to below 74° N latitude at its most extreme, while SWCV2000 loops back at about 76° N latitude. The Wolfman Curve also remains at higher longitudes in the decades before AD 1100 than SWCV2000.

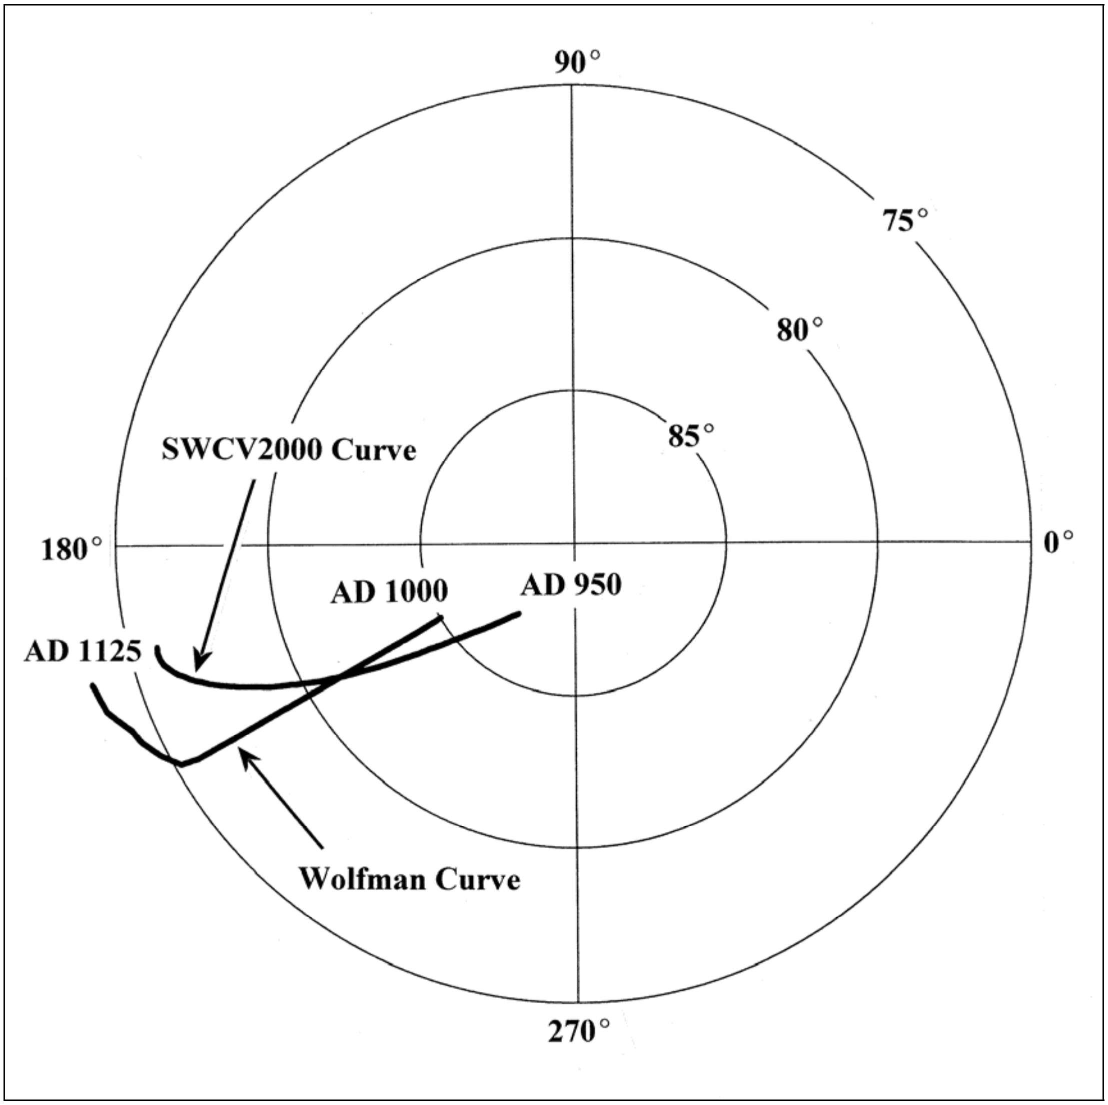

Figure 9.2. AD 950 to 1125 and AD 1000 to 1125 segments of the SWCV2000 and Wolfman VGP curves.

SWCV2000 is compared with results from the DuBois database that might date to the AD 950–1125 period in Figure 9.3. Samples that might date within the AD 950–1125 segment or earlier are indicated with circles. Open circles are results that could date as much as two segments earlier, while solid circles are probably either associated with this segment or one segment earlier. Results marked with "+" signs are assigned exclusively to this segment with relatively strong confidence. Results identified with square symbols either date to this segment or to a later segment. Solid squares could date in the next segment, while open squares could be relevant to either of the next two segments as well as perhaps being associated with Segment 5. Three results (all circles) are located between 0 and 90 longitude and clearly are related to pre-AD 950 segments of the curve. Two other possibly early results are located along this segment of VGP curve and probably date to this period. All of the sample results that were confidently expected to be along this segment are generally in the curve vicinity, validating their temporal placement. The results that might be either contemporary with or slightly later than this segment include a number of centerpoints that extend to both lower longitudes and latitudes than the AD 1125 end of the curve. Otherwise they cluster relatively evenly around the VGP path. The most temporally ambiguous of the later samples (the open squares) tend to cluster within the limits of the curve but are relatively consistently above the curve.

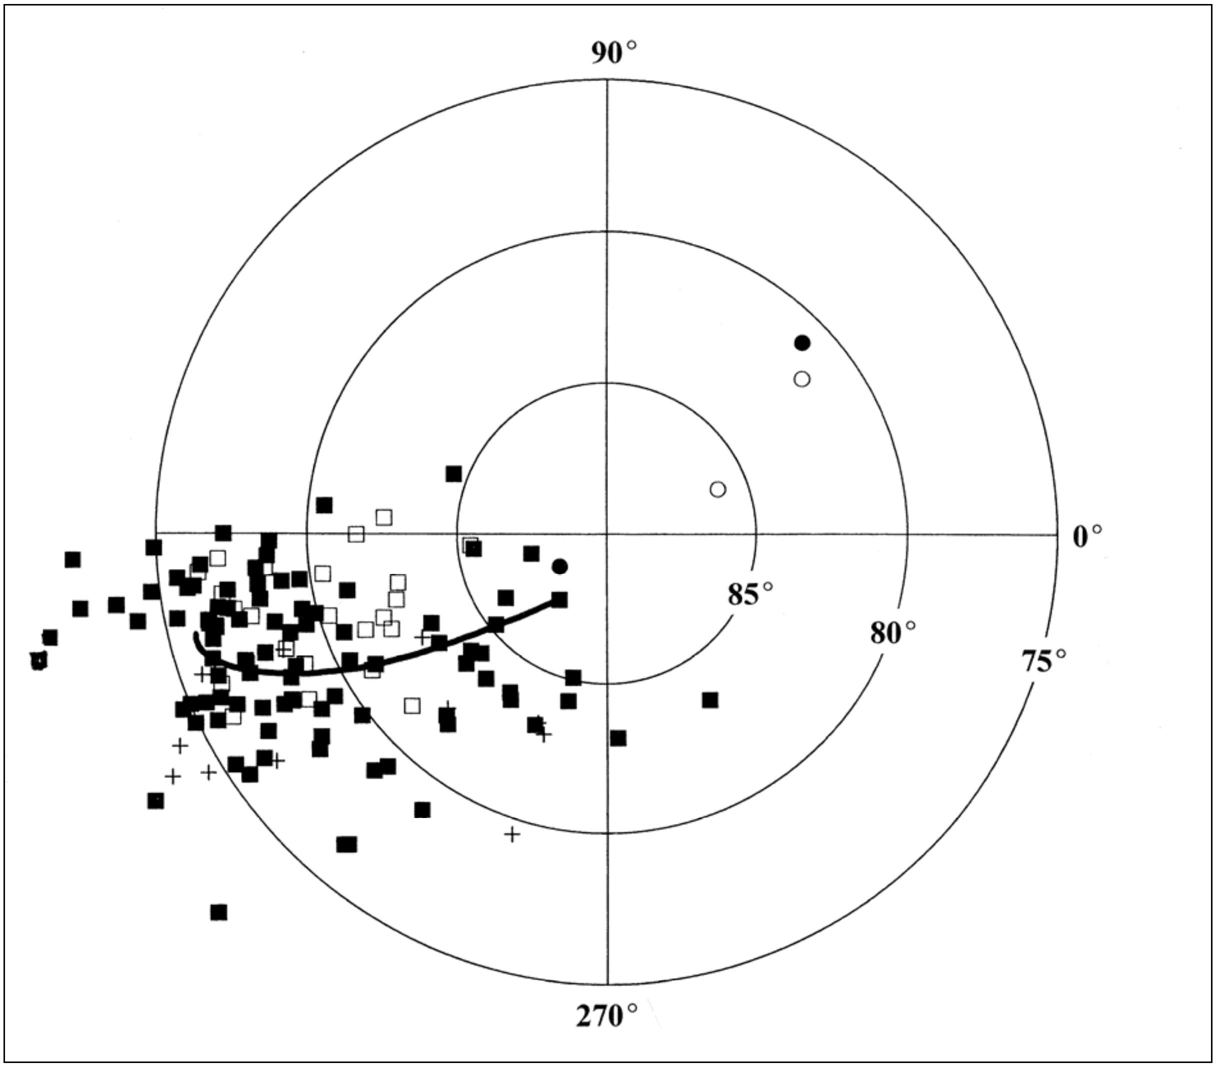

Figure 9.3. Archaeomagnetic result centerpoints from the DuBois database that could date to the AD 950 to 1125 period. Open circles denote samples that are believed to date within the AD 600 to 1125 period. Solid circles denote samples that are believed to date with the AD 800 to 1125 period. Samples denoted by a "+" are exclusively dated to the AD 950 to 1125 period. Solid squares denote samples that are believed to date within the AD 950 to 1225 period. Open squares denote samples that are believed to date within the AD 950 to 1300 period. All centerpoints are associated with α_{95} values of 3.0° or less.

Only those results that are exclusively and confidently associated with the AD 950–1125 period are presented in Figure 9.4.

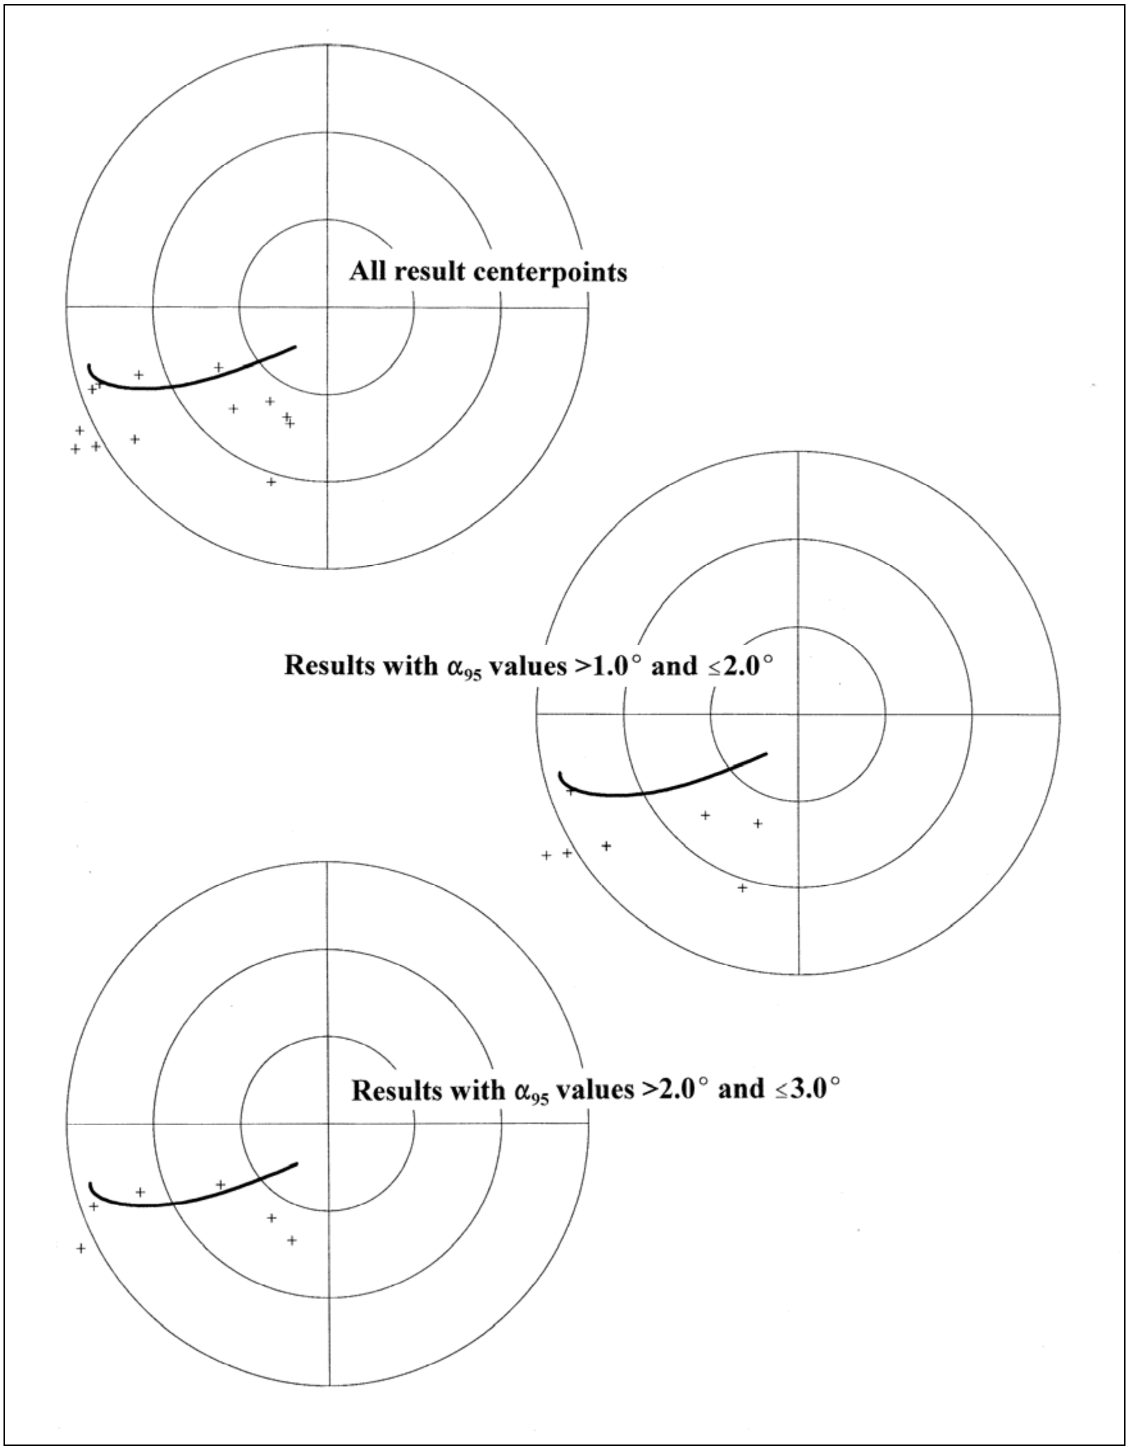

Figure 9.4. DuBois archaeomagnetic results that are confidently and exclusively associated with the AD 950 to 1125 period, contrasted with the SWCV2000 VGP curve. The upper figure includes all results, regardless of precision. The lower plots include only moderate and low precision results, respectively.

All results are plotted together, and additional plots are provided that present the same results by precision categories. These overall results strongly suggest that the SWCV2000 segment is placed too low in longitude, and this is confirmed by looking only at the moderate precision results ($\alpha_{95} \leq 2.0°$). Residuals calculated for these samples are overwhelmingly negative for the entire length of the curve segment, as graphed against time (date of the closest point on the SWCV2000 curve) in Figure 9.5. This discrepancy in curve path is consistent with the observation by Lengyel and Eighmy (2002) that there is anecdotal evidence for a lower latitude path than was produced by the moving average technique using the independently dated samples alone.

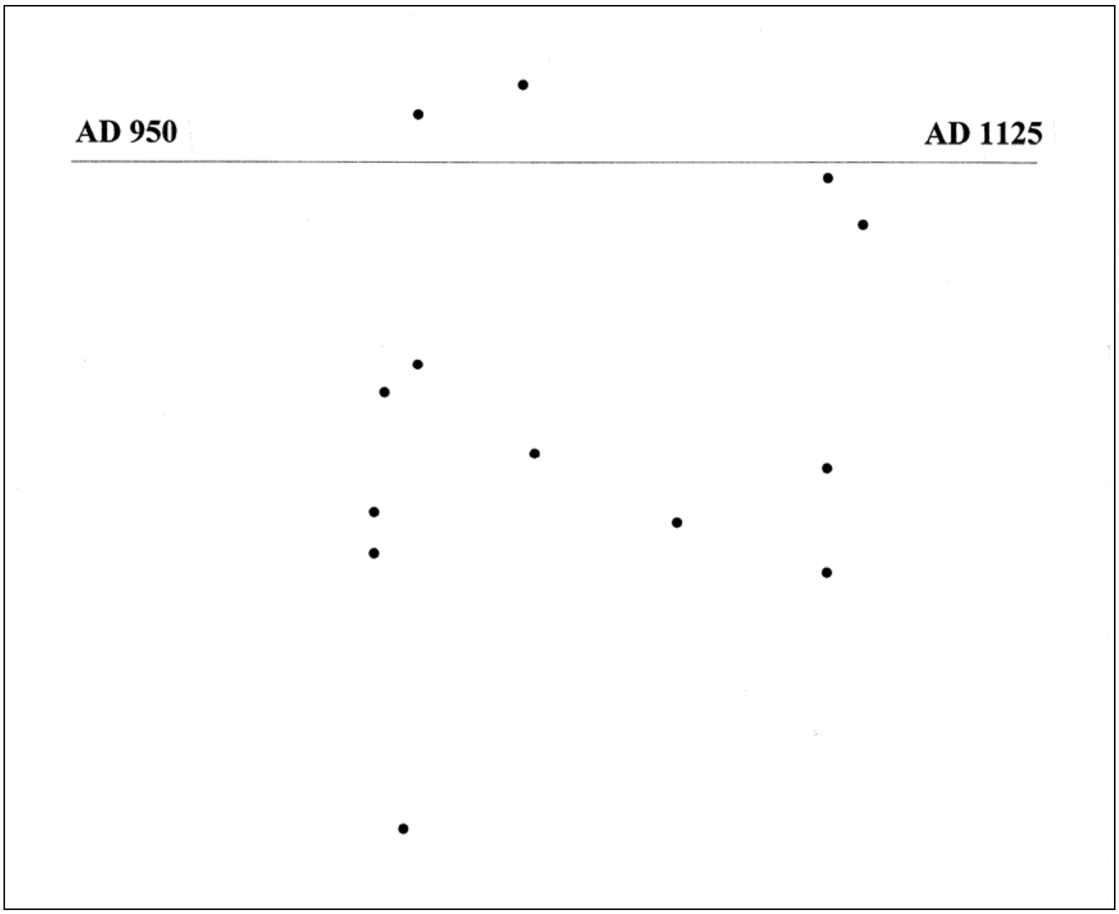

Figure 9.5. Plot of residual distances from confidently attributed AD 950 to 1125 sample centerpoints and nearest points along the AD 950 to 1125 segment of SWCV2000.

The same DuBois AD 950–1125 result dataset is contrasted with the Wolfman Curve in Figure 9.6. Although the Wolfman Curve begins at AD 1000 rather than 950, as with the SWCV2000 curve, four of the potentially early samples (solid and open circles) fall off the curve at the younger end. The potentially contemporary or slightly later samples (solid squares) are clustered both around the curve and off of the later end of the curve, while the potentially contemporary and much later samples (open squares) tend to fall above the curve (lower longitudes).

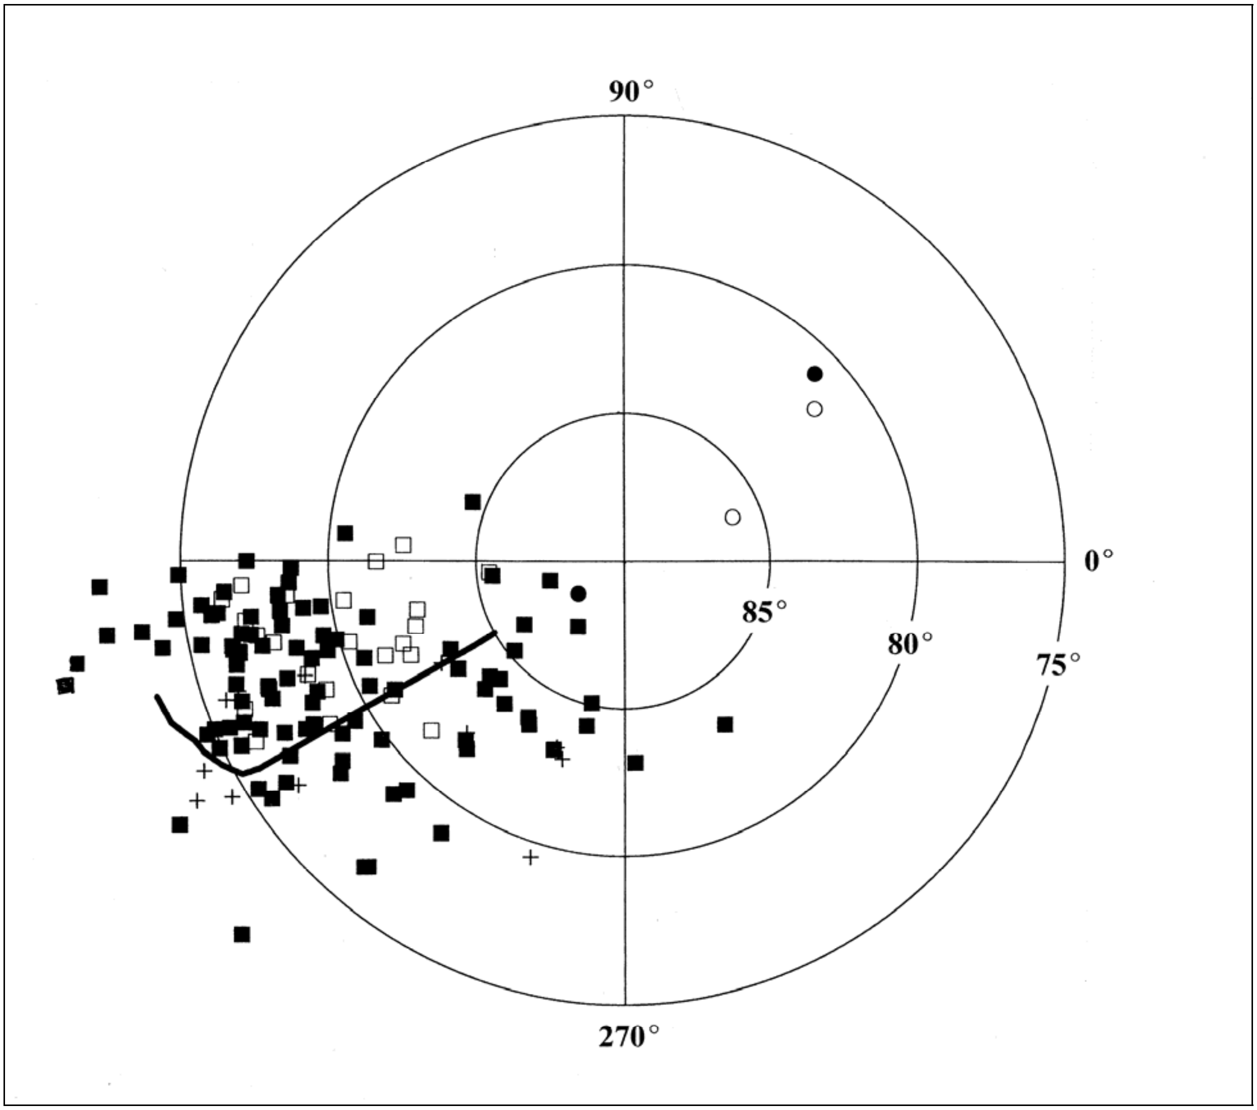

Figure 9.6. The AD 1000 to 1125 segment of the Wolfman Curve and archaeomagnetic result centerpoints from the DuBois database that could date to the AD 950 to 1125 period. Open circles denote samples that are believed to date within the AD 600 to 1125 period. Solid circles denote samples that are believed to date within the AD 800 to 1125 period. Samples denoted by a "+" are exclusively dated to the AD 950 to 1125 period. Solid squares denote samples that are believed to date within the AD 950 to 1225 period. Open squares denote samples that are believed to date within the AD 950 to 1300 period. All centerpoints are associated with α_{95} values of 3.0° or less.

The 13 results that are confidently associated with the AD 910–1125 time period (+) are presented without the more ambiguous data points in Figure 9.7. The scatter suggests that the Wolfman Curve is more consistent than the SWCV2000 curve in representing the results, but only slightly more consistent and only in the last half of the curve segment. The first half of the curve segment appears to be at a lower latitude than is suggested by the locations of the DuBois centerpoints, a suggestion supported by both the moderate and low precision results. This conclusion is clearly evident in the residual plot for the pre-AD 1050 period (Figure 9.8).

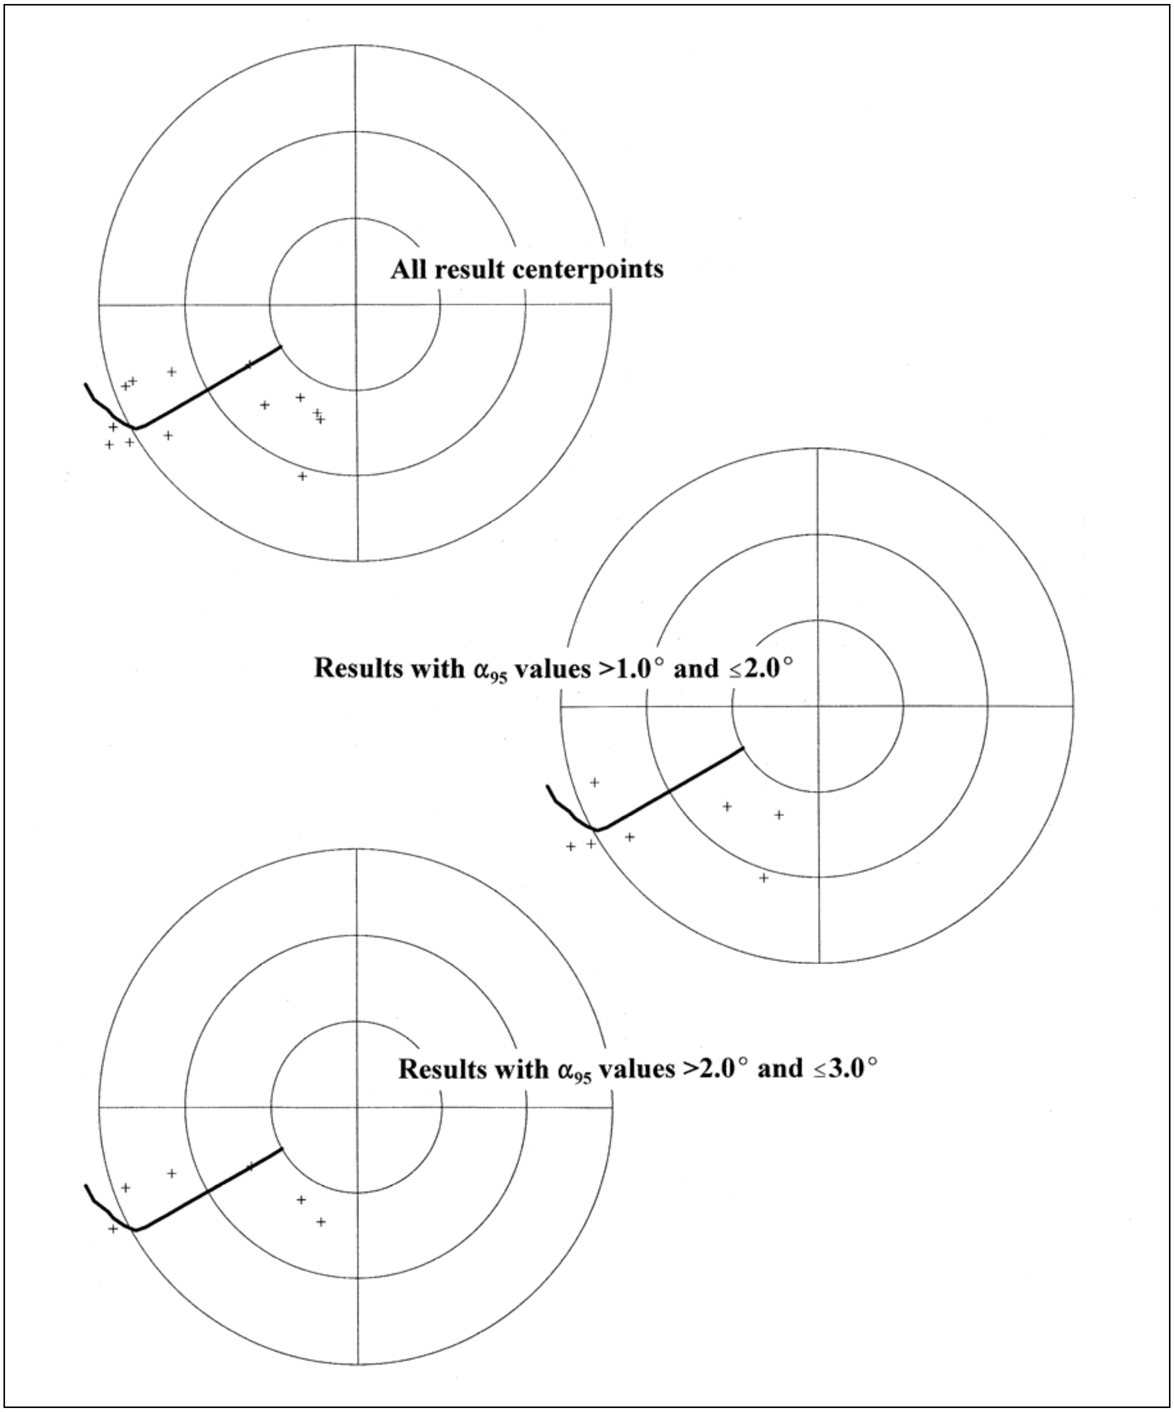

Figure 9.7. DuBois archaeomagnetic results that are confidently and exclusively associated with the AD 950 to 1125 period, contrasted with the Wolfman VGP curve from the AD 1000 to 1125 period. The upper figure includes all results regardless of precision. The lower plots include only moderate and low precision results, respectively.

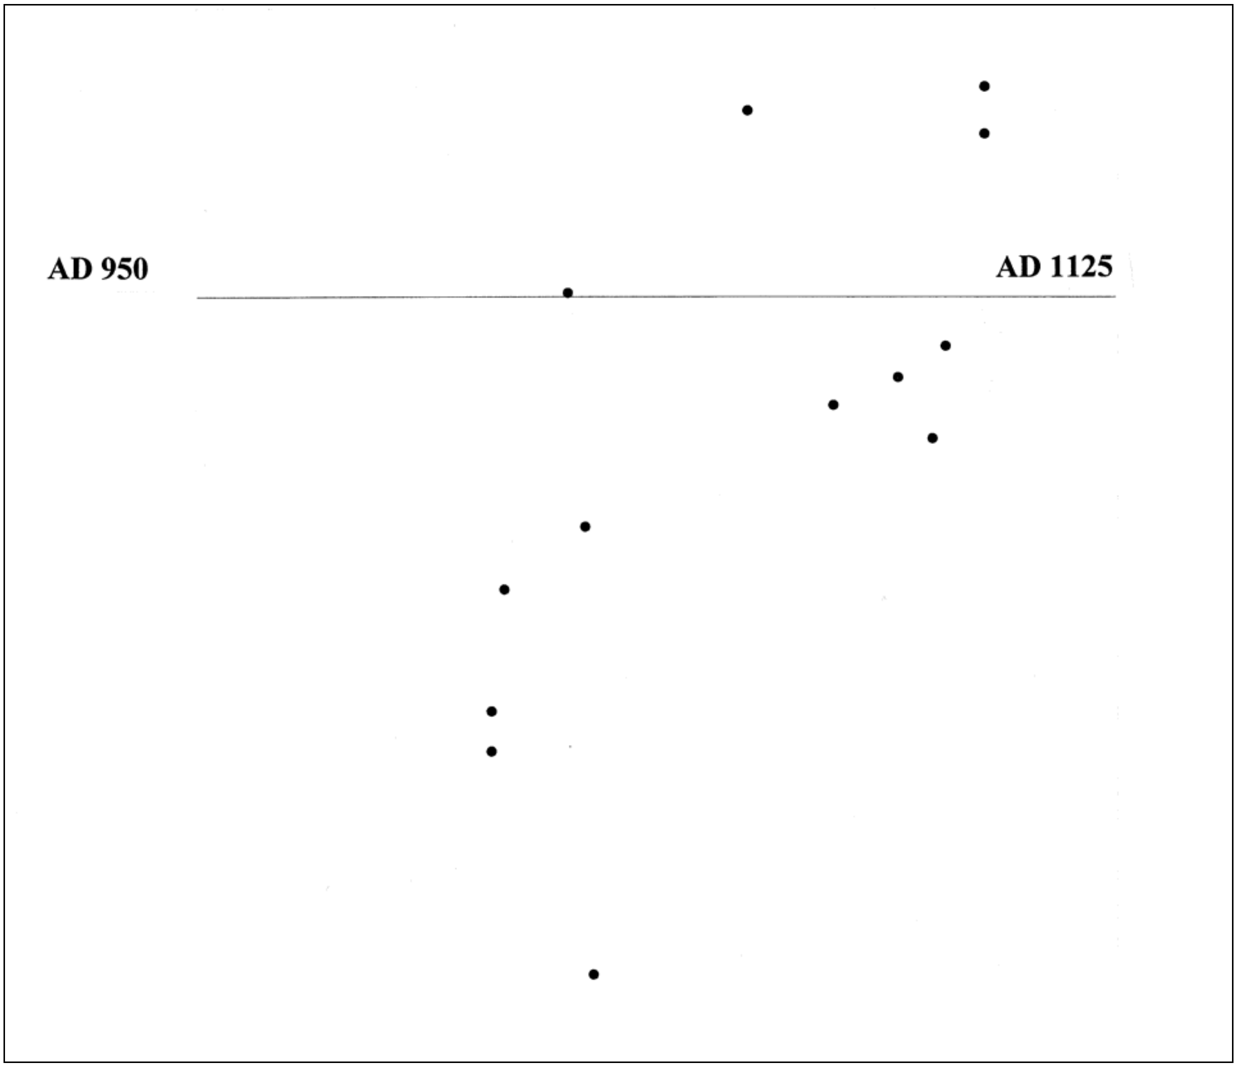

Figure 9.8. Plots of residual distances from confidently attributed AD 950 to 1125 sample centerpoints and nearest points along the AD 1000 to 1125 segment of the Wolfman Curve.

The post-AD 1050 segment has a more normally distributed pattern of residuals, but the termination of this curve segment may be slightly too extreme (too low in both latitude and longitude). The latter observation is weak simply because there are too few points in the DuBois dataset to be confident, and there are a number of potentially contemporary or later results (solid squares) that are at lower latitudes and longitudes.

This tentative evaluation of Segment 5 suggests that neither the SWCV2000 nor Wolfman Curves adequately represent a VGP path that would best account for the samples in the DuBois dataset. The post-AD 1050 segment of the Wolfman Curve may be more accurate, while the paths of both curves appear to need adjustment toward higher longitudes in the pre-AD 1050 period.

AD 1125–1225 (Segment 6)

The VGP path reverses itself in a loop at some time near or after AD 1125. The SWCV2000 and Wolfman approximations of the AD 1125–1255 VGP path are presented in Figure 9.9. The VGP curves are in relatively close agreement of the pole position at about AD 1225, but they disagree at AD 1125 and for the subsequent 50 to 60 years. The Wolfman Curve begins at a lower latitude and remains below 76° latitude until shortly after AD 1180. Where SWCV2000 presents the inflection point of the reversal at AD 1125, the Wolfman Curve proposes that the inflection is delayed until approximately AD 1150.

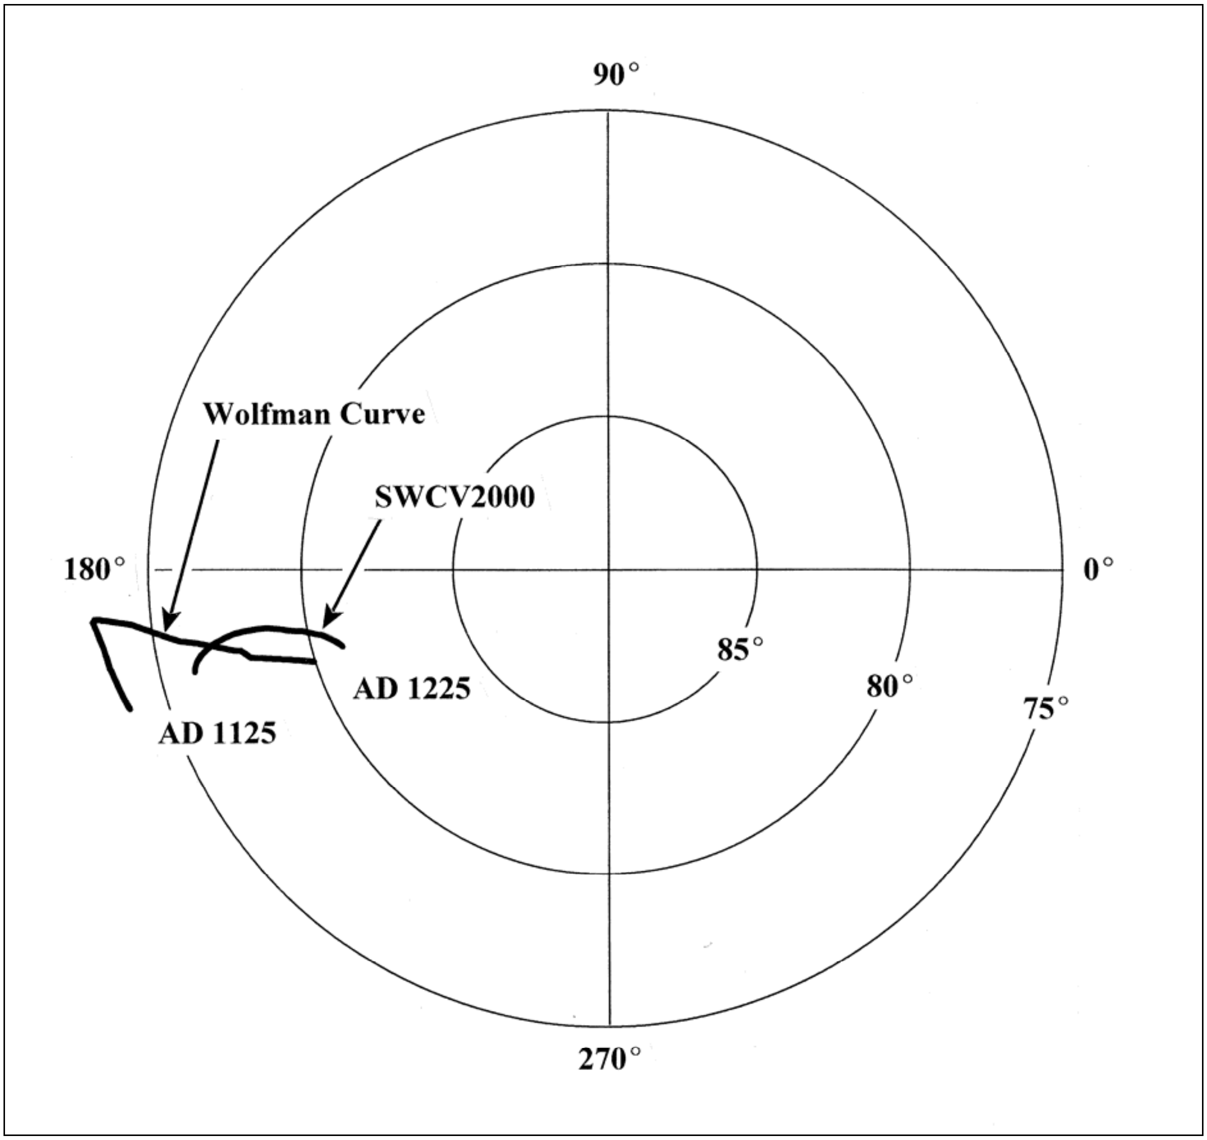

Figure 9.9. AD 1125 to 1225 segments of the SWCV2000 and Wolfman VGP curves.

Sample results from the DuBois database that could be contemporary with the AD 1125–1225 period are plotted with the AD 1125–1225 segment of SWCV2000 in Figure 9.10. Those results whose independent dating suggests that they are contemporary with or earlier than the segment (solid circles) are scattered around the segment, with the majority below (at higher longitudes) where earlier samples might be expected to fall. A small number are located off the early end of the curve, at lower latitudes. Results whose independent dating could be contemporary with or either slightly later (solid squares) or significantly later (open squares) tend to be located around the curve, below the curve (lower longitudes), or to the right (higher latitudes).

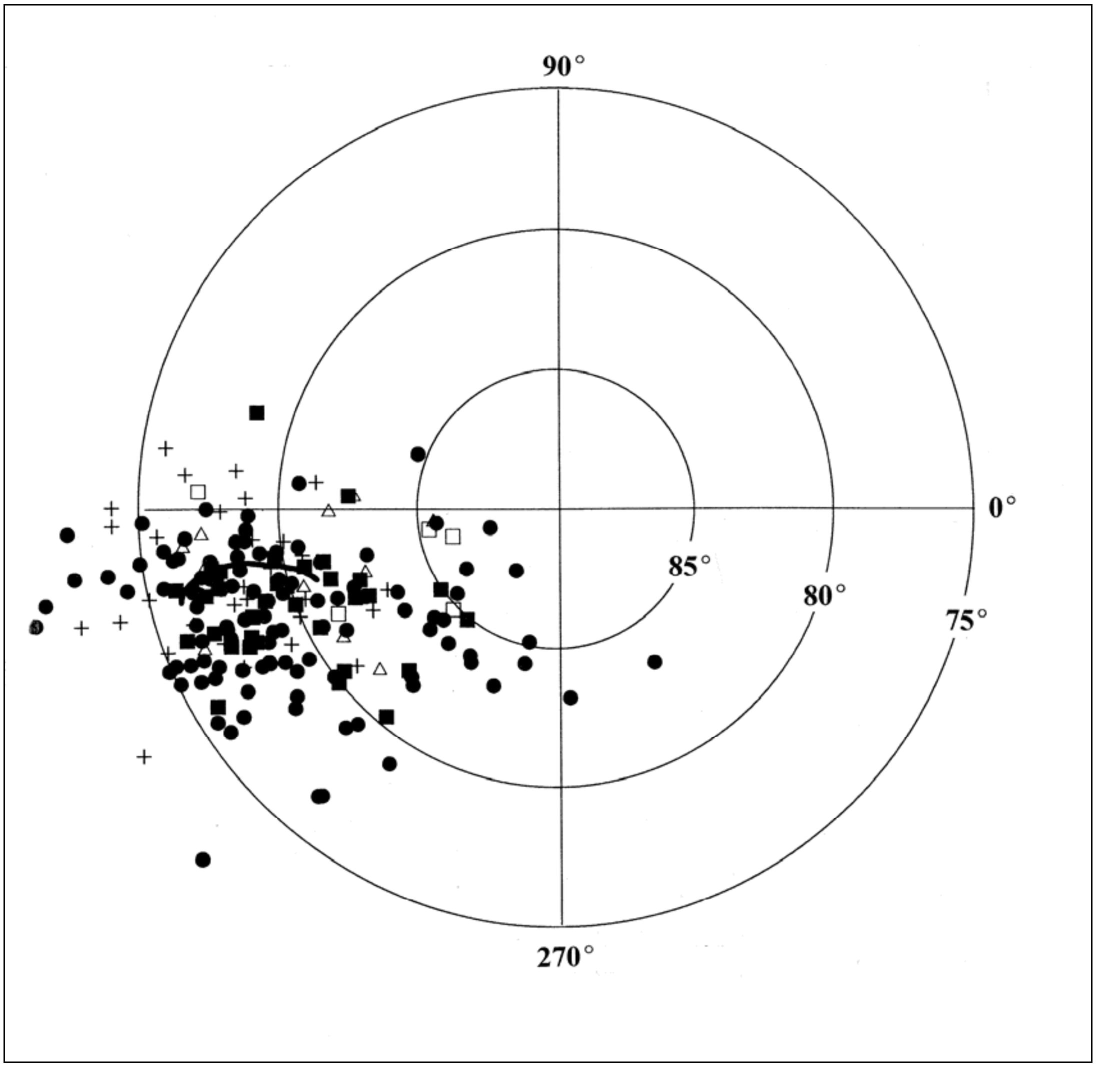

Figure 9.10. SWCV2000 and archaeomagnetic result centerpoints from the DuBois database that could date to the AD 1125 to 1225 period. Open circles denote samples that are believed to date within the AD 800 to 1225 period. Solid circles denote samples that are believed to date within the AD 950 to 1225 period. Samples denoted by a "+" are exclusively dated to the AD 1125 to 1225 period, while samples marked with an open triangle are dated to the broader AD 950 to 1300 period. Solid squares denote samples that are believed to date within the AD 1125 to 1300 period. Open squares denote samples that are believed to date within the AD 1125 to 1400 period. All centerpoints are associated with α_{95} values of 3.0° or less.

Those samples that are confidently and exclusively associated with AD 1125–1225 period based on independent evidence are illustrated without the less precisely dated results in Figure 9.11.

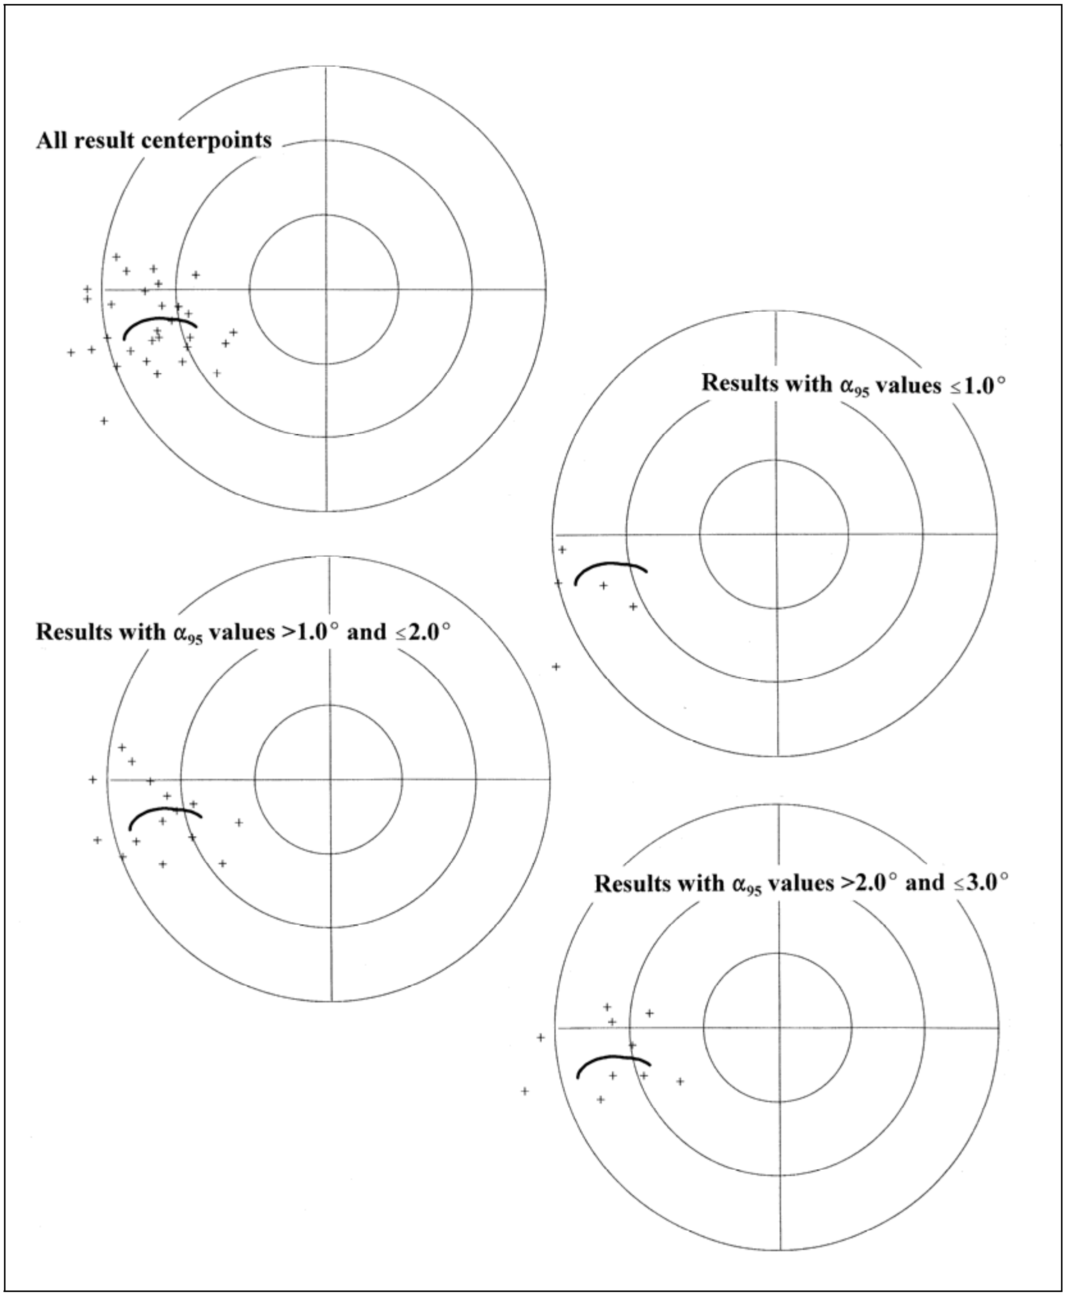

Figure 9.11. DuBois archaeomagnetic results that are confidently and exclusively associated with the AD 1125 to 1225 period, contrasted with the SWCV2000 VGP curve. The upper plot includes all results, regardless of precision. The other plots distinguish high, moderate, and low precision results.

One extremely precise result (α_{95}<1.0°) falls at a considerable distance from the curve at higher longitudes and latitudes. Moderately precise results (1.0°<α_{95}<2.0°) include several that fall at lower longitudes and lower latitudes. The low precision results are all closely within their errors of the SWCV2000 segment. A plot of the residual distances of these high precision results from their closest points on the curve is presented in Figure 9.12.

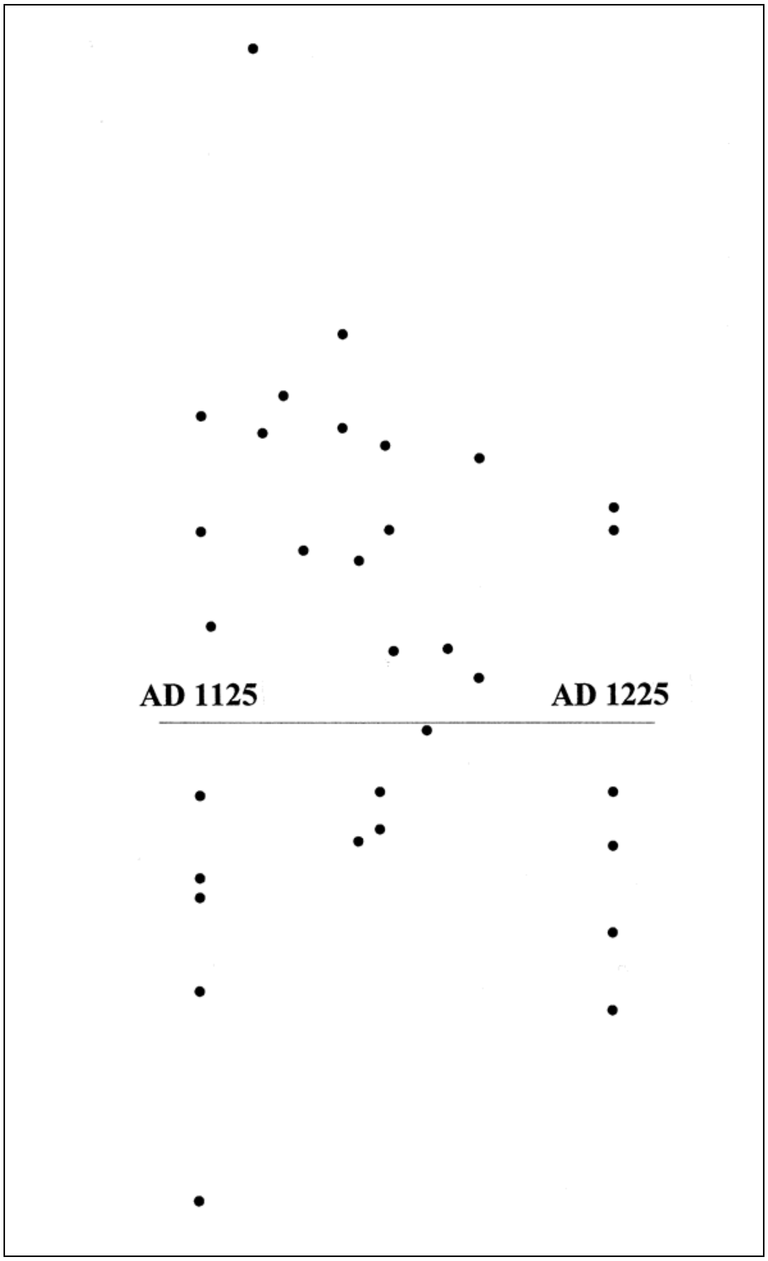

Figure 9.12. Plot of residual distances from confidently attributed AD 1125 to 1225 sample centerpoints and nearest points along the AD 1125 to 1225 segment of SWCV2000.

Unlike the previous segment, residuals are not patterned on either side of the curve, but there are concentrations of large residuals at the ends of the segment. The three results that are substantially distant from the AD 1225 end of the segment are associated with moderate and low precision VGP estimates. A larger number of results, including high precision estimates, are at a distance from the AD 1125 end of the segment.

The same DuBois results are contrasted with the Wolfman Curve for the AD 1125–1225 period in Figure 9.13.

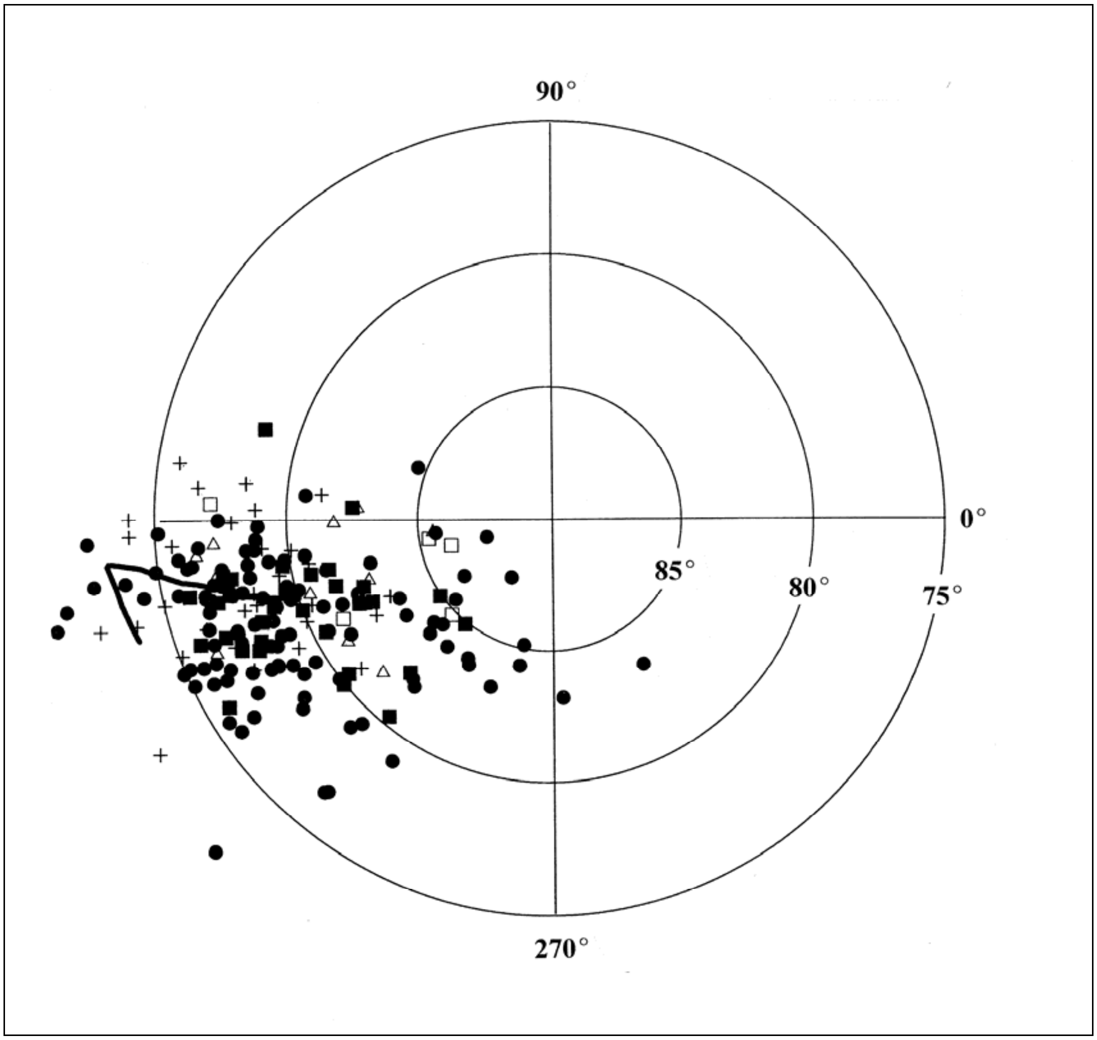

Figure 9.13. The AD 1125 to 1225 segment of the Wolfman Curve and archaeomagnetic result centerpoints from the DuBois database that could date to the AD 1125 to 1225 period. Open circles denote samples that are believed to date within the AD 800 to 1225 period. Solid circles denote samples that are believed to date within the AD 950 to 1225 period. Samples denoted by a "+" are exclusively dated to the AD 1125 to 1225 period. Solid squares denote sample that are believed to date within the AD 1125 to 1300 period. Open squares denote samples that are believed to date within the AD 1125 to 1400 period. All centerpoints are associated with α_{95} values of 3.0° or less.

In general, the same comparisons hold for the samples that could be earlier and the samples that could be later. There is, however, a slightly better fit between the Wolfman Curve segment and the results that can be confidently and exclusively attributed to this period (Figure 9.14). A single high precision result is significantly off the AD 1125 end of the curve, but the discrepancy is less than that associated with the SWCV2000 curve. The late end of the segment seems to be at an appropriate longitude, although there is a slight suggestion in the moderate precision results that the AD 1225 point should be extended to a slightly higher latitude. There is less support for the low latitude path of the portion of the curve between AD 1125 and 1150, and there is even some suggestion that the inflection point should be closer to 76° latitude and 180° longitude.

Because of the inflection of this segment of the Wolfman Curve, the residual plot is somewhat less useful than it might be, especially for the pre-AD 1175 portion of the curve (Figure 9.15). However, a slight dominance of positive residuals along the last half of this segment supports the suggestion that a slightly lower latitude path from the inflection point may be appropriate. Also, the cluster of residuals that fall off the AD 1225 end of the curve segment support the need to extend this portion of the curve to higher latitudes.

In comparing the performance of the two curves for the AD 1125–1225 period (see Figures 9.9, 9.11, and 9.14), a compromise between the two paths would seem to be called for. The DuBois dataset does not support the excursion of the early portion of the Wolfman Curve along such a low latitude path, but it does suggest that the path needs to extend to lower latitudes than is represented by SWCV2000. A very slightly wedge-shaped distribution of points along the low latitude end of the scatter provides weak support for an inflection point in the early portion of this time period (as represented in the Wolfman Curve), but that point would need to be closer to 76° latitude and 180° longitude than where the inflection point is currently drawn. The slightly lower (higher longitude) termination path of the Wolfman Curve for the period is supported by the high and moderate precision results of the confidently and exclusively attributed samples, but that support fades when the low precision results are added to the evaluation. Regardless, the comparison suggests that the AD 1225 extension of the SWCV2000 curve is probably more accurate and that the AD 1225 point may even need to be pushed to a slightly higher latitude.

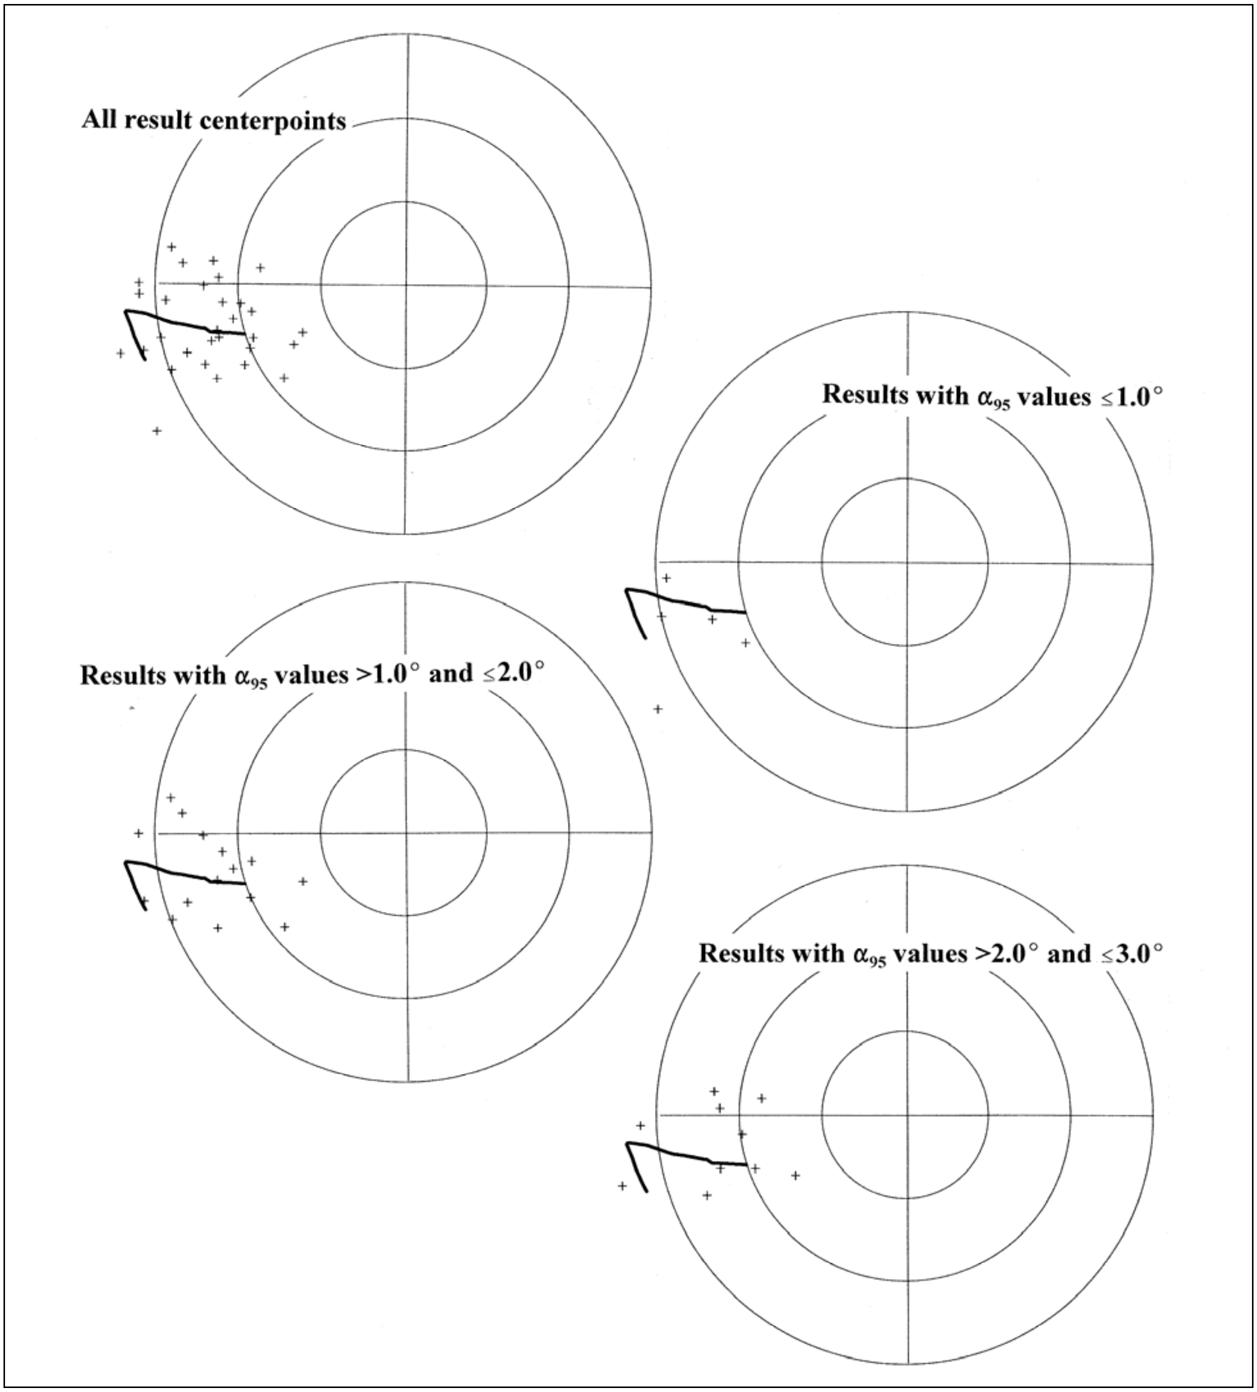

Figure 9.14. DuBois archaeomagnetic results that are confidently and exclusively associated with the AD 1125 to 1225 period, contrasted with the Wolfman VGP curve for the AD 1125 to 1225 period. The upper figure includes all results, regardless of precision. The lower plots include only moderate and low precision results, respectively.

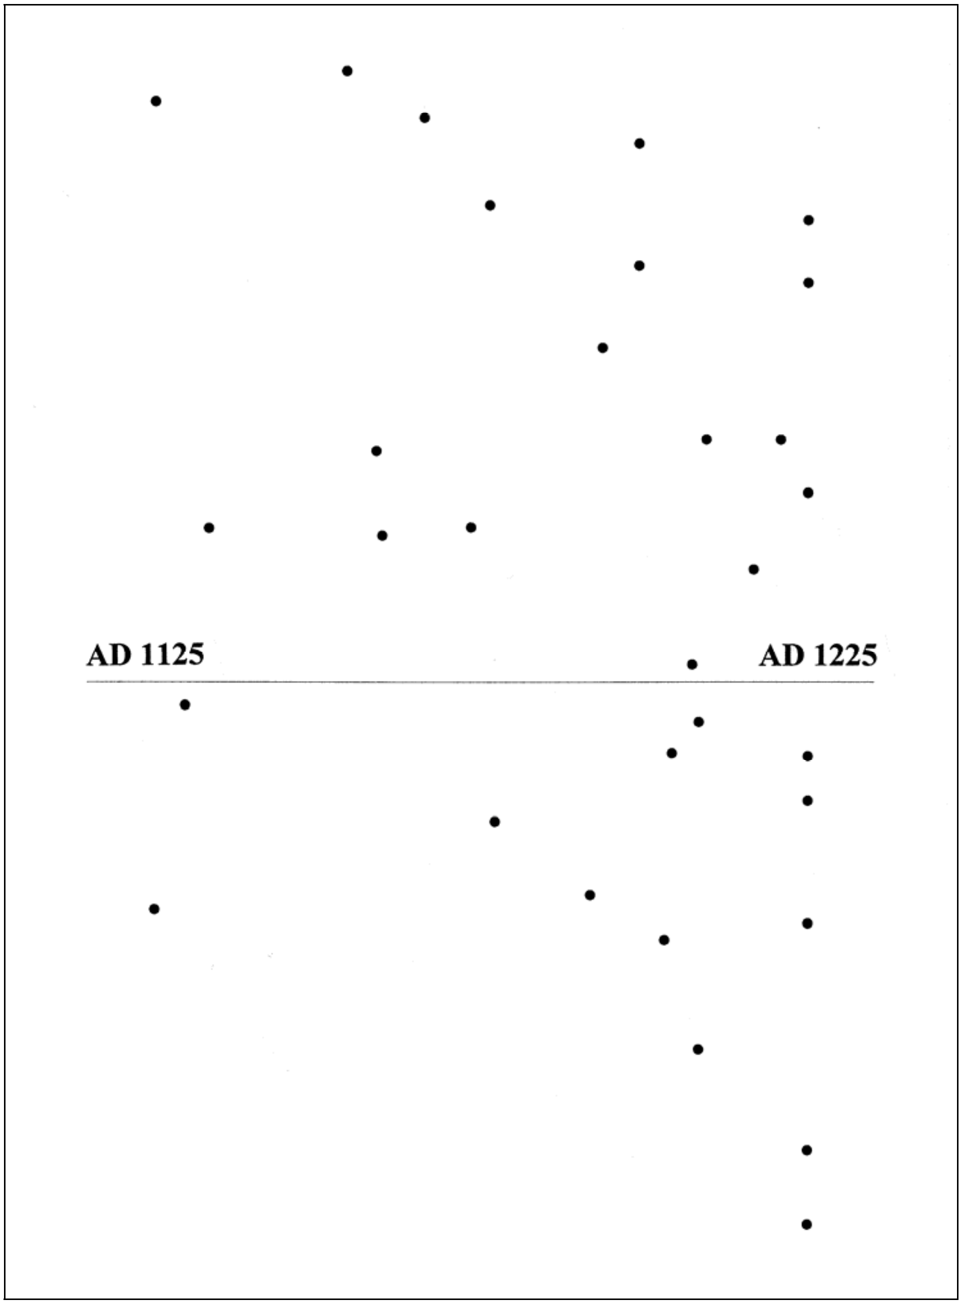

Figure 9.15. Plot of residual distances from confidently attributed AD 1125 to 1225 sample centerpoints and nearest points along the AD 1125 to 1225 segment of the Wolfman Curve.

AD 1225–1300 (Segment 7)

The greatest discrepancies between current Southwest VGP curves begin at AD 1225. The SWCV2000 and Wolfman Curve segments for the AD 1225–1300 period are presented in Figure 9.16. Both begin at approximately the same position, but the end points differ radically. SWCV2000 portrays the VGP movement as extremely slow and in the form of a relatively tight loop. The progression of the curve is so slow that only samples with remarkably precise results ($\alpha_{95} \lesssim 0.5°$) could distinguish features that dated to the extreme ends of the period. The Wolfman Curve is radically different, suggesting polar movement at approximately the same rate as the preceding period, and with a termination point significantly distant from the starting point.

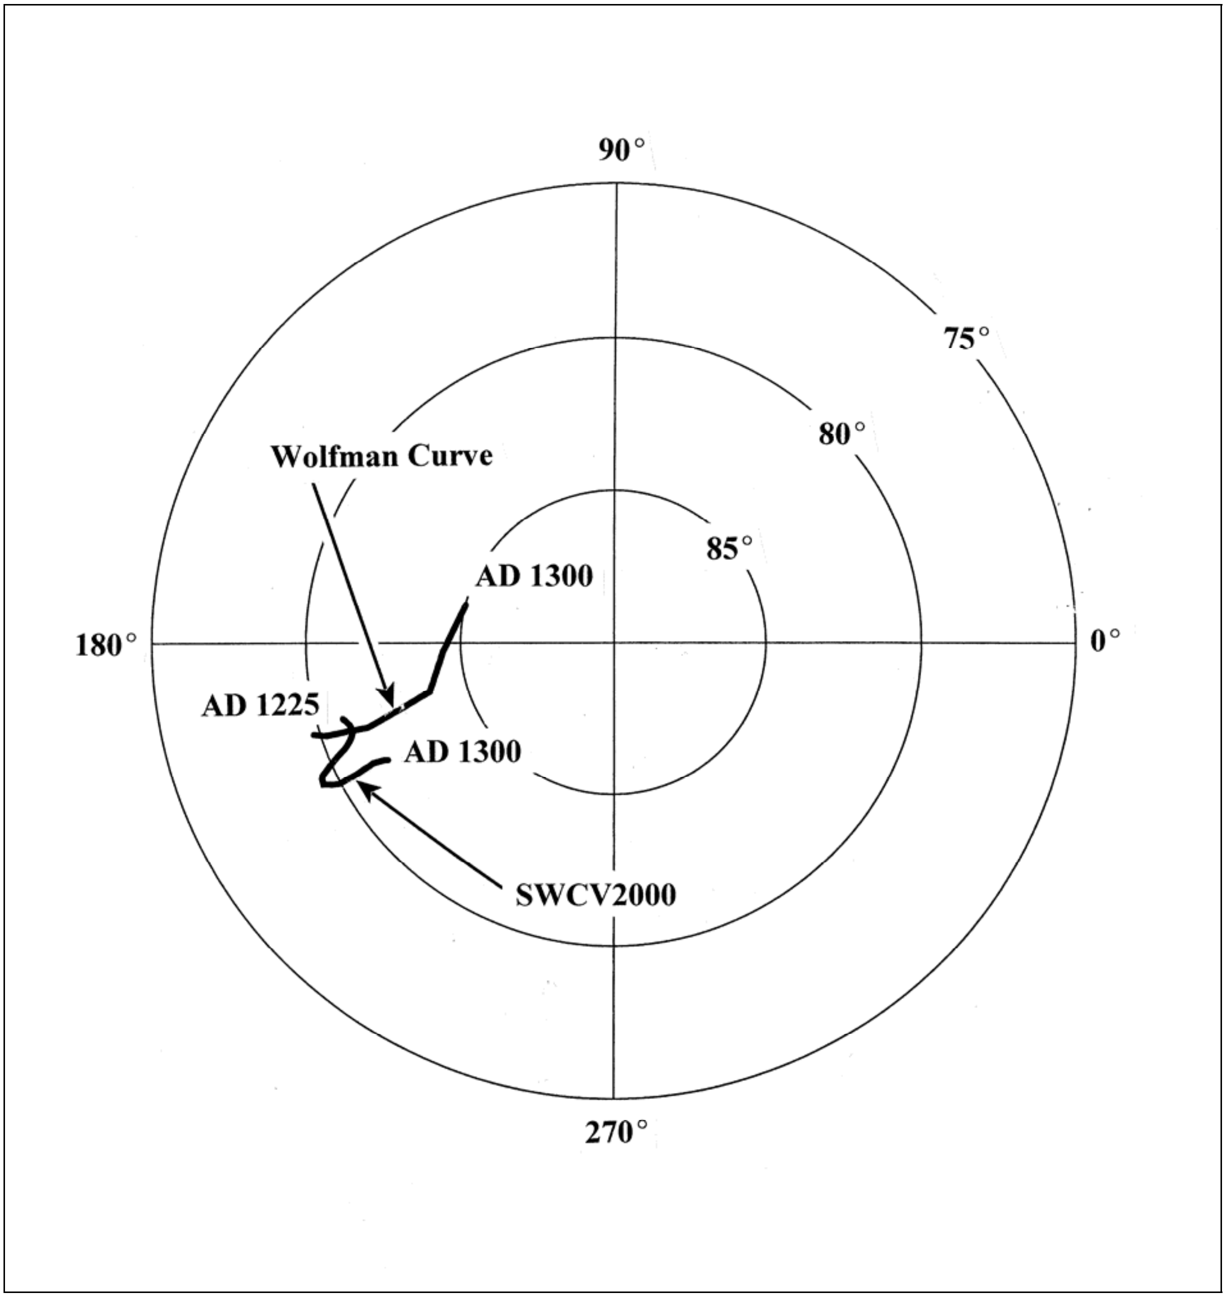

Figure 9.16. AD 1225 to 1300 segments of the SWCV2000 and Wolfman VGP curves.

The DuBois dataset is contrasted with the SWCV2000 curve in Figure 9.17. Contemporary or potentially earlier results (solid and open circles) tend to be scattered both around the curve segment and toward lower latitudes (in the area of the AD 1125–1225 segment). Contemporary or potentially later results (solid and open squares) are much more dispersed, with clusters both around the segment and at higher latitudes and slightly higher longitudes.

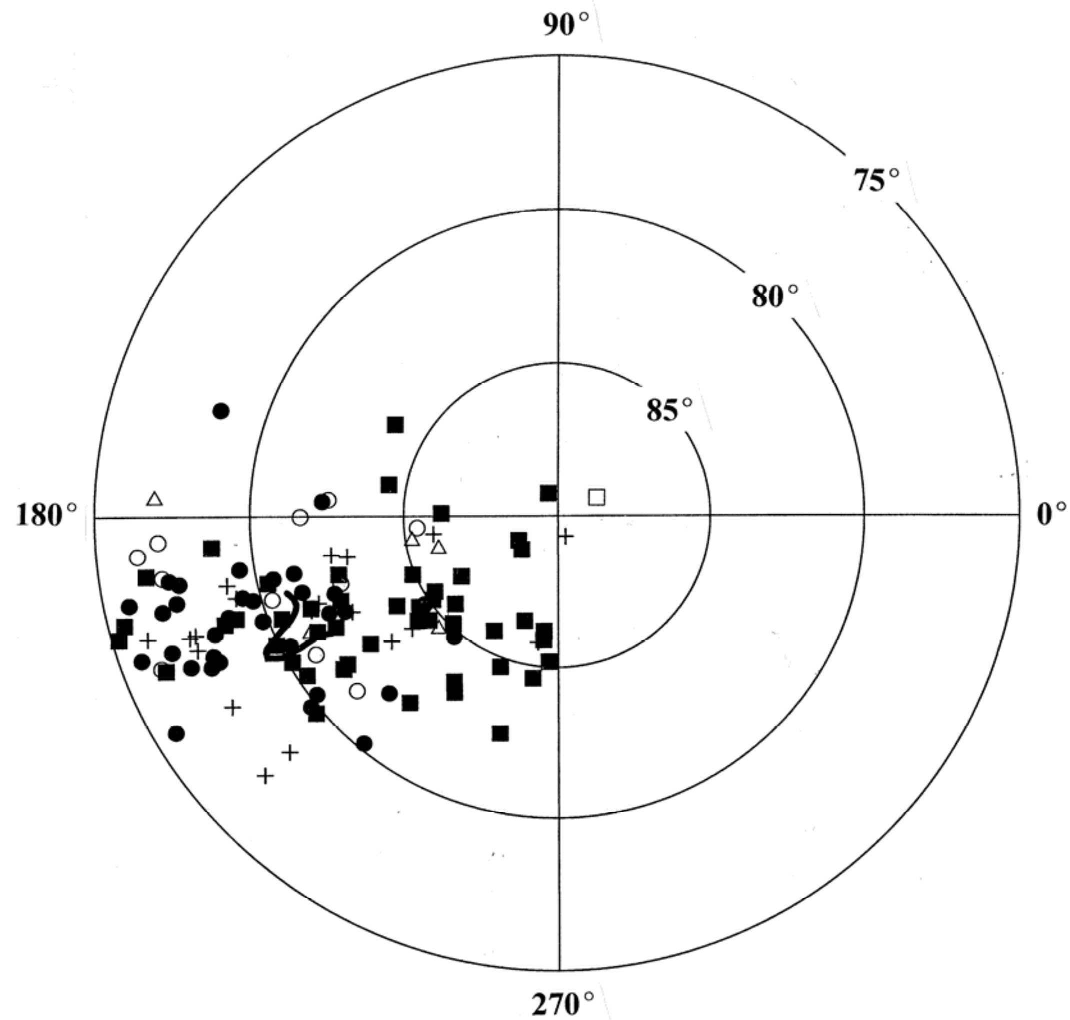

Figure 9.17. SWCV2000 and archaeomagnetic result centerpoints from the DuBois database that could date to the AD 1225 to 1300 period. Open circles denote samples that are believed to date within the AD 950 to 1300 period. Solid circles denote samples that are believed to date within the AD 1125 to 1300 period. Samples denoted by a "+" are exclusively dated to the AD 1225 to 1300 period, while samples marked with an open triangle are dated to the broader AD 1125 to 1400 period. Solid squares denote samples that are believed to date within the AD 1225 to 1400 period. Open squares denote samples that are believed to date within the AD 1225 to 1500 period. All centerpoints are associated with a α_{95} values of 3.0° or less.

Results that are confidently and exclusively attributed to the AD 1225–1300 period are isolated from the less-well-dated results in Figure 9.18.

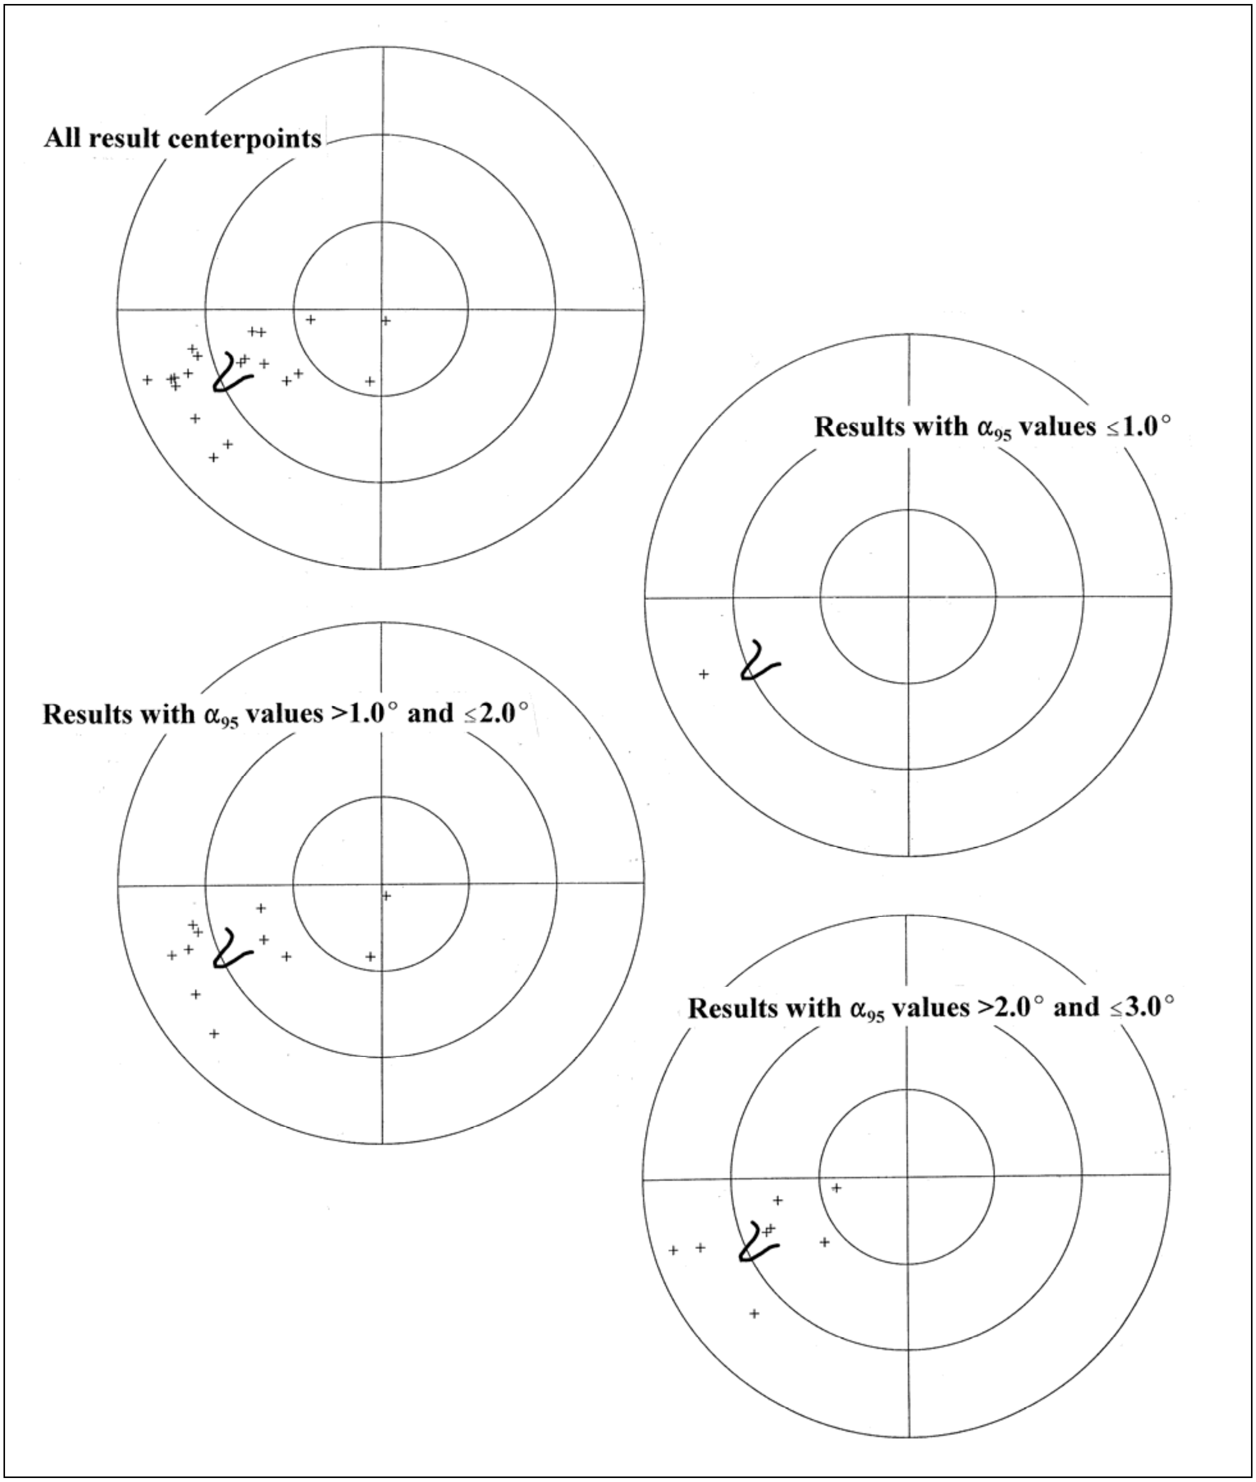

Figure 9.18. DuBois archaeomagnetic results that are confidently and exclusively associated with the AD 1225 to 1300 period, contrasted with the SWCV2000 VGP curve. The upper plot includes all results, regardless of precision. The other plots distinguish high, moderate, and low precision results.

Only one of the results is extremely precise, and it lies off of the curve at a lower latitude. Moderately precise results both cluster around the curve and tend to spread linearly, toward and away from the North Pole. The centerpoints associated with low precision results are similar in dispersion to the moderate precision results. Residual distances between the centerpoints and the curve are less useful as an analytic tool for this segment due to the short and reflexive nature of the curve segment. The distances were divided into those for centerpoints that are closer to the North Pole (positive) and those centerpoint distances that are further away (negative), and the distances are plotted in Figure 9.19. Positive residuals tend to be greater in magnitude, reflecting an apparent longitudinal linearity that is not captured by the SWCV2000 curve.

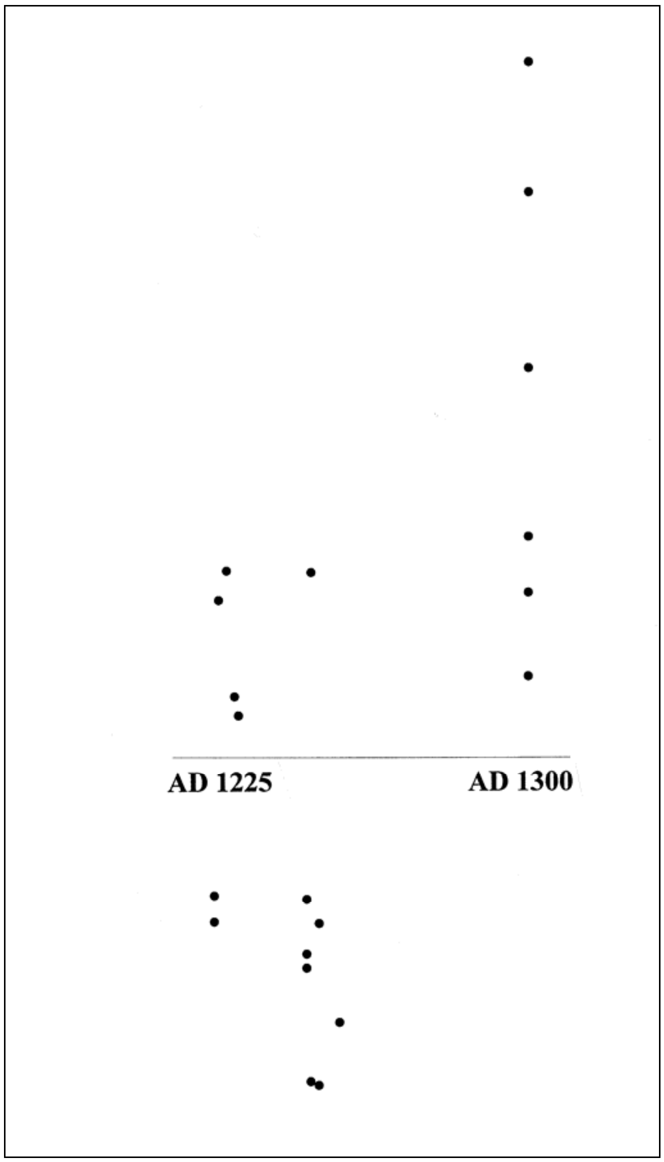

Figure 9.19. Plot of residual distances from confidently attributed AD 1225 to 1300 sample centerpoints and nearest points along the AD 1225 to 1300 segment of SWCV2000.

The same Dubois AD 1225–1300 dataset is contrasted with the Wolfman Curve in Figure 9.20.

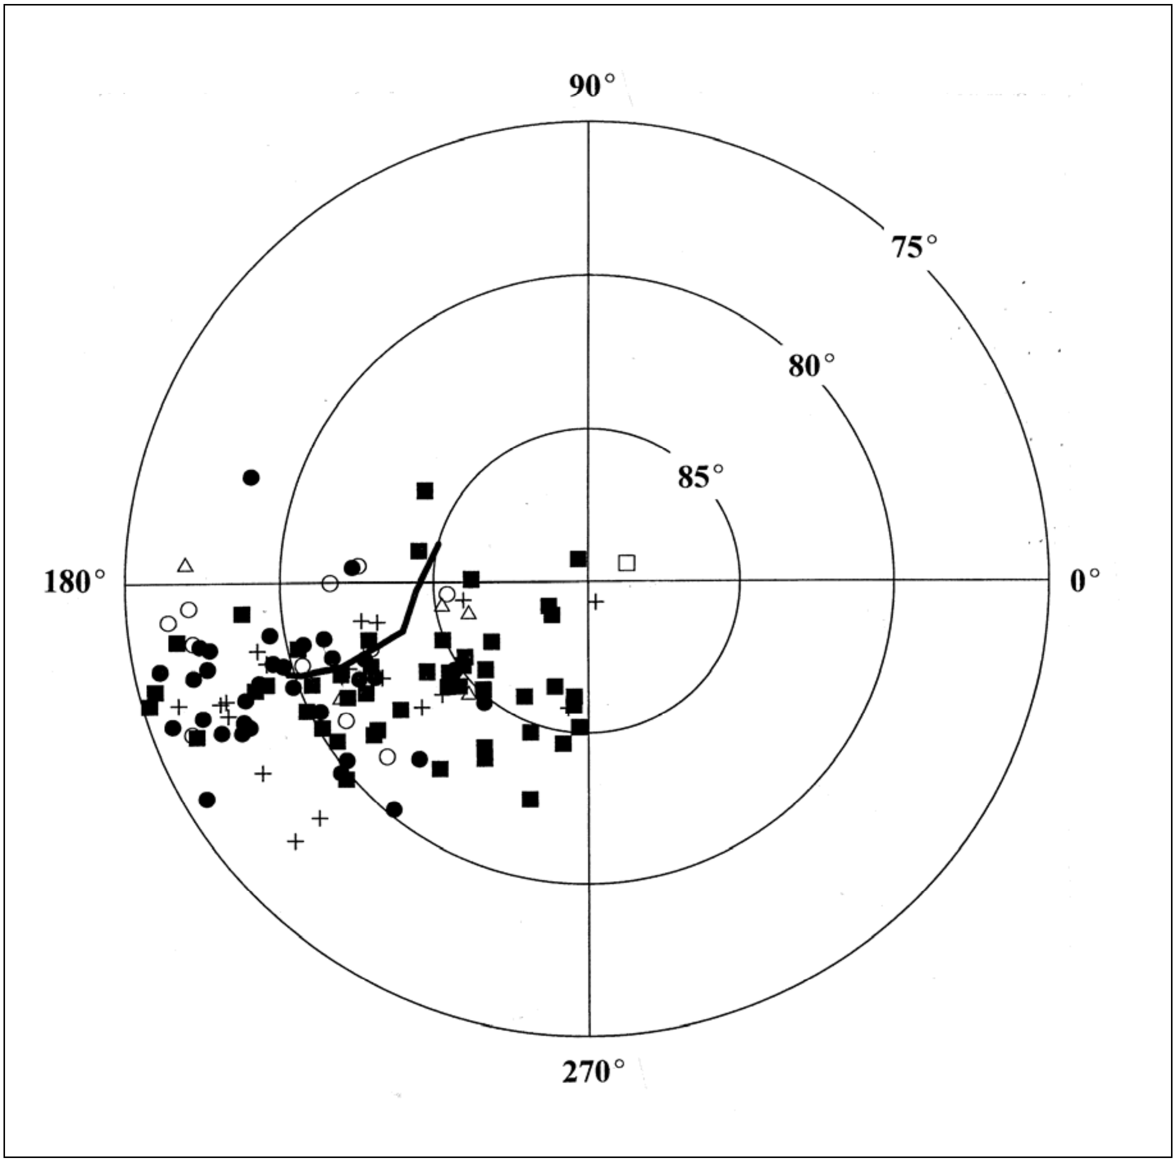

Figure 9.20. The AD 1225 to 1300 segment of the Wolfman Curve and archaeomagnetic result centerpoints from the DuBois database that could date to the AD 1225 to 1300 period. Open circles denote samples that are believed to date within the AD 950 to 1300 period. Solid circles denote samples that are believed to date within the AD 1125 to 1300 period. Samples denoted by a "+" are exclusively dated to the AD 1225 to 1300 period, while samples marked with an open triangle are dated to the broader AD 1125 to 1400 period. Solid squares denote samples that are believed to date within the AD 1225 to 1400 period. Open squares denote samples that are believed to date within the AD 1225 to 1500 period. All centerpoints are associated with α_{95} values of 3.0° or less.

Contemporary or potentially earlier results (solid and open circles) tend to cluster around the earlier one-third of the Wolfman Curve segment and extend to lower latitudes in the approximate area of the AD 1125–1225 segment. Samples that are contemporary or potentially later (solid and open squares) are more broadly distributed, again clustering around the earlier half of the Wolfman Curve segment as well as filling an area toward higher latitudes and slightly higher longitudes. A few of the contemporary or potentially later sample results are near the AD 1330 end of the curve segment, but much fewer than are in the other areas of the scatter.

Only the results that are confidently and exclusively attributed to the AD 1225–1300 period are included in the plots of Figure 9.21. The single high precision result is just outside the early end of the curve. The moderate precision results are scattered mainly below the curve (higher longitudes), and a cluster of results extends beyond the early end of the segment. No samples cluster around the later one-third of the segment, while two centerpoints are much closer to the north pole. Low precision results mirror the moderate precision scatter, and the total distribution suggests that a slightly longer path at higher longitudes would better match the DuBois data. The residual distance between the centerpoints and the nearest points on the curve segment support this conclusion (Figure 9.22), with an inordinately high proportion of negative residuals and a large numbers of and magnitudes for residuals associated with the end points of the segment.

If the samples in the DuBois dataset are representative of the AD 1225–1300 time period, neither curve adequately reflects the true VGP path. There appears to be greater linearity to the path than is represented by the reflexive and short SWCV2000 segment. The Wolfman segment is too low in longitude, and there is little support for the even lower longitude termination of the segment. In both cases, a path toward the north pole would more completely account for the available data.

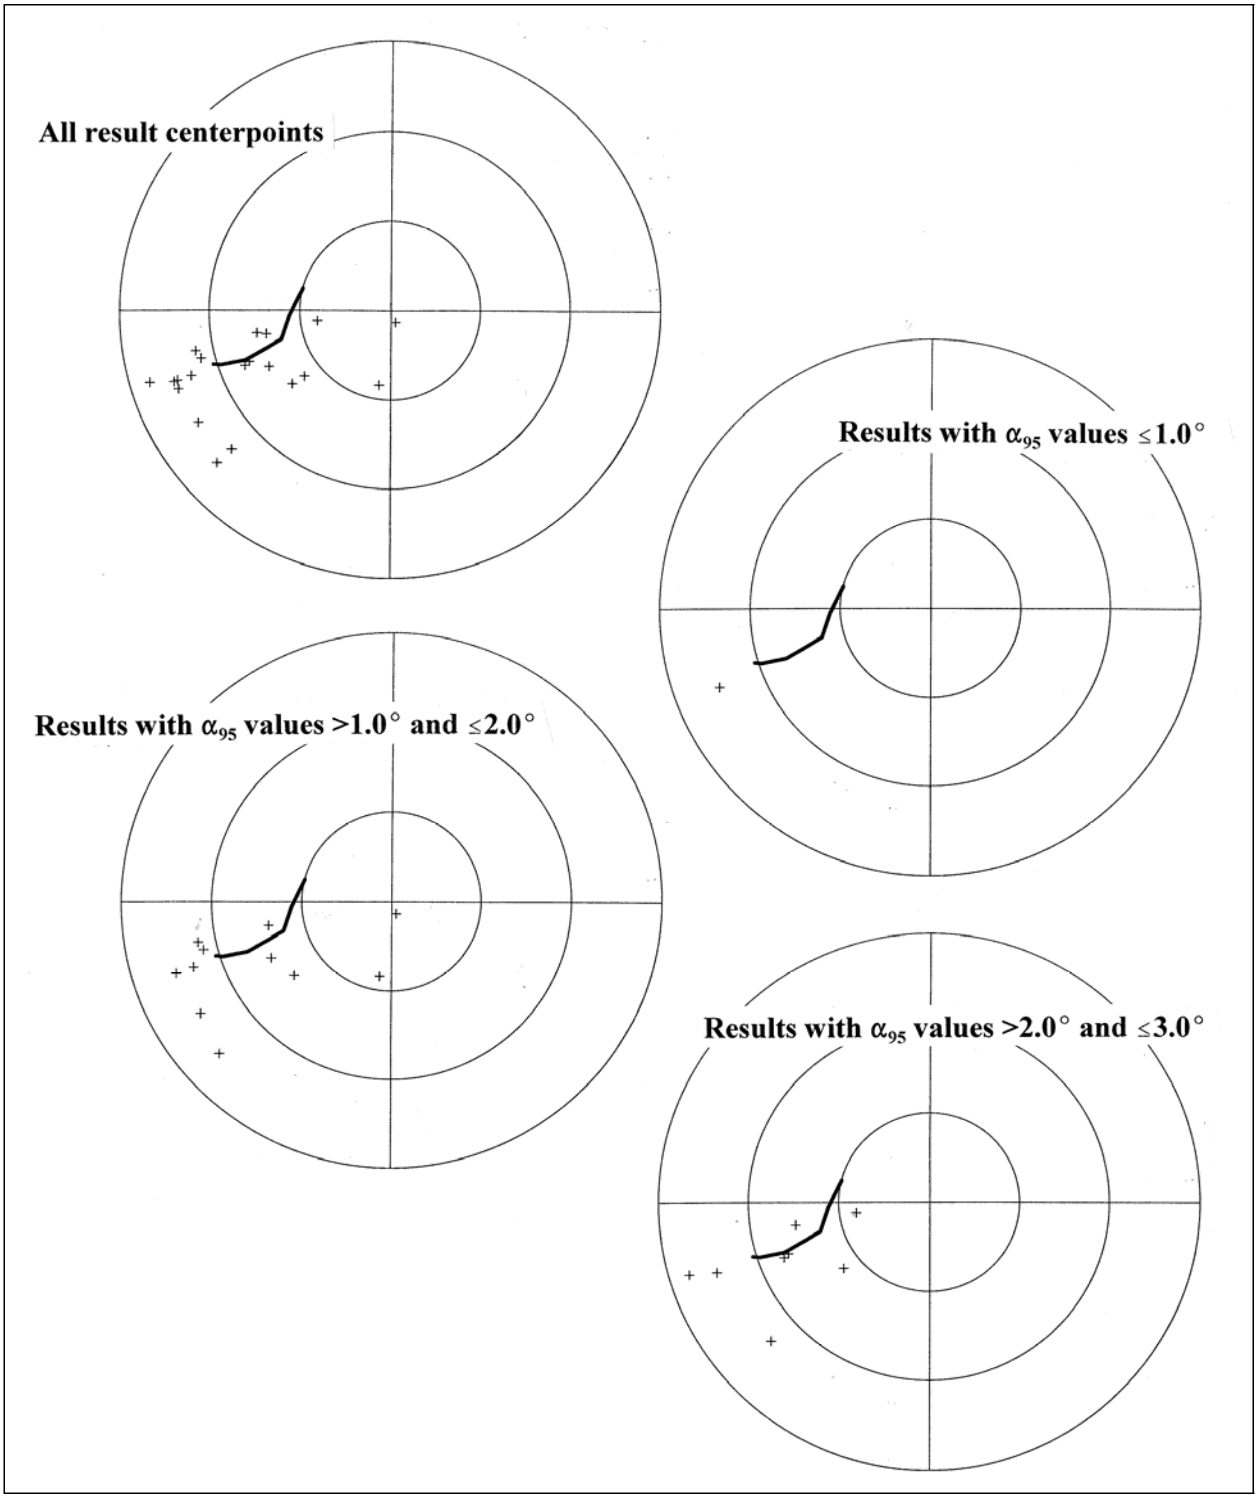

Figure 9.21. DuBois archaeomagnetic results that are confidently and exclusively associated with the AD 1225 to 1300 period, contrasted with the Wolfman VGP curve for the AD 1225 to 1300 period. The upper figure includes all results, regardless of precision. The lower plots include only moderate and low precision results, respectively.

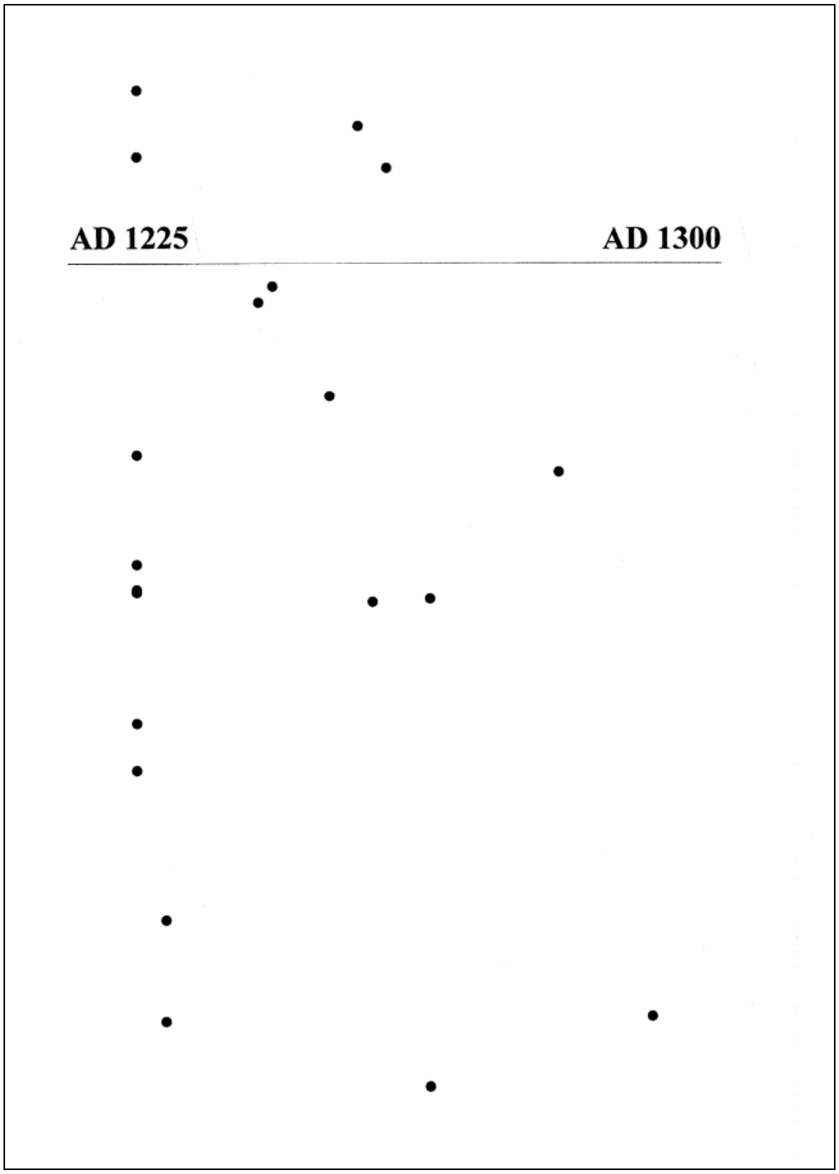

Figure 9.22. Plot of residual distances from confidently attributed AD 1225 to 1300 sample centerpoints and nearest points along the AD 1225 to 1300 segment of the Wolfman Curve.

AD 1300–1400 (Segment 8)

Differences between the SWCV2000 and Wolfman approximations of the AD 1300–1400 curve segment are extreme, although both segments terminate at approximately the same location (Figure 9.23). The SWCV2000 VGP path is relatively short and has a kink or inflection in the middle of the period. High precision results could conceivably discriminate events at either end of the period, but moderate precision results could encompass the entire segment. The Wolfman Curve represents a path more than twice as long, beginning with an excursion to longitudes of less than 170E, significantly distant from the nearest point on the SWCV2000 curve. For nearly the first half of the period, the Wolfman segment remains at latitudes greater than 85E, returning to the vicinity of the SWCV2000 curve for the post-AD 1350 portion of the segment. The Wolfman Curve segment terminates at a higher longitude than SWCV2000, but they are similar in latitude.

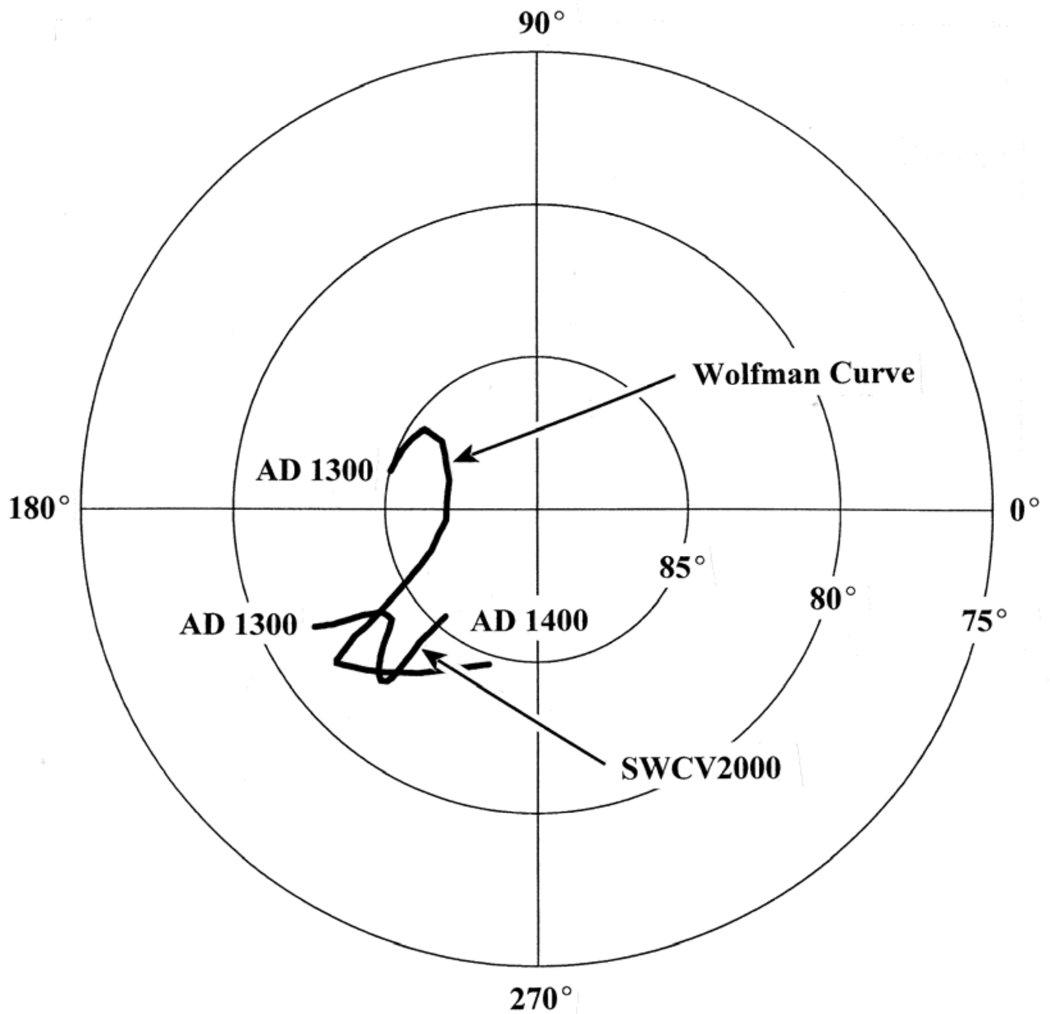

Figure 9.23. AD 1300 to 1400 segments of the SWCV2000 and Wolfman VGP curves.

The DuBois dataset is contrasted with the SWCV2000 curve in Figure 9.24. Contemporary or potentially earlier results (solid and open circles) tend to be scattered both around the curve segment, above it (toward lower longitudes), and toward lower latitudes. Contemporary or potentially later results (solid and open squares) are more tightly clustered, both around the later half of the segment and at higher longitudes.

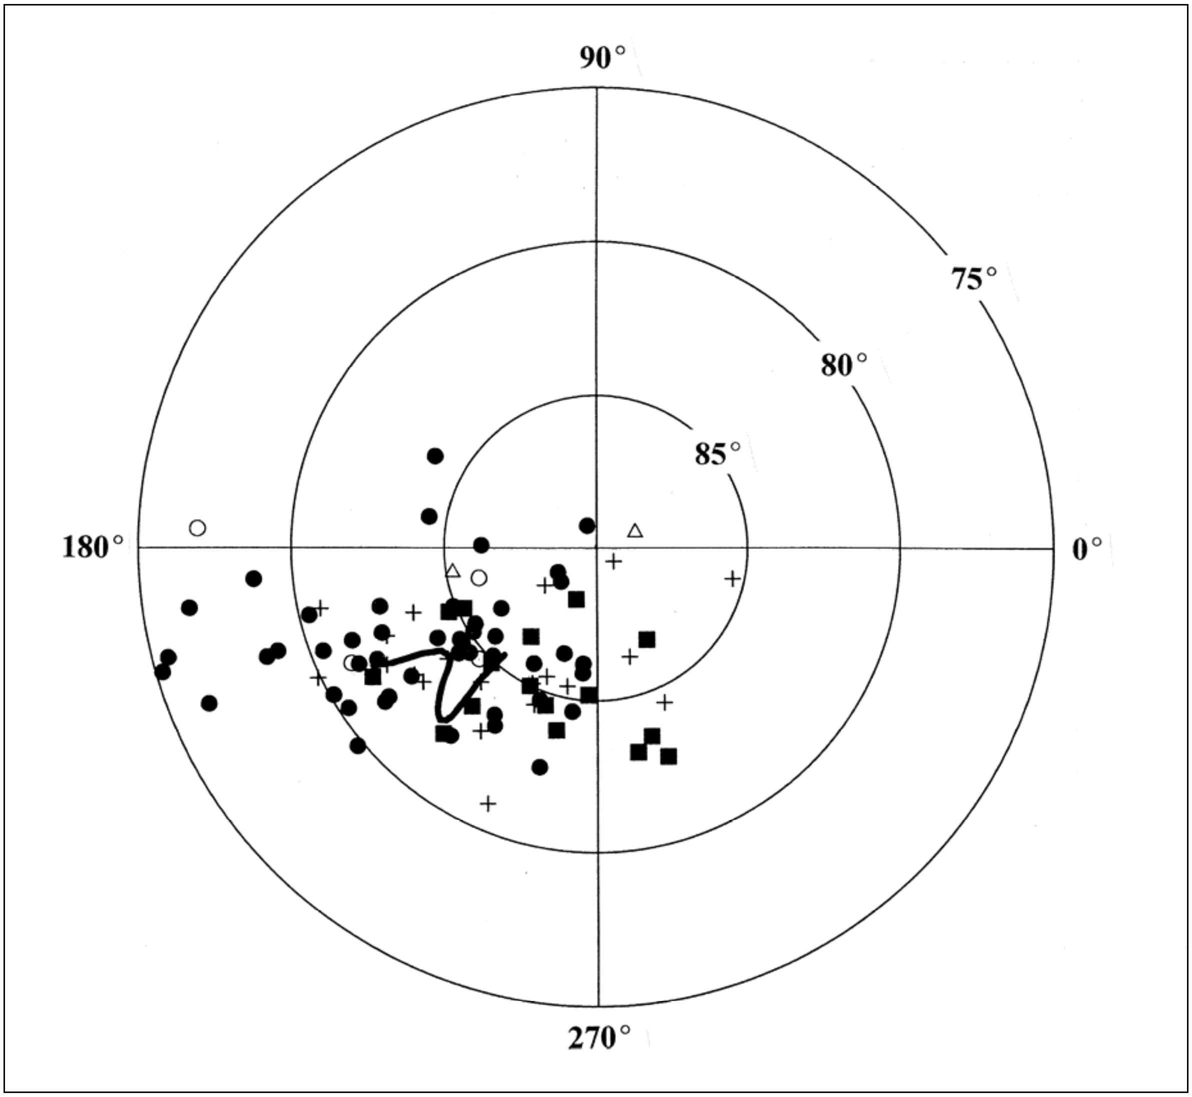

Figure 9.24. SWCV2000 and archaeomagnetic result centerpoints from the DuBois database that could date to the AD 1300 to 1400 period. Open circles denote samples that are believed to date within the AD 1125 to 1400 period. Solid circles denote samples that are believed to date within the AD 1225 to 1400 period. Samples denoted by a "+" are exclusively dated to the AD 1300 to 1400 period, while samples marked with an open triangle are dated to the broader AD 1225 to 1500 period. Solid squares denote samples that are believed to date within the AD 1300 to 1500 period. All centerpoints are associated with α_{95} values of 3.0° or less.

Results that are confidently and exclusively attributed to the AD 1300–1400 period are isolated from the less precisely dated results in Figure 9.25. The scatter of all results clusters around the curve and also extends to higher longitudes. These higher longitude points extend the late end of the segment, and they include results of high, moderate, and low precision.

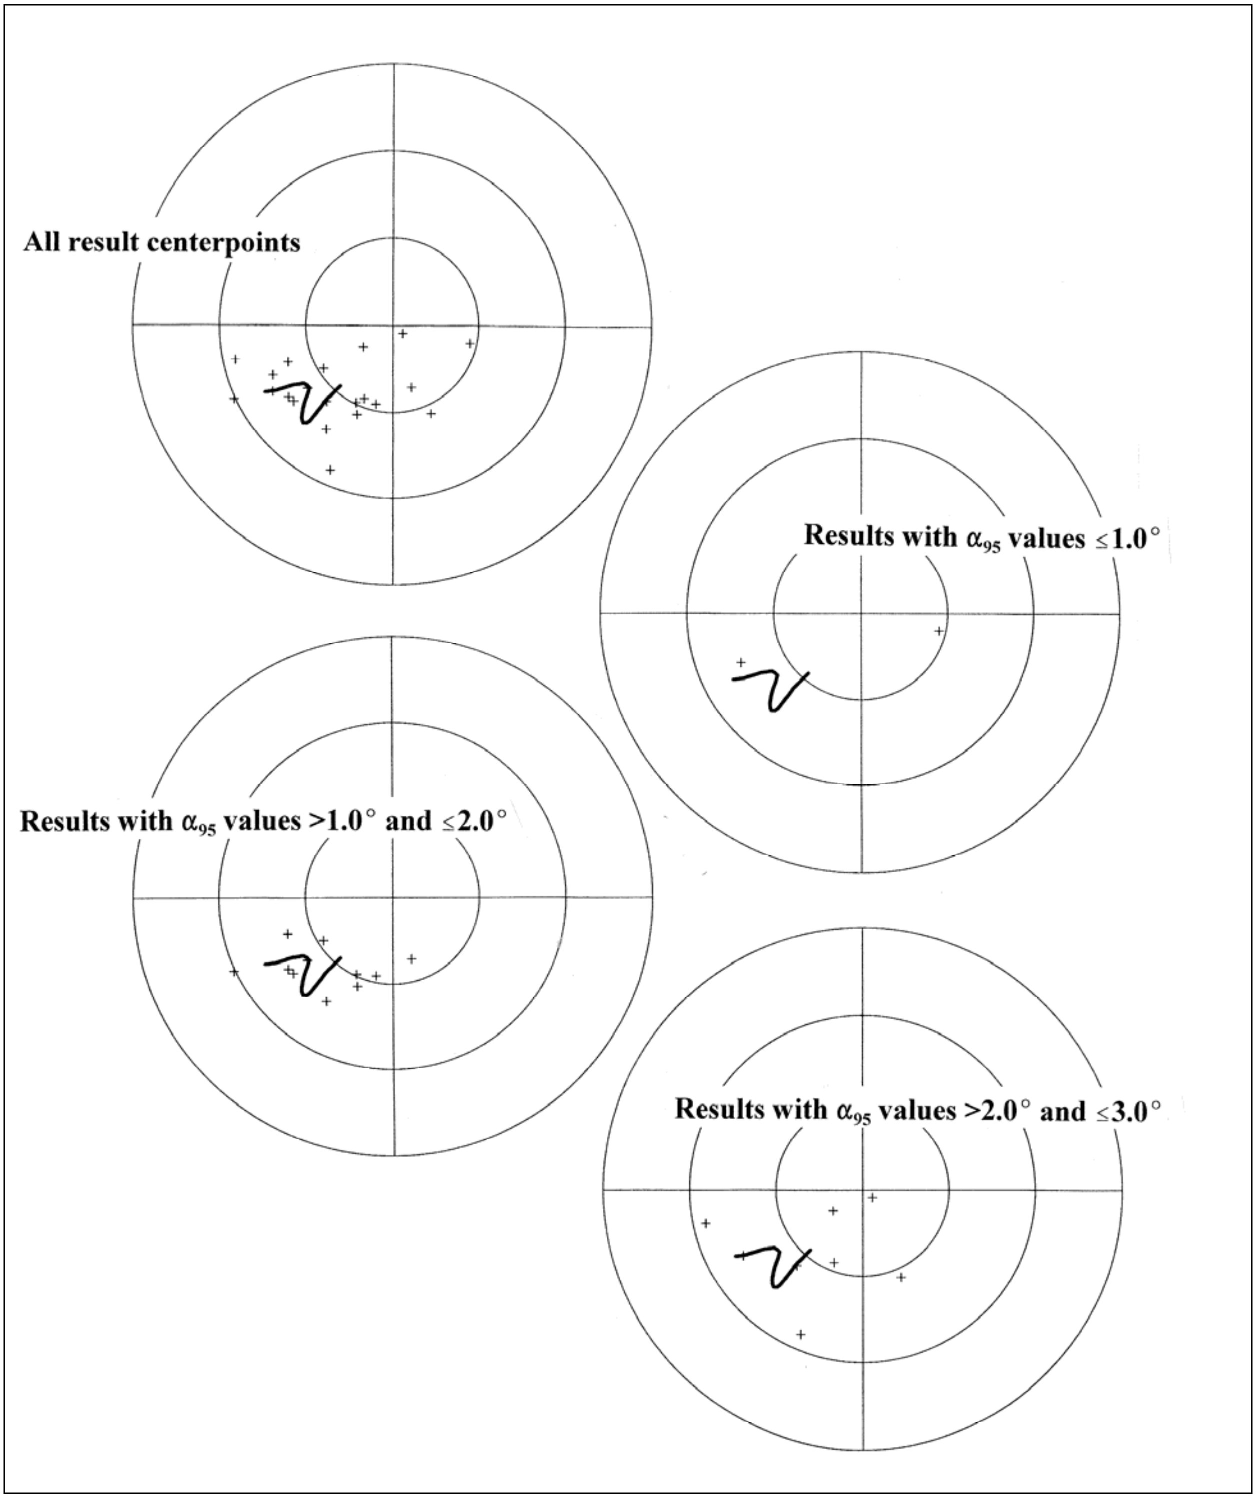

Figure 9.25. DuBois archaeomagnetic results that are confidently and exclusively associated with the AD 1300 to 1400 period, contrasted with the SWCV2000 VGP curve. The upper plot includes all results, regardless of precision. The other plots distinguish high, moderate, and low precision results.

Residual distances between the result centerpoints and the nearest points along the curve segment (Figure 9.26) are less meaningful due to the relatively nonlinear nature of the curve segment. The distances were divided into those for centerpoints that are graphically above the curve as extended (positive) and those centerpoints that are below the curve segment (negative). Negative residuals are more common than positive residuals, and there is an unusually large number of large residuals at the end of the segment (AD 1400).

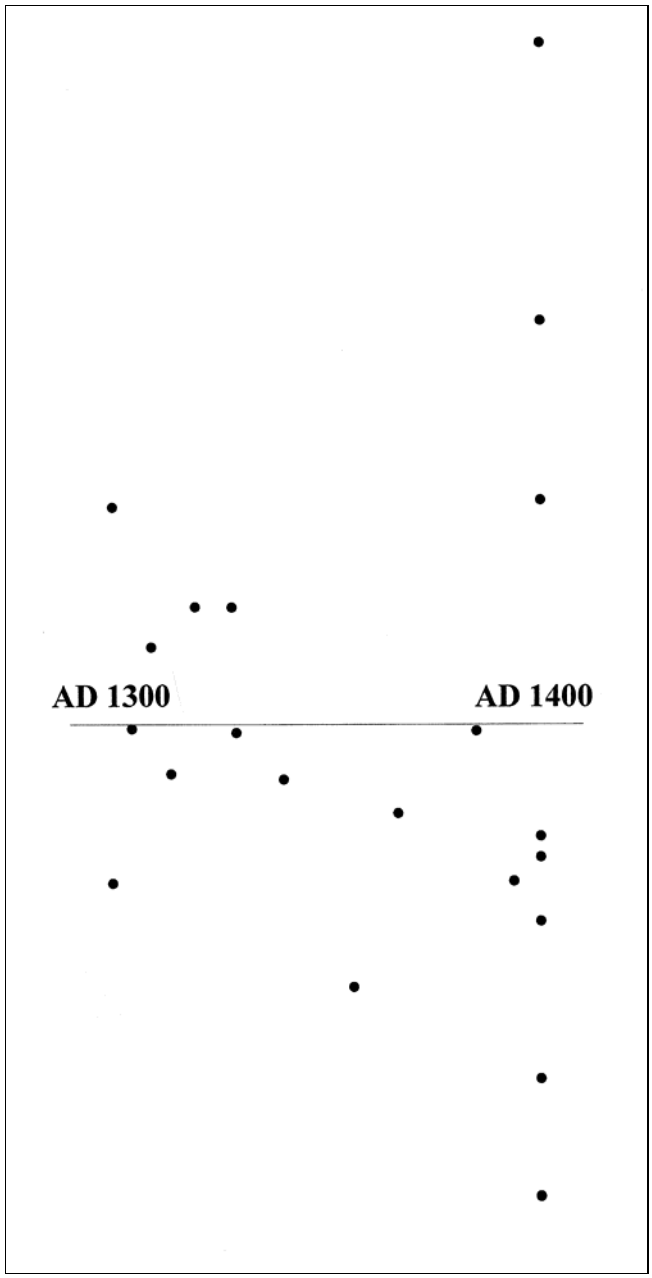

Figure 9.26. Plot of residual distances from confidently attributed AD 1300 to 1400 sample centerpoints and nearest points along the AD 1300 to 1400 segment of SWCV2000.

The same DuBois dataset is contrasted with the AD 1300–1400 segment of the Wolfman Curve in Figure 9.27.

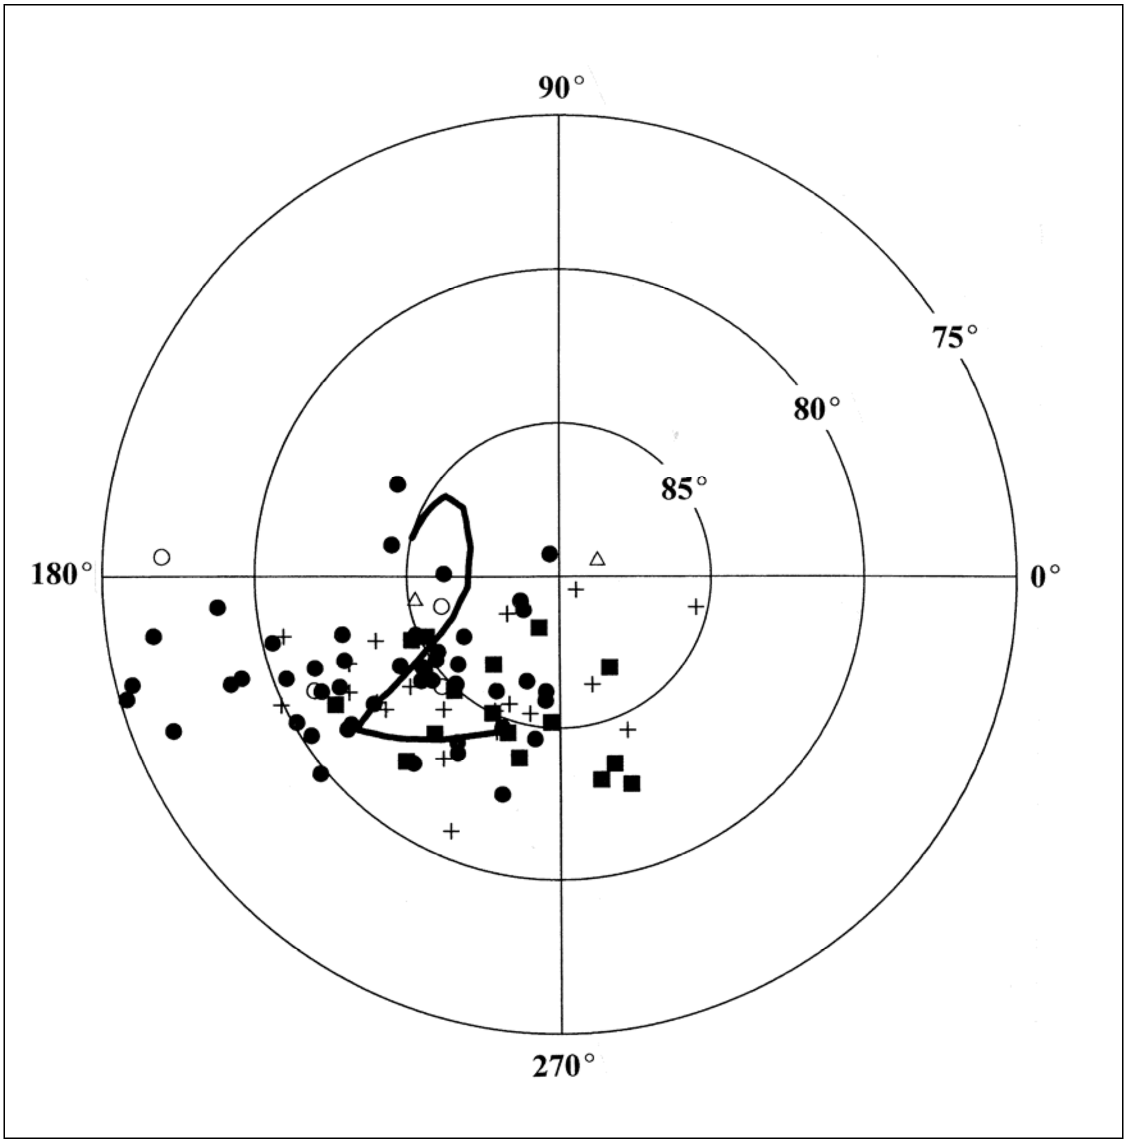

Figure 9.27. The AD 1300 to 1400 segment of the Wolfman Curve and archaeomagnetic result centerpoints from the DuBois database that could date to the AD 1300 to 1400 period. Open circles denote samples that are believed to date within the AD 950 to 1300 period. Solid circles denote samples that are believed to date within the AD 1125 to 1300 period. Samples denoted by a "+" are exclusively dated to the AD 1225 to 1300 period, while samples marked with an open triangle are dated to the broader AD 1125 to 1400 period. Solid squares denote samples that are believed to date within the AD 1225 to 1400 period. All centerpoints are associated with α_{95} values of 3.0° or less.

Results that are either contemporary with or earlier than the segment (solid and open circles) cluster either around the curve or at lower latitudes. Several of these results are proximate to the early third of the curve segment (180° longitude or less). Sample results that are either contemporary with, or later than, the segment (solid and open squares) cluster around the segment or lie at higher longitudes off of the late end of the segment.

The results that are confidently and exclusively attributed to the AD 1300–1400 period are plotted with the Wolfman Curve segment in Figure 9.28. One high precision result is near the curve while the other is significantly removed off of the late end of the segment. Moderate precision results are all clustered in the area of the later two-thirds of the curve, as are the low precision results albeit with a slightly more diffuse scatter. None of the precisely attributable results falls proximate to the early one-third of this segment. The residual distances are defined as positive if the centerpoint lies to right of the curve segment, while negative distances denote centerpoints to the left of the curve (Figure 9.29). One large positive residual is the single high precision result, but the most significant observation is the scarcity of results that are linked to the first quarter of the curve path.

The DuBois dataset suggests that some revision of these segments is warranted. The resolution (precision) of the DuBois results is insufficient to evaluate the validity of the recurved path represented in SWCV2000, but the scatter does suggest that the segment may need to be extended toward lower latitudes. The Wolfman Curve is more ambiguous. There are no results in the well-dated DuBois samples that can validate the extension of the early one-third of the curve segment to the lower longitudes. Either this extension is invalid or the early 14th century is not represented by the results in the database.

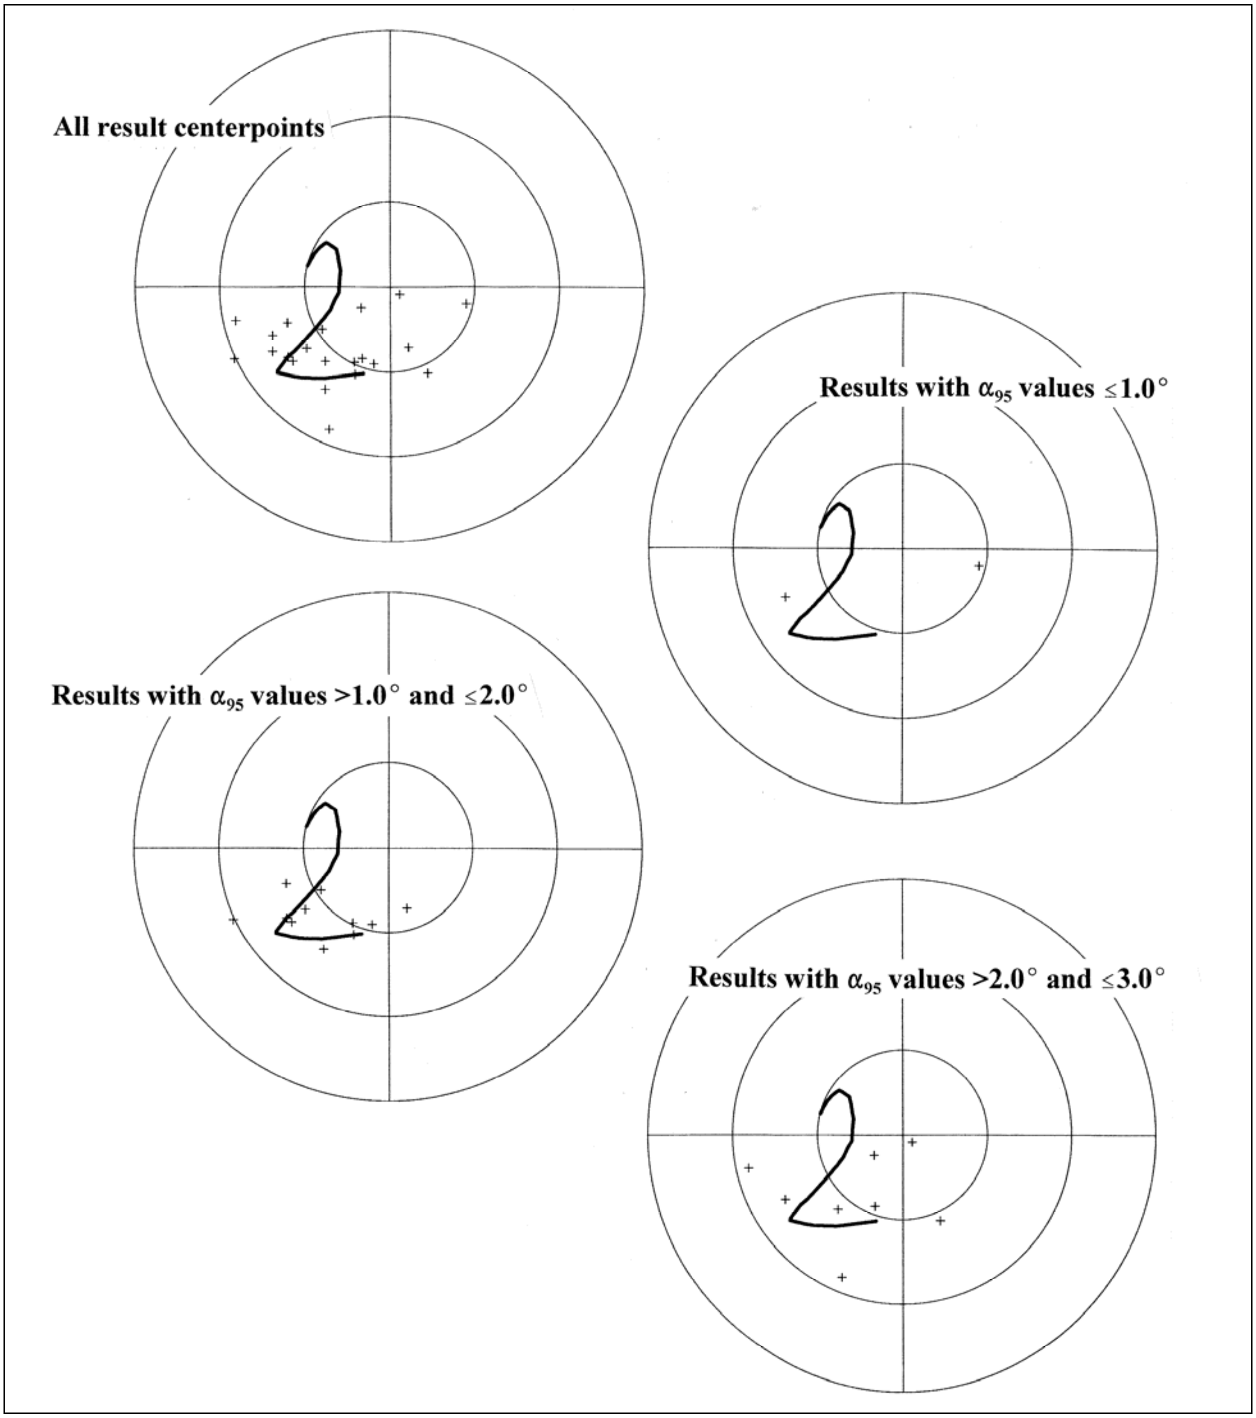

Figure 9.28. DuBois archaeomagnetic results that are confidently and exclusively associated with the AD 1300 to 1400 period, contrasted with the Wolfman VGP curve for the AD 1300 to 1400 period. The upper figure includes all results, regardless of precision. The lower plots differentiate high, moderate, and low precision results, respectively.

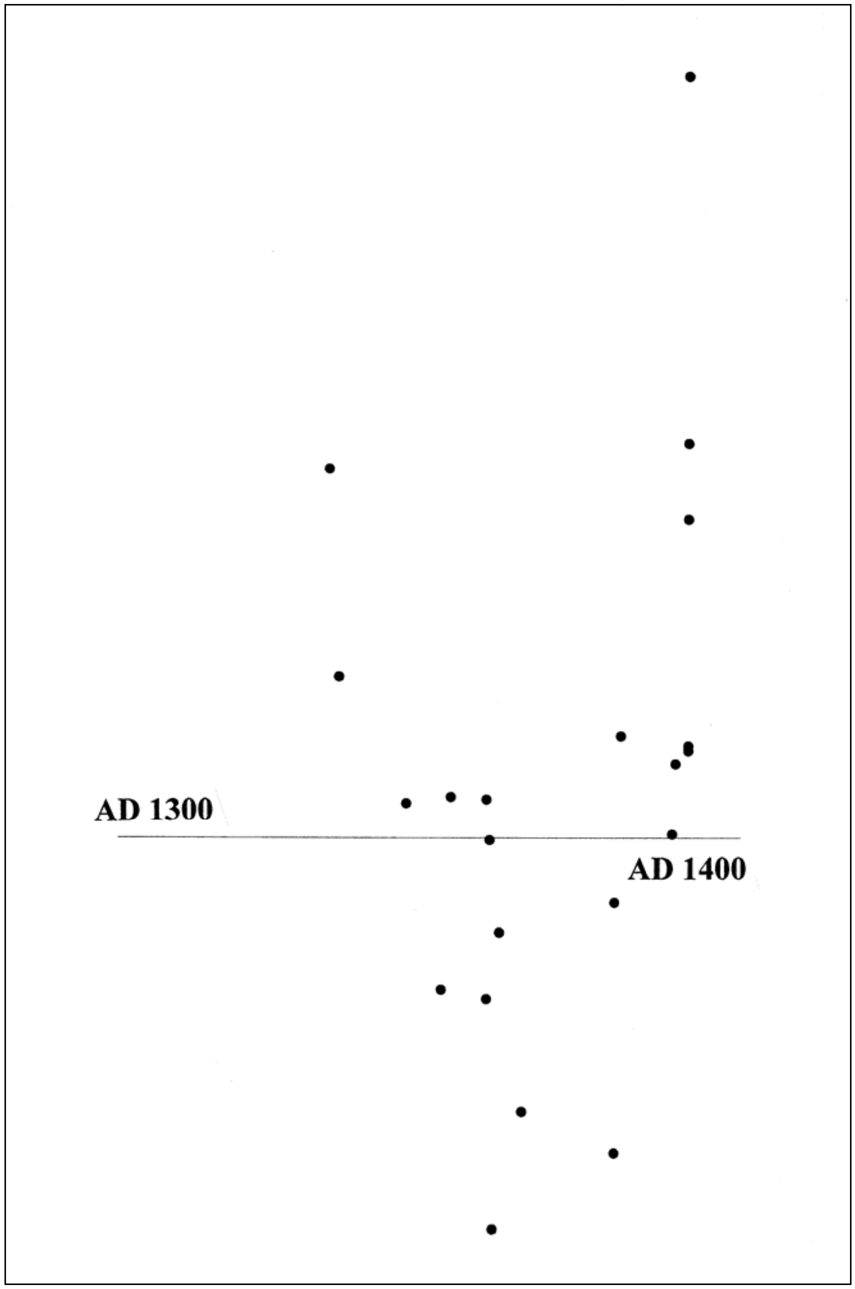

Figure 9.29. Plot of residual distances from confidently attributed AD 1300 to 1400 sample centerpoints and nearest points along the AD 1300 to 1400 segment of the Wolfman Curve.

AD 1400–1500 (Segment 9)

The final segment of this study covers the AD 1400–1500 period. The SWCV2000 and Wolfman Curves for the period are presented in Figure 9.30. The two curve segments have approximately the same starting point, but they again diverge radically, and high precision results would easily distinguish the two proposed AD 1500 positions. The difference between the proposed VGP segments lies in the abrupt excursion of the Wolfman Curve toward the pole, followed by movement to lower latitudes in the area between 10° and 350° longitude. The Wolfman Curve implies polar movement at nearly twice the rate implied by the SWCV2000 path.

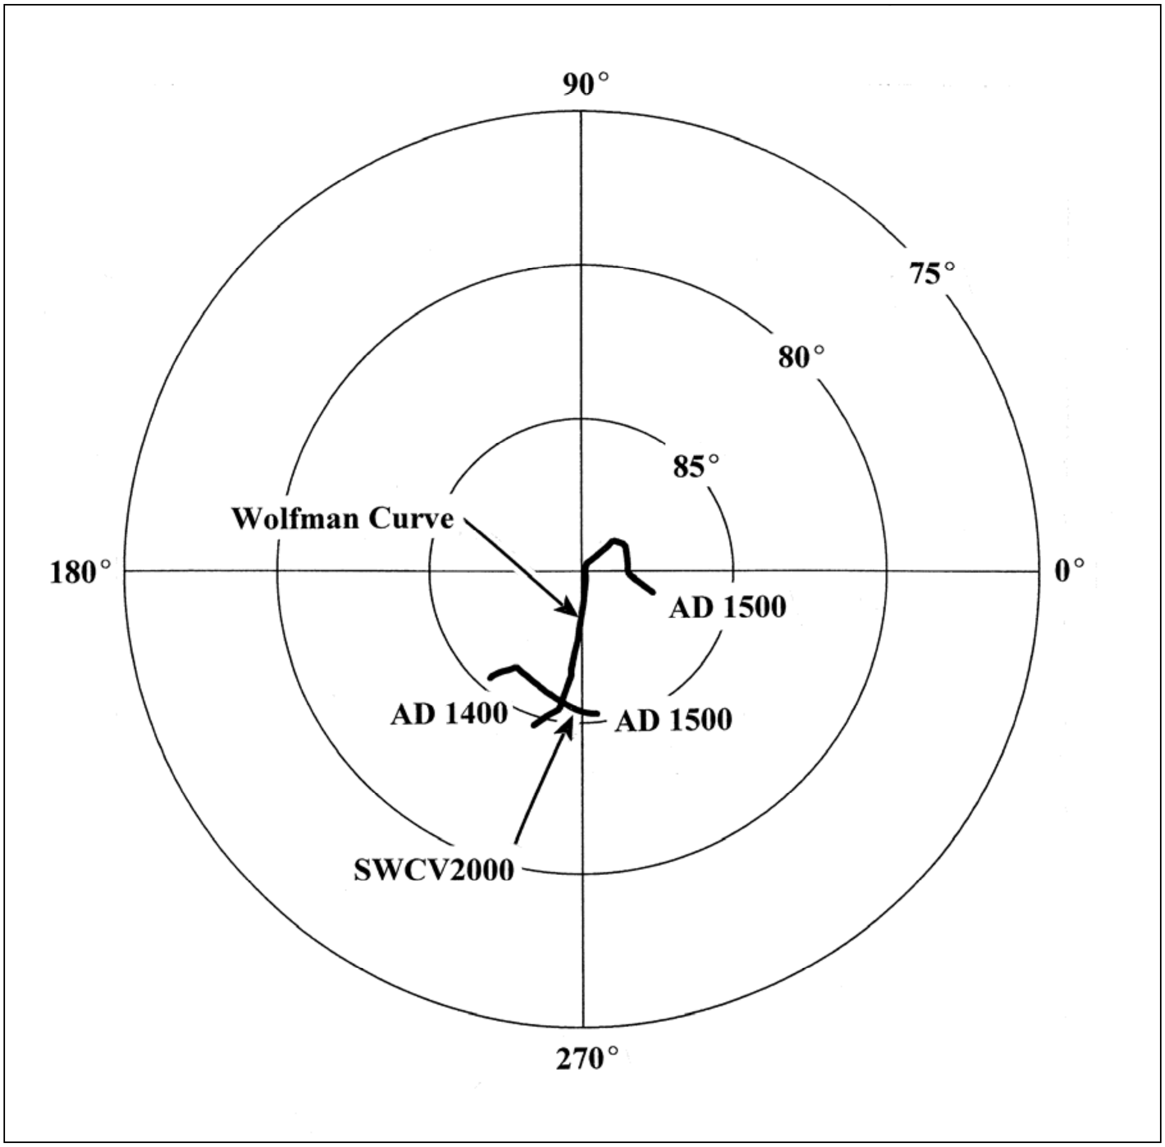

Figure 9.30. AD 1400 to 1500 segments of the SWCV2000 and Wolfman VGP curves.

Potentially relevant results from the DuBois dataset are contrasted with the SWCV2000 curve in Figure 9.31. Contemporary or potentially earlier results (solid and open circles) tend to be clustered around the curve segment, with slightly more results at lower latitudes. Contemporary or potentially later results (solid squares) are restricted to higher longitudes.

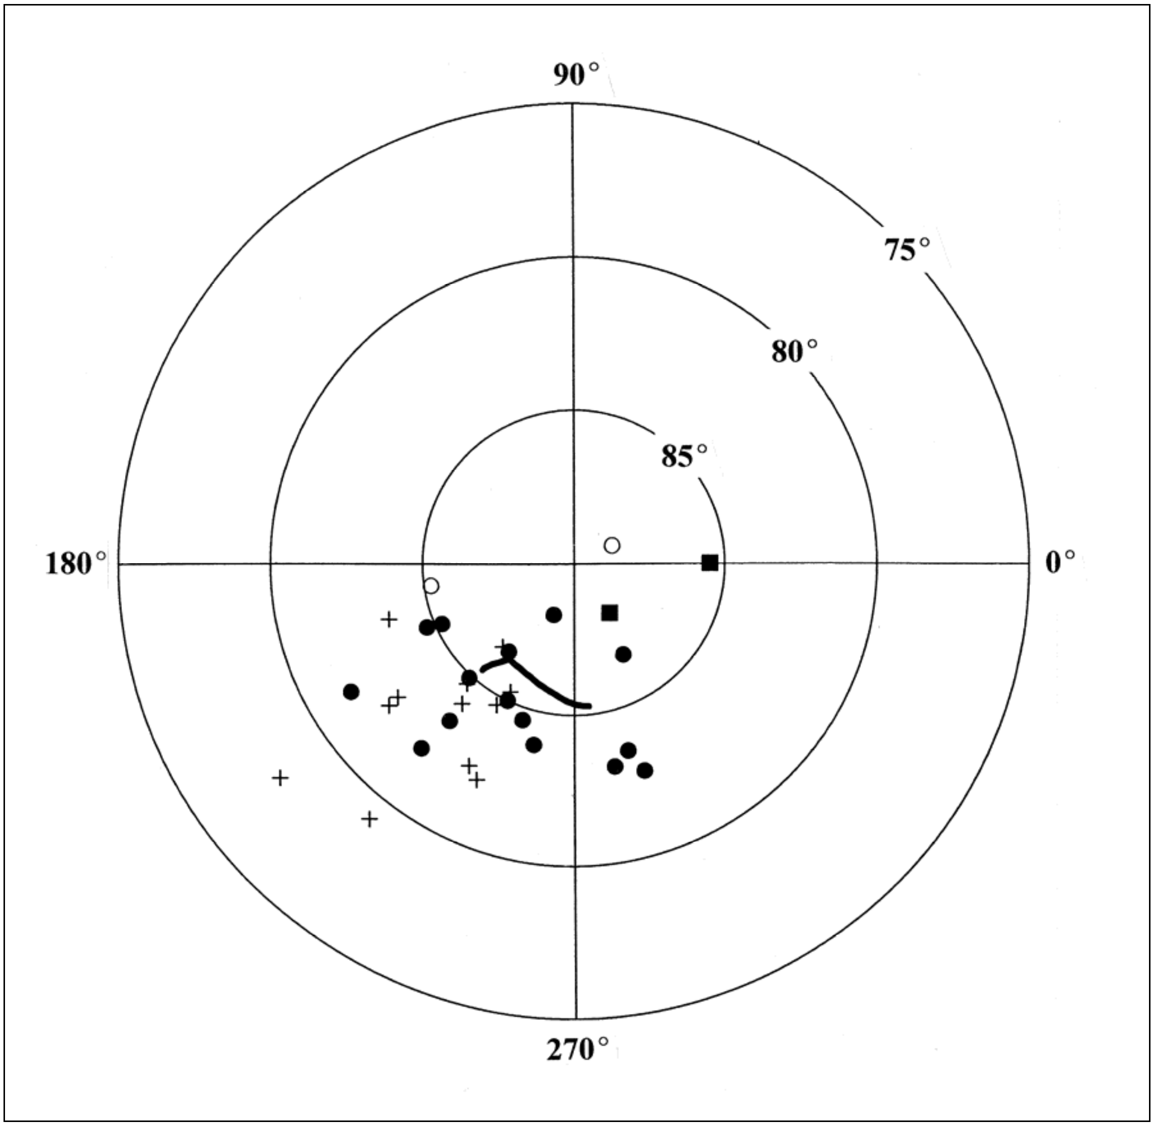

Figure 9.31. SWCV2000 and archaeomagnetic result centerpoints from the DuBois database that could date to the AD 1400 to 1500 period. Open circles denote samples that are believed to date within the AD 1225 to 1500 period. Solid circles denote samples that are believed to date within the AD 1300 to 1500 period. Samples denoted by a "+" are exclusively dated to the AD 1400 to 1500 period. Solid squares denote samples that are believed to date within the AD 1400 to 1600 period. All centerpoints are associated with α_{95} values of 3.0° or less.

Results that are confidently and exclusively attributed to the AD 1400–1500 period are isolated from the less precisely dated results in Figure 9.32. Where potentially earlier results were scattered around the curve segment, the AD 1400–1500 result centerpoints barely overlap the curve path. All but one are located at lower latitudes and at equivalent or lower longitudes. This is true of both moderate and low precision results, although the scatter of low precision result centerpoints is greater. The systematic offset of these results from the curve segment prompted a cursory examination of the source of these samples.

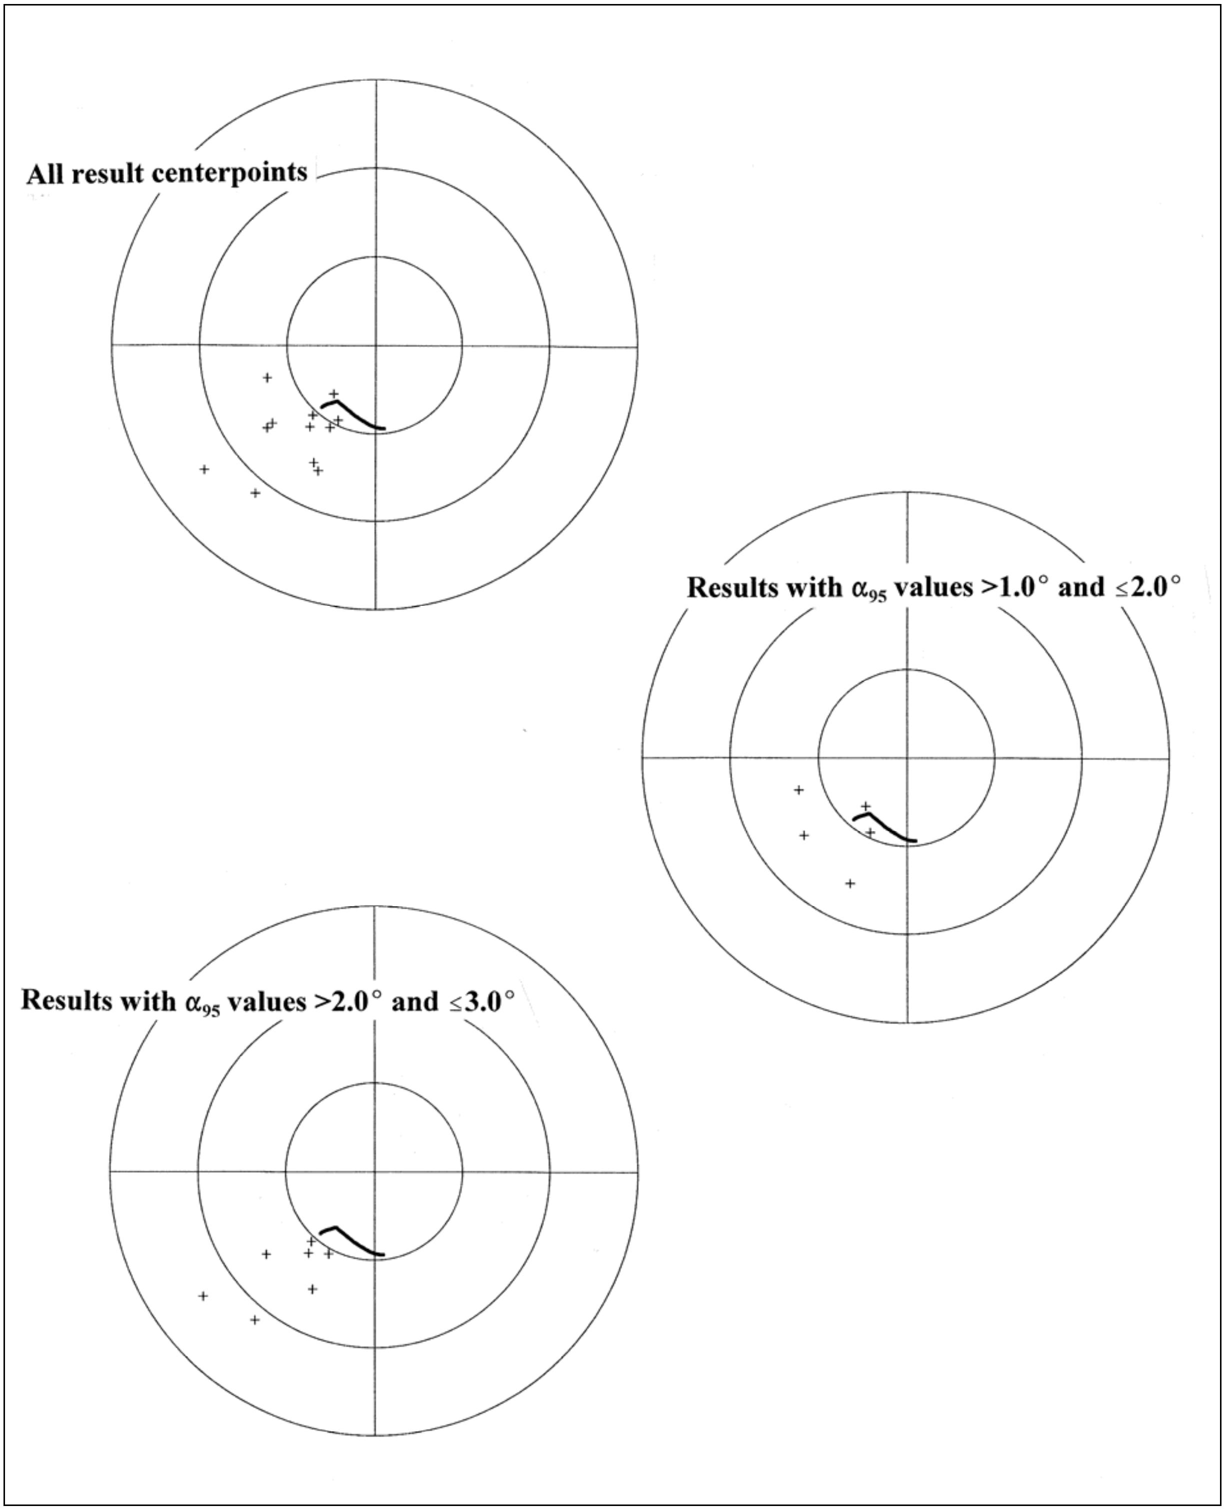

Figure 9.32. DuBois archaeomagnetic results that are confidently and exclusively associated with the AD 1400 to 1500 period, contrasted with the SWCV2000 VGP curve. The upper plot includes all results, regardless of precision. The other plots distinguish moderate and low precision results.

All but two of the exclusively attributed results are from Component II at Arroyo Hondo (LA 12). This component is given an initiation date of AD 1388 and an abandonment date of shortly after AD 1410. An additional sample is dated by the 15th century by non-cutting tree-ring dates of 1401 and 1412, while the final sample is dated by the presence of Glaze C to the early 15th century. All of these results could conceivably fall within the first 25 years of the AD 1400–1500 period, explaining their placement near the early end of the SWCV2000 curve segment, but they are sill falling off of the curve. Residual distances between the result centerpoints and the nearest points along the curve segment (Figure 9.33) reflect this relationship in both their magnitude and their date associations.

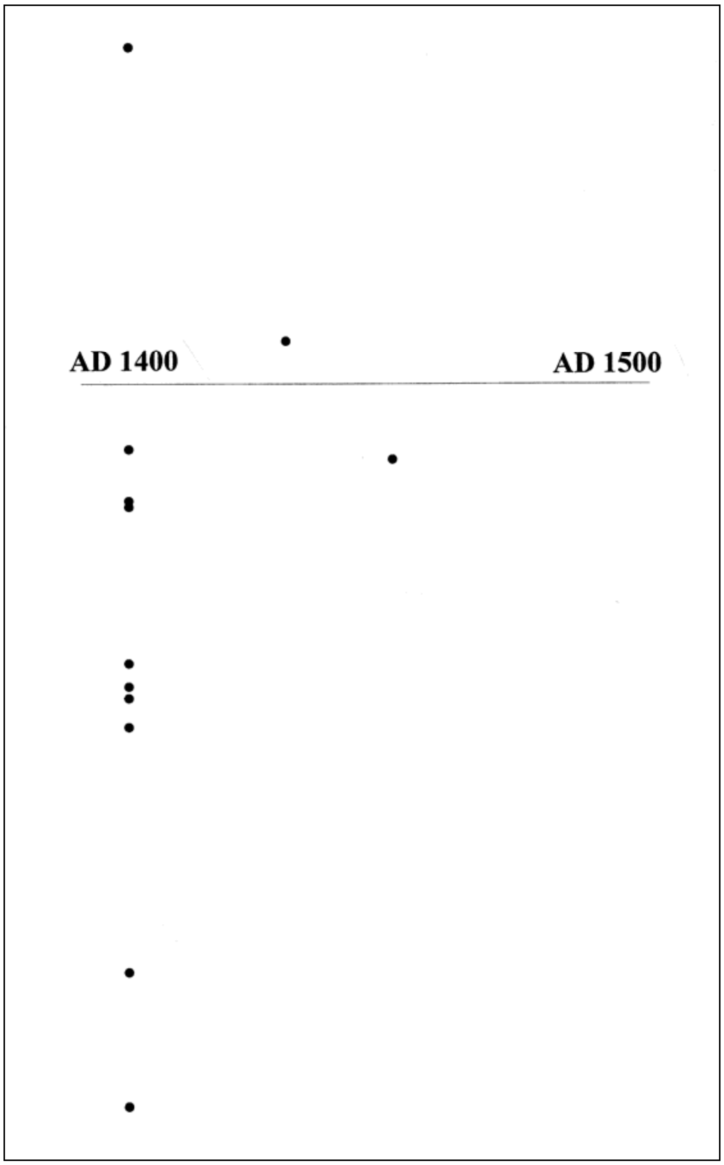

Figure 9.33. Plot of residual distances from confidently attributed AD 1400 to 1500 sample centerpoints and nearest points along the AD 1400 to 1500 segment of SWCV2000.

The same DuBois data are contrasted with the Wolfman Curve segment for the 1400–1500 period in Figure 9.34. Contemporary or potentially earlier results (solid and open circles) tend to be clustered around the early one-half of the curve segment, with slightly more results at lower latitudes. Contemporary or potentially later results (solid squares) are both located near the termination of the curve segment.

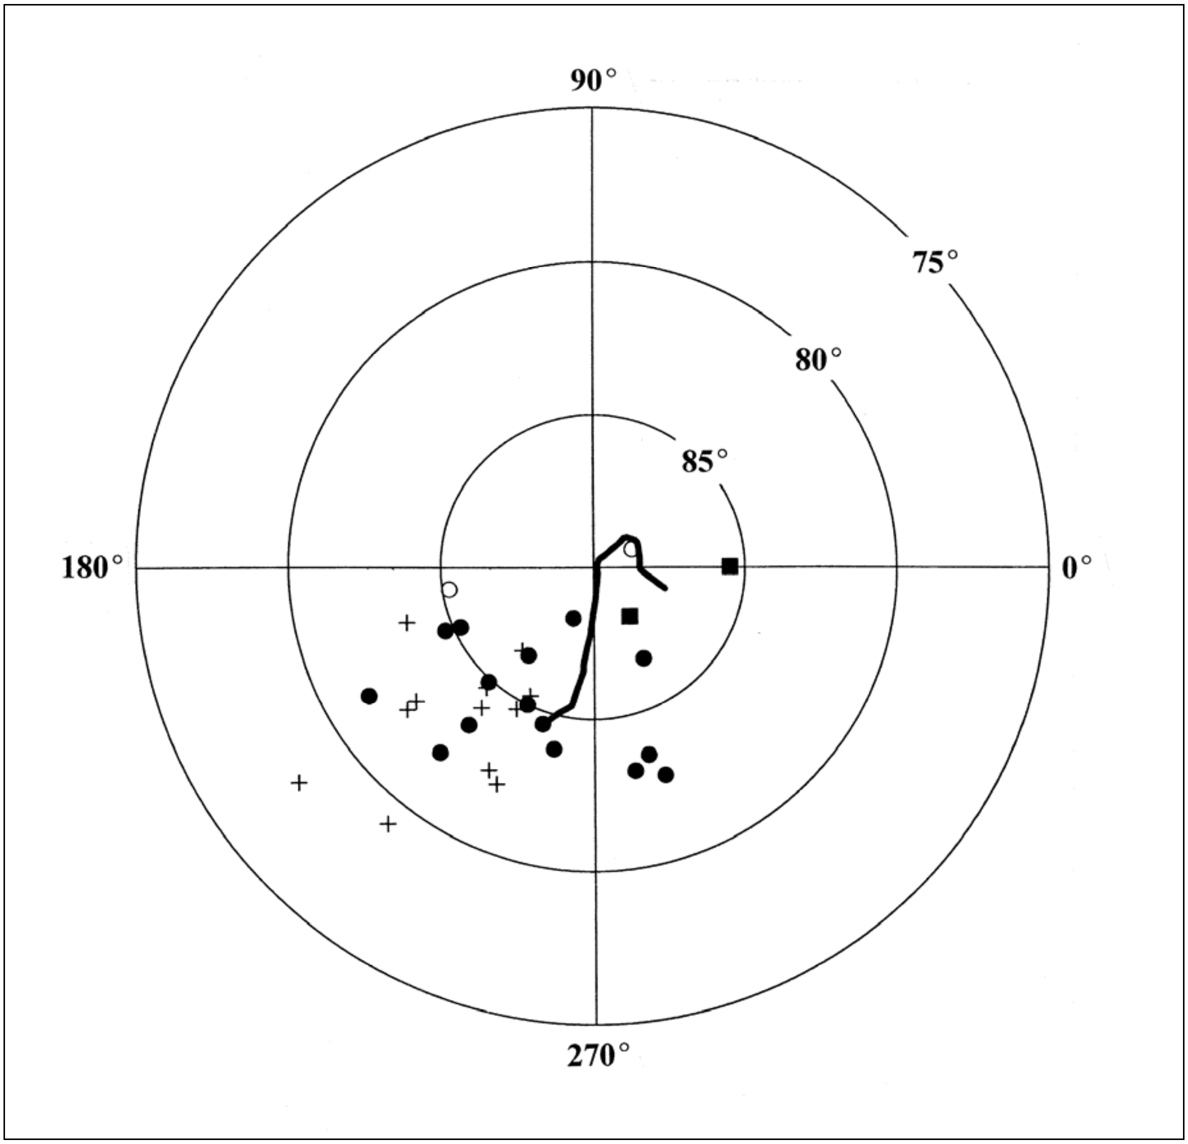

Figure 9.34. The AD 1400 to 1500 segment of the Wolfman Curve and archaeomagnetic result centerpoints from the DuBois database that could date to the AD 1300 to 1400 period. Open circles denote samples that are believed to date within the AD 1225 to 1500 period. Solid circles denote samples that are believed to date within the AD 1300 to 1500 period. Samples denoted by a "+" are exclusively dated to the AD 1400 to 1500 period. Solid squares denote samples that are believed to date within the AD 1400 to 1600 period. All centerpoints are associated with α_{95} values of 3.0° or less.

The results that are exclusively dated to the AD 1400–1500 period are contrasted with the curve segment in Figure 9.35.

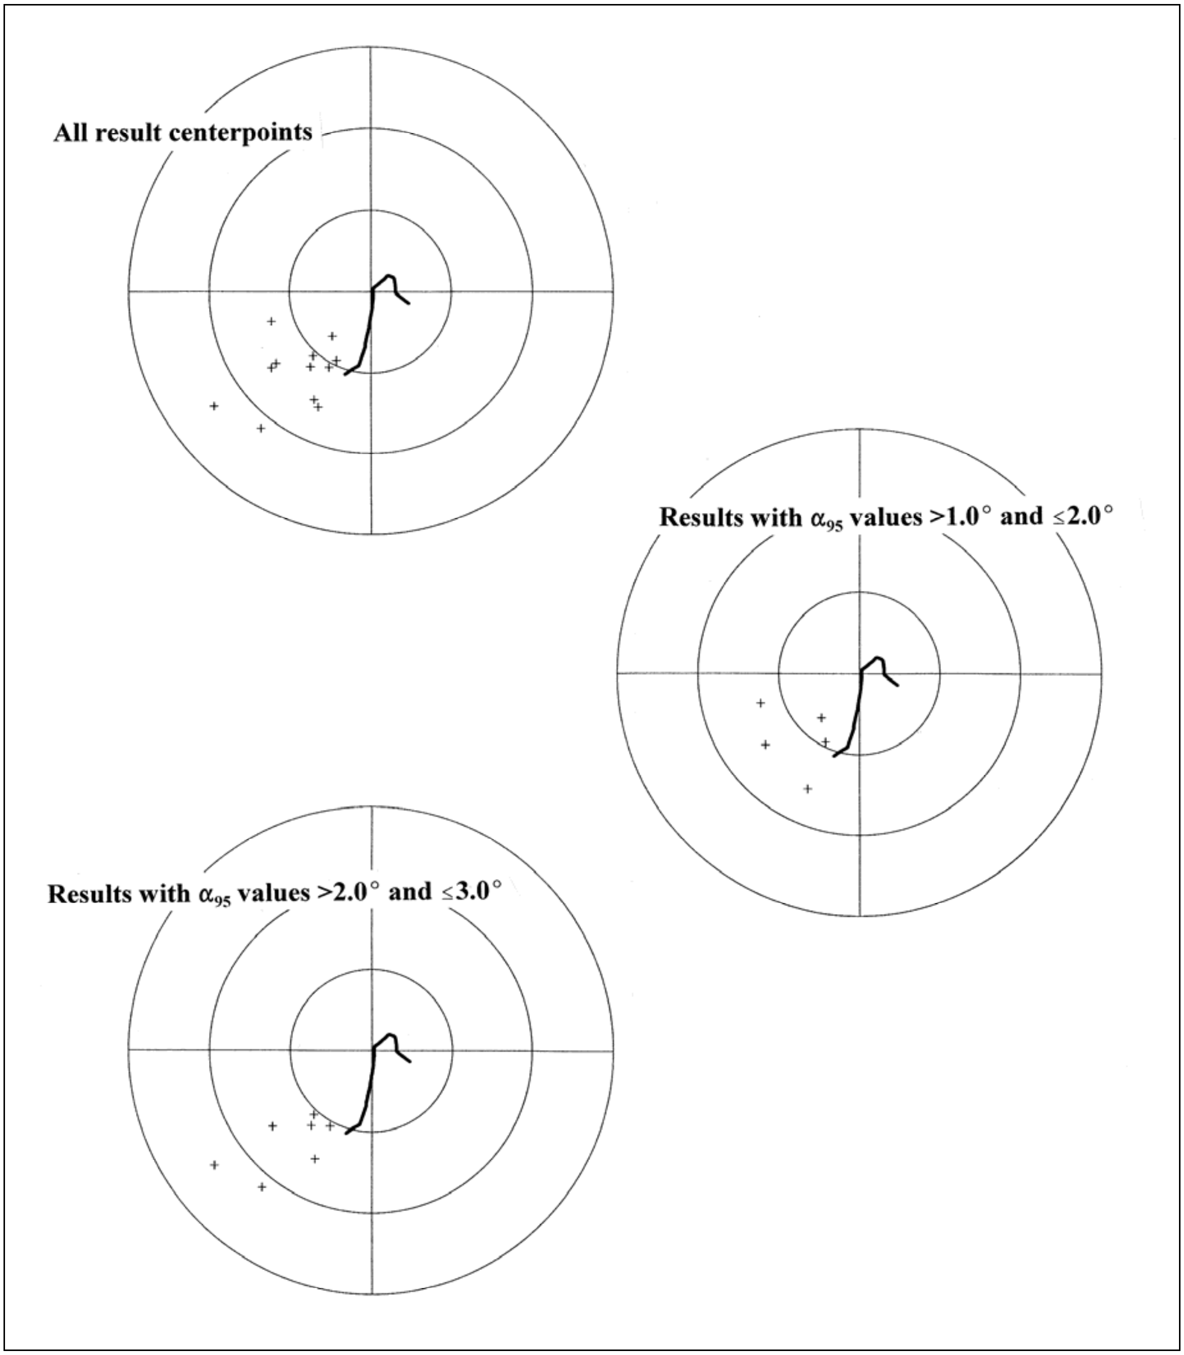

Figure 9.35. DuBois archaeomagnetic results that are confidently and exclusively associated with the AD 1400 to 1500 period, contrasted with the Wolfman VP curve for the AD 1400 to 1500 period. The upper figure includes all results, regardless of precision. The lower plots differentiated moderate and low precision results, respectively.

There is slight overlap between the moderate precision results and the early portion of the curve segment, but the majority of the results are located at lower latitudes and slightly lower longitudes than the AD 1400 end of the curve. Since these results are biased toward the AD 1400–1425 period, overlap with the early end of the curve only would be expected, but they clearly tend to fall off of the early end of the curve. This is reflected in the residual pattern (Figure 9.36), which is similar to that for the SWCV2000 curve.

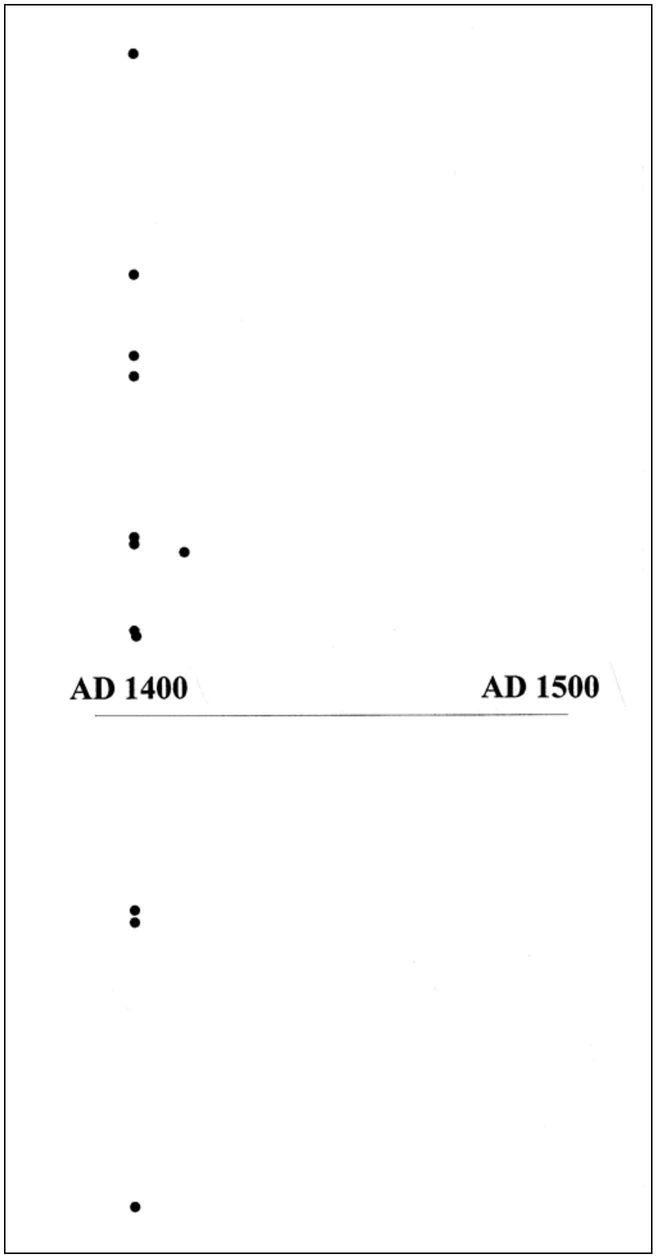

Figure 9.36. Plot of residual distances from confidently attributed AD 1300 to 1400 sample centerpoints and nearest points along the AD 1300 to 1400 segment of the Wolfman Curve.

Neither the SWCV2000 nor Wolfman VGP paths appear to be accurate for the AD 1400–1500 period, but the DuBois dataset for this period is an incomplete basis for evaluation. Both curves appear to be too high in latitude for their representations of the first few decades of the 15th century, but after about AD 1425, we have no DuBois data to compare with the remaining 75 years of polar movement. Two "contemporary or later than" sample results (solid squares in Figure 9.34) are the only suggestions that the Wolfman Curve may be correct in proposing an excursion toward the pole in the later half of the 15th century. Otherwise, the differences between the two proposed paths cannot be resolved at this time.

Summary

The DuBois dataset has provided a relatively unique opportunity to evaluate the SWCV2000 and Wolfman VGP dating curve performances with an independent body of archaeomagnetic results. Neither of the curves appears to be validated for their entire path, some segments appear to be more valid than others, and a hybrid curve will probably prove to be a stronger approximation of the true curve. The weakest areas of the curve are, unfortunately, in the very segments of interest for the interpretation of Pajarito Plateau archaeomagnetic dating results (AD 1125–1500). In most cases, even the more extreme differences in the curves will not result in serious chronological errors, as long as the full date ranges of archaeomagnetic date ranges are used in archaeological interpretations. However, there is one ironic consequence of the differences between the curves and the weaknesses in both that have been suggested by the DuBois dataset. For some time periods, the discrepancies are large enough that precise samples (small α_{95} values) will fall off the dating curves and are in greater jeopardy of misinterpretation than are less precise results.

The extent to which the DuBois dataset is representative of the full time periods used in the segment analysis has yet to be studied, but in one case (AD 1400–1500) it is clear that cluster effects (many samples from one site or one component) must be investigated before the trends noted in this evaluation can be acted on. The next steps in this study of curve performance will be the integration of the individual Colorado State University results that were used to develop SWCV2000, a more detailed evaluation of within-segment chronology, and an evaluation of the calibration of the curves. These efforts can be compared with the summaries of Deaver (1997) for the Hohokam region, ultimately resulting in the proposal of a hybrid curve that can be applied as the next approximation for dating purposes.

ARCHAEOMAGNETIC RESULTS FROM THE NORTHERN RIO GRANDE REGION

In addition to chronological interpretation based on regional VGP curves and date ranges, archaeomagnetic results can be used directly in both intra-site and inter-site comparisons. Toward this end, we have compiled the DuBois dataset archaeomagnetic results from sites within the broadly defined northern Rio Grande region. The region has been defined as the area within 35.0 to 36.5° north latitude and 105 to 107° west longitude (253 to 255° longitude). These results have been previously distributed as date ranges based on various generations of the DuBois curve, but the VGP positions and error ellipses have not been published. The individual and grouped results are presented in Table 9.2, plotted with either the Wolfman Curve or with the pre-AD 950 portion of the SWCV2000 curve for comparison. The samples are listed with available contextual information in Table 9.2.

Table 9.2. Robert DuBois dataset for the northern Rio Grande region.

AD 400–600 and AD 600–800

Only a single result falls within each of these periods. Field assessment of the context was that the burn should date to the Basketmaker III period. The location of the result (11) agrees with that placement, probably shortly before AD 650.

AD 800–950

Five samples are potentially attributable to this period. Four (1854, 1857, 1858, and 1859) are from Early Developmental structures in the Jemez River Valley, and all four results are consistent with age assignments in the AD 825–875 period. The fifth sample (30) was collected from the Cochiti Reservoir area. Field expectation was for an age around AD 1000, and the result is consistent with that expectation.

AD 950–1125

Six samples are potentially attributable to this period. One (30), discussed above, falls at the early end of the period. Two samples from Valdez Phase structures (167, 1904) have relatively imprecise results ($\acute{\alpha}_{95}$>2.0°) but may belong to this segment within the AD 1025–1125 portion of the curve. Sample 905 was collected from a Late Developmental structure at Nambe Falls and was expected to date within the AD 850–1125 period. The location of the result is consistent with the very end of that span. The remaining two results are samples from Gallina phase structures. Sample 1075 is unlikely to be from a context that dates before AD 1125. Sample 1076 has an imprecise result that could accommodate either a pre- or post-AD 1125 interpretation. However, a post-AD 1125 age is more likely.

AD 1125–1225

Thirteen samples are potentially attributable to this period. One (1183) from excavations at LA 12121 in Bandelier National Monument is exclusively and confidently dated to the last quarter of the 12th century. Three others from LA 12119 in Bandelier National Monument (1185, 1282, and 1287) are from a component with construction at the end of the 12th century and should date to the end of this period or the early decades of the next period. Two Valdez phase samples (167 and 1904) are ambiguously dated (see above). A sample from a fieldhouse within the Cochiti Reservoir pool (1113) is remarkably precise (α_{95}<1.0°), but its independent dating is weak within this period or perhaps the subsequent period. The result from Nambe Falls (905) either dates to the previous period or perhaps falls within the first decade or two of this period. Five samples are from Gallina structures, two of which may either date earlier or later than this period (1075 and 1076) and three of which may date to this period or to the AD 1225–1300 period (1398, 1399, and 1400).

AD 1225–1300

Twenty-eight of the DuBois samples are potentially attributable to this period. Two samples (24 and 25) from LA 6462 are associated with construction in the 1280s, and the results fall either at the very end of this period or the beginning of the next period. Pueblo Alamo is associated with construction dates spanning 1263–1284, and two hearths (536 and 537) have results that also fall either at the very end of this period or the early decades of the next. Saltbush Pueblo within Bandelier National Monument is ambiguously dated with non-cutting dates in the mid to early 13th century. The samples were taken from kiva hearths, one earlier (615) than the other (614). Four samples were measured from rooms in 29SF10 in the Nambe Falls area. Construction at the site as a whole appears to have been in the mid to late 13th century, but the abandonment date for the structures may fall within the early decades of the 14th century. Cochiti Reservoir excavations yielded sample 1113, which may date to this period or to the earlier period, while another sample (1444) could date to this period or the subsequent period. Samples from LA 12119 in Bandelier National Monument (1185, 1282, and 1287) either date to the early decades of this period or the final decades of the previous period. Two samples (1584 and 1585) from a room hearth at LA 13197 (AS-8) near San Ysidro are believed to date to the very late 13th century or perhaps into the first decade of the 14th century. A single sample from Rowe Pueblo (1829) may date to this period but probably dates to the 14th century. The remaining 10 samples are from Gallina sites. Five of these (1075, 1076, 1398, 1399, and 1400) are not associated with precise sources of independent dating and could date within this period or earlier periods. All of the remaining results (samples 1069, 1070, 1072, 1074, and 1077) are from sites and components with tree-ring dates in the mid-13th century.

AD 1300–1400

Twenty results could potentially fall within this period. Two samples (24 and 25) from LA 6462, discussed above, are associated with construction in the 1280s and may date as late as the first decade of the 14th century. Another sample from the original Cochiti Reservoir excavations (26) was estimated to date to AD 1400 based on field observations, and it may date to this period or the subsequent period. Two samples from a fire pit in Room 166 at LA 70 (74 and 75) are associated with tree-ring dates in the 1360s and the results probably date to the late 14th century. One sample from Pot Creek Pueblo (91) should date late within the first quarter of the 14th century. A sample from an as yet unidentified site (283) was estimated to date to around 1400 based on field observations. Two samples from Pueblo Alamo (536 and 537) date the abandonment of rooms that were constructed in or after the 1280s, and they date to either the very end of the previous period or within the first decades of this period. Four samples were recovered from three sites in the Bernalillo area. A kiva sample from Coronado State Monument (545) was estimated in the field to have a 14th century age and could be relevant to either this period or the subsequent period. The other three samples are all associated with Glaze B occupations (1740, 1812, and 1813) either at the end of this period or within the first decades after AD 1400. Two samples from Saltbush Pueblo within Bandelier National Monument are associated with non-cutting dates as late as the mid-13th century (614 and 615). The results probably date to the preceding period, but they may extend into the early decades of this period. Two samples represent Component I at Arroyo Hondo (705 and 936) and therefore are well-dated to the mid-14th century, while a third sample from the site (943) was not assigned to either Component 1 or Component II and could date either to the mid-14th century or the early 15th century. LA 13086 within the Cochiti Reservoir pool was characterized as a Pueblo III component and could date to the 13th or early 14th century. Finally, a sample from a pit room at LA 25852 (1855) is associated with Glaze A, B, and small amounts of Glaze C pottery. It should be slightly later than samples 1812 and 1813, so it may fall within the last decades of this period or the first decades of the subsequent period.

AD 1400–1500

Seventeen results could be potentially relevant to this period. Samples 26, 283, 545, 943, 1740, 1812, 1813, and 1855 all have independent dating that either straddles the AD 1400 threshold or is ambiguous between this period and the previous period. Seven samples (693, 694, 696, 700, 702, 703, and 706) were collected from features and burned walls associated with Component II at Arroyo Hondo. Component II is well dated with initial construction in the 1380s and remodeling and additional construction as late as AD 1410. Abandonment and the burning documented by the samples should have occurred within the AD 1410s. LA 16097 is associated with non-cutting tree-ring dates in the first two decades of the 15th century, and sample 1562 should be dated at some point in the second decade of the 15th century or later. The final sample attributed to this period is from LA 25852 (1814) and is associated with a Glaze C occupation that suggests a date within the middle third of the 15th century.

AD 1500–1600

No results within the DuBois database can be attributed to this time period at this time.

AD 1600–1900

Historic period sample results include a suite from Pecos Pueblo that are broadly assigned to the AD 1620–1790 period (144, 145, and 146). Another trio of samples from Pecos Pueblo is potentially contemporary, but the samples were not given an upper limiting age. Samples 123 and 124 are more narrowly dated to the AD 1700–1750 period based on their association with the site of Las Majadas, Unit 1. These compare with the much later (circa AD 1860) samples from Fort Burgwin (92 and 93).

Summary

There is a surprisingly rich body of comparative data for the northern Rio Grande region, especially when results from the DuBois dataset are combined with those of the Museum of New Mexico's ADL and the laboratory at Colorado State University. Although few data points originate from sites on the Pajarito Plateau itself, the complex culture history of the Coalition and Classic periods are well represented.

CONCLUSIONS

This review of archaeomagnetic dating is a work in progress. Unlike some other dating techniques, archaeomagnetic dating is accretional. The calibration curves must be compiled from the growing body of results from sample measurements. Although individual results are discrete and stable, the date range interpretations from those results are ephemeral, changing as the quality of the approximation of the true VGP curve changes. Despite a considerable amount of work by the three major practitioners of the technique over the past half-century, there is room for improvement in the performance of the current approximations of the VGP curve for the Southwest. Access to the Robert DuBois dataset is the single greatest step forward in this process, since the data have been only indirectly applied to the development of the two most commonly used dating curves in the Southwest. Improvements, both technical and theoretical, are expected over the next decade that will improve the reliability of this dating technique, but those improvements will require a thorough understanding of the strengths and limitations of the technique on the part of regional archaeologists.

CHAPTER 10
ARCHAEOLOGICAL OBSIDIAN AND SECONDARY DEPOSITIONAL EFFECTS IN THE JEMEZ MOUNTAINS AND THE SIERRA DE LOS VALLES, NORTHERN NEW MEXICO

M. Steven Shackley

INTRODUCTION

Distributed in archaeological contexts over as great a distance as Government Mountain in the San Francisco Volcanic Field in northern Arizona, the Quaternary sources in the Jemez Mountains, most associated with the collapse of the Valles Caldera, are distributed at least as far south as Chihuahua through secondary deposition in the Rio Grande, and east to the Oklahoma and Texas Panhandles through exchange. And like the sources in northern Arizona, the nodule sizes are up to 10 to 20 cm in diameter; El Rechuelos, Cerro Toledo Rhyolite, and Valle Grande (Valles Rhyolite derived from the Cerro del Medio dome complex) glass sources are as good a media for tool production as anywhere. While there has been an effort to collect and record primary source obsidian, the focus here has been to understand the secondary distribution of the Jemez Mountains sources. Until the recent land exchange of the Baca Ranch properties, the Valle Grande primary domes (i.e., Cerro del Medio) have been off limits to most research. The discussion of this source group here is based on collections by Dan Wolfman and others, facilitated by Los Alamos National Laboratory (LANL), the Museum of New Mexico, and recent sampling courtesy of the Valles Caldera National Preserve (VCNP; see Broxton et al. 1995; Shackley 2005a; Wolfman 1994).

Due to its proximity and relationship to the Rio Grande Rift System, potential uranium ore, geothermal possibilities, an active magma chamber, and a number of other geological issues, the Jemez Mountains and the Toledo and Valles Caldera particularly have been the subject of intensive structural and petrological study, particularly since the 1970s (Bailey et al. 1969; Gardner et al. 1986; Heiken et al. 1986; Ross and Smith 1955; Self et al. 1986; Smith et al. 1970; Figure 10.1 and 10.2). Half of the 1986 *Journal of Geophysical Research*, volume 91, was devoted to the then current research on the Jemez Mountains. More accessible for archaeologists, the geology of which is mainly derived from the above, is Baugh and Nelson's (1987) article on the relationship between northern New Mexico archaeological obsidian sources and procurement on the southern Plains, and Glascock et al.'s (1999) more intensive analysis of these sources, including the No Agua Peak source in the Taos Plateau Volcanic Field at the Colorado/New Mexico border.

This study is focused on the analysis of obsidian and rock samples submitted by LANL, and the report of the long-term secondary depositional study by this laboratory, in part funded by LANL. The secondary depositional study is geared toward an understanding of the probable patterns of prehistoric procurement of artifact-quality obsidian from sources in the Jemez Mountains.

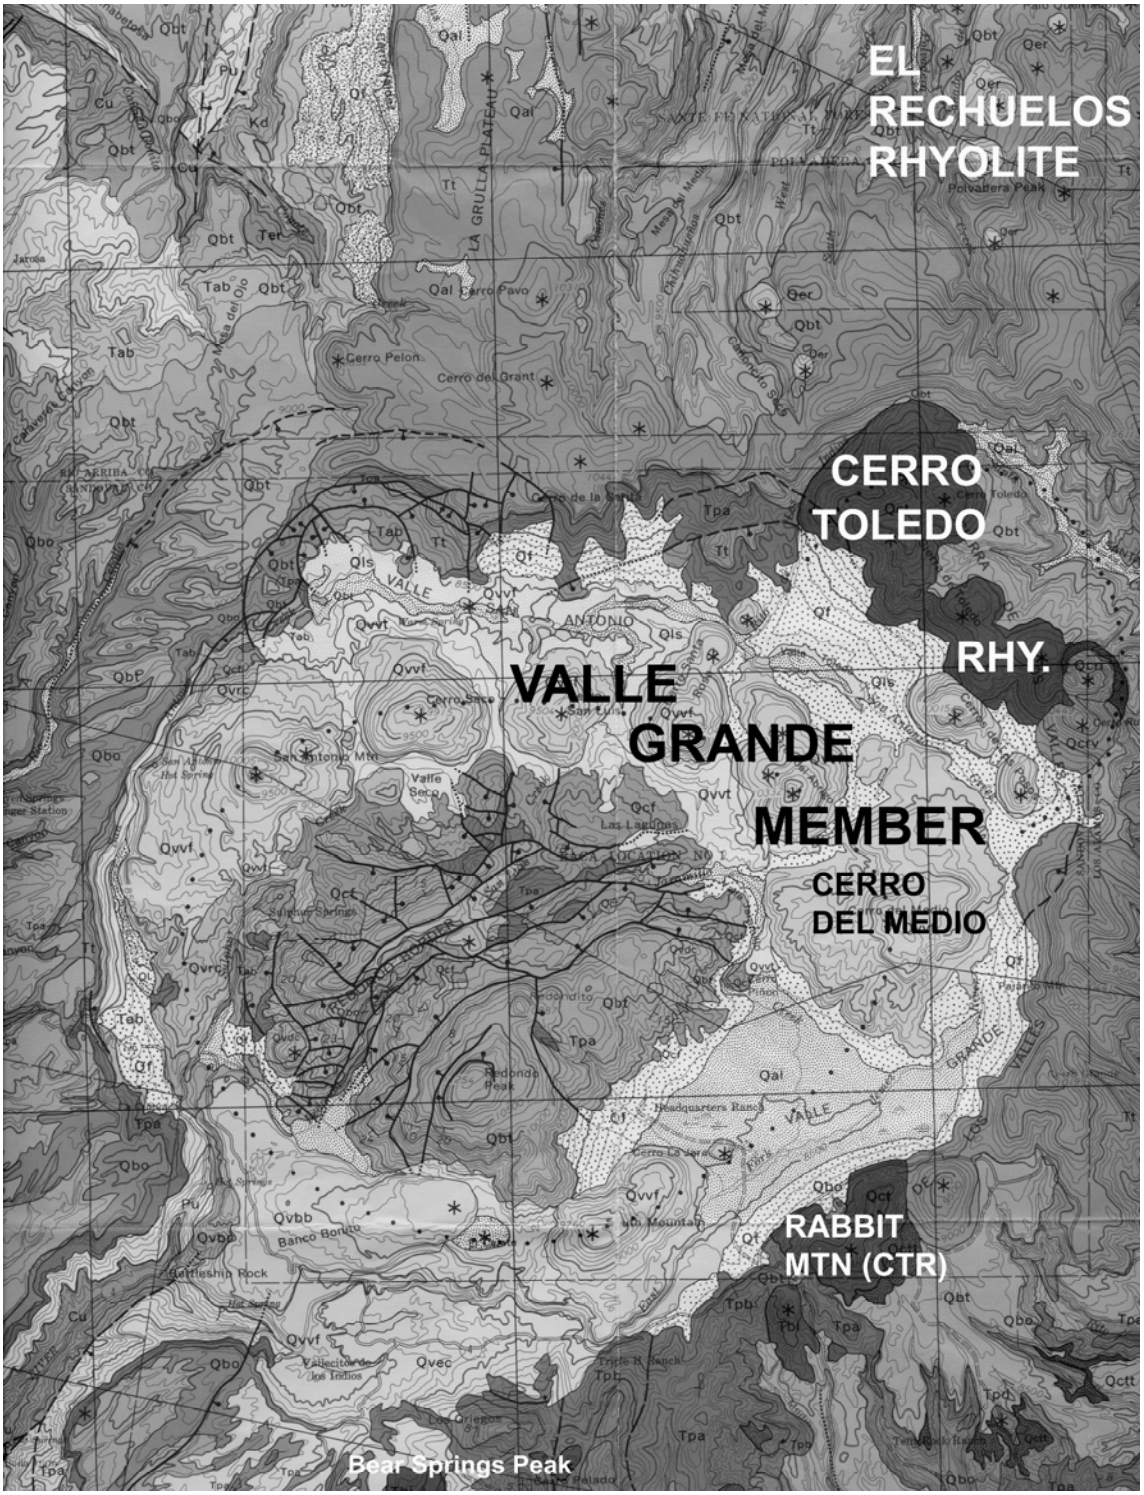

Figure 10.1. Topographical rendering of a portion of the Jemez Mountains, Valles Caldera, and relevant features (from Smith et al. 1970; formation explanations in Smith et al. 1970).

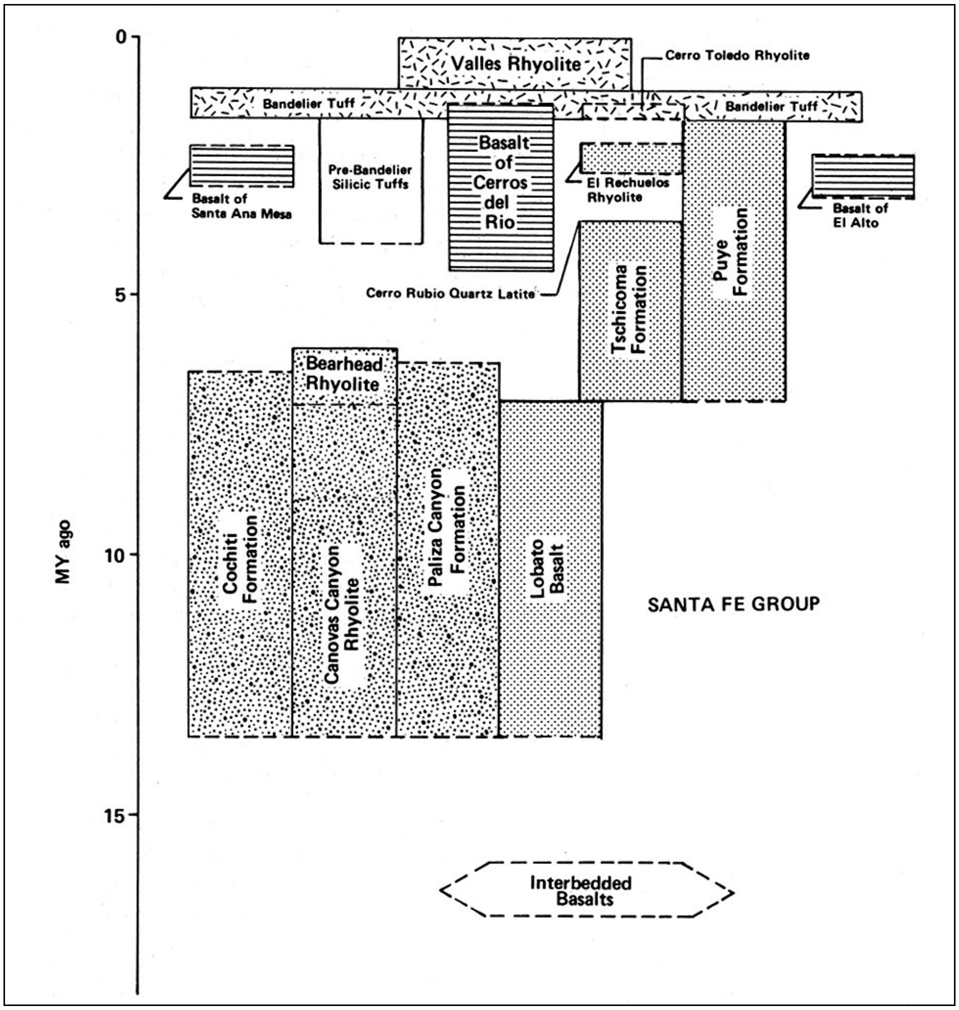

Figure 10.2. Generalized stratigraphic relations of the major volcanic and alluvial units in the Jemez Mountains (from Gardner et al. 1986). Note the near overlapping events at this scale for the Cerro Toledo and Valles Rhyolite members, and the position of Cerro Toledo Rhyolite at the upper termination of the Puye Formation.

BEDROCK AND ALLUVIAL DEPOSITION OF THE SIERRA DE LOS VALLES

Due to continuing tectonic stress along the Rio Grande, a lineament down into the mantle has produced a great amount of mafic volcanism during the last 13 million years (Self et al. 1986). Similar to the Mount Taylor field to the west, earlier eruptive events during the Tertiary more likely related to the complex interaction of the Basin and Range and Colorado Plateau provinces produced bimodal andesite-rhyolite fields, of which the Paliza Canyon (Keres Group), Canovas Canyon Rhyolite (Bear Springs Peak obsidian) and probably the Polvadera Group (El Rechuelos obsidian) is a part (Broxton et al. 1995; Shackley 1998a, 2005a; Smith et al. 1970). While both these appear to have produced artifact quality obsidian, the nodule sizes are relatively small due to hydration and devitrification over time (see Hughes and Smith 1993; Shackley 1995, 2005a). Later, during rifting along the lineament and other processes not well understood, first the

Toledo Caldera (ca. 1.45 Ma) and then the Valles Caldera (1.12 Ma) collapsed causing the eruptive events that were dominated by crustally derived silicic volcanism and dome formation (Self et al. 1986). The later eruptive sequence of the Valle Grande Member is significant for the prehistoric procurement of the obsidian as discussed below. The Cerro Toledo Rhyolite and Valle Grande Member obsidians are grouped within the Tewa Group due to their similar magmatic origins. The slight difference in trace element chemistry is probably due to evolution of the magma through time from the Cerro Toledo event to the Valle Grande events (see Hildreth 1981; Mahood and Stimac 1990; Shackley 1998a, 1998b). Given the relatively recent events in the Tewa Group, nodule size is large and hydration and devitrification minimal, yielding the best natural glass media for tool production in the Jemez Mountains.

Some of the potentially minor sources of archaeological obsidian from the Jemez Mountains area such as the glass from the Bland Canyon area appear to be better artifact-quality obsidian than previously reported. The exact sampling location for the Glascock et al. (1999) samples is apparently unknown (see also Wolfman 1994). The Bland Canyon data reported appear to be rare nodules from the Canovas Canyon Rhyolite, Bear Springs Peak eruptive events (ca. 8 to 9 mya), since obliterated by subsequent volcanism and thus making the nodules rare. In 2004, the Bear Springs Peak dome complex, part of the Canovas Canyon Rhyolite, was "discovered" and the elemental chemistry is identical to the "Bland Canyon Apache Tears" as reported by Glascock et al. (1999; see discussion below). This certainly suggests by this research that the eruptive history and trace element chemistry of artifact quality obsidian from the Jemez Mountains is somewhat more complex than originally described and warrants more intensive geoprospection, a major stimulus for the LANL project here.

SECONDARY DEPOSITION AND PREHISTORIC PROCUREMENT IN NORTHERN NEW MEXICO

Recent research investigating the secondary depositional regime from the Jemez Mountains (Sierra de los Valles), indicates that: 1) Valle Grande Member rhyolite and obsidian in the Jemez Mountains, the result of the most recent eruptive event that produced glass in the caldera, does not erode out of the caldera in nodules of any workable size; 2) During the Pleistocene, Cerro Toledo Rhyolite and glass, mainly the result of the Rabbit Mountain ash flow eruption deposited vast quantities of ash and quenched rhyolite through erosion in the Rio Grande basin as discussed above (Shackley 1998a, 2005a). While Cerro Toledo Rhyolite obsidian is found in secondary contexts in the Puye Formation along the northeastern margin of the caldera (Figures 10.3 and 10.4), the greatest quantity of obsidian found today in the Rio Grande alluvium most likely came from the Rabbit Mountain ash flow event (Gary Smith, personal communication 2005).

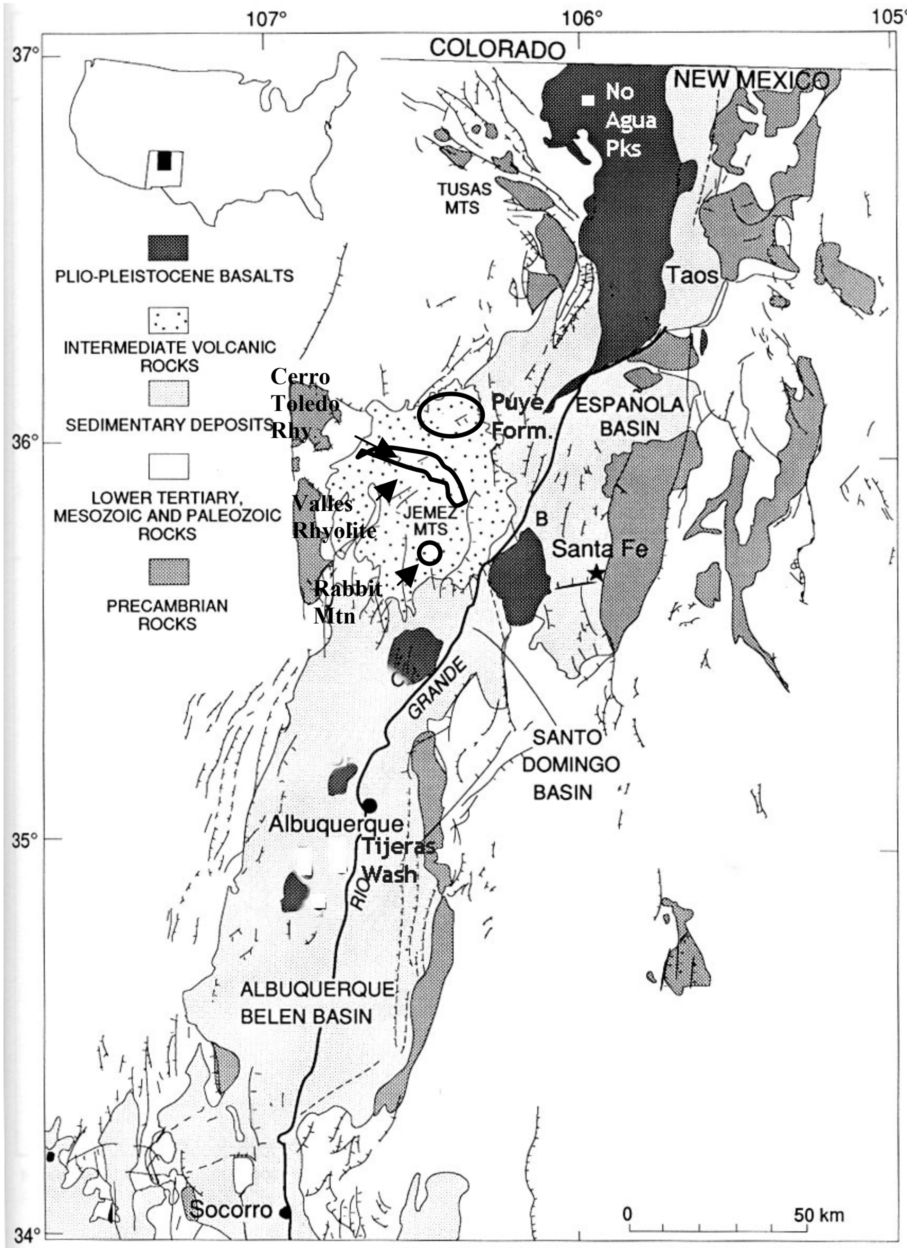

Figure 10.3. Generalized large-scale view of major obsidian source areas and relevant secondary depositional features in north-central New Mexico (adapted from Heiken et al. 1986).

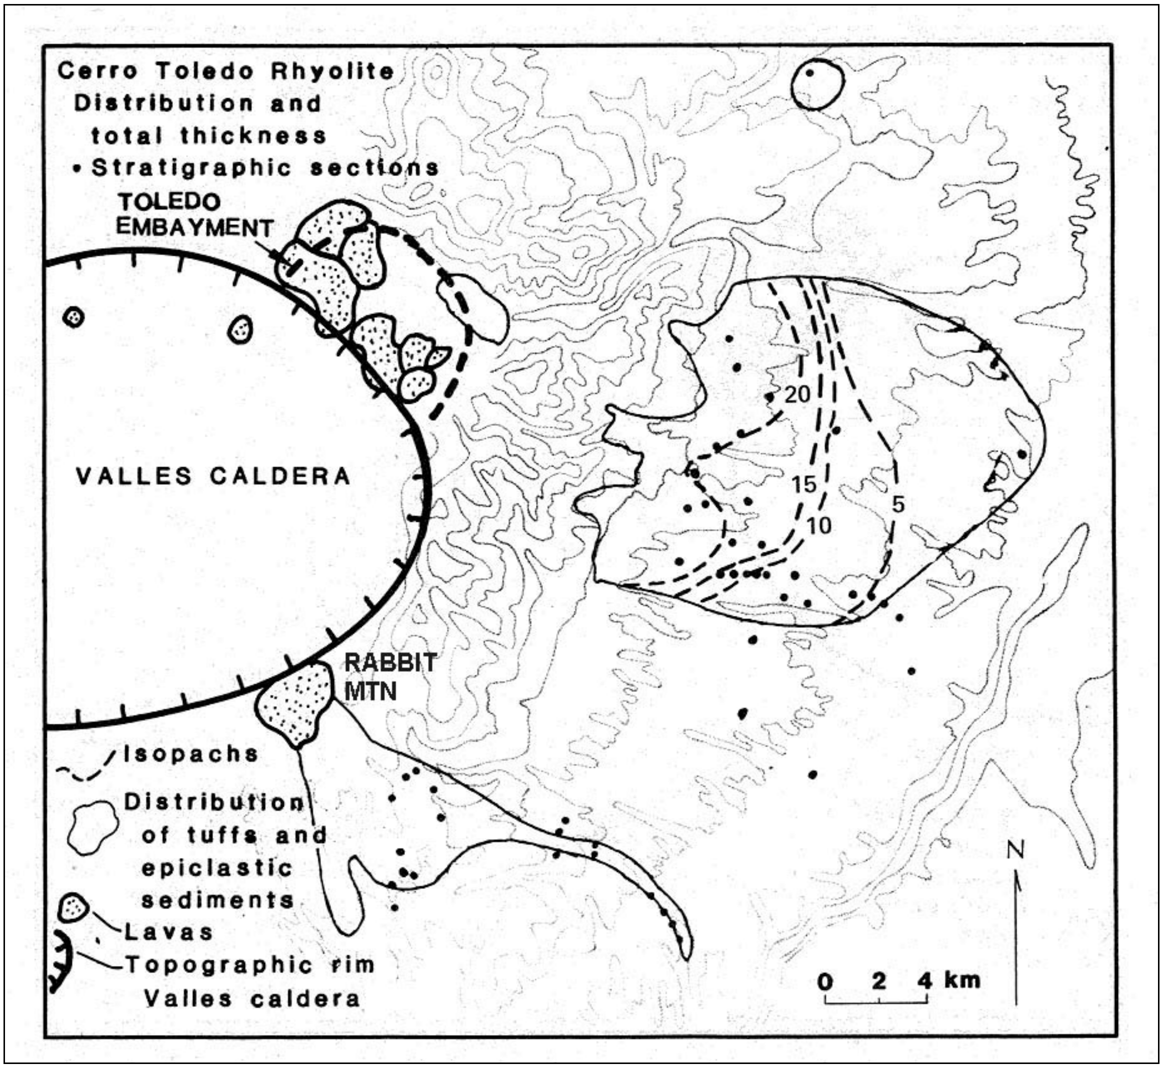

Figure 10.4. Distribution of tuffs and epiclastic sediments derived from Toledo Embayment and Rabbit Mountain eruptions (from Heiken et al. 1986).

There were six pyroclastic eruptive events associated with the Cerro Toledo Rhyolite:

> All tuff sequences from Toledo intracaldera activity are separated by epiclastic sedimentary rocks that represent periods of erosion and deposition in channels. All consist of rhyolitic tephra and most contain Plinian pumice falls and thin beds of very-fine-grained ash of phreatomagmatic origin. Most Toledo deposits are thickest in paleocanyons cut into lower Bandelier Tuff and older rocks [as with the Rabbit Mountain ash flow]. Some of the phreatomagmatic tephra flowed down canyons from the caldera as base surges (Heiken et al. 1986:1802).

Two major ash flows or ignimbrites are relevant here. One derived from the Toledo embayment on the northeast side of the caldera is a 20-km-wide band that trends to the northeast and is now highly eroded and interbedded in places with the earlier Puye Formation from around Guaje Mountain north to Santa Fe Forest Road 144. This area has eroded rapidly and obsidian from this tuff is now an integral part of the Rio Grande alluvium north of Santa Fe. The other major ash flow is derived from the Rabbit Mountain eruption and is comprised of a southeast-trending 4-km-wide and 7-km-long "tuff blanket" interbedded with a rhyolite breccia 3 to 6 m thick that contains abundant obsidian (Heiken et al. 1986; see also Broxton et al. 1995). All of this is still eroding into the southeast trending canyons toward the Rio Grande. The surge deposits immediately south of Rabbit Mountain contain abundant obsidian chemically identical to the samples from the ridges farther south and in the Rio Grande alluvium. Heiken et al.'s ((1986:1810) neutron activation analysis of Rabbit Mountain lavas is very similar to those from this study (Table 10.1 here).

Table 10.1. Selected wavelength X-ray fluorescence spectroscopy (WXRF) oxide values (wt. %) for the three major archaeological obsidian source standards from the Jemez Mountains. Sample prefix "CDM" is from the Wolman (1994) sample collected from Cerro del Medio and designated as Valle Grande Rhyolite here. Samples analyzed whole after polishing to present a flat surface to beam as in Shackley (1998a, 2005a).

Sample Locality	Source Name	SiO_2	TiO_2	Al_2O_3	Fe_2O_3	MnO	MgO	CaO	Na_2O	K_2O	P_2O_3
081199-1-7	Cerro Toledo Rhyolite	74.44	0.09	10.74	1.07	0.06	0.00	0.19	4.06	3.93	0.02
CDM3-B	Valle Grande Rhyolite	75.07	0.10	11.56	1.19	0.05	0.20	0.43	4.10	4.75	0.04
080999-2-1	El Rechuelos Rhyolite	74.51	0.10	11.20	0.54	0.06	0.00	0.36	3.79	4.07	0.02

Both the Cerro Toledo Rhyolite glass and Mount Taylor glass is common in Quaternary alluvium of the Rio Grande as far south as Chihuahua and was frequently used as a toolstone source in prehistory (Church 2000; Shackley 1997). It is impossible to determine, however, in a finished artifact whether the raw material was procured from the primary or secondary sources, unless the artifact is very large (>5 to 10 cm), when it can be assumed that the artifact was procured from nearer the source.

COLLECTION LOCALITIES

The collection localities discussed here are not the result of a systematic survey to collect and record all the potential sources in the Jemez Mountains, but the result of an attempt to understand the secondary depositional regime of the sources flowing out from the Jemez Mountains into the surrounding stream systems, as noted above. The emphasis here was on understanding the secondary distribution of the major sources that appear in the archaeological record in the northern Southwest—El Rechuelos, Cerro Toledo Rhyolite, and Valle Grande. Additionally, the obsidian sample collection localities for those sources submitted by LANL are not described here specifically, but are plotted on Figure 10.5 and discussed in general below. The results of the analysis will be discussed below.

El Rechuelos

El Rechuelos is mistakenly called "Polvadera Peak" obsidian in the archaeological vernacular (see also Glascock et al. 1999). Polvadera Peak, a dacite or rhyodacite dome, did not produce artifact-quality obsidian. The obsidian artifacts that appear in the regional archaeological record are from El Rechuelos Rhyolite as properly noted by Baugh and Nelson (1987). Indeed, El Rechuelos obsidian is derived from a number of small domes north, west, and south of Polvadera Peak as noted by Baugh and Nelson (1987) and Wolfman (1994; see also Figure 10.5 here). Collections here were made at two to three small coalesced domes near the head of Cañada del Ojitos and as secondary deposits in Cañada del Ojitos (collection locality 080999 in Table 10.2). The center of the domes is located at UTM 13S 0371131/3993999 north of Polvadera Peak on the Polvadera Peak quadrangle. The three domes are approximately 50 meters in diameter each and exhibit an ashy lava with rhyolite and aphyric obsidian nodules up to 15 cm in diameter, but dominated by nodules between 1 and 5 cm. Core fragments and primary and secondary flakes are common in the area.

Small nodules under 10 to 15 mm are common in the alluvium throughout the area near Polvadera Peak. It is impossible to determine the precise origin of these nodules. Presumably they are remnants of various eruptive events associated with El Rechuelos Rhyolite. The samples analyzed, the results of which are presented in Table 10.2, are statistically identical to the data presented in Baugh and Nelson (1987) and Glascock et al. (1999).

El Rechuelos obsidian is generally very prominent in northern New Mexico archaeological collections. Although it is not distributed geologically over a large area, it is one of the finest raw materials for tool production in the Jemez Mountains. Its high quality as a toolstone probably explains its desirability in prehistory. Cerro Toledo Rhyolite and Valle Grande Rhyolite, while present in large nodule sizes, often have devitrified spherulites in the glass, so more careful selection had to be made in prehistory. In nearly 500 nodules collected from the El Rechuelos area, few of the nodules exhibited spherulites or phenocrysts in the fabric. Additionally, El Rechuelos glass is megascopically distinctive from the other two major sources in the Jemez Mountains. It is uniformly granular in character, apparently from ash in the matrix. Cerro Toledo and Valle Grande glass is generally not granular and more vitreous.

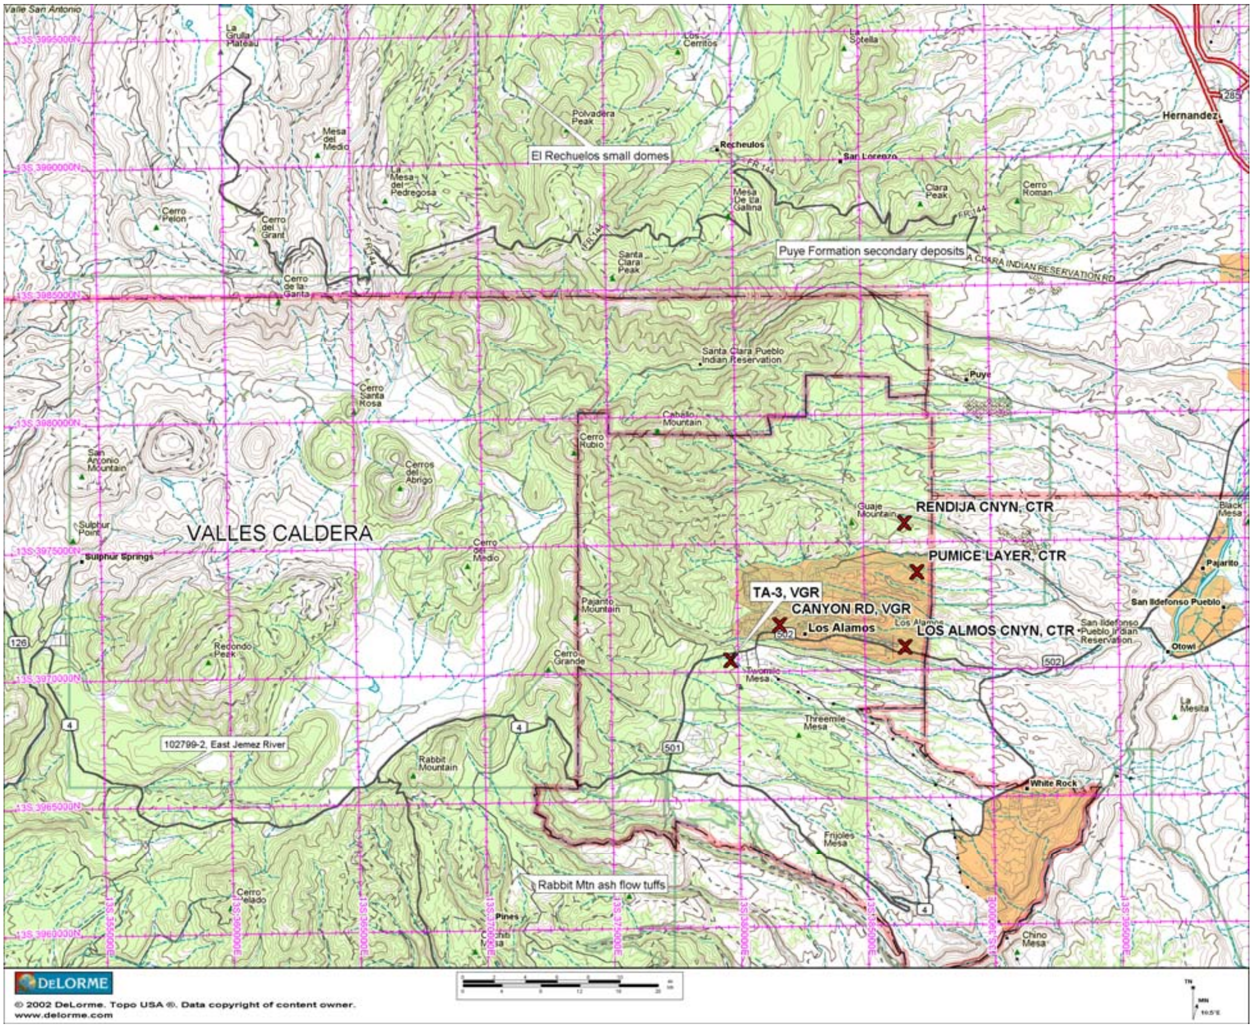

Figure 10.5. Obsidian collection localities in the Jemez Mountain region. Localities marked with an "X" are LANL marekanite collections as analyzed in the tables here. The others are collection localities by this lab as discussed here.

Table 10.2. Source standard elemental concentrations for El Rechuelos Rhyolite obsidian. Samples with "PP" prefix are those from the Wolfman collections as discussed in Wolfman (1994) and Glascock et al. (1999), and analyzed with energy-dispersive X-ray fluorescence spectroscopy (EDXRF) at Berkeley. Those with a "080999" prefix are from this study and locality discussed above and analyzed with WXRF at Berkeley (instrument settings as in Shackley 1998a, and http://www.swxrflab.net/ philipspw2400. htm).

SAMPLE	Ti	Mn	Fe	Rb	Sr	Y	Zr	Nb	Ba

Rabbit Mountain Ash Flow Tuffs and Cerro Toledo Rhyolite

Known in the vernacular as "Obsidian Ridge," this obsidian is derived from the Cerro Toledo Rhyolite/Rabbit Mountain eruptions, and following Baugh and Nelson (1987) and the geological literature are all classified as Cerro Toledo Rhyolite (Bailey et al. 1969; Gardner et al. 1986; Heiken et al. 1986; Self et al. 1986; Smith et al. 1970; Figures 10.1 and 10.5).

While Obsidian Ridge has received all the "press" as the source of obsidian from Cerro Toledo Rhyolite on the southern edge of the caldera, the density of nodules and nodule sizes on ridges to the west is greater by a factor of two or more. The tops of all these ridges, of course, are remnants of the Rabbit Mountain ash flow and base surge, and the depth of canyons like Cochiti Canyon is a result of the loosely compacted tephra that comprises this plateau. At Locality 081199-1 (UTM 13S 0371337/3962354), nodules on the ridge top are up to 200 per m^2 with over half that number of cores and flakes (Figures 10.6 and 10.7). This density of nodules and artifacts forms a discontinuous distribution all the way to Rabbit Mountain. The discontinuity is probably due to cooling dynamics and/or subsequent colluviation. Where high-density obsidian is exposed, prehistoric production and procurement are evident. At the base of Rabbit Mountain, the density is about 1/8 that of Locality 081199-1, and south of this locality the density falls off rapidly. At Locality 081199-1, nodules range from pea gravel to 16 cm in diameter (Figures 10.6 and 10.7 and Table 10.3). Flake sizes suggest that 10-cm-size nodules were typical in prehistory.

Figure 10.6. Locality 081199-1 south of Rabbit Mountain in the ash flow tuff. This locality has the highest density of artifact-quality glass of the Rabbit Mountain ash flow area. The apparent black soil is actually all geological and archaeological glass; one of the highest densities of geological and archaeological obsidian in the Southwest.

Figure 10.7. Mix of high-density geological obsidian and artifact cores and debitage (test knapping) at Locality 081199-1 south of Rabbit Mountain. Nodules ≈200/m^2, cores and debitage ≈100/m^2, some of the latter could be modern. Elemental concentrations for samples from this locality are shown in Table 10.3.

Cerro Toledo Rhyolite obsidian both from the northern domes and Rabbit Mountain varies from an excellent aphyric translucent brown glass to glass with large devitrified spherulites that make knapping impossible. This character of the fabric is probably why there is so much test knapping at the sources—a need to determine the quality of the nodules before transport. While spherulites in the fabric occur in all the Jemez Mountain obsidian, it seems to be most common in the Cerro Toledo glass and may explain why Valle Grande obsidian occurs in sites a considerable distance from the caldera even though it is not secondarily distributed outside the caldera in any quantity while Cerro Toledo obsidian is common throughout the Rio Grande alluvium. Indeed, in Folsom period contexts in the Albuquerque basin, Valle Grande obsidian was selected for tool production almost exclusively even though Cerro Toledo obsidian is available almost on-site in areas such as West Mesa (LeTourneau et al. 1996). So, while Cerro Toledo Rhyolite obsidian is and was numerically superior in the Rio Grande Basin, it wasn't necessarily the preferred raw material.

Table 10.3. Elemental concentrations for Cerro Toledo Rhyolite obsidian in the Jemez Mountains. All measurements in parts per million (ppm). Samples with numeric designations from Shackley's surveys. Those with alpha-numeric surveys from the Wolfman and LANL collections. Samples with Ti, Mn, and Fe concentrations analyzed by EDXRF. All others analyzed by WXRF. Instrumental conditions for both instruments discussed in Shackley (1998a).

Valle Grande Rhyolite

While the primary domes like Cerro del Medio of Valle Grande Rhyolite (also called Valles Rhyolite and Cerro del Medio) were not originally visited for this study due to restrictions on entry to the caldera floor, surveys of the major stream systems radiating out from the caldera were examined for secondary deposits; San Antonio Creek and the East Jemez River, as well as the canyons eroding the outer edge of the caldera rim. In 2005 and 2006, the University of California, Berkeley, Archaeological Petrology Field School in collaboration with the VCNP began a more systematic collection of Cerro del Medio source standards from the dome complex, and collections along San Antonio Creek in the caldera proper. These data are included in Table 10.4.

In 1956, two geology graduate students from the University of New Mexico published the first paper on archaeological obsidian in the American Southwest, a refractive index analysis of Jemez Mountains obsidian (Boyer and Robinson 1956). In their examination of the Jemez Mountains sources, they noted that obsidian did not occur in the alluvium of San Antonio Creek where it crosses New Mexico State Highway 126, but did occur “in pieces as large as hen’s eggs, but the material is not plentiful and must be searched for with care” in the East Jemez River alluvium where it crosses State Highway 4 (Boyer and Robinson 1956:336). A return to the latter locality, courtesy of Ana Steffen of VCNP (Locality 102799-2), exhibited about the same scenario as that recorded 43 years earlier. The alluvium exhibits nodules up to 40 mm in diameter at a density up to 5/m^2, but generally much lower. Boyer and Robinson did find nodules up to 15.5 cm in diameter along the upper reaches of San Antonio Creek as shown in their plate reproduced here (Boyer and Robinson 1956:337; Figure 10.8).

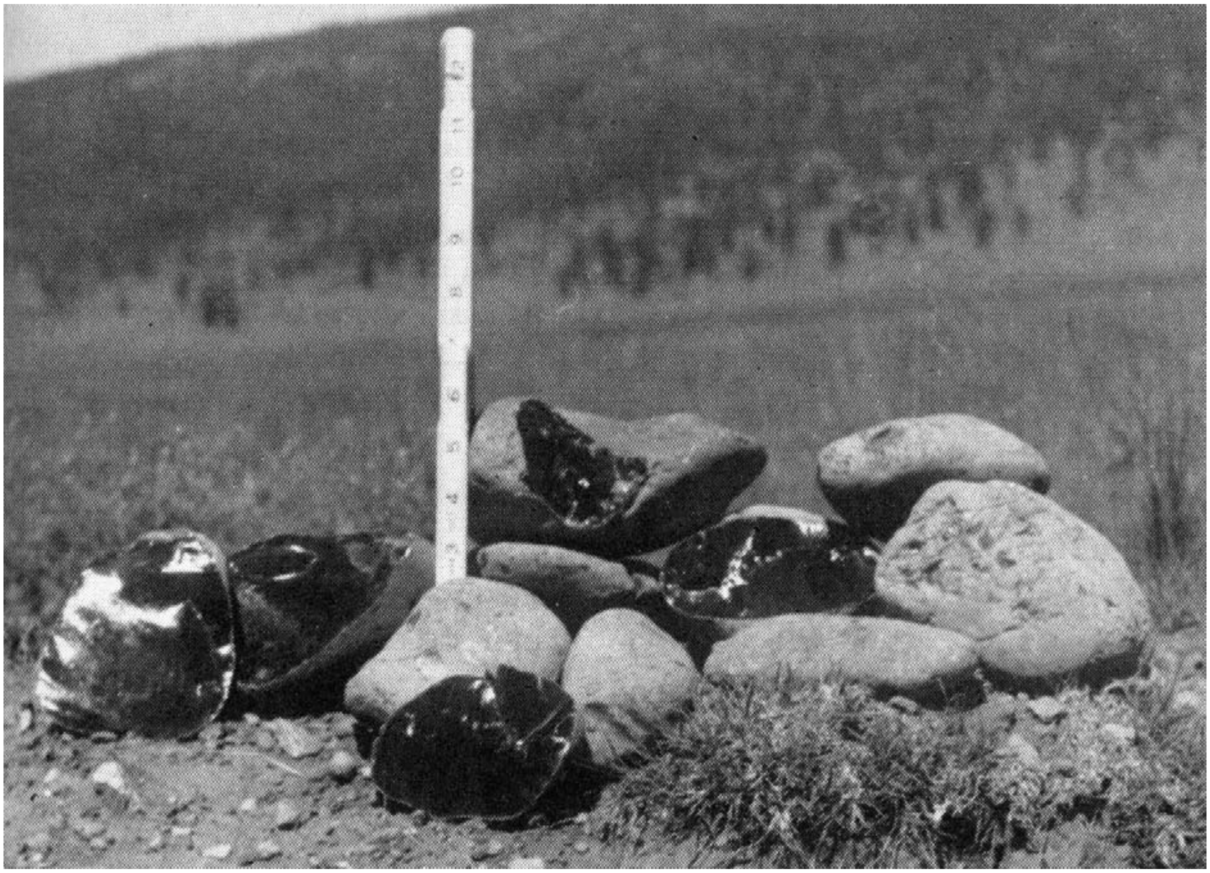

Figure 10.8. Valle Grande Rhyolite obsidian nodules photographed by Boyer and Robinson collected along San Antonio Creek in the caldera (1956:337).

My survey along San Antonio Creek from its junction with State Highway 126 for 10 miles upstream did not reveal any obsidian, as in the Boyer and Robinson study. Both Phil Letourneau and Ana Steffen discovered the same in similar surveys. It appears then that Valle Grande Rhyolite obsidian does not enter secondary contexts outside the caldera, at least in nodules of any size compared to Cerro Toledo Rhyolite. The 2005 and 2006 surveys along San Antonio Creek in the caldera indicate that by the time the secondary deposits reach the caldera rim, the nodule size is near pea gravel in diameter.

Valle Grande Rhyolite obsidian exhibits a fabric that seems to be a combination of El Rechuelos and Cerro Toledo. Some of the glass has that granular texture of El Rechuelos and some has devitrified spherulites similar to Cerro Toledo, and much of it is aphyric black glass. Flakes of Valle Grande obsidian can be indistinguishable from El Rechuelos or Cerro Toledo in hand sample. An elemental analysis of samples collected by Dan Wolfman from Cerro del Medio and the nodules in San Antonio Creek in this study are identical, indicating that Cerro Toledo glass does not enter the East Jemez River system (see Table 10.4).

In the Valle Grande Rhyolite obsidian so far analyzed from both Cerro del Medio proper and secondary deposits in the caldera, it is apparent that there is considerable variability in Rb (140 to 184 ppm; Table 10.4). Ana Steffen at the VCNP has noticed significant variability in ferric versus ferrous iron (Steffen, 2005 personal communication). It would be worthwhile to sample the Cerro del Medio dome complex in a variety of areas in order to determine both the level of variability and the spatial distribution of that variability.

Canovas Canyon Rhyolite and Bear Springs Peak

The oldest (Tertiary: ca. 8 to 9 mya) obsidian source in the Jemez Mountains is the Bear Springs Peak dome complex, part of the Canovas Canyon Rhyolite domes and shallow intrusions (Tcc and Tcci) as reported by Kempter et al. (2003). Located at the far southern end of the Jemez Mountains, just south and adjacent to Jemez Pueblo Nation land, this Tertiary Period source exhibits only relatively small marekanites now, most smaller than 2 cm in diameter (see Figure 10.1). Although the nodule size was apparently small, Bear Springs Peak obsidian was used in prehistory, and was recovered in samples analyzed from Early Historic period contexts at Zuni Pueblo, probably a result of relationships between the Zuni and Jemez in the 17th century (Shackley 2005a). The data as analyzed by Craig Skinner and my lab, suggest that this may be the "Bland Canyon & Apache Tears" source as reported by Glascock et al. (1999:863), collected by Wolfman and reported by him in 1994 (Table 10.5).

Table 10.5. Elemental concentrations for Bear Springs Peak obsidian in the Jemez Mountains. All measurements in parts per million (ppm). Skinner and Shackley analyses combined.

Nb	24	40	61	53	5
Ba	15	293	717	352	102

As with many of the Tertiary Period sources in the Southwest, Bear Springs Peak obsidian is present as marekanites in perlitic lava at the Bear Springs Peak dome proper and domes trending to the northeast toward and into Jemez Pueblo land. Nodules up to 5 cm occur as remnants in the perlite not unlike the environment at Sand Tanks (Shackley 2005a:20). The density of the nodules from pea gravel to 5 cm in the perlite lava is as much as $100/m^2$, although most of the marekanites are under 2 cm. The glass itself is aphyric and nearly transparent in thin flakes similar to Cow Canyon and Superior obsidian, and some have noticeable dark black and nearly clear banding. It is an excellent media for tool production so that bipolar flakes are easily produced and pressure flaking is effective.

The marekanites have eroded into the stream systems to the south possibly as far as the Rio Grande, but marekanites bearing the chemistry have never been recorded in the southern Rio Grande alluvium as reported by Church (2000). Most likely the nodules are expended in the sediment load long before reaching the Rio Grande or have been covered by subsequent Quaternary sediments. It is safe to conclude that artifacts assigned to Bear Springs Peak would have to be originally procured at or near the Bear Springs dome complex. Probably the reason this source is not found in archaeological contexts more frequently is that it simply cannot "compete" with the large nodule sources just to the north including Cerro Toledo Rhyolite, Valle Grande Rhyolite, and El Rechuelos obsidian. Finally, a new geology map for the Bear Springs Peak Quad is in draft form (Kempter et al. 2003).

MAGMATIC RELATIONSHIP BETWEEN THE GLASS SOURCES

The relatively short time period of eruptive events that produced artifact-quality obsidian in the Jemez Mountains from El Rechuelos to Valle Grande Rhyolite is reflected in the elemental chemistry as reported by a number of others discussed above (e.g., Baugh and Nelson 1987; Broxton et al. 1995; Gardner et al. 1986; Glascock et al. 1999). This relationship is readily evident in three-dimensional and biplots of the incompatible elemental composition of these sources as shown in Figures 10.9 and 10.10, the analysis of major and minor elements shown in Tables 10.2 through 10.4. Rubidium, zirconium, and yttrium are most sensitive in separating these sources. Indeed, a biplot of the elemental concentrations Zr versus Y can effectively separate all four Jemez Mountains sources, although it is NOT sufficient to eliminate the possibility that the analyzed artifacts could be from outside the Jemez Mountains group (Figures 10.9 and 10.10).

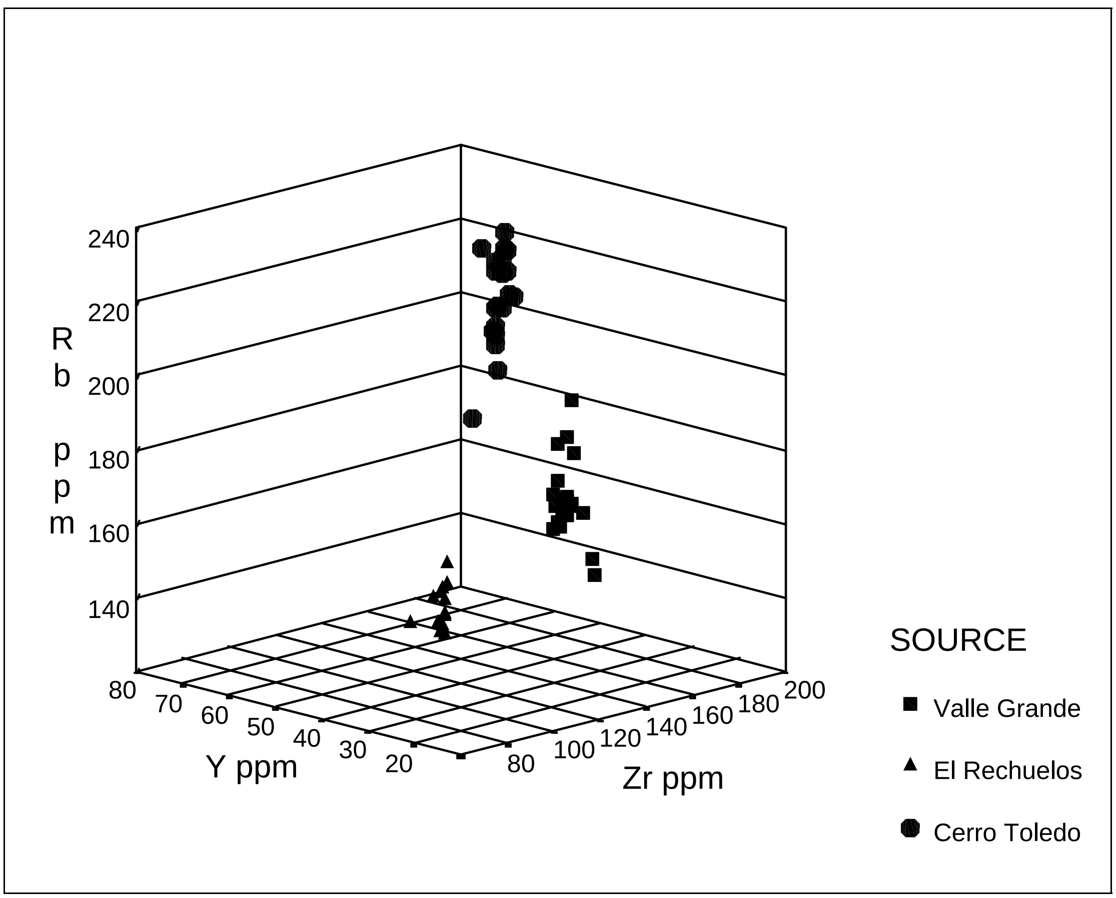

Figure 10.9. Rb, Y, Zr three-dimensional plot of Valle Grande, El Rechuelos, and Cerro Toledo Rhyolite obsidian source standards.

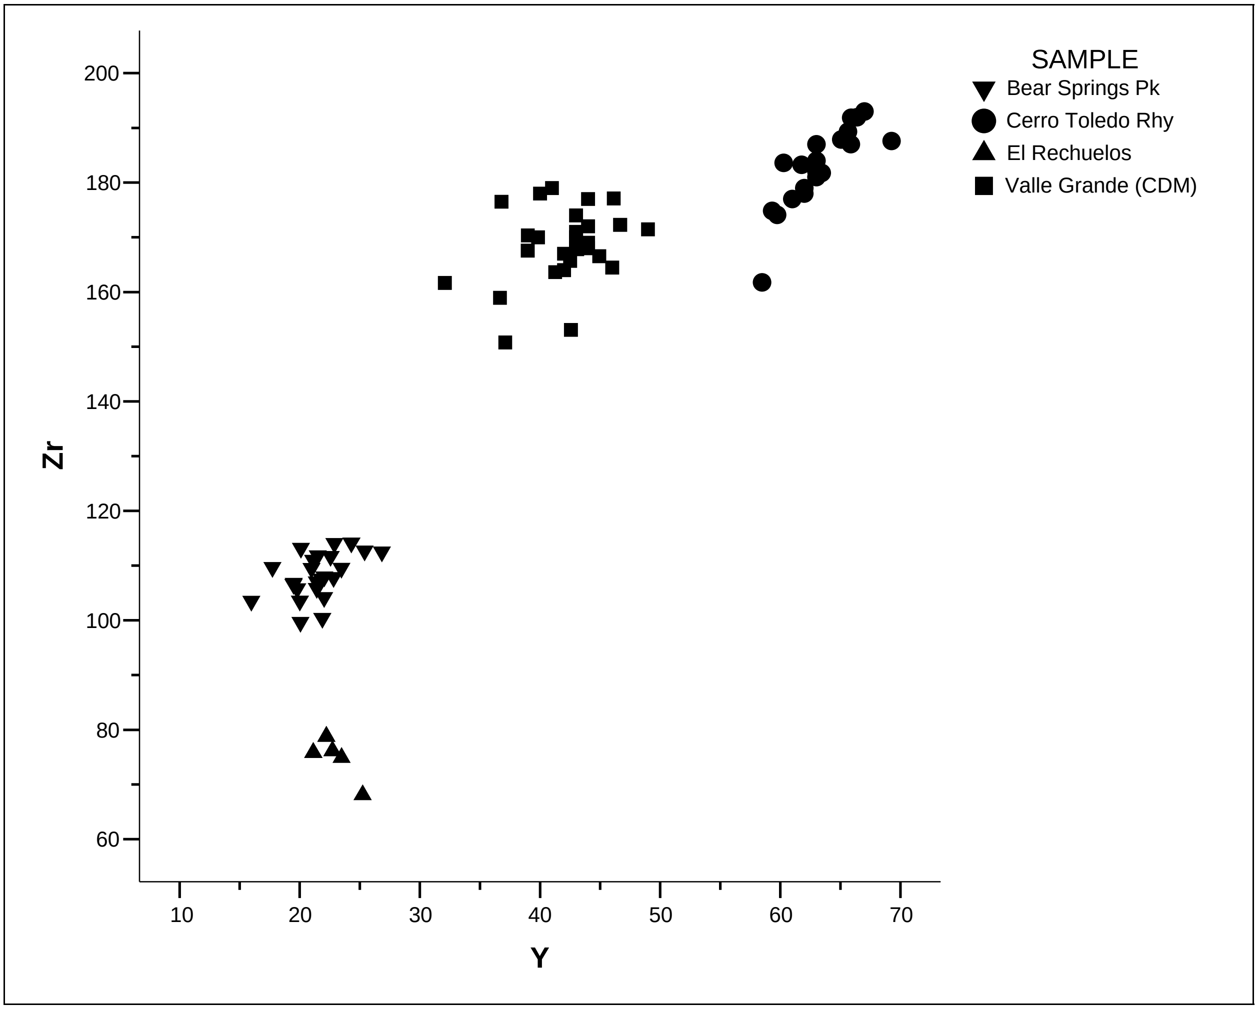

Figure 10.10. Zr versus Y biplot of the elemental concentrations for Valle Grande (Cerro del Medio), El Rechuelos, Cerro Toledo Rhyolite, and Bear Springs Peak obsidian source standards. High variability in Valle Grande and Cerro Toledo data are the result of the analysis of small secondary distribution nodules (see Davis et al. 1998).

THE LANL STUDY

A number of marekanite (obsidian) and ignimbrite or tephra samples were submitted for non-destructive WXRF analysis, in part to enlarge the secondary depositional study, and in part to determine the relationship between the marekanites and the ignimbrite or tuff that they are contained within (Table 10.6 and Figures 10.11 and 10.12). While this nondestructive study is certainly not as thorough as a more intensive analysis with prepared pellets and WXRF, the results are revealing. Most of these localities have been described by David Broxton in field notes from July 2002.

Table 10.6. WXRF nondestructive elemental analysis of obsidian and other rock samples from the LANL collection. Some samples submitted were too friable for nondestructive analysis.

Obsidian Samples

Obsidian marekanite samples from five localities were submitted for analysis as shown in Table 10.6. While most of the samples were obsidian associated with the Cerro Toledo Rhyolite events and the Bandelier Tuff, a few of the samples appear to be post-Bandelier and exhibit an elemental composition consistent with Valle Grande Rhyolite obsidian (TA-3 and BV-07-02-16 localities; see Table 10.6, and Figures 10.11 and 10.12). While the sample is small here, it does appear that Valle Grande obsidian occurs in what Broxton designates as "post-Bandelier" sediments and these are in the western portion of LANL property closest to Cerro del Medio. Importantly, although this is the first example of Valle Grande obsidian *outside* the caldera rim, the nodule sizes are quite small, possibly representing small pieces of rhyolite lava quenched as pyroclastics during the eruption. I would stand by the conclusion that no archaeologically significant Valle Grande obsidian has eroded outside the caldera.

Rock Sample Analysis

Figures 10.10 and 10.11 exhibit the Rb, Y, and Zr plots of Cerro Toledo Rhyolite and Valle Grande Rhyolite obsidian source standard data and the submitted tephra samples, without the basalt or dacite lava included. Immediately apparent is that the vast majority of samples, based on these three elements, are most similar to Valle Grande, the post-Bandelier event, although none of the rock samples plot within the range of variability of the glass. This is typical of rhyolite versus obsidian, where post-emplacement weathering and other processes affect the crystalline lava more than glass (Shackley 1990; Zielinski et al. 1977). Additionally, concentration of Ba and Sr in feldspars, such as sanidine in rhyolites will often elevate the concentration of these elements relative to the obsidian produced by the same event in X-ray fluorescence analyses. This appears to be the case in this dataset in the obsidian recovered from locality BV-07-02-16 where the obsidian, consistent with Valle Grande glass, is relatively low in Ba and Sr, while the tephra sample is high in Ba and Sr (Table 10.6). I would, however, if given these samples as a blind test, suggest that they were somehow related to the Valle Grande Rhyolite.

Prehistoric Procurement and Secondary Deposition

The LANL study expands the range of the larger secondary depositional study. While some very small Valle Grande Rhyolite marekanites occur outside the caldera, their small size makes them insignificant as a raw material source. Cerro Toledo Rhyolite obsidian is a much more viable raw material source, apparently, in association with the Bandelier Tuff all around the perimeter of the caldera, including the LANL area and sediments further south and east. While it is impossible to determine whether obsidian artifacts recovered from sites in the LANL property were produced from primary or secondary sources, for Valle Grande at least, if the artifacts are larger than about 15 or 20 mm, the raw material probably came from the caldera floor near Cerro del Medio. With artifacts produced from Cerro Toledo Rhyolite obsidian, inferences about procurement are more difficult. Since large nodules (>30 mm) are common in sediments outside the caldera, these artifacts could be procured anywhere.

This study and the greater secondary depositional study reveal that an understanding of both primary and secondary sources of raw material are crucial in reconstructing procurement, exchange, and group interaction, and simple conjecture that obsidian is located somewhere in the Jemez Mountains yields but simple conclusions.

THE DACITE STUDY

More recently, a collaborative study between LANL, the Archaeological XRF Lab at Berkeley, and the Smithsonian Institution, has focused on the dacite used frequently for biface production in the Paleoindian and Archaic periods and for flake tools during the ceramic periods (Vierra et al. 2005; Shackley 2005b).

For a number of years we have noticed a very-fine-grained what appeared to be mafic or basalt raw material source in late Paleoindian contexts in northern New Mexico and southern Colorado. Indeed, a number of Cody, Plainview, and Folsom bifaces are produced from this material. Pegi Jodry and Brad Vierra have been working for a number of years with collectors and others, and determined that there were two possible very fine-grained volcanics that could be the sources for these raw materials—San Antonio Mountain in far northern New Mexico, in the Taos Plateau Volcanic Field, and Cerros del Rio, on the east side of Bandelier National Monument right above the river. After reconnaissance collections at the two probable sources, the short story is that the vast majority of "basalt" artifacts were indeed produced from one of these sources (Table 10.7).

However, these two "basalt" sources are not basalt at all. The San Antonio Mountain volcanics have been called basalt by archaeologists for years, despite Lipman and Mehnert's (1979) early analysis indicating a "rhyodacite." As you can see by the major compound rock classification, these rocks are firmly dacites (Figure 10.13). So, the two primary volcanic sources other than obsidian used by Late Paleoindian and Early Archaic knappers in the northern Rio Grande is a fine-grained dacite. Additionally, as originally reported by Newman and Nielsen (1987), a third dacite dome is located just east of Cerro Montoso, and this third source, called the Newman Dome here, takes care of that small group of dacite artifacts that are not produced from the other two "major" sources of dacite (Table 10.7). The elemental chemistry of these three sources is quite distinct (Figure 10.14). These analyses will form the database for future studies of volcanic rocks used in regional prehistory.

Table 10.7. Elemental concentrations for the three dacite sources in northern New Mexico. All measurements in parts per million. BHVO is a U.S. Geological Survey Hawaiite basalt source standard.

CHAPTER 11
OBSIDIAN HYDRATION DATING BY INFRARED SPECTROSCOPY

Christopher M. Stevenson

INTRODUCTION

The obsidian hydration dating method provides an age estimate for natural glass artifacts based upon the penetration depth of diffused molecular water into the obsidian surface. A successful implementation of the dating method requires an estimation of the water diffusion coefficient and the precise measurement of the depth of diffusion. In this paper, the fundamental process behind water diffusion in obsidian is considered and it is demonstrated that infrared spectroscopic analysis of the glass matrix and hydrated layer has the potential to provide precise estimates of the critical variables. It is argued that the use of an IR approach will result in a more unified approach to the problem and result in a higher level of analytical precision.

The water diffusion process in obsidian has been poorly understood for many years and has lacked a good theoretical understanding. As a result, archaeometric studies evaluated the suitability of experimental designs to estimate diffusion coefficients through comparison with external chronological data (Stevenson 2000; Stevenson et al. 1998). Convergence in age estimates between obsidian samples and radiocarbon assays implied that the methods were appropriate even though a thorough explanation was lacking. However, investigations in the field of glass science have changed this situation. Hydrogen profiling of the hydrated layer has demonstrated that concentration-dependent diffusion is the dominant process (Anovitz et al. 1999) rather than the Fickian model previously proposed (Friedman and Long 1976). In addition, experimentation has shown that the *structural* water within the unaltered glass matrix in the form of hydroxyl and molecular water controls the forward advancement of the hydration layer (Stevenson et al. 1998; Tomozawa 1985) and the mobile species within the hydration layer is *molecular* water (Zhang and Behrens 2000) (Figure 11.1). Both of these key variables may be precisely estimated by infrared spectroscopy and have the potential to greatly improve the dating process. In this paper, the value of IR technology in measuring the structural water concentration and the extent of surface hydration is discussed.

PREVIOUS OBSIDIAN HYDRATION STUDIES IN NEW MEXICO

The obsidian hydration dating method has been extensively applied over the last 20 years in the New Mexico region with major projects occurring at Ft. Bliss in the Sonoran desert and within the Jemez Mountains (see Vierra and Harmon 2006 for a summary). Much of this earlier work was spurred by new developments in the method that included the use of high-temperature-derived hydration constants (Friedman and Long 1976; Michels 1983; Stevenson et al. 1989) for the estimation of archaeological rates at ambient conditions. A variety of experimental designs were used that included hydrothermal reaction at elevated pressure and vapor hydration at one atmosphere. Many of these initial experiments have been subsequently revised. However, the utility of the induced hydration approach has been demonstrated as a viable experimental approach and one that continues today. In this paper, I continue to refine the induced hydration approach by the addition of infrared spectroscopy to the pool of analytical options.

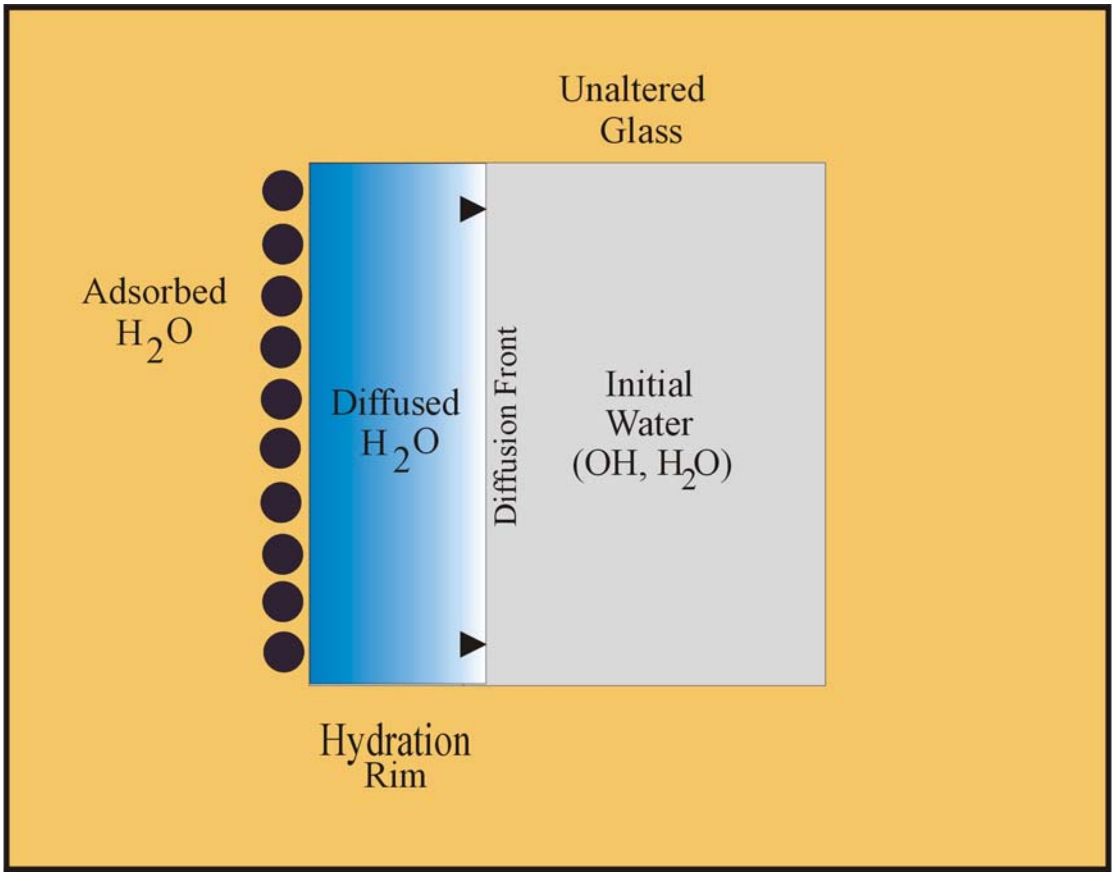

Figure 11.1. A schematic of the hydration layer showing the various forms of water on, and within, the glass.

This early laboratory work was accompanied by an effort to model the hydration history of sites and regions. Ground temperature and soil relative humidity were investigated as functions of elevation, aspect, depth below surface, and ground cover (Mundy 1993; Ridings 1991). The outcome of these studies revealed that precise estimates of these variables were highly complex, difficult to replicate, and inherently variable. For example, although a general relationship exists between altitude and declining temperature, there were always outliers that could not be explained by the modeling process. These same difficulties in developing temperature prediction equations have been encountered in regional studies conducted in New Zealand where the influence of micro-topographic differences and surface vegetation were recognized as having a profound influence (Jones et al. 1997). For the moment, it appears that high-resolution studies of soil temperature and relative humidity are required for each site under study.

Each of these avenues of investigation have raised questions and promoted the development of methodological improvements. Several recent reviews of the obsidian hydration dating method have tracked these events (Stevenson et al. 1998; Stevenson et al. 2000). These reviews stress two important points that will impact the use of obsidian hydration dating over the long term.

First, it is critical to understand the depositional context from which a datable artifact is recovered. How did that artifact cycle through the society, how was it discarded, and what cultural and natural processes result in its burial? Only then can the dated event (use/manufacture of the obsidian tool) be linked to the target event (Dean 1978), which may be the occupation of a pueblo room or the filling of a trash pit. If the depositional history of the artifact can be understood, then appropriate temperature and humidity values can be applied. Second, the direct measurement of glass structural water content is critical. Obsidian sources will exhibit a range in structural water concentration and even small differences can alter hydration rate estimates. It is no longer appropriate to infer that an obsidian source is uniform in structural water even though the trace element chemistry is highly uniform across the flow. Such uniformity must be demonstrated on a case-by-case basis. Only with this control over glass composition and context can the changes in approach to obsidian hydration dating discussed below be evaluated against other chronological indicators in the archaeological record.

Water Diffusion in Glass

The model of water diffusion in amorphous silicates developed by Doremus (1969) is the most appropriate descriptor of water diffusion in rhyolitic glass at low temperature because it accounts for the patterning in much of the experimental data (Doremus 1995). In a vapor environment, molecular water enters the glass network and reacts with the silicon-oxygen network to form SiOH groups:

$$\text{Si-O-Si} + H_2O = \text{SiOH} + \text{OHSi}$$

The molecular water is the mobile species while the newly formed OH groups are relatively fixed. It is assumed that OH group formation lags behind the movement of mobile water molecules and does not reach equilibrium.

It was also assumed in previous model development that the initial concentration of water in the glass is zero. However, obsidians may have structural water concentrations up to several weight percent. This will serve to exponentially increase the diffusion coefficient for ambient molecular water (D) as concentration increases (Stevenson et al. 1998; Zhang and Behrens 2000; Zhang et al. 1991). In the diffusion process this is believed to occur because the bonds of the Si-O-Si network are broken with the activation energy determined by the energy needed to break a single Si-O bond (Bruckner 1970; McMillan et al. 1994). The occurrence of greater amounts of SiOH in the network may weaken the neighboring Si-O-Si bonds, causing them to easily break and therefore lower the overall activation energy. It therefore becomes critical to determine the concentration of water within each sample to be dated.

It has been demonstrated that structural water is present within unhydrated obsidian as both molecular water (H_2O_m) and as hydroxyl (OH) (Newman et al. 1986; Silver and Stolper 1989; Stolper 1982). The sum of both species is referred to as the total water concentration (H_2O_t). Silver et al. (1990) demonstrated the relationship between the two species as a function of total water concentration. To develop obsidians of varying water content, obsidian from Mono Craters, California, was heated and quenched in a cold seal reactor at varying temperatures and cooling rates. Spectroscopic analysis revealed that at total water concentration of less than about 3 percent (weight percent) hydroxyl is the dominant species (Figure 11.2). As H_2O_t increases, the concentration of OH reaches a plateau at around 1 percent concentration. In contrast to this, molecular water is not detectable by infrared analysis when the total water is less than about 0.3 percent but then the concentration increases rapidly. The experimental data shows this trend to continue up to about 3 percent H_2O_m (Silver et al. 1990).

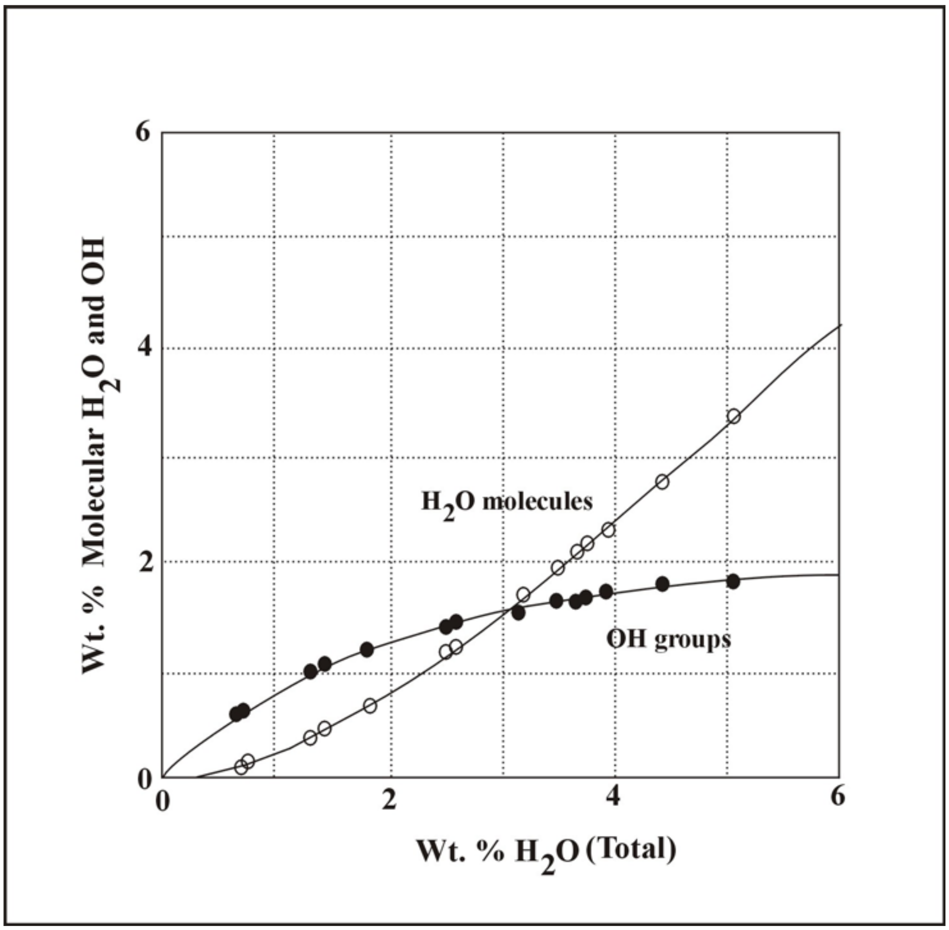

Figure 11.2. The proportional concentration between OH groups and H_2O molecules in obsidian (from Silver et al. 1990).

The diffusion of water in amorphous silicates is also strongly correlated with the concentration of water within the surface hydration layer (Drury et al. 1962; Lee et al. 1974; Nogami and Tomozawa 1984). This phenomenon is referred to as concentration-dependent diffusion. Within a narrow compositional range, the anhydrous component of the glass has little influence on the mobility of water (Behrens and Nowak 1997). Under ambient temperatures (0 to 30^o C), the diffusion coefficient does not follow the non-steady-state diffusion process and cannot be mathematically estimated with Fick's second law. Instead, as water enters the glass network the structure is depolymerized and allows additional water to enter the glass at a faster rate. This changing diffusion coefficient results in the formation of an S-shaped concentration-depth profile (Figure 11.3). However, experimental work shows that the leading edge of the diffusion profile advances into manufactured and natural glasses at the square root of time (Lanford et al. 1979; Stevenson et al. 1998; Tsong et al. 1980).

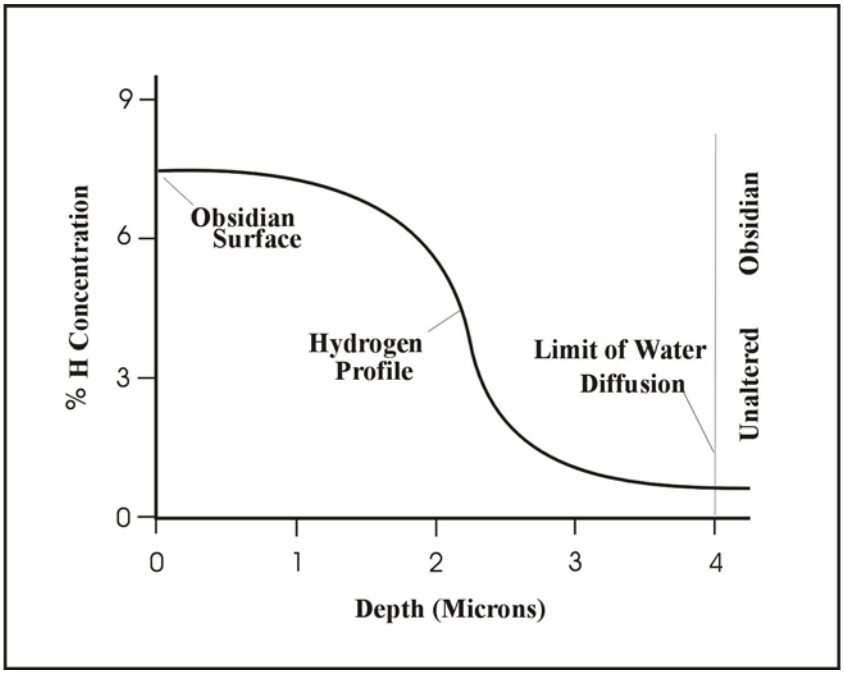

Figure 11.3. Concentration-dependent diffusion profile for obsidian.

The Hydration Dating Method

Based upon the discussion of water diffusion in obsidian, the implementation of the dating method will require two steps. The first step is to determine the depth of molecular water penetration into the glass from the surface. Conventional approaches have used optical microscopy because of the low cost. However, the uncertainty associated with each measurement is +/-0.25 um. This magnitude of error can lead to very generalized age estimates because of the wide standard deviations and defeats the objective of arriving at a precise chronological estimate. Secondary ion mass spectrometry (SIMS) has been used to significantly increase precision to +/-0.05 to 0.1 um, but the cost per sample is prohibitive for routine application. Infrared technology offers a compromise of high precision and lower cost. For example, the infrared photoacoustic (PAS) accessory (McClelland et al. 1993) has been used to successfully measure the absorbance of surface hydration layers and has been correlated with SIMS depth values to provide a highly precise depth calibration (Stevenson et al. 2000).

The second critical step is to determine the diffusion coefficients of H_2O_m at a specified ambient temperature as a function of the amount of glass structural water. Hydrothermal experimentation on obsidian and tektites with initial water concentrations between 0.01 percent and 0.4 percent have shown that the diffusion of molecular water (D) is exponentially related to initial concentration (Stevenson et al. 1998). The magnitude of D varies in response to OH at low structural water concentration and is further increased when structural H_2O_m is present. It is therefore critical to distinguish between OH and H_2O_m when assessing glass composition. Infrared transmission measurement on 0.5- to 2.0-mm-thick parallel-sided glass wafers have a precision of less than 2 percent (Newman et al. 1986) and is the conventional approach although determinations of H_2O_m have been successfully achieved by micro-reflectance Fourier transform infrared spectroscopy (FTIR) (G. Moore and McMillan 2000).

Infrared Spectroscopy

Infrared spectroscopy is a very useful technique for analyzing organic compounds, such as water, in the mid-infrared region (2.5 to 16 um; 5000 to 900 cm^{-1}). It is based on the principle that infrared radiation is absorbed by covalently bonded atoms, or molecules, and causes them to vibrate at the same frequency as the light source. A spectrum is created when a molecular vibration absorbs light at a specific frequency. This is very useful in the analysis of materials because there are several functional groups, or associations of atoms, that vibrate at the same frequency irrespective of the material in which they occur. One such association is hydrogen and oxygen; the focus of this study. A discussion of the properties of light, the types of vibrations and the determination of peak intensities and widths is covered in detail by B. Smith (1999) and the reader is referred to that paper for the fundamentals.

IR transmission spectroscopy has been extensively used to measure water in both manufactured and natural glasses (Bartholomew et al. 1980; Ihinger et al. 1999; Nowak and Behrens 1995; Scholze 1966; Wakabayashi and Tomozawa 1989). The concentration of water in obsidian has been the focus of extensive research because important clues exist about the eruptive history of volcanoes (Newman et al. 1988; Zhang and Behrens 2000). As a result, the number of water species in obsidian, their band locations, and absorption coefficients have been presented in detail (Newman et al. 1986; Zhang et al. 1997). In this paper, the focus was measuring the structural water (OH, H_2O_m) as well as the surface-diffused water (H_2O_m). An accurate determination will provide control over the critical parameters that control the hydration process.

Water Band Assignments

When the energy of the infrared light matches the vibrational energy level of a molecule it will be absorbed and excite the molecule causing the atoms to move. These complex vibrations can be partitioned into a set of *modes* (bending, stretching, contracting) that occur at specified frequencies within the infrared spectrum (Table 11.1). The total number of modes can be calculated. For a linear molecule such as hydroxyl (OH), the number of modes is estimated from the formula *3N-5*, where *N* is the number of atoms in the molecule. In the case of OH where only two atoms are present, the number of modes is equal to one. For a non-linear molecule such as water, the formula is *3N-6* and the number of modes is equal to three for this three-atom molecule (B. Smith 1999).

Table 11.1. Water species, IR band location, and vibrational motion.

Band Location (cm^{-1})	Water Species	Vibration Motion
7100	OH	OH stretching, 1st overtone
	H_2O	OH stretching, 1st overtone
5200	H_2O	Combination OH stretching and HOH bending
4500	OH	Combination of Si-OH and Al-OH stretching
4000	OH	Uncertain
	H_2O	Uncertain
3570	OH	Fundamental stretching
	H_2O	Fundamental stretching
1630	H_2O	Fundamental bending

Figure 11.4 shows an infrared absorbance spectrum from 900 and 7100 cm^{-1} for an obsidian sample with the characteristic water peaks.

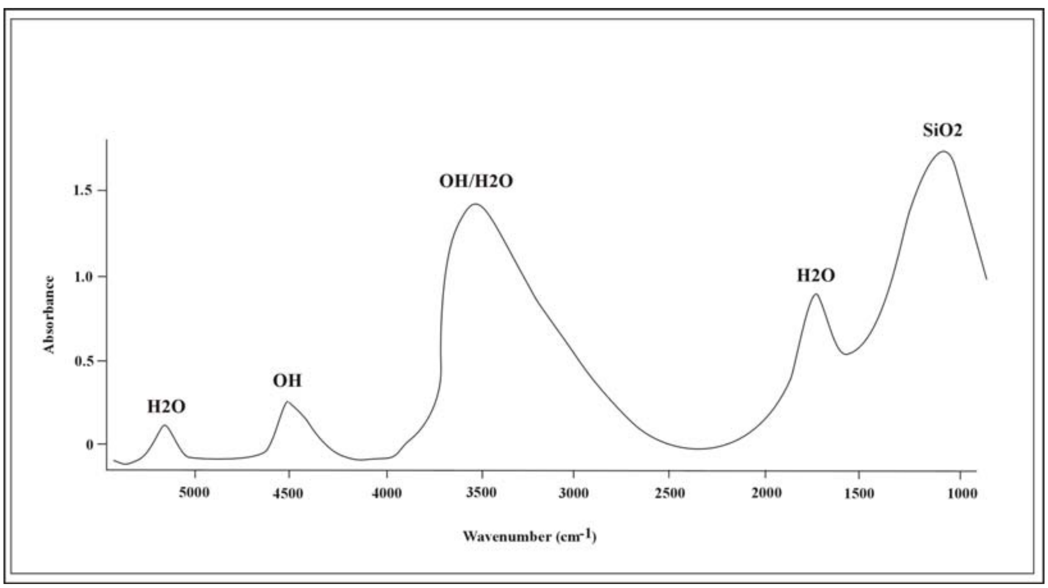

Figure 11.4. Water band locations in obsidian between 900 and 5200 cm^{-1}.

Six water bands are present within the wavenumber range (Newman et al. 1986). At 1630 cm^{-1}, there is a nearly symmetrical band that represents the fundamental bending mode of molecular water. The next band at 3570 cm^{-1} is a fundamental OH stretch for both hydroxyl and molecular water. It is a wide band whose asymmetry is generated by the numerous hydrogen bonds with other constituents of the glass. The small shoulder at 4000 cm^{-1} is a water band of uncertain assignment. It has been variously interpreted to represent hydrogen bonded to silanol groups, molecular water and hydroxyl, and just molecular water. The band at 4500 cm^{-1} is a well-documented combination stretch of OH groups bonded as Si-OH and possibly OH-Al within the glass structure. The next at 5200 cm^{-1} is a band generated by basic OH stretching and HOH bending of molecular water. The last band at 7100 cm^{-1} is outside of the fundamental region and represents the first overtone of a fundamental OH stretch that occurs both in hydroxyl and molecular water (Newman et al. 1986).

The measurement uncertainty associated with all bands is less than 5 percent except for the band at 4000 cm^{-1}. At this wavenumber, background subtraction procedures are problematic and prevent highly repeatable measurements. The best precision can be obtained with the 3570 cm^{-1} water band where a 0.02 error in absorbance units translates into a 2 percent error at one unit of sample absorbance and a 4 percent error when the total absorbance is 0.5 units. This makes the 3570 cm^{-1} desirable for the measurement of very low amounts of structural water (<0.10%) in obsidian (Newman et al. 1986). Other less absorbing bands such as the molecular water bands at 1630 cm^{-1} and 5200 cm^{-1} , and the OH band at 4500 cm^{-1}, are more suitable for measuring greater water concentration levels (>0.10%) that compose the hydration layer.

Water Band Calibration

A quantitative determination of water concentration can be accomplished using Beer's law where weight percent concentration is related to absorbance intensity:

$$A = \varepsilon * l * c$$

where: A = absorbance, l = path length through the material expressed in microns or millimeters, c = the concentration in parts per million or weight percent, and ε is the molar absorptivity or a proportionality constant. This last value is an absolute measure of infrared absorbance at a specified wavenumber for a molecule. It is used to relate concentration to absorbance and must be empirically determined for each water band in the obsidian. To accomplish this, the intensity of infrared spectra is often compared with water concentrations determined by manometry.

The calibration of water bands in rhyolitic glass was initially attempted by Stolper (1982) and then quantified by Newman et al. (1986) for the concentration of total water between 0 and 2.5 percent. Ihinger et al. (1999) subsequently revised the molar absorptivity values based on refined manometry data but the molar absorptivities of Newman et al. (1986) were widely used for many years. A little more than 10 years later, Zhang et al. (1997) demonstrated that ε was not constant. They demonstrated that the ratio of the OH band at 4520 cm^{-1} to the H^2O band at 5230 cm^{-1} changed as a function of total water concentration, thus violating the fundamental assumption necessary for quantitative determinations. Zhang et al. (1997) developed new calibrations for these two water bands to compensate for changing values of ε that we will use in this analysis. This calibration can accurately calculate the concentration of total water up to 2.7 percent and is reported to be six times more reproducible than the previous calibration. The final equations for calculating the weight percent concentrations of H_2O_t, OH and H_2O_m are

$$H_2O_t = a_o A_{5230} + (b_o + b_1 A_{5230} + b_2 A_{4520}) A_{4520}$$

$H_2O_m = a_o A_{5230}/H_2O_t$

$OH = (b_o + b_1A_{5230} + b_2A_{4520}) A_{4520}/ H_2O_t$

where: a_o = 0.04217 +/- 0.0013 mm

b_o = 0.04024 +/- 0.0023 mm

b_1 = -0.02011 +/- 0.0051 mm^2

b_2 = 0.0522 +/- 0.0051 mm^2

Application of IR Spectroscopy to Obsidian Hydration Dating

The discussion of the obsidian hydration dating method demonstrated that molecular water from the environment enters the glass at a constant rate and forms an increasingly thick water rich surface layer over time. The rate of molecular water diffusion is dictated by the quantity of structural water present within the unaltered glass if temperature and other environmental parameters remain constant. IR spectroscopic analysis can obtain precise estimates of each water species (H_2O_m, OH) within the bulk matrix and on the surface of the glass. However, different IR sampling methods need to be used for bulk glass and the surface characterization.

Structural Water Measurement

Quantitative measurement of OH and H_2O_m in the unhydrated glass matrix may be obtained on transparent obsidians using the calibration constants discussed above. In this procedure, parallel-sided 1-mm-thick sections, approximately 1 cm^2 in area, are cut from an artifact or geological sample with a slow-speed wafering saw equipped with a diamond blade. Each side is polished to a 2-um finish using a variety of polishing grits to prevent scattering of the infrared beam. A mechanical polisher is commonly used so that the parallel sides are retained during the abrasion of the sample.

The prepared sample is placed on a sample mount within the spectrometer compartment and the infrared beam is passed through the sample (Figure 11.5). Absorption of the infrared light is converted into an infrared spectrum. The intensity of the water bands at 4500 cm^{-1} (OH) and 5200 cm^{-1} (H_2O) are determined by measurement of the peak heights using a flat background drawn at a tangent to the minima of each spectra. The measured absorbance values are then converted to water concentration values in units of weight percent.

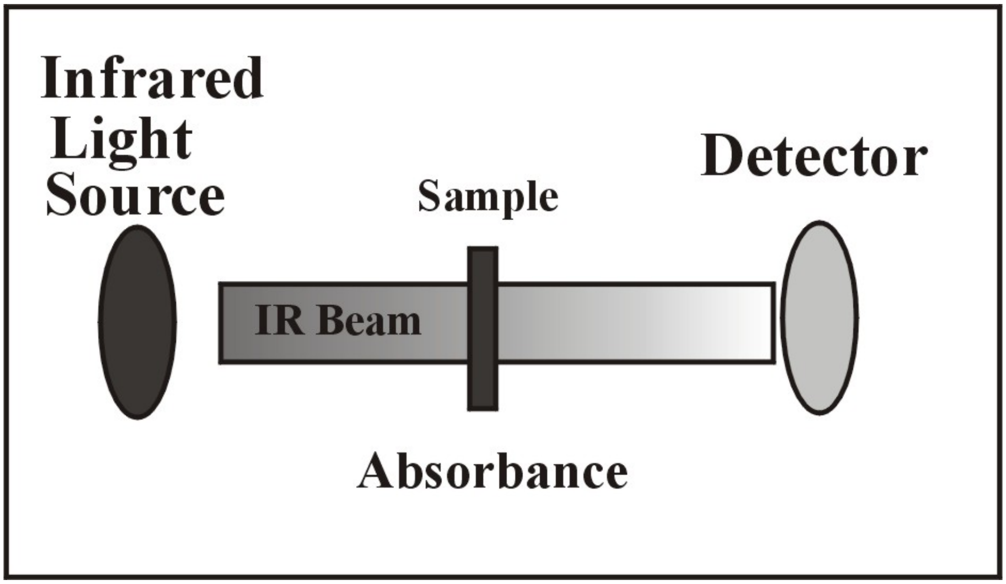

Figure 11.5. Infrared transmission measurement.

In order to obtain high-quality results, care must be taken to avoid imperfections and inclusions in the obsidian. Small voids or bubbles reduce the total quantity of glass exposed to the infrared beam and can lower water values. In contrast, concentrations of microlites may block the infrared beam and mimic a higher absorbance. This will inflate the final concentration. To avoid erroneous results it is necessary to avoid both voids and microlites by sampling regions of clear glass. To do this, a small aperture 3 to 6 mm in diameter is placed over the sample to allow only the preferred area to receive infrared light. The procedure will result in a representative value of water within the glass matrix. However, the use of a smaller sample area will result in a lower signal-to-noise ratio and a larger number of scans may be required to obtain satisfactory results. The analysis of opaque obsidians is not possible in transmission.

Our analysis of a variety of obsidians over the years has shown that total structural water content may vary significantly. Obsidians located within the American Southwest reflect this wide concentration range with total water values occurring between 0.10 percent and 1.58 percent. Table 11.2 lists the water concentration values for eight sources in Arizona and New Mexico. The Superior and Red Hill sources have been characterized with two to three separate samples and show that water concentrations may vary within a source. The remaining assays are on single samples. These data show the differences in structural water between obsidian sources but do not reflect the internal variation within each source. It is clear that if the infrared approach to obsidian hydration dating is to be correctly applied, each obsidian artifact represented within a lithic assemblage will need to be characterized to determine the concentration range of structural water. Some sources may have a restricted concentration range and may be represented by a single value with a low standard deviation. Other sources (e.g., Red Hill) may be highly variable. In this case, it may be required to assess the structural water content for each artifact to be dated. Only then can the correct rate constants be calculated.

Table 11.2. Structural water concentrations for some Southwestern obsidian sources.

Source	Location	Percent OH	Percent H_2O	Percent H_2O_t	A	E	Rate
Superior	Arizona	0.21–0.28	0	0.21–0.28	2.12/2.63	82703/81586	23.6/33.6

Hydration Layer Water Measurement

The optical measurement of the hydration layer at high magnification has been the standard for over 50 years. Determination of the inward limit of the diffusion front and thickness measurement relies on a change in the refractive index of the glass that is caused by the incorporation of molecular water into the matrix. The optical approach has produced much useful data but is fraught with many potential errors that can arise in sample preparation and focusing techniques (Jackson 1984; Stevenson et al. 1989). More importantly, a comparison of optically measured samples with layer hydrogen profiles conducted by SIMS revealed that optical measurements do not consistently occur at the diffusion front boundary (Anovitz et al. 1999). Infrared spectroscopy has the potential to overcome these problems by the elimination of sample preparation and through direct measurement of the diffusing species (H_2O_m).

The determination of the water concentration level within a hydration layer can be obtained with an infrared photoacoustic accessory (Figure 11.6). In this technique, a sample less than 10 mm in diameter is placed in a helium-filled chamber equipped with a high sensitivity microphone. The specimen absorbs the infrared radiation and undergoes an oscillatory heating and becomes a source of thermal waves. The waves within the bulk sample propagate to the surface and into the helium atmosphere. The photoacoustic signal is generated at the surface and is caused by the thermal expansion of the gas (McClelland et al. 1993). The magnitude of the signal varies in proportion to the concentration of the water species. The absorbance values are calculated from integrated peak areas. Each absorbance value represents an averaged measure for the entire surface of the sample exposed to the 5-mm-diameter infrared beam.

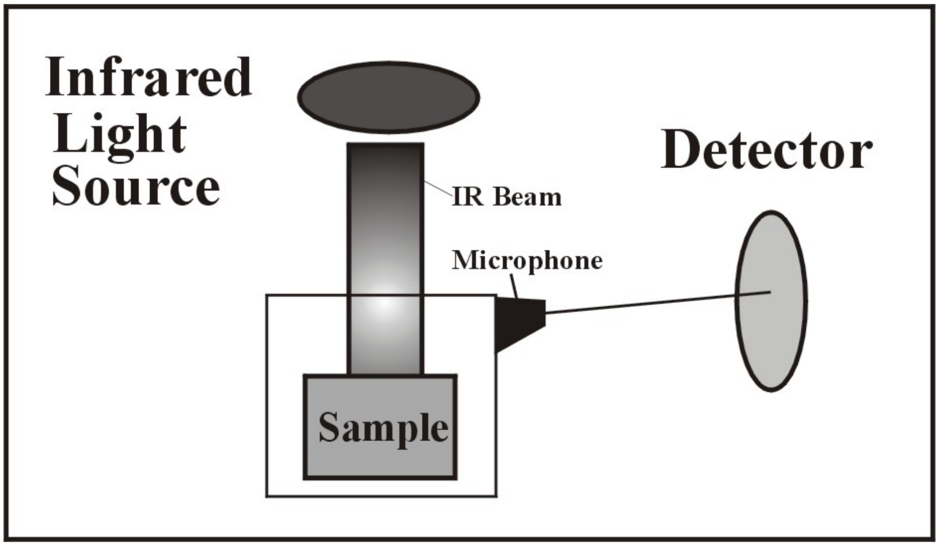

Figure 11.6. Infrared photoacoustic measurement.

No calibrations currently exist for the conversion of PAS band intensities to water concentration values. However, PAS absorbance intensities have been correlated with hydration layer depth measurements as determined by SIMS (Stevenson et al. 2000). Quantitative estimates of hydration layer thickness can be made up to a depth of 15 um (Figure 11.7).

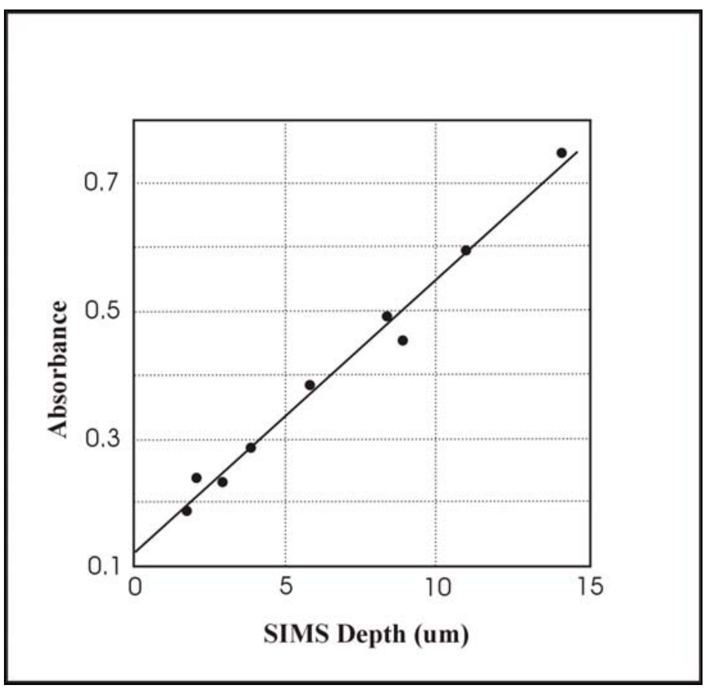

Figure 11.7. The relationship between infrared absorbance and depth of the hydration layer as determined by SIMS (after Stevenson et al. 2000).

The assumption behind this calibration is that water concentration, as reflected by absorption, will increase proportionally over time as diffusion proceeds. The linear relationship between IR absorption values and thickness supports this assumption.

Estimation of the Diffusion Coefficients

The diffusion coefficients for many types of obsidian have been empirically determined through hydrothermal experiments conducted at elevated temperatures. In the previous work of the author and others, glasses from different sources were hydrated in a vapour environment to determine the water diffusion coefficient at single temperature (160^{o}C) and at multiple temperatures (150 to 180^{o}C) to calculate the temperature dependence of diffusion or the activation energy. The coefficients were calculated from the optical thickness measurement of the induced hydration layers formed under known times of exposure to water vapour (Stevenson et al. 1998). These results provide the numerical constants for the Arrhenius equation so that a diffusion coefficient may be extrapolated to archaeological site conditions where temperatures are lower (10 to 30^oC). The experimental coefficients were regressed with the glass structural water concentrations (Figure 11.8a, 11.8b) to develop prediction equations for the high-temperature-rate constants:

Pre-exponential (A) = 2.35 * (ln (percent OH)/ln (10))^2

Activation Energy (E) = 76642 + (8943 * (ln percent OH))

The infrared analysis of a sample of New Mexico obsidians (Table 11.2) has yielded water content values that range between 0.10 percent and 0.71 percent OH. Estimation of a diffusion coefficient for an ambient site temperature of 25^{o}C is accomplished with the Arrhenius equation:

K = A exp E/R*T

where: K = archaeological diffusion coefficient (um^2/1000 years)
A = preexponential (um^2/day at 160^{o}C)
E = activation energy (Joules/mol)
R = universal gas constant
T = temperature (Kelvin)

This yields a diffusion coefficient that reflects the structural water concentration of the obsidian, a value may be used to convert measured hydration rim values to archaeological age estimates.

CONCLUSIONS

Water diffusion in glass is a complex problem. However, the fundamental components of the process are now beginning to be understood. It is clear that concentration-dependent diffusion accounts for the movement of molecular water into the glass structure. It is also established that the initial rate of molecular water diffusion is controlled by the quantity of structural water present within the glass matrix as a result of the incomplete removal of volatiles as the obsidian changes from a melt to a solid.

As a result of this understanding, it is possible to match the analytical methods to the problem at hand. Infrared spectroscopy is one method particularly suited to directly measuring the quantity of water in glass and the various species (OH, H_2O). Structural water can be quantitatively measured by simple infrared transmission and has replaced the difficult wet chemical methods. The amount of water in the hydration layer can be semi-quantitatively determined by infrared photoacoustic spectroscopy. An error estimate has not yet been determined for this application but we anticipate that it will approach that of other IR techniques and will only be several percent. This is preferable to the optical approach that involves extensive sample preparation and the estimation of the layer thickness under conditions of low resolution (+/-0.2 um).

The challenge for the immediate future requires that the calibration for the estimation of diffusion coefficients and activation energies from OH concentration be redone (Figure 11.8a and 11.8b). This calibration was developed by optical methods. Although there is a strong correlation between PAS signal intensity and SIMS depth, we anticipate that greater precision can be obtained if PAS is used to determine diffusion coefficients and activation energies on experimental samples. This is not a trivial experiment, but when completed it will tie all aspects of the obsidian hydration method to infrared spectroscopy.

CHAPTER 12
LUMINESCENCE DATING IN ARCHAEOLOGY

James Feathers

INTRODUCTION

Luminescence dating has long been treated with skepticism by American archaeologists (Feathers 2000). Although its popularity has been increasing lately, it remains under-utilized despite many recent advances in methodology and its potential for resolving chronological problems (Feathers 2003; Roberts 1997). Part of the reason for its under-utilization has been a lack of understanding of the rather arcane physics that underlie the method. This report is an attempt to increase this understanding.

Luminescence dating was developed in the 1960s and 1970s in the context of dating pottery and other ceramics. It has since been applied to dating burned lithics (Valladas 1992) and hearthstones as well as to dating buried sediments (Aitken 1985, 1998). In the case of pottery and burned lithics, the event dated is the last time the object was exposed to sufficient heat to reset the luminescence clock. For sediments the event dated is the last exposure to sufficient light. Often times these events are the ones that the archaeologist is interested in. Pottery is dated to when it was made or last used. Hearths can be dated to when the stones were heated, adobe when the bricks were made, and lithics either when they were heat-treated or accidentally burned during use. Sediments are dated to the time of their deposition. The convergence of the event of interest and the event that can be dated is the main strength of luminescence in archaeological applications (Feathers 2003). Unlike the case for radiocarbon, where dating artifacts often relies on association with organic matter, luminescence does not usually depend on making such connections.

The disadvantage of luminescence is the complicated underlying physics and the large number of variables that must be estimated to derive a date. This means that luminescence often has less precision than other dating methods, although methodological advances in the last few years (e.g., Murray and Wintle 2000) have improved considerably both precision and accuracy (Murray and Olley 2002). Error terms of less than 10 percent are commonplace. During some periods of time, such as the late prehistoric period (in the Americas), when radiocarbon has low resolution due to the flatness of the calibration curve, luminescence has been shown to outperform radiocarbon (e.g., Feathers 2005a; Lipo et al. 2005).

PHYSICAL BACKGROUND

Luminescence dating is rooted in what for most archaeologists is the unfamiliar world of solid state physics (Aitken 1985, 1998; Bøtter-Jensen et al. 2003). The phenomenon of luminescence is defined as light emitted from a substance after absorption of energy from an external source (Chen and McKeever 1997). What distinguishes luminescence from similar phenomena such as fluorescence is a time lag between the absorption of energy and the emission of light.

Luminescence can be used for dating for two reasons. First, the time lag, during which the substance remains in an excited or metastable state, may extend for millions of years, thereby providing a stable clock. Second, the metastable state can be removed in a matter of minutes or seconds by a stimulus, most commonly heat or light. When the stimulus is heat, the emitted light is called thermoluminescence (TL). When the stimulus is light, it is called optically stimulated luminescence (OSL). Such stimuli are, in effect, zeroing mechanisms and represent the events that are dated.

The external source of energy for dating applications is naturally occurring radioactivity in the sample and its immediate surroundings. Because such radioactivity is a continual process, the absorbed energy is built up through time, usually at a constant rate, until release by heat or light. This accumulated dose is called the paleodose, or equivalent dose (D_e). Dividing by the dose rate yields an age.

Luminescence is explained by reference to energy band theory (Figure 12.1) (Bøtter-Jensen et al. 2003, Chen and McKeever 1997; McKeever and Chen 1997). In complex crystalline solids with three-dimensional arrays of atoms, various energy levels of individual atoms overlap and form bands. In insulating materials, such as most constituents in ceramics or sediments, a gap is present between a lower band called the valence band, which corresponds to the ground state, and a higher band called the conduction band. In the valence band, electrons are closely tied to their parent atoms. The ionizing ability of natural radioactivity removes electrons from their parents and raises them across the gap to the conduction band where they can move about freely. In theory electrons cannot occupy energy levels within the gap, because of quantum rules, and if radioactivity (e.g., from ^{14}C) lacks the energy to raise electrons across the gap, no ionization occurs. When an electron is removed from an atom, the vacancy left behind in the valence band is called a hole. Electrons from an adjacent atom can fill the hole, creating a new hole in the adjoining atom. In this way holes can diffuse through the valence band in a similar way that electrons move through the conduction band. In ideal crystals, electrons that have been excited to the conduction band will return to the valence band and recombine with a hole once the energy from the external source is removed. But natural crystals contain defects in the form of substitutions, displaced atoms and lattice distortions. These can create localized charge deficiencies (balanced by an opposite charge deficiency elsewhere in the crystal). Electrons in the conduction band or holes diffusing through the valence band become attracted to these defects and can be "trapped." These traps occupy energy levels within the otherwise forbidden gap.

Once an electron or hole becomes trapped, a stimulus is required to remove them from the trap to the corresponding delocalized band. The amount of energy required to accomplish this is called the trap depth. Shallow traps require very little stimulus (heat or light) to empty and do so in a relatively short time under ambient conditions. Deep traps require high-energy stimulus to empty and can remain populated for very long periods of time. These latter traps are used for dating. When an electron or hole is released from a trap, it may recombine with opposite charge at another trap, called a recombination center, and both return to the ground state. The process of recombination is what results in the emission of light, or luminescence. Recombination centers have very high energy depth and release of charge from them is much more likely via recombination than from stimulus. Figure 12.1 illustrates the various transitions.

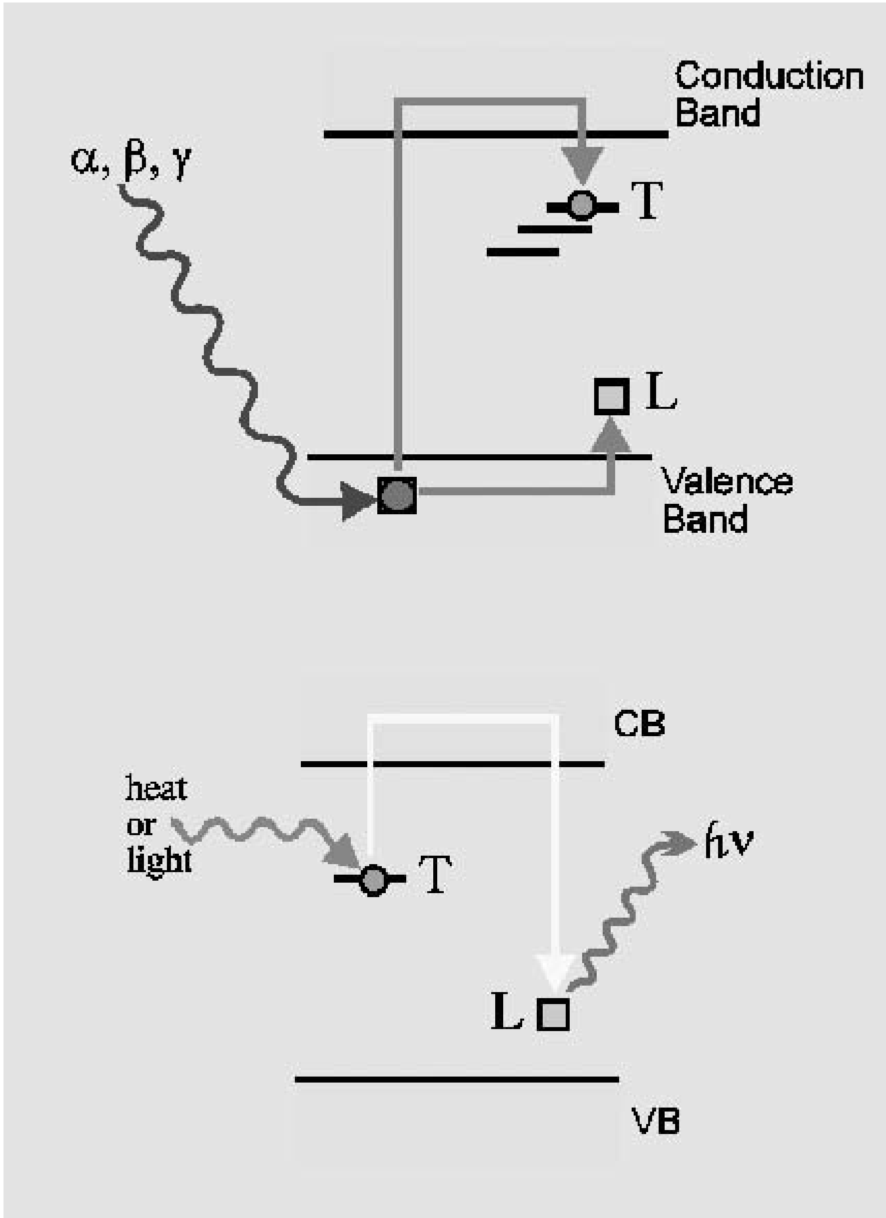

Figure 12.1. Energy level diagrams showing traps and various charge transitions. The ground state is represented by the valence band, while the conduction band is an excited state. Between the bands is a forbidden zone, which nevertheless contains energy levels associated with localized charge deficiencies caused by crystalline defects. T represents electron traps of various depths, while L represents a hole trap called a recombination or luminescence center. In the top diagram, ionizing radiation (alpha, beta or gamma radiation) lifts electrons to the conduction band where some of them are trapped at T. Electron vacancies or holes are trapped at L. In the bottom diagram heat or light provides a stimulus that releases the electron from the trap to the conduction band, where it then recombines with the hole at a recombination center resulting in the emission of photons (*h*υ). These diagrams were constructed by Dorothy Godfrey-Smith.

Figure 12.2 shows the full process involved. The horizontal axis is time and the vertical axis is the amount of absorbed energy in terms of the number of electrons and holes populating traps. Because luminescence is emitted when the traps are emptied, the luminescence signal intensity is proportional to the amount of trapped charge and can also be represented by the vertical axis. At some point in deep geological time, when the crystal is first formed, the traps are empty. With time, exposure to natural radioactivity ionizes atoms in the crystal and the traps begin to populate. Eventually, all the traps are filled and no additional radioactivity will increase the amount of trapped charge. This saturated level defines an upper limit to dating, which is around 100,000 years for quartz and perhaps a million years for feldspar. Then at some point in prehistoric time—when a pot was fired or when sediments associated with artifacts were exposed to light and deposited—the traps are emptied. After the pot is removed from heat or the sediments are buried, electron and hole traps begin to be repopulated and absorbed energy rebuilds. When the materials are transported to the lab and measured by heating (TL) or exposure to light (OSL), the resulting luminescence intensity is proportional to the amount of trapped charge accumulated since the last zeroing event. If the dose rate has been constant over this time, the luminescence intensity is proportional to time.

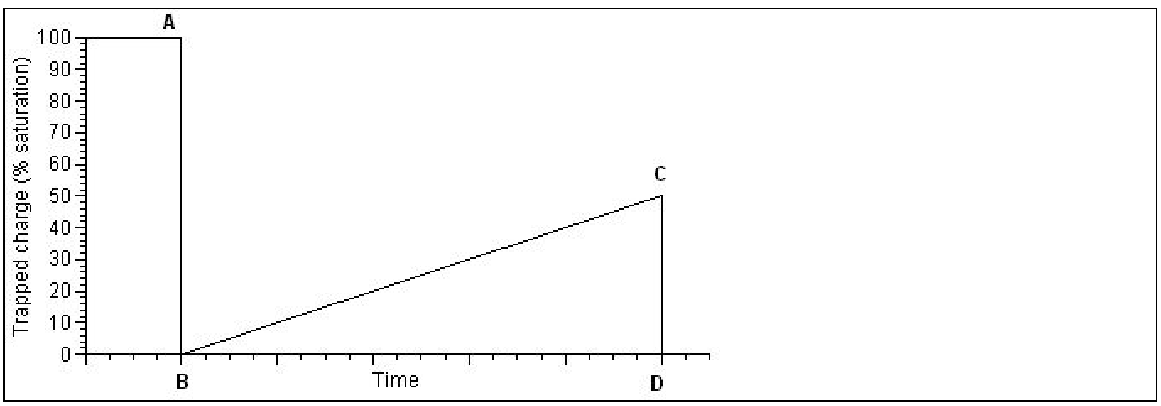

Figure 12.2. Schematic of the dating process. At some point in geological time (not shown) the traps are empty. Continual radioactivity results in filling of the traps until they are all filled to some saturation point (A). An event in prehistory, either exposure to heat or to light (B), empties the traps. As time goes on, the traps start filling again, until point C when the traps are emptied in the laboratory by applying heat (TL) or light (OSL), this time measuring the luminescence. The intensity of the signal is proportional to the amount of trapped charge, which if the dose rate is constant can be related to the time elapsed from B to D. (Figure from Feathers 2003).

RADIOACTIVITY

Can the dose rate be assumed constant through time? The principle contributors to the natural dose rate come from ^{40}K and the decay chains of ^{232}Th and ^{238}U. ^{232}Th and ^{238}U are parent radionuclides, the decay of which is the first of a series of decays through a number of daughter radionuclides until a stable isotope of lead is reached. The daughters have half lives much shorter than those of the parents, the consequence of which leads, in the absence of any other geological process, to the activities of daughter and parents becoming the same. This condition where parent and daughters decay at the same rate is called secular equilibrium. The half lives of the two parents and of ^{40}K are very long, on the order of 10^9 years. Because the decay rates are so slow (but nevertheless measurable), radioactive composition changes only very slightly over archaeological time, meaning that the decay rate is virtually constant. The radioactivity measured today will almost be the same as what it would have been at the time of zeroing had it been measured then. Of course, radioactivity is not the only process affecting composition. Various geological processes, such as leaching, ion-exchange, or addition/removal of overburden, can alter the concentration of radionuclides within the effective range of the sample (about 30 cm). In many cases the effects of such processes are not significant and the constant dose rate assumption is safe. Changed concentrations can often be detected (and some times corrected) by the presence of systematic changes down a profile or by a condition of disequilibrium in the decay chains (where selective daughters or the parent have been added or removed) (Krbetschek et al. 1994). The possibility of changes in dose rate is something that always has to be taken into account in dating, but samples that cannot be dated because of it are not common (Olley et al. 1996). In addition to the major contributors to the dose rate, there are minor contributions from ^{87}Rb, ^{235}U (parent of another decay chain) and cosmic radiation. The latter can be significant for surface samples that have little internal radioactivity.

Another variable affecting radioactivity is the moisture content of the sample and its surroundings. Moisture absorbs radioactivity at a different rate than the sample, such that higher moisture contents mean a lower dose rate to the sample. Some estimate of past moisture content, which can change dramatically over time, is necessary, although large uncertainties in this estimation can be tolerated.

MEASUREMENTS

Two sets of measurements are required to produce a date. One is to measure the equivalent dose (D_e). This is done by calibrating the natural luminescence signal, measured on selected portions of the sample, against artificial radiation provided in the laboratory. The amount of radiation needed to produce a given amount of luminescence is called the sensitivity. The challenge is to make sure the natural signal and the calibrating signal are responding to the same sensitivity, and various procedures including a preheat to a temperature of about 200 to 260°C before each measurement are applied to accomplish this (Wintle and Murray 1998). The preheat is also designed to remove any unstable signal from shallow traps. The second set of measurements is to estimate the dose rate both of the sample and its immediate surroundings. These normally take place in the laboratory but field assessments of radioactivity are also employed—and recommended for complex environments.

The portion of the sample useful for dating is governed by both the composition and the effective ranges of various types of radioactivity. Terrestrial radioactivity consists of alpha, beta, and gamma radiation. Alpha particles are helium nuclei with high energies and short ranges, on the order of about 20 µm. Beta particles are electrons with medium ranges of up to 2 mm. Gamma particles are high-energy photons with ranges up to 30 cm in soil. ^{40}K is a beta and gamma emitter, while the various steps of the decay chains emit all three. Some minerals, such as quartz, have little internal radioactivity, so that sand-sized quartz particles, for example, are affected just on their surfaces by alpha radiation. If a sample containing both coarse-grained quartz and fine grains were mixed together, the luminescence signal of the mixture could not readily be related to the dose rate because some of the luminescence is a function of just betas and gammas and some a function of betas, gammas, and alphas. One alternative is to measure luminescence on just coarse grains, usually either quartz or feldspars. Both produce luminescence signals that are responsive to dose and neither have internal sources of alpha irradiation. For quartz, the outer surfaces of the grains are removed by hydrofluoric acid, so that the luminescence is only a function of betas and gammas, easing analysis. Only a very weak etch can be applied to feldspars without dissolving the whole grain, but alpha radiation still only plays an insignificant role. Potassium-based feldspars do have internal beta radiation from ^{40}K. If the sample is fine-grained, like many ceramics, an option is to isolate polymineral fine grains, usually 1 to 8 or 4 to 11 μm. These are small enough to not attenuate alpha radiation, so the luminescence is a function of all three. Sample preparation then is a matter of isolating either coarse grains of quartz or feldspar or fine grains for measurement.

A further complication with alpha irradiation if fine grain measurements are being made is the lower efficiency of alpha particles in producing luminescence. Because alphas are so energetic and so short-ranged, they saturate all the traps in their immediate vicinity before they use up all their energy. The remaining energy goes to waste, in terms of luminescence, with the result that alphas are only about one-tenth as effective at producing luminescence as betas or gammas. This has to be taken into account when determining the dose rate. It is usually measured by comparing luminescence sensitivity determined by either alpha or beta irradiation. The ratio is called the b-value (Huntley et al. 1988).

The gamma radiation that affects the sample luminescence arises largely from outside the sample, because of its relatively long range. An estimation of the radioactivity of the immediate surroundings of the sample is therefore necessary. This can be measured in the field either by implanting radiation-sensitive dosimeters or by using portable gamma spectrometers. If the environment is relatively homogeneous, a representative sediment sample can also be collected and measured in the laboratory. This is what is normally done for ceramic dating. Figure 12.3 illustrates radioactive ranges and their effects on samples.

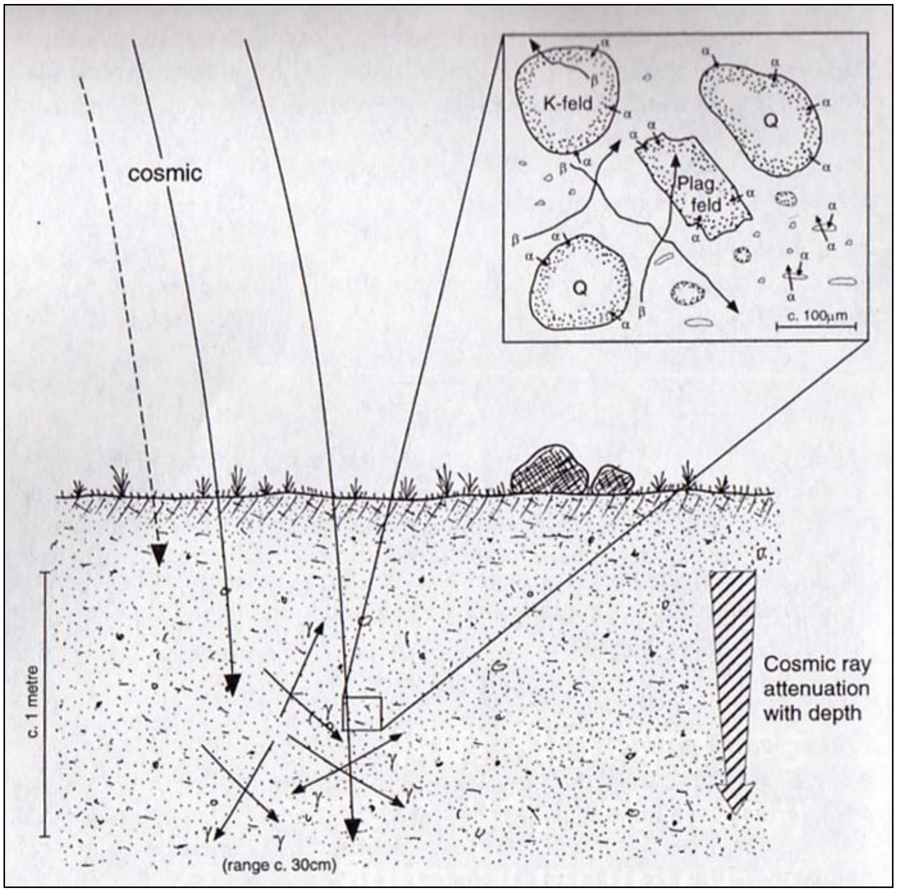

Figure 12.3. Ranges of different kinds of radiation are shown for typical sediment. The inset shows the penetration range of beta and alpha particles for different grain sizes. Dating is usually performed on either sand-sized grains of quartz or feldspar or on polymineral fine grains (4 to 11µm). (Figure by Stephen Stokes [Aitken 1998]).

Quartz and feldspar are both ubiquitous minerals, but they have their advantages and disadvantages. Feldspars have brighter luminescence signals and saturate at higher levels, making them useful for both very old and very young samples (Duller 1997). They are also the only mineral that responds significantly to infrared light stimulation (called IRSL), so that mineral separation is not necessary. But they suffer from a malady called anomalous fading. This is the loss of electrons through time under ambient conditions from traps that have sufficient depth that the electrons should not escape. It is explained by a concept in quantum theory called tunneling. If fading has occurred, the age will be underestimated, although various procedures have been proposed to circumvent fading or correct for its effects (Huntley and Lamothe 2000). Because it does not exhibit fading, quartz is often the preferred mineral for dating. But some quartz has low sensitivity and it saturates at relatively young ages (as young as ~ 50,000 years), so feldspars are commonly employed as an alternative. Polymineral fine grains may also suffer from anomalous fading, because feldspars often dominate the signal from them.

Calibration against artificial irradiation to determine D_e is accomplished through construction of a growth curve plotting irradiation against luminescence (Aitken 1985). Two general methods are used. The first, called additive dose, involves applying increments of artificial dose to aliquots still containing the natural signal. D_e is determined by extrapolating the growth curve to the dose axis, a procedure that assumes the growth curve is the same shape in the extrapolated region as among the measured points. The assumption is often not valid (particularly for young samples) and the extrapolation is often with poor precision (common for old samples). The second, called regeneration, involves first reducing the natural signal to background on aliquots and then giving increments of dose to them. The growth curve is thus constructed from zero and D_e is determined by interpolating the natural signal into the growth curve. The problem with regeneration is possible sensitivity changes brought about in the process of reducing the natural signal to background. Sensitivity changes are caused by the redistribution of trapped charge that can alter preferred pathways of recombination. If the sensitivity changes, the regenerated growth curve may not have the same slope as the curve of which the natural signal is a part. In such cases, interpolation will produce an inaccurate D_e.

Traditionally, D_e has been measured using multi-aliquots. One set of aliquots is used to construct an additive dose curve and a second set (usually the ones from which the natural signal was measured on the first set) is used for regeneration. D_e is determined by an additive dose extrapolation corrected by an offset determined by the dose intercept of the regeneration curve (called supralinearity correction). Alternatively, the slope of the regeneration curve is adjusted by a multiplicative factor to match the sensitivity of the additive curve. The two curves are then shifted along the dose axis into coincidence by an amount equal to the D_e. This is called the slide method (Prescott et al. 1993) (Figure 12.4). The original authors of the slide method used the multiplicative factor just to test for sensitivity change and questioned whether it could be used to correct for it, but our laboratory has shown empirically, at least for TL on ceramics, that the slide method, even using the correction, produces the same answer as the method using supralinearity correction but often with better precision.

More recently, D_e from OSL has been determined using growth curves constructed on single aliquots. This has the obvious advantage of obviating the need to normalize among aliquots and has some other distinct benefits for sediment dating, which will be discussed later. The first attempt was using an additive dose technique (Duller 1995), but this did not overcome the extrapolation problems of additive dose and required some problematic corrections for successive measurements. A regeneration procedure became possible when a means to correct for sensitivity change was discovered. This was accomplished by administering a small test dose after each regeneration measurement (including the natural) (Murray and Wintle 2000). The OSL signal from the test dose has the same sensitivity as the regeneration measurement preceding it, allowing a way to normalize all measurements to the same sensitivity. This method is called single-aliquot regenerative dose (SAR) and is now the preferred method for measuring D_e with OSL (Table 12.1). A practical single-aliquot technique for TL has not been devised.

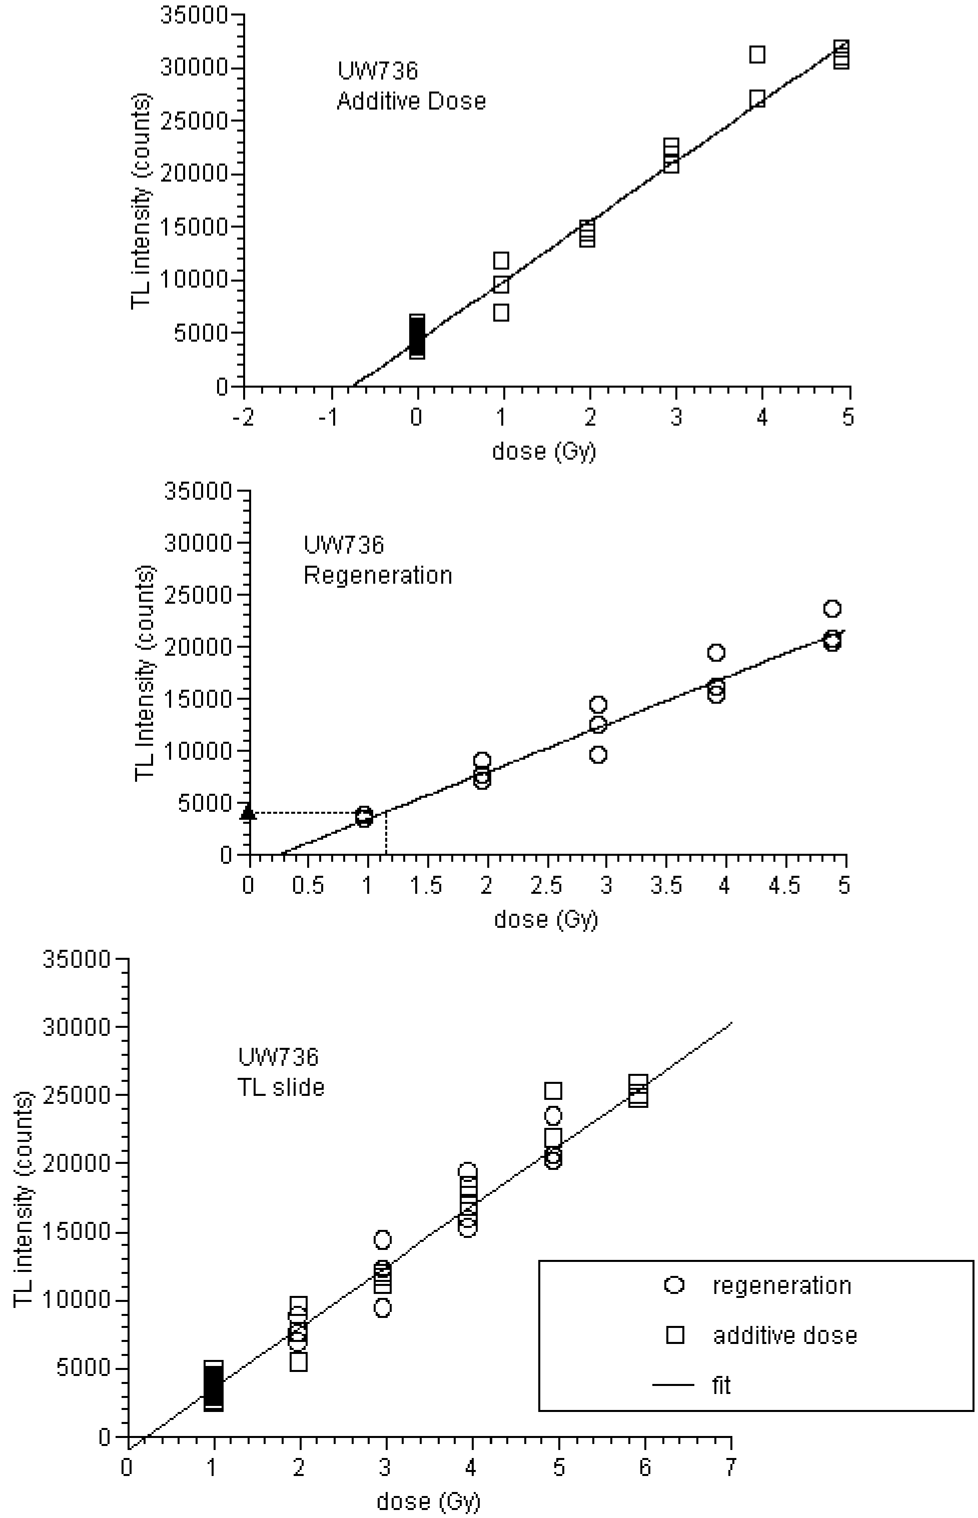

Figure 12.4. TL intensity. The top diagram shows an additive dose growth curve. The x-axis is artificial radiation dose administered in the laboratory (in Gy, the unit of absorbed dose). The points at zero dose represent the natural signal. Increments of dose are added to aliquots still containing the natural signal to construct the curve. Extrapolation from the

natural signals to the x-axis gives the amount of dose required to achieve the natural level. The middle diagram shows a regeneration growth curve, where increments of dose are administered to aliquots that have been zeroed. The natural signal is then interpolated into the curve as shown. The bottom diagram shows the additive dose and regeneration curves brought into coincidence by adjusting the regeneration points by a scale factor to make them parallel to the additive dose points and by shifting the points along the x-axis by an amount taken to be the equivalent dose. The sample is a prehistoric ceramic from New Mexico (Figure from Feathers 2003).

Table 12.1. Typical SAR sequence on single aliquot (Murray and Wintle 2000).

1. Dose (= 0 Gy if natural signal)
2. Preheat (e.g., 260°C for 10 seconds)
3. OSL (e.g., 60s at 125°C, stimulation using blue light, emission in UV), gives L_i
4. Fixed test dose (e.g., 5 Gy)
5. Cut heat (e.g., 160°C)
6. OSL (same as step 3), gives T_i
7. Repeat steps 1-6 for a range of regeneration doses bracketing the natural dose, a zero dose and a repeat (or recycle) point
8. Calculate L_i/T_i for natural and regeneration points and construct regeneration curve to determine D_E

DATING CERAMICS AND LITHICS

Dating ceramics are usually straightforward, because the heat necessary to make the ceramic is sufficient to reset fully the luminescence signal. This is not always the case with hearth stones or burned cherts. Sufficient heat from hearths does not always penetrate to the center of the rocks that form the hearth, requiring to sample near the surface or in the case of coarse-grained rocks using single-grain dating to isolate those grains most likely to have been heated sufficiently. Cherts were often heated in antiquity to improve flaking abilities, but often not high enough for luminescence dating (Dunnell et al. 1994). Cherts suitable for dating are often those that have been accidentally heated high enough, either by finding their way into a fire or by overheating during manufacture.

For either ceramics or lithics that have been heated sufficiently, luminescence provides a potential for dating that few other methods can match. For example, luminescence can be applied successfully to surface finds (Dunnell and Feathers 1994). This obviates the need for excavation to find datable material and thereby provides a cost-efficient way of dating for regional surveys. The ability of luminescence to date artifacts directly opens many opportunities (Feathers 2005a). It allows dating of small sites that lack diagnostics or other datable material. It allows the teasing apart of multiple occupations or otherwise mixed assemblages. By dating many artifacts from a single occupation, it allows estimations of occupation duration.

A drawback of luminescence dating of ceramics or lithics is lower precision than is obtainable from methods such as radiocarbon. In our laboratory, relative errors on ceramic or lithic dates average about 10 percent. Lower precision is a consequence of the large number of variables that must be estimated to achieve a date and therefore the propagation of the errors from each. Inaccurate estimations of any one variable can also lead to systematic errors. These often stem from changes in dose rate through time, varying moisture contents (which affect the dose rate), and anomalous fading. Our laboratory is experimenting with using OSL and IRSL on fine grains for determining D_e. These have the advantage of allowing single aliquot methods that provide higher precision. We predict that relative errors of as low as 5 percent can be achieved. By measuring first with IRSL and then with OSL, called the double SAR method (Banerjee et al. 2001; Roberts and Wintle 2001), it may also be possible to circumvent fading on fine grains if the IRSL can largely remove the feldspar signal, so that the subsequent OSL stems largely from quartz. Work needs to be done to see how b-value differs among OSL, IRSL, and TL.

As already mentioned, luminescence for some periods can currently provide better resolution than radiocarbon because of the flatness of the radiocarbon calibration curve.

DATING SEDIMENTS

Because of its utility in geology, luminescence research has focused on sediment dating, rather than ceramics or lithics. Dating sediments is more difficult because of a stronger possibility that sunlight was not of sufficient intensity to reset the luminescence signal at the time of deposition and also because of the propensity of sediments to become mixed through turbation processes after deposition (Bateman et al. 2003). In either case, some grains will provide the correct age of deposition, while others will not.

The luminescence community has addressed this question in two ways. One is to base dating on the most bleachable components of the luminescence signal. OSL has gained popularity over TL because it involves traps that are much more readily emptied by sunlight (although a rapidly bleaching TL component can be isolated in quartz, the procedure is cumbersome.) Even within OSL, there are some components more bleachable than others and efforts have been made to detect partial bleaching by comparison of fast and slow components (Bailey et al. 2003; Singarayer and Bailey 2003). A popular method for this is the use of linear modulated OSL (LM-OSL), where the intensity of stimulating light is steadily increased during exposure (Bulur et al. 2000). The early part of the resulting curve is associated with the fast component, the latter part with slower components (Olley et al. 2004a; Yoshida et al. 2003).

Another way to assess partial bleaching or mixing from turbation is by dating single grains, or less desirably single aliquots with a small number of grains (Roberts et al. 1999). Most work has been done with quartz, but some with feldspar (Lamothe et al. 1994). To make this practical, special instrumentation has been developed that uses a finely tuned green light laser to stimulate single grains that have been isolated in grids on specially designed sample holders (Bøtter-Jensen et al. 2003). The resulting distribution of D_e values is not easy to interpret. Some of the variation is due to differences in precision (bright grains have higher precision than dull ones), differences in microdosimetry (at the scale of individual grains, dose rates will vary from grain to grain) and differences in luminescence properties (fading, thermal transfer) (Galbraith et al. 2005). The challenge is to separate out these kinds of variation (which are largely random) from those caused by partial bleaching or turbation. Statistical models have been applied to determine an over-dispersion value that expresses the percentage of variation that cannot be accounted for by differential precision (Galbraith et al. 1999). For single grains, over-dispersion values of less than 10 to 15 percent are rare, and some have observed from independently dated samples that values less than about 20 percent represent single-aged samples (Olley et al. 2004a, 2004b). Geological evidence is often used to decide what portion of the distribution will likely represent the best age estimate. For example, for fluvial sediments, where partial bleaching is often a concern because of transport turbidity and the filtering effects of water on sunlight, the distributions are often positively skewed with a long tail of larger values (Jain et al. 2004; Wallinga 2002). In this case a "minimum age" is calculated to represent the best bleached grains. Minimum age models, which statistically isolate the lowest value grains that could form a single-age distribution, have also been applied to dating paleosols (Bush and Feathers 2003) and in sand dunes where there is evidence of deflation (Feathers et al. 2005).

Despite these problems, sediment dating has great potential in archaeology. Single-grain dating can be used to assess stratigraphic integrity (if sediments are mixed or not), which is very important for controversial issues such as pre-Clovis occupation. Evidence of mixing can also help with questions concerning site formation.

SAMPLE COLLECTION

Archaeologists collecting samples for luminescence dating only need to remember four guidelines. One is to avoid exposing the sample to radiation that will affect the luminescence signal: heat, light, X-rays. Ceramics are not usually a problem during the collecting process because the sherd surfaces can be exposed to light. In the laboratory, the outer surfaces are removed and only the internal portion is used for luminescence measurements. For the same reason, lithics are not usually a problem unless they are translucent. In the latter case they should be placed in an opaque container soon after collection. Unconsolidated sediments require more care to avoid light. A common practice is to collect the samples from cleared profiles or by coring using opaque cylinders. The ends of the cylinders will be exposed to light but they can be removed in the laboratory and the inner part used for dating. Airport X-rays are some times a problem and samples should be sent ground freight when possible.

The second guideline is to think about the radioactive environment. Because gamma radiation has a range of about 30 cm in sediment, anything within 30 cm of the sample will contribute to the dose rate of the sample. This is why for ceramics and lithics, it is customary to collect a sediment sample from adjacent to the sample. Assuming this sediment is representative of the radioactivity surrounding the sample, the gamma dose rate can be measured from it. Ideally one should choose sample locations where the radioactive environment is not too complex, so that this assumption holds. Samples from deposits that are homogeneous in composition will have the least ambiguity in determining the external dose rate. If complex environments cannot be avoided, consideration of how the external dose rate will be determined is necessary. Additional samples may need to be collected or on site dosimetry measurements may be advisable. In all cases, consultation with the luminescence specialist before collection is recommended. (Because the radioactivity of the sample itself also needs to be measured, it is important not to alter the composition in any way. Adding glue or other substances to repair or label ceramics, for examples, should be avoided.

The third guideline is to select samples that have a high probability of having been zeroed at the time of interest. Again ceramics are usually not a problem, although specimens that are particularly soft, indicating very low firing temperatures, should be avoided. For lithics, choose samples that have clear evidence of heat damage. Sediments are more problematic and consultation with geologists about how they were deposited is advised. Aeolian deposits are usually well exposed to sunlight during deposition. Fluvial deposits can be problematic since water attenuates shorter wavelengths of light and high sediment load can further reduce light penetration. Colluvial sediments may also be problematic, depending on the mode of deposition. Even where bleaching is not complete, however, single-grain dating may allow isolation of those grains that were well-exposed.

The fourth guideline is the collection of sufficient sample. Ceramics should be at least 3 cm in diameter and 5 mm thick. In this case, bigger is better. Lithics should be somewhat larger to allow for difficulties in preparation. Samples for measuring radioactivity need only be about 100 g. Sediment samples for dating need to be about 400 g, depending on the grain-size distribution.

A final requirement is to provide the dating specialists with full provenience information on the sample, including latitude, longitude, altitude, depth of burial, stratigraphic relationships, sediment textures, and observations about moisture content. A profile map or photograph of sample contexts is useful.

CHAPTER 13
INTRODUCTION TO THE LAND CONVEYANCE AND TRANSFER EXCAVATIONS

Bradley J. Vierra

Although the Pajarito Plateau has witnessed almost 100 years of archaeological research, very little of this work has been published in synthetic volumes. Most notable of the published reports is the work of Hewett and Wilson at the large Classic period sites of Otowi and Tsirege (Hewett 1906, 1938; Wilson 1916a, 1918b). In the 1950s to 1970s, there was a resurgence in the excavation of sites on the Pajarito Plateau. Worman, Steen, and the Los Alamos Archaeological Society were responsible for this increase, but little of it has been fully published (see Fretwell 1954, 1959; Maxon 1969; Poore 1981; Steen 1974, 1977, 1982; Worman 1967; Worman and Steen 1978; and Young 1954 for exceptions). More recently, three major survey projects have been conducted on the Pajarito Plateau. The Pajarito Archaeological Research Project (PARP) (Hill and Trierweiler 1986; Hill et al. 1996), the Bandelier Archaeological Survey (BAS) (Powers and Orcutt 1999b), and the Land Conveyance and Transfer Project (Hoagland et al. 2000). In the latter two cases, detailed reports presenting the results of these surveys were completed. Reports were also done for small-scale excavations conducted by Washington State University in conjunction with the BAS Project (Kohler 1989, 1990; Kohler and Linse 1993; Kohler and Root 1992b). For the PARP, however, only a series of theses and dissertations and a single summary article were written. All of this underscores the general lack of data currently available regarding the archaeology of the Pajarito Plateau. Nonetheless, three synthetic volumes have recently been produced that provide archaeological overviews of the Pajarito Plateau (Kohler 2004; Powers 2005; Vierra and Schmidt 2006).

This chapter provides a detailed review of the project field and laboratory methods. The results of the site excavations are presented in a series of descriptions for the White Rock, Airport, and Rendija Canyon tracts in Volume 2. As such, it represents the largest archaeological excavation dataset for the Pajarito Plateau.

FIELD METHODS

Geomorphic evaluations were conducted at each tract by Steve Reneau and Paul Drakos to assess the geomorphic context and integrity of the sites (see Volume 3, Chapter 57). Their assessments included a review of the previous geomorphic studies done in the project area, as well as digging a series of shovel test holes in various locations throughout the tracts. One- by one-m soil test pits were also hand excavated at each of the archaeological sites to identify the natural geomorphic sequence.

Geophysical studies using ground-penetrating radar (GPR) were also conducted at a select sample of sites to identify the presence of subsurface features (e.g., see Conyers and Goodman 1997). The GPR survey was conducted by Jennifer Nisengard, Kimberly Henderson, and John Isaacson and the results were interpreted primarily by Henderson (see Volume 3, Chapter 70).

The use of this technique was often limited by surface vegetation that obscured buried features, but did provide useful information in some cases.

Fieldwork began with a field assessment of each site. The crew initially walked over the site area and delineated the site boundaries and identified the presence of artifact concentrations and features. A central site datum and baselines for a 1- by 1-m grid system were established. The baselines were oriented to magnetic north, with the exception of LA 85859, LA 85464, and all of the tested sites, which were oriented to true north. The datum was located at the 100N/100E grid point with an elevation of 10.0 m. The intersection of the southwest corner of each grid determined its grid coordinates. Site elevation worked the same as topographic elevation (i.e., increasing with elevation). Site maps included a detailed topographic map. These maps contained topographic features, the site datum, surface collected areas, excavation units, the relationship of the site and features to other natural and cultural features, activity areas, site and provenience boundaries, and in some cases, point-provenienced artifacts. Each map was documented with a legend, site number, scale, north arrow, names of the recorders, and the date the map was drawn. Controlled surface collections were conducted and all materials were bagged separately by individual grid unit.

Site excavation involved the hand excavation of grid units. This technique was used to define the extent, depth, and character of subsurface deposits. Excavations were carried out by natural stratigraphic layer, or in cases where the stratum was greater than 10 cm in thickness, in arbitrary 10-cm levels. A stratum was defined as a distinct depositional unit. Descriptions for strata included soil kind, texture, compactness, and color (Munsell soil chart). Excavation units were profiled. Features were recorded in three dimensions when appropriate and included a cross-section with feature descriptions, including information on measurements, nature of the fill, stratigraphic context, construction data, and the relationship to other features. With the exception of pollen, soil, and macrobotanical samples, all hand-excavated materials were screened through 1/8-in. mesh. The only exception was the three tipi rings at LA 85869; the soil matrix in these features was sieved through 1/16-in. mesh.

A daily log was maintained by each crew chief. These notes included summary information on daily activities and preliminary interpretations of site excavations. A series of recording forms were designed to document the expected variability at the sites, including a field specimen catalog, instrument mapping form, stratigraphy form, grid excavation form, sample log, feature form, room floor form, room summary form, photographic log, auger form, and burial form.

All samples suitable for dating (e.g., radiocarbon, archaeomagnetic, or obsidian hydration), pollen analysis, and macrobotanical analysis were recovered during fieldwork, and later selected for analysis on the basis of their potential to answer specific research questions. A catalog of all samples (sample log) was maintained throughout the project. Pollen and flotation samples were taken from each cultural stratum and feature. A trowel cleaned with distilled water and dried with a sterile laboratory wipe was used to take each pollen sample. Approximately one cup of sediment was collected and placed within a whirly-pac. Flotation samples consisted of two liters of sediment placed within a set of paper bags.

The sites, and the components that make up the sites, were photographed with a digital camera and black-and-white film. These photographs served as records of each excavation unit and feature and as evidence of disturbance. Primary documentation photographs contained a scale and north arrow. A photographic log was used to record all exposures, including photograph number, subject and provenience, direction of photograph, photographer, and date.

Human remains were encountered during site excavations. A comprehensive agreement between the United States Department of Energy, National Nuclear Security Administration, Los Alamos Site Office, and San Ildefonso Pueblo in compliance with the Regulations of the Native American Graves Protection and Repatriation Act (NAGPRA) Title 43, Part 10, Subpart A was implemented before initiation of the project. This agreement outlined our field excavation, laboratory analysis, temporary storage, and final disposition procedures for the remains, associated funerary objects, sacred objects, and objects of cultural patrimony defined by NAGPRA and in consultation with San Ildefonso Pueblo. This agreement was also reviewed by Santa Clara Pueblo. Monitors from San Ildefonso Pueblo were present during the White Rock and Airport Tract excavations, with monitors from San Ildefonso and Santa Clara Pueblos being present during the excavations in the Rendija Tract. These monitors were responsible for observing the excavations, identifying any sacred objects, and reviewing the treatment of human remains.

SITE TYPES

Artifact Scatters

Artifact scatters consisted of Archaic lithic scatters or Ceramic period lithic and ceramic scatters. The surface areas of the sites were collected in 1- by 1-m grid units and the artifact distributions and features were identified. The surface artifact data were used to produce artifact density maps using Surfer Ver. 7.0. These maps are located in the individual chapters. Block excavations focused on the areas containing features and/or artifact concentrations (i.e., possible activity areas). Systematic augering and isolated 1- by 1-m test pits were also placed in other portions of the site to determine the nature and extent of subsurface deposits. Given the general lack of features on these sites, obsidian hydration dating was used when appropriate to develop a baseline for differentiating possible Archaic and Ceramic period sites and multiple site occupations. However, the Cerro Grande fire likely affected some of the surface materials present on the Rendija Canyon sites.

Roomblocks

Three Coalition period linear roomblocks were excavated. LA 86534 appeared to be disturbed, with a few rock alignments and a sparse surface artifact scatter. Initial excavations confirmed the partially disturbed nature of the site, but test pits identified the presence of an intact roomblock and kiva. There were no surface indications of a kiva, and the GPR study failed to identify the buried features because of the vegetation cover. LA 12587 also contained several areas of masonry blocks that may have represented a small roomblock. Excavations determined that the site was a multi-component site and included a fieldhouse and two separate roomblocks. In contrast, LA 135290 consisted of a single linear-shaped mound that was in good condition. Excavations revealed the presence of an intact roomblock within the mound.

A basic stratigraphic sequence was identified during previous excavations conducted at Coalition period pueblos at Los Alamos National Laboratory. This sequence includes four major stratigraphic units at a typical roomblock site. From top to bottom these layers include 1) a recent surface soil, 2) a cap of rubble debris, 3) post-occupational fill that may or may not include some roofing material, and 4) interior room floor surfaces. Like the artifact scatters, surface collections were conducted in the site area, including the rubble mound, areas peripheral to the mound, and middens.

Isolated features and artifact concentrations were also identified during this process. Middens were lacking at LA 86534 and LA 135290, but were characterized by a concentration of artifacts located east of the roomblock at LA 12587. Excavations at the roomblocks began by defining wall alignments. Preliminary north-south trenches were excavated across the rubble areas to define wall alignments and the nature of subsurface deposits. Excavations continued by exposing the top of the wall alignments, until the outline of the roomblock was defined. Once the outline was defined, a map was made and individual rooms were designated by a sequential series of numbers (i.e., 1-n). Stratigraphic profiles were drawn and room fill was removed in natural layers. Each interior room floor was mapped. Maps included the location of features, samples, and all artifacts lying directly on the floor. Pollen samples were taken from underneath artifacts lying on the floor, features, and other locations where the context might preserve these remains. After all the floor artifacts were removed, samples taken, and the features excavated, a single subfloor test pit was excavated to identify the presence of any earlier floors or features.

Block excavations or a series of test pits were also excavated in the plaza areas surrounding the roomblocks. It was hoped that GPR studies would identify the presence of any subsurface features (e.g., kivas) located in this area, but the kiva at LA 86534 was identified by backhoe trenching across the plaza area to the east of the roomblock. The single kiva was excavated using the same method as those employed during the excavation of the roomblocks. Particular attention was also paid to identifying plaza features and activity areas. A midden was identified only at LA 12587 and a systematic set of test pits were hand excavated as were a series of backhoe trenches in the midden area. Care was taken to identify and remove individual strata to isolate a complete stratigraphic sequence. Lastly, small block excavations were also conducted around other features identified at the site. These excavations included possible agricultural features at LA 12587 and rock alignments in the plaza at LA 135290.

Fieldhouses

Possible fieldhouses consist of one- to three-room structures. These small structures were excavated using the same techniques discussed for the roomblocks. In addition, limited excavations were conducted around the periphery of the structure to identify the presence of any exterior occupational surfaces, features, and activity areas. The limited excavations consisted primarily of a single row of 1- by 1-m units located adjacent to the north, west, and south sides of the fieldhouses; however, a larger block excavation was also excavated to the east of the fieldhouses since this is typically where midden deposits and activity areas are located. This excavation strategy was very successful in identifying the presence of exterior features and artifact scatters within the eastern sections of the site.

Agricultural Sites

Three agricultural sites were excavated, including two grid gardens (LA 128803 and LA 139418) and a possible check dam (LA 128804). Block excavations were conducted at the grid garden site to identify the construction techniques used for the feature. This approach included exposing rock alignments and excavating a cross-section through a series of grids that enabled the identification of the stratigraphic sequence present. Previous pollen studies in the area indicate that the surface of these ancient fields is relatively close to the modern surface. Samples taken from 0 to 20 cm below the surface yielded most of the cultigen pollen in one study (Smith 1997:7), whereas samples taken from deeper contexts within a B horizon yielded poor results (G. Dean 1989a, 1991, 1994). Pollen samples were therefore taken from the exposed stratigraphic column, including post-occupational fill, grid garden fill, and pre-occupational fill. In addition, samples were also taken from the exposed profile continuing outside and adjacent to the grid garden feature.

A trench was excavated perpendicular to the axis of the check dam, above and below the rock wall. The exposed stratigraphic sequence was documented, and a column pollen and flotation samples taken from above and below the rock wall.

Athabaskan Sites

Two possible Athabaskan sites were excavated in Rendija Canyon (LA 85864 and LA 85869). A metal detector survey was conducted by Charles Haecker to locate all metal artifacts at the site, including those immediately below the surface. Test pits were excavated within the rock rings at both of these sites (Peterson and Nightengale 1993). At LA 85864, a possible hearth consisting of a burned area was identified at a depth of 16 cm below the current surface. A radiocarbon date obtained from charcoal in this feature yielded a date of AD 130±60 BP, reflecting a 19th century occupation. A pit excavated within the rock ring at LA 85869 also exposed a burned area 5 to 15 cm below the surface that may have been the remains of an unprepared hearth. As a result, excavations focused on the areas in and around the rock rings, which included relocating and expanding the previous excavations. In addition, the area immediately surrounding the rings was excavated to identify any exterior features or activity areas.

Homestead Era Sites

A single Homestead era site (LA 85407) with a cabin and multiple features was excavated in Rendija Canyon. The site consisted of several features, including the remnants of a log cabin, an horno, remnants of a small log structure, a corral, and two trash areas. Most of the wooden structures were burned during the Cerro Grande fire, and only a few pieces of the cabin, structure, and corral remained at the time of excavation. Several wood fence posts also remained along the periphery of the site. Test excavations were conducted by Peterson and Nightengale (1993) in the area of the horno and a rock alignment. Burned portions of the horno were exposed, but no cultural materials were identified around the rock alignment. As a result, excavations at the site focused on the area of the cabin, the small structure, the corral, and the horno, and both trash areas were collected. Tree-ring samples were also taken from the remaining sections of the cabin and corral, and samples had previously been collected during the post-Cerro Grande fire assessment of the site (Nisengard et al. 2002; also Towner, Volume 1).

An historic log corral (LA 70026) had been recorded in Cabra Canyon, which drains into Rendija Canyon. This area was severely burned during the Cerro Grande fire and the wooden portions of the corral were totally destroyed. The site, therefore, could not be relocated and no further work was conducted.

A small section of a Homestead era wagon road (LA 86553) runs across the floor of Rendija Canyon, west of the Serna Homestead. The road segment could not be relocated during the post-Cerro Grande fire assessment. The area was severely burned and the fire appears to have obliterated any obvious surface evidence of the road. As a result, no further work was conducted at the site.

LABORATORY METHODS

After excavation, artifacts were washed, sorted, and rebagged following the Laboratory of Anthropology curation guidelines. These guidelines included providing provenience information on curation quality paper within each bag and using ziploc bags that are 4-mil thick. The field specimen (FS) catalog was cross-checked with the bags and entered into a Microsoft Excel database. The catalog included the following fields: site number, FS number, room number, feature number, grid coordinates, starting and ending elevations, stratum, level, date, recorder, and contents. The contents field consisted of lithics, ceramics, ground stone, bone, metal, glass, botanical, flotation, pollen, dendrological sample, or other (described in the field). Each bag was given an individual FS number, and the number of items within each bag was noted in the catalog.

Flotation samples were processed using the standard decant flotation system as described by Hammett and McBride (1993). Each sample was poured into a bucket of water, agitated gently until the botanical material floated to the surface, and then decanted onto a clean piece of chiffon material to dry. This botanical material is referred to as the light flotation (or fraction). The residue at the bottom of the bucket (called the heavy flotation or fraction) was rinsed to eliminate the soil matrix, dried, and examined to recover lithic and bone material. A soil processing form was filled out and included information on site number, FS number(s), total bags in flotation, volume of processed soil, weight of light flotation, weight of heavy flotation, and notes. Pollen washes were done on a few artifacts collected in the field, including ground stone artifacts such as manos and metates.

Table 13.1 presents the labels used on site maps and profiles in this volume. This primarily relates to the distribution of artifacts and samples in floor contexts, but can also be found in other illustrations and in the text. The number following the artifact/sample refers to its specific field specimen number.

Table 13.1. Artifact and sample abbreviations.

Artifact/Sample	Abbreviation
Ceramic sherd	C
Core	Core
Faunal element	Bone
Field specimen number	FS#

LAND TRACTS

White Rock Tract (A-19)

The White Rock Tract (A-19) contains approximately 40 ha (100 ac) that range in elevation from 2133 to 2186 m (6400 to 6560 ft). The eastern tip of Mesita del Buey is located in the west-central portion of the tract. The remaining tract area is situated within the Cañada del Buey floodplain or along the slope that forms the northern edge of the canyon. Approximately 20 percent of the tract has been disturbed by development (roadway, electrical substation, power lines, pump station, and visitor center). The remaining undisturbed areas of the tract are covered with vegetation associated with a piñon-juniper woodland.

Four of the archaeological sites were located in the western section of the White Rock Tract along the eastern tip of Mesita del Buey (Figure 13.1). These sites include LA 12587 (roomblock and scatter), LA 127631 (fieldhouse), LA 128804 (check dam), and LA 128805 (fieldhouse). This area of the tract is characterized by a light to medium background scatter of artifacts. Tables 13.2 and 13.3 present information on ceramic and lithic artifact types for this scatter. A total of 60 ceramic and 353 lithic artifacts were collected from the background scatter between the sites. The ceramics include a range of Coalition and Classic period types, whereas, the lithic artifacts presumably represent Archaic and Ceramic period activities.

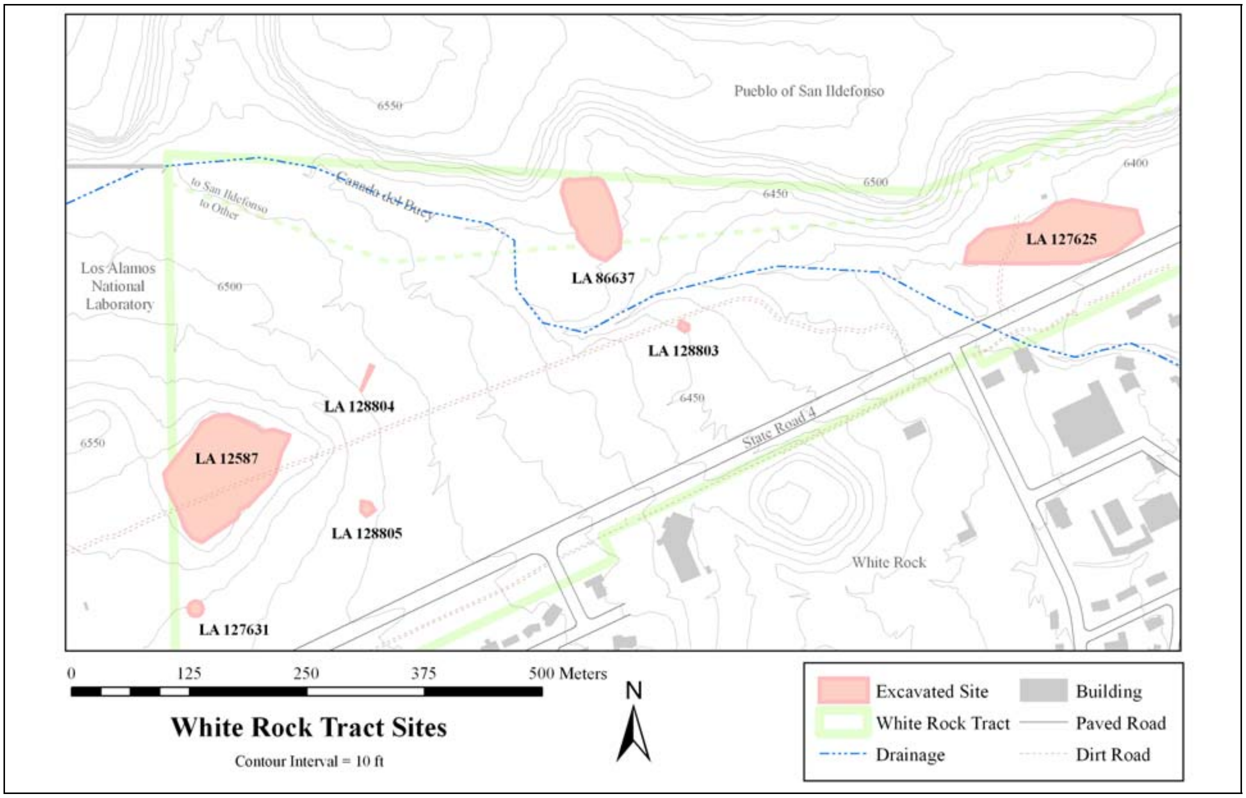

Figure 13.1. Distribution of sites within the White Rock Tract.

LA 128803 (grid garden) is situated on a slight east-trending slope and LA 86637 (artifact scatter) is situated at the southern end of a small ridge located in the central area of the tract. LA 127625 is a very light artifact scatter located in the partially disturbed area of the electrical substation at the eastern end of the tract.

Airport Tract

The Airport Tract is located near the eastern end of the mesa that is situated between Pueblo and DP Canyons to the immediate east of the Los Alamos town site. The tract ranges in elevation from 2153 to 2196 m (7060 to 7200 ft) and includes about 82 ha (205 ac). The tract includes land along both sides of State Road 502, which serves as the main entrance to the community of Los Alamos. The northeastern portion of the tract has been disturbed by construction of the Los Alamos airport, and the construction of State Road 502, parking lots, a runway, and buildings have disturbed about 40 percent of the tract. The remaining undisturbed areas of the tract are covered with vegetation associated with a piñon-juniper woodland, with lesser amounts of ponderosa pine forest.

All the archaeological sites are situated at the eastern end of the Airport Tract. LA 86534 (roomblock), LA 135290 (roomblock), and LA 141505 (fieldhouse) are located along the north side of State Road 502 (Figure 13.2), while LA 86533 (scatter) and LA 139418 (grid garden) are located along the south side of the road. LA 86534 is in the Airport-East Tract (A-3), LA 135290 and LA 141505 are in the Airport-Central Tract (A-7), and LA 86533 and LA 139418 are in the Airport-South Tract (A-5-1).

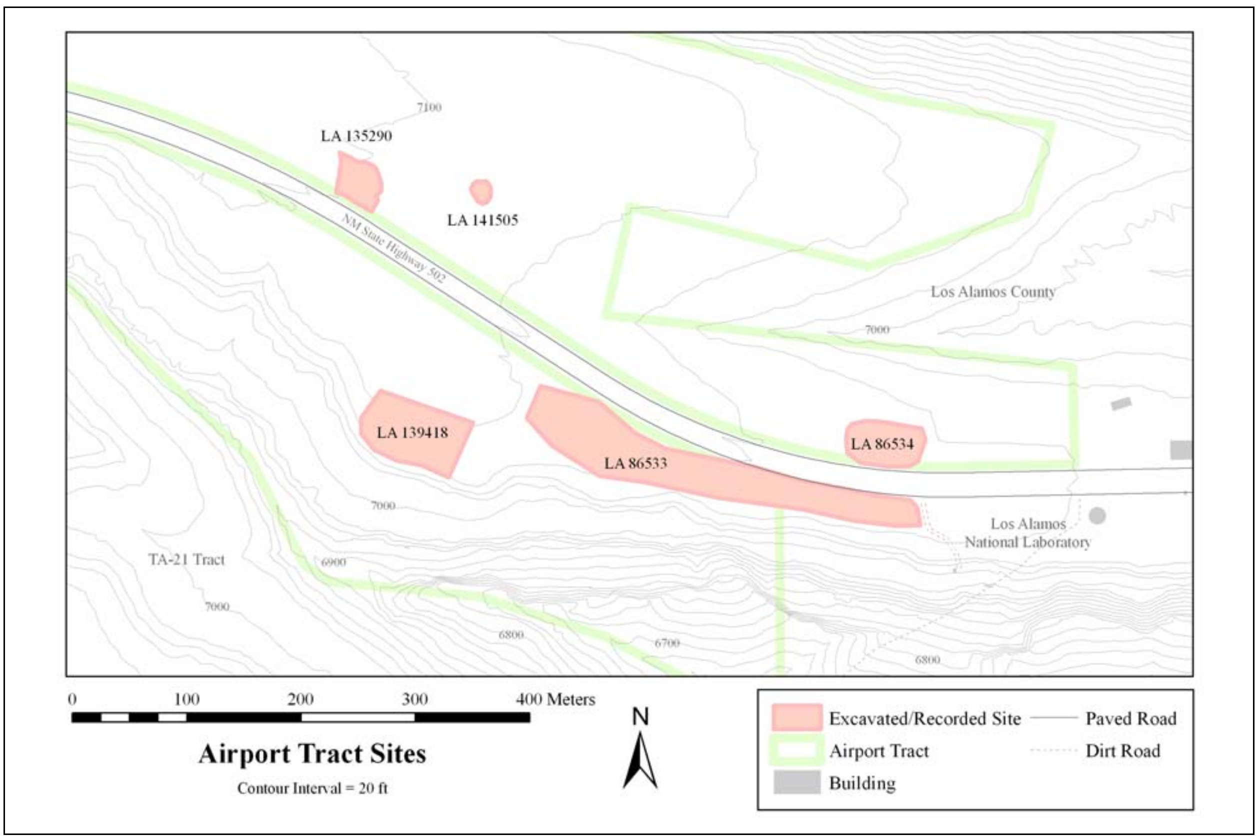

Figure 13.2. Distribution of sites within the Airport Tract.

Rendija Canyon Tract

The Rendija Canyon Tract (A-14) contains portions of Rendija and Cabra Canyons. Barranca Mesa forms the southern boundary and Guaje Mountain forms the northern boundary of Rendija Canyon. The tract is divided into canyon bottom along most of its southern section and mesa top in most of its northeastern section. Cabra Canyon is a tributary to Rendija Canyon at the northwestern end of the tract. The Rendija Canyon creek flows towards the east eventually connecting with Guaje Canyon. The tract contains about 364 ha (910 ac) that range in elevation from 2293 to 2426 m (6880 to 7280 ft). Approximately 8 ha (20 ac) of the tract have been developed by the Los Alamos Sportsman's Club. Off-road vehicle recreational activities have also disturbed a small portion of the tract on the northeastern mesa top. The canyon bottoms are primarily covered with ponderosa pine forest and the mesa top with piñon-juniper woodland.

The archaeological sites in Rendija Canyon are distributed between lowland (canyon bottom) and upland (mesa top) areas. Eleven sites are located within Rendija Canyon and three within nearby Cabra Canyon (Figure 13.3).

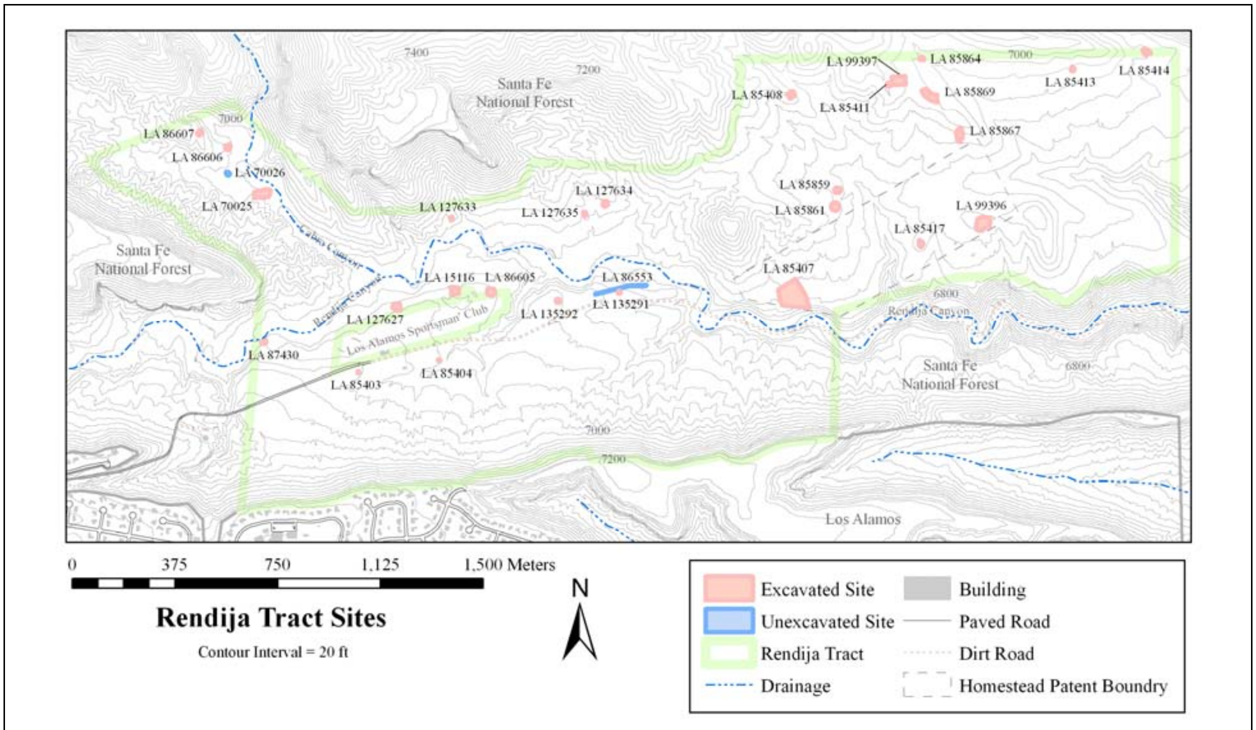

Figure 13.3. Distribution of sites within the Rendija Canyon Tract.

The remaining 13 sites are located on the mesa top in the northeastern section of the tract. The lowland sites consist of fieldhouses and a single isolated storage feature; whereas, the upland sites consist of fieldhouses, lithic scatters, Jicarilla Apache tipi rings, and the Serna Homestead site.

TA-74 and White Rock Y Tracts

The TA-74 (A-18-a) and White Rock Y (C-2) tracts are situated to the east of the Airport Tract. TA-74 contains 1100 ha (2715 ac) and the White Rock Y Tract contains 210 ha (540 ac). Together they bisect cross sections of Bayo and Barrancas Canyon, Pueblo Canyon, and Los Alamos Canyon from north to south. The area is covered with piñon-juniper woodland and contains stands of ponderosa pine. Elevations in the tracts range from 2013 to 2333 m (6040 to 7000 ft). Unlike the other tracts, the TA-74 and White Rock Y Tracts were not proposed for development by Los Alamos County. Instead, portions of the area were transferred to San Ildefonso Pueblo for historic preservation (including Otowi) and to Los Alamos County for open space. A total of 13 sites were tested to determine their eligibility for inclusion to the New Mexico State Register of Cultural Properties (Figure 13.4). More information on the preservation of these sites is provided in Masse et al. (Chapter 73, Volume 3).

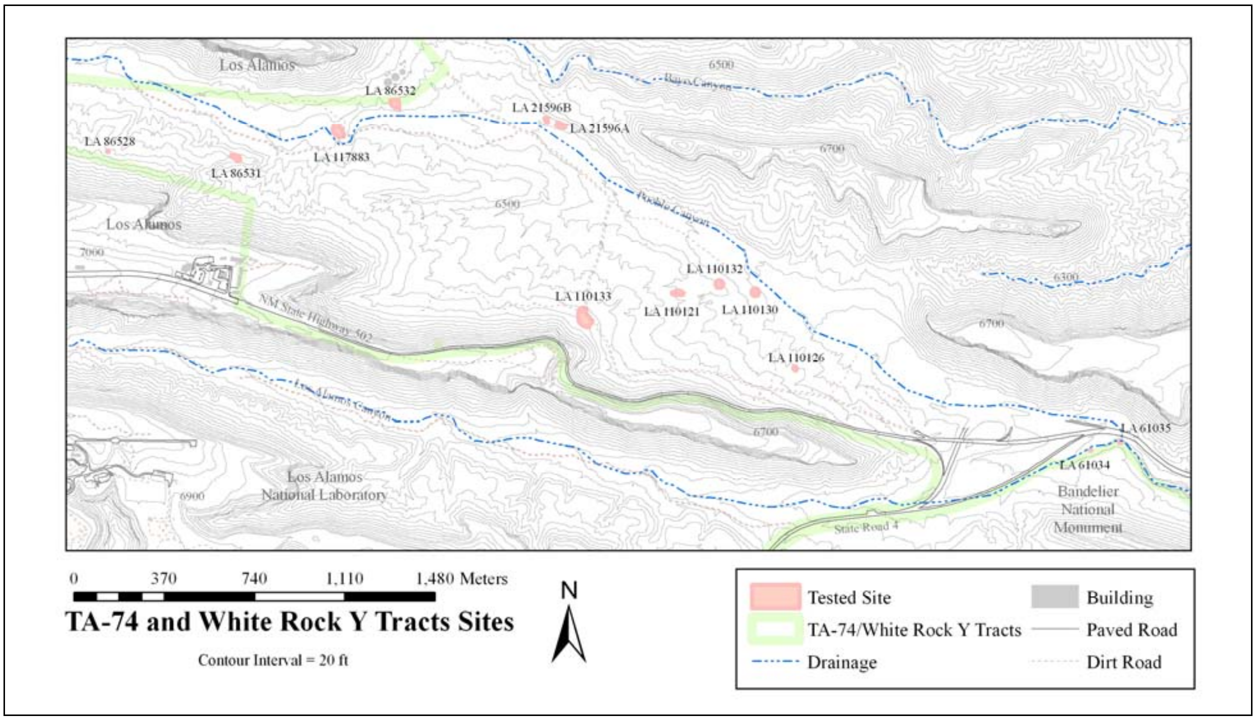

Figure 13.4. Distribution of sites within the TA-74 and White Rock Y Tracts.

PROJECT STAFF

The project would not have been completed without the hard work and commitment of its staff. Fifty individuals worked during the four-year excavation project from 2002 to 2005 (Figure 13.5; 2005 crew) and we want to thank all of them:

Project Director: Bradley Vierra

Crew Chiefs and Laboratory Directors: Sandi Copeland, Michael Dilley, Brian Harmon, Steve Hoagland, Michael Kennedy, Greg Lockard, Janet McVickar, Jennifer Nisengard, and Kari Schmidt.

Crew Members: Joseph (Woody) Aguilar, Bonnie Bagley, David Barsanti, Jennifer Boyd, Maggie Dew, Hannah Dodd (Lockard), Sam Duwe, Amy Fredericks, Truman Futch, Joaquin Gallegos, Kari Garcia, Kevin Hanselka, Mark Hungerford, Mia Jonsson, Bettina Kuru'es, Aaron Lenihan, Alan Madsen, Gerald Martinez, Bruce Masse, Ellen McGehee, Alysia McLain, Jay Nash, Karen Overton, Todd Pitezel, Rhonda Robinson, Sue Ruth, Marwin Shendo, Sherrie Sherwood, Joanne Tactikos, Chris Wenke, Jeannine Wood, Scott Worman, Marjorie Wright, and John Zarht.

San Ildefonso Pueblo Tribal Monitors: Aaron Gonzales and Timothy Martinez.

Santa Clara Pueblo Tribal Monitors: Paul Baca, Michael Chavarria, and Jeremy Yepa.

CHAPTER 14
WHITE ROCK TRACT (A-19): LA 12587

Brian C. Harmon and Janet L. McVickar

INTRODUCTION AND SITE SETTING

LA 12587 is a multi-component Puebloan and Archaic site. The earliest occupation is represented by a lithic artifact scatter dating to the Late Archaic period; this component is described by Schmidt in Chapter 15 of this volume. The components discussed in this chapter consist of a seven-room pueblo and associated midden dating to the Late Coalition period, a partially completed 13-room pueblo dating to the Late Coalition or Early Classic period, and multiple surface agricultural features, including a grid garden and a one-room structure that probably date to the Early or Middle Classic period.

LA 12587 is situated on a wide ridge at the east end of Mesita del Buey at an elevation of 1979 m (6500 ft). The ground gently slopes away from the site to the north, south, and east. To the west the mesa ridge slowly rises to the Classic period pueblo of Tsirege (LA 170); which is 760 m from LA 12587. Cañada del Buey and the steep, 70-m-tall cliff face that defines its northern boundary lie 300 m to the north. Four hundred meters to the south is the wide floodplain of Pajarito Canyon. The site is located in piñon-juniper woodland and the overstory is an equal mix of these two species. The understory consists of scattered sagebrush, prickly pear cactus, and grama grasses.

A variety of soil types occur in the vicinity of LA 12587 and include Hackroy sandy loam, Penistaja sandy loam, Prieta silt loam, Servilleta loam, and Totavi gravelly loamy sand. Outcrops of tuff and basalt are also present (Nyhan et al. 1978). Outside of the colluvial mound surrounding the roomblocks the local stratigraphy consists of up to 17 cm of A and Bw horizons. Discontinuous remnants of an eroded Pleistocene soil (a Btk horizon) up to 16 cm thick underlay the Bw horizon. The Btk horizon is underlain by bedrock consisting of the Tshirege Member of the Bandelier Tuff.

A powerline and a dirt access road traverse the southern edge of the Puebloan components, separating them from the Archaic artifact scatter.

SITE DESCRIPTION

LA 12587 consists of two roomblocks, a midden, a one-room structure, and agricultural features (Figure 14.1). The smaller, earlier roomblock (Roomblock 1) consists of seven rooms (1, 2, 4/5, 6, 7, 8, and 9): three habitation rooms in the front (east) of the roomblock, three storage rooms in the back (west), and a fourth, larger back room contiguous to the south of the storage rooms. All the rooms contain plaster floors in variable states of preservation and each front room contains a hearth.

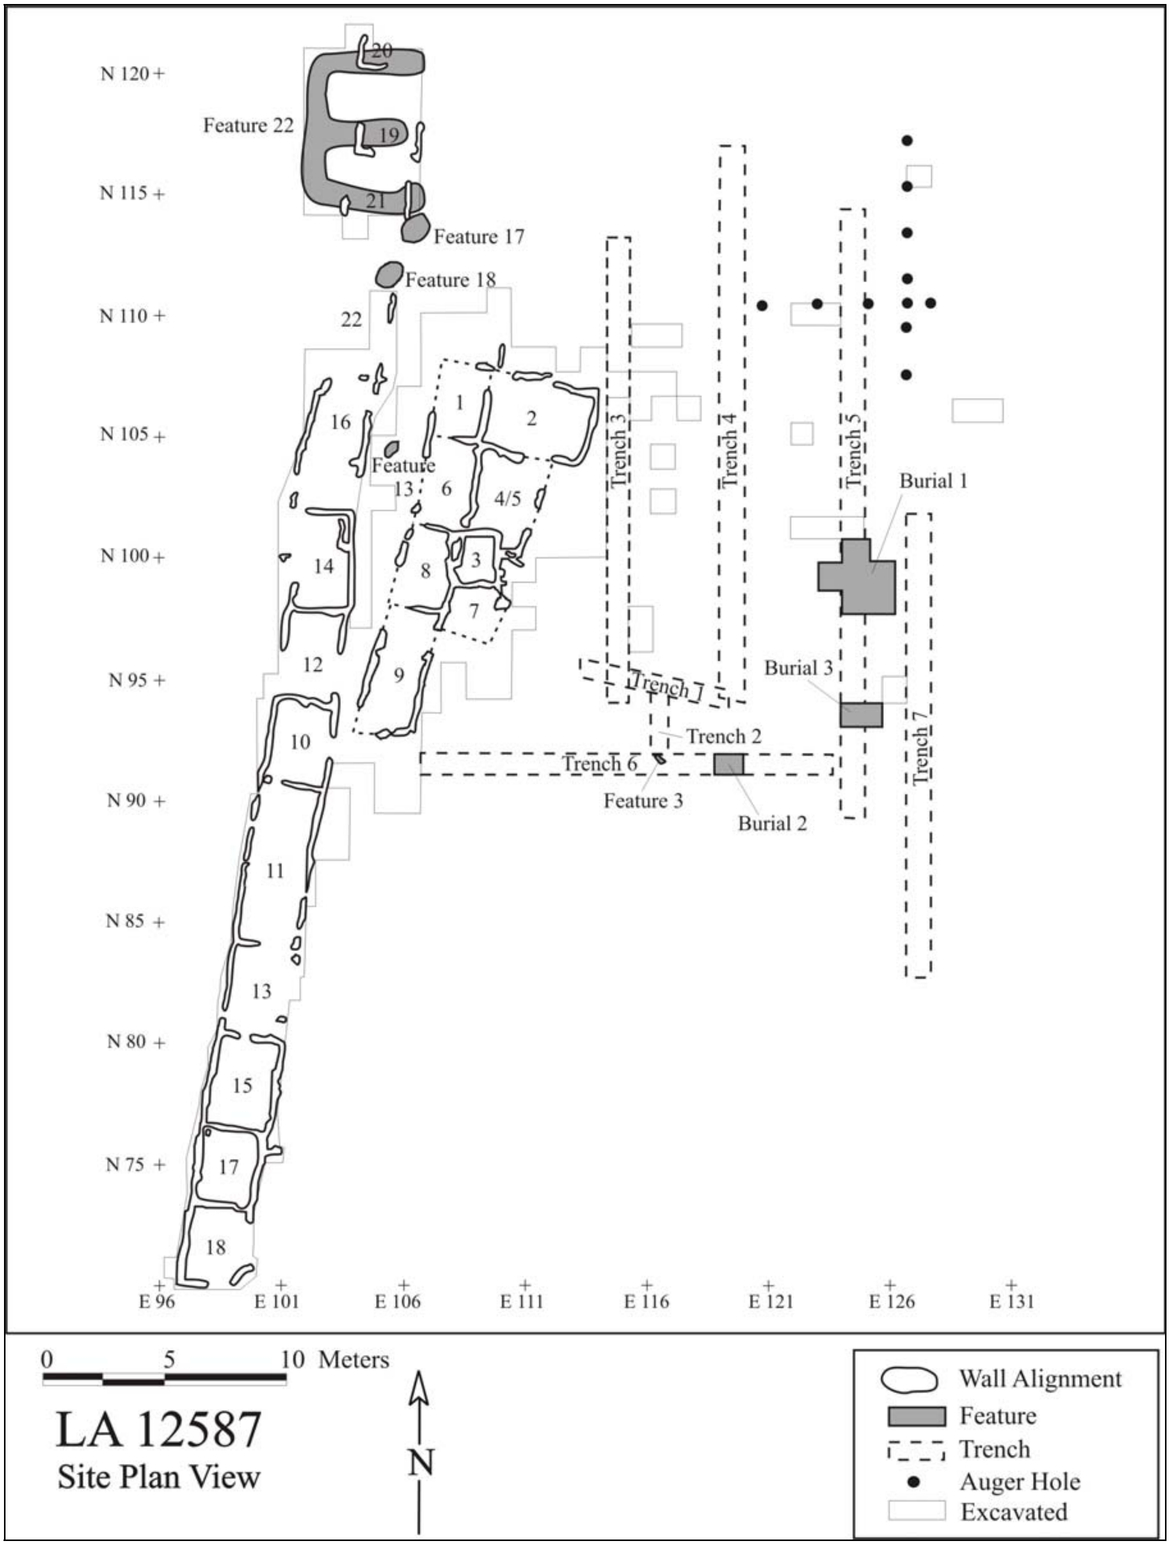

Figure 14.1. Final map of LA 12587, including excavated areas.

The roomblock measures 16 by 7 m and is oriented northeast-southwest. Superimposed over the roomblock is a one-room structure (Room 3, initially recorded as Roomblock 2) oriented north-south. An extensive midden is present to the east of Roomblock 1. Surface artifacts cover a 45- by 30-m area. Three burials were found in the midden.

Roomblock 3 is a linear, one-room-wide roomblock oriented roughly northeast-southwest and located immediately west of Roomblock 1. Thirteen rooms were identified in the 3- by 50-m roomblock. Most rooms consist only of a basal course of masonry. Very little wallfall was found, although a few rooms contained enough masonry to indicate that at least partial walls were once present. East-west-oriented rock berms overlay the three northernmost rooms of Roomblock 3. The berms are probably agricultural features and may be associated with Room 3. Additional alignments are present to the west and northeast of the roomblock complex but were not excavated.

FIELD METHODS

Work at LA 12587 began on June 5, 2002, and ended on March 6, 2003. Over the span of the field season two crews were employed. The summer crew consisted of Janet McVickar (crew chief), Brian Harmon (assistant crew chief), Joseph Aguilar, Sandi Copeland, Amy Fredericks, John (Kevin) Hanselka, Jennifer Nisengard, and Susan Ruth. Aaron Gonzales was the San Ildefonso tribal monitor. Bonnie Bagley, David Barsanti, Bettina Kuru'es, and F. Scott Worman worked at the site intermittently. The fall/winter crew consisted of Janet McVickar (crew chief), Brian Harmon (assistant crew chief), Sandi Copeland, Truman Futch, Mark Hungerford, Gregory Lockard, Jay Nash, Jennifer Nisengard, Karen Overton, and John Zahrt. Timothy Martinez was the San Ildefonso tribal monitor. Late in the season Michael Dilley, Steven Hoagland, Mia Jonsson, Michael Kennedy, W. Bruce Masse, Kari Schmidt, and Bradley Vierra assisted in the excavations. Leo Martinez operated the bobcat during surface scraping and trenching operations.

Both before, and during the course of excavation, geomorphic and ground-penetrating radar (GPR) evaluations were conducted. The project geomorphologists assessed the site's geomorphic context and integrity by digging shovel test holes around the site and by visits to the site during excavation (Drakos and Reneau, Volume 3). Five GPR surveys were conducted at the site to identify possible buried features and structures (Nisengard et al., Volume 3). These surveys suggested several possible locations for subsurface structures to the east of Roomblock 1. Excavation in these areas did not uncover any structures, and only undulations in the bedrock were found.

The 1- by 1-m grid system that was laid out on true north during the initial GPR survey was also used during excavation to facilitate data corroboration. The main site datum was designated as 100N/100E with an elevation of 10 m. Using the established grid, a 425-m^2 area was established over Roomblock 1 and 100 percent of the surface artifacts were collected by grid. A second surface collection area of 116 m^2 was located 16 m to the south. Collections were made in this area as the artifact screens were to be set up here.

After the surface collection was completed the site was divided into seven areas on the basis of specific surface manifestations (Figure 14.2)

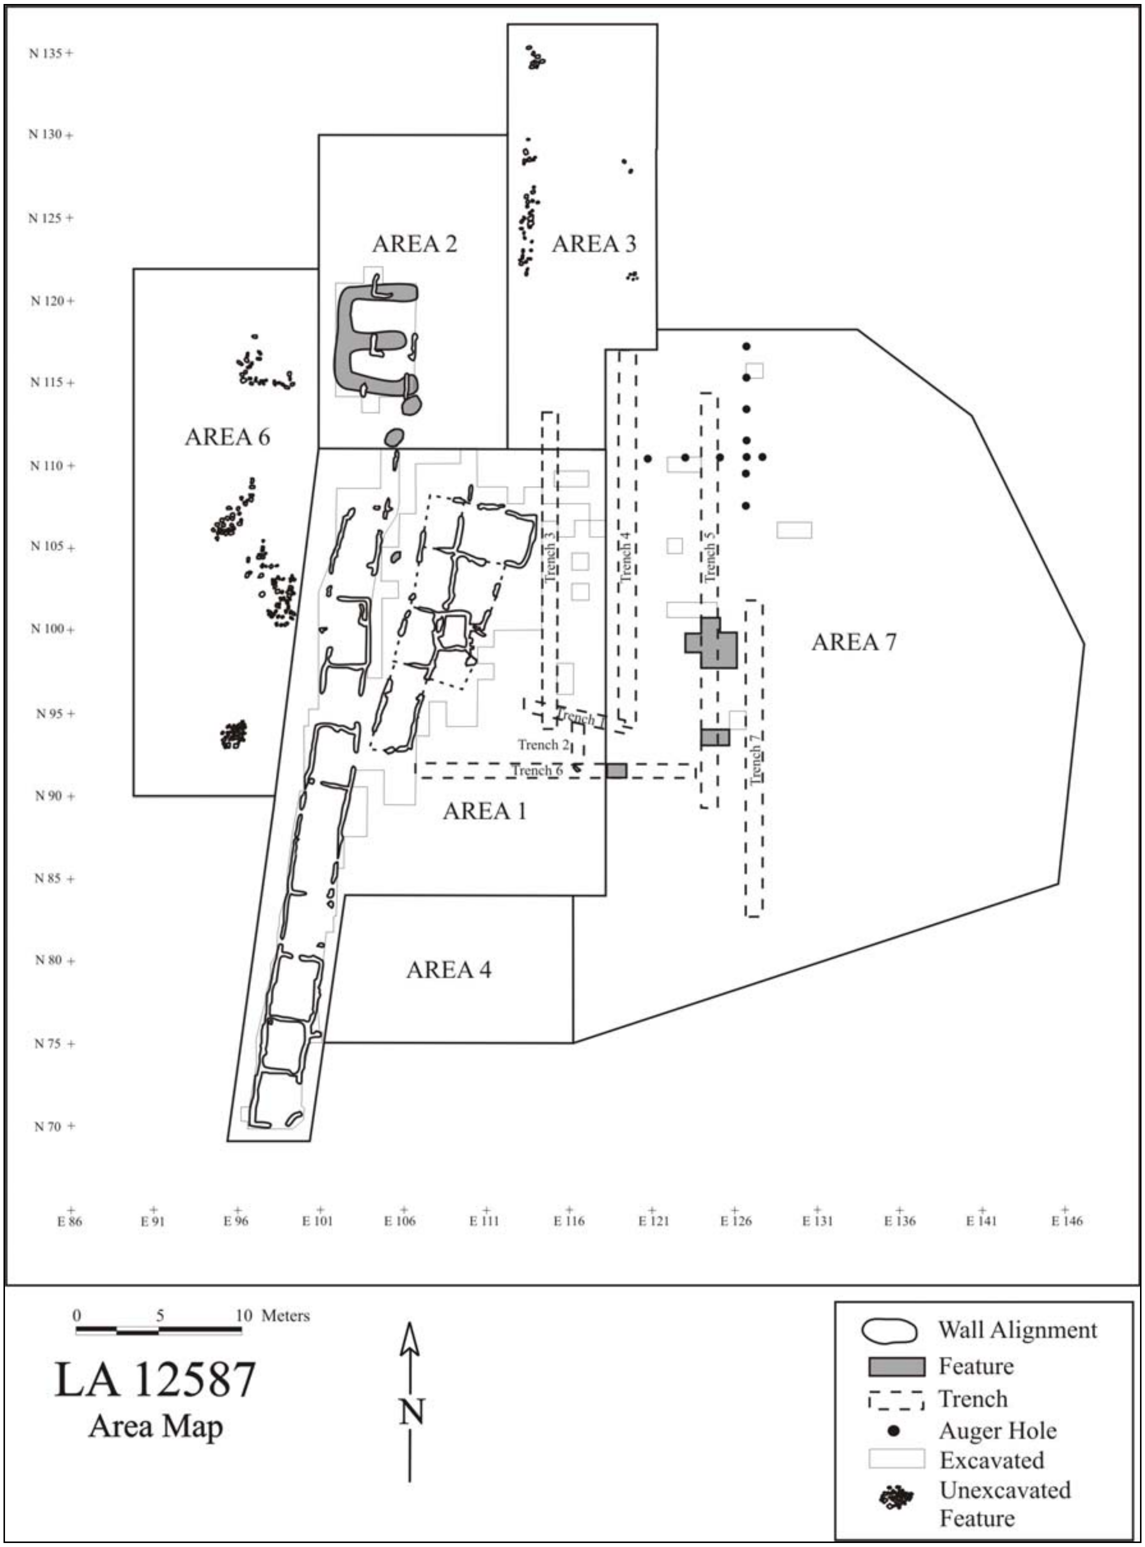

Figure 14.2. Area map of LA 12587, excluding Area 8.

Area 1 was first defined to include only Roomblock 1. It was later expanded to include Area 5 and Roomblock 3. Area 2, which is located immediately north of Area 1, includes several possible agricultural features. Area 3, which is east of Area 2, includes poorly defined alignments that may be additional structures or features. The southern surface collection area was defined as Area 4. Area 5 was originally established to include the alignments south of Area 1. This area was incorporated into Area 1 when it became evident that the alignments were part of Roomblocks 1 and 3. Area 6 lies west of Area 1 and incorporates alignments west of Roomblocks 1 and 3 thought to be additional structures. Area 7 is the midden. Area 8 is the Late Archaic lithic artifact scatter (see Chapter 15, this volume).

Excavation began by digging 1- by 1-m excavation units along the 109E line to form a north-south trench through Roomblock 1. Units were then excavated east and west of this trench to investigate exposed walls. The poor condition of the north and south walls made it difficult to identify individual rooms. For these reasons room numbers were not assigned until late in the field season.

Mechanical surface scraping south and west of Roomblock 1 resulted in the exposure of Room 9 and verified the suspicion that an additional roomblock (Roomblock 3) was present. In the course of excavation it became apparent that this roomblock was much larger than initially expected. Partial units were dug for the express purpose of exposing wall alignments. Initially this material was screened but subsequently the walls were exposed without screening. Instead of excavating entire room interiors, 1- and 2-m-wide trenches were excavated through the rooms from the east wall to the west wall to provide a representative sample of room fill.

Excavations in the midden (Area 7) were carried out with three goals in mind: to investigate possible alignments detected by the GPR, to determine if/where human burials were present, and to characterize the extent and nature of the midden. Several different excavation techniques were used to achieve these goals: auguring, hand excavation, mechanical surface scrapping, and mechanical trenching.

Possible alignments identified in the midden by the GPR were investigated by two intersecting series of auger holes. Five holes were dug every other meter along the 111N grid line, and six holes were dug every other meter along the 127E gridline. All 11 holes were dug to bedrock. No evidence for room fill or architecture was encountered during this process.

Hand excavation was used to characterize the nature of the midden. This was achieved by placing a series of 1- by 1-m units from north to south. These units are 116N/127E, 110N/122E, 110N/123E, 106N/129E, 106N/130E, 105N/122E, 101N/122E, 101N/124E, and 95N/126E. Units excavated east of Roomblock 1 that may be in the midden, but were not specifically part of the Area 7 investigations are 109N/115, 109N/116E, 107N/115E, 107N/116E, 106N/115E, 106N/117E, 104N/116E, 102N/116E, 98N/115E, and 97N/115E. A profile was drawn in units 101N/122 to 102N/124E.

Possible alignments detected by the GPR immediately southeast of Roomblock 1 were investigated by mechanical surface scraping and trenching (Trenches 1 and 2). The trenches were placed in an area thought to have the highest potential for a kiva. No evidence for room fill or architecture was encountered during this process.

Five additional trenches were excavated to ensure that Area 7 was fully investigated and that any features or burials outside the roomblocks would be encountered. Three north-south trenches (Trenches 3, 4, and 5) were placed 5 m apart. Trench 7, the farthest east and the last to be dug, was placed only 3 m from Trench 5. Trench 6 ran east-west and was placed to the south of Trenches 3 and 4. Fill from the trenches was not screened, although grab samples of cultural materials were collected in 3-m increments (excluding Trenches 1 and 2). Table 14.1 gives the locations and dimensions of the trenches. No structural features were encountered during trenching but three human burials were found. These were subsequently excavated by hand. The trenching process and excavation of the burials completed the work in Area 7.

Table 14.1. Backhoe trenches.

Trench #	Coordinates		Dimensions	
	From	To	Length (m)	Width (m)
1	95.8N/113E	95.1N/119.2E	6.6	0.80
2	92.6N/117.2E	95.4N/117.2E	2.6	0.80
3	117N/114E	97N/114E	20	0.80
4	116N/119E	98N/119E	18	0.80
5	116N/124E	98N/124E	18	0.80
6	92N/106E	92N/124E	18	0.80
7	102N/127E	83N/127E	19	0.80

Time constraints prevented the excavation of all the features present in Area 3 and Area 6, but two circular rock features (Features 17 and 18) in Area 2 were drawn in plan view, photographed, partially excavated, and sampled for pollen. Feature 18 was also drawn in profile.

SITE STRATIGRAPHY

This section is divided into two parts. The first part summarizes the geomorphic stratigraphy of LA 12587. This part is excerpted with minor modifications from Drakos and Reneau (see Volume 3). The second part summarizes the stratigraphic sequence used during excavation. For detailed discussions of the stratigraphy of specific areas or of specific strata, see the relevant parts of the Site Excavation section below.

Stratigraphy Derived from Geomorphological Examination (Paul Drakos and Steve Reneau)

The discontinuous Pleistocene soil underlying LA 12587 consists of an eroded Btk horizon (Bt horizon with Stage I carbonate). Pleistocene soil thickness in the site vicinity ranges from 0 to 16 cm. The remnant Pleistocene soil is inferred to be 100 to 200 ka or older. The Pleistocene soil at LA 12587 is a polygenetic soil in which the Bt horizon formed during the Pleistocene, and the Stage I carbonate formed later, probably during the Holocene. Evidence for the polygenetic nature of Pleistocene soils in the White Rock Tract is shown by several profiles where peds in Btk horizons exhibit translocated clay in ped interiors but are coated with carbonate.

Near the roomblocks, the Bt horizon is overlain by Bw horizons formed in eolian or reworked eolian sediment plus colluvium derived in part from Roomblock 1. In areas where the roomblocks are located close to one another, the Roomblock 3 walls are built on top of a lower Bwk or Bw horizon (typically a Bw2), which is overlain by a Bwk1 or Bw1 horizon. Upper Bw horizons are overlain by A horizons also formed in eolian or reworked eolian sediment plus colluvium derived in part from Roomblock 1. Total thickness of post-occupational soils in the vicinity of the roomblocks ranges from 10 to 54 cm. Greater sediment thickness corresponds in general to the roomblock locations, except for a mound of relatively thick sediment located immediately east and north of Roomblock 1. Outside of the colluvial mound surrounding the roomblocks, post-occupational soil thickness ranges from 0 cm on stripped bedrock surfaces east, north, and west of the roomblocks to 17 cm. The 17-cm A-Bw profile overlies a stripped Btk horizon and likely represents eolian deposition that occurred both during the Late Coalition period and that post-dates the Puebloan occupation (see below).

Roomblock 1 and Midden Deposits

Eolian or reworked eolian sediment is interpreted to largely comprise the upper soil that partially buries blocks of tuff derived from wall collapses. The upper soil also includes clasts of tuff derived from the roomblocks and a variety of ceramic and lithic artifacts, and is inferred to also contain the dissolved remnants of mortar and roofing material. The different soil components are well mixed, which indicates extensive bioturbation of the post-occupational soil by burrowing and other processes. Roomblock 1 is typically buried by 30 to 40 cm of young material that overlies the former floors and the underlying Btk horizon and Bandelier Tuff. The upper soil layers that post-date the occupation are anomalous in that Bw or Bwk horizons typically strongly effervesce, indicating the presence of $CaCO_3$; whereas, other young soils nearby do not effervesce. The reason for this is not certain. One hypothesis is that $CaCO_3$ was present in the mortar used in wall construction and that this material is weathered out of the mortar and concentrated in the post-occupation soil. A soil profile with post-occupational A-Bw horizons described in sheet trash deposits approximately 17 m east of Roomblock 1 also strongly effervesce, indicating that sediments derived from the roomblock contain significant $CaCO_3$. Sediments derived from the roomblock have been reworked east and north of the ruin, forming a colluvial apron at least 30 cm thick extending approximately 21 m east and 16 m north of the center of the roomblock.

Roomblock 3

Roomblock 3 is an Ancestral Puebloan roomblock that, based on stratigraphic relationships, is younger than Roomblock 1. In some areas, wall blocks are set on top of a lower (Bw2 or Bwk2) horizon that contains rubble and artifacts inferred to be derived from Roomblock 1. In other areas, Roomblock 3 walls are built either directly on Bandelier Tuff or on the remnant stripped Pleistocene soil. Roomblock 3 is typically buried by 20 to 30 cm of young soil that overlies the wall foundations, underlying soil horizons, and Bandelier Tuff. Post-occupation soils in Roomblock 3 also contain $CaCO_3$. There is a much smaller colluvial apron emanating from

Roomblock 3 (the 30-cm-thick deposit extends approximately 4 m east of Roomblock 3) than is associated with Roomblock 1, suggesting that Roomblock 3 walls were not built as high as were the walls forming Roomblock 1. These data support the hypothesis that Roomblock 3 was not completed.

Feature 22

A series of five soil descriptions were completed in the vicinity of Feature 22. The rock alignments of Feature 22 were constructed on top of a post-occupational Bw horizon 16 to 23 cm thick, and lie within, or are partly buried, by an A or AC horizon 9 to 15 cm thick. Shaped blocks, inferred to be part of the Roomblock 3 construction, occur within the Bw horizon and below the rock alignments.

Two profiles (12587-1 and 12587-5) were described outside and three profiles (12587-2, 12587-3, and 12587-4) were described inside the rock alignments. No textural differences were observed between profiles described inside versus outside the rock alignments. Soils described inside the rock alignments have a greater thickness (average 30 cm versus average 22 cm) than do the soils described immediately outside the rock alignments, due to generally thicker A horizons inside the rock alignments than outside the alignments. This is observed most clearly in comparing profiles 12587-2 and 12587-1, where the A or AC horizon thins from 15 cm inside to 8 cm outside the northern rock alignment. These observations indicate that the rock alignments are either acting to preferentially trap eolian or slopewash sediment, or that dirt was placed inside the alignments. The placement of dirt inside the rock alignments is suggested by the greater A horizon thickness and the absence of textural differences inside versus outside the rock alignments, and by the orientation of the alignments oblique to a slope with a relatively shallow gradient.

The presence of a 16- to 23-cm-thick Bw horizon formed in sediment composed predominantly of eolian or reworked eolian sediment underlying the agricultural rock alignments is evidence for significant eolian deposition during the Coalition (likely Late Coalition) period. Roomblock 1 was built on a stripped bedrock surface with remnant Pleistocene soils; therefore, deposition of the sediment underlying the possible agricultural rock alignments occurred subsequent to construction of Roomblock 1. Whereas eroding roomblocks provided a source for coarse colluvium, the predominantly fine-grained nature of upper Bw horizons indicates an eolian source for most of the sediment burying Roomblock 3 features. Additionally, thinner (9 to 15 cm) sediment partially buries Feature 22, indicating smaller inputs of eolian sediment or reworked eolian sediment following the last occupation. This sediment deposition could date to the latest Coalition period, the Classic period, or the Historic period.

Stratigraphic Sequence used During Excavation

Table 14.2 summarizes all the excavated strata at LA 12587. During the early stages of excavation a profusion of stratum numbers were assigned. It was subsequently determined that many of these strata represented a single depositional unit. As a result, many strata were combined and new stratum numbers were assigned. The numbers in the New Stratum Number are used throughout the text. The Old Stratum Number is included solely as a concordance to be used by researchers examining the original field notes, bags, and other provenience information.

Stratum 1 covers the entire site. It is composed of fine-grained, loose, unconsolidated brown sandy loam. The loam contains varying densities of artifacts, sparse vegetation, tuff blocks, fragmented tuff gravels, and, in some locations, tree duff. Below Stratum 1 the stratigraphy of each component varies and so will be described individually.

Roomblock 1

Most of the fill of Roomblock 1 consists of Stratum 10. With very few exceptions, wallfall and rooffall cannot be distinguished. The sediment of Stratum 10 is moderately compact brown sandy loam that is fine-grained with occasional tuff gravel inclusions. Stratum 10 contains wallfall composed of construction blocks, chinking stones, and chunks of adobe mortar. Artifacts, burned maize kernels and cob fragments, and bits of charcoal are also common, as are pieces of naturally derived tuff. Occasional lenses and pockets of charcoal staining are present in some rooms. Disturbance from roots, rodents, and insects is prevalent throughout this stratum.

Below Stratum 10, a shallow stratum was occasionally encountered within the rooms immediately above the floors (Stratum 70). This stratum is a loosely consolidated sandy loam that is 2 to 5 cm in depth and sometimes contains artifacts. Stratum 70 is interpreted as post-occupational fill that was deposited before the walls collapsed.

The uppermost floor surface across each room was given a stratum number (Strata 121, 122, 124, 126, 127, 128, and 129). Individual lower floor surfaces, floor matrices, and feature strata were also given stratum numbers. Because of the number and complexity of these strata they are not described here: full descriptions can be found in the Site Excavation section below.

Where Roomblock 1 was not built directly on bedrock it is underlain by either a Bw horizon (Stratum 170) or a Pleistocene-aged Btk horizon (Stratum 175). Because of extensive bioturbation, artifacts and charcoal are present in Stratum 175. Bedrock is the devitrified tuff unit (Qbt-1vc) of the Tshirege Member of the Bandelier Tuff. Stratum 200 was assigned to the Bw deposits immediately outside of the roomblock and below Stratum 1.

Midden

In the midden area, Stratum 1 is underlain by mixed A and B horizons, a Bw horizon, and a Bwk horizon. All of these horizons were assigned a single stratum (Stratum 60). Below Stratum 60, Stratum 175 was occasionally present. See the description of Area 7 in the Site Excavation section below for more details.

Note: The average or most common color and soil texture for a given stratum is used. For range of variability see specific proveniences.

Roomblock 3

Four general strata are associated with Roomblock 3. Stratum 1 is underlain by Stratum 201. Stratum 201 is post-occupational fill. It is similar to Stratum 10, although it contains less wallfall and considerably less adobe. Near the surface, Stratum 201 is a sandy to silty loam. Near its base the stratum begins to grade into a sandy clay loam. The base of Stratum 201 was arbitrarily determined to be the base of the walls of Roomblock 3. The underlying Stratum 208 is a Bw horizon, composed in part, of Roomblock 1 colluvium. The lower portions of Stratum 208 are probably the same as Stratum 170. In places Stratum 175 is present. Strata associated with localized deposits (e.g., ash lenses and possible living surfaces) are described in the Site Excavation section below.

Stratum 202 was assigned to the Bw deposits immediately outside of the roomblock and below Stratum 1.

Room 3 and Feature 22

The fill of Room 3 (Stratum 20) was indistinguishable from Stratum 10. It was given a separate stratum number for analytical purposes. No floor was found in Room 3.

Below Stratum 1 the A and Bw horizons of Feature 22 were assigned a single stratum (Stratum 280). Where Feature 22 was underlain by Roomblock 3, Strata 201 and 208 were assigned as appropriate.

SURFACE COLLECTION

Figure 14.3 shows the distribution of ceramic artifacts from the surface-collected areas of the site (including Area 8). The distribution of lithic artifacts and total number of artifacts is essentially the same as the distribution of ceramic artifacts. The highest artifact density is located to the north-northeast of Roomblock 1, which is the northwest corner of the midden. The artifacts in Area 4 and at the northeast end of Area 8 define the southern edge of the midden. In contrast there is a relative paucity of artifacts over Roomblock 1 itself. Figure 14.3, coupled with in-field observations, indicates that the surface distribution of midden artifacts at LA 12587 resembles that seen at other Coalition period roomblocks on the Pajarito Plateau. There is a dense C-shaped scatter of artifacts terminating at the north and south end of the pueblo. The greatest density of artifacts is found 15 to 30 m in front of the pueblo, and there are relatively few artifacts on the pueblo mound (see Harmon and Binzen 2002, Figure 5.2; Schmidt, this volume, Figure 24.10; Vierra, this volume, Figure 25.4).

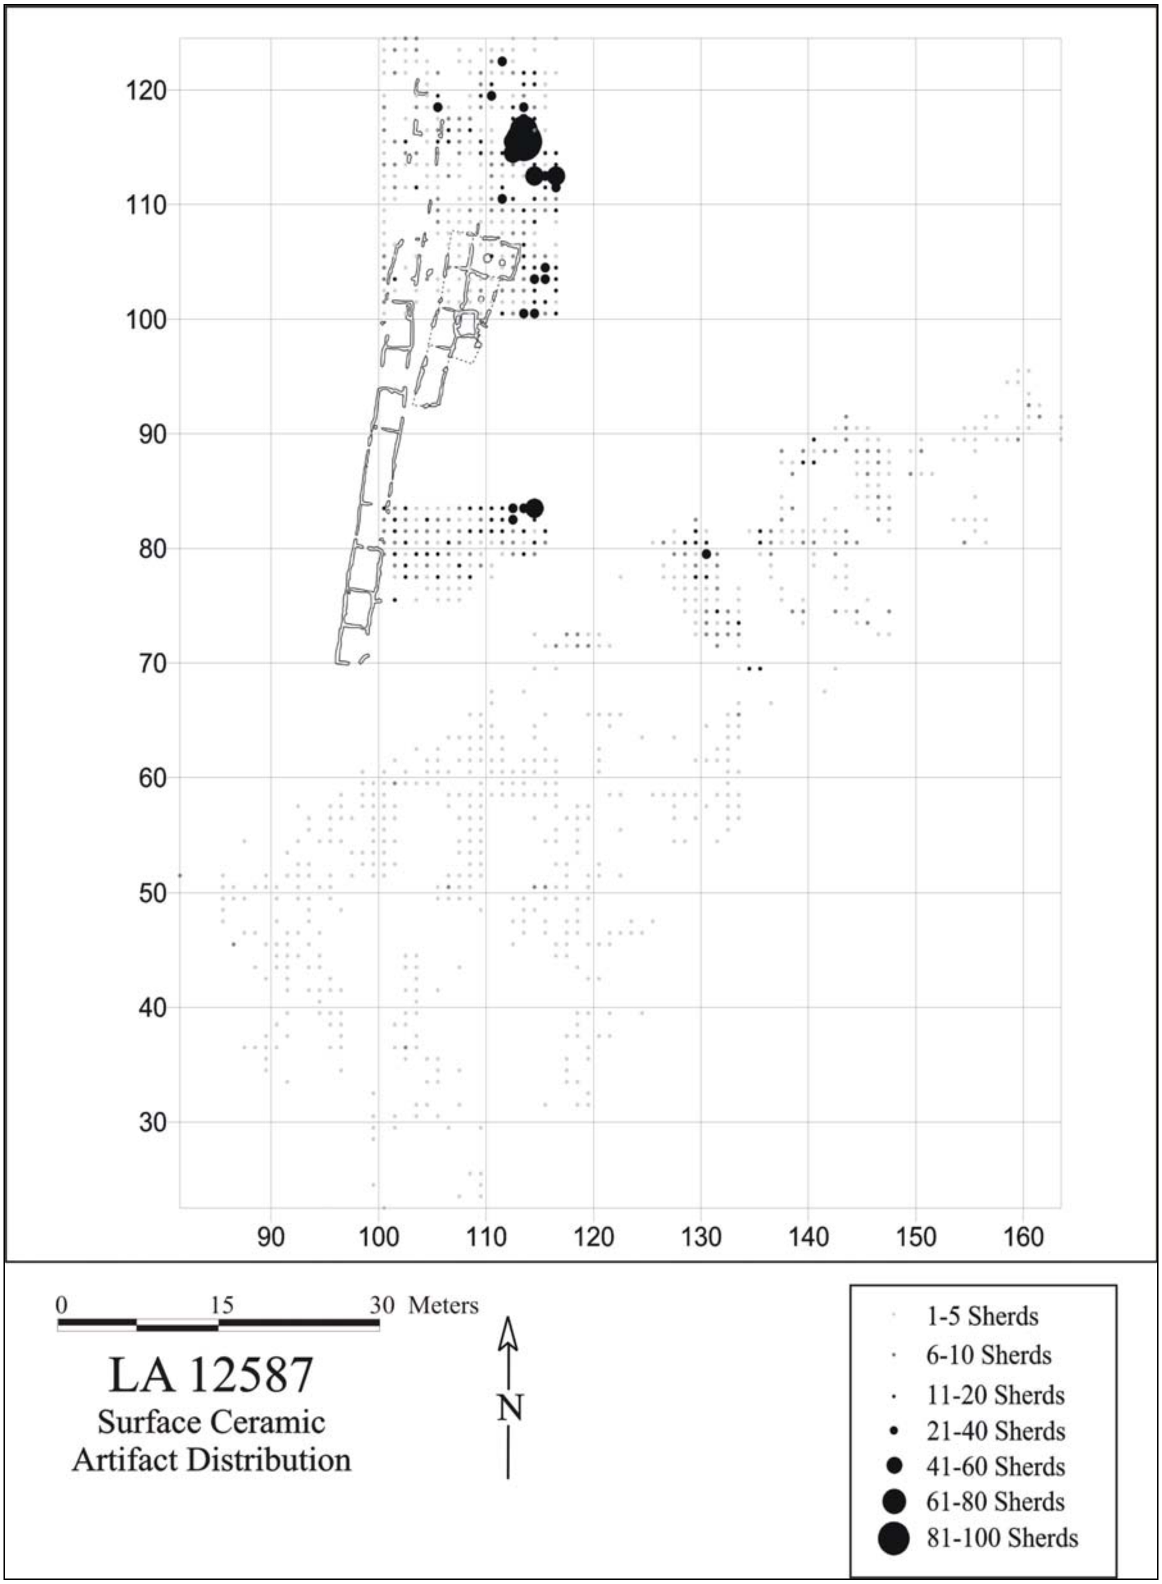

Figure 14.3. Surface distribution of ceramic artifacts (including Area 8).

SITE EXCAVATION

Area 1

Area 1 encompasses Roomblocks 1 and 3 and Room 3.

Roomblock 1

Roomblock 1 consists of two rows of rooms oriented approximately 12° east of true north. The front rooms (Rooms 2, 4/5, and 7) each contain a hearth and postholes and are interpreted as habitation rooms. An ash box and possible deflector in Room 7 may be indicative of ceremonial functions. Three of the back rooms (Rooms 1, 6, and 8) are smaller and each is paired with a front room. They are interpreted as storage rooms. A fourth back room, Room 9, is contiguous to Room 8 on the south side. The function of Room 9 is unclear, although in placement and in its lack of internal features it resembles a storage room. In floor area it resembles the front rooms. Table 14.3 shows the interior dimensions and area for each of the rooms.

Table 14.3. Room dimension summary for Roomblock 1.

Room	*Front*/Back Room	Length (m)	Width (m)	Floor Area (m^2)
1	Back	2.9	2.1	6.1
2	*Front*	*3.1*	*3.6*	*10.4*[1]
4/5	*Front*	*4.0*	*2.8*	*11.2*
6	Back	3.6	2.2	7.9
7	*Front*	*4.0*	*3.0*	*9.9 or 12.0*[2]
8	Back	3.5	2.1	7.4
9	Back	4.9	1.9	9.3

1. Room 2 is slightly L-shaped and thus its area cannot be calculated by simply multiplying length by width.
2. The exact size of Room 7 could not be determined. See the room description below.

Architecture. The rooms were constructed with shaped and unshaped tuff blocks and occasional dacite cobbles, adobe mortar, and chinking stones. One adobe block was encountered during excavation. As noted by earlier researchers (Steen 1977:43; Van Zandt 1999) roomblocks on the Pajarito Plateau often exhibit a variety of wall construction styles. Such is the case with Roomblock 1. Generally, four construction techniques were observed: wet laid coursed masonry, uncoursed upright block masonry, turtleback adobe construction, and a core and veneer construction.

Wet laid coursed masonry is constructed by horizontally laying shaped or unshaped tuff blocks onto a prepared mortar bed. Another layer of mortar is placed on top of the blocks and another course of blocks is laid horizontally onto it. These blocks are secured with additional mortar in the vertical joints. Chinking stones are inserted into both horizontal and vertical joints to prevent the mortar from cracking and to provide stability to the blocks.

The use of uncoursed upright block construction often occurs with the coursed masonry in a wall. It usually is employed for relatively short expanses and is quite variable in appearance. Generally, a thick bed of mortar is laid down and various sizes of masonry blocks and chinking stones are inserted into and on top of it. More adobe mortar is added, and additional blocks and chinking stones are added in a seemingly indiscriminate fashion. The result is a wall segment with abundant adobe interspersed with stones or irregular shapes and sizes. In Roomblock 1, segments of this construction technique terminate at large upright masonry blocks placed across the width of the wall. These cross-blocks help to stabilize the broad applications of mortar.

The third construction technique common in Roomblock 1 is the use of turtleback adobe. In this method, large blocks or slabs are secured in an upright position parallel to the length of the wall and then thick layers of adobe mortar are applied to the tops of these blocks until a relatively flat surface is achieved. This construction technique was used primarily in wall foundations; once the relatively horizontal mortar bed was achieved other techniques were used above it.

The final construction technique used was core and veneer. At LA 12587, the veneer consists of either upright tuff blocks or a thick layer of adobe and chinking stones. The core consists of sediment and rubble.

Many of the room corners of the pueblo were in poor condition, making bond/abut determinations difficult. Nevertheless, it appears that the central wall (the wall between the front and back rooms) was built first and then Rooms 1 to 8 were built off of it. Room 9 may be a later addition.

Floor construction in Roomblock 1 varied. The most common method of construction was initiated with the deposition of small tuff rocks over the irregular Bw or Btk horizon or the bedrock surface. A thick layer of adobe was placed over the rocks to create a level surface and was allowed to dry. One or more layers of plaster were then applied to the surface of the adobe and smoothed, resulting in an even floor surface. A floor surface was found in all nine rooms of Roomblock 1. Up to three floors had been constructed in the front rooms but no more than one floor was found in the back rooms. On some floors several layers of plaster had been applied, indicating the occurrence of (seasonal?) rejuvenation of the floor.

Room 1

Room 1 is located at the northwest corner of the roomblock (Figure 14.4). The interior is 6.1 m^2 (2.9 m long and 2.1 m wide) in size. Only one interior feature (Feature 2), a dacite cobble, and ash concentration were present.

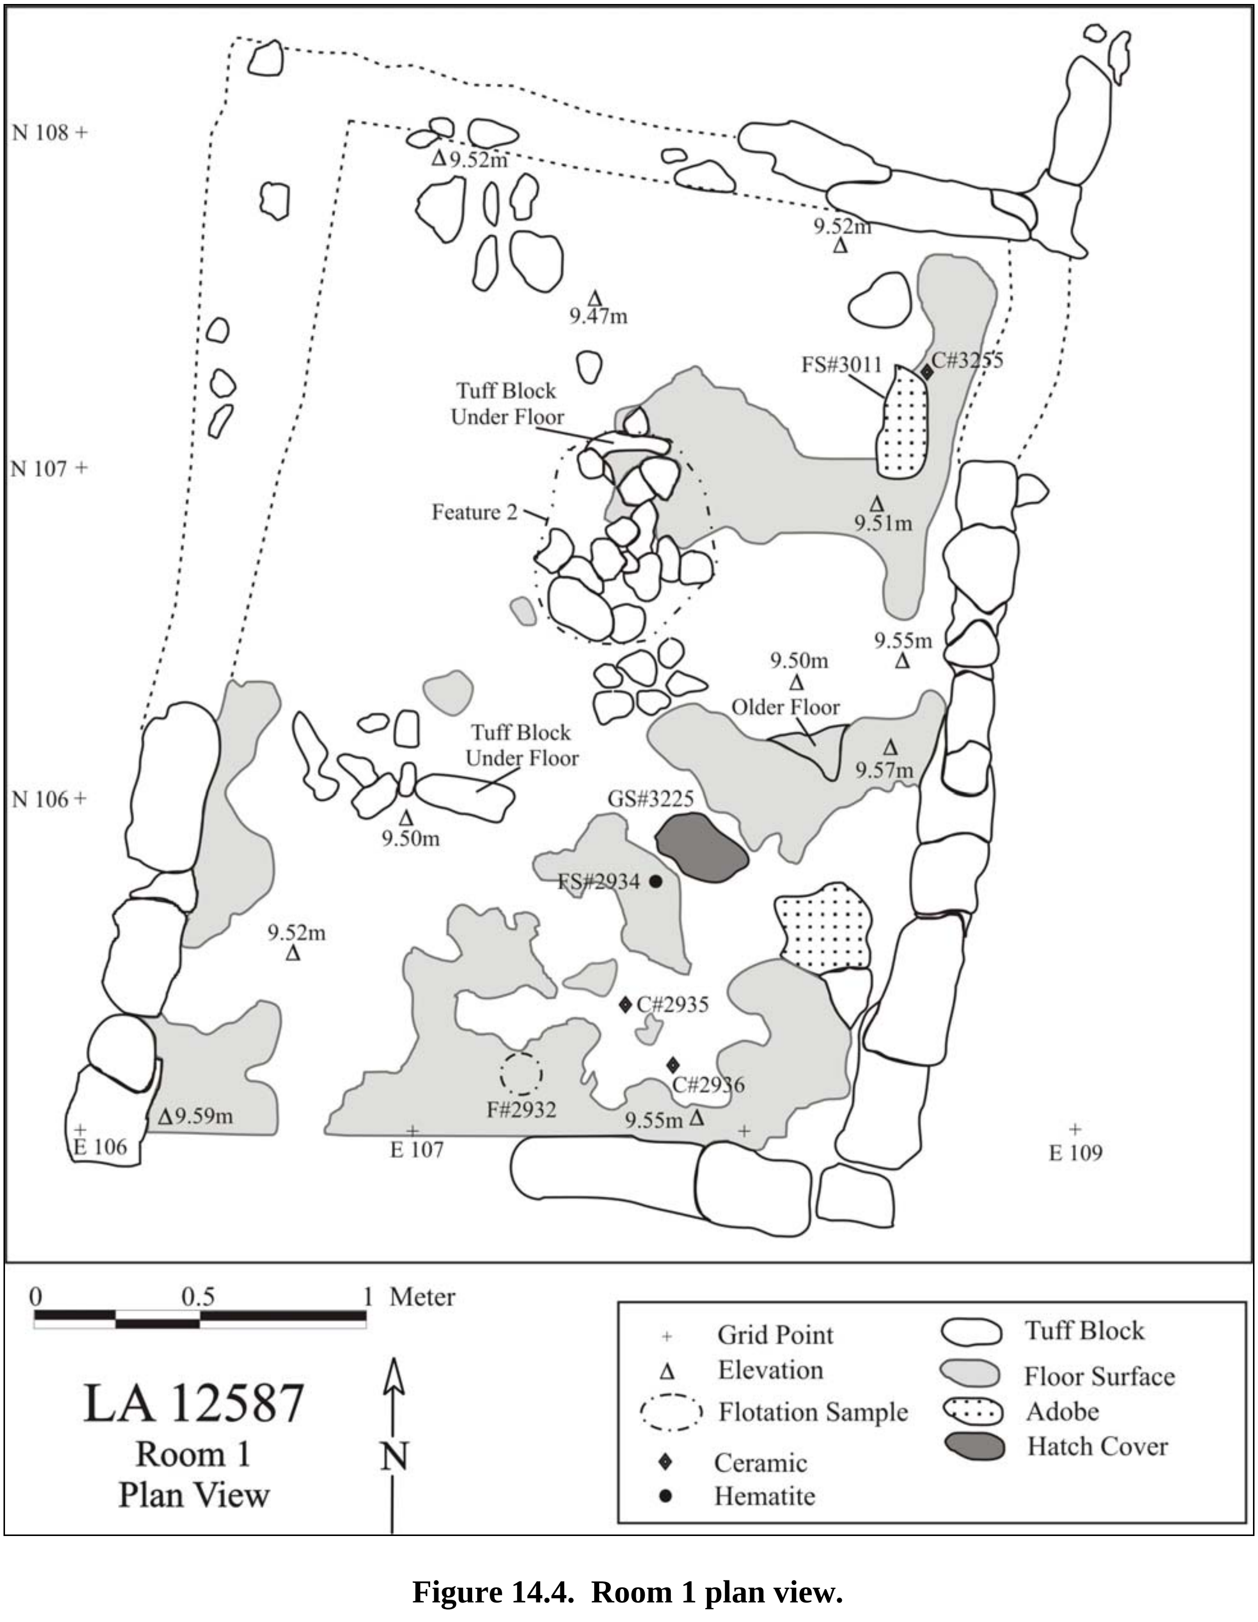

Figure 14.4. Room 1 plan view.

Stratigraphy. Table 14.4 summarizes the strata in Room 1. A large anthill, a small sagebrush, a prickly pear cactus, and pine duff were present on the surface of Room 1. The surface fill

(Stratum 1) consisted of a shallow stratum of loose, unconsolidated brown sandy loam that is present throughout the site. Tuff blocks, tuff cobbles, and artifacts were recovered from this stratum. Stratum 1 was underlain by post-occupational fill (Stratum 10), which ranged from 31 to 38 cm thick. The sediment was moderately consolidated brown sandy loam. Shaped and unshaped tuff blocks (approximately 35), chinking stones (approximately 250), chunks of adobe, and melted adobe were encountered in the room fill. No discernable rooffall or pre-structural collapse fill was observed. The room floor (Stratum 121), the sub-floor sediments (Stratum 170), and the fill of Feature 2 (Stratum 210) are described below.

Table 14.4. Room 1 stratigraphy.

Stratum	Thickness (cm)	Color	Texture	Description
0	0	10YR 4-5/3	sandy loam	Surface
1	2–5	10YR 4-5/3	sandy loam	Unconsolidated surface soil
10	31–38	10YR 4-5/3	sandy loam	Wallfall and post-occupational fill
121	0	10YR 7/1	silty clay	Floor surface
170	3–5	10YR 4/3	silt loam	Sub-floor soil
210	1–3	7.5YR 4/3	silt loam/ash	Feature 2, fill

Table 14.5 shows the artifact counts by stratum for Room 1. The "Other" category includes an adult human right talus (Field Specimen [FS] 1208), a freshwater shell fragment (FS 1012), a piece of gem-quality hematite (FS 2934), an adobe block (FS 3011), and several other miscellaneous samples. Noteworthy artifacts include a ceramic cloud blower pipe fragment (FS 1269), three pieces of turkey eggshell (FS 1175, FS 1371, and FS 1427), and two bone beads (FS 1287 and FS 1417).

Table 14.5. Room 1 artifact counts by stratum.

Stratum	Chipped Stone	Ceramics	Ground Stone	Nonhuman Bone	Other	Total
0	9	16	0	0	0	25
1	66	285	2	0	1	354
10	387	1803	27	26	6	2249
121	0	3	1	0	1	5
170	0	0	0	0	0	0
210	8	22	16	0	0	46
Total	**470**	**2129**	**46**	**26**	**8**	**2679**

Floor. Intact portions of plastered floor were present in the eastern and southeastern portions of the room. Extensive bioturbation and exposure after abandonment destroyed the remainder of the floor. Due to subsidence and rodent burrowing, the floor surface undulates and varies between elevations of 9.57 and 9.51 m. Floor plaster, which was whitish gray in color (10YR 7/1) and contained charcoal flecks, was applied over a layer of grayish brown adobe that covered soil in some places and bedrock in others. Before the adobe was laid down, irregular tuff rocks were used to fill depressions in Stratum 170 and the bedrock. In a few places the floor plaster still articulates with the interior wall plaster to form a continuous surface curving from floor to wall. In other areas there was probably never any coping between the floor plaster and the wall plaster. A small patch of floor on the east side of the room is 2 cm lower in elevation than the surrounding plaster. This difference in elevation does not appear to be the result of subsidence or bioturbation; instead, it appears that the floor was resurfaced at least once.

Three sherds were recovered from the floor surface and included a Santa Fe Black-on-white bowl sherd (FS 2935), an unidentified sherd (FS 2936), and a smeared-indented corrugated jar sherd (FS 3255). Other artifacts found on the floor included an andesite hatch cover fragment (FS 3225) and a piece of gem-quality hematite (FS 2934). An adobe brick (FS 3011) from the east wall was found on the floor in the northeast corner of the room. No pollen or macrobotanical samples were collected, but a single flotation sample (FS 2932) was collected from the floor. Taxa identified in this sample included four-wing saltbush (*Atriplex canascens*), cheno-ams (*Chenopodium/Amaranthus*), juniper (*Juniperus*), ponderosa pine (*Pinus ponderosa*), and maize (*Zea mays*).

Wall Construction. It appears that the east and west walls of the room were built first and then the north and south walls were abutted to them. Wall construction styles used in Room 1 include wet laid coursed masonry, uncoursed upright block masonry, and turtleback adobe construction.

None of the walls are complete although remnants of foundation adobe help to confirm the perimeter of the room where the walls are missing (Table 14.6). The preserved southern wall segment consists of one upright tuff block with the long axis situated parallel to the wall, two uprights that are perpendicular to the wall, and one horizontally laid tuff block on top of an adobe and cobble mass. The western wall segment consists of a single course of tuff blocks set into adobe mortar. A small amount of plaster remained on the interior of this wall. Aside from the eroded adobe foundation, the only other remnant of the north wall was a long, horizontally laid tuff block near the east end of the wall.

Table 14.6. Room 1 wall dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	0.80	0.24	0.17
East	2.20	0.44	0.26
South	2.03	0.44	0.22
West	1.19	0.19	0.25

The east wall (Figure 14.5) is one of the best-preserved walls of the roomblock. It was built with shaped and unshaped tuff blocks, adobe, and adobe bricks. The basal course consists of upright unshaped tuff blocks that were secured into the Btk horizon. The uprights were then covered with multiple layers of adobe (turtlebacks) forming a thick platform upon which the overlying course was laid. The second course consists of masonry and chinking stones set in mortar.

The gap in the north end of the east wall may have provided access to Room 2. At this location the floor slopes gradually up and over a slightly raised adobe that may be the remains of a sill. In contrast, the floor south of this section slopes up, then abruptly terminates just before it encounters the wall. Here, the interior wall plaster extends down the wall surface but, instead of forming a coping with the floor plaster, it extends below the level of the floor.

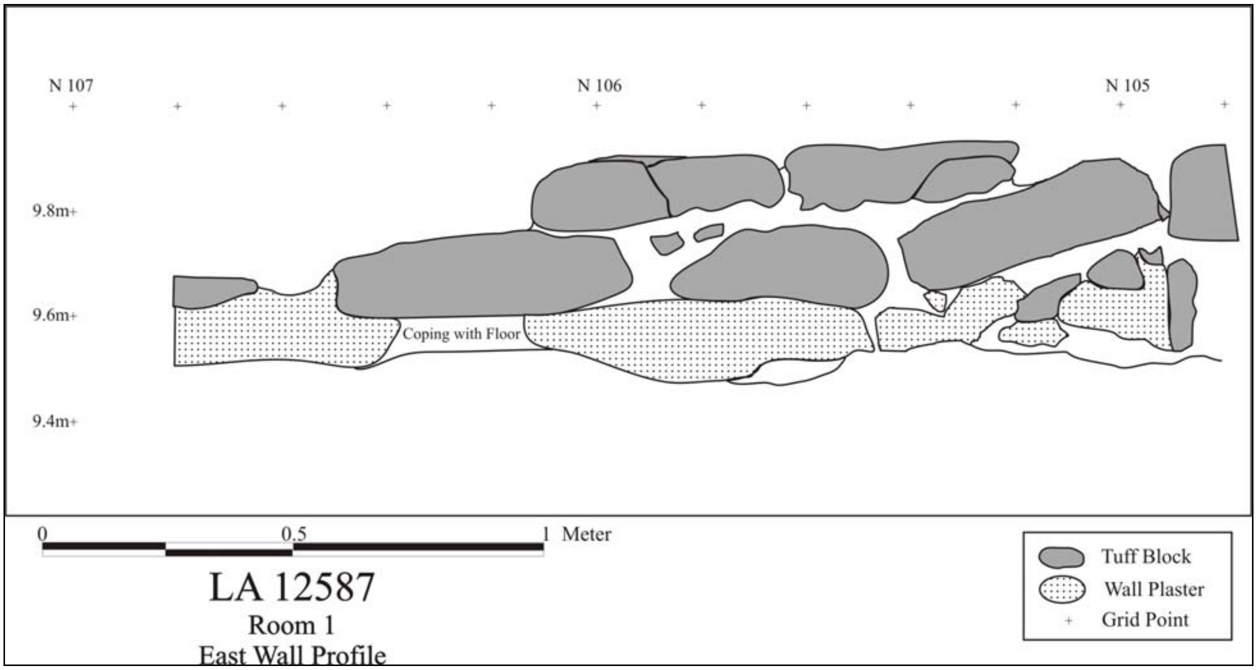

Figure 14.5. Room 1, east wall profile.

Artifacts and Samples. All the artifacts from units 106N/107E and 107N/107E were analyzed. All the macrobotanical material from unit 106N/107E was also analyzed. All the faunal remains were analyzed. All the artifacts found on the floor (except for FS 2936, which is missing) were analyzed and include a quartzite hoe fragment (FS 1396) and a shaped andesite slab fragment (FS 2868). Table 14.7 lists the samples analyzed from Room 1.

Table 14.7. Room 1 analyzed samples by stratum.

Stratum	Flotation	Pollen	Macrobotanical[1]
1	None	None	1029
10	1280	1251	1350
121	2932	None	None
170	None	None	None
210	1485, 2876	1484, 1486, 2875	None
Adobe Block	3011	None	None

1 In addition to the macrobotanical material from unit 106N/107E

Feature 2

A single feature was identified in Room 1 east of center and oriented north-south (Figure 14.6). Feature 2 is 100 cm long and 80 cm wide and consists of about 20 smooth and flattened cobbles, most of which are dacite. The cobbles range in size from 12.3 by 10.9 cm to 24.4 by 15.7 cm and are heavily coated with $CaCO_3$. Some of the cobbles overlap each other.

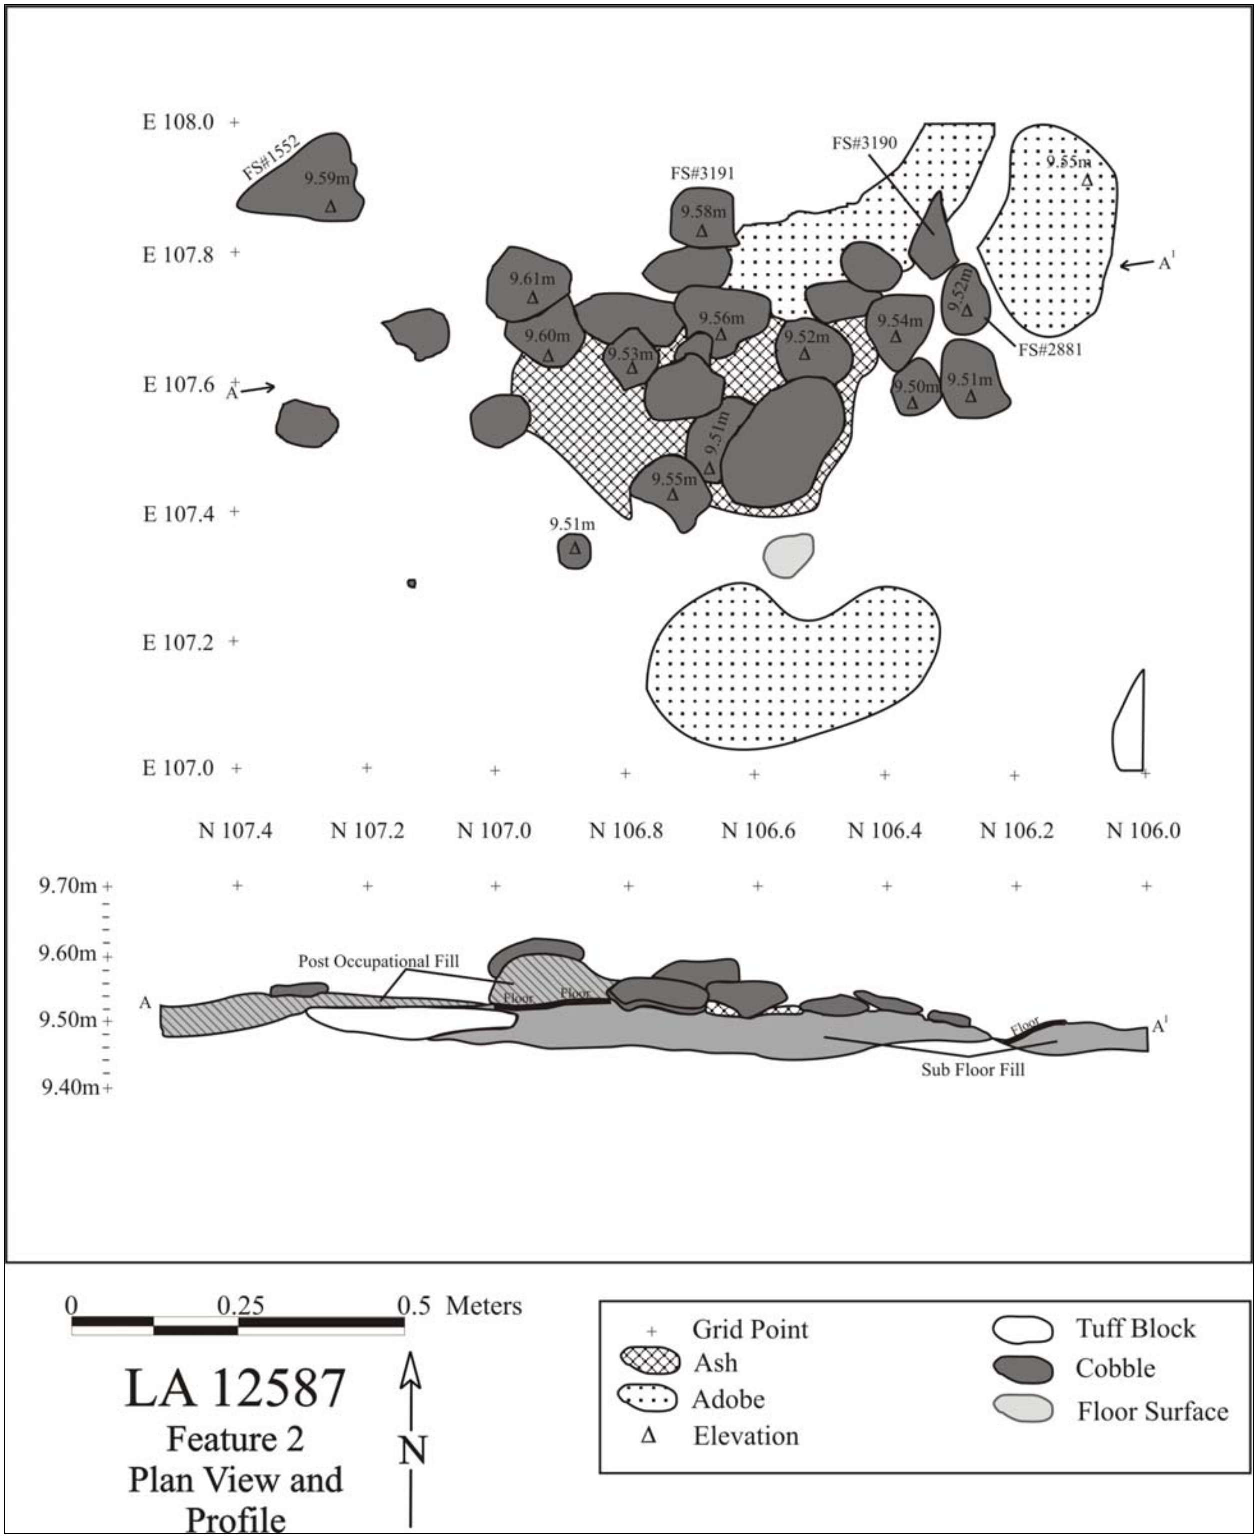

Figure 14.6. Feature 2 plan view and profile.

Three cobbles (FS 2881, FS 3190, and FS 3191) exhibit cultural modification. FS 2881 is a dacite cobble with a small (6.8 by 6.7 cm) circular area of grinding wear on one side. FS 3190 is a discoidal quartzite cobble. One face shows a small area of grinding, while the opposite face is dimpled as if it was used as an anvil. Two edges show battering. FS 3191 is a wedge-shaped dacite cobble that is ground on both faces. The narrow edge is unifacially flaked and may have been used for scraping. The cobbles were situated in a thin ashy matrix.

The floor surface had been destroyed beneath most of Feature 2. However, 5 cm of fill was present between one cobble and the floor surface at the north end of the feature. It is possible that the feature post-dates the abandonment of Room 1 but pre-dates its collapse. Several tabular piece of andesite (FS 1551, FS 1552, and FS 3189) covered the cobbles. These artifacts appear to be fragments of a hatch cover. Additional pieces of tabular andesite, possibly from the same hatch cover, were found in the room (e.g., FS 3225).

Two flotation samples (FS 1485 and FS 2876) and three pollen samples (FS 1484, FS 1486, and FS 2875) were analyzed from Feature 2. Taxa identified in the flotation samples included sagebrush (*Artemisia*), saltbush/greasewood (*Atriplex*/*Sarcobatus)*, cheno-ams, unidentified conifer (Gymnospermae), juniper, ponderosa pine, prickly pear cactus (*Opuntia*), cottonwood/willow (*Populus*/*Salix*), piñon pine, and maize. Taxa identified in the pollen samples include maize, cheno-ams, grass family (Poaceae), parsley family (Apiaceae), sunflower family (Asteraceae), ragweed/bursage (*Ambrosia*), spurge family (Euphorbiaceae), unidentified pine, piñon pine, juniper, and sagebrush.

The function of Feature 2 is unclear, although it appears to be a warming feature. The cobbles may have been heated elsewhere and brought in along with ash from the incinerated fuel. However, the cobbles do not appear to be thermally altered.

Room 2

Room 2 (Figure 14.7) is located in the northeast end of the roomblock. The interior east-west dimension of the room is 3.6 m and the north-south dimensions are 3.1 m on the west side and 2.4 m on the east side. The interior area is 10.4 m^2. Two hearths (Features 4 and 20) and two groups of postholes (Features 10 and 11) are present. A small exterior storage area (Feature 5) is associated with Room 2. A considerable amount of charred maize was found, indicating that the room was probably burned.

Stratigraphy. Table 14.8 summarizes the strata associated with Room 2. Several sagebrush were growing on top of Room 2 at the time of excavation. Stratum 1 consists of a shallow stratum of loose, unconsolidated sandy loam that is present throughout the site. Tuff blocks, tuff cobbles, and artifacts were recovered from this stratum. Stratum 1 is underlain by post-occupational fill, wallfall, and rooffall (Stratum 10). The stratum consists of moderately compact sandy loam with varying amounts of tuff gravel, fist-sized tuff rocks, and masonry. Wallfall consists of approximately 66 shaped and unshaped tuff blocks, approximately 56 fist-sized tuff rocks, and numerous chunks of adobe.

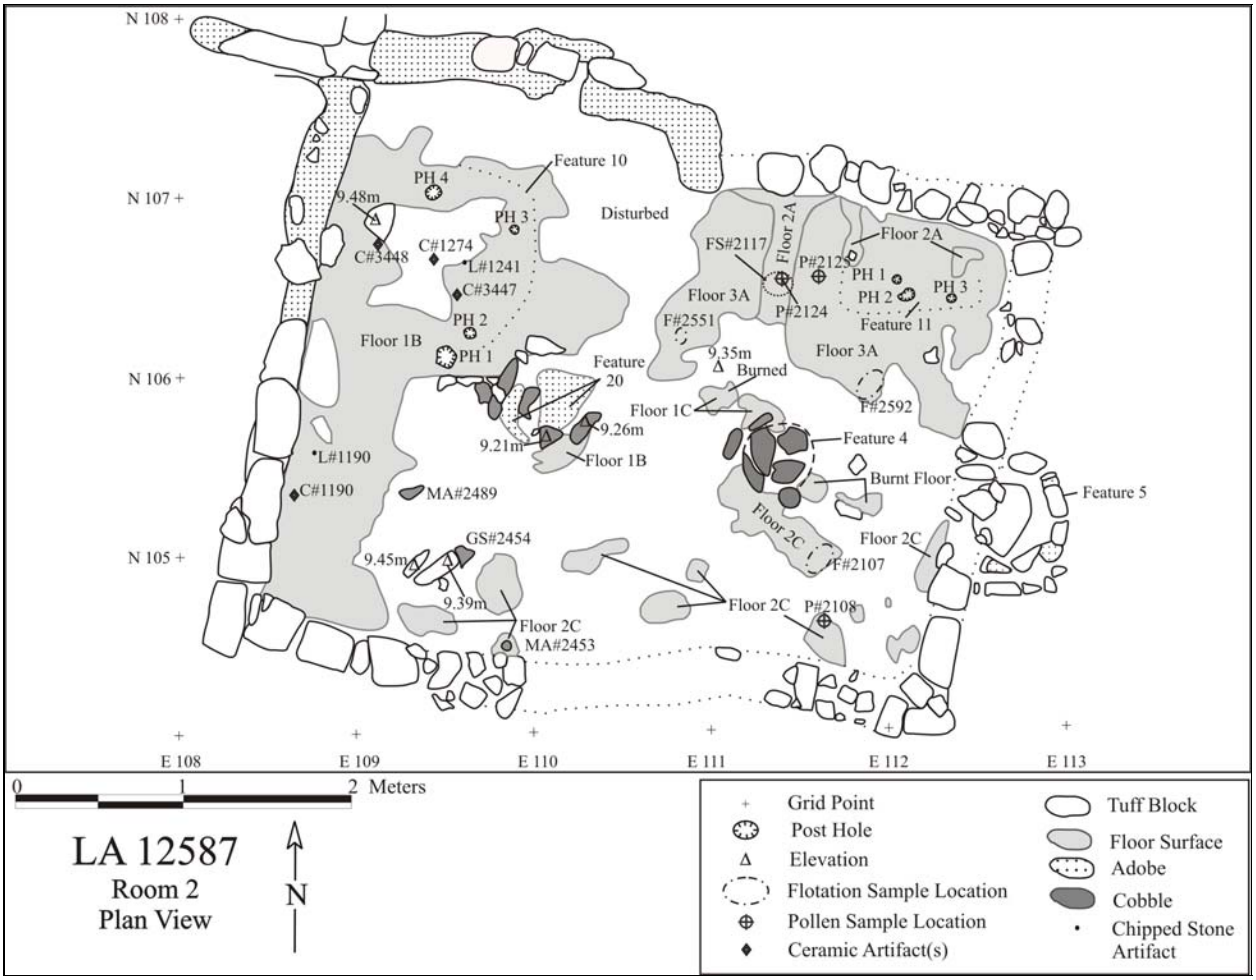

Figure 14.7. Room 2 plan view.

Rooffall was found in several places. In the southwest corner of the room, rooffall consists of reed-impressed adobe chunks, chunks of burned adobe, and a partly charred juniper beam fragment (FS 850). Large pieces of charcoal, chunks of heavily oxidized adobe, and a concentration of adobe chunks with roof material impressions were found in the southeast quadrant of the room. About 4 to 5 cm above the floor in the northeastern corner, a partially charred chunk of juniper wood was recovered (FS 2119) that may be a roof beam fragment. An abundance of charred maize kernels and cob fragments were recovered from Stratum 10. The densest concentration of charred maize was found in the southeast quadrant of the room.

Table 14.8. Room 2 stratigraphy.

Stratum #	Thickness (cm)	Color	Texture	Description

311	18	7.5YR 4/3	silt and ash	Feature 20, fill

A 2- to- 4-cm stratum of pre-wall collapse (Stratum 70) is present. Stratum 70 is less consolidated, sandier in texture, and contains less architectural material than Stratum 10. However, as in Stratum 10 there is an abundance of carbonized maize kernels and cob fragments. An ash lens was noted in Stratum 70, from which a flotation sample was taken (FS 2080). Taxa identified in this sample included pigweed (*Amaranthus*), sagebrush, saltbush/greasewood, goosefoot, unknown conifer, juniper, unidentified pine, piñon pine, ponderosa pine, cottonwood/willow, dropseed grass (*Sporobolus*), and maize.

The strata associated with the floors and features of Room 2 are discussed in the Floor and Features sections below. Table 14.9 shows the artifact counts by stratigraphic unit for Room 2. The 'Other' category includes an adult human right intermediate pedal phalanx (FS 787), an adult human right cuneiform (FS 1469), an adult human right intermediate pedal phalanx (FS 1515), an adult human right second metatarsal (FS 1941), an unidentified freshwater shell pendant (FS 895), a cf. *Anodonta* sp. umbo fragment (FS 1238), an unidentified freshwater shell fragment (FS 1522), a possible *Anodonta* sp. shell fragment (FS 2430), a biotite bead blank (FS 1199), a turquoise nugget (FS 1543), a possible pale green clay pigment fragment (FS 2478), a rock with pigment (FS 1569), a fragment of hematite (FS 1197), and a number of floor/roof samples. Other noteworthy artifacts include three bone beads (FS 1521 and FS 2830) and a possible ceremonial bundle (FS 2117). The bundle is described below.

Table 14.9. Room 2 artifact counts by stratum.

Floors. At least three flooring episodes occurred in Room 2. Stratum 122 refers to the uppermost floor surface throughout the room, regardless of what flooring episode it is associated with (an association that cannot always be determined, as discussed below). Stratum 122 is patchy and undulating. Typically the floor was encountered at 9.41 or 9.42 m, although a range in elevation from 9.55 m to 9.39 m was recorded. The floor slopes up to the walls (coping) in all places where the floor and walls articulate. The floor surface is relatively well-preserved in the western portion of the room and in the northeast corner, but has deteriorated elsewhere. All the flooring episodes in Room 2 were performed using the same technique: an ashy light gray (7.5 to 10YR 7/1) plaster was applied over a layer of adobe. In places, tuff cobbles were used to create an even surface over bedrock and soil.

Since the floor was not contiguous across the room, it was divided into three areas. In Area A (the northeastern corner) there were three distinct floor layers. The uppermost floor (3A) is approximately 2 cm thick. The middle floor (2A) is of approximately equal thickness. Floors 2A and 3A exhibit a fine layering of plaster indicative of multiple resurfacing episodes. In some places, the undersides of Floors 3A and 2A exhibit grass-like impressions. The lowest floor (1A) is 1 to 2 cm thick.

The western portion of the room is Area B. Floor 1B is a single floor (3 to 7 cm thick) in which no sub-layers were discerned. Because of extensive floor deterioration between Areas A and B, the floor surfaces of these areas could not be correlated. It is possible that the floor in Area B formerly consisted of three layers, which were compressed over time to become one thick floor. The combined thickness of the floors in Area A approximates the thickness of Floor 1B. Underneath Floor 1B there are small and medium-sized tuff cobbles that form a foundation over the uneven bedrock. The tuff cobbles below a portion of the floor (at 106.3N/110.0E) are mortared together with adobe. Some of this adobe is smeared up against the vertical surface of the remaining floor; finger impressions are visible in this adobe. The purpose of this adobe and cobbles cluster is not clear. It may be the remains of a sub-floor feature.

Area C consists of isolated patches of floor in the southeastern third of the room. Two floors were identified. Floor 2C is the uppermost floor and is 0.5 cm thick. The lower floor (1C) is 1 to 4 cm thick. No resurfacing layers were evident in either floor. Some of the patches of Floor 1C around the younger hearth (Feature 4) were burned. Again, because of deterioration of the floor surfaces, the Area C floors could not be correlated with the floors in Areas A and B.

Six sherds were recovered from the floor surface (Stratum 122). These included five smeared-indented corrugated jar sherds (FS 1190, FS 3447, and FS 3448) and one Santa Fe Black-on-white bowl sherd (FS 1274). Two pieces of chalcedony debitage were recovered and included a core flake (FS 1190) and a piece of microdebitage (FS 1241). Three ground stone artifacts were recovered. These included a quartzite two-hand mano fragment (FS 2453), an andesite hatch cover fragment (FS 2454), and a dacite one-hand mano fragment (FS 2489).

In the northeast corner of the room, a number of burned chunks of adobe and a large piece of burned juniper wood (FS 2119) were found on the floor. A cluster of charred artifacts believed to be the remains of a ceremonial bundle (FS 2117) was found below the juniper fragment. It is possible FS 2119 is part of a roof beam from which the bundle was suspended. FS 2117 consists of four or five bird bone tubes, a basalt flake, a Santa Fe Black-on-white worked sherd, and a burned rock. All of these artifacts were found within a 16- by 16-cm area.

Each bone tube has one fragmented end and one cut/shaped end. The tubes are between 1.5 and 14 cm long. One of the bone tubes (11 cm long) has a medial perforation indicating that it might have been a whistle. All of the bone tubes were heavily burned to white/gray. One of the bone tubes is an ulna; the other tubes could not be identified to a specific skeletal element. The upper three tubes (11 cm, 14 cm, and 6 cm long, from north to south) were parallel to each other and aligned roughly west-northwest to east-southeast. The eastern ends of the tubes were fragmented and the west ends were cut and shaped. The west ends of the tubes were situated about 2.5 cm above the floor and the east ends were about 1 cm above the floor. When these three tubes were removed, a fourth tube was exposed parallel to and below the two northernmost tubes. This tube is also cut and shaped on the west end, fragmented on the east end, and 8.5 cm long. It was situated 0.5 cm above the floor. A fifth tube lay perpendicular to the other four tubes. It was in contact with the floor and lay below the eastern ends of the two northernmost tubes. It is 1.5 cm long and cut and shaped on one end. It is unclear if the short tube is a discrete item or part of one of the other tubes. The basalt flake, the worked sherd, and the burned rock were situated a few cm south of the bone tubes and were 0.5 to 1.0 cm above the floor.

Wall Construction. It appears that the west wall of the room was built first and then the north, south, and east walls were built as one unit. The north and south walls appear to be bonded with the east wall and abutted to the west wall. Table 14.10 gives the dimensions of the extant wall segments.

The remaining portions of the north wall consist of the western 1.86 m and a 0.96-m segment east of center. A thin remnant of adobe at floor level was all that remained of the rest of the wall. The extant segments were constructed by setting upright tuff blocks into a thick bed of adobe mortar (7 to 14 cm thick) that was laid onto Stratum 175. Adobe mortar was applied to the stone surfaces and to the interface of the masonry and the basal mortar. Only a single course of upright stones remained.

The eastern and western portions of the south wall remain. The wall consists of a basal course of core and veneer segments separated by upright tuff blocks and capped by horizontal tuff blocks. Dissection of the west end of the east segment revealed that the veneer consists of a thick layer of adobe and small tuff stones that was thickly plastered and smoothed. The core consists of sediment and rubble and appears to be material from the midden. No additional courses remain. The eastern end of this wall was heavily oxidized near floor level.

The best-preserved portion of the east wall is the southeast corner where it is bonded to the south wall (Figure 14.8). Although this wall was not dismantled to study its construction, it appears to consist of an adobe foundation capped by large tuff blocks. The basal course of the wall consists of segments of adobe mortar from which fist-sized tuff rocks protrude. It is likely that the segments consist of the same core and veneer construction that is found in the south wall. Vertical upright tuff blocks separate the segments. The overlying course consists of horizontally placed tuff blocks set in a mortar bed. No additional courses remain. The west wall is described in Room 1.

Figure 14.8. Room 2 east wall.

Table 14.10. Room 2 wall dimensions (extant walls segments).

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	1.86, 0.96	0.27	0.29
East	3.0	0.35	0.25
South	1.4, 1.5	0.46	0.30
West	2.3	0.46	0.25

Artifacts and Samples. All the artifacts from units 105N/111E and 106N/111E were analyzed. All the macrobotanical material from unit 105N/111E was also analyzed. All the faunal remains were analyzed. All the artifacts found on the floor were analyzed and included an andesite axe fragment (FS 1670), a shaped andesite slab fragment (FS 2454), an El Rechuelos obsidian corner-notched Puebloan projectile point (FS 2340), a Cerro Toledo obsidian drill (FS 1705), one Pedernal chert core flake (FS 2886), and one chalcedony core flake (FS 2886). Table 14.11 lists the samples analyzed from Room 2.

1. In addition to the macrobotanical material from 105N/111E

Features

Feature 4 (Hearth). Feature 4 is a circular collared hearth situated 80 cm west of the east wall and 85 cm north of the south wall (Figures 14.9 and 14.10). The exterior diameter of the hearth is 60 cm, the interior diameter is 40 cm, and it is 29 cm deep. Eleven cobbles of assorted materials (andesite, dacite, quartzite, rhyolite, sandstone, and vesicular basalt) were used to line the sides and base of the hearth. Four of these cobbles were identified as manos or mano fragments (FS 4202, FS 4204, FS 4205, and FS 4207), and three were identified as grinding slabs (FS 4200, FS 4203, and FS 4206). Plaster covers the cobbles on the north, west, and south-

southeast sides of the hearth; elsewhere it has deteriorated. The cobbles forming the base of the hearth were mortared into place.

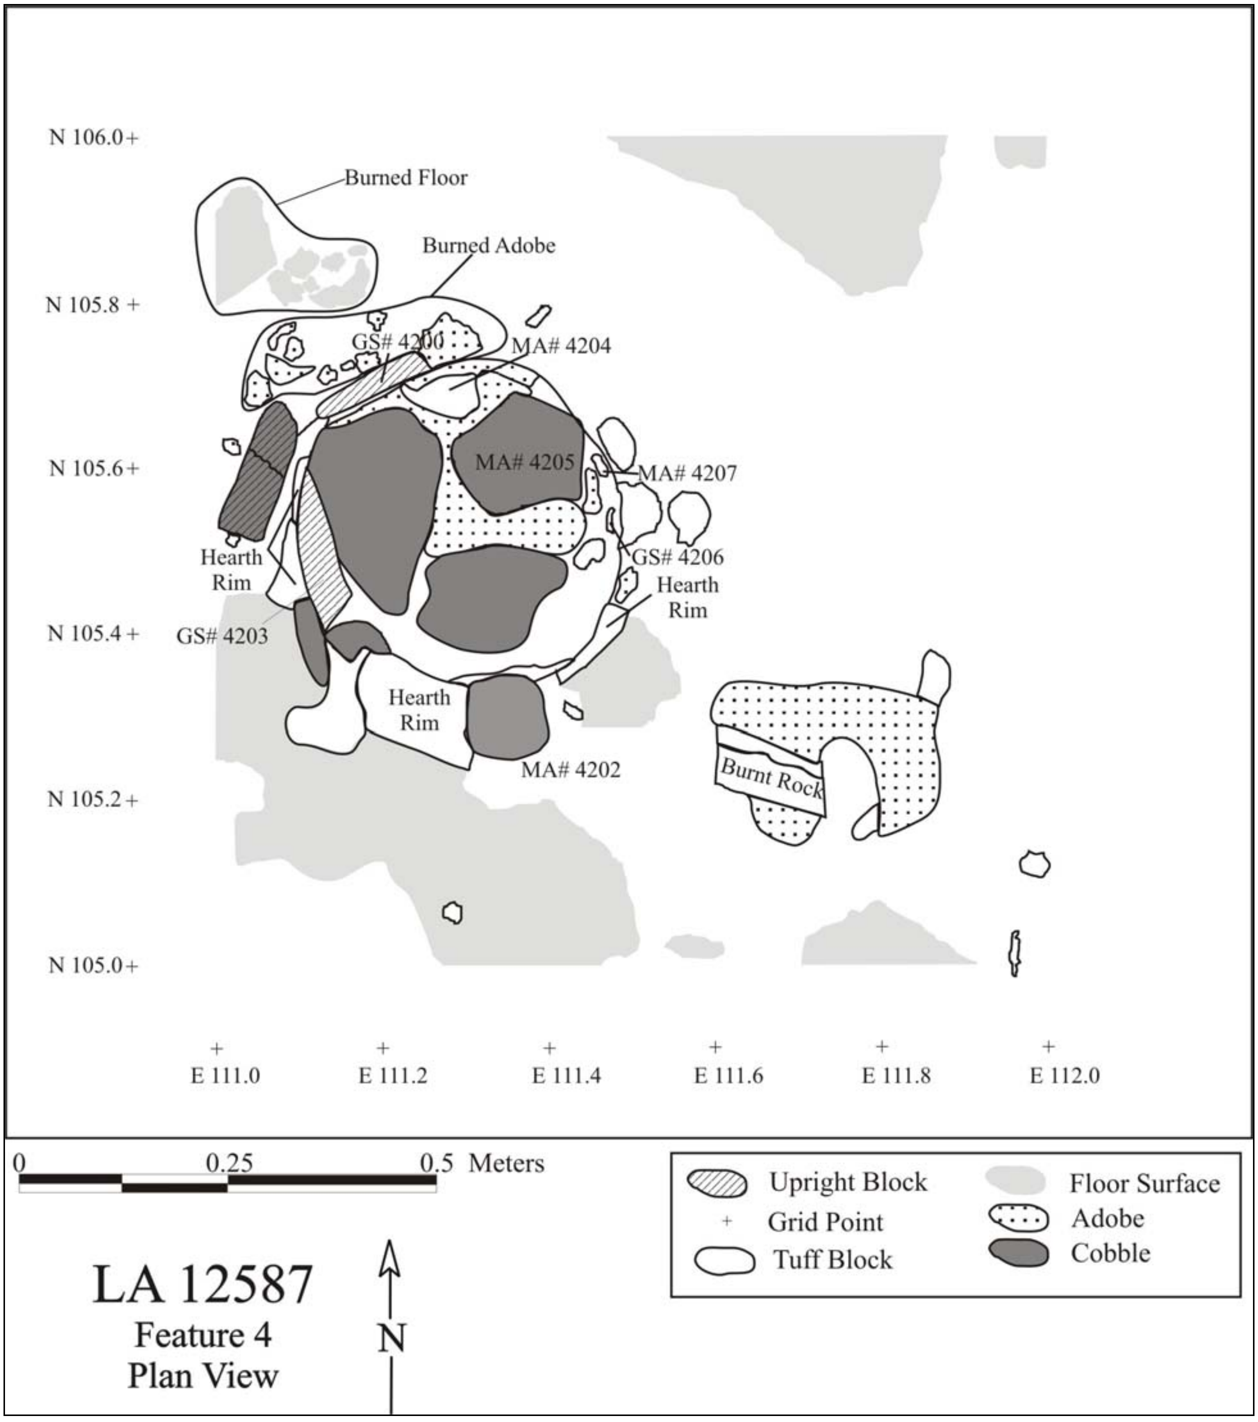

Figure 14.9. Feature 4 plan view.

Figure 14.10. Feature 4 after excavation.

The fill of the hearth consists of a mix of silt loam and ash (Stratum 260) and, in the southeast part of the hearth, a deposit of ash (Stratum 261) (Figure 14.11). The floor surrounding the hearth (Floor 2C to the south and east, Floor 1C to the north) is only partially preserved. Both the plastered floor and the damaged areas without plaster show evidence of burning. An upright dacite block set into adobe is located 14 cm east of the hearth. This block appears to be from the south side of a depression. It is possible that this is the remains of an ash pit; however, the area is so disturbed that a clear determination cannot be made. The hearth, the possible ash pit, and the external feature (Feature 5) are aligned east-northeast to west-southwest.

Ten flotation samples, two pollen samples, and one macrobotanical sample were taken from Feature 4. Taxa identified in the flotation sample included pigweed, sagebrush, goosefoot, saltbush/greasewood, cheno-ams, hedgehog cactus (*Echinocereus*), spurge (*Euphorbia*), Desert olive (*Foresteria*), unknown conifer, juniper, mint family (Labiatae), groundcherry (*Physalis*), unidentified pine, piñon pine, ponderosas pine, prickly pear, cottonwood/willow, purslane, oak (*Quercus*), buffalo burr, dropseed grass, and maize. Given the amount of bioturbation in Room 2 and the amount of maize present in the room, most or all of the maize recovered from Feature 4 is probably not directly associated with the use of the hearth. Taxa identified in the pollen samples taken from the hearth included maize, cholla (*Opuntia*), prickly pear, beeweed (*Cleome*), cheno-ams, grass family, sunflower family, spurge family, evening primrose (Onagraceae), fir (*Abies*), unidentified pine, piñon pine, juniper, and sagebrush. A macrobotanical sample from the hearth was submitted (FS 2712) and identified taxa included piñon pine, maize, and juniper.

Figure 14.11. Feature 4 profile.

An archaeomagnetic dating sample (set 1210) and a maize fragment (FS 2644) from the hearth were submitted for dating. The archaeomagnetic sample returned a number of possible dates but the preferred date interpretation is AD 1245–1310 (see Blinman and Cox, Volume 3). The maize fragment returned an age of 870±70 BP (Beta-183747) and a date of cal AD 1180 with a two-sigma date range of cal AD 1020–1280.

Feature 5 (Masonry Structure). Feature 5 is affixed to the exterior east wall of Room 2 (Figures 14.12 and 14.13). This feature is a small semicircular masonry structure that measures 64 cm north-south and 38 cm east-west and has a maximum depth of 20 cm. A poorly preserved use surface was evident surrounding the feature. It was constructed with small and medium-sized tuff rocks. Two courses were present on the south side of the feature, only a single course is present on the east and north sides. The west side is formed by the Room 2 wall. Adobe mortar was present in places on top of and between the rocks, but no plaster or adobe was evident inside the feature. The absence of thermal alteration on the interior indicates that Feature 5 was not a hearth or other thermal feature, but may have functioned as an external storage cist.

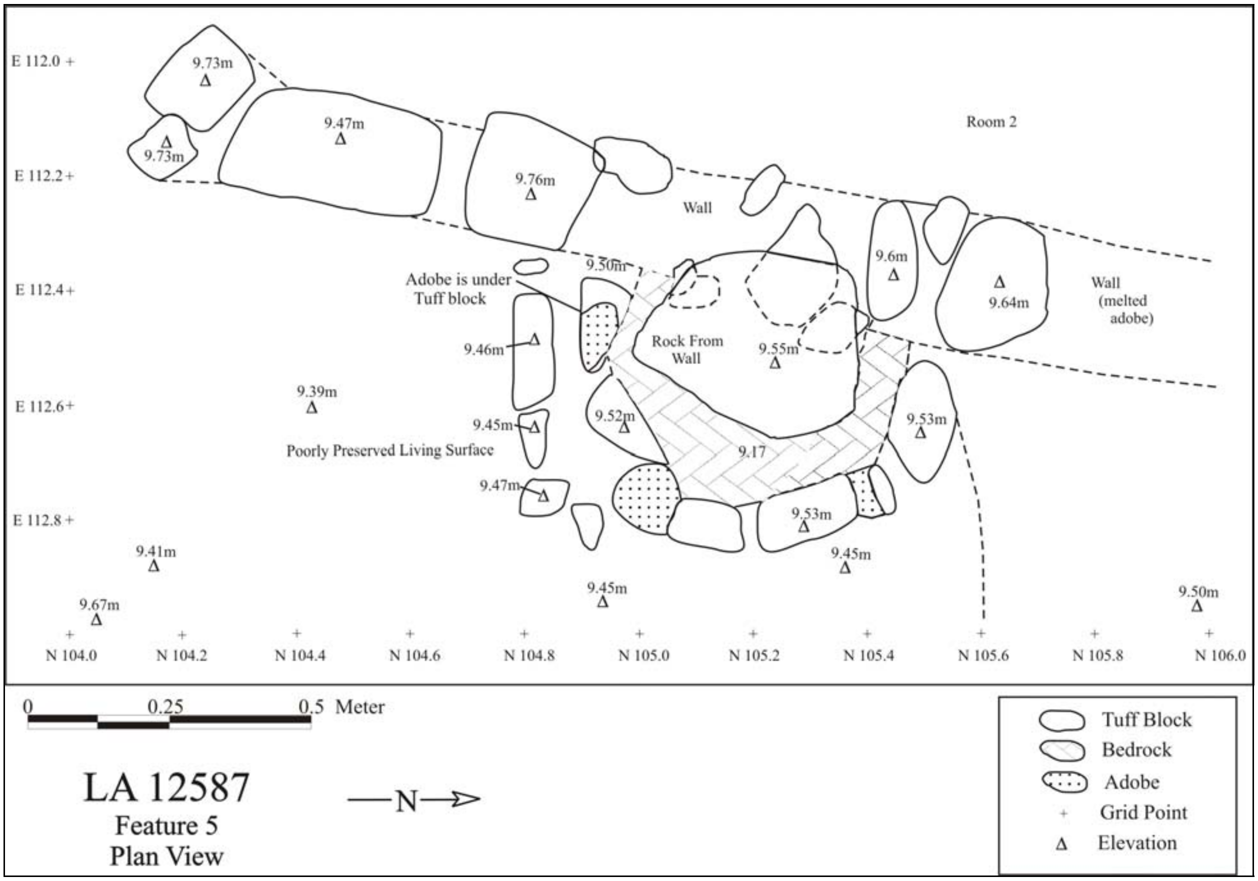

Figure 14.12. Feature 5 plan view.

A large tuff block that was once part of the Room 2 wall was found inside Feature 5. It is unclear if this block was intentionally placed, or if it simply fell into the feature. The fill of Feature 5 (Stratum 213) contained three pieces of lithic debitage (FS 2995), 17 ceramic sherds (FS 2991), and charcoal and charred maize. Below the base of the tuff rocks (the probable floor of the feature), cultural materials became less common. The fill was sterile at contact with bedrock. Charred botanical remains identified from two flotation samples (FS 2989 and FS 2994) consists of the following taxa: pigweed, sagebrush, saltbush/greasewood, goosefoot, cheno-ams, bugseed (*Corispermum*), unknown conifer, juniper, unidentified pine, piñon pine, ponderosa pine, prickly pear, cottonwood/willow, and maize. Two pollen samples were collected from the feature (FS 2988 and FS 2993) and taxa identified included maize, cholla, prickly pear, beeweed, cheno-ams, grass family, sunflower family, spurge family, fir, unidentified pine, piñon pine, juniper, oak, Mormon tea (*Ephedra*), and sagebrush. A macrobotanical sample was submitted (FS 2992) and maize remains were identified.

Figure 14.13. Feature 5 after excavation.

Feature 20 (Hearth). Feature 20 is a hearth that predates Feature 4; it was found below the tuff cobble foundation of Floor 1B (Figure 14.14). The hearth is located 1.1 m east of the west wall and 1.3 m north of the south wall. The presence of Feature 20 at this location may explain why Feature 4 was positioned so far to the east, rather than nearer the center of the room (as are the hearths in Rooms 4/5 and 7). The interior dimensions of the hearth are 45 cm north-south and 40 cm east-west; and it is 18 cm deep. The hearth is in poor condition, but portions of the adobe collar and plastered hearth wall remain on the southwest side. The rocks that lined the hearth remain on the north, northwest, and southeast sides. These rocks are all mano (FS 4137, FS 4142, and FS 4143) and metate (FS 4144 and FS 4210) fragments. The southern perimeter of the hearth is missing. Some plaster is present at the base of the hearth. Several rodent burrows were dug through Feature 20. Several small areas of floor surface were present on the southeast edge of the hearth and it may have been contemporaneous with Feature 20.

The fill (Stratum 311) consists of mixed silt and ash that became increasingly ashier with depth. Towards the base of the western side of the hearth, a lens of clean sandy fill was encountered during excavation. It is not clear whether this sandy deposit is cultural in origin or if it is a result of rodent burrowing.

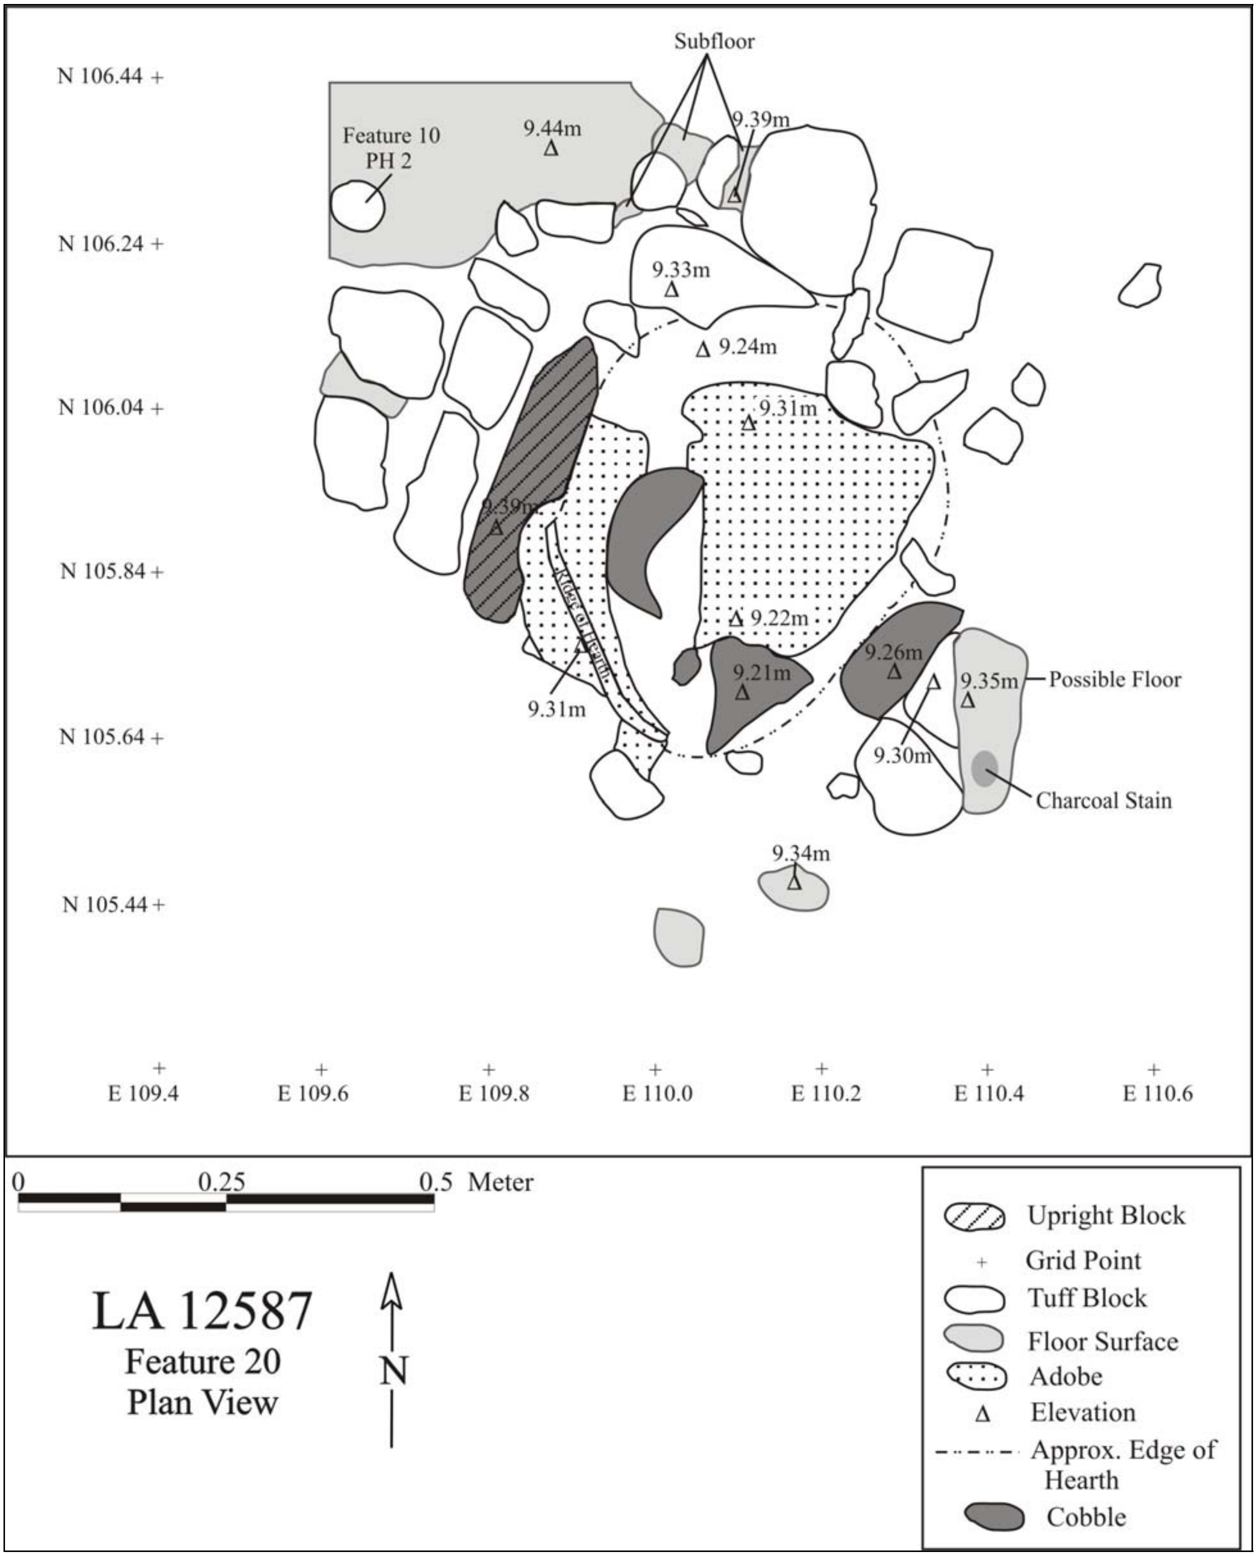

Figure 14.14. Feature 20 plan view.

Four flotation samples (FS 4138, FS 4139, FS 4197, and FS 4198), one pollen sample (FS 4141), and one macrobotanical sample (FS 4146) were taken from Feature 20. Charred wood from the following taxa were identified in the flotation samples: pigweed, saltbush/greasewood, mountain mahogany (*Cercocarpus*), squash/coyote gourd (*Cucurbita*), unknown conifer, juniper, oak, unidentified pine, cottonwood/willow, purslane, and maize. Taxa identified in the pollen sample included maize, beeweed, mint family, cheno-ams, grass family, sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon pine, rose family (Rosaceae), and sagebrush. A macrobotanical sample was submitted and saltbush/greasewood, piñon pine, maize, and juniper remains were identified. Given the rodent disturbance in Feature 20, most or all of this material is probably associated with the Room 2 assemblage at the time of abandonment and not with the use of the hearth.

Two archaeomagnetic sets (1214 and 1215) were submitted for analysis, a fragment of hearth plaster (FS 4209) was submitted for thermoluminescence dating, and a maize fragment (from FS 2644) was submitted for accelerator mass spectroscopy (AMS) radiocarbon analysis. The archaeomagnetic samples returned a highly precise date of circa AD 1200. The thermoluminescence sample returned a date of 1122±160 (two-sigma). The maize fragment returned a date of 650±40 BP (Beta-183748) and a date of cal AD 1300 with a two-sigma date range of cal AD 1280–1400. Since the maize fragment is probably associated with the room abandonment and since thermoluminescence dates tend to be too early (Harmon and Vierra, Volume 3), the archaeomagnetic dates are the best dates for this hearth.

Feature 10 (Postholes). This feature consists of three, possibly four, postholes that are associated with Floor 1B in the northwest quadrant of the room. The southernmost posthole, Posthole 1, is the largest (12 cm north-south by 11 cm east-west) and is pentagonal in shape (Figure 14.15). The posthole was plastered over so that it was only visible as an outline in the floor surface. It was not excavated. Posthole 2 is 10 cm to the northeast of Posthole 1 and measures 6 cm north-south by 7 cm east-west and is 11 cm deep. The fill of Posthole 2 was collected as a pollen sample (FS 3369). Taxa identified in this sample included cholla, prickly pear, beeweed, cheno-ams, grass family, sunflower family, mustard family (Brassicaceae), unidentified pine, piñon pine, juniper, and sagebrush. Posthole 2 may reflect a repositioning of the Posthole 1 post. Posthole 3 is located 52 cm north and 18 cm east of Posthole 2. It is 4 cm in diameter and 6 cm deep. The fill of Posthole 3 was collected for a pollen sample (FS 3370), and identified taxa included beeweed, cheno-ams, grass family, sunflower family, unidentified pine, piñon pine, juniper, and sagebrush. Both Postholes 2 and 3 extend through the full thickness of Floor 1B. A possible fourth posthole (Posthole 4) is located 40 cm northwest of Posthole 3. It is not clearly cultural and it was not excavated.

Feature 11 (Postholes). This feature consists of three postholes in the northeast corner of the room. Posthole 1 measures 5.5 cm by 4.5 cm and is 5 cm deep. Posthole 2 is located 5 cm southeast of Posthole 1. It measures 5.5 cm by 5.0 cm and is 6 cm deep. Postholes 1 and 2 have rounded plaster rims. Posthole 3 is approximately 20 cm east of Posthole 2. The edges of this hole are fragmented, making it difficult to determine the exact dimensions; it is probably 5 cm in diameter and 3 cm deep. All three postholes were built into all three floor layers (e.g., Floors 1A, 2A, and 3A).

Figure 14.15. Feature 11, postholes 1 and 2.

Room 4/5

Room 4/5 (Figure 14.16) is the middle room of the front row of rooms. The interior dimensions are 4.0 m north-south and 2.8 m east-west. The interior area is 11.2 m^2. A hearth (Feature 1), an isolated posthole (Feature 8), and a set of four postholes (Feature 16) are present. Room 4/5 was built as a single room but was subsequently divided by an east-west-running wall.

Stratigraphy. Table 14.12 summarizes the strata associated with Room 4/5. Several sagebrush and a small juniper tree were removed before excavation. Stratum 1 consisted of loose unconsolidated sandy loam and pine duff. Tuff blocks, tuff cobbles, and artifacts were recovered from this stratum. Stratum 1 is underlain by post-occupational fill, wallfall, and rooffall (Stratum 10). Stratum 10 consisted of moderately compact sandy loam with varying amounts of tuff gravel, cobbles, and masonry. Wallfall consisted of 60+ shaped and unshaped tuff blocks, 90+ tuff cobbles, and 120+ tuff chinking stones. Rodent disturbance was extensive in the room.

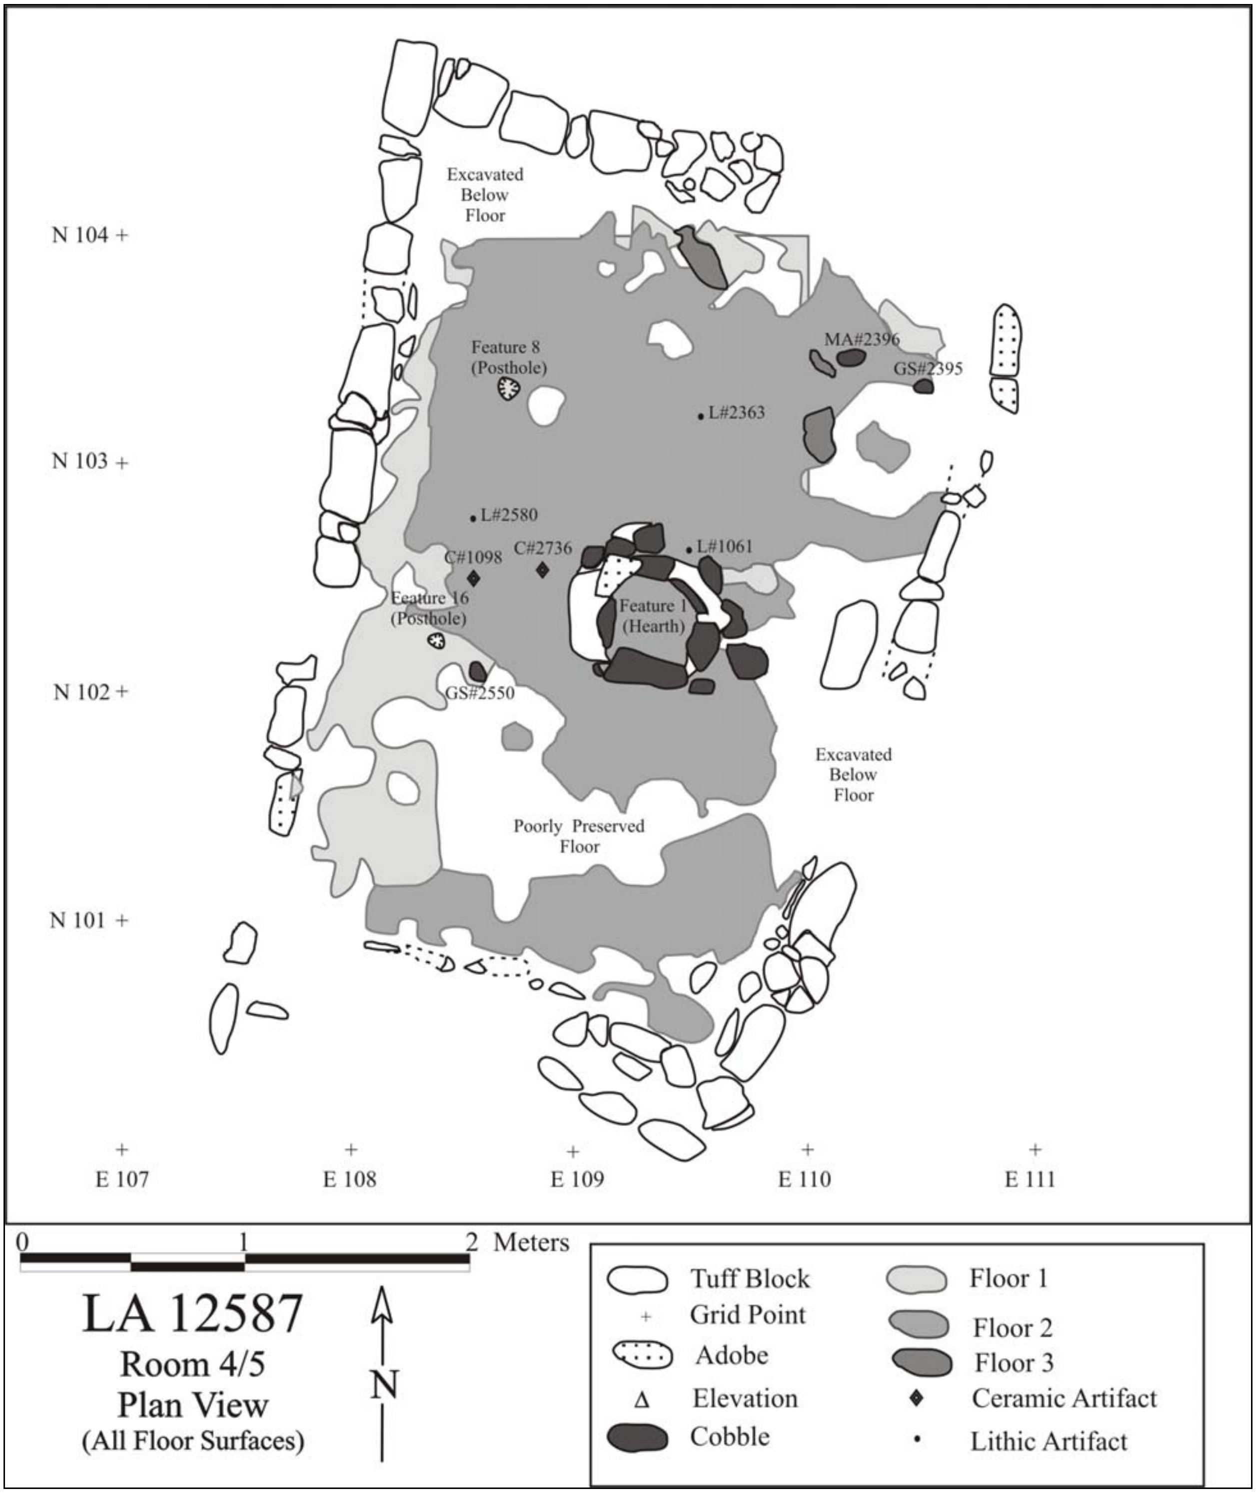

Figure 14.16. Room 4/5 plan view.

Table 14.12. Room 4/5 stratigraphy.

Stratum	Thickness (cm)	Color	Texture	Description
0	0	10YR 4-5/3	sandy loam	Surface
1	2-8	10YR 4-5/3	sandy loam	Unconsolidated surface soil
10	30-41	10YR 5/3	sandy loam	Wallfall and post-occupational fill
14	9	7.5YR 5/3	sandy loam	Sediment from wall alignment across Room 4/5 and top of Feature 1
70	10	10YR 4/3	sandy loam	Fill below wallfall and above floor
124	0	Gley 2 7/10B	silty clay	Floor surface across entire room
170	3-5	10YR 4/4	sandy clay loam	Sub-floor soil
250	15	7.5YR 4/4	silt loam	Feature 1, upper fill

255	3	Gley 2 7/10B	silty clay	Floor 3, matrix
256	7-8	10YR 4/4	sandy loam	Feature 16, fill
305	1-3	7.5YR 4/6	sandy clay	Soil below Feature 1
306	N/A	N/A	clay	Feature 1, plaster

An intermittently present stratum of sandy loam lying over the floor was designated as Stratum 70. Stratum 70 is similar to Stratum 10 although it is less consolidated and contains a greater amount of sand. Stratum 70 was probably deposited before most of the room collapse occurred. Stratum 14 is the fill and mortar in the east-west-oriented wall that divides the room. Artifacts in the sub-floor fill (Stratum 170) have probably been introduced through bioturbation. The strata associated with the floors and features of Room 4/5 are discussed in the subsequent section.

Table 14.13 shows the artifact counts by stratum for Room 4/5. The ‘Other’ category includes an adult human right capitate (FS 673), an adult human intermediate hand phalanx (FS 1059), an adult human left humerus fragment (FS 1242), an adult human right first metatarsal (FS 2319), an adult human right rib fragment (FS 2323), two unidentified human rib fragments (FS 2323), a freshwater shell fragment (FS 2686), and obsidian nodule (FS 2580), an unfired ceramic bird (turkey) effigy (FS 1416), and several miscellaneous samples. The bird effigy has a round body with wings and tail formed by pinching out the clay. The wings and tails were incised to suggest feathers, but the head was missing.

Table 14.13. Room 4/5 artifact counts by stratum.

Floor. Two, possibly three, flooring episodes occurred in Room 4/5. Stratum 124 is the uppermost floor surface throughout the room, regardless of what flooring episode it is associated with. Stratum 124 is well-preserved in most of the room, especially in the north and the southeast corner, however the surface is undulating due to bioturbation and subsidence. In areas where floor and wall contact was preserved, coping was common. Each floor was built by applying plaster over a 1- to 5-cm-thick layer of adobe. There is no evidence of fill between the different floors, which suggests that they represent episodes of remodeling during a continuous occupation. It was sometimes difficult to trace the floor surfaces across the entire room. Different floors were most easily distinguished in the northern portion of the room and most difficult to distinguish in the southern portion. In places, tuff cobbles have been used beneath the floor to create an even surface over bedrock and soil.

In the northeast corner of the room there are three small patches of a final plastering episode (Figure 14.17). Although designated as Floor 3, it is not clear if these patches represent a reflooring episode or are just spot-repairs. The matrix of Floor 3 is Stratum 255. The western patch was collected as a flotation sample (FS 3308). Taxa identified in this matrix included pigweed, saltbush/greasewood, unknown conifer, juniper, unidentified pine, piñon pine, prickly pear, Douglas fir (*Pseudostoga menziesii*), oak, and maize.

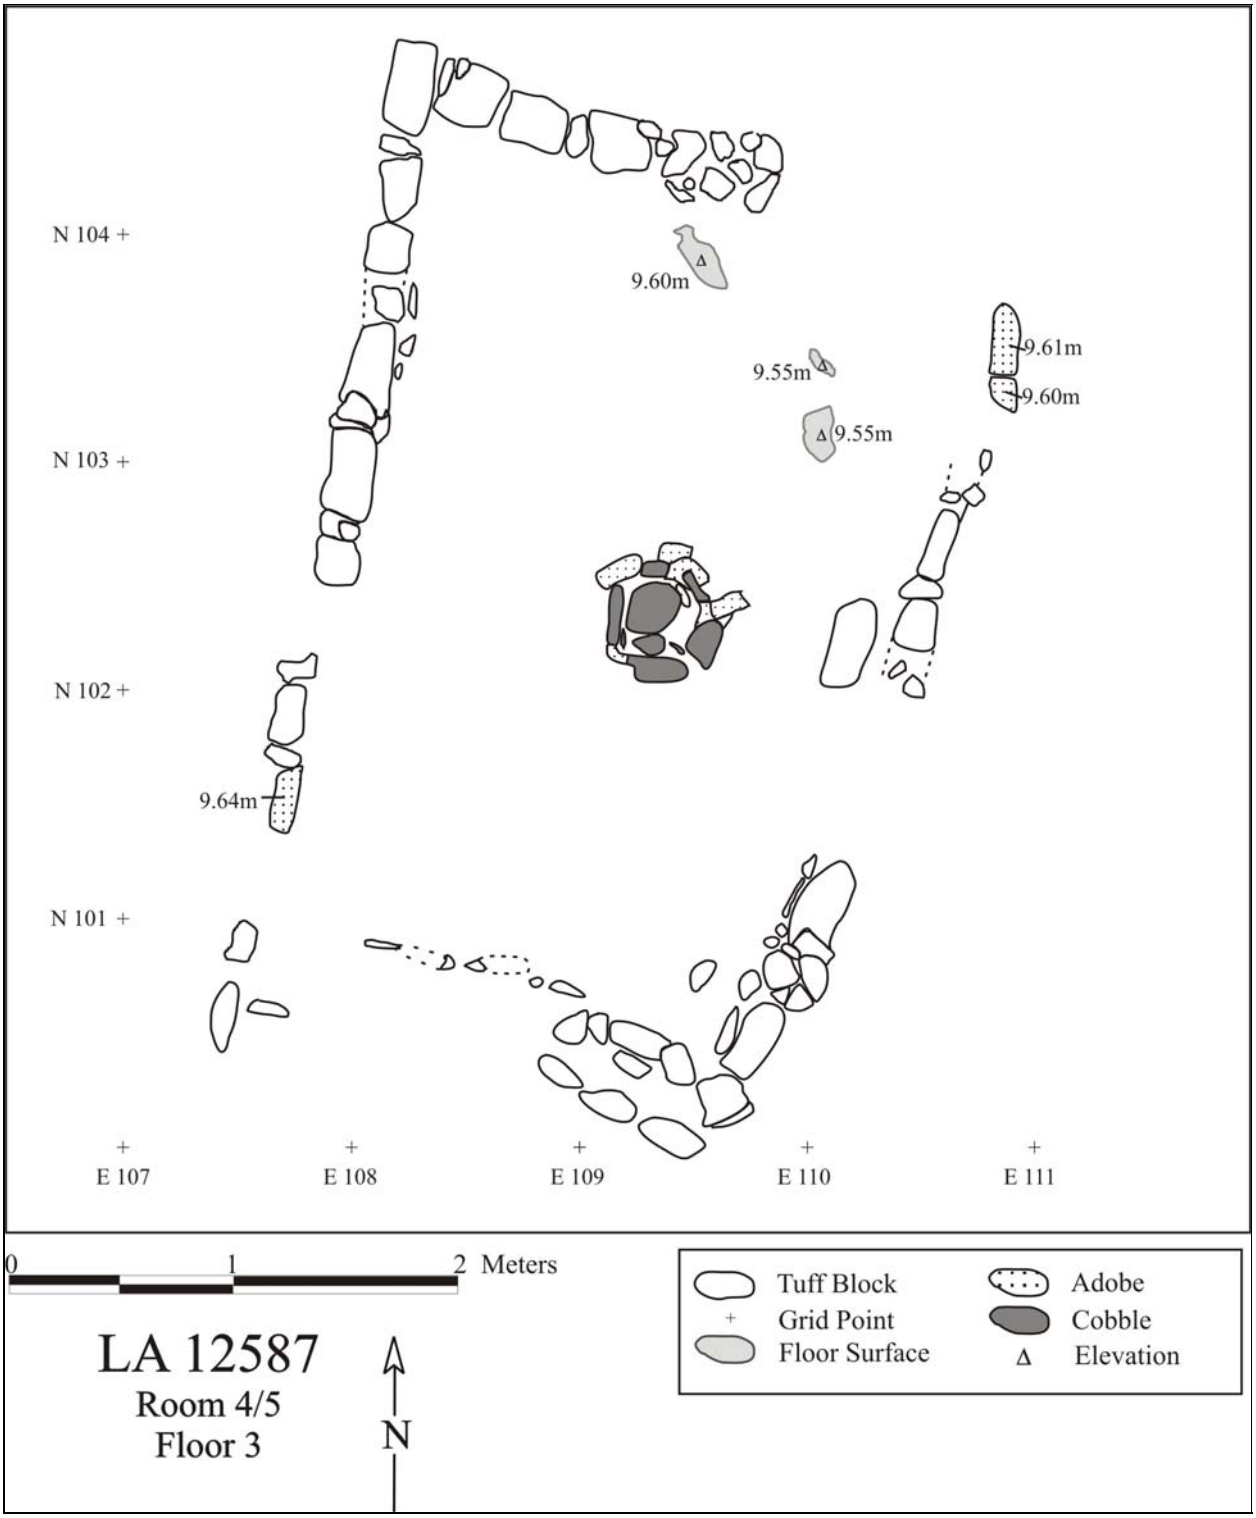

Figure 14.17. Room 4/5, Floor 3.

The youngest full floor is Floor 2 (Figure 14.18). The floor matrix (Stratum 252) is compact, indurated, and slightly ashy in content. It contains a surprisingly high number of artifacts (see

Table 14.13), suggesting that the floor matrix is composed of midden material. A patch of this floor was collected as a flotation sample (FS 3256) and identified taxa included pigweed, sagebrush, saltbush/greasewood, unknown conifer, juniper, unidentified pine, and maize. Floor 2 was removed in a 4-m^2 area to expose the lower floor and sub-floor deposits.

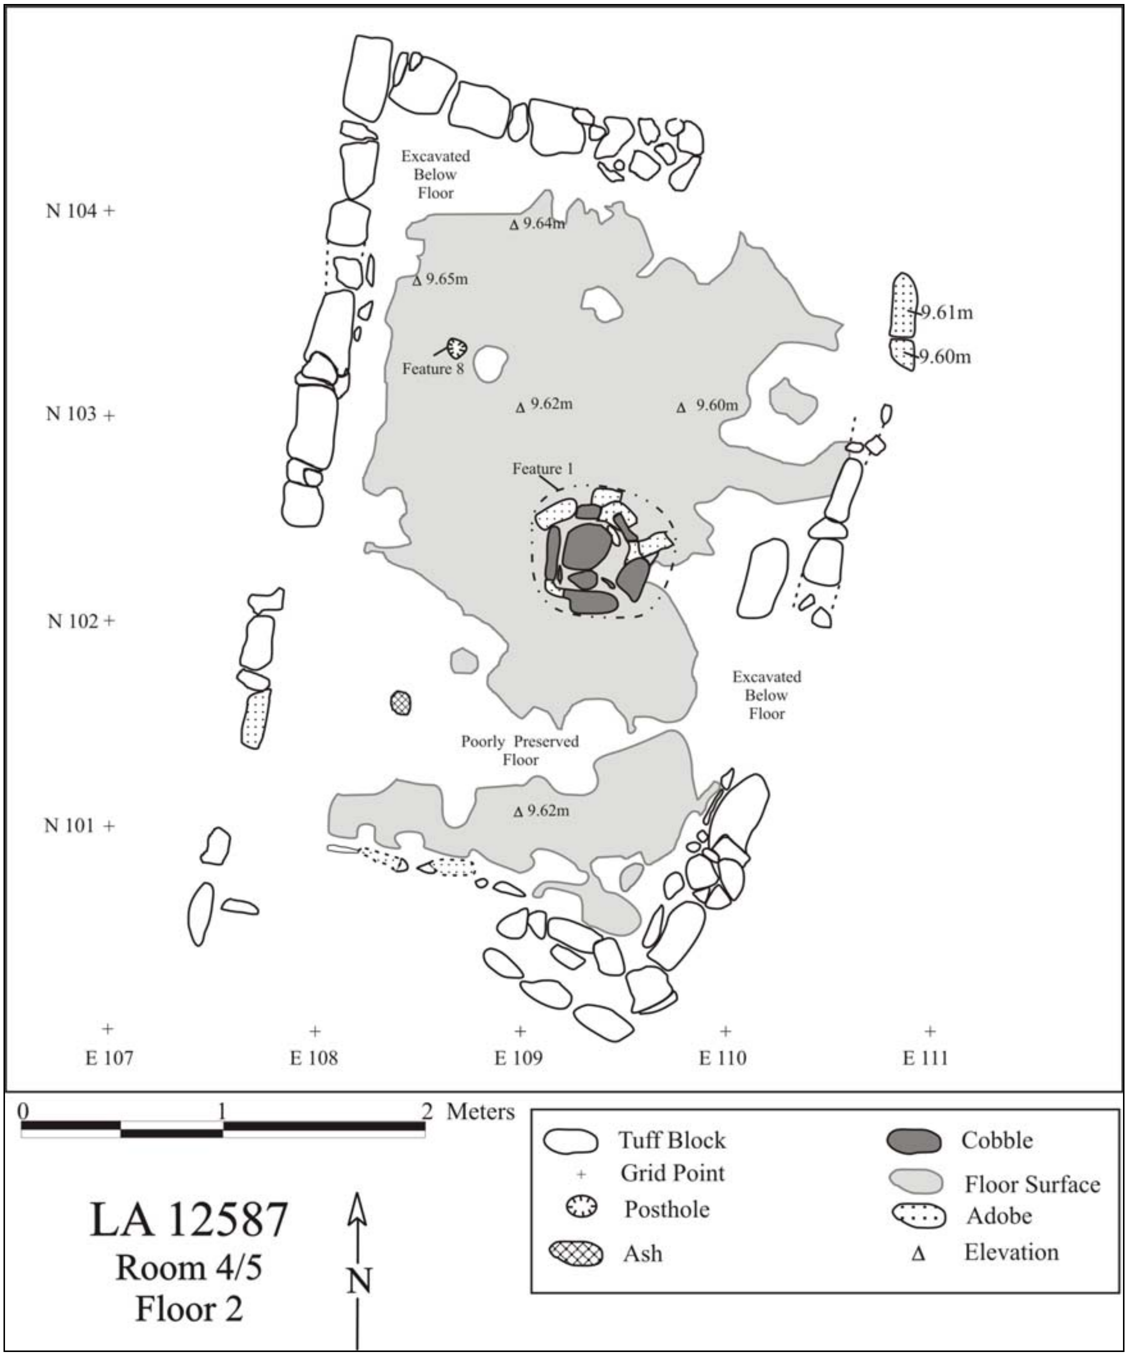

Figure 14.18. Room 4/5, Floor 2.

Floor 1 was immediately below Floor 2 (Figure 14.19). Like Floor 2, Floor 1 is uneven, of variable thickness, and well-preserved. However, screening of the floor matrix (Stratum 253) resulted in the recovery of no artifacts. Unlike Floor 2, this floor must have been made of sterile sediment rather than midden material. Possibly the floor was made before an accumulation of midden material was available. The base of the Floor 1 matrix exhibited impressions of what appears to be tall grass or thin reeds. A patch of Floor 1 was collected as a flotation sample (FS 3299) and identified taxa included juniper, unidentified pine, and maize.

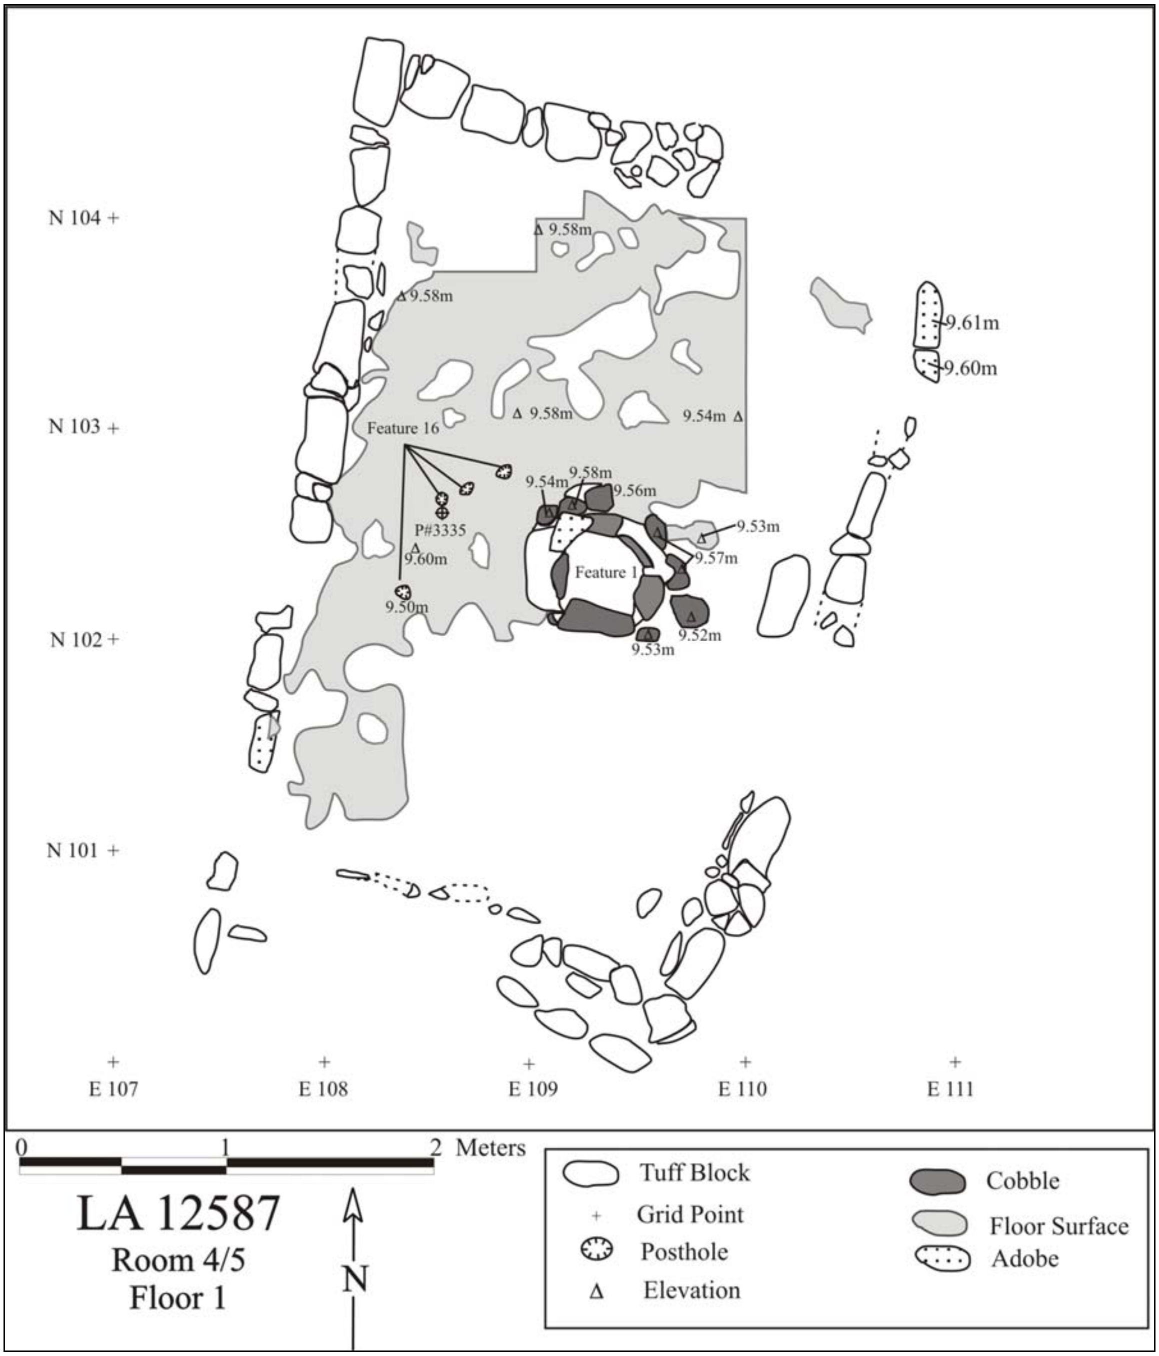

Figure 14.19. Room 4/5, Floor 1.

Eight artifacts were found on the floor surface and included a dacite abrading stone (FS 2395), a dacite two-hand mano fragment (FS 2396), a quartzite polishing stone (FS 2550), a Pedernal chert core fragment (FS 1061), a Pedernal chert flake fragment (FS 2363), two smeared-indented corrugated jar sherds (FS 1098 and 2736), and an obsidian nodule (FS 2580).

Wall Construction. The west wall was built first, followed by the north and south walls. Both of these walls abut the west wall. The east wall abuts the south wall. The relationship between the north wall and the east wall is undetermined, as that corner is missing. Table 14.14 gives the dimensions of the extant segments. The north wall is described in the Room 2 section. The only difference is that no plaster is present on the south face of the wall.

Table 14.14. Room 4/5 wall dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	2.6	0.30	0.33
East	1.0, 0.90	0.34	0.26
South	0.40	0.35	0.41
West	3.75	0.33	0.21

The extant central fragment of the east wall is constructed of upright and semi-coursed unshaped tuff blocks. The southern fragment is constructed of irregular upright blocks and small stones placed at irregular intervals into a mass of mortar (Figure 14.20). Despite the fragmentary condition of the southeast corner, the south wall clearly abuts the east wall.

The extant portion of the south wall consists of two parallel rows of upright tabular tuff blocks (18 to 20 cm apart). The interior was probably filled with sediment and rubble. Remnants of adobe at the west end of the south wall indicate that the foundation is a bed of adobe into which the uprights were secured. An alignment of small, mostly upright stones was encountered at the base of the walls and set slightly into the room away from the surface of the wall. These small stones were probably placed to provide support for a fairly robust application of wall plaster.

The northern portion of the west wall is built of large upright tuff blocks placed into a bed of adobe. Where a second course is present, it consists of horizontally laid tuff blocks. The southern portion of the wall is built of semi-coursed irregular tuff blocks secured with copious amounts of mortar. A slightly raised remnant of adobe present near the south end of the wall may be an eroded sill indicating a connection between Room 4/5 and Room 6.

The basal course of an east-west-aligned wall was found in the middle of the room. The wall was built on top of the plastered floor surface and one masonry block had been placed in an upright position in the hearth (Feature 1). It could not be determined if this wall was ever built to full height.

Figure 14.20. Room 4/5 southeast corner.

Artifact and Samples. All the artifacts from units 102N/109E and 103N/109E were analyzed. All the macrobotanical material from unit 103N/109E was also analyzed. All the faunal remains and all the artifacts found on the floor were analyzed. Table 14.15 lists the samples analyzed from Room 4/5.

1 In addition to the macrobotanical material from 103N/109E

Features

Feature 1 (Hearth). Feature 1 is a circular collared hearth located near the center of Room 4/5 (Figures 14.21 and 14.22). The exterior diameter of the hearth is 54 cm, the interior diameter is 36 cm, and it is 18 cm deep. Cobbles and ground stone artifacts formed the walls and base of the hearth, and these were mortared into place. The Floor 2 surface articulates with the hearth and covers the adobe collar. Parts of the hearth walls and base are also coated with plaster.

When Floor 2 was removed, an arc of cobbles on the north and east side of the hearth was exposed (Figure 14.23). On the north side of the hearth, Floor 1 extends a few centimeters down into a pit that was dug to accommodate this outer arc of cobbles. The removal of Floor 2 also revealed that Floor 1 abuts the south wall of the hearth. This arc of stones may represent the extent of the hearth when Floor 1 was in use. If this is the case, then the earlier hearth had an exterior diameter of approximately 72 cm and interior dimensions of 46 cm north-south by 58 cm east-west. Removal of the exterior arc of rocks revealed a 40-cm-long arc of deteriorated, oxidized, and very friable plaster northwest of the hearth. This plaster may be the remains of an even earlier floor or hearth.

Eight ground stone artifacts were part of the hearth walls, base, and outer arc. These included a vesicular basalt slab metate fragment (FS 4017), a dacite metate fragment (FS 4018), two andesite metate fragments (FS 4019 and FS 4022), a quartzite mano fragment (FS 4020), a dacite two-hand mano fragment (FS 4021), a rhyolite or rhyolitic tuff grinding slab fragment (FS 4045), a welded tuff slab metate fragment (FS 4046), and a dacite grinding slab (FS 4047).

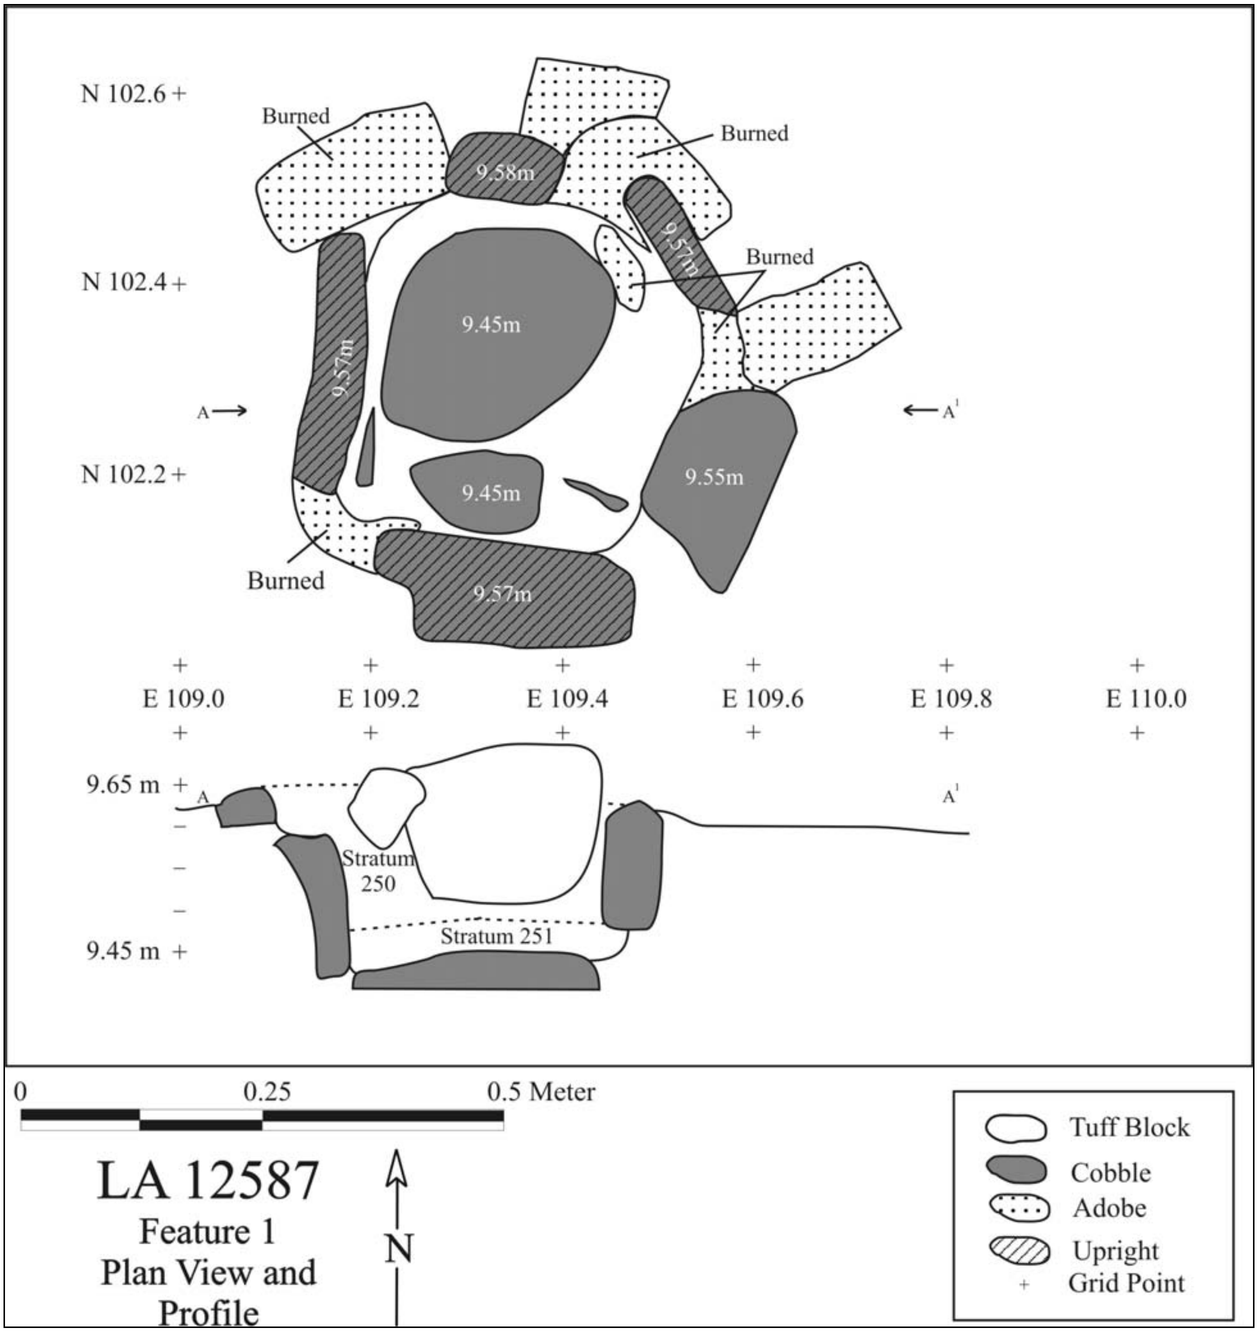

Figure 14.21. Feature 1 plan view and profile.

Figure 14.22. Feature 1.

A large rock that was part of the wall dividing Room 4/5 was placed in the hearth, filling most of its interior. Two strata were found beside and below the masonry block. Stratum 250 is the fill in the upper portion of the hearth and Stratum 251 is a thin ash- and charcoal-rich layer at the base of the hearth. Stratum 250 surrounds the masonry block and so post-dates, or is contemporaneous with it. Stratum 251 is associated with the use of Feature 1 although the thinness of this stratum (3 cm) suggests that the hearth was partially cleaned out before construction of the wall.

Five flotation samples were analyzed from Feature 1. Taxa identified in Stratum 250 (FS 2630 and FS 2632) included sagebrush, four-wing saltbush, saltbush/greasewood, unknown conifer, juniper, tobacco (*Nicotiana*), unidentified pine, piñon pine, ponderosa pine, oak, and maize. Charred wood from the following taxa were identified in the Stratum 251 flotation samples (FS 2635 and FS 4023): saltbush/greasewood, sunflower family, sunflower (*Helianthus*), bugseed, grass family, juniper, mint family, unidentified pine, piñon pine, ponderosa pine, and maize. The following charred material was found in a flotation sample of the plaster of Feature 1 (FS 4049): cheno-ams, beeweed, bugseed, grass family, juniper, unidentified pine, piñon pine, ponderosa pine, and maize. A pollen sample from Stratum 250 (FS 2631) produced the following taxa: maize, prickly pear, beeweed, cheno-ams, grass family, sunflower family, spurge family, unidentified pine, juniper, and sagebrush. Taxa identified in the pollen sample taken from Stratum 251 (FS 2634) included maize, prickly pear, beeweed, purslane, cheno-ams, grass family, mustard family, sunflower family, ragweed/bursage, piñon pine, and sagebrush.

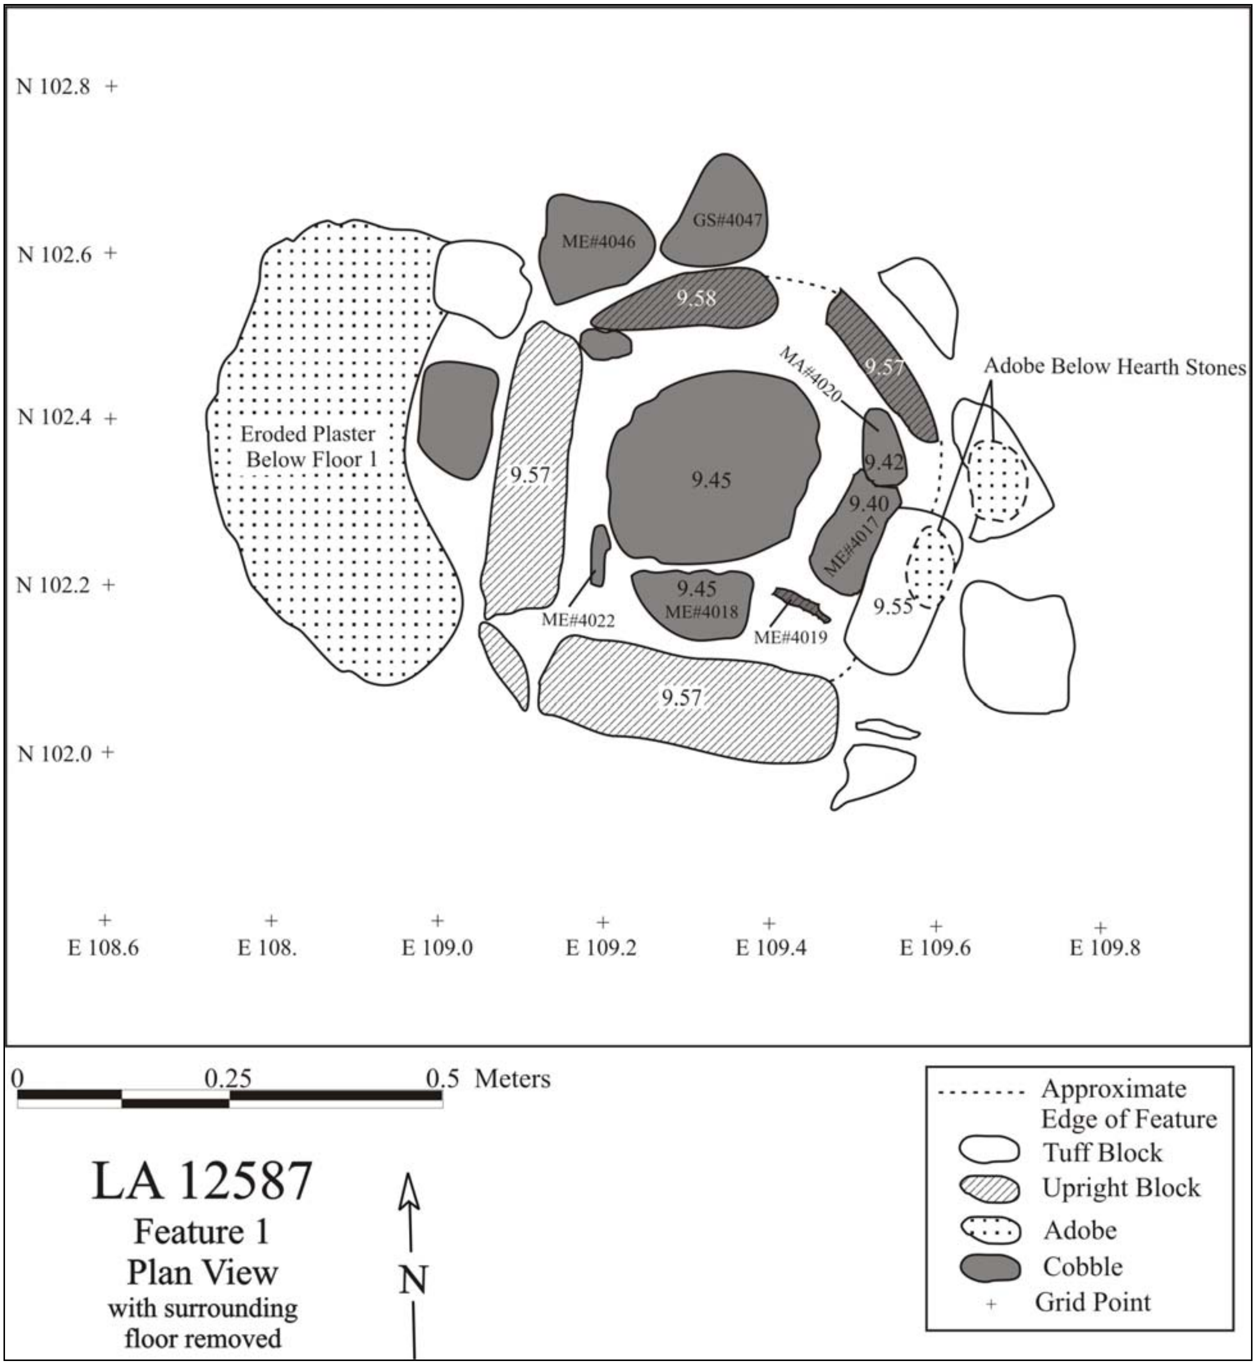

Figure 14.23. Feature 1 with surrounding floor removed.

A maize specimen (from FS 2632) from Feature 1 was subjected to AMS radiocarbon dating. The sample returned an age of 690±40 BP (Beta-183752) and a date of cal AD 1290 with a two-sigma date range of cal AD 1270–1320 and cal AD 1350–1390. An archaeomagnetic sample from the hearth (set 1209B) returned an imprecise date suggesting that the final burning of the hearth occurred sometime in the late 13th or early 14th century.

Feature 8 (Posthole). Feature 8 is an elliptical posthole in Floor 2 situated 1 m northwest of the hearth. Floor 1 forms the base of the posthole. Feature 8 measures 10 by 7.5 cm across and is 3 cm deep. The plaster from the floor does not appear to extend down the lip into the hole.

Feature 16 (Postholes). Feature 16 consists of four postholes in Floor 1. The holes form a rough arc west of the hearth (Feature 1) (Figure 14.24).

Figure 14.24. Feature 16.

Posthole 1 is 20 cm northwest of the hearth and measures 6 cm in diameter. It is 7 cm deep. Posthole 2 is 12 cm southwest of Posthole 1 and 32 cm northwest of the hearth. It is slightly triangular in shape and measures 6 by 5 cm. It is 8 cm deep. Posthole 3 is 6 cm further to the southwest. This hole is 5 cm in diameter and 7 cm deep. Posthole 4 lies 68 cm west of Feature 1 and it is 44 cm southwest of Posthole 3. It measures 6 cm in diameter and is 8 cm deep.

Room 6

Room 6 (Figure 14.25) is south of Room 1 and west of Room 4/5. The interior dimensions of the room are 2.2 m east-west and 3.6 m north-south. The interior area is 7.9 m^2. A shallow sub-floor pit (Feature 7) is present.

Stratigraphy. Table 14.16 summarizes the strata associated with Room 6. A portion of an anthill was located in the northeast corner of the room. Stratum 1 consists of loose, unconsolidated, fine-grained sandy loam. Stratum 10 contains a heterogeneous mix of sandy loam and adobe melt. In a few areas the adobe melt is up to 16 cm thick. In other areas large chunks of adobe are in a sandy loam matrix. In still other areas there are only isolated fragments of adobe. In spots, a thin layer of adobe melt was found just above the floor. The number of masonry blocks removed from Stratum 10 was not recorded. In the northwest corner of the room an 8- to 11-cm-thick deposit of loose, sandy loam (Stratum 70) is present below a thick deposit of adobe melt. This stratum is pre-room collapse fill. Stratum 175, the Pleistocene Btk horizon, underlies the floor in most places and is only a few centimeters deep. Stratum 175 is underlain by bedrock. Strata 126 and 290 are discussed below.

Table 14.16. Room 6 stratigraphy.

Stratum	Color	Texture	Thickness	Description
0	7.5-10YR 4-5/3	sandy loam	0	Surface
1	7.5YR 5/3, 10YR 4-5/3, 5/4	sandy loam	1–7	Unconsolidated surface soil
10	7.5YR 5/3, 10YR 4-5/3, 5/4	sandy loam and adobe melt	22–42	Wallfall and post-occupational fill
70	10YR 5/4	sandy loam	8–11	Fill below wallfall and above floor
126	10YR 7/1	silty clay	0	Floor, surface
175	7.5YR 4/5	sandy clay	2–7	Btk horizon
290	10YR 4/4	sandy loam	15	Feature 7, fill

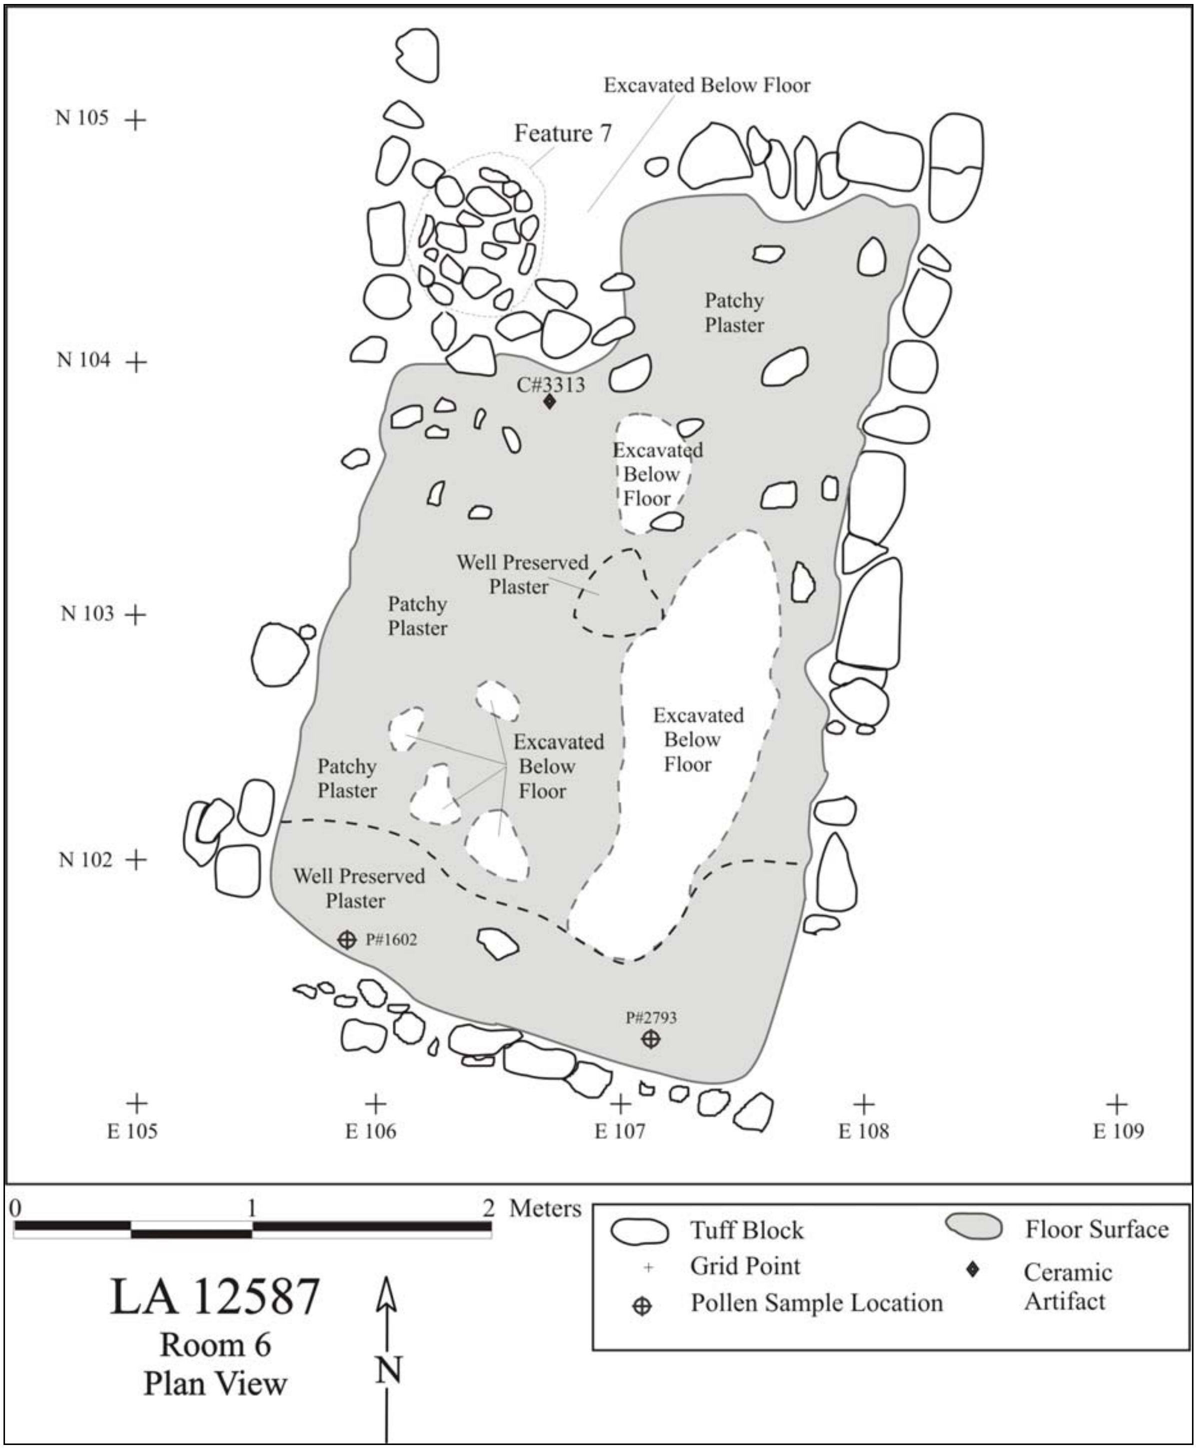

Figure 14.25. Room 6 plan view.

Table 14.17 shows the artifact counts by stratigraphic unit for Room 6. The 'Other' category consists of an adult human left distal humerus fragment (FS 1373), a freshwater shell fragment (FS 1358), an *Anodonta* sp. umbo fragment (FS 1462), two turquoise beads (FS 835 and FS

1375), a hematite fragment (FS 839), three reddish-brown micaceous shale fragments (FS 2223), and several miscellaneous samples.

Table 14.17. Artifact counts by stratum in Room 6.

Stratum	Chipped Stone	Ceramics	Ground Stone	Nonhuman Bone	Other	Total
0	13	26	0	0	0	39
1	117	295	1	1	4	418
10	463	1432	37	15	10	1957
70	5	18	0	0	0	23
126	0	1	0	0	0	1
175	1	3	1	0	0	5
290	0	0	0	0	0	0
Total	**599**	**1775**	**39**	**16**	**14**	**2443**

Floor. The plastered floor surface of Room 6 (Stratum 126) is well-preserved along the south wall; elsewhere it is either absent or greatly disturbed by root and rodent activity. In these areas it appears that some of the adobe floor foundation is present, but not the surficial plaster. Coping is present between the floor, the south wall, and the east wall and in the southwest corner. No evidence of multiple plastering episodes was found, although this may be due to the poor preservation of the floor. Tabular tuff cobbles are set into Stratum 175 in the northern third of the room in order to level the ground surface. A smeared-indented corrugated jar sherd (FS 3313) was the only artifact unambiguously associated with the floor surface of Room 6.

Wall Construction. The north wall abuts the east wall but no other corners are intact. This makes it difficult to determine the room construction sequence. However, based on the construction sequence of the other rooms, it seems likely that the east wall was built first and then the other walls were added. While shaped and unshaped tuff blocks were found in the fill of the room, the field notes give the impression that there was less masonry present here than in some other rooms (e.g., Rooms 2 and 7). As a great deal of adobe melt was found in the room, a significant portion of the Room 6 walls may have been made of adobe. Table 14.18 gives the dimensions of the extant wall segments. The north wall is described above as the south wall of Room 1 and the east wall is described above as the west wall of Room 4/5. Occasional upright tuff blocks and cobbles of the basal course are all that remain of the west wall. A small patch of plaster is present on the interior face of the wall near its north end. The south wall is poorly preserved. The remains of the basal course consist only of a tuff upright and several fist-sized tuff cobbles set in adobe. A horizontally laid tuff block is all that remains of the second course.

Table 14.18. Room 6 wall dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	0.90	0.31	0.23
East	2.21	0.35	0.20
South	1.48	0.22	0.20
West	0.50, 1.48	0.32	0.20

Artifact and Samples. All the artifacts from units 104N/106E and 104N/107E were analyzed. All the macrobotanical material from unit 104N/107E was also analyzed. The single sherd from the floor and all the faunal remains were analyzed. Two shaped andesite slab fragments (FS 2203) were also analyzed. Table 14.19 lists the samples analyzed from Room 6.

Table 14.19. Room 6 analyzed samples by stratum.

175	None	None	None
290	3309	3310	None

1 In addition to the macrobotanical material from 104N/107E

Features

Feature 7 (Pit). Feature 7 is a shallow sub-floor pit (63 cm north-south, 42 cm east-west, and 15 cm deep) that is located adjacent to the west wall in the northwest corner of Room 6 (Figure 14.26). A rough circle of upright tuff cobbles defines the perimeter of the feature; the base consists of fragmented bedrock. The fill of Feature 7 (Stratum 290) was indistinguishable from Stratum 10. The floor around Feature 7 was too disturbed to determine how the former articulated with the latter.

No artifacts were found in the feature and no evidence of burning was observed. One pollen and one flotation sample were recovered from the feature. The following charred taxa were found in the flotation sample (FS 3309): unknown conifer, juniper, and maize. Taxa identified in the pollen sample (FS 3310) included prickly pear, beeweed, cheno-ams, grass family, sunflower family, spurge family, spruce (*Picea*), unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush.

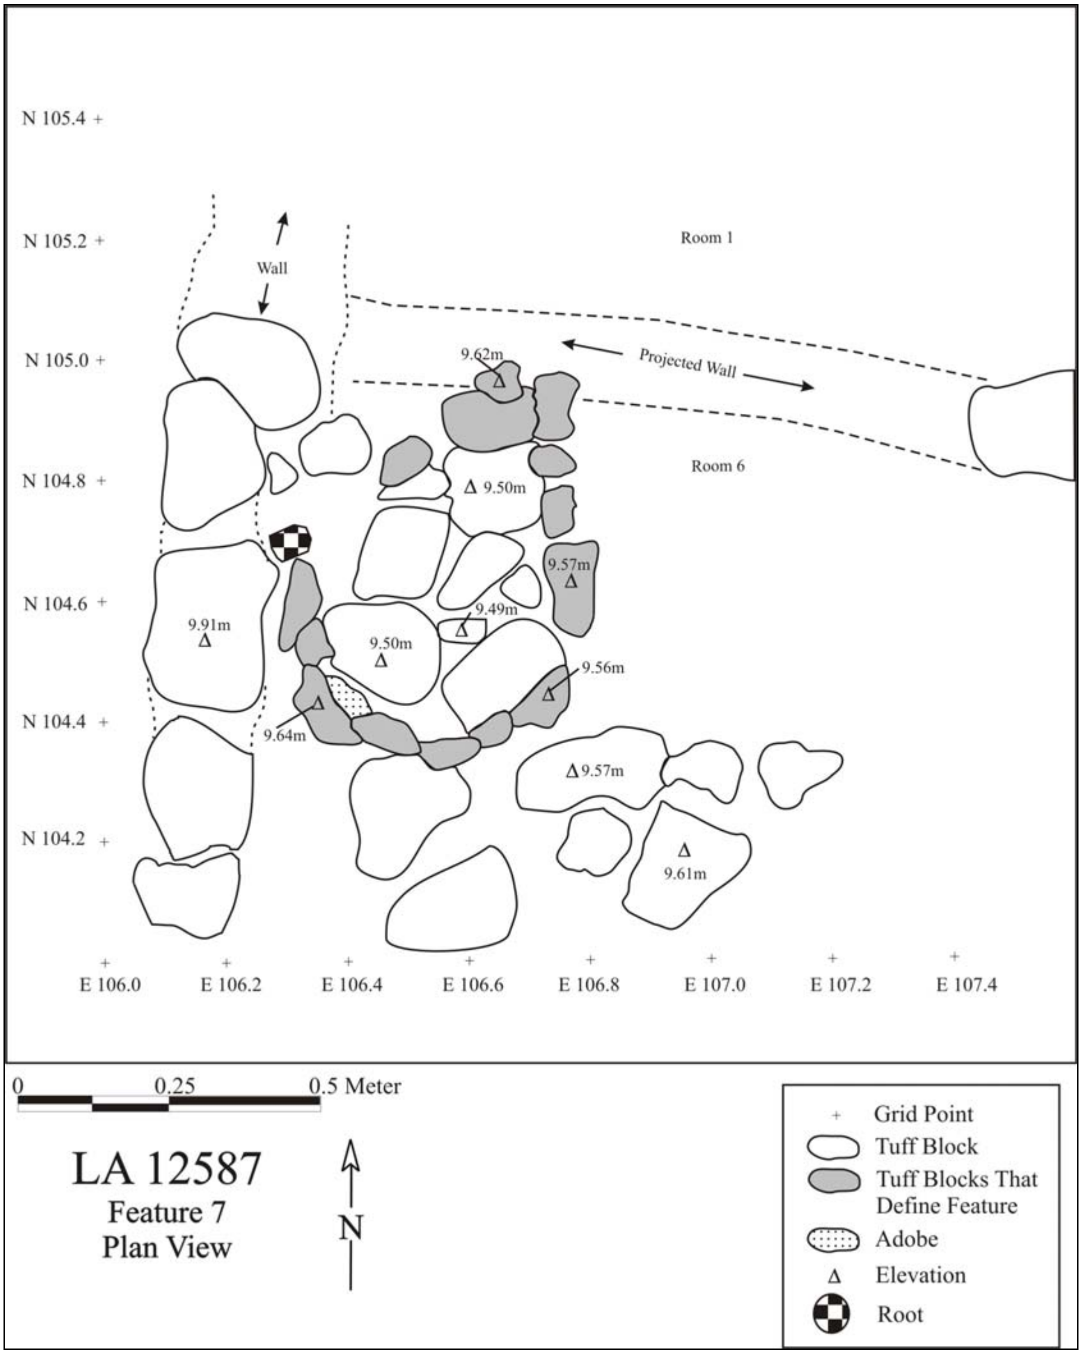

Figure 14.26. Feature 7 plan view.

Room 7

Room 7 is located in the southeast corner of Roomblock 1 (Figures 14.27 and 14.28). It is south of Room 4/5 and east of Room 8. Because the shape and extent of the east and south walls could not be defined, the room size cannot be precisely determined. If it is assumed that the room is rectangular in shape, then the floor area is about 12 m^2. Based on the extant floor, the room is shaped like a blocky, upside down "L" and has an area of about 9.9 m^2. A hearth and ash box complex (Feature 6) and four postholes (Feature 12) were identified in the room.

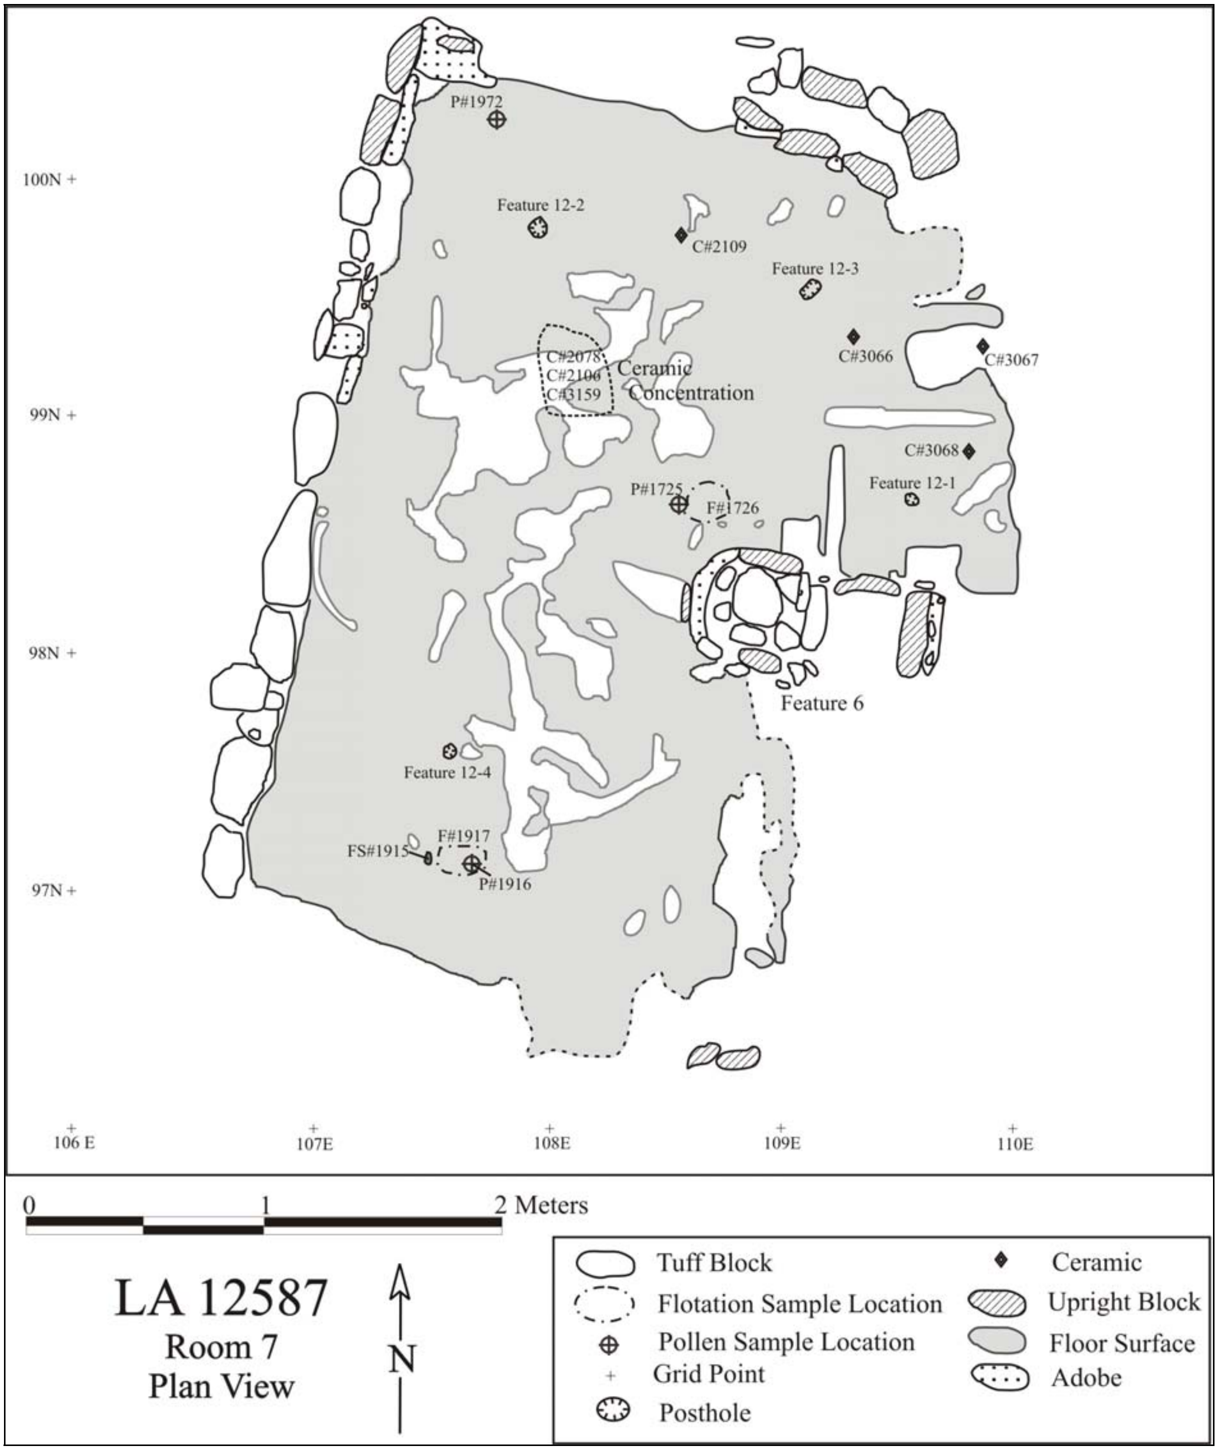

Figure 14.27. Room 7 plan view.

Figure 14.28. Room 7.

Stratigraphy. Table 14.20 summarizes the strata associated with Room 7. Several plants grew in and near Room 7 at the time of excavation, including several prickly pear cacti and one sagebrush. A piñon tree was located just off the southwest corner of the room. The ground surface in this area was covered with pine needles. Stratum 1 consisted of loose, unconsolidated, fine-grained sandy loam. Six tuff masonry blocks were found in this stratum. Stratum 10 consisted of moderately compact sandy loam with varying amounts of tuff gravel, wallfall, and occasional ashy stains. Wallfall includes approximately 160 shaped and unshaped tuff blocks, fist-sized tuff cobbles, adobe chunks, and adobe melt. No rooffall could be identified. The strata associated with the floors and features of Room 7 are discussed subsequently.

Table 14.20. Room 7 stratigraphy.

Stratum	Color	Texture	Thickness (cm)	Description
0	10YR 4-5/3, 10YR 4.5/4	sandy loam	0	Surface
1	10YR 5/3	sandy loam	1–7	Unconsolidated surface soil
10	10YR 4-5/3, 10YR 3-3.5/4-4.5	sandy loam	18–34	Wall fall and post-occupational fill
127	10YR 6.5/1	silty clay	0	Floor, surface
170	10YR 4/4	sandy loam	2–5	Sub-floor soil

Stratum	Color	Texture	Thickness (cm)	Description

309	N/A	plaster/adobe	N/A	Feature 6, earlier wall of hearth

Table 14.21 shows the artifact counts by stratigraphic unit for Room 7. The 'Other' category consists of two freshwater shell fragments (FS 1850) and a plaster sample. The first total row in Table 14.21 includes only artifacts found in Room 7. This total is less than that from other rooms because artifacts found in Room 3 (which overlays Room 7 and covers 3.2 m^2) are not included. When artifacts from Room 3, many of which are probably associated with Room 7, are included, the total number of artifacts is similar to that of other rooms.

Table 14.21. Room 7 artifact counts by stratum.

Floor. The floor surface (Stratum 127) of Room 7 is fairly even with only slight undulations. In the corners the floor is well-preserved but there is a great deal of rodent and root disturbance in the center of the room. The edges of the floor are well defined along the north wall and in the southwest corner where they cope up to the walls or show evidence of coping where the walls are absent. Coping also occurs in spots along the west wall. More frequently the floor has broken away from the wall leaving a 5- to 10-cm gap between the wall and the floor. In the east and southeast of the room there is no clear edge of the floor. Instead, the floor grades into the sandy loam exterior fill (Stratum 200). Two episodes of floor plastering are evident but in many areas the two surfaces merge into one, making it impossible to determine which surface is being observed.

The floor assemblage consists of a partial ceramic vessel in 12 sherds (FS 2078, FS 2106, FS 2109, and FS 3159; several sherds from FS 2104 may also be part of this vessel), three sherds that are not part of the vessel and include a smeared-indented corrugated jar sherd (FS 3066), an indented corrugated jar sherd (FS 3067), and a Santa Fe Black-on-white bowl sherd (FS 3068), and a dacite ground stone fragment (FS 1915). In addition, two flotation and two pollen samples were collected from the floor. Taxa identified in the flotation samples include sagebrush, cheno-ams, saltbush/greasewood, plantain (*Plantago*), unknown conifer, juniper, groundcherry, piñon pine, ponderosa pine, prickly pear, and maize. Taxa identified in the pollen samples include maize, cholla, prickly pear, beeweed, cheno-ams, grass family, sunflower family, spurge family, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush.

Wall Construction. No corners of the room were intact, so the construction sequence of the room was undetermined. Table 14.22 gives the dimensions of the extant wall segments. The west wall consists of a single row of coursed tuff blocks and chinking stones set in mortar (Figure 14.29). All of the masonry blocks are horizontally laid except for the two northernmost blocks; these are both uprights. Two courses are present at the center of the wall but only one course survives at the north and south ends. The masonry of the wall ranges in size from 20 by 17 by 5 cm to 45 by 18 by 18 cm. Although a few blocks exhibit some minor shaping, most of the masonry is unshaped. Two small tuff uprights near the southeast corner of the room may have been part of the south wall. Nothing else remains of the south wall. No evidence of an east wall was found, although, presumably, one was present. The north wall is described with Room 4/5.

Table 14.22. Room 7 dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	0.63, 0.97	0.25	0.38
East	n/a	n/a	n/a
South	0.48	0.10	0.15
West	3.66	0.35	0.33

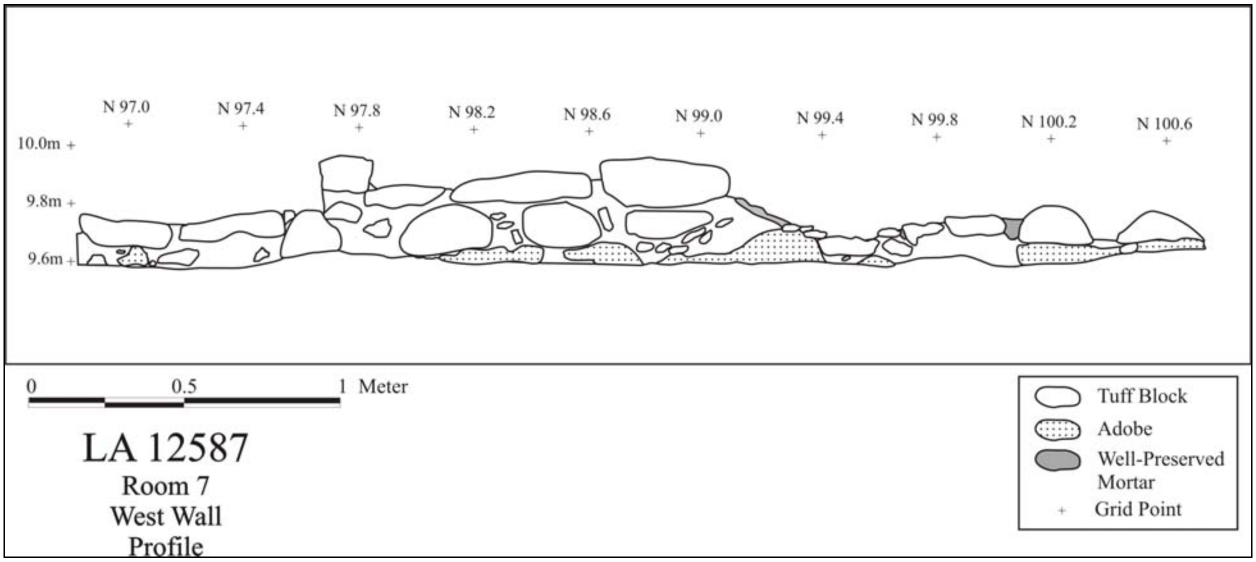

Figure 14.29. Room 7 west wall profile.

Artifacts and Samples. All the artifacts from units 98N/107E and 98N/108E were analyzed as were all the artifacts from below the base of the Room 3 walls in unit 99N/108E. All the macrobotanical material from unit 98N/107E was analyzed. All the artifacts found on the floor and all the faunal remains were analyzed. A Cerro Toledo obsidian side-notched Puebloan point was also analyzed (FS 2284). Table 14.23 lists the samples analyzed from Room 7.

Table 14.23. Room 7 analyzed samples by stratum.

1 In addition to the macrobotanical material from 98N/107E

Features

Feature 6 (Hearth and Ash Box). Feature 6 is a hearth and ash box complex. The hearth shows evidence of initial construction and a later remodeling. The initial construction of the hearth consisted of arranging a ring of dacite and tuff uprights in a pit in the floor (Figures 14.30 and 14.31). Three of these stones (A, B, and C in Figure 14.30) were clearly set into the earlier floor. The interior of the ring of uprights was plastered over. The interior diameter at the top of the hearth after the initial construction was approximately 50 cm.

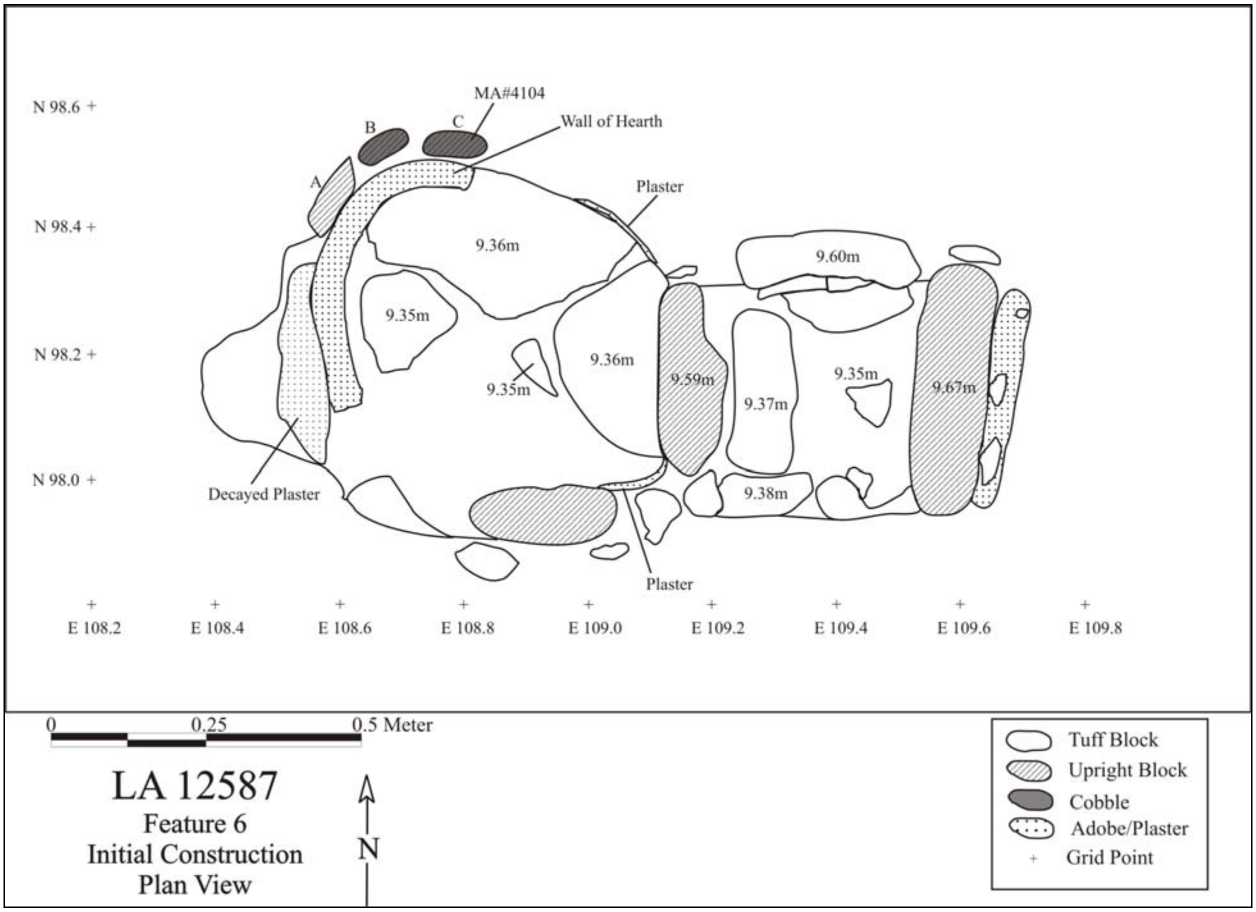

Figure 14.30. Feature 6 initial construction plan view.

Later, the hearth was remodeled (Figures 14.32 and 14.33). Stones A, B, and C were covered by floor plaster and a new layer of plaster was laid in the hearth interior. Dacite and tuff slabs were placed into this plaster to form the walls of the hearth. In some areas, the old interior was merely covered by 1 or 2 cm of plaster. Along the northwest arc of the hearth, several thin slabs were placed between the first and second interiors. The interior diameter at the top of the remodeled hearth is approximately 45 cm and 19 cm deep. In both hearth construction episodes several ground stone fragments were used to form the hearth walls. These include a dacite grinding slab (FS 3982), two vesicular basalt two-hand mano fragments (FS 3986 and FS 4104), an andesite slab metate fragment (FS 3987), a tuff milling stone (FS 3988), a basalt hoe (FS 3989), and a dacite two-hand mano (FS 4105).

Figure 14.31. Feature 6 initial construction.

Figure 14.32. Feature 6 remodeled hearth.

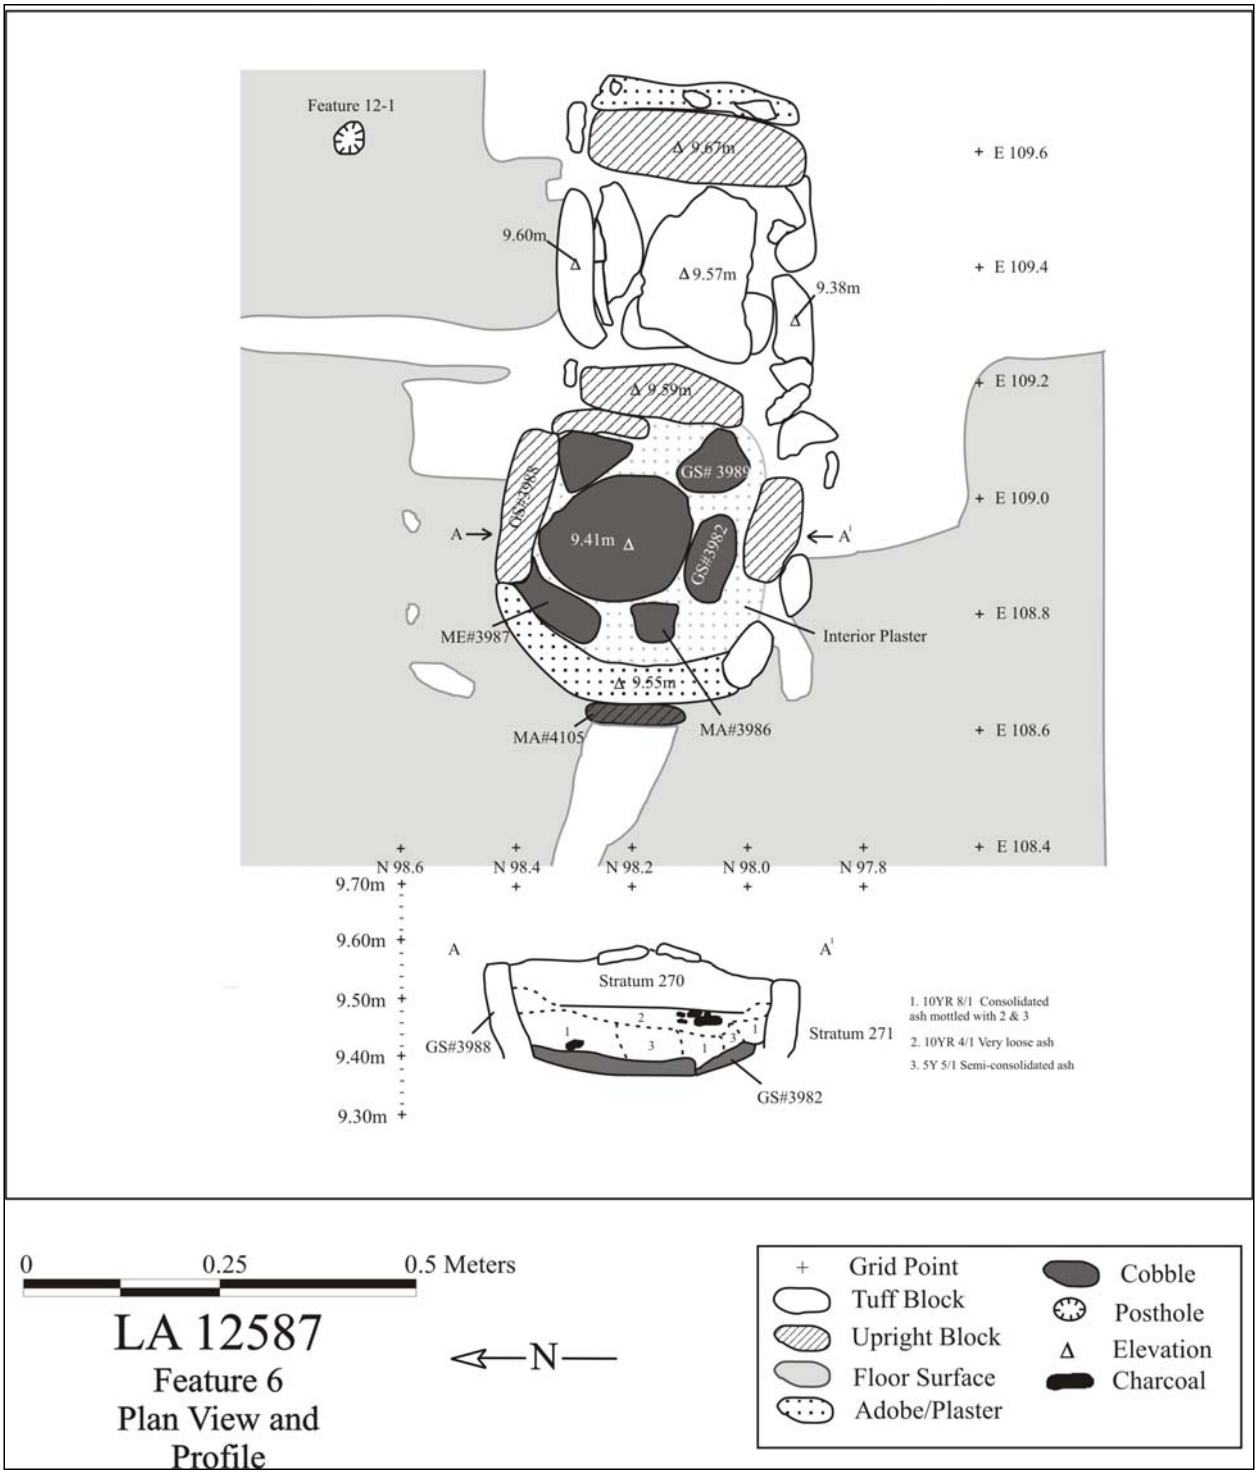

Figure 14.33. Feature 6 remodeled hearth plan view and profile.

The base of the hearth (34 by 24 cm after the remodeling) consists of a large, flat, dacite cobble. This cobble seems to be too small to have served as the base of the original hearth, suggesting that the hearth base may have been remodeled in addition to the walls. A small amount of ash was found below the dacite cobble.

The fill of the hearth consists of two strata. The upper stratum (Stratum 270) is generally 10 cm thick and consists of sandy loam. It is indistinguishable from Stratum 10. Below Stratum 270 there is a deposit of ash that is approximately 8 cm deep (Stratum 271). Other strata associated with the hearth are Stratum 300 (the interior plaster of the remodeled hearth), Stratum 301 (material between the first and second layers of interior plaster), Stratum 308 (the ashy material below the hearth base), and Stratum 309 (the original hearth plaster). Flotation and pollen samples were taken from each of these strata.

Charred taxa identified in the Stratum 270 flotation samples (FS 3273, FS 3274, FS 3275, FS 3276, FS 3319, FS 3320, and FS 3321) include sagebrush, pigweed, saltbush/greasewood, four-wing saltbush, bugseed, goosefoot, cheno-ams, grass family, unknown conifer, Desert olive, juniper, bean (*Phaseolus*), tobacco, unidentified pine, piñon pine, ponderosa pine, prickly pear, cottonwood/willow, purslane, Douglas fir, oak, and maize. Taxa identified in the Stratum 270 pollen sample (FS 3358) include maize, cholla, beeweed, cheno-ams, grass family, sunflower family, spurge family, unidentified pine, piñon pine, and sagebrush.

Taxa identified in the Stratum 271 flotation samples (FS 3277, FS 3278, FS 3279, FS 3280, FS 3281, FS 3282, FS 3322, FS 3323, and FS 3324) include saltbush/greasewood, goosefoot, bugseed, unknown conifer, juniper, tobacco, evening primrose, unidentified pine, piñon pine, bean, prickly pear, groundcherry, cottonwood/willow, purslane, ponderosa pine, Douglas fir, and maize. Taxa identified in the Stratum 271 pollen sample (FS 3360) include maize, cholla, prickly pear, beeweed, purslane, cheno-ams, grass family, spurge family, sunflower family, unidentified pine, piñon pine, juniper, and sagebrush.

Taxa identified in the Stratum 300 flotation samples (FS 3983, FS 3984, and FS 3985) include pigweed, sagebrush, saltbush/greasewood, goosefoot, cheno-ams, Desert olive, unknown conifer, juniper, groundcherry, unidentified pine, piñon pine, ponderosa pine, purslane, oak, and maize. Taxa identified in the pollen sample (FS 3985) from this stratum include maize, prickly pear, beeweed, cheno-ams, grass family, sunflower family, ragweed/bursage, unidentified pine, piñon pine, juniper, and sagebrush.

Taxa identified in the Stratum 301 flotation samples (FS 3990 and FS 3991) include sagebrush, saltbush/greasewood, goosefoot, Desert olive, unknown conifer, juniper, piñon pine, ponderosa pine, cottonwood/willow, and maize. No pollen samples were collected from this stratum.

Taxa identified in the Stratum 308 flotation sample (FS 4102) include saltbush/greasewood, goosefoot, unknown conifer, juniper, piñon pine, oak, and maize. A pollen sample (FS 4100) was collected from this stratum but it was not analyzed.

No charred material was recovered from the Stratum 309 flotation sample (FS 4098), although piñon pine needles were identified. Taxa identified in the single pollen sample taken from this stratum (FS 4098) include maize, prickly pear, cheno-ams, sunflower family, spurge family, unidentified pine, piñon pine, juniper, and sagebrush.

A maize specimen (from FS 3274 and FS 3319) from Feature 6 was submitted for AMS radiocarbon dating. The sample returned an age of 860±40 BP (Beta-183753) and a date of cal AD 1190 with a two-sigma date range of cal AD 1040–1260. A sample (UW 1032) of the earlier hearth plaster (Stratum 309) was submitted for thermoluminescence dating. The sample returned a date of AD 981 with a two-sigma date range of AD 803–1159.

An ash box was identified east of the hearth. An upright tuff block that was part of the eastern hearth wall formed the west wall of the ash box. The north wall was formed by a second tuff upright and two underlying tuff cobbles. The top of the west wall and north wall is 1 to 2 cm above the floor level. The east wall of ash box was formed by a larger, shaped tuff block, the top of which was 7 cm above the floor level. This block may have served as a deflector, or the base of a deflector. There is no obvious south wall. The ash box had no obvious floor but bedrock was encountered at 22 cm below the floor level, and a shaped tuff slab lying diagonally between the bedrock and the west fall formed a partial floor/wall. The interior dimensions of the ash box are 32.5 cm east-west and 35 cm north-south.

A large (24 by 21 by 12 cm), unshaped tuff block was found in the center of the ash box just below floor level. The rest of the fill (Stratum 307) was similar to Stratum 10. No ash and only a few flecks of charcoal were found. Two flotation samples were analyzed from Stratum 307 (FS 4074 and FS 4075) and the identified taxa included pigweed, sagebrush, saltbush/greasewood, goosefoot, squash/coyote gourd, spurge, Desert olive, unknown conifer, juniper, groundcherry, unidentified pine, piñon pine, prickly pear, cottonwood/willow, oak, purslane, buffalo burr, dropseed grass, and maize. One pollen sample (FS 4073) was collected from Stratum 307 and identified taxa included maize, cheno-ams, sunflower family, unidentified pine, piñon pine, and sagebrush.

Feature 12 (Postholes). Feature 12 consists of four postholes. Posthole 12-1, located 50 cm northwest of the hearth, is the smallest of the four postholes (5 cm in diameter) and has a smooth plaster interior but not a plaster bottom. Postholes 12-2, 12-3, and 12-4 may define three corners of a 2.3- by 1.4-m rectangular structure, although a posthole that would form the southeast corner was not found. Postholes 12-2 (7.5-cm diameter) and 12-4 (7.0-cm diameter) are well-preserved and both have smooth plaster interiors. Posthole 12-3 is slightly damaged and lacks a well-defined southwest arc, but was probably 8 cm in diameter. It appears to have had a smooth plaster interior.

Room 8

Room 8 (Figure 14.34) is one of the back rooms in Roomblock 1. Room 8 is south of Room 6, north of Room 9, and west of Room 7. The room interior measures 3.5 m north-south by 2.1 m east-west and has an interior floor area of 7.4 m^2. No interior features were identified during excavations.

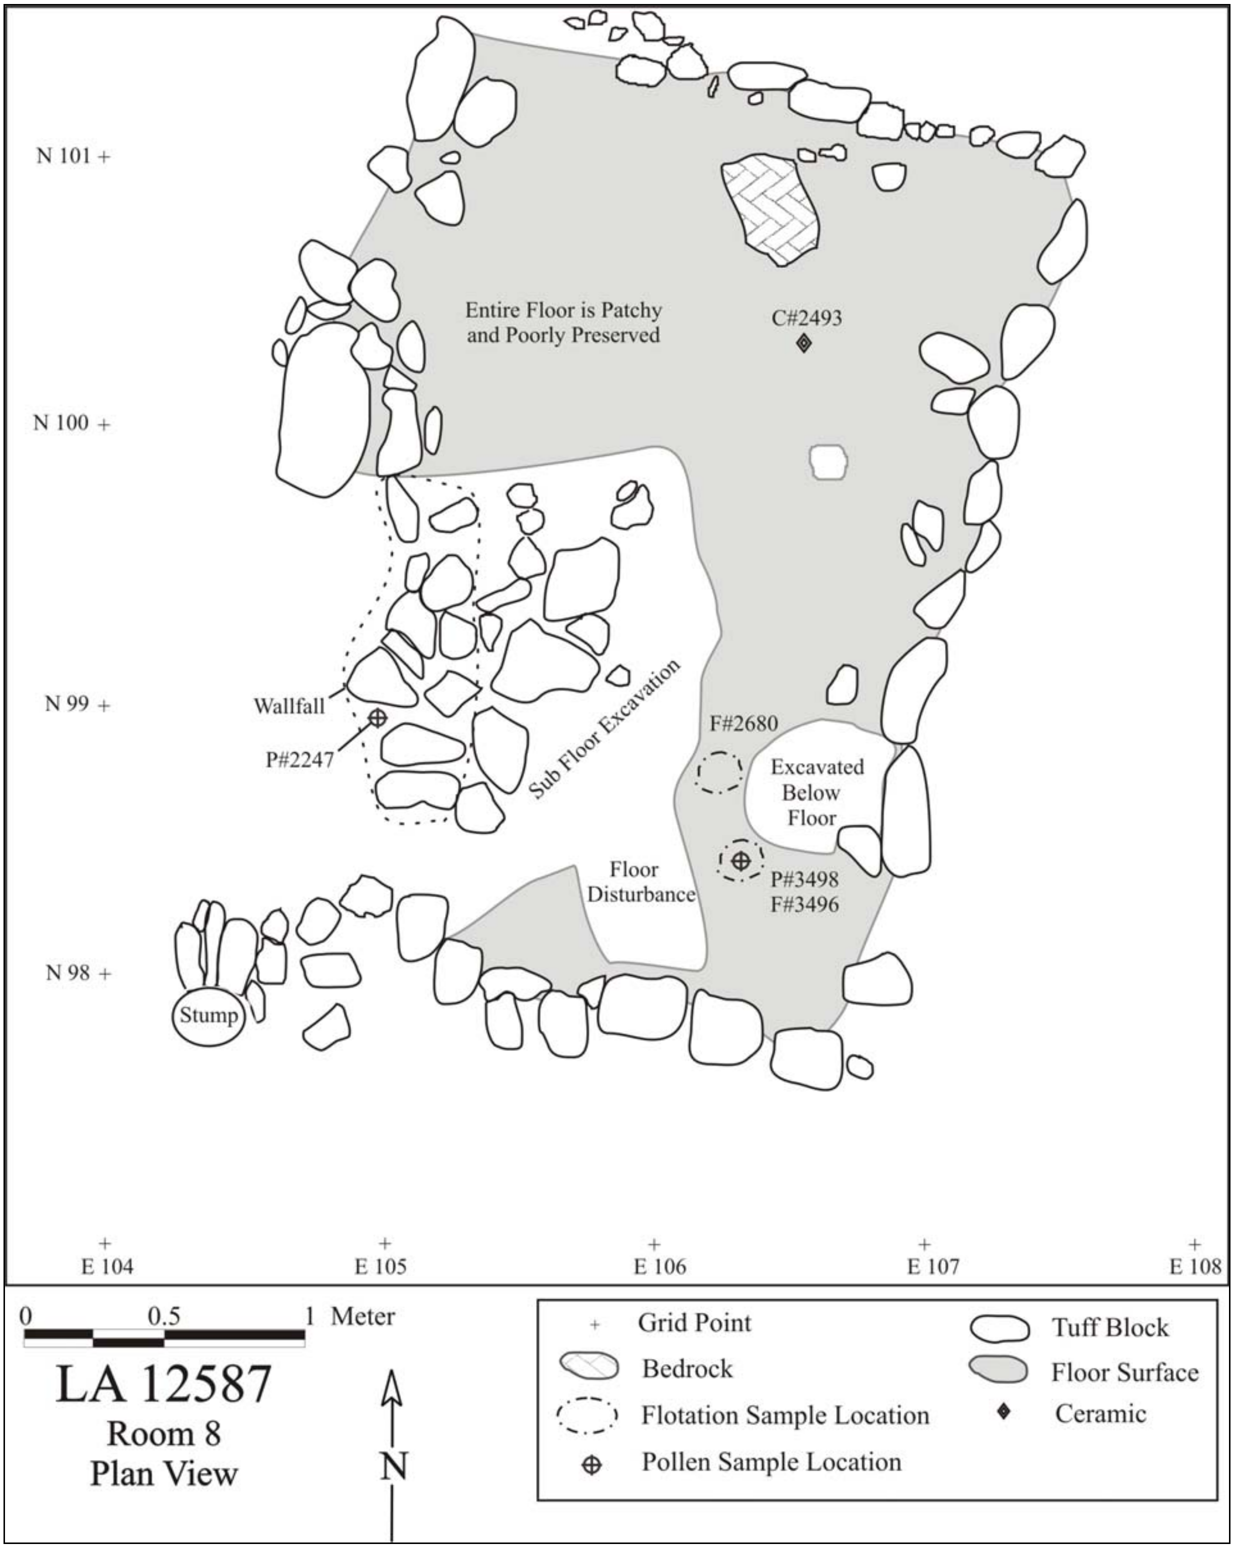

Figure 14.34. Room 8 plan view.

Stratigraphy. Table 14.24 summarizes the strata associated with Room 8. Much of the ground surface was covered by pine duff and twigs from a nearby piñon tree. Stratum 1 consists of loose, unconsolidated, sandy loam. Stratum 10 consists of compact sandy loam and areas of consolidated adobe melt. Many masonry blocks were found in this stratum. Strata associated with the floor and sub-floor are discussed in the subsequent section.

Table 14.24. Room 8 stratigraphy.

Stratigraphic Unit	Thickness (cm)	Color	Texture	Description
0	0	10YR 4/3	sandy loam	Surface
1	1–5	10YR 4/3	sandy loam	Unconsolidated surface soil
10	24–35	10YR 4/3	sandy loam	Wallfall and post-occupational fill
128	0	10YR 7/1	silty clay	Floor, surface
170	1–2	10 YR 4/3	sandy loam	Sub-floor soil

Table 14.25 shows the artifact counts by stratigraphic unit for Room 8. The 'Other' category consists of a freshwater shell fragment (FS 2426).

Table 14.25. Room 8 artifact counts by stratum.

Stratum	Chipped Stone	Ceramic	Ground Stone	Nonhuman Bone	Other	Total
0	0	0	0	0	0	0
1	40	65	0	0	0	105
10	187	778	6	8	1	980
128	0	1	0	0	0	1
170	0	0	0	0	0	0
Total	**227**	**844**	**6**	**8**	**1**	**1086**

Floors. The floor surface of Room 8 (Stratum 128) is patchy and poorly preserved. It has been greatly disturbed by roots (including the roots of a large piñon in the southwest corner of the room) and rodent activity. The floor foundation is 1 to 4 cm thick. In many areas, shaped and unshaped tuff blocks are set into the loose sandy loam sub-floor deposits (Stratum 170) to provide a level surface for the floor foundation. In other areas, the floor is built directly on bedrock. There is no evidence of multiple plastering events. In some areas there is coping between the floor and the walls. Coping is best preserved in the northeast and southeast corners of the room. A smeared-indented corrugated jar sherd was found on the floor. Two pollen (FS 2247 and FS 3498) and flotation (FS 2680 and FS 3496) samples were taken on the floor. Taxa identified in the pollen samples included maize, cholla, prickly pear, beeweed, cheno-ams, grass family, sunflower family, ragweed/bursage, chicory tribe (Liguliflorae), spurge family, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush. Taxa identified in the flotation samples included pigweed, goosefoot, cheno-ams, Desert olive, piñon pine, juniper, and maize. A pollen (FS 3499) and flotation (FS 3497) sample were collected from the sub-floor context. Taxa identified in the pollen sample included cholla, prickly pear, beeweed, cheno-ams, sunflower family, unidentified pine, piñon pine, and sagebrush. Taxa identified in the flotation sample included saltbush/greasewood, goosefoot, unknown conifer, juniper, piñon pine, ponderosa pine, and maize.

Wall Construction. The room corners are poorly preserved so the construction sequence of the room could not be determined. Table 14.26 gives the dimensions of the extant wall segments. The north wall is described above as the south wall of Room 6 and the east wall is described above as the west wall of Room 7. The south and the west wall are poorly preserved; all that could be determined about their construction was that the basal course was made of tuff blocks set into adobe mortar. On all walls, faint remnants of plaster were occasionally found.

Table 14.26. Room 8 wall dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	1.48	0.20	0.20
East	3.66	0.33	0.22
South	1.75	0.22	0.20
West	1.80	0.22	0.40

Artifacts and Samples. All the artifacts from units 100N/105E and 100N/106E were analyzed. All the faunal remains from this room were analyzed. Table 14.27 lists the samples analyzed from Room 8.

Table 14.27. Room 8 analyzed samples by stratum.

Stratum	Flotation	Pollen	Macrobotanical
10	None	2679	2492
70	1699	1698	None
128	2680, 3496	2247, 3498	None
170	3497	3499	None

Room 9

Room 9 (Figure 14.35) is located at the southwest end of the Roomblock 1. The interior dimensions of the room are 4.9 m north-south and 1.9 m east-west. The interior area is 9.3 m^2. No interior features were identified in the room.

Stratigraphy. Table 14.28 summarizes the strata associated with Room 9. Stratum 1 consists of loose, unconsolidated, sandy loam. Stratum 10 consists of compact sandy to clayey loam, wallfall, adobe, and rooffall. Stratum 70, the fill below the wallfall but above the floor, consists of loose, unconsolidated, and relatively homogeneous sandy to silty loam. The strata associated with the floor and sub-floor are discussed below in the following section.

Table 14.28. Room 9 stratigraphy.

Stratigraphic Unit	Thickness (cm)	Color	Texture	Description
0	0	10YR 4/3	sandy loam	Surface
1	1–6	10YR 4/3	sandy loam	Unconsolidated surface soil
10	16–22	7.5 YR 4/4	sandy loam, clay loam	Wallfall and post-occupational fill
70	8–10	10YR 4/3	sandy to silty loam.	Fill below wallfall and above floor
129	0	10YR 6/3	silty clay	Floor, surface
170	4–20	10YR 4/3	sandy to silty loam	Sub-floor soil

Table 14.29 shows the artifact counts by stratigraphic unit for Room 9. The 'Other' category includes a small piece of turquoise (FS 2389), a fragment of hematite (FS 2955), and several miscellaneous samples.

Table 14.29. Room 9 artifact counts by stratum.

Stratum	Chipped Stone	Ceramic	Ground Stone	Nonhuman Bone	Other	Total
0	0	1	0	0	0	1
1	82	200	2	1	0	285
10	278	1028	9	3	2	1320
129	0	0	0	0	1	1
170	13	49	2	12	3	79
Total	**373**	**1278**	**13**	**16**	**6**	**1686**

Floor. Floor plaster was found only in the northern half of the room. Here the floor surface was patchy and poorly preserved. In the southern half of the room it was not possible to follow the floor and the entire area was excavated to 4 to 20 cm below floor level. Coping is visible between the floor and the walls, but only in the northeast corner of the room. Where the floor is present it appears to have been built directly on top of bedrock. In areas where the bedrock undulates, flattened, shaped tuff blocks were used to create a level surface. There is no evidence for multiple plastering episodes. No artifacts were found on the floor surface. Two pollen (FS 2570 and FS 3502) and two flotation samples (FS 2571 and FS 3500) were collected from the floor surface. Taxa identified in the pollen samples included maize, cholla, prickly pear, beeweed, cheno-ams, grass family, sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon pine, juniper, and sagebrush. Taxa identified in the flotation samples included saltbush/greasewood, juniper, piñon pine, cottonwood/willow, and maize. A flotation (FS 3501) and pollen (FS 3503) sample were collected from sub-floor contexts. Taxa identified in the pollen sample included maize, cholla, prickly pear, cheno-ams, sunflower family, ragweed/bursage, unidentified pine, piñon pine, and sagebrush. Taxa identified in the flotation sample included saltbush/greasewood, juniper, unidentified pine, piñon pine, rose family, cottonwood/willow, dropseed grass, and maize.

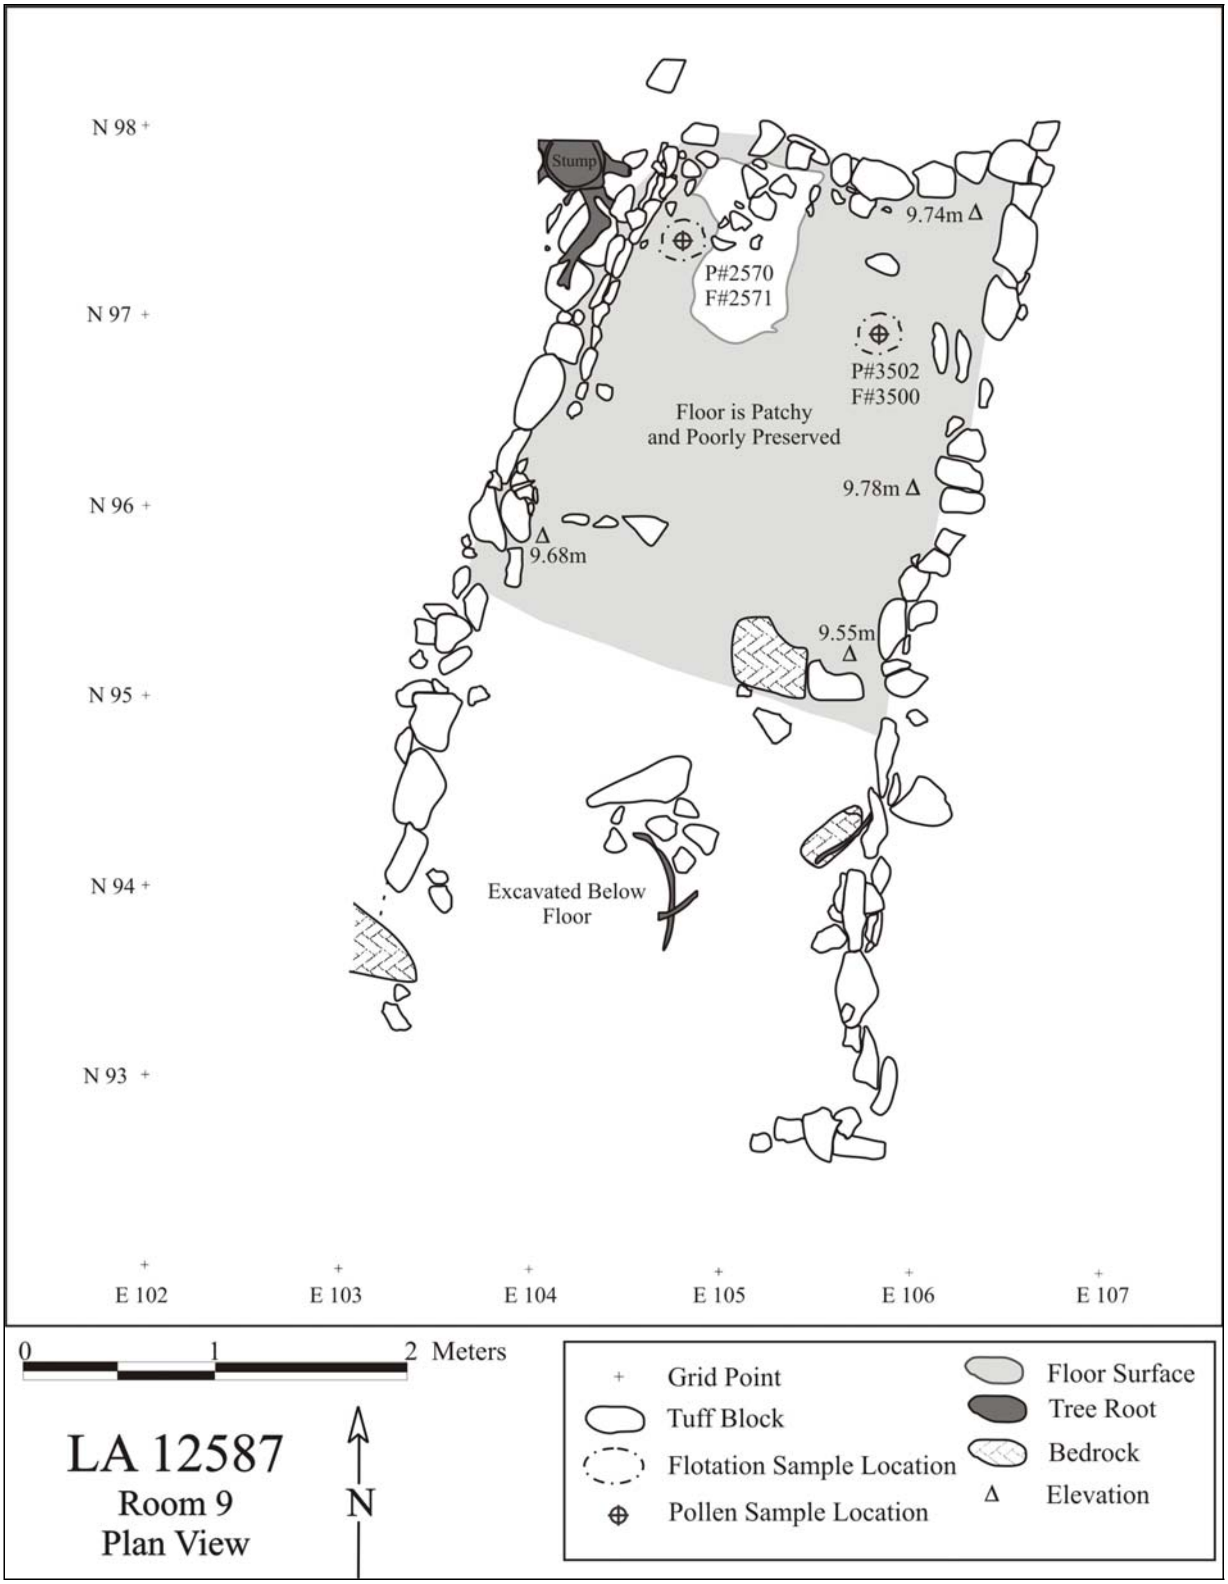

Figure 14.35. Room 9 plan view.

Wall Construction. The sequence of wall construction in this room is difficult to determine because all of the remaining corners are in poor condition. It is possible that the north and south walls are bonded with the east wall. Table 14.30 gives the dimensions of the extant wall segments.

Table 14.30. Room 9 wall dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	1.75	0.30	0.20
East	4.80	0.18	0.20
South	0.70	0.35	0.29
West	4.33	0.23	0.38

The north wall of Room 9 is described in Room 8. Five tuff blocks in the southeast corner of the room are all that remain of the south wall. The basal course of the east and west walls consists of tuff uprights set into an adobe bed. Additional adobe mortar was applied to the sides and tops of the uprights. In places, the west wall is two uprights thick. A few segments of the second course of the west wall were preserved. These segments consist of horizontally laid flat tuff blocks.

Artifacts and Samples. All the artifacts from units 96N/104E and 97N/105E were analyzed. All the faunal remains from the room were analyzed. Table 14.31 lists the samples analyzed from Room 9.

Table 14.31. Room 9 analyzed samples by stratum.

Stratum	Flotation	Pollen	Macrobotanical
1	None	None	2567
10	2397	2229	2233
129	2571, 3500	2570, 3502	3404
170	3501	3503	3624

Roomblock 2 (Room 3)

During excavation it became apparent that a later structure overlay Roomblock 1 and this structure was originally designated Roomblock 2. Subsequently, Roomblock 2 was discovered to consist of only a single room (Room 3).

Room 3

Room 3 is situated over the northwest corner of Room 7 of Roomblock 1 and small portions of Rooms 8 and 4/5 (Figures 14.36 and 14.37). The room has an interior area of 3.2 m^2 (1.9 by 1.7 m). No internal features were identified during excavation. Room 3 is interpreted as a fieldhouse and may be contemporaneous with one or more agricultural features at the site (e.g., Features 17, 18, and 22).

Stratigraphy. Table 14.32 summarizes the strata associated with Room 3. Stratum 1 is loose, unconsolidated, fine-grained sandy loam. Ten tuff masonry blocks were recovered from this stratum. Stratum 20 consists of moderately compact sandy loam and a mix of approximately 40 shaped and unshaped tuff blocks, chinking stones, chunks of adobe, and adobe melt. Stratum 20 was generally less compact than Stratum 10; otherwise the two strata were indistinguishable. Fill above the base of the Room 3 walls was assigned to Stratum 20; fill below was assigned to Stratum 10. The fill in, and immediately below, the walls of Room 3 was designated as Stratum 21.

Table 14.32. Room 3 stratigraphy.

Stratum	Color	Texture	Thickness (cm)	Description
0	10YR 5/3	sandy loam	0	Surface
1	10YR 5/3	sandy loam	2–5	Unconsolidated surface soil
20	7.5YR 4/2, 10YR 4-5/3, 4/4	sandy loam	14–25	Wallfall and post-occupational fill
21	10YR 4/4	sandy loam	N/A	Wall fill

Figure 14.36. Room 3 after excavation.

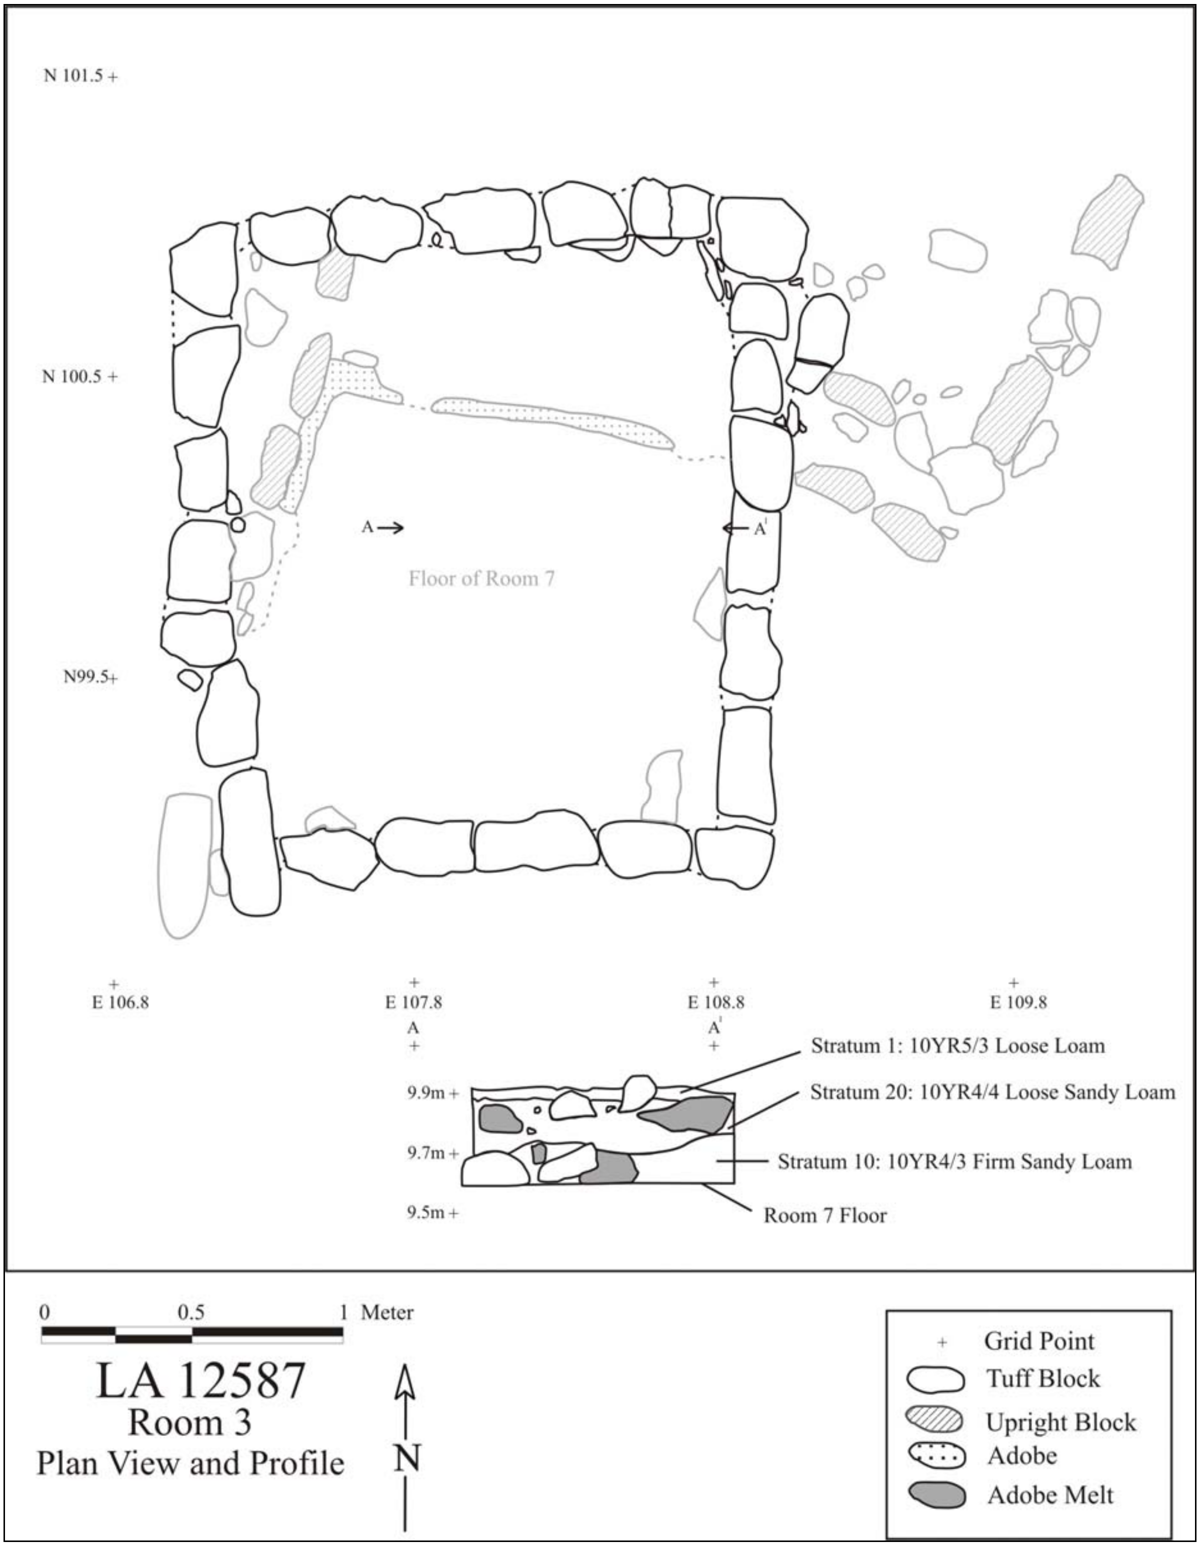

Figure 14.37. Room 3 plan view and profile.

Table 14.33 shows the artifact counts by stratigraphic unit for Room 3. The 'Other' category consists of a freshwater shell fragment (FS 1499) and several miscellaneous samples. Given the amount of bioturbation at the site and the difficulty distinguishing between Stratum 20 and Stratum 10, many of the artifacts in Table 14.33 are probably associated with Roomblock 1 not Room 3 (Roomblock 2).

Table 14.33. Room 3 artifact counts by stratum.

Stratum	Chipped Stone	Ceramic	Ground Stone	Bone	Other	Total
0	1	3	0	0	0	4
1	30	91	1	0	0	122
20	67	219	6	1	1	294
21	24	45	0	1	2	72
Total	**122**	**358**	**7**	**2**	**3**	**492**

Floor. No floor or use surface was found in Room 3.

Wall Construction. The walls of Room 3 (Table 14.34) were constructed of a single row of horizontally laid coursed tuff blocks held together by mortar. At the eastern end of the north wall, two courses are present; elsewhere only one course survives (Figure 14.38).

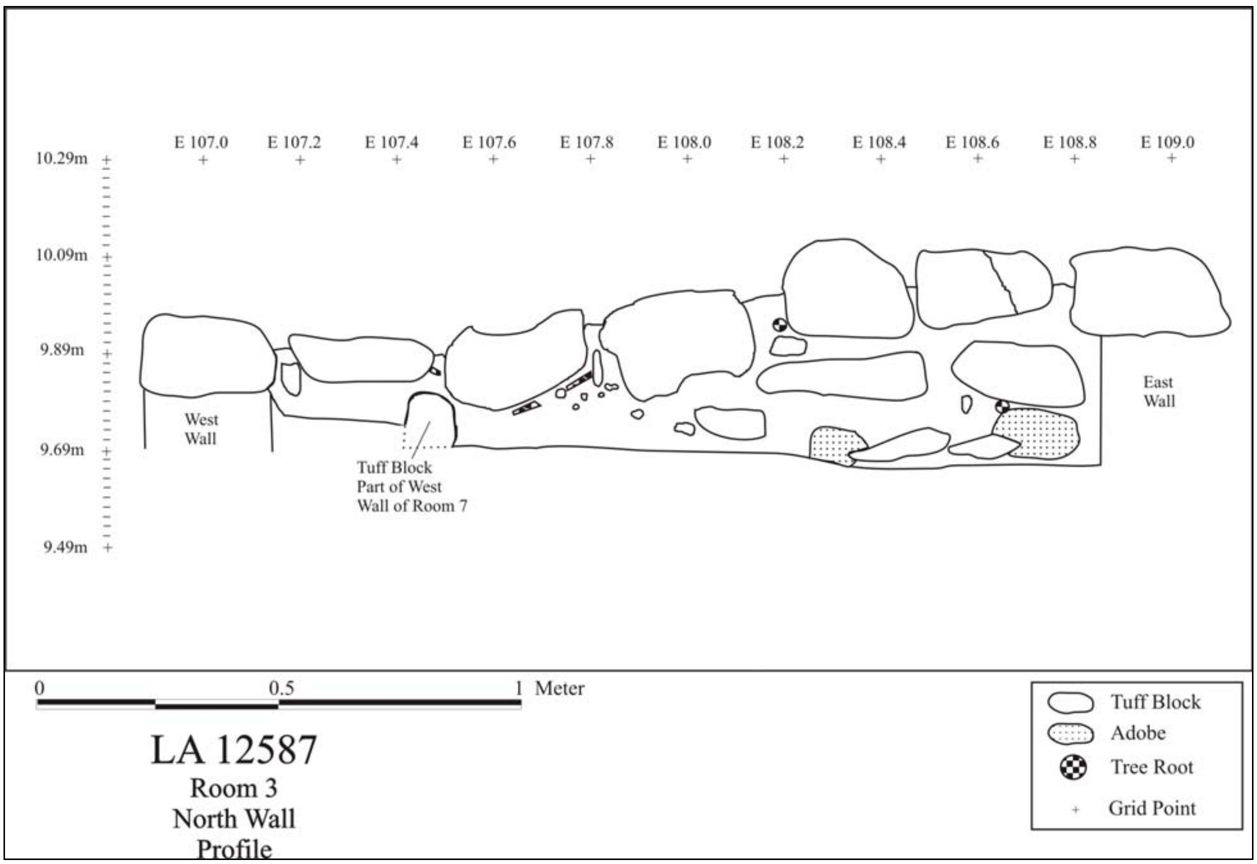

Figure 14.38. Room 3 north wall profile.

Most of the masonry measures approximately 30 by 20 by 12 cm. While three or four blocks show minor shaping, most of the blocks are unshaped. Two chinking stones are present in the north wall. The mortar between the masonry is decayed and nearly indistinguishable from the surrounding matrix, although a few less decayed patches are present. A thin (1 to 5 cm thick) layer of mortar is present below the basal course of the walls in some locations. Room 3 was built after Room 7 had collapsed and it is possible that the tops of some of the Roomblock 1 walls were incorporated into the Room 3 wall foundations. For example, the north wall of Room 3 was built almost directly on top of masonry from the west wall of Room 7.

Table 14.34. Room 3 wall dimensions.

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	1.73	0.33	0.24
East	1.90	0.14	0.21
South	1.50	0.17	0.20
West	1.94	0.20	0.24

Artifacts and Samples. All the artifacts recovered in Room 3 were analyzed. Table 14.35 lists the samples analyzed from Room 3.

Table 14.35. Room 3 analyzed samples by stratum.

Stratum	Flotation	Pollen	Macrobotanical
20	1593	1591	1491, 1500, 1592, 2044
20 (from base of stratum)	1493, 2040	1492, 1590	None
21	3000	3003, 3158	None

Roomblock 3

Roomblock 3 is a one-room-wide linear roomblock that is oriented about 8.5° east of north and is situated immediately west of Roomblock 1. Thirteen rooms (Rooms 10 through 22; Table 14.36) were identified in the 52-m-long roomblock. Ten of the rooms are contiguous (Rooms 10 through 18 and 22), while portions of the remaining three rooms (Room 19, 20, and 21) were exposed during excavation of the agricultural berms (Feature 22) in Area 2. The northern three rooms are aligned with the lower group of rooms and are assumed to be continuous with them even though the intervening three meters was not excavated.

It appears that Roomblock 3 was never completed. In Rooms 13, 17, and 18 and the southern portion of Room 11, the fill was nearly devoid of wallfall and only one to two standing courses were found. However, enough wallfall was present in the northern portion of Room 11 and in Rooms 10, 12, 14, and 16 to indicate that the walls of these rooms were at least several courses high. Too little of Rooms 15 and 19 through 22 was excavated to determine the amount of wallfall present. None of the rooms in Roomblock 3 had prepared or plastered floors and possible use surfaces were only found in Rooms 11 and 18.

Due to time constraints, the Roomblock 3 rooms were only partially excavated. The plan view maps for each room differentiate between excavated and unexcavated areas.

Table 14.36. Room dimension summary for Roomblock 3.

Room Number	Length (m)	Width (m)	Floor Area (m^2)
10	3.4	2.3	7.8
11	6.5	2.4	15.6
12	3.6	2.2	7.9
13	3.7	2.4	8.9
14	3.9	2.3	9.0
15	3.7	2.4	8.9
16	5.4	2.3	12.4
17	3.4	2.5	8.5
18	3.0	2.3	6.9
19	*3.3*	*2.2*	*7.3*
20	?	?	?
21	?	*2.4*	?
22	?	?	?

Numbers in italics are estimates for incomplete rooms. A "?" indicates that no estimate of that dimension could be made.

Architecture and Stratigraphy. All the rooms in Roomblock 3 were constructed with shaped tuff blocks of fairly uniform size. It appears that the only construction style employed was that of coursed masonry. No upright blocks or turtleback construction was evident. Facing stones are present on the interior and exterior of several walls. This architectural feature consists of a single row of closely spaced tabular tuff cobbles running parallel to the base of the walls. The facing stones may have functioned as an anchor for the wall plaster to adhere to the floor surface. Similar facing stones were infrequently used in Roomblock 1.

Wall foundations were simple. No prepared trenches were noted and many of the walls were constructed directly on top of the underlying bedrock. Others were built upon varying depths of cultural fill (presumably from Roomblock 1) or on the Btk horizon (Stratum 175).

It appears that the north-south-oriented walls were built first and then the cross walls were added. At several locations along the north-south walls, masonry blocks were placed such that their long axes were perpendicular to the walls. These tie-stones projected into the space between the walls. Where cross walls incorporate tie-stones, a bonded relationship is created between the north-south wall and the east-west wall.

Stratigraphic Relationship Between Roomblocks 1 and 3. The stratigraphic relationship between the two roomblocks is seen in the profile between Rooms 9 and 12 (Figure 14.39). Because of the importance of this profile, its stratigraphy was studied in detail by the project geomorphologists. As a result, the stratigraphy in Figure 14.39 is specific to the profile and is more fine-grained than the general excavation stratigraphy. Table 14.37 summarizes the Figure 14.39 stratigraphy and correlates it with the excavation strata.

Table 14.37. LA 12587 stratigraphic summary.

Profile Stratum	Excavation Stratum	Color	Texture	Description
I	1	N/A	N/A	Compact pine duff. Modern.
II	1/200/202	10YR 4/4	coarse sandy loam	Abrupt upper boundary, clear and wavy to irregular lower boundary. Massive structure, slightly hard. Abundant gravel inclusions. Covers Roomblock 1 wall remnant. Post-occupational natural deposit containing structural debris.
III	200/202	10YR 5/3	sandy clay loam	Sharp boundary with Strata V to VII, clear boundary with Strata IV and VIII, generally irregular. Massive and single-grained structure, slightly hard to soft. Contains charcoal and sparse gravel. Probably post-dates Roomblock 1.
IV	200/202	7.5YR 4/3	sandy clay loam	Clear horizontal boundary with Strata III, VII, VIII, and X, abrupt boundary with Stratum IX. Massive and single-grained structure (due to root disturbance), slightly hard. Contains charcoal. Probable root/rodent disturbance.
V	200/202	10YR 6/3	sandy clay	Sharp boundaries but very irregular from disturbances. Hard angular structure. Possible adobe melt from Roomblock 1.
VI	200/202	10YR 5/3	sandy clay loam	Slightly lighter brown than Stratum III. Clear boundaries. Massive structure, soft. May be part of Stratum III.
VII	200/202	10YR 6/2	sandy loam	Sharp boundaries. Massive coherent single grained structure, loose to soft. Appears to contain ash, and charcoal on margin may be associated. Possibly burned structural debris or Roomblock 1 trash.
VIII	170	10YR 5/3	coarse sandy loam	Abrupt boundary with Strata V and IX, clear boundary on all other contacts. Massive structure, soft. Very disturbed from abundant roots. Contains charcoal and tuff gravel inclusions. May represent native preoccupation topsoil.
IX	175	7.5YR 4/4	sandy clay	Abrupt boundaries. Contains degraded spalls of bedrock.
X	175?	7.5YR 4/5	coarse sandy clay	Sharp boundaries. Massive single-grain structure, very soft. Contains tuff gravel and a chert flake. May represent a deposit of Stratum IX material that was redeposited during

Profile Stratum	Excavation Stratum	Color	Texture	Description
				excavation of Room 9 foot trench.

Sub-floor and sub-wall observations of Roomblock 1 indicated that it was built on preoccupation topsoil (Stratum 170), remnant Pleistocene soil (Stratum 175), or occasionally on bedrock. Roomblock 3 was sometimes built on these deposits, but in some areas strata containing cultural debris were found to underlie the walls of this pueblo. Figure 14.39 depicts cultural deposits (Strata V and VII) that were probably derived from Roomblock 1 at depths that are below the east wall of Room 12. The east wall of Room 12 was built in Stratum III, a stratum that appears to post-date Roomblock 1. Based on these observations, it is inferred that the construction of Roomblock 3 post-dates the abandonment of Roomblock 1.

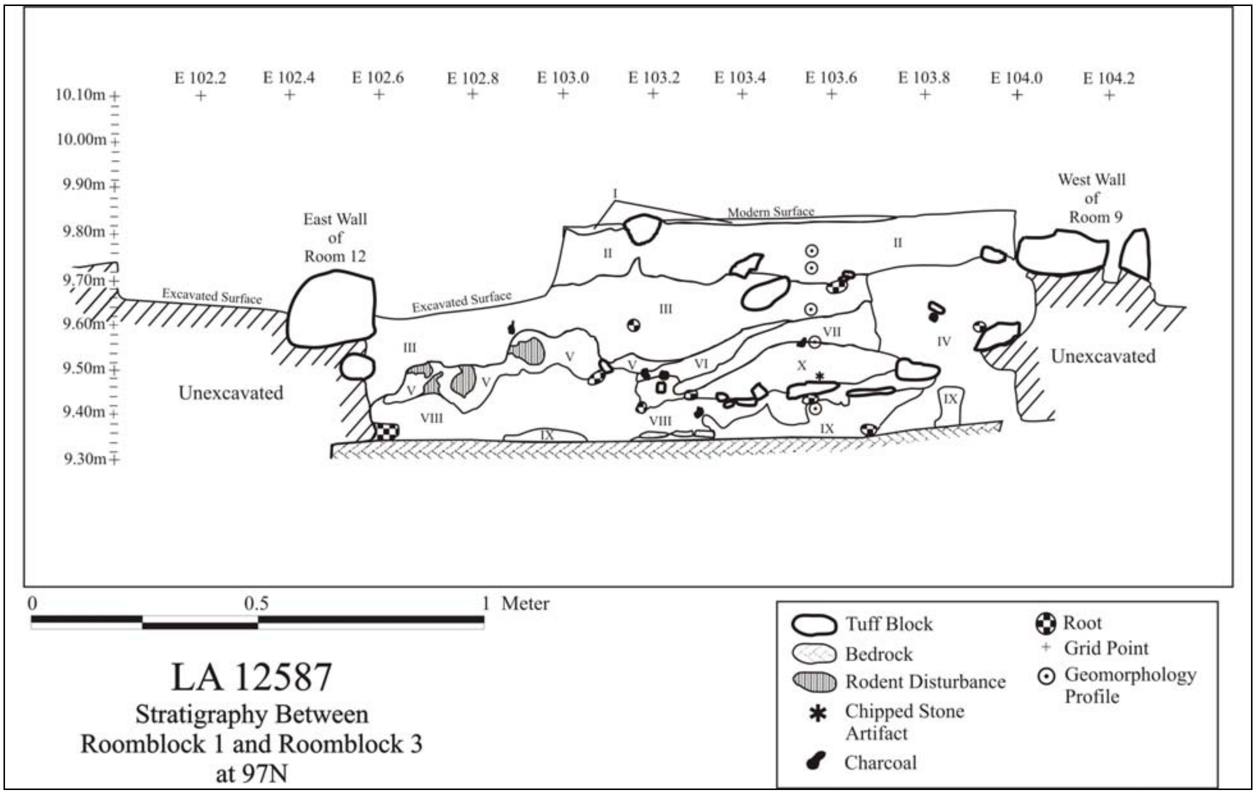

Figure 14.39. Stratigraphic relationship between Roomblocks 1 and 3.

Room 10

Room 10 (Figure 14.40) is located near the center of Roomblock 3 between Rooms 11 and 12. The interior dimensions of the room are 3.4 m north-south by 2.3 m east west, and it has an interior area of 7.8 m^2.

Stratigraphy. Five strata are associated with Room 10 and are summarized in Table 14.38. At the time of excavation a juniper tree was growing inside the room near the southwest corner. Stratum 1 consists of loose, unconsolidated, and fine-grained sandy loam.

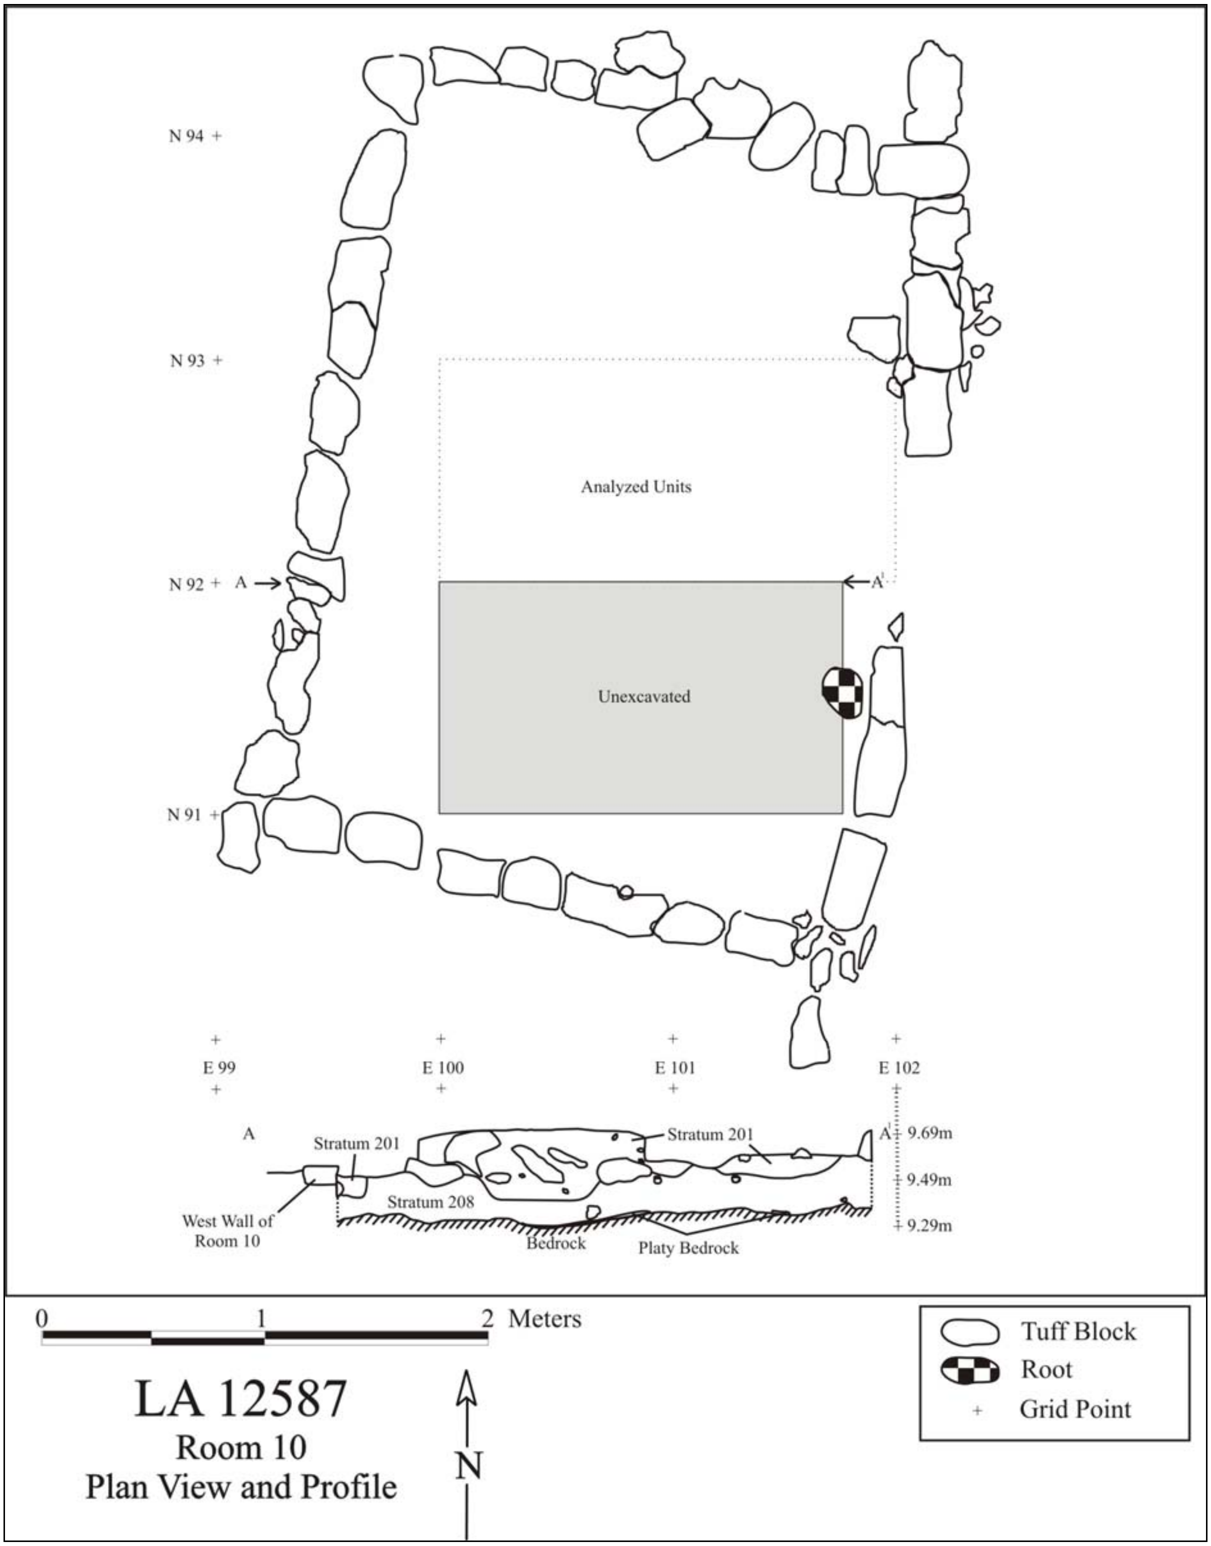

Figure 14.40. Room 10 plan view and profile.

Stratum 201 is composed of two sub-strata. The uppermost sub-stratum consists of sandy loam that grades into sandy clay loam as depth increases. A good deal of wallfall was found in this sub-stratum. The upper sub-stratum is 20 to 30 cm thick and ends 4 to 12 cm above the base of the walls. The lower sub-stratum is a layer of sandy clay loam that is largely free of masonry blocks and tuff cobbles, but contains many artifacts. This sub-stratum extends to, and in some areas to slightly below, the base of the walls.

Stratum 208 consists of sandy clay loam and an intermittently occurring layer of tuff cobbles. Where the cobbles are present there are about 20 per square meter. Some cobbles are in contact with the bedrock, although most are 0.5 cm or more above it. These cobbles may have been placed as a foundation for the living surface/intended floor of Room 10.

In the southwest corner of the room (in unit 91N/99E), a possible use surface (Stratum 203) of clay loam was found below Stratum 208 and just above bedrock. Given its depth beneath the wallfall (approximately 25 cm) and its depth below the base of the walls (5 cm below the west wall, 16 cm below the south wall), it is unlikely that this surface is associated with the habitation of Room 10. It may be associated with the occupation of Roomblock 1, or an even earlier component. No artifacts were found in association with this surface.

The bedrock below this room was smooth, compact, and lightly undulating with a few deep (circa 10 cm) crevices that had been cut by roots or water. A light layer of carbonate covered the bedrock, giving it a white color. Three- to five-centimeter-thick patches of thinly layered and easily separated decaying tuff bedrock overlay the more compact material below.

Table 14.38. Room 10 stratigraphy.

Stratum	Color	Texture	Thickness (cm)	Description
0	10YR 3/3	sandy loam	0	Surface
1	10YR 3/3	sandy loam	2–18	Unconsolidated surface soil
201	10YR 3/3	sandy loam to sandy clay loam	18–35	Fill to base of walls
208	10YR 3/3	sandy clay loam	4–16	Soil below base of walls to bedrock
203	5YR 4/3	clay loam	0.1–2	Possible use surface

Table 14.39 shows the artifact counts by stratum for Room 10. Since the walls of the room were not visible on the surface, Strata 1 and 201 from units that straddle the walls incorporate some artifacts that came from outside the room. Additionally, portions of Room 10 were excavated to bedrock before Stratum 208 was introduced to designate fill below the level of the base of the walls. Therefore, the artifact tallies for Strata 1 and 201 are somewhat inflated, while those for Stratum 208 are somewhat deflated. The ‘Other’ category consists of a fragment of malachite (FS 2577), a quartzite manuport (FS 3713), and several other miscellaneous samples.

Table 14.39. Room 10 artifact counts by stratum.

Stratum	Chipped Stone	Ceramic	Ground Stone	Bone	Other	Total
0	0	0	0	0	0	0
1	12	51	0	0	0	63
201	193	1008	11	2	5	1219
203	0	0	0	0	0	0
208	30	256	1	0	0	287
Total	**235**	**1315**	**12**	**2**	**5**	**1569**

Floors. No floors or living surfaces were associated with Room 10 except for Stratum 203, which predates the room. A pollen (FS 2746) and flotation (FS 2745) sample were collected from this stratum. Taxa identified in the pollen sample include maize, cholla, prickly pear, beeweed, cheno-ams, grass family, sunflower family, spurge family, unidentified pine, piñon pine, juniper, and sagebrush. Taxa identified in the flotation sample include sagebrush, saltbush/greasewood, juniper, and maize.

Some tuff cobbles in Stratum 208 may have been placed as a floor foundation. A pollen (FS 3541), flotation (FS 3544), and two macrobotanical (FS 3612 and FS 3721) samples were collected from Stratum 208. Taxa identified in the pollen sample include maize, beeweed, cheno-ams, grass family, sunflower family, spurge family, unidentified pine, piñon pine, juniper, and sagebrush. Taxa identified in the flotation sample from Stratum 208 include Desert olive, juniper, and oak. Taxa identified in the macrobotanical samples include saltbush/greasewood, cottonwood/willow, piñon pine, ponderosa pine, unknown conifer, and unidentified pine.

Wall Construction. The north wall is bonded with the east wall; all other walls abut. Table 14.40 gives the dimensions of the extant wall segments. The walls are constructed of a single row of coursed and mortared horizontally laid masonry of shaped and unshaped tuff blocks. Near the west end of the south wall, an adobe mass with embedded tuff cobbles takes the place of one or two tuff blocks. A few chinking stones are present between masonry blocks. Along the interior base of the east, west, and south walls, a row of facing stones are intermittently present.

Two courses of masonry are present on the east half of the north wall, the northern half of the east wall, and the entire south wall. Elsewhere the walls are one course high except for a 1.25-m gap at the center of the east wall. There are several facing stones in the gap, indicating a missing masonry block.

Table 14.40. Room 10 wall dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	2.69	0.32	0.24
East	1.38, 1.31	0.32	0.24
South	2.69	0.35	0.23
West	3.38	0.14	0.22

Artifacts and Samples. All the artifacts from units 92N/100E and 92N/101E were analyzed. All the macrobotanical material from unit 92N/100E was also analyzed. Table 14.41 lists the samples analyzed from Room 10.

Table 14.41. Room 10 analyzed samples by stratum.

Stratum	Pollen	Flotation	Macrobotanical[1]
1	2674	2673	None
201	3710	3709	3720
203	2746	2745	None
208	3541	3544	3612, 3721

1 In addition to the macrobotanical material from 92N/100E

Room 11

Room 11 (Figure 14.41) is located in the southern half of Roomblock 3 between Rooms 10 and 13. It is the largest room in the roomblock with internal dimensions of 6.5 m north-south by 2.4 m east-west and an internal area of 15.6 m^2.

Stratigraphy. Seven strata are associated with Room 11 (Table 14.42). At the time of excavation, three piñon trees were growing inside the room. Stratum 1 consists of loose, unconsolidated, and fine-grained sandy loam. It contains a few tuff blocks and chinking stones.

The stratigraphy in the northern half of the room is more complex than in the southern half of the room. Here, the upper part of Stratum 201 consists of 10 to 20 cm of silty to sandy loam. A considerable amount of wallfall is present, including a four- to five-course-tall section of the east wall that fell into the room intact. The lower part of Stratum 201 is a 10-cm-thick sub-stratum of masonry-free sandy clay loam that contains many artifacts. Below the wallfall in unit 90N/100E, there is a 9- to 12-cm-thick stratum (Stratum 205) of sandy clay loam and clay loam mixed with charcoal and ash. Stratum 205 is also present in 90N/99E; however, this unit was excavated before the deposit was recognized as a distinct stratum. Just above the bedrock in units 90N/99E and 90N/100E there is a thin, patchy layer of sandy clay loam that may have been a use surface (Stratum 204). In unit 89N/100E, there is a thin layer of adobe melt covering the bedrock. In other areas a thin deposit of Stratum 175 is present. There is no Stratum 208 in the northern part of the room as the base of the walls is only 1 to 3 cm above bedrock.

Table 14.42. Room 11 stratigraphy.

Stratum	Color	Texture	Thickness (cm)	Description
0	10YR 3/3	sandy loam	0	Surface
1	10YR 3/3	sandy loam	1–13	Unconsolidated surface soil
175	10YR 4/4	sandy clay	1–3	Btk horizon
201	10YR 3/3	sandy/silt loam to sandy clay loam	13–27	Fill to base of walls
204	10YR 3/3	sandy clay loam	0.1–1	Possible use surface

Stratum	Color	Texture	Thickness (cm)	Description
205	8.75 YR 3/3.5	sandy clay loam and clay loam	9–12	Ashy lenses
208	10YR 3/3	sandy clay loam	10–27	Soil below base of walls to bedrock

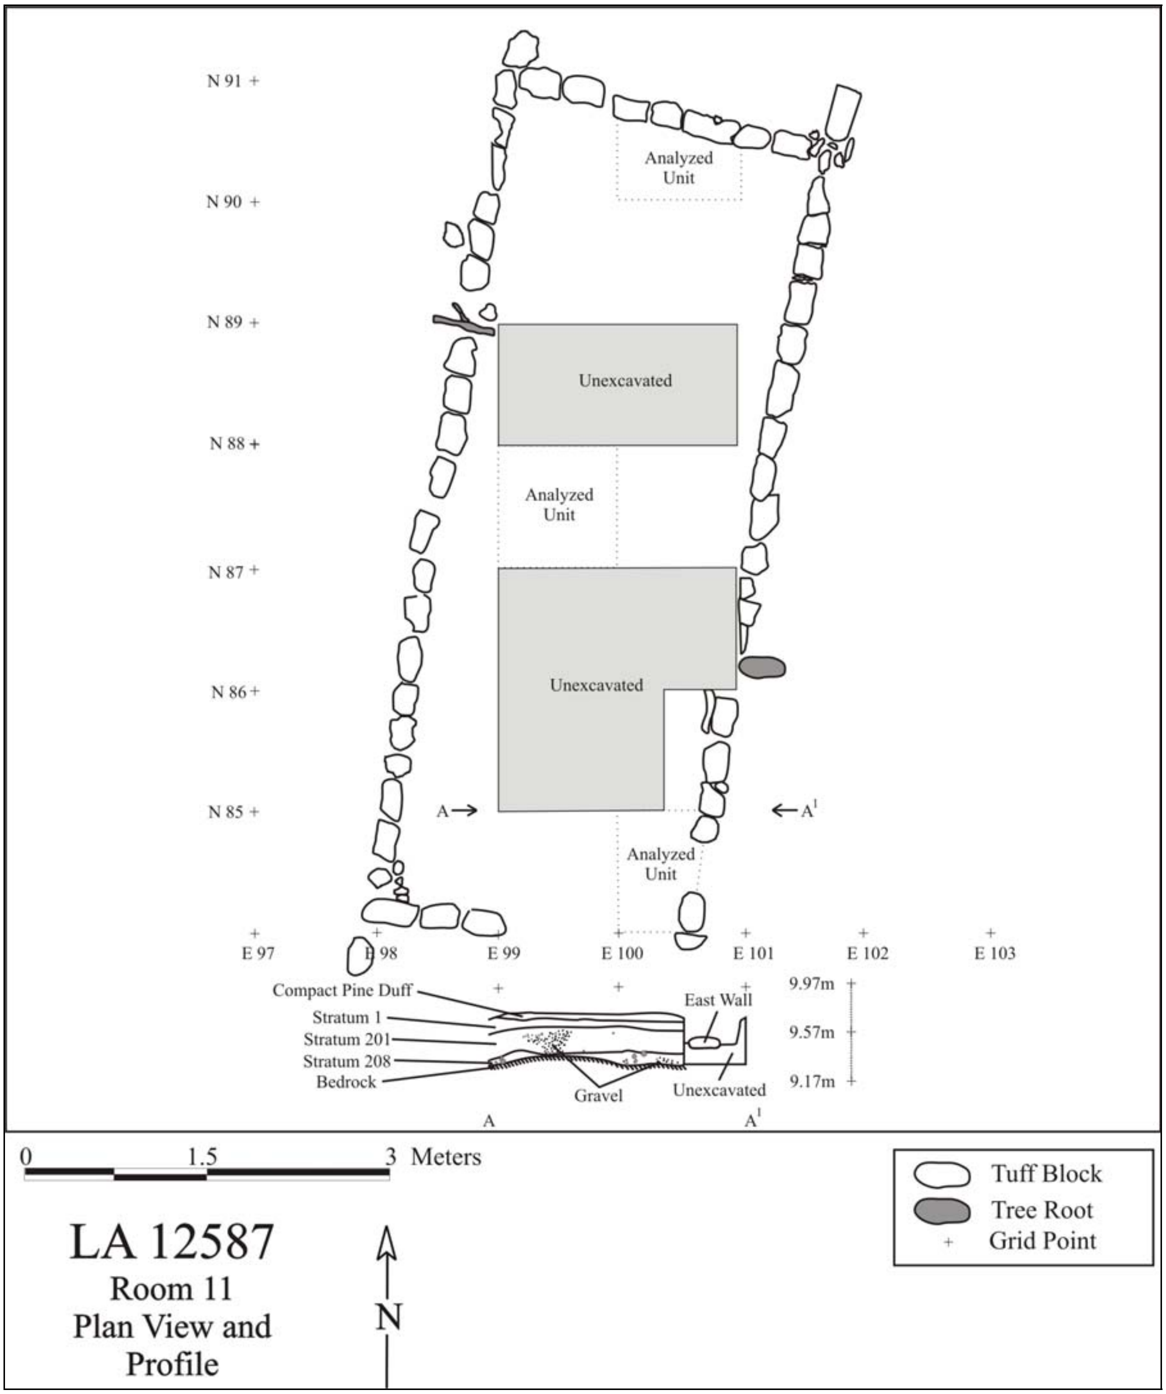

Figure 14.41. Room 11 plan view and profile.

The stratigraphy is less complex in the central and southern portions of the room. There is very little wallfall in Stratum 201 and most of what is present is in the central part of the room. Stratum 201 is fairly uniform throughout and overlays Stratum 208 (a sandy clay loam), except in the southwest corner. Here, the walls are built directly on an elevated section of bedrock. Stratum 175 is present in the central portion of the room, but not in the southern portion. Strata 204 and 205 are both absent.

Table 14.43 shows the artifact counts by stratum for Room 11. Since the walls of the room were not visible on the surface, Strata 1 and 201 from units that straddle the walls incorporate some artifacts that came from outside the room. Stratum 208 was not always excavated separately from Stratum 201. In most cases, the lowest "stratum" of a unit can only be identified as Stratum 201/208. As noted above, in unit 90N/99E, Stratum 205 was excavated as Stratum 201 before it was recognized as a distinct stratum.

Table 14.43. Room 11 artifact counts by stratum.

Stratum	Chipped Stone	Ceramic	Ground Stone	Bone	Other	Total
0	0	0	0	0	0	0
1	9	33	0	0	1	43
175	0	0	0	0	0	0
201	313	1358	4	3	0	1678
201/208	30	195	0	2	0	227
204	0	3	0	0	0	3
205	10	43	0	0	0	53
Total	**362**	**1632**	**4**	**5**	**1**	**2004**

Floors. A possible living surface (Stratum 204), which was identified as a clear, flat break between Stratum 201 and a thin, sterile sandy clay loam deposit, was encountered in the northern part of the room. Three smeared-indented corrugated jar sherds (FS 2907 and FS 2964) were found in contact with the possible living surface. Two pollen samples (FS 2906 and FS 2963) were analyzed. Identified taxa included maize, prickly pear, cholla, beeweed, cheno-ams, grass family, mustard family, sunflower family, spurge family, evening primrose, fir, unidentified pine, piñon pine, juniper, oak, and sagebrush. Two flotation samples (FS 2905 and FS 2962) were collected from the floor and the charred identified taxa included saltbush/greasewood, goosefoot, cheno-ams, grass family, juniper, groundcherry, unidentified pine, piñon pine, and maize.

Wall Construction. The north wall abuts the east and west walls, the west wall and the south wall are bonded, and the southeast corner does not exist. Table 14.44 gives the dimensions of the extant wall segments. The walls are constructed of a single row of coursed, horizontally laid masonry of shaped and unshaped tuff blocks held together with mortar. Chinking stones are often present in horizontal rows between masonry courses. A section of the east wall fell into the room but otherwise remained intact. This section shows that for four courses above the base course, the wall was built with the same coursed masonry style that the basal courses display. Facing stones are only present along the interior and exterior of the east wall. The base of the north wall, the northern portions of the east and west walls, and the southwest corner were all built on or within 1 to 3 cm of bedrock. Elsewhere the walls were built on Strata 175 and 208.

All the extant walls are one course high except for the west end of the north wall, which is two courses high (Figure 14.42). A single masonry block from the second course of the west wall is also present. Occasionally there are gaps in the walls where masonry was displaced by roots.

Table 14.44. Room 11 wall dimensions (extant wall segments).

Wall	Length (m)	Height (m)	Thickness (m)
North	2.69	0.33	0.20
East	1.21, 4.02	0.14	0.20
South	1.19	0.10	0.21
West	1.81, 4.50	0.21	0.22

Figure 14.42. Room 11 north wall.

Artifacts and Samples. All the artifacts from units 84N/100E, 87N/99E, and 90N/100E were analyzed. All the faunal remains were analyzed. A Cerro Toledo obsidian biface fragment (FS 3701) was also analyzed. Table 14.45 lists the samples analyzed from Room 11.

Table 14.45. Room 11 analyzed samples by stratum.

Stratum	Pollen	Flotation	Macrobotanical
1	4122	None	None

Stratum	Pollen	Flotation	Macrobotanical
201	4123	4245	2904
208	None	3761	3759
204	2906, 2963	2905, 2962	None

Room 12

Room 12 is located near the center of Roomblock 3 between Rooms 10 and 14 (Figure 14.43). The interior dimensions of the room are 3.6 m north-south by 2.2 m east-west, and the interior area is 7.9 m^2.

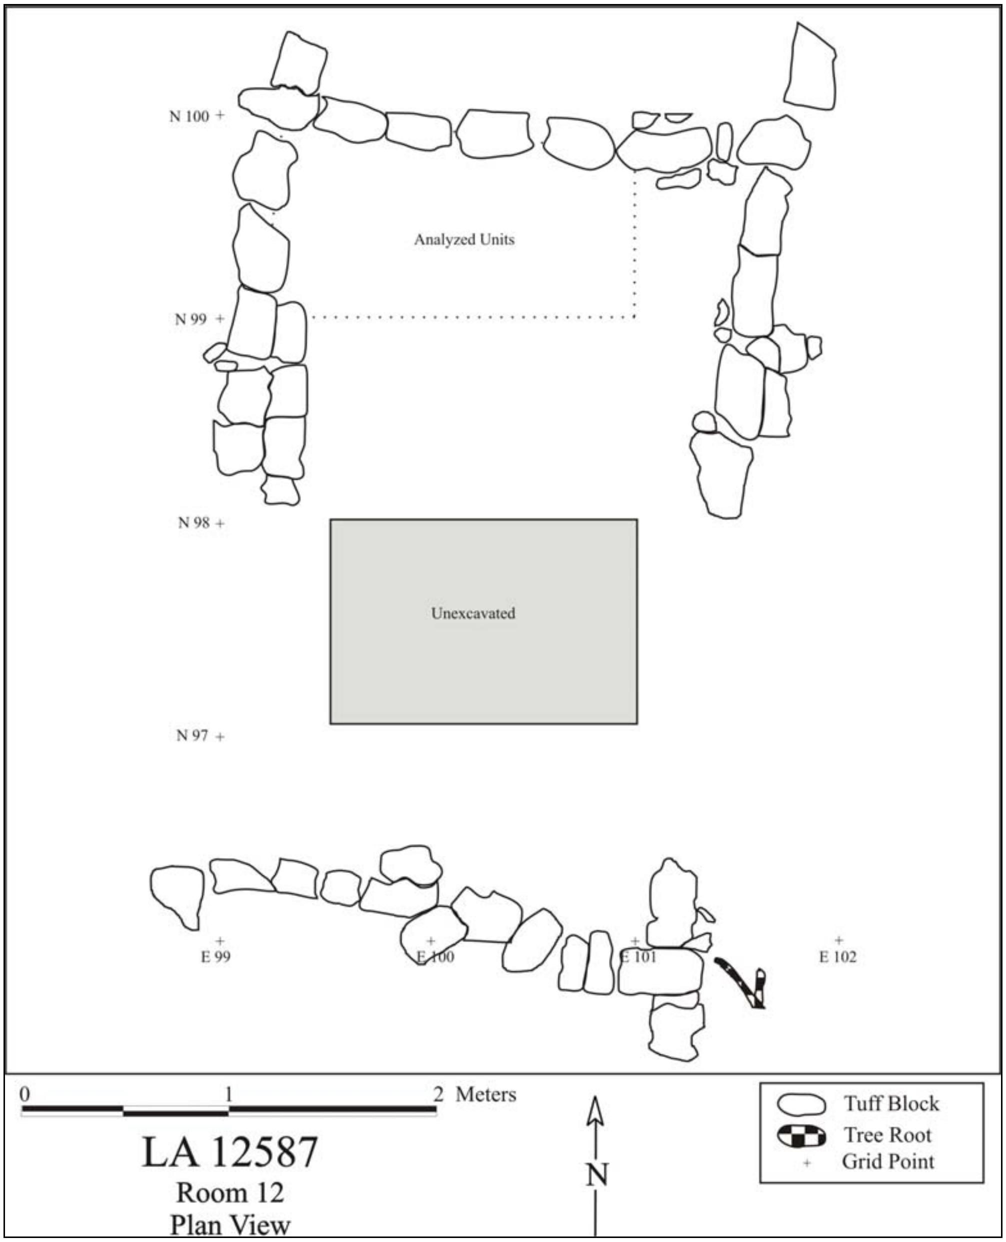

Figure 14.43. Room 12 plan view.

Stratigraphy. The four strata associated with Room 12 are summarized in Table 14.46. Stratum 1 consists of loose sandy loam. It contains a few masonry blocks and melted adobe. Stratum 201 consists of moderately compact sandy loam. In the northern half of the room, approximately 20 masonry blocks were found in Stratum 201. Stratum 208 was similar to Stratum 201 although it graded to sandy clay loam near bedrock. The only masonry in Stratum 208 consisted of a few tuff blocks along and under the east wall. This material is probably wallfall from Roomblock 1. Small patches of Stratum 175 are present just above the bedrock.

Table 14.46. Room 12 stratigraphy.

Stratum	Color	Texture	Thickness (cm)	Description
0	10YR 4/3	sandy loam	0	Surface
1	10YR 4/3	sandy loam	2–10	Unconsolidated surface soil
201	7.5YR 4/3	sandy loam	27–38	Fill to base of walls
208	7.5YR 4/3-4/4	sandy loam to sandy clay loam	3-18 (up to 25 cm deep along east wall)	Soil below base of walls to Stratum 175
175	7.5YR 4/4	sandy clay	1–3	Btk horizon

Table 14.47 shows the artifact counts by stratum for Room 12. Since the walls of the room were not visible on the surface—and in some areas are non-existent—Strata 1, 201, and 208 from units that straddle the walls incorporate artifacts that came from outside the room.

Table 14.47. Room 12 artifact counts by stratum.

Stratum	Chipped Stone	Ceramics	Ground Stone	Bone	Other	Total
0	1	3	0	0	0	4
1	48	249	0	0	0	297
201	223	1444	8	2	1	1678
208	88	383	1	9	1	482
175	3	15	0	0	0	18
Total	**363**	**2094**	**9**	**11**	**2**	**2479**

Floors. No floors or living surfaces were found in Room 12.

Wall Construction. The north wall of the room is bonded with the east and west walls, and the south wall is bonded with the east wall. Not enough masonry is left in the southwest corner to tell if the corner is bonded or abutted. Table 14.48 gives the dimensions of the extant wall segments. The walls are constructed of a single row of coursed, horizontally laid masonry of shaped and unshaped tuff blocks held together with mortar. A few chinking stones are present in each wall. Facing stones are present in the northeast corner of the room and at the west end of the south wall. Most of the walls are only one course high, although two courses are present in the northwest corner at the east end of the south wall and near the north end of the west wall. The southern half of both the east and west walls is absent.

Table 14.48. Room 12 wall dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	2.75	0.15	0.25
East	1.98	0.15	0.20
South	2.69	0.32	0.26
West	1.82	0.17	0.25

Artifacts and Samples. All the artifacts from units 97N/100E and 97N/101E were analyzed, as were all the macrobotanical material from 96N/101E. All the faunal remains were analyzed. A Valle Grande obsidian projectile point (FS 2584) was also analyzed. One pollen sample (FS 3650) from Stratum 208 was analyzed. No flotation samples were analyzed.

Room 13

Room 13 (Figure 14.44) is located in the southern half of Roomblock 3 between Rooms 11 and 15. The interior dimensions of the room are 3.7 m north-south by 2.4 m east west, and it has an interior area of 8.9 m^2.

Stratigraphy. The three strata associated with Room 13 are summarized in Table 14.49. A backhoe scraped away several centimeters of Stratum 1 along the western and southern edges of this room. This accounts for the shallowness of the stratum. Stratum 201 consists of moderately compact sandy loam and contained almost no wallfall. Excavation ended when the sterile Stratum 175 was reached, which was several centimeters below the base of the walls.

Table 14.49. Room 13 stratigraphy.

Stratum	Color	Texture	Thickness (cm)	Description
0	7.5YR 4/4	sandy loam	0	Surface
1	7.5YR 4/4	sandy loam	1–3+	Unconsolidated surface soil
201	7.5YR 4/4, 10YR 3/3	sandy loam	10–31	Fill to base of walls

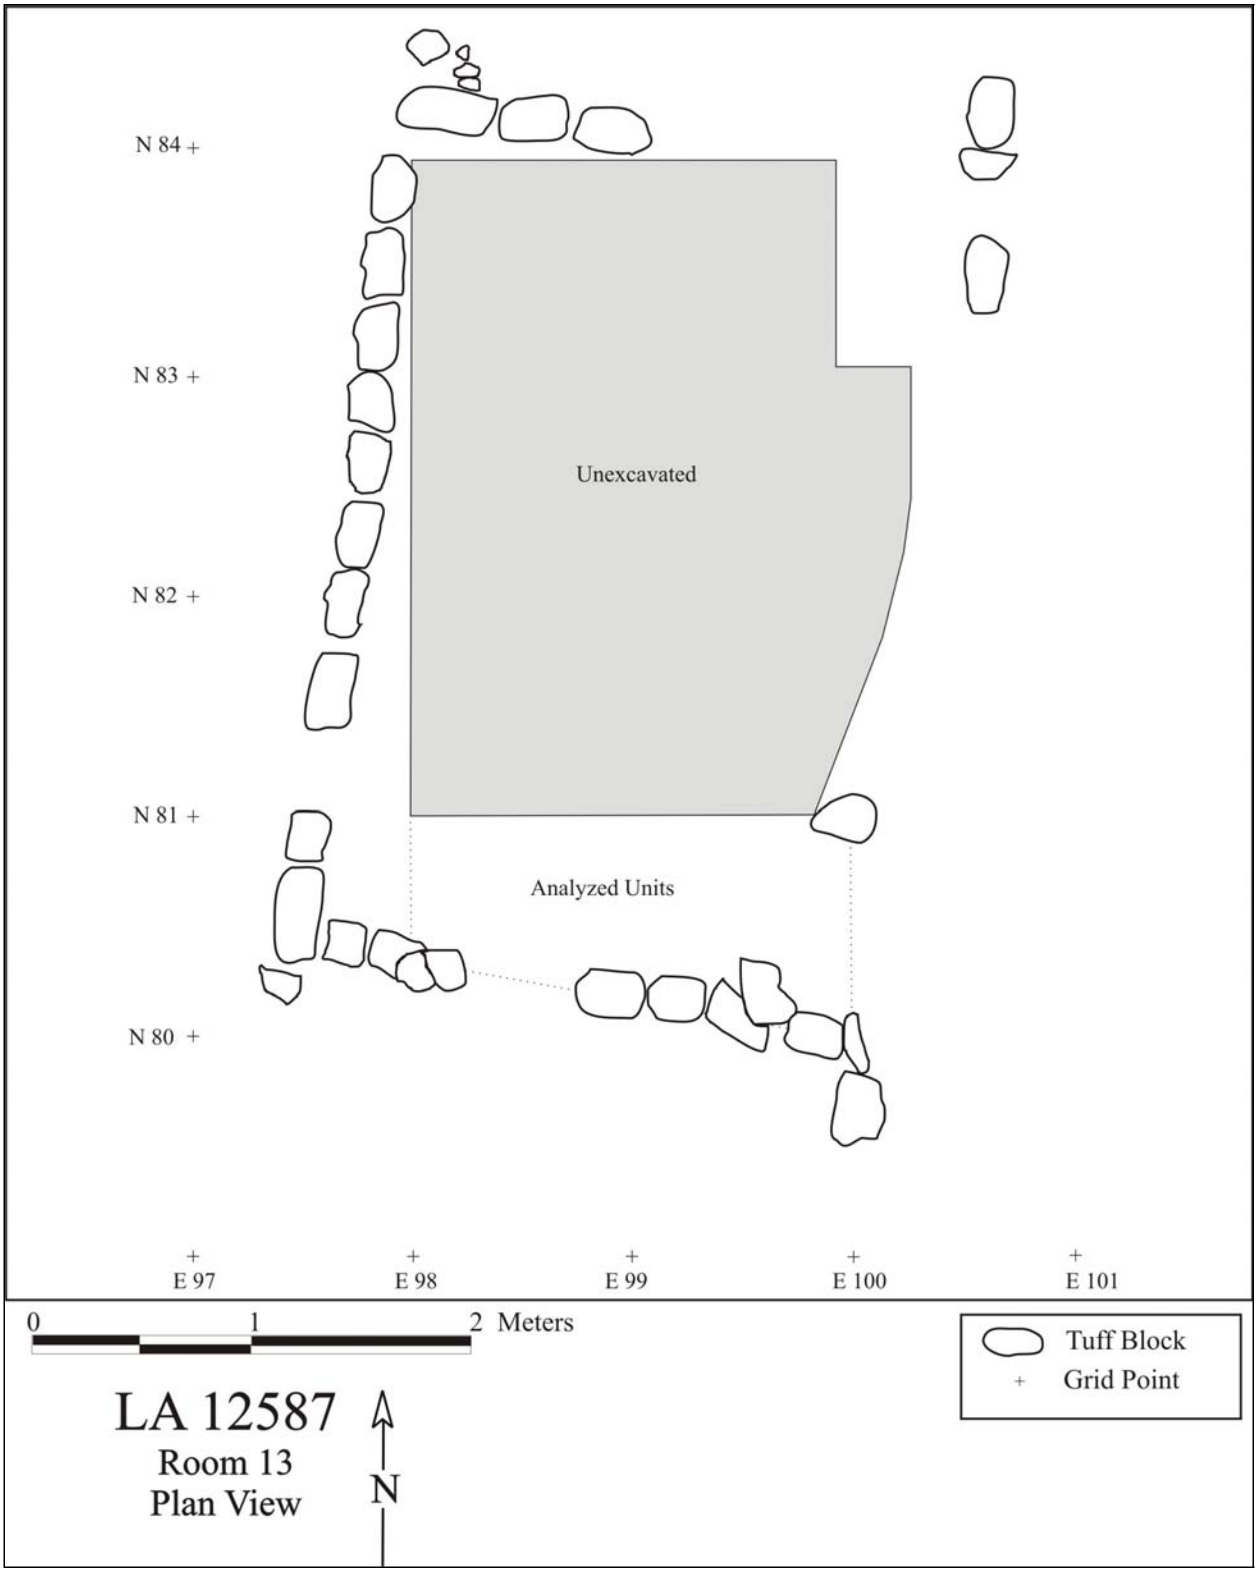

Figure 14.44. Room 13 plan view.

As most of the excavated units of Room 13 straddled the walls, the artifact counts (Table 14.50) for this room are somewhat inflated. It is not clear if artifacts from the exterior and interior of Room 13 were always kept separate. Additionally, small areas of 80N/97E and 80N/98E lie in Room 15, but were not excavated separately. Artifacts from these units have been designated as being from Room 13, as the largest areas of these units are in that room.

Table 14.50. Room 13 artifact counts by stratum.

Stratum	Chipped Stone	Ceramics	Ground Stone	Nonhuman Bone	Other	Total
0	0	0	0	0	0	0
1	3	9	0	0	0	12
201	60	274	4	0	0	338
Total	**63**	**283**	**4**	**0**	**0**	**350**

Floors. No floors or living surfaces were found in Room 13.

Wall Construction. The north wall is bonded with the west wall, and the south wall abuts the east and west walls. Not enough masonry remains in the northeast corner of the room to determine the relationship between the north and east walls. Table 14.51 gives the dimensions of the extant wall segments. The walls are constructed of a single row of coursed, horizontally laid masonry of shaped and unshaped tuff blocks held together with mortar. Facing stones were not observed. All the walls are one course high except for the south wall, where two separate masonry blocks of the second course are still in place. The east wall of Room 13 is almost non-existent. About half a dozen scattered masonry blocks were found where the wall should have been. It is unclear if this wall ever existed. There is a 50-cm-wide gap in the south wall. It is not clear if this gap was intentionally left in the wall or if there was masonry here that was subsequently lost. A similar 40-cm-wide gap is present in the west wall.

Table 14.51. Room 13 wall dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	1.19	0.12	0.21
East	n/a	0.10	0.18
South	0.88, 1.28	0.20	0.21
West	0.63, 2.81	0.12	0.20

Artifacts and Samples. All the artifacts from 80N/98E and 80N/99E were analyzed. Ceramics from FS 3550 were also analyzed. One flotation sample (FS 3730) from Stratum 201 was analyzed. Taxa identified included juniper and piñon pine. No pollen samples were analyzed.

Room 14

Room 14 is located in the central portion of the roomblock between Rooms 12 and 16 (Figure 14.45). The interior dimensions of the room are 3.9 m north-south by 2.3 m east west, and it has an interior area of 9.0 m^2. A small internal rock feature (Feature 19) is present.

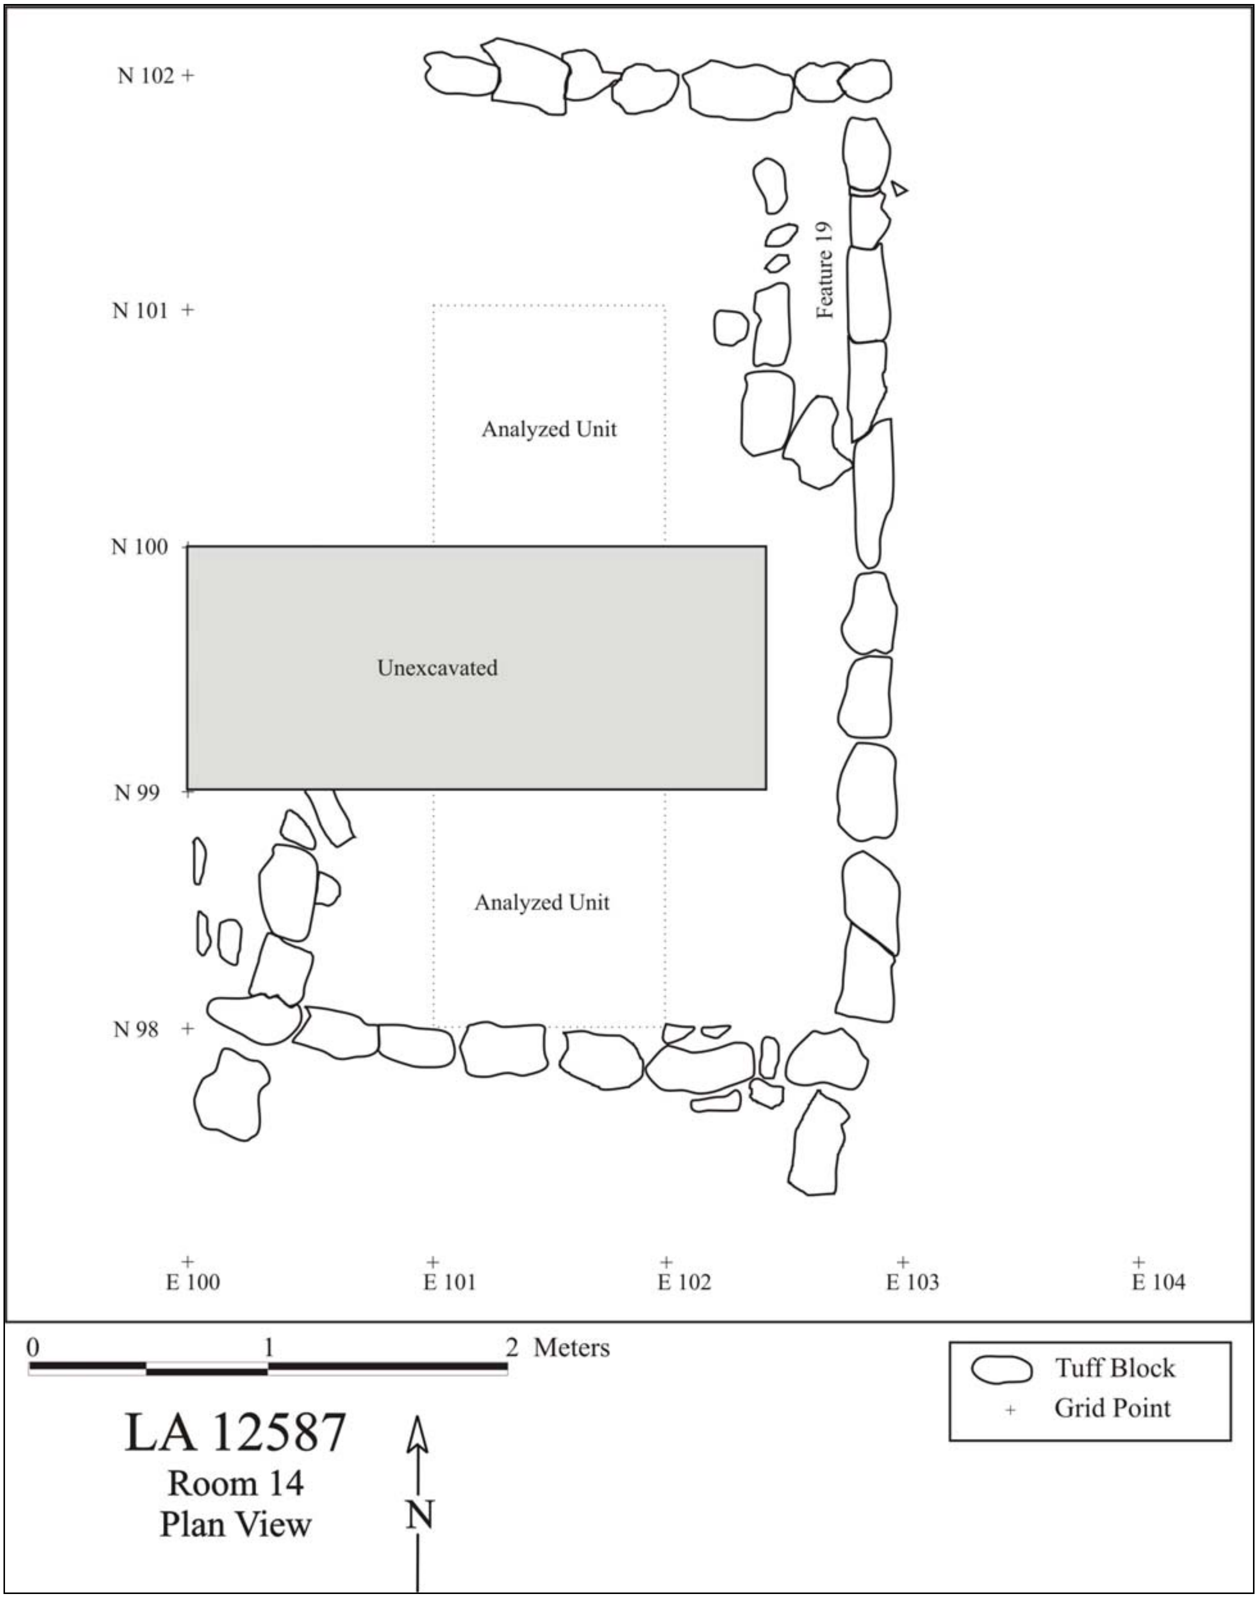

Figure 14.45. Room 14 plan view.

Stratigraphy. The four strata associated with Room 14 are summarized in Table 14.52. Stratum 1 consists of loose unconsolidated fill. A backhoe scraped away several centimeters of this stratum. Stratum 201 consists of moderately compact sandy loam. It contains burned daub, a few pieces of fire-cracked rock, many shaped and unshaped tuff blocks, and chinking stones. Stratum 208 is indistinguishable from Stratum 201 (save that no burned daub or fire-cracked rock was present). Near the base of Stratum 208, shallow patches of the reddish brown clay were observed (probably Stratum 175), but were not given a separate stratum number.

Table 14.52. Room 14 stratigraphy.

Stratum	Thickness (cm)	Color	Texture	Description
0	0	7.5YR 4/3	sandy loam	Surface
1	1	7.5YR 4/3	sandy loam	Unconsolidated surface soil
201	19–29	7.5YR 4/3-4	sandy loam	Fill to base of walls
208	13–24	7.5YR 4/3-4	sandy loam	Soil below walls to bedrock

Table 14.53 shows the artifact counts by stratigraphic unit for Room 14. The ‘Other’ category includes a freshwater shell fragment (FS 3620), a possible *Anodonta* sp. fragment (FS 3839), a land gastropod shell (FS 3839), a manuport of unidentified material (FS 3906), and a miscellaneous sample.

Table 14.53. Room 14 artifact counts by stratum.

Stratum #	Chipped Stone	Ceramics	Ground Stone	Nonhuman Bone	Other	Total
0	7	18	0	0	0	25
1	1	8	0	0	0	9
201	226	1341	11	4	4	1586
208	123	607	6	2	1	739
Total	**357**	**1974**	**17**	**6**	**5**	**2359**

Floors. No floors or living surfaces were found in Room 14.

Wall Construction. The south wall is bonded with the east and west walls, the north wall was bonded with the east wall, and the northwest corner is missing. Table 14.54 gives the dimensions of the extant wall segments. The walls are constructed of a single row of coursed and mortared horizontally laid masonry of shaped tuff blocks. All the extant walls are a single course high.

Table 14.54. Room 14 wall dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness
North	2.0	0.14	0.23
East	3.8	0.10	0.22
South	2.75	0.15	0.25
West	0.78	0.15	0.27

Artifacts and Samples. All the artifacts from units 98N 101E and 100N 101E were analyzed, as were the macrobotanical materials from unit 98N 100E. All the faunal remains were analyzed. Other analyzed artifacts include a tuff vent plug (FS 3693), a tested cobble of quartzite (FS 3694), an andesite polishing stone (FS 3694), and a basalt hoe (FS 3735). Table 14.55 lists the samples analyzed from Room 14.

Table 14.55. Room 14 analyzed samples by stratum.

Stratum	Flotation	Pollen	Macrobotanical[1]
201	3769	3692	3691
208	3873	3872	3738

1 In addition to the macrobotanical material from 98N/100E

Features

Feature 19 (Rock Alignment). Feature 19 is located in the northeast corner of Room 14. It consists of a north-south alignment of four rocks; a fifth rock at the southern end of the feature lies between the alignment and the east wall of the room. The north end is open. The interior of Feature 19 is 32 cm wide by 88 cm long. The exterior dimensions are 46 cm wide and 97 cm long. The feature is 16 cm tall. The function of Feature 19 is unknown.

Room 15

Room 15 (Figure 14.46) is located in the southern half of Roomblock 3 between Rooms 13 and 17. The interior dimensions of the room are 3.7 m north-south and 2.3 m east-west and it has an interior area of 8.9 m^2.

Stratigraphy. The three strata associated with Room 15 are summarized in Table 14.56. This room was excavated almost entirely as Stratum 201: 79N/97E was the only unit in which Stratum 1 was dug separately, and in no unit was Stratum 208 distinguished from Stratum 201. Six masonry blocks were found in Stratum 201.

Table 14.56. Room 15 stratigraphy.

Stratum	Color	Texture	Thickness (cm)	Description
0	7.5YR 4/4	sandy loam	0	Surface
1	7.5YR 4/4	sandy loam	2–4	Unconsolidated surface soil
201	7.5YR 4/4, 10YR 3/3	sandy loam	31–41	Fill to base of walls

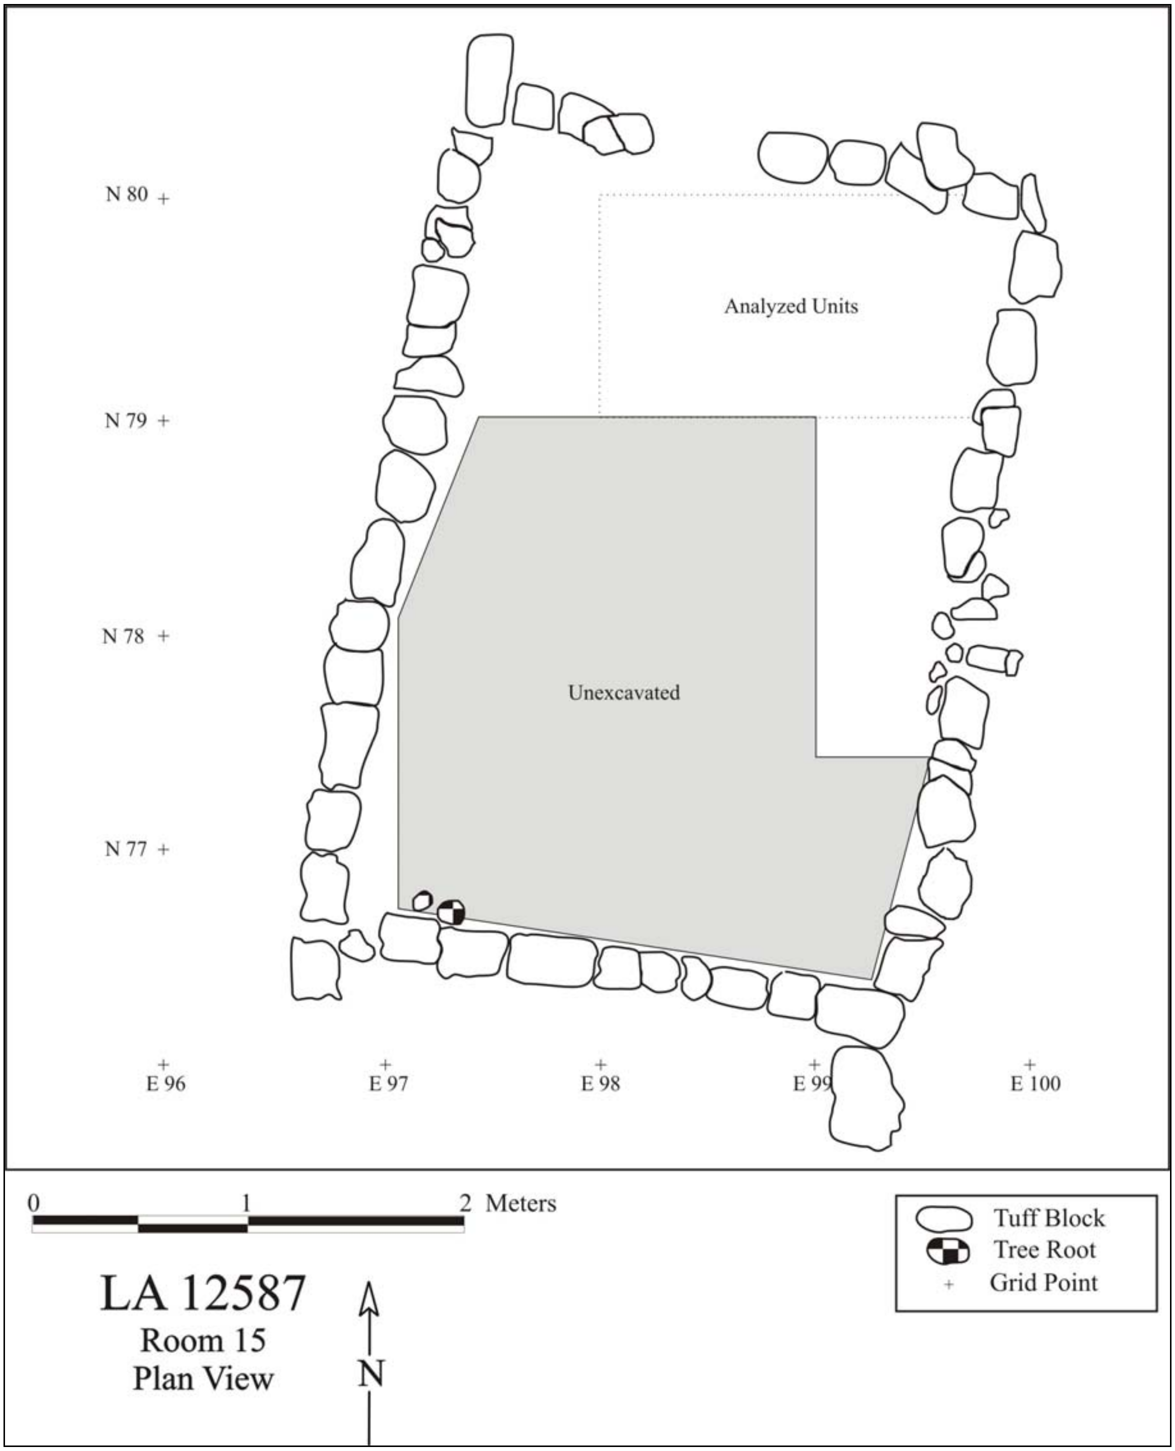

Figure 14.46. Room 15 plan view.

The artifact counts for Room 15 (Table 14.57) are low, since material from units 80N/97E and 80N/98E were designated as belonging to Room 13 (see the Room 13 discussion). Conversely, some material from 79N/97E may have come from outside the room walls.

Table 14.57. Room 15 artifact counts by stratum.

Stratum	Chipped Stone	Ceramics	Ground Stone	Nonhuman Bone	Other	Total
0	0	0	0	0	0	0
1	3	6	0	0	0	9
201	46	237	4	0	0	287
Total	**49**	**243**	**4**	**0**	**0**	**296**

Floors. No floors or living surfaces were found in Room 15.

Wall Construction. All the corners of this room are abutted except for the southeast corner. In the southeast corner, the south wall is bonded with the east wall. Table 14.58 gives the dimensions of the extant wall segments. The walls are constructed of a single row of coursed, horizontally laid masonry of shaped and unshaped tuff blocks held together with mortar. In a few places on the north, east, and west walls, isolated masonry blocks of the second course are present. A single masonry block of the third course is present on the east wall. Several of these multiple courses were placed to compensate for the uneven terrain the walls are built on (i.e., even though the number of courses varies along the length of a wall, the top of the wall is level along its length). A 40-cm-long row of facing stones is present on the interior of the east wall; another 40-cm-long row of facing stones is present on the exterior of the west wall. There is a 50-cm-long gap in the north wall. It is not clear if this gap was intentionally left in the wall, or if there was masonry here that was subsequently lost. A smaller (20 cm long) gap is present at the west end of the wall. This gap was probably not part of the original wall construction.

Table 14.58. Room 15 wall dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	0.88, 1.28	0.20	0.21
East	3.96	0.30	0.24
South	2.81	0.10	0.19
West	4.03	0.20	0.25

Artifacts and Samples. All the artifacts from units 79N/98E and 79N/99E were analyzed. One flotation sample (FS 4000) from Stratum 201 was analyzed. Identified charred taxa included unknown conifer, juniper, and maize. No pollen samples were analyzed.

Room 16

Room 16 (Figure 14.47) is located in the central portion of Roomblock 3 between Rooms 14 and 22. The interior dimensions of the room are 5.4 m north-south by 2.3 m east-west, and it has an interior area of 12.4 m^2.

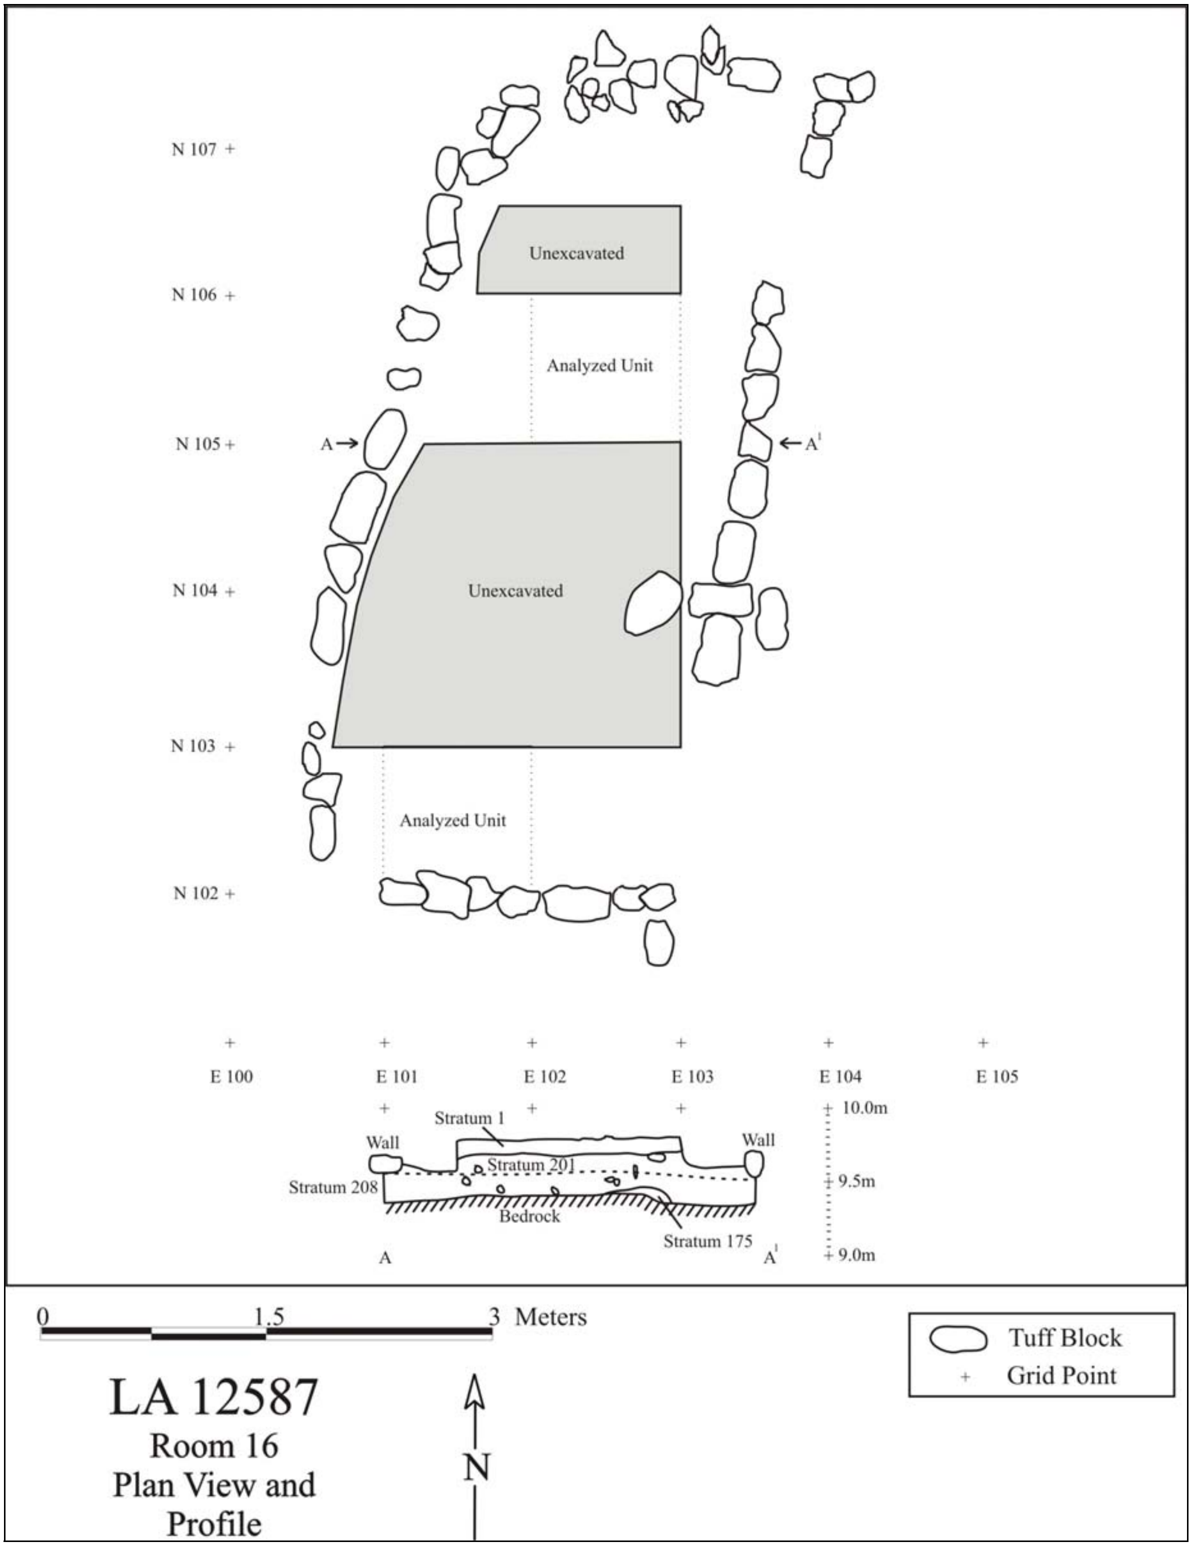

Figure 14.47. Room 16 plan view and profile.

Stratigraphy. The four strata associated with Room 16 are summarized in Table 14.59. At the time of excavation a piñon tree was growing in the northwest corner of the room. Stratum 1 consists of loose, unconsolidated, and fine-grained sandy loam. Stratum 201 consists of sandy loam. Many masonry blocks and chinking stones were recovered from this stratum. Stratum 208 is similar to Stratum 201, although it is slightly less consolidated and contains less wallfall. Bedrock and infrequent patches of Stratum 175 underlay Stratum 208. Table 14.60 gives the artifact counts by stratum for Room 16.

Table 14.59. Room 16 stratigraphy.

Stratum	Thickness (cm)	Color	Texture	Description
0	0	7.5YR 4/3	sandy loam	Surface
1	3–6	7.5YR 4/4	sandy loam	Unconsolidated surface soil
201	11–29	7.5-10YR 4/4	sandy loam	Fill to base of walls
208	13–35	7.5-10YR 4/4	sandy loam	Soil below walls to bedrock

Table 14.60. Room 16 artifact counts by stratum.

Stratum	Chipped Stone	Ceramics	Ground Stone	Nonhuman Bone	Other	Total
0	8	15	1	0	0	24
1	34	43	0	0	0	77
201	271	1323	13	2	0	1609
208	158	630	7	20	1	816
Total	**471**	**2011**	**21**	**22**	**1**	**2526**

Floors. No floors or living surfaces were found in Room 16.

Wall Construction. The northeast and southeast corners of the room are in poor condition, although it appears that the south walls are bonded to the east wall. The other corners are not intact. Table 14.61 gives the dimensions of the extant walls segments. The walls are constructed of a single row of coursed, horizontally laid masonry of shaped and unshaped tuff blocks. The north wall was in poor condition due to considerable disturbance from tree roots. The rest of the walls are a single course high, although rubble found inside the room suggests that they were several courses higher at some point. The southern end of the east wall is missing as are several stones from the north end. The basal course of the west wall is mostly intact, although occasional gaps are present. The north end of this wall is distorted by tree roots.

A possible tie stone is present at 103.9N/103.2E in the east wall. It is possible that this is the remains of a south wall or of some other internal division. However, lacking other evidence for a wall at this location, the north wall of Room 14 is assumed to be the south wall of Room 16.

Table 14.61. Room 16 wall dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness
North	--	--	--
East	0.56, 2.56	0.27	0.24
South	2.0	0.17	0.24

Wall Orientation	Length (m)	Height (m)	Thickness
West	5.54	0.25	0.25

Artifacts and Samples. All the artifacts from units 102N/101E and 105N/102E were analyzed, as were all the macrobotanical materials from unit 102N/102E. All the faunal remains were analyzed. Other analyzed artifacts include a dacite palette (FS 3683) and a welded tuff maul (FS 3706). Table 14.62 lists the samples analyzed from Room 16.

Table 14.62. Room 16 analyzed samples by stratum.

Stratum	Flotation	Pollen	Macrobotanical
201	3888	3820	3874
208	4010	4009	4011

Room 17

Room 17 (Figure 14.48) is located near the south end of Roomblock 3 between Rooms 15 and 18. The interior dimensions of the room are 3.4 m north-south by 2.5 m east-west and it has an interior area of 8.5 m^2.

Stratigraphy. The four strata associated with Room 17 are summarized in Table 14.63. At the time of excavation, a large piñon tree and two small juniper trees were present in the center of the room. Stratum 1 consists of loose, unconsolidated, and fine-grained sandy loam. Stratum 201 consists of sandy loam grading to clay loam and contains very little wallfall. Stratum 208 is similar to Stratum 201 although it is mostly clay loam. Infrequent patches of Stratum 175 were found just above bedrock. Table 14.64 summarizes the artifacts from Room 17 by stratum.

Table 14.63. Room 17 stratigraphy.

Stratum	Thickness (cm)	Color	Texture	Description
0	0	10YR 4/3	sandy loam	Surface
1	1–5	10YR 4/3	sandy loam	Unconsolidated surface soil
201	5–45	10YR 4/4	sandy/clay loam	Fill to base of walls
208	6–30	10YR 4/4	clay loam	Soil below walls to bedrock

Total	**12**	**34**	**2**	**0**	**0**	**48**

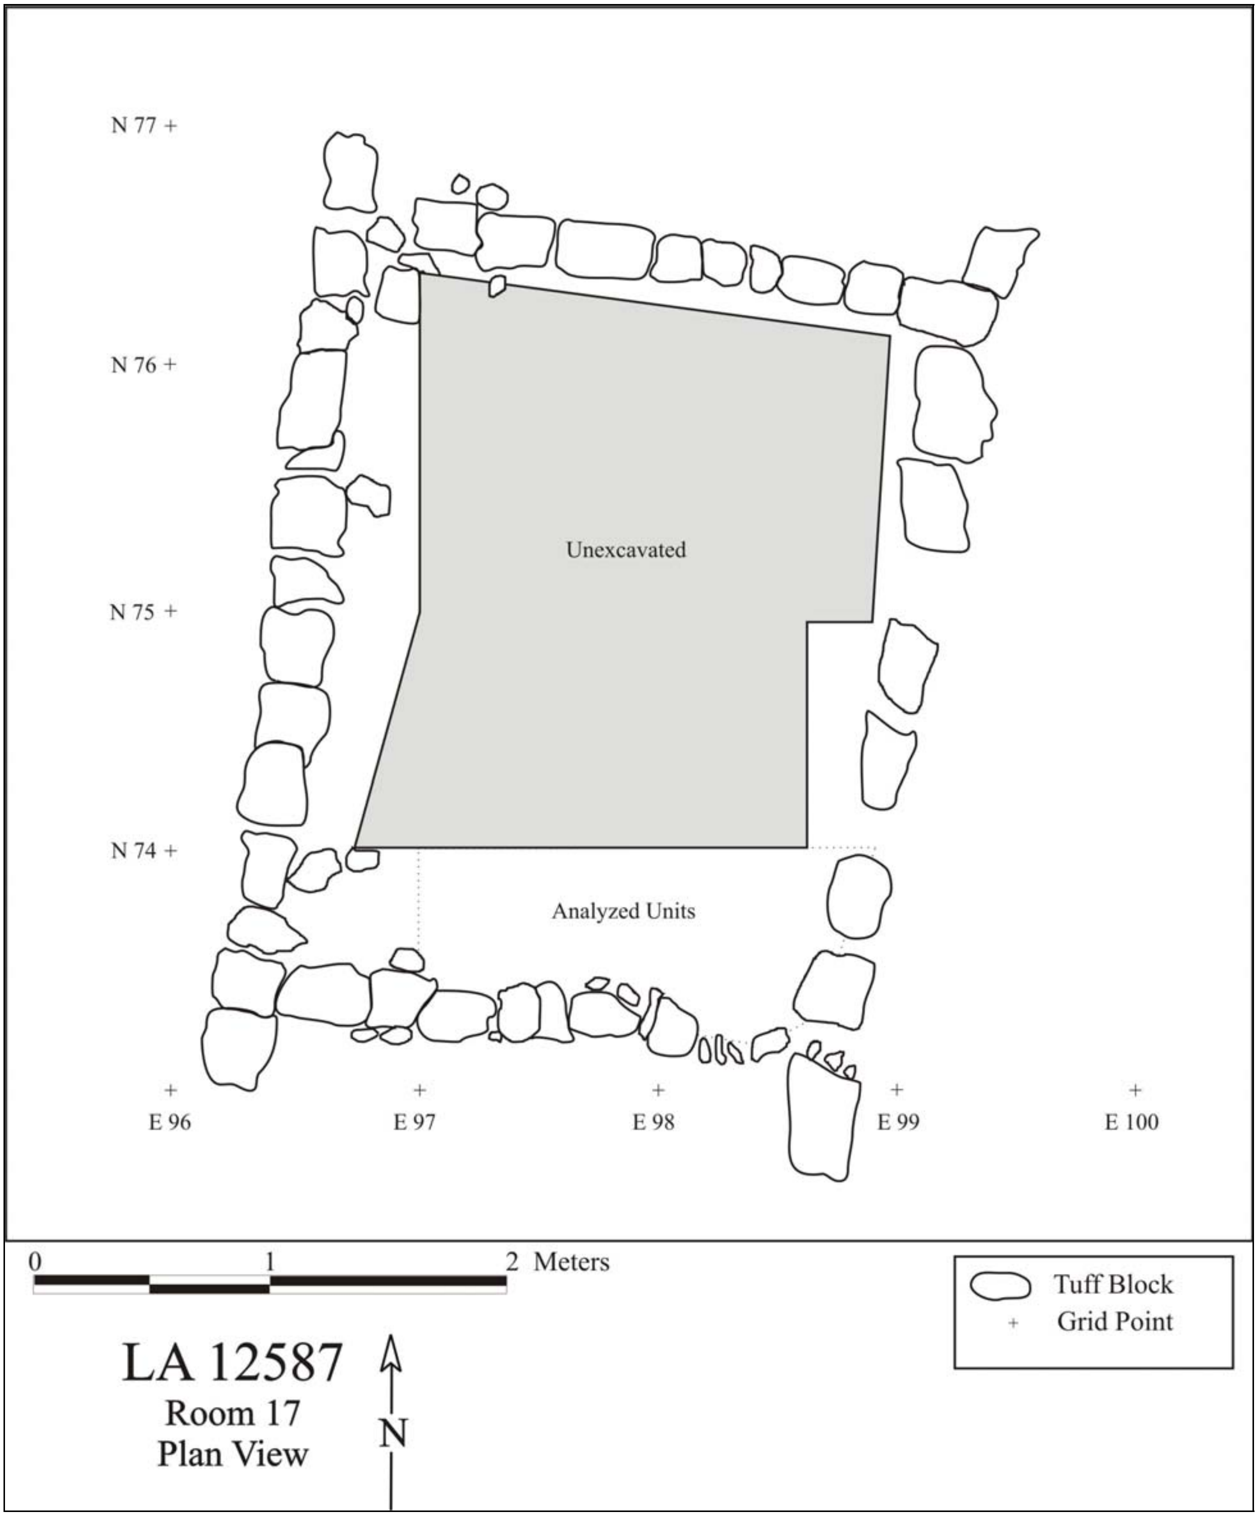

Figure 14.48. Room 17 plan view.

Floors. No floors or living surfaces were found in Room 17.

Wall Construction. The north wall is bonded with the east wall. All other corners abut. Table 14.65 gives the dimensions of the extant wall segments. The walls are constructed of a single row of coursed, horizontally laid masonry of shaped and unshaped tuff blocks held together with mortar. The basal courses of all the walls are intact except for the east wall, which has a few gaps. The west wall is two courses tall near the northwest corner of the room; otherwise the walls are only one course high.

Table 14.65. Room 17 wall dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	2.70	0.11	0.22
East	2.30	0.23	0.28
South	3.38	0.23	0.26
West	3.45	0.10	0.25

Artifacts and Samples. All the artifacts from units 73N/97E and 73N/98E were analyzed. Table 14.66 lists the samples analyzed from Room 17.

Table 14.66. Room 17 analyzed samples by stratum.

Stratum	Pollen	Flotation	Macrobotanical
1	4128	None	None
201	3860, 4129, 4130	4036, 4037, 4131, 4132	3853, 3857

Room 18

Room 18 (Figure 14.49) is the southernmost room of Roomblock 3. It is south of Room 17. The interior dimensions are 3.0 m north-south by 2.3 m east west, and it has an interior area of 6.9 m^2. Excavation ended at a possible living surface that was level with, to a few centimeters below, the top of the walls. The dirt access road for the power line lies about 1 m south of Room 18.

Stratigraphy. The four strata associated with Room 18 are summarized in Table 14.67. Stratum 1 consists of loose, unconsolidated, and fine-grained sandy loam. The stratum is 1 to 2 cm thick in the south portion of the room. It is deeper in the north where it averaged 5 to 7 cm in thickness, although the maximum thickness was 14 cm. Stratum 201 consists of loose, medium-grained sandy loam. The stratum is not present in the southern portion of Room 18 and it is shallow in the center of the room (1 to 5 cm). At the north end of the room, Stratum 201 is up to 17 cm deep. Both Stratum 1 and Stratum 201 contained very little wallfall. Stratum 310 is discussed below in the ‘Floor’ section. Table 14.68 gives the artifact counts by stratum for Room 18.

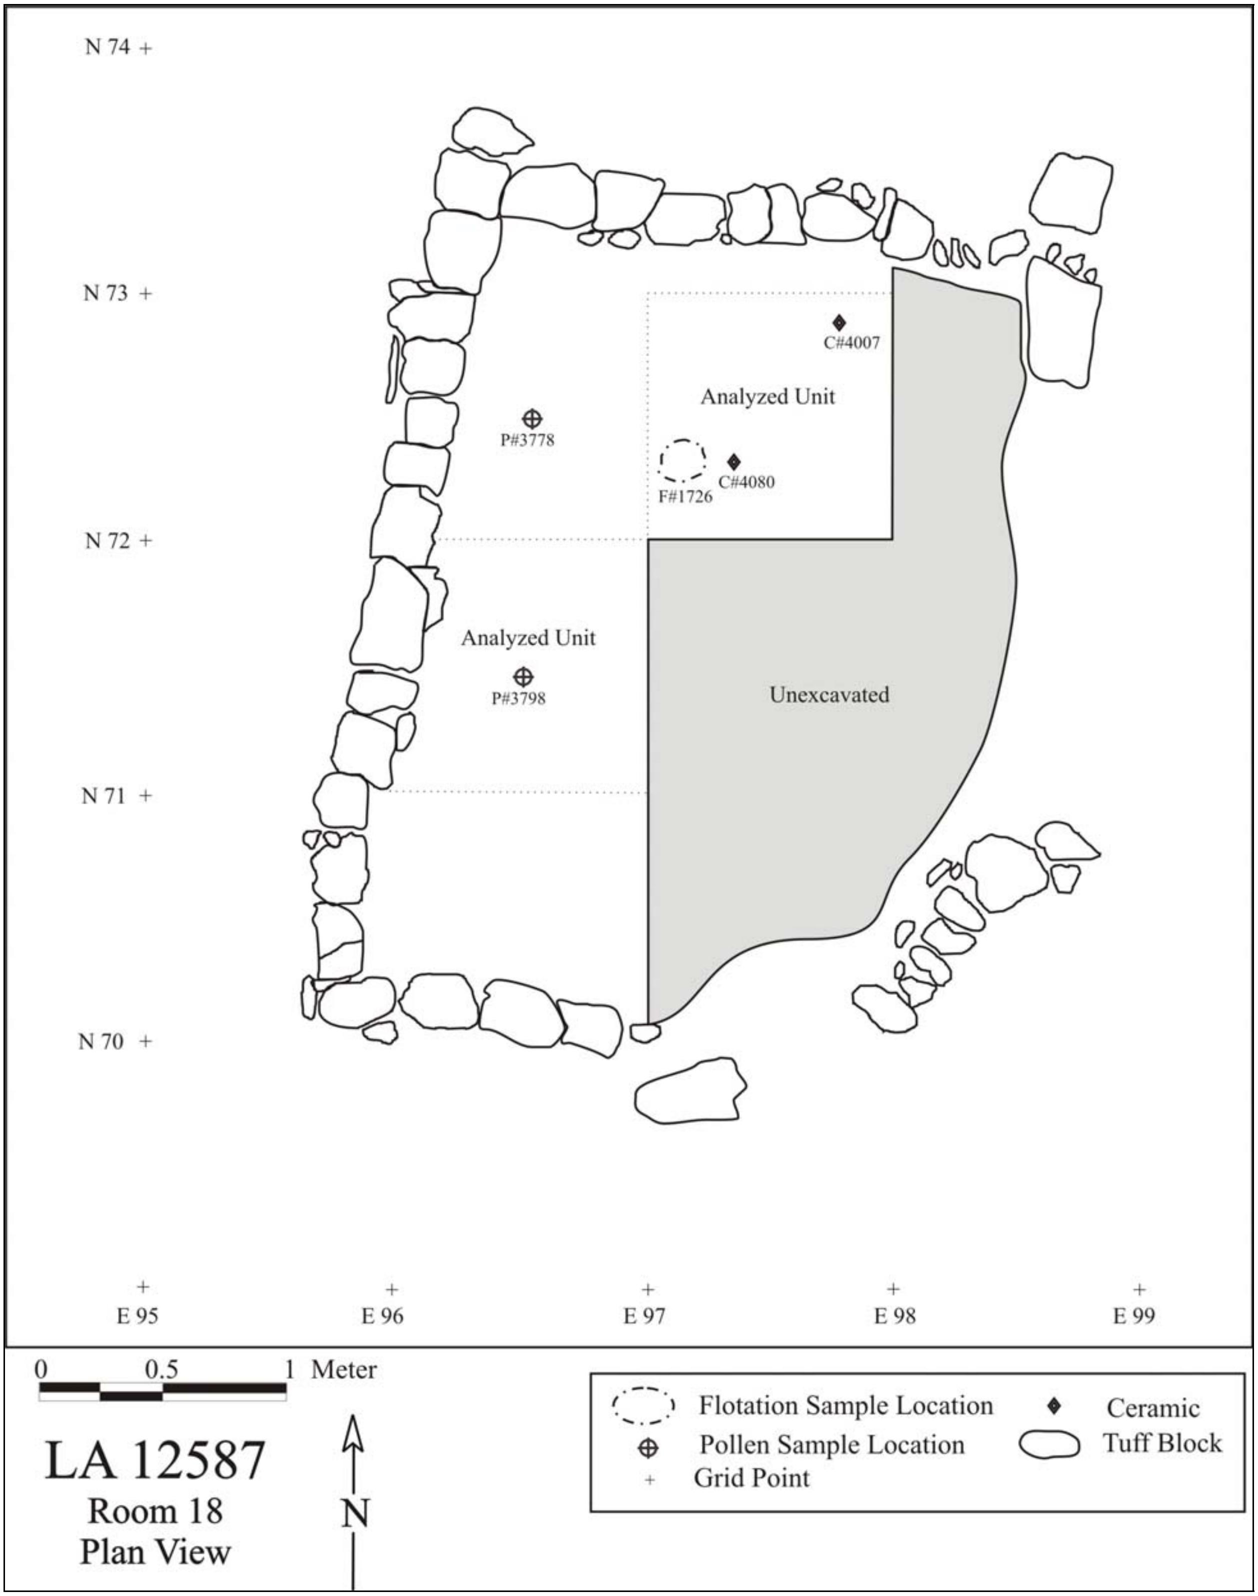

Figure 14.49. Room 18 plan view.

Table 14.67. Room 18 stratigraphy.

Stratum	Color	Texture	Thickness (cm)	Description
0	7.5YR 4/4	sandy loam	0	Surface
1	7.5-10YR 4/4	sandy loam	1–14	Unconsolidated surface soil
201	7.5-10YR 4/4	sandy loam	1–17	Fill to Stratum 310
310	7.5YR 5/3	sandy loam	0	Possible use surface

wall trenches grab sample	1	11	0	0	0	12
Total	**45**	**72**	**5**	**1**	**0**	**123**

Floors. Stratum 310, a possible use surface (Figure 14.50), underlies Stratum 1 in the south half of the room, and Stratum 201 in the north half of the room. It is underlain by an unexcavated Bw2 horizon. Stratum 310 consists of a compact and even surface that was level with, and articulated with, the top of the west and south walls. The top of Stratum 310 is a few centimeters below the top of the north wall. Several tuff cobbles were embedded in Stratum 310 and rise above its surface, indicating the Stratum 310 may not actually be a use surface. Two smeared-indented corrugated jar sherds (FS 4007 and FS 4080) were found on the surface of Stratum 310.

Wall Construction. The north wall abuts the west wall and probably abutted the east wall, but the relationship between the west wall and the south wall is unclear. The southeast corner does not exist. Table 14.69 gives the dimensions of the extant wall segments. The walls are constructed of a single row of horizontally laid masonry of shaped and unshaped tuff blocks held together with mortar. Facing stones are occasionally present on both the interior and exterior of the walls. All the walls are one course tall. The lack of wallfall in the fill suggests that the walls were never built up beyond their present height. The basal courses of the north and west wall are both intact, save for a 30-cm-long gap at the east end of the north wall. Only the west half of the south wall is present and the east wall is non-existent except for one masonry block in the northeast corner.

Table 14.69. Room 18 wall dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	2.14	0.15	0.25
East	0.44	0.11	0.27
South	1.43	0.12	0.21
West	3.56	0.10	0.25

Figure 14.50. Room 18, Stratum 310.

Artifacts and Samples. All the artifacts from units 71N/96E and 72N/97E were analyzed. Analyzed samples consist of one flotation sample (FS 4079) and two pollen samples (FS 3778 and FS 3798) taken from just above Stratum 310. Only juniper remains were identified in the flotation sample. Taxa identified in the pollen samples include maize, beeweed, buckwheat, cheno-ams, grass family, mustard family, sunflower family, ragweed/bursage, globemallow (*Sphaeralcea*), spurge family, Douglas fir, fir, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush.

Features. At the southeast corner of the room there is a detached, meter long, southwest-northeast-oriented alignment of unshaped and unmortared tuff blocks. It seems unlikely that this alignment is associated with the Room 18 walls. The tuff blocks are smaller than the masonry blocks of the room walls, the alignment of the blocks is different from that of the wall (their long axes are perpendicular, not parallel, to the alignment of the feature), and the top of the alignment is about 15 cm below the top of the walls. The function/origin of this alignment is unknown.

Room 19

Room 19 (Figure 14.51) is located near the north end of Roomblock 3 between Rooms 20 and 21. Room 19 is stratigraphically below Feature 22 (Figure 14.52).

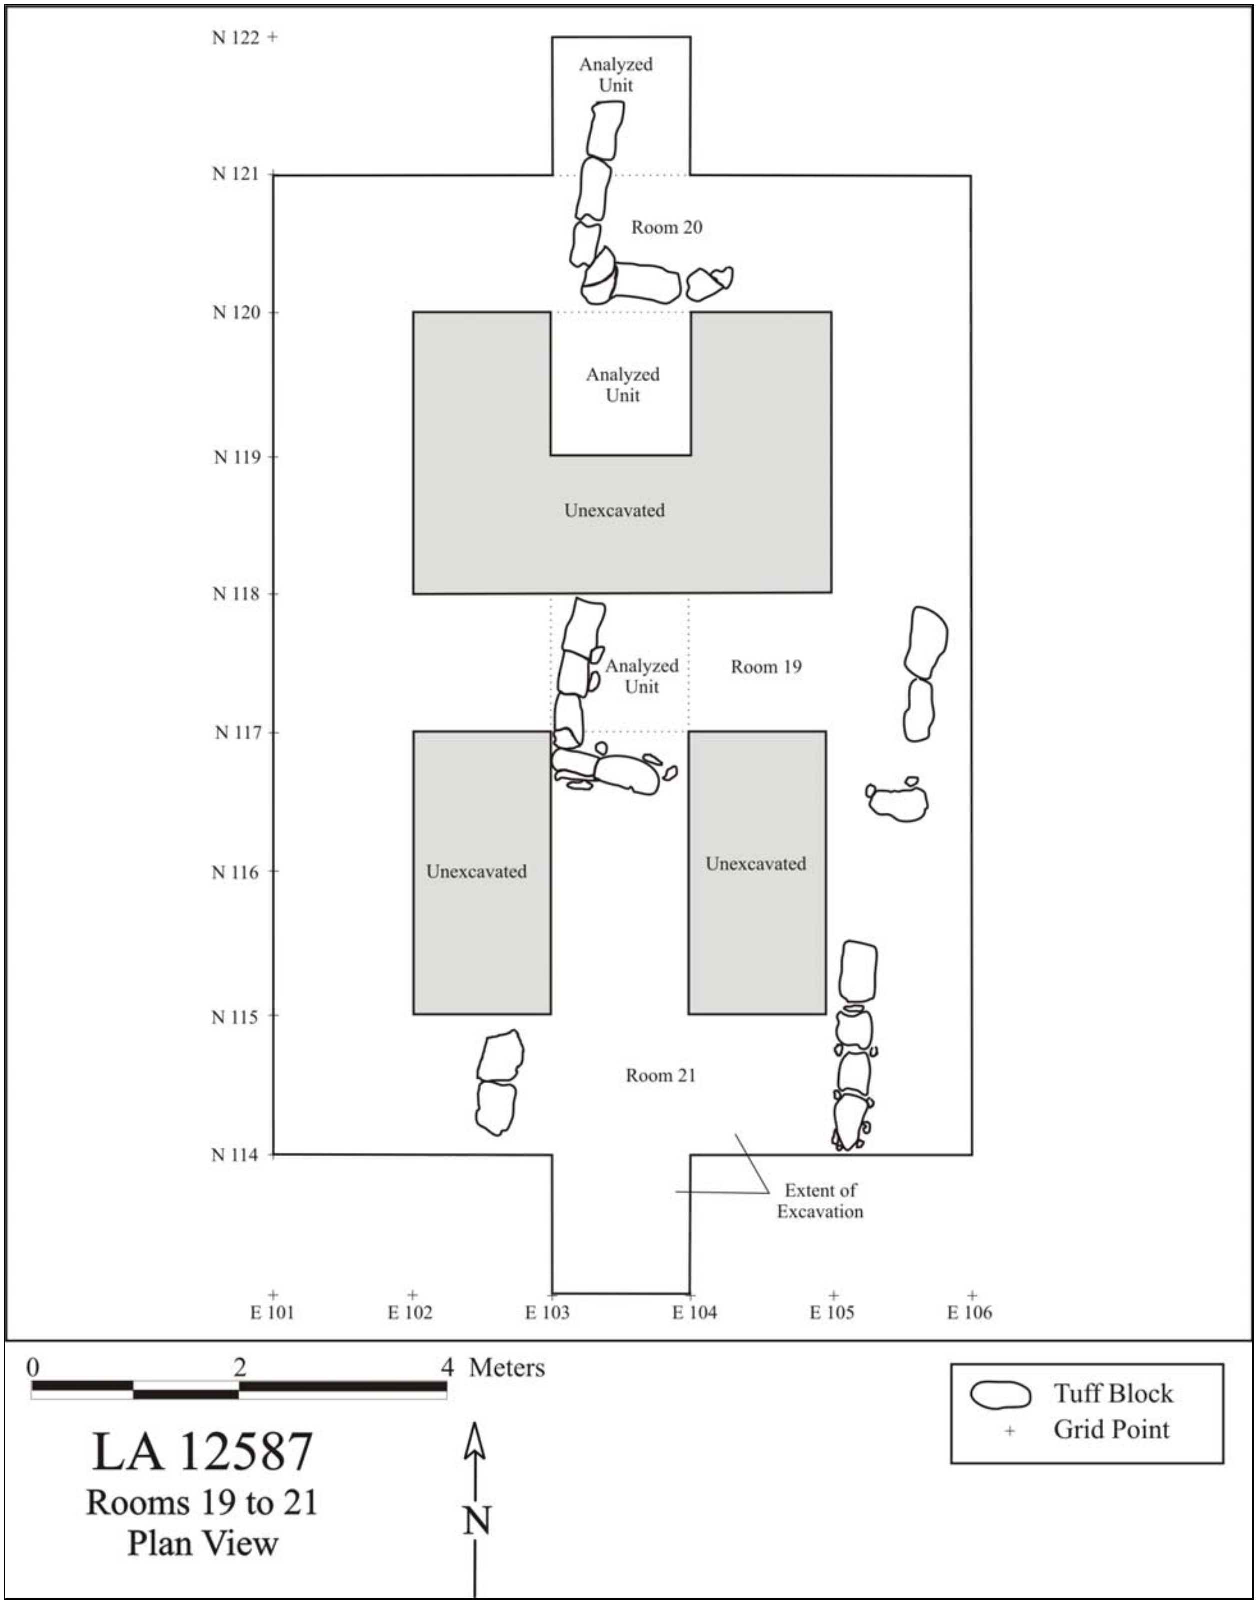

Figure 14.51. Rooms 19 to 21 plan view.

Figure 14.52. Room 19 underlies Feature 22.

Only one course of the southwest corner, fragments of the southeast corner, and a small part of the north wall were exposed. The room probably had internal dimensions of 3.3 m north-south by 2.2 m east-west and an area of 7.3 m^2. Only the basal course of the wall fragments survived and it is not clear if this was the extent of the Room 19 construction or if much of the room was destroyed by the construction of Feature 22.

Stratigraphy. The fill above the room walls is described in the discussion of Feature 22 below. Only the lower levels of Stratum 280 in three units (117N/103E, Level 4; 119N/103E, Levels 3 and 4; and 120N/103E, Level 4) were assigned to Room 19. Stratum 280 consists of 7.5YR 3/3 sandy loam and is 6 to 20 cm deep. It begins at the top of the Room 19 walls and ends slightly below the walls at the sandy clay of Stratum 175. Table 14.70 gives a count of the artifacts found in this stratum.

Table 14.70. Room 19 artifact counts by stratum.

Stratum	Chipped Stone	Ceramic	Ground Stone	Nonhuman Bone	Other	Total
280	25	80	3	0	1	109

Floors. No floors or living surfaces were found in Room 19.

Wall Construction. Very little of the Room 19 walls remain (Table 14.71). The southwest corner is defined by three masonry blocks of the west wall and by two masonry blocks of the south wall. The southeast corner is defined by two masonry blocks of the east wall and by one masonry block of the south wall. The three westernmost blocks of the north wall are also present. Facing stones are present on both the interior and exterior of the southwest corner and on the interior of the southeast corner. The base of the walls is approximately 12 cm above bedrock. All the masonry blocks are shaped.

Table 14.71. Room 19 wall dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	1.06	0.10	0.27
East	0.94	nd	nd
South	0.78	0.10	0.20
West	1.28	0.17	0.22

nd = no data recorded

Artifacts and Samples. All the artifacts from units 117N/103E and 119N/103E were analyzed. Three pollen samples (FS 4059, FS 4061, and FS 4063) were also analyzed. Taxa identified in the pollen samples included maize, cholla, beeweed, buckwheat, cheno-ams, grass family, sunflower family, spurge family, Douglas fir, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush.

Room 20

Room 20 (see Figures 14.51 and 14.52) is the northernmost room of Roomblock 3. Feature 22 overlies Room 20. Because only the southwest corner of the room was exposed, the room dimensions could not be determined. The only excavated units associated with Room 20 are 120N/103E and 121N/103E.

Stratigraphy. The fill above the room walls is described in the discussion of Feature 22 below. Only the lower levels of Stratum 280 in units 120N/103E and 121N/103E were assigned to Room 20. Stratum 280 begins at the top of the walls and ends below the base of the walls at Stratum 175. It consists of 10 to 19 cm of 7.5YR 3/3 to 10YR 4/4 medium-grained sandy loam. Two masonry blocks were found in Stratum 280. Table 14.72 gives a count of the artifacts found in this stratum.

Table 14.72. Room 20 artifact counts by stratum.

Stratum	Chipped Stone	Ceramic	Ground Stone	Nonhuman Bone	Other	Total
280	4	41	1	0	0	46

Floors. No floors or living surfaces were found in Room 20.

Wall Construction. A single course of three shaped tuff blocks makes up the west wall, and a single course of three shaped tuff blocks makes up the south wall (Table 14.73). The masonry ranges in size from 26 by 20 by 8 cm to 40 by 28 by 11 cm. It is possible that the foundation of the southwest corner was all that was built of Room 20 as there is no evidence for additional segments of the south and west walls.

Table 14.73. Room 20 wall dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	n/a	n/a	n/a
East	n/a	n/a	n/a
South	1.06	0.10	0.27
West	1.10	0.10	0.18

Artifacts and Samples. All the artifacts from unit 121N/103E were analyzed. Three pollen samples (FS 4065, FS 4066, and FS 4067) were also analyzed. Taxa identified in these samples included maize, cholla, prickly pear, beeweed, purslane, cheno-ams, grass family, sunflower family, ragweed/bursage, spurge family, evening primrose, Douglas fir, unidentified pine, piñon pine, juniper, rose family, and sagebrush.

Room 21

Room 21 (see Figure 14.51) is located near the north end of Roomblock 3 between Rooms 19 and 22. Feature 22 overlays Room 21. Only portions of the basal courses of the north, east, and west walls were found. It is not clear if this was the extent of the Room 22 construction or if much of the room was destroyed by the construction of Feature 22. The east-west width of the room is 2.4 m, and since no south wall was found, the north-south dimension is unknown.

Stratigraphy. Due to the minimal remains of Room 21, all the strata and artifacts encountered in this area were assigned to Feature 22.

Floors. No floors or living surfaces were found in Room 21.

Wall Construction. Very little of the walls remain (Table 14.74). The easternmost block and the two westernmost blocks of the north wall are present. Four contiguous blocks of the east wall survive, as do two contiguous blocks of the west wall. All the masonry blocks are shaped and range in size from 33 by 23 by 10 cm to 40 by 20 by 10 cm. Facing stones are present on both the interior and exterior of the north and east walls. Along the east wall most of the facing stones are placed at the joints between the masonry blocks. The base of the walls is a few centimeters above bedrock.

Table 14.74. Room 21 wall dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	0.78	0.10	0.20
East	1.50	0.10	0.21

Wall Orientation	Length (m)	Height (m)	Thickness (m)
South	n/a	n/a	n/a
West	0.67	0.1	0.25

Artifacts and Samples. Two pollen (FS 4056 and FS 4057) samples from Room 21 were analyzed. Taxa identified in the pollen samples included maize, cholla, prickly pear, beeweed, purslane, cheno-ams, grass family, sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush.

Room 22

Room 22 is located in the northern portion of Roomblock 3 between Rooms 21 and 16. Only the area around the south wall and the south half of the east wall was excavated. The north and west walls could not be located. Because so little of the room was unexcavated, no dimensional data are available.

Stratigraphy. Because only a small area of the room was excavated, a stratigraphic description is also unavailable. Since most of the fill excavated from Room 22 was not screened, only four chipped stone artifacts are associated with the room.

Floors. No floors or living surfaces were found in Room 22.

Wall Construction. Two segments of the east wall remain (Table 14.75, Figure 14.53). The southern segment consists of three shaped tuff blocks that extend north for 60 cm from the north wall of Room 16. The northern segment lies 1.75 m further north and consists of two parallel rows of small upright tuff cobbles and four masonry blocks. The south wall is described above as the north wall of Room 16.

Table 14.75. Room 22 wall dimensions (extant wall segments).

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	n/a	n/a	n/a
East	0.60, 1.05	0.12	0.19
South	n/a	n/a	n/a
West	n/a	n/a	n/a

Artifacts and Samples. No artifacts or samples were analyzed from Room 22.

Figure 14.53. Room 22 east wall.

Area 1 Exterior Features

Four external features were identified in Area 1. Feature 3 is an ash stain located about 5 m east of Room 7. Feature 5, a possible storage cist, was constructed against the exterior of the east wall of Room 2. It was included in the Room 2 description. Feature 13 is a set of bedrock grinding slicks located 1 m west of Room 6. A northern extension of the center wall of Roomblock 1 and an associated floor surface and charcoal stain were identified as Feature 21.

Feature 3 (Ash Stain). During mechanical scraping to the east and southeast of Roomblock 1, a 3.3- by 1.9-m scatter of tuff blocks was encountered. An ashy stain was located near the center of the scatter. The stain measures 64 by 38 cm and is 5 to 8 cm deep (Figure 14.54).

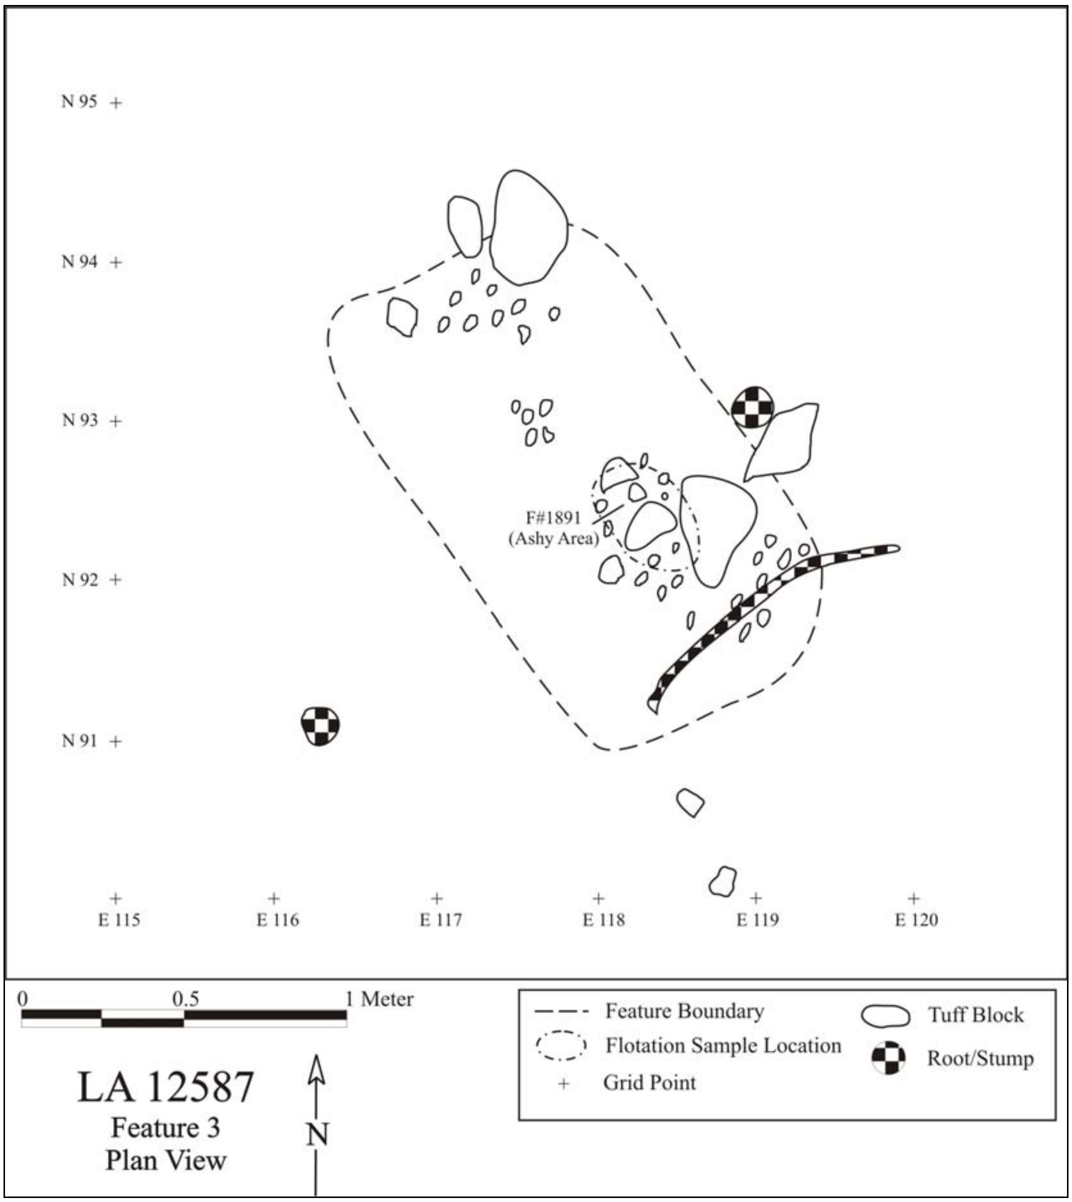

Figure 14.54. Feature 3 plan view.

The ashy deposit was collected as a flotation sample (FS 1891) and the charred taxa included unknown conifer, juniper, piñon pine, unidentified pine, saltbush/greasewood, and maize. Seven smeared-indented corrugated jar sherds (FS 1888), one plain body jar sherd (FS 1888), and one basalt core flake (FS 1889) were recovered from the feature. Feature 3 may be the remains of an informal hearth.

Feature 13 (Grinding Slicks). Feature 13 consists of six grinding slicks in the tuff bedrock, which were identified approximately 35 cm below surface. The slicks varied in depth from 2 to 6 cm and were 15 to 28 cm long and 10 to 14.5 cm wide. Five were oriented northwest-southeast (Slicks 1 through 5), and the sixth was oriented north-south (Figures 14.55 and 14.56).

Figure 14.55. Feature 13.

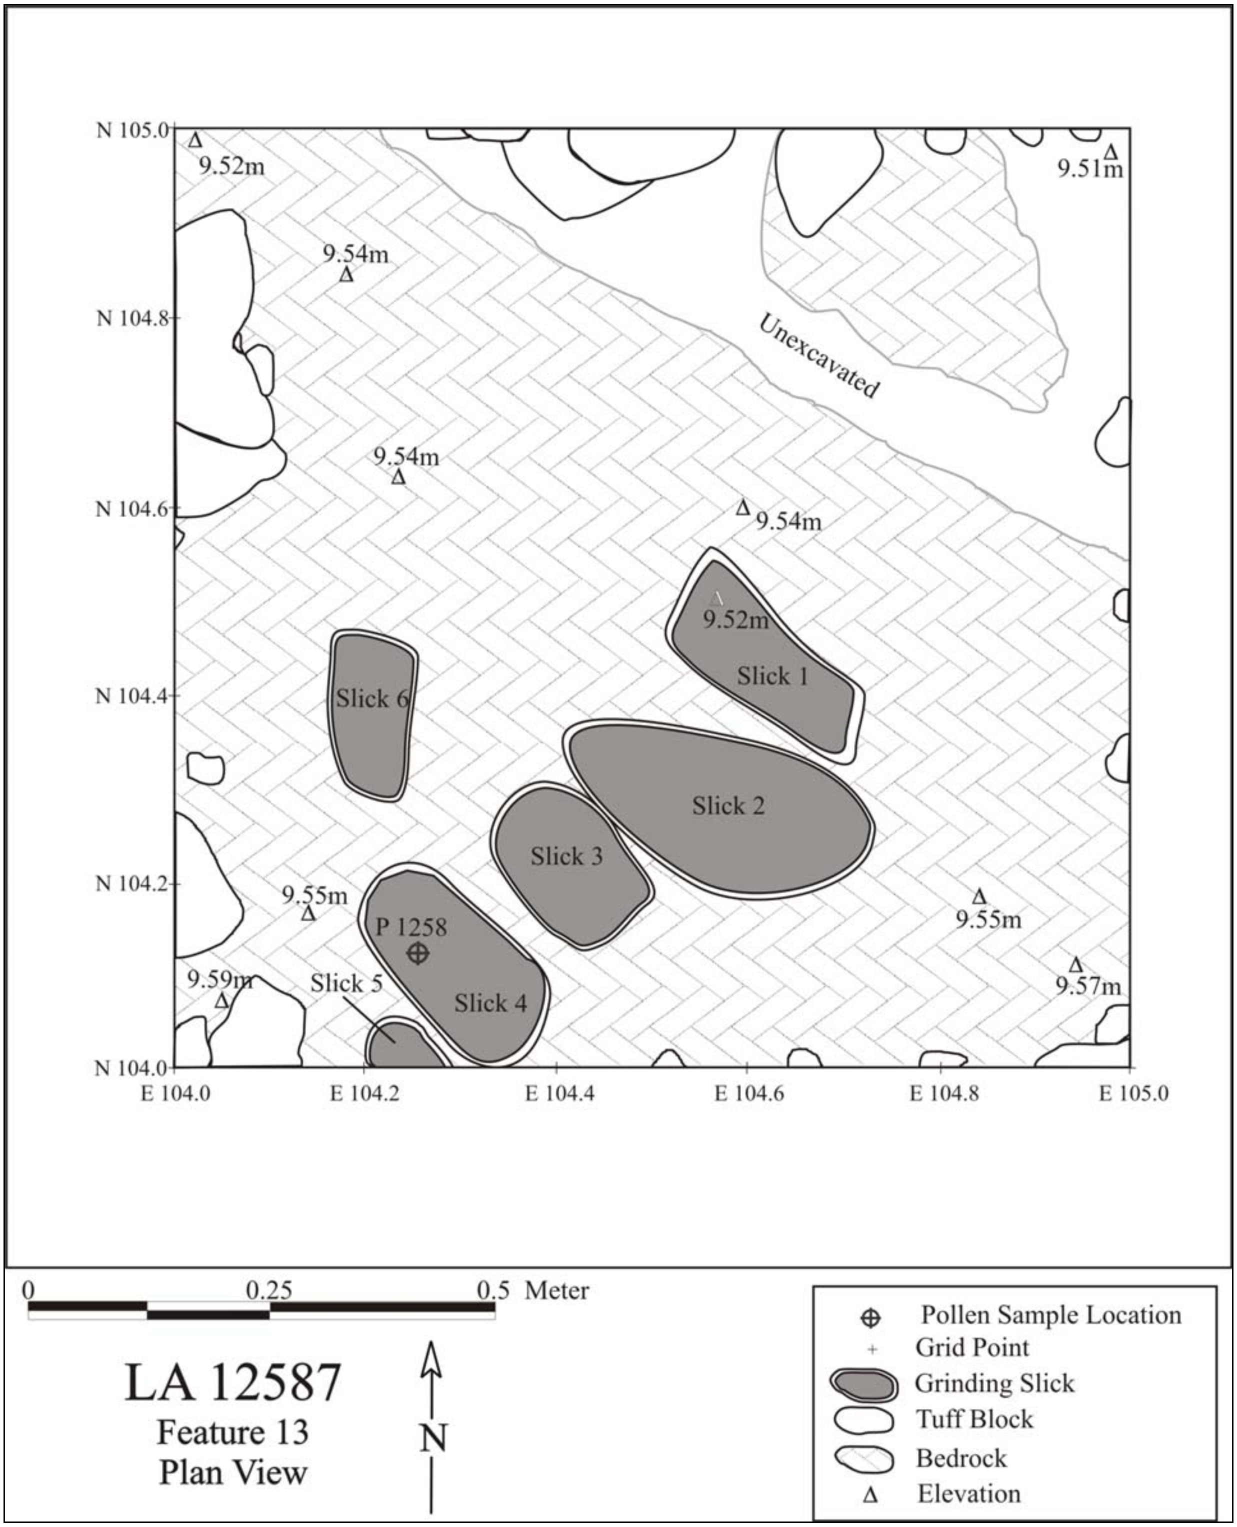

Figure 14.56. Feature 13 plan view.

Slick 1 is 25 cm long, 10 cm wide, and 2.5 cm deep. The width is uniform. The north side is nearly vertical, angling out slightly at the top. In contrast, the south side slopes evenly up to the bedrock surface. Both ends slope up evenly to the bedrock surface. Striations are present at the base of the slick and are parallel with the long axis.

Slick 2 varies in width from 11 cm at the ends to 16 cm in the center. It is 28 cm long and up to 6 cm deep. The ends and sides slope uniformly up to the bedrock surface. Striations are present at the base of the slick and are parallel with the long axis.

Slick 3 shares a common edge with Slick 2. This slick is 22 cm long, 12.5 cm wide at the northwest end, 10 cm wide at the southeast end, and 11 cm wide at the center. It is 3 cm deep. A hole, 3 cm in diameter and 2.5 cm deep was pecked into the northwest end of the slick. Striations are present at the base of the slick and are parallel with the long axis. The grinding surface of Slick 3 overlaps the south edge of Slick 2 suggesting that Slick 3 is younger.

Slick 4 is 22 cm long, 10 to 10.5 cm wide, and 5.5 cm deep. Its sides are relatively vertical, angling out slightly at the top. Both ends feather out. A small hole at the southeast end, which was 1 cm in diameter, may have been produced by pecking. A pollen sample (FS 1258) collected from just above this slick was analyzed. Taxa identified in the sample included prickly pear, cheno-ams, grass family, sunflower family, spurge family, fir, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush.

Slick 5 is shallow and less distinct than the others. It is 15 cm long, 10 cm wide, and not more than 1 cm deep. Striations are not evident. A conical hole that is 3 cm in diameter and 1 cm deep is located immediately southwest of the slick. It may have been produced by pecking.

Slick 6 is 16.5 cm long, 11.5 cm wide at the center, and 2 cm deep. Its sides are relatively vertical. Striations are present at the base of the slick and are parallel with the long axis.

Feature 13 is either associated with the Archaic component (Area 8) of the site or with Roomblock 1. The stratigraphic relationship between Roomblock 1 and later components indicates that Feature 13 was buried after the abandonment of Roomblock 1.

Feature 21 (Alignment). Feature 21 consists of an 80-cm-long extension of the middle wall of Roomblock 1 north of Rooms 1 and 2. Remnants of wall mortar were noted on the east side of the wall extension. Directly east of the wall extension there was a fragment of plastered floor surface. The north wall of Room 2 forms the south side of the feature. No northern and eastern boundaries were found. An ash and charcoal stain was exposed in the southwest corner of the feature. A flotation sample (FS 4211) was collected from the stain and the taxa identified included squash/coyote gourd, unknown conifer, juniper, unidentified pine, purslane, oak, and maize. The function/origin of this feature is unknown.

Area 2

Area 2 was defined by the presence of three parallel tuff rock alignments (Feature 22) and scattered rubble. Two other features (Feature 17 and Feature 18) were excavated in Area 2.

Feature 17 is a surficial rock cluster situated immediately southeast of Feature 22. Feature 18 is a similar rock cluster situated about 1 m south of Feature 17. Additional rubble and alignments lie north of Feature 22. These were not investigated, but likely represent additional agricultural features. Features 17, 18, and 22 are all situated in the A horizon at a shallow depth, indicating that they are at least roughly contemporaneous.

Feature 17 (Rock Cluster). Feature 17 is located immediately southeast of Feature 22. It is a circular rock cluster of unshaped tuff rocks. The feature is approximately 1 m in diameter and 15 cm high. In profile it is clear that Feature 17 is situated in the A horizon. The function of the feature is not evident. It may be an agricultural feature, possibly where seeds were planted to take advantage of the moisture and heat-retention qualities of the rock. Or it may be the result of rock clearing and stockpiling that possibly occurred during the preparation of Feature 22. A pollen sample was taken from beneath a large tuff block in the cluster (FS 4097). Taxa identified in this sample included maize, cholla, prickly pear, cheno-ams, grass family, spurge family, sunflower family, ragweed/bursage, Douglas fir, unidentified pine, piñon pine, juniper, oak, cottonwood/willow, and sagebrush.

Feature 18 (Rock Cluster). Feature 18 is situated approximately 1 m south of Feature 17. It is a circular rock cluster that consists of 24 unshaped tuff blocks in a 1.72- by 1.70-m area (Figures 14.57 and 14.58).

Figure 14.57. Feature 18.

The feature is slightly mounded with a maximum height of 8 cm. The rocks are irregular in shape and range in size from 23 by 18 cm to 8 by 6 cm. Many of the cobbles are lichen-covered. In profile it is clear that Feature 18 is situated in the A horizon (Figure 14.58). The function of the feature is not evident. It may be an agricultural feature, possibly where seeds were planted to take advantage of the moisture and heat-retention qualities of the rock. Or it may be the result of rock clearing and stockpiling, possibly during preparation of Feature 22. A pollen sample (FS 4154) was collected from within the feature and a second pollen sample (FS 4155) was collected from below it. Taxa identified in FS 4154 include maize, prickly pear, cheno-ams, grass family, sunflower family, spurge family, evening primrose, Douglas fir, piñon pine, unidentified pine, juniper, and sagebrush. Taxa identified in FS 4155 include maize, prickly pear, beeweed, cheno-ams, grass family, sunflower family, ragweed/bursage, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush.

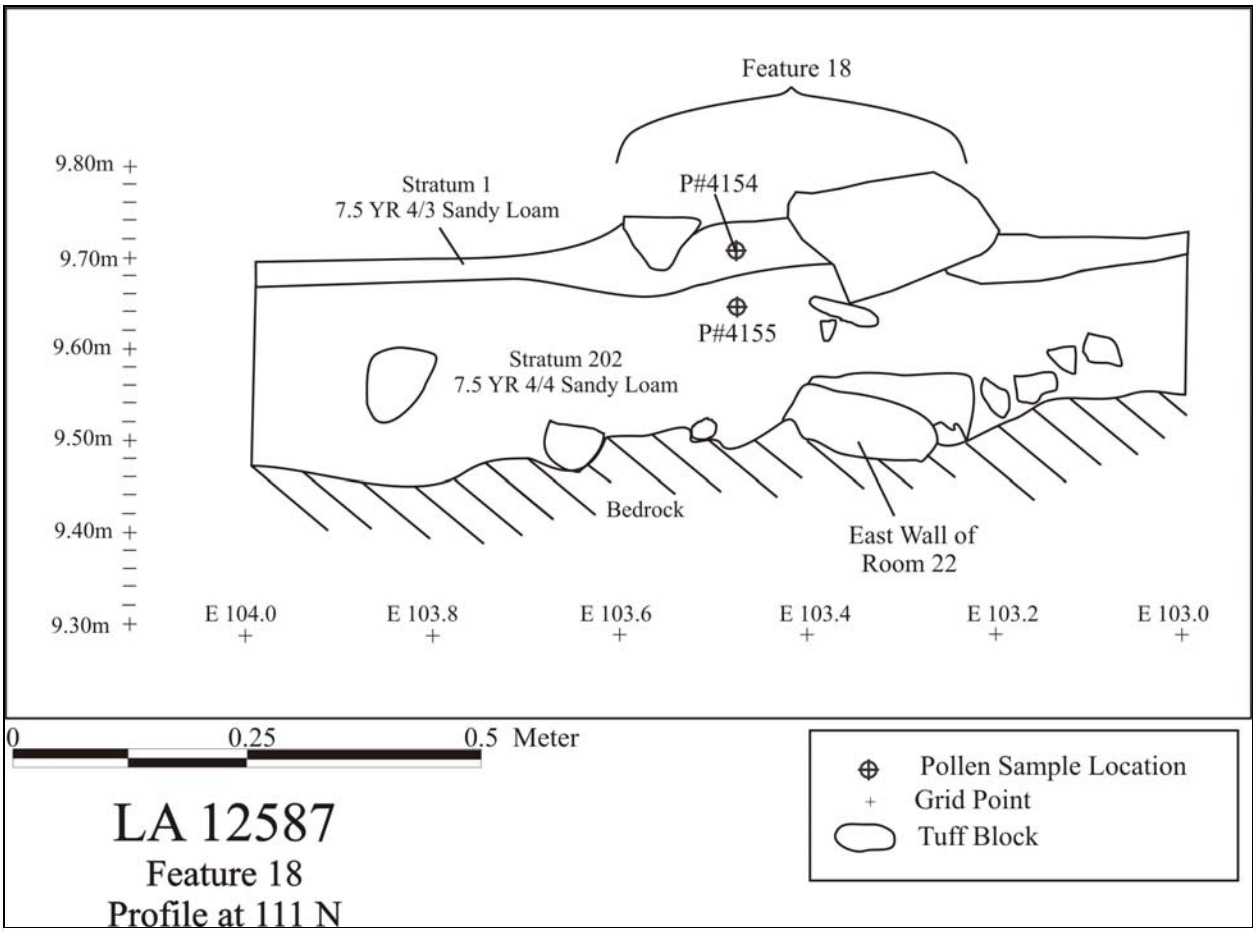

Figure 14.58. Feature 18 profile.

Feature 22 (Berms). Feature 22 is located near the north end of the site and consists of three east-west-running berms of unshaped tuff cobbles. The berms are 4 to 5 m long, 0.5 to 1.0 m wide, and 0.15 to 0.20 m high (Figures 14.59, 14.60, and 14.61). A few rocks on the west side of the feature create a rough boundary. The cobbles making up the feature are loosely placed together and stacked no more than three high. They are partially buried by A horizon soil

(Stratum 1) and rest on or just in the Bw horizon (Stratum 280). The A horizon is somewhat deeper inside the feature than outside, suggesting that dirt was intentionally placed inside the berms (see Drakos and Reneau, Volume 3). Isolated wall segments of Rooms 19 to 21 immediately underlie Feature 22. Feature 22 is interpreted as an agricultural feature.

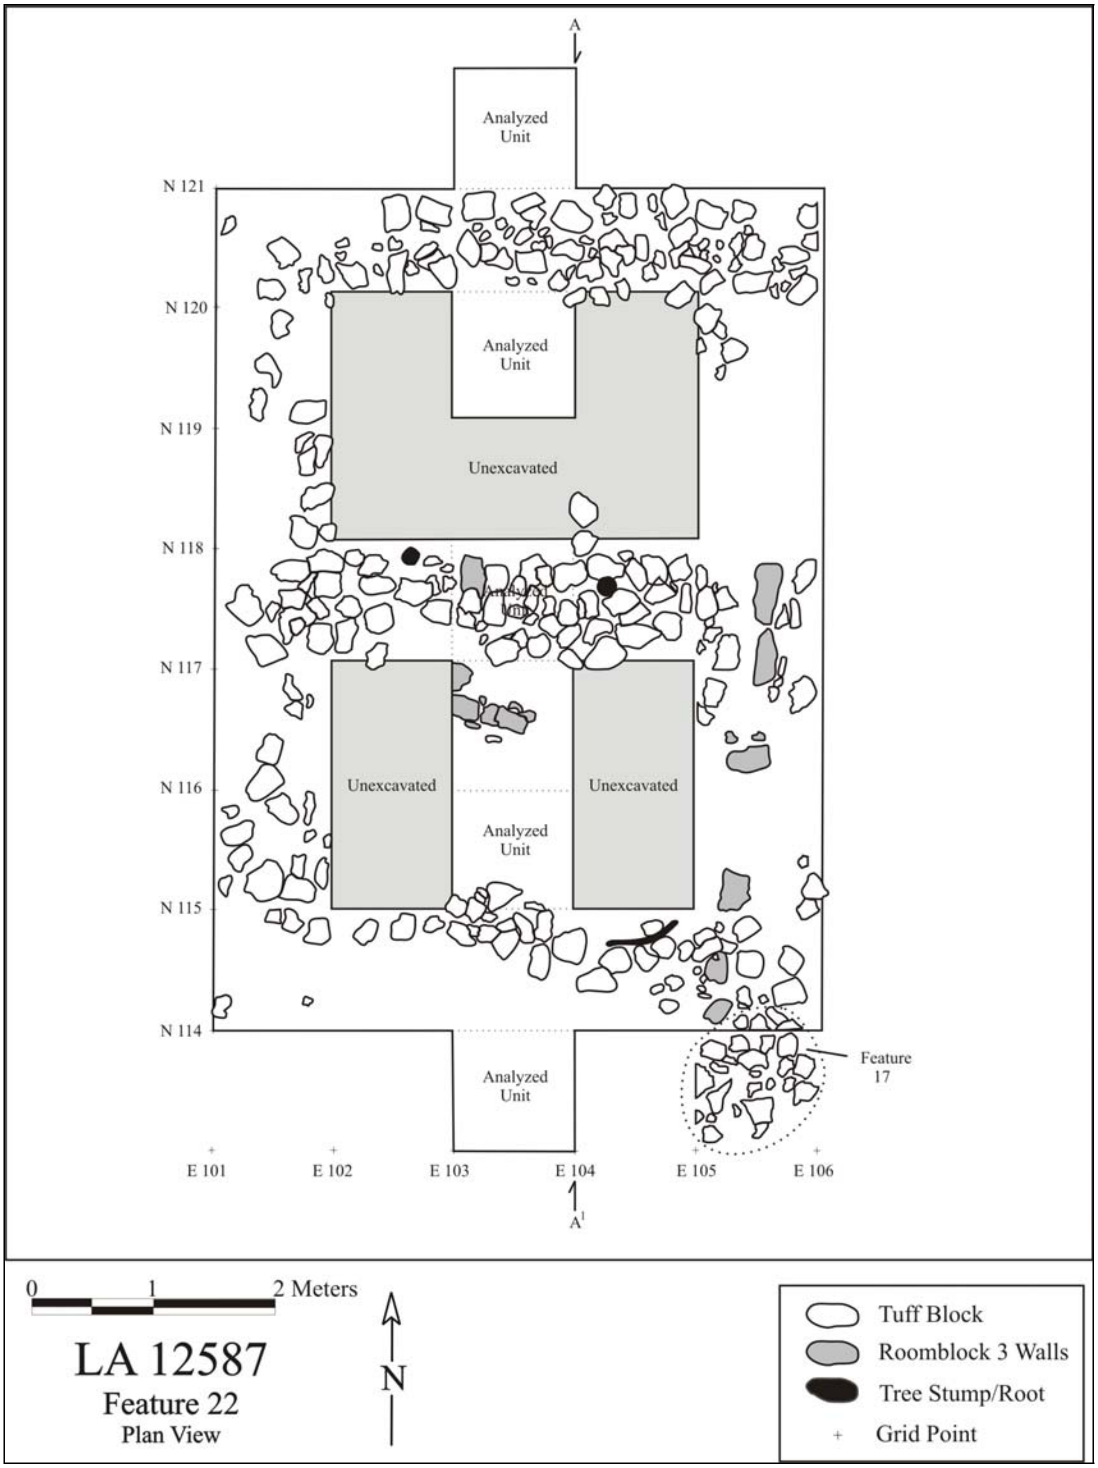

Figure 14.59. Feature 22 plan view.

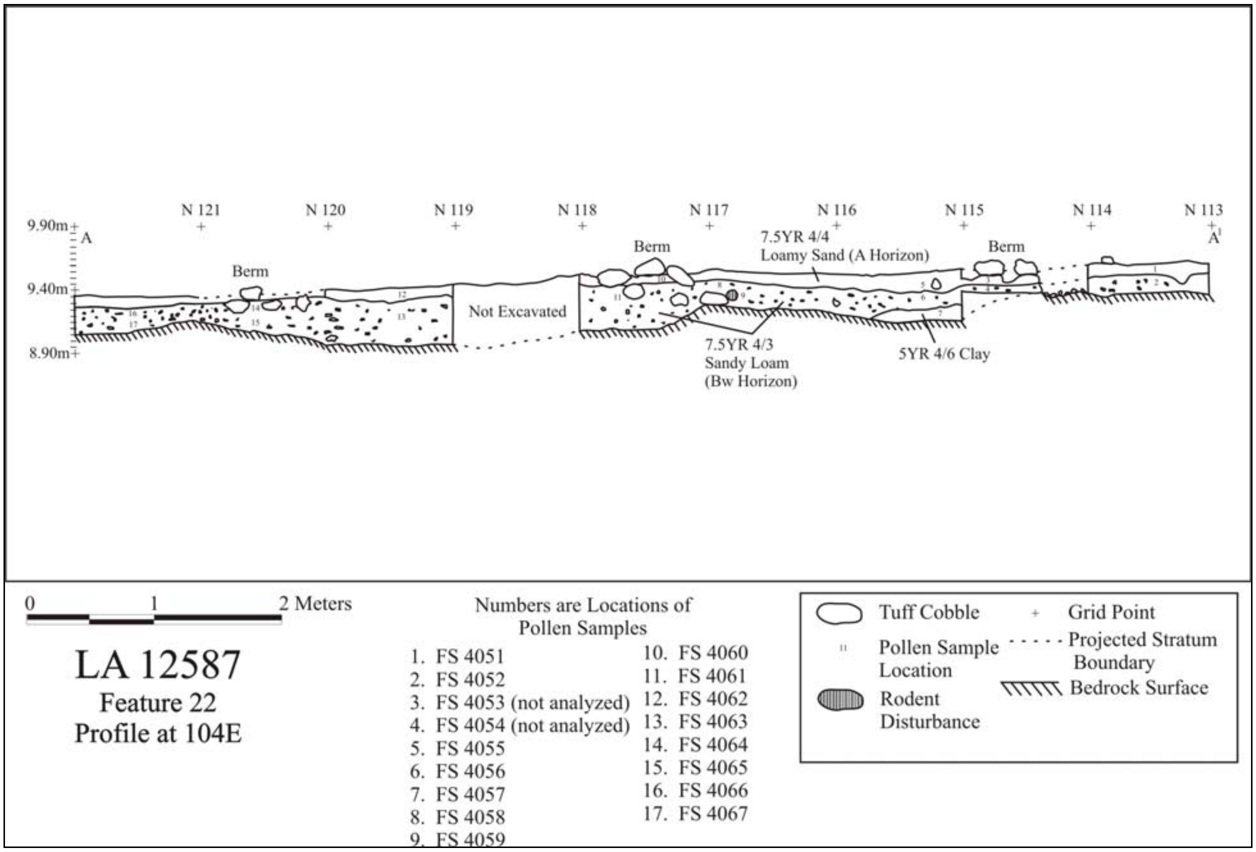

Figure 14.60. Feature 22 profile.

Artifacts from every other grid along the 103E line (starting at 113N and ending at 121N, inclusive) were analyzed. Fifteen pollen samples were analyzed from Feature 22 (FS 4051, FS 4052, FS 4055, FS 4056, FS 4057, FS 4058, FS 4059, FS 4060, FS 4061, FS 4062, FS 4063, FS 4064, FS 4065, FS 4066, and FS 4067). Taxa identified in these pollen samples included cotton (*Gossypium*), maize, prickly pear, cholla, beeweed, mint family, purslane, buckwheat, cheno-ams, grass family, mustard family, sunflower family, ragweed/bursage, spurge family, evening primrose, Douglas fir, unidentified fir, unidentified pine, piñon pine, juniper, oak, rose family, Mormon tea, and sagebrush. Table 14.76 gives a count of the number of artifacts per stratum from Feature 22. The 'Other' category consists of a turquoise fragment (FS 3340) and several miscellaneous samples.

Table 14.76. Feature 22 artifact counts by stratum.

Stratum	Chipped Stone	Ceramic	Ground Stone	Nonhuman Bone	Other	Total
0	59	189	3	0	0	251
1	152	318	2	0	1	473
280	436	1449	10	3	5	1903
Total	**647**	**1956**	**15**	**3**	**6**	**2627**

Figure 14.61. Feature 22.

Area 3

Area 3 is east of Area 2 (see Figure 14.2). It includes rock alignments and concentrations that are likely the remains of agricultural features. Due to time constraints, data recovery efforts were not conducted in this area.

Area 4

Area 4 is south of Area 1 (see Figure 14.2). It is the designation given to the southern surface collection area. Surface collection was conducted here before setting up tripod screens for screening fill from excavation. No surface features were identified, and no excavation was conducted. The artifacts collected from the surface are part of the Roomblock 1 midden and may include some material associated with the Archaic period artifact scatter (Area 8).

Area 6

Area 6 is west of Areas 1 and 2 (see Figure 14.2). This area includes various rock concentrations and alignments. The end of an isolated room or grid garden was identified at 116N/97E and a rock concentration resembling Features 17 and 18 was identified at 93.5N/95.0E. Between these two features additional rock alignments and concentrations were identified. These are probably the remains of structures and/or agricultural features. Data recovery efforts were not conducted in this area.

Area 7

Area 7 includes most of the midden associated with Roomblock 1 (see Figure 14.2). Investigations in Area 7 focused on areas with the highest artifact density. In-field inspection indicated that in areas east of 130E and south of 90N artifact densities declined significantly.

Stratigraphy. The midden strata are summarized in Table 14.77. Stratum 1 consists of soft, medium-grained, sandy loam. Stratum 60 incorporates the A, Bw, and Btk horizons. This stratum contains most of the midden deposits. The considerable variation in the depth of Stratum 60 is attributed to the undulating surface of the bedrock (Figure 14.62).

Table 14.77. Midden stratigraphy.

Stratum	Color	Texture	Thickness (cm)	Description
0	10YR 4/4	sandy loam	0	Surface
1	10YR 4/4	sandy loam	2–10	Unconsolidated surface soil
60	10YR 4/4	sandy loam	10–44	Midden fill
175[1]	7.5YR 4/6	sandy clay	1–15	Btk horizon

1. Stratum 175 was not differentiated from Stratum 60 during excavation.

Table 14.78 gives the artifact counts by stratum for the midden. These counts are complied from excavation units 116N/127E, 110N/122E, 110N/123E, 106N/129E, 106N/130E, 105N/122E, 101N/122E, 101N/123E, 101N/124E, and 95N/126E). The 'Other' category consists of a human adult right first pedal phalanx (FS 2523), a small fragment of turquoise (FS 2414), and eight pieces of fire-cracked rock (FS 3224, FS 3232, FS 3238, and FS 3242).

Table 14.78. Midden artifact counts by stratum.

Stratum	Chipped Stone	Ceramics	Ground Stone	Nonhuman Bone	Other	Total
0	14	49	0	0	0	63
1	101	469	0	1	1	572

Total	**713**	**3440**	**39**	**22**	**10**	**4224**

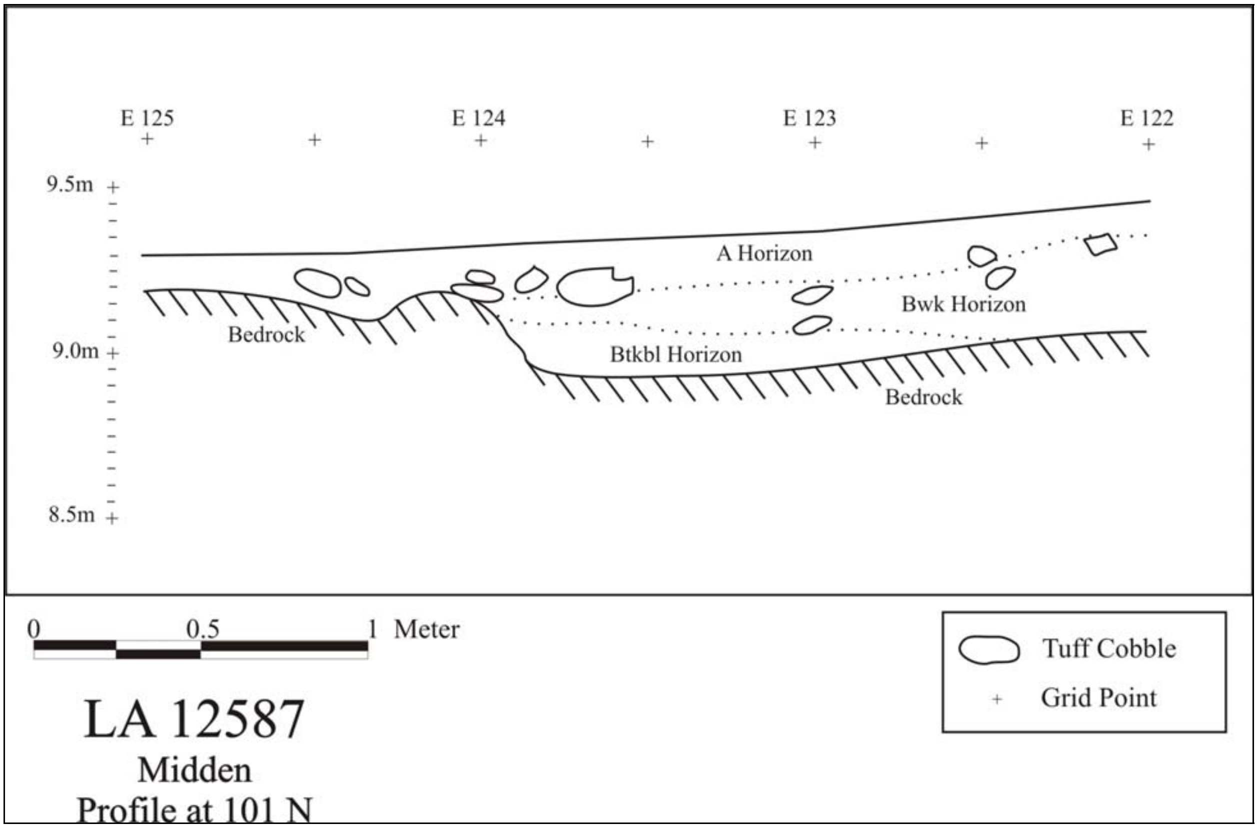

Figure 14.62. Midden profile at 101N/122 to 125E.

Artifacts and Samples. All the artifacts are from units 116N/127E, 110N/122E, 106N/129E, 106N/130E, 105N/122E, 101N/122E, 101N/123E, and 95N/126E. Artifacts from unit 92N/118E were also analyzed. All the faunal remains were analyzed. Other analyzed artifacts include a Cerro Toledo obsidian biface fragment (FS 3227), a Valle Grande obsidian biface fragment (FS 3234), and a tuff mortar (FS 3907). Table 14.79 lists the samples analyzed from the midden.

Table 14.79. Midden analyzed samples by excavation unit.

Grid Unit	Pollen FS	Flotation FS	Macrobotanical FS
95N/126E	3080 and 3083	3081	3079 and 3087
101N/123E	2923	2924	None
116N/127E	3050	3049	None

Taxa identified in the pollen samples from 95N/126E included maize, prickly pear, beeweed, cheno-ams, grass family, sunflower family, spurge family, unidentified pine, piñon pine, juniper, and sagebrush. Taxa identified in the flotation sample from this unit included pigweed, sagebrush, saltbush/greasewood, goosefoot, cheno-ams, unknown conifer, juniper, groundcherry, piñon pine, purslane, and maize. Taxa identified in the macrobotanical samples included juniper, mountain mahogany, unidentified pine, and piñon pine.

Taxa identified in the pollen sample from 101N/123E included maize, prickly pear, beeweed, cheno-ams, sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon pine, and rose family. Taxa identified in the flotation sample included saltbush/greasewood, unknown conifer, juniper, and maize.

Taxa identified in the pollen sample from 116N/127E included cheno-ams, grass family, sunflower family, spurge family, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush. Taxa identified in the flotation sample from this unit included goosefoot, juniper, piñon pine, and maize.

Human Burials. Three human burials were found during trenching activities in the midden. The excavation, provenience, and associated artifacts of the burials are discussed below (see Schillaci, Volume 3 for details). Since all three burials were found in the midden, many artifacts were recovered during their excavation. Only artifacts identified as funerary objects, sacred objects, and/or objects of cultural patrimony (Native American Graves Protection and Repatriation Act [NAGPRA] artifacts) by the Tribal Monitor are included in the burial descriptions.

Burial 1 (Feature 9)

Burial 1 was disturbed by backhoe operations. Skeletal remains of a 30+ year old Native American female were found in units 100N/124E, 99N/123E, 99N/124E, 99N/125E, 98N/124E, and 98N/125E. The skeleton was disarticulated and many elements were missing, including the head, pelvis, and lower limbs. Most of the remains were found between 8.95 and 8.88 m (38 to 45 cm below ground surface). Due to the disturbed nature of the burial, no skeletal orientation or internment data were gathered. Tables 14.80 to 14.82 summarize the artifacts associated with Burial 1.

Shell bead	1
Total	**16**

Burial 2 (Feature 14)

Burial 2 was located in unit 92N/118E. Initial identification of the burial occurred when bones were unearthed during the excavation of Trench 6. Most of the skeletal remains were disturbed by the backhoe although the skull, upper torso, and upper right arm remained in situ. These elements were semi-articulated and were the remains of a 45- to 59-year-old Native American female.

The in situ remains were found between 9.13 and 8.88 m (10 to 35 cm below ground surface). The individual was placed in a natural niche in the bedrock on her back (with her upper back and head slightly elevated), with her head oriented to the southwest and facing northeast. This burial may have been covered with a tuff slab. Tables 14.83 and 14.84 summarize the artifacts associated with Burial 2.

Table 14.83. Burial 2 NAGPRA ceramic artifacts.

Total	**1**	**2**	**2**	**2**	**7**

One pollen sample (FS 5123), one flotation sample (FS 5127), and two macrobotanical samples (FS 5129 and FS 5141) from this burial were analyzed. Taxa identified in the pollen sample included maize, cholla, prickly pear, beeweed, cheno-ams, grass family, sunflower family, spurge family, ragweed/bursage, unidentified pine, piñon pine, and sagebrush. Taxa identified in the flotation sample included saltbush/greasewood, goosefoot, cheno-ams, hedgehog cactus, unknown conifer, juniper, piñon pine, purslane, and maize. Taxa identified in the macrobotanical samples included saltbush/greasewood, Desert olive, sagebrush, maize, unknown conifer, piñon pine, and juniper.

Burial 3 (Feature 15)

Burial 3 was situated in units 94N/124E and 94N/125E. Initial identification of the burial occurred when two arm bones were unearthed during trenching activities. The burial was in poor condition and many elements were missing, including the vertebrae and lower limbs. The remaining elements were quite fragmented and articulation was poor. The skeleton was identified as a 20- to 30-year-old Native American female.

Most of the skeletal remains were found between 8.88 and 8.79 m (30 to 40 cm below ground surface). The lower end of this elevation range was only a few centimeters above bedrock. About one dozen unshaped tuff cobbles (8 by 8 cm to 28 by 18 cm) were found immediately above the remains and were probably deliberately placed to cover the burial. The individual was interred laying on her right side with her head oriented to the east and facing north. Her right arm was fully extended. Tables 14.85 and 14.86 list the artifacts associated with Burial 3.

Table 14.85. Burial 3 NAGPRA ceramic artifacts.

SITE CHRONOLOGY AND ASSEMBLAGE

Sampling Strategy

Approximately 88,500 artifacts and samples were recovered from LA 12587. Since all of these artifacts and samples could not be analyzed, an analysis sample was selected as described below. All the artifacts in at least two 1- by 1-m units from Rooms 1 through 18 were analyzed. In general, units that contained the most artifacts were selected. When rooms contained many macrobotanical samples, a 1- by 1-m unit was selected and all macrobotanical samples from the unit were analyzed (Table 14.87). When available, at least one pollen sample, flotation sample, and macrobotanical sample was analyzed from each stratum in each room. Several samples of each type (when available) from each interior feature were analyzed. Additionally, all artifacts found on a floor surface were analyzed.

Outside of the roomblocks, artifacts from Feature 22 in every other 1- by 1-m unit along the 103E line were analyzed. Some artifacts from these units were assigned to Rooms 19 and 20 based on stratigraphy. Artifacts from nine 1- by 1-m units in the midden were analyzed (Table 14.87). Fifteen pollen samples were analyzed from Feature 22 and several samples of various types were analyzed from the other exterior features and midden contexts.

Because of their relatively small numbers, all the human remains, NAGPRA artifacts, faunal remains, and shell artifacts recovered from the site were analyzed. Several noteworthy artifacts not falling into any of the 1- by 1-m units or the categories already mentioned were also analyzed. In all, approximately 14,150 artifacts and samples were analyzed.

Table 14.87. Systematic sample of ceramic and lithic artifacts and macrobotanical samples.

Provenience	Artifact Columns	Macrobotanical Column
Room1	106N/107E, 107N/107E	106N/107E

Chronology

Radiocarbon Dating

Seven radiocarbon samples (all *Zea mays*) were submitted for analysis (Table 14.88) and the returned results are all consistent with a Late Coalition period occupation. The relatively late radiocarbon date from maize (FS 4138) found in Feature 20 (archaeomagnetically dated to circa AD 1200) is not surprising given the amount of disturbance in and around the feature. FS 4138 is probably intrusive from the fill of Room 2.

Table 14.88. LA 12587 radiocarbon dating results.

FS	Context	Laboratory (Beta)#	Conventional radiocarbon age	Intercept of radiocarbon age	2-sigma calibrated result
2644	Room 2, Feature 4	183747	870±70 BP	AD 1180	AD 1020–1280

Archaeomagnetic Dating

Burned sediments were collected from the hearths in Rooms 2, 4/5, and 7 (Table 14.89). Feature 20 from Room 2 appears to be the earliest in the sequence, separated from Room 2, Feature 4 by a significant remodeling event that relocated the hearth. Feature 6 in Room 7 was significantly remodeled through its use-life through the addition of linings that reduced the interior capacity of the hearth. Only one (from the earliest hearth plaster) of the three lining samples taken produced a sufficiently precise result for date estimation. Feature 1 in Room 4/5 represents a single, apparently late, hearth in the sequence of site occupation. In sum, the final burning of Feature 20 probably occurred circa AD 1200; the final burning of the other features probably occurred in the late 13th or early 14th century AD (see Blinman and Cox, Volume 3).

Table 14.89. LA 12587 archaeomagnetic dating results.

Sample Number	Feature	VGP Curves and Date Estimates (AD)		
		Wolfman	SWCV2000	DuBois
1209a	Room 4/5, Feature 1 Lining and tuff block	Dates disregarded		
1209b	Room 4/5, Feature 1 Lining only	1015–1130 1160–1275 1335–1410	1005–1375	
1209c	Room 4/5, Feature 1 Tuff block only	Not culturally relevant		
1210	Room 2, Feature 4	925–1015 1245–1310 1315–1355	925–1015 1370–1510 1550–1700	1200– 1320 1265–

Sample Number	Feature	VGP Curves and Date Estimates (AD)		
		Wolfman	SWCV2000	DuBois
				1325
1211	Room 7, Feature 6 Upper west inner lining	Too imprecise for date range estimation		
1212	Room 7, Feature 6 Upper north inner lining	930–1025 1235–1305 1315–1360	925–1015 1260–1465	
1213	Room 7, Feature 6 Lower west inner lining	Too imprecise for date range estimation		
1214	Room 2, Feature 20 west wall	1185–1205	1145–1170	
1215	Room 2, Feature 20 Base lining	1175–1220	1125–1185	

Note: When date ranges are expressed in parentheses, the closest points on the curve segment was outside of the error ellipse when the result was originally plotted. VGP is virtual geomagnetic pole.

Thermoluminescence Dating

Two burned plaster samples and two sherds were submitted for thermoluminescence dating (Table 14.90). Except for FS 1274, all the dates were earlier than expected. The thermoluminescence results are discussed further in Volume 3 (see Feathers, Chapter 67).

Table 14.90. LA 12587 thermoluminescence dating results.

FS#	Lab #	Context	Burial depth (cm)	Years BP	Percent error	Years AD
1274	UW1030	Sherd from Room 2 floor	43	777±68	8.7	1226±68
2078	UW1031	Sherd from Room 7 floor	32	916±77	8.5	1087±78
4098	UW1032	Room 7, Feature 6	35	1022±89	8.7	981±89
4209	UW1033	Room 2, Feature 20	63	881±80	9.1	1122±80

Obsidian Hydration

Sixteen artifacts were submitted for obsidian hydration dating. Due to analytical problems, four of the artifacts (FS 2284, FS 3655, FS 3780-1, and FS 5094) could not be dated. Table 14.91 summarizes the results for the 12 dateable artifacts. Most of the obsidian hydration dates are much younger than expected. For additional discussion of the obsidian hydration dates see Stevenson (Volume 3).

Table 14.91. LA 12587 obsidian hydration dating results.

Summary of Dating Results

Figure 14.63 shows a summary of the dating results (only one obsidian hydration date, FS 3234, is included). The figure shows that radiocarbon and archaeomagnetic dates are generally in agreement and indicate the use of Roomblock 1 in the late 13th and/or early 14th century AD (ca. AD 1275-1325). The two archaeomagnetic dates from Feature 20 indicate use of the site as early as circa AD 1200. The radiocarbon dates from Feature 4 and Feature 6 appear to correspond well to the AD 1200 date. However, the context from which these samples were derived suggests that they are associated with the final occupation of Roomblock 1. Similarly, the thermoluminescence dates are derived from contexts most likely associated with the final occupation of Roomblock 1 (save for the thermoluminescence date from Feature 20).

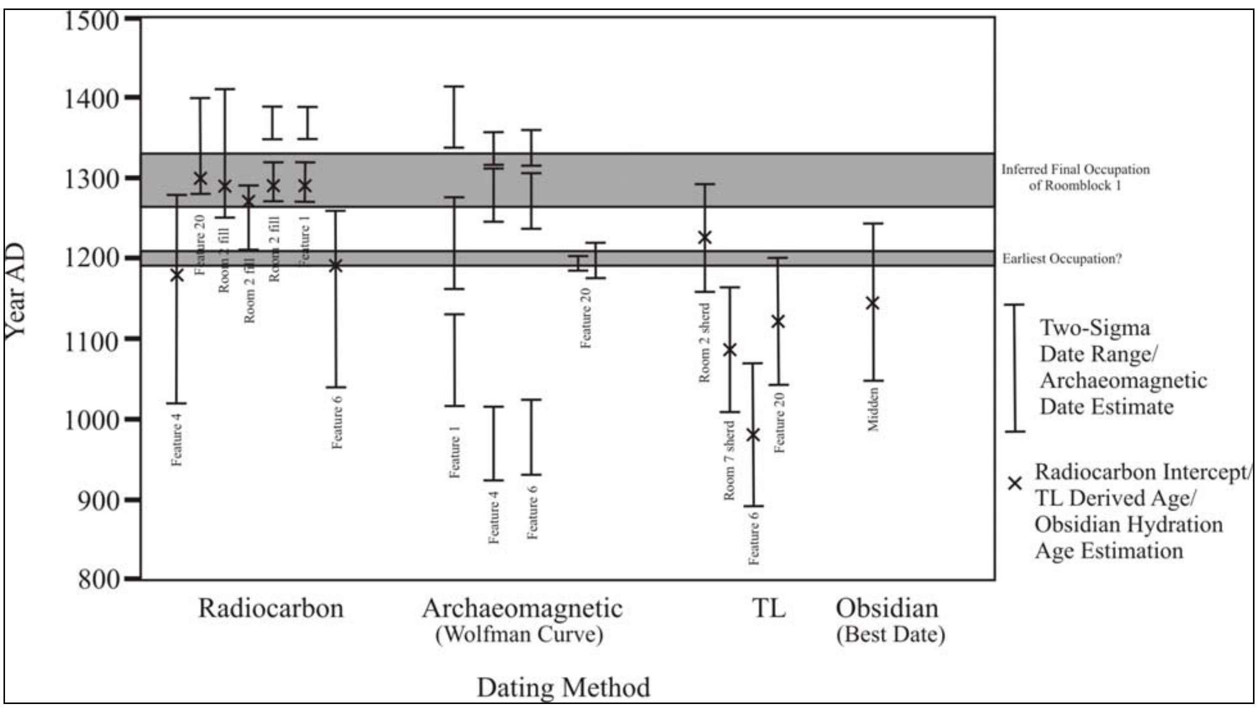

Figure 14.63. Summary of dating results.

The ceramic data (see Wilson, Volume 3) indicate that most of the Coalition period occupation at LA 12587 occurred during the early and middle 13th century and probably continued into the late 13th or early 14th century. Some samples of dated materials exhibit date ranges in the early to middle 13th century. Dated material indicates that there definitely was occupation in the late 13th or early 14th century. See Harmon and Vierra (Volume 3) for an evaluation of the different dating techniques

Ceramic Artifacts (Dean Wilson)

A total of 10,363 sherds were examined from the Late Coalition period contexts at LA 12587 (Tables 14.92 and 14.93). Ceramics from the Late Archaic component (Area 8) were also analyzed and are discussed in Chapter 15 of this volume. The LA 12587 assemblage indicates an occupation dating primarily to the Coalition period (Table 14.92). The majority (just more than 80%) of pottery is represented by gray utilityware types (Table 14.93). The majority of whiteware pottery was derived from Santa Fe Black-on-white vessels, and the majority of utilitywares are represented by corrugated and smeared-indented corrugated types tempered with anthill sand. Kwahe'e Black-on-white, Wiyo Black-on-white, and White Mountain Redwares are present in extremely low frequencies. A small number of sherds from LA 12587 reflect a probable Classic period contamination. Identified types are biscuitwares and Sankawi Black-on-cream. Low frequencies of glazewares include Glaze-on-red, Glaze-on-yellow, and Agua Fria Red-on-glaze. Santa Fe Black-on-white is the dominant decorated type at the site with just over 12 percent. The majority of pottery is represented by gray utilitywares (Table 14.93) exhibiting a combination of plain, corrugated, and smeared-indented corrugated textures (Table 14.93).

Total	**10,363**	**100.0**

Stylistic analysis of a sample of Santa Fe black-on-white rim sherds indicated a similar range of decorations and manipulations from LA 12587 (Tables 14.94 through 14.98). The majority of rim sherds are unpainted and tapered, and most of the bowl sherds were decorated only on the interior side. The majority of the rim sherds exhibit a single framing line close to the top of the rim.

Table 14.94. Distribution of Santa Fe Black-on-white rim orientation.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 2,493 artifacts were analyzed from LA 12587. The assemblage consists of 20 cores, 2,296 pieces of debitage, 61 retouched tools, 110 ground stone artifacts, one hammerstone, and five pieces of fire-cracked rock, which represents a 16 percent sample of the 15,430 total lithic artifacts recovered during the site excavations. Table 14.99 presents the data on lithic artifact type by material type. The majority of the cores, debitage, and retouched tools are made of chalcedony, with lesser amounts of obsidian, Pedernal chert, and basalt. The presence of cortex on 12.1 percent of the debitage indicates that these materials were collected from waterworn

(87.0%) and nodular (12.9%) sources. The chalcedony and Pedernal chert are available from local Rio Grande Valley gravel sources, the basalt from gravels and bedrock outcrops, and the obsidian from primary sources in the Jemez Mountains. The ground stone artifacts are primarily made from igneous materials, which are available both as bedrock outcrops and in stream gravels that cross-cut the Pajarito Plateau. Quartzite is, however, only available from the nearby Rio Grande Valley gravels. The source of the sandstone is difficult to determine, but it could be derived from gravel formations near Totavi or from more distant sources in the Santa Fe or Abiquiu areas.

Fourteen pieces of debitage and 18 retouched tools were submitted for X-ray fluorescence analysis. Most of these projectile points were not included in the sample analysis from the site. Nonetheless, the majority of the artifacts were from the Cerro Toledo source, with less from the Valle Grande and El Rechuelos sources (Table 14.100). The Cerro Toledo (Rabbit Mountain/Obsidian Ridge) and Valle Grande (Cerro del Medio) source areas are located about 17 km (11 miles) and 22 km (14 miles) as the “crow flies” to the southwest and west of the site, whereas, the El Rechuelos (Polvadera Peak) source area is situated about 30 km (19 miles) to the northwest. Most of the debitage is made of Cerro Toledo obsidian, while the retouched tools were manufactured on a variety of materials. All but one of the El Rechuelos artifacts are retouched tools.

Lithic Reduction

The cores consist of five single-directional, eight bi-directional, five multi-directional, and one flake core. The single-directional cores are single (n = 3) and multi-faces (n = 2), while the bidirectional cores are change-of-orientation (n = 2), bifacial (n = 1), opposed-different-face (n = 4) and ninety-degrees (n = 1). Lastly, the multi-directional cores are all globular-shaped and the flake core is a change-of-orientation. None of the cores exhibit any obvious evidence of platform preparation. Most of the cores were discarded due to material flaw fractures (n = 7) and exhaustion (*n* = 7), with fewer due to a culturally induced fracture (*n* = 2) or extensive hinging/stepping (*n* = 1). Otherwise, only three cores were classified as still useable. One of the single-directional cores was burned. Table 14.101 presents the metric information on the whole cores. A single tested chalcedony cobble was identified. It weighs 172.1 g and exhibits numerous fracture planes and flaws.

Table 14.101. Core type dimensions (mm) and weight (gm).

Core Type	Length	Width	Thickness	Weight
Single-directional	27	30	18	16.1
Single-directional	57	73	45	207.7
Single-directional	31	46	41	64.4
Single-directional	46	25	18	26.5
Bi-directional	47	45	18	40.9
Bi-directional	49	37	25	50.1
Bi-directional	41	27	18	27.6
Bi-directional	39	34	24	38.0
Bi-directional	52	38	27	56.6
Bi-directional	41	36	28	46.8
Bi-directional	27	17	14	6.0
Bi-directional	31	28	23	14.2
Multi-directional	31	30	22	17.7
Multi-directional	33	24	21	18.9
Multi-directional	49	37	32	57.7
Multi-directional	34	25	22	26.3
Multi-directional	31	26	24	21.5
Flake	38.0	27.0	14.0	16.2

The debitage assemblage consists mainly of core flakes (53.3%) with lesser amounts of microdebitage (24.8%), angular debris (12.8%), and biface flakes (5.4%). Table 14.102 summarizes the various stages of reduction represented by the whole core and biface (tertiary) flakes. The debitage assemblage is composed primarily of secondary non-cortical, with lesser amounts of secondary cortical, tertiary, and primary flakes. The overall cortical:non-cortical ratio of 0.42 reflects this emphasis on the later stages of core reduction.

Table 14.102. Debitage reduction stages.

Material	Primary	Secondary Cortical	Secondary Non-cortical	Tertiary	Cortical: Non-cortical ratio
Basalt	0	4	9	0	0.44
Obsidian	0	4	10	5	0.26
Chalcedony	3	55	126	7	0.43
Pedernal Chert	0	5	11	0	0.45
Silicified Wood	0	0	6	0	---
Quartzite	1	2	0	0	---

Material	Primary	Secondary Cortical	Secondary Non-cortical	Tertiary	Cortical: Non-cortical ratio
Total	4	70	162	12	0.42
Percentage	1.6	28.2	65.3	4.8	

The majority of the flakes exhibit single-faceted platforms (51.7%; *n* = 269), with lesser amounts of cortical (*n* = 92), crushed (*n* = 75), collapsed (*n* = 63), multifaceted (*n* = 11), and dihedral (*n* = 10) platforms. Sixty-seven (12.8%) of the flake platforms exhibit evidence of preparation; most of these were abraded/crushed (*n* = 56), with fewer retouched (*n* = 8), and abraded/ground (*n* = 3) platforms. The paucity of retouched platforms is in part due to the large number of crushed and collapsed platforms on obsidian biface flakes. The majority of the core flakes consist of distal fragments (*n* = 563; 45.9%), with fewer whole (*n* = 262), proximal (*n* = 200), midsection (*n* = 174), lateral (*n* = 12), and undetermined fragments (*n* = 13). Most of the biface flakes are also distal fragments (*n* = 48; 38.4%), with fewer whole (*n* = 12), proximal (*n* = 37), and midsection fragments (*n* = 28). The whole core flakes have a mean length of 21.0 mm (*std* = 9.3), whereas the whole biface flakes exhibit a mean length of 18.5 mm (*std* = 7.8). Lastly, angular debris have a mean weight of 2.4 g (*std* = 4.8).

The retouched tools consist of a mix of expedient flakes tools such as retouched pieces, perforators, a notch, a graver, and perforator/notches. The formal tools consist of bifaces, projectile points, and drills. The retouched pieces exhibit marginal retouch along a single edge (*n* = 16), with lesser amounts of retouch along two edges (*n* = 9). Table 14.103 presents the information on retouch type by edge outline.

Table 14.103. Retouched pieces.

Retouch Type	Edge Outline						
	Straight	Concave	Convex	Straight/ concave	Straight/ convex	Concave/ convex	Projection
Unidentified ventral	4	1	0	0	0	0	0
Unidentified dorsal	7	3	3	1	2	0	3
Bidirectional	4	0	0	0	0	0	1
Alternating	0	0	0	1	0	0	0
Alternate	0	0	0	0	0	0	1
Total	**15**	**4**	**3**	**2**	**2**	**0**	**5**

Most of the edges are characterized by a straight outline with retouch along the dorsal surface. The edge angles range from 40 to 75 degrees with a mean of 59.5 degrees (*std* = 10.2); indeed, as Figure 14.64 illustrates, there is a modal distribution with a peak at 55 degrees. This presumably reflects an emphasis on cutting activities at the site. The perforators exhibit unidirectional dorsal and alternate retouch that was used to accentuate the pointed end of a flake with edge angles of about 75 degrees. The notch is a core flake with a single notch retouched onto the ventral surface of the flake along its distal and lateral edges. The graver is a core flake with a unidirectional dorsal retouched projection with a blunt end. The drills consist of four distal and two midsection fragments that exhibit bidirectional retouch with edge angles ranging from 40 to 70 degrees. The unifaces are roughly worked flakes with unidirectional dorsal retouch and edge angles ranging from 60 to 70 degrees. In contrast, a single formal endscraper fragment was also identified, consisting of a distal fragment with an edge angle of 70 degrees. Figure 14.65 illustrates some of the retouched tools.

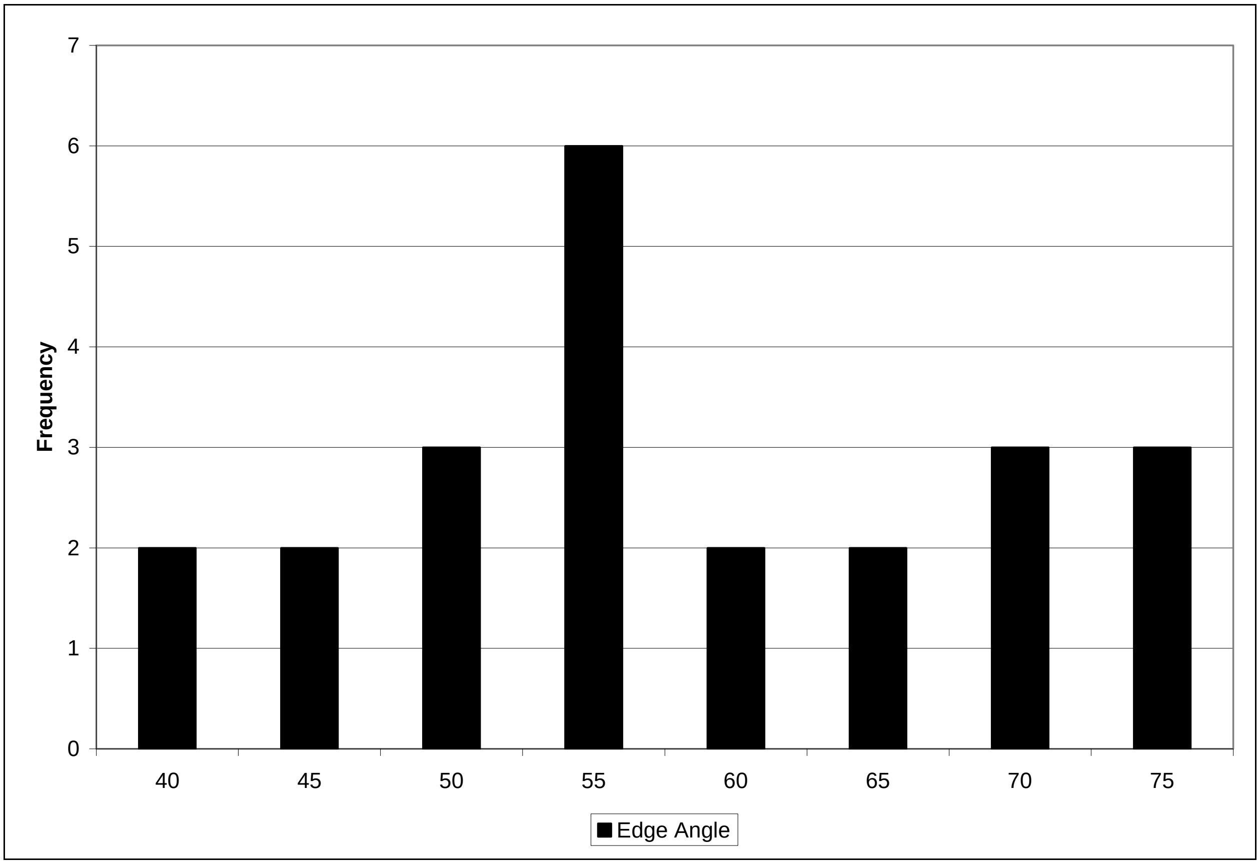

Figure 14.64. Edge angle distribution for retouched pieces.

Only two stages of biface production were identified during the analysis. No early-stage bifaces are present. The middle-stage bifaces (*n* = 4) are 8 to 12 mm thick and exhibit edge angles ranging from 50 to 60 degrees, while the late-stage bifaces (*n* = 7) are 2 to 4 mm thick and exhibit edge angles ranging from 25 to 35 degrees (preforms). One of the middle-stage bifaces was manufactured on a flake blank and the platform was present at the proximal end. It is made of chert and appears to have been heat-treated. Most of the bifaces are ovoid-shaped, with a single lanceolate-shaped late-stage biface (Figure 14.66).

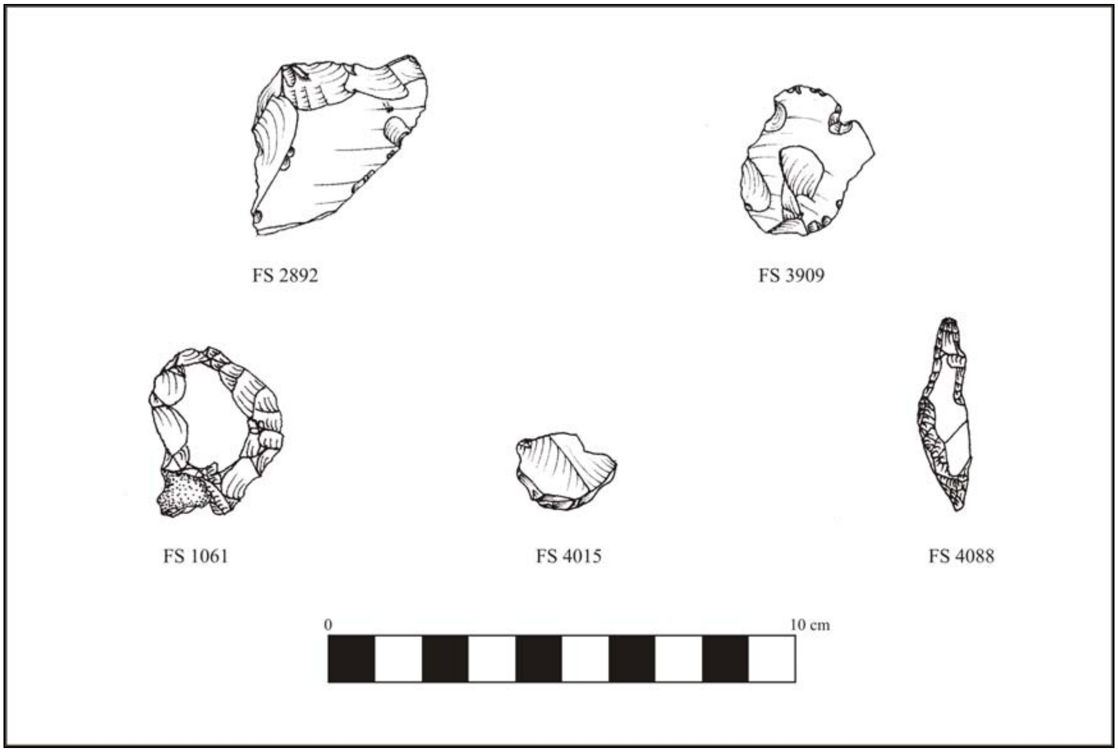

Figure 14.65. Retouched flake, notch, uniface, endscraper, and drill.

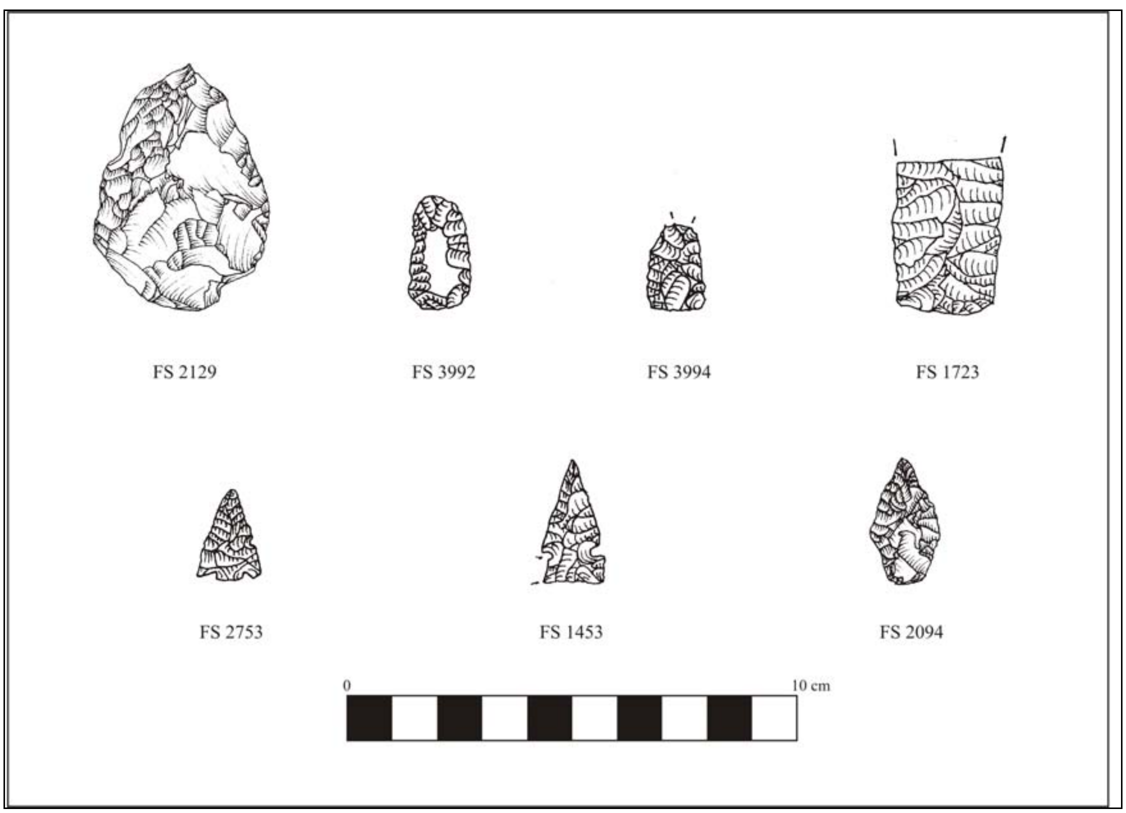

Figure 14.66. Bifaces and projectile points.

Metrical and descriptive information on the projectile points is presented in Table 14.104. The five projectile points exhibit some variation, with two corner-notched, a side-notched, a contracting stem, and an undetermined fragment (see Figure 14.66). Three of these represent arrow points with neck widths ranging from 5 to 8 mm, and one a lance/dart point with a neck width of 13 mm. Only two of the points are whole, with the other three being midsection or distal fragments.

Table 14.104. Projectile point metrical (mm) and descriptive data.

FS #	Material	Condition	Overall Length	Blade Length	Neck Width	Stem Length	Stem Width	Thickness	Weight (gm)	Haft Type	Blade Shape	Base Shape
1146	Obsidian	Mid-section	--	--	8	--	--	1	0.2	Corner-notched	Straight	Und.
1453	Chert	Whole	26	19	8	7	--	4	1.1	Side-notched	Straight	Und.

2753	Chalce-dony	Distal	--	18	5	--	--	5	0.8	Corner-notched	Straight	Und.
3971	Obsidian	Mid-section	--	--	--	--	--	3	1.2	Und.	Und.	Und.

Tool Use

Only 15 flakes (0.1%) exhibit evidence of damage that could be attributed to use-wear. The edge damage is evenly distributed between the lateral edge of the flake (*n* = 8) and the end of the flake (*n* = 7). Most of the edge outlines are straight (*n* = 13), with a single concave-shaped outline for both the lateral and end of two flakes. Edge angles range from 35 to 70 degrees, with a mean of 53 degrees (*std* = 10.8). This is similar to the pattern exhibited by the retouched flakes.

In contrast to the debitage, 32 of the retouched tools (52.4%) exhibit evidence of use-wear. This consists of 16 retouched pieces, a notch, a biface, a projectile point, three unifaces, four drills, three perforators, the graver, and one perforator/notch. The biface is a middle stage biface that exhibits polishing and rounding along a lateral edge. The projectile point is a midsection fragment with impact fracture.

One hundred and ten ground stone artifacts were identified during the analysis. Identified artifacts included manos, metates, polishing stones, abrading stones, and other ground stone items (Figure 14.67). The manos are nearly evenly distributed between one- and two-hand varieties. Most of the one-hand manos exhibit one (*n* = 9) or two (*n* = 4) grinding surfaces. In contrast, most of the two-hand manos have two (*n* = 10) grinding surfaces. Only two of the two-hand manos have two grinding surfaces. This divergent pattern is also reflected in mano cross-section. The one-hand manos exhibit mostly plano/flat cross-sections (*n* = 7) as compared to wedge-shaped cross-sections for the two-hand manos (*n* = 7). Undetermined mano fragments appear to reflect both one- and two-hand varieties with one and two grinding surfaces, but mostly have plano/flat cross-sections.

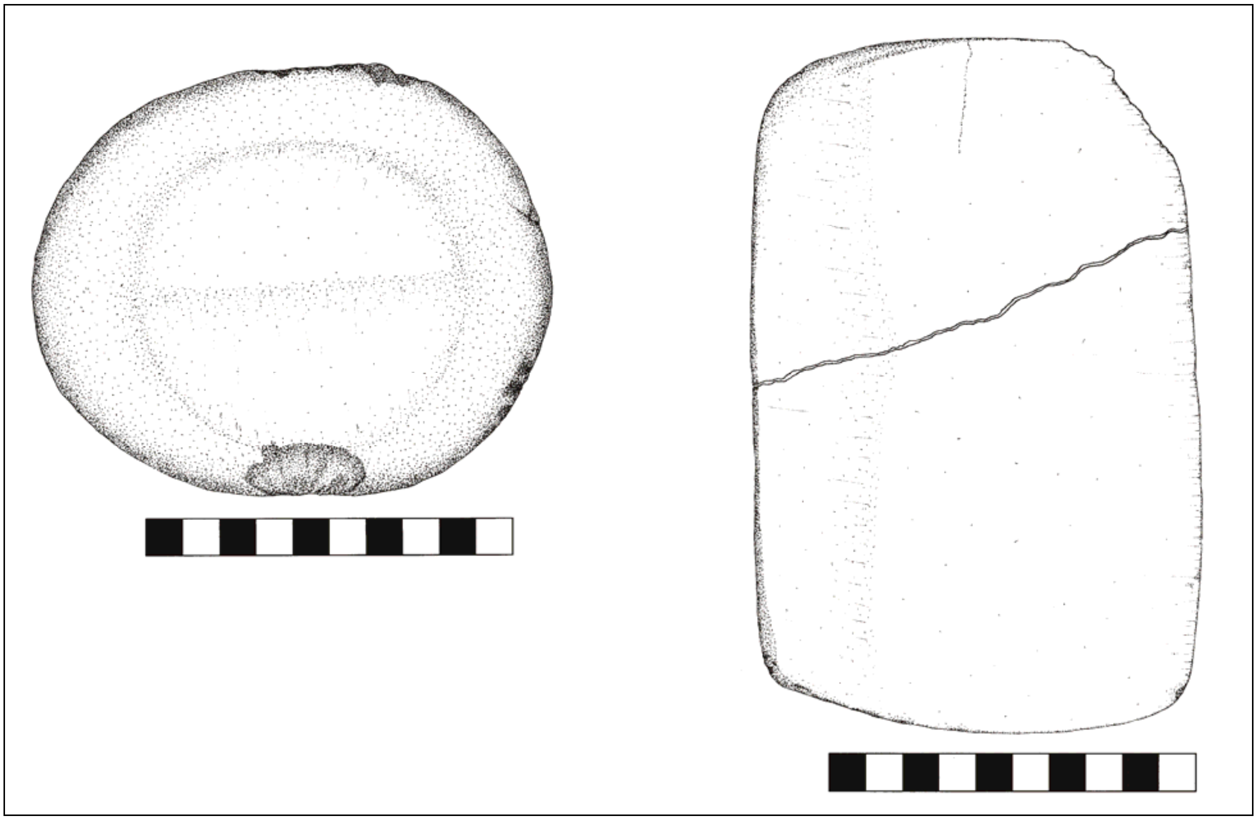

Figure 14.67. One- and two-hand manos.

A single generalized millingstone and four formal slab metates were identified. The formal slab metates are all broken fragments, with shaped perimeters and large, mostly flat, well-worn grinding surfaces. The formal slab metates are made of a variety of materials, including tuff, dacite, andesite, and vesicular basalt. About half of the two-hand manos are also made of vesicular basalt, reflecting the importance of milling maize at the site. The polishing stone is a chalcedony pebble with a finely ground surface, whereas the abrading stones are dacite and andesite pebbles with irregularly ground surfaces.

The axe is a quartzite cobble with flaked and heavily crushed edges. The artifact broke in half along the hafting area. The maul is a vesicular basalt cobble that is heavily battered on both ends and has a ground full-groove. The hoes were made on a thin piece of tabular basalt and a thick piece of tabular andesite; both had several flakes removed from their bit that also exhibited rounding. The andesite hoe also exhibits hafting notches and some polish along the middle portion of the artifact. The ornament is a shale bead that may have been part of a tube that was broken into individual beads.

Faunal Remains (Kari Schmidt)

In general, the overall preservation of the bones from LA 12587 is good. For the most part, bones tended to be in large fragments, and a number of complete elements were identified. Weathering on the faunal remains was present, although the frequency and severity was generally low (n = 18), suggesting the remains may not have been exposed to the elements for a long period of time before burial. The bones show minimal evidence of root-etching, and no evidence of rodent gnawing, carnivore gnawing, or carnivore digestion. Modifications resulting from burning were present on 183 pieces of bone, constituting some 28 percent of the total assemblage. Pathologies were identified on two specimens: a pocket gopher femur and pubis. Thirty-two specimens recovered from LA 12587 were worked.

Of the 649 faunal remains recovered from the excavations at LA 12587, 33 percent (n = 217) were identified to at least the level of class. The 217 identified remains were recovered from a variety of contexts. Table 14.105 shows all the identified taxa that were recovered from the site. Because the most abundant taxa represented in the assemblage were intrusive pocket gopher remains (*Thomomys* sp.), Table 14.106 presents the same data with this taxon removed. Pocket gopher burrows were extensive in the immediate site area, and the visual appearance of their bones was quite distinct from the majority of the other bones recovered from the site.

Table 14.105. Identified faunal remains from all contexts at LA 12587.

Table 14.106 shows that the majority of the identified fauna (25%) at LA 12587 is turkey (*Meleagris gallopavo*), followed by cottontail (*Sylvilagus* sp.), mule deer (*Odocoileus hemionus*), indeterminate large bird, jackrabbit (*Lepus californicus*), and indeterminate medium/large mammal remains. The remainder of the assemblage consists of a wide variety of taxa, including fish, amphibians, small and large birds, rodents, and carnivores. The variation present in the assemblage attests to its location near a number of distinct biomes.

Archaeobotanical Remains (Pamela J. McBride)

Flotation Remains

The Coalition period at LA 12587 is characterized by the predominance of maize, with a few instances of possible squash and beans to round out the traditional triad of domesticated plants (Table 14.107). Annual seeds were the next most common plant remains, easily procured in cultivated fields and other disturbed areas. Annual taxa included bugseed, goosefoot (the most common annual taxon, which was found in 24% of samples), pigweed, and purslane. Pitseed goosefoot, sunflower, and tobacco were less common annual taxa, found in less than 5 percent of samples. Perennial taxa were primarily those associated with firewood use like conifer needles, bark, and twigs, but cactus seeds and piñon nutshell indicate cactus fruits and piñon nuts were gathered and eaten. Four-wing saltbush fruits could be firewood debris or evidence for their use as food or for their salty flavor. Grass taxa diversity and abundance is low with grass family and dropseed grass occurring in less than 4 percent of samples and ricegrass occurring in 12 percent of samples.

Table 14.107. Ubiquity of flotation sample carbonized plant remains from LA 12587.

*Number of samples with common name/plant part present; **Number of samples with common name/plant part divided by total number of flotation samples with charred remains (112) × 100.

Wood from flotation and vegetal samples was dominated by juniper and unknown conifer (Table 14.108). Other conifers included Douglas fir, piñon, and ponderosa pine. Although non-conifers were diverse, saltbush/greasewood was the only one that was present in significant quantities. New Mexico locust, cottonwood/willow, desert olive, mountain mahogany, oak, rabbitbrush, rose family, sagebrush, and sumac complete the list of non-conifer taxa identified at the site. There were no remarkable differences in wood taxa from back rooms versus front rooms and wood from both thermal and non-thermal contexts was primarily juniper and unknown conifer.

Table 14.108. Ubiquity of flotation sample wood charcoal taxa from LA 12587.

Common Name	Count*	%**

Unknown non-conifer	18	16

*Number of samples with wood taxon present; **Number of samples with wood taxon present divided by total number of flotation samples with wood charcoal (112) × 100.

Roomblock 1

The majority of samples were collected from Roomblock 1 (Rooms 1 to 9; only 15% were from Roomblock 3) and focused on the hearths in the front Rooms 2, 4/5, and 7. Based on the macrobotanical remains recovered, it appears as though Rooms 4/5 and 7 may have been primarily used for food preparation, while Room 2 served as a location for both food preparation and storage. Fused masses of kernels that were found in Room 2 indicate that stacks of cobs were stored on the floor or on top of the roof. Most of the cobs holding the kernels were burned to ash, leaving kernels still fused in alignment. Several thousand loose kernels were also recovered in Room 2, primarily from post-occupational fill and rooffall (1,563 kernel fragments, 2,771 whole), but from floor, fill above the floor, and hearth contexts as well.

There were two hearths in Room 2; Feature 4 was a plastered, collared hearth associated with the Late Coalition occupation of the site, and Feature 20 was the oldest feature at the site and dating to the Early Coalition (AD 1200). Maize is the most common taxon in both hearths; weedy annual seeds and dropseed grass were recovered from both features. Possible squash/coyote gourd rind was identified in the older hearth, while groundcherry, mint family, and hedgehog seeds were restricted to Feature 4. This indicates that the diets of earlier and later site occupants were probably not considerably different, especially when sample bias is taken into account (4 samples were analyzed from Feature 20 versus 10 from Feature 4). The possible extramural storage cist constructed on the east wall of Room 2 contained annual seeds, maize, and piñon needles along with at least five wood taxa, indicating a trashy fill signature, and thus obfuscating any clues about the contents of the cist.

The recovery of three of four tobacco seeds from the site in the lower and general hearth fill of Room 7, as well as the presence of a deflector and ash box that do not occur in other rooms, indicates the room might have had a ceremonial function. A bean cotyledon and three cotyledon fragments were also recovered from the Room 7 hearth.

Diversity of taxa from back Rooms 1, 6, and 8 is very low, and evidence of their use as storage rooms is not apparent in the macrobotanical assemblage. Taxonomic diversity was also low in Room 9, the largest of the back rooms. The back rooms could have been cleaned out before abandonment or the macrobotanical assemblage may be biased by sample size differences, as 15 flotation samples were analyzed from back rooms compared to 76 from front rooms. The heavy focus on front room sampling is a function of the paucity of features in backrooms, extensive rodent disturbance, and a lack of the concentrated deposits of plant material (i.e., piles of maize) found in the front rooms.

Room 3

The probable fieldhouse (Room 3) flotation and vegetal samples were taken from post-occupational fill and wallfall. Macrobotanical remains consisted of maize embryo and kernel fragments, as well as cupules, and piñon needles. Cottonwood/willow, juniper, mountain mahogany, oak, piñon, ponderosa, sagebrush, saltbush/greasewood, unknown conifer, unknown non-conifer, and wolfberry wood were also identified. Piñon needles may be part of firewood debris and maize parts probably represent a combination of cooking accidents and the use of cobs for fuel.

Roomblock 3

Roomblock 3 was only partially excavated and in most cases only a basal course of masonry existed to define room outlines. A lack of wallfall in many of the 13 rooms indicates that construction of rooms may never have been completed. Carbonized plant material consisted of cheno-am, goosefoot, groundcherry, and grass seeds, grass stems, maize cupules and kernels, conifer cone scales, twigs, and needles, four coniferous woods, and nine non-conifers. Uncharred plant material was abundant and included Russian olive seeds, an obvious intrusive species. Occupants of this roomblock utilized disturbance-loving plants and grasses, grew maize, and collected local wood species for fuel and construction material.

Extramural Features

Flotation samples from a midden to the east of Roomblock 1 contained annual seeds, maize cupules, cupule segments, and kernels, groundcherry seeds, piñon nutshell and needles, along with juniper, piñon, sagebrush, saltbush/greasewood, and unknown conifer wood. The fill around Burial 2 that was found in the midden contained similar plant material, indicating that although the individual was placed in a natural niche in the bedrock and may have been covered with a tuff slab, plant material from the sample derives from midden deposits.

Maize and juniper, piñon, and saltbush/greasewood wood were recovered from an ashy area east and southeast of Roomblock 1 (Feature 3). This feature may be a deflated hearth, representing an extramural area where maize may have been prepared. Another ash/charcoal stain (Feature 21) in an extension of the middle wall of Roomblock 1 with an associated floor surface produced maize, possible squash, and purslane seeds along with juniper, pine, and oak wood and could represent cooking accidents from additional extramural activities.

Vegetal Samples

Ubiquity of wood from the vegetal samples is close to that of flotation charcoal with the exception of ponderosa and cottonwood/willow (Table 14.109). In the flotation samples, ubiquity of cottonwood/willow was 18 percent and ponderosa pine was 23 percent. In the vegetal samples, the percent presence of cottonwood/willow (43%) and ponderosa pine (46%) is double that found in the flotation samples. This appears to be an example of a bias toward larger diameter specimens when collecting vegetal samples in the field. Box elder, New Mexico locust, and wolfberry wood were identified in the vegetal samples but not in the flotation samples. Two beam fragments from Room 2 were identified as juniper.

Table 14.109. Ubiquity of vegetal sample wood charcoal from LA 12587.

Common Name/Plant Part	Count*	%**
Box elder wood	2	2
Cottonwood/willow wood	42	43
Desert olive wood	15	15
Douglas fir wood	9	9
Juniper wood	78	80
Mountain mahogany wood	11	11
New Mexico locust wood	2	2
Oak wood	25	26
Pine wood	47	48
Piñon wood	52	53
Ponderosa pine wood	45	46
Rabbitbrush wood	1	1
Rose family wood	3	3
Sagebrush wood	28	29
Saltbush/greasewood wood	40	41
Unknown conifer wood	60	61
Unknown non-conifer wood	23	23
Wolfberry wood	5	5

*Number of samples with common name/wood present; **Number of samples with common name/wood divided by total number of vegetal samples with wood charcoal (98) × 100.

Six percent (330) of the incredibly large number of whole kernels (n = 5264) recovered in flotation and vegetal samples was measured (Appendix V). The average height of the sub-sampled kernels was 7.3 mm, the average width was 6.6 mm, and the average thickness was 4.0 mm. Four kernels from LA 4624, an Early Coalition period pueblo also on Mesita del Buey (McBride and Smith 2002) and 122 kernels from LA 135290, a Middle Coalition roomblock on the Los Alamos Town Site Mesa (Chapter 25, this volume), will be compared with those from LA 12587 later in the discussion section.

The average row number of 20 maize cobs from LA 12587 was 10 and rows were straight in appearance (Table 14.110). The average rachis segment length was 3.4 mm, the average cob diameter was 10.3 mm, and the average cupule width was 5.2 mm. Environmental stress such as high temperatures and water or nutrient deficiencies during various early developmental stages of a maize plant can lead to ears that are partially or completely barren (Muenchrath and Salvador 1995:316). Only one cob with an undeveloped row may have been a product of this kind of environmental stress. Five cobs from LA 86534 (Chapter 24, this volume), two from LA 4624 (McBride and Smith 2002), and 17 from LA 135290 (Chapter 25, this volume) will also be compared to cobs from LA 12587 in the discussion section later.

Table 14.110. *Zea mays* cob morphometrics (in mm) from LA 12587.

*2 rows of cob have kernels; T = tip, U = undeveloped row present.

Other charred non-wood plant parts were limited to pine bark scales and cone umbos. These are probably part of the record as a result of firewood use. An uncharred grape seed was recovered in FS 1029 from Room 1 (Stratum 1) that is described as a loose surface deposit with some artifacts and vegetal material. The context and the uncharred state of the seed suggest it is non-cultural or modern in origin.

Pollen Remains (Susan J. Smith)

A total of 122 pollen samples were analyzed from LA 12587. Table 14.111 lists the frequency of identified pollen types. Cultigens identified in the assemblage included cotton and squash in low numbers, with higher amounts of maize, maize aggregate pollen, and cholla. Economic resources identified in the pollen assemblage included prickly pear and prickly pear aggregates, cactus family and cactus family aggregates, beeweed, sunflower type, lily family (which includes yucca, wild onion, and sego lily), nightshade family, parsley family, cattail, sedge, mint family, and purslane. A number of other potential economic resources were identified in the assemblage (Table 14.111), and these are described in detail in Smith's chapter in Volume 3 (Chapter 63).

SITE OCCUPATIONAL HISTORY

The earliest component at LA 12587 is an Archaic lithic scatter (Chapter 15, this volume). The first evidence for post-Archaic period use of the site comes from two early archaeomagnetic dates from one of the Room 2 hearths (Feature 20) and the presence of a small amount of early 13th century ceramics. These indicate that there was a Puebloan occupation of LA 12587 at circa

AD 1200. However, no other features or architectural elements can be linked with this occupation. Given the buried context of Feature 20 and the lack of early dates associated with other Roomblock 1 features, it is possible that the present pueblo was built over (or incorporated into) an earlier structure, perhaps one that had been uninhabited for some time. Based on his analysis of the ceramic artifacts, Wilson (Volume 3) argues that most of the Coalition period occupation at LA 12587 occurred during the early and middle 13^{th} century. Some samples of dated materials exhibit date ranges in the early to middle 13^{th} century. A cluster of radiocarbon and archaeomagnetic dates indicates that the final occupation of Roomblock 1 occurred in the late 13^{th} or early 14^{th} century. Unfortunately, it is unclear if Roomblock 1 was continually inhabited from circa AD 1200 to the late 13^{th}/early 14^{th} century of if there were multiple episodes of habitation.

After Roomblock 1 was abandoned, construction of Roomblock 3 began. This roomblock was never finished and was probably never inhabited. No firm dates can be assigned to Roomblock 3, but based on its stratigraphic relationship to other components, it dates to the Late Coalition or Early Classic period.

The last component at LA 12587 consists of an isolated room (Room 3) and several rock features (Features 17, 18, and 22). Room 3 was built on top of Roomblock 1 wallfall and so post-dates the pueblo. The temporal relationship between Room 3 and Roomblock 3 is less clear. One line of tenuous evidence indicating a younger age for Room 3 is that, before excavation, some wall tops of Room 3 were visible on the surface whereas most of Roomblock 3 was buried. While unlikely, it is *possible* that Room 3 pre-dates, or is contemporaneous with, Roomblock 3. Features 17, 18, and 22 overlay parts of Roomblock 3. All three features are situated in the A horizon indicating that they are at least roughly contemporaneous. It is possible that some or all of the rock features in Areas 3 and 6 are also part of this final component. While it cannot be demonstrated that Room 3 and Features 17, 18, and 22 are all contemporaneous, all four of these elements do appear to represent an agricultural use of the site. The presence of several biscuitware and glazeware sherds may indicate an Early to Middle Classic period date for these features.

SUMMARY OF SITE EXCAVATIONS

LA 12587 is a multi-component Puebloan and Archaic site. The earliest occupation is represented by a lithic artifact scatter dating to the Late Archaic period (Chapter 15, this volume). The components discussed in this chapter consist of a seven-room pueblo and associated midden dating to the Late Coalition period (an early hearth in this roomblock indicates there may also have been an Early and/or Middle Coalition period occupation), a partially completed 13-room pueblo dating to the Late Coalition or Early Classic period, and multiple agricultural features including a grid garden and a one-room structure that probably date to the Early or Middle Classic period.

LA 12587 does resemble other excavated Coalition period sites on the Pajarito Plateau, containing front habitation rooms with hearths and smaller rear storage rooms. A range of botanical remains were identified from flotation samples recovered from the hearths, including maize, beans, cheno-ams, dropseed grass, and tobacco. In addition, squash rind, piñon nuts, groundcherry and sunflower were also represented at the site. The faunal remains also include a variety of species like jackrabbit, cottontail, rock squirrel, mule deer, turkey, and red-tailed hawk.

The ceramic assemblage primarily consists of Santa Fe Black-on-white and smeared-indented corrugated ceramics. The dominance of these ceramics types, coupled with the paucity of Kwahe'e and the presence of Wiyo, Galisteo, and Mesa Verde Black-on-white, reflects a Late Coalition period of occupation. The AMS and archaeomagnetic dates overlap and cover a similar two-sigma range from AD 1275 to 1325.

The stone tool technology reflects an emphasis on core reduction of materials like chalcedony, Pedernal chert, and obsidian. Most of the obsidian appears to have been obtained from nearby sources in the Valles Caldera. The retouched tool assemblage includes a mix of expedient flake tools like retouched pieces and perforators and formal tools like bifaces, projectile points, and unifaces. The manos are represented by both one- and two-hand varieties. The metates consist of undetermined fragments, which could represent millingstones or slab types. In addition, the presence of polishing stones, abrading stones, and an axe indicates that a variety of domestic activities were occurring at the site.

CHAPTER 15
WHITE ROCK TRACT (A-19): LA 12587 (AREA 8)

Kari M. Schmidt

INTRODUCTION AND SITE SETTING

LA 12587 is a multi-component site that includes the remains of a Late Coalition period roomblock (see Chapter 14, this volume) and a Late Archaic period lithic scatter (Area 8). Area 8 is situated on a knoll at the southern end of Mesita del Buey and lies at the confluence of Cañada del Buey and Pajarito Canyon. The area is covered with piñon and juniper trees and sits at an elevation of 1979 m (6500 ft). The roomblock portion of the site is located on a small knoll and is located slightly upslope and to the north of the lithic scatter. To demarcate the lithic scatter from the roomblock portion of the site, the scatter was given a separate area number (Area 8) during excavation activities at the site. Area 8 consists of a Late Archaic period lithic scatter at the southern end of LA 12587, as well as the continuation of the midden associated with the roomblock at LA 12587.

Area 8 is located south of a two-track road that runs northeast to southwest along the ridge on which LA 12587 sits (see Figure 14.3). The two-track road is used by Los Alamos County to aid in the servicing of an existing Los Alamos County power line. From the two-track, the artifact scatter extends southeast to the edge of the hilltop where a distinct line of outcropping bedrock marks the hilltop edge. From this point southward and eastward, the land slopes steadily downward until the valley bottom flattens out some 50 m distant. There is a fairly heavy cover of piñon and juniper across the surface of the scatter with small but contiguous patches of outcropping bedrock.

SITE DESCRIPTION

Area 8 consisted of two concentrations of artifacts: a Late Archaic occupation in the southern portion of the area and the continuation of the midden associated with the roomblock at LA 12587 in the northern portion. In-field analyses conducted during the original assessment of the site sampled two dogleashes and a linear transect. The dogleash samples were 1 and 2 m samples, respectively, and the transect was 5 by 27 m. Both of the dogleash samples were located within the boundaries of the Coalition period roomblock, while the sample transect was located in Area 8, the Late Archaic period lithic scatter.

Obsidian comprised over 96 percent of the chipped stone debitage identified within the sample transect; other identified materials included Pedernal chert, other chert, and basalt. Excluding over 100 pieces of obsidian microdebitage located on an anthill in the transect, the chipped stone in this area was fairly evenly split between core flakes (32%), biface flakes (29%), and microdebitage (26%). The remaining pieces of debitage were either unidentified flakes (12%) or angular debris (1%). The base of a Late Archaic obsidian projectile point and a one-handed rhyolite mano were identified in this area of the site. Based on the high percentage of obsidian debitage and the Late Archaic projectile point in the area south of the roomblock, it was determined that there were multiple components at LA 12587, including both Archaic and Coalition periods.

FIELD METHODS

Fieldwork began with the initial assessment of the Area 8 site area. The crew walked over the site, delineated the boundaries, and identified the presence of artifact concentrations and features. A 1- by 1-m grid system that was laid out during the initial ground-penetrating radar survey of the roomblock at LA 12587 was also used during the excavations of Area 8. The central site datum (100N/100E) was established near the center of the roomblock, with controlled surface collections being made across the entire site area.

After the grid was laid out and before the collection of any artifacts, the crew walked around the site area and pin-flagged surface artifacts. Based on the visual demarcation of artifact density displayed by the distribution of pin-flags, surface artifacts were collected in a 5200-m^2 area. This area included both the Late Archaic lithic scatter and the midden associated with the roomblock.

During the surface collection, all artifacts were collected according to their unit designation. Artifacts were bagged separately according to material type (except when the total number of artifacts from the grid was less than five), and each bag was given a separate field specimen (FS) number. While chipped stone debitage and ceramics were collected within the general 1- by 1-m grid they were located in, the location of formal chipped stone tools and ground stone items were point-provenienced. A total of 1842 pieces of chipped stone, 1802 ceramics, and 96 pieces of ground stone were collected from the surface in Area 8. Figure 15.1 shows personnel conducting the surface collection in Area 8.

Figure 15.1. Surface collection of Area 8.

Subsequent to the field season, all artifacts collected from the individual grids were entered into Surfer, version 7. From these data, maps of surface artifact distribution were generated. Figures 15.2 through 15.4 show the distribution of ceramics, chipped stone, and ground stone and fire-cracked rock (FCR), respectively. These maps show a distributional pattern commensurate with the multi-component nature of the site: ceramics dominate to the north and follow a general arc curving around the southern portion of the roomblock while the chipped stone materials dominate in the southern portion of the area where the Late Archaic use of the site occurred.

Many of the artifacts collected during the surface collection were submitted for analysis. Utilitywares formed the bulk of the ceramic assemblage comprising almost 80 percent. Decorated wares were dominated by Santa Fe Black-on-white (13%), with smaller percentages of Wiyo Black-on-white, Biscuit A (Abiquiu Black-on-gray), and San Juan whiteware (all less than 1%).

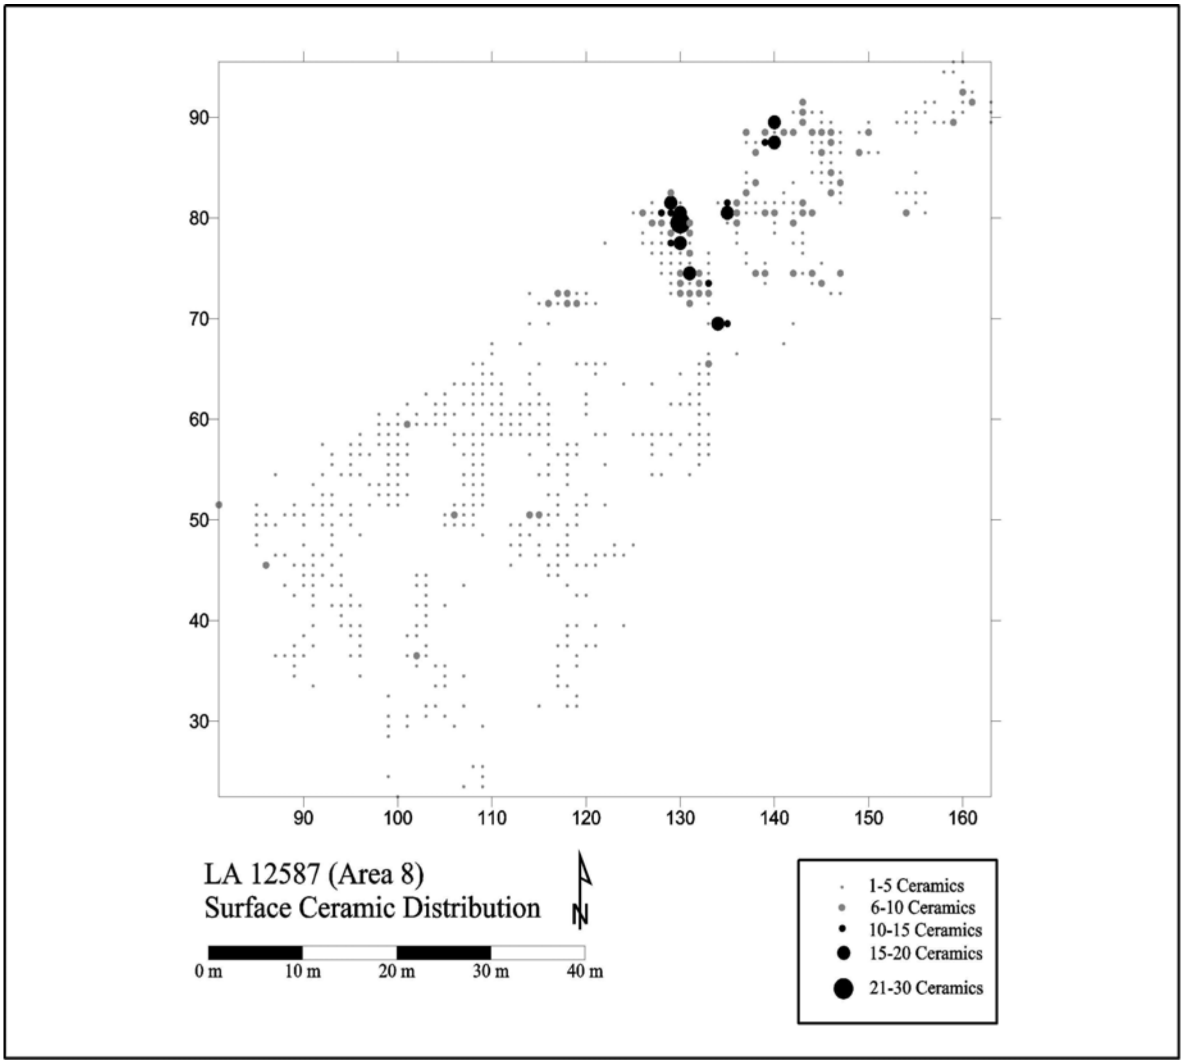

Figure 15.2. Distribution of ceramics on the surface of the site.

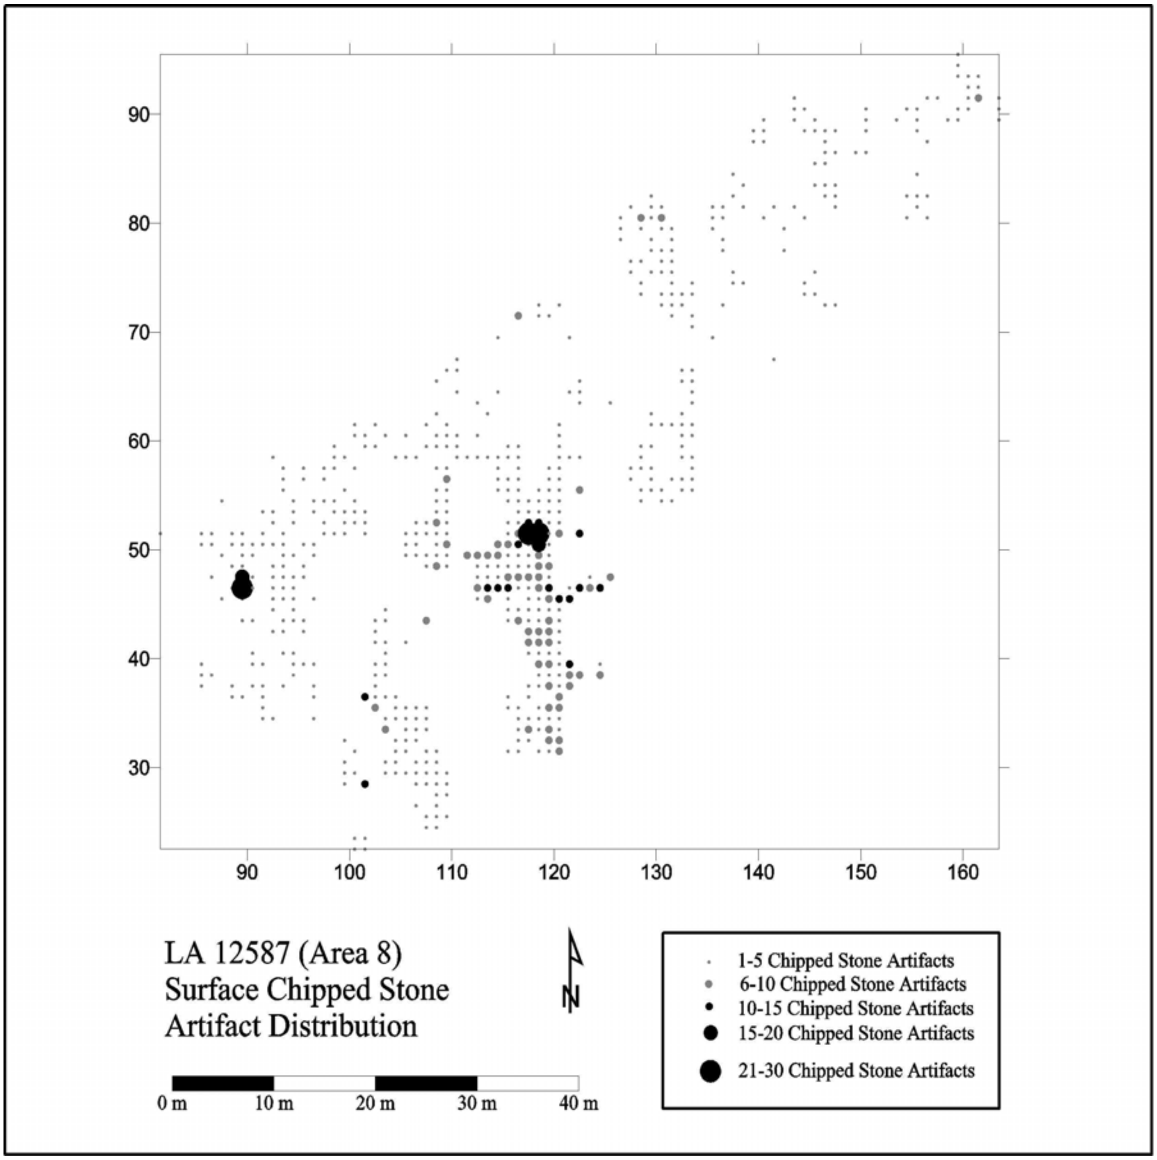

Figure 15.3. Distribution of chipped stone materials on the surface of the site.

Chipped stone material was also collected from the surface of Area 8. The most abundant type of material recovered from the analyzed surface sample was obsidian (*n* = 440, 91%), followed by chalcedony (*n* = 17, 4%), Pedernal chert (*n* = 6, 1%), and negligible amounts of rhyolite, basalt, and quartzite. Microdebitage comprised the majority of the debitage assemblage at nearly 53 percent. Biface and core flakes were the second most abundant type of debitage, making up 26 percent and 15 percent of the assemblage, respectively. Angular debris and unidentified flake fragments each comprised about 3 percent of the debitage assemblage. One chalcedony core was recovered. An obsidian biface and projectile point were each recovered from the surface of Area 8. No other retouched tools were identified.

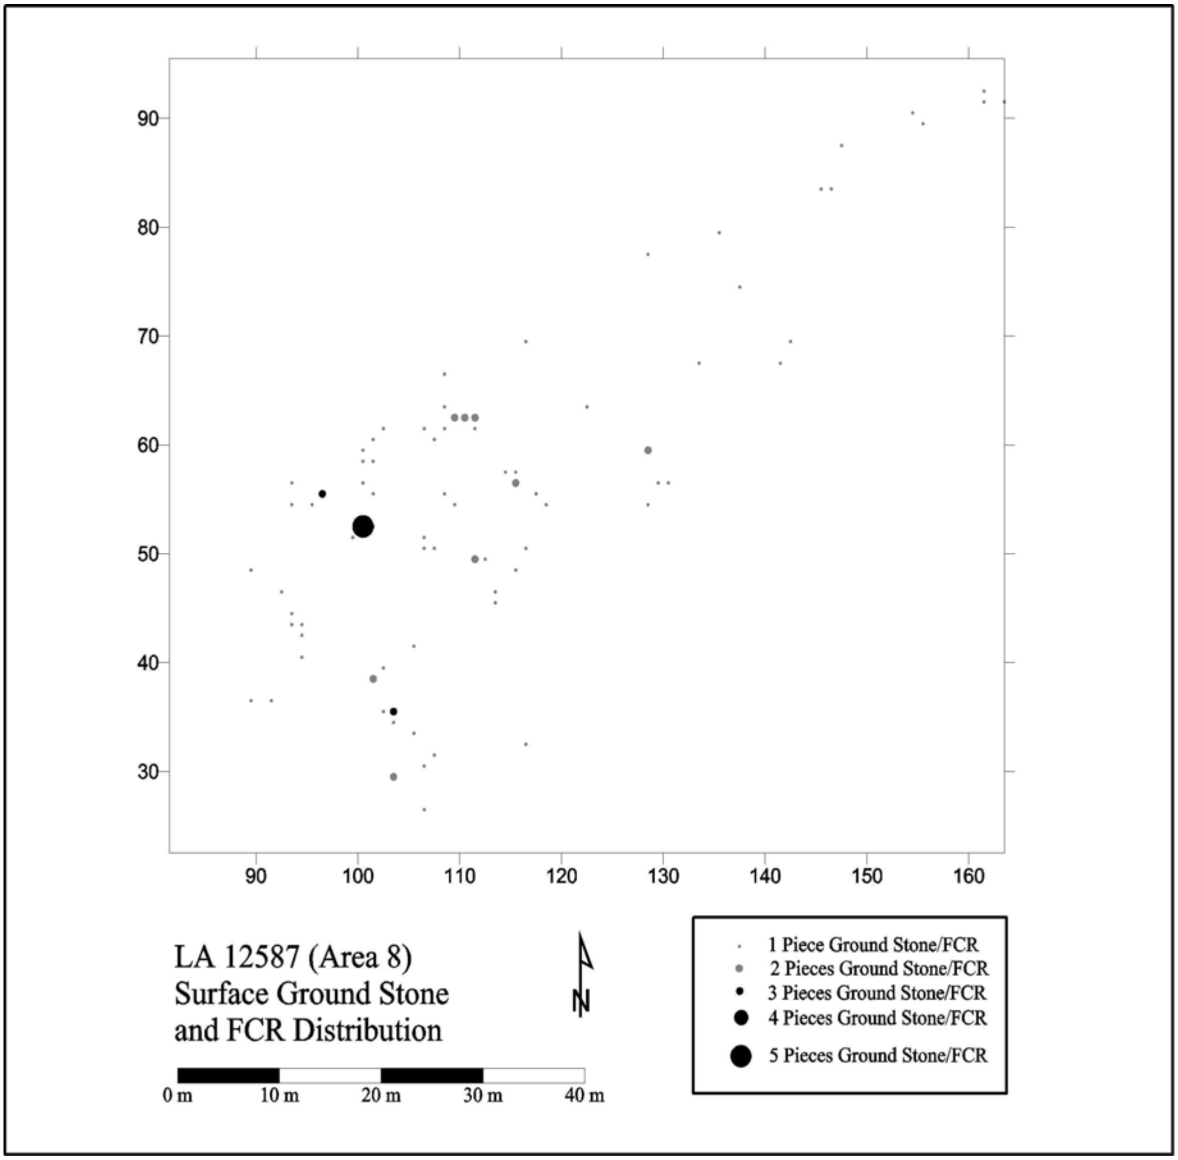

Figure 15.4. Distribution of ground stone and FCR across the surface of the site.

Eleven pieces of ground stone were analyzed from selected areas of Area 8. Just over half of these were made from dacite cobbles (*n* = 6), followed by andesite (*n* = 3) and quartzite and vesicular basalt (*n* = 1). Three of the dacite cobbles were mano fragments, while the other three were unidentified ground stone fragments. Andesite materials consisted of an unidentified metate fragment, an abrading stone, and an unidentified ground stone fragment. One quartzite polishing stone was identified, as was an unidentified vesicular basalt ground stone fragment.

Areas selected for excavation were placed in areas of high artifact density and/or in areas where it was suspected that greater soil depth might increase the chances of locating any subsurface features. Four 1- by 1-m units were selected for excavation. In all four of the excavation units, digging continued until bedrock was reached (see section on site excavation for more details).

STRATIGRAPHY (Paul Drakos and Steve Reneau)

The Late Archaic period lithic scatter is located in an area of thin soils over tuff bedrock that appears to have experienced significant erosion, and the lithic scatter may in part represent a lag left following erosion of an unknown thickness of mesatop soils (Drakos and Reneau, Volume 3). Excavations into relatively thick pockets of soil (up to 28 cm thick) inside the main artifact scatter revealed the presence of both ceramics and obsidian flakes to the base of a weakly developed soil (Table 15.1; see Appendix K for key). An excavation completed outside the main artifact scatter revealed a young colluvial deposit of similar thickness (20 cm) and a weakly developed soil (Table 15.2). Soils in the vicinity of the lithic scatter lack the Bw horizons typically observed in older post-Puebloan soils, and instead exhibit A-BC or A-C horizons. This weak soil development is consistent with a post-Puebloan age, possibly less than 500 years old. This observation is consistent with the interpretation that this is an actively eroding surface with minimal potential for preserving an intact archaeological record. Four 1- by 1-m units were excavated in Area 8, but soil profiles were only conducted in two units. Excavation units were placed in areas of greater soil development in an attempt to locate subsurface features. Stratigraphic sequences are described in the following pages and in Table 15.3.

Table 15.1. Geomorphologic analysis of test pits in Area 8, Test Pit Number 4, 51N/118E; inside main artifact scatter.

* = centimeters below ground surface

51N/118E

Unit 51N/118E, which is located inside the Late Archaic lithic scatter, had several discrete stratigraphic units. The A horizon in this unit extended from the surface to 9 cm below the surface and contained 20 percent to 30 percent gravels. It was dark yellowish-brown in color and was identified as a sandy loam. This horizon had a weak subangular blocky to massive structure, was soft to loose in consistency, contained no observed argillans, and was slightly effervescent. The lower bounder of this horizon was identified as clear and smooth. Soils in this horizon were associated with the post-Puebloan period.

The BC horizon in this unit extended from 9 to 28 cm below surface and contained 10 percent to 20 percent gravels. The sediments were dark yellowish-brown in color, sandy clay loam in composition, and medium subangular blocky in structure. The horizon had a soft consistency with no observed argillans and was strongly effervescent. The lower boundary was abrupt and irregular and was thought to be post-Puebloan in age. The R (bedrock) horizon began at 28 cm below surface. Figure 15.5 shows this unit at the completion of excavation.

Figure 15.5. Unit 51N/118E at the end of excavation.

36N/103E

Unit 36N/103E, which was located outside the Late Archaic lithic scatter, also contained several stratigraphic units. The A horizon in this unit extended from 0 to 2 cm below the surface and contained 30 percent gravels. It was a brown, sandy clay loam with a weak to moderate medium platy structure. This horizon had a soft consistency, with no observed argillans, and was strongly effervescent. Its lower boundary was clear and smooth, and was likely post-Puebloan in age.

The C horizon extended between 2 and 20 cm below the surface and also contained approximately 30 percent gravels. Like the overlying A horizon, the C horizon was also brown in color, but had a sandy loam composition and a medium structure. It had a loose consistency with no observed argillans, was strongly effervescent, and had a clear, smooth lower boundary. Similar to the A horizon, this horizon is only several hundred years old and is likely post-Puebloan in age. The R horizon (bedrock) in this unit began about 20 cm below the surface. Figure 15.6 shows this unit after it was excavated.

Figure 15.6. Unit 36N/103E at the end of excavation.

SITE EXCAVATION

Excavations at LA 12587 (Area 8) were conducted in November and December of 2002. The crew consisted of Kari Schmidt (crew chief), Mia Jonsson, Mike Kennedy, Timothy Martinez, Bruce Masse, and Marjorie Wright. These personnel excavated four 1- by 1-m units in Area 8. Two were located in the western half of the scatter and two were located in the eastern half.

These units were excavated in arbitrary stratigraphic levels, until natural strata became clear enough to be used for excavation.

35N/90E (Test Pit 1)

The fill in this unit was a brown sandy loam soil down to bedrock, which was shallow in this unit and was encountered at about 12 to 15 cm below the surface. The majority of the unit was excavated to this depth, although a deep fissure ran through the center of the grid extending to 30 cm in depth. Lying atop the bedrock was a layer of matted roots that covered virtually the whole bedrock surface in the grid. The only cultural remains that were recovered in this unit were four small obsidian flakes, four smeared-indented corrugated ceramics, and a piece of piñon pine (*Pinus edulis*). A single flotation sample taken from excavations in this unit produced the following taxa: goosefoot (*Chenopodium*), unknown conifer (Gymnospermae), juniper (*Juniperus*), unidentified pine (*Pinus* sp.), and piñon pine.

36N/103E (Test Pit 2)

The soil in this unit was also brown and a sandy loam down to the top of bedrock. The bedrock was encountered about 12 cm below the surface in the northwest corner of the unit and sloped down generally toward the southeast to a depth of 30 cm. The upper 10 cm of fill contained large, fragmented chunks of unconsolidated bedrock, while closer to bedrock the soil was more consolidated. In the upper 10 cm of fill, 15 pieces of chipped stone (obsidian and Pedernal chert) and three plainware body and a smeared-indented corrugated sherd were recovered. In the sediments deeper than 10 cm below the surface, eight pieces of chipped stone (obsidian and chert) were found.

47N/118E (Test Pit 3)

In the upper 10 cm of this unit the soil was sandy loam, and between 10 and 25 cm below the surface it became a sandy clay loam. In the lower part of this level, just above the bedrock, there were fragmented pieces of bedrock mixed with the soil. From 0 to 10 cm there were 47 obsidian flakes, one chert flake, and two smeared-indented corrugated ceramics recovered from the fill. Between 10 and 25 cm below surface, 43 obsidian flakes, a Santa Fe Black-on-white sherd, a smeared-indented corrugated sherd, and a ground stone fragment were found. Additionally, a piece of piñon pine was identified in a macrobotanical sample and juniper remains were identified in a flotation sample.

51N/118E (Test Pit 4)

The soil in this unit was a brown, sandy loam from the surface down to bedrock, which presented itself as a somewhat discontinuous layer at approximately 30 cm below the surface. In the upper 10 cm there were 107 pieces of obsidian and a whiteware, plainware body and smeared-indented corrugated sherds. From 10 to 20 cm below the surface, 30 more obsidian flakes were found, and a flotation sample was collected from the fill. Identified taxa from this sample include unknown conifer and juniper. In the 20- to 30-cm level, seven pieces of obsidian and a single smeared-indented corrugated sherd were recovered.

SITE CHRONOLOGY AND ASSEMBLAGE

Some 4100 total artifacts were recovered from excavations in Area 8 at LA 12587. Analyses of the ceramics, lithics (chipped and ground stone), and archaeobotanical materials were conducted. Ceramic samples were taken from two transects in the northern portion (southern portion of the LA 12587 midden) of Area 8, while chipped stone materials were collected from two transects in the western section (Late Archaic focus) of Area 8. No faunal remains were recovered in the deposits, and taxa were identified in the single pollen sample from the site. No materials were submitted for radiocarbon analyses due to a lack of suitable material in the excavation units. However, obsidian artifacts were submitted for hydration dating. Results of the analyses that were conducted are presented in the following sections.

Obsidian Hydration

Ten obsidian artifacts from Area 8 at LA 12587 were submitted for age determination using the obsidian hydration method. In order to calculate the absolute date for an obsidian artifact, three analytical procedures were completed. First, the amount of surface hydration, or the thickness of the hydration rind, was measured. Second, the high temperature hydration rate constants for each artifact were determined from the composition of the glass. Lastly, the soil temperature and relative humidity at the archaeological site was estimated in order that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. Using these methods, a hydration rate for the obsidian artifacts was calculated (Table 15.4).

Table 15.4. Obsidian hydration dates for Area 8 at LA 12587.

The obsidian hydration dates provide a wide range from 3049 BC to AD 1668. On the other hand, a Late Archaic point was dated to AD 482, which seems to be in the appropriate range.

Later dates could reflect the reuse of the site, although the AD 1668 date seems quite late, and the three earliest dates seem too early.

Ceramics (Dean Wilson)

The majority of the ceramics analyzed from Area 8 are Santa Fe Black-on-white, smeared-indented corrugated wares, and plainwares suggesting a Coalition period occupation of the northern portion of the area. The percentages of pottery types, as well as the types of wares are very similar to the roomblock at LA 12587, suggesting the northern portion of Area 8 is likely a continuation of the arc-shaped midden forming the eastern and southeastern boundary of the site. Very few biscuitwares were identified, and no glazewares were identified. Tables 15.5 and 15.6 show the distribution of pottery types and temper types identified in ceramic samples collected and analyzed from Area 8.

Table 15.5. Distribution of ceramic types from Area 8 of LA 12587.

Chipped and Ground Stone (Bradley Vierra and Michael Dilley)

Material Selection

A total of 485 artifacts were analyzed from two transects in the western portion (Late Archaic focus) of Area 8 at LA 12587, consisting of one core, 465 pieces of debitage, two retouched tools, and 11 ground stone items. This total represents a 22 percent sample of the 2196 total lithic artifacts recovered during the site excavations. Table 15.7 presents the data on lithic artifact type by material type. The majority of the debitage consists of obsidian, with a few items made from other materials. The presence of cortex on 4.0 percent of the debitage indicates that the materials were collected from both primary nodular (63.1%) and secondary waterworn sources. The obsidian and rhyolite are present at nearby sources in the Jemez Mountains, but obsidian flakes also exhibit waterworn cortex. In contrast, chalcedony, Pedernal chert, and quartzite are available from local Rio Grande Valley gravel sources.

Twenty-three pieces of debitage and two retouched tools were submitted for X-ray fluorescence analysis (Shackley, Volume 3). The majority of the artifacts were obtained from the Cerro Toledo source, with a single piece from the Valle Grande and El Rechuelos source areas (Table 15.8). The Cerro Toledo (Rabbit Mountain/Obsidian Ridge) and Valle Grande (Cerro del Medio) source areas are located about 15 km (10 miles) as the "crow flies" to the southwest and west of the site, while the El Rechuelos (Polvadera Peak) source area is situated about 30 km (19 miles) to the northwest.

Lithic Reduction

The single core was reduced using a bidirectional, opposed-different-face technique and was classified as being exhausted when discarded. Table 15.9 presents the metric information on this core.

Table 15.9. Core type dimensions (mm) and weight (gm).

Core Type	Length	Width	Thickness	Weight
Bi-directional	35	25	17	13.3

The debitage consists primarily of microdebitage (52.9%) and biface flakes (26.2%), with some core flakes (15.2%), and other items. The majority of the flakes exhibit single platforms (45.4%; *n* = 1 5), with dihedral (*n* = 1), multi-faceted (*n* = 4), collapsed (*n* = 3), and crushed (*n* = 10) platforms. Nineteen (57.5%) of the flake platforms exhibit evidence of preparation, with most of these being abraded/crushed and only four retouched/abraded platforms.

The majority of the core flakes consist of distal fragments (*n* = 37; 52.1%), with fewer whole (*n* = 1), proximal (*n* = 4), midsection (*n* = 27), lateral flake (*n* = 1), and undetermined flake (*n* = 1) fragments. Most of the biface flakes are also midsection fragments (*n* = 53; 43.4%), with fewer whole (*n* = 1), proximal (*n* = 25), and distal (*n* = 42) fragments. The single whole core flake has a length of 21.0 mm and the two whole biface flakes exhibit a mean length of 22.5 mm (*std* = 16.2). Lastly, angular debris have a mean weight of 0.7 g (*std* = 0.6).

The retouched tools consist solely of formal tools such as bifaces and projectile points. No retouched pieces were identified.

The biface is a distal fragment that was probably broken during manufacturing. It does exhibit an edge angle of 45 degrees, indicating that it could have been broken during the middle- to late-stage reduction process. Both projectile points are base fragments that are quite similar in form. The points contract towards the neck and contain a straight base that could reflect Late Archaic corner-notched base fragments.

Tool Use

Only three flakes (0.06%) exhibit evidence of damage that could be attributed to use-wear**.** Two have straight lateral edges with angles of 35 and 60 degrees, while the third was utilized on an edge with a straight outline and angle of 45 degrees. Three undetermined mano fragments, an undetermined metate fragment, a polishing stone, and five pieces of undetermined ground stone were identified during the analysis. The mano fragments probably represent broken one-hand cobble manos. The metate fragment is a burned piece of andesite with a single ground surface. The polishing stone is a quartzite pebble with some polish on one surface. Lastly, the undetermined ground stone consists of small fragments that exhibit a ground surface. Some of these fragments are burned.

Archaeobotanical Remains (Pamela McBride)

Goosefoot and pitseed goosefoot seeds comprised the only carbonized floral remains from excavations in Area 8 (Table 15.10). Non-cultural material consisted primarily of conifer duff along with goosefoot, spurge, and prickly pear cactus seeds. Fragments of juniper and unknown conifer charcoal were recovered in flotation samples. Vegetal samples from Units 1 and 3 yielded five specimens of piñon wood. The meager botanical information indicates that some weedy annual seeds may have been used for food, whereas, locally available conifers could have provided a source for firewood.

Table 15.10. Flotation sample plant remains from Area 8 at LA 12587.

FS No.	8876	8877	8888
Feature	**Test Pit 3**	**Test Pit 4**	**Test Pit 1**

Prickly pear cactus		+	

All plant remains are seeds unless indicated otherwise. Cultural plant remains are charred, non-cultural plant remains are uncharred. + 1-10/liter.

SUMMARY

Area 8 at LA 12587 contains a large, fairly dense scatter of artifacts. While there was a general scatter of debitage over the entire area, there were distinct concentrations identified during mitigation. Of the total assemblage, 52 percent was chipped stone, 45 percent was ceramics, and less than 1 percent was ground stone. Most of the ceramics were located in the northeastern third of the site and were associated with the midden at the roomblock portion of LA 12587. Ceramic analyses confirm a Coalition period occupation. In contrast, the majority of chipped and ground stone artifacts were found in the southwestern half of the site, in the area thought to represent an Archaic occupation.

The chipped stone assemblage consisted primarily of small obsidian biface-thinning flakes, with a biface and possible Late Archaic dart points; whereas, the ground stone artifacts included possible one-hand cobble mano fragments and metate fragments. The different artifact classes and wide range of obsidian hydration dates recovered within Area 8 support multiple uses of the area, corroborating the initial assertion that LA 12587 was a multi-component site. A Late Archaic point was dated to AD 482±110, which lies within the defined temporal range of the point style. The few botanical items recovered from the test pits indicate that weedy annuals could have been used as food items at the site, although the context is poorly defined.

CHAPTER 16
WHITE ROCK TRACT (A-19): LA 86637

Kari M. Schmidt and Michael D. Kennedy

INTRODUCTION AND SITE SETTING

LA 86637 was identified during the initial pedestrian survey of the White Rock Tract as a fieldhouse surrounded by a dispersed ceramic and lithic artifact scatter. The fieldhouse is located on a small rise above an ephemeral drainage at the mouth of Cañada del Buey, and dominant vegetation in the area includes piñon and juniper trees, with an understory comprised of saltweed, snakeweed, yucca, and various other native grasses, shrubs, and forbs. The site is situated at an elevation of 1973 m (6475 ft). The fieldhouse is located on property owned by San Ildefonso and was not excavated as part of this project. A small portion of the artifact scatter was located just across the San Ildefonso/Los Alamos National Laboratory (LANL) boundary and several test pits were placed on properties that were being transferred from LANL to Los Alamos County. A fairly prominent arroyo that runs east-west is located approximately 5 m south of the artifact scatter. This arroyo joins the larger one that is just north of LA 128803, the grid garden (see Chapter 19, this volume). Large basalt outcrops are located immediately south of the artifact scatter.

SITE DESCRIPTION

The site is comprised of a small one- to two-room fieldhouse situated within a much larger lithic and ceramic artifact scatter. The fieldhouse was not excavated because it was on property owned by San Ildefonso Pueblo. A large percentage of the artifact scatter was also on San Ildefonso property and, as a result, artifacts from only a small portion of the site were collected and test excavations were limited to the most southern portion of the site. Much of the material associated with the fieldhouse appeared to be part of a background scatter that reflected a long period of use over a 45- by 90-m area. The fieldhouse is a small rubble mound measuring 2.5 by 3.7 m in size that was constructed from shaped tuff blocks. The largest of these blocks measures about 80 by 45 cm. The structure itself appears to be in good condition, but has been impacted on the east and west sides by active erosion associated with two small arroyos.

During the initial survey, an in-field analysis was conducted in a 10-m catchment area around the structure. This sample produced a total of 46 artifacts, including a Biscuit B (Bandelier Black-on-gray) sherd, a single obliterated corrugated sherd, and several pieces of Pedernal debitage. Additionally, artifacts were collected from a 10- by 20-m transect. Artifacts in this transect included a few Santa Fe Black-on-white sherds, Wiyo Black-on-white sherds, biscuitwares, a Sankawi Black-on-cream sherd, several Tewa Polychrome sherds, and utilitywares (n = 15). Most of the chipped stone artifacts in the artifact cluster were Pedernal chert and obsidian core flakes, with a few other debitage types. Other materials included two cores, a retouched flake, two projectile points, a one-hand mano, two unmodified quartzite river cobbles, and three quartzite one-hand manos. The projectile points were both made of obsidian and appeared to be Late Archaic in age.

Only the portion of the site containing the lithic and ceramic scatter was transferred to Los Alamos County, the remainder of this chapter deals only with that area. The portion of the lithic and ceramic scatter of concern to this project is located about 50 m downslope of the fieldhouse. Figure 16.1 shows the plan view of the site and shows which portions were subject to collection.

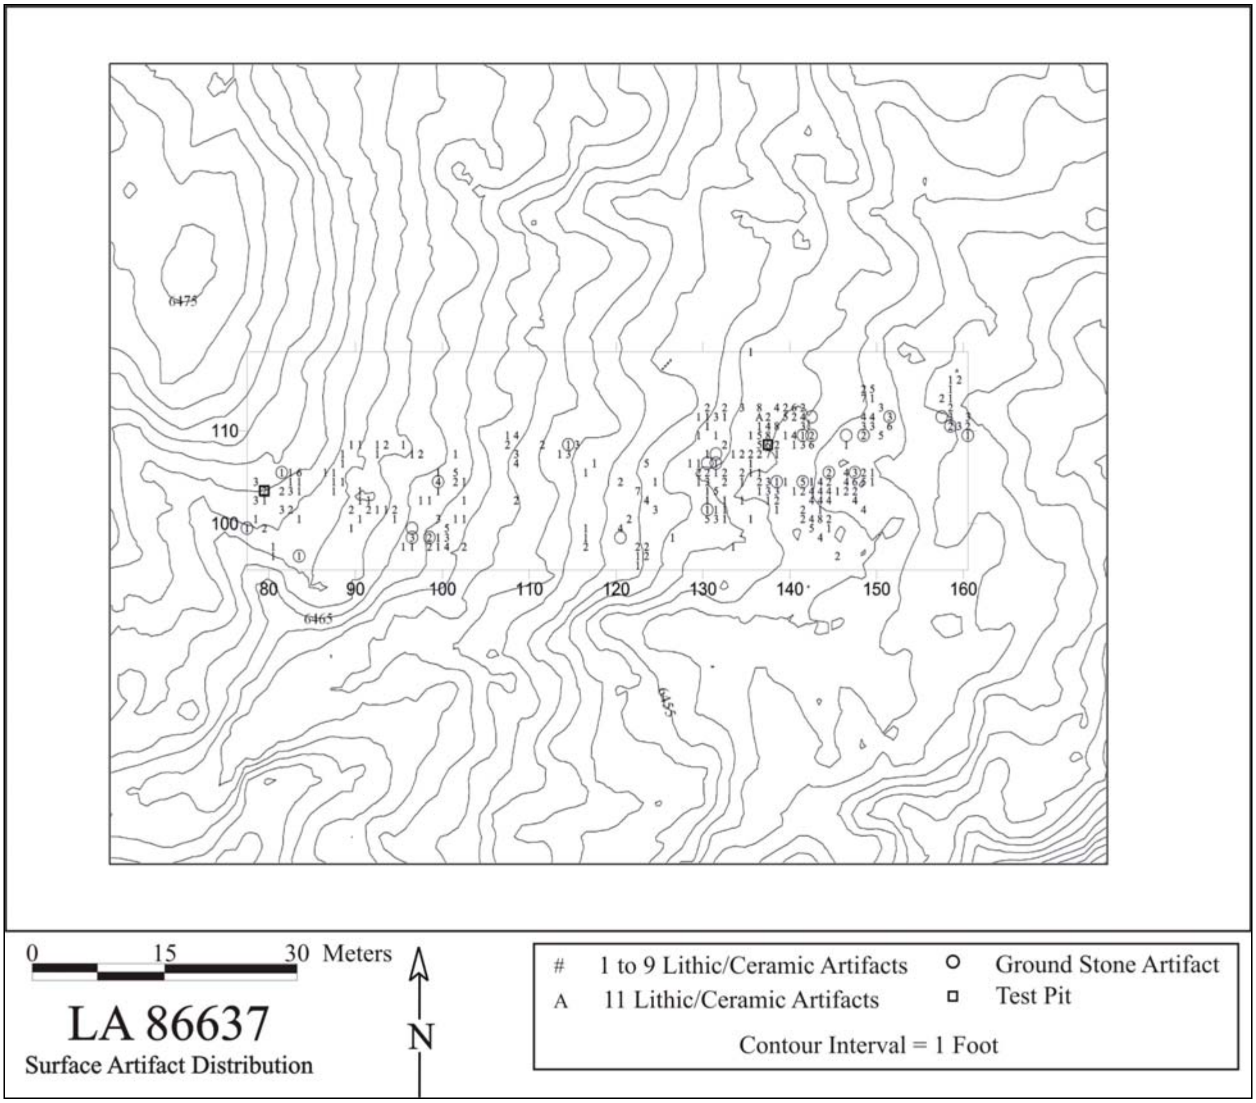

Figure 16.1. Surface artifact distribution at LA 86637.

FIELD METHODS

Fieldwork began at LA 86637 in December of 2002 and continued for just over two weeks. Work began with an initial assessment of the site. The crew walked over the site area, delineating the site boundaries and identifying the presence of artifact concentrations and features (Figure 16.2). Additionally, with the aid of a GPS unit, the San Ildefonso boundary was delineated and demarcated and no collections were made on the San Ildefonso side of the line. Mitigation of LA 86637 was limited to that portion of the site that lay south of the boundary between San Ildefonso and Los Alamos County. This included an area that was roughly 80 m east-west by 10 to 15 m north-south. The artifacts were located during a pedestrian survey and their locations were marked with pin flags. Once the extent of surface debitage and site limits were delineated, the site was gridded out in 1- by 1-m units. Individual grid units were designated by the horizontal coordinates at their southwest corner. The site datum was established near the center of the artifact scatter at 100N/100E for horizontal control.

Figure 16.2. North-south view of LA 86637.

Surface artifacts from Los Alamos County land were collected, bagged, and provenienced by the square meter. Figure 16.1 shows the distribution of surface artifacts that were collected. A total of 468 lithics, 118 ceramics, and 28 ground stone artifacts were collected. No bone or charcoal samples were recovered. The lithic assemblage included a reworked Late Archaic projectile point, but interestingly, the ceramics included historic Tewa polychrome sherds. In the ground stone assemblage there were several mano and metate fragments that also appeared to be Archaic in form.

Two 1- by 1-m test units were excavated. These units were located in different areas of the scatter with one in the southern portion of the site, where surface rock indicated the possibility of buried deposits, and one near the northern end of the site in an area where an Archaic point was noted during the original survey. All artifacts from the excavations were collected and recorded and the soils were sampled for flotation and/or pollen from appropriate stratigraphic levels. All fill was screened through 1/8-in. mesh.

STRATIGRAPHY (Paul Drakos and Steve Reneau)

The portion of LA 86637 of concern here contains a lithic and ceramic scatter that probably represents material transported down a colluvial slope from a Classic period fieldhouse. As already mentioned, the fieldhouse lies on San Ildefonso property and is therefore outside the scope of the current undertaking. Because of the extensive erosion in this area, and because the site lies between two channels incised into the colluvial slope, in situ deposits are unlikely. This is confirmed by stratigraphic assessments presented and discussed in the following pages (Table 16.1).

Table 16.1. Stratigraphic sequence used in the field at LA 86637.

LA 86637 STRATIGRAPHIC SUMMARY							
Stratum #	Provenience	Maximum Thickness	Minimum Thickness	Elevation	Color	Texture	Comments
1	Test pits 1 and 2	0.10	0.04	0 to 10 cm bgs*	10YR5/3	Loamy sand	Ac Horizon. Loose and massive. Five percent to 10% gravels, no argillans.
2	Test pits 1 and 2	0.21	0.10	10 to 31 cm bgs	7.5YR5/3	Sandy loam	Soft to slightly hard, lots of carbonates, 10% to 20% gravels, BkB horizon, no argillans, discontinuous, effervescent.
3	Test pits 1 and 2	0.15	0.07	31 to 46	7.5YR4/3	Sandy loam	Soft to slightly hard, cicada burrows, 10% to 20% gravels, plastic, effervescent, Bk-B_2 horizon. Boundary is clear and irregular.
4	Test pits 1 and 2	--	0.05	46+	7.5YR6/4	Sandy loam	Small nodules, slightly hard, Bk-B_2 horizon, slightly plastic, less than 10% gravels. Found to bottom of test pit, but stratum may have gone deeper.

*centimeters below ground surface

103N/79E

The soil profile from this unit shows that the test unit has an AC-Bw1b1-Bw2b1-Btkb2 horizon sequence that represents very young colluvium from 0 to 6 cm that overlies post-Coalition period colluvium that was observed to a depth of 43 cm (Table 16.2; see Appendix K for key). The young colluvium overlies a Pleistocene colluvial soil. Artifacts (lithics and ceramics) scattered throughout the AC, Bw1b1, and Bw2b1 horizons are interpreted to be part of the young colluvial package and therefore are not in archaeological context.

The AC horizon falls between 0 and 10 cm and contained 5 percent to 10 percent gravels. The sediments were a brown loamy sand with a loose consistency. They were strongly effervescent with a clear, but smooth, lower horizon boundary. The Bk1b1 horizon was located between 10 and 31 cm and contained 10 to 20 percent gravels. It was a brown sandy loam, had soft to slightly hard consistency, was strongly to violently effervescent, and had a gradual, smooth lower horizon boundary. The Bk2b1 horizon was located between 31 and 46 cm. It had 10 percent to 20 percent gravels, was a brown sandy loam, had soft to slightly hard consistency, was strongly to violently effervescent, and had a clear, irregular lower horizon boundary. The Bkb2 horizon fell between 46 and 50 cm below the surface. It contained less than 10 percent gravels, was a light brown sandy loam, had a slightly hard consistency, and was violently effervescent.

108N/137E

The soil profile of 108N/137E had an AC-Bwk1b1-Bwk2b1-Bkb2 horizon sequence interpreted to represent deposition of young colluvium from 0 to 10 cm. This layer overlaid 2 to 4 ka colluvium with Stage I carbonate from 10 to 46 cm (Table 16.3; see Appendix K for key). The age estimate for the Bwk horizons with Stage I carbonate was based on comparison with the Fence Canyon borrow pit description, which exhibited a Stage I carbonate with a surface age of approximately 4 ka and an 8 ka age at depth (Reneau and McDonald 1996). The Holocene colluvium overlies a Pleistocene colluvial soil. Ceramics and lithics observed in the upper 10 cm are part of the young colluvial package and are not in archaeological context. Lithics were only observed in the Bwk1b1 horizon and were interpreted to be part of an older (mid- to late-Holocene) colluvial package. The lithics in the Bwk1b1 horizon were apparently reworked from an Archaic site upslope and are therefore likely not in archaeological context at this location.

The AC horizon is between 0 and 6 cm. It contains about 10 percent gravels, is a pale brown loamy sand, has a soft consistency, is strongly to violently effervescent, and has a clear, smooth lower horizon boundary. This stratum is less than 100 years old. The Bw1b1 horizon is between 6 and 15 cm and contains 10 percent gravels. This stratum is a brown sandy loam, has a loose to soft consistency, is strongly to violently effervescent, and has a gradual smooth lower horizon boundary. This stratum is said to be less than 800 years old. The Bw2b1 horizon is found between 15 and 43 cm and has 20 percent gravels. It is a light brown sandy loam, has a soft and slightly plastic consistency, and is strongly effervescent. This stratum has an abrupt, irregular lower horizon boundary and is also thought to be less than 800 years old. The Btkb2 horizon falls between 43 and 50 cm and has 10 percent gravels. It is light reddish brown and is a sandy clay loam. It has a soft to slightly hard consistency, and is strongly effervescent.

SITE EXCAVATION

Excavations at LA 86637 were conducted in December of 2002. The crew consisted of Kari Schmidt (crew chief), Mia Jonsson, Mike Kennedy, Timothy Martinez, and Marjorie Wright. In addition to surface collection, personnel excavated two 1- by 1-m units, one each located in the eastern and western portions of the site. These units were excavated in arbitrary stratigraphic levels. The excavation units were placed about 50 m apart in areas with the highest density of surface artifacts. Therefore, no central site datum was used, rather vertical measurements were taken as centimeters below ground surface at each of the two test units.

103N/79E

103N/79E was located in the western portion of the artifact scatter in an area where an Archaic projectile point was identified during the original survey of the site. The unit was located above a shallow arroyo running through the site, about 5 m south of the San Ildefonso property boundary. From the surface down to about 30 cm below ground surface, the soil was silty sand, with gravels being at about 5 percent to 10 percent in the top 10 cm of fill and increasing to about 10 percent to 20 percent, with a few specks of $CaCO_3$ appearing by 30 cmbgs. From 30 to 40 cm below ground surface the amount of silt and $CaCO_3$ increased. In the top 10 cm of fill, there were six pieces of debitage and two ceramics recovered, mostly from the upper half of the level. Five pieces of debitage were found from 10 to 20 cm below ground surface, six pieces of debitage from 20 to 30 cm below ground surface, and three pieces of debitage from 30 to 40 cm below ground surface. The debitage were mostly obsidian, with some chalcedony or Pedernal chert, and the ceramics were dominated by biscuitwares and utilitywares (see Table 16.4).

Two pollen samples (Field Specimen [FS] 274 and FS 275) and flotation samples (FS 272 and FS 273) were collected. Taxa identified in the pollen samples include prickly pear (*Opuntia*), buckwheat (*Eriogonum*), sunflower family (Asteraceae), ragweed/bursage (*Ambrosia*), spurge family (Euphorbiaceae), unidentified pine (*Pinus*), piñon pine (*Pinus edulis*), juniper (*Juniperus*), rose family (Rosaceae), sagebrush (*Artemisia*), cheno-ams, and unidentified grasses (Poaceae). Taxa identified in the flotation samples were all uncharred and included juniper, unidentified pine, and piñon pine. No macrobotanical samples were identified during the excavations. Figure 16.3 shows 103N/79E looking north along the boundary of Los Alamos County and San Ildefonso properties.

Figure 16.3. 103N/79E, looking north.

108N/137E

This unit was located in the southeastern portion of the site where it was thought a possible buried feature was located. The top few centimeters of this unit were covered by pine duff and loose sand. The tuff rocks originally thought to be of possible cultural origin turned out to be merely sitting atop the surface, with no underlying structure. The top 20 to 25 cm of fill was a clayey-sandy loam with about 20 percent pea gravels. Below this and down to about 50 cm the silt was more of a silty, sandy loam with about 10 percent pea gravels and some broken tuff that appeared to be from bedrock. Artifacts recovered from this test unit included four pieces of debitage from the top 4 cm of fill and 23 pieces of debitage from 4 to 50 cm. The debitage were mostly obsidian, with some chalcedony, Pedernal chert, and basalt.

Two pollen samples (FS 276 and FS 277) and flotation samples (FS 270 and FS 271) were collected. Taxa identified in the pollen samples include the following: maize (*Zea mays*), beeweed (*Cleome*), sunflower family, ragweed/bursage, spurge family, evening primrose (Onagraceae), unidentified pine, juniper, oak (*Quercus*), rose family, sagebrush, cheno-ams, and unidentified grasses. Identified taxa in the flotation samples were all uncharred and included juniper, unidentified pine, piñon pine, and ponderosa pine (*Pinus ponderosa*). Figure 16.4 shows both of the excavated units in profile. The stratigraphy depicted in this figure is based on what excavators described during excavation; it does not depict the more complicated nature of the sediments described by Drakos and Reneau in the previous section.

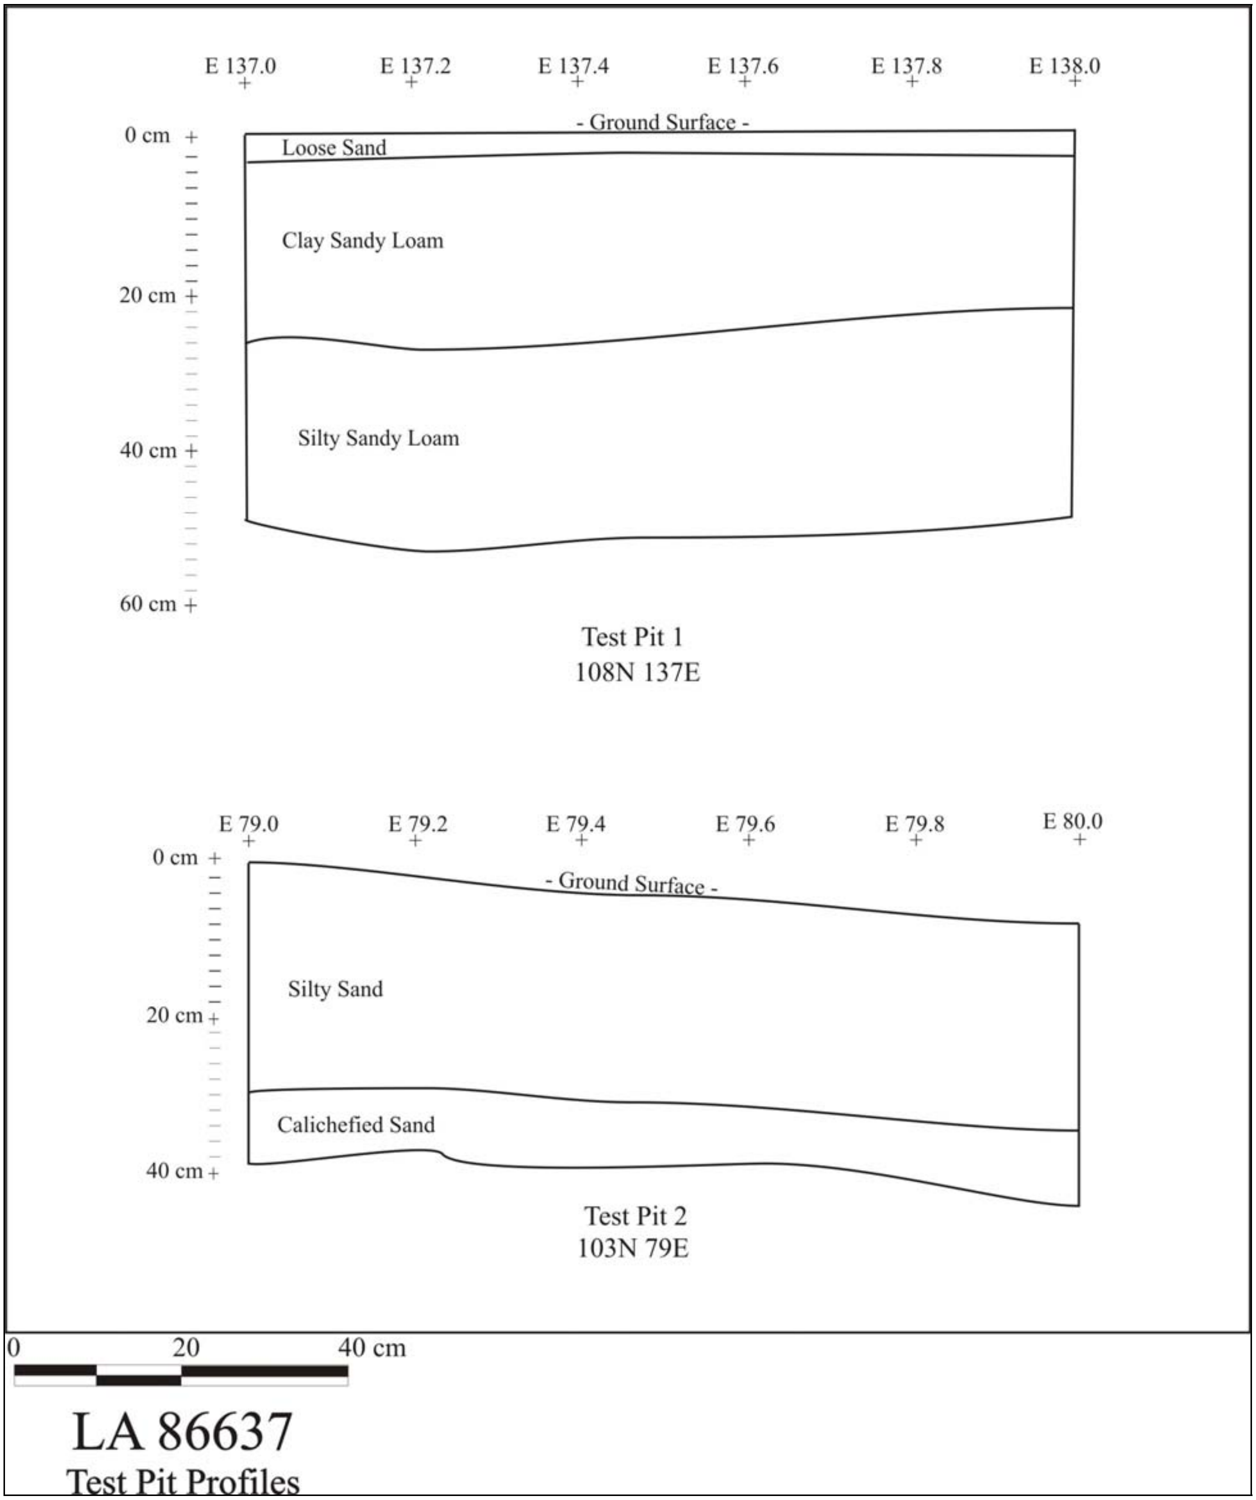

Figure 16.4. Soil profiles from LA 86637.

SITE CHRONOLOGY AND ASSEMBLAGE

Some 650 total artifacts were recovered from excavations at LA 86637 and all recovered artifacts were analyzed. Analyses of the ceramics, lithics (chipped and ground stone), archaeobotanical, and palynological materials were conducted. No faunal remains or vegetal remains were recovered during excavations, and no radiocarbon dates were submitted due to a lack of organic materials; however, obsidian artifacts were submitted for hydration dating. Results of analyses are presented in the following sections.

Obsidian Hydration

Ten obsidian artifacts from LA 86637 were submitted to Diffusion Laboratory for age determination using the obsidian hydration method. In order to calculate the absolute date for an obsidian artifact, three analytical procedures were completed. First, the amount of surface hydration, or the thickness of the hydration rind, was measured. Second, the high temperature hydration rate constants for each artifact were determined from the composition of the glass. Lastly, the soil temperature and relative humidity at the archaeological site was estimated in order that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. Using these methods, a hydration rate for the obsidian artifacts was calculated (Table 16.4).

Table 16.4. Obsidian hydration dates for LA 86637.

FS No.	Lab No.	Source	Rim (um)	AD/-BC	1 S.D.
2	2003-100	Cerro Toledo	3.91	-2215	216
11-2	2003-101	Valle Grande	3.79	-2015	212
11-1	2003-102	Cerro Toledo	4.74	-3996	254
18	2003-103	Valle Grande	3.63	-1710	205
86-1	2003-104	Cerro Toledo	3.24	-880	177
86-2	2003-105	Valle Grande	4.07	-2726	233
181	2003-106	Cerro Toledo	N/A		
230	2003-107	El Rechuelos	3.05	-699	177
245	2003-108	Cerro Toledo	4.68	-3991	257
S#3	2003-109	Cerro Toledo	3.67	-1567	194

The obsidian hydration dates provide a wide range from 3996 to 699 BC. On the other hand, a possible Late Archaic point was dated to 1567 BC. It is heavily reworked with a concave base and could reflect an Armijo (or San Jose) style point. Nonetheless, the dates appear to reflect both Middle and Late Archaic occupations.

Ceramics (Dean Wilson)

The distributions of ceramic types documented during the analysis of 110 sherds from the fieldhouse and artifact scatter at LA 86637 indicate a Late Coalition and Early Classic period assemblage (Table 16.5).

Table 16.5. Ceramic types from LA 86637.

Ceramic Type	Frequency	Percent
Unpainted undifferentiated	17	18.5
Indeterminate organic paint	1	1.1
Santa Fe Black-on-white	5	6.4
Biscuitware painted unspecified	22	23.9
Unpainted Biscuitware (slipped one side)	2	2.2
Biscuit A (Abiquiu Black-on-gray)	3	3.3
Biscuit B (Bandelier Black-on-gray)	2	2.2
Biscuit B/C	2	2.2
Unknown gray rim	2	2.2
Plain gray body	11	12.0
Indented corrugated	5	5.4
Plain corrugated	1	1.1
Smeared plain corrugated	3	3.3
Smeared-indented corrugated	7	7.6
Glaze red body unpainted	2	2.2
Los Padillas glaze polychrome	1	1.1
Total	**110**	**100.0**

A fairly late date is reflected by distributions of decorated whiteware types that make up 70.9 percent of the pottery from this site. All the whitewares exhibit tuff temper, pastes, and styles indicative of Rio Grande (or Tewa) tradition types (Tables 16.6 and 16.7). The majority of whitewares consist of jar forms (Table 16.8), and this dominance of whiteware jars may partly reflect the influence of only a few vessels. Decorated whiteware assemblages from all major contexts are dominated by Biscuitware types with Biscuit B (Bandelier Black-on-gray), Biscuit A (Abiquiu Black-on-gray), and some Santa Fe Black-on-white sherds.

Table 16.6. Tradition by ware for ceramics from all contexts.

Tradition	Ware			Total
	Gray	White	Glaze	
Northern Rio Grande (Prehistoric)	29	78	--	107
Middle Rio Grande	--	--	3	3
Total	**29**	**78**	**3**	**110**

Table 16.7. Temper by ware for all contexts.

Temper	Ware						Total	
	Gray		White		Glaze			
Indeterminate	1	3.4	--	--	--	--	1	0.9
Granitic (mica, quartz, and feldspar)	12	41.4	1	1.3	--	--	13	11.8
Fine tuff or ash	--	--	68	87.2	--	--	68	61.8
Gray crystalline basalt	--	--	--	--	3	100.0	3	2.7
"Anthill" sand	16	55.2	--	--	--	--	16	14.5
Mica and tuff	--	--	2	2.6	--	--	2	1.8
Tuff and phenocrysts ("anthill" sand)	--	--	7	9.0	--	--	7	6.4
Total	**29**	**100.0**	**78**	**100.0**	**3**	**100.0**	**110**	**100.0**

An Early Classic period association is also supported by the presence of glazewares, which represent 2.7 percent of the pottery from this site. Glazeware types noted include red slipped body and Los Padillos Polychrome that dates to the 14th century. All of these sherds are tempered with basalt (Table 16.7) commonly found in pottery produced in areas of the Middle Rio Grande to the south.

Gray utilityware types consist of 26.4 percent of the pottery from this site and indicate similar trends. The graywares show a fairly even mix of anthill sand and micaceous granite temper (Table 16.7). Surface manipulations are about equally divided between plain and smeared corrugated forms.

Table 16.8. Form by ware for LA 86637 ceramics.

Vessel Form	Ware						Total	
	Gray		White		Glaze			
Indeterminate	2	6.9	6	7.7	--	--	8	7.3
Bowl rim	--	--	4	5.1	--	--	4	3.6
Bowl body	--	--	15	19.2	1	33.3	16	14.5
Jar neck	3	10.3	19	24.4	--	--	22	20.0
Jar rim	2	6.9	2	2.6	--	--	4	3.6
Jar body	22	75.9	32	41.0	--	--	54	49.1
Body sherd polished int-ext	--	--	--	--	2	66.7	2	1.8
Total	**29**	**100.0**	**78**	**100.0**	**3**	**100.0**	**110**	**100.0**

The combination of decorated and utilityware pottery from LA 86637 is consistent with a component dating to the Early Classic period, spanning from circa AD 1300 to 1400. The five Santa Fe Black-on-white sherds are consistent with a Late Coalition period component.

Chipped and Ground Stone (Bradley Vierra and Michael Dilley)

Material Selection

A total of 533 lithic artifacts were analyzed from LA 86637, consisting of five cores, 244 pieces of debitage, five retouched tools, and 26 ground stone items. This represents a 100 percent sample of the lithic artifacts recovered during the site excavations. Table 16.9 presents the data on lithic artifact type by material type. The majority of the debitage is made of obsidian, with some chalcedony, basalt, and Pedernal chert materials. The presence of cortex on 10.9 percent of the debitage indicates that the materials were collected from both secondary waterworn (52.8%) and primary nodule sources. The obsidian is present at nearby sources in the Jemez Mountains, whereas, the chalcedony and Pedernal chert are available from local Rio Grande Valley gravel sources and the basalt from local bedrock outcrops. Otherwise, the ground stone artifacts are made of local igneous materials, with quartzite and sandstone. The source of the sandstone is difficult to determine, but it could have been derived from gravel formations near Totavi or more distant sources in the Santa Fe or Abiquiu areas.

Table 16.9. LA 86637 lithic artifact type by material type.

Seventeen pieces of debitage, one core, and two projectile points were submitted for X-ray fluorescence analysis (Table 16.10). Analyses show that the majority of the artifacts were obtained from the Cerro Toledo source, with three from the Valle Grande and four from the El Rechuelos source areas (see Shackley, Volume 3). The Cerro Toledo (Rabbit Mountain/Obsidian Ridge) and Valle Grande (Cerro del Medio) source areas are located about 15 km (10 miles) as the "crow flies" to the southwest and west of the site, while the El Rechuelos (Polvadera Peak) source area is situated about 30 km (19 miles) to the northwest.

Table 16.10. Obsidian source samples from LA 86637.

Lithic Reduction

The cores were reduced using single-directional/single-face, bidirectional/opposed-different-face, and multi-directional/globular technique. Figure 16.5 illustrates the multi-directional core. Two cores were produced on large flake blanks and another was identified as a core fragment. Three of the cores were broken due to material flaws, two were exhausted, one was considered still useable and reason for discard was undetermined for the core fragment. Table 16.11 presents the metric information on these cores.

Table 16.11. Core type dimensions (mm) and weight (gm).

Core Type	Length	Width	Thickness	Weight
Single-directional	28	37	38	38.8
Bi-directional	52	90	45	227.6
Multi-directional	67	55	50	201.5
Multi-directional	27	26	17	8.3
Flake core	35	45	18	24.6
Flake core	23	63	47	73.2

The debitage mainly consists of core flakes (46.7%) and biface flakes (26.7%), with some angular debris, microdebitage, and other items. Table 16.12 summarizes the various stages of reduction represented by the whole core and biface (tertiary) flakes. An overall cortical:noncortical ratio of 0.22 reflects an emphasis on the later stages of core reduction.

Table 16.12. Debitage reduction stages.

Material	Primary	Secondary Cortical	Secondary Non-cortical	Tertiary	Cortical: Non-cortical ratio
Basalt	0	0	7	1	---
Obsidian	0	1	2	5	0.14
Chalcedony	0	4	9	2	0.36
Pedernal chert	0	1	1	0	0.50

Material	Primary	Secondary Cortical	Secondary Non-cortical	Tertiary	Cortical: Non-cortical ratio
Total	0	6	19	8	0.22
Percentage	0	18.1	0.50	21.0	---

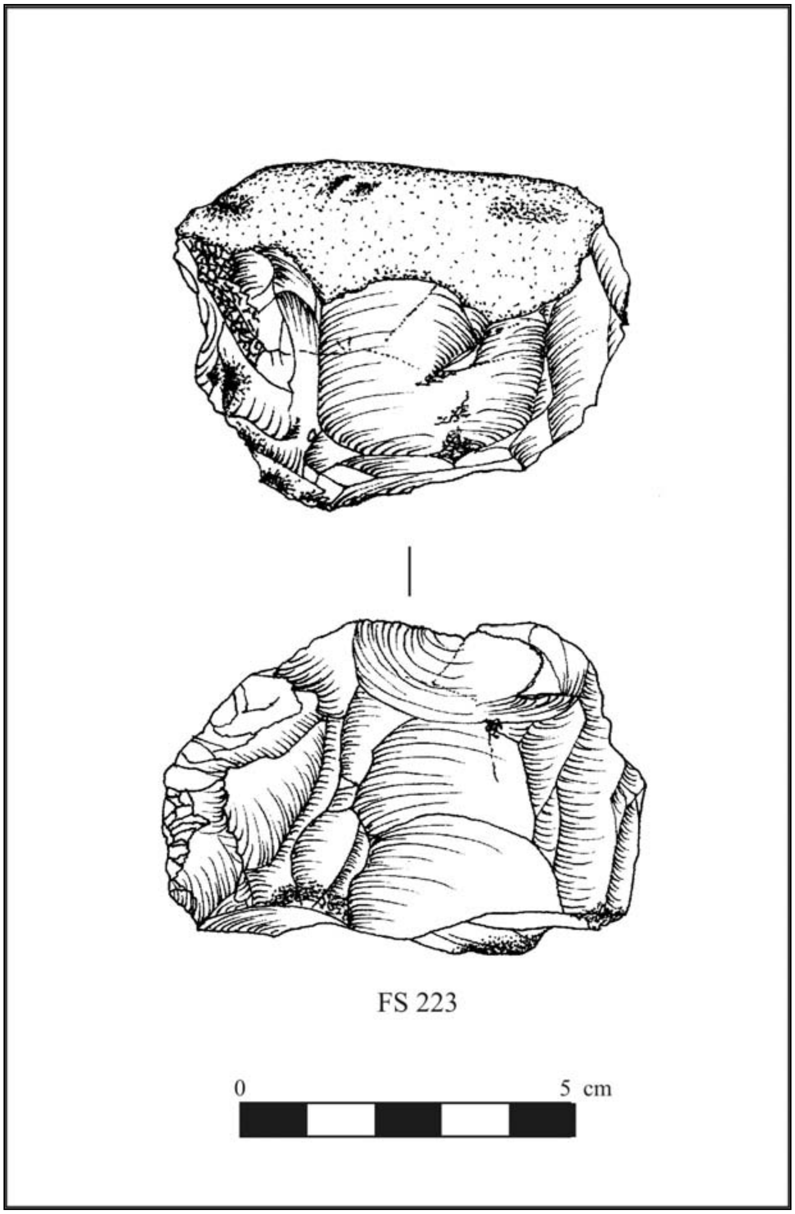

Figure 16.5. Multi-directional core (top and side).

The majority of the flakes exhibit single platforms (48.4%; *n* = 38), with cortical (*n* = 9), dihedral (*n* = 3), multi-faceted (*n* = 6), collapsed (*n* = 15), and crushed (*n* = 18) platforms as well. Thirty six (36.6%) of the flake platforms exhibit evidence of preparation, with most of these being abraded/crushed, retouched/abraded (*n* = 7), and ground (*n* = 1).

The majority of the core flakes consist of distal fragments (*n* = 125; 55.3%), with fewer whole (*n* = 30), proximal (*n* = 27), midsection (*n* = 42), lateral (*n* = 1), and undetermined flake (*n* = 1) fragments. Most of the biface flakes are also midsection fragments (*n* = 43; 41.0%), with fewer whole (*n* = 9), proximal (*n* = 33), and distal (*n* = 44) fragments. The whole core flakes have a mean length of 27.0 mm (*std* = 8.9), whereas, the whole biface flakes exhibit a mean length of 21.7 mm (*std* = 8.5). Lastly, angular debris have a mean weight of 6.2 g (*std* = 8.8).

The retouched tools mostly consist of formal tools like bifaces, projectile points, and unifaces, with some expedient tools like retouched pieces. The retouched pieces primarily exhibit marginal retouch along a single edge, with one having two retouched edges. Table 16.13 presents the information on retouch type by edge outline. Two other expedient tools were also identified. One is a retouched piece/perforator and the other is a notch or denticulate.

Table 16.13. Retouched pieces from LA 86637.

Retouch Type	Edge Outline						
	Straight	Concave	Convex	Straight/ concave	Straight/ convex	Concave/ convex	Projection
Unidentified ventral	1	0	0	0	0	0	0
Unidentified dorsal	0	0	1	2	0	0	0
Bidirectional	1	0	0	0	0	0	0
Total	**2**	**0**	**1**	**2**	**0**	**0**	**0**

The biface is whole and irregularly shaped. It has a thickness of 7 mm and edge angle of 55 degrees, indicating that it was discarded at the early to middle stage of the reduction process. The projectile points appear to be Late Archaic dart points with neck widths of 9 to 17 mm. Two are corner-notched and one is a stemmed point. One of the corner-notched points has a broken tip and the other two points have heavily resharpened blades. Metrical and descriptive information on the projectile points is presented in Table 16.14 and illustrated in Table 16.13 and Figure 16.6.

Table 16.14. Projectile point metrical (mm) and descriptive data.

FS	Material	Condition	Overall Length	Blade Length	Neck Width	Stem Length	Stem Width	Thickness	Weight (gm)	Haft Type	Blade Shape	Base Shape
S3	Obsidian	Whole	20	13	17	7	22	5	2.1	Stemmed	Straight	Concave
2	Obsidian	Whole	18	13	9	5	14	3	0.9	Corner-notched	Straight	Straight

FS	Material	Condition	Overall Length	Blade Length	Neck Width	Stem Length	Stem Width	Thickness	Weight (gm)	Haft Type	Blade Shape	Base Shape
86	Obsidian	Proximal	--	--	13	8	17	4	2.7	Corner-notched	Straight	Straight

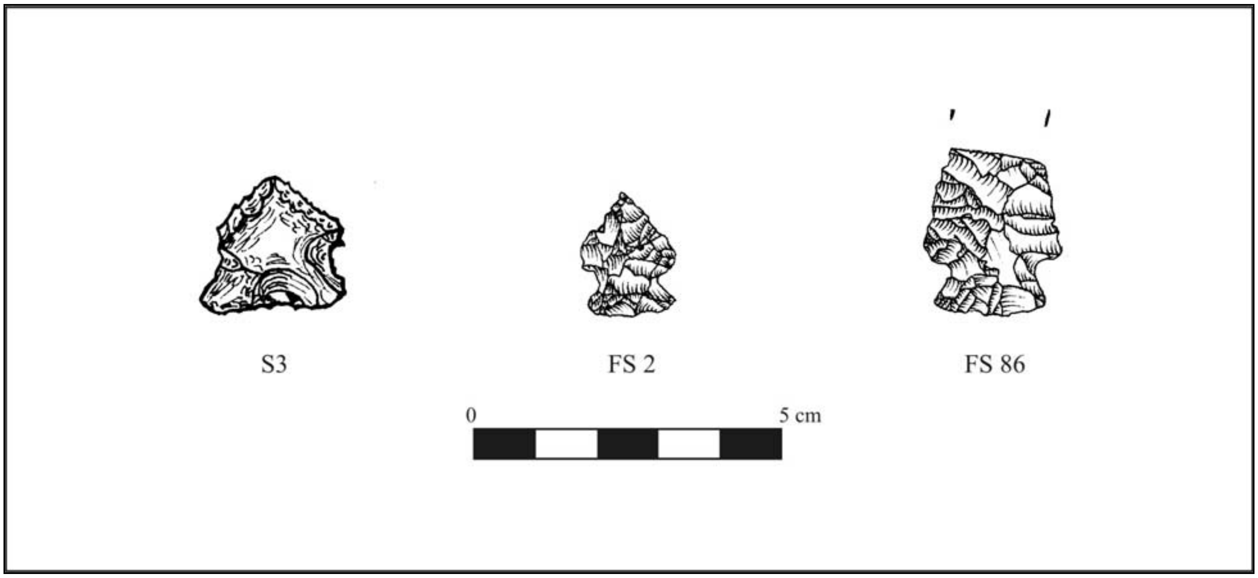

Figure 16.6. Projectile points.

Tool Use

Only six flakes (1.2%) exhibit evidence of damage that could be attributed to use-wear**.** Three have straight and one has a convex lateral edge with angles ranging from 20 and 70 degrees, whereas, the fifth was utilized on an end with a straight outline and angle of 25 degrees. The sixth flake exhibits a utilized projection.

Three of the retouched pieces exhibit rounding/scarring use-wear and the proximal projectile point fragment may have an impact fracture.

A large number of ground stone items were present in this assemblage. The one-hand manos are all cobbles with one or two grinding surfaces. The grinding slab is a tabular piece of sandstone that is ground on both surfaces, which may actually represent a millingstone fragment. The undetermined metate fragments mostly consist of burned tabular pieces of possible millingstones, whereas, the undetermined ground stone fragments are small pieces of tabular or cobble materials. Many of these also exhibit evidence of burning.

Archaeobotanical Remains (Pamela McBride)

One unidentifiable plant part fragment was the sole cultural plant remains recovered from LA 86637 (Table 16.15). The balance of the floral assemblage was unburned conifer duff, including twigs, needles, cones, and bark. This artifact scatter appeared to contain components dating from the Late Archaic, Coalition, and Classic periods and was also associated with a Classic period fieldhouse. The paucity of cultural plant remains is not surprising given the secondary nature of the deposits.

Table 16.15. Flotation sample plant remains from Test Pits 1 and 2.

Feature	Test Pit 1 108N/137E		Test Pit 2 103N/79E	
	stratum 2, level 2	stratum 3, level 2	stratum 1, level 1	stratum 2, level 4
Cultural Other				
Unidentifiable		pp 1(0)		
Non-Cultural Perennials				
Juniper	twig +	twig +	♀ cone +, twig +	twig +
Pine	♂ cone +	bs +	♂ cone +	
Piñon	needle +	needle +	needle +	needle +
Ponderosa pine	needle +			

Cultural plant remains are charred, non-cultural plant remains are uncharred.
+ 1-10/liter, bs barkscale, cf. compares favorably.

Pollen Remains (Susan J. Smith)

Three pollen samples were analyzed from LA 86637. Table 16.16 lists the frequency of identified pollen types. No cultigens were identified in the assemblage. Economic resources identified in the pollen assemblage included only prickly pear. A number of other potential economic resources were identified in the assemblage (Table 16.16), and these are described in detail in Smith's chapter in Volume 3 (Chapter 63).

Table 16.16. Pollen types identified by taxa and common names with sample frequency.

SUMMARY

The artifact assemblage at LA 86637 appears to represent a multi-component site. The projectile points and obsidian hydration dates indicate a possible Middle to Late Archaic component. In contrast, the ceramic assemblage may in part be associated with a nearby Early Classic period fieldhouse (Biscuitwares), with some sherds dating to the Late Coalition period. However, since both the surface as well as the subsurface artifacts appear to be located in a secondary context, it is probable that the majority of the assemblage originated from upslope and was subsequently deposited across the colluvial fan.

CHAPTER 17
WHITE ROCK TRACT (A-19): LA 127625

Kari M. Schmidt

INTRODUCTION AND SITE SETTING

LA 127625 (K-170) is a dispersed artifact scatter situated in a low-lying, flat area just east of the mouth of Cañada del Buey. Some 40 m west of the scatter, the flat lowland gives way to the talus slope of the adjacent mesa. The local vegetation includes juniper, ponderosa pine, prickly pear, sage, and various grasses. The site is situated at an elevation of 1951 m (6400 ft) and is immediately below an electrical substation. Figure 17.1 shows the general site layout.

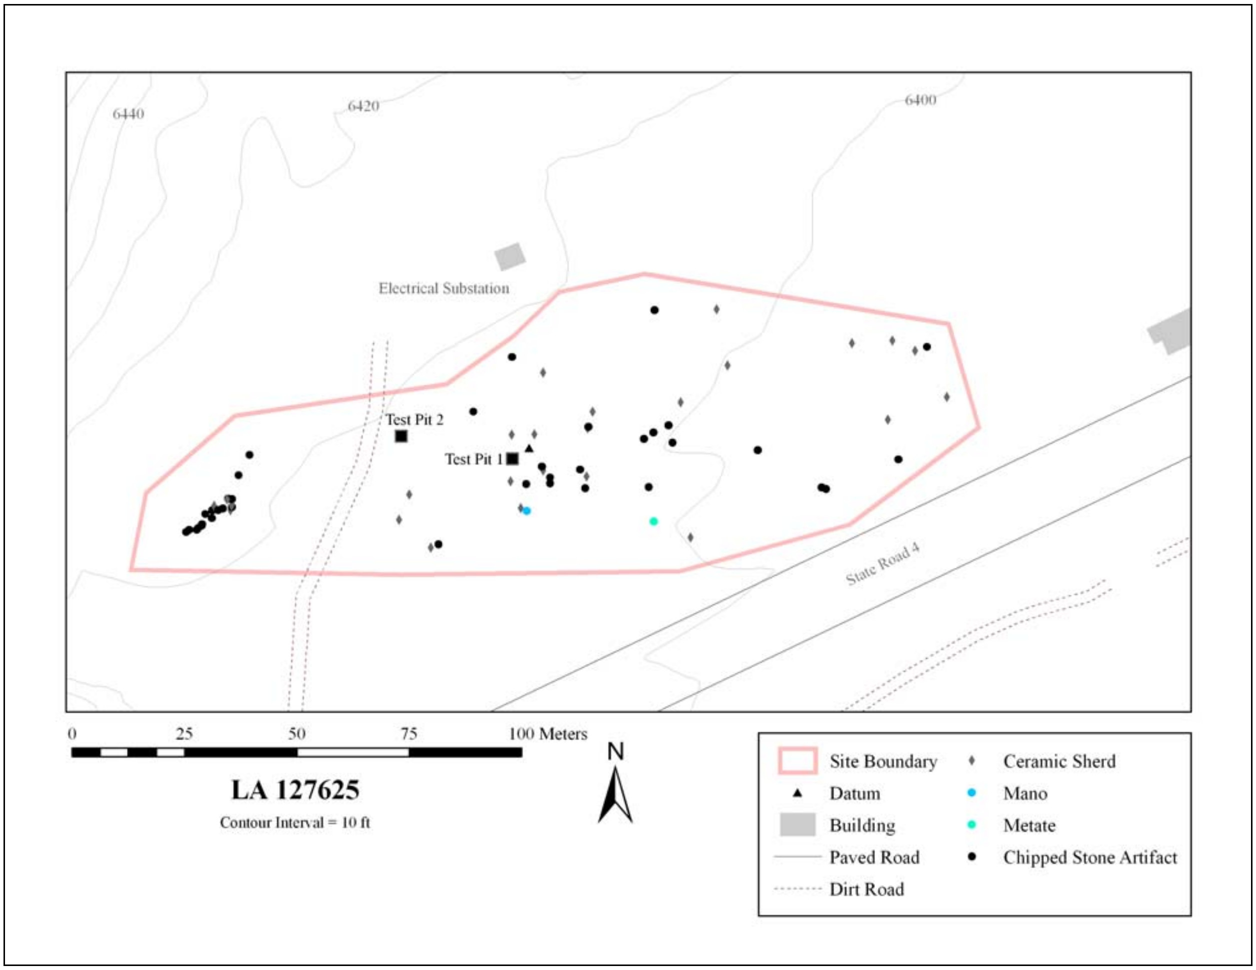

Figure 17.1. General overview of LA 127625.

SITE DESCRIPTION

The artifact scatter is distributed over a 190-m east-west by 65-m north-south area. An in-field analysis was conducted during the initial recording of the site. During this analysis, information was collected on approximately 50 percent of all flagged artifacts (*n* = 140), which are shown in Figure 17.1. Santa Fe Black-on-white ceramics comprised 34 percent of the total ceramic assemblage and smeared-indented and indented corrugated sherds accounted for another 36 percent. Lesser amounts of undefined redwares and Sankawi Black-on-cream were also present, along with a very small number of miscellaneous sherds. Lithic materials were mostly Pedernal chert with lesser amounts of black translucent and opaque brown Jemez obsidian and Polvadera Peak obsidian. A few pieces of basalt and rhyolite debitage were also present. Most of the chipped stone artifacts at LA 127625 were core flakes or pieces of angular debris. One small projectile point fragment was located but was too fragmentary to be identified. A rhyolite milling stone was also recorded during the analysis. Based on the artifact assemblage recorded during the initial phase of this project, the site was thought to date to the Coalition period.

FIELD METHODS

Due to the sparseness of the artifacts at LA 127625 and to their secondary depositional context in colluvium, a site grid was not established. Rather, the site was mapped by acquiring a Global Positioning System (GPS) location for each of the collected artifacts. First, all surface artifacts were located during an intensive pedestrian survey and all identified artifacts were marked with pin flags. Subsequent to this activity, each artifact in the surface assemblage was collected, bagged, and recorded with the GPS unit. Figure 17.2 shows the crew locating and recording the artifacts.

The location of the original site datum, two excavated pits (see below), and a geomorphological pit were also recorded with the GPS unit. A total of 56 lithics, 28 ceramics, and two pieces of ground stone were identified and collected. The lithics found at the site were a mixture of obsidian, chert, and basalt (see results of analysis later in this chapter). The ceramics were a mix of biscuitwares and utilitywares. The ground stone remains included a cobble metate fragment and a one-handed mano fragment.

The artifacts recovered during the surface collection were submitted for analysis. Utilitywares formed the bulk of the ceramic assemblage comprising some 55 percent (Table 17.1). These consist of indented corrugated (3.6%), smeared plain corrugated (21.4%), and plainwares (28.6 %). The majority of decorated ceramics from the surface assemblage were biscuitwares, with lesser amounts of glazewares.

Figure 17.2. Collection of surface artifacts at LA 127625.

Table 17.1. Ceramic types from LA 127625.

Ceramic Types	Frequency	Percent
Northern Rio Grande Whitewares		
Unpainted undifferentiated	3	10.7
Indeterminate organic paint	2	7.1
Biscuitware, slipped both sides	2	7.1
Biscuitware, painted unspecified	2	7.1
Biscuitware, slipped one side	1	3.6

Biscuit B/C body	1	3.6
Northern Rio Grande Utilitywares		
Plain gray body	8	28.6
Indented corrugated	1	3.6
Smeared plain corrugated	6	21.4
Middle Rio Grande Glazeware		
Glaze red body unpainted	1	3.6
Total	**28**	**100.0**

Based on the collection of surface artifacts, two concentrated artifact areas were identified. One was near the site datum in the center of the scatter, and the other was near the geomorphological pit used during the pre-project soil assessment. Two test units were excavated at the site, one in each concentration. These units were designated as Test Pit 1 (near the site datum) and Test Pit 2 (near the geomorphologic test pit). Units were dug in 10-cm levels to a depth of 50 cm. No artifacts were recovered in the subsurface testing.

STRATIGRAPHY (Paul Drakos and Steve Reneau)

The artifacts recovered at LA 127625 are scattered in an area of thick, late-Holocene colluvium with little soil development (Table 17.2). The colluvium at the site post-dates the Ancestral Puebloan occupation in the area, and the cultural material was likely transported to the site in runoff episodes from nearby slopes and mesa top sites. The cultural material recovered at the site is therefore not in its original archaeological context.

Table 17.2. Stratigraphic sequence used during excavation at LA 127625.

LA 127625 Stratigraphic Summary							
Stratum	**Prov.**	**Maximum Thickness**	**Minimum Thickness**	**Elev.**	**Color**	**Texture**	**Comments**
1	Test pits 1 and 2	0.10	0.04	0–10 cm bgs	10YR5/4	Silty sand	Very thin stratum of silty sand. Also a lot of duff and other vegetal matter. Very recent colluvium.
2	Test pits 1 and 2	0.40	0.20	4–50 cm bgs	10YR4/4	Sandy loam	Sandy loam with slightly more inclusions than Stratum 1 including pebbles and artifacts. No mottles. Lower boundary not identified. Thick layer of colluvium.

SITE EXCAVATION

Excavations at LA 127625 were undertaken by Kari Schmidt (crew chief), Mia Jonsson, Mike Kennedy, Timothy Martinez, and Marjorie Wright. As already mentioned, two test pits were dug at this site. The first, Test Pit 1, was located near the center of the site. The surface of this unit consisted of sparse vegetation and pine duff, which continued down only a couple of centimeters or so. Below this the soil was a sandy loam down to at least 45 cm, where excavations ceased because no artifacts were recovered. Test Pit 2 was located in an area that was free of pine duff, so the soil was a sandy loam from start to finish. The only variation in this soil was the presence of some $CaCO_3$ from 35 to 40 cm below the ground surface. As with the other test pit, no subsurface artifacts were found. Figure 17.3 shows both excavated pits in profile.

SITE CHRONOLOGY AND ASSEMBLAGE

Only 86 artifacts were recovered during excavation and recording activities at LA 127625, and all artifacts were analyzed. Analyses of the ceramics, lithics (chipped and ground stone), and archaeobotanical materials were all conducted. Pollen samples were not taken because the artifacts were all recovered from the surface, which was redeposited late-Holocene soil. No faunal remains were recovered at the site. Three pieces of obsidian were submitted for hydration dating. The results of these analyses are presented in the following pages.

Chronology

Obsidian Hydration Dating

Three obsidian artifacts from LA 127635 were submitted to Diffusion Laboratory for age determination using the obsidian hydration method. In order to calculate the absolute date for an obsidian artifact, three analytical procedures were completed. First, the amount of surface hydration, or the thickness of the hydration rind, was measured. Second, the high temperature hydration rate constants for each artifact were determined from the composition of the glass. Lastly, the soil temperature and relative humidity at the archaeological site was estimated in order that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. Using these methods, a hydration rate for the obsidian artifacts was calculated (Table 17.3).

Table 17.3. Obsidian hydration dates for LA 127625.

FS* No.	Lab No.	Source	Rim (um)	AD/-BC	1 S.D.
7	2003-61	Cerro Toledo	3.18	-740	172

12	2003-63	Valle Grande	4.44	-3291	239

* Field Specimen

The obsidian hydration dates provide a wide range from 3665 to 740 BC, reflecting Middle to Late Archaic occupations.

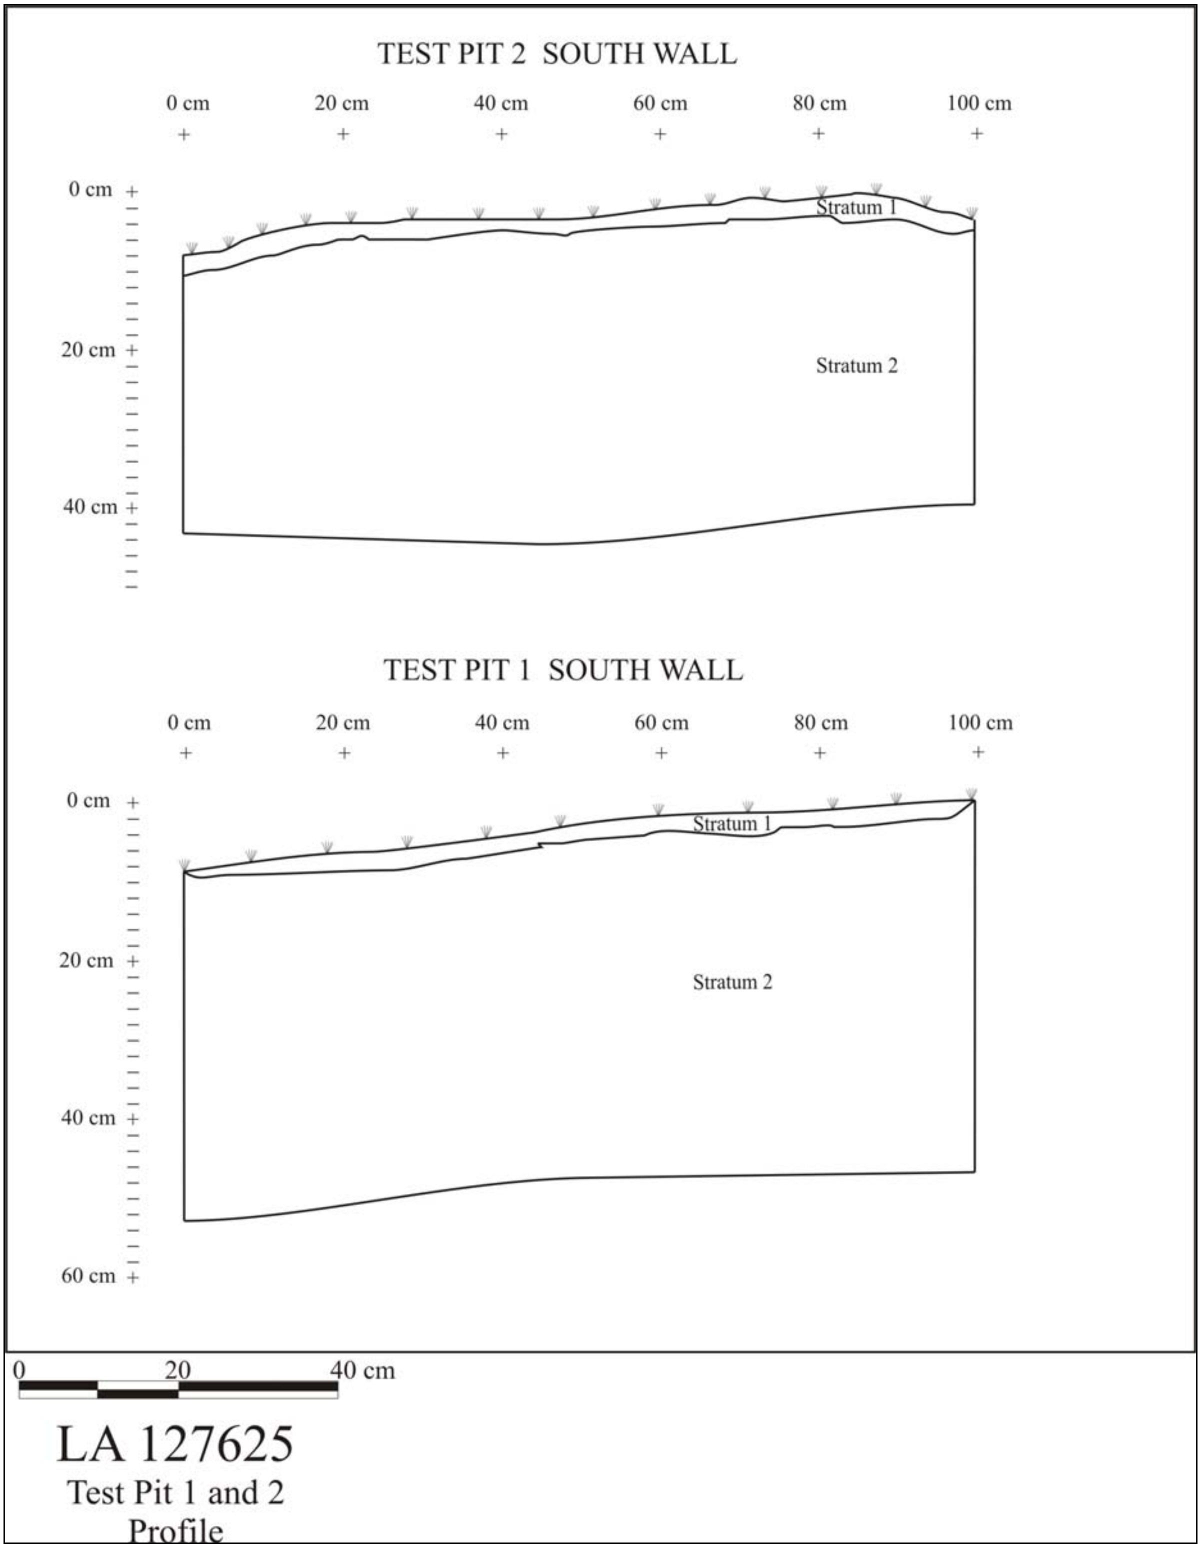

Figure 17.3. Post-excavation profiles of Test Pits 1 and 2.

Ceramic Artifacts (Dean Wilson)

Tables 17.1 and 17.4 through 17.6 show summary ceramic data for LA 127625, including general type, types by tradition, temper material by ware type, and ware by vessel form. Based on the presence of Biscuit B and B/C (Biscuit B?), it appears that the ceramic assemblage primarily reflects a Middle Classic (15th century) occupation.

Table 17.4. Tradition by ware for the LA 127625 ceramic assemblage.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 56 artifacts were analyzed from LA 127625, consisting of one core, 53 pieces of debitage, and two ground stone items. These artifacts represent a 100 percent sample of the lithic artifacts recovered during the site excavations. Table 17.7 presents the data on lithic artifact type by material type. The majority of the debitage is made of obsidian, with less chalcedony and other materials. The presence of cortex on 7.5 percent of the debitage indicates that the materials were collected from both primary nodular (*n* = 1) and secondary waterworn sources (*n* = 3). The obsidian is present at nearby sources in the Jemez Mountains, but two obsidian flakes also exhibit waterworn cortex. In contrast, chalcedony, Pedernal chert, and quartzite are available from local Rio Grande Valley gravel sources and the basalt and andesite from bedrock or stream gravels.

Table 17.7. Lithic artifact type by material type at LA 127625.

Artifact Type		Material Type						
		Basalt	**Andesite**	**Obsidian**	**Chalcedony**	**Pedernal**	**Quartzite**	**Total**
Cores	Core	1	0	0	0	0	0	1

Ground Stone	One-hand mano	0	0	0	0	0	1	1
	Basin metate	1	0	0	0	0	0	1
	Subtotal	1	0	0	0	0	1	2
Total		**4**	**1**	**31**	**15**	**4**	**1**	**56**

Eight pieces of debitage from LA 127625 were submitted for X-ray fluorescence analysis (Table 17.8). Most of the artifacts were identified from the Cerro Toledo (Rabbit Mountain/Obsidian Ridge) source, with only two artifacts coming from the Valle Grande (Cerro del Medio) source (see Shackley, Volume 3). Both of these areas are situated about 15 km (10 miles) as the "crow flies" to the southwest and west of the site.

Table 17.8. Obsidian source samples.

FS #	Artifact	Color	Source
7	Debitage	Translucent	Cerro Toledo rhyolite
10	Debitage	Black opaque	Cerro Toledo rhyolite
12	Debitage	Translucent	Valle Grande rhyolite
21	Debitage	Black opaque	Cerro Toledo rhyolite
55	Debitage	Black opaque	Valle Grande rhyolite

60-1	Debitage	Translucent	Cerro Toledo rhyolite
60-2	Debitage	Translucent	Cerro Toledo rhyolite
62	Debitage	Translucent	Cerro Toledo rhyolite

Lithic Reduction

The single core recovered from this site was reduced using a single-directional, multi-face technique and was classified as still useable when discarded (Figure 17.4). Table 17.9 presents the metric information on this core.

Figure 17.4. Core (FS 37) from LA 127625.

Table 17.9. Core type dimensions (mm) and weight (gm).

Core Type	Length	Width	Thickness	Weight
Single-directional	58	71	54	295.6

The debitage from LA 127625 mainly consists of core flakes (62.6%), with some biface flakes, microdebitage, angular debris, and undetermined flake fragments. The majority of the flakes exhibit single platforms (*n* = 5), with cortical (*n* = 2), crushed (*n* = 3), and collapsed (*n* = 2) platforms. Only two of the flakes exhibit abraded/crushed platforms.

The majority of the core flakes consist of distal fragments (*n* = 17), with fewer whole (*n* = 4), proximal (*n* = 5), and midsection (*n* = 3) fragments. Most of the biface flakes are distal fragments (*n* = 6), with fewer whole (*n* = 1), proximal (*n* = 2), and midsections (*n* = 2). The whole core flakes have a mean length of 20.7 mm (*std* = 5.7), whereas, the single whole biface flake has a length of 33.0 mm. Lastly, the angular debris have a mean weight of 1.0 g (*std* = 0.9).

Tool Use

Only a single flake exhibits evidence of damage that could be attributed to use-wear. It was utilized on the end of the flake with a convex edge outline and angle of 40 degrees.

The ground stone consists of a single one-hand cobble mano with slight grinding on both surfaces and a basin metate fragment.

Archaeobotanical Remains (Pamela McBride)

A single charred goosefoot seed was recovered from Test Pit 1 and a fragment of unknown conifer charcoal was recovered from Test Pit 2 (Tables 17.10 and 17.11). Other floral material consisted of unburned goosefoot (*Chenopodium*), purslane (*Portulaca*), and spurge (*Euphorbia*) seeds and conifer (Gymnospermae) duff. The presence of unburned plant material is not surprising considering that samples were taken from Stratum 1, which was a thin layer of silty sand along with a lot of duff and other detritus. The recovery of the charred floral material is somewhat unexpected and problematic. With no thermal feature present, it is unknown how a carbonized goosefoot seed and conifer charcoal became part of the archaeobotanical record at this lithic scatter.

Table 17.10. LA 127625 flotation sample plant remains.

SUMMARY

In general, LA 127625 appears to be an area of redeposited colluvium, which probably resulted in the secondary deposition of artifacts from sites located upslope of LA 127625. No subsurface cultural deposits were found during excavations in two 1- by 1-m test pits, and with the site situated just below the eastern edge of a mesa where several large pueblo sites are located, it is likely that this factor resulted in the scatter of artifacts found at the site. Based on the presence of Biscuit B and Biscuit B/C (Biscuit B?), it appears that the site primarily dates to the Middle Classic period (15th century); however, the obsidian hydration dates indicate the possible presence of a Middle to Late Archaic component or reuse of these older materials.

CHAPTER 18
WHITE ROCK TRACT (A-19): LA 127631

Kari M. Schmidt

INTRODUCTION AND SITE SETTING

This chapter presents the results of excavations conducted at LA 127631, an Early Classic period fieldhouse and associated artifact scatter located in the White Rock Tract. LA 127631 (Q-247) is a fieldhouse located on the floodplain at the mouth of Pajarito Canyon. Vegetation in the area of the site is dominated by piñon and juniper woodland, with an understory of saltweed, snakeweed, yucca, and various other native grasses, shrubs, and forbs. LA 127631 is situated at an elevation of 1977 m (6494 ft) and is located approximately 75 m downslope to the south of Area 8 at LA 12587 (Chapter 15, this volume). It is also about 75 m north of New Mexico State Road 4.

SITE DESCRIPTION

The site consists of an eroded one-room fieldhouse and a small artifact scatter. The rock alignments consist of approximately 25 shaped and unshaped tuff blocks situated within a 3.0- by 2.2-m area. The tuff blocks average 25 by 18 by 10 cm in size. Active erosion from a small arroyo leading into the canyon floodplain was visible in the western portion of the site area. Figure 18.1 shows the fieldhouse as it looked before excavation. Pin flags show the location of surface artifacts.

During the survey portion of this project (Vierra et al. 2002a), one Santa Fe Black-on-white sherd was observed in a drainage located 2 m from the feature. No other artifacts were identified in the site area. Based on the presumed association of the sherd to the structure, this site was thought to date to the Coalition period. Excavations in the one-room fieldhouse support this assignation, and the paucity of artifacts and the small size suggests the structure may have been used more for on-site storage rather than shelter. Artifacts recovered from the site suggest either (or both) a Late Coalition or Early Classic period use of the fieldhouse.

FIELD METHODS

Fieldwork was conducted at LA 127631 in October 2002, beginning with an initial assessment of the site. The crew walked over the site area, delineating the site boundaries and identifying the presence of artifact concentrations and features. A 1- by 1-m grid system that was laid out during the initial ground-penetrating radar survey (see Chapter 70, Volume 3) was also used during the excavations to facilitate data corroboration. The central site datum (100N/100E for horizontal control, 10.0 m for vertical control) was established in the area to the southwest of the roomblock and a 1- by 1-m grid was laid out. The intersection of the southwest corner of each grid determined its grid coordinates. Using the established grid, controlled surface collections were made across the entire site, with all the materials being bagged separately by individual grid unit. A 225-m^2 area was surface collected.

Figure 18.1. LA 127631 before excavation.

Hand excavations were conducted in 1- by 1-m grid units around the fieldhouse. Excavations were carried out using natural stratigraphic units, or in cases where the natural stratum was greater than 10 cm thick, in arbitrary 10-cm levels. Strata were defined as distinct depositional units and descriptions for each included soil kind, texture, compactness, and color, which were determined by using a Munsell soil chart (see the following section for an in-depth discussion of the stratigraphic sequence). With the exception of materials removed for pollen, soil, and macrobotanical samples, all hand-excavated materials were screened through 1/8-in. mesh.

Stratigraphic profiles were drawn for several of the individual units. Once the fill in the room was removed in stratigraphic layers, the interior room floor was mapped. Locations of floor features, samples, and artifacts were all included on the maps. Pollen samples were taken from underneath artifacts lying on the floor and in features and other locations (corner of the room) where the context might better preserve these remains. Once excavation of the structure was completed, an additional grid unit (108N/104E) was excavated approximately 4 m to the north of the structure to examine the natural stratigraphy of sediments surrounding the fieldhouse. The test unit was excavated to a depth of 50 cm below the ground surface, with an auger test going down to a depth of 1 m.

STRATIGRAPHY (Paul Drakos and Steve Reneau)

LA 127631 is located at the base of a low gradient colluvial hill slope, with an area of fan deposition to the southwest. Excavations at the site show the hillslope is mantled by a thin (<25 cm) layer of young colluvium overlying a Pleistocene soil (Table 18.1; see Drakos and Reneau, Volume 3 for key). Colluvium is fine to very fine sand and may be composed primarily of reworked aeolian sediment. The fieldhouse is buried by 10 to 19 cm of colluvium, with roomblocks set within a Bw horizon at the boundary between a Bw1 and Bw2 horizon (Table 18.2). The site stratigraphy is consistent with the fieldhouse construction corresponding to the time of construction of Roomblock 3 at LA 12587, which is located about 100 m upslope from the site. Scattered lithics and potsherds occur on the surface in this area and may largely represent a lag or may consist of material transported by surface runoff.

SITE EXCAVATION

The excavations at LA 127631 were undertaken by Kari Schmidt (crew chief), Mia Jonsson, Mike Kennedy, and Timothy Martinez. The fieldhouse was excavated in 1- by 1-m units. Natural stratigraphic levels were used. The top centimeter of fill was a combination of duff and loose sand. Below this, the fill consisted of sandy loam, which had several immature pines growing in it. Below the sandy loam was a reddish clay loam. The clay loam stratum was utilized as a floor by the occupants of the fieldhouse. Figure 18.2 shows the excavated structure and the prepared floor. The floor was not plastered, but was compacted from use.

The uppermost stratum (Stratum 1), which contained the majority of the duff, contained only a single flake. More artifacts were found in the room fill (Stratum 2), which was a sandy loam (Table 18.3). This stratum yielded 15 flakes, 12 sherds, nine fragments of ground stone, and six macrobotanical samples.

The six macrobotanical samples submitted for analysis from Stratum 2 produced the following charred and uncharred taxa: rabbitbrush (*Chrysothammus*), unidentified pine (*Pinus* sp.), juniper (*Juniperus*), unknown conifer (Gymnospermae), unknown non-conifer, and saltbush/greasewood (*Atriplex/Sarcobatus*). The chipped stone artifacts recovered from the fieldhouse consist of obsidian and chalcedony debitage and a mix of ceramics, including Santa Fe Black-on-white, Biscuit A (Bandelier Black-on-gray), Glaze red, plain gray, smeared-indented corrugated, and Sapawe Micaceous. A single bifacial core was found on the floor (Stratum 4) and is shown in situ in Figure 18.3 (noted as a scraper). The total size of the structure was approximately 2 by 1.5 m, and no features were identified (Figure 18.4).

Figure 18.2. LA 127631 after excavation.

Table 18.3. Stratigraphic sequence used during excavation at LA 127631.

Provenience	Maximum Thickness	Minimum Thickness	Elevation	Color	Texture	Comments
Stratum 1 (Room 1)	0.04 (m)	0.03 (m)	10.49–10.02	10YR5/4	Duff	Very few inclusions, no artifacts. Some fire-cracked rock on surface and small pebbles in duff. Post-occupational fill.
Stratum 2 (Room 1)	0.35	0.04	10.48–9.98	5YR3/3	Sandy loam	Room fill. Few inclusions, some mottles, and few artifacts. Bottom is Stratum 4, a compact use surface.
Stratum 3 (108N 104E)	0.10	0.02	10.20–10.12	5YR2.5/1	Clay loam	Outside of fieldhouse. Lots of mottles, few artifacts, few to no pebbles. Dark reddish brown.
Stratum 4 (Room 1)	0.01	0.01	10.12–10.00	7.5YR5/3	Clay	Compact use surface of Room 1. Prepared floor. Few artifacts on 'floor', but artifacts and charcoal present. No mottles, some rootlets on surface.
Stratum 5 (108N 104E)	0.07	0.07	10.12–9.99	7.5YR5/4	Silty clay	Outside of fieldhouse. Blocky peds, sub-angular, caliche. Less clay than Strata 3 and 4, but still some present. No artifacts—sterile. Platy.

Eleven flotation samples were processed from materials recovered from the fieldhouse. Charred and uncharred taxa identified in the samples include the following: pigweed (*Amaranthus*), goosefoot (*Chenopodium*), pitseed goosefoot (*Chenopodium berlandieri*), purslane (*Portulaca*), cholla (*Opuntia*), Russian olive (*Elaeagnus angustifolia*), spurge (*Euphorbia*), raspberry/thimbleberry (*Rubus*), grass family (Gramineae), unknown conifer, sunflower (*Helianthus*), juniper, tarweed (*Madia glomerata*), unidentified pine, piñon pine (*Pinus edulis*), prickly pear cactus (*Opuntia*), squash/coyote gourd (*Cucurbita*), maize (*Zea mays*), and sumac (*Rhus*).

Six pollen samples were analyzed from sediments taken from the fieldhouse. Taxa identified in the Stratum 1 (post-occupational fill) pollen samples include the following: sunflower family (Asteraceae), ragweed/bursage (*Ambrosia*), spurge family (Euphorbiaceae), unidentified pine, piñon pine, juniper, rose family (Rosaceae), sagebrush (*Artemisia*), cheno-ams, and unidentified grasses (Poaceae). Taxa identified in the pollen samples (*n* = 2) from Stratum 2 (room fill) include the following taxa: maize, lily family (Liliaceae), nightshade family (Solanaceae), mustard family (Brassicaceae), sunflower family, rose family, penstemon family (Scrophulariaceae), evening primrose (Onagraceae), unidentified pine, piñon pine, juniper, sagebrush, cheno-ams, and unidentified grasses. Taxa identified in Stratum 4 (the floor/surface, *n* = 2) include the following taxa: maize, prickly pear, beeweed (*Cleome*), long spine sunflower, sunflower family, parsely family (Apiaceae), spurge family, rose family, unidentified pine, piñon pine, juniper, cheno-ams, and unidentified grasses. A 1- by 1-m geomorphological test pit was excavated just north of the structure. A single pollen sample was taken from this pit and the following taxa were identified: sunflower family, piñon pine, juniper, cheno-ams, and unidentified grasses.

Figure 18.3. Bifacial core on fieldhouse floor.

SITE CHRONOLOGY AND ASSEMBLAGE

Approximately 40 artifacts were recovered from excavations at LA 127631; all artifacts were analyzed. Analyses of the ceramics, lithics (chipped and ground stone), fauna, pollen, and archaeobotanical materials were all conducted. Juniper wood was submitted for radiocarbon dating and two obsidian artifacts for hydration dating. The results of these analyses, as well as associated tables, are presented in the following pages.

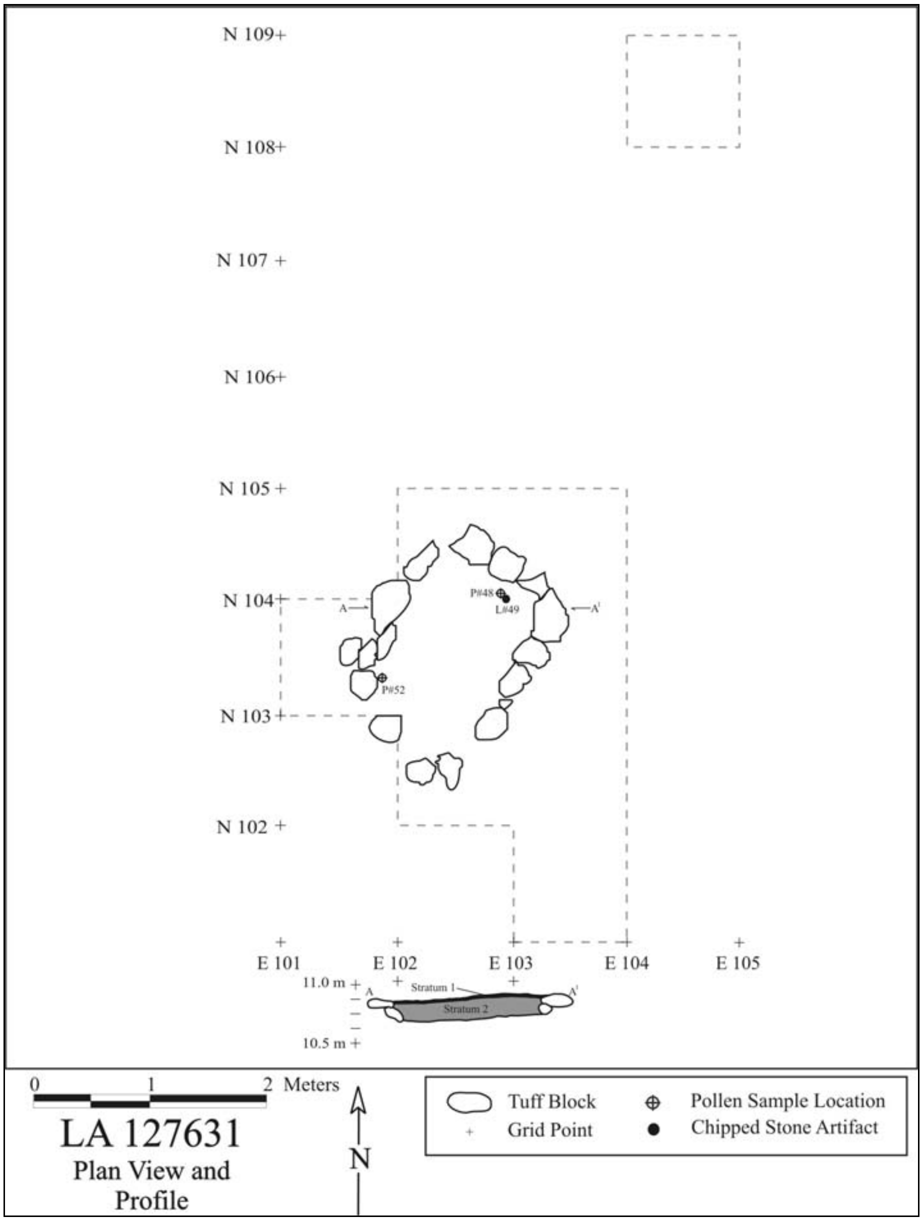

Figure 18.4. Plan view of excavated fieldhouse.

Chronology

Radiocarbon Dating

A single radiocarbon sample was submitted for analysis from this site. A small piece of juniper was collected from a flotation sample (Field Specimen [FS] 32) and dated to the Early Classic period. Table 18.4 presents the information generated from this analysis.

Table 18.4. Radiocarbon dates from LA 127631.

FS#	Material	Laboratory (Beta)#	Conventional radiocarbon age	Intercept of radiocarbon age	2-sigma calibrated result
32	juniper	183754	570±40 BP	AD 1400	AD 1300–1430

Obsidian Hydration Dating

Two obsidian artifacts from LA 127631 were submitted to Diffusion Laboratory for age determination using the obsidian hydration method. In order to calculate the absolute date for an obsidian artifact, three analytical procedures were completed. First, the amount of surface hydration, or the thickness of the hydration rind, was measured. Second, the high temperature hydration rate constants for each artifact were determined from the composition of the glass. Lastly, the soil temperature and relative humidity at the archaeological site was estimated in order that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. Using these methods, a hydration rate for the obsidian artifacts was calculated (Table 18.5).

Table 18.5. Obsidian hydration dates for LA 127631.

FS No.	Lab No.	Source	Rim (um)	AD/-BC	1 S.D.
43	2003-59	El Rechuelos	n/a		
58	2003-60	Cerro Toledo	2.41	395	131

The single obsidian hydration date of AD 395 does not correspond with the radiocarbon date of circa AD 1400 and appears to be much too early. It could therefore reflect the reuse of material dating to the Late Archaic.

Ceramic Artifacts (Dean Wilson)

While only 12 sherds were recovered from the fieldhouse at LA 127631, a wide range of types including Santa Fe Black-white, Biscuit A (Abiquiu Black-on-gray), Glaze red, plain gray, smeared corrugated, and Sapawe Micaceous were noted (Table 18.6). This combination of pottery could indicate either, 1) components dating to both the Coalition and Classic periods, or 2) a period sometime intermediate between these periods. Radiocarbon dates recovered from the fieldhouse (see above) support the latter. Tables 18.7 through 18.9 show the summary ceramic data for this site, including general type, types by tradition, temper material by ware type, and ware by vessel form.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 17 artifacts were analyzed from LA 127631, consisting of a core, 14 pieces of debitage, and two ground stone items. This represents a 100 percent sample of the lithic artifacts recovered during the site excavations. Table 18.10 presents the data on lithic artifact type by material type. The debitage mostly consist of chalcedony and obsidian, with some other materials. Only a single Pedernal chert flake exhibited waterworn cortex, reflecting 7.1 percent of the total debitage assemblage. The obsidian is present at nearby sources in the Jemez Mountains, chalcedony and Pedernal chert from local Rio Grande Valley gravel sources, and the basalt and andesite from bedrock or stream gravels.

Table 18.10. Lithic artifact type by material type from LA 127631.

Artifact Type		Material Type					
		Basalt	Andesite	Obsidian	Chalcedony	Ped-ernal	Total
Cores	Core	0	0	0	1	0	1
	Subtotal	0	0	0	1	0	1
Debitage	Angular debris	1	0	0	0	0	1
	Core flake	0	0	5	4	1	9
	Biface flake	0	0	0	1	0	1
	Microdebitage	0	0	0	2	0	2
	Subtotal	1	0	5	7	1	14
Ground Stone	Undetermined mano fragment	0	1	0	0	0	1
	Abrading stone	0	1	0	0	0	1
	Subtotal	0	2	0	0	0	2
Total		**1**	**2**	**5**	**8**	**1**	**17**

Five pieces of debitage from LA 127631 were submitted for X-ray fluorescence analysis (Table 18.11). The artifacts were from the Cerro Toledo (Rabbit Mountain/Obsidian Ridge) and Valle Grande (Cerro del Medio) source areas, which are located about 15 km (10 miles) as the "crow flies" to the southwest and west of the site (see Shackley, Volume 3). The El Rechuelos (Polvadera Peak) source area is located about 24 km (15 miles) northwest.

Table 18.11. Obsidian source samples.

18	Debitage	Translucent	Valle Grande rhyolite
23	Debitage	Translucent	Cerro Toledo rhyolite
43-1	Debitage	Translucent	Valle Grande rhyolite
43-2	Debitage	Translucent	El Rechuelos
58	Debitage	Translucent	Cerro Toledo rhyolite

Lithic Reduction

The single core identified at LA 127631 was reduced using a bi-directional, bifacial technique and was classified as still useable when discarded. However, given its roughly ovoid shape, the artifact could also be classified as an early stage biface. Table 18.12 presents the metric information on this core. The debitage mainly consists of core flakes (64.2%), with a biface flake, a piece of angular debris, and two pieces of microdebitage.

Table 18.12. Core type dimensions (mm) and weight (gm).

Core Type	Length	Width	Thickness	Weight
Bi-directional	70	57	32	128.5

Only three flake platforms are present and all of these are single-faceted; however, two of the three flakes do exhibit abraded/crushed platforms. The majority of the core flakes consist of distal fragments (n = 6), with fewer whole (n = 1), proximal (n = 1), and midsection (n = 1) fragments. The single biface flake is whole. The single whole core flake has a mean length of 27.0 mm, whereas, the single whole biface flake has a length of 12.0 mm. Lastly, the single piece of angular debris has a weight of 33.3 gm.

Tool Use

None of the flakes exhibits evidence of damage that could be attributed to use-wear**.**

The ground stone consisted of the fire-cracked midsection of a mano that could represent a two-hand variety. The abrading stone is characterized by a small ground surface on an odd-shaped cobble.

Faunal Remains (Kari Schmidt)

A single animal bone was recovered during the excavations at LA 127631. The bone was identified as a proximal cottontail (*Sylvilagus* sp.) femur, was from the right side, and was burned. Because the bone was recovered from the surface, it is not clear whether it was associated with the occupation of the site or not.

Archaeobotanical Remains (Pamela McBride)

One sample (from room fill) of the nine flotation samples from LA 127631 yielded cultural plant remains. These consisted of maize cupules, a maize embryo fragment, and possible squash/coyote gourd (*Cucurbita*) rind (Table 18.13).

Table 18.13. Flotation sample plant remains from LA 127631.

Feature	Post-occupational fill (FS 15)	Room fill, stratum 2, level 1 (FS 29, 32)		Room fill, stratum 2, level 2 (FS 17, 28, 53)			Outside fieldhouse, stratum 3 (FS 42)	Outside fieldhouse, stratum 5 (FS 51, 55)

cf. Sumac									+

All plant remains are seeds unless indicated otherwise; Cultural plant remains are charred, non-cultural plant remains are uncharred; + 1-10/liter, bs barkscale, e embryo, nsg needle spindle gall, pc partially charred, wp whole plant.

Non-cultural plant remains consisted of conifer duff, cactus seeds, weedy annual seeds, grass, a raspberry or thimbleberry seed, a possible sumac seed, and a Russian olive seed. The uncharred seeds from perennial plants are all from fruits and may represent the remains of a meal enjoyed by a rodent or bird. Nine pieces of juniper and two of unknown conifer charcoal were also recovered in flotation samples. Vegetal samples yielded a fragment of unburned, unknown wood and small pieces of juniper, pine, possible rabbitbrush, and saltbush/greasewood charcoal (Table 18.14). The carbonized maize and possible squash rind suggest the occupants may have been enjoying the fruits of their labor and using local conifer and shrub wood for fuel.

Pollen Remains (Susan J. Smith)

Six pollen samples were analyzed from sediments taken from the fieldhouse. Taxa identified in the Stratum 1 (post-occupational fill) pollen samples include the following: sunflower family (Asteraceae), ragweed/bursage (*Ambrosia*), spurge family (Euphorbiaceae), unidentified pine (*Pinus*), piñon pine, juniper, rose family (Rosaceae), sagebrush, cheno-ams, and unidentified grasses (Poaceae). Taxa identified in the pollen samples (n = 2) from Stratum 2 (room fill) include the following taxa: maize, lily family (Liliaceae), nightshade family (Solanaceae), mustard family (Brassicaceae), sunflower family, rose family, penstemon family (Scrophulariaceae), evening primrose (Onagraceae), unidentified pine, piñon pine, juniper, sagebrush, cheno-ams, and unidentified grasses. Taxa identified in Stratum 4 (the floor/surface, n = 2) include the following taxa: maize, prickly pear (*Opuntia/Platy*), beeweed (*Cleome*), long spine sunflower, sunflower family, parsely family (Apiaceae), spurge family, rose family, unidentified pine, piñon pine, juniper, cheno-ams, and unidentified grasses. A 1- by 1-m pit was excavated just north of the structure for geomorphological analyses. A single pollen sample was taken from this pit and the following taxa were identified: sunflower family, piñon pine, juniper, cheno-ams, and unidentified grasses. Maize was the only cultigen identified in the pollen assemblage. Other economic resources in the assemblage included sunflower family, lily family, nightshade family, beeweed, and parsley family.

SUMMARY

LA 127631 is a one-room fieldhouse that may have been used for the in-field storage of crops and/or agricultural equipment. The very small size of the structure indicates that it is unlikely to have been used for even short-term habitation, as it would have been too small to offer much comfort. However, its location near areas suitable for farming and the presence of maize indicate that the site did play a role in agricultural activities. At the time of excavation, the west wall had two stone courses, but the other walls had only a single course. The south wall appeared somewhat disarticulated and was probably where the entryway was located. The ceramic and radiocarbon dates indicate that the structure was probably occupied during the Early Classic period (14th century).

CHAPTER 19
WHITE ROCK TRACT (A-19): LA 128803

Kari M. Schmidt

INTRODUCTION AND SITE SETTING

This chapter presents the results of excavations conducted at LA 128803, an Early Classic period grid garden located in an area of the White Rock Tract slated for economic development. LA 128803 (previous numbers LA 12587A and H-2) is a grid garden located at the mouth of Cañada del Buey, about 140 m north-northwest of State Road 4. Dominant vegetation in the area includes primarily piñon and juniper trees, with an understory comprised of saltweed, snakeweed, yucca, and various other native grasses, shrubs, and forbs. The site is situated at an elevation of 1967 m (6462 ft) and is located on a gentle northeast-facing slope. A fairly deep arroyo that runs east-west is located approximately 35 m north of the grid garden. A two-track powerline road forms the northern boundary of the site perimeter. Large basalt outcrops are located immediately south of the site and were likely the source of construction materials for the grid garden.

SITE DESCRIPTION

The portion of the grid garden that was excavated is composed of several basalt rock alignments located within an area measuring 6 by 3 m. Other subsurface grids were located in a ground-penetrating radar (GPR) survey of the site (see Nisengard et al., Volume 3), but only two were excavated. The site is somewhat eroded, although the integrity of the rock alignments appear to be intact. Figure 19.1 shows the plan view of the site. Only a few artifacts were identified on the surface in the initial visit to the site. These include one chert flake and a quartzite hoe. No ceramics were observed. Based primarily on the construction style of the grid garden and secondarily by the few associated artifacts, the site was given a Classic period assignation. Figure 19.2 shows the relocated hoe on the surface near the southeastern corner of the grid garden. In January of 2003, the quartzite hoe was in the same location as when it was originally identified in 1999, suggesting little disturbance to the area in the four intervening years. The basalt cobbles visible in the photo form the northeastern corner of the eastern grid (see Figure 19.1).

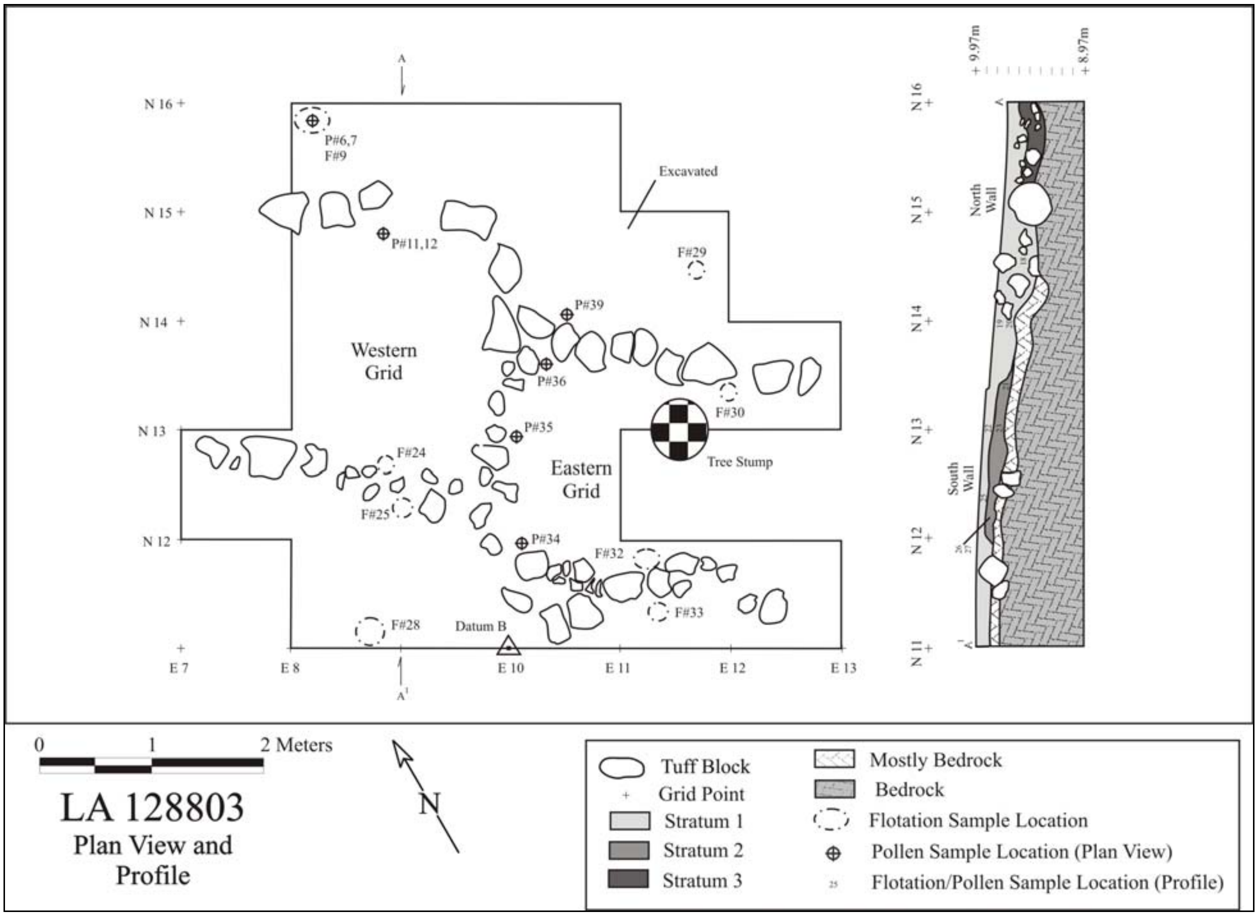

Figure 19.1. Plan view and profile of the grid garden.

FIELD METHODS

Fieldwork began at LA 128803 in early January 2003, with the initial assessment of the site. The crew walked over the site area, delineating the site boundaries and identifying the presence of artifact concentrations and features. Only two surface artifacts were located although a 450-m^2 area was collected. The site grid was set up on the pre-established GPR grid (100N/100E for horizontal control, 10.0 m for vertical control), which was oriented to true north. However, since the excavation strategy for the grid garden was to bisect it as uniformly as possible, a second grid for excavation was laid over the grid garden, matching its orientation. This grid was located at 30 degrees east of north and started at 10N/10E. The 10N/10E point of the superimposed grid corresponded with 100N/106E in the original GPR grid. By doing this, it enabled the trench to be excavated matching the original orientation of the grid garden. In both grids, the intersection of the southwest corner of each grid determined its grid coordinates.

Figure 19.2. Hoe recovered from surface of grid garden.

After the brief surface collection, and starting at the 10N/10E grid point, a meter-wide trench was excavated from outside the upper (or southern) garden wall, through the interior of the grid garden, and on through the lower (or northern) garden wall. This produced a profile that ran parallel to the slope that the grid garden was built to accommodate, thereby offering a look at how effective the garden may have been. Additional excavation was limited to shovel-wide trenches along the inside and outside of the other rock alignments that formed the garden walls. These trenches were dug for two purposes: to increase the number of pollen and flotation samples and to assess the depth and integrity of the grid garden walls. The trenches that paralleled the garden walls averaged approximately 20 to 25 cm deep.

In the meter-wide trench, pollen and flotation samples were collected in distinct stratigraphic units that were determined during site visits by project geomorphologists. Samples of both types were collected upslope and outside of the garden, at several places within the grid garden especially along the middle garden wall and downslope of the garden. Figure 19.1 shows the locations where pollen and flotation samples were collected. The profile can be identified on the plan view by the A-A^1 line. Figures 19.3 and 19.4 show the grid garden as it looked before excavation and after the completion of the meter-wide trench.

Figure 19.3. LA 128803 before excavation with southwest grid visible (north).

Figure 19.4. Trench through LA 128803; upper wall at bottom, middle wall in center, and lower wall at top of photo (south).

STRATIGRAPHY (Paul Drakos and Steve Reneau)

The grid garden is located in an area of discontinuous thin colluvial soils over basalt bedrock. There is a long colluvial slope west of the site that provides surface runoff to the site. The grid gardens may be partially buried by slope wash colluvium. East of the site, the soils thin and the slope becomes steeper above an incised channel of Cañada del Buey.

Four soil profiles were described upslope, within, and downslope of the rock alignments forming the grid garden (Table 19.1; see Drakos and Reneau, Volume 3 for key). Soils were moist when described, and therefore weakly developed soil structure, if present, was difficult to discern. However, two trends are apparent in the soils described in the immediate vicinity of the grid garden. One trend is that the thickness of post-Puebloan soil is greater upslope and within the grid garden, ranging from 16 to 21 cm, than was observed downslope of the grid garden, where the post-Puebloan soil thickness was 10 cm. A second trend is that upper-horizon post-Puebloan soils are finer-grained (a silt loam) within and immediately downslope of the grid garden than was observed upslope of the grid garden (a sandy loam). Both trends are consistent with the rock alignments acting to retain surface runoff and fine-grained slope wash, and are consistent with the rock alignments functioning as a grid garden.

An additional observation was the absence of remnant Pleistocene soils in relatively deep pockets in the basalt within the rock alignments, although such soils were present outside the rock alignments and in a test pit south of the alignments. This observation suggests that first excavating the relatively dense, clay-rich Pleistocene soils, and replacing this material with looser soil may have prepared the area inside the alignments. In general, the soils at LA 128803 are very weakly developed and apparently lack development of Bw horizons observed in Coalition period soils at other White Rock Tract sites. It is therefore inferred that LA 128803 is likely a Classic period feature.

SITE EXCAVATION

The excavations at LA 128803 were undertaken by a combination of graduate and post-baccalaureate students and LANL contractors. The crew consisted of the following people: Aaron Gonzales, Mia Jonsson, Mike Kennedy, Kari Schmidt, and Marjorie Wright.

Table 19.1. Geomorphological characteristics of the LA 128803 deposits.

	R	20+												basalt

Initial excavation at LA 128803 concentrated on units just outside the grid garden walls, at the upslope and downslope extents. Beginning with these first two external excavation units, a trench was completed, connecting them through the grid garden to provide a continuous trench. Due to the fact that the excavation was being done in the winter, much of the soil was frozen, which made for slow going. This being the case, and with time constraints on the project, excavations other than the trench were limited to shovel-wide trenches along either side of grid garden walls to be able to collect pollen and flotation samples from as many parts of the garden as possible for comparison. For this purpose, 15 flotation and 21 pollen samples were collected both inside and outside the grid walls for comparative analysis. The grid garden consisted of two U-shaped rock alignments (eastern and western grids) facing in opposite directions and sharing a common baseline, which were slightly offset from one another (see Figure 19.1). The rocks outlining the sides of the "U" were larger, particularly the ones furthest downslope.

Approximately 5 m to the east of the grid garden, another 1- by 1-m unit was excavated as a geomorphologic control unit to compare the soils associated with the grid garden to that of the surrounding natural stratigraphy (Table 19.2; see stratigraphy section for information on how these two areas differed).

Table 19.2. Stratigraphic sequence used during excavations at LA 128803.

LA 128803 Stratigraphic Summary							
Stratum	**Provenience**	**Maximum Thickness**	**Minimum Thickness**	**Elevation**	**Color**	**Texture**	**Comments**
1	11-14N/9E and 94N/107E	0.37 (m)	0.13 (m)	10.02–9.50	7.5YR4/3	Silty loam	Recent colluvium, upper level. In and out of grid garden.

4	94N/107E	0.10	0.10	9.85–9.75	5YR3/3	Clay	Middle Pleistocene clay. Outside grid garden only.

SITE CHRONOLOGY AND ASSEMBLAGE

Only four artifacts were recovered from excavations at LA 128803 and included three pieces of chipped stone and a quartzite hoe. Analyses of the lithics (chipped and ground stone), pollen, and archaeobotanical materials were all conducted, but no faunal materials were recovered. Results of these analyses are presented in subsequent sections.

Chronology

Only a single radiocarbon sample was submitted for analysis from this site. Several maize (*Zea mays*) cupules were collected from a flotation sample (Field Specimen [FS] 21) taken from inside the western grid and dated to the Early Classic period. Table 19.3 presents this information.

Table 19.3. Radiocarbon dates from LA 128803.

FS#	Context of sample	Laboratory (Beta)#	Conventional radiocarbon age	Intercept of radiocarbon age	2-sigma calibrated result

Chipped and Ground Stone (Bradley Vierra and Michael Dilley)

A total of four artifacts were analyzed, consisting of two pieces of debitage and a hoe. This represents a 100 percent sample of the lithic artifacts recovered during the site excavations. The debitage consists of a chalcedony core flake and piece of rhyolite angular debris. The hoe consists of a tabular quartzite cobble that is notched on both sides, but with no obvious use-wear (Figure 19.5).

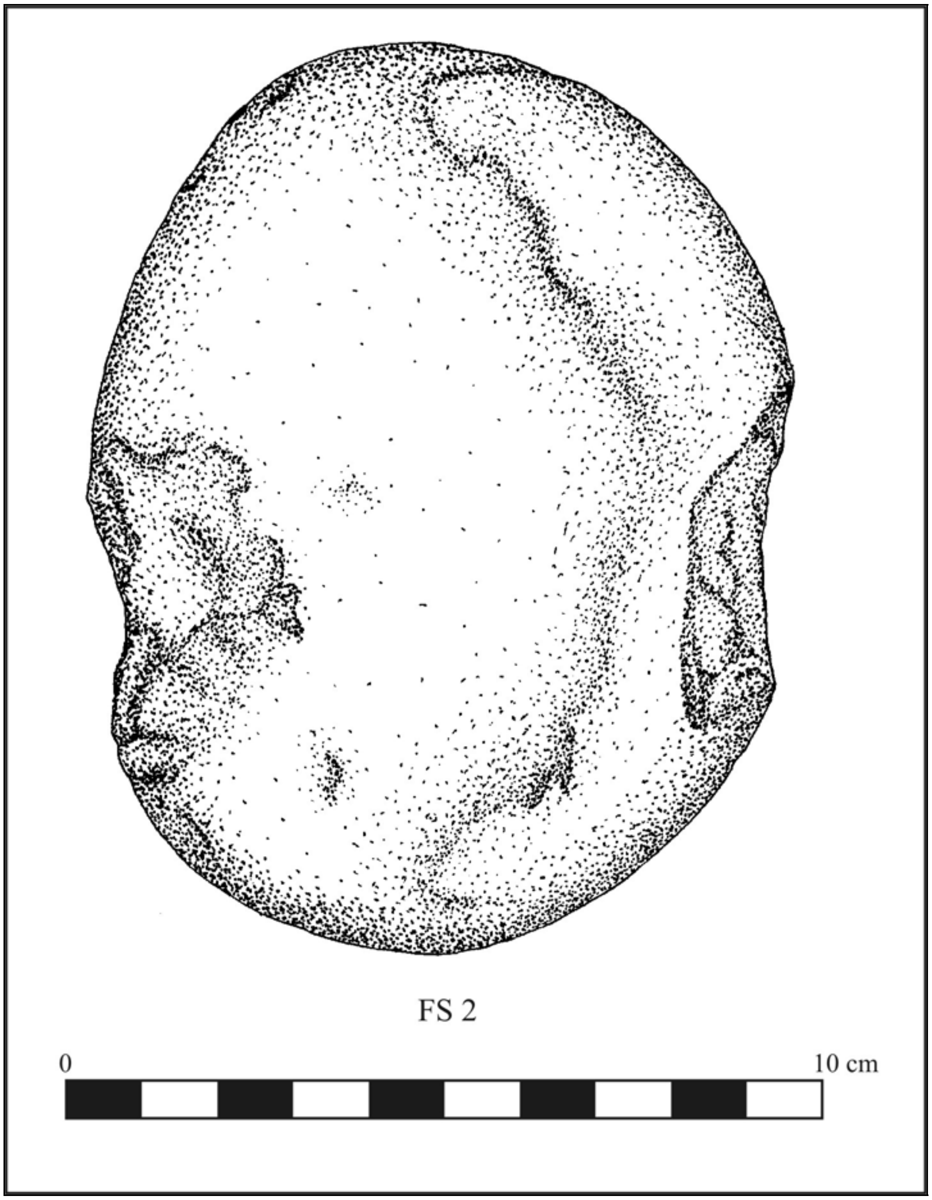

Figure 19.5. Hoe from LA 128803.

Archaeobotanical Remains (Pamela McBride)

Situated at the mouth of Cañada del Buey, farmers who used these grid gardens were taking advantage of run-off from the uplands and the rock borders of the gardens served to capture nutrient-rich sediment. Carbonized corn cupules and goosefoot (*Chenopodium*) and cheno-am (*Chenopodium/Amaranthus*) seeds were identified from three of 10 samples collected from within the grid garden borders (Table 19.4).

All plant remains are seeds unless indicated otherwise; cultural plant remains are charred, non-cultural plant remains are uncharred; + 1-10/liter, bs barkscale, cs conescale, nsg needle spindle gall.

Curiously, a corn cupule fragment was also recovered from Stratum 3 of the test pit that was to the south of the grid gardens. Unknown conifer (Gymnospermae), oak (*Quercus*), rose family (Rosaceae), and saltbush/greasewood (*Atriplex/Sarcobatus*) charcoal were also present. Nearby thermal features were not recorded so it is curious how charred plant remains came to be deposited. Cushing (1974) describes in detail the process of creating a run-off field at the mouth of an arroyo at Zuni. The first year the farmer piles soil up to make an outline of the field boundary and marks the corners with columnar stones. Vegetation is cut away and placed in the center of the field where it is burned. A brush fence is also constructed and strategically placed to catch eolian sediment that results in a fine loam deposit over the field.

Brandt (1995) states that burning brush and the collection of nutrient-laden sediment are the only references to fertilizing fields found in the ethnographic literature. Along with the collection of sediment behind garden borders, it is possible that shelled corncobs and brush were burned to clear or fertilize grid gardens in a similar manner described by Cushing.

Pollen Remains (Susan J. Smith)

Sixteen pollen samples were analyzed in intensive analyses from sediments taken from the grid gardens at LA 128803. Table 19.5 lists the frequency of identified pollen types. Maize and cotton were the only cultigens identified in the pollen assemblage. Economic resources identified in the pollen assemblage included only prickly pear and parsley family. A number of other potential economic resources were identified in the assemblage (Table 19.5), and these are described in detail in Smith's chapter in Volume 3 (Chapter 63).

39	Grid garden	1	1	Out of grids (north end)	Eastern	31	R

Eastern Grid

A trench was excavated through the center of the eastern grid. Taxa identified outside of the grid garden to the north (downslope; FS 6 and FS 7, see Figure 19.1) included the following: cheno-ams, unidentified grasses (Poaceae), mustard family (Brassicaceae), sunflower family (Asteraceae), spurge family (Euphorbiaceae), evening primrose (Onagraceae), unidentified pine (*Pinus*), piñon pine (*Pinus edulis*), juniper (*Juniperus*), oak, rose family, Mormon tea (*Ephedra*), and sagebrush (*Artemisia*). Taxa identified inside the eastern grid just inside the northern wall (FS 11 and FS 12) include the following taxa: maize, ragweed/bursage (*Ambrosia*), cheno-ams, unidentified grasses, sunflower family, globemallow (Sphaeralcea), spurge family, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush. Taxa identified from the center of the eastern grid (FS 19 and FS 20) include the following: maize, cheno-ams, unidentified grasses, mustard family, sunflower family, spurge family, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush. Taxa identified inside the eastern grid just inside the southern (upslope; FS 22 and FS 23) wall include the following taxa: maize, cheno-ams, unidentified grasses, sunflower family, spurge family, evening primrose, fir (*Abies*), unidentified pine, piñon, juniper, oak, rose family, Mormon tea, and sagebrush. Taxa identified outside of the grid garden to the south (upslope; FS 26 and FS27) include the following: maize, prickly pear (*Opuntia*), cheno-ams, unidentified grasses, sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon pine, juniper, oak, rose family, and sagebrush.

Western Grid

Excavations in the western grid were conducted along the grid walls, where shallow trenches were dug. Four pollen samples were analyzed from this grid and were taken from outside the northern (downslope) grid, as well as along the central grid wall (shared with the eastern grid) and in the center. The pollen sample analyzed from just inside the southern (upslope: FS 34) grid wall includes the following taxa: maize, cheno-ams, unidentified grasses, sunflower family, spurge family, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush. Taxa identified along the central wall in the western grid (FS 35) include the following: cheno-ams, unidentified grasses, sunflower family, spurge family, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush. Identified taxa from just inside the northern (downslope) wall of the western grid (FS 36) include the following: cheno-ams, sunflower family, spurge family, piñon pine, and sagebrush. And, taxa identified outside the western grid to the north (downslope; FS 39) include the following: parsley family (Apiaceae), cheno-ams, unidentified grasses, mustard family, sunflower family, ragweed/bursage, spurge family, fir, unidentified pine, piñon pine, juniper, and sagebrush.

Control Unit

Approximately 5 m to the east of the grid garden, another 1- by 1-m unit was excavated as a geomorphologic pit to compare the soils associated with the grid garden to that of the surrounding natural stratigraphy (Table 19.2; see stratigraphy section for information on how these two areas differed). Two pollen samples (FS 15 and FS 17) were collected from this unit to compare the taxa identified inside the grid garden to those identified outside the walls of the garden. Interestingly, the only cotton (*Gossypium*) samples were identified in the area outside the immediate vicinity of the grid garden walls. Taxa identified in this control unit include the following: cotton, prickly pear, cheno-ams, unidentified grasses, sunflower family, ragweed/bursage, evening primrose, spruce (*Picea*), fir, unidentified pine, piñon pine, juniper, oak, rose family, Mormon tea, and sagebrush.

Textiles

Two small pieces of fiber and textile were identified in the flotation samples analyzed from this site, and these items were analyzed by Laurie Webster. The first item was a small tuft of rabbit fur that may have been associated with a rabbit fur blanket. The second item was a small (1.0 cm wide by 1.5 cm long) piece of textile that was identified as a small scrap of silk ribbon (or other textile) woven in satin weave. The selvages on this piece of textile were missing. Webster (personal communication) deemed that this piece of textile was not a pre-contact fabric and that its earliest possible date was Spanish-Colonial. She also concluded that the fabric could have been more recent.

SUMMARY

LA 128803 is a basalt rock grid garden that was constructed using the abundant outcrops located near the site. The grid garden was built by placing U-shaped alignments back to back but slightly offsetting them and sharing the same interior wall. The opening of each grid is perpendicular to the slope of the hill on which the grid garden is located. These openings could have allowed the water to drain after being slowed by the rocks, preventing over-saturation of the ground. Although only two grids were excavated, additional grids were identified during the GPR survey conducted at the site (see Nisengard et al., Volume 3). It appears that the Middle Classic period farmers who used the grid gardens had dug out the native fill from inside the grids of the garden and then refilled them with a more arable mixture of soil. This soil contained the burned remains of maize, as well as maize pollen. In addition, cotton pollen was identified in a separate test pit. However, it is presumed that this pollen was derived from other unexcavated grid garden features in the area. The results of the geomorphological study indicate that these grid gardens were indeed effective in collecting and retaining soil for growing crops.

CHAPTER 20
WHITE ROCK TRACT (A-19): LA 128804

Kari M. Schmidt

INTRODUCTION AND SITE SETTING

This chapter presents the results of the excavations conducted at LA 128804, a Historic period check dam and Late Coalition/Early Classic artifact scatter. LA 128804 (previous numbers LA 12587-B and H-3) includes an isolated check dam situated on a shallow slope at the mouth of Cañada del Buey. The vegetation in the area is dominated by piñon and juniper trees with an understory of saltbush, snakeweed, yucca, and various other native grasses, shrubs, and forbs. The site sits at an elevation of 1980 m (6495 ft), is located approximately 200 m north-northwest of State Road 4, and lies downslope and approximately 140 m east of LA 12587 (Chapter 14, this volume).

SITE DESCRIPTION

The check dam is an alignment of 12 large basalt blocks ranging in size from 0.60 to 1.25 m in length. The 7-m-long alignment bisects a small northeast-to-south-trending drainage. The site area, including artifacts associated with LA 12587, lies primarily in a 10- by 10-m area. Although a few artifacts were present in the immediate area of the feature when it was originally recorded for this project, it is unclear, and probably unlikely, that they are associated with the feature. Artifacts identified in the site area include smeared-indented utilitywares, Santa Fe Black-on-white, and Wiyo Black-on-white sherds, and numerous pieces of chipped and ground stone, which arre commensurate with the occupation of LA 12587. The date and cultural affiliation of the site during the original recording were undetermined. Figure 20.1 shows the check dam before excavation. Pin flags in the vicinity represent uncollected artifacts identified during the surface collection.

FIELD METHODS

Fieldwork began with an initial assessment of the site. The crew walked over the site area, delineating the site boundaries and identifying the presence of artifact concentrations and features to ascertain if and how they related to the check dam. The area was then gridded into 1- by 1-m units, with the site datum (100N/100E for horizontal control, 10.0 m for vertical control) located next to the check dam. These artifacts were collected and bagged for analysis and provenienced to the nearest meter, using the southwest grid corner for the grid designation. Once the surface collection was finished, a 1- by 2-m grid was excavated perpendicular to the angle of the check dam. This feature was actually offset from the site grid by approximately 28 degrees east of north, and the excavation units were likewise offset so as to orient them to the check dam. A 625-m^2 area was collected around the check dam.

Figure 20.1. LA 128804 before excavation; pin flags represent artifacts.

STRATIGRAPHY (Paul Drakos and Steve Reneau)

LA 128804 is a check dam that is approximately 6 m long and consists of tuff clasts up to 60 cm long. The check dam is aligned across a shallow drainage on a colluvial slope downslope from a large Coalition period roomblock (LA 12587). The dam has been partially breached by an incised channel, and some of the tuff has been transported downslope. Additional tuff blocks are scattered down the gradient along this same channel to the east and may represent the eroded remnants of similar structures.

Soil descriptions for Test Pit 1 show that the check dam was constructed on top of young stratified alluvium, possibly less than 100 years old and deposited in an aggrading stream channel (Table 20.1; see Drakos and Reneau, Volume 3 for key). Deposition of approximately 16 cm of young alluvium has occurred at Test Pit 1 and behind the west part of the dam, with minimal deposition apparent elsewhere. Soils and geomorphic data indicate that the check dam at LA 128804 is a recent structure that is likely post-Puebloan in age and less than 100 years old.

Table 20.1. Geomorphological characteristics of soils in Test Pit 1.

Horizon	Depth (cm)	Gravel (%)	Dry Color (Matrix)	Moist Color (Matrix)	Texture	Structure	Dry Consistence	Wet Consistence	Argillans	$CaCO_3$	$CaCO_3$ Stage	Lower Horizon Boundary	Preliminary Age Estimate	Notes
C1	0-16	<2	10YR5/4	10YR4/3	s	sg	lo	so,po	n.o.	none	-	cs	<100 yrs?	slightly moist bits of reworked $CaCO_3$, ms-cs
C2	16-32	<2	-	10YR4/4	ls	m	lo	so,po	n.o.	none	-	aw		stratified fs, moist; blocks set on top of C2
Bwb1	32-42+	<2	10YR5/4	10YR4/3	sl	1msbk	so-lo	so,po	n.o.	none	-	-	<1000 yrs	fine-grained alluvium

The C_1-C_2 horizon was found between 0 and 16 cm below the surface and contained less than 2 percent gravels. The sediments in the horizon are a massive, single-grain, brown sand with a loose consistency. Sediments are non-effervescent except for bits of reworked $CaCO_3$, with a clear, smooth lower horizon boundary. The C_2 horizon is located between 16 and 32 cm below the surface and also contains less than 2 percent gravel. Like the stratum above it, it is massive, loose, and single grain, but is dark yellowish brown and loamy sand. Sediments in this stratum are non-effervescent and form an abrupt boundary. The Bwb1 horizon is located between 32 and 42+ cm below the surface and also contains less than 2 percent gravel. Sediments are massive, sub-angular, blocky, brown and have a sandy loam consistency. They are also non-effervescent.

SITE EXCAVATION

The excavations at LA 128804 were undertaken by Kari Schmidt (crew chief), Aaron Gonzales, Mia Jonsson, Mike Kennedy, Bettina Kuru'es, and Timothy Martinez.

Two units were excavated perpendicular to the check dam (Figure 20.2). Test Pit 1 included the area downslope of the dam, as well as the stones of the dam itself and a small portion of the upslope side of the dam. Test Pit 2 was immediately adjacent to Test Pit 1 and on the upslope side of the dam.

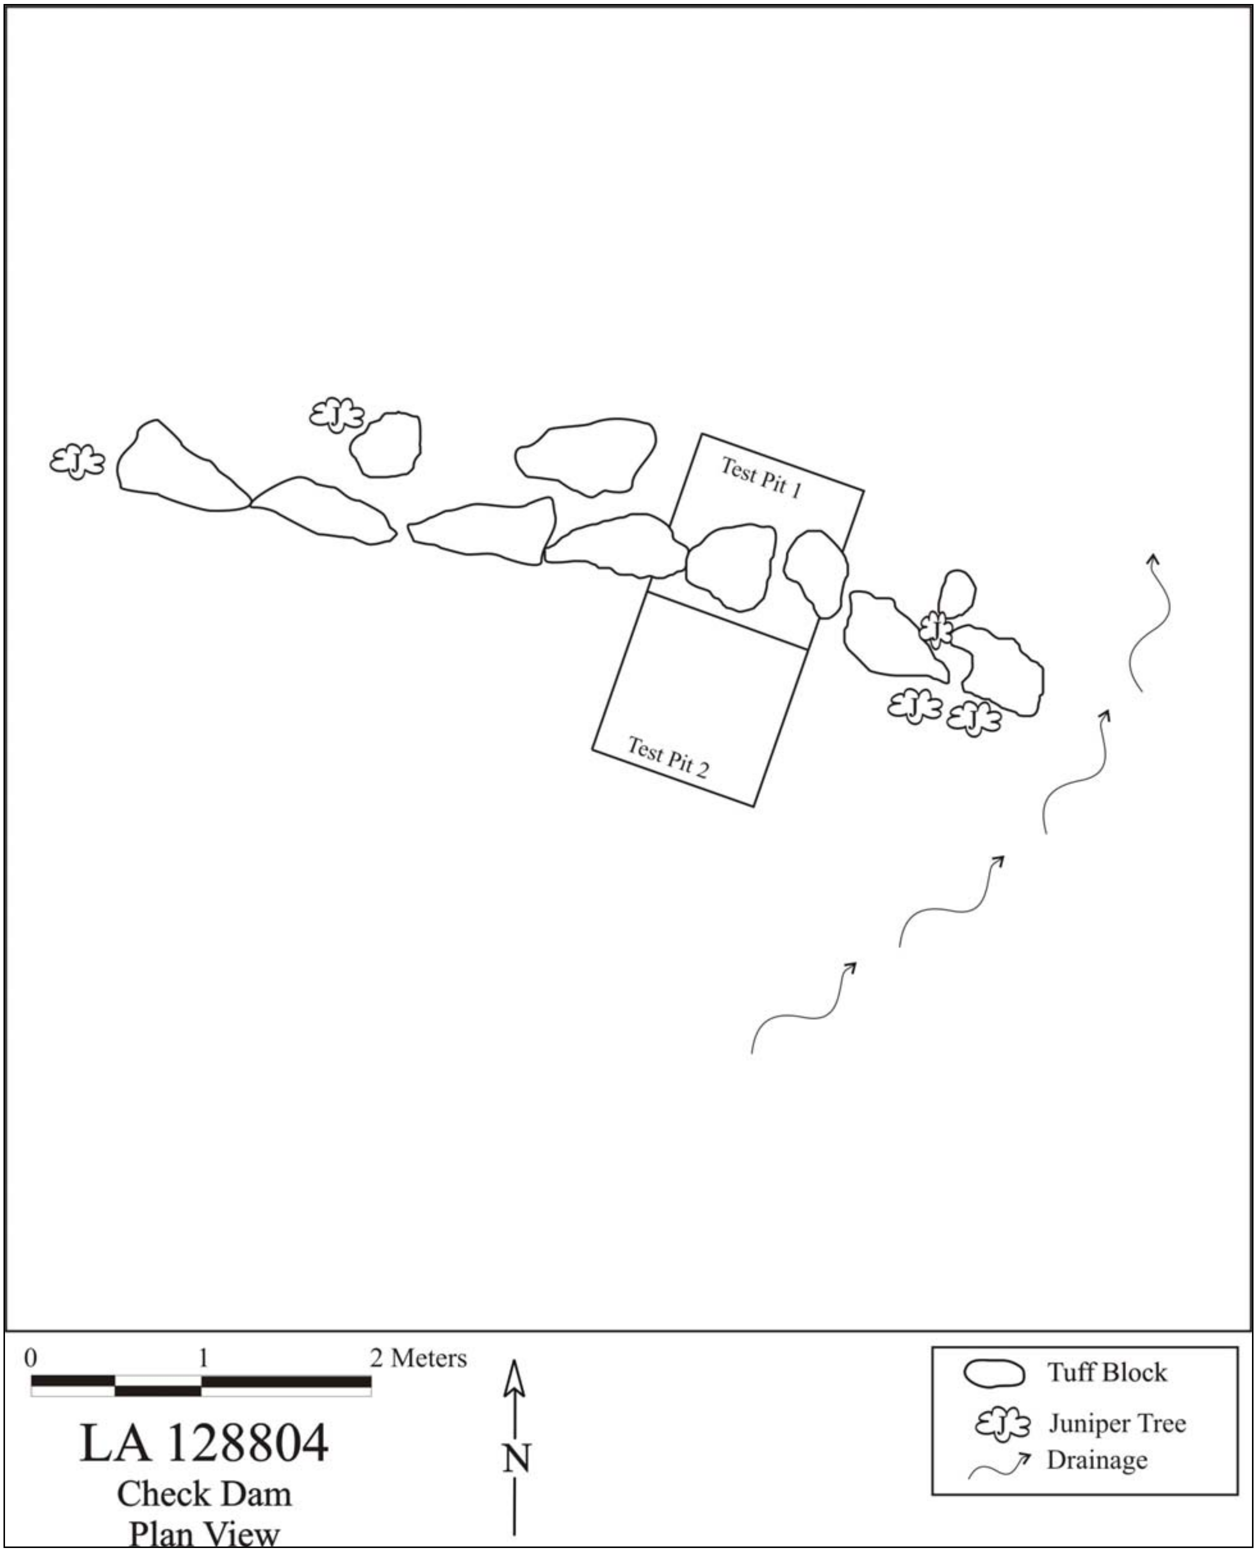

Figure 20.2. Overview of the check dam site.

Test Pit 1

The fill in this 1- by 1-m unit was very loose and sandy (Table 20.2 for strata defined during excavation). Two pieces of obsidian debitage and a smeared-indented corrugated sherd were recovered from the 0- to 10-cm level, and flotation and pollen samples were collected. In the next 10 cm of fill, which were loose and fine, a total of five pieces of obsidian debitage were recovered. From 20 to 30 cm, the sediment was still very loose and sandy, with two pieces of obsidian debitage being recovered. The test pit was excavated down another 10 cm to 40 cm below the ground surface, but no additional artifacts were recovered. The fill in all levels was a sandy loam.

Test Pit 2

The soil of this unit duplicated that of the adjacent Test Pit 1. Artifacts recovered from this unit consist of two pieces of obsidian and chalcedony debitage and a smeared-indented corrugated sherd from the 0- to 10-cm level and eight pieces of obsidian and chalcedony debitage from the 10- to 20-cm level.

Table 20.2. Stratigraphic sequence used during excavation at LA 128804.

LA 128804 Stratigraphic Summary							
Stratum #	Provenience	Maximum Thickness	Minimum Thickness	Elevation	Color	Texture	Comments
1	Test pits 1 and 2	0.40	0.40	0–40 cm below ground surface	10YR5/3	Sandy loam	Very loose sediments. No peds and only inclusions are a few sherds and lithics. Very recent soil, on the order of less than 100 years of development. Bottom of strat not reached, but only identified to bottom of excavated test pits.

SITE CHRONOLOGY AND ASSEMBLAGE

Approximately 510 artifacts were recovered during excavations at LA 128804. All of the ceramics that were identified at the site were analyzed, and just under 50 percent of the chipped stone materials were analyzed. Analyses of the ceramics, lithics (chipped and ground stone), pollen, and archaeobotanical materials were all conducted. No faunal remains were recovered, and no radiocarbon samples were submitted for analysis due to the lack of suitable material. However, nine obsidian artifacts were submitted for hydration dating.

Chronology

Obsidian Hydration Dating

Nine obsidian artifacts from LA 128804 were submitted to Diffusion Laboratory for age determination using the obsidian hydration method. In order to calculate the absolute date for an obsidian artifact, three analytical procedures were completed. First, the amount of surface hydration, or the thickness of the hydration rind, was measured. Second, the high temperature hydration rate constants for each artifact were determined from the composition of the glass. Lastly, the soil temperature and relative humidity at the archaeological site was estimated in order that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. Using these methods, a hydration rate for the obsidian artifacts was calculated (Table 20.3).

Table 20.3. Obsidian hydration dates for LA 128804.

FS* No.	Lab No.	Source	Rim (um)	AD/-BC	1 S.D.

230	2003-76	Cerro Toledo	3.56	-1479	195

* Field Specimen

The obsidian hydration dates provide a wide range from 3839 BC to AD 1610. It is possible that the surface scatter surrounding the feature is associated with multiple use episodes ranging from Archaic through Ceramic period. Most of the hydration dates seem to reflect a Middle to Late Archaic component.

Ceramic Artifacts (Dean Wilson)

The distribution of ceramic types documented during the analysis of 262 sherds from the artifact scatter surrounding the check dam indicates a Classic period date (Table 20.4). This assignation is reflected by distributions of decorated whiteware types that make up 77.5 percent of the pottery from this site. All the whitewares exhibit tuff temper, pastes, and styles indicative of Rio Grande (or Tewa) tradition types (Tables 20.5 and 20.6). Most of the whiteware sherds at the site represent bowl forms (Table 20.7). Decorated whiteware assemblages from all major contexts are dominated by Biscuitware types, with Biscuit B/C outnumbering Biscuit A (Abiquiu Black-on-gray) by over four to one. On the other hand, the presence of Santa Fe Black-on-white and Wiyo Black-on-white also reflects an earlier Late Coalition period component.

Table 20.4. Distribution of ceramic types from LA 128804.

Pottery Type	Frequency	Percent
Northern Rio Grande Whiteware		
Unpainted undifferentiated	5	1.9
Indeterminate organic paint	2	0.8

A Classic period association is also supported by the presence of glazewares, which represent 1.5 percent of the pottery from this site. This includes sherds derived from glaze-on-red and glaze-on-yellow vessels. These sherds are tempered with basalt and latite commonly found in pottery produced in areas of the Middle Rio Grande to the south. Gray utilityware types consist of 75.9 percent of the pottery from this site and indicate similar trends. The majority of this pottery is tempered with "anthill sand" (Table 20.6). While a wide range of exterior surface manipulations were noted, most exhibit smeared corrugated exteriors.

Table 20.6. Temper by ware for ceramics from LA 128804.

Temper	Ware								Total	
	Gray		White		Glaze		Micaceous

The combination of decorated and utility pottery outlined in Tables 20.4 through 20.7 is consistent with a component dating to the Middle Classic period (15th century). That is, assuming that the Biscuit B/C body sherds represent the Biscuit B type, which seems likely given the presence of Biscuit A. However, the presence of Santa Fe and Wiyo Black-on-white also represents a Late Coalition period component.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 113 chipped stone artifacts were analyzed from LA 128804, consisting of 108 pieces of debitage, three retouched tools, and two ground stone items. This represents a 44.4 percent sample of the 254 lithic artifacts recovered during the site excavations. Table 20.8 presents the data on lithic artifact type by material type. The majority of the debitage is made of obsidian, with less chalcedony, Pedernal chert, basalt, and other materials. The presence of cortex on 9.4 percent of the debitage indicates that the materials were collected from both secondary waterworn (65.2%) and primary nodule sources. The obsidian is present at nearby sources in the Jemez Mountains. In contrast, chalcedony, Pedernal chert, and chert are available from local Rio Grande Valley gravel sources. The basalt is present in outcrops and stream gravels.

Table 20.8. Lithic artifact type by material type from LA 128804.

Artifact Type		Material Type							
		Undetermined Igneous	Basalt	Andesite	Obsidian	Chalcedony	Chert	Pedernal	Total

Twelve pieces of debitage and a biface from LA 128804 were submitted for X-ray fluorescence analysis (Table 20.9). Most of the artifacts were from the Cerro Toledo (Rabbit Mountain/Obsidian Ridge) source area, with fewer from the Valle Grande (Cerro del Medio) source, which are located about 15 km (10 miles) as the "crow flies" to the southwest and west (Shackley, Volume 3).

Table 20.9. Obsidian source samples.

FS #	Artifact	Color	Source

66-2	Debitage	Black opaque	Cerro Toledo rhyolite
85	Debitage	Translucent	Valle Grande rhyolite
127	Debitage	Translucent	Cerro Toledo rhyolite
131	Debitage	Translucent	Cerro Toledo rhyolite
134	Tool	Translucent	Valle Grande rhyolite
181	Debitage	Translucent	Cerro Toledo rhyolite
224	Debitage	Translucent	Valle Grande rhyolite
230	Debitage	Black opaque	Cerro Toledo rhyolite

Lithic Reduction

The debitage consists of a mixture of core flakes and biface flakes, with fewer pieces of angular debris, microdebitage, and undetermined flake fragments. The majority of the flakes exhibit single platforms (n = 25), with cortical (n = 3), dihedral (n = 1), multi-faceted (n = 5), collapsed (n = 5), and crushed (n = 11) platforms. Sixteen (32.0%) of the flake platforms exhibit evidence of preparation, with most of these being abraded/crushed and five being retouched/abraded platforms.

The majority of the core flakes consist of distal fragments (n = 53; 51.9%), with fewer whole (n = 16), proximal (n = 14), midsection (n = 17), lateral flake (n = 1), and undetermined flake (n = 1) fragments. Most of the biface flakes are midsection fragments (n = 30) and distal (n = 28) fragments, with fewer whole (n = 2), proximal (n = 16), and lateral (n = 1) fragments. The whole core flakes have a mean length of 24.8 mm (*std* = 10.2), whereas, the whole biface flakes have a mean length of 15.0 mm (*std* = 1.4). Lastly, the angular debris have a mean weight of 11.2 g (*std* = 11.5).

The retouched tools consist of a retouched piece and two bifaces. The retouched piece consists of the proximal fragment of a large dacite flake with a bidirectionally retouched lateral edge. The bifaces are both distal fragments that exhibit edge angles from 35 to 45 degrees, indicating that they may have been broken during the middle to late stages of tool manufacturing. One of the bifaces is heavily burned with pot lids.

Tool Use

Only four flakes (3.7%) exhibit evidence of damage that could be attributed to use-wear. All four flakes have straight edge outlines, with one on the end and three along the lateral sides of the artifact. The edge angles range from 35 to 45 degrees. The retouched piece exhibits rounding and polish along the marginally retouched edge and the opposite unretouched edge.

The ground stone assemblage consists of two undetermined metate fragments. One is probably a fragment of a large formal metate with a heavily ground and polished concavity. The other is a small burned fragment that also exhibits a highly ground and polished concave surface.

Archaeobotanical Remains (Pamela McBride)

Non-cultural debris in flotation samples from upslope and downslope of the check dam included spurge seeds, juniper twigs, and piñon needles (Table 20.10). Cultural plant remains were absent from samples, which is not remarkable considering the context and relatively isolated location of the feature.

Table 20.10. Flotation sample plant remains from LA 128804.

FS No.	213	215	219	222
Feature	Test Pit 1			
	Stratum 1, level 1		Stratum 1, level 2	
Non-Cultural Annuals				
Spurge	+			
Perennials				
Juniper	twig +	+, twig +	twig +	twig +
Piñon	needle +	needle +	needle +	

All plant remains are seeds unless indicated otherwise.
Non-cultural plant remains are uncharred.
+ 1-10/liter.

Pollen Remains (Susan Smith)

Four pollen samples were analyzed from around the vicinity of the check dam. Two samples were taken from sediments located upslope of the check dam (FS 214 and FS 223) and downslope from the check dam (FS 216 and FS 220). Taxa identified in the sediments located upslope from the check dam include the following: prickly pear (*Opuntia*), cheno-ams, unidentified grasses (Poaceae), sunflower family (Asteraceae), ragweed/bursage (*Ambrosia*), spurge family (Euphorbiaceae), unidentified pine (*Pinus*), piñon pine (*Pinus edulis*), juniper (*Juniperus*), oak (*Quercus*), Mormon tea (*Ephedra*), and sagebrush (*Artemisia*).

Taxa identified in the sediments located downslope from the check dam include the following: prickly pear, cattail (*Typha*), cheno-ams, unidentified grasses, sunflower family, ragweed/bursage, chicory tribe (Liguliflorae), spurge family, spruce (*Picea*), fir, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush.

SUMMARY

Based on appearance and geomorphological assessments conducted at LA 128804, it is probable that the check dam is a relatively recent construction that dates to the Historic period. This supposition was initially based on the relatively pristine condition in which the check dam was found, and indeed, the geomorphologic information also indicated that it is less than 100 years in age. The Puebloan artifacts found in association with the check dam appear both upslope and downslope of the feature in the stream channel within which it is located. The site is also situated immediately downslope of LA 12587 (Chapter 14, this volume), a Late Coalition period roomblock. Nonetheless, the ceramic assemblage indicates a mixture of Late Coalition and Classic period components, with the obsidian hydration dates possibly reflecting a Middle to Late Archaic component.

CHAPTER 21
WHITE ROCK TRACT (A-19): LA 128805

Kari M. Schmidt

INTRODUCTION AND SITE SETTING

This chapter presents the results of excavations conducted at LA 128805, a Middle Classic period fieldhouse and associated artifact scatter. LA 128805 (temporary numbers LA 12587D and H-1) is a large, one-room fieldhouse located on the floodplain between the mouth of Cañada del Buey and Pajarito Canyon. Vegetation in the site area is dominated by piñon and juniper woodland and has an understory dominated by saltbush, snakeweed, yucca, and various other native grasses, shrubs, and forbs. LA 128805 is situated at an elevation of 1978 m (6490 ft) and is located approximately 200 m east of LA 127631 (Chapter 18, this volume), a one-room Late Coalition period fieldhouse. LA 128805 is located about 75 m north of State Road 4 in White Rock.

SITE DESCRIPTION

LA 128805 consists of a one-room fieldhouse with visible wall alignments on a small mound. The room measures 3.3 by 2.5 m in size, and the masonry blocks used in construction range from 0.45 to 1.35 m in length and average 0.35 m in width. The site area has been impacted by heavy erosion and a small drainage runs along the southern edge of the mound. In-field artifact analyses conducted during the initial recording of the site show that Santa Fe Black-on-white and smeared-indented corrugated utilityware sherds dominated the artifact scatter located to the west of the fieldhouse. The lithic artifacts in this area included mostly basalt (60%), with less obsidian, and chert flakes. Artifacts were sparse and scattered in a 15- by 15-m area around the feature, but were heaviest to the southwest along the aforementioned drainage. Figure 21.1 shows the fieldhouse before excavation.

FIELD METHODS

Fieldwork at the site occurred in October and November of 2002. Work began with an initial assessment of the site. The crew walked over the site area, delineating the site boundaries and identifying the presence of artifact concentrations and features to ascertain if and how they related to the fieldhouse. The site was divided into two areas for mitigation: the mounded area of the fieldhouse and the area immediately surrounding the mound were designated as Area 1, and the surface artifact scatter located to the west of the fieldhouse was designated as Area 2. Both areas were then gridded into 1- by 1-m units, with the site datum (100N/100E for horizontal control, 10.0 m for vertical control) located southwest of the fieldhouse. Artifacts were collected and bagged for analysis and provenienced to the nearest meter, using the southwest corner of the grid for its coordinates. Surface collections produced a total of 216 lithics, 113 ceramics, one metate fragment, and one piece of animal bone. In all, a 600-m^2 area around the fieldhouse was surface collected. The distribution of these artifacts is depicted in Figure 21.2.

Figure 21.1. LA 128805 before excavation.

Excavations at LA 128805 occurred only in Area 1. The rubble mound from the fieldhouse covered an area of approximately 23 m^2 but, when excavations were completed, the structure occupied part or all of 10 m^2. Excavation was done in individual meter grids and in natural stratigraphic levels. All fill removed from excavated units was screened through 1/8-in. mesh. Artifacts were collected and bagged by type from each level, and pollen, flotation, and other samples were collected from appropriate locations in the structure.

STRATIGRAPHY (Paul Drakos and Steve Reneau)

LA 128805 is situated on a broad colluvial slope that displays abundant evidence for active erosion. The fieldhouse is at the upslope end of eroding channels that extend to the east, with about 0.5 m of recent erosion estimated on the southeast side. Eroded channels also wrap around the northwest side of the structure. The tuff blocks in the fieldhouse appear to be acting as a local armor, protecting the area occupied by the fieldhouse from erosion while surrounding slopes are stripped. There is potential for some deposition of slope wash colluvium on the upslope (west) side of the fieldhouse, whereas other adjacent areas are experiencing erosion.

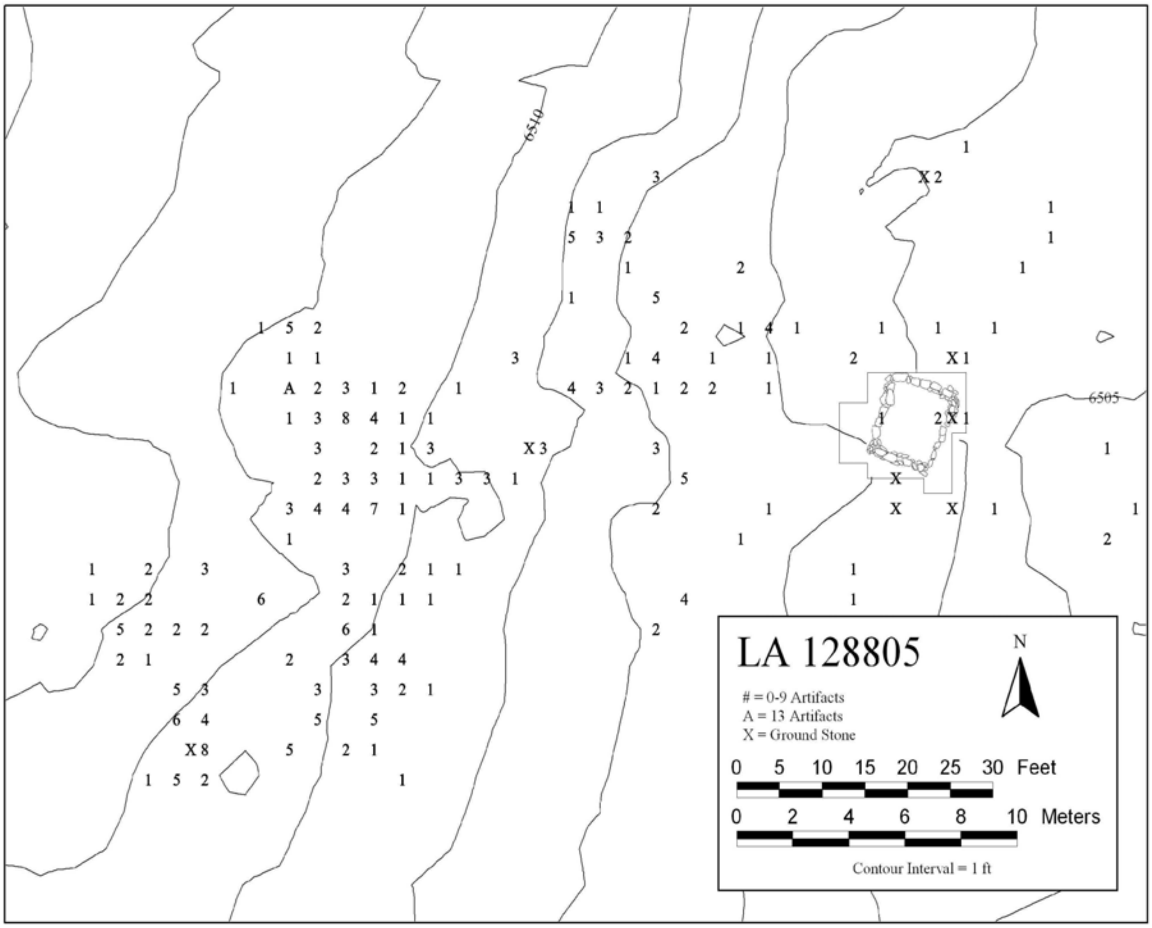

Figure 21.2. Surface distribution of artifacts collected at LA 128805.

An examination of soils in a test pit, which was located 1 m southeast of the southeast corner of the structure, suggests that LA 128805 was constructed on an aggrading colluvial slope that experienced post-occupation deposition before the recent erosion that has occurred at the site (Table 21.1; see Drakos and Reneau, Volume 3 for key). A thin (10 cm thick) A horizon is inferred to post-date occupation of the site (i.e., is less than 500 yrs old). The A horizon overlies a buried (Bwb1) horizon, with soil structure development similar to that observed for older post-Coalition period soils, and is inferred to be 500 to 800 years old. The Bwb1 horizon overlies a buried Pleistocene soil formed in colluvium. The sequence of buried soils at this site suggests rapid deposition of colluvium, possibly during the Coalition period, with continued aggradation after abandonment of this Late Classic period fieldhouse, followed by recent erosion (Drakos and Reneau, Volume 3). Stratigraphic designations used in the field during excavation are shown in Table 21.2.

Table 21.1. Geomorphological characteristics of test pit at LA 128805; pit located 1 m southeast of southeast corner of fieldhouse.

*Thickness in meters

SITE EXCAVATION

The excavations at LA 128805 were undertaken by Kari Schmidt (crew chief), Aaron Gonzales, Mia Jonsson, Mike Kennedy, and Marjorie Wright.

The fieldhouse at LA 128805 was excavated in 1- by 1-m units and natural stratigraphic levels were used. Three natural strata were encountered. The top centimeter or so was a grayish-brown duff and loose sandy loam that was clearly post-occupational fill. The subsequent stratum was a sandy clay loam and varied from 5 to 20 cm in thickness. Stratum 3 was also a sandy clay loam, but with a higher clay content and varied from 5 to 13 cm thick. The fourth stratum was a prepared floor and its boundary was abrupt. Clay content in this stratum was high, and artifacts were in contact with the surface. Figures 21.3 and 21.4 show the fieldhouse after it was excavated and at the level of the prepared surface. Pink flagging tape in the photo denotes grid coordinates.

During excavations, the boundary between the second and third strata was originally thought to be the floor of the structure, as there were stretches along the west wall where there was good articulation between the wall and floor. This was supported by a mano that was recovered at about the same level. However, upon further excavation, more artifacts were found below the "floor," and excavations down another 10 cm or so revealed an obvious surface. The surface was not plastered, but was clearly prepared. Several artifacts were encountered on the floor and it also contained small patches of charcoal-stained areas that were not present on the upper "floor." The lower surface was clearly the one associated with the use of the fieldhouse.

Figure 21.3. LA 128805 after excavation.

The walls of the fieldhouse were at least two courses high, and in some cases along the eastern wall were three courses high (see Figure 21.4). For the most part, the tuff blocks used in construction were shaped, but several small and unshaped blocks were present in the interstitial spaces along the walls. The corners of the room were all buttressed with smaller cobbles, probably for extra support in the uneven ground. Figure 21.4 shows the site in profile.

Excavations at the fieldhouse produced a total of 131 lithics, 93 ceramics, and eight pieces of ground stone. Of this total, 122 lithics, 89 ceramics, and all of the ground stone artifacts were found in the sandy clay loam fill (Strata 2 and 3).

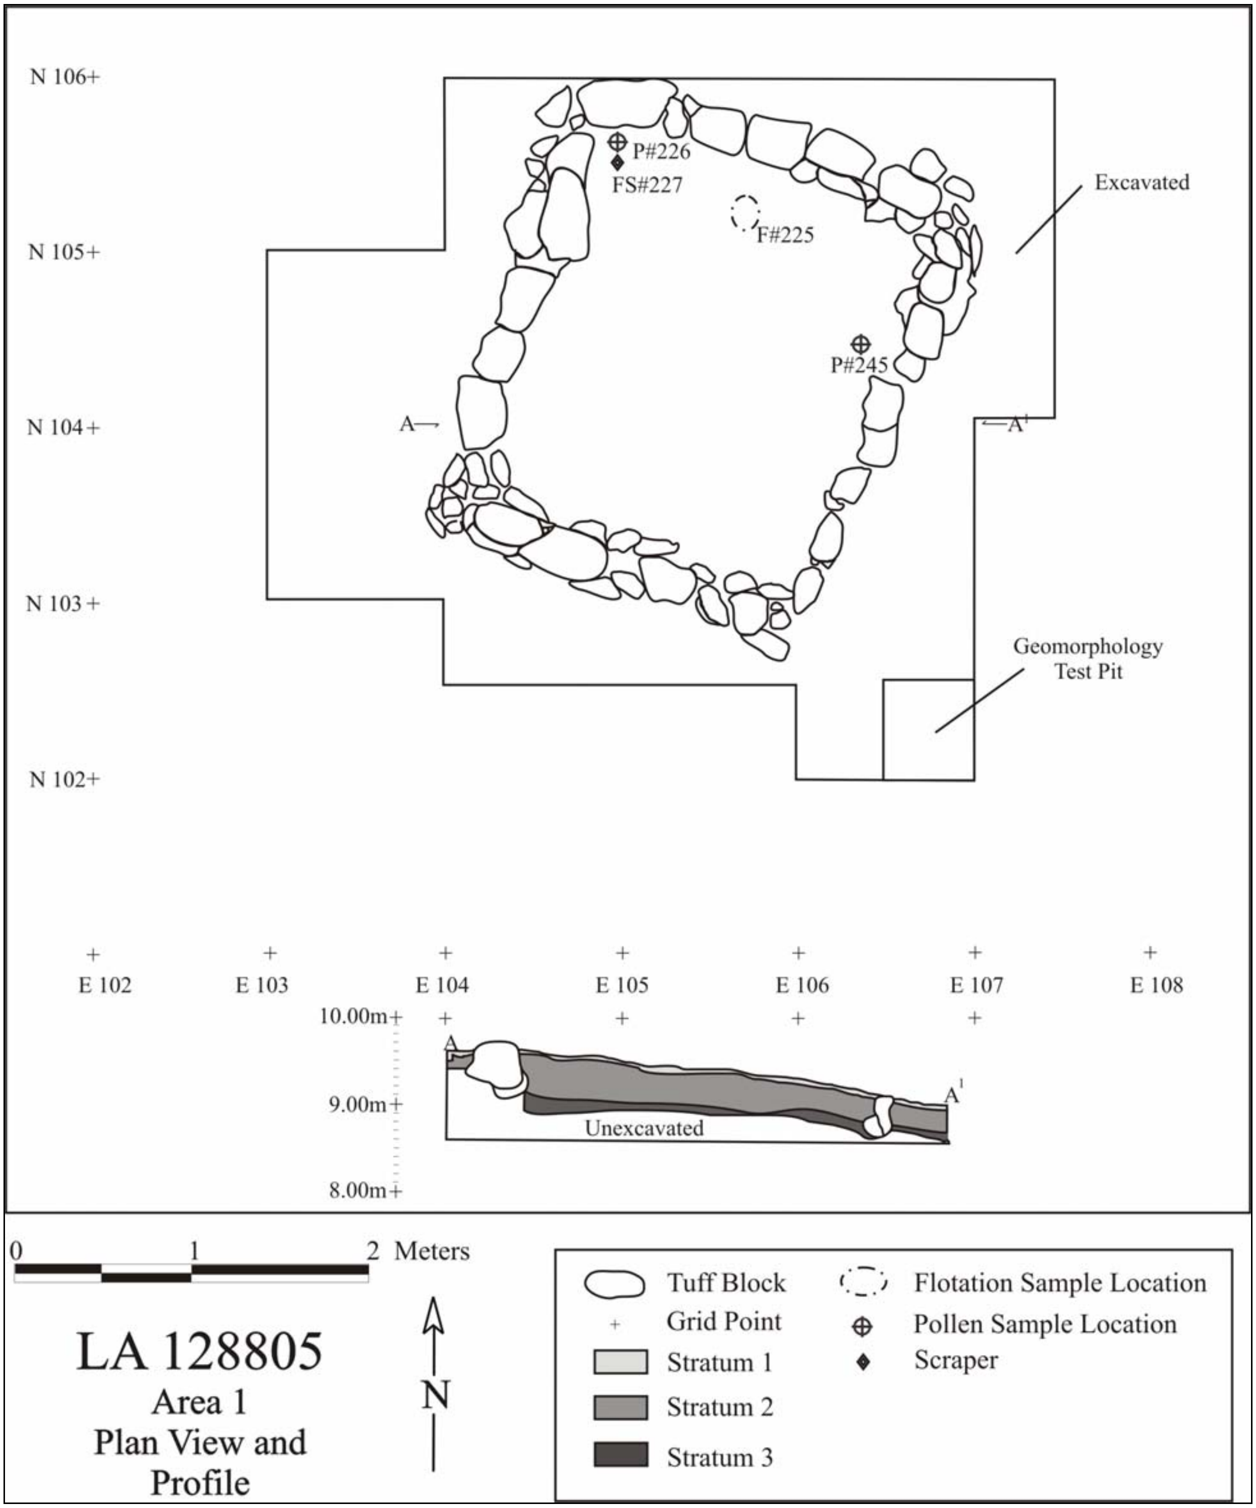

Figure 21.4. Plan view and profile drawing of LA 128805.

SITE CHRONOLOGY AND ASSEMBLAGE

Approximately 550 artifacts and samples were recovered during excavations at LA 128805 and all were submitted for analysis. Analyses of the ceramics, lithics (chipped and ground stone), pollen, and archaeobotanical materials were all conducted. No faunal remains were recovered. A maize sample was submitted for radiocarbon dating and 10 pieces of obsidian for hydration dating. Results of these analyses are presented in subsequent sections.

Chronology

Radiocarbon Dating

A single radiocarbon sample was submitted for analysis from this site. Several maize (*Zea mays*) cupules were collected from a flotation sample (Field Specimen [FS] 225) taken from inside Room 1 just above the floor and dated to the Middle Classic period (AD 1420–1500). Table 21.3 presents the chronometric information.

Table 21.3. Radiocarbon dates from LA 128805.

FS#	Material	Laboratory (Beta)#	Conventional radiocarbon age	Intercept of radiocarbon age	2-sigma calibrated result
225	maize	183756	440±40 BP	AD 1440	AD 1420–1500

Obsidian Hydration Dating

Ten obsidian artifacts from LA 128805 were submitted to Diffusion Laboratory for age determination using the obsidian hydration method. In order to calculate the absolute date for an obsidian artifact, three analytical procedures were completed. First, the amount of surface hydration, or the thickness of the hydration rind, was measured. Second, the high temperature hydration rate constants for each artifact were determined from the composition of the glass. Lastly, the soil temperature and relative humidity at the archaeological site was estimated in order that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. Using these methods, a hydration rate for the obsidian artifacts was calculated (Table 21.4).

Table 21.4. Obsidian hydration dates for LA 128805.

FS No.	Lab No.	Source	Rim (um)	AD/-BC	1 S.D.
6	2003-44	Cerro Toledo	4.69	-3866	251
62	2003-45	Cerro Toledo	5.85	1360	20
71	2003-46	Cerro Toledo	4.13	1338	30
114	2003-47	Cerro Toledo	4.35	-3163	238
157	2003-48	Cerro Toledo	4.68	564	60
163	2003-49	Cerro Toledo	3.91	-2224	216

FS No.	Lab No.	Source	Rim (um)	AD/-BC	1 S.D.
186	2003-50	Cerro Toledo	4.32	-3140	238
247	2003-51	Cerro Toledo	4.94	-177	87
253	2003-52	Cerro Toledo	2.68	31	146
254	2003-53	Cerro Toledo	2.17	689	119

The obsidian hydration dates provide a wide range from 3866 BC to AD 1360. The two 14th century dates are closest to the radiocarbon date of circa AD 1440. However, the remainder of the dates are much older than the site occupation and may represent reuse of Middle to Late Archaic materials.

Ceramic Artifacts (Dean Wilson)

The distribution of ceramic types documented during the analysis of 199 sherds from the fieldhouse indicates that the assemblage dates to the Middle Classic period (15th century) (Table 21.5). The Middle Classic period date is reflected by distributions of decorated whiteware types that make up 24.6 percent of the pottery from the site, including Biscuit A, Biscuit B, and Biscuit B/C (Biscuit B?). All the whitewares exhibit tuff temper, pastes, and styles indicative of Rio Grande (or Tewa) tradition types (Tables 21.6 and 21.7). In contrast to assemblages from most other sites examined during this project, a slight majority of the whitewares consist of jar forms (Table 21.8). Decorated whiteware assemblages from all major contexts are dominated by Biscuitware types, with Biscuit A (Abiquiu Black-on-gray), Biscuit B (Bandelier Black-on-gray), and Biscuit B/C. Other Classic period pottery includes Sankawi Black-on-cream. Earlier types are limited to a single Santa Fe Black-on-white sherd.

Table 21.5. Ceramic types from LA 128805.

Pottery Type	Frequency	Percent
Northern Rio Grande Whiteware		
Unpainted undifferentiated	3	1.5
Indeterminate organic paint	7	3.5
Santa Fe Black-on-white	1	0.5
Unpainted Biscuit (slipped one side)	14	7.0
Biscuitware (slipped both sides)	2	1.0
Biscuitware painted unspecified	6	3.0
Biscuit A (Abiquiu Black-on-gray)	3	1.5
Biscuit B (Bandelier Black-on-gray)	3	1.5
Biscuit C (Cuyamunge Black-on-tan)	1	0.5
Biscuit B/C body	7	3.5
Sankawi Black-on-cream	2	1.0
Northern Rio Grande Utilityware		
Plain gray rim	10	5.0
Plain gray body	52	26.1

Pottery Type	Frequency	Percent
Unknown gray rim	1	0.5
Indented corrugated	6	3.0
Plain corrugated	6	3.0
Smeared plain corrugated	19	9.5
Smeared-indented corrugated	32	16.1
Sapawe Micaceous	5	2.5
Middle Rio Grande Glazeware		
Glaze red body unpainted	4	2.0
Glaze yellow body unpainted	2	1.0
Glaze unslipped body	7	3.5
Glaze polychrome body	2	1.0
Glaze-on-red body	2	1.0
Glaze-on-yellow body	1	0.5
White Mountain Redware (Cibola)		
Wingate Black-on-red	1	0.5
Total	**199**	**100**

A Classic period association at the fieldhouse is also supported by the presence of glazewares that represent 9 percent of the pottery from the site. While no rim sherds were present, a combination of glaze-on-red, glaze-on-yellow, and glaze polychrome sherds are represented. Most of these sherds are tempered with basalt and latite commonly found in pottery produced in areas of the Middle Rio Grande to the south.

Table 21.6. Tradition by ware for LA 128805 ceramics.

Tradition	Ware										Total	
	Gray		White		Red		Glaze		Micaceous			
Rio Grande (Prehistoric)	126	100.0	49	100.0	--	--	--	--	5	100.0	180	90.4
Middle Rio Grande	--	--	--	--	--	--	18	100.0	--	--	18	9.0
Cibola	--	--	--	--	1	100.0	--	--	--	--	1	0.0.5
Total	**126**	**100.0**	**49**	**100.0**	**1**	**100.0**	**18**	**100.0**	**5**	**100.0**	**199**	**100.0**

Gray utilityware types consist of 63.3 percent of the pottery from this site and indicate similar trends. The majority of the corrugated pottery is tempered with “anthill” sand, in contrast to the plain gray and Sapawe Micaceous shreds which are tempered with micaceous granite (Table 21.7). While a wide range of exterior surface manipulations was noted, it is about equally divided between plain and smeared corrugated forms.

Table 21.7. Temper by ware for LA 128805 ceramics.

Temper	Ware										Total	
	Gray		White		Red		Glaze		Micaceous			
Sand	3	2.3	--	--	--	--	--	--	3	60.0	6	3.0

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 353 artifacts were analyzed from LA 128805, consisting of two cores, 331 pieces of debitage, four retouched tools, and 16 ground stone items. This represents a 100 percent sample of the lithic artifacts recovered during the site excavations. Table 21.9 presents the data on lithic artifact type by material type. The majority of the debitage is made of obsidian, with less chalcedony, basalt, and other materials. The presence of cortex on 10.2 percent of the debitage indicates that the materials were collected from both primary nodular (58.8%) and secondary waterworn sources. The obsidian is present at nearby sources in the Jemez Mountains, but four obsidian flakes also exhibit waterworn cortex. In contrast, chalcedony, Pedernal chert, and quartzite are available from local Rio Grande Valley gravel sources.

Table 21.9. Lithic artifact type by material type at LA 128805.

Eleven pieces of debitage and a retouched tool were submitted for X-ray fluorescence analysis from LA 128805 (Table 21.10). All of the artifacts were obtained from the Cerro Toledo (Rabbit Mountain/Obsidian Ridge) source area, which is located about 15 km (10 miles) as the "crow flies" to the southwest (Shackley, Volume 3).

Lithic Reduction

The platform core was reduced using a bidirectional, change-of-orientation technique; whereas, the flake core was reduced using a single-directional, single-face technique. The platform core was discarded due to material flaw and the flake core was classified as still useable. Table 21.11 presents the metric information on these cores.

Table 21.11. Core type dimensions (mm) and weight (gm).

Core Type	Length	Width	Thickness	Weight
Flake core	41	49	18	46.8
Bi-directional	59	39	26	57.6

The debitage mainly consists of core flakes (36.3%) and microdebitage (30.1%) with some biface flakes, angular debris, and undetermined flake fragments. Table 21.12 summarizes the various stages of reduction represented by the whole core and biface (tertiary) flakes. The overall cortical:non-cortical ratio of 0.63 reflects an emphasis on later stages of core reduction and tool production.

Table 21.12. Debitage reduction stages.

Material	Primary	Secondary Cortical	Secondary Non-cortical	Tertiary	Cortical: Non-cortical ratio
Basalt	0	0	2	0	---

Material	Primary	Secondary Cortical	Secondary Non-cortical	Tertiary	Cortical: Non-cortical ratio
Obsidian	0	3	1	1	1.5
Chalcedony	0	4	7	0	0.57
Pedernal Chert	0	0	0	0	---
Total	0	7	10	1	0.63
Percentage	0	38.8	55.5	5.5	---

The majority of the flakes exhibit single platforms (42.4%; *n* = 31), with cortical (*n* = 10), dihedral (*n* = 2), multi-faceted (*n* = 7), collapsed (*n* = 9), and crushed (*n* = 14) platforms. Twenty-four (28.9%) of the flake platforms exhibit evidence of preparation, with most of these being abraded/crushed and only seven retouched/abraded platforms.

The majority of the core flakes consist of distal fragments (*n* = 60; 41.3%), with fewer whole (*n* = 20), proximal (*n* = 28), midsection (*n* = 34), lateral flake (*n* = 2), and undetermined flake (*n* = 1) fragments. Most of the biface flakes are also midsection fragments (*n* = 23; 33.8%), with fewer whole (*n* = 1), proximal (*n* = 22), and distal (*n* = 22) flakes. The whole core flakes have a mean length of 21.6 mm (*std* = 8.9), whereas, the single whole biface flake has a length of 14.0 mm. Lastly, the angular debris have a mean weight of 4.0 g (*std* = 7.2).

The retouched tools consist of a retouched piece, two bifaces, and one uniface. The retouched piece consists of the distal end of flake with unidirectional dorsal retouch along a lateral edge with an angle of 35 degrees. One of the bifaces is a lateral fragment with an edge angle of 40 degrees, whereas, the other biface is a proximal fragment that may have been broken while attempting to notch the artifact. This break occurred along a material flaw. The uniface is a large flake with unidirectional dorsal retouch along the lateral end and ends with a steep edge angle of 70 degrees (Figure 21.5).

Tool Use

Only six flakes (1.8%) exhibit evidence of damage that could be attributed to use-wear**.** Three have straight lateral edges with angles ranging from 35 to 45 degrees, whereas, two are utilized ends with straight and convex edge outlines and angles of 50 degrees. The last item is a utilized projection.

The uniface is the only retouched tool with evidence of use-wear consisting of some polish and scarring.

The ground stone consists of a one-hand mano, basin metate, and some metate fragments. The one-hand mano is a dacite cobble with a single grinding surface. The basin metate is a fragment that was made on a large piece of andesite. It has grinding surfaces on both sides that consist of deep concavities. The abrading stone is a tuff cobble that exhibits some grinding along high spots on one surface. The undetermined metate and ground stone fragments are tabular pieces of material that exhibit a grinding surface(s). The metate fragments are larger and may represent pieces of millingstones with slightly concave grinding surfaces. Several of the fragments are burned.

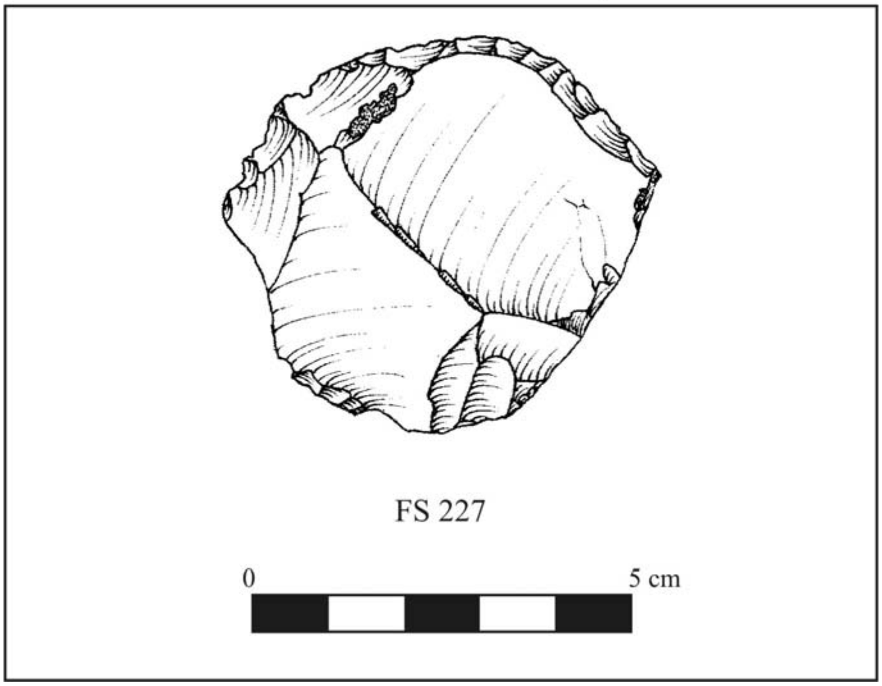

Figure 21.5. Uniface recovered at LA 128805.

Archaeobotanical Remains (Pamela McBride)

Cultural floral remains consisted of an unidentifiable plant part, a maize glume, cupule, and kernel fragments. Unburned intrusive plant parts included weedy annual seeds, grass stems, dropseed grass seeds, prickly pear cactus seeds, and conifer duff (Table 21.13).

All plant remains are seeds unless indicated otherwise; Cultural plant remains are charred, non-cultural plant remains are uncharred; + 1-10/liter, bs barkscale, cf. compares favorably.

Flotation wood charcoal included unidentified pine, piñon, and saltbush/greasewood (Table 21.14). Vegetal samples from room fill yielded a maize kernel and kernel fragments and cupules (Table 21.15). Piñon was the most common wood by weight in vegetal samples, followed by ponderosa and cf. rabbitbrush. Two fragments of cf. wolfberry were also identified, along with several pieces of oak, pine, unknown conifer, saltbush/greasewood, and unknown non-conifer. Since maize was the only identifiable non-wood plant recovered, it might be safe to say that tending maize fields was the primary focus of fieldhouse occupants. Despite the absence of a formal thermal feature, the presence of maize and wood charcoal indicates maize was processed inside the structure and that a variety of locally available conifers and shrubs were used for fuel or construction material.

Pollen Remains (Susan Smith)

Eight pollen samples were analyzed from the fieldhouse. Taxa identified in the Stratum 1 (post-occupational fill) pollen sample include the following: prickly pear (*Opuntia/Platy*), cheno-ams, unidentified grasses (Poaceae), sunflower family (Asteraceae), ragweed/bursage (*Ambrosia*), evening primrose (Onagraceae), fir (*Abies*), unidentified pine (*Pinus*), piñon pine (*Pinus edulis*), juniper (*Juniperus*), Mormon tea (*Ephedra*), and sagebrush (*Artemisia*). Taxa identified in the pollen samples (*n* = 5) from Stratum 2 (room fill) include the following taxa: prickly pear, beeweed (*Cleome*), buckwheat (*Eriogonum*), sunflower family, ragweed/bursage, globemallow (Sphaeralcea), spurge (Euphorbiaceae), evening primrose, fir, unidentified pine, piñon pine, juniper, oak (*Quercus*), birch (*Betula*), Mormon tea, sagebrush, cheno-ams, and unidentified grasses. Taxa identified in the pollen samples (*n* = 1) from Stratum 3 (wallfall/room fill) include the following taxa: maize, sunflower family, ragweed/bursage, unknown sunflower family (possibly marshelder), unidentified pine, piñon, oak, rose family (Rosaceae), sagebrush, cheno-ams, and unidentified grasses (Poaceae). Taxa identified in Stratum 4 (the floor/prepared surface, *n* = 1) include the following taxa: prickly pear, cattail (*Typha*), sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon, juniper, sagebrush, cheno-ams, and unidentified grasses.

SUMMARY

LA 128805 consists of a large single-room fieldhouse, constructed of both shaped and unshaped tuff blocks. The presence of maize and numerous jar sherds reflects the agricultural function of the site, with some core reduction and milling activities. The site is located downslope from LA 12587 (Chapter 14, Volume 2) and some of the Coalition period artifacts may have come from the occupation of this site. Nonetheless, the main occupation of the fieldhouse (Area 1) and the artifact scatter (Area 2) date to the Middle Classic period (15th century), as evidenced by the radiocarbon date and ceramic assemblage. The presence of the artifact scatter reflects an extended period of occupation at the site, presumably during the maize growing season.

CHAPTER 22
AIRPORT-SOUTH TRACT (A-5-1): LA 86533

Jennifer E. Nisengard

INTRODUCTION AND SITE SETTING

This chapter presents the results of the archaeological fieldwork conducted at LA 86533. The site consists of a dispersed artifact scatter that is located east of the Los Alamos town site and south of State Road 502 (see Figure 13.2). The Airport Tract parcel includes a gently sloping mesa between a tributary to Pueblo Canyon on the north and DP Canyon, a tributary to Los Alamos Canyon, on the south. The tract ranges in elevation from 2153 m to 2196 m (7060 to 7200 ft), and the vegetation is primarily piñon-juniper woodland with areas of ponderosa pine forest and an understory of saltweed, snakeweed, yucca, and various other native grasses, shrubs, and forbs. The site is located at an elevation of 2123 m (6965 ft).

LA 86533 is an artifact scatter located south of LA 86534 (see Chapter 24, this volume) and east of LA 139418 (see Chapter 23, this volume) and dates to the Ancestral Pueblo period. The site was identified during a pedestrian survey of the area in 1984 and rerecorded in 1991 by Los Alamos National Laboratory (LANL) archaeologists. An initial surface survey identified a dispersed lithic and ceramic scatter that included a Late Archaic (Armijo) projectile point. In May of 2003, LANL personnel conducted a surface reconnaissance of the site area to identify the overall distribution of artifacts. This work was completed by Jennifer Nisengard (crew chief), Aaron Gonzales, and Bettina Kuru'es.

SITE DESCRIPTION

The site consists of a lithic and ceramic scatter that is dispersed across a 350- by 40-m area. The majority of the artifacts were recovered from an open grassy area south of Highway 502 (Figures 22.1 and 22.2). No features or structures were identified at the site, although a possible rock alignment was noted. Nine of the 11 ceramics at LA 86533 were recovered from the east end of the scatter, which lies directly south of LA 86534. It, therefore, seems likely that these sherds were originally associated with this Coalition period roomblock.

FIELD METHODS

Due to the sparse nature of the artifact distribution, a geographic positioning system (GPS) point location was taken for each artifact at LA 86533. The artifact was collected and bagged and the GPS location was noted. The site area was highly eroded, with shallow colluvial soils or exposed bedrock. Therefore, no subsurface testing was conducted.

SURFACE COLLECTION

Forty-six artifacts were recovered from LA 86533. Most of the artifacts consist of debitage with two retouched tools and 14 sherds (Figure 22.1). The debitage primarily consists of obsidian core flakes, with an obsidian biface and Late Archaic point. On the other hand, most of the ceramics are Santa Fe Black-on-white and smeared-indented corrugated sherds. A single ceramic ladle handle was also recovered. The assemblage appears to include Late Archaic and Coalition period components. As previously noted, the latter is presumably associated with the roomblock at LA 86534.

Figure 22.1. Establishing the grid at LA 86533 with the Nikon DTM.

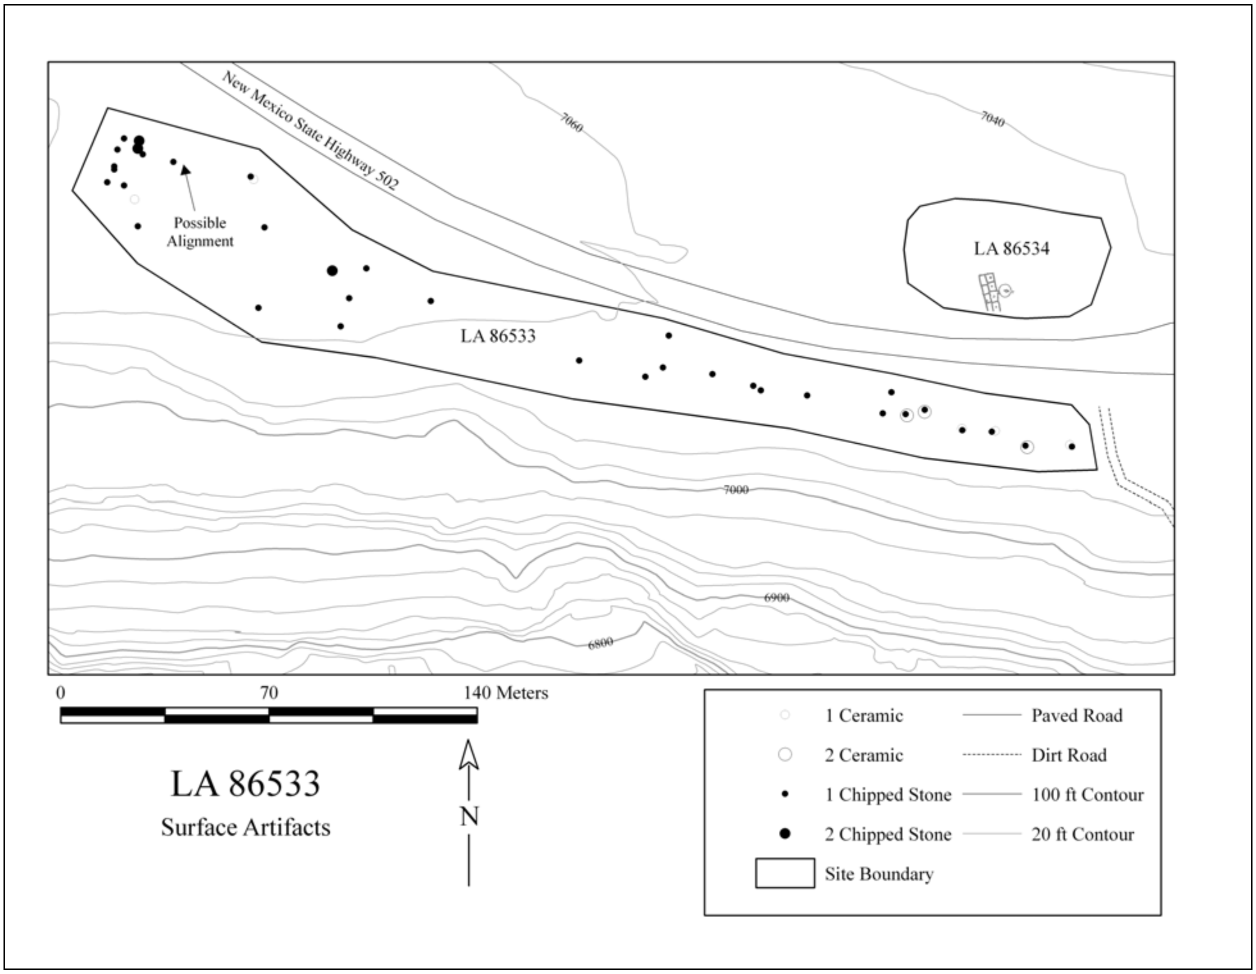

Figure 22.2. Distribution of surface artifacts at LA 86533.

ANALYSES

All 46 artifacts recovered from LA 86533 were analyzed. No archaeobotanical, pollen, or faunal remains were recovered since no subsurface excavations were conducted at the site.

Ceramics (Dean Wilson)

The ceramic assemblage is limited to 14 sherds (Table 22.1). Most of these are either Santa Fe Black-on-white or smeared-indented corrugated ceramics which date to the Coalition period.

Table 22.1. Ceramic types from LA 86533.

Pottery Type	Frequency	Percent
Northern Rio Grande Whiteware		
Undetermined painted ware	4	28.6

Pottery Type	Frequency	Percent
Santa Fe Black-on-white	3	21.4

Northern Rio Grande Utilityware		
Smeared-indented corrugated	5	35.7
Total	**14**	**100.0**

Chipped and Ground Stone (Bradley Vierra and Michael Dilley)

Material Selection

A total of 32 artifacts were analyzed from LA 86533, consisting of 30 pieces of debitage, and two retouched tools. This represents a 100 percent sample of the lithic artifacts recovered during the site surface collections. Table 22.2 presents the data on lithic artifact type by material type. The majority of the debitage is obsidian, with lesser amounts of other materials. In addition, both retouched tools are also made of obsidian. Obsidian is present in the nearby Jemez Mountains source areas. The chalcedony, Pedernal chert, and chert are available from local Rio Grande Valley gravel sources. Otherwise, the basalt is available both as bedrock outcrops and in stream gravels that cross-cut the Pajarito Plateau.

Table 22.2. Lithic artifact type by material type from LA 86533.

Artifact Type		Material Type

Most of the debitage consists of core flakes, with fewer biface flakes, pieces of angular debris, and microdebitage. The biface consists of a broken midsection, and the projectile point is the base of a Late Archaic stemmed dart point (Figure 22.3). The tip was presumably broken during impact, but cracked on an inclusion in the obsidian. Metrical and descriptive information on the projectile point is presented in Table 22.3.

Table 22.3. Projectile point metrical (mm) and descriptive data.

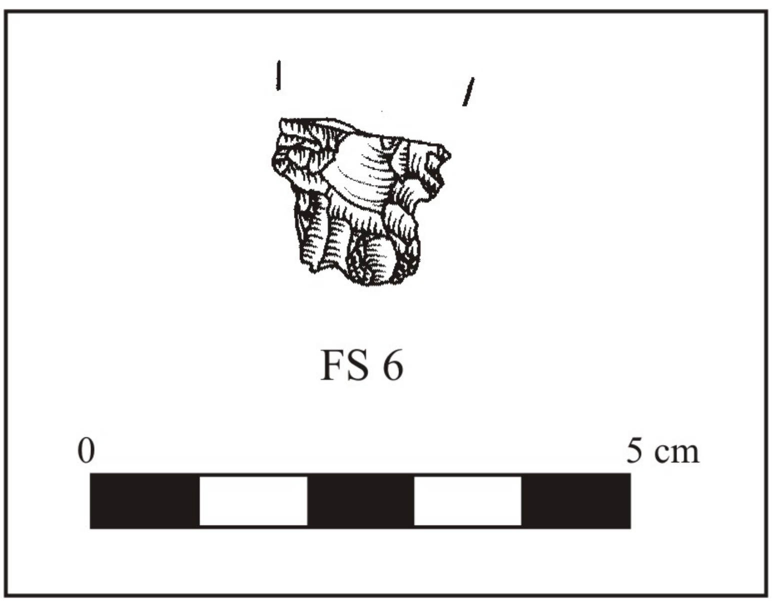

Figure 22.3. Late Archaic projectile point.

SUMMARY AND CONCLUSIONS

LA 86533 consists of a dispersed lithic and ceramic scatter that includes at least two temporal components. One of these components dates to the Late Archaic period and is primarily situated in the western area of the site. On the other hand, the Santa Fe Black-on-white and smeared-indented corrugated sherds located in the eastern section of the site are probably associated with the nearby Coalition period roomblock at LA 86534.

CHAPTER 23
AIRPORT-SOUTH TRACT (A-5-1): LA 139418

Jennifer E. Nisengard, Kari M. Schmidt, and Bradley J. Vierra

INTRODUCTION AND SITE SETTING

This chapter presents the results of surface collections and excavations conducted at LA 139418. The site is located in the Airport-South Tract east of the Los Alamos town site and south of State Road 502. LA 139418 consists of a grid garden and surrounding lithic and ceramic scatter. A Coalition period roomblock (LA 135290) is located to the north of the site and a multi-component artifact scatter to the east (LA 86533) (see Figure 13.2). The site was identified during a pedestrian survey of the area in 2002, with excavations being conducted by Jennifer Nisengard (crew chief), Joseph Aguilar, Jennifer Boyd, and Todd Pitezel in 2003. The site is situated on a piñon and juniper covered mesa top at an elevation of 2123 m (6965 ft).

SITE DESCRIPTION AND FIELD METHODS

LA 139418 consists of an isolated grid garden feature that was surrounded by an extensive lithic and ceramic scatter. Overall, the artifact scatter covers approximately 2000 m^2. It is situated on a gentle southeast-sloping area of the mesa that affords minimal runoff over the site. Unlike LA 86533, which was heavily eroded, there appears to be about 70 cm of soil overlying the bedrock. Nonetheless, small erosional drainages are present in the area that have cut down through these surface soils and partially affected the distribution of surface artifacts.

A pedestrian survey was conducted by the field crew to identify the aerial extent of the scatter. The site was subsequently divided into 1- by 1-m grid units. The initial site grid was established using a transit and a Nikon DT 521 Electronic Mapping Station. Using baseline points, 100-m tapes were laid out and a surface collection was conducted in 1- by 1-m units. This grid system covered a roughly 40- by 50-m area (60-95N/80-125E). The crew encountered hundreds of artifacts, with surface items being collected and bagged by artifact type within the specific grid units. Figure 23.1 illustrates the location of the grid garden relative to the chipped stone artifact scatter. As can be seen, there are several artifact concentrations that are spread across the site area. The artifact scatter and grid gardens were therefore divided into five separate areas or providences (Table 23.1).

Area 1 is 26 by 18 m in size and includes the grid garden feature. Excavations were limited to the grid garden, with few surface artifacts being present in the area. Area 2 is 40 by 12 m in size and is situated to the east and southeast of Area 1. Two dense concentrations of artifacts were identified in Area 2, although no features were present. Area 3 is 25 by 14 m in size and is located to the south of Area 1. Area 3 includes an artifact scatter and a southeast-trending erosional drainage, within which a concentration of chipped stone artifacts was identified. Otherwise, no features were identified within this locale. Area 4 is 17 by 9 m in size and is situated to the west and northwest of Area 1. It contains a concentration of artifacts, but also includes portions of the southeast-trending erosional drainage that continues into Area 3. Again, no features were identified within this area. Lastly, Area 5 is situated to the south and southeast of Area 1 and was defined by the presence of three isolated artifact clusters located adjacent to the mesa edge and DP Canyon. Artifacts within this area were collected by geographic positioning system (GPS) location and not within the 1- by 1-m site grid system.

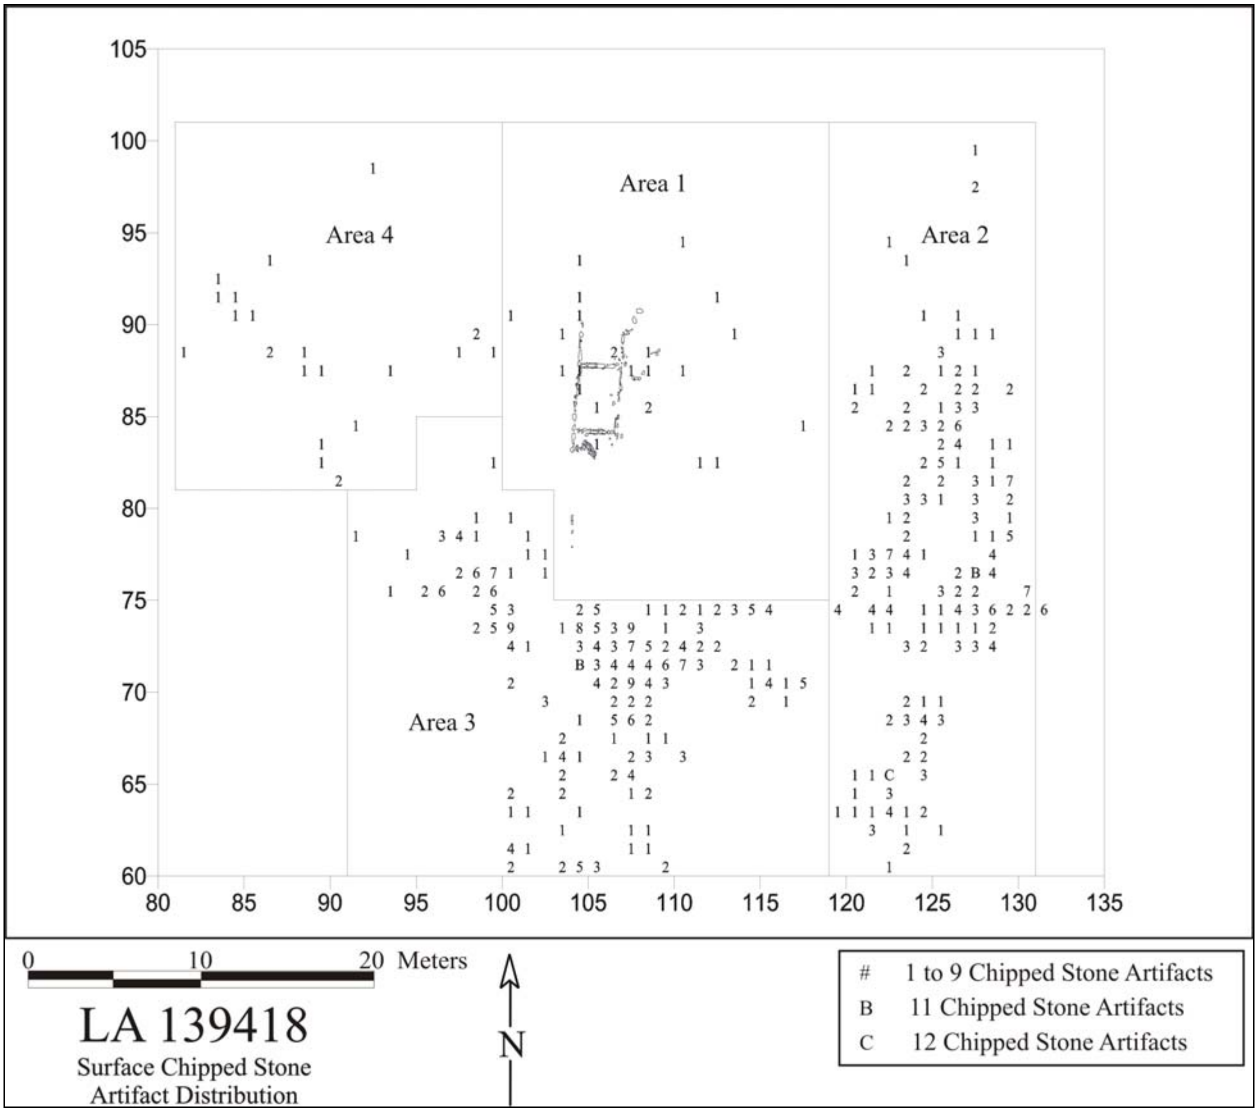

Figure 23.1. Distribution of chipped stone artifacts and features at LA 139418.

Table 23.1. Areas defined during the excavation of LA 139418.

Area Number	Area Location (Grids N/E)	Area Description
1	N 75-100/E 100-118	Grid gardens and the associated artifact scatter.
2	N 60-100/E 119-131	Sample area of artifact scatter to the east of Area 1.

Area Number	Area Location (Grids N/E)	Area Description
3	N 60-85/E 91-118	Artifact concentration south of Area 1.
4	N 81-100/E 81-99	Artifact concentration west of Area 1.
5	3970926N 386014E	Three artifact concentrations near canyon rim.

STRATIGRAPHY

Geomorphologists Steve Reneau and Paul Drakos (Voulme 3, Chapter 57) characterized the stratigraphy at LA 139418 using three profiles from inside the grid gardens and one from the control unit to the east (Table 23.2). Four major soil horizons were defined within the grid garden. These consist of AC (Stratum 1), Bw (Stratum 2), Btb2 (Stratum 3), and Btkb2 (Stratum 5). They correlated the soil profile at LA 139418 with the soil profile at the nearby Classic period fieldhouse at LA 141505 and suggest that the both sites are associated with the top of the Bw soil horizon. This contrasts with the Coalition period roomblock at LA 135290, which is situated at the bottom of the Bw soil and at the Bw and Bwb1 interface. Therefore, the LA 139418 grid garden would appear to date to the Classic period.

Table 23.2. Stratigraphic descriptions for LA 139418.

Stratigraphic Unit	Area	Grid	Thickness (meters)	Color	Texture	Description
0	1	1, 2, 3	0	10YR 4/4	Silty loam	Post-occupational fill. Loose aeolian surface sediments.
1	1	1, 2, 3	0–0.04	10YR 4/4 to 3/4	Silty loam	Post-occupational fill. Loose aeolian surface sediments with some crumbling tuff block and some modern trash.
2	1	1, 2, 3	0.04–0.15	10YR 3/4 to 4/5	Silty loam	Grid garden fill. Loose, unconsolidated silty loam with small rocks and gravels, small roots, and few artifacts.
3	1	1, 2, 3	0.15–0.55	10YR 4/4	Silty clay	Pre-occupational fill. More structured with some mottles, larger roots, very few rocks, gravels, and/or artifacts.
4	1	1	0.15–0.20	10YR 4/4	Silty clay	Pre-occupational fill.
5	1	2, 3	0.55–0.80	7.5YR 4/4	Silty clay	Pre-occupational fill. Compact silty clay with peds and some calcium

Stratigraphic Unit	Area	Grid	Thickness (meters)	Color	Texture	Description
						carbonate. Roots in Grid 3 not in Grid 2.
6	1	3	0.04–0.07	7.5YR 4/6	Silty loam	Pre-occupation fill. Thin layer of reddish-brown compact silty loam with a few volcanic tuff inclusions. Strata not recognized by geomorphologists.
7	2	-	0.79–0.81	10YR 4/3	Silty clay	Thin layer of unconsolidated clay directly atop bedrock (only identified in 86N 121E).
8	1, 2	-	0.07–0.15	10YR5/3 (dry) 10YR 3/3 (wet)	Silty loam	Thin layer of whitish-gray silty loam, between Strata 1 and 3. Only found in units outside the grid gardens, indicative of a strong soil formation.

Table 23.3 presents all of the artifacts recovered during excavation of the grid garden in their stratigraphic context.

Table 23.3. LA 139418 artifact counts by stratum.

Stratum	Ceramics	Chipped Stone	Ground stone	Total Number of Artifacts

SITE EXCAVATION

Area 1

Excavation of the grid garden feature was conducted in June and July, 2003. It consists of three attached grid garden units within a 3 by 8 m area. Figure 23.2 illustrates the plan view and profile of the north-south excavation trench that cross-cuts the agricultural feature. Root and rodent disturbance was a problem in the uppermost levels of the excavated units, with two juniper trees and one large piñon tree being located south of Grid 3. Rodent disturbances were most common in the excavation units closest to the grid walls, where gaps between wall rocks and soft sediments associated with the grids were plentiful. In addition, a 1- by 1-m control unit (86N/121E) was also excavated to the east of the feature to establish a comparative stratigraphic soil profile.

Grid 1. Grid 1 is the northernmost grid and appears to have sustained some minimal damage that may be associated with nearby road construction. The eastern and westerns walls of Grid 1 are a single course high and extended approximately 2 m from the central wall. Strata 1 to 5 were exposed within this bounded area (Figure 23.3). Three pieces of chalcedony, obsidian, and basalt debitage and a smeared-indented corrugated, Sapawe Micaceous, and undifferentiated whiteware sherd were recovered during excavation of Grid 1 (Table 23.4). Maize pollen was identified in samples taken from Strata 1 and 2.

Grid 2. Grid 2 is the central grid and is the most complete and elaborate of the three grids. The upper sections of the northern and southern walls are relatively narrow, while the bottom course of the wall is almost twice as wide. Relatively thin, wide blocks were used to build the foundation for the northern and southern walls, while larger blocks were used to construct the upper course (Figure 23.4). Interestingly, the eastern and western walls were constructed in a different manner. These walls consist of a single course of tuff blocks, many of which are upright.

Strata 1, 2, 3, and 5 were exposed in Grid 2 (Figure 23.5). However, unlike Grid 1, no maize pollen was identified in any of the strata. Cultural deposits associated with Grid 2 are relatively shallow (4 to 15 cm), although the wall is quite deep (0 to 30 cm). Calcium carbonate was observed within 10 cm of the surface in some of the units within Grid 2. Most of the artifacts recovered from the grid garden were derived from Grid 2 (Table 23.5). These primarily consist of obsidian and chalcedony microdebitage, with Sapawe Micaceous, plain gray body, and undifferentiated whiteware sherds.

Grid 3. The eastern and western walls of Grid 3 were quite similar to those exposed in Grid 1. That is, they consisted of a single course of shaped and unshaped tuff blocks, except in this case, the grid opens to the south. Strata 1, 2, 3, and 5 were also exposed within Grid 3, and like Grid 2, no maize pollen was identified. However, like Grid 1, very few artifacts were recovered during the excavation of Grid 3 (Table 23.6). These consist of chalcedony and Pedernal chert debitage and smeared-indented corrugated and undifferentiated whiteware sherds.

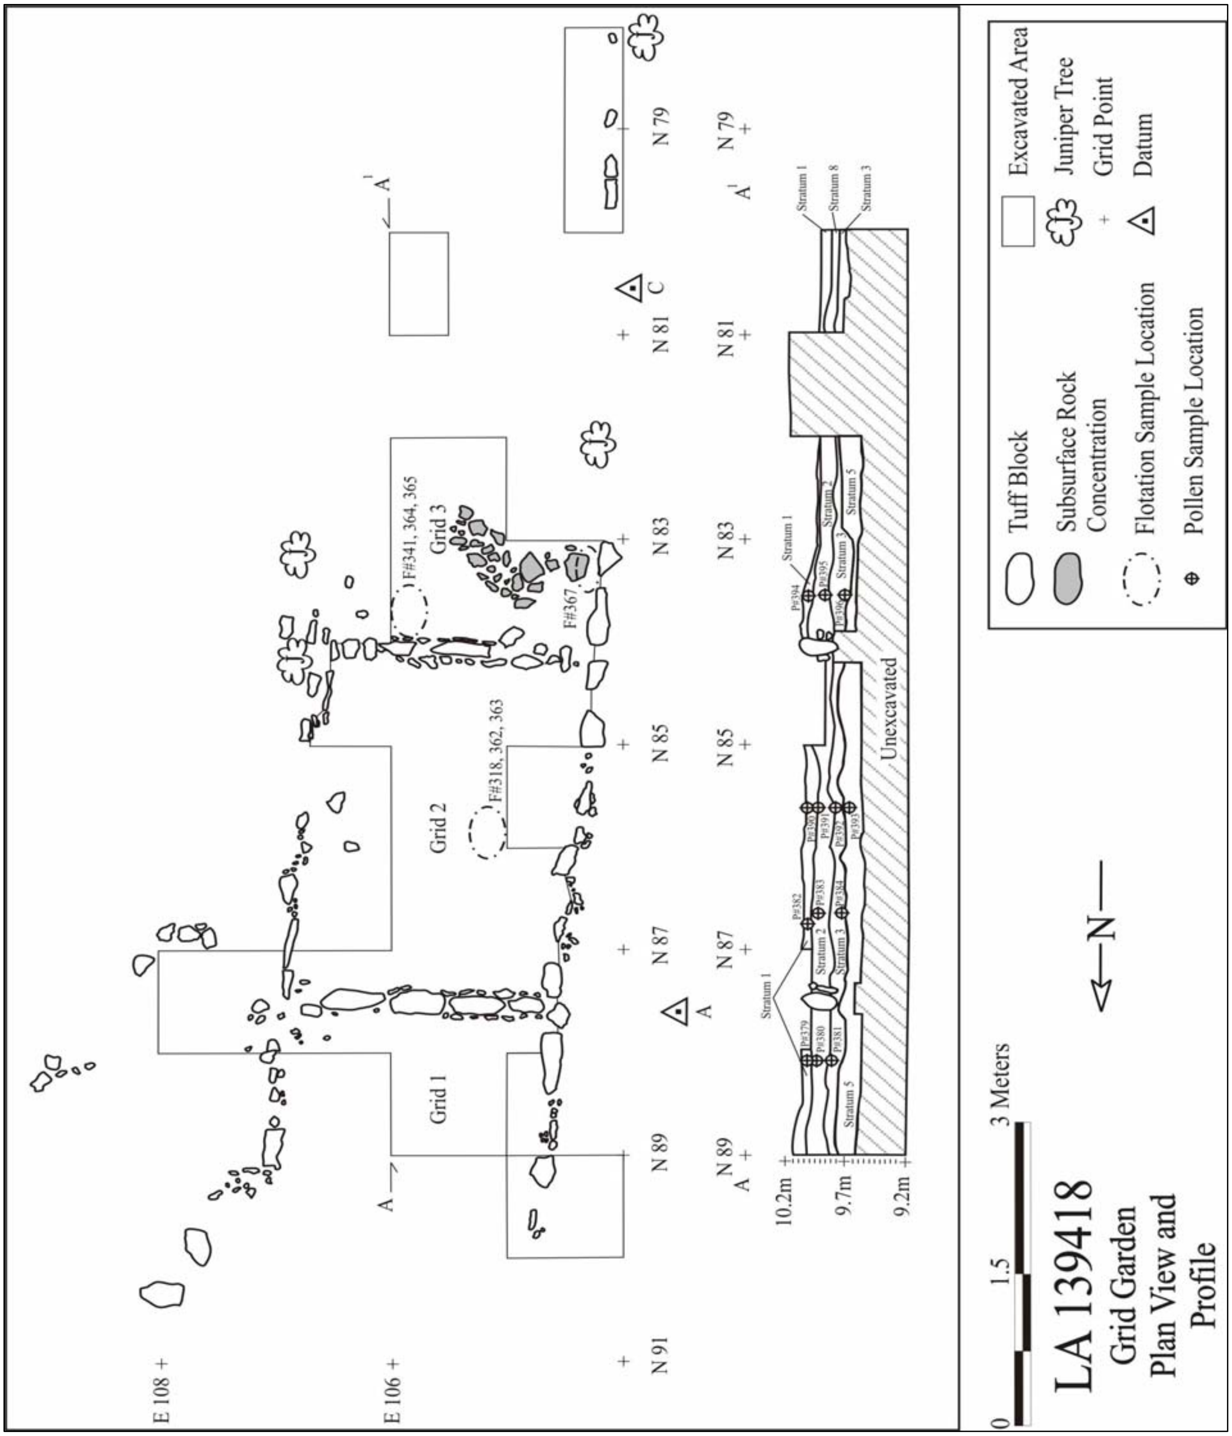

Figure 23.2. Plan view and profile of LA 139418 after excavation.

Figure 23.3. East wall profile of Grid 1.

2	1	2	3
3	1	1	1

Two 0.50- by 1-m units were also excavated to the south of Grid 3 to determine if any cultural remains were present in this area. Although none were encountered, the stratigraphic sequence is informative. Strata 1, 8, and 3 were exposed. In this case, Stratum 8 replaces Stratum 2 (cultural grid fill) and consists of a well-developed soil horizon; that is, the undisturbed virgin soil present around the grid garden feature.

A concentration of fist-sized rocks was identified in the northwest corner of Grid 3 in units 82N/105E, 83N/105E, and 83N/104E (Figure 23.6). The rock concentration was relatively shallow and did not appear to have been part of any formal construction. Excavators hypothesized that these rocks may have been stacked for use during grid construction or for wall repair.

Figure 23.6. A concentration of small tuff blocks encountered near the wall separating Grids 2 and 3.

Areas 2, 3, 4, and 5

Area 2 is located east and southeast of the grid garden. A total of 313 artifacts were recovered from surface collections in 131 1- by 1-m grid units (Figures 23.1 and 23.7). These consist of 303 pieces of chipped stone, nine ceramics, and one piece of ground stone.

A 1- by 1-m control unit was excavated within Area 2 to provide a geomorphic comparison with the soil profile observed in the grid garden. Excavation of 86N/121E proceeded in arbitrary 10-cm levels down to a depth of 60 cm below the surface. Strata 1, 3, 5, and 7 were exposed in the soil profile. That is, the soil profile is similar to the one exposed within the grid garden, with the exception of the absence of Stratum 2 (cultural fill). This also corresponds with the excavation unit located south of Grid 3, which failed to identify the presence of Stratum 2. Several pollen and flotation samples were collected from the unit, but no artifacts were recovered. Prickly pear, cheno-ams, grass, piñon pine and juniper pollen were the most common species identified.

Area 3 is situated south of Area 1. A total of 338 artifacts were surface collected within this provenience. The majority of these are obsidian, chalcedony, Pedernal chert, and basalt pieces of debitage, with three utilityware sherds.

Figure 23.7. Area 2 artifact scatter.

Area 4 consists of a sparse surface scatter located to the west of Area 1. Forty-nine artifacts were collected from 29 1- by 1-m grids. These consist of 23 chipped stone artifacts, 25 ceramics, and one ground stone fragment.

Area 5 consists of three small obsidian concentrations near the canyon edge. Ninety six chipped stone artifacts and two ceramics were collected in this locale. All the artifacts were found on the exposed bedrock and were point located using a GPS unit. In at least one case, it appears that some of the artifacts were collected from the nearby surface scatter and then placed in a pile on the exposed bedrock.

Figure 23.8 illustrates the distribution of ceramic and ground stone artifacts at the site. These artifacts are primarily distributed across the northern section of the site where the grid gardens are located. This contrasts with the distribution of chipped stone artifacts, which are primarily situated in the eastern (Area 2) and southern (Area 3) portions of the site. This northern ceramic assemblage is dominated by the presence of Classic period glazeware ceramics, which could be associated with the use of the grid garden and/or the fieldhouse located to the north at LA 141505. On the other hand, the remainder of the lithic scatter may represent a separate component that, in part, dates to the Late Archaic. A single Late Archaic projectile point was found in Area 2, and this scatter could represent a continuation of the Late Archaic period occupation located to the east at LA 86533.

SITE CHRONOLOGY AND ASSEMBLAGE

Approximately 400 artifacts were recovered during the excavations and surface collections at LA 139418. All of these artifacts were analyzed, with a set of pollen, flotation, and macrobotanical samples that were analyzed from the excavations conducted within the grid garden. The pollen and flotation samples were selected from each stratigraphic layer within the three individual garden grids. No faunal remains were recovered. A single piece of piñon pine was submitted for radiocarbon dating and eight obsidian artifacts for hydration dating. The results of these artifact and sample analyses are presented in this section.

Chronology

Radiocarbon Dating

A single radiocarbon sample was submitted for analysis from this site. Several piñon pine (*Pinus edulis*) fragments were collected from a macrobotanical sample (Field Specimen [FS] 334) taken from Stratum 2 within Grid 1. Maize pollen was recovered from this grid, so the sample was presumed to be in good association with the use of the grid garden. However, this yielded an intercept date of AD 690, with a two sigma range of AD 650 to 790 (Table 23.7). Based on the surface ceramics and geomorphologic context, it seems probable that the feature dates to the Classic period. If so, this charcoal may represent surface material that simply washed down into the grid from its open northern end.

Table 23.7. Radiocarbon dates from LA 139418.

FS#	Material	Laboratory #	Conventional radiocarbon age	Intercept of radiocarbon age	2-sigma calibrated result
334	piñon pine	199390	1310±50 BP	AD 690	AD 650–790

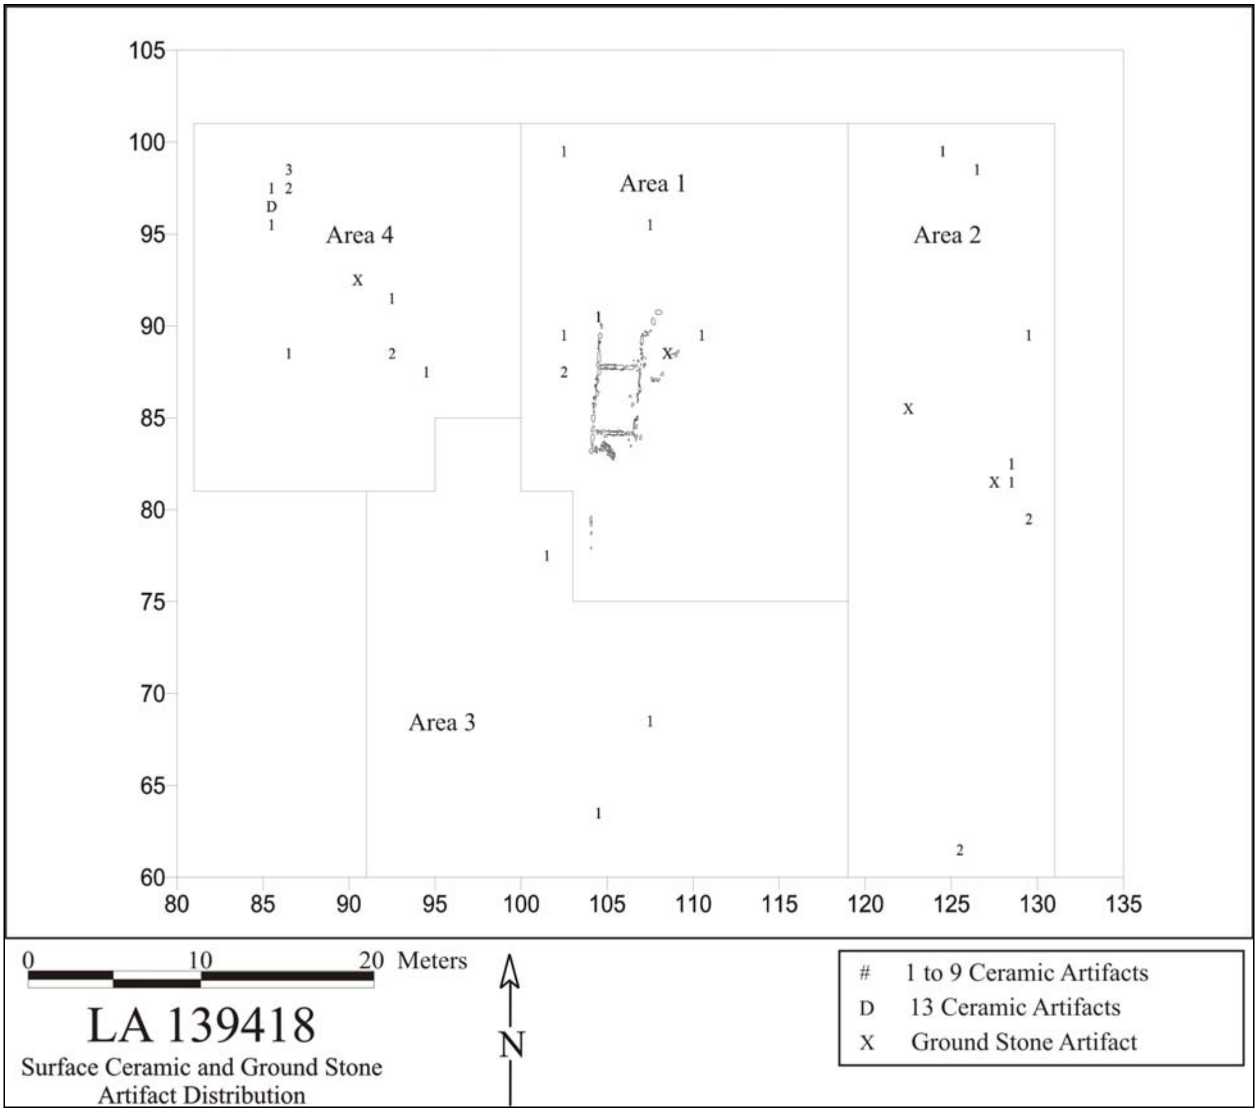

Figure 23.8. Distribution of ceramics, ground stone artifacts, and features at LA 139418.

Obsidian Hydration Dating

Eight obsidian artifacts from LA 139418 were submitted to the Diffusion Laboratory for age determination using the obsidian hydration dating method. In order to calculate the absolute date for an obsidian artifact, three analytical procedures were completed. First, the amount of surface hydration, or the thickness of the hydration rim, was measured. Second, the high temperature hydration rate constants for each artifact were determined from the composition of the glass. Lastly, the soil temperature and relative humidity at the archaeological site was estimated in order that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. Using these methods, a hydration rate for the obsidian artifacts was calculated (Table 23.8).

Table 23.8. Obsidian hydration dates for LA 139418.

FS No.	Lab No.	Source	Rim (um)	AD/-BC	1 S.D.
4	2006-48	Valle Grande	3.77	669	69
26	2006-49	Valle Grande	4.99	-7908	399
53	2006-50	Cerro Toledo	3.31	-2379	265
104	2006-51	Valle Grande	4.29	-341	108
109	2006-52	Valle Grande	3.61	-3113	284
111	2006-53	Cerro Toledo	3.38	-2460	265
116	2006-54	Valle Grande	3.17	-1901	247
146	2006-55	Valle Grande	3.22	-2151	259

All of the hydration dates are from artifacts recovered in the Areas 2 and 3 surface scatter. Based on these dates, it would appear that Early, Middle, and Late Archaic components may be represented, as well as the Developmental period. However, only Late Archaic points with Coalition and Classic period ceramics were recovered from these contexts.

Ceramic Artifacts (Dean Wilson)

The ceramic assemblage can be separated into the artifacts recovered during the excavation of the grid garden feature in Area 1 and artifacts recovered from surface contexts across the site.

The ceramics from the grid garden consist of plain gray body, smeared-indented corrugated, Sapawe micaceous, and several undifferentiated whiteware sherds (Table 23.9). These ceramics appear to represent a mix of Coalition and Classic period types that could have been derived from adjacent surface deposits. The small surface assemblage recovered from the site is dominated by Classic period glazeware ceramics, with a few biscuitwares and Coalition period whiteware sherds (Table 23.10). The 21 glazeware sherds are all tempered with crushed basalt and appear to represent both jars and bowls. In contrast, the biscuitware sherds are from jars, but the Coalition period whitewares are from bowls. The latter could have been derived from the nearby Coalition period roomblock at LA 135290, with the remainder being associated with the use of the grid garden feature.

Table 23.9. LA 139418 (Area 1, grid garden) ceramic types.

Pottery Type	Frequency	Percent

Glaze Red body undifferentiated	2	7.7
Glaze unslipped body	1	3.8
Total	**26**	**100.0**

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 365 artifacts were analyzed from LA 139418, consisting of 352 pieces of debitage, 10 retouched tools, and three ground stone artifacts. This represents a 44 percent sample of the 831 total lithic artifacts recovered during data recovery activities. The site was separated into two distinctive proveniences. Area 1 includes the excavated grid garden feature and Areas 2 through 5 consist of the surrounding lithic and ceramic scatter. Table 23.11 presents the data on lithic artifact type by material type for Area 1 (n = 42). Debitage was the only lithic artifact recovered during the excavations. The majority of these consist of core flakes, angular debris, and microdebitage, with two biface flakes. The artifacts are primarily made of chalcedony with lesser amounts of obsidian and other materials. In contrast, a total of 323 artifacts were collected from surface contexts in Areas 2, 3, and 4. The information on artifact type by material type is presented in Table 23.12. Again, most of the debitage is made of chalcedony with lesser amounts of obsidian, Pedernal chert, and other materials. The retouched tools are also primarily made of chalcedony and obsidian. Lastly, the ground stone items are made of igneous materials.

Table 23.11. Area 1 lithic artifact type by material type.

The presence of cortex on 5.4 percent of the debitage from Areas 2 and 3 indicates that these materials were collected from nodule and waterworn sources. The chalcedony, Pedernal chert, and quartzite are available from local Rio Grande Valley gravel sources and the basalt from gravels and bedrock outcrops. Obsidian is present at nearby primary sources in the Jemez Mountains. Otherwise, the ground stone artifacts are primarily made from igneous materials, which are available both as bedrock outcrops and in stream gravels that cross-cut the Pajarito Plateau.

Ten pieces of debitage, three retouched tools, and a projectile point were submitted for XRF analysis. With the exception of the projectile point, all of these artifacts were recovered from Areas 2 and 3. Most of the artifacts were from the Valle Grande source, with three from the Cerro Toledo source and a single retouched tool from the El Rechuelos source (Table 23.13; see Shackley, Volume 3). The Valle Grande (Cerro del Medio) and Cerro Toledo (Rabbit Mountain/Obsidian Ridge) source areas are located about 18 km (11 miles) as the "crow flies" to the west and southwest of the site; whereas, the El Rechuelos (Polvadera Peak) source area is situated about 24 km (15 miles) to the northwest.

Table 23.13. Obsidian source samples.

259	Tool	Black opaque	Cerro Toledo rhyolite

Lithic Reduction

The majority of the flakes in Areas 2 and 3 exhibit single-faceted platforms (*n* = 17), with crushed (*n* = 13), collapsed (*n* = 7), multi-faceted (*n* = 5), and cortical (*n* = 2) platforms. Ten (22.7%) of the flake platforms do exhibit evidence of preparation, with all but one of these being abraded/crushed and the other being abraded/ground.

The majority of the core flakes consist of distal fragments (*n* = 71; 44.3%), with fewer whole (*n* = 12), proximal (*n* = 26), midsection (*n* = 46), and undetermined fragments (*n* = 5). Most of the biface flakes are proximal fragments (*n* = 16; 40.0%), with fewer whole (*n* = 2), midsection (*n* = 13), and distal (*n* = 9) fragments. The whole core flakes have a mean length of 24.2 mm (*std* = 8.3), whereas, the whole biface flakes exhibit a mean length of 19.7 mm (*std* = 0.1). Lastly, angular debris have a mean weight of 2.6 g (*std* = 2.8).

The retouched tools consist of a mix of expedient flakes tools like retouched pieces and a notch, whereas the formal tools consist of bifaces and a projectile point. All of the retouched pieces exhibit a unidirectional dorsal retouched edge, with a straight outline and angles ranging from 55 to 75 degrees. The notched tool consists of a single notch situated at the distal end of a flake with an edge angle of 35 degrees. The bifaces are midsection and distal fragments. They were presumably broken during the middle to late stages of the manufacturing process, having edge angles that range from 35 to 50 degrees. The projectile point is a Late Archaic stemmed point midsection with distinctive tangs (Figure 23.9).

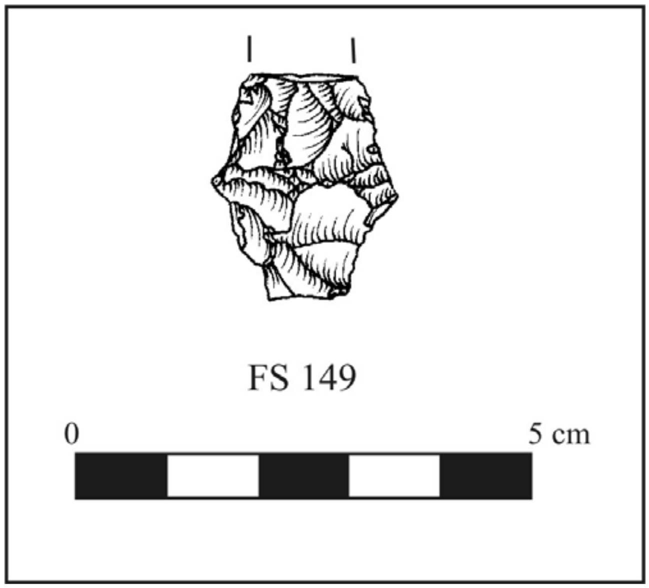

Figure 23.9. Late Archaic stemmed point from LA 139418.

Tool Use

Only two flakes (1%) exhibit evidence of damage that can be attributed to use. One of these was used at the end of the flake with an edge angle of 65 degrees and the other was used along the lateral side of the flake with an edge angle of 45 degrees. The projectile point was presumably broken during the use, having a broken tip and base.

The ground stone artifacts consist of two undetermined mano fragments that are broken cobbles with ground surfaces. The polishing stone is a pebble with a slightly concave polished surface. The polished area exhibits a gray discoloration, as compared to the rest of the pebble, which is a tan/orange color.

Samples

Pollen, flotation, and macrobotanical samples were collected from the grid garden and from the control unit (Table 23.14). Four stratigraphic units were included from the grid garden: Stratum 1 (AC), Stratum 2 (Bw), Stratum 3 (Btb2), and Stratum 5 (Btkb2). An additional soil horizon (Stratum 7; Btkb2/3) was also included from the control unit.

Archaeobotanical Remains (Pamela McBride)

Flotation samples from two of the three garden grids at LA 139418 produced unburned non-cultural plant remains, all representative of plants or trees growing in the immediate vicinity of the site today, including goosefoot seeds and conifer duff (Table 23.16). A fragment of pine and another of unknown conifer charcoal were recovered from the rock concentration in the northwest corner of Grid 3. Vegetal sample charcoal was primarily pine (75% by weight), with lesser amounts of cf. piñon, cf. ponderosa pine, unknown conifer, and saltbush/greasewood (Table 23.17). The presence of charcoal in the grid garden could be a product of burning brush to clear or fertilize the fields as described in the discussion of grid gardens at LA 128803. On the other hand, it could also represent natural slope wash into the grids.

Pollen Remains (Susan Smith)

A total of 18 pollen samples were analyzed from LA 139418. Table 23.18 lists the frequency of identified pollen types. Cultigens identified in the assemblage included maize and cholla. Economic resources identified in the pollen assemblage included prickly pear, cactus family, beeweed, sunflower type, and cattail. A number of other potential economic resources were identified in the assemblage (Table 23.18), and these are described in detail in Smith's chapter in Volume 3 (Chapter 63).

Pollen samples were collected from Grids 1, 2, and 3, as well as from a control unit located several meters east of the grid garden. The results of these analyses are presented below.

Grid 1. Three samples were analyzed from Grid 1. Taxa identified in Stratum 1 included maize (*Zea mays*), prickly pear (*Opuntia*), cheno-ams, grass family (Poaceae), sunflower family (Asteraceae), ragweed/bursage (*Ambrosia*), broad spine sunflower, fir (*Abies*), unidentified pine (*Pinus* sp.), piñon pine (*Pinus edulis*), juniper (*Juniperus*), oak (*Quercus*), Mormon tea (*Ephedra*), and sagebrush (*Artemisia*). Taxa identified in Stratum 2 included maize, beeweed (*Cleome*), cheno-ams, grass family, sunflower family, fir, piñon pine, juniper, oak, and sagebrush. Taxa identified in Stratum 3 included cheno-ams, grass family, sunflower family, ragweed/bursage, fir, unidentified pine, piñon pine, juniper, rose family (Rosaceae), Mormon tea, and sagebrush.

Grid 2. Seven pollen samples were analyzed from Grid 2. The two samples from Stratum 1 included the following taxa: prickly pear, cheno-ams, grass family, broad spine sunflower, sunflower family, ragweed/bursage, spurge family, penstemon family (Scrophulariaceae), fir, unidentified pine, piñon pine, juniper, oak, rose family, Mormon tea, and sagebrush. Two samples were collected from Stratum 2, and the identified taxa included cholla (*Opuntia*), prickly pear, cactus family (Cactaceae), buckwheat (*Eriogonum*), cheno-ams, grass family, sunflower family, evening primrose (Onagraceae), spurge family, piñon pine, rose family, sagebrush, and juniper. Two samples were analyzed from Stratum 3. Identified taxa included prickly pear, cheno-ams, grass family, sunflower family, long spine sunflower, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush. A single sample was analyzed from Stratum 5. Taxa identified in this stratum included prickly pear, long spine sunflower, cheno-ams, grass family, sunflower family, ragweed/bursage, broad spine sunflower, unidentified pine, piñon pine, juniper, and oak.

Grid 3. Three pollen samples were analyzed from Grid 3, one each from Strata 1, 2, and 3. Taxa identified in Stratum 1 included prickly pear, beeweed, cattail (*Typha*), cheno-ams, sunflower family, broad spine sunflower, ragweed/bursage, penstemon family, fir, unidentified pine, piñon pine, juniper, oak, walnut (*Juglans*), rose family, Mormon tea, and sagebrush. Taxa identified in Stratum 2 included prickly pear, beeweed, cheno-ams, grass family, sunflower family, Douglas fir (*Pseudotsuga*), unidentified pine, piñon pine, juniper, oak, rose family, and Mormon tea. Taxa identified in Stratum 3 included cheno-ams, grass family, sunflower family, ragweed/bursage, fir, unidentified pine, piñon pine, juniper, oak, and sagebrush.

Control Unit. Six pollen samples were collected in a control unit that was excavated south of Grid 3. Taxa identified in two samples from the uppermost stratum included prickly pear, cheno-ams, grass family, sunflower family, Douglas fir, unidentified pine, piñon pine, juniper, oak, rose family, Mormon tea, and sagebrush. Two samples were taken in Stratum 3. Identified taxa included prickly pear, cheno-ams, grass family, sunflower family, ragweed, spurge family, unidentified pine, piñon pine, juniper, and oak. One sample was collected in Stratum 5 and identified taxa included: cheno-ams, grass family, spurge family, fir, unidentified pine, piñon pine, and sagebrush. One sample was collected from Stratum 7. Pollen grains in this sample were too deteriorated to be identified.

CONSTRUCTION HISTORY

The central grid garden walls, those dividing Grids 1 and 2 and 2 and 3, appear to have been constructed first (Figure 23.10). The central walls consisted of two courses of shaped and unshaped tuff blocks. As previously mentioned the lower course was wider than the upper course, although the blocks used for construction were thinner. The eastern and western walls, which run uninterrupted from north to south were added to the central walls and consist solely of one course.

SUMMARY AND CONCLUSIONS

LA 139418 represents a relatively small agricultural feature, which consisted of one complete and two partial grids. The central grid garden (Grid 2) was 2 by 3 m and the northern and southern walls were very well constructed, with large shaped tuff blocks in the center and smaller unshaped tuff blocks on either side. The eastern and western walls of Grids 1, 2, and 3 were not as elaborate as the northern and southern walls and were constructed using fewer rocks with several gaps between the rocks. Grid 1 was not enclosed at the northern end and Grid 3 was not enclosed on the southern end. Deposits further than 2 m from the central walls were determined to be natural and not cultural, thereby supporting the contention that Stratum 2 represented the cultural fill of the grid garden. Maize pollen was recovered from Strata 1 and 2 in Grid 1, but not within either Grids 2 or 3. Nonetheless, it indicates that this important food staple was being grown at the site. The ceramic and geomorphological evidence indicate that the agricultural feature probably dates to the Classic period, being situated in a similar context as the Classic period fieldhouse located to the north at LA 141505.

On the other hand, hundreds of artifacts were found distributed across the site in Areas 2 and 3. Although these may include a Ceramic period component, it seems likely that much of this reflects a Late Archaic period occupation. If so, it would represent a continuation of the Late Archaic surface scatter situated to the east at LA 86533. The obsidian hydration dates indicate that a Middle Archaic component may also be represented.

CHAPTER 24
AIRPORT-EAST TRACT (A-3): LA 86534

Kari M. Schmidt

INTRODUCTION AND SITE SETTING

This chapter presents the results of excavations conducted at LA 86534. The site is located in the Airport-North Tract, east of the Los Alamos town site along the north side of State Road 502. The tract is situated near the eastern end of a gently sloping mesa between a tributary to Pueblo Canyon on the north and DP Canyon, a tributary to Los Alamos Canyon, on the south. The parcel ranges in elevation from 2153 m to 2196 m (7060 to 7200 ft) and is covered with a piñon-juniper woodland, isolated ponderosa pines, and an understory of saltweed, snakeweed, yucca, and various other native grasses, shrubs, and forbs.

The site is well-situated between the mountain slopes and the canyon lowlands, with ready access to both environments. The piñon nuts, grass seeds, and other plant foods available in the area were probably attractive to the settled agriculturalists, and the tree cover at the site and extending up the valley toward the mountain likely provided reliable fuel. Game animals on the mountain slopes and in the adjacent canyons could have provided food and hides, and the riparian zone along the drainage would have offered resources not widely available in this arid region.

Geologically, the soil within the tract is a Hackroy sandy loam that generally has a high potential for agriculture (Nyhan et al. 1978). However, with the tract being near the tip of the mesa, the soil deposit is fairly thin and often absent along the mesa edges. The lack of soil and rooting depth severely limits the potential to support agriculture. Bedrock beneath the mesa consists of the Tshirege Member of the Bandelier Tuff (unit Qbt). The mesa is capped by fine-grained soils that likely constitute either eolian sediments or locally reworked eolian sediments. Recent (late Holocene) sediments unconformably overly thin Pleistocene soils.

SITE DESCRIPTION

LA 86534 is located immediately north of Highway 502 at an elevation of 2149 m (7050 ft). The original cultural resource survey identified LA 86534 (temporary number S-11) as a possible roomblock. The roomblock area was characterized by several alignments of shaped and unshaped tuff blocks that measured approximately 18 m north-south by 16 m east-west. The rock alignments were situated amongst several piñon and juniper trees that partially obscured surface visibility. Figure 24.1 shows the site as it looked before excavation but with the 1- by 1-m grid laid out and several cleared piñon and juniper trees. Note the presence of abundant architectural stone on the surface and the mounded appearance.

Figure 24.1. Gridded units before excavation in western area of LA 86534.

In addition to the possible roomblock, a midden area was also identified in the southwest section of the site consisting of a small mound or rise that was located adjacent to New Mexico Highway 502. Although there was a sparse artifact scatter in the area to the east of the possible roomblock, it was unclear at the time of the cultural resource survey whether this rise reflected a buried cultural deposit or was simply disturbed road fill. The associated artifact scatter covered an area measuring approximately 50 m north-south by 44 m east-west. The majority of the identified ceramics consisted of Santa Fe Black-on-white with fewer indented corrugated, smeared-indented corrugated, St. John's Black-on-red, and Wiyo Black-on-white. The lithic artifacts consisted of obsidian and chert debitage, and a single obsidian projectile point tip was observed. One mano fragment was found in the midden area, and one possible polishing stone was also noted. Based on the diagnostic surface ceramics identified during the initial survey, it was thought the site likely dated to the Coalition period.

Initial excavations were undertaken at LA 86534 in the area identified as the possible roomblock. Within a couple of weeks, it became clear that the area associated with the shaped and unshaped tuff blocks on the surface was actually in a heavily disturbed area. Based on the excavations, it was determined that the tuff blocks were secondarily deposited in the area during road construction and that there were no intact alignments.

In addition to the excavations in the area of the possible roomblock and in accord with the data recovery plan (Vierra et al. 2002a), several test pits were placed in areas where 1) there was a high concentration of surface artifacts and 2) where there were areas of stone concentrations. The first test pit was placed over a stone concentration in the area identified as the midden in the initial survey. Just below the surface, an intact wall was identified. The excavation of the test pit and the exposure of the identified wall are shown in Figure 24.2. Excavation efforts immediately shifted to this area, and eventually, a nine-room pueblo was uncovered in an area where little to no surface rubble was present (Figure 24.3). The area suspected to be a roomblock during the initial survey turned out to be redeposited tuff blocks, while the area identified as the midden was overlying a buried roomblock and kiva.

Figure 24.2. Test pit in midden area where roomblock eventually was uncovered.

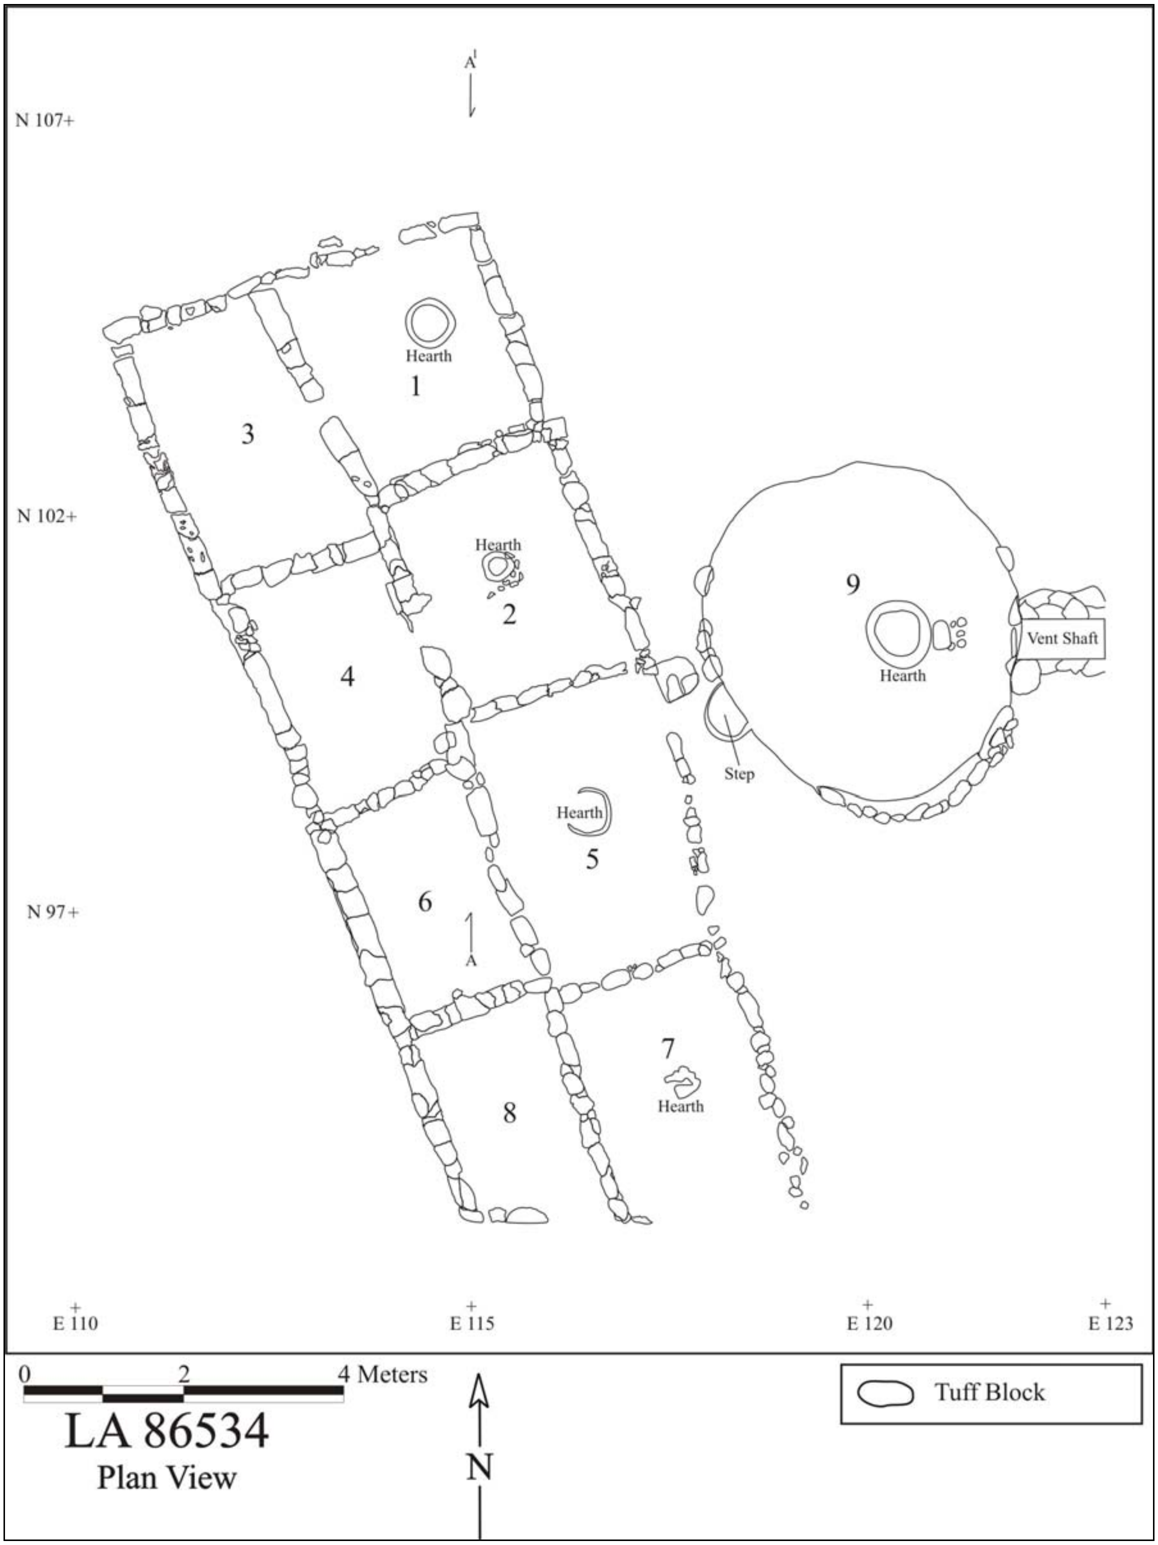

Figure 24.3. Final plan view map of LA 86534.

FIELD METHODS

Prior to any subsurface excavations at the site, both geomorphic and geophysical evaluations were conducted. The project geomorphologists visited the site and assessed its geomorphic context and integrity by digging shovel test holes in the areas around the sites (see Drakos and Reneau, Volume 1). The geophysical evaluation of the site involved a ground-penetrating radar (GPR) survey that was conducted over the surface of the site (see Nisengard et al., Volume 3). The GPR study was conducted in January 2002 to identify possible rock alignments, buried features, and rooms present at the site. The GPR technique was especially important at the outset of excavations at LA 86534 because of the poor condition of the site and the lack of surface visibility resulting from dense vegetative cover.

The site area at LA 86534 was not cleared of trees before the GPR survey and, as a result, portions of the site covered with piñon and juniper trees were not included. In addition to this complication, the area that was GPR'ed was directly correlated with the area where the possible roomblock was thought to be located. As already mentioned, this location turned out to be disturbed, and the actual location of the roomblock was some 8 m to the east. Because of this, the GPR survey picked up only the very western edge of the roomblock and missed the kiva entirely. Rock alignments thought to be walls were noted in the analysis of the data, but were not immediately recognized because of their distance from the supposed location of the roomblock. Post-excavation ground-truthing showed that the location of the possible walls correlated with the southwestern portion of the roomblock.

Fieldwork began at LA 86534 in June, 2002 with an initial assessment of the site. The crew walked over the site area, delineating the site boundaries and identifying the presence of artifact concentrations and features. A 1- by 1-m grid system that was laid out during the initial GPR survey was also used during the excavations to facilitate data corroboration. The central site datum (100N/100E for horizontal control, 10.0 m for vertical control) was established in the area to the southwest of the roomblock and a 1- by 1-m grid was laid out. The intersection of the southwest corner of each grid determined its grid coordinates. Using the established grid, controlled surface collections were made across the entire site, with all the materials being bagged separately by individual grid unit (see section on surface collections later in this chapter). Based on the distribution of surface artifacts and suspected features, three areas were designated at the site. Table 24.1 describes each of these areas and Figure 24.4 shows the relative proximity of these areas to each other.

Table 24.1. Designated areas at LA 86534.

Area Number	Area Location (Grids N/E)	Area Description
1	90 to 130N/125 to 140E	Midden area east of roomblock
2	90 to 130N/90 to 125E	Roomblock (western is original, eastern is actual)
3	130 to 135N/100 to 135E	Disturbed two-track just north of roomblock and midden

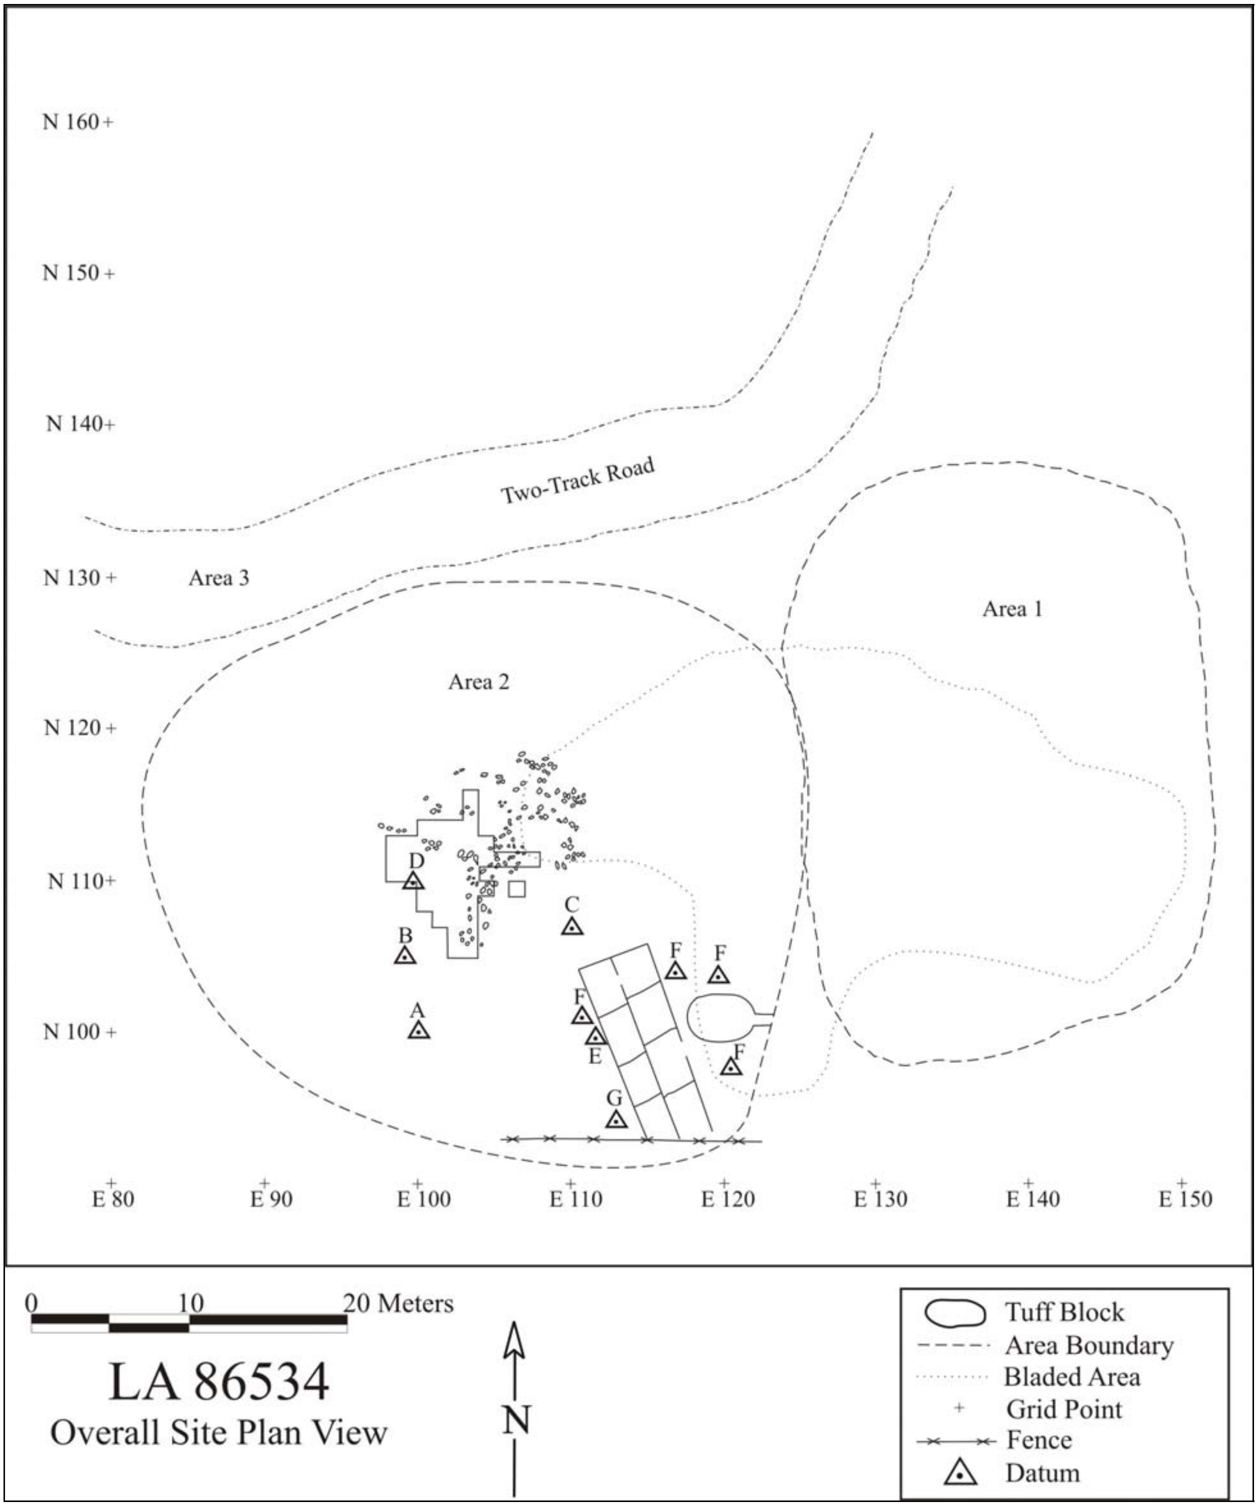

Figure 24.4. Map showing the general areas at LA 86534.

The designation of areas at LA 86534 was based on the presumed location of the possible roomblock at the beginning of excavation. Area 2 was designated as the roomblock and a demarcation point of 125E was selected. Initial observations of the artifact distribution showed a visible increase of artifacts to the east of this line, possibly suggesting a midden. As a result, the site was divided at this location to demarcate Area 1 (the midden) from Area 2 (the roomblock). Although the location of the actual roomblock was some 8 m east of the original presumed location, the revised location still fell within the confines of Area 2. A new area number was not given to the actual roomblock but was simply designated as the eastern portion of Area 2. Consequently, the western portion of Area 2 contains only the original area of excavation in the possible roomblock.

There was also a dense concentration of artifacts to the north of Areas 1 and 2, but they were clearly in a disturbed area. A fairly large two-track road paralleled the northern boundary of the site. The road had a number of prehistoric and historic artifacts associated with it, but it also had areas of gravel and concrete placed throughout its length. The two-track seemed to drop off into the canyon to the north of the site. Surface artifacts in Area 3 were sampled differently than Areas 1 and 2. In Areas 1 and 2, the artifacts from each 1- by 1-m grid were collected and bagged separately. In Area 3, which was heavily disturbed, two 3-m dogleash samples were collected. The southwest corner of a particular grid was used as the center point and artifacts were collected from 1.5 m in a complete circle around the grid point.

Hand excavation of LA 86534 began in earnest on June 24, 2002. Excavations were carried out by natural stratigraphic units, or in cases where the stratum was greater than 10 cm thick, in arbitrary 10-cm levels. Strata were defined as distinct depositional units and descriptions for each included soil kind, texture, compactness, and color using a Munsell soil chart (see the following section for an in-depth discussion of the stratigraphic sequence). With the exception of pollen, soil, and macrobotanical samples, all hand-excavated materials were screened through 1/8-in. mesh.

As outlined in Vierra et al. 2002a, roomblock excavations began by defining visible wall alignments based on surface indications (also see this volume). Once the outline of rooms was defined and the approximate center of the mound was identified, a north-south cross-section through the roomblock was excavated. The entire grid line was excavated minus the 1- by 1-m unit where the east-west cross-section intersected the north-south line. Although this procedure was implemented at LA 86534, the north-south line was tied in to the original test pit (101N/115E) conducted in the area of the roomblock and was not located directly in the center of the mound as there were no surface indications of the roomblock. As it happened, the 115E line ran through the front set of rooms and was located just east of the center. Once the majority of the 115E line was excavated, a profile was drawn. The intersecting east-west line was not excavated in one block as critical units in the 103N line were removed before a complete profile was drawn.

Stratigraphic profiles were drawn for many of the individual units. Once the fill in each of the rooms was removed in stratigraphic layers, each interior room floor was mapped. Locations of floor features, samples, and artifacts were all included on the maps. Pollen samples were taken from underneath artifacts lying on the floor and in features and other locations (corners of rooms) where the context might preserve these remains. After the floor artifacts were removed, the floor samples were taken, and the features were excavated, a single sub-floor test pit was dug to identify the presence of any earlier floors or features.

In previous excavations conducted at Coalition Period roomblocks at Los Alamos National Laboratory (LANL), kivas have typically been located east of the roomblock. Because there were no surface indications of the roomblock at LA 86534, and based on the pattern mentioned above, the area all around the roomblock was stripped in an attempt to locate potential wall alignments and possible features in the midden area. In late August 2002, a bobcat was brought to the site and an area about 25 m north-south by 45 m east-west to the north and east of the roomblock was surface-stripped (see Figure 24.4, bladed area). On average, 10 to 15 cm of sediment was removed in this 1125-m^2 area. While no dense concentrations of artifacts or obvious extramural features were found in the large area that was surface-stripped, not too surprisingly, a wall alignment was located to the east of the roomblock. A test pit was placed over this small exposure of linear rubble that was located 15 cm below the surface and a wall was identified almost immediately. Figure 24.5 shows this wall as it was initially being exposed.

Figure 24.5. Room 9 wall exposed in test pit; note rubble flush with bladed surface.

A 1- by 2-m test pit was dug on top of this wall alignment and an intact plastered floor was uncovered at 1.75 m below the bladed surface (8.02- to 7.98-m elevation). Due to time constraints, the hand excavation of Room 9 was not possible, and a bobcat was eventually used to remove the post-occupational fill and the wallfall in the kiva. Before the upper fill was removed, however, the entire perimeter of the kiva was exposed by hand excavation (Figure 24.6). To avoid damaging the walls, the perimeter grids were dug in 1- by 1-m units and were excavated to create a visual demarcation of Room 9 before mechanical excavation.

Figure 24.6. Perimeter of Room 9 being exposed before mechanical excavation of the fill.

Using the stratigraphic sequence established in the hand excavation of the 1- by 2-m unit, the bobcat removed the fill in the kiva to the top of rooffall. During the mechanical excavation of Room 9, the room was divided down the center along the 120E line. The bobcat removed the fill in four sections: west half, Stratum 1 (post-occupational fill), west half, Stratum 2 (wallfall), east half, Stratum 1 (post-occupational fill), and east half, Stratum 2 (wallfall). Figure 24.7 shows the removal of the west half of Stratum 1. The fill removed by the bobcat was screened through 1/8-in. mesh, and it was recorded and bagged according to the provenience enumerated above. At approximately the 8.3-m elevation, or the top of rooffall, the use of mechanical excavation ceased and we returned to hand excavation. For the excavation of Stratum 15 (kiva rooffall), 1- by 1-m grids were again used. This stratum was excavated down to the plastered floor of the kiva.

After excavation of the roomblock was completed in November of 2002, three walls were knocked down to assess the construction history of the roomblock. The knocked-down walls include the north wall of Room 2 (an interior wall), the west wall of Room 4 (an exterior wall), and the east wall of Room 5 (adjacent to the kiva entrance). The results of these efforts are discussed in detail later in this chapter.

Figure 24.7. Removal of kiva fill in the west half of Stratum 1.

SITE STRATIGRAPHY

This section is divided into two parts. The first section will document the general stratigraphic sequence used during the hand excavations at LA 86534. It will include an overall table describing the strata encountered during excavation and provides brief descriptions of these strata. It then presents total artifact counts for each individual stratum (i.e., post-occupational fill, room fill, wallfall, rooffall, and floor) in each room. The second part of this section is a post-excavation summary, which was generated by Paul Drakos and Steve Reneau (see Volume 3).

Stratigraphic Sequence used During Excavation

A basic stratigraphic sequence has been identified during previous excavations conducted at Coalition period pueblos at LANL. This sequence includes four major stratigraphic units. From top to bottom they are recent surface soil, a cap of rubble debris, construction debris that may or may not include roofing material, and interior room floor surface. This general stratigraphic sequence was also present at LA 86534 (Figure 24.8). All features were assigned a separate stratum number. Table 24.2 presents the general stratigrahic sequence for the site and gives data on stratum numbers, general provenience, feature numbers, color, texture, and thickness and then gives a general description of each stratum.

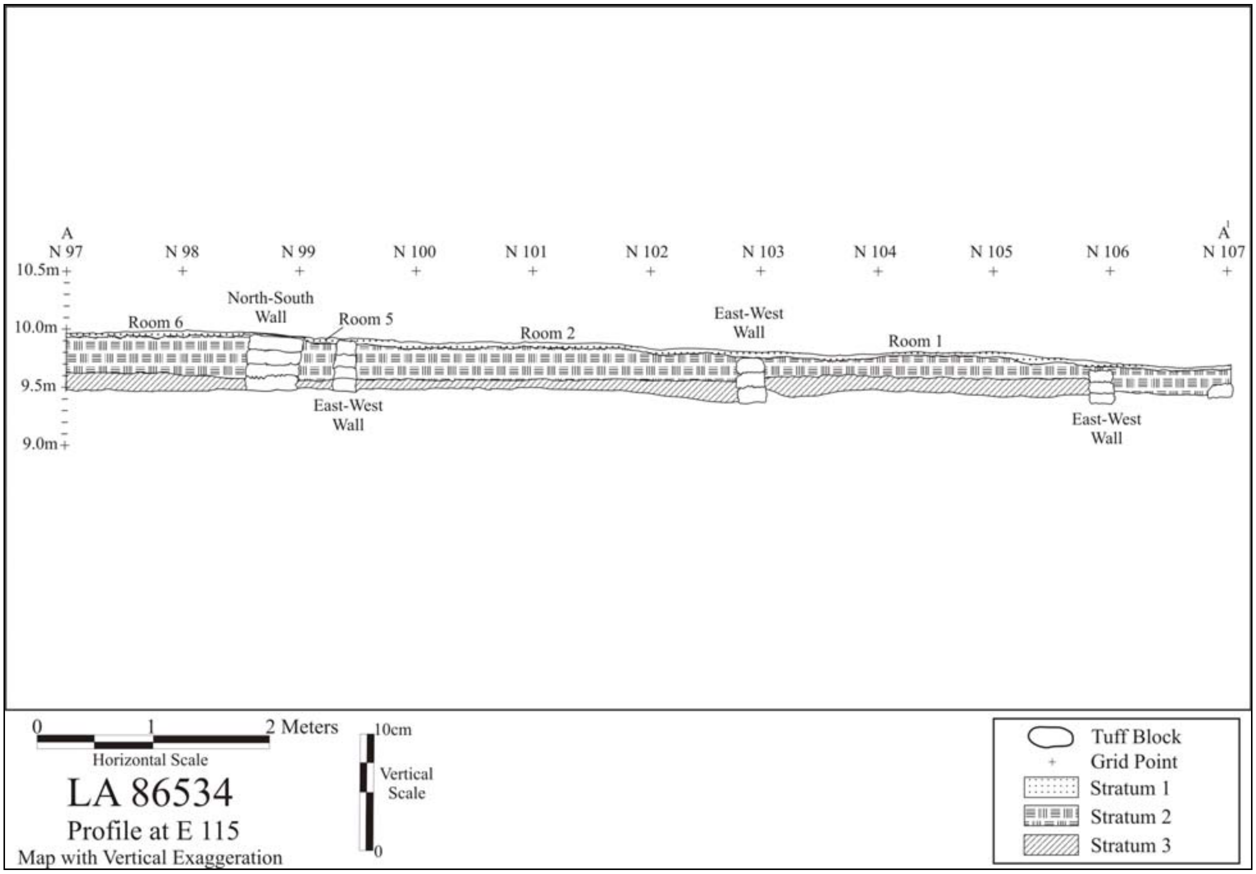

Figure 24.8. Profile of the E115 line through the roomblock.

Table 24.2. General stratigraphic descriptions for LA 86534.

LA 86534 Stratigraphic Summary							
Stratum #	**Provenience**	**Maximum Thickness**	**Minimum Thickness**	**Elevation**	**Color**	**Texture**	**Comments**
1	Area 2 (eastern and western areas)	1.03*	0.12*	10.03–9.00	7.5YR5/3–6/3	Loamy sand	Post-occupational fill. Loose topsoil. Very unconsolidated. Some areas of high organic content from pine duff. A/o Horizon.
2	Area 2 (eastern and western areas)	1.30	0.30	9.70–8.40	7.5YR5/3–6/4	Loamy sand	Room fill and rubble wallfall in eastern area, disturbed tuff blocks in western area. Loose and unconsolidated. Abrupt lower boundary (rooffall) in eastern area. Inclusions include artifacts, charcoal, and pieces of tuff.
3	Area 2 (Disturbed western area)	0.30	0.07	9.60–9.30	7.5YR 6/3.5	Sandy loam	Disturbed colluvium. Hard sub-angular blocky peds. Upper boundary distinct from loose, disturbed soil.
4	Area 2 (Disturbed western area)	0.20	0.05	9.40–9.20	5YR4/3	Clay loam	Late Pleistocene clay. Hard, sub-angular blocky peds. No bioturbation. Red.
5	Area 2 (Disturbed western area)	0.10	0.04	9.76–9.66	5YR4/2	Clay	Middle Pleistocene clay. Mottles are present. Pebble and gravel inclusions. No bioturbation. Red.
6	Area 2 Roomblock (eastern area)	0.11	0.04	9.60–9.49	7.5YR5/3	Clay loam with adobe	Rooffall from roomblock. Consolidated adobe with small pebbles, charcoal, and artifacts. In some areas, small layer of fill beneath (7), in other areas, lower boundary is floor (8).

LA 86534 Stratigraphic Summary							
Stratum #	**Provenience**	**Maximum Thickness**	**Minimum Thickness**	**Elevation**	**Color**	**Texture**	**Comments**
7	Area 2 Roomblock (eastern area)	0.10	0.02	9.55–9.45	7.5YR4/3	Silty loam	Loose fill below rooffall and above floor in some areas of the roomblock. Inclusions include small pieces of tuff and charcoal. Lower boundary is a plastered floor.
8	Area 2 Roomblock (eastern area)	0.07	0.02	9.55–9.48	10YR7/1	Plastered floor	Patchy floor. Plaster in some areas in quite thick, in others, very thin. Very rodent disturbed. Artifacts on top of floor. Some charcoal inclusions.
9	Room 1, Feature 4 Hearth, remodeling	0.19	0.11	9.62–9.42	7.5YR5/4	Ashy sand	Fill from most recent use of the collared hearth in Room 1. Ash and sand with scattered flecks of charcoal. Some small pieces of tuff in the fill. Lower boundary is plastered.
10	Room 2, Feature 2 Hearth	0.16	0.02	9.55–9.47	7.5YR5/4	Ashy sand	Fill from most recent use of the collared hearth in Room 2. Ash and sand with scattered flecks of charcoal, and some small pieces of tuff. Lower boundary is plastered.
11	Room 1, Feature 4 Hearth, primary use	0.08	0.03	9.45–9.36	7.5YR5/4	Ashy sand	Hearth fill, original use. Ashy soil with small bits of charcoal and oxidized soil. Ash comprises about 60% of the fill, with remaining portions being small bits of tuff.
12	Room 5, Feature 5 Hearth	0.12	0.05	9.50–9.38	7.5YR4/3	Ashy sand	Hearth fill. Very loose and granular. Significantly rodent disturbed. Sediments are ashy but mixed with quite a bit of sand from rodents. Some inclusions (artifacts and charcoal). Lower boundary is plastered.

LA 86534 Stratigraphic Summary							
Stratum #	**Provenience**	**Maximum Thickness**	**Minimum Thickness**	**Elevation**	**Color**	**Texture**	**Comments**
13	--	--	--	--	--	--	This stratum was designated, and then duplicated by stratum 19. See stratum 19 for description.
14	Room 6, Feature 12 Amorphous pit	0.28	0.14	9.58–9.30	7.5YR4/4	Silty	Fill from an amorphous pit in back central room. Very loose and unconsolidated. Heavily rodent disturbed. Inclusions include small pebbles and a few artifacts. Bedrock boundary.
15	Room 9, Kiva	0.33	0.07	8.30–7.97	7.5YR5/3	Sandy loam	Kiva rooffall. Consolidated adobe with small pebbles and charcoal inclusions. Lower boundary is plastered kiva floor. Some pieces of tuff and artifacts also. Timber impressions.
16	Room 6, Feature 13, Milling bin	0.22	0.05	9.71–9.49	--	Silty	Mealing bin fill. Very loose and unconsolidated. Rodent disturbed. Inclusions include pebbles, pieces of tuff, artifacts, and charcoal. Lower boundary is bedrock.
17	Room 9, Kiva	0.05	0.02	8.02–7.97	7.5YR5/3	Plastered floor	Kiva floor. Very compact and nicely plastered. In excellent condition. Tuff and clay temper. Lower boundary is bedrock.
18	Room 9, Kiva	0.27	0.02	7.97–7.70	10YR5/2	Silty sand	Sub-floor in kiva. Very sandy. Mostly in fissures between areas of bedrock.

LA 86534 Stratigraphic Summary							
Stratum #	**Provenience**	**Maximum Thickness**	**Minimum Thickness**	**Elevation**	**Color**	**Texture**	**Comments**
19	Room 7, Feature 9 Hearth				7.5YR4/3	Ashy sand	Hearth fill. Loose, ashy, and unconsolidated. Pebbles, artifacts, and charcoal in fill. Lower boundary is plastered but condition of both floor and hearth are poor and heavily deteriorated because of extensive rodent activity.
20	Room 9, Feature 16 Hearth	0.30	0.05	8.05–7.75	10YR8/1	Ashy	Fill from kiva hearth. Loose, but pieces of consolidated ash in the bottom of the hearth. Inclusions are pebbles, some artifacts, and charcoal. Plastered floor and collar.
21	Room 9 Feature 17 Ash pit	0.13	0.03	7.97–7.84	10YR5/2	Ashy sand	Fill from the ash pit in the kiva. Very loose and unconsolidated. Almost all ash with far less sand. Few pebbles, artifacts, or charcoal. Some pieces of tuff. Bottom is bedrock.
22	Room 9 Feature 18, Sipapu	0.22	0.22	8.02–7.80	10YR5/2	Silty sand	Fill from the sipapu in the kiva. Very loose and unconsolidated. Few pebbles, artifacts, or charcoal. Some pieces of tuff. Bottom is bedrock.

*Thickness in meters

At LA 86534, the first stratum was used in both the eastern and western portions of Area 2 and was generally a 10- to 15-cm layer of post-occupational fill, except in the kiva (Room 9), where it was just over 1 m thick. Where trees were present up to, and during, the time of excavation, this layer was typically thicker. Artifacts were most abundant in this stratum, but are likely skewed by the thick layer of post-occupational fill in the kiva. Table 24.3 shows the general artifact counts by strata across the site.

Table 24.3. General artifact counts by stratum.

21	0	12	0	0	**12**
TOTAL	**17,949**	**2181**	**218**	**174**	**20,522**

The second stratum is composed primarily of wallfall and contains a large amount of shaped and unshaped tuff blocks along with some chunks of adobe. Artifacts were also abundant in this stratum, again, likely skewed by inclusion of materials from the kiva. The stratigraphic designation “1,2” combines materials from both of these strata. As the end of the season neared and time became an issue, excavations continued in one large level down to rooffall (Stratum 6 in the roomblock and Stratum 15 in the kiva). As a result, Strata 1 and 2 were combined and artifacts from both lumped together. Stratum 1,2 in the kiva also included the large bulk removed by the bobcat.

Rooffall, the third stratigraphic level, consisted primarily of hard-packed adobe fragments and small pieces of charcoal in a soil matrix. However, no evidence of roof beams was encountered. This stratum was abundant at this site and was generally about 5 to 8 cm thick. Rooffall was consistently present in all of the rooms and, often, many artifacts were encountered either in the rooffall layer or at the level of wallfall and rooffall contact. In some areas, particularly the upslope portion of the roomblock at the northern end, there was a thin layer of sediment (Stratum 7) between rooffall and the floor. This suggests the floor may have been exposed for some time before the collapse of the room. It may also suggest more bioturbation, of which there was some evidence, in this portion of the roomblock. The Stratum “6,7” designation was used because Stratum 7 was difficult to detect and excavators were often already to floor before they realized they had gone through it. Stratum 7 was very thin and was only confidently detected in Room 1, but no artifacts were recovered. As a result, the Stratum 6 and 6,7 designations are from the same context.

The number of artifacts, with the exception of ceramics, associated with the floors (Stratum 8) is generally low. In general, the room floors (Stratum 8) were plastered and in fair condition. For the most part, they were largely patchy and had some smoke staining. The two middle rear rooms (4 and 6) were in the best condition, while the front rooms were in much poorer condition. Significant bioturbation was noted in many of these rooms. The floor of the kiva (Room 9) was in excellent condition. It was nearly 100 percent intact and was slightly smoke-stained in areas near the hearth and ash pit. Aside from these general stratigraphic designations, all features were given their own stratum numbers.

In addition to the strata assigned to the general stratigraphic sequence in the roomblock, the strata in the western portion of Area 2 (or the original area of excavation) were assigned different numbers because of their highly disturbed nature. A small number of artifacts came from this area of the site, but the artifacts were of the same general type as those from the roomblock and the midden. This suggests the disturbed area may be related to the original LA 86534 roomblock and the artifacts could have come from the southern end of the roomblock when it was damaged and disturbed by the construction of New Mexico Highway 502. Geomorphic analyses of these soils suggest they post-date the Puebloan occupation. The presence of tuff blocks overlying a fine-grained, post-Puebloan soil lacking colluvium derived from the roomblock area indicates that the surficial tuff blocks are not in place.

Stratigraphic Sequence Derived from Geomorphological Examination (Paul Drakos and Steve Reneau)

The following section contains a brief summary of the geomorphological deposits identified at LA 86534. Drakos and Reneau describe soil profiles in three locations and derive interpretations regarding the geomorphological history at the site. Their chapter (Drakos and Reneau, Volume 3) should be consulted for additional information of the general geomorphic setting at LA 86534 and in the Airport Tract and on the analytical methods they employed during their analyses.

LA 86534 Geomorphology and Stratigraphy

LA 86534 is underlain by a thin (15 to 20 cm thick) Pleistocene Bt horizon inferred to be 100 to 200 ka or older, based on correlation with soils described by McFadden et al. (1996). The Bt horizon is a reddened (5YR) silty to sandy clay that is a potential clay source. Roomblocks were apparently built on top of the Bt horizon. In proximity to the roomblock, the Bt horizon is overlain by Bw horizons formed in colluvium derived in part from the roomblock. Outside of the rubble mound surrounding the roomblock, the Bt horizon is overlain by a 20- to 25-cm eolian deposit that apparently post-dates the Puebloan occupation. The Bt horizon appears to be the lower part of an originally thicker Pleistocene soil that has been partially stripped by erosion. The presence of only a thin Pleistocene soil underlying young eolian deposits in the vicinity of LA 86534 suggests that erosional processes predominated in this area before the Coalition period. Near the roomblock (approximately 3 m northeast), two episodes of mixed colluvial and eolian deposition are recorded in soil profile LA 86534b (Table 24.4).

A 5-cm-thick AC horizon, inferred to be less than 200 years old, overlies a 27-cm-thick buried soil (Bw1b1-Bw2b1) formed in sediments derived in part from erosion of the roomblock. The Bw1b1-Bw2b1 soil is therefore less than 750 to 850 years old. The Bw2b1 horizon overlies the Pleistocene Bt horizon. The Bw2-Bw1 horizon sequence is developed in a colluvial deposit derived from erosion of the roomblock, with fines representing likely eolian deposition. The greater abundance of tuff clasts (60% to 70% gravel) in the lower (Bw2b1) horizon is indicative of sediment derived primarily from the roomblock, whereas a decrease in gravel content to 10 percent in the Bw1b2 horizon suggests eolian deposition in the rough surface created by wall remnants and the rubble mound surrounding the ruin.

West and north of the buried roomblock, scattered tuff blocks were observed on the surface. These tuff blocks were originally thought to represent the location of a roomblock. However, the tuff blocks occur within or on top of an A horizon that overlies fine-grained deposit dominated by silt and very fine sand with little soil development (Bw horizon, location LA 86534a, approximately 8 m west and 3 m north of the roomblock). This deposit, extending to a depth of 25 cm, apparently post-dates the Puebloan occupation here. The presence of tuff blocks overlying a fine-grained, post-Puebloan soil lacking colluvium derived from the roomblock indicates that the surficial tuff blocks are not in place. These blocks may have been moved during highway construction. Beneath the post-Puebloan deposit is the reddish, clay-rich Pleistocene Bt soil horizon that directly overlies tuff bedrock. The contact between the two soil horizons is abrupt and probably records stripping of part of the older soil followed by fairly recent burial of the horizon by eolian sediments.

The mesa top soil described outside of the roomblock rubble mound (LA 86534c) comprises a non-gravelly AC horizon overlying an eroded Bt horizon (Table 24.4). The AC horizon consists of well-sorted fine sand and extends to a depth of 21 cm. This horizon likely represents eolian deposition, possibly mixed with fine-grained colluvium. Based on the relative absence of soil structure, the AC horizon is inferred to post-date Puebloan occupation. The 21-cm-thick AC horizon and eolian deposit at LA 86534c is roughly correlative to the 25-cm-thick A-Bw profile and eolian deposit at LA 86534a.

Key in Appendix K.

SURFACE COLLECTION

All surface artifacts within the boundary of the site were collected using a 1- by 1-m grid system. Using the grid initially established during the GPR survey of the site, the site was gridded out in 1- by 1-m units (Figure 24.9). Magnetic north was used in both the GPR and excavation grids.

The 100N/100E site datum was established in the southwestern corner of the site. After the grid was laid out and before the collection of any artifacts, the crew walked around the site area and pin-flagged surface artifacts. The use of pin flags allowed for better visualization of the site boundary. Based on the visual demarcation of artifact density, surface artifacts were collected in a 2400-m^2 area. This area included the original possible roomblock slated for excavation, the associated midden (actual roomblock), and the actual midden area (not originally documented in the cultural resource survey). Figure 24.9 shows the surface collections being undertaken in the area of the eastern portion of the kiva. Note the lack of architectural stones on the surface at the beginning of the field season.

Figure 24.9. Surface collection in Area 1.

During the surface collection, all artifacts were collected according to their unit designation. Artifacts were bagged separately according to material type (except when the total number of artifacts from the grid was less than five), and each bag was given a separate field specimen (FS) number. While chipped stone debitage and ceramics were collected within the general 1- by 1-m grid they were located in, the location of formal chipped stone tools and ground stone items was point provenienced.

At the time of surface collection, trees had only been removed from the area surrounding the possible roomblock in the western portion of Area 2. This left several trees standing in the immediate area of the roomblock. Their presence created a thick accumulation of duff and, as a result, few surface artifacts were visible in the areas under the trees. If artifacts were missed during the original surface collection because of elevated amounts of duff, they were collected during the excavation of the 1- by 1-m grids.

Subsequent to the field season, all artifacts collected from the individual grids were entered into Surfer, version 7. From these data, maps of surface artifact distribution were generated. Figure 24.10 shows the distribution of all surface artifacts from the site. These maps show a general distributional pattern seen at several Coalition period roomblocks at LANL: a low density of surface artifacts on top of the roomblock that is surrounded by an increasingly dense arched area of artifacts from northeast of the roomblock to southeast of the roomblock. In this case, the area to the southeast of the roomblock has been disturbed by the construction of New Mexico Highway 502.

SITE EXCAVATION

Excavations at LA 86534 were conducted from June through October 2002. The field crew consisted of Kari Schmidt (crew chief), Bonnie Bagley, David Barsanti, Sandi Copeland, Mike Dilley, Joaquín Gallegos, Aaron Gonzales, Brian Harmon, Mia Jonsson, Mike Kennedy, Bettina Kuru'es, Timothy Martinez, Janet McVickar, Jennifer Nisengard, Joanne Tactikos, Brad Vierra, and Scott Worman. Leo Martinez operated the bobcat during the surface scraping and the mechanical excavation of the kiva. Timothy Martinez and Aaron Gonzales were tribal monitors for San Ildefonso Pueblo.

As already discussed in the site methods for LA 86534, three areas were designated at the site based on the distribution of surface artifacts and suspected features (see Figure 24.4). Excavations were conducted in Area 2. Except for surface scraping by the bobcat, no earth-moving activities occurred in Areas 1 and 3.

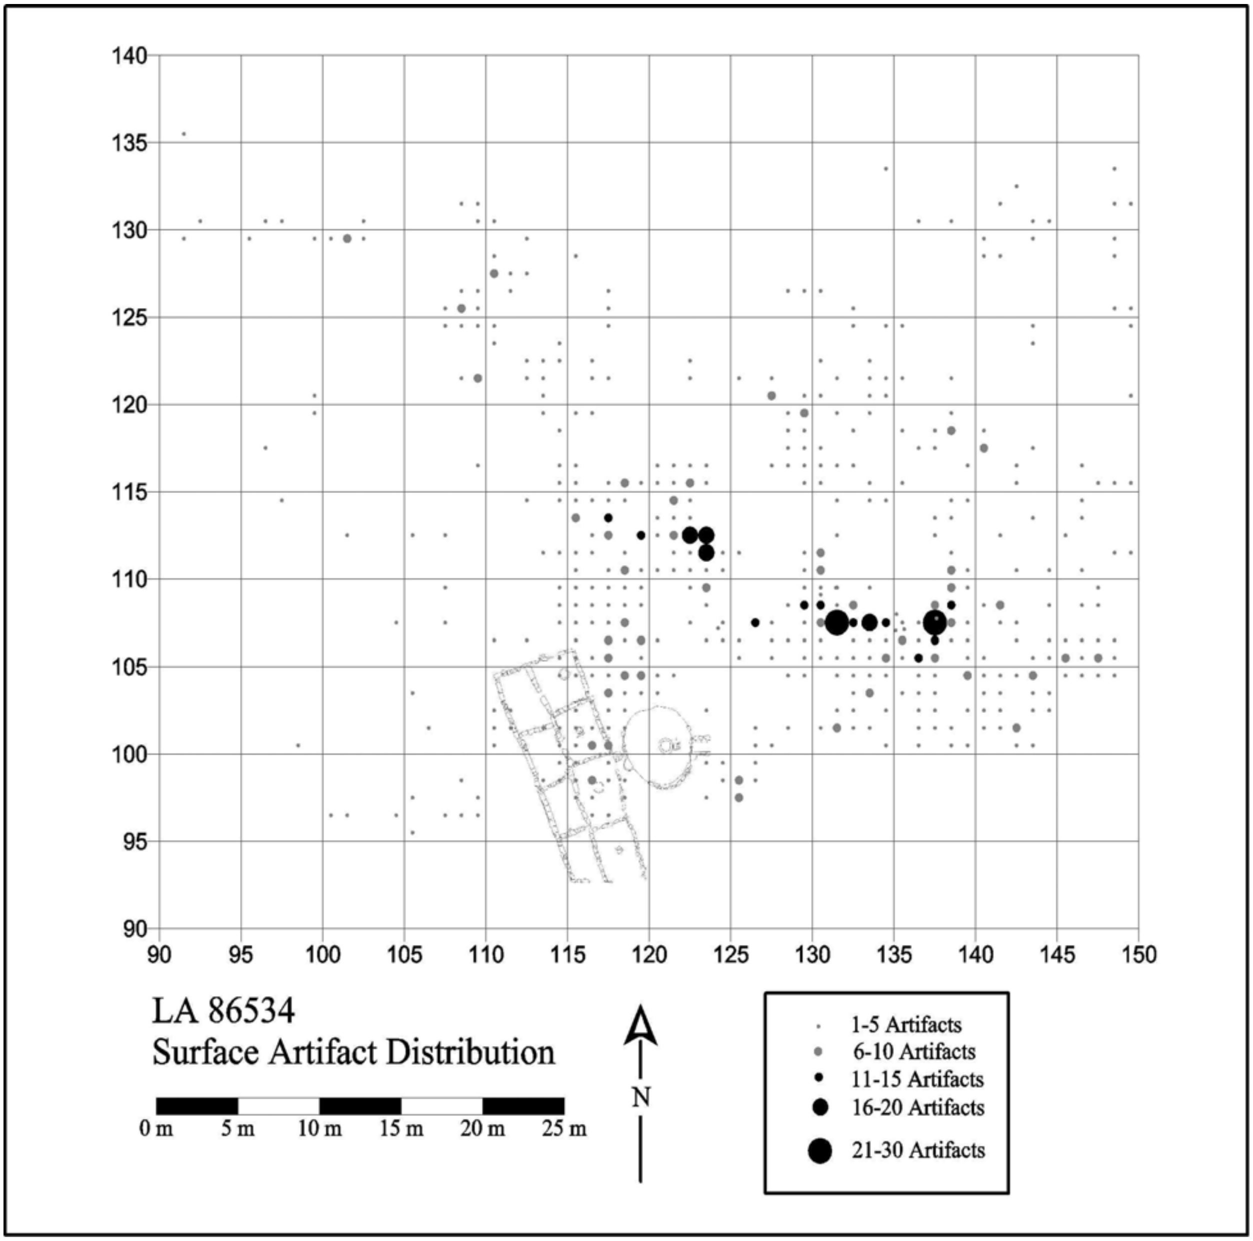

Figure 24.10. Map showing the distribution of surface artifacts.

Area 1

Area 1 was demarcated based on an increased density of surface artifacts immediately to the north and east of the roomblock. Although the area was not a formal midden per se, the higher density suggested a different use and warranted a distinct notation. The area was delineated at the 125E line; all artifacts to the east of this line were associated with Area 1 and all artifacts to the west were associated with Area 2. No features were identified in Area 1 despite extensive surface scraping by the bobcat. Of the 1125 m^2 bladed at the site, some 742 m^2, or just over two-thirds, were in Area 1. The artifacts in Area 1 are similar to those recovered from the roomblock. Surface artifacts from 106-108N/124-147E were selected for analysis. Based on their demonstrated relatedness, it is probable that Area 1 may have been a midden area used by inhabitants of the roomblock.

Area 2

The designation of areas at LA 86534 was based on the presumed location of the possible roomblock at the beginning of excavation. Area 2 was designated as the roomblock and a demarcation point of 125E was selected. The demarcation was based on two things: 1) the increased density of artifacts to the east of this line and 2) the cessation of architectural stone on the surface. Although the location of the actual roomblock was some 8 m east of the original presumed location, the revised location still fell within the confines of Area 2. A new area number was not given to the actual roomblock but was simply designated as the eastern portion of Area 2. Consequently, the western portion of Area 2 contains only the original area of excavation in the possible roomblock, while the eastern area contains a nine-room pueblo with an associated kiva.

Western Portion of Area 2 (Original location of possible roomblock)

In the original cultural resource survey of the site area, LA 86534 was identified as a possible roomblock. The area of the site designated as the possible roomblock was characterized by several possible alignments of shaped and unshaped tuff blocks that covered an area of approximately 18 m north-south by 16 m east-west and was slightly mounded. Because of the presence of architectural surface stone and a mound, it was presumed that a roomblock was likely present in this locale. Excavation of the area began on the 24th of June and continued until the second week of July. Per provisions in the data recovery plan, a north-south line through the approximate center of the front set of rooms was selected for excavation. Additionally, an east-west line through the approximate center of the mound was also selected for excavation. By the time these units were excavated (105-116N/104E and 111N/98-107E), it was clear that excavations were progressing in a disturbed area. Although the presence of possible alignments of shaped and unshaped blocks associated with artifacts was at first perplexing, it soon became clear that excavators were digging in redeposited sediments that likely resulted from highway construction south of the mound. Figure 24.11 shows the distribution of tuff blocks in the area of the mound at the cessation of excavation. Based on the arrangement of stones at the end of excavations in the area, it is clear that no intact alignments were present.

Artifact density in the western portion of Area 1 was not great, but ceramics, chipped stone, ground stone, and faunal remains were all present. Artifacts were analyzed from the north-south trench through the mound (104E line) as well as from the two adjacent north-south lines (103N and 105N). Identified ceramics included Santa Fe Black-on-white and a number of utilitywares, and the chipped stone remains included Pedernal chert and obsidian. These results show that the artifacts in the disturbed mound were of similar composition to that in the roomblock (the eastern portion of Area 2), thereby supporting the contention that the western portion of Area 2 is likely disturbed fill from the eastern portion of Area 2.

Figure 24.11. Western portion of Area 2 just before the end of excavation.

Table 24.2 shows the stratigraphic units identified in this portion of the site. Strata 1 and 2 (post-occupational fill and rubble fill) are comparable to those located in the eastern portion of Area 2. Strata 3, 4, and 5 were identified in the western portion of Area 2. These strata include disturbed colluvium (Stratum 3), Late Pleistocene clay (Stratum 4), and Middle Pleistocene clay (Stratum 5). Figure 24.12 shows a stratigraphic profile drawn along the eastern wall of 104E. All five strata are clearly visible and the presence of tuff cobbles becomes increasingly sparse with depth. No features were identified in the excavated areas of the western portion.

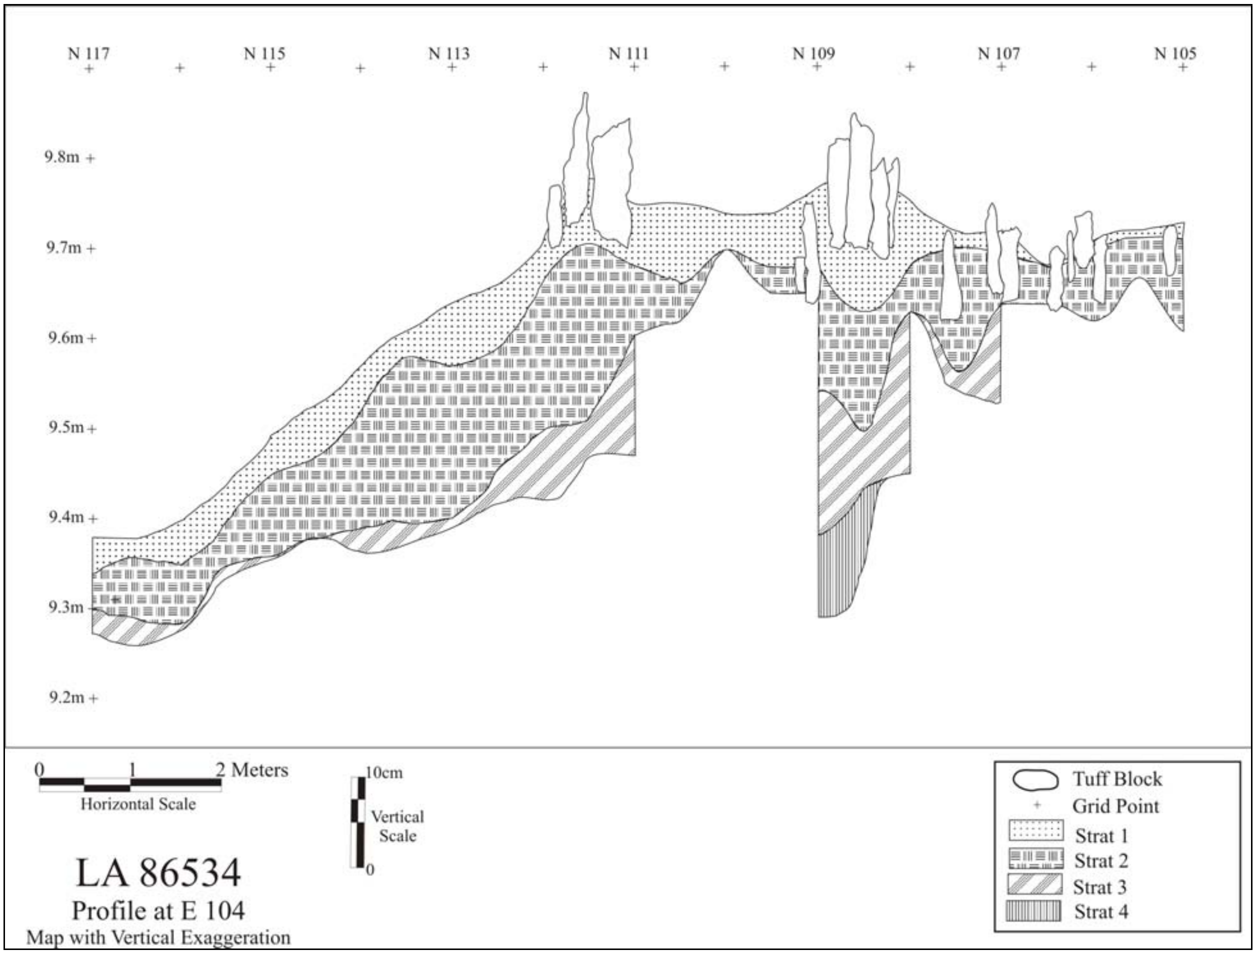

Figure 24.12. Profile of the E104 line in the western portion of Area 2.

Eastern Portion of Area 2 (Actual location of LA 86534 roomblock)

As mentioned above, the initial excavations at LA 86534 were conducted in a disturbed area some 8 m west of the actual roomblock. The lack of surface architectural stones in the area of the roomblock, and their presence in the disturbed area, dictated where the early excavations at the site occurred. When the test pit in 101N/115E was excavated and it was clear that there were intact room deposits in the area, all excavation shifted to this locale. By mid-October, a total of eight habitation rooms (Rooms 1 through 8) had been excavated, as had a circular kiva (Room 9) that was located just east of the roomblock. Room 9 was not attached to the roomblock, but a section of the western wall was less than 1 m away from the northeastern corner of Room 5. These two areas were attached by a small passageway (Feature 15; see Room 9 summary).

Architecture and Stratigraphy

The site consisted of a compact roomblock of nine rooms, a sparse but extensive artifact scatter, and a disturbed two-track road on the northern perimeter of the site. The roomblock consisted of a rectangular block of eight rooms (four front and four back) and a circular kiva located just to the east of the roomblock (Figure 24.13). The roomblock was oriented slightly west-of-north off the cardinal directions. The roomblock walls were generally in good condition, with one to two courses present on the northern end and up to four courses present in the center of the rooms. The southern walls of Rooms 7 and 8 were destroyed during the construction of NM 502.

Figure 24.13. Roomblock and kiva.

Walls were constructed from unshaped and shaped tuff blocks and had an adobe mortar. The walls also had a foundation of upright tuff blocks. These blocks were roughly shaped and were slightly smaller than the tuff blocks used in wall construction. The general size of the basal upright stones was approximately 25 by 15 by 10 cm, while the general size of wall blocks was approximately 40 by 20 by 10 cm. Figure 24.14 shows the upright stones still in place after the north wall of Room 2 had been knocked down. The horizontal block visible on the left side of the photo is part of the basal course of the north wall of Room 2 and is 42 by 22 by 18 cm. The upright stones had been set in a shallow trench filled with some adobe mortar, and the bases of the stones were resting on the bottom of the trench. Therefore, they probably represent the foundation of the walls.

Construction techniques at LA 86534 were similar to other Coalition period roomblock sites on the Pajarito Plateau (see Figure 24.3). It appears as though the central north-south wall was continuous and presumably built first, with the wall between Rooms 6 and 8 built at the same time. The east-west walls in the back rooms were then built, followed by the back north-south wall. It then appears that the front rooms were built, which denotes a construction configuration of four possible units: 1) center wall and east-west wall between Rooms 6 and 8; 2) Rooms 3, 4, 6, and 8; 3) Rooms 1 and 2; and 4) Rooms 5 and 7. However, there is no evidence to show that any appreciable length of time passed between the construction of the units. It is probable that all eight rooms in the roomblock were built within a short period of time and possibly in a single building episode. It is not clear when Room 9 was built relative to the rest of the roomblock, but it is likely that it was built at the same time as Rooms 5 and 7 given the connecting feature between Rooms 5 and 9.

Figure 24.14. Wall foundation of upright stones in situ, Room 2.

In several isolated places in each of the rooms, a tan clay plaster covered the tuff blocks on the interior faces of the rooms. No rooms lacked wall plaster suggesting that preservation at the site was good. This is corroborated by the abundance of rooffall in the rooms. The fill of all rooms contained abundant, but usually small, fragments of adobe similar to that observed in the walls. Although these fragments could represent rooffall, wall debris, or both, it is most likely that they represent rooffall given the presence of impressions and fingerprints on several of the chunks, as well as an abundance of artifacts at the top of the rooffall stratum (6). No postholes were identified in the rooms, suggesting that the walls were load-bearing and indicating that the roof was not substantial. This follows the general Ancestral Puebloan pattern of viga and latilla roofs covered with mud and (probably) juniper.

Room floors at LA 86534 were thinly plastered with fine clay mud, identical to and occasionally coping into the surviving wall plaster. Floors in the roomblock were differentially preserved. In the well-preserved sections (Rooms 4 and 6; Figure 24.15), the floor was compact and appears to have been burnished. Little cracking was present in these two rooms, and they were the most level of all the floors. The floor in Room 3 was semi-intact. It was easily discernible in the southern half of the room, but was patchier in the northern half. A large stump was in the northern wall and its roots likely destroyed the floor in this room. Floors in Rooms 1, 2, 5, 7, and 8 were essentially non-existent. The floor in Room 1 was destroyed by a large piñon stump and its associated roots, as well as by extensive rodent damage. Rooms 2 and 5 were both heavily rodent disturbed. In both of these rooms, the only areas with intact floor were around the hearths, but both of the hearths were significantly destroyed. The floor in Rooms 7 and 8 were heavily damaged by road construction as these rooms were immediately adjacent to the construction berm. Only a single patch was identified in the northwestern corner of Room 7.

Figure 24.15. Room 4 (back, center) floor.

The front rooms of the roomblock were typically slightly larger than those in the back. This fits the general pattern visible on the Pajarito Plateau. Table 24.5 shows the room dimensions and floor area for each of the nine rooms. Due to the destruction of the southern portions of Rooms 7 and 8 by construction activities, their dimensions are incomplete. A histogram was generated based on the surface area of the floors in each of the nine rooms (Figure 24.16). The figure groups the front rooms, the back rooms, and the circular kiva. The two incomplete rooms are the last in each of their respective series.

Table 24.5. Room dimensions and floor area.

Room Number	Length (m)	Width (m)	Floor Area (m^2)
1	2.60	2.48	6.45
2	3.11	2.40	7.46
3	3.20	2.00	6.40
4	3.10	1.80	5.58

Room Number	Length (m)	Width (m)	Floor Area (m^2)
5	3.50	2.30	8.05
6	2.95	1.80	5.31
7	3.10*	2.20	6.82*
8	2.60*	1.80	4.68*
9	4.30	4.10	17.63

*incomplete dimensions due to highway construction

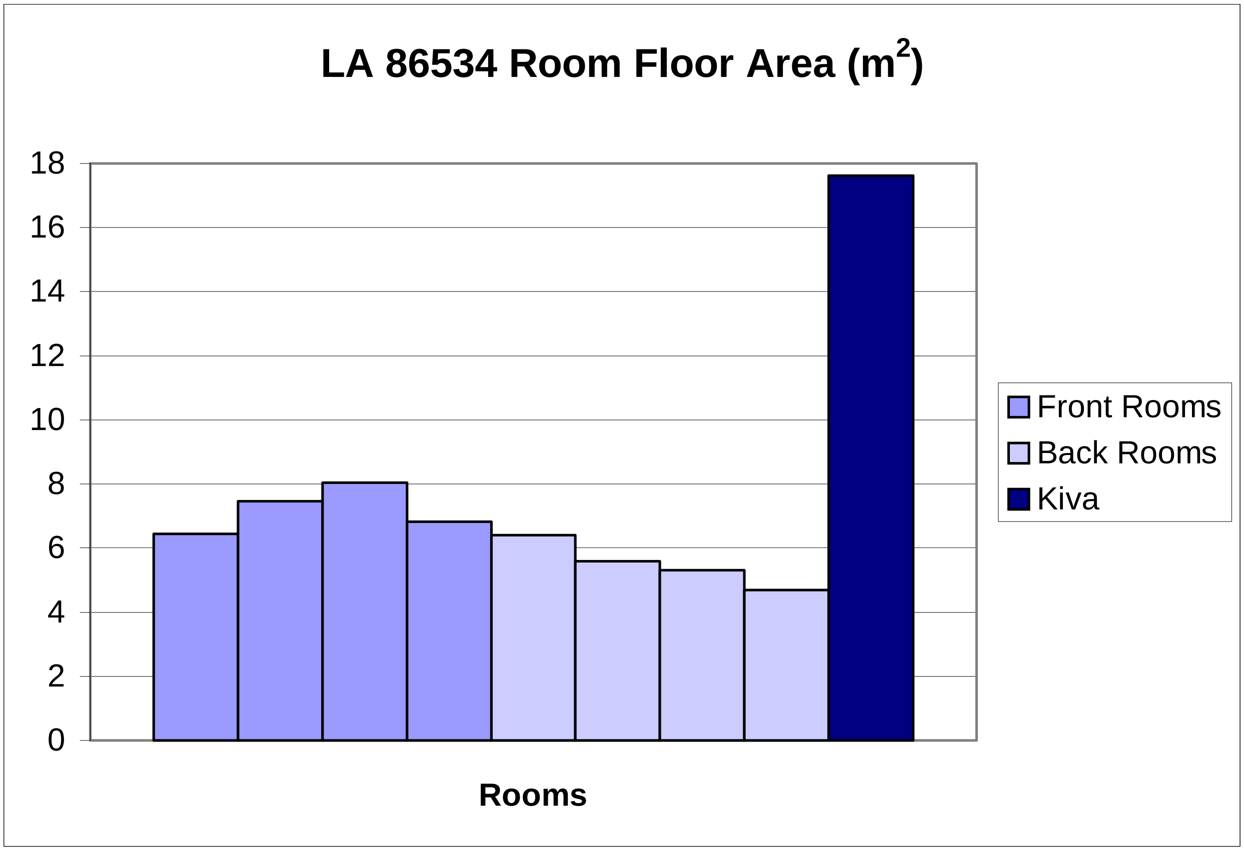

Figure 24.16. Histogram showing room size at LA 86534.

Room 1

Sequence of Excavation. Room 1 is located in the northeastern corner of the roomblock and is the most northerly of the front rooms. The room measures 2.6 m north-south by 2.48 m east-west, giving 6.45 m^2 of interior space. The room was highly disturbed by both rodents and roots. A large juniper stump was located in the center of the room, just over the eventual location of the hearth (Feature 4) and extends to the north wall (Figure 24.17). Its roots incurred a significant amount of damage to the collar, shape, and fill of the upper use of the hearth. Units in the 115E line were excavated first as part of the overall profile trench of the roomblock. These units were excavated in stratigraphic units (and in 10-cm levels within the strata if it was thicker than 10 cm) to the top of rooffall (Stratum 6). At this point, excavations ceased temporarily until all units in the roomblock were down to the top of the rooffall level. Units in Room 1 that were not in the 115E line were excavated in one large level (Strata 1 and 2) down to the top of the rooffall level. All units in the room were then excavated down to floor (Stratum 8). A doorway (Feature 10) was identified between the west wall of Room 1 and the east wall of Room 3.

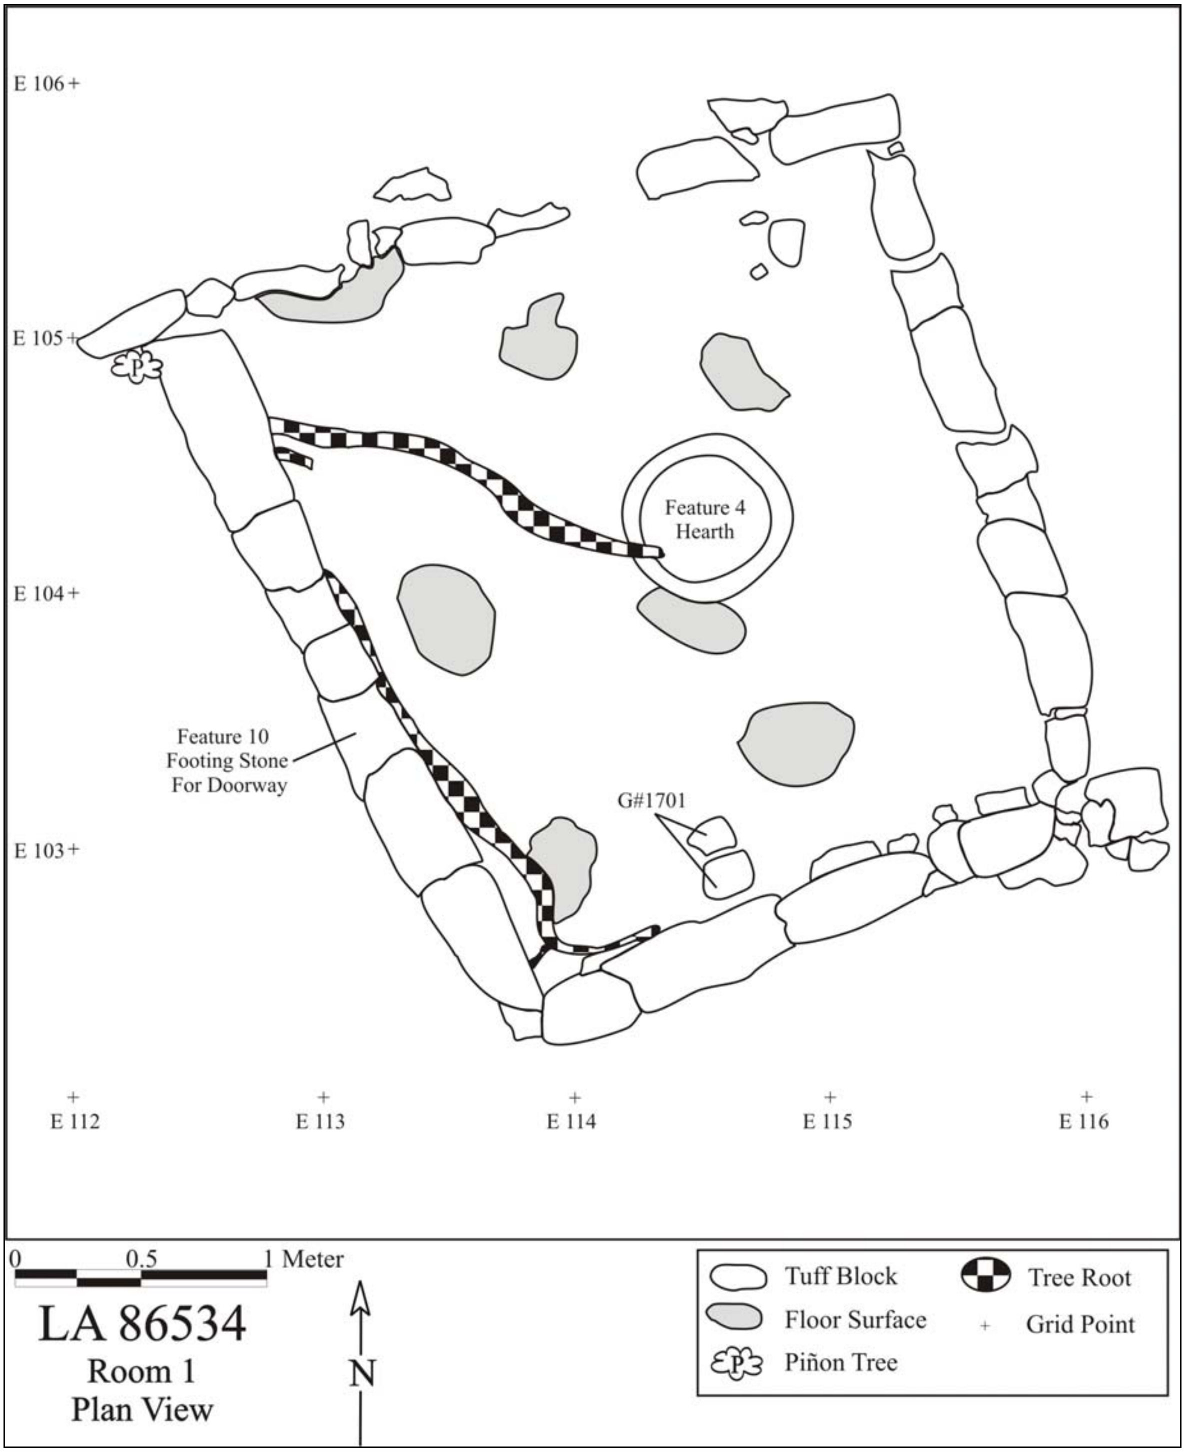

Figure 24.17. Room 1, post-excavation.

Fill. On average, Stratum 1 was an approximately 10-cm-thick layer of post-occupational fill and consisted of very loose and unconsolidated soil. Some areas contained a high organic content from the duff associated with the juniper located just outside the north wall. Artifact density in this level was high. Stratum 2 consisted of the general room fill, which contained an abundant amount of rubble wallfall and was about 25 cm thick. The stratum was also loose and unconsolidated, and artifact density was lower than Stratum 1. The bottom of this stratum contained the abrupt contact with rooffall (Strata 6 and 7). Stratum 6 is the actual rooffall layer, but Stratum 7, only positively identified in Room 1, was a very thin layer of sediment between the rooffall and the floor. This stratum was present throughout the roomblock, but was very difficult to identify due to heavy rodent disturbance. As a result, Stratum 7 is combined with Stratum 6 throughout the roomblock, but no artifacts or samples, except for a flotation sample (FS 1271) from Room 1, were collected from this stratigraphic unit.

Taxa identified in the flotation sample from Stratum 7 included maize (*Zea mays*), unknown conifer (Gymnospermae), and piñon pine (*Pinus edulis*). Counts in Table 24.6, as well as those in the following pages, will combine Stratum 6 and 7 but will essentially only represent Stratum 6. In Room 1, Stratum 6 was about 20 cm thick at its thickest point, but averaged about 7 cm thick. Rooffall in this room contained abundant, but usually small, fragments of adobe similar to that observed in the walls, and artifact density was about half as much as in Stratum 2. Stratum 8 was associated with the floor in this room, which was only present along the western wall where it articulated with the wall under the doorway (Feature 10). Stratum 11 was the fill from the centrally located collared hearth (Feature 4). Table 24.6 shows the general artifact counts by stratigraphic unit for this room.

Table 24.6. Room 1 artifact counts by stratigraphic units.

Stratum #	Ceramics	Chipped Stone	Ground Stone	Faunal Remains	Total
1	873	82	8	4	**967**
2	479	33	3	1	**516**
6	216	27	1	1	**245**
6,7	19	4	0	0	**23**
8	2	0	4	0	**6**
11	0	0	1	0	**1**
Total	**1589**	**146**	**17**	**6**	**1758**

Floor. The floor in this room was in very poor shape. The only place where intact floor existed was along the western wall just under the doorway (Feature 10). In this area, the plastered floor coped with the wall plaster. Very small patches of floor (smaller than a quarter) were visible in the areas around the collar of the hearth. One tuff grinding slab (FS 1701) was recovered from the floor of this room, but was broken into four pieces (thus, $n = 4$ in Table 24.6). The ceramics associated with the floor were recovered in a general floor sweep, and because their exact provenience was unknown, they were not analyzed. One macrobotanical sample (FS 1700) was collected from the floor and the following taxa were identified: mountain mahogany (*Cercocarpus*), unknown conifer, ponderosa pine (*Pinus ponderosa*), and Douglas fir (*Pseudotsuga menziesii*).

Wall Construction. Shaped and unshaped tuff blocks were used in the construction of this room. It appears as though the western wall of the room was constructed first, then the eastern wall was built, and finally the northern and southern walls were abutted to the eastern and western walls. One to two courses were present for all walls except the southern wall where up to four courses were present. Table 24.7 shows the general wall measurements for all four walls.

Table 24.7. Room 1 wall measurements.

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	2.42	0.25	0.24
South	2.46	0.44	0.22
East	2.58	0.28	0.22
West	2.62	0.41	0.23

Artifacts and Samples. Artifacts from two 1- by 1-m units were selected for analysis. Grids selected from Room 1 include 103N/114E (FS 1030 through FS 1035, FS 1042, FS 1248 through FS 1251, and FS 1701) and 104N/114E (FS 353, FS 887, FS 1068 through FS 1074, FS 1076 through FS 1078, FS 1271 through FS 1279, and FS 1333 through FS 1338). All artifacts from these two columns were analyzed. Analyzed artifacts from this room that were not recovered in either of these two units included an obsidian projectile point (FS 706) and a tuff grinding slab (FS 1042) that was selected for a pollen wash, but was determined post-excavation to be a less than acceptable sample. Neither of the other two artifacts that were selected for pollen washes (FS 1001 and FS 680) were submitted for the analysis because of post-excavation determinations of sample integrity.

Identified ceramics from these two grids include nine unpainted sherds, one Wiyo Black-on-white sherd, 11 Santa Fe Black-on-white sherds, four plainware sherds, 17 smeared-indented corrugated sherds, one coiled necked sherd, five indented corrugated sherds, one wide neckbanded sherd, two organic-painted sherds, and one plain corrugated sherd. Ground stone artifacts identified in the sampled grids include one siltstone ground stone fragment, two dacite one-handed manos, and two tuff grinding slabs. All of the faunal remains recovered from this room were analyzed and identified remains included one pocket gopher bone, one small/medium-sized mammal long bone fragment, and a fragment of a mule deer (*Odocoileus hemionus*) radius. Table 24.8 lists the chipped stone materials recovered in this room.

Table 24.8. Chipped stone artifacts recovered from sampled units in Room 1.

Type	Material	Number
Core	Chalcedony	1
Unidentified flake fragment	Chalcedony	3
	Black translucent obsidian	1
Ground stone flake	Dacite	1
Core flake	Chalcedony	12
	Basalt	1
	Cerro del Medio obsidian	1

Type	Material	Number
	Black translucent obsidian	1
	Pedernal chert	4
Biface flake	Chalcedony	1
	Black translucent obsidian	1
Hammerstone flake	Quartzite	1
Microdebitage	Chalcedony	4
	Black translucent obsidian	2
	Basalt	1
	Orthoquartzite	1
Angular debris	Chalcedony	5
	Pedernal chert	2

Macrobotanical remains from the same grids selected for the artifact samples were identified for analysis. However, due to the paucity of macrobotanical items at the site, a sufficient sample was not attained. Therefore, a 20 percent sample from each stratum within each room was selected. This strategy was employed in each of the rooms except Room 9 (see Room 9 for discussion of sampling strategy for macrobotanical remains in that room). Based on a 20 percent sampling strategy, a sufficient sample was assembled. A total of 9 macrobotanical samples were analyzed from Room 1 and identified taxa include ponderosa pine, piñon pine, unknown conifer, Douglas fir, juniper, mountain mahogany, and cottonwood/willow (*Populus/Salix*). Samples were collected from all strata except 7 and 9, which represent the most recent use of the hearth. Only ponderosa pine wood was identified in the hearth (FS 1333). Table 24.9 lists the samples taken from Room 1. No pollen or flotation samples were taken from the floor because of its extremely patchy nature and the heavy root and rodent disturbance.

Table 24.9. Samples selected for analysis in Room 1.

Stratum	SAMPLE TYPE					
	Pollen	Pollen wash	Flotation	Macrobotanical	TL	Archaeomagnetic
1,2	1000	1042, 1001	1002	999, 1070	--	--
2	727	680	--	794, 828, 961	--	--
6	--	--	--	1393, 1396	--	--
7	--	--	1271	--	--	--
8	--	--	--	1700	--	--
9	1275	--	1272, 1273, 1274	--	1336	Taken
11	1334	--	1335	1333	--	--

Taxa identified in the flotation fill sample from Room 1 (FS 1002) include the following: goosefoot, purslane (*Portulaca*), maize, unknown conifer, juniper, unidentified pine, piñon pine, and oak (*Quercus*). Taxa identified in the two pollen samples from Room 1 fill (FS 727 and FS 1000) include beeweed (*Cleome*), cheno-ams (*Chenopodium/Amaranthus*), grass family, sunflower family, ragweed (*Ambrosia*), spurge family (Euphorbiaceae), unidentified pine, piñon pine, juniper, rose family (Rosaceae), and sagebrush (*Artemisia*).

Room 1 Features

Feature 4 (Hearth). This feature is a plaster-lined collared hearth in Room 1 (104N/114E; Figure 24.18). There were two uses of this hearth: Stratum 9 represents a remodeling of the hearth and a secondary use, while Stratum 11 is from the primary use of the hearth.

Figure 24.18. Hearth (Feature 4) in Room 1.

The hearth is approximately 50 by 50 cm in size and is circular in shape. The depth of the hearth is about 20 cm below the room floor (Figure 24.19; plan and profile). The collar around the hearth is raised approximately 10 cm above the floor. This is distinct from the hearths in Rooms 2 and 5, which were flush with the floor. The hearth was misshapen from a large juniper root running along its western edge, but was not heavily rodent disturbed. No artifacts were recovered from the fill of the hearth. An archaeomagnetic sample was taken from Stratum 9; see subsequent section for results. When sampling was finished, the top of a one-handed dacite mano was visible (FS 1337), suggesting a second use of the hearth.

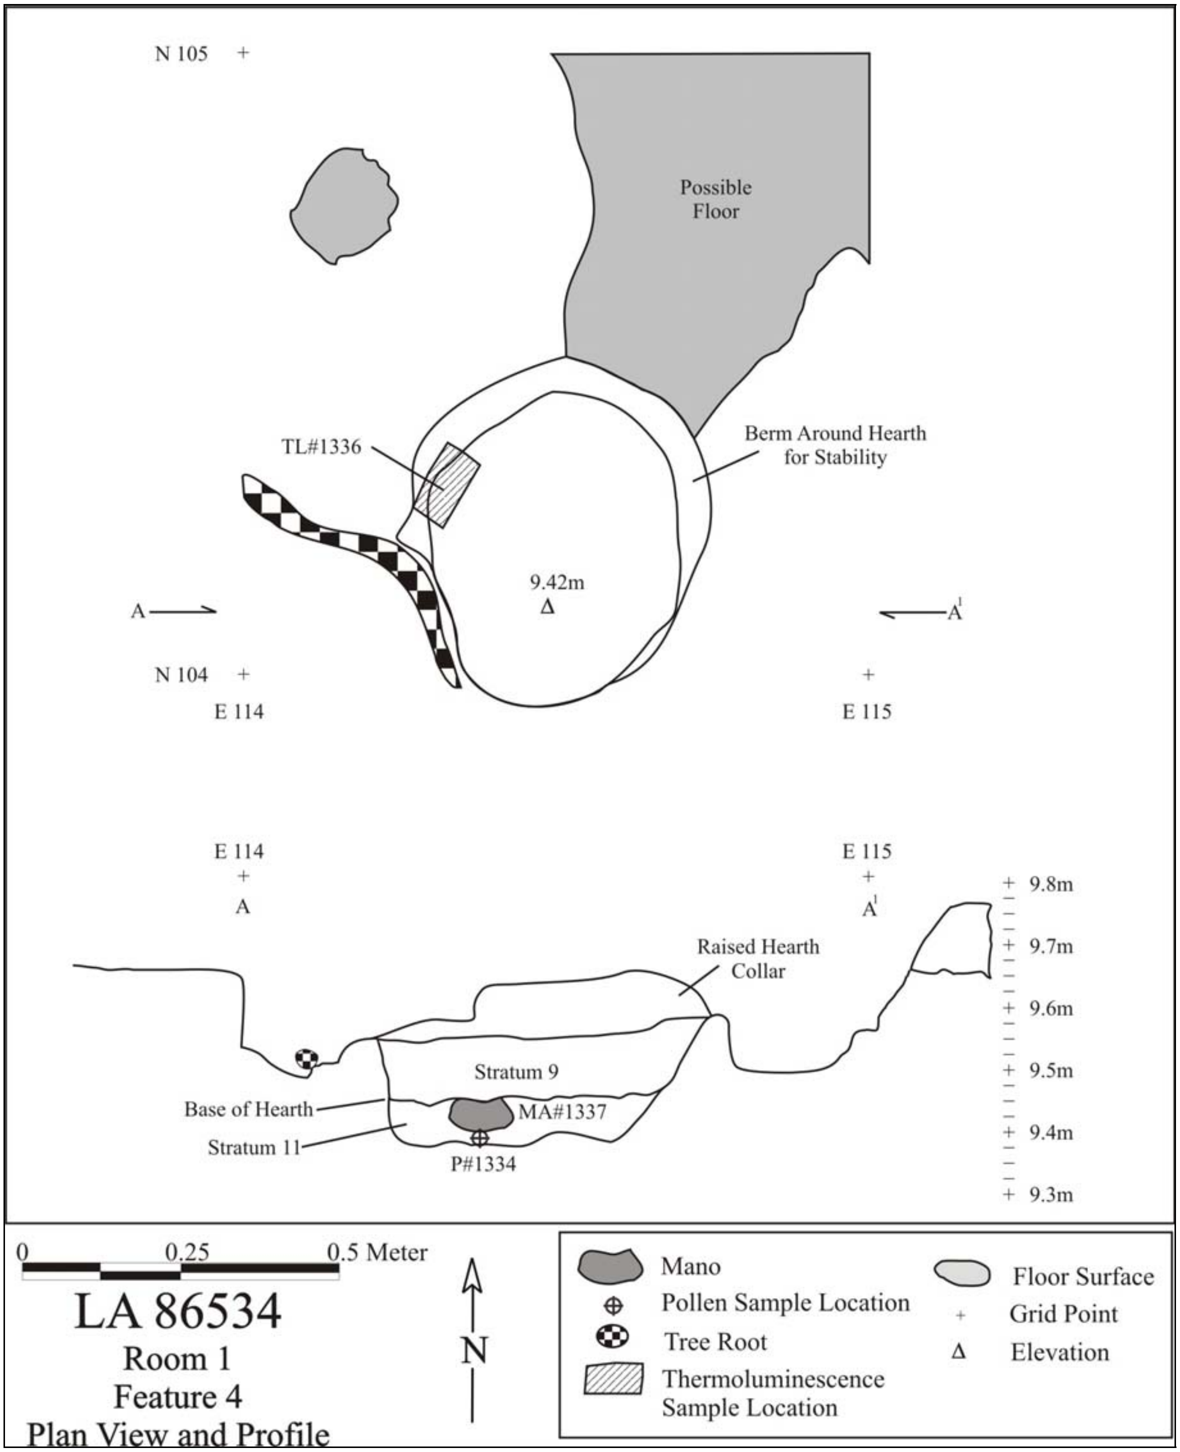

Figure 24.19. Plan view and profile of Feature 4.

Further excavations identified that the hearth contained two separate use episodes. The lower and original use of the hearth includes the Stratum 11 fill. Archaeomagnetic samples taken from the burned adobe associated with Stratum 11 produced a date range of AD 1065 to 1265; whereas, burned adobe associated with the upper fill (Stratum 9) and the subsequent remodeling event provided a date range from AD 1170 to 1230. A piece of maize (*Zea mays*) identified in FS 1272 from Stratum 9 was submitted for radiocarbon analysis. This sample yielded an age for Feature 4 of 860±40 BP (Beta-183760) and a date of cal AD 1190 with a two-sigma date range of cal AD 1040–1260, which is nearly identical to the archaeomagnetic result. The thermoluminescence analysis, which was conducted on a piece of burned plaster from the collar of the hearth (FS 1336), produced a date of 1230±42. This dated slightly later than both results derived from archaeomagnetic and radiocarbon analyses.

In addition to the dated materials collected from the hearth, two pollen samples and four flotation samples were taken. Taxa identified in the pollen samples (FS 1275 and FS 1334) included beeweed, purslane, sunflower family, prickly pear, ragweed/bursage, spurge family, Douglas fir, unidentified pine, piñon, juniper, sagebrush, rose family, cheno-ams, and unidentified grasses. Taxa identified in the flotation samples (FS 1272, FS 1273, FS 1274, and FS 1335) included goosefoot, goosefoot family (Chenopodiaceae), cheno-ams, grass family, maize, mountain mahogany, snow-on-the-mountain, saltbush/greasewood (*Atriplex/Sarcobatus*), purslane, unknown conifer, unidentified pine, ponderosa pine, juniper, and piñon pine.

Feature 10 (Doorway). Located centrally along the western wall, this doorway goes between Rooms 1 and 3. The dimensions of the doorway are 40 by 21 by 16 cm. A shaped footing stone was present at the base of the doorway. Because much of the western wall of Room 1 was collapsed and this portion of the wall was only one course high, there was no fill remaining when the feature was identified. As a result, no artifacts were recovered from the fill and no samples were taken. No plan map or profile was drawn.

Room 2

Sequence of Excavation. Room 2 is located in the middle of the roomblock in the northern section. Room 2 is 3.40 m north-south by 2.40 m east-west, giving an interior floor space of 7.46 m^2. Room 2 is in the front set of rooms and is located immediately south of Room 1. The initial test pit that identified the roomblock was in the center of this room. The room was highly disturbed by bioturbation and, as a result, the floor was in very poor condition (Figure 24.20). Units in the 115E line were excavated first as part of the overall profile trench of the roomblock (see Figure 24.8). These units were excavated in stratigraphic units (and in 10-cm levels within the stratum if it was thicker than 10 cm) to the top of rooffall (Stratum 6). At this point, excavations ceased temporarily until all units in the roomblock were down to the top of the rooffall level. Units in Room 2 that were not in the 115E line were excavated in one large level (Strata 1 and 2) down to the top of the rooffall level. All units in the room were then excavated down to floor (Stratum 8). Two features were identified in the room: Feature 2 was a collared hearth located near the center of the room, and Feature 3 was the doorway between the western wall of Room 2 and the eastern wall of Room 4 (Figure 24.20).

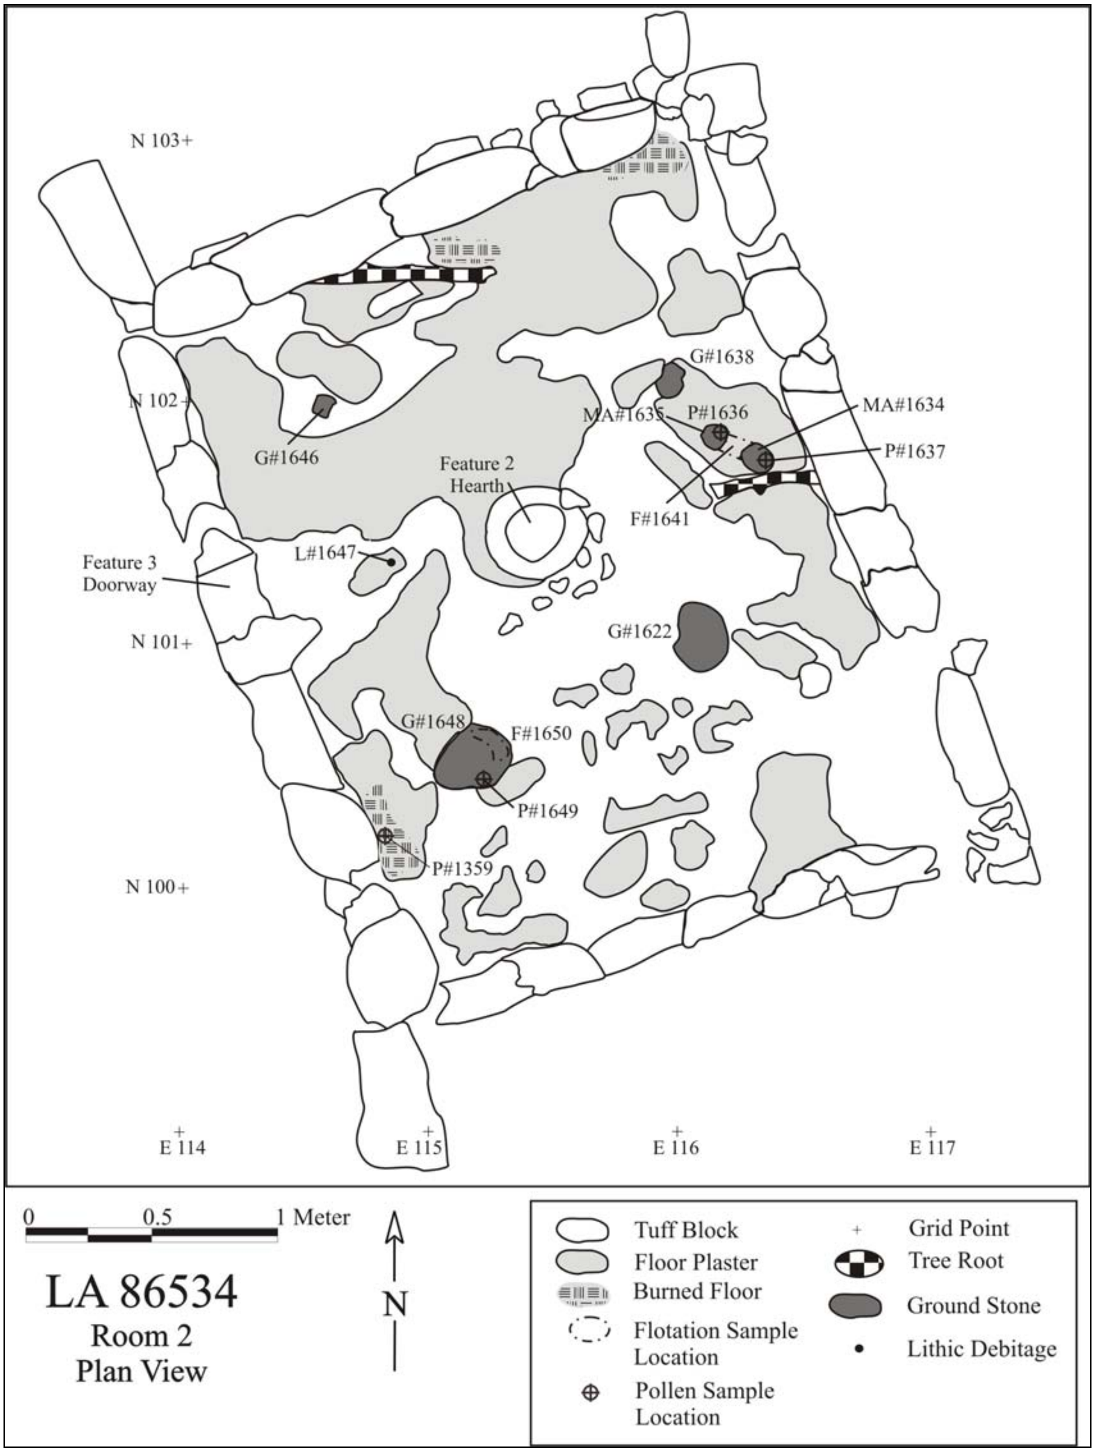

Figure 24.20. Plan view map of Room 2 after excavation.

Fill. Stratum 1 was an approximately 10-cm-thick layer of post-occupational fill that consisted of the very loose and unconsolidated soil. Some areas contained a high organic content from the duff associated with piñon and juniper trees in the area. Artifact density in this level was the highest. Stratum 2 consisted of the general room fill, which contained an abundant amount of rubble wallfall and was about 25 to 30 cm thick. Stratum 2 was also loose and unconsolidated, and artifact density was lower than Stratum 1, but still considerably high. The bottom of Stratum 2 contained the abrupt contact with rooffall (Strata 6 and 7). Stratum 6 is the actual rooffall layer, but Stratum 7, only identified in Room 1, was a very thin layer of sediment between the rooffall and the floor.

In Room 2, Stratum 6 was anywhere from 5 to 15 cm thick at its thickest point. Rooffall in this room contained abundant, but usually small, fragments of adobe similar to that observed in the walls, and artifact density was considerably less than in Strata 1 and 2. Stratum 8 was the floor stratum in Room 2. Small patches of floor were present throughout the room, but there were no large contiguous areas of floor at all. Several times, excavators at the floor level punched through and fell into significant rodent burrows, especially in the southern half of the room. Stratum 10 was the fill from the centrally located collared hearth (Feature 2). Table 24.10 shows the general artifact counts by stratigraphic unit for this room.

Table 24.10. Room 2 artifact counts by stratigraphic units.

Stratum #	Ceramics	Chipped Stone	Ground Stone	Faunal Remains	Total
1	689	71	16	0	**776**
2	566	85	4	1	**656**
1,2	135	2	0	0	**137**
6	37	8	0	2	**47**
6,7	206	17	0	2	**225**
8	33	8	6	1	**44**
Total	**1666**	**191**	**26**	**6**	**1889**

Floor. The floor in this room was in poor condition. The best patch of floor was located along the western wall just under the doorway (Feature 3). As in Room 1, the plastered floor in this area coped with the wall plaster. Several other patches of floor along the northern and southern wall articulated with the wall plaster. In the remaining portions of the room, very small patches (less than 10 by 10 cm) of floor were visible. In addition, there were some small areas of floor plaster in the areas around the collar of the hearth. The hearth (Feature 2) was the only feature associated with the floor. A number of artifacts were found on the floor and included the following: a welded tuff millingstone (FS 1622), two quartzite one-handed manos (FS 1634 and FS 1635) and associated pollen samples (FS 1636 and FS 1637, respectively; see below), an andesite axe (FS 1638), an unidentified dacite ground stone fragment (FS 1646), a piece of obsidian debitage (FS 1647), a piece of burned juniper wood in the northeastern corner of the room (FS 1668), and a welded tuff millingstone (FS 1648) and associated pollen and flotation samples (FS 1649 and FS 1650, respectively; see below). Other artifacts, such as the 33 ceramics and seven pieces of chipped stone noted in Table 24.10, were collected from a floor sweep, and as such, were not analyzed because their exact provenience was unknown. A single jackrabbit (*Lepus* sp.) rib fragment was also identified in the floor sweep. In addition to the samples taken in association with artifacts on the floor, several other samples were taken on the floor. Flotation samples include FS 1360, FS 1625, and FS 1641 and pollen samples include FS 1359 and FS 1624.

Pollen samples were taken in association with two artifacts on the floor. Those samples associated with two quartzite manos (FS 1634 and FS 1635, respectively) produced a number of pollen signatures. Taxa identified in FS 1636 (associated with FS 1634) included cholla and prickly pear, beeweed (*Cleome*), lily family (Liliaceae), grass family (Poaceae), cheno-ams, sunflower family, unidentified pine, piñon pine, juniper, and oak. Taxa identified in FS 1637 (associated with FS 1635) included prickly pear, beeweed, cheno-ams, grass family, sunflower family, ragweed, unidentified pine, piñon pine, and sagebrush.

A pollen (FS 1649) and flotation (FS 1650) sample were also taken in association with a millingstone (FS 1648). Taxa identified in the pollen sample included prickly pear, beeweed, sunflower family, cheno-ams, ragweed, pea family (Fabaceae), unidentified pine, piñon, juniper, rose family, and sagebrush. Taxa identified in the flotation sample included goosefoot, maize, unknown conifer, juniper, unidentified pine, piñon pine, ponderosa pine, and oak.

One pollen sample (FS 1359) and one flotation sample (FS 1641) from the floor of Room 2 were analyzed. Taxa identified in the pollen sample included cholla, prickly pear, beeweed, cheno-ams, grass family, sunflower family, ragweed, spurge family (Euphorbiaceae), unidentified pine, piñon pine, juniper, rose family, and sagebrush. Taxa identified in the flotation sample included goosefoot, maize, unknown conifer, juniper, unidentified pine, piñon pine, ponderosa pine, and oak.

Wall Construction. Shaped and unshaped tuff blocks were used in the construction of this room. It appears as though the western wall of the room was constructed first as part of the central wall for the entire roomblock, that the eastern wall was built either next or at the same time as the western wall, and that the northern and southern walls were then abutted to the western and eastern walls. At least three courses were present in all the walls. Table 24.11 shows the general wall measurements for each of the walls.

Table 24.11. Room 2 wall measurements.

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	2.40	0.46	0.22
East	3.10	0.34	0.23
South	2.37	0.39	0.23
West	3.00	0.40	0.23

Artifacts and Samples. Artifacts and samples from two 1- by 1-m units were selected for analysis. Grids selected from Room 2 include 100N/115E (FS 349, FS 967, FS 968, FS 1310 through FS 1315, FS 1370 through FS 1375, and FS 1648 through FS 1650) and 101N/115E (FS 351, FS 573 through FS 575, FS 584 through FS 587, FS 596 through FS 599, FS 735 through FS 738, FS 857 through FS 861, FS 1319 through FS 1326, FS 1651, and FS 1691 through FS 1693). All artifacts from these two columns were analyzed, as was the bottom of a corrugated vessel (FS 1880). Table 24.12 lists all the samples that were selected for analysis from Room 2. Pollen and flotation samples from Stratum 8 were discussed in the section describing the Room 2 floor.

Table 24.12. Samples selected for analysis in Room 2.

Stratum	SAMPLE TYPE				
	Pollen	Flotation	Macrobotanical	TL	Archaeomagnetic
1	--	916	891, 930	--	--
2	769	--	597, 820, 846, 855	--	--
6,7	--	1291	1290, 1381	--	--
8	1359, 1636, 1637, 1649	1641, 1650	1660, 1663, 1668	--	--
10	1325, 1326	1321, 1322, 1323, 1324	--	1651	Taken

As outlined in the description of Room 1, 20 percent of the macrobotanical samples from each stratum in Room 2 were selected for analysis. A total of 11 samples were analyzed from Room 2, and samples were recovered from all strata except Stratum 10, which was the hearth fill. The following taxa were identified in the macrobotanical samples: box elder (*Acer negun*), mountain mahogany (*Cercocarpus*), saltbush/greasewood (*Atriplex/Sarcobatus*), Douglas fir (*Pseudotsuga menziesii*), juniper (*Juniperus* sp.), piñon pine (*Pinus edulis*), oak (*Quercus*), ponderosa pine (*Pinus ponderosa*), unidentified pine (*Pinus* sp.), unknown conifer (Gymnospermae), and rose family (Rosaceae). A pollen sample was taken in Stratum 2 and the following taxa were identified: maize (*Zea mays*), cholla and prickly pear, beeweed (*Cleome*), lily family (Liliaecea), buckwheat (*Eriogonum*), pea family (Fabaceae), sunflower family (Asteraceae), ragweed/bursage (*Ambrosia*), spurge family (Euphorbiaceae), evening primrose family (Onograceae), unidentified pine, piñon pine, juniper, oak, fir (*Abies*), sagebrush (*Artemisia*), rose family, long spine (Sunflower), unknown sunflower (possibly marshelder), morning glory family (Convolvulaceae), cheno-ams, and unidentified grasses (Poaceae). Two flotation samples were taken in Strata 1 and 3 and only maize, unknown conifer, and unidentified pine remains were identified.

Identified ceramics from these two grids included 29 smeared-indented corrugated sherds, 18 unpainted sherds, 19 plainware sherds (body and rim), 19 Santa Fe Black-on-white sherds, 21 indented corrugated sherds, one polished gray sherd, one coiled necked sherd, one plain incised sherd, and one undifferentiated mineral-painted sherd. One ground stone artifact, a welded tuff millingstone, was identified in the sampled grid units. All of the faunal remains recovered from this room were analyzed; identified remains included a single element from each of the following taxa: wood rat (*Neotoma* sp.), pocket gopher (*Thomomys* sp.), cottontails (*Sylvilagus* sp.), jackrabbit (*Lepus* sp.), and mule deer (*Odocoileus hemionus*). No worked bones were identified in this room. Table 24.13 lists the chipped stone materials recovered in this room.

Room 2 Features

Feature 2 (Hearth). Feature 2 is a centrally located plaster-lined collared hearth in Room 2 (101N/115E; Figures 24.21 and 24.22). Stratum 10 represents the fill removed from this hearth. The hearth is approximately 60 by 60 by 15 cm in size and is roughly circular in shape. The collar around the hearth is raised only slightly (less than 2 cm) above the floor. This is distinct from the hearth in Room 1, which is raised some 10 cm above the floor. The hearth was not disturbed significantly by rodent activity like the rest of the room was, but no artifacts were recovered from the fill of the hearth.

A number of samples were taken from Feature 2. These include an archaeomagnetic sample, two pollen samples, four flotation samples, and a thermoluminescence (TL) analysis sample. The following taxa were identified in the pollen samples (FS 1325 and FS 1326): maize, beeweed, sunflower family, ragweed/bursage, spurge family, evening primrose family, fir, unidentified pine, piñon pine, juniper, rose family, sagebrush, long spine sunflower, cheno-ams, and unidentified large grasses. The following taxa were identified in flotation samples from Feature 2 (FS 1321 through FS 1324): goosefoot, cheno-ams, maize, prickly pear, New Mexico locust (*Robinia*), tobacco (*Nicotiana*), mountain mahogany, saltbush/greasewood, oak, juniper, piñon pine, ponderosa pine, unidentified pine, and unknown conifer (Gymnospermae). The TL sample from a piece of the adobe hearth (FS 1651) dated to AD 918±180, while the archaeomagnetic sample dated later, falling between AD 1225 and 1300. A piece of maize (*Zea mays*) identified in a flotation sample (FS 1321) from the hearth was submitted for radiocarbon analysis. The maize yielded an age of 730±40 BP (Beta-183761) and a date of cal AD 1280 with a two-sigma date range of cal AD 1240–1300, which is consistent with the archaeomagnetic result, but quite different than the TL result.

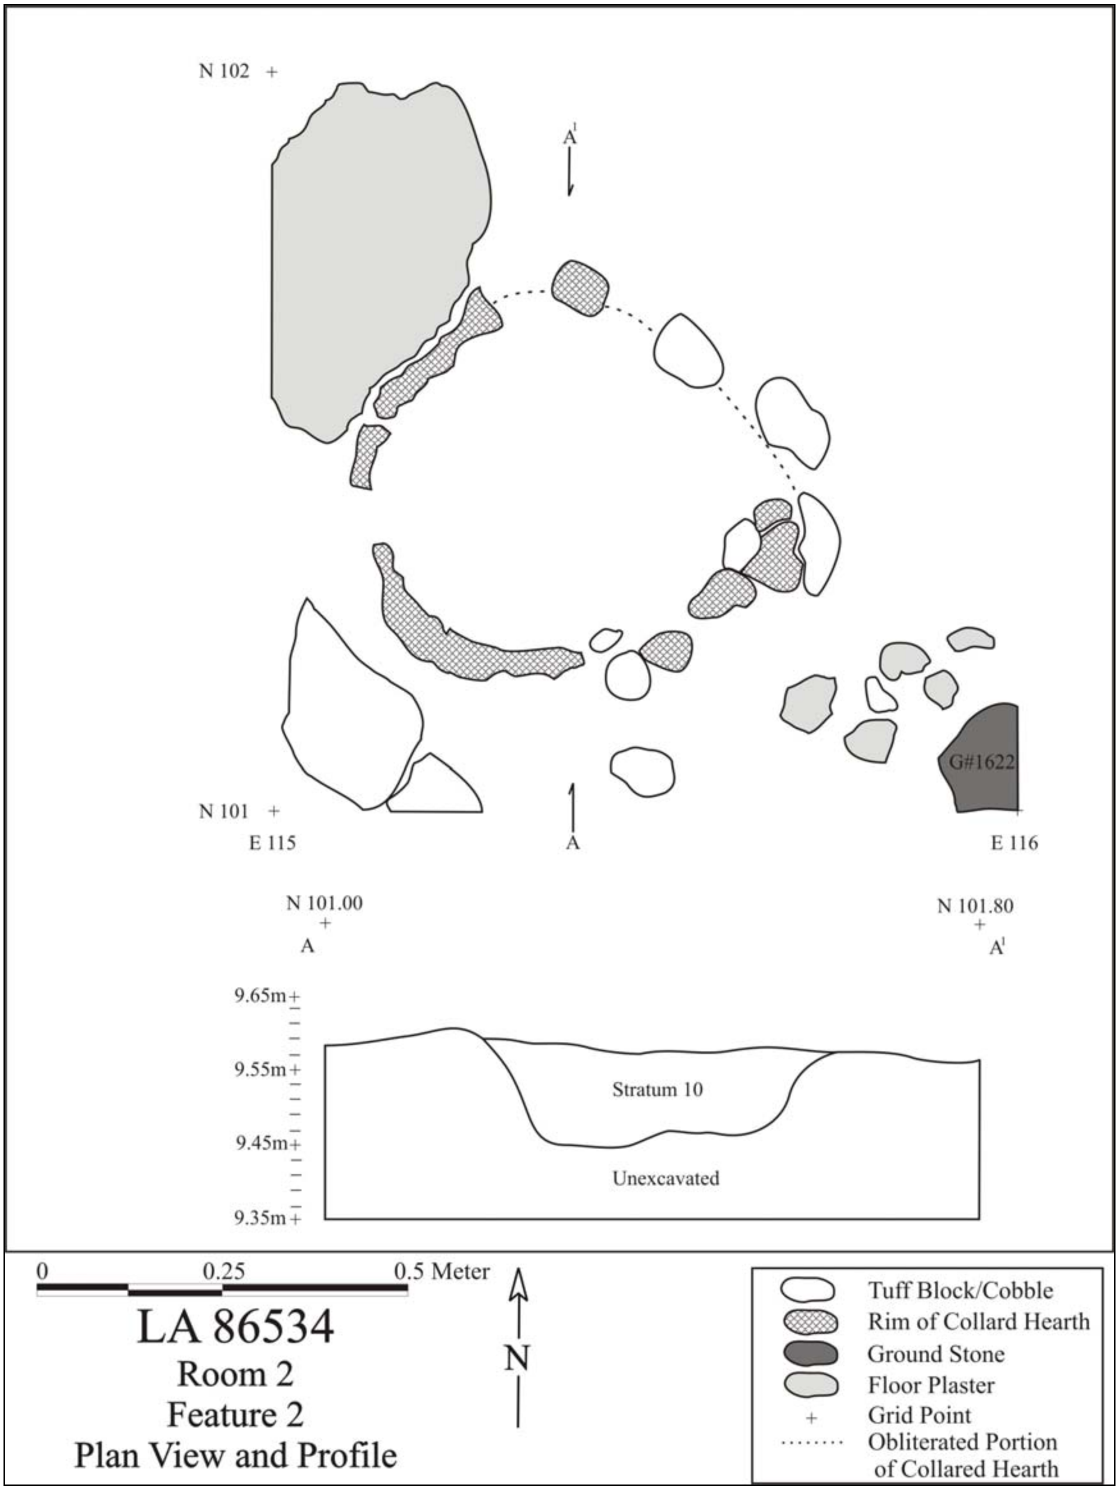

Figure 24.21. Plan view and profile of Feature 2.

Figure 24.22. Hearth (Feature 2) in Room 2.

Feature 3 (Doorway). Located centrally along the west wall, this doorway passes between Rooms 2 and 4. The dimensions of the doorway are 45 by 58 by 20 cm and it lies directly west of Feature 2. There is a considerable amount of plaster that is flush with the bottom of the doorway. As in Room 1, there is a footing stone at the base of the wall that measures 31 by 20 by 20 cm. Three courses of stone were present in the wall to the south, and two were present in the wall to the north of the doorway. Neither a plan map nor a profile was drawn for the doorway feature.

Room 3

Sequence of excavation. Room 3 is located in the northwestern corner of the roomblock. It is the most northerly of the back rooms and is 3.2 m north-south by 2.0 m east-west, giving about 6.4 m^2 of interior space. It is in the back row of rooms and is located immediately to the west of Room 1. In general, the room was uniformly disturbed in the northern two-thirds by roots associated with the juniper tree outside the north wall of Room 3. Units in this room were excavated in stratigraphic units (and in 10-cm levels within the strata if it was thicker than 10 cm) to the top of rooffall (Stratum 6). Once units were excavated to the top of rooffall, the excavations ceased temporarily until all units were dug to the same level. Then, all units in the room were excavated down to floor (Stratum 8). A single doorway feature (Feature 10) was identified in the eastern wall between Rooms 1 and 3 (Figure 24.23).

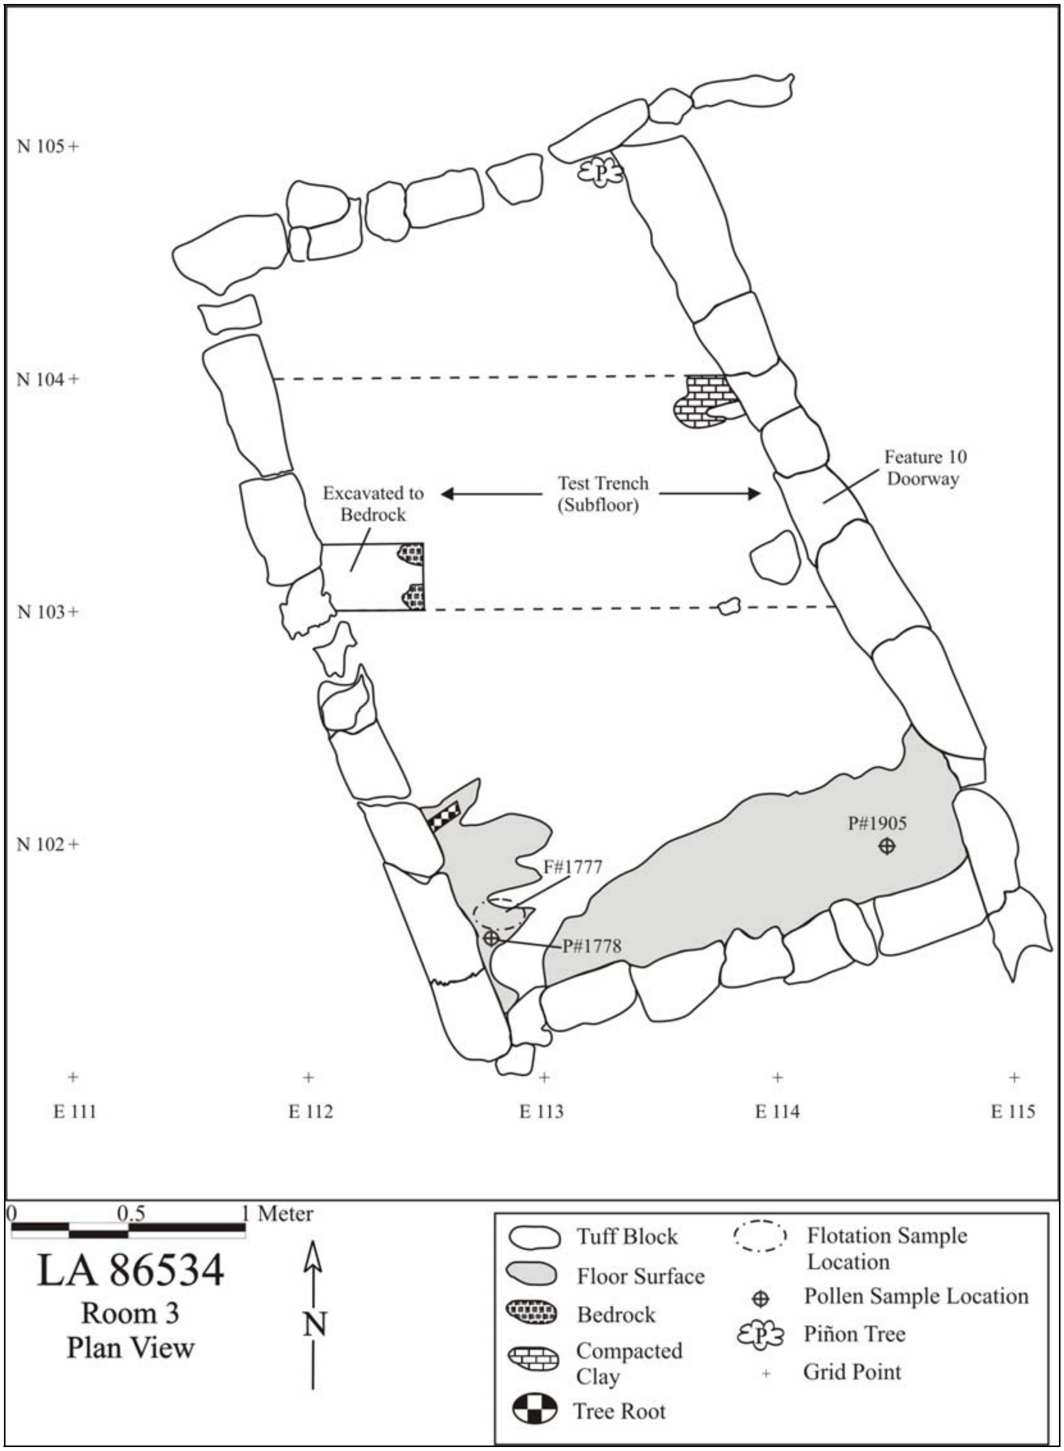

Figure 24.23. Plan view of Room 3 floor after excavation.

Fill. On average, Stratum 1 was an approximately 10-cm-thick layer of post-occupational fill that consisted of the very loose and unconsolidated soil. This stratum was much thinner in a large majority of the room but was thickest in the northeastern corner near a large juniper tree. Some areas contained a high organic content from the duff associated with piñon and juniper trees in the area. Artifact density in this stratum was the highest. Stratum 2 consisted of the general room fill, which contained an abundant amount of rubble wallfall and was about 25 to 30 cm thick. The stratum was also loose and unconsolidated, and artifact density was lower than Stratum 1, but still higher than the other strata in the room. The bottom of Stratum 2 contained the abrupt contact with rooffall (Strata 6 and 7). Stratum 6 is the actual rooffall layer, but Stratum 7, only definitively identified in Room 1, was a very thin layer of sediment between rooffall and floor.

In Room 3, Stratum 6 was anywhere from 5 to 15 cm thick at its thickest point, but averaged about 8 cm. Rooffall in this room contained abundant, but usually small, fragments of adobe similar to that observed in the walls, and artifact density was considerably less than in Strata 1 and 2. As with all the other rooms in the roomblock, Stratum 8 was the floor stratum in this room. Floor was only present in the southern one-third of the room, with a very small patch present along the northern wall. The middle one-third of the room contained no discernible floor, and, as a result, excavations in this area went too deep. It is likely that the northern two-thirds of the room incurred significant damage from two substantial piñon trees located just north of the roomblock. In general, artifact density in this back room was lower than the density of artifacts in the front rooms. No floor features were identified in this room. Table 24.14 shows the general artifact counts by stratigraphic unit for this room.

Table 24.14. Room 3 artifact counts by stratigraphic units.

Stratum #	Ceramics	Chipped Stone	Ground Stone	Faunal Remains	Total
0	2	0	0	0	**2**
1	673	77	0	1	**751**
2	282	39	3	0	**324**
6,7	204	33	8	0	**245**
8	0	0	0	0	**0**
Total	**1161**	**149**	**11**	**1**	**1322**

Floor. In general, the floor in the northern two-thirds of this room was in poor condition. The best patch of floor was located along the southern wall and in the southwest corner, and the plastered floor in this area coped with the wall plaster. No artifacts were found on the floor of this room, but one flotation sample (FS 1777) and two pollen samples (FS 1778 and FS 1905) were taken directly on the floor. Taxa identified in the flotation sample included pigweed (*Amaranthus*), goosefoot (*Chenopodium*), cheno-ams (*Chenopodium/Amaranthus*), maize (*Zea mays*), unknown conifers (Gymnospermae), juniper (*Juniperu*s), unidentified pine (*Pinus* sp.), piñon pine (*Pinus edulis*), and ponderosa pine (*Pinus ponderosa*). Taxa identified in the pollen samples include beeweed (*Cleome*), buckwheat (*Eriogonum*), mustard family (Brassicaceae), sunflower family (Asteraceae), globemallow (Sphaeralcea), spurge family (Euphorbiaceae), Douglas fir (*Pseudotsuga menziesii*), juniper, unidentified pine, piñon pine, Mormon tea (*Ephedra*), sagebrush (*Artemisia*), cheno-ams, and unidentified grasses (Poaceae).

Wall Construction. Shaped and unshaped tuff blocks were used in the construction of this room. It appears as though the western wall of the room was constructed first as part of the rear wall for the entire roomblock and that the eastern wall (central roomblock wall) was built either next or at the same time as the western wall. After these two walls were constructed, the northern and southern walls were then abutted to the western and eastern walls. One to two courses were present in the northern and eastern walls and three to four courses in the western and southern walls. Table 24.15 shows the general wall measurements for each of the walls.

Table 24.15. Room 3 wall measurements.

Wall Orientation	Length (m)	Height (m)	Thickness (m)
West	3.35	0.29	0.21
East	3.00	0.30	0.22
South	1.85	0.35	0.19
North	2.20	0.25	0.20

Artifacts and Samples. Artifacts and samples from two 1- by 1-m units were selected for analysis. Grids selected from Room 3 include 102N/113E (FS 765, FS 784 through FS 786, FS 816, FS 817, FS 841, FS 952 through FS 956, FS 960 and FS 961, FS 1316 through FS 1318, and FS 1720 through FS 1722) and 103N/112E (FS 1063, FS 1067, FS 1097 through FS 1101, and FS 1541 through FS 1544). All artifacts from these two columns were analyzed. In addition to the artifacts analyzed from these two 1- by 1-m units, several other artifacts were analyzed, including a quartzite hammerstone (FS 955), several large Santa Fe Black-on-white sherds (FS 1086), an andesite axe (FS 1947), and a welded tuff ground stone fragment (FS 1947). Table 24.16 lists the samples selected for analysis from Room 3.

Table 24.16. Samples selected for analysis in Room 3.

Stratum	SAMPLE TYPE					
	Pollen	Pollen wash	Flotation	Macrobotanical	TL	Archaeomagnetic
1	--	1087	--	972, 1083	--	--
2	1063	--	925	905	--	--
6,7	--	--	--	1530, 1532, 1543	--	--
8	1778, 1905	--	1777	--	--	--

As outlined in the description of Room 1, 20 percent of the macrobotanical samples from each stratum in Room 3 were selected for analysis. A total of six samples were submitted for analysis from Room 3. Samples are from all strata except the floor where no macrobotanical remains were encountered, but none of the samples produced identifiable material. Pollen and flotation samples were also taken from this room. The following taxa were identified in the pollen sample (FS 1063): sunflower family (Asteraceae), juniper, unidentified pine, piñon pine, oak (*Quercus*), sagebrush, cheno-ams, and unidentified grasses. Two flotation samples were taken: taxa identified in FS 1777 are discussed in association with the floor, and taxa identified in FS 925 include rose family (Rosaceae), maize, mountain mahogany (*Cercocarpus*), unknown conifer (Gymnospermae), unidentified pine, and ponderosa pine.

Identified ceramics from these two grids included nine smeared-indented corrugated sherds, one polished gray sherd, 11 unpainted sherds, six plainware sherds, six Santa Fe Black-on-white sherds, four indented corrugated sherds, and one Chupadero Black-on-white sherd. One ground stone artifact, an unidentified piece of welded tuff, was identified in the sampled grid units. All of the faunal remains recovered from this room were analyzed; identified remains include one partially burned proximal femur from a kangaroo rat (*Dipodomys* sp.). No worked bones were identified in this room. Table 24.17 shows the distribution of chipped stone materials recovered in this room.

Table 24.17. Chipped stone artifacts recovered from sampled units in Room 3.

Type	Material	Number
Hammerstone	Quartzite	1
Core flake	Chalcedony	8
	Pedernal chert	1
	Greenish/gray chert	1
Notching flake	Black translucent obsidian	1
Angular debris	Chalcedony	2
Microdebitage	Chalcedony	9
	Black translucent obsidian	2

Room 3 Features

Feature 10 (Doorway). This feature was the only feature identified in Room 3. Located centrally along the western wall, this doorway allowed passage between Rooms 1 and 3. The dimensions of the doorway measured 40 by 21 by 16 cm. A shaped footing stone was present at the base of the doorway. Because much of the eastern wall of Room 1 had collapsed and this portion of the wall was only one course high, there was no fill remaining when the feature was identified. As a result, no artifacts were recovered from the fill and no samples were taken. No plan map or profile was drawn of the feature.

Room 4

Sequence of excavation. Room 4 is located in the north-central portion of the roomblock and is 3.1 m north-south by 1.8 m east-west, giving about 5.58 m^2 of interior space (Figure 24.24). Room 4 is in the back row of rooms and is located immediately to the south of Room 3 and to the west of Room 2. In general, the room was in very good shape, with the least disturbance of any rooms. No roots or stumps were identified, and the floor was the best preserved of any rooms at the site (Figure 24.25).

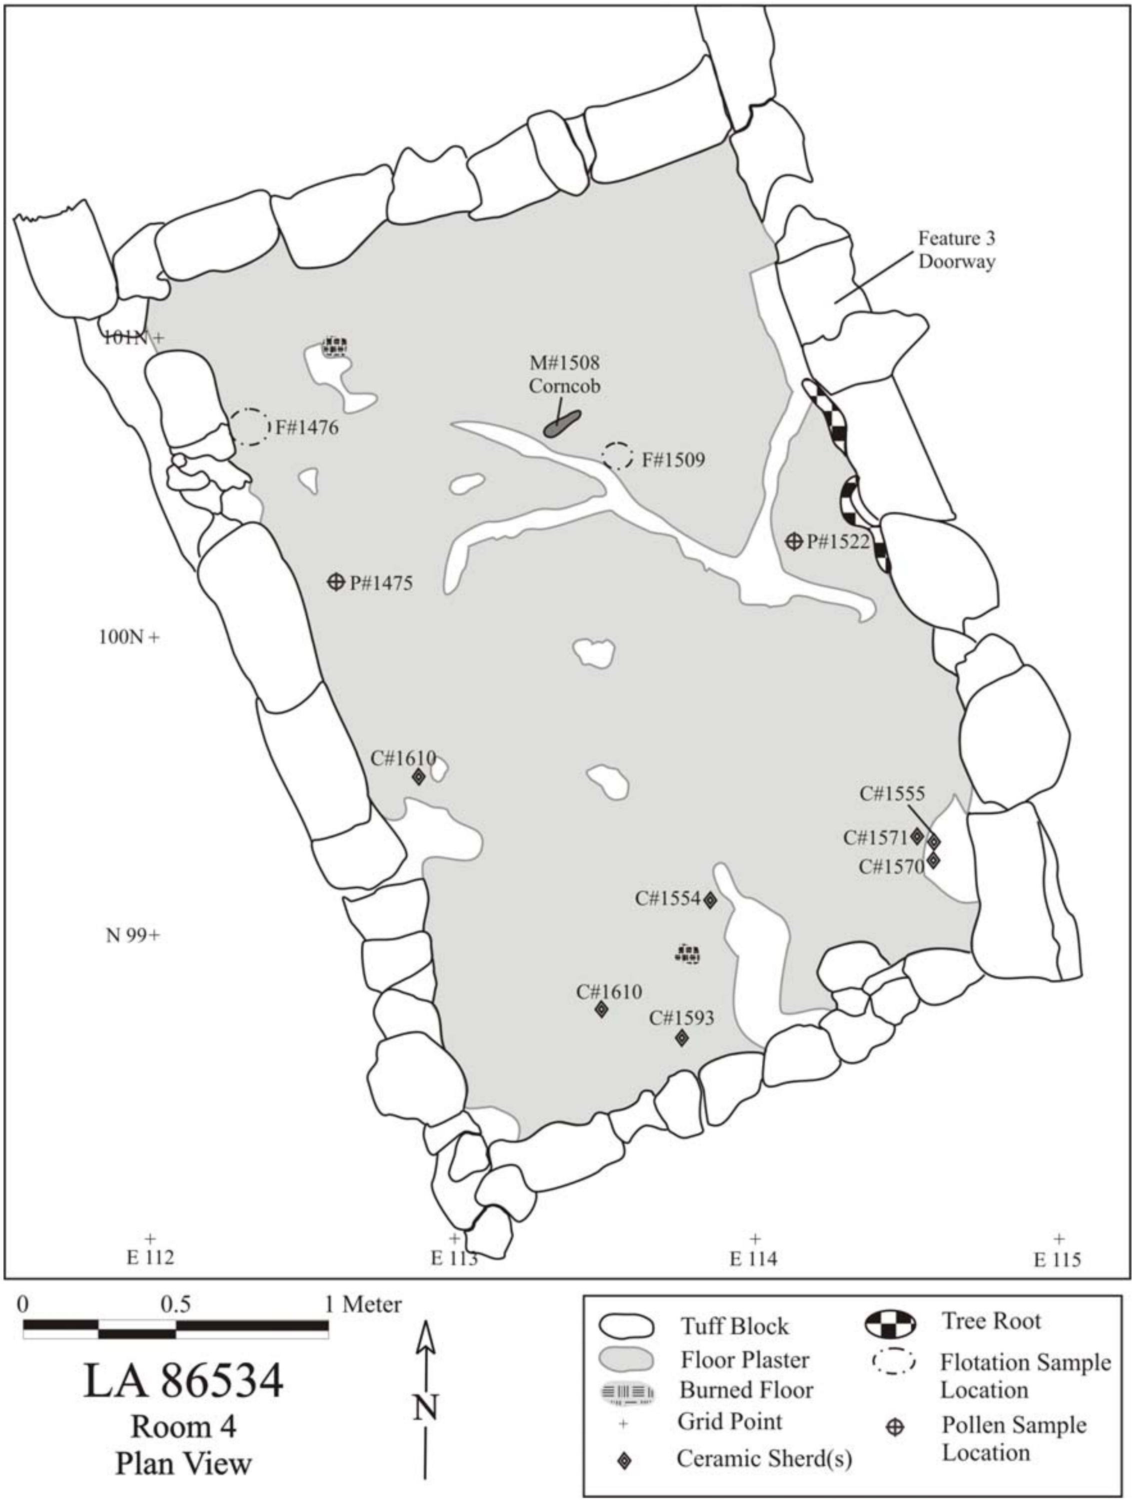

Figure 24.24. Plan view of Room 4 floor after excavation.

Figure 24.25. Floor in Room 4.

As in the other rooms, units in this room were excavated in stratigraphic units to the top of rooffall (Stratum 6). Once units were excavated to the top of rooffall, the excavations ceased temporarily until all units were at the same level. Then, all units in the room were excavated down to floor (Stratum 8). A single doorway feature (Feature 3) was identified in the eastern wall of the room between Rooms 2 and 4.

Fill. On average, Stratum 1 was an approximately 10-cm-thick layer of post-occupational fill and consisted of very loose and unconsolidated soil. Some areas contained a high organic content from the duff associated with piñon and juniper trees in the area. Artifact density in Stratum 1 was the highest. Stratum 2 consisted of general room fill, which contained an abundant amount of rubble wallfall and was about 25 to 30 cm thick. The stratum was also loose and unconsolidated, and artifact density was lower than Stratum 1, but still higher than in the subsequent strata. The bottom of Stratum 2 contained the abrupt contact with rooffall (Stratum 6).

In Room 4, Stratum 6 was anywhere from 5 to 18 cm thick at its thickest point, but averaged about 12 cm. Rooffall in this room contained abundant, but usually small, fragments of adobe similar to that observed in the walls, and artifact density was considerably less than in Strata 1 and 2. As with all the other rooms in the roomblock, Stratum 8 was the floor stratum. Floor was present throughout the entire room, with only minimal rodent disturbance present in the central and eastern portions along the southern wall and in a small area in the center of the room. In general, artifact density in this back room was lower than the density of artifacts in the front rooms. No floor features were identified in this room, but a number of sherds and a small corn cob fragment were identified on the floor. Table 24.18 shows the general artifact counts by stratigraphic unit for Room 4.

Table 24.18. Room 4 artifact counts by stratigraphic units.

Stratum #	Ceramics	Chipped Stone	Ground Stone	Faunal Remains	Total
0	1	0	0	0	**1**
1	619	65	6	3	**693**
2	161	12	2	0	**175**
1,2	107	8	0	1	**116**
6,7	124	23	1	3	**151**
8	7	0	0	0	**7**
Total	**1019**	**108**	**9**	**7**	**1143**

Floor. In general, the floor in Room 4 was in excellent condition. It was the most intact of all the floors in the roomblock, with some 80 percent of the floor still remaining. There were two small areas in the room where floor was still present, but in poor condition. These areas occurred along the central and eastern portions of the southern wall and in the center of the room (see Figure 24.25). In nearly all portions of the room along the wall, the plastered floor coped with the wall plaster. In addition, coping was present along the wall underneath the doorway (Feature 3) between Rooms 2 and 4. The base of the footing stone associated with this feature was flush with the floor plaster. A number of artifacts were found on the floor, including seven sherds (FS 1471, FS 1554, FS 1555, FS 1570, FS 1571, FS 1593, and FS 1610) and a corncob (FS 1508), which was submitted for radiocarbon analysis. The maize cob yielded an age of 850±40 BP (Beta-183763) and a date of cal AD 1200 with a two-sigma date range of cal AD 1170–1240. The identified ceramics included three basket impressed sherds, one Wiyo Black-on-white sherd, one unpainted sherd, and two plainware sherds.

In addition, two flotation samples (FS 1476 and FS 1509) and two pollen samples (FS 1475 and FS 1522) were taken directly on the floor. FS 1509 was taken in the area around the corncob and included the following charred taxa: maize (*Zea mays*), goosefoot (*Chenopodium*), cheno-ams (*Chenopodium/Amaranthus*), saltbush/greasewood (*Atriplex/Sarcobatus*), unknown conifer (Gymnospermae), unidentified pine (*Pinus* sp.), and piñon pine (*Pinus edulis*). The other flotation sample (FS 1476) produced the following charred taxa: goosefoot, goosefoot family (Chenopodiaceae), maize, unknown conifer, unidentified pine, ponderosa pine (*Pinus ponderosa*), and piñon pine. Pollen samples included the following taxa: beeweed (*Cleome*), maize, sunflower (Asteraceae), juniper, unidentified pine, piñon pine, spurge family (Euphorbiaceae), Mormon tea (*Ephedra*), rose family (Rosaceae), sagebrush (*Artemisia*), cheno-ams, and unidentified grasses (Poaceae).

Wall Construction. Construction activities in this room involved the use of shaped and unshaped tuff blocks. It appears as though the western wall of the room was constructed first as part of the rear wall for the entire roomblock and that the eastern wall (central roomblock wall) was built either next or at the same time as the western wall. After these two walls were constructed, the northern and southern walls were then abutted to the western and eastern walls. Three to four courses were present in each of the walls. Table 24.19 shows the general wall measurements for each of the walls.

Table 24.19. Room 4 wall measurements.

Wall Orientation	Length (m)	Height (m)	Thickness (m)
West	3.05	0.46	0.24
North	1.80	0.35	0.19
East	3.00	0.43	0.23
South	1.75	0.48	0.22

Artifacts and Samples. Artifacts and samples from two 1- by 1-m units were selected for analysis in this room. Grids selected from Room 4 include 100N/113E (FS 1017 through FS 1022 and FS 1505 through FS 1509) and 99N/114E (FS 406, FS 799, FS 897, FS 913 and FS 914, FS 957 and FS 958, FS 1510 and FS 1511, FS 1555, FS 1558 through FS 1561, FS 1567 through FS 1571, and FS 2240). All artifacts from these two columns were analyzed. Table 24.20 lists the samples selected for analysis from Room 4.

Table 24.20. Samples selected for analysis in Room 4.

Stratum	SAMPLE TYPE				
	Pollen	Flotation	Macrobotanical	TL	Archaeomagnetic
1	921	--	--	--	--
1,2	913	--	836, 957	--	--
6	1510	1511, 1578	1504, 1569	--	--
8	1475, 1522	1476, 1509	1508	--	--

Twenty percent of the macrobotanical samples from each stratum in Room 4 were selected for analysis. A total of five samples were analyzed from Room 4, and samples are from all strata except post-occupational fill. Wood taxa included Douglas fir, juniper, mountain mahogany, oak, unidentified pine, piñon pine, ponderosa pine, saltbush/greasewood, and unknown conifer. Maize cupules were identified in FS 836 and FS 1508. Taxa identified in the samples collected from the floor are referenced above. Flotation samples recovered in the rooffall stratum include goosefoot purslane (*Portulaca*), saltbush/greasewood, maize, unknown conifer, juniper, unidentified pine, piñon pine, and mountain mahogany (*Cercocarpus*). Taxa identified in the pollen samples include maize, prickly pear, beeweed, long spine sunflower, broad spine sunflower, sunflower, plantain (*Plantago*), nightshade family (Solanaceae), cheno-ams, grass family, ragweed/bursage, spurge family (Euphorbiaceae), evening primrose (*Onagraceae*), unidentified pine, piñon pine, juniper, oak (*Quercus*), rose family, and sagebrush.

Identified ceramics from these two grids included 17 smeared-indented corrugated sherds, 17 Santa Fe Black-on-white sherds, 18 unpainted sherds, one Glaze yellow sherd, seven plainware sherds, one plain corrugated sherd, nine indented corrugated sherds, one mineral-painted sherd, two Wiyo Black-on-white sherds, one Gallup Black-on-white sherd, two Galisteo Black-on-white sherds, and three basket impressed sherds. All of the faunal remains recovered from this room were analyzed. Identified remains include a single turkey (*Meleagris gallopavo*) tarsometatarsus, one red-tailed hawk (*Buteo jamaicensis*) phalanx, one pocket gopher (*Thomomys bottae*) innominate, an indeterminate rodent (Rodentia) bone, a mule deer (*Odocoileus hemionus*) rib and metatarsal fragment, and a single unidentified small/medium-mammal long bone fragment. No worked bones were identified in this room. Table 24.21 lists the chipped stone materials recovered in this room.

Table 24.21. Chipped stone artifacts recovered from sampled units in Room 4.

Biface	Chalcedony	1

Room 4 Features

Feature 3 (Doorway). This is the only feature identified in the room. Located slightly north of center along the eastern wall, this doorway allows passage between Rooms 2 and 4. The dimensions of the doorway are 45 by 58 by 20 cm and it lies directly west of Feature 2, the collared hearth in Room 2. There is a considerable amount of plaster that is flush with the bottom of the doorway, and there is a footing stone at the base of the wall that measures 31 by 20 by 20 cm. Three courses of stone were present in the wall to the south, and two were present in the wall to the north of the doorway. Three unpainted ceramics (FS 1691) and a sample of wall mortar (FS 1693) were collected from the doorway.

Room 5

Sequence of excavation. Room 5 is located in the south-central portion of the roomblock and is 3.50 m north-south by 2.30 m east-west, giving an interior floor space of 8.05 m^2. Room 5 is in the front set of rooms and is located immediately south of Room 2 and west of Room 9. This room is the largest of the front rooms and has an entry/exitway in the northeast corner to Room

9. The room was highly disturbed by bioturbation and, as a result, the floor was in very poor condition (Figure 24.26).

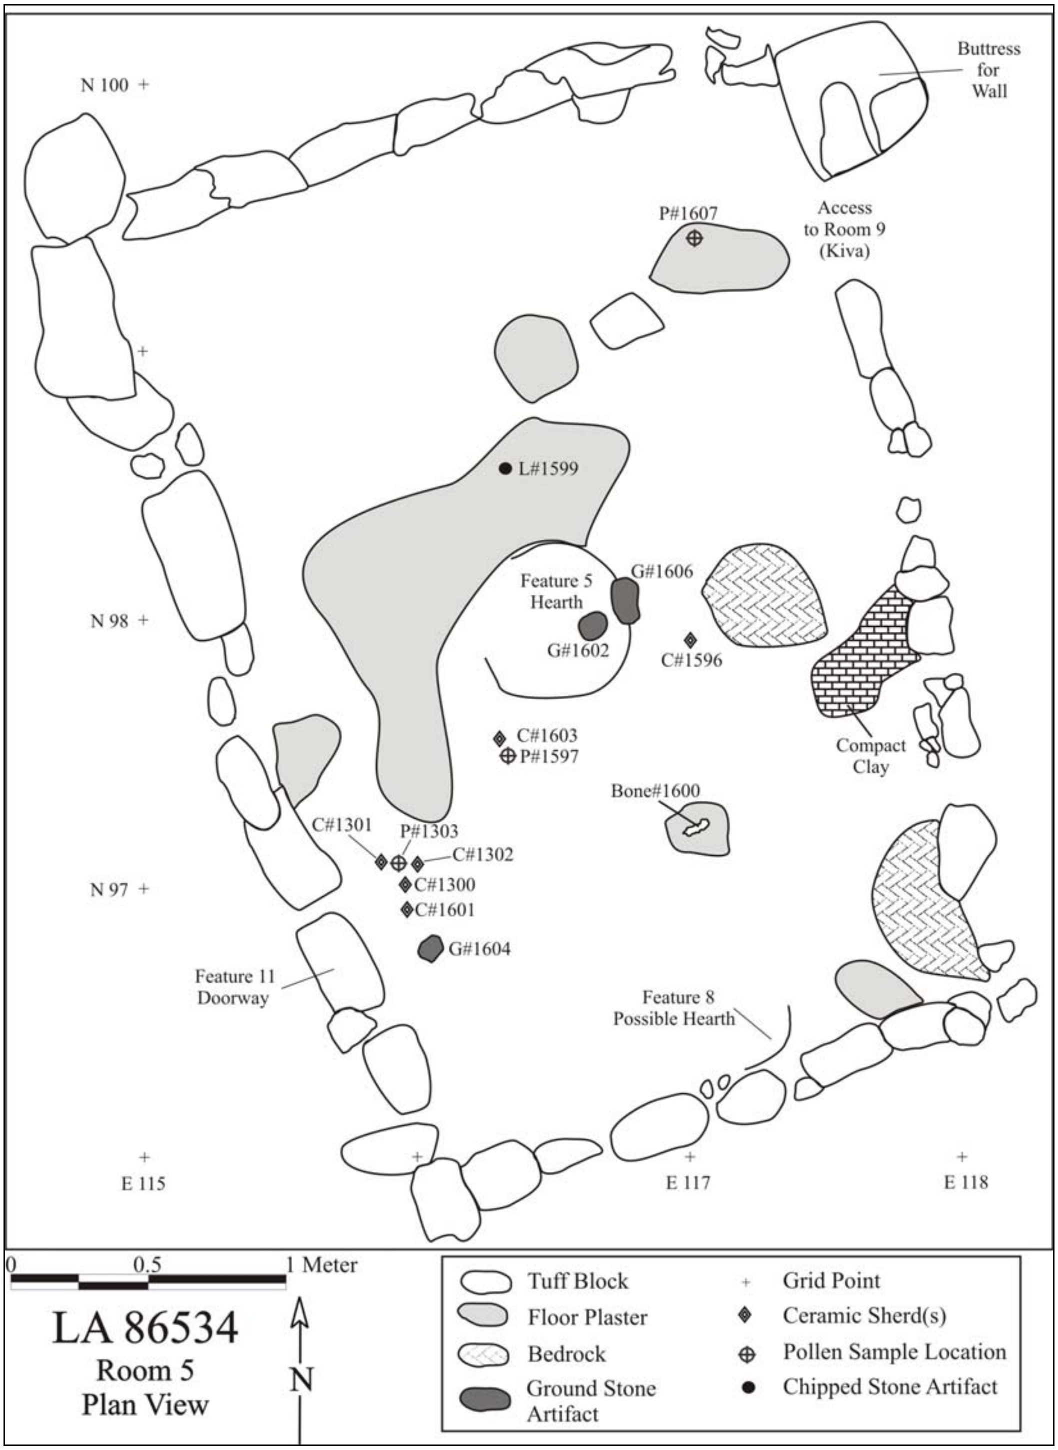

Figure 24.26. Plan view of Room 5 floor after excavation.

Units in the 115E line were excavated first as part of the overall profile trench of the roomblock. These units were excavated in stratigraphic units to the top of rooffall (Stratum 6). At this point, excavations ceased temporarily until all units in the roomblock were down to the top of the rooffall level. Units in Room 5 that were not in the 115E line were excavated in one large level (Strata 1 and 2) down to the top of the rooffall level. All units in the room were then excavated down to floor (Stratum 8).

Three features were identified in the room: Feature 5 was a collared hearth located near the center of the room, Feature 8 was a possible second hearth located along the southern wall, and Feature 11 was the doorway between the western wall of Room 5 and the eastern wall of Room 6. Feature 8 was in extremely poor condition and all that remained was a 10 cm section of probable collar. Both hearths were heavily disturbed and mostly destroyed, which precluded the collection of samples.

Fill. On average, Stratum 1 was an approximately 10- to 15-cm-thick layer of post-occupational fill and consisted of the very loose and unconsolidated soil. Some areas contained a high organic content from the duff associated with piñon and juniper trees in the area. Artifact density in this stratum was the highest. Stratum 2 consisted of the general room fill, which contained an abundant amount of rubble wallfall and was about 25 to 35 cm thick. The stratum was also loose and unconsolidated, and artifact density was lower than Stratum 1, but still considerably high. Strata 1 and 2 were combined throughout this room. The bottom of Stratum 2 contained the abrupt contact with rooffall (Strata 6 and 7).

In Room 5, Stratum 6 was anywhere from 7 to 20 cm thick at its thickest point, but averaged about 10 cm. Rooffall in this room contained abundant, but usually small, fragments of adobe similar to that observed in the walls, and artifact density was considerably less than in Strata 1 and 2. As with all the other rooms in the roomblock, Stratum 8 was the floor stratum. Floor was present in small patches throughout the room. The northern one-third of the room was particularly disturbed by rodents, and in much of this portion of the room, excavations went sub-floor because floor was never encountered. The middle one-third of the room was in better shape, with patchy floor. In general, artifact density in this front room was comparable to other front rooms and lower than the density of artifacts in the back rooms. Table 24.22 shows the general artifact counts by stratigraphic unit for Room 5.

Table 24.22. Room 5 artifact counts by stratigraphic units.

Stratum #	Ceramics	Chipped Stone	Ground Stone	Faunal Remains	Total
1	1204	160	73	4	**1441**
1,2	59	6	0	0	**65**
6	185	40	8	6	**239**
6,7	359	43	3	8	**413**
8	5	1	3	1	**10**
Total	**1812**	**250**	**87**	**19**	**2168**

Floor. The floor in this room was in poor condition. The best patches of floor were located in the center of the room, and the only area where floor plaster coped with wall plaster was located in the southeastern corner of the room. Most of the intact floor was close to the central hearth, but was patchy at best (Figure 24.27). Two hearths were identified in this room. The central hearth (Feature 5) was in good condition in terms of its external appearance, but was heavily disturbed in the interior of the hearth. Feature 8, a possible hearth located along the southern edge of the room, was in very poor condition, and all that remained was a 10-cm section of plaster. No collar was identified in association with this hearth.

Figure 24.27. Feature 5 (hearth) in center of Room 5.

A number of artifacts were found on the floor and include the following: five plainware sherds, one Santa Fe Black-on-white sherd, and one indented corrugated sherd (FS 1300, FS 1301, FS 1302, FS 1594, FS 1596, FS 1601, and FS 1603), a basalt cobble biface (FS 1599), a medium- to large-sized mammal long bone shaft fragment (FS 1600), and three pieces of ground stone (FS 1602, FS 1604, and FS 1606). These items included a one-hand basalt mano, a one-hand dacite mano, and a vesicular basalt grinding slab.

Three pollen samples were taken from under artifacts on the floor of Room 5 (FS 1303, FS 1597, and FS 1607). FS 1303 was taken from under one of the plainware sherds (FS 1302) and identified taxa included maize, cholla (*Opuntia*), lily family (Liliaceae), cheno-ams, grass family, sunflower family, ragweed/bursage, unidentified pine, piñon pine, and Mormon tea (*Ephedra* sp.). FS 1597 was taken from under the Santa Fe Black-on-white sherd (FS 1603) and identified taxa included prickly pear (*Opuntia*), cheno-ams, pea family (Fabaceae), sunflower family, ragweed/bursage, chicory Tribe (Liguliflorae), evening primrose (Onagraceae), unidentified pine, piñon pine, juniper, oak, rose family, and sagebrush. FS 1607 was taken from under a plainware sherd (FS 1601) and identified taxa included cholla, prickly pear, parsley family

(Apiaceae), cheno-ams, grass family, sunflower family, ragweed/bursage, unidentified pine, piñon pine, juniper, and sagebrush. No flotation samples were collected from the floor because of the extensive rodent disturbance.

Wall Construction. Both shaped and unshaped tuff blocks were used in the construction of this room. It appears as though the western wall of the room was constructed first as part of the central wall of the roomblock and that the eastern wall (front roomblock wall) was built either next or at the same time as the western wall. After these two walls were constructed, the northern and southern walls were then abutted to the western and eastern walls. The eastern wall is only a single course high and is not contiguous between the northern and southern walls. The northern, western, and southern walls are each three to four courses high and are generally in good condition. Table 24.23 shows the general wall measurements for each of the walls.

Table 24.23. Room 5 wall measurements.

Wall Orientation	Length (m)	Height (m)	Thickness (m)
North	2.33	0.41	0.19
South	2.21	0.32	0.21
East	3.51	0.32	0.22
West	3.63	0.29	0.23

Artifacts and Samples. Artifacts and samples from 98N/117E (FS 405, FS 1036 through FS 1038, FS 1183 through FS 1186, FS 1430 through FS 1434, FS 1605, and FS 2132 through FS 2134) and 96N/116E (FS 409, FS 1092 through FS 1096, FS 1132 and FS 1133, FS 1435 through FS 1439, and FS 1604) were selected for analysis in this room, and all artifacts from these two 1- by 1-m columns were analyzed. In addition to the artifacts analyzed from these two units, several other artifacts were selected for analysis. These include a vesicular basalt grinding slab fragment recovered from the floor (FS 1606), a Pedernal chert hammerstone (FS 1294), a basalt cobble biface (FS 1599), a polished gray ceramic pipe stem (FS 1416), a possible deflector (FS 1605), the proximal end of a black translucent obsidian projectile point (FS 1266), and a one-hand quartzite mano (FS 1390). Table 24.24 lists the samples selected for analysis from Room 5.

Table 24.24. Samples selected for analysis in Room 5.

Stratum	SAMPLE TYPE				
	Pollen	Flotation	Macrobotanical	TL	Archaeomagnetic
1	--	1170	1096, 1219	--	--
1,2	--	--	1241	--	--
6	1297	1402, 1512	1262, 1285, 1412	--	--
8	1303, 1597, 1607	--	--	--	--
12	--	1353, 1389	--	--	1205

Twenty percent of the macrobotanical samples from each stratum in Room 5 were selected for analysis. A total of six samples were analyzed from Room 5, but none of the vegetal materials were identifiable. Samples were collected from all strata except the floor and the hearth, as no macrobotanical remains were identified from either of these contexts. Pollen and flotation samples were also taken from this room. Taxa identified in the flotation samples include the following taxa: pigweed, goosefoot, saltbush/greasewood, maize, unknown conifers, juniper, piñon pine, ponderosa pine, oak, and other unidentified remains. The flotation samples from the rooffall stratum included both maize and bean remains. Taxa identified in the analyzed pollen samples include maize, cholla (*Opuntia*), lily family (Liliaceae), parsley family (Apiaceae), sunflower family, ragweed/bursage, broad spine sunflowers, spurge family (Onagraceae), unidentified pine, piñon pine, juniper, oak, rose family (Rosaceae), sagebrush, Mormon tea (*Ephedra*), Chicory tribe (Liguliflorae), cheno-ams, and unidentified grasses.

Identified ceramics from these two grids included 29 smeared-indented corrugated sherds, 16 unpainted sherds, 14 Santa Fe Black-on-white sherds, two plainwares, seven indented corrugated sherds, one plain corrugated sherd, and one Chupadero Black-on-white sherd. Five pieces of ground stone were identified and included three unidentified quartzite ground stone fragments, one dacite one-hand mano, and one welded tuff formal slab metate fragment. Of the 33 pieces of bone recovered from this room, 17 were identified to at least the level of class. The pocket gopher (*Thomomys bottae*) remains were likely intrusive, and the kangaroo rat (*Dipodomys* sp.) specimen may also have been intrusive, as all were associated with the rooffall level. Several of the bones, including the red-tailed hawk (*Buteo jamaicensis*), the cottontail (*Sylvilagus* sp.), and the coyote (*Canis latrans*) bones were recovered from just above the floor. No worked specimens were recovered from this room. Table 24.25 lists the chipped stone materials recovered in this room.

Room 5 Features

Feature 5 (Hearth). Feature 5 is a plaster-lined collared hearth located in the center of Room 5 (see Figures 24.26 and 24.27). Stratum 12 represents the fill removed from this hearth. The hearth is approximately 51 by 47 by 15 cm in size and is roughly circular in shape. The collar around the hearth is raised only slightly (less than 2 cm) above the floor, similar to the hearth in Room 2, just to the north. Both of these hearths are distinct from the hearth in Room 1, which is raised some 10 cm above the floor. The hearth was excavated into bedrock and then plastered, and the collar was burned. Feature 5 was significantly rodent disturbed, especially on the western side. Because of the heavy disturbance throughout the hearth fill, no pollen samples were taken. Two flotation samples were taken (FS 1353 and FS 1389) in the least disturbed portions of the hearth, and the following carbonized taxa were identified in the samples: goosefoot seeds, saltbush/greasewood, maize cupule and kernel fragments, unknown conifers, juniper, piñon pine needles, ponderosa pine, and oak. A single ground stone artifact, a quartzite one-hand mano (FS 1390), was recovered from the hearth. During excavation, it was difficult to distinguish the hearth fill from the general fill because of the deteriorated nature of the hearth. As a result, neither a plan map nor a profile was drawn. Archaeomagnetic samples procured from the hearth produced a date range of AD 1235–1270. Maize cupules were identified in FS 1389 and were submitted for radiocarbon analysis. The sample yielded an age of 800±40 BP (Beta-183762) and a date of cal AD 1250 with a two-sigma date range of cal AD 1210–1270, which closely matched the archaeomagnetic date from the feature.

Feature 8 (Partial Hearth). Feature 8 is a possible partial hearth located in the southern portion of Room 5 (see Figure 24.26). The feature is located due south of Feature 5 and is flush with the southern wall of the room. Only a small portion of the feature remained when it was identified during excavation. The plaster lining that remained in the feature was cracked and crumbling and was approximately 2 cm thick. The remaining portion of the hearth measures 30 by 13 cm, and there is no depth to the feature. Because of its significantly disturbed and destroyed nature, there was no fill and no samples were taken.

Feature 11 (Doorway). Feature 11 is a doorway located slightly south of center along the western wall. The doorway allowed passage between Rooms 5 and 6. The dimensions of the doorway are 47 by 20 by 16 cm, and it lies directly east of Feature 5, the collared hearth in Room 5. There is almost no plaster at the bottom of the doorway, which is flush with the floor, and there is a footing stone at the base of the doorway that measures 28 by 19 by 18 cm. Four courses of stone were present in the wall to the south and three were present in the wall to the north of the doorway. No artifacts were collected from the doorway fill. Neither a plan map nor a profile of the feature was drawn.

Room 6

Sequence of excavation. Room 6 is located in the south-central portion of the roomblock and is 2.95 m north-south by 1.8 m east-west, giving about 5.30 m^2 of interior space. It is in the back row of rooms and is located immediately to the south of Room 4 and to the west of Room 5. In general, the room was in good shape, with a minimal amount of disturbance. No roots or stumps were identified in the room, and the floor was in decent shape with about 50 percent of the floor intact (Figure 24.28).

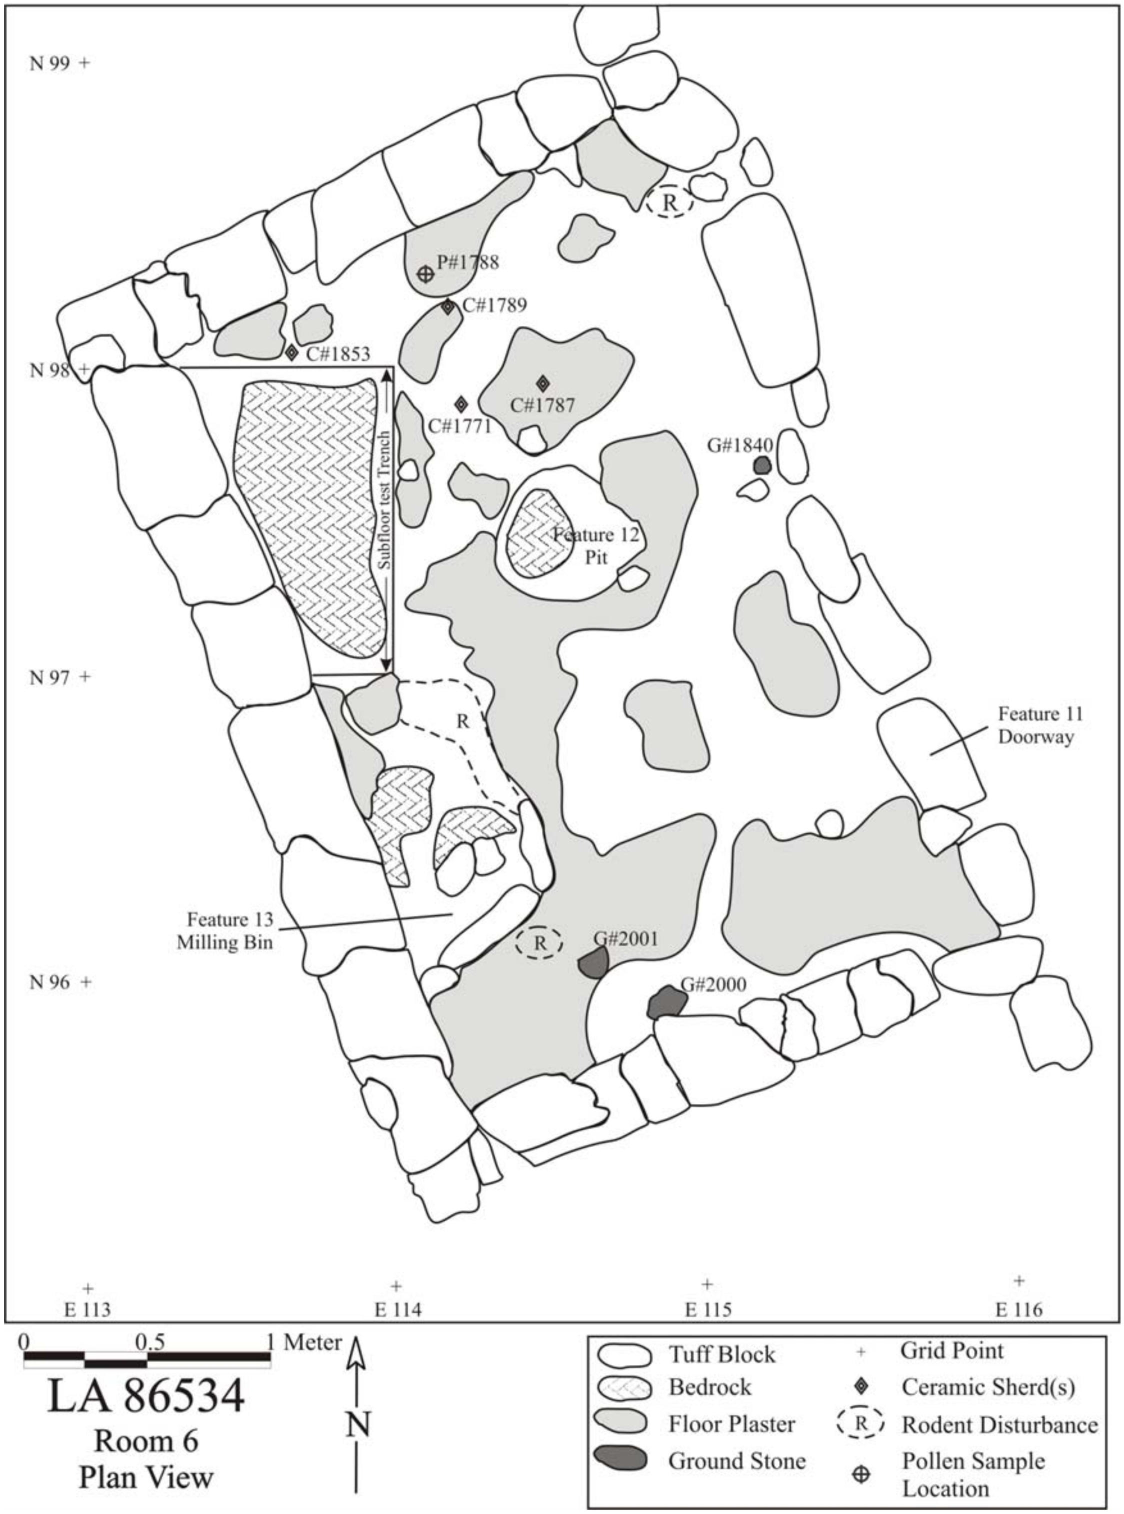

Figure 24.28. Plan view of Room 6 floor after excavation.

As in the other rooms, 1- by 1-m units in this room were excavated in stratigraphic units (and in 10-cm levels within the strata if it was thicker than 10 cm) to the top of rooffall (Stratum 6). Once units were excavated to the top of rooffall, the excavations ceased temporarily until all units were at the same level. Then, all units in the room were excavated down to floor (Stratum 8). Three features were identified in this room: a doorway (Feature 11), a shallow plaster-lined pit (Feature 12), and a milling bin (Feature 13).

Fill. On average, Stratum 1 was an approximately 10-cm-thick layer of post-occupational fill and consisted of very loose and unconsolidated soil. As in the other rooms, some areas contained a high organic content from the duff associated with piñon and juniper trees in the area. Artifact density in Stratum 1 was the highest. Stratum 2 consisted of the general room fill, which contained an abundant amount of rubble wallfall and was about 25 to 30 cm thick. The stratum was also loose and unconsolidated, and artifact density was lower than Stratum 1, but still considerably high. The bottom of Stratum 2 contained the abrupt contact with rooffall (Stratum 6).

In Room 6, Stratum 6 was anywhere from 7 to 20 cm thick at its thickest point, but averaged about 10 cm. Rooffall in this room contained abundant, but usually small, fragments of adobe similar to that observed in the walls, and artifact density was considerably less than in Strata 1 and 2. As with all the other rooms in the roomblock, Stratum 8 was the floor stratum in this room. Floor was present in about half of the room, with large patches in the southern half, the center, and along the western wall. In general, artifact density in this back room was lower than the density of artifacts in the adjacent front rooms. A shallow, plaster-lined pit (Feature 12) and a milling bin (Feature 13) were identified in this room. Stratum 14 represents the fill from Feature 12 and Stratum 16 represents the fill from Feature 13. Table 24.26 shows the general artifact counts by stratigraphic unit for Room 6.

Table 24.26. Room 6 artifact counts by stratigraphic units.

Stratum #	Ceramics	Chipped Stone	Ground Stone	Faunal Remains	Total
1	766	103	20	4	**893**
6	38	6	0	1	**45**
6,7	141	21	6	1	**169**
8	6	0	1	3	**10**
14	4	2	9	1	**16**
16	0	0	1	0	**1**
Total	**955**	**132**	**37**	**10**	**1134**

Floor. The floor in this room was in fairly good condition (see Figure 24.28). Several rooms were in much worse shape, and only Room 4 contained better patches of floor. The dominant area of floor was located in the southern half of the room and along the western wall. Small patches also exist near the center of the room and in the southeastern corner. Some of the floor plaster coped with wall plaster in the southeastern corner of the room. A milling bin was identified in the southwestern portion of the room, and a small, shallow, plaster-lined pit was identified near the center of the room. The feature was amorphous but roughly circular in shape and was heavily rodent disturbed. Its function is unknown. A concentration of ceramics (FS 1771, FS 1787, FS 1789, FS 1853, and FS 1998) and one welded tuff grinding slab (FS 2000) were found on the floor of the room. Two other ground stone fragments (FS 1840 and FS 2001) were found just above the floor. The ceramics included two smeared-indented corrugated sherds, three indented corrugated sherds, and one plainware sherd. In addition, a macrobotanical sample (FS 1997) and a pollen sample (FS 1788) were collected from the floor. Two fragments of ponderosa pine charcoal and one of unknown conifer were identified in the macrobotanical sample. The following taxa were identified in the pollen sample: maize, prickly pear, beeweed, buckwheat (*Eriogonum*), sunflower family, ragweed/bursage, unidentified pine, piñon pine, juniper, sagebrush, cheno-ams, and unidentified grasses.

Wall Construction. Both shaped and unshaped tuff blocks were used in the construction of this room. It appears as though the western wall of the room was constructed first as part of the rear wall of the roomblock and that the eastern wall (central roomblock wall) was built either next or at the same time as the western wall. After these two walls were constructed, the northern and southern walls were then abutted to the western and eastern walls. All four walls were at least three courses high. Table 24.27 shows the general wall measurements for each of the walls.

Table 24.27. Room 6 wall measurements.

Wall Orientation	Length (m)	Height (m)	Thickness (m)
West	2.96	0.30	0.21
East	2.94	0.31	0.23
North	1.80	0.47	0.20
South	1.75	0.32	0.25

Artifacts and Samples. All artifacts and samples from 97N/114E (FS 1149 through FS 1153, FS 1765 through FS 1771, FS 1787, FS 1856 through FS 1860, FS 1906 through FS 1910, FS 1915, FS 1929, FS 1961 through FS 1963, FS 1965, and FS 2247) and 96N/114E (FS 1115 through FS 1118, FS 1187 through FS 1192, FS 1652 through FS 1656, FS 1960, FS 1964, FS 1966, FS 1999, and FS 2001) were analyzed. In addition, several other artifacts were selected for analysis and included two Santa Fe Black-on-white sherds (FS 1919 and FS 1969) from Feature 12 and a black translucent obsidian projectile point (FS 1852). Table 24.28 lists the samples selected for analysis from Room 6.

Table 24.28. Samples selected for analysis in Room 6.

Stratum	SAMPLE TYPE				
	Pollen	Flotation	Macrobotanical	TL	Archaeomagnetic
1,2	--	--	1064, 1124	--	--
6	--	--	1655, 1959	--	--
8	1788	--	1997	--	--
14	1908, 1915	1860, 1906	1858, 1965	--	--
16	1960	1966	1964	--	--

Twenty percent of the macrobotanical samples from each stratum in Room 6 were selected for analysis, generating a total of eight samples. The following taxa were identified in these samples: unidentified pine, piñon pine, ponderosa pine, oak, and unknown conifer. Pollen and flotation samples were also taken from this room. Taxa identified in the flotation samples from Room 6 include goosefoot, maize, four-wing saltbush (*Atriplex*), saltbush/greasewood, unknown conifer, juniper, piñon pine, ponderosa pine, oak, and uncharred tobacco (*Nicotiana*). Pollen samples included the following taxa: maize, prickly pear, cactus family (Cactaceae), beeweed, buckwheat, purslane (*Portulaca*), sunflower family, ragweed/bursage, broad spine sunflower, long spine sunflower, unidentified pine, piñon pine, juniper, oak, sagebrush, pea family (Fabaceae), spurge family, rose family (Rosaceae), cheno-ams, and unidentified grasses.

Identified ceramics from these two grids included nine unpainted sherds, 12 Santa Fe Black-on-white sherds, one Chupadero Black-on-white sherd, 11 smeared-indented corrugated sherds, five indented corrugated sherds, one plain corrugated sherd, and three plainware sherds. Ten pieces of ground stone were identified and included one andesite mano fragment, one rhyolite mano fragment, two dacite one-hand manos, two dacite abrading stones, one dacite metate fragment, one welded tuff one-handed mano, and two welded tuff metate fragments. Of the eight pieces of bone recovered from this room, only two were identified to the level of class. Identified remains are likely intrusive and include a single pocket gopher (*Thomomys bottae*) and indeterminate rodent (Rodentia) bone. No worked bones were identified in this room. Table 24.29 lists the chipped stone materials recovered in this room.

Table 24.29. Chipped stone artifacts recovered from sampled units in Room 6.

	Black translucent obsidian	1
Biface flake	Chalcedony	1

Room 6 Features

Feature 11 (Doorway). Feature 11 is a doorway located slightly south of center along the eastern wall that sits between Rooms 5 and 6. The dimensions of the doorway are 47 by 20 by 16 cm, and it lies directly east of Feature 5, the collared hearth in Room 5. There is almost no plaster at the bottom of the doorway that is flush with the floor, and there is a footing stone at the base of the doorway that measures 28 by 19 by 18 cm. Four courses of stone were present in the wall to the south, and three were present in the wall to the north of the doorway. No artifacts were collected from the doorway fill. Neither a plan map nor a profile was draw.

Feature 12 (Pit). Feature 12 is a shallow, plaster-lined pit located near the center of Room 6 (see Figure 24.28). Stratum 14 represents the fill removed from the pit. The amorphous pit is approximately 55 by 60 by 25 cm in size and is roughly circular to ovoid in shape. The function of the pit is unknown and its integrity as a feature is doubtful, but the patches of plaster lining the pit would appear to be intentional. The north side and most of the bottom was missing due to extensive rodent disturbance. The remaining portion of the pit was constructed by lining dacite cobbles in a constructed depression, and then plastering over the cobbles. A large piece of charred ponderosa pine (*Pinus ponderosa*; FS 1858) was recovered in the feature fill. One section of the bottom of the pit was well-preserved and contained hard ash and charcoal. A few sections of the plaster lining the pit were burned, but other sections were completely unburned.

The western side of the feature was heavily rodent disturbed. Samples were taken, but are less reliable than those recovered from the intact eastern half. As a result, only one flotation sample (FS 1860) from the western half of the hearth was submitted for analysis. Charred taxa identified in this sample included maize, four-wing saltbush, unknown conifer, juniper, piñon pine, ponderosa pine, and oak. One flotation sample (FS 1906) and one pollen sample (FS 1908) were taken from the eastern half. Taxa identified in the flotation sample included maize, unknown conifer, juniper, unidentified pine, piñon pine, and oak. Taxa identified in the pollen sample included prickly pear, beeweed, purslane, sunflower family, spurge family, unidentified pine, piñon pine, juniper, rose family, sagebrush, cheno-ams, and unidentified grasses. Five pieces of ground stone were identified in the feature. They included a dacite metate fragment, a dacite one-hand mano, a welded tuff metate fragment, and two dacite abrading stones. In addition, a chalcedony hammerstone and core flake (FS 1910 and FS 1961) and four smeared-indented corrugated sherds were recovered from this feature. Figure 24.29 shows a photograph of the amorphous pit in Room 6.

Figure 24.29. Feature 12, an amorphous pit in Room 6.

Feature 13 (Milling Bin). Feature 13 is a shallow milling bin located along the western wall of Room 6 and is approximately 60 cm south of Feature 12 (see Figure 24.28). Stratum 16 represents the fill removed from the milling bin. The feature is approximately 60 by 60 by 25 cm in size and is roughly ovoid in shape. The feature is defined by two upright stones and a probable third and fourth stone that may have enclosed the bin on three sides (Figure 24.30).

The western wall of Room 6 would have formed the back of the bin. The inside of the feature was lined with plaster and had a well-preserved plastered floor. One flotation sample (FS 1966) and one pollen sample (FS 1960) were taken from this feature. The following taxa were identified in the flotation sample: uncharred tobacco (*Nicotiana*), maize, saltbush/greasewood, unknown conifer, juniper, and ponderosa pine. Results from the pollen sample included the following taxa: prickly pear, long spine sunflowers, pea family (Fabaceae), sunflower family, spurge family, unidentified pine, piñon pine, juniper, oak, sagebrush, cheno-ams, and unidentified grasses. A one-hand dacite mano (FS 1999) and a macrobotanical sample (FS 1964) were collected from the feature. The macrobotanical sample contained remnants of unknown conifer, unidentified pine, ponderosa pine, and oak.

Figure 24.30. Feature 13, a milling bin.

Room 7

Sequence of Excavation. Room 7 is located in the southeast corner of the roomblock and is 3.1 m north-south by 2.20 m east-west, giving about 6.82 m^2 of interior space. The north-south measurements and the overall interior floor space measurement are incomplete. This is due to the fact that Room 7 is the most southerly of the front rooms and was heavily impacted by the construction of NM 502. Based on the dimensions of the room, it is likely that construction just clipped the southern wall of the room, but it was not located during excavation. Room 7 is located immediately south of Room 5 and east of Room 8. In general, the remaining portion of the room was in fair shape. The south wall was gone, the floor was only present in about half of the room, and the remaining three walls were still upright (Figure 24.31). As in the other rooms, units in this room were excavated in stratigraphic units (and in 10-cm levels within the strata if it was thicker than 10 cm) to the top of rooffall (Stratum 6). Once units were excavated to the top of rooffall, excavations ceased temporarily until all units were excavated to the same level. Then, all units in the room were excavated down to floor (Stratum 8). A significantly disturbed hearth (Feature 9) was identified in the center of the room.

Fill. On average, Stratum 1 was an approximately 10-cm-thick layer of post-occupational fill and consisted of the very loose and unconsolidated soil. As in the other rooms, some areas contained a high organic content from the duff associated with piñon and juniper trees in the area. Additionally, Stratum 1 in this room included a dense concentration of road rubble that was deposited in the upper layers of the roomblock during highway construction. This stratum, as well as the top few centimeters of Stratum 2, contained a number of cobbles, gravel, and chunks of tar and concrete. Unlike any of the other rooms in the roomblock, artifact density was not the highest in Stratum 1. Stratum 2 consisted of the general room fill, which contained an abundant amount of rubble wallfall and was about 35 to 40 cm thick. This stratum was thicker in Rooms 7 and 8 because of the deposited construction material. Stratum 2 was also loose and unconsolidated, and artifact density was lower than Stratum 1. Road construction debris was present in this stratum down to the contact with rooffall (Stratum 6).

In Room 7, Stratum 6 was anywhere from 5 to 25 cm thick, but averaged about 12 cm. Rooffall contained abundant, but usually small, fragments of adobe similar to that observed in the walls, and artifact density was higher than in Strata 1 and 2. This is different compared to other rooms, but is likely due to the disturbance that resulted from construction. As in the other rooms, Stratum 8 was the floor stratum. Floor was present in about half of the room, with large patches along the eastern and western walls. A shallow, collared hearth (Feature 9) was identified near the center of the room, and no artifacts were identified on the floor. Stratum 19 represents the fill from Feature 9. Table 24.30 shows the general artifact counts by stratigraphic unit for Room 7.

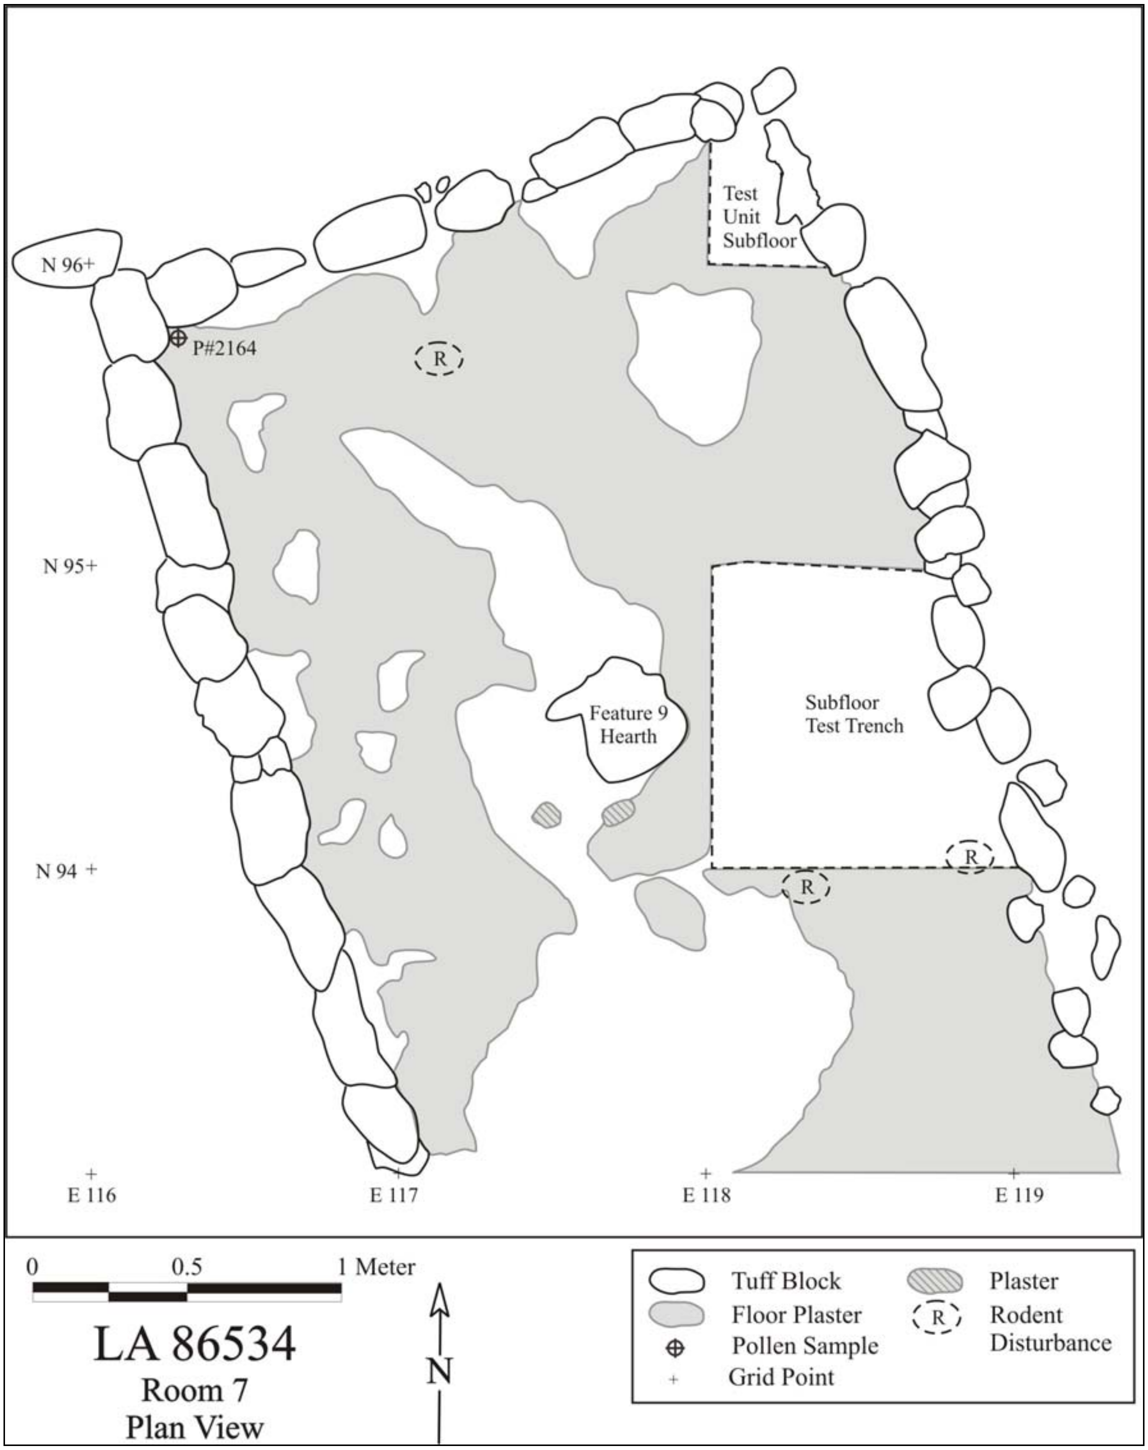

Figure 24.31. Plan view of Room 7 after excavation.

Table 24.30. Room 7 artifacts by stratigraphic units.

Stratum #	Ceramics	Chipped Stone	Ground Stone	Faunal Remains	Total
1	195	8	0	0	**203**
2	107	33	2	0	**142**
1,2	193	20	1	0	**214**
6,7	206	22	2	4	**234**
19	1	1	0	0	**2**
Total	**702**	**84**	**5**	**4**	**795**

Floor. The floor in this room was in fair condition. The dominant area of floor was located along the eastern and western walls where there were some good areas of articulation between the floor and the walls (see Figure 24.31). Small patches were also located near the center of the room, but were very disturbed around the hearth (Feature 9). The hearth is plaster-lined and was identified in the center of the room. Unlike Rooms 1, 2, and 5, the central hearth was not collared. It is possible that it may have been collared originally, but significant rodent disturbance severely damaged the structural integrity of the hearth. No artifacts were found on the floor, but one pollen sample (FS 2164) was collected. Taxa identified on the floor included prickly pear, beeweed, nightshade family, cheno-ams, grass family, sunflower family, ragweed/bursage, broad spine sunflowers, piñon pine, juniper, and sagebrush.

Wall Construction. Shaped and unshaped tuff blocks were used in the construction of this room. It appears as though the western wall of the room was constructed first as part of the central wall of the roomblock and that the eastern wall (front roomblock wall) was built either next or at the same time as the western wall. After these two walls were constructed, the northern and (probably) southern walls were then abutted to the western and eastern walls, although this is uncertain given the fact that the southern wall was obliterated by the construction of NM 502. The western wall is three courses high, while the eastern and northern walls vary between one and two courses. Table 24.31 shows the general wall measurements for each of the remaining walls.

Table 24.31. Room 7 wall measurements.

Wall Orientation	Length (m)	Height (m)	Thickness (m)
West	3.00	0.25	0.23
North	2.20	0.25	0.17
East	3.55	0.20	0.18
South	--	--	--

Artifacts and Samples. Artifacts and samples from two 1- by 1-m units were selected for analysis in this room. Grids selected from Room 7 include 95N/117E (FS 1134, FS 1135, FS 1206, FS 1976 through FS 1979, and FS 2165 through FS 2167) and 94N/118E (FS 1684 through FS 1686, FS 1726, FS 1758, FS 1760, and FS 1763 through FS 1764), and all artifacts from these two columns were analyzed. In addition to the artifacts analyzed from these two units, a single black translucent obsidian biface (FS 1615) was analyzed. Table 24.32 lists the samples selected for analysis from Room 7.

Table 24.32. Samples selected for analysis in Room 7.

Stratum	SAMPLE TYPE				
	Pollen	Flotation	Macrobotanical	TL	Archaeomagnetic
1	--	--	984	--	--
2	--	--	2004, 2143	--	--
6	--	1726	1760, 1978	--	--
8	2164	--	--	--	--
19	1645	2172	2170	--	--

Twenty percent of the macrobotanical samples from each stratum in Room 7 were selected for analysis. A total of six macrobotanical samples were analyzed from Room 7. Samples were collected and analyzed from all strata except the floor. The following taxa were identified in these samples: maize, mountain mahogany (*Cercocarpus*), cottonwood/willow (*Populus/Salix*), oak, unknown conifer, juniper, unidentified pine, piñon pine, and ponderosa pine. Pollen and flotation samples were also taken from this room. Taxa identified in the pollen samples include maize, cholla and prickly pear, beeweed, buckwheat, nightshade family, mustard family, broad spine sunflower, sunflower family, ragweed/bursage, possible marshelder (low spine), spurge family, unidentified pine, piñon pine, juniper, sagebrush, cheno-ams, and unidentified grasses. Carbonized remains identified in the flotation samples include the following taxa: cheno-ams, maize, unknown conifer, juniper, pine, piñon pine, and oak.

Identified ceramics from these two grids included 10 Santa Fe Black-on-white sherds, five unpainted sherds, 15 smeared-indented corrugated sherds, five indented corrugated sherds, one Wiyo Black-on-white sherd, one Galisteo Black-on-white sherd, and one plainware sherd. Of the seven pieces of bone recovered from this room, only one was identified to at least the level of class and was a pocket gopher (*Thomomys bottae*) humerus. Based on the appearance of this specimen, the bone is likely intrusive and not related to the original occupation of the site. No worked bones were identified in this room. Table 24.33 lists the chipped stone materials recovered in this room.

Table 24.33. Chipped stone artifacts recovered from sampled units in Room 7.

Room 7 Features

Feature 9 (Hearth). Feature 9 is a centrally located hearth in Room 7. The feature was almost completely destroyed by rodent activity, and the fill was heavily disturbed. The bottom of the hearth is patchy at best, with a few small areas of plaster still intact. There is no collar on this hearth, which makes it distinct from all of the other hearths on the site, with the exception of Feature 8, the partial hearth in Room 5. The hearth measures 55 by 40 by 15 cm. Several artifacts were recovered from the hearth. These include a piece of black translucent obsidian microdebitage (FS 2169) and a single smeared-indented corrugated sherd (FS 2171). A pollen sample (FS 1645), a flotation sample (FS 2172), and a macrobotanical sample (FS 2170) were collected from the hearth. The pollen sample included the following taxa: maize, cholla, beeweed, buckwheat, mustard family, sunflower family, ragweed/bursage, possible marshelder (low spine), spurge family, unidentified pine, piñon pine, juniper, sagebrush, cheno-ams, and unidentified grasses.

The flotation sample included the following taxa: cheno-ams, maize, unknown conifer, juniper, unidentified pine, piñon pine, ponderosa pine, and oak. Juniper, piñon pine, and ponderosa pine were identified in the macrobotanical sample collected from the hearth. Maize cupules were identified in FS 2172 and were submitted for radiocarbon analysis. This sample yielded an age of 850±40 BP (Beta-183764) and a date of cal AD 1200 with a two-sigma date range of cal AD 1170–1240.

Room 8

Sequence of Excavation. Room 8 is located in the southwest corner of the roomblock and is 2.60 m north-south by 1.80 m east-west, giving about 4.68 m^2 of interior space. The north-south measurements and the overall interior floor space measurement are incomplete. This is due to the fact that Room 8 is the most southerly of the back rooms and, like Room 7, was heavily impacted by the construction of NM 502. Based on the dimensions of the room relative to other back rooms, it is likely that construction completely obliterated the southern wall of the room and it would have been an additional meter south of where our excavations ceased.

Room 8 is located immediately south of Room 6 and west of Room 7. The remaining portion of Room 8 was in poor shape. The south wall was gone, the floor was non-existent, and the remaining three walls were semi-stable at best (Figure 24.32). As in the other rooms, 1- by 1-m units were excavated in stratigraphic units (and in 10-cm levels within the strata if it was thicker than 10 cm) to the top of rooffall (Stratum 6). Once units were excavated to the top of rooffall, the excavations ceased temporarily until all units were at the same level. Then, all units in the room were excavated down to floor (Stratum 8). No features were identified in the room.

Fill. On average, Stratum 1 was an approximately 10-cm-thick layer of post-occupational fill and consisted of the very loose and unconsolidated soil. Stratum 1 in this room included a dense concentration of road rubble that was deposited in the upper layers of the roomblock during highway construction. This stratum, as well as the top few centimeters of Stratum 2, contained a number of cobbles, gravel, and chunks of tar and concrete. As in the other rooms, artifact density was not the highest in Stratum 1.

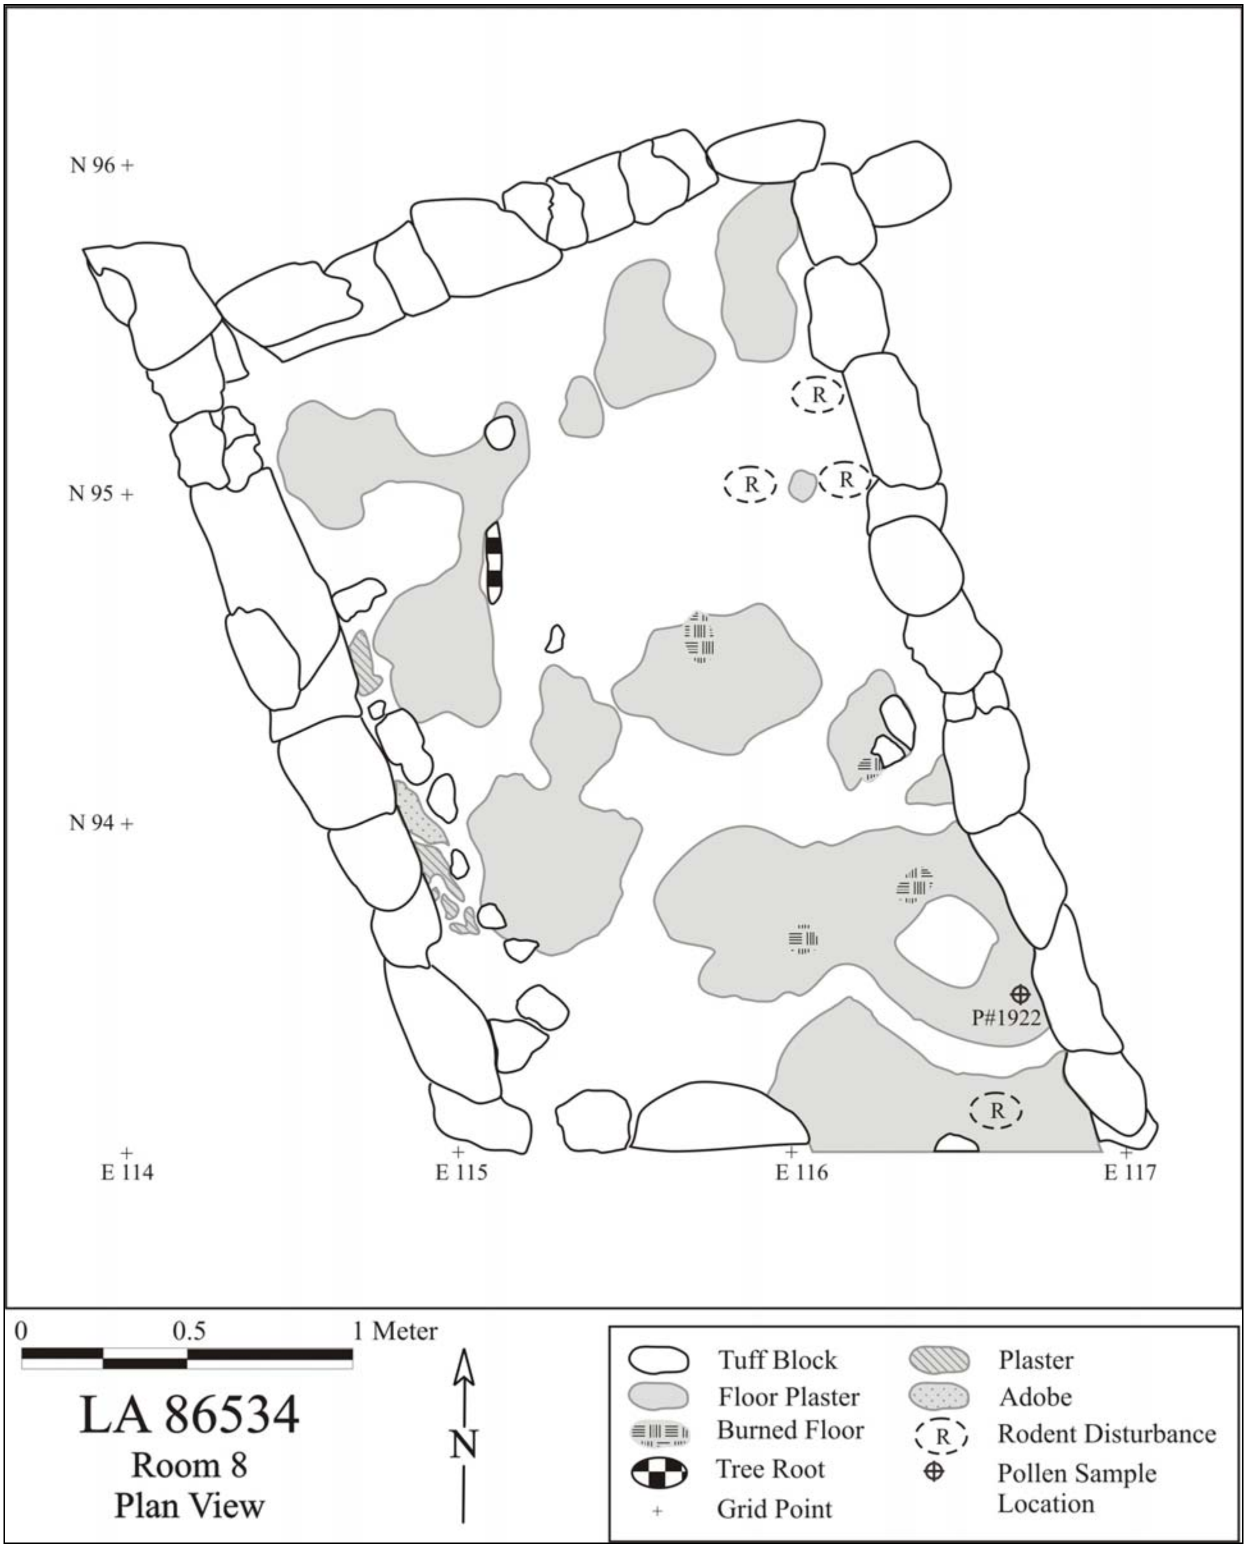

Figure 24.32. Plan view of Room 8 after excavation.

Stratum 2 consisted of the general room fill, which was about 35 to 40 cm thick and contained an abundant amount of rubble wallfall. This stratum was thicker in Rooms 7 and 8 because of the deposited construction material. Stratum 2 was also loose and unconsolidated, and artifact density was lower than in Stratum 1. Road construction debris was present in this stratum down to the contact with rooffall (Stratum 6). In Room 8, Stratum 6 was anywhere from 5 to 23 cm thick at its thickest point, but averaged about 11 cm. Rooffall in this room contained abundant, but usually small, fragments of adobe similar to that observed in the walls.

As with other rooms in the roomblock, Stratum 8 was the floor stratum. Patches of floor were present in some areas of the room and covered about one-third of the interior space. The floor was difficult to identify in this room because of disturbance related to road construction. No features were identified. Table 24.34 shows the general artifact counts by stratigraphic unit for Room 8.

Table 24.34. Room 8 artifacts by stratigraphic units.

Stratum #	Ceramics	Chipped Stone	Ground Stone	Faunal Remains	Total
1	205	28	2	2	**237**
2	14	1	0	0	**15**
1,2	112	22	0	1	**135**
6	7	3	0	1	**11**
6,7	104	47	0	1	**152**
Total	**442**	**101**	**2**	**5**	**550**

Floor. In general, the floor in this room was in poor condition. The best patch of floor was located along the western wall, and the plastered floor in this area coped with the wall plaster (see Figure 24.32). The remainder of the room contained small patches of floor, which were disturbed by rodent activity. No artifacts were found on the floor of this room, but one pollen sample (FS 1922) was taken directly on the floor. Identified taxa from this sample include prickly pear, beeweed, purslane, sunflower family, ragweed/bursage, spurge family, piñon pine, unidentified pine, juniper, sagebrush, cheno-ams, and unidentified grasses.

Wall Construction. Shaped and unshaped tuff blocks were used in the construction of this room. It appears as though the western wall of the room was constructed first as part of the rear wall of the roomblock and that the eastern wall (central roomblock wall) was built either next or at the same time as the western wall. After these two walls were constructed, the northern and (probably) southern walls were then abutted to the western and eastern walls. The southern wall was obliterated by construction of NM 502, and so its construction history is uncertain. All three walls vary between one and two courses high. Table 24.35 shows the general wall measurements for each of the remaining walls.

Table 24.35. Room 8 wall measurements.

Wall Orientation	Length (m)	Height (m)	Thickness (m)
East	2.94	0.35	0.22
North	1.77	0.45	0.20

Wall Orientation	Length (m)	Height (m)	Thickness (m)
West	2.30	0.32	0.19
South	--	--	--

Artifacts and Samples. Artifacts and samples from 95N/115E (FS 1051 through FS 1055, FS 1203 through FS 1205, FS 1579 through FS 1581, FS 1682 and FS 1683, and FS 1835 and FS 1836) and 94N/115E (FS 1193 through FS 1195, FS 1331 and FS 1332, and FS 1805 through FS 1807) were selected for analysis in Room 8. All artifacts from these two columns were analyzed. Table 24.36 lists the samples selected for analysis from Room 8.

Table 24.36. Samples selected for analysis in Room 8.

Stratum	SAMPLE TYPE				
	Pollen	Flotation	Macrobotanical	TL	Archaeomagnetic
1	--	--	1235	--	--
1,2	--	--	1258	--	--
6	--	--	1581, 1667	--	--
8	1922	--	--	--	--

As outlined in the description of Room 1, 20 percent of the macrobotanical samples from each stratum in Room 8 were selected for analysis. A total of four macrobotanical samples were analyzed from Room 8. Samples were collected and analyzed from all strata except the floor. The following taxa were identified in these samples: unidentified pine, piñon pine, and ponderosa pine. Due to the heavy disturbance from both road construction and rodent activity in this room, few samples were taken, but a single pollen sample was taken from a small patch of floor. Identified taxa include prickly pear, beeweed, purslane, sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon pine, juniper, sagebrush, cheno-ams, and unidentified grasses.

Identified ceramics from these two grids included 12 Santa Fe Black-on-white sherds, one Chupadero Black-on-white sherd, nine unpainted sherds, 15 smeared-indented corrugated sherds, four indented corrugated sherds, and one plainware sherd. Two pieces of ground stone, a dacite grinding slab and a welded tuff ground stone fragment, were identified in the room. Of the five pieces of bone recovered from this room, two were identified to at least the level of class. A single wood rat (*Neotoma* sp.) ulna and a mule deer (*Odocoileus hemionus*) naviculocuboid were recovered in this room. No worked bones were identified in this room. Table 24.37 lists the chipped stone materials recovered in this room.

Table 24.37. Chipped stone artifacts recovered from sampled units in Room 8.

Type	Material	Number

	Pedernal chert	1
	Black translucent obsidian	2

No features were identified in Room 8.

Room 9

Sequence of Excavation. Room 9 is located east of the roomblock and is immediately adjacent to Rooms 2 and 5. Room 9 is a subterranean, circular kiva that was constructed into bedrock. The room measures 4.3 m north-south by 4.1 m east-west, giving about 17.63 m^2 of interior space, which is by far the largest of any of the rooms. In general, the kiva was in excellent shape. The floor was well preserved and was continuous across the entire surface. The bedrock walls were in good condition, and the stacked masonry walls on top of the kiva were still present in the northeast and southern areas. Figure 24.33 shows Room 9 after it was completely excavated.

Figure 24.33. Room 9 after excavation.

No surface indications of the kiva were present before excavation. Therefore, a bobcat was used to scrape the area east of the roomblock, with a very ephemeral rock alignment being detected (see Figure 24.5). A 1- by 2-m test pit was placed over this alignment and was excavated almost 2 m down to floor. At this point, only one other 1- by 1-m unit was excavated by hand. This unit was located along the eastern wall of the kiva and was excavated in 20-cm arbitrary levels for stratigraphic control. Once the initial three units were excavated, all grids around the perimeter of the kiva were excavated by hand to expose the wall. This was done because the bobcat was going to remove the interior fill of the kiva and it was important for the operator to be able to see the perimeter. Once the perimeter of the kiva was entirely exposed, the bobcat removed the fill. The removal was done in four units. First, the kiva was bisected along the 120E line to separate the eastern and western halves. Then, the interior fill was separated into post-occupational fill and wallfall. The bobcat removed the fill in the following sequence: west half, post-occupational fill; west half, wallfall; east half, post-occupational fill, and east half, wallfall. Stratum 2 (wallfall) was mechanically removed to the top of the rooffall layer (Stratum 15). All kiva fill removed by the bobcat was screened and the artifacts collected. Once the fill was removed, we returned to hand excavation of 1- by 1-m grids. The rooffall stratum was removed by hand to the floor of the kiva (Stratum 17).

Nine features were identified in Room 9. These features included two wall niches (Features 7 and 20), a floor niche (Feature 6), a ventilator shaft (Feature 14), an entryway between Rooms 5 and 9 (Feature 15), a collared and plaster-lined hearth (Feature 16), an unplastered ash pit (Feature 17), a sipapu (Feature 18), and a series of five holes and a groove between the ventilator shaft and the ash pit (Feature 19). Each of these features will be discussed individually in the following pages.

Fill. On average, Stratum 1 was an approximately 90- to 110-cm-thick layer of post-occupational fill that consisted of very loose and unconsolidated soil. Some surface areas contained a high organic content from the duff associated with piñon and juniper trees in the area. This stratum contained no rubble fill, but artifact density was high. Stratum 2 consisted of the general room fill, which contained an abundant amount of rubble wallfall and was about 60 to 80 cm thick. The stratum was also loose and unconsolidated with tuff blocks in the fill. Strata 1 and 2 were comparable to strata identified in the roomblock and, as in the roomblock, were combined during excavation when necessary. The bottom of Stratum 2 contained the abrupt contact with rooffall (Stratum 15). Artifact density in Strata 1 and 2 was the highest.

In Room 9, Stratum 15 was anywhere from 20 to 44 cm thick at its thickest point, but averaged about 25 cm. Rooffall in this room contained abundant fragments of adobe similar to that observed on the walls, and artifact density was considerably less than in Strata 1 and 2. Several areas of silty concentrations were identified in the rooffall stratum, suggesting that the top of the roof may have been exposed to the elements for a period of time before the kiva was filled in. These areas of silt were distinct in texture and appearance and contained small clay balls.

The floor stratum in the kiva was Stratum 17. The floor in this room was in excellent condition, and there were only very small patches of the interior where floor was not identified. These areas were located primarily in the northwestern section of the kiva where a fissure in the bedrock had developed. Five floor features were identified in this room: Feature 6 was a floor niche, Feature 16 was a collared hearth (Stratum 20), Feature 17 was an ash pit located immediately east of the hearth (Stratum 21), Feature 18 was a sipapu located directly west of the hearth, and Feature 19 was a series of five small holes and grooves located just east of the ash pit. In addition to the floor features, four additional features were identified and included two wall niches (Features 7 and 20), a ventilator shaft (Feature 14), and an entryway between Rooms 5 and 9 (Feature 15). Table 24.38 shows the general artifact counts by stratigraphic unit for Room 9.

Table 24.38. Room 9 artifacts by stratigraphic units.

Stratum #	Ceramics	Chipped Stone	Ground Stone	Faunal Remains	Total
1	1551	140	3	7	**1701**
2	2230	283	4	9	**2526**
1,2	3673	478	17	55	**4223**
15	1331	145	1	37	**1514**
17	1	0	0	0	**1**
20	1	2	1	0	**4**
21	0	12	0	0	**12**
Total	**8787**	**1060**	**26**	**108**	**9981**

Floor. In general, the floor in Room 9 was in excellent condition and was in better shape than any of the floors in the roomblock. The plastered floor coped well with the plastered portions of the wall, and the best evidence for this occurred in the southern half of the kiva (Figure 24.34). The floor of the kiva was not burned and it was constructed immediately above bedrock. There seemed to be evidence of remodeling in some very small portions of the floor in the northwestern portion of the kiva, but two distinct floors were not observed. Five floor features were identified in this room: Feature 6 (floor niche), Feature 16 (collared hearth), Feature 17 (ash pit located immediately east of the hearth), Feature 18 (a sipapu located directly west of the hearth), and Feature 19 (five small holes and grooves located just east of the ash pit). Only one artifact (FS 1969) was recovered from the floor of the kiva and was a Santa Fe Black-on-white sherd. In addition, a number of pollen and flotation samples were taken directly on the floor.

Pollen samples taken from the floor of the kiva include the following FS numbers: 1967, 1991, 1993, and 2175. Identified taxa include maize, cholla and prickly pear, beeweed, sunflower family, parsley, buckwheat, fir (*Abies*), unidentified pine, piñon pine, juniper, oak, sagebrush, long spine sunflower, broad spine sunflower, evening primrose, spurge, and cheno-ams.

Flotation samples taken from the floor of the kiva include the following FS numbers: 1968, 1990, 1992, and 2176. Identified taxa include pigweed, goosefoot, cheno-ams, uncharred tobacco (*Nicotiana*), sunflower family, maize, saltbush/greasewood, mountain mahogany (*Cercocarpus*), unknown conifer, juniper, unidentified pine, piñon pine, ponderosa pine, and oak.

Wall Construction. The subterranean, circular kiva was constructed by excavating into the Bandelier Tuff bedrock. Shallow scoring marks were visible along the kiva walls indicating that digging sticks had presumably been used to finish these surfaces. Several courses of masonry were constructed above the level of bedrock. These courses seem to be prominent in the areas where bedrock dips significantly as along the eastern and southern walls. Figure 24.35 shows some of the masonry construction along the eastern wall just north of the ventilator shaft and above one of the wall niches (Feature 7). It is likely that masonry construction was used around the perimeter of the kiva, but much of it may have fallen into the center. This is suggested by the large amounts of rubble present in Stratum 2.

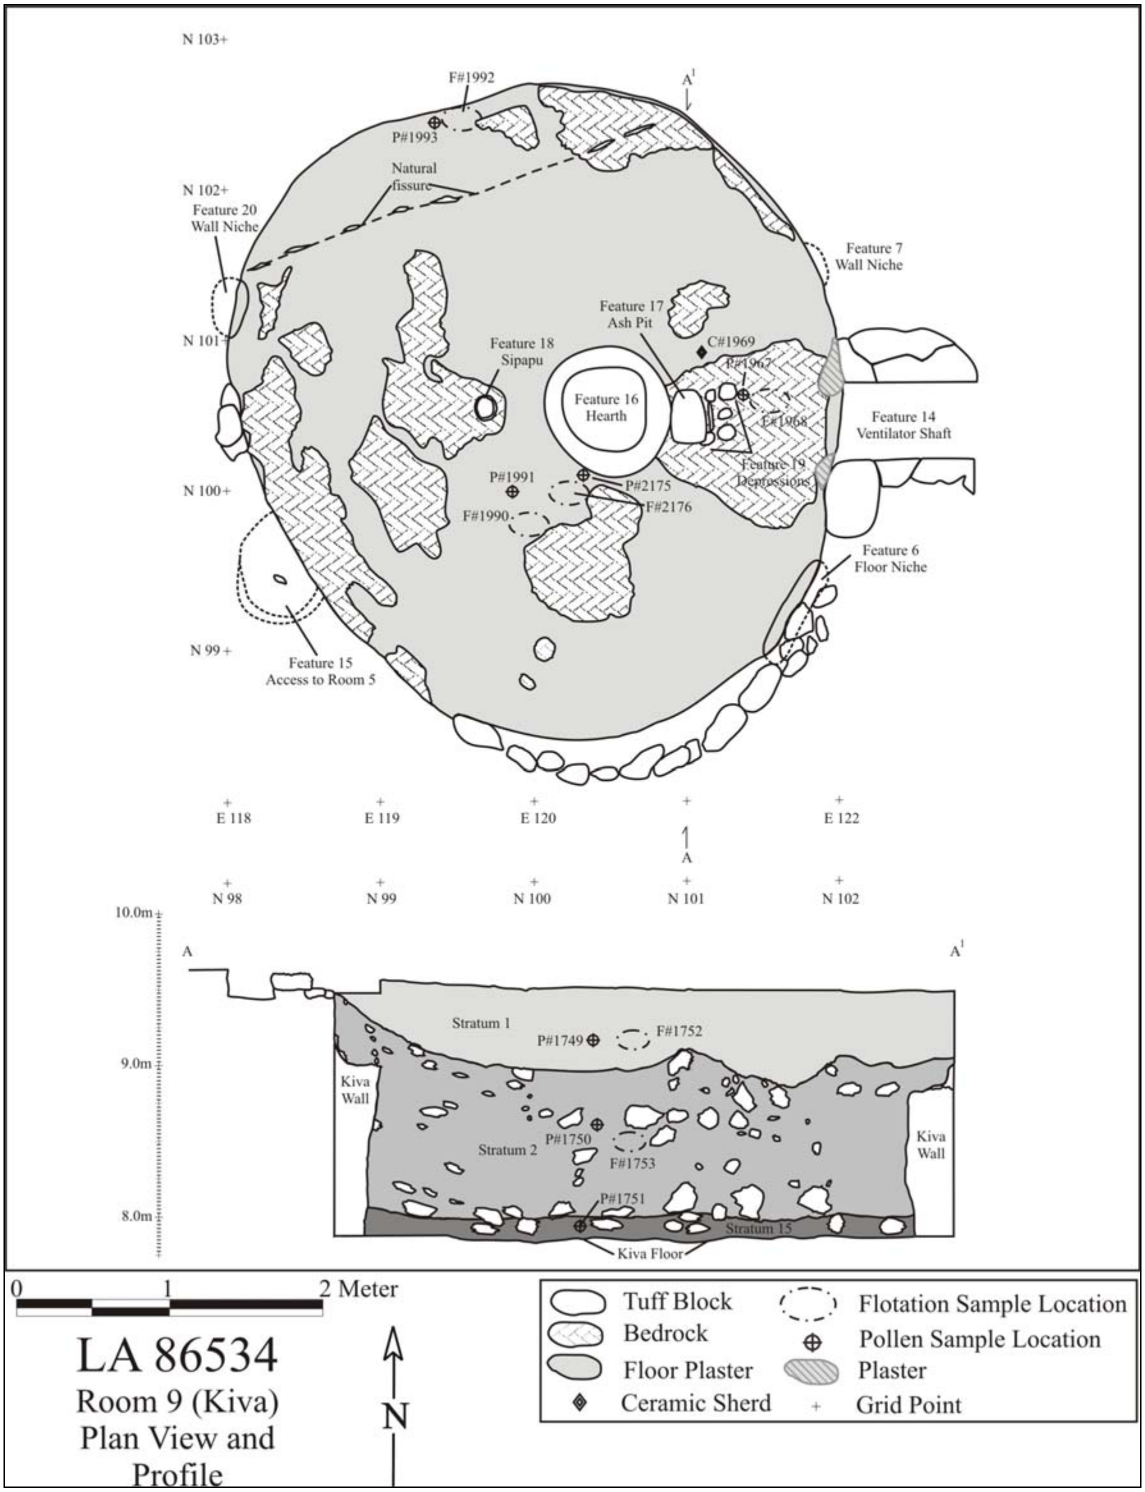

Figure 24.34. Plan view of Room 9 after excavation.

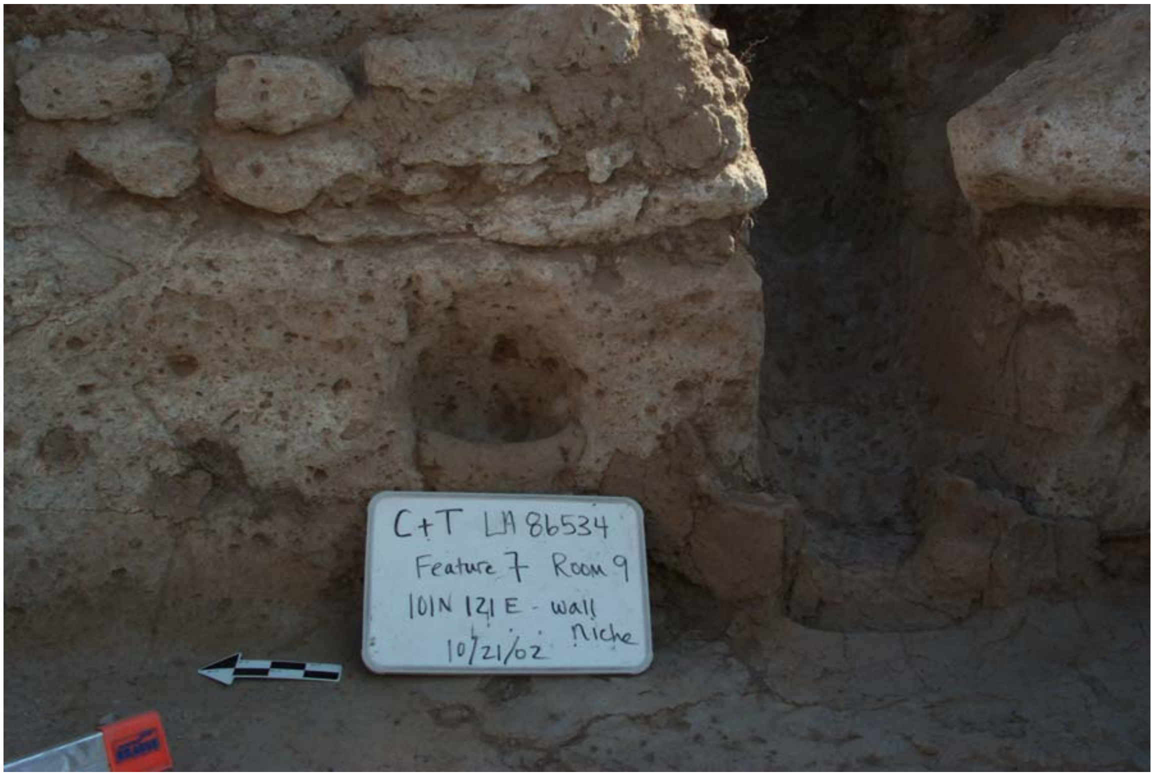

Figure 24.35. Room 9, masonry construction above bedrock.

Four features were present in the kiva walls. These include two wall niches (Features 7 and 20), the ventilator shaft (Feature 14), and an entryway between Rooms 5 and 9 (Feature 15). The entryway contained visible hand and foot holds that lead up to a shallow, ovoid feature. Features 7 and 14 are shown in Figure 24.35. Feature 7 is located on the eastern wall about 25 cm above the floor and 30 cm north of the ventilator shaft, and Feature 20 is located along the western wall about 30 cm above the floor.

Artifacts and Samples. Artifacts and samples from one 1- by 1-m unit were selected for analysis in the kiva. 100N/121E (FS 1687 through FS 1690, FS 1712 through FS 1719, FS 1727 through FS 1729, FS 1745 through FS 1748, FS 1779 through FS 1781, FS 1980 through FS 1985, FS 2175 and FS 2176, FS 2204 and FS 2205, FS 2219, and FS 2229 through FS 2232), the only completely hand-excavated grid in the kiva, was chosen. All artifacts from this column were analyzed. In addition to the artifacts analyzed from this unit, a number of artifacts were analyzed from different contexts, including three ceramic pipe fragments (FS 1459, FS 1460, and FS 1890), a ceramic ladle (FS 1872), and a ceramic pestle (FS 1878).

In addition to the artifacts analyzed from this room, macrobotanical, pollen, and flotation samples from throughout the stratigraphic sequence were analyzed (Table 24.39). Because of the paucity of macrobotanical remains alluded to earlier in this chapter, very few remains were collected in 100N/121E. To augment the sample size, materials selected for analysis were generated from the fill removed by the bobcat. Macrobotanical samples from post-occupational fill and wallfall (Strata 1 and 2) were selected from the eastern half of the kiva. Once all the wallfall was removed, hand excavation to the floor resumed. Macrobotanical samples from the rooffall stratum were generated by selecting the grids that were located beneath the eastern half of the kiva where samples were selected from Strata 1 and 2. These included 99-100N/100E. All macrobotanical samples from the rooffall context in these grids were analyzed.

Table 24.39. Samples selected for analysis in Room 9.

Stratum	SAMPLE TYPE				
	Pollen	Flotation	Macrobotanical	TL	Archaeomagnetic
1	1749, 1772	1752, 1773	1847	--	--
1,2	1974	1975	1677	--	--
2	1750, 1786	1753, 1785	1830, 1866, 1869	--	--
15	1751, 1762	1761, 2142	1988, 2009	--	--
17	1967, 1991, 1993, 2175	1968, 1990, 1992, 2176	--	--	--
20	2204, 2205, 2219	2199, 2200, 2201, 2202, 2203, 2212, 2214, 2215, 2216, 2217, 2223	2213, 2224	2238, 2250	Taken
21	2229, 2232	2234	2233	--	--
22	2225	2226	--	--	--

A total of 10 macrobotanical samples were analyzed from Room 9. Samples were collected and analyzed from all strata except the floor, which did not produce any remains suitable for analysis. The following taxa were identified in these macrobotanical samples: maize, saltbush/greasewood, mountain mahogany, cottonwood/willow, Douglas fir (*Pseudotsuga menziesii*), juniper, wolfberry (*Lycium*), unknown conifer, unidentified pine, piñon pine, ponderosa pine, and oak.

Charred and uncharred taxa identified in flotation samples from Room 9 included pigweed, goosefoot, cheno-am, tobacco, purslane sunflower family, groundcherry, sage (*Salvia*), mountain mahogany, hedgehog cactus (*Echinocereus*), mint family (Labiatae), maize, grass family, four-wing saltbush, saltbush/greasewood, juniper, unknown conifer, unidentified pine, piñon pine, ponderosa pine, prickly pear, squash/coyote gourd (*Cucurbita*), and oak.

Analyzed pollen samples included maize, squash, cholla and prickly pear, beeweed, buckwheat, plantain (*Plantago*), mustard family (Brassicaceae), sunflower family, parsley (Apiaceae), ragweed/bursage, spurge family, penstemon family (Scrophulariaceae), pea family (Fabaceae), spruce (*Picea*), unidentified pine, piñon pine, juniper, oak, rose family, buckthorn family (Rhamnaceae), Mormon tea, sagebrush, long spine sunflower, broad spine sunflower, evening primrose, cheno-ams, and unidentified grasses.

Identified ceramics from this grid included 16 plainwares, 13 unpainted sherds, 29 Santa Fe Black-on-white sherds, 23 smeared-indented corrugated sherds, 11 indented corrugated sherds, three mudware sherds, two organic-painted sherds from the Coalition period, two plain corrugated sherds, two Wiyo Black-on-white sherds, and one Biscuit A (Bandelier Black-on-gray) sherd. Two quartzite one-hand manos were recovered. Room 9 contained far more faunal remains than any other room at LA 86534. Unidentified remains were the most abundant, followed by the intrusive pocket gopher (*Thomomys bottae*) remains, cottontails (*Sylvilagus* sp.), rock squirrels (*Spermophilus variegatus*), red-tailed hawk (*Buteo jamaicensis*), mule deer (*Odocoileus hemionus*), indeterminate rodents (Rodentia), jackrabbits (*Lepus* sp.), carnivores (Carnivora), and turkey (*Meleagris gallopavo*). Species diversity was also the greatest in this room, which may be related to its use as a kiva. More birds were identified in this room relative to the rest of the site, and other unusual taxa, including toads (Ranidae), skunk (*Mephitis mephitis*), and coyote (*Canis latrans*) remains were also identified. One bone bead was recovered from the wallfall stratum in the kiva. Table 24.40 lists the chipped stone materials recovered in this room.

Kiva Features

A total of nine features were identified in the kiva. These include two wall niches (Features 7 and 20), a floor niche (Feature 6), a ventilator shaft (Feature 14), an entryway between Rooms 5 and 9 (Feature 15), a collared and plaster-lined hearth (Feature 16), an ash pit (Feature 17), a sipapu (Feature 18), and a series of five holes and grooves between the ventilator shaft and the ash pit (Feature 19). The majority of these features are visible in Figure 24.34 (plan view of kiva) and each is discussed in the following pages.

Feature 6 (Floor Niche). This feature is a floor niche located on the eastern wall of the kiva. The feature dimensions are 38 by 60 by 26 cm, and it is located 68 cm south of the ventilator shaft. The niche is medium-sized and has a plastered lip on the lower boundary that lies 3 cm above the floor. The niche is in excellent condition, with plaster on most of the base and lipped area, but only small patches on the ceiling. The fill from this feature was screened separately and produced artifacts, but was not given a different stratum designation because it was filled with the general kiva fill. Figure 24.36 shows a photograph of this niche.

Figure 24.36. Room 9, floor niche (Feature 6).

Feature 7 (Wall Niche). This feature is a wall niche located on the eastern wall 25 cm above the kiva floor. The feature dimensions are 29 by 29 by 18 cm, and it is located 30 cm north of the ventilator shaft. The niche is on the small side and has a plastered lip on the lower boundary. The niche was in good condition, with patches of plaster present throughout. As with Feature 6, the fill from this feature was screened separately and produced artifacts, but was not given a different stratum designation because it was filled with the general kiva fill. Figure 24.37 shows a photograph of this niche.

Figure 24.37. Room 9, wall niche (Feature 7).

Feature 14 (Ventilator Shaft). Feature 14 is the ventilator shaft located on the east side of the kiva. The shaft is oriented due east and is in alignment with several of the floor features. The bottom of the ventilator shaft is flush with the floor, but has a lip at its opening that rises approximately 5 cm above the floor. The shaft slopes gradually upwards to the surface. A plastered groove was identified directly in front of the opening to the ventilator shaft. The groove may represent a footing for some type of cover, although no stone was in place at the time of excavation and nothing of its likeness was identified during excavation of the adjacent areas. Some portions of the ventilator shaft were also plastered although most of it was patchy. The dimensions of the ventilator shaft are 120 by 40 by 75 cm. A number of artifacts were identified in the fill of Feature 14 (FS 1892, FS 1893, FS 1904, and FS 1971) and include one plainware sherd, a quartzite hammerstone, an andesite metate fragment, a basalt mano fragment, two chalcedony projectile points, five Pedernal chert core flakes, 12 chalcedony core flakes, six chalcedony pieces of angular debris, two chalcedony biface flakes, seven pieces of chalcedony microdebitage, one piece of black translucent obsidian microdebitage, one andesite core flake, one unidentified manuport, one piece of salmon pink chert microdebitage, one piece of quartzite microdebitage, and one orthoquartzite core flake. Figure 24.38 shows the ventilator shaft and its location relative to a number of the kiva features.

Figure 24.38. Room 9, ventilator shaft and other kiva features.

Feature 15 (Entry/Exit Way). This feature is an entry/exit way between Rooms 5 and 9. It is semi-circular in shape and contains a ledge at the edge of bedrock. This portion of the feature measures 65 by 63 by 24 cm. There is also a hand-hold at the top of the flattened bedrock and a probable toe-hold on the kiva wall directly below the feature. During initial excavations in this area, the connection between Rooms 5 and 9 was not identified. It was only after we returned to the site several weeks after the completion of excavations to examine the construction techniques used in the walls that the nature of this feature was recognized. During this visit, the eastern wall of Room 5 was knocked over and the connection between the rooms was verified (Figures 24.39 and 24.40). When the wall in Room 5 was removed, it was clear that no tuff blocks were in place. What appeared to be tuff blocks forming the wall of Room 5 were actually concentrations of plaster that resembled blocks. When the fill in this area was subsequently removed, it was clear that there was a doorway between the two rooms. A palette (FS 1970) was the only artifact recovered from this feature.

Figure 24.39. Room 9, Feature 15 as it appeared in October 2002.

Figure 24.40. Room 9, Feature 15 as it appeared in December 2002.

Feature 16 (Collared Hearth). Features 16 through 20 are all floor features and are all aligned on the same east-west line. Feature 14, the ventilator shaft, is also aligned with these five features. Feature 16 is the kiva hearth. The hearth is located slightly east of center and is immediately adjacent to the sipapu (Feature 18) to the west and the ash pit (Feature 17) on the right. The plaster-lined collared hearth measures 85 by 85 by 30 cm and is larger than the hearths in the individual rooms. It was in excellent condition, with only a small patch missing from the northern wall. The hearth was heavily burned, and the bottom 5 to 10 cm consisted of a hard-packed ash layer. Both ceramics and lithics were recovered from the interior of the feature. Figure 24.41 shows the plan map and profile of the hearth. A photograph of the hearth is shown in Figure 24.42.

A single marcrobotanical sample was collected from the hearth and included the following taxa: unknown conifer, unidentified pine, and ponderosa pine. Flotation samples included the following taxa: pigweed, goosefoot, cheno-am, tobacco, mint family, maize, four-wing saltbush, juniper, unknown conifer, unidentified pine, piñon pine, and ponderosa pine. In addition to those taxa already mentioned, the following taxa were identified in the pollen samples collected from the hearth: sunflower family, ragweed/bursage, and unidentified pine.

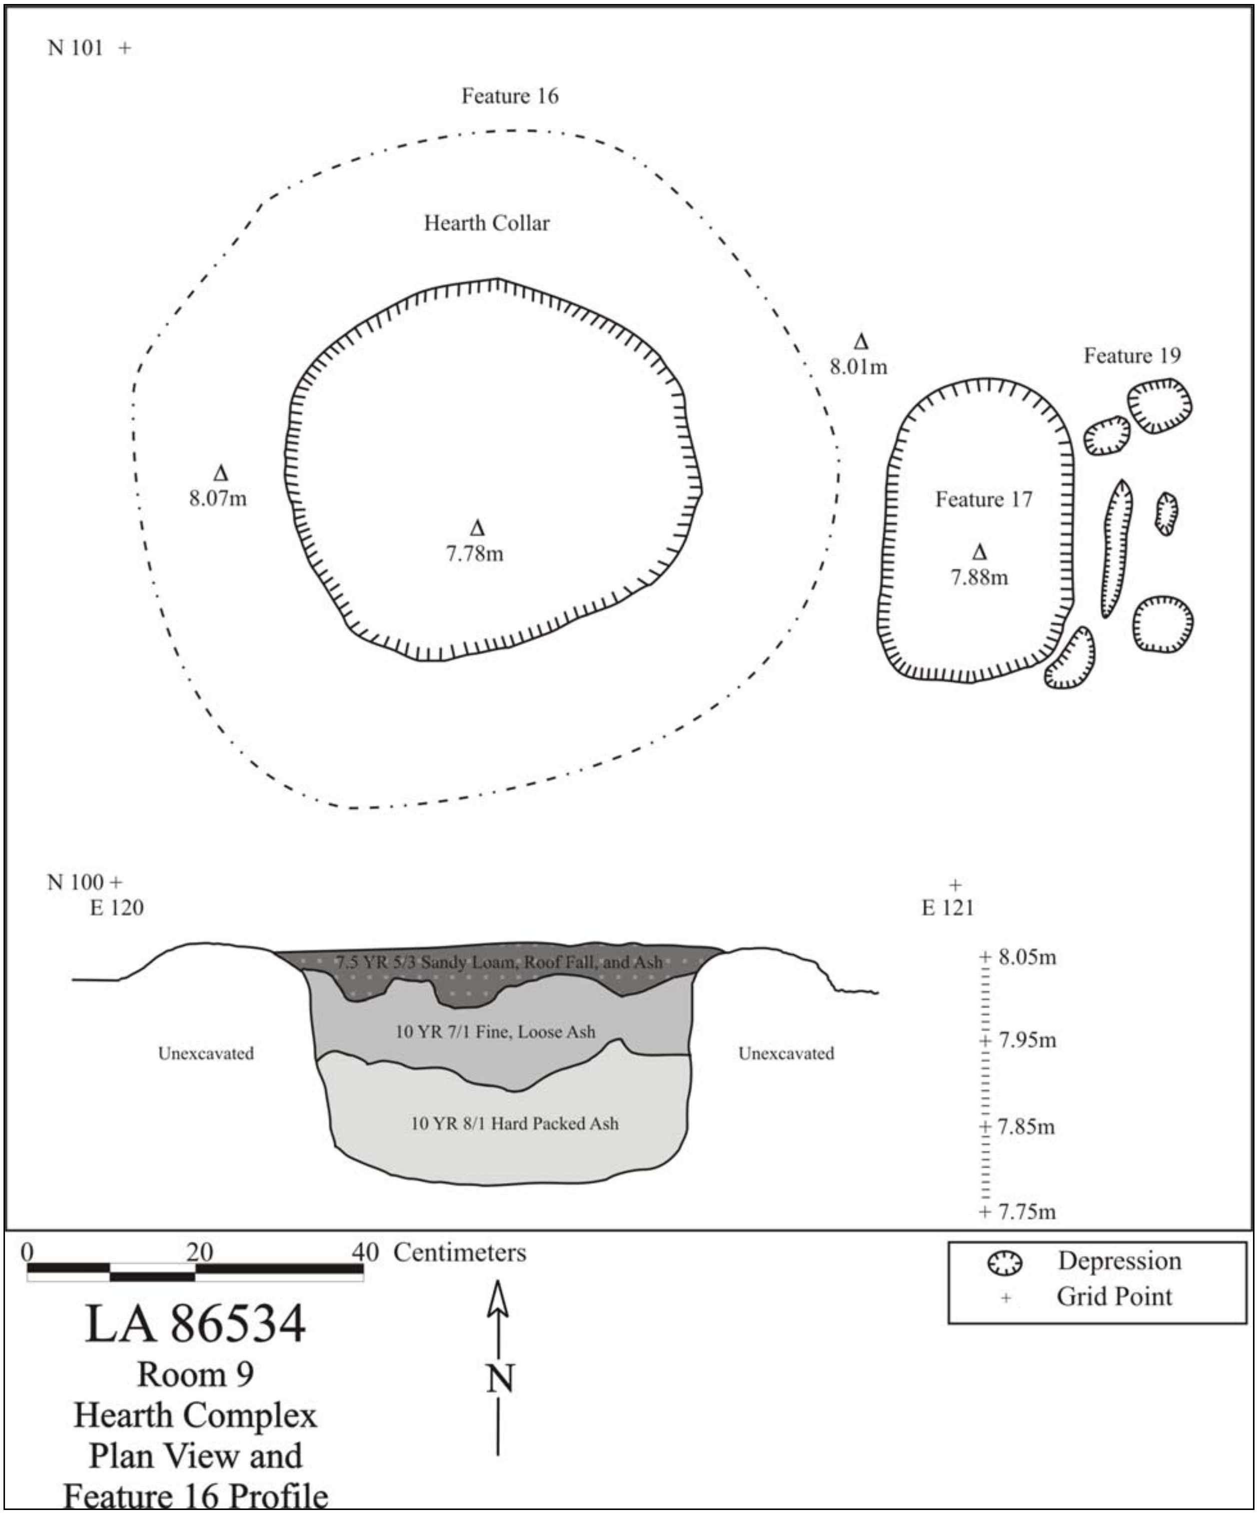

Figure 24.41. Plan view and profile of Feature 16.

Figure 24.42. Room 9, Feature 16.

Additionally, TL (FS 2238 and FS 2250), archaeomagnetic, and radiocarbon samples were all taken from the hearth and submitted for analysis. The TL sample from the adobe in the hearth (FS 2250) dated to AD 1221±52. The archaeomagnetic sample produced two probable date ranges, one at AD 1185–1240 and the other at 1250–1315. Maize cupules were identified in a flotation sample taken from the hearth (FS 2202) and were submitted for radiocarbon analysis. This sample yielded an age of 790±40 BP (Beta-183765) and a date of cal AD 1260 with a two-sigma date range of cal AD 1220–1270. These results strongly suggest a date in the middle to late 13th century, and all span a fairly tight period of time. Several artifacts (FS 2220, FS 2221, and FS 2206) were recovered from the hearth and included a smeared-indented corrugated sherd, a chalcedony core flake, an unidentified chalcedony flake fragment, and a quartzite polishing stone.

Feature 17 (Ash Pit). This feature is the ash pit associated with the hearth. As with Features 16 through 18 and Feature 20, the ash pit is aligned on an east/west coordinate. The ash pit is located just east of the hearth and just west of the holes and groove feature. The feature is an unplastered, ovoid-shaped basin that measures 35 by 25 by 13 cm. Artifacts (FS 2227, FS 2228, FS 2230, and FS 2231) recovered in the ash pit included two retouched black translucent obsidian pieces, two chalcedony core flakes, a Pedernal chert core flake, and a black translucent obsidian core flake. A macrobotanical sample (FS 2233) taken from the ash pit produced the following taxa: mountain mahogany, unknown conifer, unidentified pine, piñon pine, ponderosa pine, oak, and maize. A single flotation sample was taken (FS 2234) and produced the following taxa: goosefoot, uncharred tobacco, maize, four-wing saltbush, mountain mahogany, unknown conifer, unidentified pine, piñon pine, ponderosa pine, and oak. The only pollen sample collected (FS 2232) produced the following taxa: maize, beeweed, pea family, sunflower family, ragweed/bursage, spurge family, piñon pine, juniper, buckthorn family, sagebrush, cheno-ams, Mormon tea, and unidentified grasses. Figure 24.43 shows Features 16, 18, and 19.

Figure 24.43. Room 9, Features 16, 17, and 19.

Feature 18 (Sipapu). Feature 18 is the circular sipapu in the kiva. It is in the same east-west line as the hearth, the ash pit, the holes and grooves, and the ventilator shaft, but is the furthest west of all the features. The sipapu is located on the kiva floor, and its dimensions are 13 by 11 by 20 cm. One pollen (FS 2225) and one flotation sample (FS 2226) were taken from the sipapu. The following charred taxa were identified in the flotation sample: goosefoot, purslane, maize, unknown conifer, unidentified pine, piñon pine, ponderosa pine, and oak. Taxa identified in the pollen sample included maize, beeweed, sunflower family, spurge family, pine, piñon pine, juniper, sagebrush, cheno-ams, and unidentified grasses.

Feature 19 (Holes and Groove). This feature consists of five round holes and a linear groove. As with Features 16 through 18 and Feature 20, the ash pit is aligned on the same east-west coordinate. Feature 19 is located just east of the ash pit and just west of the ventilator shaft. Three of the round depressions line up perpendicular to the ventilator shaft and are the most easterly of the depressions. The other two depressions are also situated perpendicular to the ventilator shaft, but are immediately adjacent to the ash pit. The two series of grooves are separated by a small groove that is parallel to the opening of the ventilator shaft. The overall size of the feature is 42 by 18 by 3 cm, and the round depressions are about 3 cm deep and 5 to 7 cm in diameter. The linear groove between the series of depressions is 18 by 2 by 2 cm. It is possible that this feature represents the footing for a deflector. Figures 24.34 and 24.38 show this feature and the ash pit and hearth. The depressions might also represent ladder holes, however, the entrance appears to have been located at the opposite end of the kiva.

Feature 20 (Wall Niche). This feature is a wall niche located on the western wall, 30 cm above the kiva floor. The feature dimensions are 50 by 38 by 28 cm and it is located approximately 50 cm north of Feature 15. The niche is medium-sized and remnants of a plastered lip remain (Figure 24.44). The niche was in decent condition, with patches of plaster present in most areas, especially around the base. It appears as though a natural fissure in the bedrock was exploited to create this niche. As with Feature 6, the fill from this feature was screened separately and produced artifacts, but was not given a different stratum designation because it was filled with the general kiva fill. Four smeared-indented corrugated sherds (FS 2237) were identified in the fill removed from the wall niche.

Figure 24.44. Room 9, Feature 20.

Area 3

Area 3 was distinguished from Areas 1 and 2 based on the fact that it had been disturbed (see Figure 24.4). The area parallels the northern boundary of the site and is located between 130-135N and 100-135E. Because of the disturbed nature of the area, not all the surface artifacts were collected. As already mentioned, two 3-m dogleash samples were placed in the area. The area consists of a linear two-track, which is approximately 10 to 15 m wide and heads off toward the edge of the mesa. It is possible that this two-track may have been a possible trail or road at some point in the past, but the disturbance (visible by lots of gravel and concrete blocks) makes this difficult to discern. No features were associated with Area 3, and no samples (other than the dogleash samples) were collected.

ARTIFACT AND SAMPLE ANALYSES

Over 26,000 total artifacts were recovered from excavations at LA 86534. Analyses of ceramics, lithics (chipped and ground stone), fauna, archaeobotanical materials, and pollen were all conducted and have been incorporated into the previous sections with regard to particular contexts. Chronometric analyses were also conducted and are summarized in the next section. General analytical results are summarized in the following pages.

Chronology

Radiocarbon Dating

Six radiocarbon samples were submitted to Beta Analytic for analysis. Each sample provided plenty of material for accurate measurements and each was conducted without problem. All analyses were conducted on maize (*Zea mays*) remains. Table 24.41 lists the results of the radiocarbon analyses submitted. Results support an Early-Middle Coalition period occupation at LA 86534 (ca. AD 1190–1280).

Table 24.41. Radiocarbon dates from LA 86534.

FS#	Context of sample	Laboratory (Beta)#	Conventional radiocarbon age	Intercept of radiocarbon age	2-sigma calibrated result
1272	Room 1 hearth	183760	860±40 BP	AD 1190	AD 1040–1260
1321	Room 2 hearth	183761	730±40 BP	AD 1280	AD 1240–1300
1389	Room 5 hearth	183762	800±40 BP	AD 1250	AD 1180–1280
1508	Room 4 floor (maize)	183763	850±40 BP	AD 1200	AD 1140–1270
2172	Room 7 hearth	183764	850±40 BP	AD 1200	AD 1140–1270
2202	Room 9 hearth	183765	790±40 BP	AD 1260	AD 1180–1290

Archaeomagnetic Dating

LA 86534 represents a relatively discrete occupation, with evidence of remodeling and structure longevity, but without evidence for distinct multiple components. Five sets of specimens were collected from burned features in four different structures (Rooms 1, 2, 5, and 9). The hearth in Room 1 showed clear evidence of remodeling, and two sets were collected from its linings. Apart from these two sets, there is no clear indication of stratigraphic sequencing between the samples. The four room hearth samples were subject to some post-burning disturbance from wetting and drying, freeze-thaw, and root invasion. All of the hearths were lined with a plaster composed of volcanic ash-rich soil that appears to have been derived from weathered tuff. The clay content of the plaster was sintered by the cooking and heating fires, consolidating the material to a weak ceramic consistency. However, the fires were not particularly hot, and the linings were fragile. The surface room hearth linings were cracked and subject to displacement, raising the risk of systematic error when multiple specimens were cut from single lining blocks. In addition to eliminating lining blocks from sampling consideration if there was any suggestion of movement, whenever possible, specimens were collected from multiple blocks so that any significant internal bias could be detected. Table 24.42 lists the dates associated with the archaeomagnetic samples taken at LA 86534. These present a range from circa AD 1170 to 1300 which is similar to that provided by the radiocarbon dates.

Table 24.42. LA 86534 archaeomagnetic set results.

Sample Number	Feature	VGP* Curves and Date Estimates (AD)	
		Wolfman	SWCV2000
1202	Room 1, Hearth 4 (Upper lining)	1170–1230	1110–1200
1203	Room 1, Hearth 4 (Lower lining)	1035–1140 (1065–1265)	1010–1315 1000–1390
1204	Room 2, Hearth 2	1280–1300	1175–1230
1205	Room 5, Hearth 5	1005–1035 1235–1270	1265–1325
1206	Room 9, Hearth 16	1020–1050 1220–1255	1185–1240 1250–1315

* VGP is Virtual Geomagnetic Pole

Thermoluminescence Dating

Three burned plaster samples were submitted for TL dating from LA 86534 (Table 24.43). All derived ages are given in years BP, which refers to years before 2003. Two of these are consistent with a 13th century Coalition period occupation, with the exception of UW1035, which is early.

Table 24.43. TL dates from burned plaster samples at LA 86534.

FS#	Lab #	Context	Burial depth (cm)	Years BP	% error	Years AD
1336	UW1034	Room 1 hearth	35	773±42	5.5	1230±42
1651	UW1035	Room 2 hearth	45	1085±180	16.6	918±180
2250	UW1036	Room 9 hearth	175	782±52	6.7	1221±52

Obsidian Hydration Dating

Fourteen obsidian artifacts from LA 86534 were submitted to the Diffusion Laboratory for age determination using the obsidian hydration dating method. In order to calculate the absolute date for an obsidian artifact, three analytical procedures were completed. First, the amount of surface hydration, or the thickness of the hydration rim, was measured. Second, the high temperature hydration rate constants for each artifact were determined from the composition of the glass. Lastly, the soil temperature and relative humidity at the archaeological site was estimated in order that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. Using these methods, a hydration rate for the obsidian artifacts was calculated (Table 24.44).

Table 24.44. Obsidian hydration dates for LA 86534.

FS No.	Lab No.	Source	Rim (um)	AD/-BC	1 S.D.
534	2003-1	Valle Grande	3.32	1716	14

1676	2003-9	Valle Grande	2.68	479	112
1745	2003-10	Valle Grande	3.48	-2790	276
1873	2003-11	Valle Grande	2.38	446	129
1984	2003-12:1	Valle Grande	n/a		
2183	2003-13	Valle Grande	2.81	-1079	219
2228	2003-14	Valle Grande	2.56	-609	204

Relative to other dating methods conducted at the site, the obsidian hydration dates seem to be the least accurate (Table 24.45; Figure 24.45). Radiocarbon and archaeomagnetic results are comparable and seem to have provided the most plausible results, while the TL dates seem to be slightly less plausible given the known occupation range of the sites, but still well within the acceptable limits. Table 24.45 presents all the dated materials from this site. TL, archaeomagnetic, radiocarbon, and obsidian hydration are presented where similar contexts were sampled. It reflects a mostly 13th century occupation for the site from circa AD 1170 to 1280.

Ceramic Artifacts (Dean Wilson)

All the ceramics from two 1- by 1-m units in each room at LA 86534 were analyzed, generating a complete analysis of stratigraphic columns from 18 units. In addition to these contexts, all the ceramics from room floors were analyzed. A sample of ceramics from the western portion of Area 2 and a sample of surface artifacts from Area 1 (106-108N/125-145E) were also analyzed. Analyses of ceramics from these contexts suggest that LA 86534 dates mainly to the Middle Coalition period, being dominated by Santa Fe Black-on-white and smeared-indented corrugated (Table 24.46). The majority of pottery from this site represents local Rio Grande decorated and utilityware (Wilson, Volume 3). Extremely low frequencies of Cibola, Middle Rio Grande, and White Mountain redwares were also noted.

Table 24.46. Ceramic types from all contexts at LA 86534.

Ceramic Type	Frequency	Percent
Indeterminate Tradition

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 557 artifacts were analyzed from LA 86534, consisting of four cores, 489 pieces of debitage, 15 retouched tools, 40 ground stone artifacts, six hammerstones, two manuports, and a piece of fire-cracked rock. This represents an 18 percent sample of the 3090 total lithic artifacts recovered during the site excavations. Table 24.49 presents the data on lithic artifact type by material type. The majority of the debitage is made of chalcedony with lesser amounts of Pedernal chert, obsidian, and other materials. The presence of cortex on 11.2 percent of the debitage indicates that these materials were collected from waterworn (74.5%) and nodular (25.5%) sources. The chalcedony and Pedernal chert are available from local Rio Grande Valley gravel sources, the basalt from gravels and bedrock outcrops, and the obsidian from primary sources in the Jemez Mountains. Otherwise, the ground stone artifacts are primarily made from igneous materials, which are available both as bedrock outcrops and in stream gravels that cross-cut the Pajarito Plateau. Quartzite and silicified wood is, however, only available from the nearby Rio Grande Valley gravels. The source of other materials like orthoquartzite, greenstone, and hematite is difficult to determine, but they could be derived from gravel formations near Totavi or from more distant sources in the Santa Fe or Abiquiu areas.

Nine pieces of debitage and fifteen retouched tools were submitted for X-ray fluorescence analysis. Three of the projectile points were not included in the sample analysis from the site. Nonetheless, the majority of the artifacts were identified as being obtained from the Valle Grande source, with less from the Cerro Toledo and El Rechuelos sources (Table 24.50). The Valle Grande (Cerro del Medio) and Cerro Toledo (Rabbit Mountain/Obsidian Ridge) source areas are located about 18 km (11 miles) as the “crow flies” to the west and southwest of the site; whereas, the El Rechuelos (Polvadera Peak) source area is situated about 24 km (15 miles) to the northwest.

Lithic Reduction

The cores consist of a single-directional, a bidirectional, a bipolar core, and a cobble biface. The single-directional core was reduced using a multi-faces technique, the bidirectional core is a change-of-orientation (i.e., two oblique directions), and a piece of Pedernal chert was reduced using a bipolar technique. None of the cores exhibit any obvious evidence of platform preparation. The single-directional core was discarded due to material flaw fractures and the bi-directional core was exhausted. None of the cores were burned. Table 24.51 presents the metric information on the whole cores.

Table 24.51. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Single-directional	66	66	32	124
Bi-directional	34	25	13	14
Bipolar	43	45	26	50.8
Cobble biface	88	71	44	334.8

The debitage mainly consists of core flakes (53.1%), with some microdebitage (20.2%), angular debris (18.4%), and biface flakes (4.0%). Table 24.52 summarizes the various stages of reduction represented by the whole flakes. The debitage assemblage is primarily composed of secondary non-cortical (51.6%), with less tertiary and secondary cortical, and no primary flakes. The overall cortical:non-cortical ratio of 0.31 reflects this emphasis on the later stages of core reduction. The sample size is small, but chalcedony materials appear to be more fully reduced than the Pedernal chert.

Table 24.52. Debitage reduction stages.

Material	Primary	Secondary Cortical	Secondary Non-cortical	Tertiary	Cortical: Non-cortical ratio
Basalt	0	0	1	1	---
Obsidian	0	0	1	4	---
Chalcedony	0	3	24	1	0.12
Pedernal chert	0	8	5	0	1.6
Quartzite	0	1	1	0	1.0
Total	0	12	32	6	0.31
Percentage	0	24.0	64.0	12.0	---

The majority of the flakes exhibit single-faceted platforms (61.9%; *n* = 65), with crushed (*n* = 13), collapsed (*n* = 12), cortical (*n* = 11), and multi-faceted (*n* = 4) platforms. The majority of the collapsed platforms are on chalcedony and Pedernal core flakes and the crushed platforms on chalcedony and obsidian core flakes. Twenty-one (20.0%) of the flake platforms exhibit evidence of preparation, with most of these being abraded/crushed (*n* = 17), with fewer retouched (*n* = 3), and ground (*n* = 1).

The majority of the core flakes consist of distal fragments (*n* = 117; 45.0%), with fewer whole (*n* = 63), proximal (*n* = 33), midsection (*n* = 39), lateral (*n* = 5), and undetermined fragments (*n* = 3). Most of the biface flakes are also distal fragments (*n* = 8; 40.0%), with fewer whole (*n* = 6), proximal (*n* = 3), midsection (*n* = 2), and lateral (*n* = 1) fragments. The whole core flakes have a mean length of 21.8 mm (*std* = 10.5) and weight of 2.5 g (*std* = 4.5), whereas the whole biface flakes exhibit a mean length of 15.4 mm (*std* = 5.1) and a mean weight of 0.4 g (*std* = 0.4). Lastly, angular debris have a mean weight of 2.8 g (*std* = 4.7).

The retouched tools consist of a mix of expedient flakes tools like retouched pieces, a denticulate and a graver versus formal tools like bifaces, projectile points, and unifaces (Figure 24.46). The retouched pieces primarily exhibit marginal retouch along a single edge (*n* = 3), with one piece retouched along two edges. Table 24.53 presents the information on retouch type by edge outline.

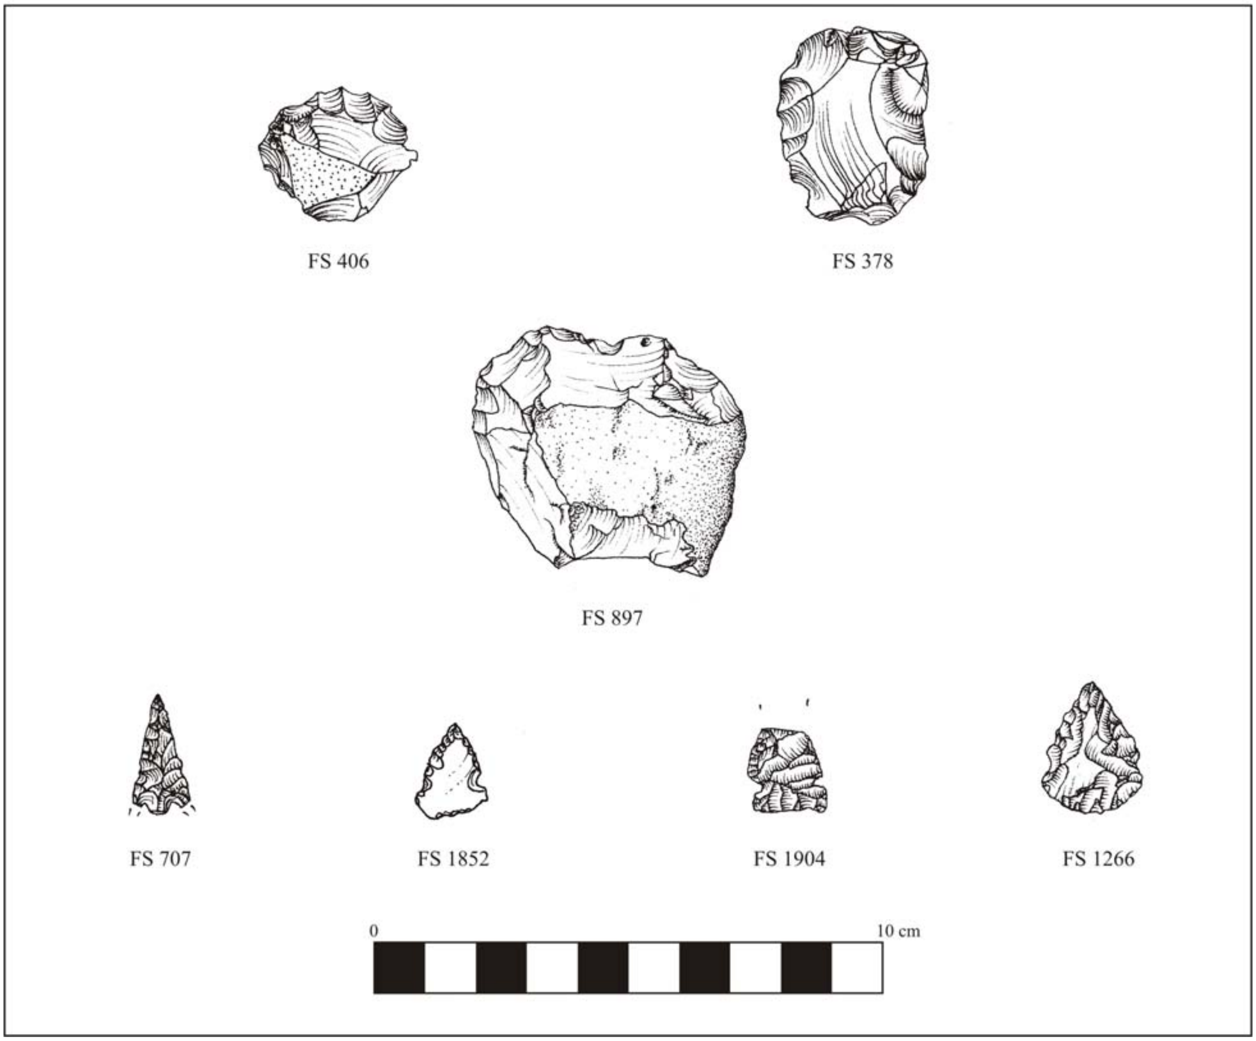

Figure 24.46. Retouched flake, denticulate, uniface, and projectile points.

Table 24.53. Retouched pieces from LA 86534.

Retouch Type	Edge Outline						
	Straight	Concave	Convex	Straight/ concave	Straight/ convex	Concave/ convex	Projection
Unidentified Ventral	1	0	0	0	0	0	0
Unidentified Dorsal	0	1	0	0	0	1	0
Bidirectional	0	0	1	0	0	0	0
Total	**1**	**1**	**1**	**0**	**0**	**1**	**4**

The four retouched edges exhibit a variety of edge outlines. The edge angles range from 30 to 70 degrees, with a mean of 52.5 degrees (*std* = 20.6). This presumably reflects a diversity of activities. The denticulate consists of a flake with a serrated lateral edge made by unidirectional ventral retouch. The graver is a flake fragment with marginally retouch (unidirectional dorsal) projection. The uniface is a large, roughly worked flake with unidirectional dorsal retouch and an edge angle of 60 degrees.

Only one of the bifaces is whole. It appears to be an ovate-shaped, late-stage biface with a thickness of 2 mm and edge angle of 35 degree. This biface was presumably broken while attempting to notch the preform. One of the other fragments could also be a late-stage biface with a thickness of 4 mm. It too could have been broken during manufacture while attempting to notch the point. The third biface is a small undetermined fragment.

Metrical and descriptive information on the two projectile points is presented in Table 24.54. One of these is a distal fragment of a corner-notched arrow point with a neck width of 4 mm, whereas the other is a whole stemmed lance/dart point with a neck width of 15 mm. The latter point has been resharpened.

Table 24.54. Projectile point metrical (mm) and descriptive data.

FS #	Material	Condition	Overall Length	Blade Length	Neck Width	Stem Length	Stem Width	Thickness	Weight (g)	Haft Type	Blade Shape	Base Shape
707	Chalce-dony	Distal	--	21	4	--	--	3	0.7	Corner-notched	Straight	Und.
1266	Obsidian	Whole	25	18	15	7	17	4	1.8	Stemmed	Straight	Con-vex

Tool Use

Only 6 flakes (1.2%) exhibit evidence of damage that could be attributed to use-wear. Most of the damage is located along the lateral edge of the flake (*n* = 4), with some at the end of the flake (*n* = 2). The former flakes have straight, concave, and convex outlines, whereas the latter consist of a convex-shaped edge and a utilized projection. Edge angles range from 35 to 65 degrees, with a mean of 49 degrees (*std* = 11.9). This is similar to the pattern exhibited by the retouched flakes. In contrast to the debitage, three of the retouched tools (20.0%) exhibit evidence of use-wear. These consist of two retouched flakes and the uniface.

Forty ground stone artifacts were identified during the analysis, including manos, metates, polishing stones, abrading stones, and other ground stone items. The manos are roughly evenly distributed between one and two-hand varieties. All 10 of the identifiable manos are one-handed. All of these are cobble manos with seven having single convex grinding surfaces, two having plano-convex grinding surfaces, and one that is an undetermined mano fragment.

Two generalized millingstones and a formal slab metate were also identified. The formal slab metate is well-worn, but consists of a broken fragment. The polishing stones are basalt and quartzite pebble with a finely ground surface, whereas the abrading stones are dacite pebbles with irregular ground surfaces.

The axe is an andesite cobble with flaked and worn edges and a battered butt. The artifact is whole and exhibits ground hafting notches (Figure 24.47).

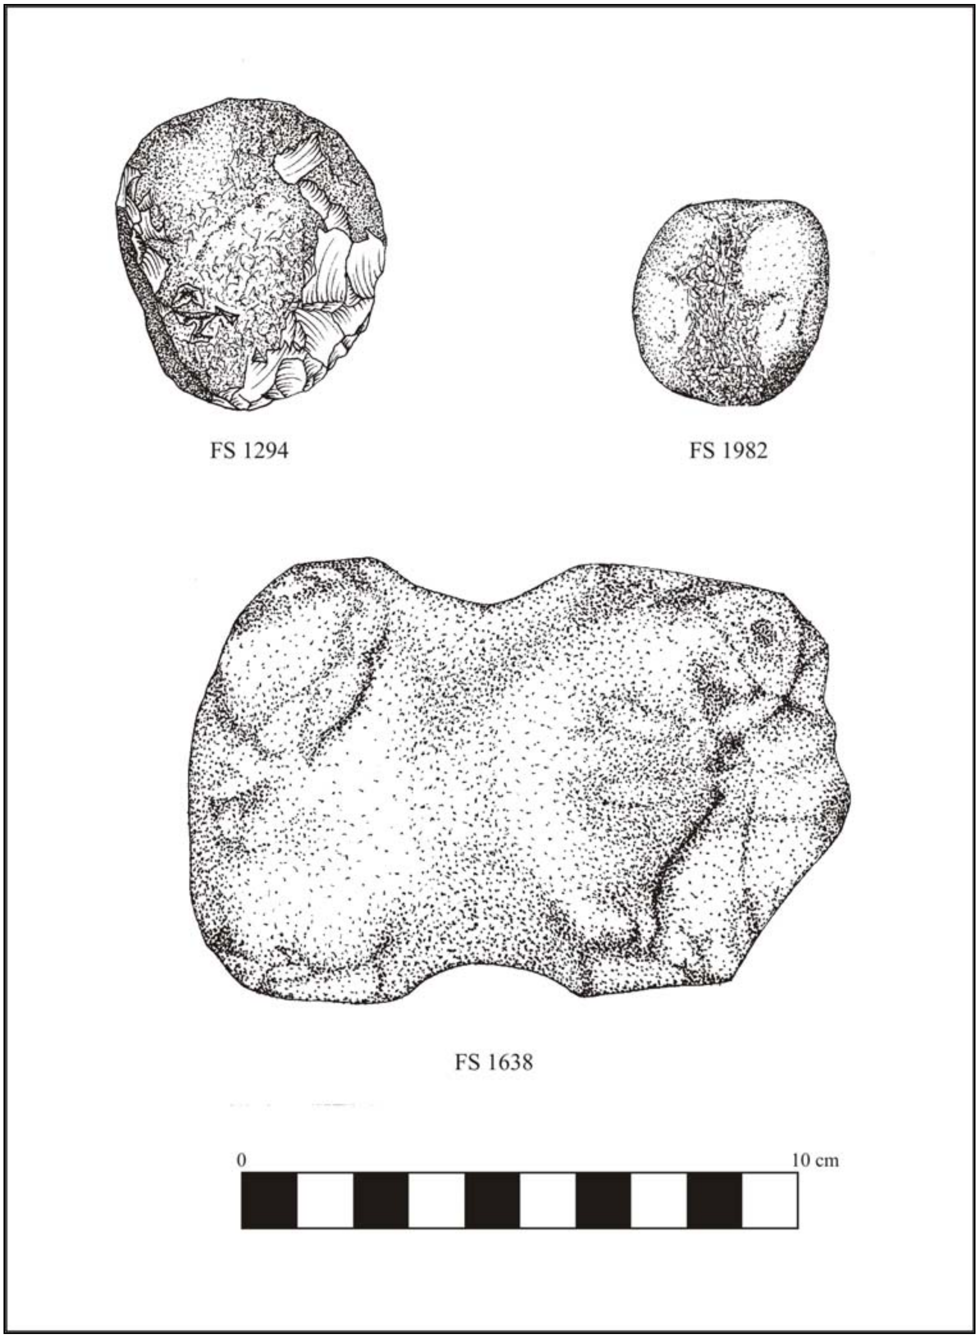

Figure 24.47. Axe and hammerstones.

Faunal Remains

In general, the overall preservation of the bones from LA 86534 was good. For the most part, bones tended to be in large fragments, and a number of complete elements were identified. Weathering on the faunal remains was present, although the frequency and severity was generally low, suggesting the remains may not have been exposed to the elements for a long period of time before deposition. The bones show minimal evidence of root-etching, and no evidence of rodent gnawing, carnivore gnawing, or carnivore-digestion. Modifications resulting from burning were present on 88 pieces of bone, constituting some 23 percent of the total assemblage. Two specimens recovered from LA 86534 were worked. Of the 388 faunal remains recovered from the excavations at LA 86534, 52 percent (*n* = 202) were identified to at least the level of class. The 202 identified remains were recovered from a variety of contexts. Table 24.55 shows all the taxa that were recovered from the site.

Table 24.55. Identified faunal remains from all contexts at LA 86534.

Archaeobotanical Remains

Maize cupules were the most frequently recovered plant remains at LA 86534, followed by goosefoot seeds (Table 24.56). The only other plant parts that occurred with a percent presence over 20 percent were pine bark scales, piñon and ponderosa needles, and purslane seeds. Maize kernels were present in only 15 percent of samples at LA 86534. Relative to this, maize kernels were present in 52 percent of flotation samples at LA 12587, yet the percent presence of maize cupules is virtually equal between the sites. Several possible explanations for this are 1) maize was grown at or near LA 86534, but shelled corn was taken elsewhere for consumption or storage, 2) unlike LA 12587 (see Chapter 14) where maize was probably stored on the roof, maize was stored in a room or pits that were not encountered during excavation, or 3) differential preservation was a factor. However, the latter is probably not a factor because preservation seems to be fairly good at LA 86534 with 14 taxa present and more occurrences of the elusive piñon nutshell than at LA 12587.

Table 24.56. Ubiquity of flotation sample carbonized plant remains at LA 86534.

*Count: Number of samples with common name/plant part present; **Percent: Number of samples with common name/plant part divided by total number of flotation samples with charred remains (53) × 100.

In contrast to LA 12587, along with unknown conifer, pine rather than juniper is the most common wood taxon in flotation samples (Table 24.57). In fact, oak and mountain mahogany occur in nearly the same frequency as juniper. Ponderosa pine was much more frequently encountered at LA 86534 (70% of samples) than at LA 12587 (23% of samples). The location of LA 86534 at over 7000 feet in elevation where stands of ponderosa grow along with piñon and juniper accounts for this disparity. Cottonwood/willow is absent from the flotation wood assemblage at LA 86534 along with several shrubby taxa found at LA 12587. Clearly, the inhabitants of both sites were exploiting species that were close at hand, a pattern that is repeated elsewhere on the Pajarito Plateau.

Table 24.57. Ubiquity of flotation sample wood charcoal taxa at LA 86534.

Common Name	Count	Percent

Unknown conifer	52	98.0
Unknown non-conifer	2	4.0

Pollen Remains (Susan J. Smith)

A total of 47 pollen samples were analyzed from LA 86534. Table 24.58 lists the frequency of identified pollen types. Cultigens identified in the assemblage included low numbers of squash with higher amounts of maize, maize aggregate pollen, and cholla. Economic resources identified in the pollen assemblage included prickly pear, cactus family, beeweed, sunflower type, lily family (which includes yucca, wild onion, and sego lily), nightshade family, parsley family, and purslane. A number of other potential economic resources were identified in the assemblage (Table 24.58), and these are described in detail in Smith's chapter in Volume 3 (Chapter 63).

Summary of Artifacts and Samples from Hearths

Four well-defined hearths were excavated at LA 86534. Two additional partial hearths were identified, but very few remains were recovered because of their heavily deteriorated nature. Comparisons of the pollen, macrobotanical, and faunal remains that were recovered in each of the four intact hearths are presented in the next four tables. Table 24.59 lists the pollen remains from each of the hearths, Table 24.60 lists the wood charcoal remains that were identified in the flotation samples, Table 24.61 lists the macrobotanical remains that were recovered in the hearths, and Table 24.62 lists the faunal remains that were identified in each of the hearths. Comparisons of these materials do not demonstrate a significant difference between hearths in the roomblock and the single kiva hearth. In fact, among identified pollen remains, taxonomic diversity was much lower in the kiva hearth than in the roomblock hearths. This difference was not as pronounced among the macrobotanical and faunal remains where taxonomic diversity between the two samples was generally similar.

Table 24.59. Identified pollen remains from the four intact hearths at LA 86534.

SUMMARY OF SITE EXCAVATIONS

Nine rooms were excavated at the LA 86534 Middle Coalition period roomblock. Rooms 1 through 8 are rectangular habitation rooms and Room 9 is a subterranean circular kiva. In addition, limited testing was done in a sparse midden area located immediately east of the roomblock. Figure 24.48 is a reconstruction of the site by artist Dave Brewer. While the depiction is mostly accurate, the kiva (Room 9) shown in the bottom left of the photo was a subterranean room and would not have been flush with the rest of the roomblock. In addition, it is doubtful that access to the kiva and back storage rooms was through the roof. Nonetheless, no outside doorways were identified in the front roomblock (except to the kiva), with connecting doorways being present between the front and back rooms. There is no evidence of any architectural remodeling events that might reflect multiple occupations; however, the hearth in Room 1 does exhibit two separate use episodes.

LA 86534 does resemble other excavated Coalition period sites on the plateau, containing front habitation rooms with hearths and rear storage rooms with milling bin features. A range of botanical remains were identified from flotation samples recovered from the hearths, including maize, beans, cheno-ams, dropseed grass, and tobacco. In addition, squash rind, piñon nuts, groundcherry, and sunflower were also represented at the site. The faunal remains also include a variety of species like jackrabbit, cottontail, rock squirrel, mule deer, turkey, and red-tailed hawk.

The ceramic assemblage primarily consists of Santa Fe Black-on-white and smeared-indented corrugated ceramics. The dominance of these ceramics types, coupled with the paucity of Kwahe'e and Wiyo Black-on-white, reflects a Middle Coalition period of occupation. The accelerator mass spectrometry and archaeomagnetic dates overlap and cover a similar two-sigma range from AD 1190 to 1280 and 1170 to 1300, respectively.

The stone tool technology reflects an emphasis on core reduction of materials like chalcedony, Pedernal chert, and obsidian. Most of the obsidian appears to have been obtained from nearby sources in the Valles Caldera. The retouched tool assemblage includes a mix of expedient flake tools like retouched pieces and perforators and formal tools like bifaces, projectile points, and unifaces. The manos are represented by both one and two-hand varieties. The metates consist of undetermined fragments, which could represent millingstones or slab types. In addition, the presence of polishing stones, abrading stones, and an axe indicates that a variety of domestic activities were occurring at the site.

CHAPTER 25
AIRPORT-CENTRAL TRACT (A-7): LA 135290

Bradley J. Vierra

INTRODUCTION AND SITE DESCRIPTION

LA 135290 is a small roomblock located on the Los Alamos town site mesa immediately north of New Mexico State Road 502. The mesa top is sparsely covered by piñon and juniper trees, with an understory including saltbush, snakeweed, yucca, and various grasses. The site is situated at an elevation of 2164 m (7100 ft) and has access to Pueblo Canyon to the north and to DP Canyon to the south.

Soils on the mesa top have been classified as a Hackroy sandy loam that have a good potential for agriculture (Nyhan et al. 1978). The site itself is underlain by a 1.5-m-thick layer of Holocene soils, with some late Pleistocene clay lying directly on the Tshirege member of the Bandelier Tuff. Soil depth is greatest in the central area of the mesa, but thins to exposed bedrock along its edges.

The original survey identified the presence of a roomblock that consisted of a north-south oriented mound that was 15 by 12 m in area and about 30 cm high (Figure 25.1a and b). The size of the mound and several probable tuff block wall alignments indicated that the mound could contain from six to 10 rooms. The associated surface artifact scatter included 300 to 400 sherds and 100 pieces of lithic debitage distributed in a 40- by 60-m area surrounding the mound. Most of these artifacts were distributed to the east of the roomblock, possibly reflecting the presence of a midden. One 2.5-m-diameter dogleash was located west of the pueblo and two 2-m-diameter dogleashes were located east of the pueblo. Analyzed ceramics include 12 decorated sherds and 94 utilityware sherds. The decorated ceramics consist of 11 Santa Fe Black-on-white and a single Wiyo Black-on-white sherd. The utilityware ceramics consist of 19 indented corrugated sherds, 49 smeared-indented corrugated sherds, 22 obliterated sherds, and four non-micaceous plainware sherds. The lithic debitage consists of a piece of angular debris, three core flakes, and three flake fragments made of Pedernal chert and one piece of angular debris and two core flakes made of basalt. Also noted within a dogleash was a basalt metate fragment. Based on the diagnostic ceramics, the site was dated to the Coalition period.

FIELD METHODS

Fieldwork began by delineating the extent of the mound and artifact scatter. A surface collection was made of all artifacts in the area of the mound and possible midden. Two east-west-oriented trenches were initially excavated across the mound. The northern trench was situated through grids 98N/106-114E (Figure 25.2) and the southern trench was located along grids 93N/105-113E. These trenches were excavated to define the walls within the roomblock and the stratigraphic sequence. After sections of the north-south walls were exposed, excavations proceeded to follow and expose the remaining wall segments, thereby identifying the presence of at least six rooms. Each room was given an individual number, and excavations continued by removing the room fill in natural stratigraphic layers and 1- by 1-m grids (Figure 25.1a and b).

Figure 25.1a. Photograph of the roomblock before it was excavated (looking north).

Figure 25.1b. Photograph of the roomblock after it was excavated (looking north).

Figure 25.2. Test trench profile of room stratigraphy.

After the main section of the roomblock was excavated, work began on the additional two front rooms located along the northeast side of the pueblo and two rock alignments situated to the immediate east of the roomblock. A block area including grids 90-96N/117-120E was excavated in this area to expose the rock alignments and identify any other features that might be present in the plaza. No other features were identified.

A series of test pits were placed in the area defined as the possible midden situated about 10 to 20 m east of the roomblock (Figure 25.3). Eight 1- by 1-m test pits were excavated (82N/121, 125, 129E; 85N/123,127,131E; 88N/129E, and 91N/131E) but no midden was identified. A few artifacts were recovered in the A horizon. Test pits were also placed to the north and west of the roomblock to identify the presence of any subsurface cultural deposits or features in these areas (91N/102E, 104N/112E, and 114N/94E). Again, no cultural deposits were identified, but a surface cluster of tuff blocks was excavated.

Ground-penetrating radar (GPR) was used to identify the presence of a kiva to the east of the roomblock (see Nisengard et al., Volume 3). A single possible buried feature was delineated to the northeast of the roomblock in the areas of grids 100-102N/116E. Seven backhoe trenches were excavated across the eastern area of the site to expose this possible feature and define the plaza area stratigraphy. The buried feature was determined to be an ancient channel or swale in the bedrock, and no other features were identified.

Figure 25.3. LA 135290 site excavation map.

The field supervisors at the site were Brad Vierra, Michael Dilley, and Jennifer Nisengard. Field crew members included Joseph Aguilar, Jennifer Boyd, Sandi Copeland, Rick Fitzgerald, Mark Hungerford, Greg Lockard, Todd Pitezel, Kari Schmidt, and Jeannine Wood. Timothy Martinez was the site monitor representing San Ildefonso Pueblo.

SITE GEOMORPHOLOGY (Paul Drakos and Steve Reneau)

Burial of an undulating Bandelier Tuff surface, and alternating periods of erosion and deposition, have resulted in variable thicknesses of the Pleistocene and Holocene sediments underlying LA 135290. The older (b2 and b3) soils of inferred Pleistocene age are present as remnant soils that were eroded and subsequently buried by swale fill and/or eolian deposits. Thickness of these buried Pleistocene deposits ranges from 0 to approximately 35 cm. The inferred mid-Holocene (b1) soil formed in fine-grained silty deposits of likely eolian origin. The 40- to 90-cm-thick mid-Holocene eolian deposit comprising the b1 soil was partially stripped (truncated) before occupation of LA 135290. The top of the mid-Holocene eolian deposit and the upper surface of Holocene swale fill deposits comprise the occupation surface for the site. The roomblock was apparently built on top of the b1 soil (either on top of the Bw1b1 or Btjb1 horizon). Soils formed in and surrounding the roomblock typically exhibit A-Bw1-Bw2 profile, which was developed in silty eolian sediment mixed with roomblock-derived colluvium. The A and Bw horizons include a variety of cultural artifacts.

SITE STRATIGRAPHY

Stratum 1 consists of the loose surface soil that covers the site area and is generally 3 to 5 cm thick (Table 25.1). Stratum 2 is a thin layer of post-occupational fill that overlies the roomblock. Underlying Stratum 2 are Strata 3 and 4. Stratum 3 is room fill with mostly adobe melt and no tuff blocks. Stratum 4 is room fill with pieces of tuff or tuff blocks. The sediment is similar between the strata, although Stratum 3 generally has more adobe, especially in Rooms 4 to 8 that contain adobe walls. For example, as one moves east to west from masonry to adobe walls, there is an increase in the amount of adobe in these sediments. There is adobe melt with a few chunks of adobe in Stratum 4, but it increases to large chunks of adobe with more melt in Stratum 3. The strata range from a silty loam to silty clay loam depending on how much adobe is present, and the colors range from brown to yellow brown.

Table 25.1. LA 135290 site stratigraphy descriptions.

Area 1	51	7.5 YR 5/3	Silty clay	--	Room 4, masonry and adobe wall matrix

During the excavation, slight differences could be discerned between the upper and lower sections of Strata 3 and 4. The room fill situated about 20 cm above the room fill contains more charcoal, botanical remains, and artifacts and a few roof casts. Therefore, the upper sections of these strata were defined as Strata 3a/4a and lower sections as 3b/4b. Strata 3b/4b appear to exhibit more water laminations, indicating that these deposits were exposed to the rain. Otherwise, there is more rodent disturbance in Stratum 4 relative to Stratum 3. This probably relates to the paucity of adobe and the presence of tuff blocks that provided overburden that was easier to burrow through. Lastly, a dense layer of adobe melt was identified adjacent to some of the adobe walls. This layer was defined as Stratum 3c (silty clay).

The remaining strata within the roomblock consist of floor surfaces, floor matrix, and feature fill. A distinction was made between artifacts found lying directly on the floor surface and artifacts or samples removed from the matrix of the adobe floor. Subfloor deposits were also exposed within the rooms. These deposits range from a silty clay to clay to a clay loam and appear to be artificial sediments that were used to level the ancient surface upon which the floors were constructed. These sediments were about 10 to 20 cm thick and were situated on the Bwb1 soil horizon. Otherwise, the roomblock is underlain with a 1.40-m-thick series of Holocene soil horizons and a single Pleistocene soil lying directly on the Bandelier Tuff bedrock. A column of pollen samples (Field Specimen [FS] 2275 to FS 2280, top to bottom) were taken from this soil profile to provide some information on paleoenvironmental conditions. Taxa identified in FS 2275 include cheno-ams (*Chenopodium/Amaranthus*), sunflower family (Asteraceae), fir (*Abies*), unidentified pine (*Pinus* sp.), piñon pine (*Pinus edulis*), juniper (*Juniperus*), and oak (*Quercus*). Those identified in FS 2276 include cheno-ams, sunflower family, unidentified pine, piñon pine, juniper, sagebrush (*Artemesia*), and four o'clock family (Nyctaginaceae). Only unidentified pine was identified in FS 2777. Taxa identified in FS 2778 included sunflower family and juniper, while only unidentified pine was identified in FS 2779 and FS 2780.

Excavations in the areas around the roomblock exposed the upper section of this Holocene sequence. This consisted of the A, Bw, and Bwb1 soil horizons. The A horizon is generally about 2 to 10 cm thick and the Bw about 2 to 7 cm thick. Only a few artifacts were recovered in the upper 10 cm of this soil profile. The top of the Bwb1 horizon represented the ancient surface used by site occupants. Indeed, the top of the Bwb1 was much more compact in the area east of the roomblock (i.e., the plaza), indicating that the surface had been consolidated by trampling.

SURFACE COLLECTION

A surface artifact collection was conducted on the mound and in the surrounding area in 1- by 1-m grids (75-121N/93-133E). Figure 25.4 illustrates the surface distribution of artifacts across the site. As can be seen, most of the artifacts are distributed in two clusters to the east of the roomblock. A small cluster is present to the immediate northeast and a larger cluster to the southeast. This latter area may represent the remains of a trash midden.

SITE EXCAVATION

The site was divided into four separate proveniences or areas (see Figure 25.3). Area 1 consists of the rubble mound of the roomblock within grids 89-112N/105-116E. Area 2 is located to the immediate east of the roomblock, including the plaza area in grids 87-94N/116-120E and 95-110N/104-128E. Area 3 comprises that portion of the site located to the immediate west of the roomblock within grids 89-120N/93-104E. Lastly, Area 4 is situated in the southeastern section of the site, including the possible midden located in grids 75-93N/121-133E.

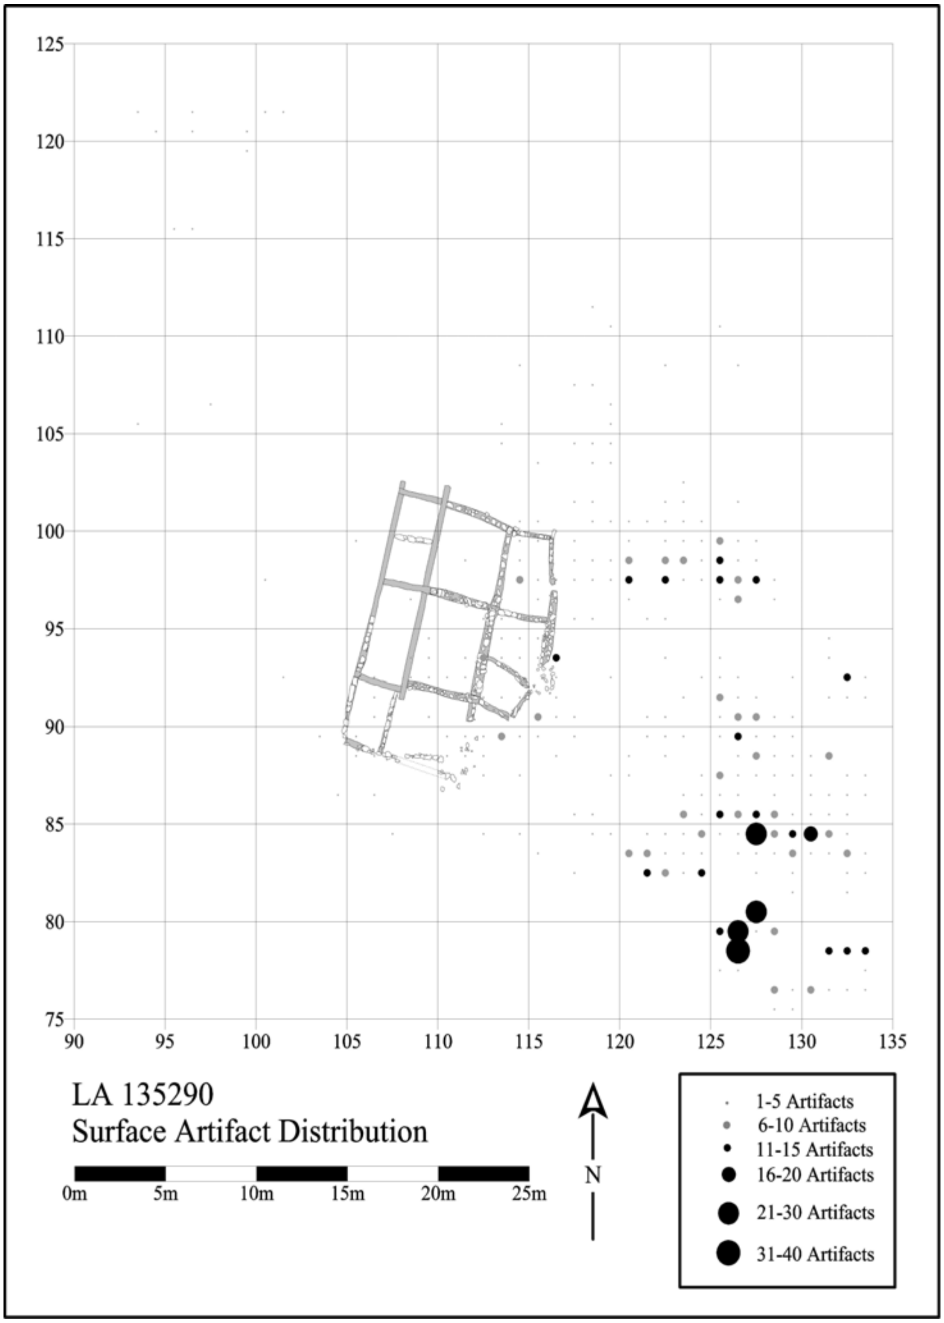

Figure 25.4. Surface artifact distribution.

Area 1 (Roomblock)

Room 1

Sequence of Excavation. Room 1 is located in the north-central part of the roomblock. The room measures 3.8 m north-south by 3.5 m east-west, with 13.30 m^2 of interior space. An east-west test trench (98N/110-113E) was initially excavated through the room to define site stratigraphy and the location of the floor. Excavations proceeded by excavating the room fill to the immediate south of the trench by grid and natural layer. Then, the majority of the room fill was removed to the north of the trench by grid and natural layer. After sections of the floor were exposed, several grids were excavated below this level. This was in part because of the disturbed nature of the floor and the exposure of subfloor deposits due to rodent activity.

Fill. After the removal of about 20 cm of post-occupational fill (Strata 1 and 2), the remainder of the room contained approximately 70 to 80 cm of Stratum 4. Stratum 4 was a silty clay loam soil mixed with wallfall and some adobe melt. Wallfall was generally present within 1 to 2 m of standing masonry walls and adobe melt adjacent to the adobe western wall. This differed from the center of the room, which contained a few small pieces of tuff with little adobe melt. The room fill was disturbed by rodent activity, although this disturbance appears to increase with depth. On the other hand, there were fewer tuff blocks with an increase in small tuff fragments and adobe melt with depth. The lower 20 cm of room fill (Stratum 4b) exhibited an increase in the amount of charcoal, charred maize kernels, and artifacts.

Flotation and pollen samples were taken from Strata 1, 2, 4a, and 4b (Table 25.4). Charred taxa identified in the flotation sample taken from Stratum 1 include piñon pine (*Pinus edulis*), ponderosa pine (*Pinus ponderosa*), cottonwood/willow (*Populus/Salix*), and maize (*Zea mays*). No charred taxa were identified in Stratum 2. Charred taxa identified in Stratum 4a include unknown conifer (Gymnospermae), piñon pine, ponderosa pine, and maize. The sample from Stratum 4b was not analyzed.

Taxa identified in the pollen sample from Stratum 1 include cholla (*Opuntia*), buckwheat (*Eriogonum*), cheno-am (*Chenopodium/Amaranthus*), grass family (Poaceae), sunflower family (Asteraceae), fir (*Abies*), unidentified pine, piñon pine, juniper, oak (*Quercus*), rose family (Rosaceae), and sagebrush (*Artemesia*). Taxa identified in Stratum 2 include maize, cheno-ams, sunflower family, unidentified pine, piñon pine, juniper, and sagebrush. Taxa identified in Stratum 4a include prickly pear (*Opuntia*), beeweed (*Cleome*), cheno-ams, grass family, mustard family (Brassicaceae), sunflower family, unidentified pine, piñon pine, juniper, and sagebrush. Taxa identified in Stratum 4b include cheno-ams, grass family, sunflower family, unidentified pine, juniper, oak, rose family, and sagebrush.

A series of macrobotanical specimens from levels 4 to 9 were also selected from Strata 4a and 4b (see Table 25.4). Taxa identified in the Stratum 4a samples (FS 1047, FS 1201, and FS 1326) include pine, ponderosa pine, cottonwood/willow, oak, bean, and maize. Taxa identified in Stratum 4b (FS 1450, FS 1550, and FS 1767) include mountain mahogany, beeweed, unknown conifer, unidentified pine, ponderosa pine, cottonwood/willow, oak, and maize.

Floor. The floor (Stratum 9) was heavily disturbed by rodent activity, with only about 10 percent of the surface being intact (Figures 25.5 and 25.6). These small intact sections were primarily situated in the northern areas of the room, consisting of a 5- to 7-cm-thick layer of adobe. The floor was defined by the presence of a burned and/or prepared adobe surface. Several pockets of ash were noted on or immediately above the level of the floor. A flotation (FS 1705) and pollen sample (FS 1706) were taken from grid 98N/111E. Taxa identified in the flotation sample include goosefoot, cheno-ams, squash/coyote gourd (*Cucurbita*), unknown conifer, juniper, bean (*Phaseolus*), ponderosa pine, cottonwood/willow, and maize. Taxa identified in the pollen sample include squash, maize, prickly pear, cheno-ams, grass family, sunflower family, ragweed/bursage (*Ambrosia*), evening primrose (Onagraceae), unidentified pine, piñon pine, juniper, oak, and sagebrush.

Flotation samples were also taken on the floor in the center of the room (FS 1896) and in the northwest corner of the room (FS 1837). Charred taxa identified in the center of the room include pigweed (*Amaranthus*), goosefoot, juniper, piñon pine, ponderosa pine, oak, and maize. Charred taxa identified in the sample taken from the northwestern corner of the room include goosefoot, cheno-ams, juniper, ponderosa pine, and maize.

Figure 25.5. Photograph of Room 1 (west).

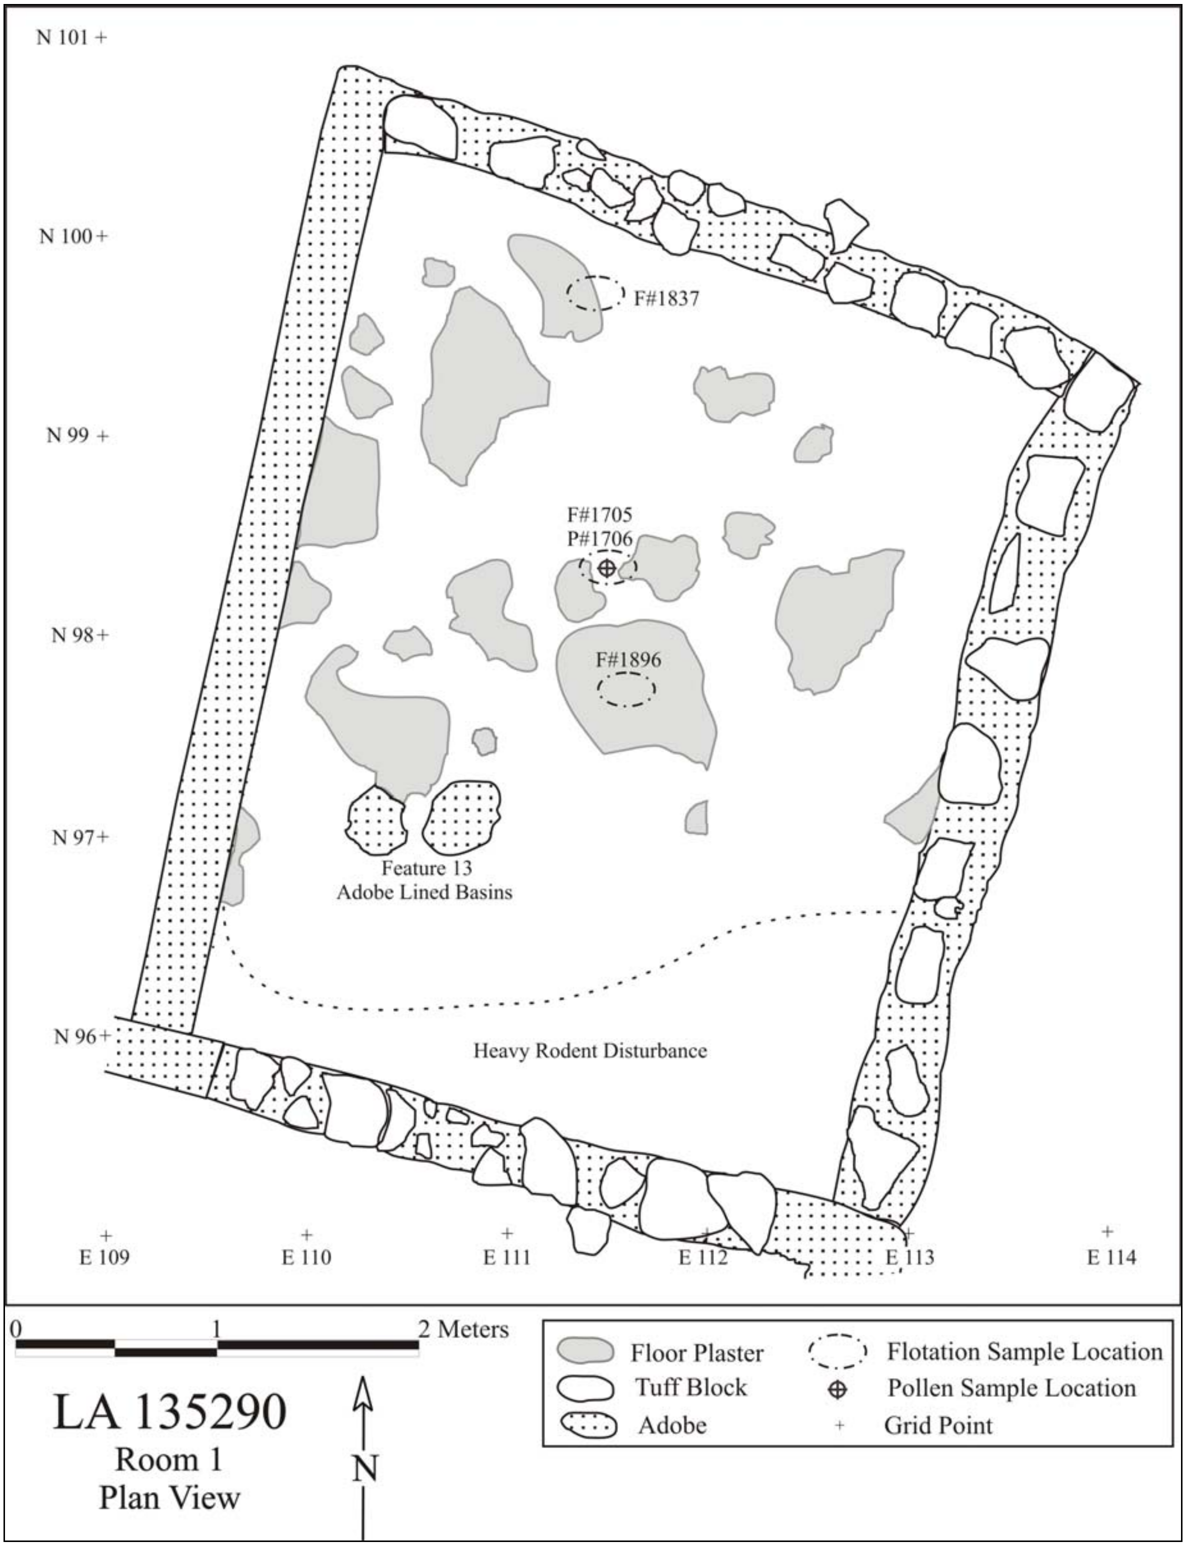

Figure 25.6. Room 1 floor map.

No artifacts were uncovered lying directly on the intact sections of the floor. But a single feature (Feature 13) was identified in the southwestern area of the room. Feature 13 consists of two heavily disturbed adobe lined basins. The basins are contiguous with each other, but only consist of the bottom portions of the basins. The features are 40 to 42 cm long, 33 to 38 cm wide, and 3 to 5 cm in depth and are situated slightly below the floor level. Although they do not articulate with the existing sections of the floor, the features are presumably associated with the original floor in Room 1.

Several grids were excavated below the level of the floor (96-97N/112E, 98N/110E, and 98-99N/111E). The soil underlying this level consisted of a clay or clay loam (Stratum 10) with a blocky structure. The sediment appears to be artificial fill that is about 15 to 20 cm thick and was situated directly on top of the Bwb1 soil horizon. Seventeen sherds and five pieces of debitage were recovered from these deposits. The artifacts were presumably derived from the upper room deposits.

Wall Construction. The northern, eastern, and southern walls of the room were constructed of masonry, with wallfall situated within about 2 m of each wall. The lower section of the west wall was constructed of adobe and the upper section was composed of masonry. The majority of the north, east, and west (masonry) walls collapsed into the room, while most of the south wall had collapsed into Room 2. Approximately 60 to 90 cm of standing walls remained, with the west wall solely consisting of adobe that was 60 cm high. There were no discernable doorways in any of the walls. Room 1 wall measurements are listed in Table 25.2.

Table 25.2. Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	# Courses
North	3.6	0.77	0.30	3
South	3.55	0.90	0.30	4
East	3.8	0.70	0.30	3
West	4.1	0.60	0.25	Adobe

Wall construction is quite different between the north and south walls. The lower section of the north wall is constructed of a series of unshaped upright tuff blocks with adobe mortar, while the upper section consists of horizontally placed blocks (Figure 25.7). The uprights range from 40 to 45 cm high by 15 to 20 cm wide. They are staggered at 20- to 40-cm intervals and are interspersed with adobe mortar and smaller pieces of tuff that are about 10 to 20 cm in size. Overall, the lower wall section is approximately 55 cm high. The upper section is composed of horizontally placed tuff blocks that range from 25 to 50 cm long by 10 to 20 cm wide. Only a single course of stones is still standing. The wall is covered by a 10-cm-thick layer of adobe.

Figure 25.7. Room 1, north wall.

The south wall is constructed quite differently from the north wall. There are no large upright blocks in the lower section of the wall. Instead, the lower section is composed of a single course of large unshaped tuff blocks that are situated contiguous to each other (Figure 25.8). The blocks range from 20 to 30 cm high by 10 to 30 cm wide. The upper section consists of 1 to 2 courses of horizontally placed tuff blocks with adobe mortar. These blocks range from 20 to 40 cm wide by 10 to 15 cm high. About 10 cm of adobe also covers the face of this wall.

Subfloor adobe footings about 15 to 20 cm thick are present under the east, west, and south walls of the room. In contrast, there is no adobe footing under the north wall. The upright tuff blocks (basal stones) were set directly into adobe about 10 cm thick. The bottom of this adobe is located at the level of the floor.

Figure 25.8. Room 1, south wall.

Artifacts and Samples. Artifacts and pollen, flotation, and macrobotanical samples were selected from grids 97N/111-112E and 98N/111E. In addition, samples were selected from floor contexts. Tables 25.3 and 25.4 provide summary information on artifacts by stratigraphic unit and samples selected for analysis, respectively.

Table 25.3. Room 1 artifact counts by stratigraphic unit.

Stratum	Ceramics	Chipped Stone	Ground Stone	Faunal Remains	Other	Total
1	26	2	0	0	0	28

Room 2

Sequence of Excavation. Room 2 is located in the east-central section of the roomblock. The room measures 4.4 m north-south by 3.56 m east-west and has 15.66 m^2 of interior space. An east-west test trench (93N/108-112E) was also excavated through the room to define site stratigraphy and the location of the floor.

Fill. After the removal of the post-occupational fill (Strata 1 and 2), the remainder of the room contained a mix of Strata 3 and 4 that was 50 to 70 cm thick. Stratum 3 was a clay loam soil that was mostly identified in the western area of the room adjacent to the adobe wall. Stratum 4 was a silty clay loam mixed with wall, some adobe melt, and possible roofing material (Stratum 19). The wallfall was primarily located adjacent to the masonry northern and eastern walls, with little near the adobe western and masonry southern walls. There was a notable increase in the density of ceramics in the northeastern area of the room. Flotation, pollen, and macrobotanical samples were taken from Strata 2, 4a, and 4b (see Table 25.7).

Taxa identified in the flotation sample collected from the fill levels (Stratum 2) include unknown conifer, piñon pine, oak, and maize. Taxa identified in Stratum 4a include cheno-ams, ponderosa pine, and maize. Taxa identified in Stratum 4b include goosefoot, cheno-ams, unknown conifer, piñon pine, ponderosa pine, and maize.

Taxa identified in the pollen samples from the fill levels (Stratum 2, post-occupational fill) include cheno-ams, grass family, sunflower family, ragweed/bursage, unidentified pine, piñon pine, juniper, oak, rose family, and sagebrush. Taxa identified in Stratum 4a include cheno-ams, sunflower family, spurge family (Euphorbiaceae), unidentified pine, piñon pine, juniper, and sagebrush. Taxa identified in Stratum 4b include maize, cholla, prickly pear, beeweed, cheno-ams, grass family, sunflower family, ragweed/bursage, unidentified pine, piñon pine, juniper, and sagebrush.

Macrobotanical samples (FS 1102, FS 1167, FS 1703, FS 1741, FS 1902, and FS 1938) from the fill levels include the following taxa: mountain mahogany, unknown conifer, ponderosa pine, juniper, unidentified pine, piñon pine, cottonwood/willow, unknown non-conifer, and maize.

Stratum 19 was identified in the central area of the room. The deposit was 5 to 10 cm thick and consisted of burned chunks of adobe mixed with charcoal in grids 93N/110-112E. This material was located on the floor and had burned this section of the floor. It presumably represents burned roofing material. Three flotation samples (FS 1897, FS 1898, and FS 2034) were taken from this deposit and included the following charred taxa: goosefoot, cheno-ams, unknown conifer, juniper, bean (*Phaseolus*), unidentified pine, piñon pine, ponderosa pine, cottonwood/willow (*Populus/Salix*), plantain (*Plantago*), purslane (*Portulaca*), oak, dropseed grass (*Sporobolus*), and maize. A macrobotanical (FS 2046) sample was also collected from the deposit and includes the following taxa: mountain mahogany, unknown conifer, juniper, unidentified pine, ponderosa pine, and oak. In addition, six smeared-indented, three indented, and four plain corrugated sherds were recovered from this stratum.

Floor. Floor 1 (Stratum 5) was first encountered in the southeastern corner of the room where there was obvious coping to the wall (Figures 25.9 and 25.10).

Figure 25.9. Photograph of Room 2 (north).

The floor was very patchy due to extensive rodent disturbance, but does cover about two-thirds of the room. Most of the floor is not burned, although there is extensive burning in the central area of the room where the floor plaster is ashy and sooted in some spots. Although the floor consists of a relatively thick 3- to 5-cm layer of adobe, it has collapsed in many sections of the room due to rodent burrows. Manganese staining is also present in some parts of the floor adjacent to the walls. Adobe coping can be found in about 90 percent of areas where the walls articulate with the floor.

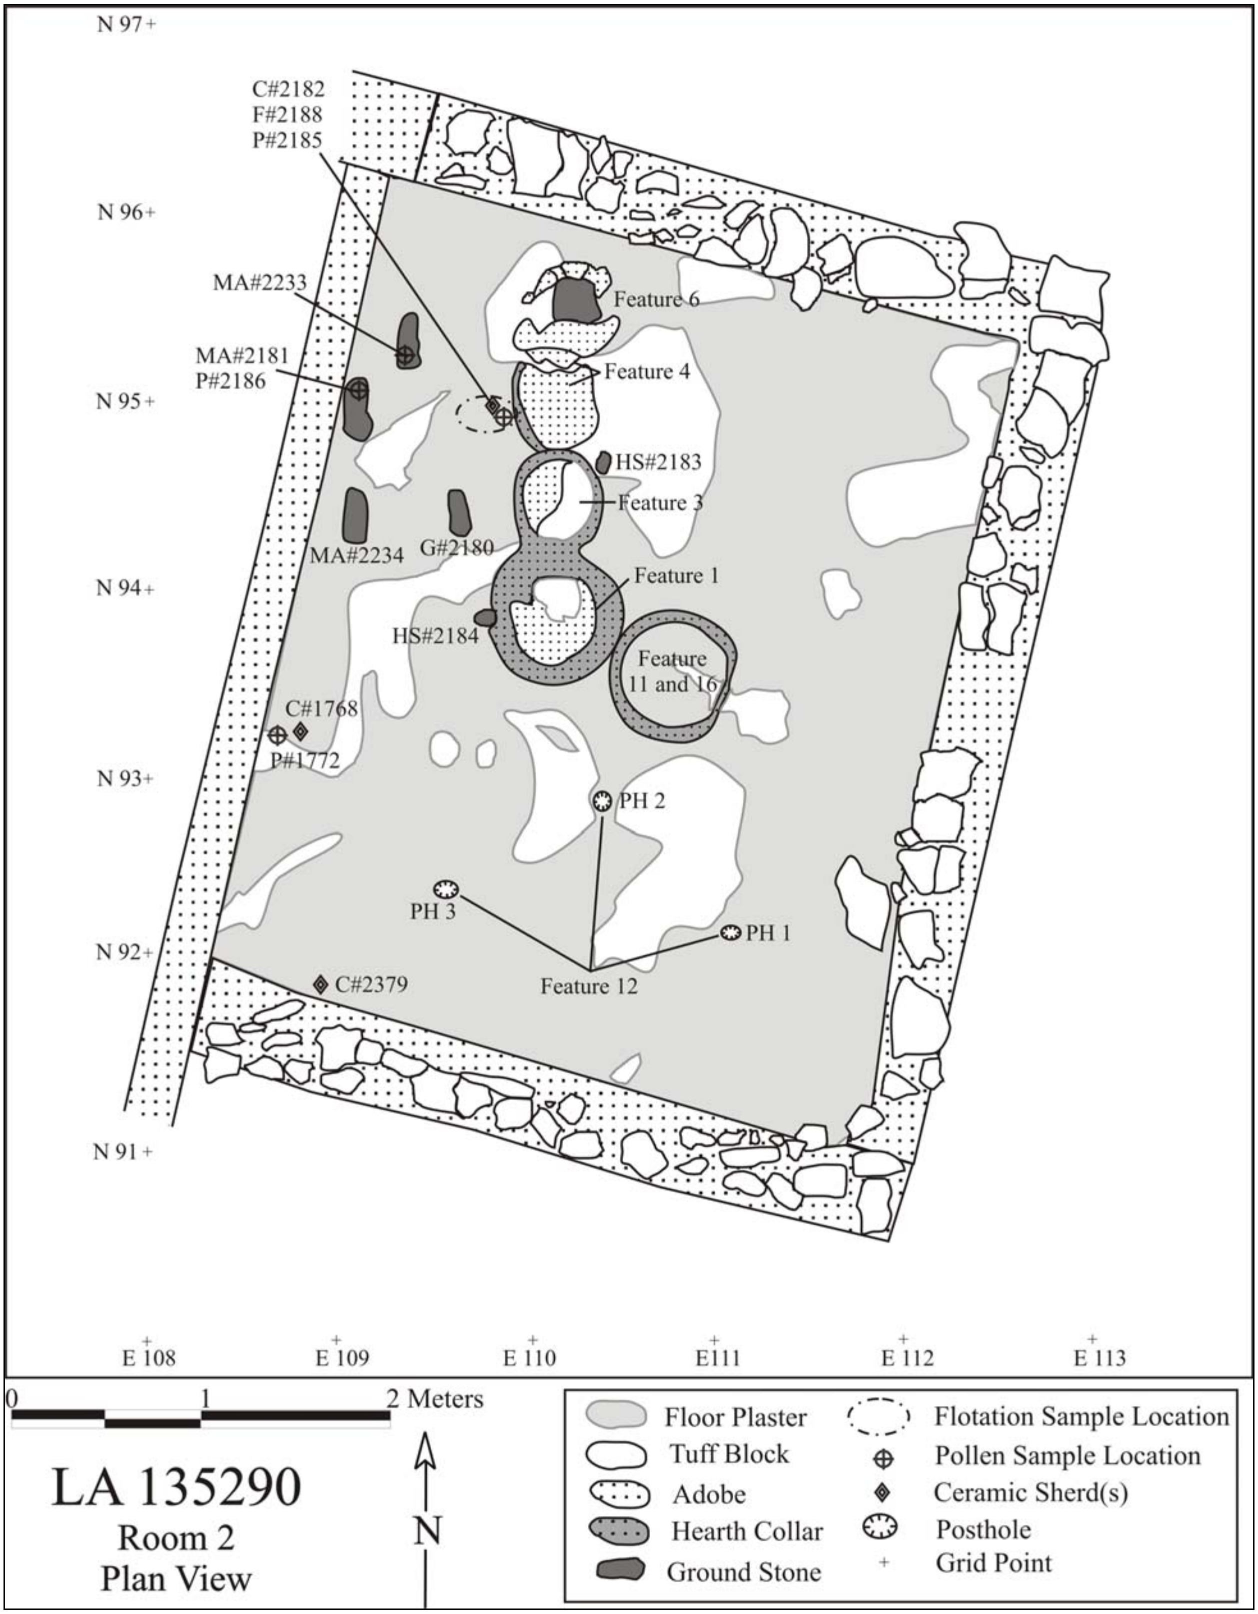

Figure 25.10. Room 2 floor map.

Several artifacts were present on Floor 1 (Stratum 5). Most of these were situated in the northwestern area of the room, to the west of Features 1, 3, 4, and 6. Eight smeared-indented corrugated sherds from the same utility jar vessel (FS 2182) were found immediately to the west of Feature 4. A pollen (FS 2185) and flotation (FS 2188) sample were taken from under the vessel. The pollen sample contained the following taxa: squash (*Cucurbita*), maize, cholla, prickly pear, cheno-ams, grass family, sunflower family, evening primrose (Onagraceae), unidentified pine, piñon pine, juniper, oak, cottonwood (*Populus*), and sagebrush. The flotation sample included the following charred taxa: unknown conifer and ponderosa pine.

A maul (FS 2180), three two-hand manos (FS 2181, FS 2233, and FS 2234), and two hammerstones (FS 2183 and FS 2184) were also found on the floor. A pollen sample was taken from under the maul (FS 2186) near the west wall, and a mano was submitted for pollen wash (FS 2234). The following taxa were identified in the pollen sample: squash, maize, cholla, prickly pear, grass family, sunflower family, evening primrose, unidentified pine, piñon pine, juniper, and sagebrush. Taxa identified in the pollen wash included squash, maize, and unidentified pine. In addition, hammerstones were present to the northeast of Feature 3 (FS 2183) and immediately west of Feature 1 (FS 2184). A very large sherd from a smeared-indented corrugated vessel (FS 1768) was also present near the west wall in the southwestern section of the room. A pollen sample (FS 1772) was taken from several centimeters of fill under the sherd and on top of the floor. Identified taxa include prickly pear, cheno-ams, grass family, sunflower family, unidentified pine, piñon pine, juniper, and sagebrush. A smeared-indented corrugated sherd (FS 2379) yielded a thermoluminescence (TL) date of AD 816±133.

Nine features were identified on the floor of Room 2. These consist of a collared hearth, three adobe-lined pits, two adjacent hearths, and three post holes. Features 1, 3, 4, and 6 comprise an interconnected complex with a collared hearth and three adobe-lined pits (Figures 25.11 and 25.12). The feature complex is situated in the northwestern area of the room and is oriented north-south. The collared hearth (Feature 1) is circular in plan view, is basin-shaped in cross-section, and measures 70 cm in diameter and 16 cm in depth. The adobe collar is approximately 10 to 15 cm thick and rises to a height of about 10 cm above the floor. When the collar was removed during excavation, the original floor plaster was exposed, indicating that the feature was a later addition. The other three pits are all directly connected to the original floor. There was no evidence of burning and the pit fill (Stratum 26) was quite similar to the Stratum 4 sediments surrounding the feature.

A chalcedony core (FS 2102), charred maize kernels, and a maize cob (FS 2103) were recovered from the fill. Flotation (FS 2099 and FS 2138) and pollen (FS 2100 and FS 2137) samples were taken. Taxa identified in the flotation samples include pigweed (*Amaranthus*), saltbush/greasewood (*Atriplex/Sarcobatus*), mountain mahogany (*Cercocarpus*), goosefoot, cheno-ams, grass family, unknown conifer, juniper, mint family (Labiatae), unidentified pine, piñon pine, ponderosa pine, cottonwood/willow, purslane, oak, and maize. Taxa identified in the pollen samples include squash, maize, cholla, cheno-ams, grass family, mint family, purslane, mustard family (Brassicaceae), sunflower family, ragweed/bursage, evening primrose (Onagraceae), fir (*Abies*), unidentified pine, piñon pine, juniper, oak, polygala type, rose family, Mormon tea (*Ephedra*), and sagebrush. It may be that Feature 1 was constructed, but never used as a hearth. The maize kernels recovered in FS 2103 were submitted for radiocarbon analysis.

This sample yielded an age of 870±40 BP (Beta-199386) and a date of cal AD 1180 with a two-sigma date range of cal AD 1040–1260.

Figure 25.11. Photograph of Features 1, 3, 4, and 6 (north).

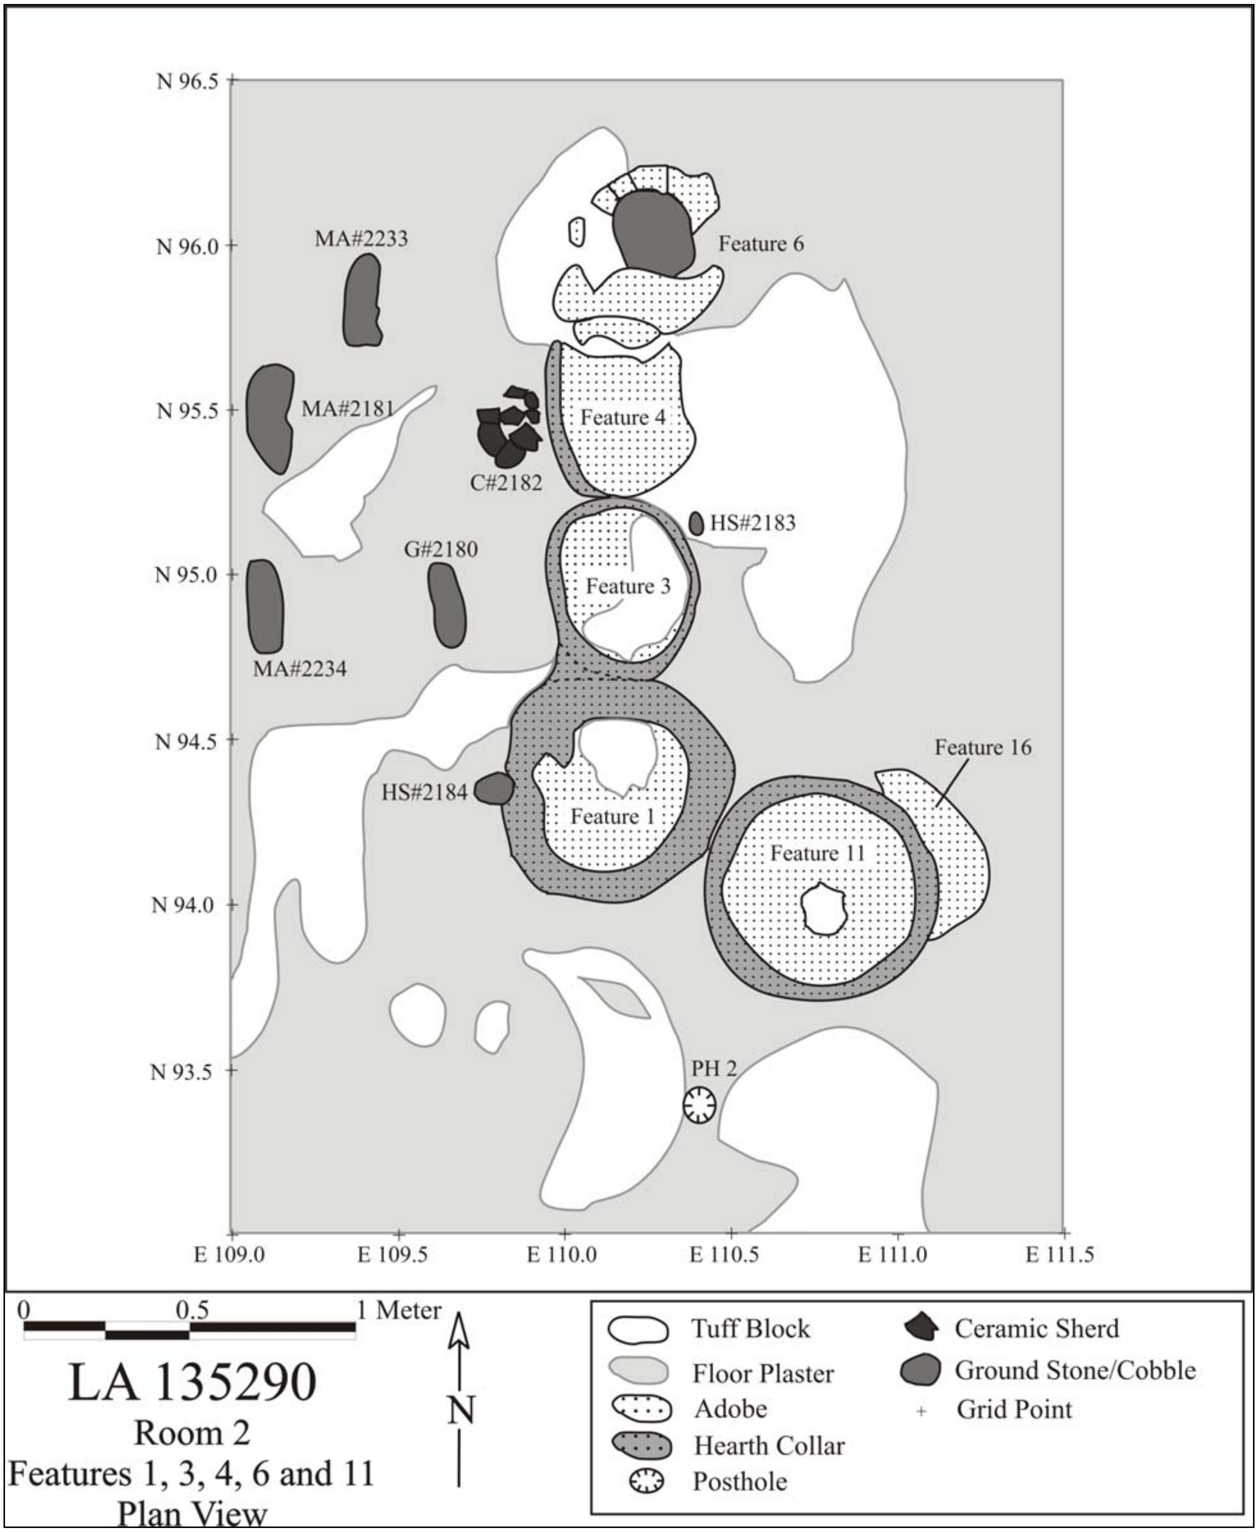

Figure 25.12. Features 1, 3, 4, 6, and 11 plan view.

Features 3, 4, and 6 all consist of adobe-lined pits running south to north, respectively. Although the area has been disturbed by rodent activity, the three features were probably connected by adobe collars. Feature 3 has been heavily disturbed by rodent burrowing and only the northern and western portions were still intact. The pit is circular-shaped in plan view and is 50 cm in diameter and 16 cm deep. There is no evidence of burning and the fill (Stratum 25) is similar to that encountered in the sediments surrounding the feature (Stratum 4). The collar around Feature 3 appeared to have been remodeled during the construction of Feature 1. When the Feature 3 collar was removed, it was determined that the feature originally had no collar and was directly connected to the floor.

A flotation and pollen sample were both collected from Feature 3. The flotation sample (FS 2083) contained the following charred taxa: pigweed, mountain mahogany, goosefoot, unknown conifer, mint family, piñon pine, ponderosa pine, oak, and maize. The pollen sample (FS 2084) contained the following taxa: squash, maize, cholla, prickly pear, beeweed, plantain, cheno-ams, grass family, sunflower family, evening primrose, fir, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush.

Feature 4 is a relatively shallow pit. It is oval-shaped in plan view, measuring 34 by 51 cm and is 10 cm deep. This feature has also been heavily disturbed by rodent burrowing, but the western side of the pit is partially intact with a slight collar. Again, the fill (Stratum 24) is similar to the surrounding sediments, with no evidence of burning. One flotation sample (FS 2069) was collected and the following carbonized taxa were identified: pigweed, saltbush/greasewood, goosefoot, cheno-ams, unknown conifer, mint family, bean, unidentified pine, piñon pine, ponderosa pine, purslane, and maize. One pollen sample (FS 2068) was collected from Feature 4 and the following taxa were identified: cotton (*Gossypium*), maize, prickly pear, beeweed, cheno-ams, grass family, sunflower family, evening primrose, and sagebrush.

Feature 6 is also a shallow oval-shaped pit. It measures 40 by 47 cm and is 2 to 10 cm deep. The feature has also been disturbed by rodent activity, but most of the bottom of the pit is intact. The bottom has a single flat dacite cobble that was set into the adobe plaster. The cobble is 20 cm wide. No burning was evident inside the pit or on the cobble.

Features 11 and 16 are hearths that were partially superimposed over each other. Both features are located immediately southeast of Feature 1. Feature 11 consists of an adobe-lined collared hearth that was capped with an ash lens (Figures 25.13 and 25.14). It is circular in plan view and somewhat basin-shaped in cross-section and measures 64 cm in diameter by 14 cm deep. The eastern portion of the hearth was destroyed by rodent activity, but the remainder of the feature was intact. The collar of the hearth was about 6 cm thick and raised approximately 5 cm above the floor. The pit fill (Stratum 32) is quite distinct from that encountered in the other pit features. The sides of the pit are burned and the fill is very ashy with lots of adobe and charcoal mixed with soil. The fill was separated into three parts: 1) upper fill with ash, charcoal, and silty loam soil ranging from pale to dark-yellow-brown in color; 2) middle fill with adobe and charcoal bits in a dark-yellow-brown clay loam soil matrix; and 3) lower fill consisting of a dark brown silty clay loam mixed with some of the adobe lining.

Flotation (FS 2253, FS 2254, FS 2255, FS 2256, FS 2257, and FS 2258) and pollen (FS 2252 and FS 2348) samples were taken from the upper fill. The flotation samples from the upper fill include the following taxa: mountain mahogany, goosefoot, cheno-ams, unknown conifers, juniper, mint family, tobacco (*Nicotiana*), bean, piñon pine, ponderosa pine, prickly pear, purslane, purslane family, cottonwood/willow, oak, and maize. Taxa identified in the pollen samples from the upper fill include maize, prickly pear, beeweed, buckwheat (*Eriogonum*), cheno-ams, grass family, sunflower family, unidentified pine, piñon pine, juniper, oak, spurge family, penstemon family (Scrophulariaceae), Mormon tea, and sagebrush. Flotation samples were also taken from the middle-lower fill (FS 2330, FS 2331, FS 2332, and FS 2350) of the pit. Taxa identified in these samples include goosefoot, cheno-ams, grass family (Graminae), winged pigweed (*Cycloloma*), unknown conifer, juniper, uncharred tobacco, unidentified pine, piñon pine, ponderosa pine, purslane, oak, and maize.

Figure 25.13. Photograph of Feature 11.

In addition, maize (FS 2333), piñon pine and ponderosa pine wood charcoal (FS 2346), three smeared-indented corrugated sherds, and two cottontail (*Sylvilagus audobonii*) and ground squirrel (*Spermophilus* sp.) bones were recovered from the pit fill. The maize kernels recovered in FS 2333 were submitted for radiocarbon analysis (Beta-199387), but the sample was too small to yield a reliable result. One of the smeared-indented corrugated sherds (FS 2259) yielded a TL date of AD 1050±90. An archaeomagnetic sample (set 1229) was taken from the burned bottom of the hearth. The error ellipse overlaps two segments of the Wolfman calibration curve in the AD 1000–1300 time period, but a pre-AD 1125 date possibility is unlikely given the Santa Fe Black-on-white pottery associations of the site. The most probable date range based on the result and the Wolfman curve is AD 1200–1270. The large range is due to the imprecise pole location estimate; the centerpoint of the result is closest to the curve at about AD 1235. The relevant date range based on the SWCV2000 curve is AD 1175–1325, encompassing the Wolfman curve date range.

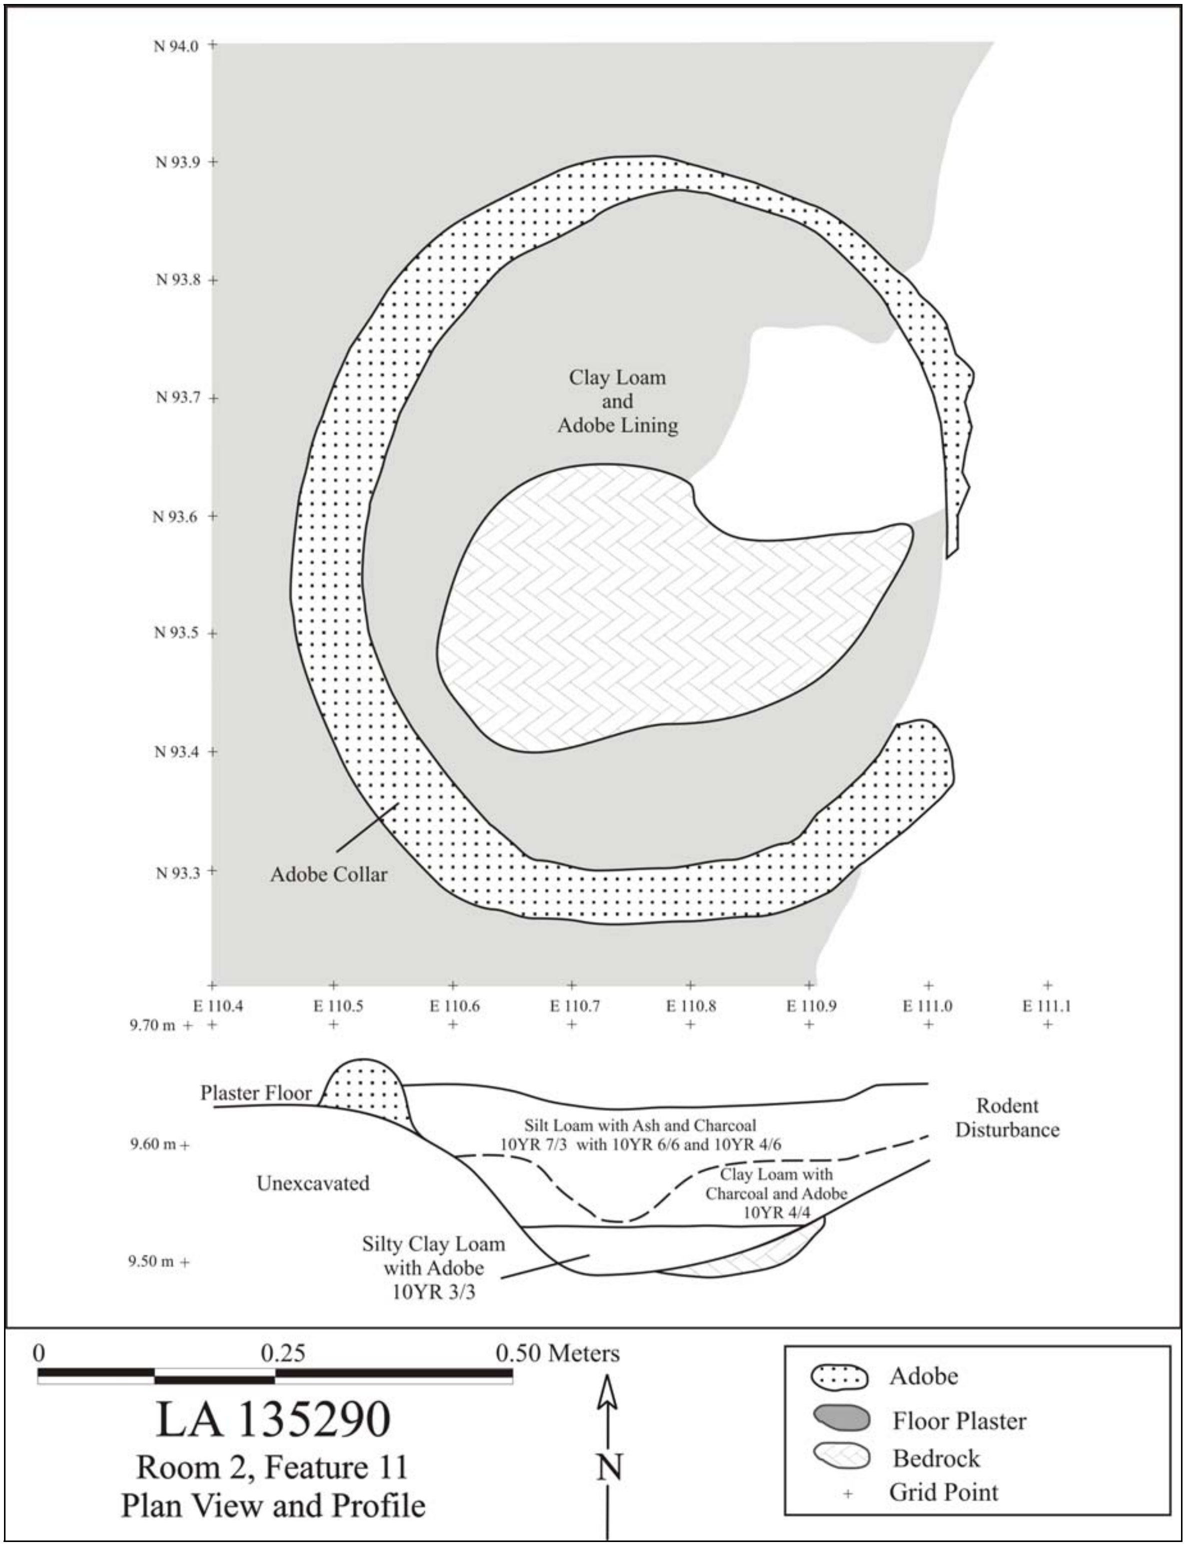

Figure 25.14. Feature 11 plan view and cross section.

Feature 16 is situated underneath the eastern section of Feature 11 and was partially destroyed by the construction of the upper hearth. Feature 16 is also an adobe-lined hearth with only slight evidence of a collar. It was probably circular in shape, but all that remains is a section that is 48 cm in length, 26 cm wide, and 8 cm deep. The sides of the pit and the collar are heavily burned, but the floor is only slightly charred with ash staining. The fill (Stratum 45) contains charcoal and ash. Flotation (FS 2563 and FS 2564) and pollen (FS 2579) samples were taken from Feature 16. Taxa identified in the flotation samples include goosefoot, unknown conifer, juniper, uncharred tobacco, piñon pine, ponderosa pine, oak, and maize. Taxa identified in the pollen sample include squash, maize, cheno-ams, grass family, sunflower family, spurge family, unidentified pine, piñon pine, juniper, and sagebrush.

An archaeomagnetic sample was taken from the floor of the hearth (set 1231). Eight specimens were collected from the lower hearth. The error ellipse overlaps two segments of the Wolfman curve within the AD 1100–1300 time span, resulting in two possible date ranges. The earlier and less likely range is AD 1105–1150, while the later range of AD 1155–1210 is a more probable date interpretation for the last burning of the hearth. The date range based on the SWCV2000 curve is AD 1035–1165, but this range is too early given contextual information, and it is believed that the SWCV2000 curve does not accurately reflect virtual geomagnetic pole (VGP) movement at this time period (see Cox and Blinman 1999 for a discussion of sources of systematic distortion in SWCV VGP curves). Maize kernels recovered in FS 2564 were submitted for radiocarbon analysis. This sample yielded an age of 860±40 BP (Beta-199389) and a date of cal AD 1190 with a two-sigma date range of cal AD 1040–1260.

Three postholes (Feature 12; Stratum 34) were identified south of Features 1 and 11. They are 4 to 6 cm in diameter and 9 to 14 cm deep. Flotation samples were taken from posthole 1 (FS 2376) and posthole 3 (FS 2378). Carbonized taxa identified in posthole 1 included unknown conifer and maize, and those identified in posthole 3 included unknown conifer, unidentified pine, and maize.

There appears to be three separate remodeling episodes represented by the construction of the floor features. Feature 16 was constructed first and is overlain by a thin layer of sandy fill between it and Floor 1. Feature 11 was built over Feature 16 and Features 3, 4, and 6 were constructed on Floor 1. Feature 1 was constructed last and was connected to Feature 3.

A subfloor test pit (93N/110E) identified the presence of about 25 cm of artificial fill (Stratum 43) overlying the Bwb1 soil horizon. This material was presumably brought in to create a level and stable surface for the construction of the room. Seven sherds, three pieces of debitage, and six bones were recovered from these deposits. A pollen and flotation sample were taken (FS 2550 and FS 2549, respectively). Taxa identified in the pollen sample include cheno-ams, grass family, sunflower family, ragweed/bursage, spruce (*Picea*), unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush. Charred taxa identified in the flotation sample include unknown conifer, piñon pine, ponderosa pine, and maize.

Wall Construction. The walls in Room 2 are in relatively good condition. The three masonry walls are constructed of mostly unshaped tuff blocks with adobe mortar. The northern masonry wall is almost 1 m high and still exhibited some intact wall plaster along the base (Figure 25.15).

Figure 25.15. Rooms 1 and 2 north walls.

The detail of the wall construction was described in Room 1. The east masonry wall is similar to the north wall, and there is intact wall plaster along the base of the wall. The south wall is the most deteriorated of the masonry walls and is two to four courses high. This was likely the original exterior wall to the room until Room 3 was added to the roomblock. The west wall was made of adobe and was in very good condition. None of the walls exhibited any evidence of burning, and there was no evidence for doorways in any of the walls. Room 2 wall measurements are listed in Table 25.5.

Table 25.5. Room 2 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	# Courses
North	3.52	0.82	0.34	3-6
South	3.60	0.33	0.35	2-3
East	4.51	0.62	0.41	2-5
West	4.40	0.48	0.38	adobe

Sub-floor adobe footings about 18 to 20 cm thick were present under the north, west, and east walls. However, the large tuff blocks (basal stones) in the south wall were set horizontally into depressions that were lined with adobe below the floor. The depressions were about 20 cm deep. Two of these large blocks measured about 50 by 40 by 20 cm in size. Otherwise, adobe footings were noted under the south wall.

Artifacts and Samples. Artifacts and pollen, flotation, and macrobotanical samples were selected from grids 93N/110-111E and 94N/111E. In addition, samples were selected from floor contexts in Room 2. Tables 25.6 and 25.7 provide summary information on artifacts by stratigraphic unit and samples selected for analysis in Room 2.

Table 25.6. Room 2 artifact counts by stratigraphic unit.

Room 3

Sequence of Excavation. Room 3 is located at the southeastern corner of the roomblock. It measures 4.0 m north-south by 3.15 m east-west, with 12.60 m^2 of interior space. Excavations proceeded from north to south in the room by grid and natural layer. The floor was exposed and a subfloor test pit (87N/110E) was excavated in the southeastern area of the room.

Fill. After the removal of a 5- to 15-cm layer of post-occupational fill (Strata 1 and 2), most of the room fill consisted of Stratum 4a deposits. This layer consisted primarily of wallfall mixed with a little charcoal. In the northern part of the room it was about 30 to 40 cm thick, whereas, in the southern section of the room it was only 10 to 15 cm thick. Most of the rubble was situated in the south-central part of the room, although a small amount was located along the north and west walls. Stratum 3b was a 5- to 10-cm-thick layer overlying the fill. This deposit exhibited a marked increase in the presence of artifacts and charcoal, but lacked tuff rubble. Pollen, flotation, and macrobotanical samples (FS 1456, FS 1572, and FS 1831) were taken from Strata 2, 4a, and 3b (see Table 25.10).

Taxa identified in the pollen samples taken from Stratum 2 include maize, cheno-ams, grass family, sunflower family, unidentified pine, piñon pine, juniper, and sagebrush. Taxa identified in Stratum 4a include cheno-ams, grass family, sunflower family, fir (*Abies*), unidentified pine, piñon pine, juniper, oak, and sagebrush. Taxa identified in Stratum 3b include maize, beeweed, cheno-ams, grass family, sunflower family, mustard family, unidentified pine, and sagebrush.

Carbonized taxa identified in the flotation samples from Stratum 2 include juniper, ponderosa pine, and maize. Maize was the only carbonized remains identified in Stratum 4a. Taxa identified in Stratum 3b include pigweed, goosefoot, cheno-ams, grass family, piñon pine, ponderosa pine, purslane, and maize.

Taxa identified in the macrobotanical samples include juniper, piñon pine, ponderosa pine, oak, unknown non-conifer, and maize.

Floor. The floor in Room 3 (Stratum 11) is poorly preserved. Indeed, it is not a plastered surface as in Rooms 1 and 2, but rather a compacted living surface (Figures 25.16 and 25.17).

Figure 25.16. Photograph of Room 3 (looking north).

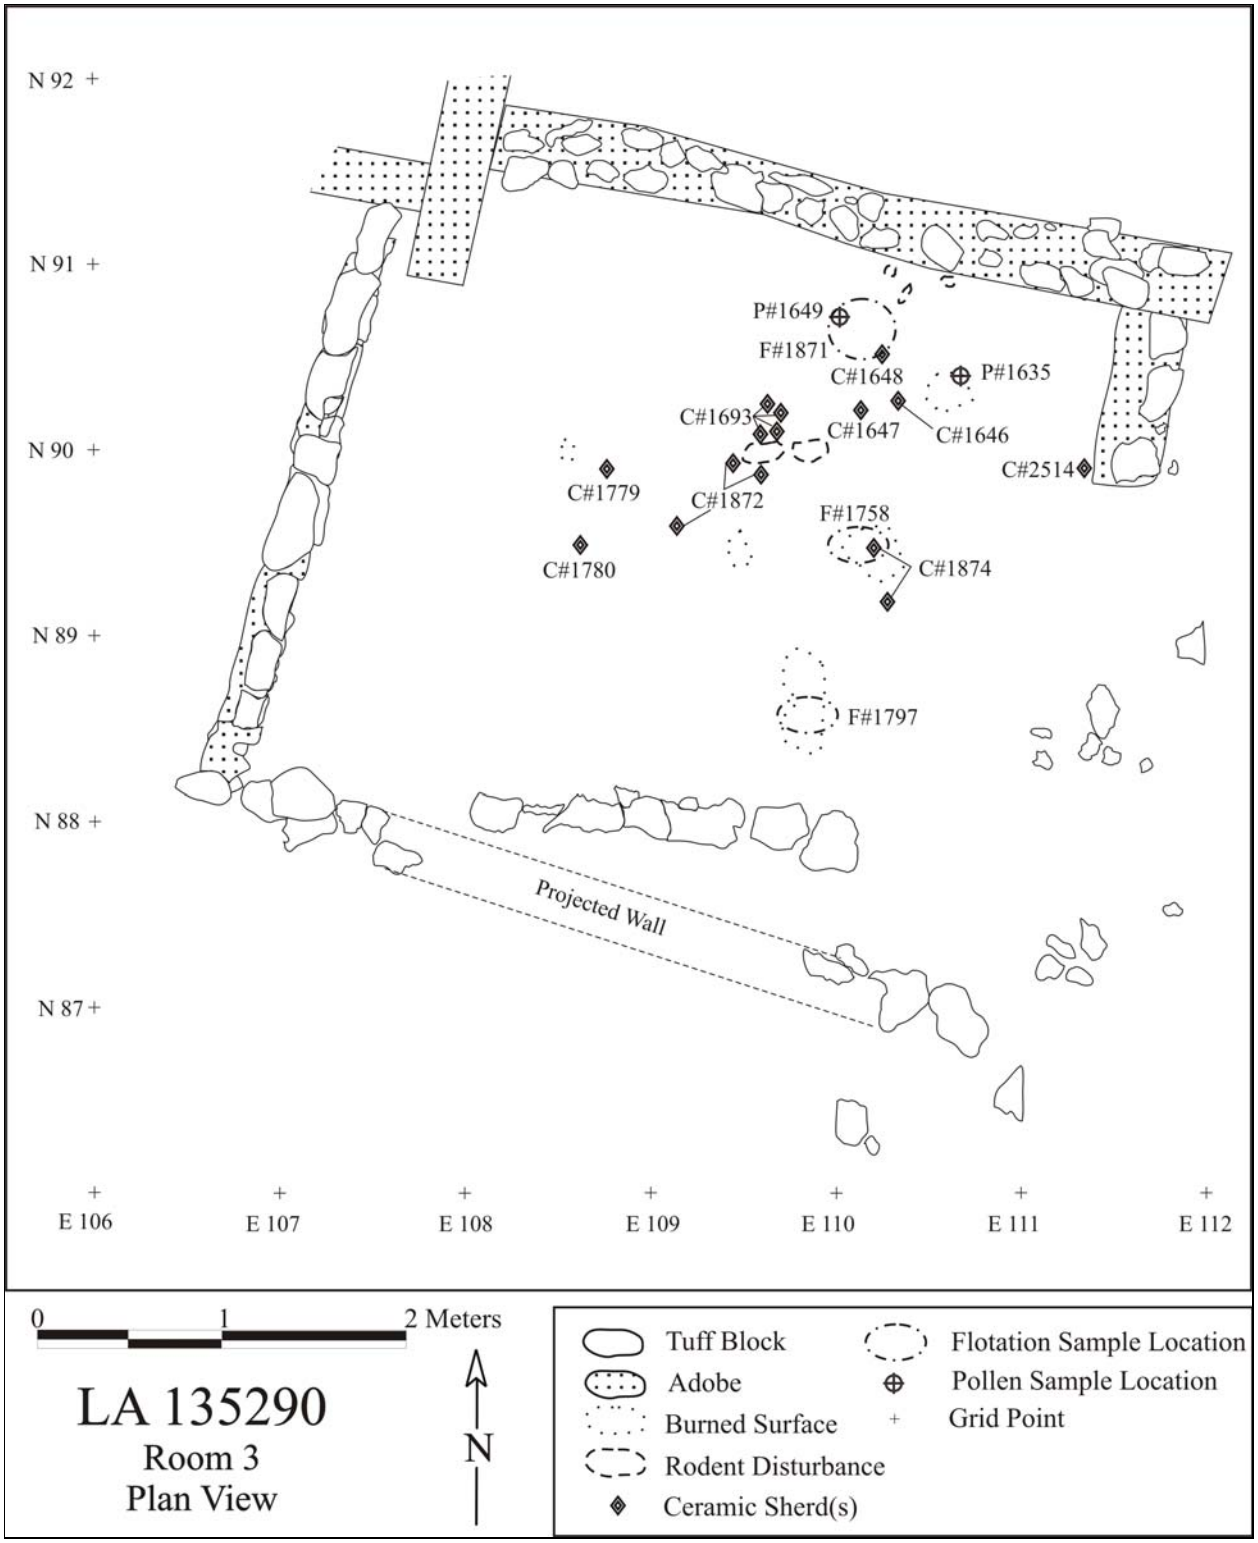

Figure 25.17. Room 3 plan view.

The floor was defined as the surface directly underlying Stratum 4a/3b. In some areas, this stratum had small burned patches. In the northern area of the room there were some sections where horizontal layers flaked off fairly easily to reveal the surface. However, these layers were continuous in other areas of the room, possibly reflecting multiple fine clay lenses of washed adobe from the nearby walls. There is no evidence of the floor being coped to the walls.

No features were identified in the room, but there were five distinct patches of burned sediment with charcoal found on the floor surface (Stratum 3b). These small patches are roughly oriented along a north-south line in the eastern side of the room and could represent rooffall. A couple of the patches contained burned maize cobs and kernels. Flotation (FS 1758 and FS 1797) and pollen (FS 1635) samples were taken from these patches. Carbonized taxa identified in the flotation samples include cheno-ams, grass family, unknown conifer, juniper, unidentified pine, piñon pine, ponderosa pine, and maize. Taxa identified in the pollen sample include maize, unidentified pine, and sagebrush.

Twenty sherds were found at or near the level of the floor surface. These consist of 12 smeared-indented corrugated, five indented corrugated, and three unpainted undetermined sherds. A flotation (FS 1871) and pollen sample (FS 1649) were taken in the northeastern area of the room where the floor was well-preserved (Stratum 11). Taxa identified in the flotation sample include juniper, unidentified pine, piñon pine, and maize. Taxa identified in the pollen sample include prickly pear, cheno-ams, grass family, sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon pine, rose family (Rosaceae), and sagebrush.

A subfloor test pit (87N/110E) identified the presence of about 15 cm of artificial fill (Stratum 6) overlying the Bwb1 soil horizon. This clay loam with a blocky structure was presumably brought in to create a level and stable surface for the construction of the room. No artifacts were recovered from this deposit.

Wall Construction. The walls in Room 3 are not as well preserved as those described in Rooms 1 and 2. The north and west wall are masonry with one to two courses of mostly unshaped tuff blocks. The west wall is offset about 35 cm to the west from the main north-south wall along Rooms 1 and 2 (Figure 25.18). It appears to be abutted up against the east-west wall that forms the north wall of the room. Therefore, the west wall represents a later addition. This is also supported by the fact that the north-south wall from Rooms 1 and 2 continues into Room 3 for an additional 60 cm immediately adjacent to the west wall of the room.

The east wall of Room 3 is barely visible, consisting solely of four upright tuff rocks. Two of these are situated at the northeastern intersection with Rooms 2, 3, and 9, while the other two are located in the central section of the wall. The blocks are about 25 cm high and were sunk into the floor about 10 to 15 cm. It is unclear if this was originally a continuous upright wall, since there was little or no wallfall in the area.

The south wall consists of seven upright tuff blocks situated in the south-central section of the room. The tuff blocks are about 20 cm high and are sunk approximately 20 cm below the level of the floor. At least some of the wallfall present in the central area of the room was derived from this wall. However, there is no evidence of the western and eastern sections of the wall, either as uprights or wallfall. On the other hand, there are western and eastern sections of a possible wall that aligns with the southern wall in Room 7. It is unclear how these two possible wall segments relate to each other. Room 3 wall measurements are provided in Table 25.8.

There is no evidence of doorways in the north and west walls. It is unclear as to whether there were doorways in the east and south walls.

Figure 25.18 Northwest corner of Room 3 with offset walls in foreground (north).

Table 25.8. Room 3 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	# Courses
North	3.60	0.40	0.40	2
South	4.20	0.20	0.25	1

Artifacts and Samples. Artifacts and pollen, flotation, and macrobotanical samples were selected from grids 89N/109E, 90N/108E, and 90N/109-110E. In addition, samples were selected from floor contexts. Tables 25.9 and 25.10 provide summary information on artifacts by stratigraphic unit and samples selected for analysis in Room 3.

Table 25.9. Room 3 artifact counts by stratigraphic unit.

Room 4

Sequence of Excavation. Room 4 is located at the northwestern corner of the roomblock. It measures 1.85 m north-south by 2.10 m east-west, with 3.89 m^2 of interior space. Excavations proceeded from south to north in the room by grid and natural layer.

Fill. After the removal of a 10-cm layer of post-occupational fill (Strata 1 and 2), most of the room fill consisted of Stratum 3 with some Stratum 4 adjacent to the west wall. This fill was about 40 to 50 cm thick. Pollen, flotation, and macrobotanical samples were taken from Strata 3b and 4a (see Table 25.13). Taxa identified in the pollen samples taken from the room fill include maize, prickly pear, sunflower family, cheno-ams, grass family, ragweed/bursage, evening primrose (Onagraceae), fir (*Abies*), unidentified pine, piñon pine, juniper, squawbush (*Rhus* type), and sagebrush. Taxa identified in the flotation samples include goosefoot, cheno-ams, unknown conifer, ponderosa pine, and maize. Taxa identified in the macrobotanical samples (FS 1135, FS 1465, and FS 1515) include mountain mahogany, unknown conifer, juniper, unidentified pine, piñon pine, ponderosa pine, and oak.

Floor. Three separate floors were identified in Room 4. Floor 3 (Stratum 35) is the lowest or original floor surface and the most disturbed of the three floors (Figures 25.19 and 25.20). An archaeomagnetic sample (Set 1232) was taken from Floor 3. Floor 3 yielded 7 specimens and two proved to be outliers and were eliminated from the final best result. Intercepts of the result provide an estimated date range of AD 1170–1265. Compared with the SWCV2000 curve, this result produces a date range of 1010–1310, encompassing the more precise interpretation based on the Wolfman curve.

Floor 3 consists of a thin wash of plaster about 1 cm thick. It was burned in the eastern third of the room and is best preserved in this area. The western two-thirds of the room was not burned and was in poor condition. Two pollen samples (FS 2449 and FS 2460) were taken from the east side of the room. Taxa identified in these samples include maize, prickly pear, beeweed, buckwheat (*Eriogonum*), cheno-ams, grass family, sunflower family, spurge family, unidentified pine, piñon pine, juniper, rose family, Mormon tea, and sagebrush. No features or artifacts were identified on the floor. However, Floor 3 in Room 4 appears to underlie the southern wall of the room and is contiguous with Floor 2 in Room 5. Therefore, the wall dividing Rooms 4 and 5 was constructed with Floor 2 in Room 4 and Floor 1 in Room 5. During a period of room abandonment, rodent burrowing (Stratum 40) destroyed sections of the floor. These holes were subsequently repaired before the construction of Floor 2. That is, the rodent burrows were filled in with either adobe and/or small pieces of tuff and then covered with Floor 2.

Figure 25.19. Photograph of Room 4, Floor 3, and Room 5, Floor 2 (south).

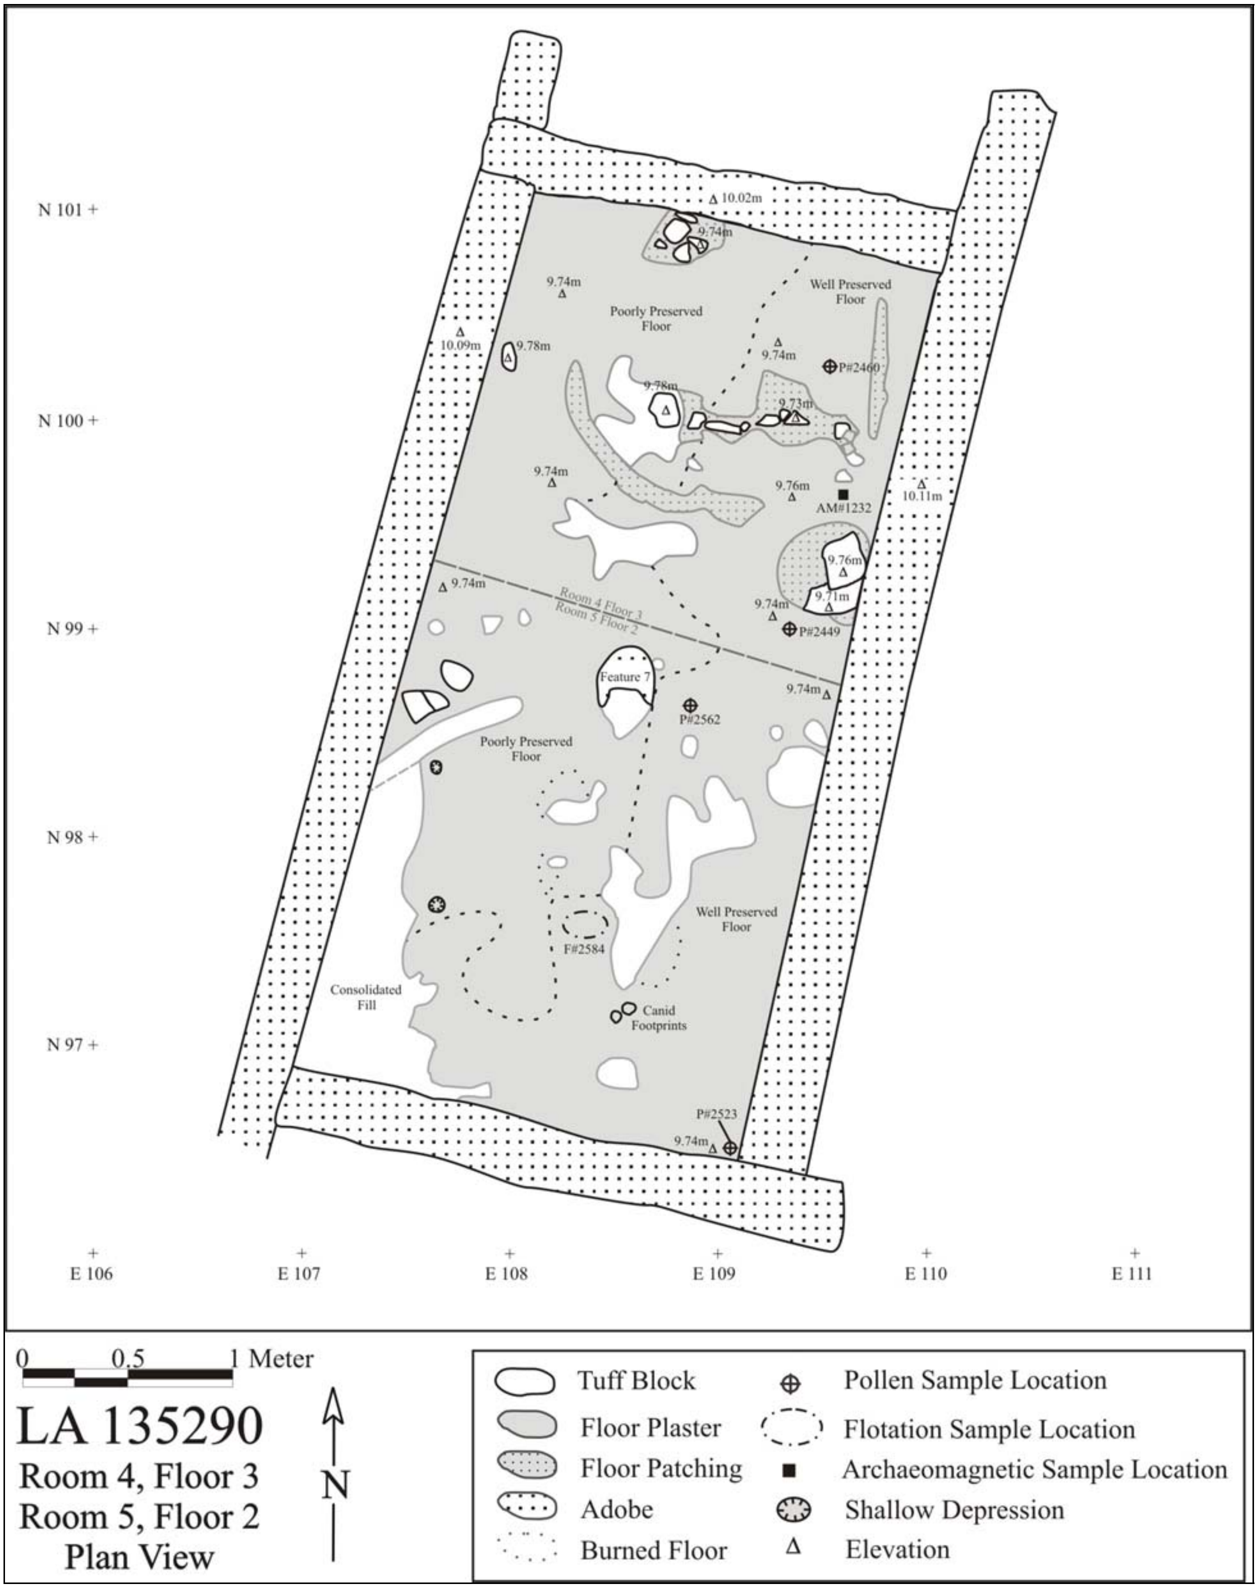

Figure 25.20. Room 4, Floor 3, and Room 5, Floor 2, plan view.

Floor 2 (Stratum 29) is the best-preserved floor in the room (Figures 25.21 and 25.22). It was constructed of clean adobe that was 3 to 4 cm thick. This floor is also partially burned, including the eastern and west-central floor areas. There are numerous small depressions in the well-preserved eastern section of the room. These depressions appear to be partial prints of the front heal of the foot, although most are indistinct. Other depressions are clear footprints, including the one located in grid N100/E109. All five toes and the arch and heel are clearly defined. A plaster caste was taken of the footprint (FS 2431), and pollen (FS 2161 and 2179) and flotation (FS 2219) samples were taken from Floor 2. Taxa identified in the pollen samples include cheno-ams, sunflower family, ragweed/bursage, pine, piñon pine, juniper, Mormon tea, and sagebrush. Carbonized taxa identified in the flotation sample include pigweed, goosefoot, grass family (Gramineae), juniper, mint family (Labiatae), and ponderosa pine.

Although no artifacts were found on the surface of the floor, three smeared-indented corrugated sherds and some charcoal (FS 2466, FS 2481, and FS 2483) were recovered from the floor matrix (Stratum 35). Taxa identified in the macrobotanical samples include juniper, piñon pine, unidentified pine, saltbush/greasewood, ponderosa pine, cottonwood/willow, and maize. Archaeomagnetic (set 1227) and TL (FS 2458) samples were taken from the floor. The burned adobe sample yielded a date of AD 888±62. The archaeomagnetic sample collected from Floor 2 consisted of seven specimens, and all were included in the calculation of the final result. The date range interpretation is AD 1180 to 1205. Comparison with the SWCV2000 curve yields a date range of AD 1125–1165, but it is believed that the SWCV2000 curve is inaccurate for this time period.

Figure 25.21. Photograph of Room 4, Floor 2 (east).

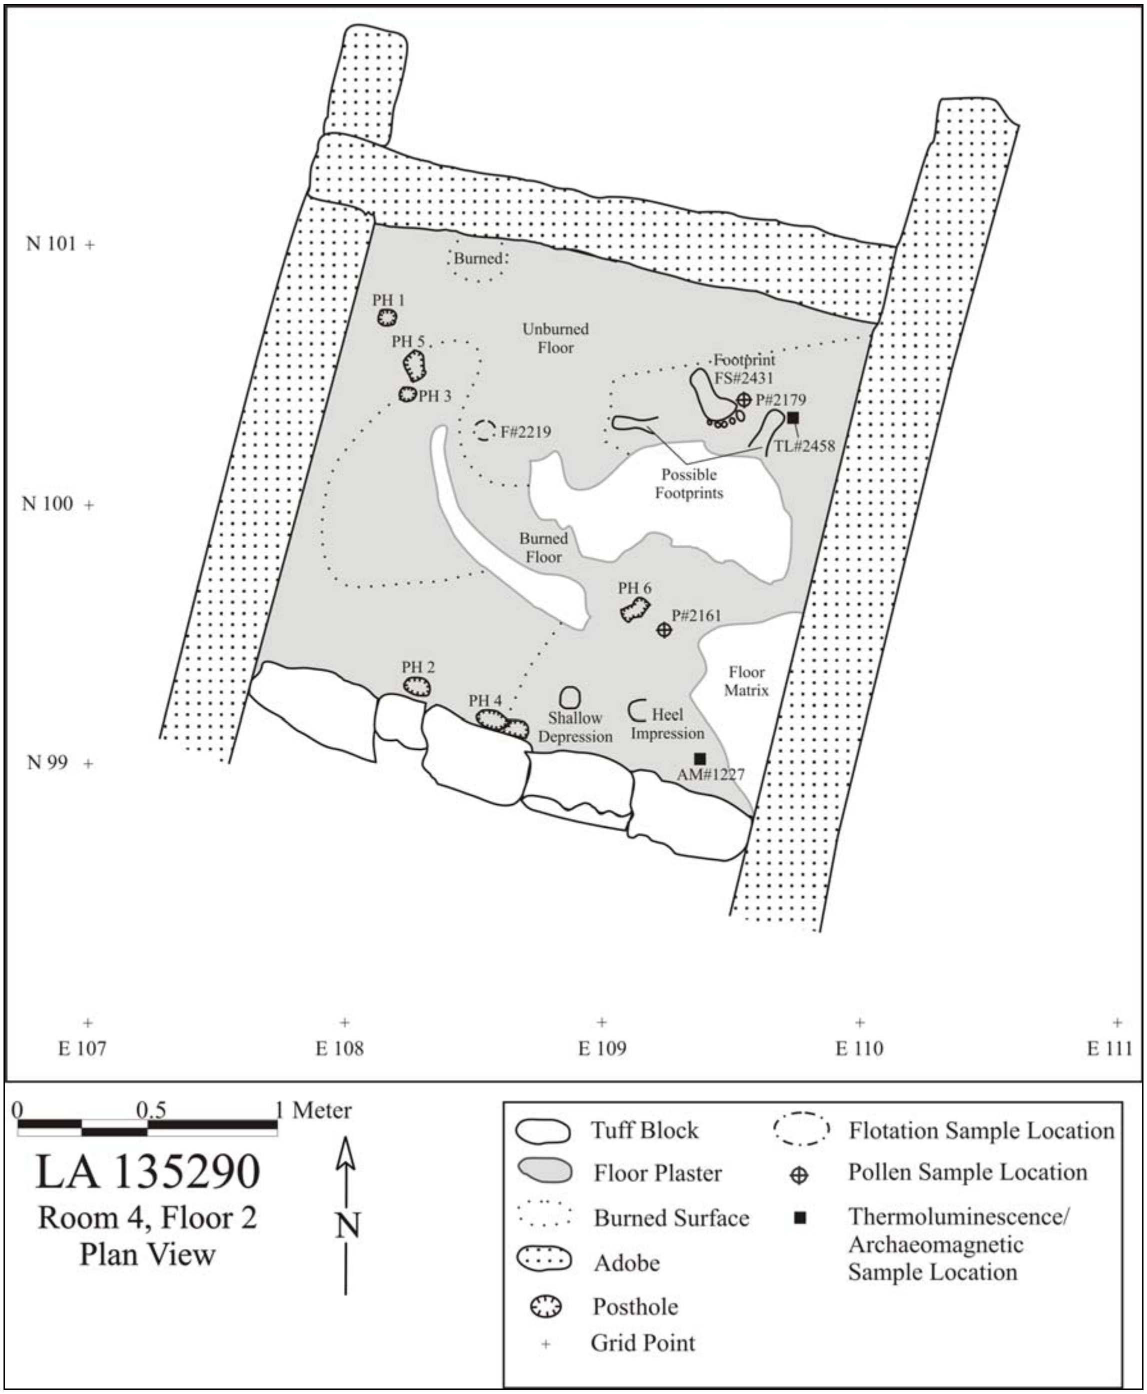

Figure 25.22. Room 4, Floor 2, plan view.

There are also a series of six postholes (Feature 10) present on Floor 2. Postholes 1 to 3 are circular in cross-section, with well-defined walls and vary from 4 to 9 cm in depth. In contrast, Postholes 4 to 6 are more irregular in shape and vary from 4 to 6 cm in depth. The latter holes are more ambiguous and may not be features. Pollen samples were taken from the fill (Stratum 30) of Postholes 1 (FS 2248) and 2 (FS 2249). Taxa identified in Posthole 1 include prickly pear, cheno-ams, grass family, sunflower family, ragweed/bursage, spurge family, evening primrose, fir, unidentified pine, piñon pine, juniper, and sagebrush. Taxa identified in Posthole 2 include maize, prickly pear, beeweed, lily family (Liliaceae), cheno-ams, grass family, sunflower family, ragweed/bursage, spurge family, evening primrose, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush.

As previously noted, the southern wall of Room 4 was constructed with Floor 2, thereby dividing Room 4 from Room 5. However, a small doorway was left at the eastern end of the wall, thereby allowing access between the rooms. The floor and adjacent wall where the doorway was located were burned, indicating that this access was open between the rooms. This doorway is visible in the Floor 3 photograph, but had not yet been identified when the Floor 2 photograph was taken. Room 4 was abandoned a second time, with rodent burrows (Stratum 40) removing sections of the floor. These holes were also filled with adobe and/or small pieces of tuff and then covered with Floor 1.

Floor 1 (Stratum 7) is the upper or most recent floor in the room (Figures 25.23 and 25.24). It consists of a two- to 4-cm-thick layer of adobe that covered the entire area of the room.

Figure 25.23. Photograph of Room 4, Floor 1 (looking east).

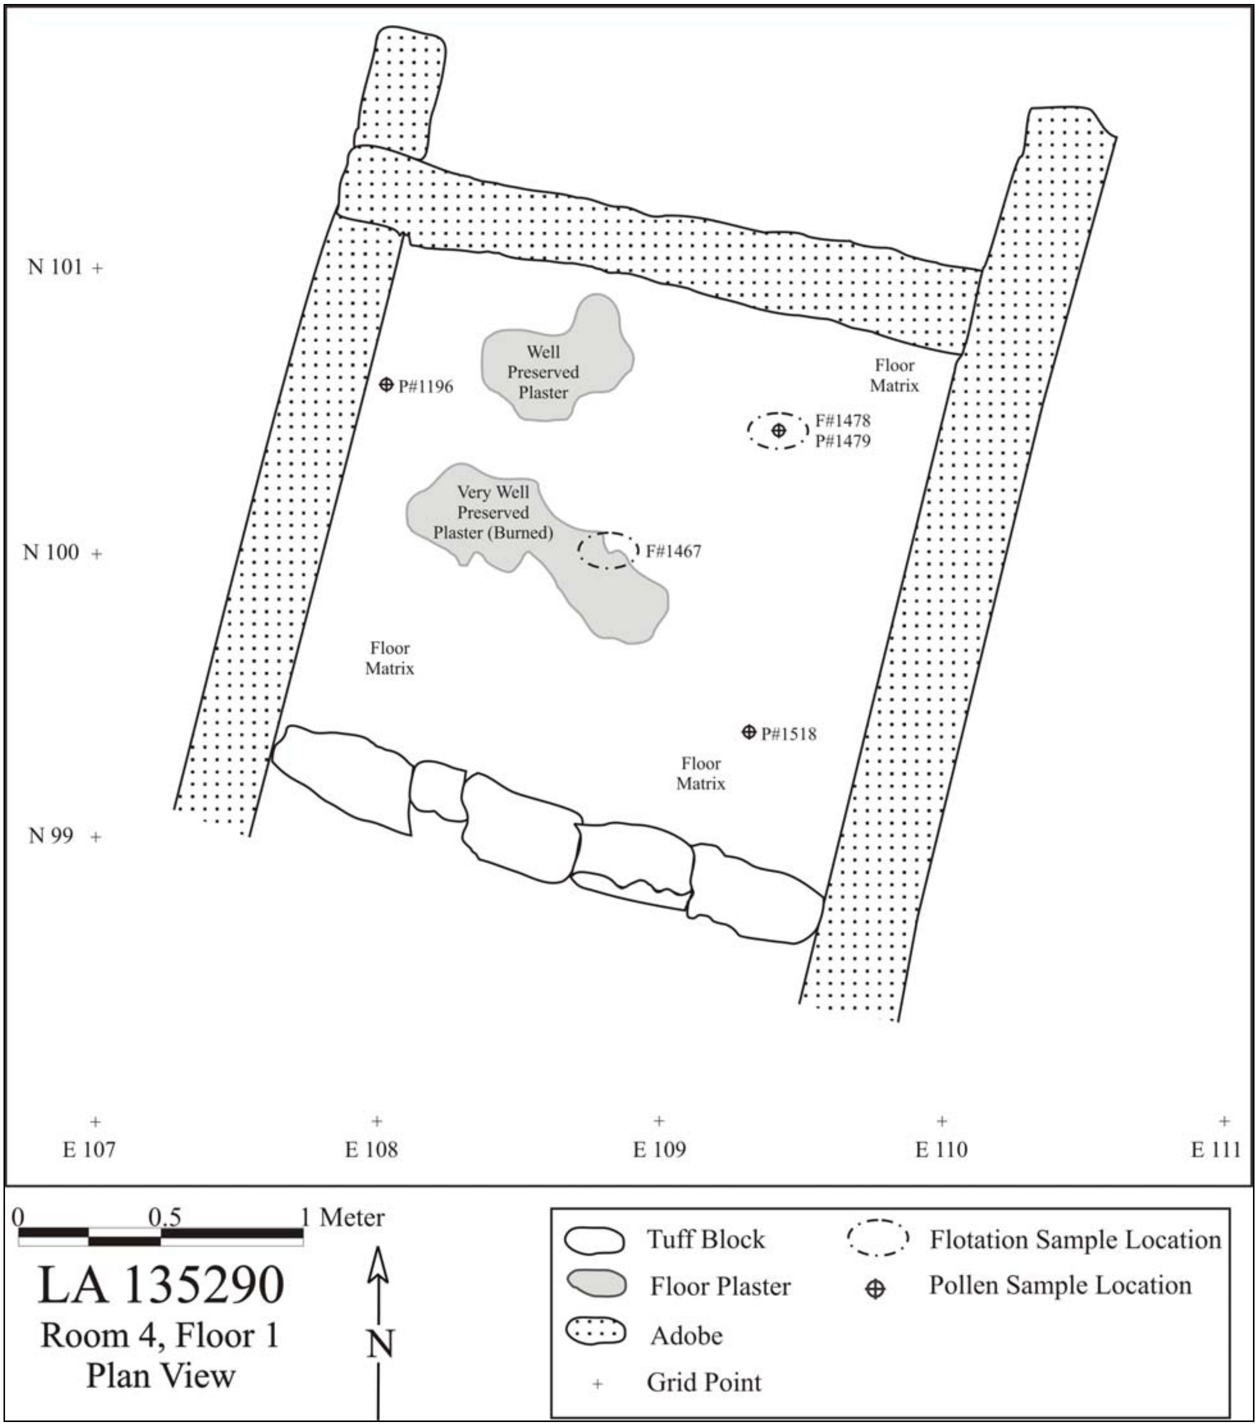

Figure 25.24. Room 4, Floor 1, plan view.

The floor was mostly unburned, except for a small heavily burned section in the middle of the floor. A small concentration of ash (Stratum 3b) was present on the floor and one pollen sample (FS 1479) was collected. Taxa identified in the pollen sample include prickly pear, cheno-ams, grass family, sunflower family, ragweed/bursage, fir, unidentified pine, piñon pine, juniper, squawbush (*Rhus* type), and sagebrush.

The rest of the floor surface is partially eroded, but the floor matrix was clearly distinguishable from the fill and underlying Floor 2 surface. Two pollen samples were taken from the eastern and western section of the floor (FS 1196 and FS 1518). Identified taxa include cheno-ams, grass family, sunflower family, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush. There are several unidentifiable impressions visible in the Floor 1 surface, including possible finger impressions. Otherwise, no features or floor artifacts were identified on the floor; although three smeared-indented and two indented corrugated sherds**,** a chalcedony core flake, and some charcoal (FS 2165, FS 2178, and FS 2199) were recovered from the matrix of the floor (Stratum 28). Identified macrobotanical taxa include saltbush/greasewood, unknown conifer, ponderosa pine, and maize. The doorway between Rooms 4 and 5 was sealed, separating the two rooms for the first time. Although Floor 1 articulates with most of the surrounding walls, it does not continue into adjacent Room 5 where the highest floor surface is situated several centimeters below Floor 1 in Room 4. This indicates that when Floor 1 was constructed in Room 4, no similar floor was constructed in Room 5. Room 4 was eventually abandoned for the last time.

Wall Construction. The east, west, and north walls of Room 4 are constructed of puddle adobe (Figure 25.25), while the south wall is constructed of masonry. The east wall is part of the central wall of the roomblock and is thicker than the other adobe walls surrounding the room. A TL sample (FS 1424) taken from a burned section of this wall yielded a date of AD 1035±77. As noted above, the south wall is a later addition that subdivided Room 4 from Room 5. There was a small doorway connecting the rooms. Otherwise, there is no evidence of any other doorways.

The east and west walls extend outside the north wall for about 50 to 90 cm. These sections appear to reflect some form of buttress. Subfloor adobe footings about 20 cm thick are present under the north, west, and east walls. Room 4 wall measurements are provided in Table 25.11.

Table 25.11. Room 4 wall measurements.

Artifacts and Samples. Artifacts and pollen, flotation, and macrobotanical samples were selected from grids 99N/108E and 100N/108-109E. In addition, samples were selected from floor contexts. Tables 25.12 and 25.13 provide summary information on artifacts by stratigraphic unit and samples selected for analysis in Room 4.

Room 5

Sequence of Excavation. Room 5 is located in the northwestern area of the roomblock. It measures 2.25 m north-south by 2.15 m east-west, with 4.84 m^2 of interior space. An east-west test trench (98N/107-109E) was excavated through the room to define site stratigraphy and the location of the floor. The excavation proceeded by removing the room fill by grid and natural layer to the south of the trench.

Fill. After the removal of a 10-cm-thick layer of post-occupational fill (Strata 1 and 2), most of the room fill consisted of 40 to 50 cm of Stratum 3, with some Stratum 4. Stratum 4a/4b were situated adjacent to the east wall of the room. In contrast, Stratum 3a was situated in the western area of the room and Stratum 3c was adjacent to the base of the walls. Pollen, flotation, and macrobotanical samples were taken from Strata 2 and 3 (see Table 25.16). Taxa identified in the pollen samples include prickly pear, grass family, cheno-ams, mustard family, sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon pine, juniper, oak, rose family, Mormon tea, and sagebrush. Only one taxon (goosefoot) was identified in the flotation sample. Taxa identified in the macrobotanical samples include maize, mountain mahogany, juniper, bean, ponderosa pine, and cottonwood/willow. One of the macrobotanical samples (FS 902) includes a section of a burned juniper branch from Stratum 3.

Floor. Two separate floors were identified in Room 5. Floor 2 (Strata 42 and 49) is the lowest and original floor and is equivalent to Floor 3 in Room 4 (Figures 25.20 and 25.26). Both rooms were connected as a single room during this period, measuring 4.40 by 2.15 m in size and containing 9.46 m^2 in area. This is similar to the adjacent back room (Room 6) that contains 9.78 m^2 of space. Floor 2 was constructed by placing down a layer of adobe that had a thin layer of plaster on top. This contrasts with the upper floor in Room 5 and upper floors in Room 4 (Floors 1 and 2), which were solely constructed of a single thick layer of adobe that was used to fill the rodent holes. Floor 2 is only burned in a few small patches in the center of the room and has been heavily disturbed by rodent activity. However, unlike Room 4, most of this disturbance appears to postdate the site occupation as is evidenced by rodent holes that were filled with loose sediment and modern plant remains (e.g., pine nut shells). The only exception to this is the large rodent disturbance located in the southwest corner of the room. This disturbance was cleaned out and filled in before the construction of Floor 1. Again, unlike Room 4, it was filled in with normal sediment rather than hardened adobe. It is possible that sediment rather than adobe was used because of the large size of the area to be filled in.

Figure 25.26. Photograph of Room 5, Floor 2 (east).

A single feature was identified on Floor 2. The feature consists of an adobe-lined pit (Feature 7) located in the west-central area of the room. The pit measures 30 by 36 cm in diameter and is 11 cm deep. The plaster lining is still intact in the northern section of the pit and exhibits no evidence of burning or a collar. A set of dog or coyote footprints were present on the south-central section of the floor, but no other artifacts were identified. Pollen samples (FS 2523 and FS 2562) were taken from the southeast and north-central sections of the floor, respectively. FS 2523 included maize, prickly pear, cheno-ams, grass family, pea family (Fabaceae), sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon pine, juniper, oak, rose family, and sagebrush. FS 2562 included prickly pear, grass family, cheno-ams, sunflower family, spurge family, fir (*Abies*), unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush. The single flotation sample (FS 2584), which was taken from the central area of the floor, included goosefoot, sunflower family, unknown conifer, and evening primrose (*Oenothera*).

Floor 1 (Strata 21 and 41) is very well preserved and covers the entire room, although the surface is eroded (Figures 25.27 and 25.28). It is mostly unburned but does exhibit some burning in the central, west-central, and northeast sections of the room. The northern dividing wall was built during this period, thereby separating Rooms 4 and 5. However, Floor 1 does extend under the eastern end of the wall, thereby connecting with Floor 2 in Room 4. A doorway appears to have existed in this location. Pollen (FS 1991 and FS 2043) and flotation (FS 1999, FS 2023, and FS 2057) samples were taken from the surface of Floor 1 (Stratum 21), and two flotation samples (FS 2526 and FS 2561) were taken from the floor matrix (Stratum 41). Taxa identified in the Floor 1 pollen samples include maize, prickly pear, beeweed, cheno-ams, grass family, sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon pine, juniper, oak, rose family, and sagebrush. Taxa identified in the Floor 1 flotation samples include pigweed, saltbush/greasewood, mountain mahogany, goosefoot, cheno-ams, squash/coyote gourd (*Cucurbita*), juniper, pincushion cactus (*Mammillaria*), unidentified pine, piñon pine, ponderosa pine, cottonwood/willow, purslane, knotweed family (Polygonaceae), oak, dropseed grass, and maize.

Figure 25.27. Photograph of Room 5, Floor 1 (east).

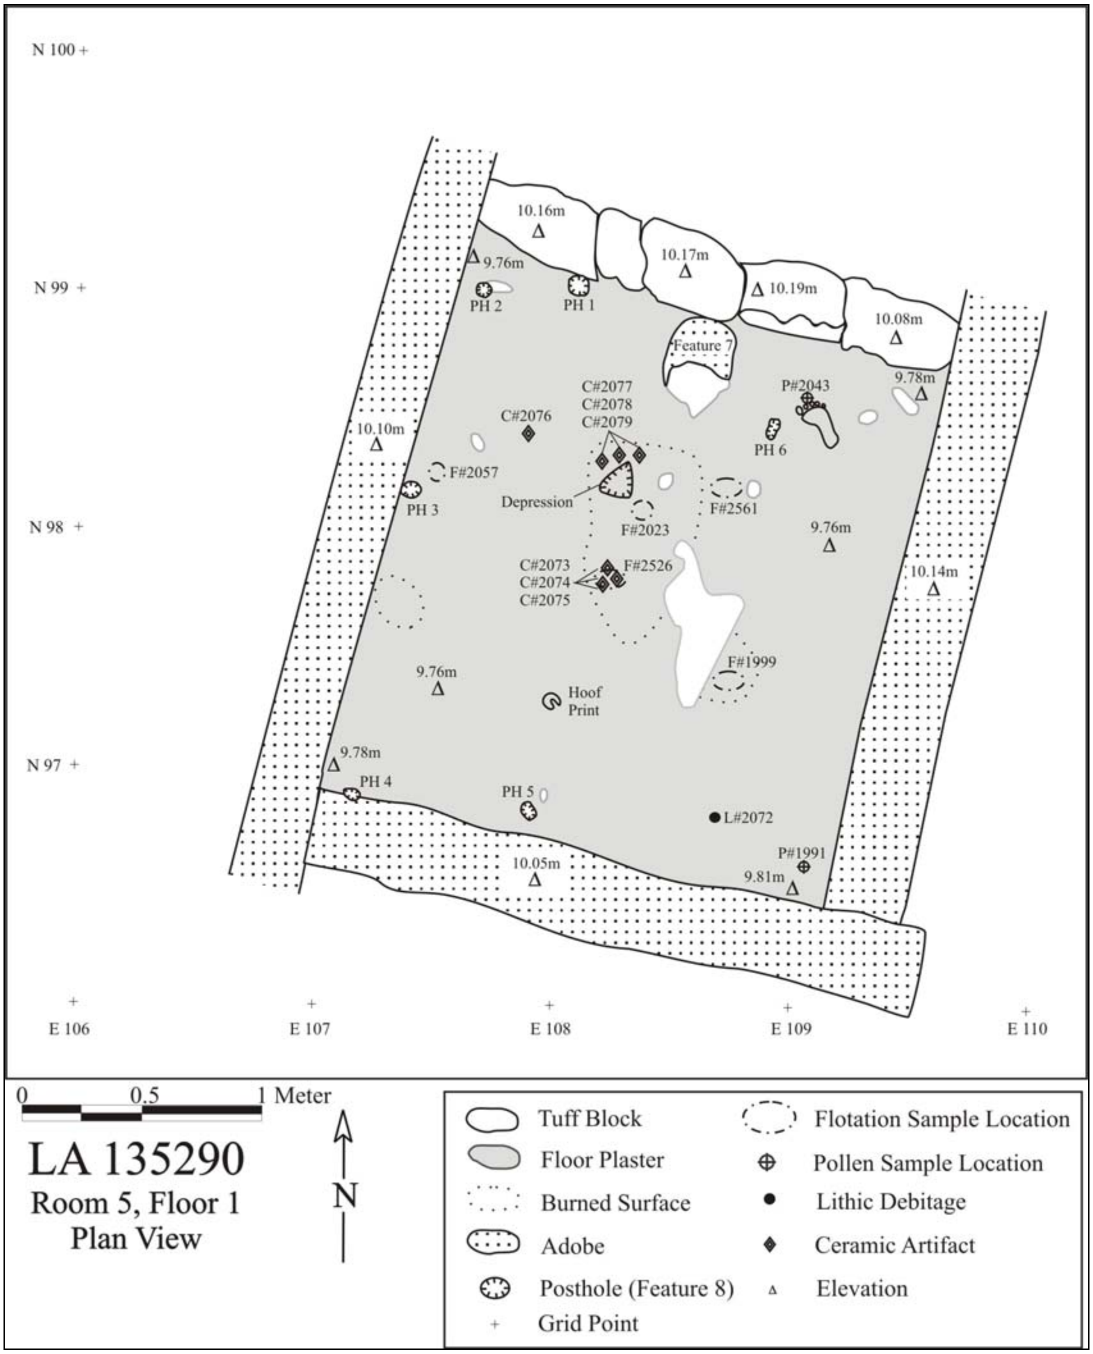

Figure 25.28. Room 5, Floor 1, plan view.

Two features were identified on Floor 1. Feature 7 continued to be used during the occupation of Floor 1, with the sides of the pit being coped to this upper floor. The fill (Stratum 22) consisted of a silty loam mixed with bits of charcoal and burned adobe. A flotation (FS 2027) and pollen (FS 2028) sample were both taken. Carbonized taxa identified in the flotation sample included pigweed, saltbush/greasewood, goosefoot, cheno-ams, sunflower family, unknown conifer, mint family (Labiatae), pincushion cactus, ponderosa pine, purslane, dropseed grass, and maize. Taxa identified in the pollen sample included prickly pear, beeweed, cheno-ams, grass family, sunflower family, spurge family, unidentified pine, piñon pine, juniper, and sagebrush.

Feature 8 consists of six possible postholes. The postholes are distributed in a westward-facing arc across the western half of the room. This is similar to the posthole pattern observed in adjacent Room 6. The single exception is Posthole 6, which is located in the northeast corner of the room near Feature 7. The postholes were generally circular in cross-section with well-defined sides and bottoms. The postholes measured about 5 to 7 cm wide and 5 to 14 cm deep. Pollen samples were taken from the fill (Stratum 27) of Posthole 1 (FS 2104) and Posthole 3 (FS 2105). This fill was identical to sediment present immediately above the floor surface. Taxa identified in Posthole 1 included maize, prickly pear, cactus family (Cactaceae), beeweed, cheno-ams, grass family, pea family, sunflower family, ragweed/bursage, penstemon family (Scrophulariaceae), unidentified pine, piñon pine, juniper, oak, rose family, Mormon tea, and sagebrush. Taxa identified in Posthole 3 included maize, cheno-ams, grass family, sunflower family, ragweed/bursage, evening primrose family (Onagraceae), fir, unidentified pine, piñon pine, juniper, oak, and sagebrush.

Three Santa Fe Black-on-white sherds, a smeared-indented corrugated sherd, three plainware body sherds (FS 2073 to FS 2079), and a chalcedony core flake (FS 2072) were found lying directly on the floor. In addition, three Santa Fe Black-on-white sherds, six smeared-indented corrugated sherds, three plainware body sherds, and two clay balls were recovered from the floor matrix. Besides these artifacts, a human footprint was present in the northeast corner of the room and a deer footprint was identified in the south-central section of the floor.

Wall Construction. The south, east, and west walls of Room 5 were constructed of adobe (Figure 25.29). These walls are about 30 to 40 cm high and 25 to 30 cm wide. In contrast, the north wall is constructed of tuff block masonry that is three courses high (40 cm) and about 25 cm wide (Figure 25.30). This wall does not fit the original roomblock design and represents a later addition that divided a single large room into two separate rooms (4 and 5). This event was associated with the construction of Floor 2 in Room 4 and Floor 1 in Room 5. The foundation of the wall consisted of the basal stones that were set into the original floor of the room. A narrow 50 cm wide entryway was left at the eastern end of the north wall, which left access between the two rooms. Both sides of the wall that were adjacent to the doorway were burned, which indicated that the doorway was open during this period. A TL sample (FS 1424) was taken from the burned section of the wall. The sample dated to 977±75. The doorway was subsequently sealed during the construction of Floor 1 in Room 4. No other doorways were identified in the roomblock.

Figure 25.29. Photograph of Room 5, south wall.

Room 5 wall measurements are provided in Table 25.14. Subfloor adobe footings about 20 cm thick are present under the east, west, and south walls.

Artifacts and Samples. Artifacts and pollen, flotation, and macrobotanical samples were selected from grids 97N/108-109E. In addition, samples were selected from floor contexts. Tables 25.15 and 25.16 provide summary information on artifacts by stratigraphic unit and samples selected for analysis in Room 5, respectively.

Room 6

Sequence of Excavation. Room 6 is located in the southwest area of the roomblock. The room measures 1.75 m north-south by 1.75 m east-west, with 3.06 m^2 of interior space. An east-west test trench (93N/106-108E) was also excavated through the room to define site stratigraphy and the location of the floor. The excavation proceeded by first removing the fill to the north of the trench and then to the south by grid and natural layer.

Fill. After 10 cm of post-occupational fill (Strata 1 and 2) was removed, most of the remaining room fill consisted of 30 to 40 cm of Stratum 3. Stratum 4 was only defined in a small area in the south part of the room. Pollen, flotation, and macrobotanical samples were taken from Strata 2, 3a, and 3b (see Table 25.19). Taxa identified in the pollen samples collected from the fill levels include beeweed, grass family, cheno-ams, sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon pine, juniper, rose family, and sagebrush. Taxa identified in the fill flotation samples include saltbush/greasewood, goosefoot, juniper, unidentified pine, unknown conifer (Gymnospermae), piñon pine, ponderosa pine, and maize. Taxa identified in the macrobotanical samples include mountain mahogany, unknown conifer, bean, unidentified pine, piñon pine, ponderosa pine, cottonwood/willow, oak, and maize.

Floor. Three distinct floors were identified in Room 6. Floor 3 (Stratum 8) is the lowest and the original floor that covers the entire area of Room 6 (Figures 25.31 and 25.32). It consists of a 3- to 4-cm-thick layer of adobe that has been hardened and blackened by burning in most areas, with a few rodent-disturbed spots. There are, however, some unburned areas situated adjacent to the walls in the southern area of the room. A human handprint is visible in the northwest corner of the room. Pollen (FS 1899) and flotation (FS 1890) samples were taken from the surface of Floor 3. Taxa identified in the pollen sample include prickly pear, cheno-ams, grass family, sunflower family, ragweed/bursage, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush. Carbonized taxa identified in the flotation sample taken on Floor 3 include cheno-ams and dropseed grass. A pollen (FS 1432) and flotation (FS 1589) sample were also taken from ashy sediment and a charcoal concentration present on the north-central section of the floor. Taxa identified in the pollen sample include maize, cheno-ams, grass family, sunflower family, penstemon family, fir, unidentified pine, piñon pine, juniper, rose family, Mormon tea, and sagebrush. Charred taxa identified in the flotation sample in the ashy concentration include piñon pine, ponderosa pine, Douglas fir (*Pseudotsuga menziesii*), oak, and maize. Portions of a small, burned ponderosa pine roof beam (FS 1587) were found in the central area of the floor where the area was extremely burned. Taxa identified in the other macrobotanical samples include unknown conifer, bean, unidentified pine, ponderosa pine, oak, cottonwood/willow, and maize.

Figure 25.31. Photograph of Room 6, Floor 3 (east).

Two archaeomagnetic samples were taken from Room 6 (sets 1226 and 1228). Results show that Room 6 experienced multiple burning incidents. Floor 3 was the original floor of the room. After a period of use, the room burned, burning the floor and littering the floor with charcoal and other structural debris (set 1226). Floor 2 was constructed on top of this debris, and it also was burned after a period of use. No archaeomagnetic samples were collected from Floor 2, but a set was collected from the east wall of the room, above the level of Floor 2 (1228). This wall would have been affected by the burning incidents associated with both Floors 3 and 2, but the Floor 2 incident would have erased the magnetic orientation created by the Floor 3 burn if the original burning reached equivalent or higher temperatures. Evidence of a final floor (Floor 1) was preserved as a large unburned adobe patch in the fill above Floor 2. Floor 1 was not visibly burned. The eight specimens collected from Floor 3 (1226 yielded a date range estimate of AD 1170–1210. The date range based on the SWCV2000 curve again appears to be too early (AD 1125–1175). The six specimens collected from the wall of the room (1228) were collected between 16 and 25 cm above Floor 3, and at that elevation they would have been affected by the fire that is associated with Floor 2 as well as that of Floor 3. Assuming that the Floor 2 fire generated a similar or greater heat than the Floor 3 fire, the magnetic orientation of this set would have been determined by the Floor 2 fire alone. The date range estimate from the Wolfman curve is AD 1185–1230. The corresponding date estimate based on the SWCV2000 curve is AD 1020–1110, which is an unlikely calibration for this time period.

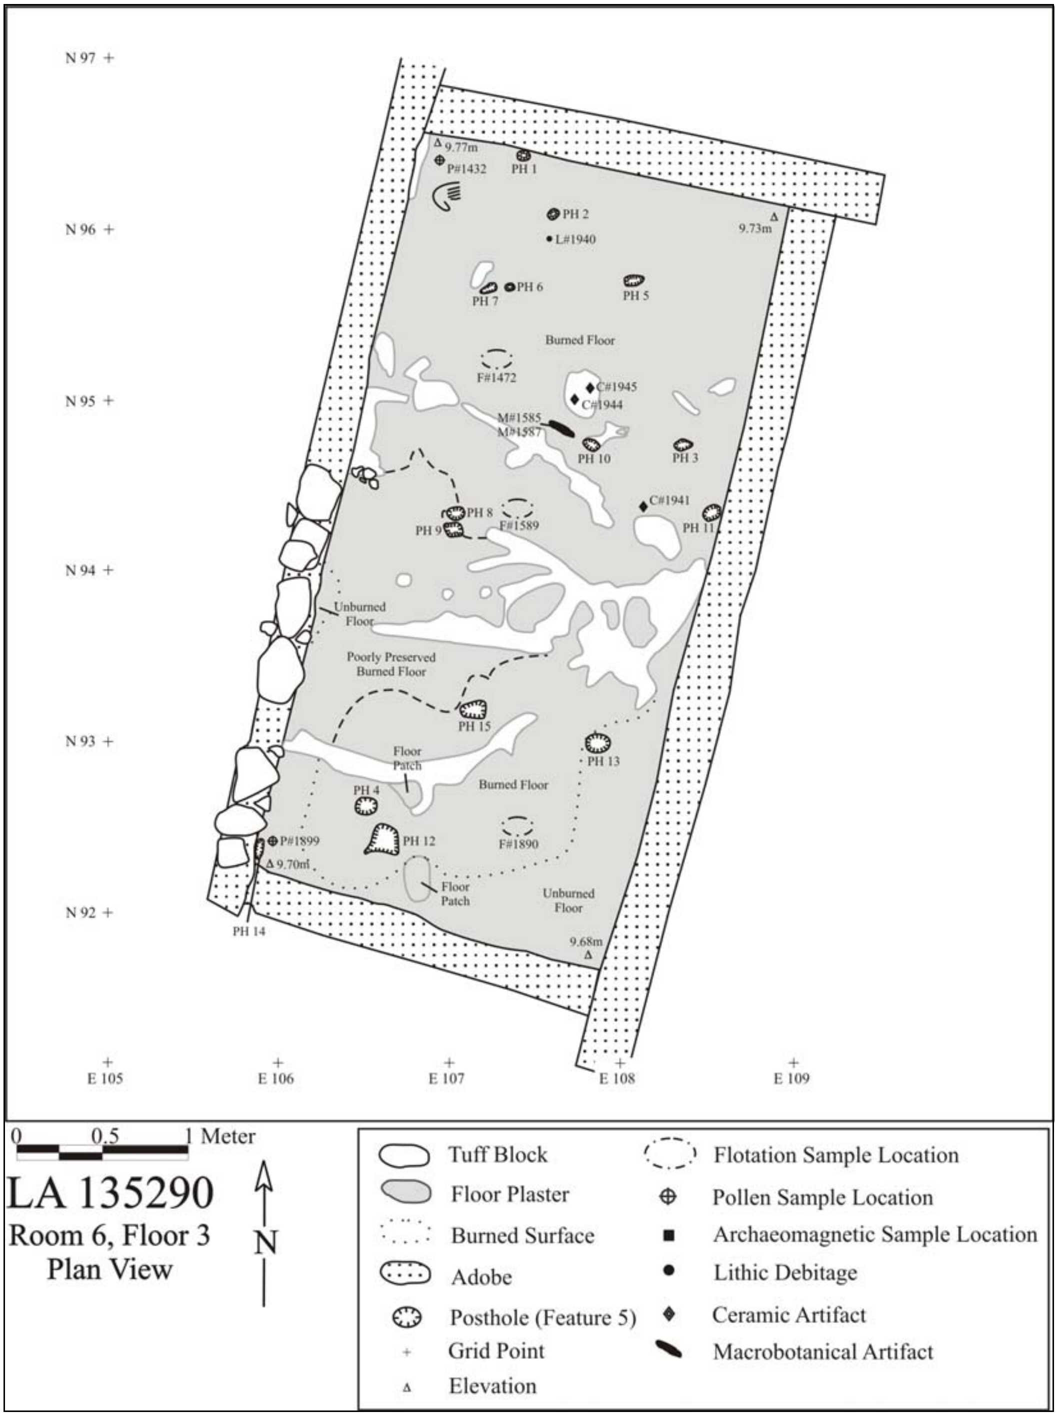

Figure 25.32. Room 6, Floor 3, plan view.

Eleven possible postholes (Feature 5) were identified on Floor 3 (Figure 25.33). The postholes were circular to oval in cross-section and were 5 to 10 cm in diameter and 7 to 14 cm in depth. Most of the posthole fill was similar to the sediments overlying the floor, but Posthole 4 contained a lot of charcoal and ash (Stratum 20).

Figure 25.33. Room 6 postholes (northeast).

A single posthole (15) was patched with adobe. A smeared-indented corrugated sherd was recovered from the fill of Posthole 14 and a chalcedony core flake (FS 1940) and three smeared-indented corrugated sherds (FS 1941, FS 1944, and FS 1945) were recovered from the floor. Pollen samples were taken from Postholes 1 (FS 1920) and 4 (FS 1923). Taxa identified in

Posthole 1 included maize, cheno-ams, grass family, sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon pine, juniper, oak, rose family, Mormon tea, and sagebrush. Taxa identified in Posthole 4 included maize, cheno-ams, grass family, sunflower family, spurge family, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush.

Floor 2 (Strata 17 and 18) is the middle floor of Room 6 (Figure 25.34). Like Floor 3, Floor 2 is also in very good condition, having been heavily burned. However, the floor represents a large adobe patch to Floor 3 situated in the south side of the room.

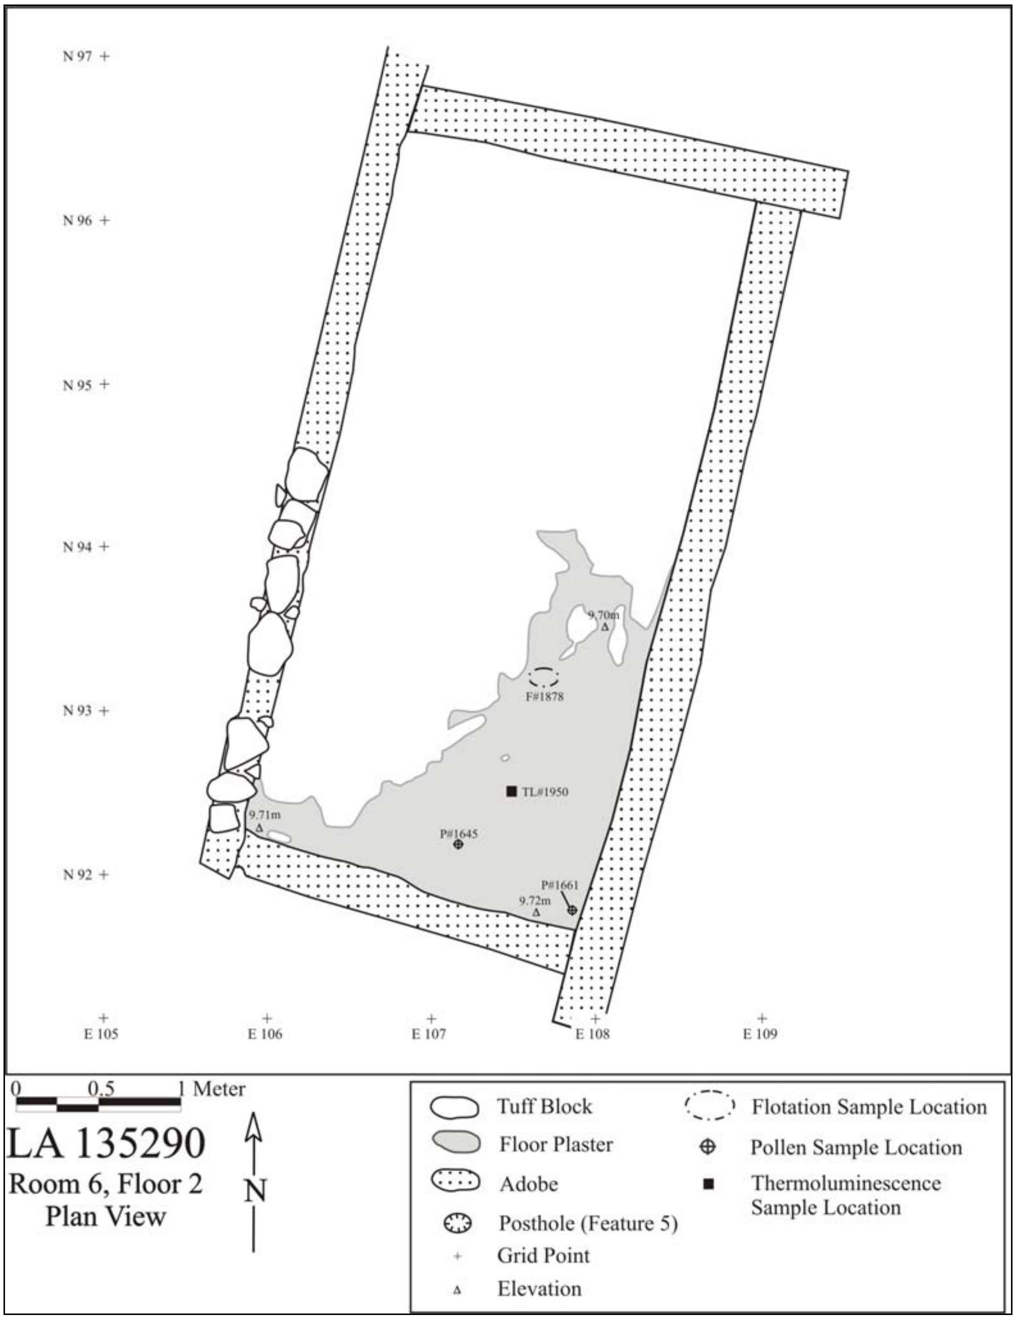

Figure 25.34. Room 6, Floor 2, plan view.

The area was presumably patched due to rodent disturbance or heavy burning. No features or artifacts were associated with this section of the floor. Pollen (FS 1645 and FS 1661) and flotation (FS 1878) samples were taken from the floor. Taxa identified in the pollen samples included maize, prickly pear, beeweed, cheno-ams, grass family, sunflower family, ragweed/bursage, spurge family, fir, unidentified pine, piñon pine, juniper, rose family, Mormon tea, and sagebrush. No carbonized taxa were identified in the flotation sample collected from Floor 2. A TL sample (FS 1950) taken from the burned floor yielded a date of AD 1134±79.

Floor 1 (Strata 12 and 15) is the uppermost floor in Room 6 (Figures 25.35 and 25.36). This floor exhibits a large adobe patch in the central part of the room that could have been used to fill some rodent disturbance or burned area, but it is not burned. Pollen (FS 1852) and flotation (FS 1851) samples were taken from the floor. Taxa identified in the pollen sample included squash (*Cucurbita*), maize, cholla (*Opuntia*), prickly pear, parsley family (Apiaceae), cheno-ams, grass family, sunflower family, ragweed/bursage, evening primrose, unidentified pine, piñon pine, juniper, and sagebrush. Carbonized taxa identified in the flotation sample included pigweed, cheno-ams, juniper, and ponderosa pine. Silicified wood and obsidian flakes were present on the floor.

Figure 25.35. Photograph of Floors 1 and 3.

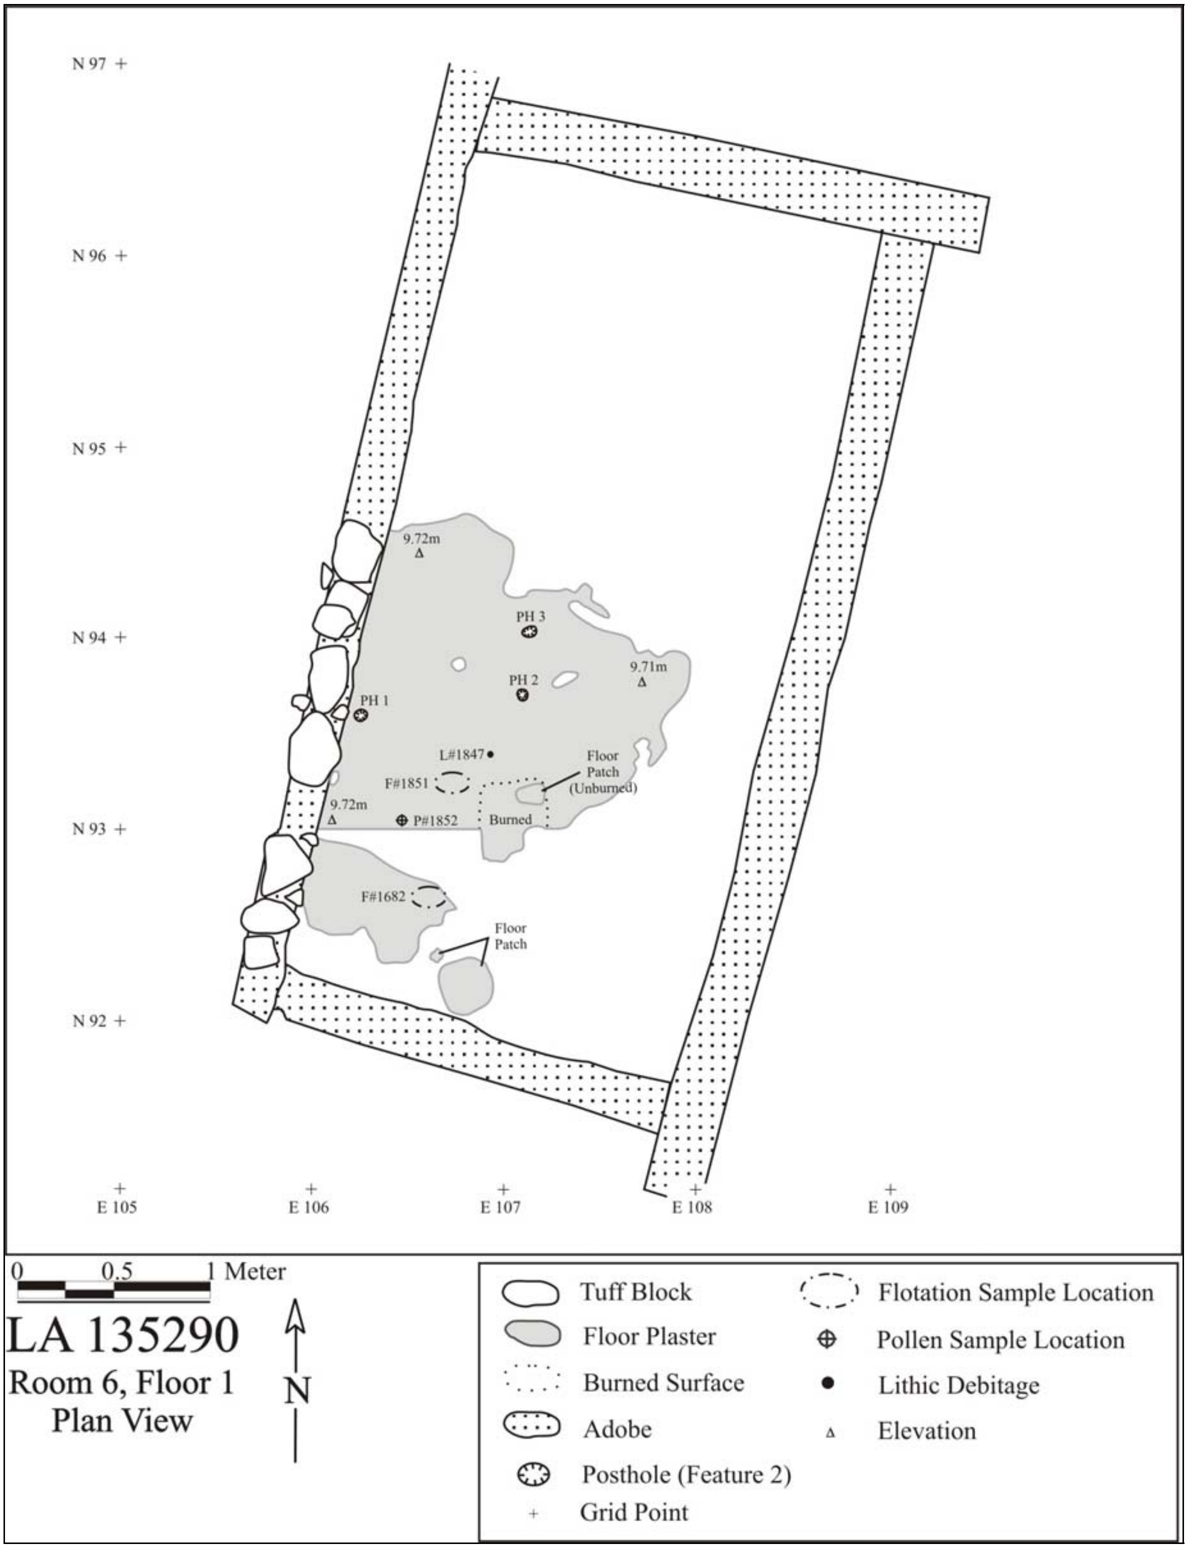

Figure 25.36. Room 6, Floor 1, plan view.

A single feature (Feature 2, three postholes) and a silicified wood core flake (FS 1847) were associated with the floor (Figure 25.37). All three postholes were circular-shaped and were approximately 5 cm in diameter and 10 cm deep. Pollen samples were taken from the fill (Stratum 14) of two postholes (FS 1820 and FS 1821). Identified taxa included prickly pear, beeweed, cheno-ams, grass family, sunflower family, spurge family, evening primrose (*Oenothera*), fir, unidentified pine, piñon pine, juniper, oak, cottonwood/willow, rose family, Mormon tea, and sagebrush.

Figure 25.37. Room 6, Floor 1, Feature 2 postholes (west).

The sub-floor deposit (Stratum 46) was a silty clay layer that was 15 to 20 cm thick, which was situated on top of the Bwb1 soil horizon. This stratum represents artificial fill that was brought to the site to level the area where the roomblock was constructed.

Wall Construction. All four walls of Room 6 are constructed of adobe and stand to a height of about 30 to 50 cm. The west wall also has two courses of unshaped tuff capping the adobe wall, as well as some wallfall outside of the wall. At least some of the wall was constructed with an adobe lower section and masonry upper section. Much of the surface of these walls was heavily burned, including the northeast corner, the northwest corner, and the southern one-third of the room (especially the east wall, but some on the south and west walls). A TL (FS 1738) and archaeomagnetic (set 1228) sample were taken from the west wall (Figure 25.38). The TL sample yielded a date of AD 1114±85 and the archaeomagnetic sample yielded a date of AD 1185 to 1230.

Figure 25.38. Burned west wall in Room 6.

Room 6 wall measurements are provided in Table 25.17. There is no evidence of doorways in any of the walls. Subfloor adobe footings about 20 cm thick are present under the north, south, east, and west walls.

Room 7

Sequence of Excavation. Room 7 is located in the southwestern corner of the roomblock. It measures 4.55 m north-south by 2.20 m east-west, with 10.01 m^2 of interior space. The excavation proceeded from north to south by grid and natural layer.

Fill. Deposits in Room 7 were quite shallow, in part reflecting the lack of wallfall in the room fill. Post-occupational deposits (Strata 1 and 2) were only 5 to 10 cm thick, with the room fill primarily consisting of 20 to 30 cm of Stratum 3, with some Stratum 4. The limited amount of wallfall was situated in the northwest and east-central sections of the room adjacent to masonry walls. Pollen, flotation, and macrobotanical samples were taken from Strata 3 and 4 (see Table 25.22). Taxa identified in the pollen samples included maize, beeweed, cheno-ams, grass family, mustard family, pea family, sunflower family, spurge family, unidentified pine, piñon pine, juniper, oak, birch (*Betula*), sedge (Cyperaceae), and sagebrush. Charred taxa identified in the flotation samples included saltbush/greasewood, piñon pine, ponderosa pine, oak, and maize. Taxa identified in the macrobotanical samples included mountain mahogany, unidentified pine, piñon pine, ponderosa pine, cottonwood/willow, bean, and maize.

Floor. There is no prepared floor in Room 7 (Figures 25.39 and 25.40). The floor (Stratum 33) simply consists of a compact living surface situated at the same level as Floors 1 and 2 in Room 6. The surface is generally in poor condition, but is best-preserved in the northern part of the room and in a small section in the southeast corner of the room. Otherwise, both erosion and root disturbance have greatly impacted the southern area of Room 7.

Figure 25.39. Photograph of Room 7 (east).

No floor features were identified, however, several artifacts were found lying directly on or embedded into it. These artifacts consist of a red burned shale bead (FS 2317), a grinding slab (FS 2396), dacite and quartzite pebbles with ground surfaces (FS 2397 and FS 2399), and two Wiyo Black-on-white sherds (FS 2400 and FS 2401). One of these sherds was submitted for TL dating and provided a date of AD 1217±56. Pollen samples were taken from underneath the grinding slab (FS 2398**)** and the two sherds. Identified taxa included squash, maize, cholla, cheno-ams, grass family, mustard family, sunflower family, ragweed/bursage, unidentified pine, juniper, and sagebrush.

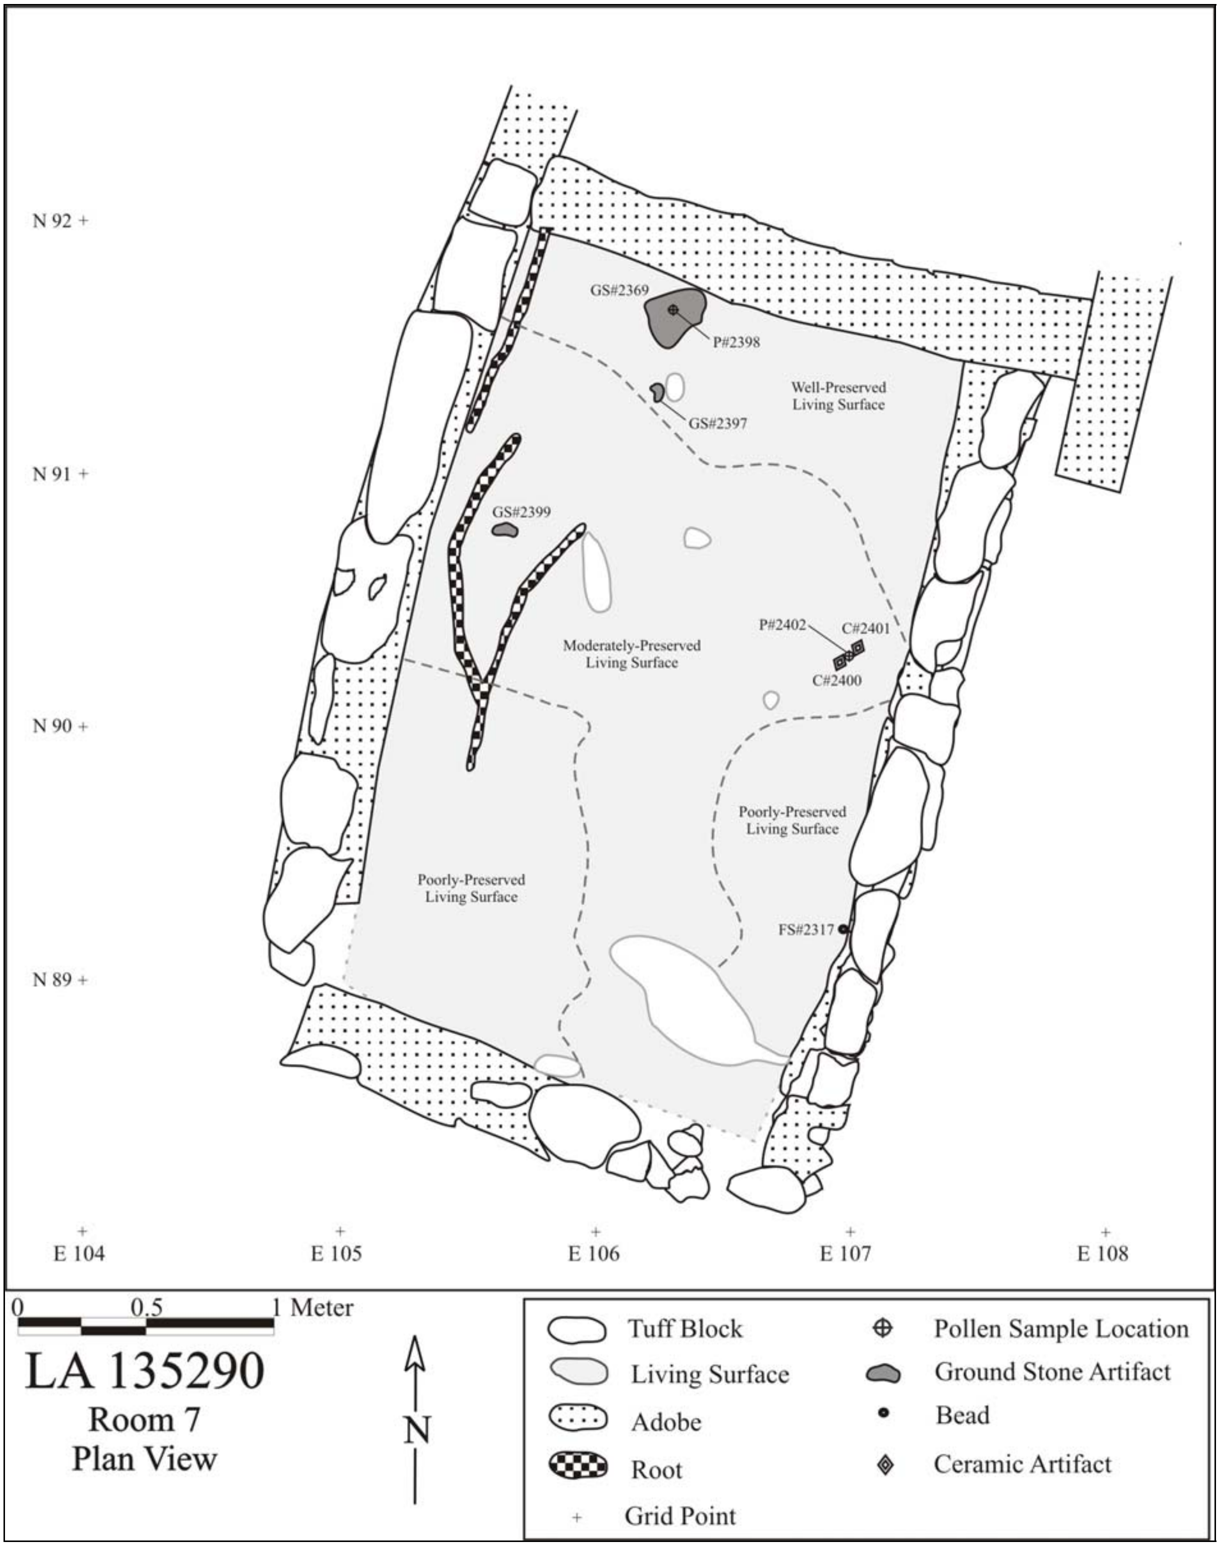

Figure 25.40. Room 7 plan view.

Wall Construction. The north wall of Room 7 is constructed of adobe. This wall is presumably the original southern wall to the roomblock. Both Rooms 3 and 7 appear to be later additions. For example, the eastern wall of Room 7 is offset with the east wall of Rooms 4 to 6, with the former being constructed of tuff blocks and the latter of adobe. The west wall of Room 7 is also constructed of tuff blocks with a shallow adobe foundation in its northern section. This wall does line up with the west wall of Rooms 4 to 6. The southern wall of the Room 7 is constructed of tuff blocks, but is in very poor condition, especially in the southwest corner of the room. The low wall height (10 cm) and paucity of wallfall may indicate that the south wall was not a full standing wall.

Room 6 wall measurements are presented in Table 25.20. There is no evidence of doorways in any of the walls. Subfloor adobe footings that are about 20 to 25 cm thick are present in the north, east, and west walls.

Table 25.20. Room 7 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	# Courses

South	1.85	0.10	0.25	1
East	3.17	0.30	0.25	2
West	3.05	0.35	0.23	1

Artifacts and Samples. Artifacts and pollen, flotation, and macrobotanical samples were selected from grids 89-91N/106E. In addition, samples were selected from floor contexts. Tables 25.21 and 25.22 provide summary information on artifacts by stratigraphic unit and samples selected for analysis in Room 7, respectively.

Room 8

Sequence of Excavation. Room 8 is located in the northeastern corner of the roomblock. It measures 4.10 m north-south by 2.80 m east-west, with 11.48 m^2 of interior space. The excavation proceeded north to south by grid and natural layer.

Fill. Deposits in Room 8 were somewhat shallower, since the room is situated at the eastern edge of the mound. Stratum 1 is only about 5 cm thick, with 20 cm of Stratum 4 mostly situated adjacent to the west wall and a similar thick layer of silty loam (Stratum 13) present in the northern area of the room near a tree stump. These deposits were underlain with approximately 10 cm of Stratum 3. No wallfall was identified adjacent to the east wall. Pollen, flotation, and macrobotanical samples were taken from Strata 3 and 4 (see Table 25.25). Taxa identified in the pollen samples included maize, prickly pear, parsley family, cheno-ams, grass family, sunflower family, spurge family, unidentified pine, piñon pine, juniper, rose family, Mormon tea, and sagebrush. Taxa identified in the flotation samples included unknown conifer, juniper, piñon pine, ponderosa pine, maize, and oak. Taxa identified in the macrobotanical samples included unidentified pine, ponderosa pine, and cottonwood/willow.

Floor. The floor (Stratum 23) is poorly preserved in Room 8, having been disturbed by rodent activity and roots (Figures 25.41 and 25.42). However, there are several small intact sections that consist of 6 to 7 cm of adobe with a thin plaster wash. These small patches are preserved in the area of the west and north walls. There were a few tiny burned spots on the floor, but it is unclear as to whether these are related to a burned roof or the presence of a nearby hearth. A cluster of three smeared-indented corrugated sherds was found in the north-central area of the floor, and a flotation sample (FS 2528) was taken nearby. Taxa identified in the flotation sample included goosefoot, cheno-ams, juniper, unidentified pine, piñon pine, ponderosa pine, and maize.

A hearth (Feature 9) is located in the middle of the room. The feature is an adobe-lined pit with heavily oxidized sides, but no collar (Figures 25.43 and 25.44). It is circular in shape, with straight side walls and a mostly flat bottom. The pit is about 65 cm in diameter and 20 cm deep. The fill of the hearth consists of an ashy soil mixed with pockets of charcoal with solid pieces of ash (Stratum 37). All of the hearth fill was taken as flotation samples (FS 2473, FS 2474, FS 2475, FS 2477, FS 2488, FS 2489, FS 2490, FS 2491, and FS 2492). Carbonized taxa identified in these samples included saltbush/greasewood, mountain mahogany, goosefoot, cheno-ams, unknown conifer, unidentified pine, juniper, piñon pine, ponderosa pine, cottonwood/willow, oak, and maize.

Two pollen samples (FS 2486 and FS 2487) and a macrobotanical sample (FS 2485) were also taken. Taxa identified in the pollen samples included maize, beeweed, cheno-ams, grass family, sunflower family, ragweed/bursage, spurge family, fir, unidentified pine, piñon pine, juniper, oak, rose family, Mormon tea, and sagebrush. Taxa identified in the macrobotanical sample include unidentified pine, piñon pine, ponderosa pine, and cottonwood/willow. Eight smeared-indented corrugated sherds were recovered from the fill. Maize kernels and cupules (FS 2475) recovered from the hearth fill yielded an accelerator mass spectrometer (AMS) date of 830±40

BP (Beta-199388) and a date of cal AD 1220 with a two-sigma date range of cal AD 1160–1270. An archaeomagnetic (set 1230) and TL sample (FS 2595) were taken from the rim of the hearth and another TL sample (FS 2574) was taken from the base of the hearth (Stratum 47). The archaeomagnetic sample yielded a date of AD 1035 to 1070 or AD 1195 to 1240, and the TL samples dated to AD 1073±135 and 851±125, respectively.

Figure 25.41. Photograph of Room 8 (south).

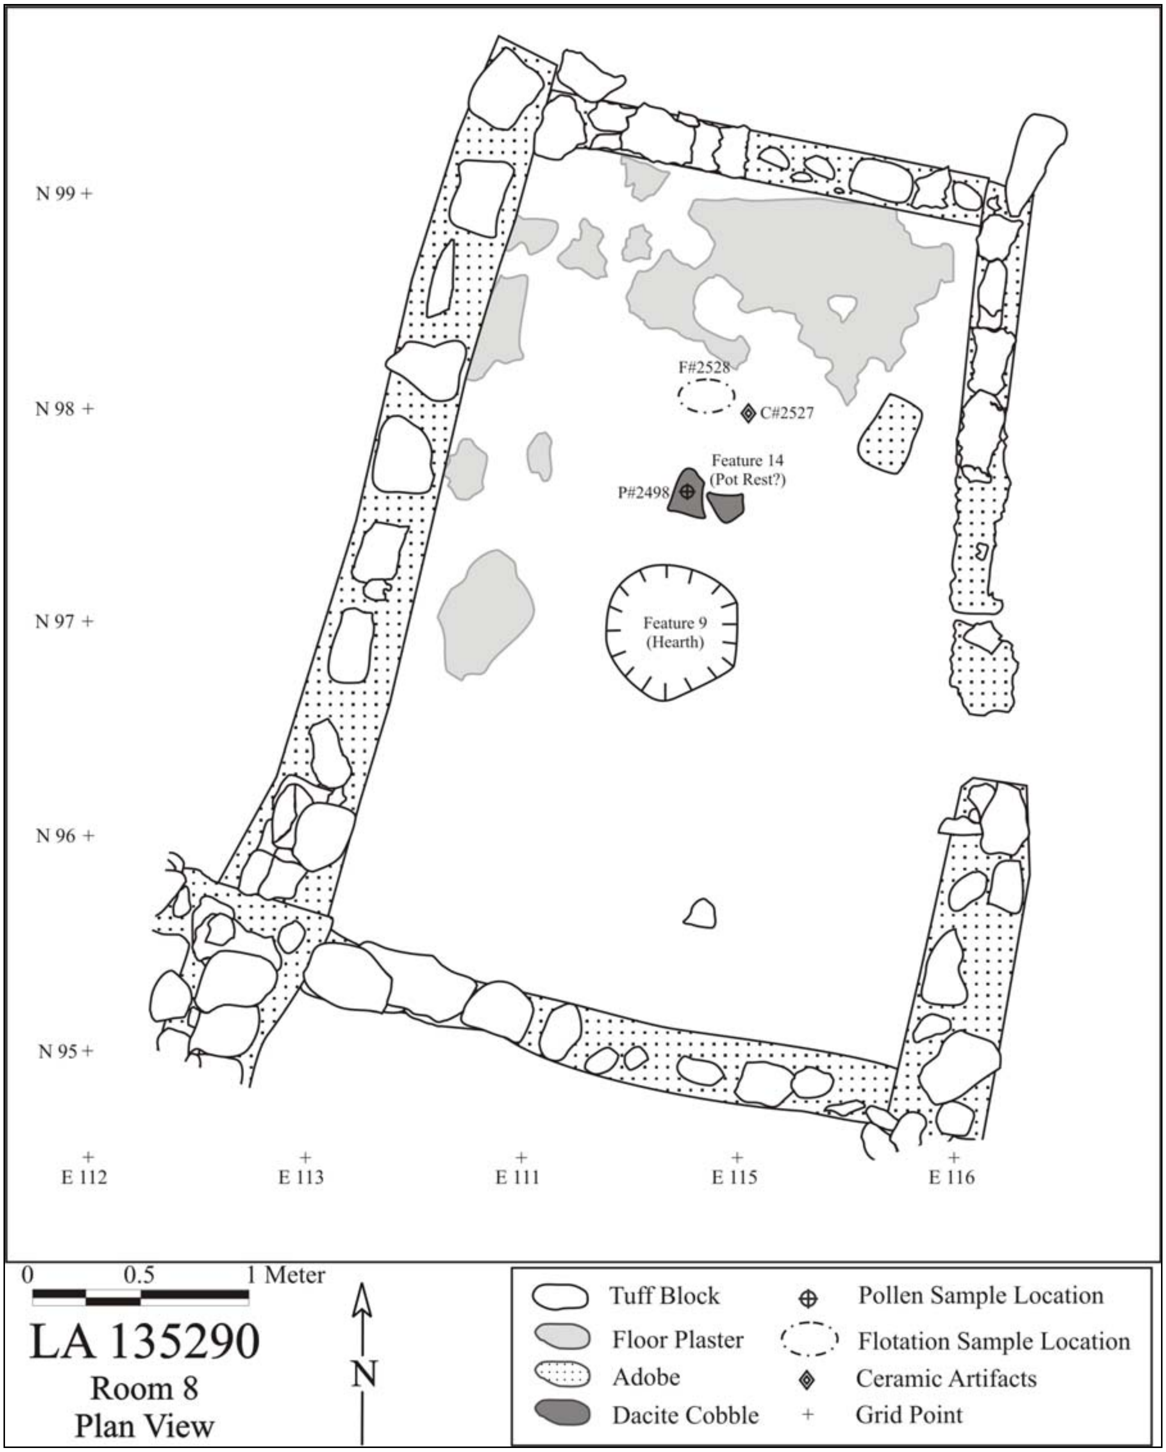

Figure 25.42. Room 8 plan view.

Figure 25.43. Photograph of Feature 9.

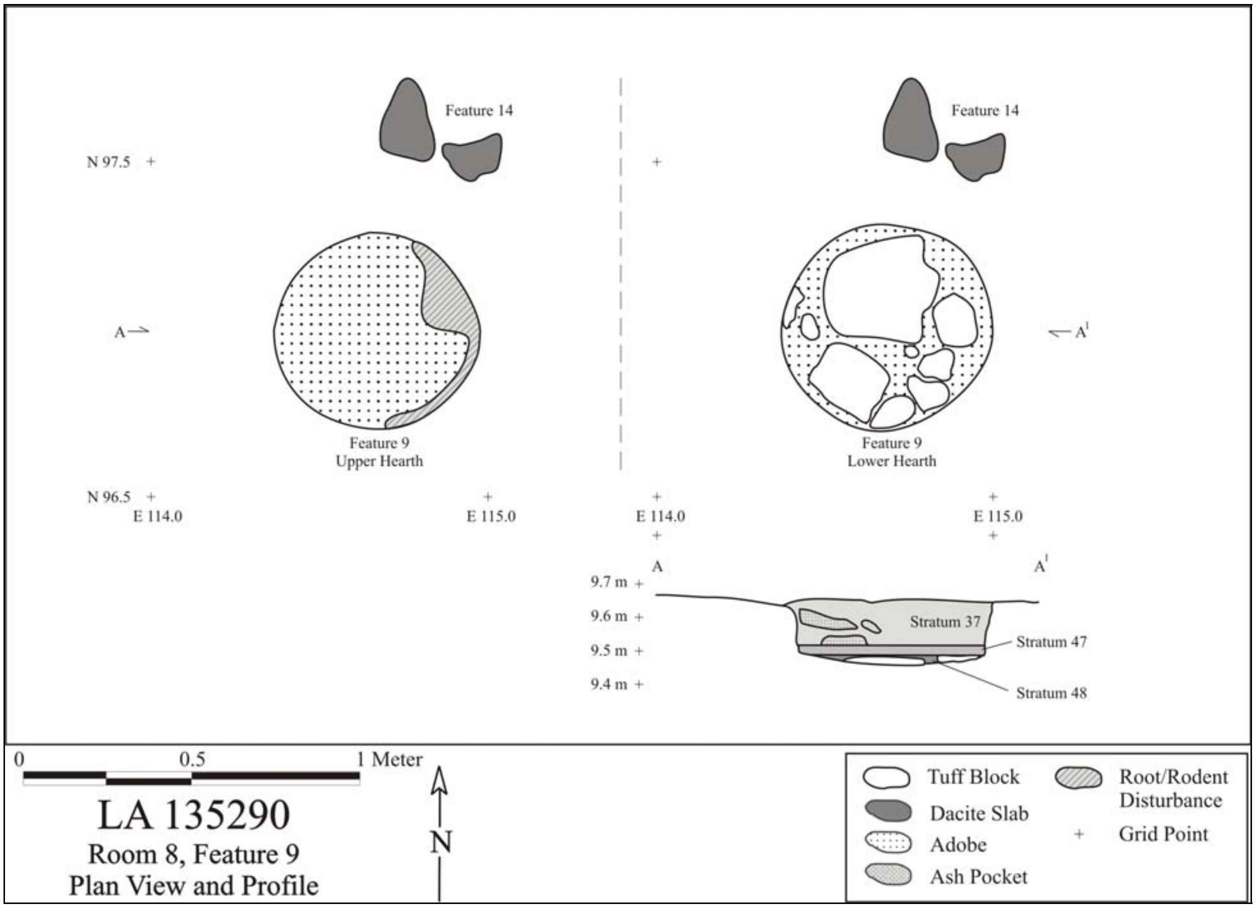

Figure 25.44. Feature 9 plan view and cross section.

After the fill was removed from the hearth, it was determined that the bottom of the hearth had been remodeled. It appears that the upper 3 to 4 cm of adobe lining the bottom of the hearth (Stratum 47) had been directly laid over a lower and older base to the hearth (Stratum 48; Figure 25.45). This lower section consisted of several pieces of tuff set in adobe mortar that was lightly oxidized with some ash staining. A pollen sample (FS 2586) was taken from this lower portion of the hearth. Taxa identified in this sample included maize, prickly pear, cheno-ams, grass family, sunflower family, evening primrose, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush.

A set of dacite cobbles (Feature 14) had been set into adobe about 20 cm to the north of the hearth. This feature may represent a pot rest. A pollen sample (FS 2498) was taken from underneath one of the cobbles. Taxa identified in this sample included maize, parsley family, cheno-ams, grass family, sunflower family, unidentified pine, piñon pine, juniper, oak, and sagebrush.

Figure 25.45. Feature 9, upper and lower hearth.

Wall Construction. The northern and western walls in Room 8 are well preserved compared to the poorly preserved east and south walls (Figures 25.46 and 25.47). All four walls were composed of tuff block masonry and had adobe mortar. The north and south walls are continuations of the east-west-running walls through Rooms 1 and 4/5. Therefore, Room 8 was constructed at the same time and does not reflect a later addition like Rooms 3 and 7. However, the upper section of the southern wall was constructed of tuff blocks, while the lower section is composed of adobe about 10 to 20 cm high. The eastern wall of Room 8 consists solely of a single course of stones. Since no wallfall was present in this area, it is unclear as to whether this was originally a full-standing wall, or whether the stone was scavenged to build the nearby rock alignments in the plaza. At any rate, there is a gap in the wall that could represent a doorway. A single Wiyo Black-on-white sherd was recovered from the east wall.

Figure 25.46. Room 8, west wall.

Figure 25.47. Room 8, south wall.

Room 8 wall measurements are provided in Table 25.23. Subfloor adobe footings about 15 cm thick were present under the north, west, and south walls. No footings were present under the east wall.

Table 25.23. Room 8 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	# Courses

Room 9

Sequence of Excavation. Room 9 is located in the southeastern corner of the roomblock. It is divided into northern (9A) and southern (9B) halves. The entire room measures 4.6 m north-south by 2.8 m east-west, with 12.88 m^2 of interior space. However, a dividing wall separates the room into two small areas with 7.28 m^2 and 3.96 m^2 of floor space, respectively. The excavation proceeded from east to west in Rooms 9A and 9B by removing the room fill by grid and natural layer.

Fill. The fill consists of a thin 5-cm layer of Stratum 1, with 10 to 20 cm of Stratum 4 underlain with 5 to 15 cm of Stratum 3. In Room 9A the lower 10 cm contained a large amount of charcoal. This concentration of charcoal was missing from Room 9B. Pollen, flotation, and macrobotanical samples were taken from Strata 3 and 4 in Rooms 9A and 9B (see Tables 25.29 and 25.31). Taxa identified in the pollen samples from the fill in Room 9A included prickly pear, cheno-ams, grass family, mustard family, sunflower family, globemallow (*Sphaeralcea*), spurge family, unidentified pine, piñon pine, juniper, rose family, and sagebrush. Taxa identified in the pollen samples from the fill in Room 9B included prickly pear, beeweed, cheno-ams, grass family, sunflower family, unidentified pine, juniper, oak, and sagebrush. Taxa identified in the flotation samples from the fill in Room 9A included mountain mahogany, goosefoot, unknown conifer, juniper, piñon pine, ponderosa pine, and maize. Taxa identified in the flotation samples from the fill in Room 9B included pigweed, goosefoot, cheno-ams, unknown conifer, juniper, mint family (Labiatae), unidentified pine, piñon pine, ponderosa pine, and maize. Taxa identified in the macrobotanical samples from the fill in Room 9A included mountain mahogany, unknown conifer, bean, unidentified pine, piñon pine, ponderosa pine, Douglas fir, oak, and maize. Taxa identified in the macrobotanical samples from the fill in Room 9B included unknown conifer, ponderosa pine, and maize.

Floor. There is no prepared adobe floor in Room 9. The floor consists of a compacted living surface in both Rooms 9A (Stratum 38) and 9B (Stratum 39; Figures 25.48 and 25.49). The living surface was identified as a partially preserved layer of hardened adobe/sediment. In some places, like the northwestern corner of 9A and the southwest part of 9B, the surface is thinly laminated, which is similar to Room 3. Room 9A is, however, different from 9B in that 9A contains a dense concentration of charcoal in the 5 to 10 cm layer just above the floor, especially in the western half of 9A. This charcoal lens did not occur in Room 9B.

Figure 25.48. Photograph of Rooms 9A and 9B (north).

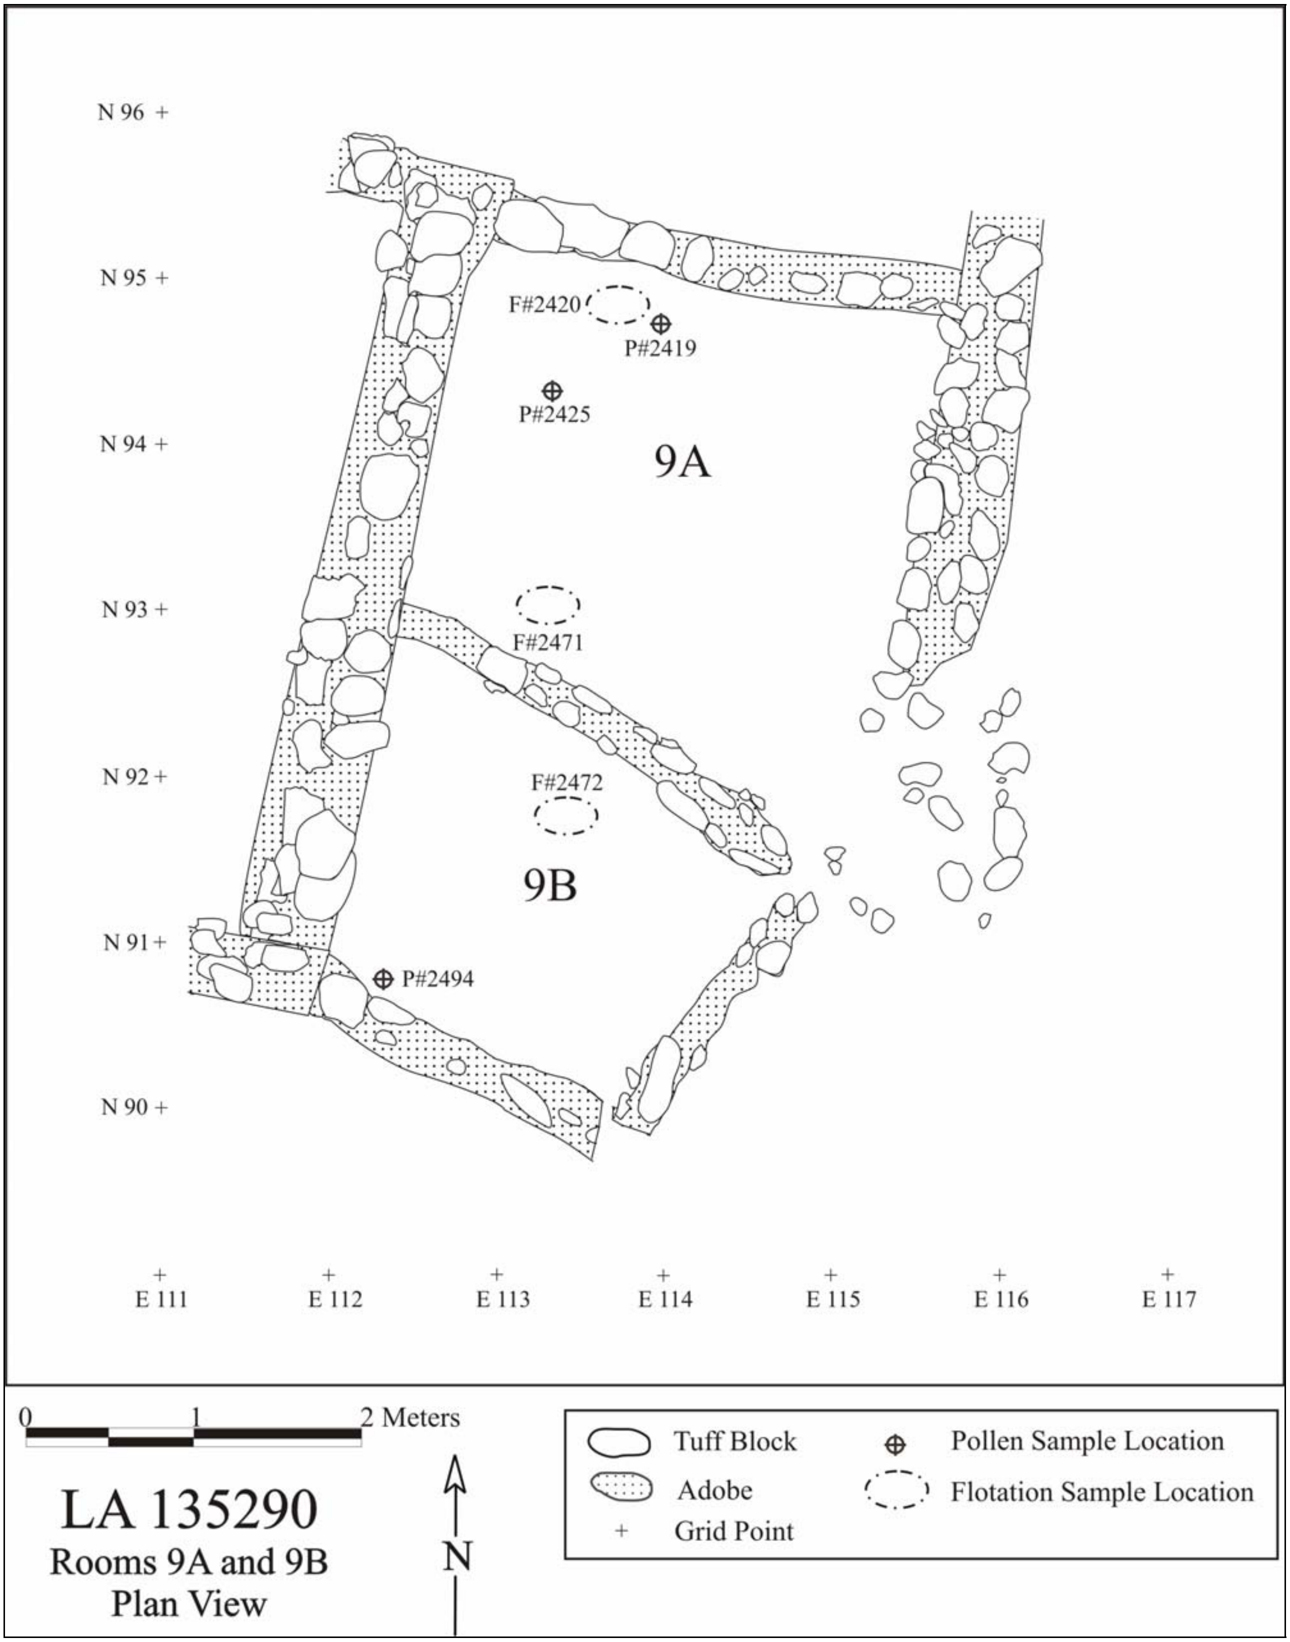

Figure 25.49. Rooms 9A and 9B plan view.

There are at least three areas of burned soil and charcoal on the living surface in Room 9A. Pollen and flotation samples were taken from this deposit (FS 2419 and FS 2420 and FS 2471, respectively). Taxa identified in the pollen sample included cheno-ams, sunflower family, unidentified pine, piñon pine, juniper, and sagebrush. Charred taxa identified in the flotation sample included goosefoot, juniper, piñon pine, ponderosa pine, purslane family, and maize. There is also a small concentration of white ash on the floor in the northwestern corner of the room and an ash concentration just below the level of the surface in the southwestern corner of Room 9A. A pollen sample (FS 2425) was taken in the northwestern corner and the identified taxa included lily family (Liliaceae), cheno-ams, grass family, sunflower family, spurge family, unidentified pine, piñon pine, oak, and sagebrush. The presence of this burned soil, charcoal, and ash clearly distinguishes Room 9A from Room 9B. However, there was a small ashy area present in the northwestern corner of Room 9B. A pollen (FS 2494) and flotation (FS 2472) sample were collected from this area of the floor. Taxa identified in the pollen sample included cheno-ams, grass family, mustard family, sunflower family, spurge family, evening primrose, unidentified pine, piñon pine, juniper, oak, rose family, and sagebrush. Charred taxa identified in the flotation sample included pigweed, cheno-ams, juniper, ponderosa pine, oak, and maize.

No floor features or artifacts were identified in the rooms.

Wall Construction. The west wall of Room 9 is a standing masonry wall that was part of the original roomblock (Figure 25.50). The upper section of the north wall of Room 9A was constructed from tuff blocks, while the lower section was composed of adobe that was 10 to 20 cm high. Although the north wall abuts against the west wall, it appears to be an extension of the east-west-running wall through the roomblock. The eastern wall of Room 9A was never a standing wall and it appears to be more similar to a berm or linear pile of rocks with soil and not adobe. The eastern wall is about 60 cm wide and is constructed of two parallel rows of flat-lying stones with dirt and smaller pieces of tuff in between. There is a gap at the southern end of the east wall that may have represented an entryway into the area of Room 9A. The south wall of Room 9A was constructed somewhat differently as it had a double row of uprights that formed the base to the wall.

The three walls that formed the north, east, and south sides of Room 9B were probably built later and all at the same time as is evidenced by the fact that they are oriented at a slightly southerly angle off the main roomblock. There is very little wallfall in the area so it is not clear as to whether these walls were ever full standing. The east wall simply consists of a single course of blocks with some adobe. The southern wall is also short and does not appear to be well made, consisting of a jumble of adobe with small tuff rocks.

Figure 25.50. West wall of Rooms 9A and B.

Rooms 9A and 9B wall measurements are provided in Tables 25.26 and 25.27.

Area 2 (Plaza Area)

Area 2 is the area to the east of the roomblock. Two north-south-oriented rock alignments (Feature 15) were visible on the surface to the immediate east of Rooms 9A and 9B (Figures 25.51 and 25.52). The eastern wall of Rooms 9A and 9B creates the western boundary of the feature. This alignment is about 7.50 m long and 0.50 m wide. The northern 5.0 m of the alignment is linear-shaped and is two to three unshaped tuff blocks wide and two blocks high (0.25 m). The blocks range in size from 15 to 35 cm in length. Soil is present in between the stones, which makes the alignment a linear berm as opposed to a wall. The southern 2.50 m of the alignment, which is located in front of Room 9B, is more of a jumble of tuff stones that connects with an east-west cluster of tuff rocks. This section of the alignment is 1.70 m long and abuts against the east wall of Room 9B. The rocks are smaller (about 10 cm in diameter) in this area.

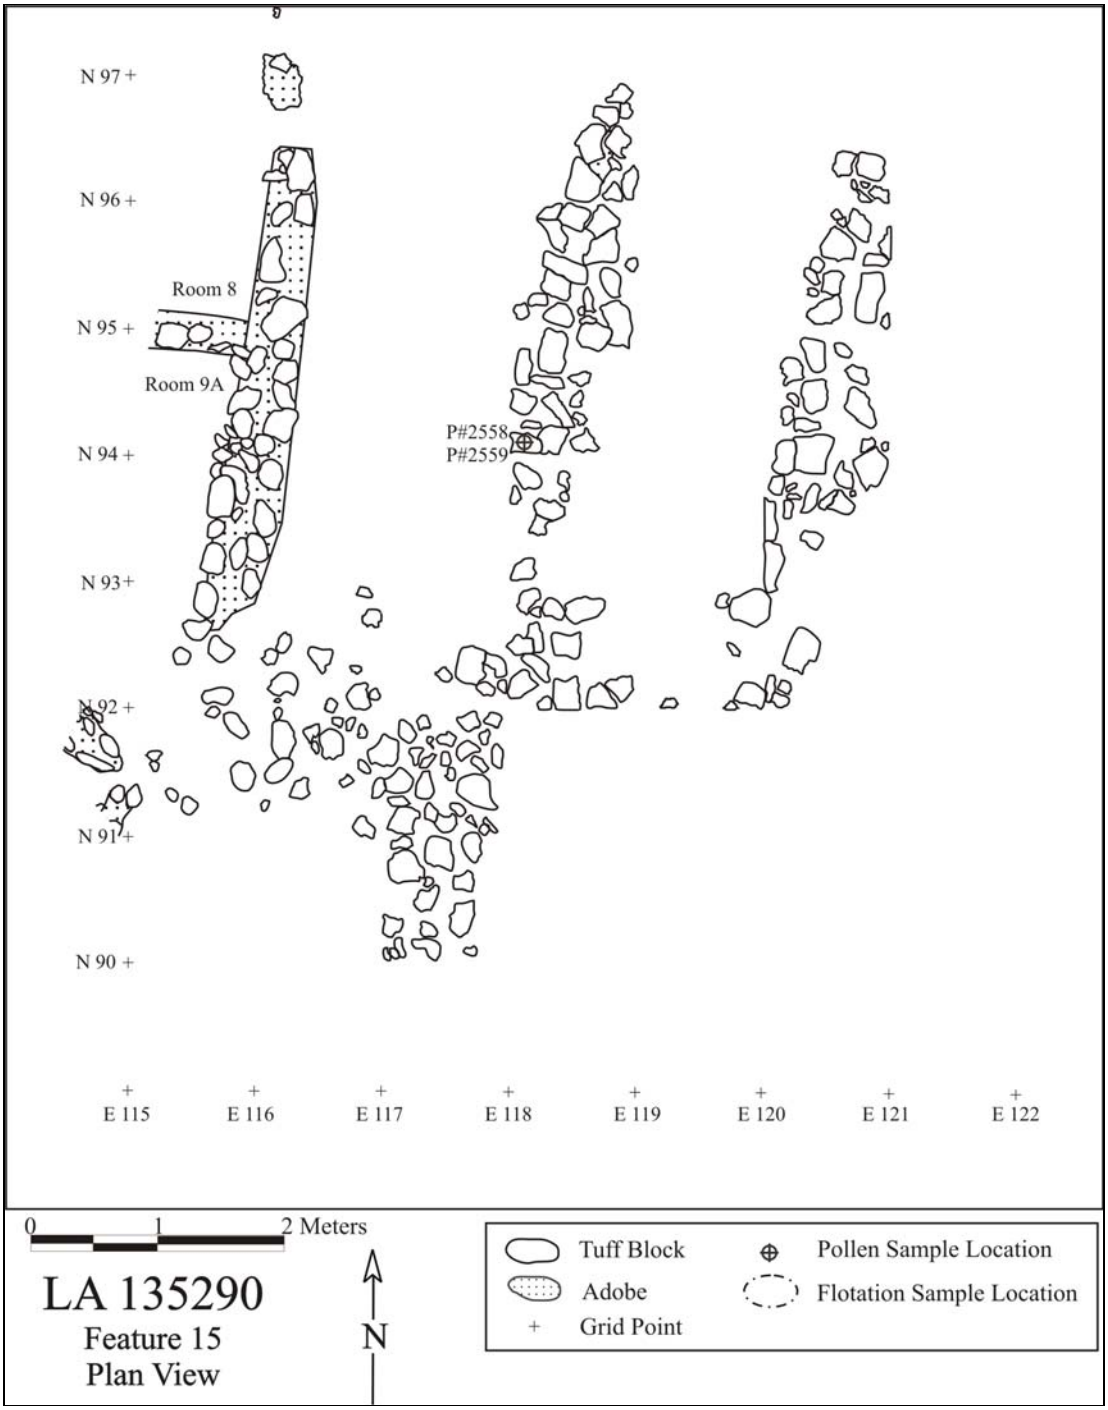

Figure 25.51. Feature 15 plan view.

Figure 25.52. Photograph of Feature 15 (west).

The eastern alignments are situated about 2.00 and 1.50 m apart. They are approximately 4.0 m long and 0.60 m wide. They appear to be a single stone high (10 to 15 cm) and two to three stones wide and have soil in between the stones. All three alignments are situated directly on top of the Bwb1 soil horizon and form two rectangular-shaped grids that open towards the north (upslope). The Bwb1 soil horizon represents the ancient surface that was present during the time the pueblo was occupied. The project geomorphologists noted that the top of the Bwb1 soil horizon is much more compact in the area of the plaza than underneath the roomblock. This presumably is due to trampling and foot traffic within the plaza. Pollen samples (FS 2558 and FS 2559) were taken from underneath an upper and lower block in the northern section of the Feature 15 alignment. Taxa identified in the alignment included prickly pear, cheno-ams, grass family, mustard family, sunflower family, ragweed/bursage, spruce (*Picea*), fir, unidentified pine, piñon pine, juniper, oak, rose family, and sagebrush.

A GPR survey was conducted of Area 2. A single anomaly was identified in the area of grid 101N/116E. As a result, a series of four backhoe trenches was excavated in the northern section of Area 2 to identify the presence of subsurface cultural deposits, features, and a kiva. Backhoe trench #1 was located at 98N/116E-98N/126E, backhoe trench #2 at 100-104N/116E, backhoe trench #3 at 100-102N/122E, and backhoe trench #4 at 100-108N/126E. The trenches were excavated down to bedrock, exposing up to 1.40 m of Holocene deposits (A, Bw, Bwb1, Btb1, Btkb1) situated on top of a late Pleistocene soil (Btkb2) and Bandelier Tuff bedrock. The soils appear to decrease in depth from south to north (1.0 to 0.50 m), with a shallow swale or gully cut into the bedrock through grids 101N/116E to 100N/122E to 98N/126E. This gully is the anomaly identified by the GPR survey and did not turn out to be a kiva. Otherwise, no cultural deposits or features were identified in the trenches.

Three other backhoe trenches were excavated to the east of the roomblock in the southern section of Area 2: backhoe trench #5 was located at 86N/114-120E, backhoe trench #6 was located at 90N/118-123E, and backhoe trench #7 was located at 94N/121-125E. Bedrock was also exposed about 1 m below the surface and no cultural deposits or features being identified.

Artifacts and Samples. Artifacts and pollen, flotation, and macrobotanical samples were selected from grids 90-96N/117-120E. Tables 25.32 and 25.33 provide summary information on artifacts by stratigraphic unit and samples selected for analysis in Area 2, respectively.

Area 3 (North and East of the Roomblock)

Area 3 is the area located immediately west of the roomblock. Three 1- by 1-m test pits were excavated in this area. Two test pits were located near the southwestern (91N/102E) and northwestern (104N/112E) corners of the roomblock. Both grids were excavated down to a depth of about 40 to 50 cm below the surface and to the top of the Bwb1 soil horizon. One Santa Fe Black-on-white sherd, 16 smeared-indented corrugated sherds, one indented corrugated sherd, two chalcedony core flakes, and one piece of angular debris were recovered from the excavation of the southwestern test pit. Four smeared-indented sherds, two plainware body sherds, one chalcedony core flake, and one piece of microdebitage were recovered in the northwestern test pit. The northwestern test pit was also placed to cross-cut a surface cluster of tuff rocks (Figure 25.53). The cluster included about 10 rocks and was distributed across grids 105N/110-112E. It was determined that the cluster was mostly surficial, with the bottom of some rocks located about 10 cm below the surface. A pollen sample (FS 2482) was taken from under one of the rocks. Taxa identified in the sample include cheno-ams, grass family, sunflower family, ragweed/bursage, fir, unidentified pine, piñon pine, juniper, rose family, and sagebrush.

Figure 25.53. Photograph of tuff rocks surface cluster (north).

One test pit was located in the area of a small sparse artifact scatter situated to the northwest of the roomblock at grid 114N/94E. The pit was excavated 11 cm down to the top of Bwb1 soil horizon. Three plainware body sherds were the only artifacts recovered.

Artifacts and Samples. All the artifacts recovered from the three test pits and a single pollen sample were analyzed from Area 3. Tables 25.34 to 25.35 provide summary information on artifacts by stratigraphic unit and samples selected for analysis in Area 3, respectively.

Area 4 (Midden East of the Roomblock)

Area 4 is a possible midden located to the east of the roomblock and Area 2. A surface collection was made in grids 75-93N/121-133/E. Subsequently, a series of eight 1- by 1-m test pits were placed across the area defined by a surface scatter of artifacts (82N/121E, 82N/125E, 82N/129E, 85N/123E, 85N/127E, 85N/131E, 88N/129E, and 91N/131E). The excavations revealed that there were very few artifacts present in the area. Most of these were limited to the upper 10 cm of the soil profile, including the A and Bw soil horizons. The sherds were often small fragments, indicating that they had probably washed down from the area of the roomblock. This corresponds with the site geomorphic study that shows a fan of colluvium sloping down towards the east from the rubble mound and indicates that this area was not a midden area.

A small (20 by 30 cm) charcoal-stained deposit was, however, exposed about 15 cm below the surface in grid 82N/125E. The deposit was situated at the break between the Bw and Bwb1 soil horizons. Pollen (FS 2149), flotation (FS 2150), and macrobotanical (FS 2145 and FS 2148) samples were taken. Taxa identified in the pollen sample included maize, lily family, cheno-ams, grass family, unidentified pine, piñon pine, juniper, and sagebrush. Charred taxa identified in the flotation sample included saltbush/greasewood, goosefoot, unknown conifer, mint family, unidentified pine, piñon pine, ponderosa pine, and maize. Taxa identified in the macrobotanical samples include piñon pine, ponderosa pine, and maize.

Artifacts and Samples. All the artifacts and pollen, flotation, and two macrobotanical samples were analyzed from Area 4. These samples include materials from surface collected grids (75-93N/121-133E) and excavated test pits. Tables 25.36 and 25.37 provide summary information on artifacts by stratigraphic unit and samples selected for analysis in Area 4, respectively.

General Summary of Architecture

The front rooms of the roomblock were typically slightly larger than those in the back, with the exception of Room 4/5. If Room 4/5 was broken into the two smaller rooms instead of being one larger room, then all the back rooms would be smaller, which fits the general pattern visible on the Pajarito Plateau. Table 25.38 shows the room dimensions and floor area for each of the rooms. A histogram was generated based on the surface area of the floors in the rooms (Figure 25.54). The figure groups the front rooms (light blue), the back rooms (blue-gray), and the plaza rooms (dark blue).

Table 25.38. Room dimensions and floor area.

Room Number	Location	Length (m)	Width (m)	Floor Area (m^2)
1	Front room	3.8	3.5	13.30

ARTIFACT AND SAMPLE ANALYSIS

A total of 10,152 pieces of pottery, 1318 chipped stone items, 127 ground stone artifacts, two ornaments, 17 minerals, and 78 faunal remains were recovered during the excavation of LA 135290. In addition, 117 flotation, 458 macrobotanical, and 134 pollen samples were collected. Given the large number of artifacts and samples recovered, the majority of the artifact classes were sampled during analysis.

Ceramic, chipped stone, and ground stone artifacts were sampled by analyzing the artifacts recovered from one, two, or three 1- by 1-m grid units in each room. Those units with the highest artifacts densities in the room fill layers were selected for analysis. In addition, all floor and feature fill artifacts were analyzed, as were all the artifacts recovered from Areas 3 and 4 and all the faunal remains. However, a sample of artifacts was also selected from surface collections in grids 89-112N/105-116E in Area 1, excavated grids 90-96N/117-120E in Area 2, surface collections in grids 75-93N/121-133E in Area 4, and the excavated test pits in Area 4.

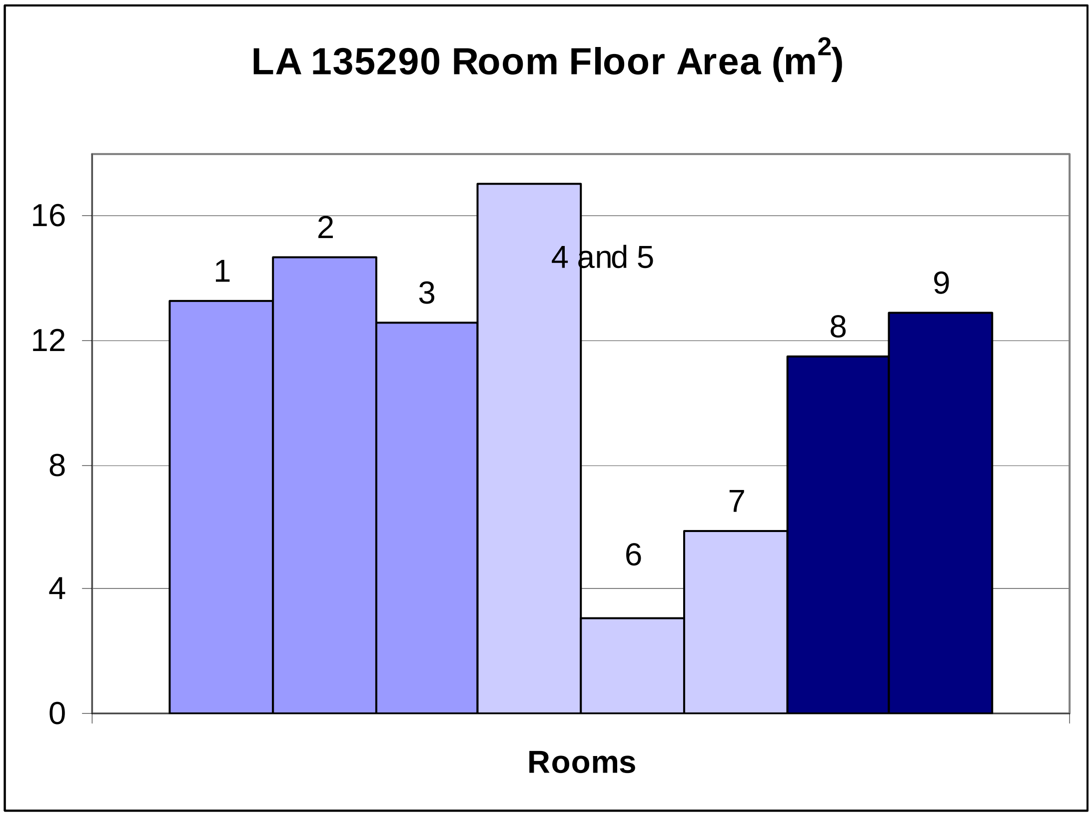

Figure 25.54. Histogram showing room size at LA 135290.

A set of archaeobotanical and pollen samples were selected from a stratigraphic sequence within each of the rooms, including the floors and features. The selected samples were listed in the previous room summaries. Maize recovered from features was also submitted for AMS radiocarbon dating. Archaeomagnetic and TL samples were taken from burned features, floors, and walls, with three sherds submitted for TL dating. Lastly, obsidian hydration dating was conducted on a sample of obsidian artifacts from the site.

Chronology

Radiocarbon Dating

Three radiocarbon samples were submitted to Beta Analytic for analysis, with each providing sufficient carbon for accurate measurements. All analyses were conducted on maize (*Zea mays*) remains. Table 25.39 lists the results of the radiocarbon analyses submitted. The results support the presence of an Early to Middle Coalition period occupation at LA 135290, with intercepts ranging from AD 1180 to 1220 and a two-sigma overlap of AD 1160 to 1260.

Table 25.39. Radiocarbon dates from LA 135290.

FS#	Material	Laboratory (Beta) #	Conventional radiocarbon age	Intercept of radiocarbon age	2-sigma calibrated result
2103	Maize kernels and cupules	199386	870±40 BP	AD 1180	AD 1040–1260
2475	Maize kernels and cupules	199388	830±40 BP	AD 1220	AD 1160–1270
2564	Maize cupules	199389	860±40 BP	AD 1190	AD 1040–1260

Archaeomagnetic Dating (Eric Blinman)

Despite the lack of formal midden accumulations at LA 135290, the rooms revealed a complex remodeling sequence, with multiple floors and hearths. This complexity suggests a long and relatively continuous, if not intense, occupation of the site. In addition to three cooking or heating hearths, at least three burning incidents occurred in the rooms, affecting both floors and walls. Stratigraphic relationships between archaeomagnetic sets are relatively clearly defined, increasing the interpretive potential of the results.

The suite of samples conservatively places the occupation of the roomblock within the AD 1155–1270 time range, but the more precise suite of results narrows that range slightly to AD 1170–1240, which corresponds with the ceramic dates from the site. The archaeomagnetic date ranges are based on the Wolfman calibration curve, and its calibration is relatively robust but not absolute. Calendric implications of the Wolfman VGP curve may be off by a decade or two, but the pole positions of the LA 135290 results are consistent with those of other early Coalition period samples from the northern Rio Grande region. To the south in the Cochiti Pueblo areas, the VGP positions for sets that document the transition between Late Developmental and Coalition pottery assemblages are slightly later along the Wolfman curve than these results from the LA 135290 roomblock. This suggests that the roomblock occupation is part of the initial establishment of Santa Fe Black-on-white as a marker of Coalition occupations in the northern Rio Grande Valley, and that the spread of Santa Fe Black-on-white technology (at least southward) lags by a generation or two. Table 25.40 lists the dates associated with the archaeomagnetic samples taken at LA 135290.

Table 25.40. Archaeomagnetic dates from LA 135290.

Sample	Feature	AM Date ranges (AD)	
		Wolfman or DuBois	SWCV2000
1226	Room 6, Floor 3	1170–1210	1125–1175
1227	Room 4, Floor 2	1180–1205	1125–1165

Sample	Feature	AM Date ranges (AD)	
		Wolfman or DuBois	SWCV2000
		1035–1070	
1231	Room 2, Hearth 16 (below and to the east of Hearth 11)	1155–1210 1105–1150	1035–1165
1232	Room 4, Floor 3	1170–1270	1010–1310

Thermoluminescence Dating

Three adobe samples (including a hearth rim and hearth base from Room 8), two floor samples, a wall sample, and three sherds were submitted for TL dating. All derived ages are given in years BP, which refers to years before 2003 (Table 25.41). Only the sample from Room 7 yielded a date within the range defined by the AMS and archaeomagnetic dating techniques; however, two other samples can be included within the standard deviation range and six others are much earlier.

Table 25.41. Thermoluminescence dates from LA 135290.

UW Lab #	Type	Room/feature	Burial depth (cm)	% error	Years AD
UW1236	Adobe	4	32	7.4	1035 ± 73
UW1237	Floor	6	35	9.1	1134 ± 79
UW1238	Wall	6	38	9.6	1114± 85
UW1239	Wiyo B/w	7	30	7.0	1217 ± 56
UW1240	Sherd*	2/11	65	9.4	1050 ± 90

* smeared-indented corrugated sherd.

Obsidian Hydration Dating

Seven obsidian artifacts were submitted to the Diffusion Laboratory for age determination using the obsidian hydration dating method. In order to calculate the absolute date for an obsidian artifact, three analytical procedures were completed. First, the amount of surface hydration, or the thickness of the hydration rim, was measured. Second, the high temperature hydration rate constants for each artifact were determined from the composition of the glass. Lastly, the soil temperature and relative humidity at the archaeological site were estimated in order that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. Using these methods, a hydration rate for the obsidian artifacts was calculated (Table 25.42).

Table 25.42. Obsidian hydration dates for LA 135290.

FS No.	Lab No.	Source	Rim (um)	AD/-BC	1 S.D.
1018	2006-41	Valle Grande	2.78	-1036	219
1055	2006-42	Valle Grande	2.69	1015	71
1255	2006-43	Valle Grande	4.72	-6500	362
1385	2006-44	Valle Grande	4.34	-5277	337
2141	2006-45	Valle Grande	2.46	1805	12
2142	2006-46	Valle Grande	2.57	1614	27
2174	2006-47	Valle Grande	2.27	-64	182

Relative to other dating methods conducted at the site, the obsidian hydration dates seem to be the least accurate (Figure 25.55; Table 25.43). Radiocarbon and archaeomagnetic results are comparable and seem to have provided the most plausible results, while the TL dates seem to be slightly less plausible given the known occupation range of the sites, but still well within the acceptable limits. Overall, the dates reflect an Early to Middle Coalition period occupation circa AD 1160 to 1260. Table 25.43 presents all the dated materials from the site. TL, archaeomagnetic, radiocarbon, and obsidian hydration are presented where similar contexts were sampled.

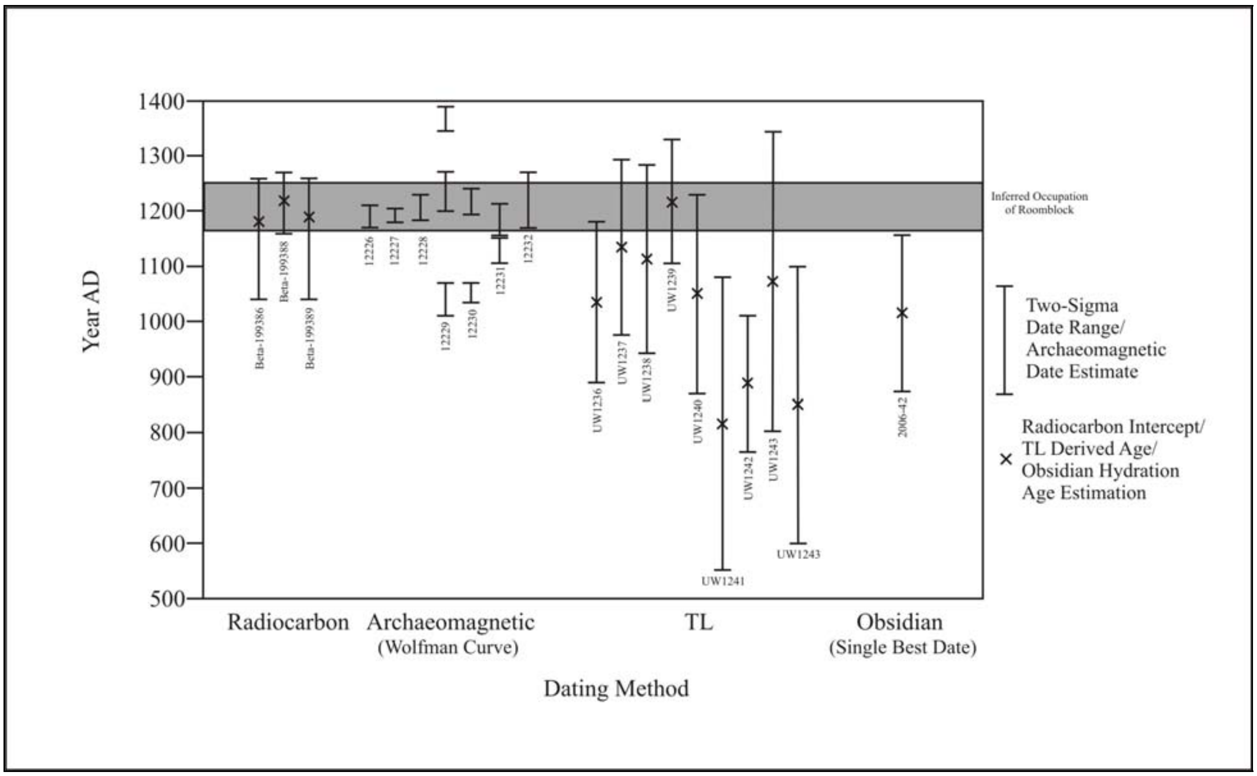

Figure 25.55. Comparison of dated materials from LA 135290.

Table 25.43. Comparison of dated materials from LA 135290.

Context	Radiocarbon Intercept	Archaeomag (Wolfman)	Archaeomag (SWCV2000)	TL	Obsidian Hydration
Room 8, Feature 9	AD 1220	1195–1240 1035–1070	1015–1050	1073 ± 135 (rim) 851 ± 125 (base)	--
Room 2, Feature 16	AD 1190	1155–1210 1105–1150	1035–1165	--	--

*all dates are AD unless otherwise noted

Ceramic Artifacts (Dean Wilson)

A total of 4021 sherds were analyzed from LA 135290. Most of these consist of Santa Fe Black-on-white and smeared-indented corrugated, which indicate a Middle Coalition period (13th century) occupation. The majority (83.7%) of the pottery from the site consists of gray utilityware types, while 16.3 percent consists of whiteware types, and redwares are represented by a single sherd (Table 25.44). The majority (55.2%) of whitewares were classified as Santa Fe Black-on-white. Most of the other whitewares (41.3%) were assigned to the unpainted undifferentiated type, and most of these appear to be represented by the unpainted portions of Santa Fe Black-on-white vessels. Types present in very low frequencies include Wiyo Black-on-white (0.5% of all whitewares), Galisteo Black-on-white (0.3%), Kwahe'e Black-on-white (1.7%), mineral-painted undifferentiated, indeterminate Cibola whiteware (0.4%), and Socorro Black-on-white (0.2%).

In addition to Coalition period whiteware types, Biscuit B (Bandelier Black-on-gray) sherds were present in low frequencies (0.3% of all whitewares) and probably reflect contaminants from a nearby Classic period pueblo. Utilitywares were exclusively represented by Northern Rio Grande grayware types. Graywares were dominated by smeared-indented corrugated sherds, and represent 83.5 percent of all graywares. Other grayware types included plain gray (2.3% of all graywares), unknown gray (trace), wiped scored gray (0.1 %), basket impressed gray (trace), indented corrugated (13.8%), incised corrugated (0.1%), plain corrugated (0.1%), smeared plain corrugated (0.1%), patterned corrugated (trace), plain incised (trace), and mudware (0.1%). The ceramics at LA 135290 were very similar to those identified at LA 86534, and both date to the Middle Coalition period.

Table 25.44. Ceramic types from all contexts at LA 135290.

Ceramic Type	Frequency	Percent
Northern Rio Grande Whiteware		
Unpainted undifferentiated	271	6.7
Mineral paint undifferentiated	1	0.1
Kwahe'e Black-on-white	11	0.3
Santa Fe Black-on-white	362	9.0
Wiyo Black-on-white	3	0.1

Ceramic Type	Frequency	Percent
Galisteo Black-on-white	2	0.1
Biscuit B (Bandelier Black-on-gray)	2	0.1
Northern Rio Grande Utilityware		
Plain gray rim	14	0.3
Unknown gray rim	1	0.1

Cibola Whiteware		
Unpainted polished whiteware	1	0.1
Mineral paint undifferentiated	1	0.1
White Mountain Redware (Cibola)		
White Mountain Redware unpainted	1	0.1
Eastern Mogollon Whiteware		
Socorro Black-on-white	1	0.1
Total	**4021**	**100.0**

Pottery distributions noted at LA 135290 most closely resemble those noted from LA 86534, which is located approximately 500 m to the east (Volume 2, Chapter 24; Wilson, Volume 3). Similarities in whitewares include the overwhelming dominance of Santa Fe Black-on-white within the whiteware assemblages along with extremely low frequencies of Kwahe'e Black-on-white, Wiyo Black-on-white, and Galisteo Black-on-white. Another characteristic shared by the ceramic assemblages is that the majority (73.4%) of whiteware bowls exhibit unpolished and unslipped exteriors. Similarities in gray utilitywares include the dominance of smeared corrugated sherds along with small but significant amounts of indented corrugated.

Temper found in Santa Fe Black-on-white sherds from LA 135290 was dominated by rounded clay fragments that were recorded as oblate shale with tuff (Table 25.45). The identification of this temper reflects a rare case in which the easy visual recognition of a temper distinct to the whitewares from a specific site was possible. A total of 52 percent of the whiteware sherds contained this temper type, which was very rare in whitewares from LA 86534 (Table 25.46). All six of the Santa Fe Black-on-white sherds from LA 135290 submitted for petrographic analysis were tempered with anthill sand with clay lumps, indicating the use of a distinct paste source in the production of whitewares at LA 135290. This lends support to other studies that suggest that Santa Fe Black-on-white ceramics were produced locally at various sites in Pajarito

Plateau and elsewhere in the Northern Rio Grande region during the Coalition period (Habicht-Mauche 1993; Powell 2002; Vint 1999).

Total	**3365**	**100.0**	**655**	**100.0**	**1**	**100**	**4021**	**100.0**

The majority of the grayware sherds from LA 135290 were tempered with some form of anthill sand. All of the nine thin-sectioned grayware sherds were tempered with anthill sand, except one that contained sanidine and quartz as the dominant particles. Samples from LA 135290, while also dominated by sanidine and quartz, show much more varied subordinate and minor temper components than utilitywares than LA 86534. In addition to sanidine felsite and minor plagioclase, these include tuff and vitric felsites, intermediate volcanics, and K-feldspar. Quantitatively, the proportion of plagioclase is lower on average and much more variable than in the samples from LA 86534.

Distributions of ware and form categories from LA 135290 are very similar to those noted at other Coalition period sites on the Pajarito Plateau (Table 25.46). Graywares are overwhelmingly represented by jar sherds (Table 25.47), while whitewares are dominated by bowl sherds, which represent over 70 percent of this ware. These distributions closely match patterns noted at other Coalition period site.

Table 25.46. Distribution of wares at LA 135290.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 540 artifacts were analyzed from LA 135290. The sampled assemblage consisted of nine cores, 496 pieces of debitage, 16 retouched tools, 16 ground stone artifacts, three hammerstones, and four pieces of fire-cracked rock, which represented a 35 percent sample of the 1530 total lithic artifacts recovered. Table 25.48 presents the data on lithic artifact type by material type. The majority of the debitage is made of chalcedony with lesser amounts of Pedernal chert, obsidian, and other materials. The presence of cortex on 16.5 percent of the debitage indicates that these materials were collected from waterworn sources. Nodule cortex was not identified on any of the items exhibiting cortex. The chalcedony and Pedernal chert are available from local Rio Grande Valley gravel sources and the basalt from gravels and bedrock outcrops. Although obsidian is present at nearby primary sources in the Jemez Mountains, a single obsidian flake also exhibited waterworn cortex, indicating that it was possibly obtained from gravel sources. Quartzite and silicified wood is, however, only available from the nearby Rio Grande Valley gravels. Otherwise, the ground stone artifacts are primarily made from igneous materials that are available both as bedrock outcrops and in stream gravels that cross-cut the Pajarito Plateau. The source of the sandstone is difficult to determine, but it could be derived from gravel formations near Totavi or from more distant sources in the Santa Fe or Abiquiu areas.

Six pieces of debitage, a core, a retouched tool, and a projectile were submitted for X-ray fluorescence analysis. All but one of the artifacts were obtained from the Valle Grande source, with a single piece of debitage obtained from the Cerro Toledo source area (Table 25.49). The Valle Grande (Cerro del Medio) and Cerro Toledo (Rabbit Mountain/Obsidian Ridge) source areas are located about 17 km (11 miles) as the "crow flies" to the west and southwest of the site. In addition, four pieces of basalt debitage were also submitted for analysis. Three of these were made from dacite from local sources and the other was basalt.

2174	Debitage	Translucent	Valle Grande rhyolite

Lithic Reduction

The cores consist of three single-directional, five bidirectional, and a core fragment. The single-directional cores were reduced using a multi-faces technique, whereas, the bidirectional cores were reduced using bifacial, opposed-same-face, opposed-different-face, and 90 degrees techniques (Figure 25.56). None of the cores exhibit any obvious evidence of platform preparation. Most of the cores were discarded due to exhaustion (*n* = 4), with one due to extensive hinging and another due to extensive edge battering. Otherwise, the remaining two cores were considered still useable. None of the cores were burned. Table 25.50 presents the metric information on the whole cores.

Table 25.50. Core type dimensions (mm) and weight (gm).

Core Type	Length	Width	Thickness	Weight
Single-directional	32	42	27	39.0
Single-directional	49	73	44	189.5
Single-directional	59	65	48	172.3
Bi-directional	81	86	68	462.7
Bi-directional	33	31	17	15.4
Bi-directional	20	25	10	5.4
Bi-directional	38	40	17	30.3
Bi-directional	30	20	16	10.3

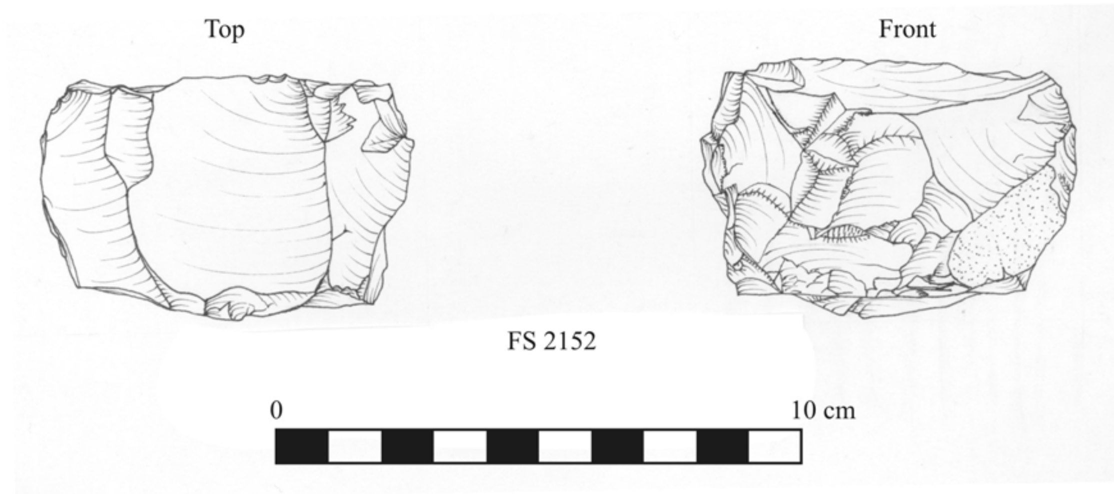

Figure 25.56. Single-directional, multi-face core (top and front).

The debitage consists mainly of core flakes (69.1%), with lesser amounts of angular debris (16.7%), microdebitage (8.6%), biface flakes (2.2%), and undetermined flake fragments (2.8%). Table 25.51 summarizes the various stages of reduction represented by the whole core and biface (tertiary) flakes. The debitage assemblage is primarily composed of secondary noncortical flakes, with lesser amounts of secondary cortical, tertiary, and primary flakes. The overall cortical:non-cortical ratio of 0.48 reflects an emphasis on the later stages of core reduction. The sample size is small, but chalcedony materials appear to be more fully reduced than the Pedernal chert.

Table 25.51. Debitage reduction stages.

Material	Primary	Secondary Cortical	Secondary Non-cortical	Tertiary	Cortical: Non-cortical ratio
Basalt	0	0	1	0	---
Obsidian	0	0	2	2	---
Chalcedony	1	14	37	1	0.36
Pedernal chert	0	12	13	0	0.92
Total	1	26	53	3	0.48
Percentage	1.2	31.3	63.8	3.6	---

The majority of the flakes exhibit single-faceted platforms (38.5%; n = 57), with cortical (n = 30), collapsed (n = 36), crushed (n = 22), multi-faceted (n = 2), and dihedral (n = 1) platforms. The majority of the collapsed and crushed platforms are on chalcedony and core flakes. Only five (3.3%) of the flake platforms exhibit evidence of preparation and all of these were abraded/crushed.

The majority of the core flakes consist of distal fragments (*n* = 179; 52.2%), with fewer whole (*n* = 96), proximal (*n* = 41), and midsection (*n* = 27) fragments. Most of the biface flakes are also distal fragments (*n* = 4; 36.4%), with fewer whole (*n* =3), proximal (*n* = 3), and midsection (*n* = 1) fragments. The whole core flakes have a mean length of 23.8 mm (*std* = 12.5), whereas the whole biface flakes exhibit a mean length of 30.0 mm (*std* = 10.5). Lastly, angular debris have a mean weight of 3.9 g (*std* = 5.5).

The retouched tools consist of a mix of expedient flakes tools like retouched pieces and perforators, with fewer formal tools such as bifaces, projectile points, and unifaces (Figure 25.57). All of the retouched pieces exhibit a single marginally retouched edge. Table 25.52 presents the information on retouch type by edge outline.

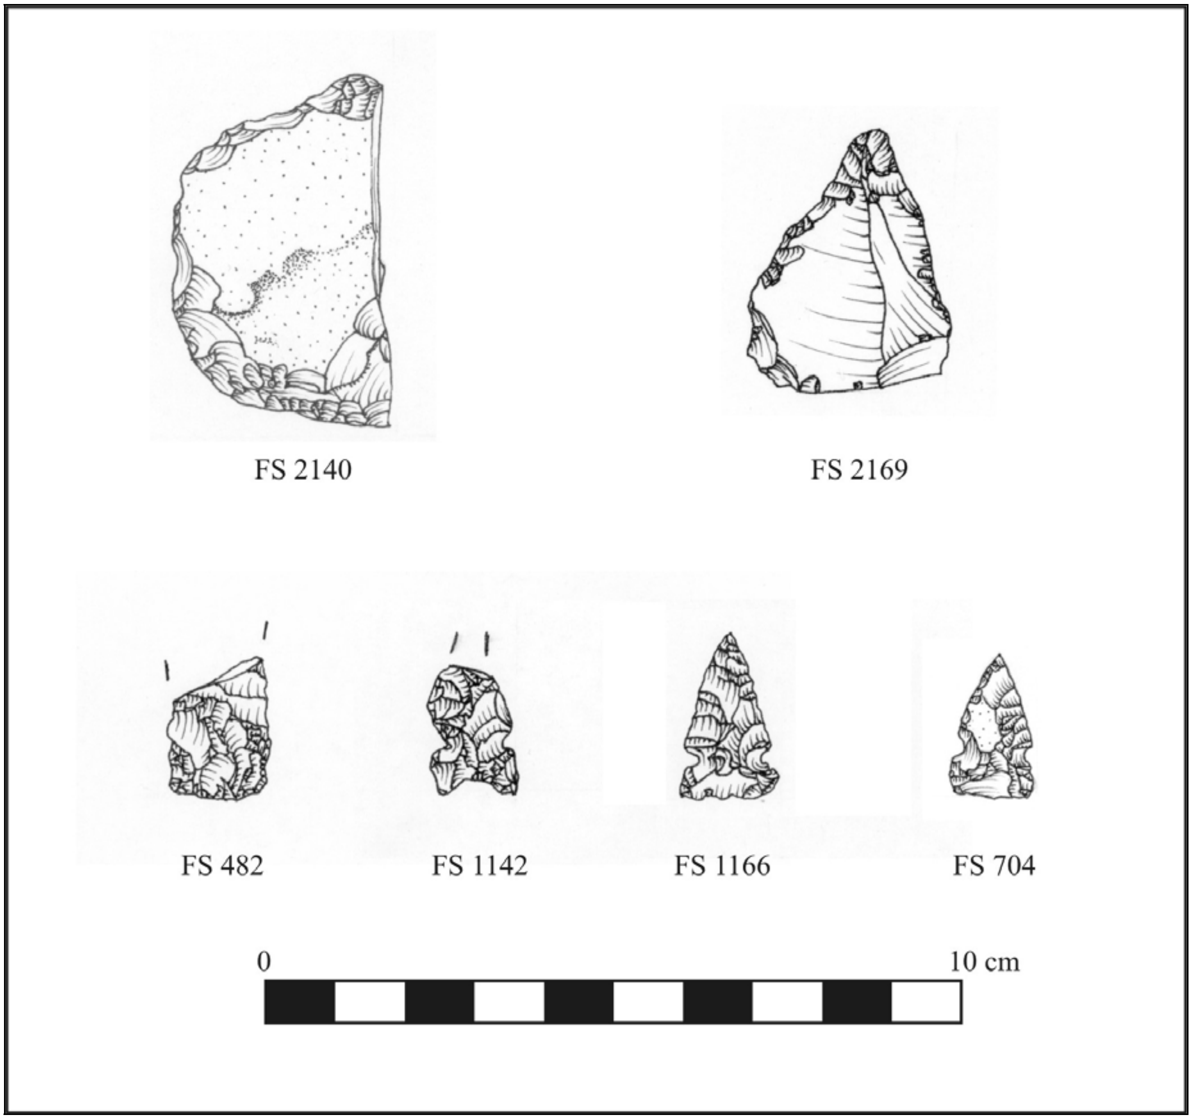

Figure 25.57. Retouched flake, perforator, biface, and projectile points.

Table 25.52. Retouched pieces.

Retouch Type	Edge Outline						
	Straight	Concave	Convex	Straight/ concave	Straight/ convex	Concave/ convex	Projection
Unidentified ventral	1	0	0	0	0	0	0
Unidentified dorsal	2	0	1	0	0	0	0
Total	3	0	1	0	0	0	0

The retouched edges primarily exhibit a straight outline. The edge angles range from 55 to 75 degrees, with a mean of 53.7 degrees (*std* = 8.5**).** This reflects an emphasis on the use of steeper edge angles. Two of the perforators are small triangular-shaped flakes that have been bifacially retouched. The third perforator is a bifacially retouched projection on a large flake. The uniface is a large roughly worked flake with unidirectional dorsal retouch and an edge angle of 75 degrees. It is a proximal fragment that might have been broken during manufacturing.

All three bifaces are fragments. One is a midsection with an edge angle of 45 degrees and the other two are proximal fragments with edge angles of 50 and 60 degrees. They may be middle stage fragments that were broken during manufacturing. Metrical and descriptive information on the four projectile points is presented in Table 25.53. They consist of three corner-notched and one side-notched arrow points with neck widths between 7 and 9 mm.

Table 25.53. Projectile point metrical (mm) and descriptive data.

FS #	Material	Condition	Overall Length	Blade Length	Neck Width	Stem Length	Stem Width	Thickness	Weight (gm)	Haft Type	Blade Shape	Base Shape
704	Obsidian	Whole	19	13	8	7	11	3	0.7	Side-notched	Straight	Straight
1142	Obsidian	Proximal	--	--	7	6	12	2	0.7	Corner-notched	Straight	Concave
1166	Obsidian	Whole	23	16	9	7	14	3	0.9	Corner-notched	Straight	Straight
1983	Obsidian	Proximal	--	--	--	--	--	--	0.1	Corner-notched	Und.	Und.

Tool Use

Only 13 flakes (2.6%) exhibit evidence of damage that could be attributed to use-wear. Most of the damage is located at the end of the flake (*n* = 6), with some along the lateral edge (*n* = 4), and the dorsal surface (*n* = 3). The former flakes have mostly straight outlines, with one convex outline and three utilized projections, while the latter are ground stone flakes. Edge angles range from 50 to 70 degrees, with a mean of 59 degrees (*std* = 8.6). This is similar to the pattern exhibited by the retouched flakes. In contrast to the debitage, eight of the retouched tools (50.0%) exhibit evidence of use-wear. These consist of four retouched flakes, three perforators, and one perforator/notch.

Twenty-eight ground stone artifacts were identified during the analysis. These included manos, metates, a polishing stone, a pestle, an abrading stone, and other unidentified ground stone items. The manos consist of one- and two-hand varieties with several undetermined fragments. The one-hand mano is a cobble with two heavily ground opposing flat surfaces, while the two-hand manos are made of vesicular basalt and sandstone and have a plano-convex and a wedge-shaped cross-section (Figure 25.58). One of these has finger impressions along a single side. The mano fragments are both cobbles with two opposing ground surfaces that are plano-convex and bi-plano in cross-section.

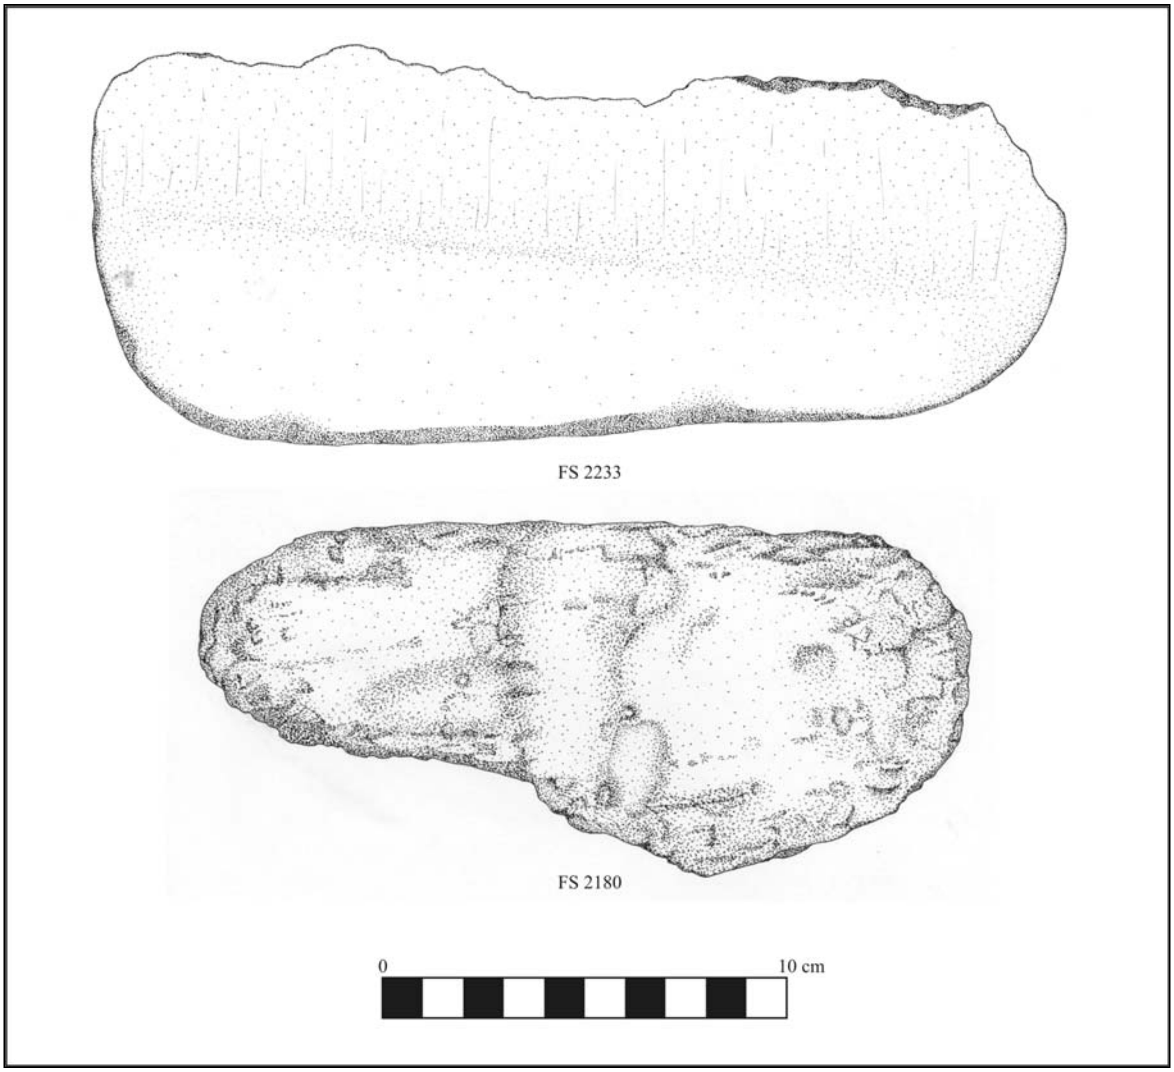

Figure 25.58. Two-hand mano and maul.

Four undetermined metate fragments were identified during the analysis. These were all dacite slab fragments with a single heavily ground flat surface. The grinding slabs are also tabular pieces of dacite with one or two flat ground surfaces. The polishing stones are andesite and dacite pebbles with a finely ground surface. The abrading stone is a quartzite pebble with irregular ground surfaces. The pestle is a dacite cobble with one narrow end that exhibits some crushing and grinding wear. One item classified as miscellaneous ground stone consists of a shaped piece of soft tuff that is circular in cross-section and pointed at one end. There are striations that run the length of the artifact (Figure 25.59).

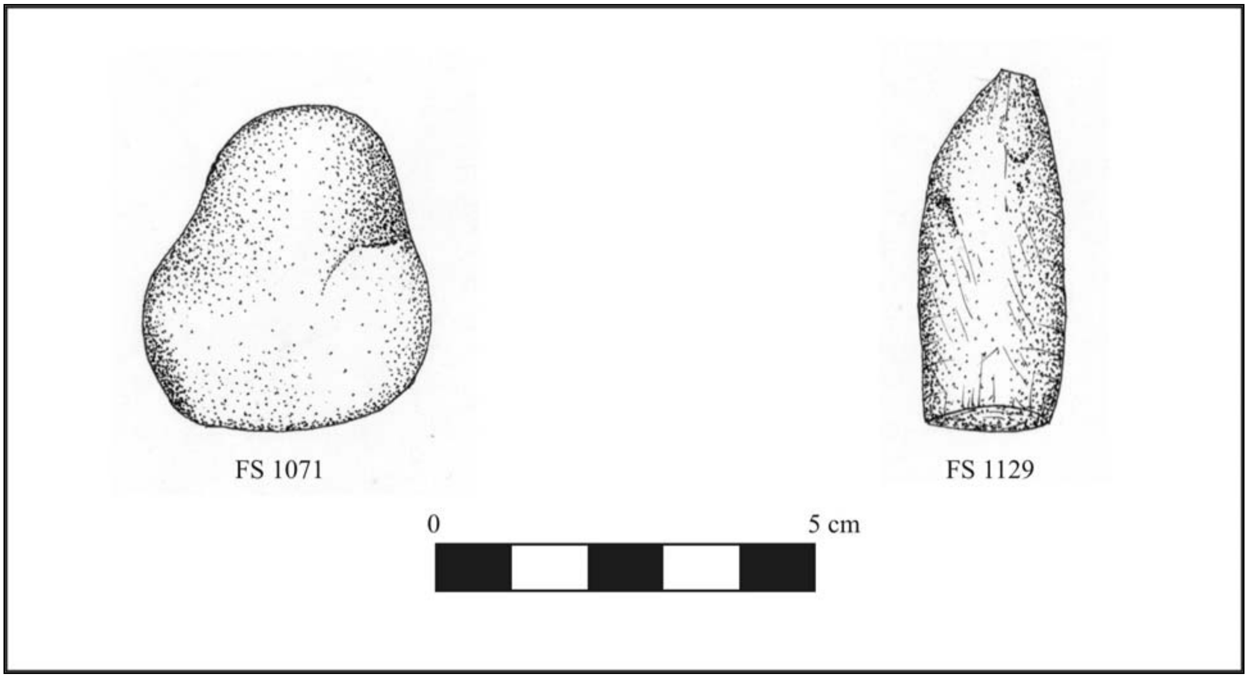

Figure 25.59. Polishing stone and miscellaneous ground stone.

The maul is a chert cobble with flaked and worn edges and a battered butt. The artifact is whole and exhibits abrasion indicative of hafting. The flaking is presumably due to use-wear and not intentional retouch. The other maul is an oblong dacite cobble that is fully grooved and exhibits some battering wear along the end (see Figure 25.58). The ornament is a red baked shale bead.

Faunal Remains (Kari Schmidt)

In general, the overall preservation of the bones from LA 135290 is good. For the most part, bones tended to be in large fragments, and a number of complete elements were identified. Weathering on the faunal remains was present, although the frequency and severity were low (n = 2), suggesting the remains may not have been exposed to the elements for a long period of time before deposition. The bones show minimal evidence of root-etching and rodent gnawing, but no evidence of carnivore gnawing or carnivore digestion. Modifications resulting from burning were present on 23 pieces of bone, constituting some 35 percent of the total assemblage. One piece of bone recovered at LA 135290 was heavily polished.

Of the 65 faunal remains recovered from the excavations at LA 135290, 52 percent (*n* = 34) were identified to at least the level of class. The 34 identified remains were recovered from a variety of contexts. Table 25.54. shows all the taxa that were recovered from the site. Because the most abundant taxa represented in the assemblage were intrusive pocket gophers (*Thomomys* sp.), Table 25.55 presents the same data with this taxon removed. Pocket gopher burrows were extensive in the immediate site area, and the visual appearance of their bones was quite distinct from the vast majority of the other bones recovered from the site.

Table 25.54. Identified faunal remains from all contexts at LA 135290.

With the intrusive pocket gopher remains removed from calculations made for Table 25.54, Table 25.55 shows that the highest percentage of the identified fauna (18%) at LA 135290 is from both cottontail (*Sylvilagus* sp.) and mule deer (*Odocoileus hemionus*). After these taxa, turkeys (*Meleagris gallopavo*), rock squirrels (*Spermophilus variegatus*), and black-tailed jackrabbit (*Lepus californicus*) each comprise 13 percent of the identified assemblage. The remainder of the assemblage consists of a wide variety of taxa, including amphibians, reptiles, rodents, and carnivores. The variation present in the assemblage attests to its location near a number of distinct biomes.

Archaeobotanical Remains (Pamela McBride)

Flotation

Evidence for the triad of maize, beans, and possible squash was present in flotation samples from LA 135290. Maize cupules were the most common plant remains recovered, followed by goosefoot and cheno-am seeds and maize kernels (Table 25.56). Beans were found on the floor of Room 1, in Room 2 rooffall, and in the fill of Features 4 and 11 in Room 2. Possible squash rind also occurred on the floor of Room 1 and on the floor surface of the doorway between Rooms 4 and 5. The most interesting phenomenon is the presence of tobacco seeds solely in an adobe-lined collared hearth (Feature 11) in Room 2. An ash lens sealed the feature and seeds were identified in both the upper and lower fill, indicating sequestered use of this important ceremonial plant.

*Number of samples with common name/plant part present; **Number of samples with common name/plant part divided by total number of flotation samples with charred remains (75) × 100.

Grasses had a low percent presence and the only perennial genera with a percent presence above 10 are those that are most likely an artifact of fuelwood use like piñon and ponderosa pine needles. Piñon nutshell in particular is extremely scarce, limited to one sample only. Ponderosa pine was the most common wood taxon encountered in flotation samples (Table 25.57). Piñon and unknown conifer were the next most prevalent taxa. Riparian resources were represented by cottonwood/willow, and several shrubby species were present, including mountain mahogany, oak, and saltbush/greasewood. Douglas fir, recovered in a single sample, is generally from slightly higher elevations or canyons and could have been brought from Pueblo Canyon or DP Canyon.

Table 25.57. Ubiquity of flotation sample wood charcoal taxa from LA 135290.

Common Name/Plant Part	Count	Percent
Cottonwood/willow wood	16	23

Saltbush/greasewood wood	9	13
Unknown conifer wood	41	58
Unknown non-conifer wood	5	7

Vegetal Samples

Maize kernels had the highest percent presence of non-wood plant remains in vegetal samples (Table 25.58). Although maize kernels were found in every room except 8 and 9A, the majority of kernels were from the fill of Rooms 1 and 6. Because the kernels are from fill, this pattern is probably related more closely to deposition after abandonment than to delineation of special activity areas. Upon first inspection of the average measurements of 122 kernels from LA 135290 (Appendix V), it would appear that kernels from the site are wider and thicker than those from LA 12587, but 11 percent more of the LA 135290 kernels are missing embryos and 5 percent more are swollen. This probably accounts for the differences in width and thickness.

Table 25.58. Ubiquity of vegetal sample carbonized plant remains from LA 135290.

*Number of samples with common name/plant part present; **number of samples with common name/plant part divided by total number of flotation samples with carbonized plant remains (64) × 100.

Maize cobs (17) from Rooms 1, 2, 3, and 5 were measured and had an average rachis diameter of 11.9 mm and an average cupule width of 5.6 mm (Table 25.59). The average row number was 11.4. Comparing these measurements to those from LA 12587 and LA 86534, it appears as if the cobs from LA 135290 are slightly more robust, with wider cupules, more rows, and larger diameters. However, the percentages of 12-row cobs are nearly equal in both cob assemblages (40% and 41%, respectively).

Table 25.59. *Zea mays* cob morphometrics from LA 12587, LA 86534, and LA 135290.

*2 rows of cob have kernels; ** a few kernels present; F = flattened, T = tip, U = undeveloped row present.

Beans were fairly widespread and were found in Rooms 1, 5, 6, 7, and 9A, primarily in room fill. Two beans were measurable from the site. One whole bean from a vegetal sample (FS 1201) was 11.6 mm in height, 6.5 mm in width, and 4.9 mm thick, and a single cotyledon from flotation sample FS 2353 was 10.8 mm in height, 6.2 mm in width, and 2.6 mm thick. Height and width measurements fall around the middle of the range given by Kaplan (1956: Table III) for the common bean (P*haseolus vulgaris)*. These also fit in the range of dimensions given for tepary beans, but the shape of the two species is quite different.

A possible beeweed stem (from vegetal sample FS 1450) and embryo (from FS 1897 flotation sample) mark the only archeobotanical evidence for the potential use of this resource for the project.

As in flotation samples, ponderosa pine was the most common wood taxon in vegetal samples. A partially burned roof beam fragment is probably ponderosa pine. Cottonwood/willow, pine, and piñon occur in nearly equal percentages of samples (34% to 39%), while juniper was found in 25 percent of samples. Douglas fir is slightly more abundant than in flotation samples, present in 5 of the 64 samples analyzed. The same shrubby species encountered in flotation samples (mountain mahogany, saltbush/greasewood, and oak) were also identified in vegetal samples.

Corn, beans, and squash were probably grown nearby, and weedy annuals that either volunteered in agricultural fields or thrived in the disturbed ground around the site were harvested for their seeds and edible greens. At least two grass taxa, beeweed, pincushion cactus, knotweed family, evening primrose, and piñon could have been used for food, dye, or medicine. The recovery of tobacco suggests this plant was part of the ceremonial life of the people who inhabited LA 135290 during the Middle Coalition period. Wood for construction and fuel was harvested from local sources.

Pollen Samples (Susan J. Smith)

A total of 83 pollen samples were analyzed from LA 135290. Table 25.60 lists the frequency of identified pollen types. Cultigens identified in the assemblage included low numbers of cotton and squash with higher amounts of maize, maize aggregate pollen, and cholla. Economic resources identified in the pollen assemblage included prickly pear, cactus family, beeweed, sunflower type, lily family (which includes yucca, wild onion, and sego lily), parsley family, sedge, mint family, and purslane. A number of other potential economic resources were identified in the assemblage (Table 25.60), and these are described in detail in Smith's chapter in Volume 3 (Chapter 63).

SITE OCCUPATIONAL HISTORY

As was discussed in the previous room summary sections, there appears to be at least two major construction episodes and three remodeling events that occurred at the roomblock. A detailed review of the bonding and abutment pattern of the walls within the roomblock reveals the overall construction history of the roomblock (Figures 25.60 and 25.61). The first construction phase at the site is represented by three separate events. Rooms 4/5 and 6 were built first. The west wall of these rooms is contiguous, with the north-south walls being abutted to the west wall and the east walls abutting to the north-south walls. There are small adobe buttresses in the northwest and northeast corners of Room 4 and the southeast corner of Room 6. These buttresses extended out about 50 cm outside of the cross-walls. Rooms 1 and 2 were added next. The north wall of Room 6 partially extends into Rooms 1 and 2. The north wall of Room 2 abuts to this wall extension and then forms a bonded corner at the intersection of the north and east walls of the room. The remainder of the corners in Rooms 1 and 2 are abutted. Room 8 appears to be the last room constructed during the initial construction phase of the roomblock. The west wall of Room 8 was constructed and then the north walls of Rooms 1 and 8 abutted to this wall. Otherwise, the remaining wall corners are all abutted. There is a single upright tuff block in the northeast corner of the room that extends north from the eastern wall, acting as a small buttress.

The second construction phase is represented by the addition of Rooms 3, 7, and 9B. The east-west walls of Rooms 3 and 7 abut with the south walls of Rooms 2 and 6. The adobe buttress in the northwest corner of Room 3 forced the west wall of the room to be offset further to the west. The southern walls of Rooms 3 and 7 and the eastern wall of Room 3 are not clearly defined and it is unclear as to whether they ever represented full standing walls. The east-west walls of Room 9B abut with the east wall of Room 2. In addition, the walls are set at a northwest-southeast orientation while the other walls in the roomblock are oriented east-west. Again, the east walls of Rooms 9A and 9B are not clearly defined and it is unclear as to whether these walls were ever full standing. It is also unclear as to whether Feature 15 was constructed during this later phase; however, it is situated on the same ancient surface and therefore may be associated with this occupation.

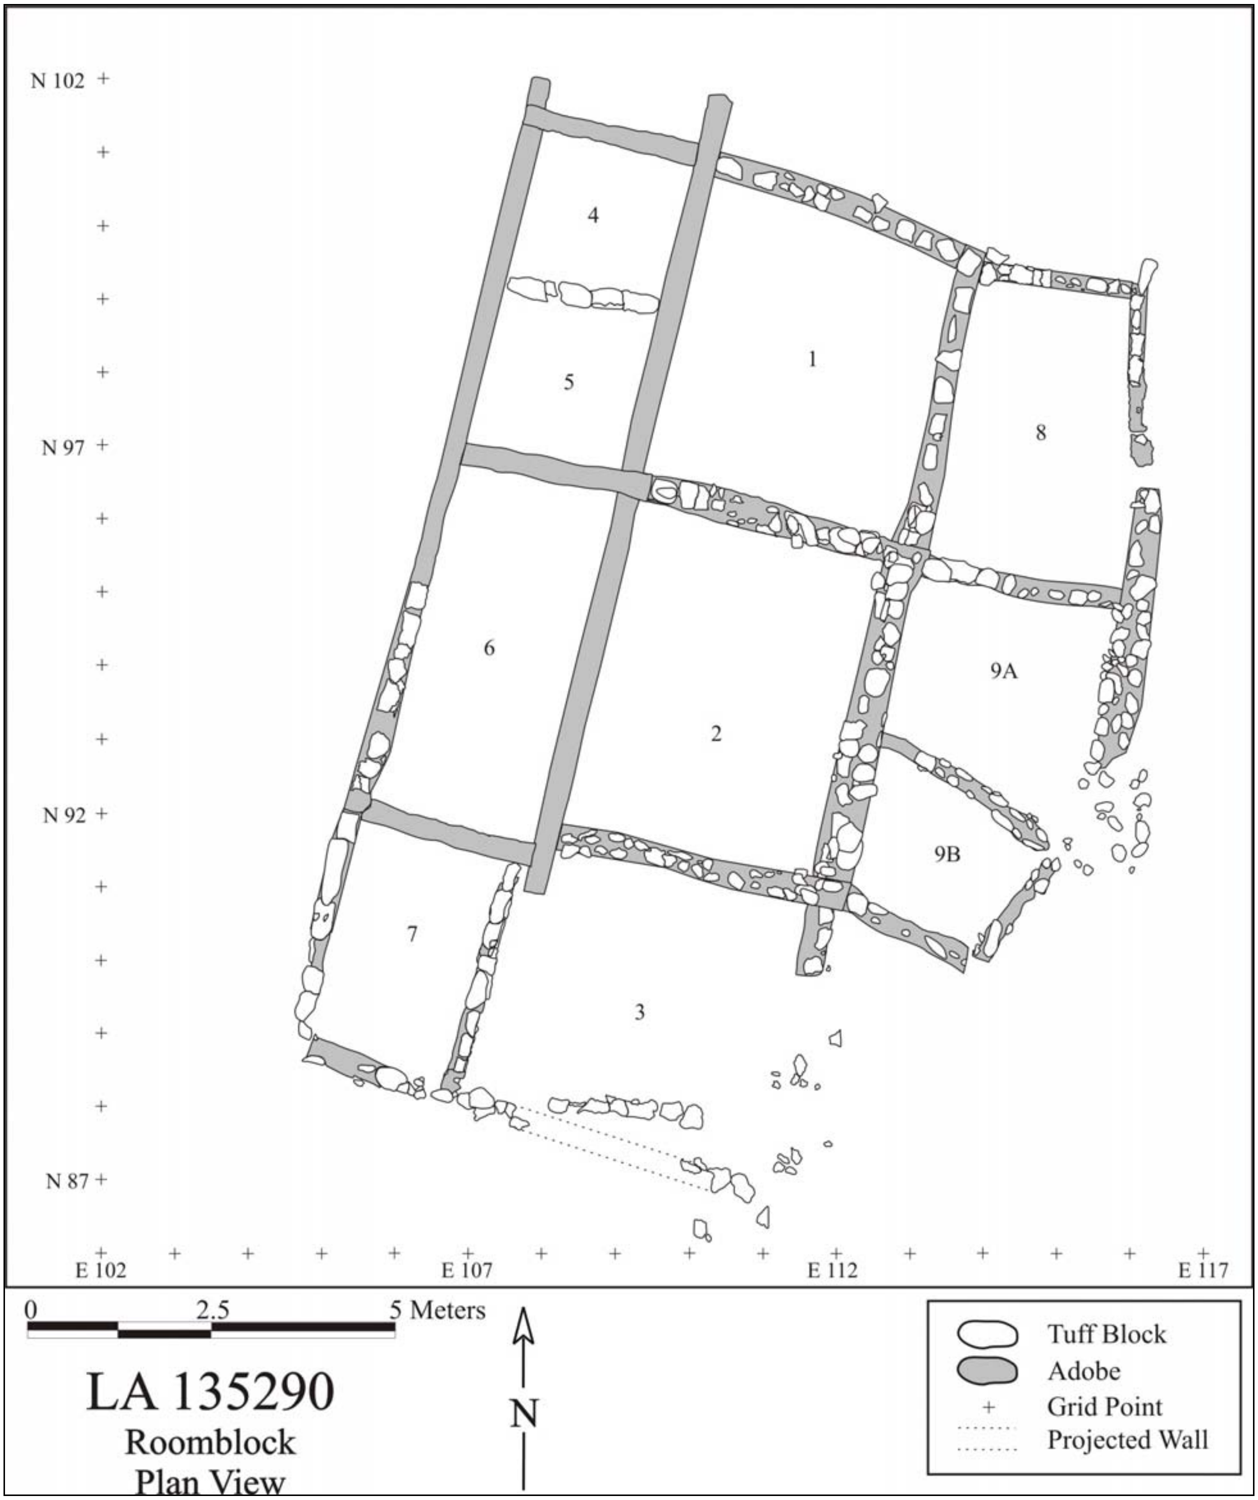

Figure 25.60. Plan view of roomblock.

Figure 25.61. Photograph of roomblock (south).

There appears to be at least three remodeling events associated with the occupation of the first construction phase of the roomblock. This is best represented in the three floors present in Rooms 4 and 6. These back rooms were presumably used for storage, and the successive burning and remodeling of these floors would seem to reflect the abandonment and later reuse of the roomblock. In contrast to the front rooms, the rear rooms are constructed of adobe and were burned on several occasions. Floors 2 and 3 in Rooms 4 and 6 are burned and Floor 1 is unburned in Room 6 and mostly unburned in Room 4. Since this burning is primarily limited to the rear rooms and the initial two floors, it may represent an intentional decision to fire-harden the rooms, making it difficult for rodents to burrow into the rooms. Nonetheless, the rooms were abandoned on several occasions with the floors being disturbed by rodent activity. These holes were subsequently repaired and a new floor was laid down over the repairs.

These three remodeling events are also represented in Room 2. Feature 16 (hearth) was constructed first and is overlain by a thin layer of sandy fill between it and Floor 1. Feature 11 (hearth) was built over Feature 16 and Features 3, 4, and 6 were constructed on Floor 1. Feature 1 (unused hearth?) was constructed last, being connected to Feature 3. The hearth (Feature 9) in Room 8 reflects only two remodeling events in this room. Additionally, the paucity of midden artifacts in the area would appear to indicate that the site was not occupied for an extended period of time, even though its construction history reflects two construction episodes and three remodeling events.

SUMMARY

LA 135290 consists of a Coalition period roomblock with a series of three front rooms, four back rooms, and three partial rooms (covered space or ramadas) that front the plaza. There is no evidence for the presence of a kiva at the site, and the midden is limited to a light surface scatter situated to the east of the roomblock. The initial occupation involved the construction of Rooms 1, 2, 4, 5, 6, 8, and 9A. The four front rooms were mostly constructed of masonry blocks, whereas the backrooms were constructed of adobe. This presumably reflects the functional differences between the use of the front rooms as domestic space and the back rooms as storage space. Three separate remodeling episodes are evident by the presence of multiple floors in Rooms 4/5 and 6, multiple features in Room 2, and a remodeled hearth in Room 8. The rear room floors were repaired during each subsequent occupation due to rodent disturbance. In addition, these floors were also fire hardened, probably as an attempt to protect food stores. It appears that the roof may have been removed during these periods of abandonment, since several of the preserved adobe floors in Rooms 4/5 and 6 exhibit both animal and human footprints. These prints were presumably made in the moist adobe that had been exposed to rainfall. Lastly, Rooms 3, 7, and 9B were added on to the existing roomblock with mostly unprepared floors. All remaining roof beams were removed from the site once the roomblock was finally abandoned.

The ceramic assemblage primarily consists of Santa Fe Black-on-white and smeared-indented corrugated, with some indented corrugated and other ceramics. The paucity of Kwahe'e and Wiyo Black-on-white reflects a Middle Coalition period of occupation. The AMS and archaeomagnetic dates overlap and cover a similar two-sigma range from AD 1160 to 1260 and 1170 to 1240, respectively.

A range of botanical remains were identified from flotation samples recovered from the hearths, including maize, beans, cheno-ams, dropseed grass, and tobacco. In addition, squash rind, piñon nuts, groundcherry, and sunflower were also represented at the site. The faunal remains also include a variety of species like jackrabbit, cottontail, rock squirrel, mule deer, turkey, and red-tailed hawk.

The stone tool technology reflects an emphasis on core reduction of materials like chalcedony, Pedernal chert, and obsidian. Most of the obsidian appears to have been obtained from nearby sources in the Valles Caldera. The retouched tool assemblage includes a mix of expedient flake tools like retouched pieces and perforators with lesser amounts of formal tools like bifaces, projectile points, and unifaces. Three of the four projectile points are corner-notched, indicating that this point type was still the dominant form being used. The manos are represented by both one- and two-hand varieties, with at least one example of the latter reflecting intensive use due to its wedge-shaped cross-section. The metates consist of undetermined fragments, which could represent millingstones or slab types. Polishing stones, abrading stones, a pestle, and mauls were also recovered, which indicates that a variety of domestic activities occurred at the site.

CHAPTER 26
AIRPORT-CENTRAL TRACT (A-7): LA 141505

Bradley J. Vierra

INTRODUCTION AND SITE SETTING

LA 141505 is a Classic period fieldhouse located on the Los Alamos town site mesa just north of New Mexico State Road 502 (Figure 26.1). The mesa top is sparsely covered by piñon and juniper trees and has an understory that is comprised primarily of saltbush, snakeweed, yucca, and various grasses. The site is situated at an elevation of 2164 m (7100 ft), but is accessible by Pueblo Canyon to the north and DP Canyon to the south.

Soils on the mesa top have been classified as a Hackroy sandy loam that have a good potential for agriculture (Nyhan et al. 1978). The site itself is underlain with about 1.50 m thick layer of Holocene soils, with some late Pleistocene clay lying directly on the Tshirege member of the Bandelier Tuff. Soil depth is greatest in the central area of the mesa, but thins to exposed bedrock along its edges.

The original survey identified the presence of several small tuff rock alignments within a 10 by 10 m area. The alignments were situated underneath a cluster of trees, so the duff obscured the nature and extent of the site. No artifacts were observed.

FIELD METHODS

Fieldwork at LA 141505 began by delineating the extent of the rock feature. The trees were cut down and the surface duff was removed. These activities exposed a small mound within the area defined by the rock alignments. Otherwise, no artifacts were observed on the surface. An east-west-oriented trench was initially excavated across the area through grids 107N/104E to 109E. This trench was excavated to define the walls within the structure and the stratigraphic sequence. After sections of the north-south walls were exposed, excavations proceeded to follow and expose the remaining wall segments thereby identifying the presence of at least two rooms. Each room was given an individual number, and excavations continued by removing the room fill in natural stratigraphic layers and 1- by 1-m grids. A block excavation including grids 104 to 110N/102E to 109E was excavated around the rooms. This area mostly contained the rock alignments situated to the east of the two rooms. The field supervisors at the site were Brad Vierra and Michael Dilley. Field crew members included Woody Aguilar, Sandi Copeland, and Greg Lockard. Timothy Martinez was the site monitor representing San Ildefonso Pueblo.

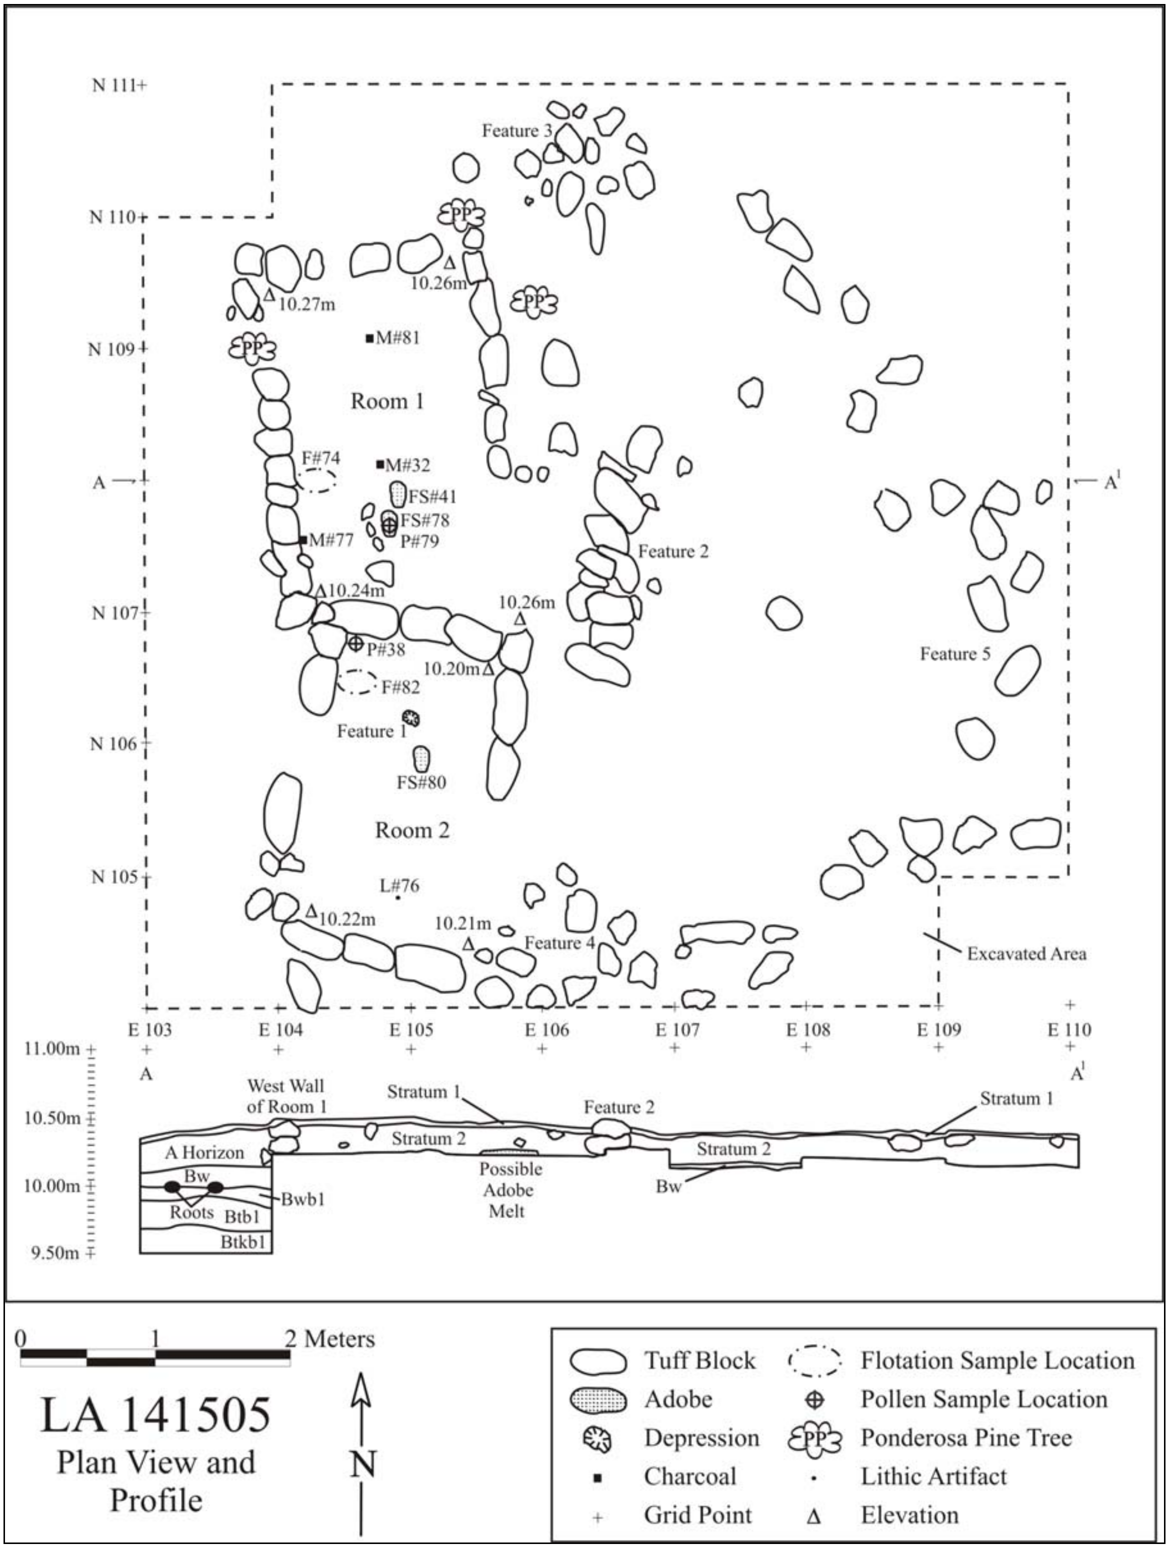

Figure 26.1. Plan view and profile maps of LA 141505.

STRATIGRAPHY

Stratum 1 consists of the loose surface soil that covers the site area and is generally 3 to 5 cm thick (Table 26.1). Stratum 2 is a thin layer of post-occupational fill that is about 5 to 10 cm thick and consists of the A and Bw soil horizons. Stratum 3 underlies Stratum 2, which is a compact silty loam that represents the Bwb1 soil horizon. This stratum was only exposed in grids 107N/103E and 107N/106E, which were excavated to lower depths. Otherwise, Stratum 2 was consistently removed across the excavation area. Strata 4 and 6 are the floors from Room 1 and 2, respectively. Stratum 5 is the fill from a rodent hole in grid 107N/103E that consisted of modern organic material. Lastly, Stratum 7 is the sediment from a single posthole (Feature 1) associated with the floor in Room 2. Table 26.2 shows the artifact counts by stratigraphic unit.

Table 26.1. Stratigraphy descriptions for LA 141505.

Stratum	Color	Texture	Thickness (cm)	Description
0	--	--	0	Surface
1	10YR 5/4	Silty loam	3–5	Unconsolidated surface soil

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is the northern room in the two-room structure (Figure 26.2). The room measures 2.5 m north-south by1.5 m east-west, with 3.75 m^2 of interior space. An east-west test trench (107N/103-106E) was initially excavated through the room to define site stratigraphy and the location of the floor. Excavations proceeded by removing the room fill to the immediate north of the trench by grid and natural layer.

Figure 26.2. Room 1 after excavation.

Fill. The room contained about 20 cm of post-occupational fill (Strata 1 and 2). This sediment consisted of a silty loam mixed with some fist-sized pieces of tuff, a few tuff blocks (wallfall), some bits of charcoal, and a few artifacts. The northern half of the room was extremely disturbed by both rodent activity and the intrusion of roots from two pine trees located just outside the northeastern corner of the room. A pollen (Field Specimen [FS] 21) and flotation (FS 22) sample were taken from the southeastern corner of the room. Taxa identified in the pollen sample include prickly pear (*Opuntia*), cheno-ams (*Chenopodium/Amaranthus*), grass family (Poaceae), sunflower family (Asteraceae), ragweed/bursage (*Ambrosia*), unidentified pine (*Pinus* sp.), piñon pine (*Pinus edulis*), juniper (*Juniperus*), Mormon tea (*Ephedra*), and sagebrush (*Artemesia*). No charred remains were identified in the flotation sample. Only a single macrobotanical sample (FS 73) was collected. Identified taxa included mountain mahogany (*Cercocarpus*) and unknown conifer (Gymnospermae).

Floor. The floor (Stratum 4) consists of an unprepared living surface. It is somewhat compacted, but was defined by a horizontal level situated at the base of the walls with bits of charcoal and roots situated on its surface. The northern area of the floor is heavily disturbed by roots and rodent activity. There is no coping between the walls and the floor.

No features or artifacts were associated with the floor. However, three large pieces of charcoal were collected from the floor in the north, south, and west parts of the room (FS 32, FS 77, and FS 81). No taxa were identified in FS 32, but Douglas fir (*Pseudotsuga menziesii*), mountain mahogany, and unknown conifer fragments were identified in the other two samples. Two large pieces of adobe were also present in the southern part of the room. A pollen sample (FS 79) was taken from underneath one of these pieces and taxa identified in the sample included maize (*Zea mays*), prickly pear, beeweed (*Cleome*), cheno-ams, grass family, sunflower family, spurge family (Euphorbiaceae), unidentified pine, piñon pine, juniper, walnut (*Juglans*), and sagebrush. These are two of only three chunks of adobe found in Rooms 1 and 2. A flotation sample (FS 74) was taken from grid 107N/105E in an area where the living surface was best preserved. Charred taxa included mountain mahogany and Douglas fir. The location where this sample was collected is also located near a possible entryway in the east wall.

Wall Construction. Table 26.3 shows the general wall measurements for Room 1. The four walls of the room are made of shaped tuff blocks that are horizontally laid with chinking stones. The blocks were about 35 by 25 by 15 cm in size and the chinking stones are fist-sized. The latter presumably reflect the isolated pieces of tuff found in the room fill. The north, west, and east walls are two courses high, whereas the southern wall is only one course high. The south wall is oriented with the walls constructing Room 2. In addition, the west wall of Room 1 abuts the northeastern corner of Room 2. Therefore, it appears that Room 1 was added after the construction of Room 2. The eastern wall of Room 1 does not connect to the south wall, leaving a 1-m-wide gap in the wall. This gap presumably reflects an entryway into the room. Given the lack of wallfall in the area, it would appear that all four walls were never full-standing walls. There was no evidence of any wall foundations or adobe footings under the walls. The base of the walls was situated near the top of the Bw soil horizon.

Table 26.3. Wall measurements for Room 1.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	1.45	0.10	0.25	2
South	1.66	0.30	0.27	1
East	1.75	0.35	0.22	2
West	2.45	0.35	0.30	2

Room 2

Sequence of Excavation. Room 2 is the southern room in the two-room structure (Figure 26.3). The room measures 2.34 m north-south by 1.35 m east-west, with 3.16 m^2 of interior space.

Excavations proceeded by removing the room fill in a north to south direction by grid and natural layer from the edge of the test trench that originally exposed the north wall of the room.

Fill. The room contained about 20 cm of post-occupational fill (Strata 1 and 2). This sediment was the same as in Room 1 with some fist-sized pieces of tuff, a few tuff blocks (wallfall), some bits of charcoal, and a few artifacts. However, most of the loose tuff blocks were situated adjacent to the west wall.

Figure 26.3. Room 2 after excavation.

Floor. The floor (Stratum 6) is also an unprepared living surface that represents the compacted top of the Bw soil horizon. A pollen sample (FS 38) and a flotation sample (FS 82) were taken from the surface in the northwestern corner of the room. Taxa identified in the pollen sample included beeweed, cheno-ams, grass family, sunflower family, spurge family, unidentified pine, piñon pine, juniper, oak (*Quercus*), and sagebrush. Taxa identified in the flotation sample included maize, unknown conifer, and unidentified pine.

A single feature (Feature 1) and a chalcedony core flake were associated with the floor. The feature consists of a small circular hole situated in the center of the room. It is 9 cm wide and 17 cm deep. The fill (Stratum 7) is composed of an unconsolidated silty loam with no charcoal or artifacts. Although there was no prepared floor in the room, there appeared to be an adobe cap over the feature. However, the presence of a few tuff blocks with adobe in the area may actually indicate that the adobe is simply melt derived from these items rather than being a formal "cap." A large chunk of adobe was also present to the immediate south of the feature. A pollen sample (FS 75) was taken from the pit fill and identified taxa included beeweed, cheno-ams, grass family, sunflower family, fir (*Abies*), unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush.

Wall Construction. Table 26.4 shows the general wall measurements for Room 2. The walls consist of a single course of shaped tuff blocks with some chinking stones. The east wall only consists of two blocks in the northeastern corner of the room, leaving a 1.30-m gap on this side of the room. The west wall also has a small (35 cm) opening in the middle; however, there is evidence that this gap may be due to a block falling outside of the room. Although some wall was present along the west wall, the amount of material was insufficient within the room to account for full-standing walls. No foundations or adobe footings were present under the walls. The base of the walls was, however, set into the Bw soil horizon.

Table 26.4. Wall measurements for Room 2.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	1.40	0.14	0.24	1
South	1.37	0.11	0.25	1
East	1.25	0.17	0.22	1
West	2.38	0.09	0.24	1

Rock Piles and Rock Alignments

Two rock piles and two rock alignments are situated to the immediate east of the structure. Feature 2 consists of a small linear rock alignment located 50 cm east of the entryway into Room 1. The alignment is 1.90 m long and is constructed from approximately 10 shaped and unshaped tuff blocks that are two courses high. It is dry-laid with no adobe mortar. Although the alignment is oriented roughly north-south, the blocks are stacked perpendicular to the long-axis of the alignment. The blocks are about 25 to 30 cm long and 20 cm wide. The base of the rock alignment is located just above the break between the A and Bw soil horizons. A pollen sample

(FS 83) was taken at the base near the center of the feature (Stratum 2). Taxa identified included sunflower family, cheno-ams, mustard family (Brassicaceae), ragweed/bursage, unidentified pine, piñon pine, juniper, oak, and sagebrush. It is unclear what the function of the alignment might have been, but it could have acted as a wind break for the entryway into Room 1 if other construction material was piled above the rock base.

Features 3 and 4 are rock piles located outside of the northeastern and southeastern corners of Rooms 1 and 2, respectively. Feature 3 is composed of a circular pile of tuff blocks about 1 m in diameter and 0.20 m high (Figure 26.4).

Figure 26.4. Feature 3 after excavation.

Feature 3 is 1 to 2 courses high and constructed of about 15 blocks. Four of the blocks are 30 to 40 cm long and 20 cm wide and the rest are 20 to 30 cm long and 10 to 15 cm wide. A pollen sample (FS 84) was taken from under a rock near the center of the pile (Stratum 2). Taxa identified in this sample included lily family (Liliaceae), cheno-ams, grass family, sunflower family, spurge family, unidentified pine, piñon pine, juniper, alder (*Alnus*), rose family (Rosaceae), and sagebrush. Feature 4 is similar to Feature 3, consisting of about 12 shaped and unshaped tuff blocks in a 1-m-diameter area. However, it is only one course high (Figure 26.5).

Figure 26.5. Feature 4 after excavation.

Feature 5 is a semi-circular arc of tuff blocks that opens towards the structure. The arc encloses about 15 m^2 of space to the immediate east of Rooms 1 and 2. The feature is composed of unshaped and shaped tuff blocks situated in a general alignment that is one course high. It measures about 6 m north-south and 3 m east-west. Feature 3 is located at the northwest end of the alignment and Feature 4 at the southwest end of the alignment. Otherwise, no features were observed within the enclosed space.

Features 3, 4, and 5 are all situated about 5 to 10 cm above the top of the Bw soil horizon and within the A horizon. This is the same stratigraphic context as Room 1. Therefore, it appears Room 2 was built first, with Room 1 and Features 3 to 5 being subsequently added on to the structure.

Test Pit

A single test pit (108N/103E) was excavated to a depth of 9.50 m (Figure 26.6), which was about 1 m below the ground surface. The profile exposed a soil sequence consisting, from top to bottom, of the A, Bw, Bwb1, Btb1, and Btkb1 soil horizons. A geomorphologic study of the site indicates that the blocks for Room 2 are set into the Bw horizon, whereas the blocks for Room 1 are set on top of the Bw horizon (see Drakos and Reneau, Volume 3). Tuff clasts that are inferred to be derived from Room 2 also lie underneath Room 1. The soil stratigraphic sequence, therefore, indicates that Room 2 is older than Room 1. The sequence also indicates that Features 2, 3, 4, and 5 are associated with the more recent occupation. Since the walls of the nearby Coalition period pueblos are associated with the top of the underlying Bwb1 soil horizon, it is assumed that the LA 141505 occupations date to the succeeding Classic period.

Figure 26.6. Photo of LA 141505 after excavation with test pit in foreground.

SITE CHRONOLOGY AND ASSEMBLAGE

Approximately 55 artifacts were recovered from excavations at LA 141505. All the artifacts were analyzed and a sample of pollen, flotation, and macrobotanical samples were selected for analysis (Table 26.5). Analysis results of the ceramics, lithics (chipped and ground stone), archaeobotanical, and pollen materials are presented in the following pages. No faunal remains were recovered from the site.

Table 26.5. Samples from LA 141505 selected for analysis.

Stratum	Sample Type		
	Pollen	Flotation	Macrobotanical
2	21, 83, 84	22	73
4	79	74	33, 77, 81
5		44

6	38	82	
7	75		

Ceramics (Dean Wilson)

While only 29 sherds were recovered from the fieldhouse at LA 141505, they included a range of types including Kwahe'e Black-on-white, Santa Fe Black-on-white, smeared-indented corrugated, Sapawe Micaceous, and glazewares (Table 26.6). This combination of pottery could reflect a Coalition or Classic period occupation; however, all these artifacts were recovered from post-occupational fill and none were recovered from the floor. Therefore, the earlier ceramics may be derived from the nearby roomblock at LA 135290. If so, the Classic period ceramics would support the geomorphic interpretation that the site dates to the later time period. Tables 26.7 through 2.9 show the summary ceramic data for the site, including general type, types by tradition, temper material by ware type, and ware by vessel form.

Table 26.6. Distribution of ceramic types from LA 141505.

Ceramic Types	Frequency	Percent

Lithic Analysis (Bradley Vierra and Michael Dilley)

Material Selection

A total of 26 chipped stone artifacts were analyzed from LA 141505. The assemblage consisted of a core, 19 pieces of debitage, three retouched tools, and three pieces of undetermined ground stone. This represents a 100 percent sample of the lithic artifacts recovered during the site excavations. Table 26.10 presents the data on lithic artifact type by material type from LA 141505. The majority of the debitage is made of chalcedony with lesser amounts of other materials. The presence of cortex on 42.1 percent of the debitage indicates that these materials were collected from waterworn (100.0%) sources. The chalcedony, Pedernal chert. and chert are available from local Rio Grande Valley gravel sources. Otherwise, the single ground stone artifact is made of dacite, which is available both as bedrock outcrops and in stream gravels that cross-cut the Pajarito Plateau.

Table 26.10. Lithic artifact type by material type.

Lithic Reduction

The single core recovered from the site was reduced using a single-directional, single-face technique. It was discarded as a result of a break along a material flaw. Table 26.11 presents the metric information on the core.

Table 26.11. Core type dimensions (mm) and weight (g).

Core Type	*n*	Length (*std*)	Width (*std*)	Thickness (*std*)	Weight (*std*)
Single-directional	1	28	47	39	59.4

The debitage mainly consists of core flakes (84.2%), with some angular debris and a single flake that was removed from a ground stone artifact. The majority of the flakes exhibit collapsed platforms (*n* = 4), with a cortical, a single-faceted, and a crushed platform. None of the platforms exhibit any evidence of preparation.

The majority of the core flakes consist of distal fragments (*n* = 7), with fewer whole (*n* = 5), proximal (*n* = 2), and midsection (*n* = 2) fragments. The whole core flakes have a mean length of 36.0 mm (*std* = 6.8) and the angular debris a mean weight of 34.7 g (*std* = 48.5).

The retouched tools consist solely of three retouched pieces. Each has a bi-directionally retouched edge, with straight, concave, and convex edges and edge angles of 70, 45, and 65 degrees, respectively.

Tool Use

Four flakes (21.0%) exhibit evidence of damage that could be attributed to use-wear. Most of the damage is located along the lateral edge of the flake (*n* = 3), with one on the dorsal surface (i.e., ground stone flake). The lateral edges are all straight with edge angles ranging from 45 to 60 degrees.

The three pieces of undetermined ground stone consist of dacite cobble fragments with ground surfaces. All three of these artifacts are burned.

Archaeobotanical Remains (Pamela McBride)

A possible corn cupule fragment from the northwestern corner of the Room 2 floor was the only cultural plant part recovered from flotation samples besides wood charcoal (Table 26.12). Modern intrusive material comprised the balance of the flotation plant record. These included uncarbonized weedy annual seeds, juniper twigs, pine umbos, and piñon needles.

Table 26.12. Flotation sample plant remains from LA 141505.

Mountain mahogany	14/0.4 g	
Totals	**20/0.4 g**	**7/<0.1 g**

A sample from the fill of a rodent hole was taken as a control sample and, indeed, this sample was quite different from others, resembling a cache of rodent edibles that included large numbers of unburned juniper seeds and twigs, pine umbos, piñon seeds, and prickly pear cactus seeds (absent in all other samples; Table 26.14). Vegetal sample wood was similar to flotation with possible Douglas fir, mountain mahogany, and unknown conifer identified in the fill and floor of Room 1.

Table 26.14. Vegetal sample plant remains by count and weight in grams from LA 141505.

Total Wood	-	12/0.4 g	28/3.5 g	6/0.6 g

+1–10/liter, t twig, u umbo.

The possible corn cupule fragment on the Room 2 floor could indicate that corn was processed or burned for fuel in the room. Pine and mountain mahogany are readily available today at LA 141505, but Douglas fir may have come from Pueblo Canyon to the north or DP Canyon to the south of the site. It is also possible that during the time the site was occupied Douglas fir grew closer, as this species has a range of 6500 feet to nearly tree line and the site is at an elevation of 7100 feet.

Pollen (Susan J. Smith)

A total of six pollen samples were analyzed from various contexts at LA 141505. Table 26.15 lists the frequency of identified pollen types from the site. Maize was the only cultigen identified in the assemblage. Economic resources identified in the pollen assemblage included prickly pear, beeweed, sunflower type, and lily family (which includes yucca, wild onion, and sego lily). A number of other potential economic resources were identified in the assemblage and are listed in Table 26.15. Pollen types and resources are described further in Volume 3 (Chapter 63).

SUMMARY

LA 141505 is a two-room Classic period fieldhouse that was constructed from both shaped and unshaped tuff blocks. The site is located near LA 135290, a Middle Coalition period roomblock, which is located several hundred meters to the west. The small size of the structure indicates that it was unlikely to have been used for even short-term habitation, as it would have been too small to offer much comfort. However, its location near areas suitable for farming and the presence of maize indicate that the site did play a role in agricultural activities.

CHAPTER 27
AIRPORT TRACT: AIRPORT SITES 1 AND 2

Charlie Steen and Bradley J. Vierra

INTRODUCTION

Excavations were conducted at two archaeological sites situated in the area of the Los Alamos airport in 1951. The exact location of these sites is undetermined, but they are presumed to be situated where the current standing buildings of the airport are located. The airport is also situated on the Los Alamos town site mesa, with the site area being over 1000 m west of LA 135290 (Chapter 25, this volume). The airport sites were denoted as Airport 1 and 2 and were excavated by Frederick Worman of Los Alamos Scientific Laboratory. The only information available on these excavations is presented in simple summary form by Steen (1977:65–66). This information is presented here, with additional data collected from the analysis of collections curated at the Laboratory of Anthropology and photographs curated at the Los Alamos Historical Society.

SITE DESCRIPTIONS

Airport 1 probably had five rooms with walls of unshaped tuff blocks. There is no ground plan available for the site. The ceramics were described as including Santa Fe Black-on-white, with a flaked axe and a broken mano also being identified.

Airport 2 contained nine rooms with walls of large unshaped tuff blocks (Figures 27.1 and 27.2). It is unclear as to whether there was no kiva present at the site, or whether Worman simply failed to excavate in the area to the east (in front) of the roomblock to determine if one was present. Although no features were noted, many charred maize cobs and kernels were recovered from Room 3. Santa Fe Black-on-white is also identified as the main pottery type being present, with no lithic artifacts being noted. Figure 27.3 shows Worman during the excavation of one of the sites. As can be seen, a large formal slab metate, two two-hand manos, and a vent plug are visible in the photograph. In addition, the excavation method is clearly evident. That is, the fill was removed by shovel and discarded directly into a truck.

A total of 148 sherds were analyzed by Dean Wilson (see Volume 3, Chapter 58) from the collections curated at the Laboratory of Anthropology. Most of these sherds, however, were recovered from the Airport 2 site (Tables 27.1, 27.2, and 27.3). The analyzed sherds likely represent a biased collection from the excavations, but they do indicate that both the Airport 1 and Airport 2 sites date to the Late Coalition period and include Santa Fe, Wiyo, and Galisteo Black-on-white ceramics.

McBride's (see Volume 3, Chapter 62) analysis of the burned maize from Room 3 at Airport Site 2 indicated that several masses of kernels were present and that the regular arrangement of the kernels for many of these indicates that maize was being stored on the cob and stacked in very orderly rows that were multiple layers high. The cob rachis was burned away and ears were probably husked before storage (kernels were fused "head to head" with no husk remnants between and no space where a husk might have been). A similar pattern was identified at the Late Coalition period roomblock at LA 12587. Table 27.4 provides information on maize kernel size measurements for the Airport 2 site, LA 12587 (see Chapter 14), and LA 135290 (see Chapter 25). The kernels from LA 135290 are slightly thicker and wider than those from Airport 2 and LA 12587, and may, therefore, have been treated with lime or had a higher moisture content when burned, causing slightly more swelling and loss of embryos (King 1987; Stewart and Robertson 1971).

Site	*n*	Height	Width	Thickness
Airport 2	50	7.4	6.6	4.1
LA 12587	330	7.3	6.6	4.0
LA 135290	122	7.6	7.2	4.4

Two pieces of bone were identified in the collections from the Airport 2 site that are curated at the Laboratory of Anthropology in Santa Fe. Both pieces of bone were in Catalog number 20116 and both pieces were recovered from Trench 1. The fragments were identified as being unidentified medium/large-sized mammal long bones. Neither of the bones showed evidence for burning and no other identifying marks were present.

CHAPTER 28
RENDIJA TRACT (A-14): LA 15116

Gregory D. Lockard

INTRODUCTION AND SITE SETTING

LA 15116 is a small structure located on the north-facing slope on the south side of Rendija Canyon that dates to the Middle Classic period. The site is located a few hundred m to the northeast of the entrance to the Los Alamos Sportsmen's Club in the western half of the Rendija Tract. Vegetation on the site consists of ponderosa pine trees, which were severely burned during the Cerro Grande fire, as well as some piñon and juniper trees and a predominantly grass understory. The site is situated at an elevation of 2116 m (6944 ft).

The site was first surveyed on November 1, 1976, by Charlie Steen and given the temporary site number T233. Steen believed the site was a one-room fieldhouse. The site was re-recorded on April 23, 1999, by Los Alamos National Laboratory cultural resources personnel and given the temporary site number K138. It was noted by personnel on this visit that "the fieldhouse was constructed primarily of unshaped tuff cobbles stacked against large boulders which [sic] form part of the southern section of the structure." No surface artifacts were detected during the site visit because of a thick layer of pine duff that covered the site and likely obscured any artifacts that were on the surface.

FIELD METHODS

Before excavation, the site and surrounding area were cleared of trees and large undergrowth. The site was then visible as a ring of rubble with interior dimensions of 3 by 3.5 m. An arbitrary site datum (designated 100N/100E, 10.0 elevation) was set up in the southwest corner of the site. The site was then covered with a 1- by 1-m grid system that extended 6 m north and 8 m east of the site datum. Two subdata (A and B) were set up for taking elevations. The site was then photographed and surface collected. Two ceramic sherds were the only artifacts encountered in the surface collection.

A 6- by 1-m east-west trench was initially excavated across the middle of the ring of rubble (103N/101E to 106E). The purpose of this trench was to expose a profile of the site stratigraphy, as well as to determine the location of the structure's east and west walls. Units were excavated by strata, and thicker strata were excavated in arbitrary 10-cm levels. Within the structure, the trench units were excavated down to a compact surface thought to be the room's living surface. Outside of the structure, the trench units were excavated down to the top of the sterile Btb1 horizon. The westernmost unit in the trench (103N/101E) was chosen to serve as a test pit for geological analysis. Excavation in this unit therefore continued through the Btb1 horizon down to the Otowi Member of Bandelier Tuff (bedrock). The southern profile of the trench was then drawn and photographed. The rest of the site was subsequently excavated, again by strata and arbitrary levels for thicker strata.

In all, 28 units were excavated. Within the structure, excavation proceeded down to the living surface encountered while excavating the trench. Outside of the structure, excavation proceeded down to the top of the sterile Btb1 horizon. Excavation focused on defining the structure's walls, removing wallfall, and locating features. Soil samples were taken from select locations, and all other soil was passed through screens with 1/8-in. mesh to aid in the recovery of artifacts. The excavation area extended approximately 1 m beyond the structure in all directions to locate any associated external features and/or outdoor activity areas. The area to the east of the structure contained the highest concentration of artifacts, as well as a short, external wall. The excavation area was therefore extended 2 m to the east of the structure to fully define the external wall and to sample more of this area of concentrated artifacts. The site was then photographed (Figure 28.1) and mapped (Figure 28.2).

Figure 28.1. Post-excavation photograph of Room 1 at LA 15116.

The excavation of the site was supervised by Greg Lockard. The field crew included Joseph Aguilar, Brandon Gabler, and Kari Schmidt. Aaron Gonzalez and Michael Chavarria served as site monitors, representing San Ildefonso and Santa Clara pueblos, respectively.

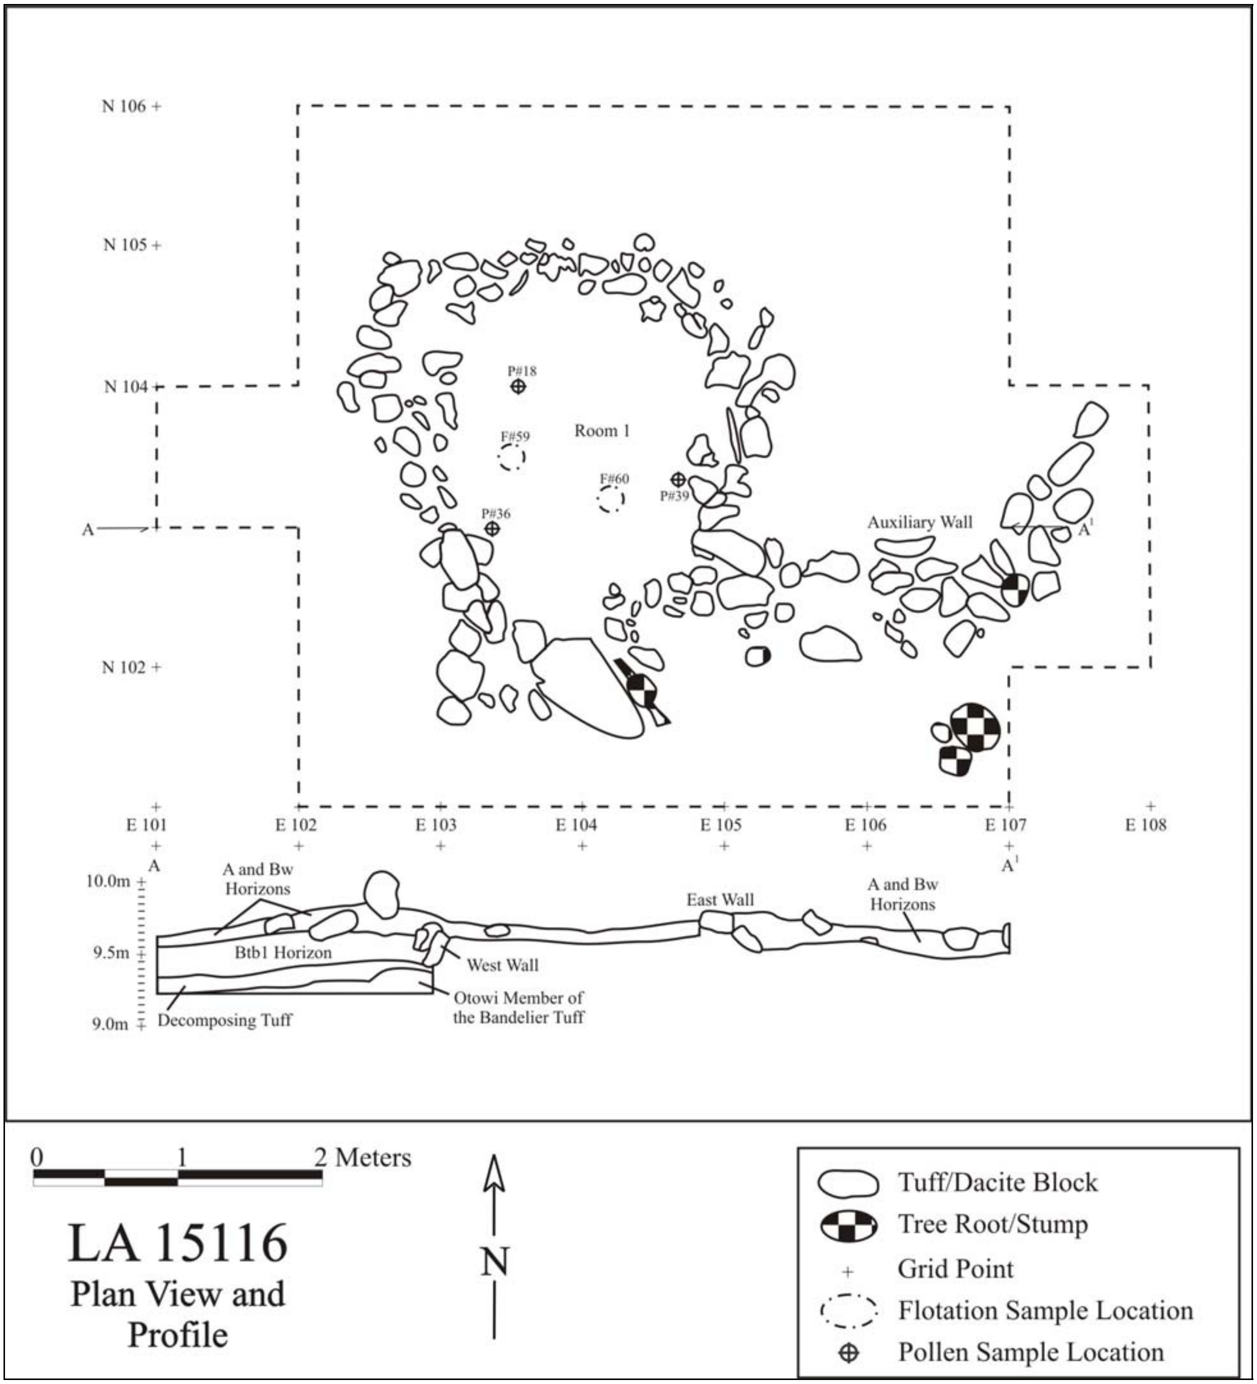

Figure 28.2. Plan view and profile drawings of Room 1 at LA 15116.

STRATIGRAPHY

Stratum 1 is composed of loose surface sediment (Tables 28.1 and 28.2). It is uniformly 2 to 5 cm thick across the site and is roughly equivalent to the top half of the A horizon (topsoil). Stratum 2 is post-occupational fill and ranges from 2 to 20 cm thick in the area excavated. The fill was thickest in and around the collapsed walls of the structure and thinned away from the walls and towards the center of the room. Stratum 2 includes the lower half of the A horizon and the Bw horizon. Stratum 3 is the Room 1 living surface, and Stratum 4 is the sterile Btb1 horizon. Artifact counts from each stratum are shown in Table 28.3. The Btb1 horizon rests on top of the Otowi Member of Bandelier Tuff (bedrock).

Table 28.1. LA 15116 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10YR 5/3	Loamy sand	2–5	Surface sediment
2	10YR 6/3	Loamy sand	2–20	Post-occupational fill
3	10YR 6/3	Loamy sand	-	Room 1 living surface
4	7.5YR 5/4	Loamy sand	35	Early-middle Holocene soil

Table 28.2. LA 15116 soil horizon descriptions from the north profile of the geological test pit (grid unit 103N/101E).

Horizon	Color	Texture	Depth (cm)	Description
A	10YR 5/3	Loamy sand	0–10	Topsoil
Bw	10YR 6/3	Loamy sand	10–20	Late-Holocene soil
Btb1	7.5YR 5/4	Loamy sand	20–40	Early/middle-Holocene soil
R	-	-	40+	Otowi Member of Bandelier Tuff (bedrock)

Total	**83**	**40**	**0**	**0**	**123**

SITE EXCAVATION

Room 1

Sequence of Excavation. LA 15116 is a one-room (Room 1) structure that probably functioned as a fieldhouse. Due to the fact that the walls were poorly constructed and poorly preserved, the exact shape of the room could not be determined. Some of the walls defined through excavation were quite straight, while others curved significantly outwards. The room does not appear to be D-shaped, however, and can be best described as elliptical. The room measures 2.50 m north-south by 1.90 m east-west, with approximately 4.75 m^2 of interior space. Excavation of the room began with an east-west trench that extended across the site (103N/101-106E). The excavation of this trench served to define the stratigraphy and locate the east and west walls and living surface of the room. After the excavation of the trench, the rest of the room was excavated down to the presumed living surface encountered in the trench. After the entire room was excavated and its living surface photographed, a small test pit was excavated below the living surface in grid 103N/103E. The purpose of this test pit was to determine whether or not there were any floors or additional living surfaces below, as well as to ascertain how deep the foundation of the west wall extends in that location. No additional living surfaces were encountered, and the wall foundation was found to extend approximately 20 cm into the Btb1 horizon.

Fill. The room was filled with 2 to 5 cm of surface sediment on top of 4 to 15 cm of post-occupational fill. The fill was thickest in and around the collapsed walls, and thinned away from the walls and towards the center of the room. Flotation (Field Specimen [FS] 31) and pollen (FS 32) samples were taken from the Room 1 fill. Charred taxa identified in the flotation sample included sunflower family (Compositae), piñon pine (*Pinus edulis*), and ponderosa pine (*Pinus ponderosa*). Taxa identified in the pollen sample included cheno-ams (*Chenopodium/Amaranthus*), grass family, sunflower family (Asteraceae), ragweed/bursage (*Ambrosia*), chicory tribe (Liguliflorae), unidentified pine (*Pinus* sp.), piñon pine, juniper (*Juniperus*), oak (*Quercus*), and sagebrush (*Artemesia*).

Floor. No formal, prepared floor was encountered during the excavation of Room 1. Nevertheless, an informal living surface was identified. This surface was distinguishable from the post-occupational fill above (Stratum 2) and the sterile Btb1 horizon below (Stratum 4) in a number of ways. First, it was more compact than the fill above and relatively devoid of rocks. The few rocks that were embedded in the surface were generally large. These rocks appear to be wallfall that fell onto the living surface when it was wet, and thus became embedded in the surface. The living surface is also slightly darker in some locations than both the fill above and sterile Btb1 horizon below. These darker areas appear to be ash stains. The living surface also differs from the sterile Btb1 horizon in that the former lacks the ped structure of the latter. The location of the living surface directly on top of the Btb1 horizon suggests that the surface was constructed by clearing the loose sediment from on top of this harder, subsurface soil. This harder surface then appears to have been leveled, as indicated by the fact that although the site was constructed on a slope, the living surface is almost completely level. The living surface was therefore purposefully constructed. There is no evidence, however, that the surface was ever covered with a formal, prepared floor composed of adobe and/or plaster.

No artifacts were encountered in direct association with the living surface. Pollen samples were taken from beneath rocks lying directly on top of the living surface in the northwest (FS 18) and southwest (FS 36) quadrants of the room. Taxa identified in FS 18 included maize (*Zea mays*), cheno-ams, grass family, mustard family (Brassicaceae), sunflower family, ragweed/bursage, spruce (*Picea*), fir (*Abies*), unidentified pine, piñon pine, juniper, oak, Mormon tea (*Ephedra*), and sagebrush. Taxa identified in FS 36 included cholla (*Opuntia*), cheno-ams, grass family, sunflower family, spruce, fir, unidentified pine, piñon pine, juniper, oak, knotweed (*Polygonum* frilly type), rose family (Rosaceae), Mormon tea, and sagebrush. A third pollen sample (FS 39) was taken from directly on top of the living surface in the east-central portion of the room. Taxa identified in this sample included cheno-ams, grass family, sunflower family, ragweed/bursage, unidentified pine, piñon pine, juniper, oak, rose family, Mormon tea, and sagebrush. Two flotation samples (FS 59 and FS 60) were taken of the living surface matrix in the center of the room. Taxa identified in these samples included ponderosa pine, unknown conifer (Gymnospermae), and mountain mahogany (*Cercocarpus*).

Wall Construction. As mentioned above, Room 1 appears to have been more elliptical than rectangular. As a result, it is impossible to clearly differentiate between the north, south, east, and west walls. In addition, the wall was poorly constructed and poorly preserved. Consequently, it was often difficult when excavating the room to differentiate between *in situ* portions of the wall and wallfall. The wall does appear, however, to have been composed of a single row of unshaped dacite and tuff cobbles. A large number of rocks were encountered directly outside of this wall, many of which are firmly embedded in the Btb1 horizon. These rocks may have formed a second, exterior ring of rocks that functioned to give the wall added support. It is more likely, however, that they were wallfall.

In some locations, the wall foundation was composed of two long, thin, parallel upright slabs. This type of wall foundation has been encountered at several Coalition period (AD 1200–1325) roomblocks on the Pajarito Plateau, including LA 12587 in the White Rock Tract. In most places, however, either a single row of large rocks or several small, unaligned rocks formed the wall foundation. Much of the southern portion of the wall was formed by a very large rock that is too large to have been brought to the site. This indicates that the people who constructed Room 1 incorporated a naturally occurring rock into the wall. The presence of this large rock may in fact have been the reason that the structure was built in that location. In general, dacite cobbles were utilized in the wall foundation, and tuff blocks were reserved for upper courses of the walls. These rocks range in size from very large, immovable boulders to small, fist-sized cobbles. None of the rocks were shaped, although rectangular rocks and rocks with flat surfaces appear to have been selected when readily available.

Judging from the amount of wallfall removed during the excavation of the area in and around Room 1, the masonry portion of the room's walls were originally considerably higher than they were at the time of excavation. In order to estimate the original height of the walls, all of the rocks removed as wallfall during the site's excavation were placed in one stack, which was then measured. The stack measured 3.70 by 0.60 by 0.60 m, for a total of approximately 1.33 m^3 of wallfall. Based on this volume of wallfall and the overall length, average thickness, and average height of the extant portions of the wall, the masonry portion of the room's walls were originally approximately 0.69 m in height. The upper portion of the wall and ceiling, if it ever had them, were most likely composed of vegetal material and adobe. These materials are rarely preserved at archaeological sites on the Pajarito Plateau. In fact, only two small pieces of burned adobe were recovered from the site (FS 35 and FS 37).

Auxiliary Wall

During the excavation of the area to the east of Room 1, an alignment of rocks was encountered. The alignment, which is most likely the remains of a short wall, extends eastward from the southeast portion of Room 1 and then curves to the north. This wall probably served to define the southern and eastern boundaries of a small, outdoor work area or patio. In fact, the area to the east of Room 1 and north of the wall contained the highest concentration of artifacts at the site. This "auxiliary" wall is about 2.90 m long and appears to have been constructed of either a double row of rocks that was one course high or, more likely, a single row of rocks that was two courses high. The general wall measurements for Room 1 and the auxiliary wall are provided in Table 28.4. Because Room 1 was more elliptical than rectangular and the auxiliary wall was curved, the lengths provided below are approximations.

Table 28.4. LA 15116 Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	2.00	0.04–0.16	0.14–0.45	1
South	1.70	0.08–0.60	0.15–0.90	1 to 2
East	1.75	0.05–0.30	0.15–0.58	1 to 2
West	2.35	0.05–0.44	0.16–0.34	1 to 2
Auxiliary	2.90	0.07–0.24	0.22–0.55	1

Geological Test Pit

A single unit (103N/101E) was excavated below the top surface of the Btb1 horizon to serve as a geological test pit. The north profile of this unit, which was analyzed by geologists Paul Drakos and Steven Reneau, contained a soil sequence consisting of an A horizon (topsoil), and Bw horizon (a late-Holocene soil), and a Btb1 horizon (an early/middle-Holocene soil). Below the Btb1 horizon was a thin layer of decomposing tuff on top of the Otowi Member of Bandelier Tuff (bedrock). After the site was completely excavated and photographed, the southernmost portion of the test pit was extended eastward to the west wall of Room 1 in order to determine the depth of the wall's foundation. The excavation revealed that the foundation of this section of the wall extended about 20 cm into the Btb1 horizon, just a few cm above bedrock.

Artifact Distribution

As Table 28.5 demonstrates, the majority of artifacts recovered from LA 15116 are from the area just east of Room 1 and just north of the auxiliary wall (103-105N/105-106E). In addition, more artifacts were encountered in the northern half than in the southern half of the excavated area. No entryway was encountered during the excavation of Room 1. A number of factors, however, suggest that it was located to the east. First, the auxiliary wall is located to the east and would have served to funnel anyone approaching the room from this direction to the east-central portion of the room's wall. Secondly, the increased artifact density to the east of the structure most likely represents an activity area or patio to the east of the structure. Activity areas associated with Rendija Canyon fieldhouses excavated during the Conveyance and Transfer Project tend to be located just outside the entryway. An alternative explanation for the increased artifact density to the east of the room is that the artifacts were swept from inside the room through the entryway and into this area. This again would indicate that the room's entryway was located to the east.

The increased artifact density to the east of the structure is therefore the result of cultural formation processes (i.e., an activity area or the result of cleaning the interior of the room). The increased artifact density in the northern, downhill half as opposed to the southern, uphill half of the excavated area, on the other hand, is most likely due to natural formation processes (i.e., erosion).

Table 28.5. LA 15116 artifact counts by grid unit.

	101E	102E	103E	104E	105E	106E	107E
105N	--	1	4	3	5	16	--
104N	--	**1**	**1**	**2**	11	7	--

102N	--	0	**2**	**0**	0	14	7
101N	--	0	0	0	3	0	--

Note: counts do not include two artifacts found outside of the excavated area during surface collection; bold numbers indicate grid units that are located completely or partially within Room 1.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 124 artifacts were analyzed from excavations at LA 15116. Analyses of the ceramics, lithics, pollen, and archaeobotanical materials were conducted (Table 28.6). No faunal remains or ground stone items were recovered from the excavations. The results of these analyses are presented in the following pages.

Ceramic Artifacts (Dean Wilson)

Eighty-five sherds were recovered from LA 15116. Most of these are Biscuit B/C body sherds, with Biscuit B and Sapawe Micaceous. Assuming that the Biscuit B/C sherds actually represent Biscuit B, then the site would date to the Middle Classic period (15th century). This corresponds with the presence of glazeware ceramics, which also indicate a Classic period occupation. Tables 28.7 through 28.10 show the summary ceramic data for the site, including general type, types by tradition, temper material by ware type, and ware by vessel form. Most of the grayware and whiteware ceramics are made from local anthill sand or tuff temper; however, a single plain gray body and the Sapawe Micaceous sherds are tempered with non-local granite with mica, and the three glazeware sherds with non-local basalt. All of the utilitywares, glazewares, and micaceous wares are broken fragments from jars. In contrast, most of the whitewares are bowls, with some jar vessel forms.

Table 28.7. Distribution of ceramics types from LA 15116.

Ceramic Types	Frequency	Percent
Northern Rio Grande Whiteware		
Unpainted undifferentiated	2	2.4

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 39 artifacts were analyzed from LA 15116, consisting of a core and 38 pieces of debitage. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 28.11 presents the data on lithic artifact type by material type. The majority of the debitage is made of chalcedony and Pedernal chert with lesser amounts of other materials. The presence of cortex on 18.4 percent of the debitage indicates that these materials were collected from waterworn (n = 7) sources. The chalcedony, Pedernal chert, and general chert are available from local Rio Grande Valley gravel sources. Otherwise, the rhyolite is available both as bedrock outcrops and in stream gravels that cross-cut the plateau.

Lithic Reduction

The single core was reduced using a single-directional, multi-face technique (Figure 28.3). It was classified as still useable when discarded. Table 28.12 presents the metric information on this core.

Table 28.12. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Single-directional	41	61	83	298.7

The debitage mainly consists of core flakes with a few pieces of angular debris and a microdebitage. The overall cortical:non-cortical ratio of 0.20 reflects an emphasis on the later stages of core reduction.

The majority of the flakes exhibit single-faceted platforms (*n* = 10), with cortical (*n* = 1), collapsed (*n* = 3), and crushed (*n* = 4) platforms. None of the flake platforms exhibit evidence of preparation. Most of the core flakes consist of whole flakes (*n* = 18), with fewer proximal (*n* = 3), midsection (*n* = 2), and distal (*n* = 9) fragments. The whole core flakes have a mean length of 25.8 mm (*std* = 8.9) and the angular debris have a mean weight of 1.2 g (*std* = 1.2).

Tool Use

None of the flakes exhibit any obvious evidence of edge damage that could be attributed to use.

Archaeobotanical Remains (Pamela McBride)

The majority of plant remains from this Middle Classic period one-room circular fieldhouse consisted of burned and unburned conifer needles (Table 28.13). Aside from the piñon and ponderosa pine needles, cultural material was limited to single occurrences of burned seeds that compared favorably to dock, as well as grass family seeds and unidentifiable plant parts. The conifer needles are probably part of conifer fuel wood residue. Although young dock leaves can be eaten like spinach (Harrington 1967:90), basing use of the plant on the recovery of a single seed is dubious. Unburned seeds of this taxon were recovered from all three samples as well, making it even more difficult to say with any certainty that the seed represents economic use.

All plant remains are seeds unless indicated otherwise. Cultural plant remains are charred, non-cultural plant remains are uncharred. + 1-10/liter, cf. compares favorably, pp plant part.

Ponderosa pine dominated the wood assemblage, but oak, piñon, sagebrush, and unknown conifer were also present (Table 28.14). The most that can be said about subsistence at LA 15116 is that local wood resources were used for fuel or construction.

Pollen Remains (Susan J. Smith)

A total of four pollen samples were analyzed from LA 15116. Table 28.15 lists the frequency of identified pollen types. Cultigens identified in the assemblage included maize and cholla. A number of potential economic resources were identified in the assemblage (Table 28.15), and these are described in detail in Smith's chapter in Volume 3 (Chapter 63).

SUMMARY

LA 15116 is a one-room Middle Classic period fieldhouse that was constructed from both shaped and unshaped tuff blocks. The site is located in Rendija Canyon on a terrace overlooking the creek. Maize pollen was recovered from the site excavation, therefore, the one-room structure was presumably occupied during the growing season.

CHAPTER 29
RENDIJA TRACT (A-14): LA 70025

Michael J. Dilley and Bradley J. Vierra

INTRODUCTION

LA 70025 is a small structure located on an eroding east-west-trending finger ridge that extends into Cabra Canyon and that dates to the Early/Middle Classic period. The site is located approximately 40 m to the west of the canyon bottom. Vegetation on the site consists of a few scattered junipers and various wild grasses and low shrubs. Vegetation in the surrounding area consists of ponderosa pine trees, many of which were severely burned during the Cerro Grande fire, as well as piñon pine and juniper trees. The site is situated at an elevation of 2122 m (6960 ft).

The site was first surveyed on June 23, 1988, and given a temporary site number of L-53. It was revisited by Los Alamos National Laboratory cultural resources personnel on March 16, 1992, and given a temporary site number of B-18. The site was initially recorded as two one-room structures, both of which were probable fieldhouses and that were constructed of roughly coursed tuff blocks. Two surface artifacts were recorded: a Wiyo/Biscuit A (Abiquiu Black-on-gray) sherd, which was worked on one edge, and one Pedernal chert flake.

FIELD METHODS

Before excavation proceeded, the area was cleared of fallen trees and undergrowth to ensure safe working conditions and to expose the extent of the structure (Area 1). An arbitrary site datum (designated 100N/100E) was established in the southwest corner of the site. A 1- by 1-m grid system was then established, covering the site and extending 2 m north, 2 m south, and 6 m east of the site datum. Two subdata (A and B) were set up for taking elevations. Pre-excavation photographs were taken and the site was surveyed for surface artifacts (Figure 29.1).

A 5- by 1-m trench was initially excavated across the middle of the site (grids 100N/102-106E) to determine extent of the structure and stratigraphy and to locate the east and west walls of the structure. Units were excavated by strata and thicker strata were excavated in arbitrary 10-cm levels. Within the structure, the trench units were excavated to a compact surface thought to be the living surface. Outside the structure, the trench units were excavated to the top of the sterile soil horizon. The westernmost unit of the trench (100N/101E) was selected for a test pit for geomorphologic analysis. This unit was excavated through the Btjb 1 (sandy clay loam) horizon to the sterile BC horizon (silty loam). The southern profile of the trench was then drawn and photographed.

Figure 29.1. Pre-excavation photo of LA 70025.

The rest of the site was then excavated by grid and strata, with arbitrary levels for thicker strata. A total of 17 units were excavated in and around the structure. Inside the structure, units were excavated to the living surface determined during the excavation of the trench. Outside the structure, units were excavated to the sterile Btjb 1 horizon. Excavation of the structure focused on defining walls, removing wallfall, and locating any features. Soil and pollen samples were taken from selected locations and all other soil was screened through 1/8-in. mesh to recover any artifacts. The excavation extended approximately 1 m around the perimeter of the structure in all directions to locate any associated external features and/or outside activity areas. No artifact concentrations were noted, but the remains of a nearly complete Sapawe Micaceous jar were recovered from the living surface in the southwest corner of the structure. Pollen samples and a flotation sample were taken from inside the vessel and underneath it.

Additionally, a small rubble mound (Area 2) was located approximately 7 m to the west of the structure. The grid system was extended to include this area and a subdatum (C) was established to take elevations. Two units were excavated and it was determined that this area was either non-cultural in nature or so badly eroded that it contained no useful data.

The excavation of the site was supervised by Michael Dilley. The field crew included Sandi Copeland, Hannah Lockard, and Alan Madsen. Timothy Martinez and Michael Chavarria served as site monitors, representing San Ildefonso and Santa Clara pueblos, respectively.

STRATIGRAPHY

The strata excavated at LA 70025 are described in Tables 29.1 and 29.2. Stratum 1 is composed of loose, surface sediment that was 1 to 5 cm in thickness across the site. It is roughly equivalent to the top half of the A horizon (topsoil). Stratum 2 consists of post-occupational fill and ranges from 1 to 18 cm in thickness throughout the excavated area. Stratum 2 includes the lower half of the A horizon and the Bw1 and the top of the Bw2 horizon. Artifact counts by strata are presented in Table 29.3.

Table 29.1. Stratigraphic descriptions from sediments at LA 70025.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10yr 5/3	Loamy sand	1–4	Surface sediment
2	10yr 5/3	Sandy loam	4–10	Post-occupational fill
3	10yr 6/3	Sandy clay loam	-	Room 1 Living surface

Table 29.2. Soil horizon descriptions from geomorphic test pit profile at LA 70025.

Horizon	Color	Texture	Depth (cm)	Description
A	10yr 5/3	Loamy sand	0–5	Late Holocene
Bw1	10yr 4/3	Sandy loam	5–14	Late Holocene
Bw2	10yr 4/3	Sandy clay loam	14–29	Late Holocene
Btjb1	10yr 5/4	Sandy clay loam	29–40	Middle-late Holocene
BC	10yr 4/4	Silty loam	40–50	Middle-late Holocene

Table 29.3. Artifact counts by strata.

Stratum	Ceramics	Chipped Stone	Ground Stone	Faunal Remains	Total
0	15	0	6	0	**21**
1	33	1	0	0	**35**
2	133*	15	2	0	**148**
3	0	0	0	0	**0**
Total	**181**	**16**	**7**	**0**	**204**

*This total includes 72 sherds recovered in the southwest corner of Room 1, representing the remains of a utilityware bowl.

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is a one-room structure that probably functioned as a fieldhouse. Due to its location on an eroding finger ridge, the structure was poorly preserved. Construction of the room consisted of one to two courses of either unshaped tuff block or unshaped dacite block. Only portions of two walls remained, and a few blocks that suggested a third wall (Figures 29.2 and 29.3). As best as could be determined, the room would have been roughly rectangular in shape. The room measures 2.72 m east-west by 1.65 m north-south, with approximately 4.50 m^2 of interior space. Excavation of the room began with an east-west trench that extended across the site (100N/102-106E). The excavation of this trench served to define the stratigraphy within the room and to locate the east and west walls and the living surface. After the trench was excavated, the rest of the room was excavated by grid down to the presumed living surface (the top of the Btjb1 soil horizon). Subsequent to the excavation of the room, photographs were taken of extant walls and the living surface.

Figure 29.2. Post-excavation photo of LA 70025.

Fill. The interior of the room was filled with 1 to 4 cm of loose surface sediment overlying 4 to 10 cm of semi-consolidated post-occupational fill. Flotation (Field Specimen [FS] 21) and pollen samples (FS 22) were taken from the room fill. Only ponderosa pine (*Pinus ponderosa*) culms were identified in the flotation sample. Taxa identified in the pollen sample included maize (*Zea mays*), cheno-ams (*Chenopodium/Amaranthus*), grass family (Poaceae), sunflower family (Asteraceae), ragweed/bursage (*Ambrosia*), spruce (*Picea*), fir (*Abies*), unidentified pine (*Pinus* sp.), piñon pine (*Pinus edulis*), juniper (*Juniperus*), oak (*Quercus*), Mormon tea (*Ephedra*), and sagebrush (*Artemisia*).

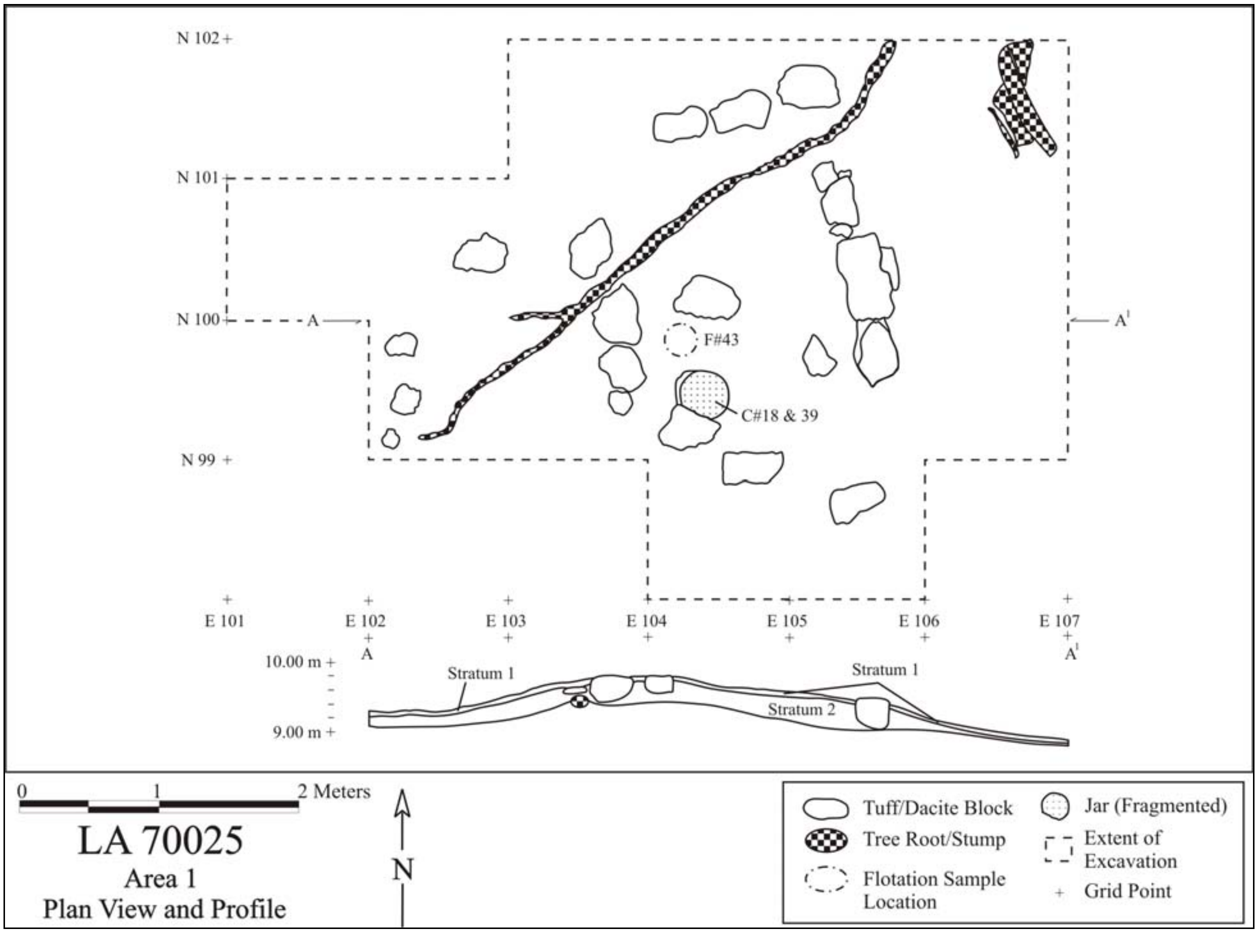

Figure 29.3. Plan view and profile of LA 70025.

Floor. There was no prepared or formal floor encountered during excavation of the room. Due to the poorly preserved nature of the structure from erosion and root disturbance, determination of a prepared floor would have been difficult if any had remained. However, an informal living surface was determined at the break between the loamy sand post-occupational fill, the Bw1 and Bw2 horizons (Stratum 2), and the top of the more consolidated, sterile sandy-clay-loam surface, the Btjb 1 horizon (Stratum 3). This surface was more compact than the general fill, and an increase in rootlets was noted between the fill and the contact zone of the more compact surface. There was also a slight color change in the soil to a lighter shade of brown with orange-hued patches of clayey soil.

A few dacite or tuff blocks were either resting on top of this surface or slightly imbedded into it and were determined to be wallfall. Several ceramic sherds were recovered from this surface, including the remains of a Sapawe Micaceous jar (FS 18 and FS 39) that was resting on a flat piece of tuff in 99N/104E. The tuff fragment and bowl were directly on top of the more compact surface, further indicating that this was likely the prehistoric living surface. This surface was also fairly level compared to the surrounding area outside of the room. A flotation sample was taken from the living surface (FS 43). Charred taxa identified in the flotation sample included ponderosa pine and unknown conifer (Gymnospermae). One pollen sample (FS 28) was taken from underneath the jar fragment; identified taxa included beeweed (*Cleome*), buckwheat (*Eriogonum*), cheno-ams, grass family, sunflower family, spurge family (Euphorbiaceae), fir, unidentified pine, piñon pine, juniper, oak, and sagebrush. Pollen and flotation samples were also collected from inside the jar (FS 23 and FS 24, respectively). Taxa identified in the pollen sample included maize, sunflower, cheno-ams, grass family, sunflower family, spurge family, fir, unidentified pine, piñon pine, juniper, rose family (Rosaceae), and sagebrush. Taxa identified in the flotation sample included grass family, unknown conifer, mountain mahogany (*Cercocarpus*), and ponderosa pine. No interior features were encountered during the excavation/exposure of the living surface.

Wall Construction. Due to the poor preservation of the site there were just two wall alignments (east and west) determined for Room 1 and their positioning suggested a rectangular shape (Figure 29.4). These were not complete wall alignments. Three additional tuff blocks were noted at the north end of the room and may represent the remains of another wall alignment. However, these blocks did not form a corner with the other alignments. The south end of the room was open, with scattered blocks forming no alignments.

The alignments, for the most part, appear to be a single row and single course of unshaped tuff and dacite blocks (Table 29.4). The majority of the blocks were tuff. Wallfall blocks within the room and in the area immediately outside of the room suggest that originally the walls were two or three courses higher, with a superstructure. The superstructure would likely have been constructed of stick and adobe. Two pieces of burned adobe (FS 12) were recovered just outside of the room, in unit 100N/103E (Stratum 2, Level 3), and several small adobe fragments were recovered inside the room in unit 99N/104E (Stratum 2, Level 3), suggesting the presence of a superstructure. Several tuff and dacite fragments/cobbles associated with the alignments were recovered during excavation of the room and may have served as chinking stones. No plaster or mortar was encountered.

An additional small rubble mound (Area 2), which was located 7 m to the west of Room 1, was also investigated. Two grid units were excavated producing no wall alignments or discernible structural elements. The material in the mound consisted of tuff blocks and fragments. This area was subject to severe erosion, root disturbance, and rodent activity.

Table 29.4. Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	1.20	0.16	0.26	1
South	Und	Und	Und	Und
East	1.60	0.22	0.32	1
West	0.85	0.21	0.31	1

Figure 29.4. Interior of the east wall of Room 1.

Geomorphic Analysis

A single grid unit (100N/102E) was excavated below the Bw2 horizon to serve as a geomorphic test pit. The profile of this unit was analyzed by geomorghologists Paul Drakos and Steve Reneau. A soil sequence was determined consisting of an A horizon topsoil (late Holocene), a Bw 1 and Bw 2 horizon (late Holocene), a Btjb 1 horizon (middle-late Holocene), and a BC horizon (middle-late Holocene). The A, Bwb1, and Bw2 horizons were all listed as post-occupation soils and the Btjb 1 and BC horizons were listed as pre-occupation soils.

Artifact Distribution

A total of 204 artifacts were recovered from the excavation of LA 70025. The majority of artifacts were recovered from excavation in and around Room 1 (Area 1). There were no artifact concentrations of note (other than the Sapawe Micaceous jar sherds recovered from Room 1) and no activity areas described. The highest density of artifacts outside of Room 1 was in unit 101N/106E and consisted of 26 ceramic sherds and eight chipped stone artifacts (most of which were recovered from Stratum 2, Level 2). The next highest density was recovered from unit 101N/105E and consisted of five ceramic sherds and four chipped stone artifacts (all of which were recovered from Stratum 2, Level 2). Both of these units were located on the northeast side of the site, just outside of the room. Across the remainder of the site artifacts were fairly evenly distributed. However, no chipped stone artifacts were recovered from inside Room 1. The higher density of artifacts recovered from the east side of the site is consistent with other fieldhouses excavated in Rendija Canyon, where activity areas may be located just outside the entryway of the structure.

This may be the result of a specific activity or the result of sweeping out the room. However, no entryway was determined for this structure and the density of artifacts, specifically chipped stone, does not seem to warrant calling this area an activity area. In the southwest corner of Room 1 (99N/104E; Stratum 2, Level 2), 72 ceramic sherds were recovered in a concentration that represented the remains of a Sapawe Micaceous jar. These sherds were resting on top of a tuff slab fragment that was situated directly above the living surface and may represent an *in situ* deposit.

Few artifacts were recovered from Area 2. Two ground stone fragments were surface collected from units 96N/96E and 99N/98E, which were not excavated. One ground stone fragment was recovered from unit 96N/95E (Stratum2, Level 2). Three ceramic sherds were recovered from unit 96N/95E; one from Stratum 1, Level 1 and two from Stratum 2, Level 2. One chipped stone artifact was recovered from this area in grid 96N/94E, Stratum 2, Level 2. Table 29.5 lists the artifacts recovered from each of the excavated grid units.

Table 29.5. Artifact counts by grid unit.

	94E	95E	96E	98E	101E	102E	103E	104E	105E	106E
96N	2	5	3	0	0	0	0	0	0	0
99N	0	0	1	1	0	4	6	104 (cer)	0	0
100N	0	0	0	0	3	0	6	9	7	6
101N	0	0	0	0	0	0	0	4	9	34

As was stated previously, this site is located on a narrow, eroding finger ridge. Artifacts recovered from Room 1 and the immediate surrounding area likely represent the bulk of the site assemblage, but it is also possible that some artifacts eroded downslope and into the drainages that bound the site on the north and south side. The relatively low artifact density and the poorly preserved nature of the site do not provide any reliable evidence of activity areas associated with the structure (Room 1).

SITE CHRONOLOGY AND SAMPLE ANALYSIS

A total of 204 artifacts were analyzed from the excavations conducted at LA 70025. In addition, flotation and pollen samples were selected for analysis from the post-occupational fill (Stratum 2) and the living surface (Stratum 3) (Table 29.6).

Table 29.6. Soil samples selected for analysis from LA 70025.

Ceramic Artifacts (Dean Wilson)

A total of 185 ceramics were analyzed from LA 70025. The majority of the pottery consists of Biscuit A, Biscuit B/C, and Sapawe Micaceous types, which reflect an Early to Middle Classic period occupation (Table 29.7). Information on ceramic tradition by ware, temper by ware, and vessel form by ware are provided in Tables 29.8 to 29.10. The graywares and whitewares appear to have been locally made from smeared-indented sand or tuff, in contrast to Sapawe Micaceous, which contained a non-local micaceous temper. All of the grayware and micaceous ceramics consist of jars, although the whitewares include a mix of bowl and jar vessel forms.

Table 29.7. Ceramic types from LA 70025.

Ceramic Type	Frequency	Percent
Northern Rio Grande Whiteware		
Unpainted undifferentiated	2	1.1
Santa Fe Black-on-white	2	1.1
Unpainted Biscuit one side slipped	5	2.7
Unpainted Biscuit both sides slipped	9	4.9
Biscuit paint and slip absent	7	3.8

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 19 artifacts were analyzed from LA 70025. The assemblage consisted of a core, 14 pieces of debitage, and four ground stone artifacts and represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 29.11 presents the data on lithic artifact type by material type. The majority of the debitage is made of chalcedony, with lesser amounts of Pedernal chert and obsidian. The presence of cortex on 14.2 percent of the debitage indicates that these materials were collected from waterworn (n = 2) sources. The chalcedony and Pedernal chert are available from local Rio Grande Valley gravels and the obsidian from the nearby sources in the Jemez Mountains. Otherwise, the dacite is available both as bedrock outcrops and in stream gravels that cross-cut the Pajarito Plateau.

Lithic Reduction

The single core was reduced using a single-directional, multi-face technique. It was classified as still useable when discarded. Table 29.12 presents the metric information on this core.

Table 29.12. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Single-directional	62	105	91	697.3

The debitage assemblage consists of core flakes. The overall cortical:non-cortical ratio of 0.17 reflects an emphasis on the later stages of core reduction. The flakes exhibit both single-faceted (n = 6) and collapsed (n = 2) platforms. None of the flake platforms exhibit evidence of preparation. Most of the core flakes consist of whole flakes (n = 8), with fewer proximal (n = 2), midsection (n = 1), and distal (n = 3) fragments. The whole core flakes have a mean length of 24.2 mm (*std* = 18.4).

Tool Use

None of the flakes exhibit any obvious evidence of edge damage that could be attributed to use.

Four ground stone artifacts were identified during the analysis. The two-hand mano is a fragment that is plano-convex in cross-section. The flat surface is heavily ground, whereas the convex surface is only slightly ground on high spots. The undetermined mano fragments consist of cobble fragments that are heavily ground on both opposing surfaces. One of the manos was burned and broken into three parts, which fit back together. The other was battered on the end indicating that it was also used as a hammerstone.

Archaeobotanical Remains (Pamela McBride)

LA 70025, which is a Early/Middle Classic period fieldhouse, is located on a ridge near the mouth of Cabra Canyon. The site yielded very little in the way of non-wood cultural plant remains (Table 29.13). Charred grass stems from inside a pot base were the only possible materials associated with the occupation of the site. Unburned grass stems, sunflower seeds, and ponderosa pine needles were recovered as well, but have no cultural affiliation.

Table 29.13. Flotation sample plant remains showing count and abundance per liter.

FS No.	**24**	**43**

+ 1-10/liter.

Ponderosa pine was the primary wood charcoal taxon identified; mountain mahogany and unknown conifer were also present (Table 29.14). The grass stems could have been used as a cushion for the pot or as tinder and local wood resources were used for fuel or construction.

Pollen Remains (Susan J. Smith)

Two pollen samples were analyzed from LA 70025. Table 29.15 lists the frequency of identified pollen types. Maize was the only cultigen identified in the assemblage. Sunflower type was the only economic resource identified in the assemblage. A number of potential economic resources were also identified in the assemblage (Table 29.15), and these are described in detail in Smith's chapter in Volume 3 (Chapter 63).

Table 29.15. Pollen types identified by taxa and common names with sample frequency.

SUMMARY

LA 70025 is a one-room Early/Middle Classic period fieldhouse that was constructed from both shaped and unshaped tuff blocks. The site is located on a ridge at the mouth of Cabra Canyon. Maize pollen was recovered during the site excavation, therefore, the one-room structure was presumably occupied during the growing season.

CHAPTER 30
RENDIJA TRACT (A-14): LA 85403

Gregory D. Lockard

INTRODUCTION

LA 85403 is a one-room Classic period structure located on a south terrace in Rendija Canyon. The site is located approximately 75 m west of the Los Alamos Sportsmen's Club archery range and approximately 30 m south of Rendija Canyon Road. Vegetation in the site area consists of ponderosa pine and piñon-juniper woodland with an understory composed primarily of grasses. The site is situated at an elevation of 2131 m (6990 ft).

LA 85403 was first recorded on August 14, 1991, by David Hill (1991) during a survey for the Bason Land Exchange Project. Hill believed the site was a one- or two-room fieldhouse. Two obsidian flakes and a chalcedony flake were the only artifacts observed on the surface. As Hill noted, the paucity of surface artifacts may be a result of surface collection by users of the archery range. The site was re-recorded and given the temporary site number of Q193 by Bradley Vierra on April 6, 1999. Vierra identified the site as a one-room fieldhouse and noted that several rocks had recently been removed from the surface of the mound. He observed no artifacts. He also documented the presence of two nearby outhouses, and noted that the paucity of artifacts could have been the result of surface collection by the people who built and utilized the outhouses.

FIELD METHODS

Before excavation, the site and surrounding area were cleared of trees and large undergrowth. The site was then visible as a small rubble mound approximately 5 by 4.8 m in area (Figure 30.1). An arbitrary site datum (designated 100N/100E, 10.00 m elevation) was set up in the southwest corner of the site. The site was then covered with a 1- by 1-m grid that extended 5 m north and 5 m east of the site datum. Three subdata (A-C) were set up for taking elevations. The site was then photographed. A surface collection was attempted, however no artifacts were observed on the surface. A 5- by 1-m east-west trench (units 102N/100-104E) was initially excavated across the remains of the structure. The purpose of this trench was to expose a profile of the site stratigraphy, as well as to determine the location of the room's east and west walls. Units were excavated by strata, and thicker strata were excavated in arbitrary 10-cm levels. The room's west wall was encountered in grid unit 102N/101E, and the interior face of the south wall was encountered along the southern border of grid units 102N/101-103E. An east wall was not encountered during the excavation of the trench. It was later determined that the reason for this is that an entryway in the east wall was located within the trench (grid unit 102N/102E). No obvious living surface was encountered within the room during the excavation of the trench.

Figure 30.1. LA 85403 before excavation.

Excavation proceeded down to the level of the base of the room's walls. After the excavation of the trench units, the north profile of the trench was drawn and photographed. The rest of the area was subsequently excavated, again by strata and arbitrary levels for thicker strata. In all, 20 units were excavated. No obvious living surface was encountered anywhere within the room. As a result, excavation within the room proceeded down to the base of the room's walls. Outside the structure, excavation proceeded down to the top of a sterile Btb1 horizon. Excavation focused on defining the room's walls, removing wallfall, and locating features. Soil samples were taken from select locations, and all other soil was passed through screens with 1/8-in. mesh to aid in the recovery of artifacts. The excavation area extended at least 1 m beyond the structure in all directions to locate external features and/or outdoor activity areas. The structure was then mapped (Figure 30.2) and photographed (Figure 30.3). Finally, the southern half of that portion of grid unit 102N/101E that is within Room 1 was excavated an additional 12 cm. This excavation served as a test pit for geological analysis.

The excavation of the site was supervised by Greg Lockard. The field crew included Michael Dilley, Joseph (Woody) Aguilar, Alan Madsen, Brian Harmon, Jennifer Nisengard, Sandi Copeland, Bettina Kuru'es, and Hannah Lockard. Timothy Martinez and Aaron Gonzalez served as site monitors from San Ildefonso Pueblo and as screeners. Michael Chavarria was the site monitor representing Santa Clara Pueblo, as well as an additional screener.

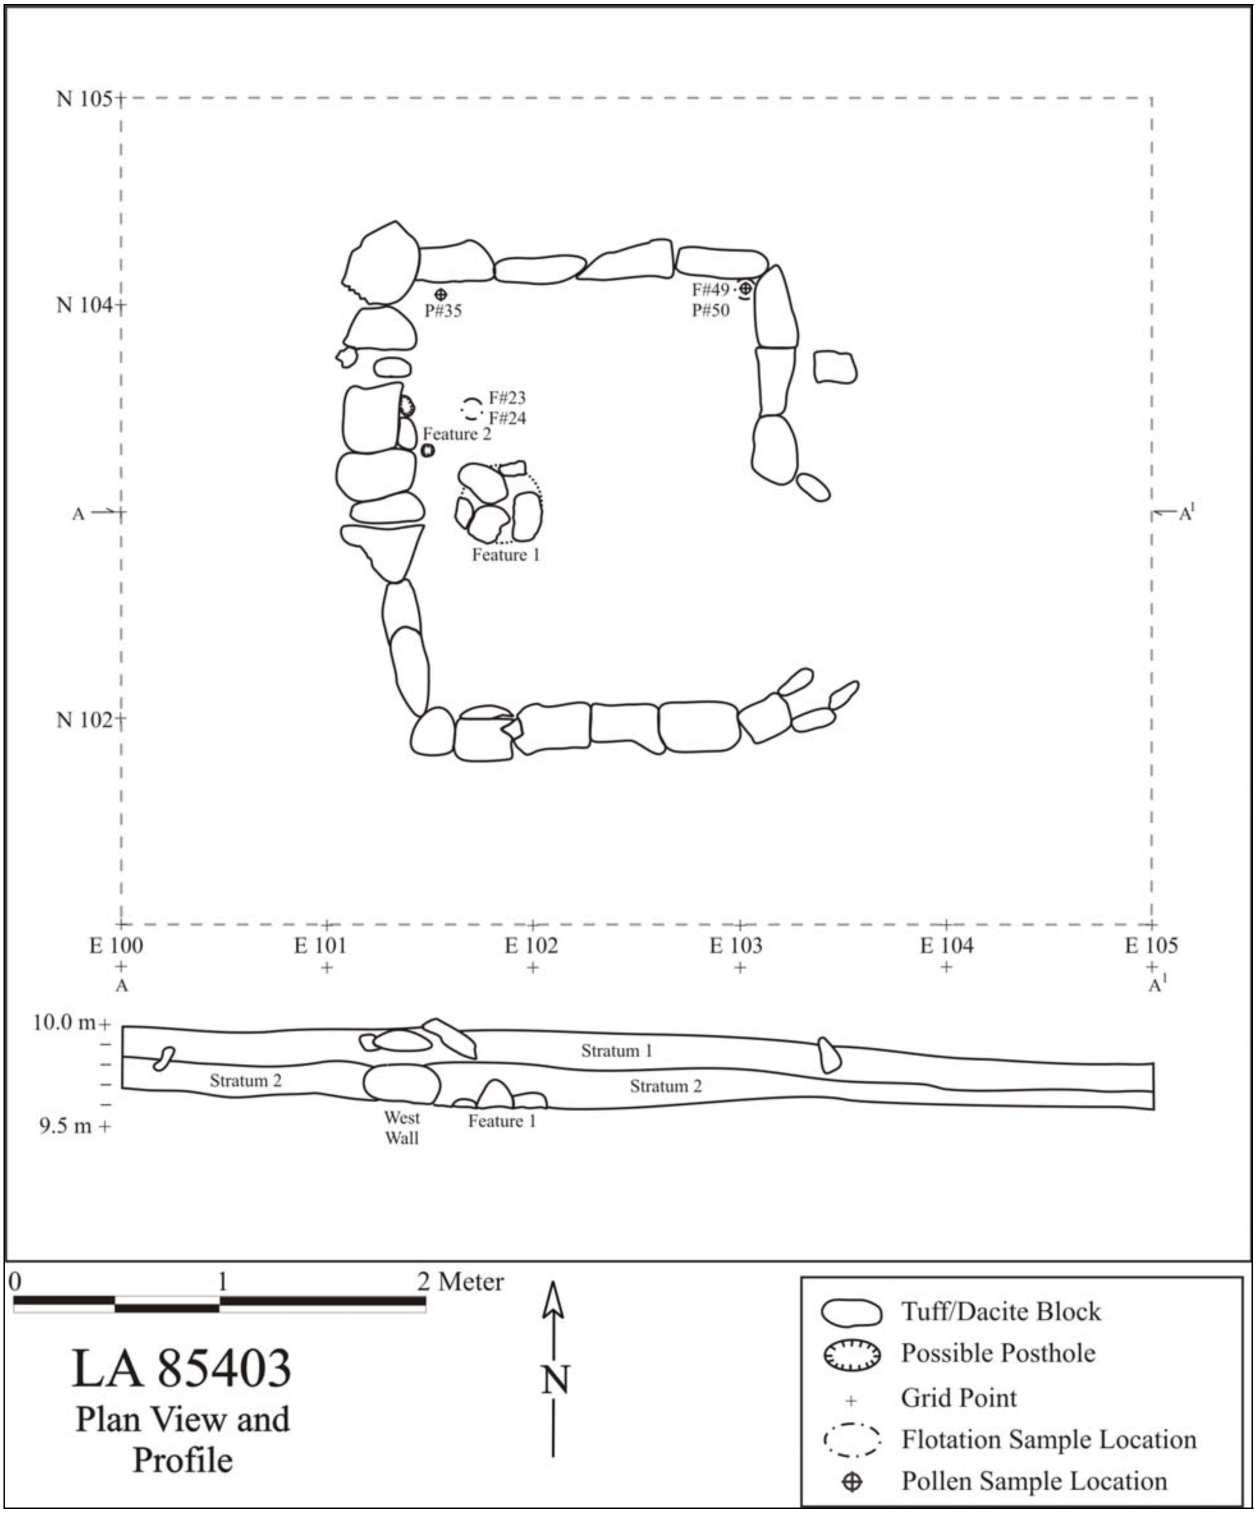

Figure 30.2. Plan view and profile of fieldhouse at LA 85403.

Figure 30.3. Post-excavation photograph of the fieldhouse at LA 85403.

STRATIGRAPHY

Stratum 1 is composed of loose, surface sediment. It is uniformly 1 to 7 cm thick across the site and is more or less equivalent to the A horizon (topsoil). Stratum 2 is post-occupational fill and ranges from 15 to 35 cm in thickness. The post-occupational fill was thickest within Room 1 and thinned away from the room. Stratum 2 is more or less equivalent to the Bw and Bwb1 horizons. Stratum 3 is the fill removed from Feature 2, which was identified as a posthole. Stratum 4 is the sterile soil removed from the geological test pit and is part of the Btb1 horizon. LA 85403 strata are summarized in Tables 30.1, 30.2., and 30.3, and artifact tallies are reported in Table 30.4.

Table 30.1. LA 85403 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10YR 3/4	Sandy loam	1–7	Surface sediment
2	8.75YR 3/4	Silt	15–35	Post-occupational fill
3	8.75YR 3/4	Silt	6	Feature 2 (posthole) fill
4	7.5YR 4/5	Silty clay	12	Early/middle-Holocene soil

Table 30.2. LA 85403 soil horizon descriptions from the west profile of 102N/100E.

Horizon	Color	Texture	Depth (cm)	Description
A	10YR 3/4	Sandy loam	0–9	Topsoil
Bw	8.75YR 3/4	Silt	9–22	Late-Holocene soil
Bwb1	7.5YR 4/5	Silt	22–30+	Early/middle-Holocene soil

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is a small, rectangular structure that probably functioned as a fieldhouse. The room measures 2.06 m in length (north-south) by 1.82 m in width (east-west), with approximately 3.75 m^2 of interior space. Excavation of the room began with an east-west trench that extended across the room (102N/100-104E). The excavation of this trench served to define the room's stratigraphy, as well as to locate the room's west and south walls. The room's entryway was also encountered in 102N/103E, although it was not recognized as such until the grid units to the north were excavated. No living surface was encountered in the trench. As a result, the excavation proceeded down to the base of the room's walls. After the excavation of the trench, the rest of the room was excavated to the base of the room's walls. After all of the grid units within Room 1 were excavated to this level, Feature 1 (a prehistoric pit) and Feature 2 (a posthole) were excavated, sampled, and mapped. After the features were excavated, the southern half of that portion of 102N/101E that is within Room 1 (i.e., the far southwest corner of Room 1) was excavated an additional 12 cm. The purpose of this excavation was to determine whether or not there were any living surfaces below and to document the depth of the wall's foundations. This excavation also served as a test pit for geological analysis (see Table 30.3).

Fill. The interior of Room 1 was filled with 1 to 6 cm of surface sediment on top of 30 to 35 cm of post-occupational fill. Two flotation samples (Field Specimen [FS] 18 and FS 27) and one pollen sample (FS 28) were analyzed from the Room 1 fill. Carbonized taxa identified in the flotation samples included unidentified pine (*Pinus*), ponderosa pine (*Pinus ponderosa*), and oak (*Quercus*). Taxa identified in the pollen sample included lily family (Liliaceae), sunflower family (Asteraceae), cheno-ams (*Chenopodium/Amaranthus*), grass family (Poaceae), penstemon family (Scrophulariaceae), unidentified pine, piñon pine (*Pinus edulis*), juniper (*Juniperus*), and sagebrush (*Artemisia*).

Floor. No floor or obvious living surface was encountered during the excavation of Room 1. The living surface was estimated to be a few cm above the base of the room's walls. At this level, the soil was fairly indurated and contained small tuff inclusions. This surface was a few cm above the Btb1 horizon. Two features were associated with the Room 1 living surface. The first, Feature 1, was identified as a prehistoric pit that was filled with rocks. This pit was mostly likely an animal burrow. The rocks and fill within the pit appear to have been placed there by the people who constructed and/or utilized the fieldhouse. In all likelihood, the animal burrow postdates the initial construction of the fieldhouse, as it is unlikely that a structure would have been built around a large hole. Instead, the burrow was probably dug while the fieldhouse was temporarily abandoned. When the fieldhouse was reoccupied, the burrow was filled in with rocks and sediment in order to repair the room's living surface.

Feature 2 consists of two small holes located in the northwest quadrant of the room. One of these, located just inside the room's west wall, is most likely a posthole. The other, located 14 cm to the southeast, may or may not have been a second posthole. Flotation samples were taken from two elevations in the northwest quadrant of Room 1 (FS 23 and FS 24). Carbonized taxa identified in these samples included unknown conifer (Gymnospermae), goosefoot (*Chenopodium*), purslane (*Portulaca*), oak (*Quercus*), and maize (*Zea mays*). At least one of these samples is probably at or very near the level of the living surface. Another flotation sample was taken from the approximate elevation of the living surface in the far northeast corner of the room (FS 49). Charred taxa identified in this sample included ponderosa pine wood charcoal. Pollen samples were taken from the approximate elevation of the living surface in the far northwest (FS 35) and far northeast (FS 50) corners of the room. Taxa identified in FS 35 included beeweed (*Cleome*), buckwheat (*Eriogonum*), grass family, cheno-ams, sunflower family, ragweed/bursage (*Ambrosia*), spurge family (Euphorbiaceae), penstemon family, unidentified pine, piñon pine, juniper, Mormon tea (*Ephedra*), and sagebrush. Only sunflower family remains were identified in FS 50.

Wall Construction. The rocks that formed the Room 1 walls are mostly dacite, with a few tuff blocks. The foundation rocks are all dacite, most of which are thin upright slabs (Table 30.5). The foundation slabs are all that remain of the north and east walls. A number of rocks that formed a second course of the south and west walls, and a single rock that formed a third course in the south wall, were encountered *in situ* (Figure 30.4). These rocks are unshaped dacite cobbles. The walls are formed by a single row of rocks in all but the southeast corner of the room. The north, south, and west walls extend for the entire length of the room. In the east wall, there is a gap in the wall that is 95 cm wide. This was most likely the room's entryway. To the north of the entryway, the east wall is composed of three upright slabs. There is also a small, thin, upright rock that extends outward at about a 45 degree angle from the south end of this portion of the east wall. This rock may have functioned as a door jamb, or to mitigate the amount of dust blowing into the room from outside. The southeast corner of the room, unlike the other corners, is not a right angle. Instead, two upright slabs extend outward at about a 45 degree angle from the east end of the south wall. These rocks, which were considered to be part of the east wall, probably had the same function as the similarly angled rock on the north side of the entryway.

Table 30.5. Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	1.63	0.25–0.31	0.10–0.21	1
South	1.65	0.23–0.39	0.16–0.22	2 to 3
East	1.12 (2.07)	0.18–0.23	0.09–0.17	1
West	2.04	0.22–0.44	0.08–0.34	2

Note: the length of the east wall including the entryway is given in parentheses.

Figure 30.4. South wall of LA 85403.

Judging from the amount of wallfall removed during the excavation of the area in and around Room 1, the masonry portions of the room's walls were originally considerably higher than they were at the time of excavation. In order to estimate the original height of the walls, all of the rocks removed as wallfall during the site's excavation were placed in three stacks, which were then measured. The stacks measured 0.56 by 0.90 by 0.42 m, 0.50 by 0.50 by 0.45 m, and 3.43 by 0.53 by 0.46 m, for a total of approximately 1.16 m^3 of wallfall. Based on this volume of wallfall and the overall length, average thickness, and average height of the extant portions of the walls, the masonry portions of the room's walls were originally approximately 1.33 m high. This is slightly higher than the average wall height calculated for fieldhouses excavated in the Rendija Tract during the Conveyance and Transfer (C&T) Project, excluding those in areas that are naturally rocky. LA 85403, however, is not located in an area with a lot of naturally occurring rocks. This number is therefore probably a fairly accurate reflection of the original height of the masonry portions of the room's walls. The uppermost portions of the walls, as well as the ceiling, were most likely composed of wattle and daub. These materials are rarely preserved at archaeological sites on the Pajarito Plateau. In fact, no adobe was recovered during the excavation of the site.

Room 1 Features

Feature 1 (Prehistoric Pit)

Feature 1 was a prehistoric pit filled with rocks and sediment. The feature first appeared as a cluster of five dacite rocks at or just below the estimated level of the Room 1 living surface (Figures 30.5 and 30.6).

Figure 30.5. Features 1 and 2 in Room 1.

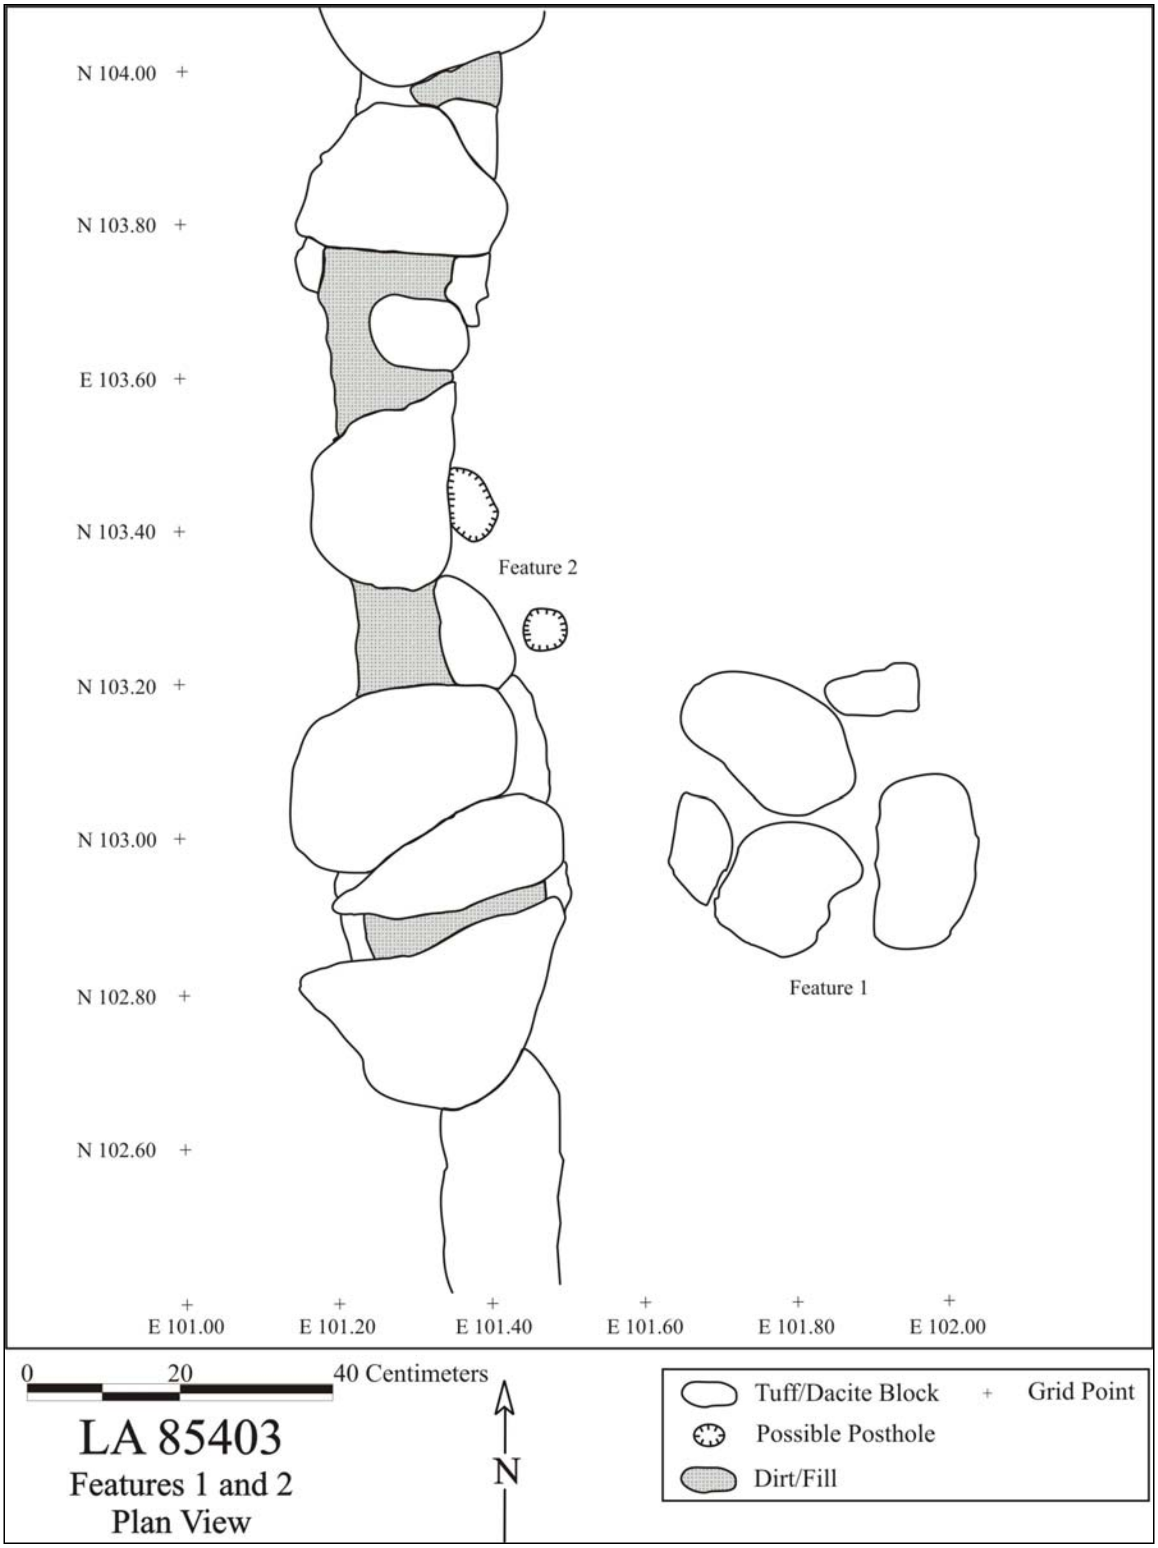

Figure 30.6. Plan view drawings of Features 1 and 2.

The dacite rocks were located in the west-central portion of the room, directly inside the room's west wall. No ash or charcoal was visible in the vicinity of the feature, and the rocks did not appear to have been burned. As a result, the feature did not appear to have been a hearth. The rocks were removed to determine their function. During the excavation of the feature, a sixth rock was encountered below the rocks visible at the presumed living surface. Compact sediment similar to the Room 1 post-occupational fill was encountered between the rocks. Beneath the rocks, a large animal burrow was encountered (Figure 30.7). The burrow was filled with soil that was considerably softer and looser than the sediment between the rocks. The rocks and fill within the pit appear to have been placed there by the people who constructed and/or utilized the fieldhouse. In all likelihood, the animal burrow postdates the initial construction of the fieldhouse, as it is unlikely that the structure would have been built around a large hole. Instead, the burrow was probably dug while the fieldhouse was temporarily abandoned. When the fieldhouse was reoccupied, the burrow was filled in with rocks and sediment in order to repair the room's living surface

Figure 30.7. Feature 1 after excavation.

Much of the sediment removed during the excavation of Feature 1 was retained as a flotation sample (FS 53). Charred taxa identified in this sample included unknown conifer, ponderosa pine, and maize. In addition, a pollen sample (FS 54) was taken from directly beneath one of the rocks in the feature. Taxa identified in this sample included beeweed, grass family, cheno-ams, sunflower family, penstemon family, unidentified pine, piñon pine, oak, Mormon tea, and sagebrush.

Feature 2 (Posthole)

Feature 2 consists of two small holes located in the northwest quadrant of Room 1 (see Figures 30.2 and 30.5). The first hole is located just inside the room's west wall, 26 cm northwest of Feature 1. The interior walls of the hole were vertical and highly compact, indicating that it was most likely a posthole. It measured 9 cm north-south by 7 cm east-west and was approximately 15 cm deep. A pollen sample (FS 51) was taken of the fill removed from the posthole. Taxa identified in this sample included knotweed (*Polygonum*), grass family, cheno-ams, spurge family, fir (*Abies*), unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush. Pine aggregates were also identified. The second small hole was located 14 cm to the southeast of the first. The interior walls of this hole were irregular and unconsolidated. It was therefore most likely a rodent burrow or root disturbance rather than a second posthole.

Geological Analysis

Geologists Paul Drakos and Steven Reneau utilized two profiles to reconstruct the natural soil horizons at the site (see Tables 30.2 and 30.3). The upper strata were described from the west profile of 102N/100E. This profile contained a soil sequence consisting of an A horizon (topsoil), a Bw horizon (a late-Holocene soil), and a Bwb1 horizon (an early/middle-Holocene soil). The lower strata were described from the west profile of the geological test pit. The geological test pit was located in the southern half of that portion of 102N/101E that is within Room 1. It consists of the interior face of the west wall of Room 1 and below. The profile contained a soil sequence consisting of the Bwb1 horizon encountered in the first profile on top of a Btb1 horizon (another early/middle-Holocene soil).

Artifact Distribution

Few artifacts were recovered from LA 85403. Nevertheless, there is a noticeable pattern in the artifact distribution at the site (Table 30.6).

Table 30.6. Artifact counts by grid unit.

	E100	E101	E102	E103	E104
N104	1	**4**	**1**	**1**	1
N103	0	**2**	**1**	**2**	5
N102	0	**3**	**4**	**1**	2
N101	0	0	1	3	2

Note: bold numbers indicate grid units that are located completely or partially within Room 1.

Most of the artifacts were recovered from within Room 1 or to the east of the room. A significant number of artifacts were also recovered from the grid units to the north of the room. Most of these, however, came from a single grid unit (104N/101E). Only a single artifact was recovered from the grid units to the west of the room. The three westernmost grid units to the south of the room also contained only a single artifact. The concentration of artifacts to the east of the fieldhouse most likely reflects an outdoor activity area, the sweeping of artifacts through the entryway in the east wall by the site's occupants, or both. Within the sample of fieldhouses in the Rendija Tract excavated during the C&T Project, there is a strong tendency for activity areas, reflected in a higher concentration of artifacts, to be located to the east.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 33 artifacts were analyzed from excavations at LA 85403. Analyses of the ceramics, lithics (chipped and ground stone), archaeobotanical, and pollen materials were conducted (Table 30.7). The results of these analyses, as well as associated tables, are presented in the following pages.

Table 30.7. Samples selected for analysis from LA 85403.

Chronology

Radiocarbon Dating

A single maize sample was submitted for accelerator mass spectroscopy dating. The sample provided a date of 310±40 BP (Beta-215549), with a calibrated intercept of AD 1530 and a two-sigma range of AD 1470 to 1660. The sample was recovered from a flotation sample taken from Stratum 2.

Ceramic Artifacts (Dean Wilson)

Seven sherds were recovered from the fieldhouse. These consist primarily of utilitywares, with a single undifferentiated whiteware. Tables 30.8 through 30.11 show the summary ceramic data for the site, including general type, types by tradition, temper material by ware type, and ware by vessel form. All of the graywares and the whiteware sherd are made from local anthill sand or tuff temper, whereas, the micaceous ware sherd is made from non-local granite with mica. All of the graywares and the micaceous sherd represent jar vessel form, in contrast to the whiteware sherd, which is from a bowl.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

Twenty-six lithic artifacts were analyzed from LA 85403. This assemblage consisted of four cores, 17 pieces of debitage, two retouched tools, and three ground stone artifacts. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 30.12 presents the data on lithic artifact type by material type. The debitage is made of chalcedony, Pedernal chert, obsidian, and andesite. The presence of cortex on 11.7 percent of the debitage indicates that these materials were collected from waterworn (*n* = 2) sources. The chalcedony, Pedernal chert, and possibly the greenstone are all available from local Rio Grande Valley gravels and the obsidian from the nearby sources in the Jemez Mountains. Otherwise, the igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the Pajarito Plateau. Three pieces of basalt debitage were submitted for X-ray fluorescence analysis. Two of these were identified as basalt and the other as dacite.

Lithic Reduction

The four cores were reduced using a bi-directional/bifacial, bi-directional/opposed-same-face, and multi-directional/opposed-same-and-different-face technique. Two of the cores were fragments that were discarded due to material flaws, whereas the other two cores were classified as still useable. Table 30.13 presents the metric information on these cores.

Table 30.13. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Bi-directional	61	59	29	93.0
Bi-directional	68	55	29	135.2

Core Type	Length	Width	Thickness	Weight
Bi-directional	46	85	62	237.9
Multi-directional	83	54	50	257.2

The debitage primarily consists of core flakes and angular debris, with a biface flake and a piece of microdebitage. The overall cortical:non-cortical ratio of 0.10 reflects an emphasis on the later stages of core reduction. The flakes exhibit single-faceted (n = 3), collapsed (n = 1), and crushed (n = 2) platforms. Two of the flake platforms exhibit evidence of preparation as they are both ground. Most of the core flakes consist of distal fragments (n = 5), with fewer whole (n = 1), proximal (n = 3), and midsection (n = 1) fragments. The single whole core flake has a mean length of 27.0 mm and the angular debris a mean weight of 8.78 g (*std* = 5.6).

The retouched tools consist of two retouched flakes. One of these is a large flake with unidirectional dorsal retouch along the distal end with an angle of 85 degrees. The other also exhibits unidirectional retouch, but along two lateral edges with angles of 70 degrees. These edges are slightly serrated in outline.

Tool Use

None of the flakes and only one of the retouched tools exhibit any obvious evidence of edge damage that could be attributed to use. The retouched tool exhibits a slightly serrated edge with rounding and scarring.

Three ground stone artifacts were identified during the analysis. The undetermined mano fragment consists of a piece of greenstone with two opposing surfaces that are slightly ground. The undetermined ground stone items consist of two tabular pieces of dacite that refit together. The edges have been shaped and the artifacts could represent a ceramic jar lid.

Archaeobotanical Remains (Pamela McBride)

Maize cupules, a possible goosefoot seed fragment, a purslane seed, pine bark, and an unidentifiable plant part comprised the cultural plant material recovered from this one-room masonry fieldhouse (Table 30.14). Maize could have been grown near the fieldhouse that was located on a relatively flat, open area along the south side of Rendija Canyon. Pine bark is most likely part of the firewood residue. The goosefoot seed fragment and purslane seed may indicate use of these weedy annual plants that proliferate in agricultural fields. Local woods were used as fuel and included oak, ponderosa pine, and unknown conifer (Table 30.15).

Pollen Remains (Susan Smith)

Five pollen samples were analyzed from LA 85403. Table 30.16 lists the frequency of identified pollen types. No cultigens were identified in the assemblage. Economic resources identified in the assemblage included only beeweed and lily family, which includes yucca, wild onion, sego lily, and others. A number of potential economic resources were also identified in the assemblage (Table 30.16), and these are described in detail in Smith's chapter in Volume 3 (Chapter 63).

SUMMARY

LA 85403 is a one-room Classic period fieldhouse that was constructed from both shaped and unshaped tuff blocks. The site is located on a south terrace in Rendija Canyon, about 75 m west of the Los Alamos Sportsmen's Club archery range. Burned maize cupules were recovered during the site excavation, therefore, the one-room structure was presumably occupied during the growing season. Dated maize remains indicate the site was occupied circa AD 1530, during the Late Classic.

CHAPTER 31
RENDIJA TRACT (A-14): LA 85404

Gregory D. Lockard

INTRODUCTION

LA 85404 consists of one-room Classic period fieldhouse located to the northwest of an intermittent drainage. The site is located on the Los Alamos Sportsmen's Club archery range, approximately 20 m south of Rendija Road. Vegetation around the site consists of ponderosa pine and juniper woodland with a grass understory. The site is situated at an elevation of 2120 m (6954 ft).

LA 85404 was first recorded on August 15, 1991, by David Hill (1991) during a survey for the Bason Land Exchange Project. According to Hill, the site consisted of three rock features. Feature 1 is a rectangular outline of unshaped tuff blocks that is 4.3 by 5 m in area. Hill believed it was a fieldhouse. Feature 2 was identified as a linear arrangement of unshaped tuff cobbles that measured 2.5 by 13 m in area. Due to the fact that the feature was oriented parallel rather than perpendicular to the surrounding slope, Hill believed it was a structure rather than an agricultural terrace. Feature 3 measured 4 by 3.5 m in area and was believed to be a fieldhouse. Surface artifacts recorded by Hill included obsidian and a heat-treated chalcedony flake. Three sherds (an unpainted Biscuitware sherd, a Wiyo Black-on-white sherd, and a Santa Fe Black-on-white sherd) were also recorded.

In April of 1999, the site was re-recorded and given the temporary site number of Q194. Only Hill's Feature 3 was recorded at this time. Due to the fact that the site was covered with a thick layer of pine duff, no artifacts were observed on the surface. The other features at the site may not have been visible for the same reason. Los Alamos National Laboratory personnel believed that the feature that they did record was a one-room fieldhouse. During the Conveyance and Transfer Project, this was the only feature excavated at LA 85404.

FIELD METHODS

Before excavation, the site and surrounding area were cleared of trees and large undergrowth. The site was then visible as a small rubble mound approximately 4 by 3.5 m in area. An arbitrary site datum (designated 100N/100E, 10.00 m elevation) was set up in the southwest corner of the site. The site was then covered with a 1- by 1-m grid that extended 6 m north and 5 m east of the site datum. Three subdata (A-C) were set up for taking elevations. The site was then photographed before excavation (Figure 31.1). A surface collection was attempted, however no artifacts were observed on the surface. A 5- by 1-m east-west trench (103N/100-104E) was initially excavated across the remains of the structure. The purpose of this trench was to expose a profile of the site stratigraphy, as well as to determine the location of the room's east and west walls. Units were excavated by strata, and thicker strata were excavated in arbitrary

10-cm levels. The room's west wall was encountered in 103N/101E, and the east wall in 103N/103E. No living surface was encountered in the trench.

Figure 31.1. LA 85404 before excavation.

Excavation of the trench units continued until a sterile Pleistocene soil (i.e., the Btb1 horizon) was reached. After the excavation of the trench units, the north profile of the trench was drawn and photographed. The north profile of 103N/102E was also examined by geologists Paul Drakos and Steven Reneau at this time. The rest of the site was subsequently excavated, again by strata and arbitrary levels for thicker strata. In all, 23 units were excavated. A patch of burned floor was encountered in the northeast corner of the room (within units 104N/102-103E). The patch of floor measured approximately 45 by 50 cm and was located directly on top of the Btb1 horizon. No floor was encountered in any other portion of the room. As a result, excavation of these areas terminated at the top of the Btb1 horizon. The excavation of areas outside the structure also terminated at the top of this soil horizon. Excavation focused on defining the room's walls, removing wallfall, and locating features. Soil samples were taken from select locations, and all other soil was passed through screens with 1/8-in. mesh to aid in the recovery of artifacts. The excavation area extended at least 1 m beyond the structure in all directions to locate external features and/or outdoor activity areas. The structure was then mapped (Figure 31.2) and photographed (Figure 31.3).

The excavation of the site was supervised by Greg Lockard. The field crew included Brad Vierra, Joseph (Woody) Aguilar, Jennifer Nisengard, and Bettina Kuru'es. Timothy Martinez and Aaron Gonzalez served as site monitors from San Ildefonso Pueblo and as screeners.

Michael Chavarria was the site monitor representing Santa Clara Pueblo, as well as an additional screener.

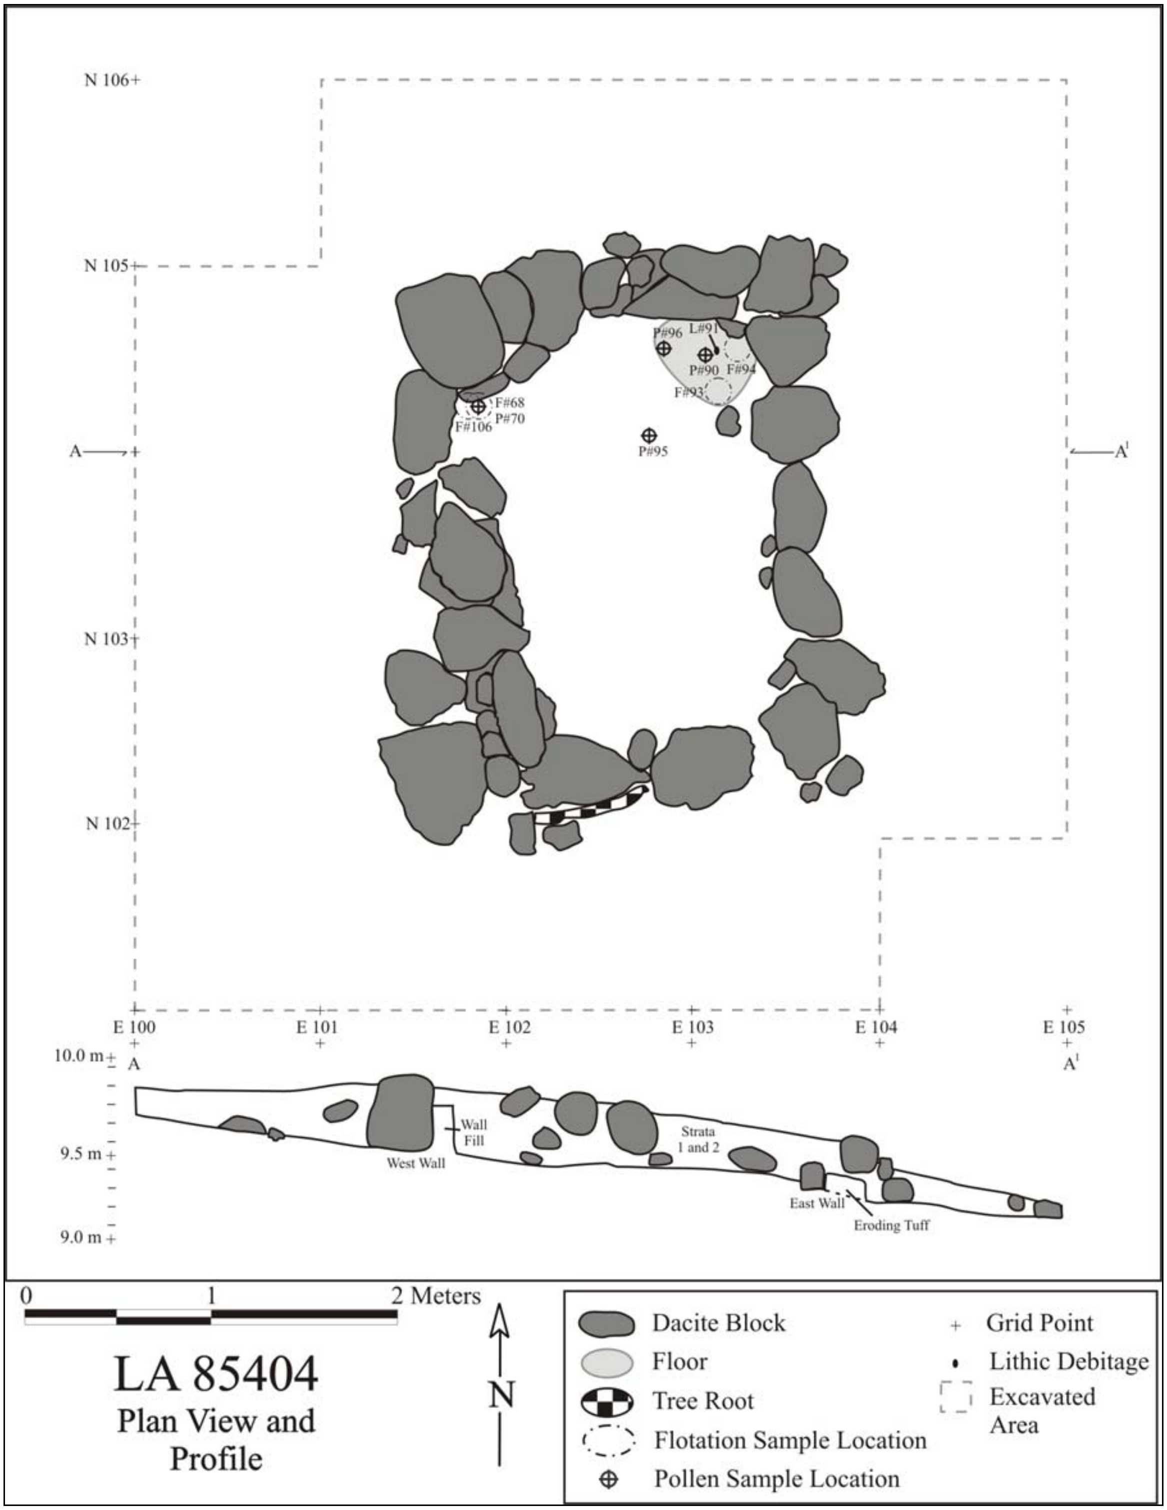

Figure 31.2. Plan view and profile views of LA 85404.

Figure 31.3. Post-excavation photograph of LA 85404.

STRATIGRAPHY

Stratum 1 is composed of loose, surface sediment. It is uniformly 1 to 7 cm thick across the site, and is more or less equivalent to the A horizon (topsoil). Stratum 2 is post-occupational fill, and ranges from 10 to 35 cm in thickness. The post-occupational fill was thickest on either side of the west wall of Room 1, and thinned to the southeast (i.e., downhill). Stratum 2 is more or less equivalent to the Bw horizon. Stratum 3 is the patch of burned floor encountered in the northeast corner of Room 1. Tables 31.1, 31.2, 31.3, and 31.4 describe the stratigraphy and summarize artifact counts from LA 85404.

Table 31.1. LA 85404 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10YR 4/3	Sandy loam	1–7	Surface sediment
2	10YR 5/3	Sandy loam	10–35	Post-occupational fill
3	10YR 6/4	Clay	-	Room 1 floor

Table 31.2. LA 85404 soil horizon descriptions from the north profile of 103N/102E.

Horizon	Color	Texture	Depth (cm)	Description
A	10YR 4/3	Sandy loam	0–9	Topsoil
Bw1	10YR 5/3	Sandy loam	9–21	Late-Holocene soil
Bw2	10YR 5/3	Sandy clay loam	21–30+	Late-Holocene/reworked Pleistocene soil

Table 31.3. LA 85404 soil horizon descriptions from the west profile of 102N/100E.

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is a small, rectangular structure that probably functioned as a fieldhouse. The room measures 2.25 m in length (north-south) by 1.70 m in width (east-west), with approximately 3.83 m^2 of interior space. Excavation of the room began with an east-west trench that extended across the room (103N/100-104E). The excavation of this trench served to define the room's stratigraphy, as well as to locate the room's west and south walls. The west wall was encountered in 103N/101E, and the east wall in 103N/103E. No living surface was encountered in the trench. As a result, the excavation of the trench units continued until a sterile Pleistocene soil (the Btb1 horizon) was reached. After the excavation of the trench, the rest of the room was excavated. A patch of burned floor was encountered in the northeast corner of the room (104N/102-103E). The floor is located directly on top of the Btb1 horizon. No floor was encountered anywhere else within the room. Excavation in these areas therefore terminated at the top of the Btb1 horizon.

Fill. The interior of Room 1 was filled with 3 to 6 cm of surface sediment on top of 30 to 35 cm of post-occupational fill. One flotation sample (Field Specimen [FS] 72) and one pollen sample (FS 73) were analyzed from the Room 1 fill. Carbonized taxa identified in the flotation sample included unidentified pine (*Pinus*), piñon pine (*Pinus edulis*), ponderosa pine (*Pinus ponderosa*), sagebrush (*Artemisia*), and unknown conifer (Gymnospermae). Taxa identified in the pollen sample included squash (*Cucurbita*), cheno-ams (*Chenopodium/Amaranthus*), grass family (Poaceae), sunflower family (Asteraceae), ragweed/bursage (*Ambrosia*), penstemon family (Scrophulariaceae), unidentified pine, piñon pine, juniper (*Juniperus*), Mormon tea (*Ephedra*), and sagebrush. Grass aggregates were also identified.

Floor. A patch of burned floor was encountered in the northeast corner of the room (in units 104N/102-103E) (Figure 31.4). The patch of floor measures approximately 45 cm north-south by 50 cm east-west. The floor is located directly on top of the Btb1 horizon, indicating that the people who constructed the room first cleared the area of loose surface soil to expose the considerably more compact Btb1 horizon. This compact surface was then used as a foundation for the room's floor. The floor itself was composed of a thin (1 to 2 cm) layer of highly compacted clay-rich mud. The floor appears to have been smoothed but not plastered. No floor was encountered in the rest of the room. In these areas, excavation terminated at the top of the Btb1 horizon. The surface was slightly burned in much of the northern half of the room.

Figure 31.4. A patch of burned floor in Room 1.

A single flake (FS 91) was the only artifact encountered on the patch of floor. A pollen sample was scraped from the surface of this floor (FS 90), and identified taxa included maize (*Zea mays*), buckwheat (Eriogonum), grass family, cheno-ams, sunflower family, ragweed/bursage, spurge family, penstemon family, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush. Grass aggregates were also identified. Another pollen sample (FS 96) was taken from directly beneath a rock lying on the floor, and identified taxa included grass family, cheno-ams, sunflower family, piñon pine, juniper, and sagebrush. The majority of the floor was removed and kept as two flotation samples (FS 93 and FS 94). Carbonized taxa identified in these samples included piñon pine, ponderosa pine, oak, unknown conifer, Douglas fir (*Pseudotsuga mensiezii*), sagebrush, groundcherry (*Physalis*), and goosefoot (*Chenopodium*). Uncharred tobacco (*Nicotiana*) was also identified in both samples. Two flotation samples (FS 68 and FS 106) and a pollen sample (FS 70) were taken from around floor level in the northwest corner of the room. Charred taxa identified in the flotation samples included unidentified pine, piñon pine, ponderosa pine, maize, and unknown conifer. Taxa identified in the pollen sample from the northwest corner of the room included squash, grass family, cheno-ams, sunflower family, ragweed/bursage, penstemon family, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush. A pollen sample (FS 95) was also taken from on top of the burned surface of the Btb1 horizon in the north-central portion of the room. Taxa identified in this sample included maize, cheno-ams, grass family, sunflower family, penstemon family, unidentified pine, piñon pine, and sagebrush.

Wall Construction. The Room 1 walls were constructed of dacite rocks. Most of the rocks were irregular in shape. Some of the rocks, however, had flat surfaces that were used to form the interior faces of the room's walls. The cobbles varied considerably in size, ranging from fist-sized cobbles to very large rocks. Some of the rocks were in fact so large that they would have been difficult to transport long distances by hand. There are abundant naturally-occurring dacite cobbles, however, in the drainage located a few m to the south and east of the site. In all likelihood, the drainage was mined for the rocks used to construct the room. Most of the foundation rocks were placed in shallow trenches dug into the Btb1 horizon. The larger rocks, however, appear to have been placed directly on top of or even a few cm above the Btb1 horizon. Presumably, these rocks were deemed heavy enough to be stable without being placed in a trench.

In some locations, small dacite cobbles were encountered just inside the interior wall faces. These rocks probably functioned as a foundation for floor coping. No entryway into the room was discovered. All four walls extended the entire length of the room and had a minimum height of 10 cm or greater (Table 31.5). Assuming the entryway was in one of the room's walls rather than its ceiling, it likely had a door sill of considerable height. Three tuff blocks were recovered during the excavation of the site. All three were found just above floor level within the room. These rocks were probably part of one of the higher courses of masonry in the room's walls. A flat dacite cobble was also encountered just above floor level within the room. There was no use wear visible on any of its surfaces, so it does not appear to have been a metate. This rock probably also represents wallfall. If not, it is of unknown function.

Table 31.5. LA 85404 Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	1.76	0.19–0.53	0.33–0.57	1 to 2
South	1.40	0.10–0.24	0.16–0.43	1
East	1.99	0.13–0.28	0.12–0.40	1
West	2.00	0.30–0.50	0.23–0.50	1 to 2

Judging from the amount of wallfall removed during the excavation of the area in and around Room 1, the masonry portions of the room's walls were originally considerably higher than they were at the time of excavation. In order to estimate the original height of the walls, all of the rocks removed as wallfall during the site's excavation were placed in two stacks, which were then measured. The stacks measured 1.50 by 1.60 by 0.65 m and 0.90 by 1.00 by 0.65 m, for a total of approximately 2.15 m^3 of wallfall. Based on this volume and the overall length, average thickness, and average height of the extant portions of the walls, the masonry portions of the room's walls were originally approximately 1.16 m high. The uppermost portions of the walls, as well as the ceiling, were most likely composed of wattle and daub. These materials are rarely preserved at archaeological sites on the Pajarito Plateau. In fact, no adobe was recovered during the excavation of the site.

Geological Analysis

Geologists Paul Drakos and Steven Reneau utilized two profiles to reconstruct the natural soil horizons at the site (see Tables 30.2 and 30.3). The first, the north profile of 103N/102E, was examined after the excavation of the east-west trench and before the excavation of the rest of the site. This profile contained a soil sequence consisting of an A horizon (topsoil) on top of two Bw horizons. The upper Bw1 horizon is a late-Holocene soil. The lower Bw2 horizon is a mixture of the late-Holocene soil in the Bw1 horizon and a reworked Pleistocene soil. This horizon probably represents the disturbed remains of the Room 1 floor mixed with post-occupational fill. The second profile examined was the west profile of 102N/100E. This profile contained a soil sequence consisting of an A horizon (topsoil), a Bw horizon (a late-Holocene soil), and a Btb1 horizon (a Pleistocene soil).

Artifact Distribution

Most of the artifacts at LA 85404 were recovered from within, to the north, and to the west of Room 1 (Table 31.6). The grid unit with the highest number of artifacts is 103N/102E, located in the center of the room. The grid unit with the second highest number of artifacts is 105N/102E, located directly north of the room. Few artifacts were recovered from the grid units to the east and south of the room, with the exception of grid unit 101N/102E, which contained 14 artifacts. This pattern of artifact distribution is probably largely the result of natural site formation processes. The site's natural surface slopes downward to the southeast. Normally, artifact density is higher in the downhill portion of a site. The fieldhouse, however, is located near the edge of a small, eroding ridge. The ridge is bounded to the south and east by an incised drainage. Many of the artifacts to the south and east of Room 1 may therefore have eroded downhill into the drainage. For this reason, it is impossible to determine whether the higher concentration of artifacts to the north and west of the room is culturally significant. The artifact distribution at the site therefore does not provide any reliable evidence concerning the location of outdoor activity areas and/or the room's entryway.

Table 31.6. LA 85404 artifact counts by grid unit.

	E100	E101	E102	E103	E104
N105		9	38	7	5
N104	8	**12**	**27**	**11**	7

N101	0	1	14	0	

Note: bold numbers indicate grid units that are located completely or partially within Room 1.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 265 artifacts were analyzed from the excavations conducted at LA 85404. In addition, flotation and pollen samples (Table 31.7) were selected for analysis from the post-occupation fill (Stratum 2) and the floor (Stratum 3). The results of the artifact and sample analyses are presented in the following sections. A maize sample was submitted for radiocarbon dating.

Table 31.7. Samples selected for analysis from LA 85404.

Stratum	Sample Type			
	Flotation	Pollen	Radiocarbon	TL*
1				
2	68, 72, 93, 94, 106	73, 95, 96	68	
3		90		

*thermoluminescence

Chronology

Radiocarbon Dating

A single maize sample was submitted for accelerator mass spectroscopy dating. The sample provided a date of 400±40 BP (Beta-215550), with a calibrated intercept of AD 1460 and a two-sigma range of AD 1440 to 1500. The sample was recovered from a flotation sample taken from Stratum 2.

Thermoluminescence Dating

A sample of burned floor (UW 1586, FS 92) was dated from this site. It yielded an age of AD 1388±49.

Ceramic Artifacts (Dean Wilson)

A total of 199 ceramics were analyzed from LA 85404. The majority of the pottery consists of smeared-indented corrugated, glazewares, and Biscuit A (Abiquiu Black-on-gray), which presumably reflects an Early Classic period occupation (Table 31.8). These dates indicate a 14th century occupation for the site, which contradicts the 15th century radiocarbon date. Information on ceramic tradition by ware, temper by ware, and vessel form by ware are provided in Tables 31.8 through 31.11. The graywares and whitewares appear to have been locally made from smeared-indented sand or tuff, in contrast to Sapawe Micaceous wares, which contained a non-local micaceous temper and the glazewares with basalt. All of the grayware and micaceous ceramics consist of jar vessel forms; however, the whitewares include mostly bowls, with some jars, while the glazewares contain mostly jars and some bowls.

Table 31.8. Ceramic types from LA 85404.

Ceramic Type	Frequency	Percent

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 66 artifacts were analyzed from LA 85404. The lithic assemblage consisted of one core, 59 pieces of debitage, five retouched tools, and one hammerstone, which represents a 100 percent sample of the recovered lithic artifacts. Table 31.12 presents the data on lithic artifact type by material type. The debitage assemblage is comprised of chalcedony, Pedernal chert, obsidian, and rhyolite. The presence of cortex on 15.2 percent of the debitage indicates that these materials were collected from waterworn (n = 9) sources. The chalcedony and Pedernal chert are available from local Rio Grande Valley gravels and the obsidian from nearby sources in the Jemez Mountains. Otherwise, the igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the Pajarito Plateau.

Table 31.12. Lithic artifact type by material type.

Three pieces of obsidian and one piece of basalt debitage were submitted for X-ray fluorescence analysis. All of these artifacts were obtained from the Valle Grande source (Table 31.13). The Valle Grande (Cerro del Medio) source area is located about 17 km (11 mi) as the “crow flies” to the west of the site. In addition, the single basalt flake is actually dacite.

Table 31.13. Obsidian source samples.

FS #	Artifact	Color	Source

30	Debitage	Translucent	Valle Grande rhyolite
79	Debitage	Translucent	Valle Grande rhyolite

Lithic Reduction

The single core was reduced using a multi-directional/opposed-same-and-different-face technique. The core was classified as still useable when discarded. Table 31.14 presents the metric information on this core.

Table 31.14. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Multi-directional	59	53	31	115.5

The debitage consisted primarily of core flakes and angular debris, a biface flake, microdebitage, and an undetermined flake fragment also present. The overall cortical:non-cortical ratio of 0.33 reflects an emphasis on the later stages of core reduction. The flakes mostly have single-faceted (*n* = 13) platforms with fewer cortical (*n* = 3) platforms. None of the platforms exhibit any evidence of preparation. The majority of the core flakes are whole (*n* = 14) or distal (*n* = 13) with fewer proximal (*n* = 4) and midsection (*n* = 3) fragments. The whole core flakes have a mean length of 26.4 mm (*std* = 12.7) and the angular debris a mean weight of 4.8 g (*std* = 5.6).

The retouched tools consist of two projectile points, a retouched piece, a uniface, and a scraper (Figure 31.5). The retouched piece is the distal end of a flake that is slightly serrated in outline. This fragment could represent a piece off of a scraper with unidirectional dorsal retouched edge and an angle of 60 degrees. One of the projectile points appears to be a Late Archaic stemmed point with the tip, tangs, and corner of the base broken. A neck width of 13 mm indicates that it represents a dart or lance point. The other point is a tip fragment that could also be from a well-made biface. The scraper consists of a core flake with unidirectional retouch along the perimeter that forms a circular-shaped artifact with a 65 degree edge angle. On the other hand, the uniface was made on a large cortical flake with rough retouch along the lateral and distal ends. The retouched edges exhibit a steep angle of 80 degrees.

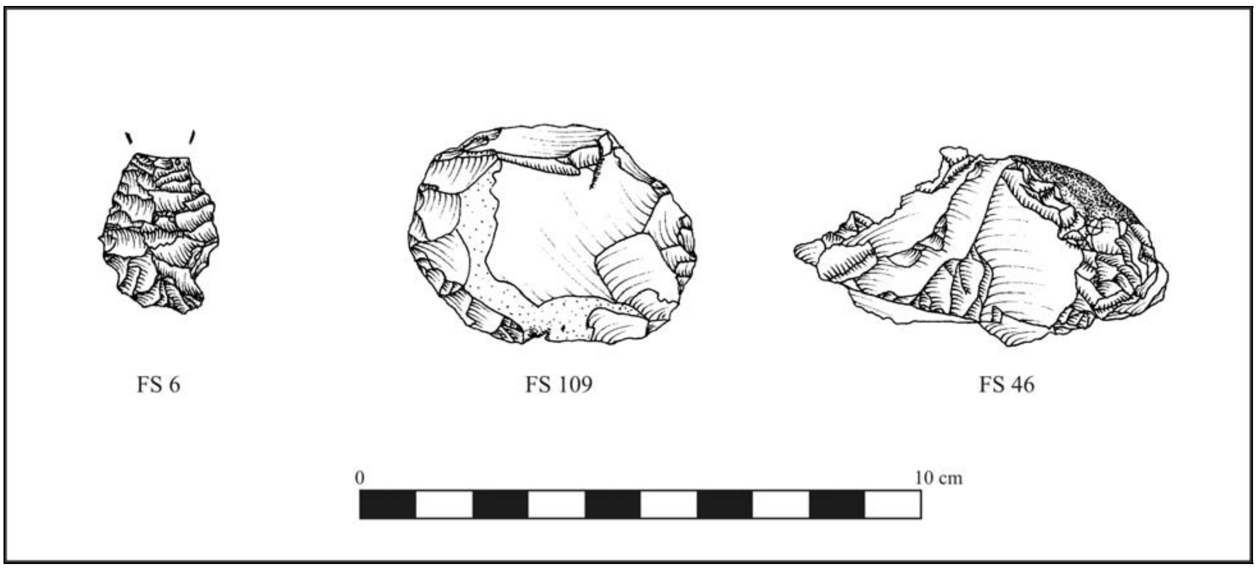

Figure 31.5. Projectile point and unifaces from LA 85404.

Tool Use

None of the flakes and two of the retouched tools exhibit any obvious evidence of edge damage that could be attributed to use. The uniface and scraper have rounding/polish or micro-scarring along their edges.

Faunal Remains (Kari Schmidt)

One piece of bone was recovered from Room 1 (Stratum 2, Level 3) of this fieldhouse. The bone was a mule deer (*Odocoileus hemionus*) distal metatarsal fragment (right), and was also manufactured into a partial fragment of a bone awl. The bone was unburned, but contained a possible cut-mark just above the epiphyseal fusion. The mark did not appear to be recent and was probably not incurred during excavation activities.

Archaeobotanical Remains (Pamela McBride)

Charred goosefoot and groundcherry seeds, found on the floor of the structure, and two corn cupule fragments from the northwest corner were the only cultural plant remains aside from conifer duff that were recovered from LA 85404 (Table 31.15). A possible pine seed and ponderosa pine needles comprised the unburned, probably non-cultural material from flotation samples. Uncharred tobacco seeds were recovered from both burned floor samples. These could be residue from plants brought into the structure for ceremonial use, although because the seeds are unburned this is uncertain. Goosefoot seeds could have been ground into meal, groundcherry fruits may have been boiled or eaten raw, and corncobs were probably used for fuel along with piñon, ponderosa pine, oak, sagebrush, and possible Douglas fir wood (Table 31.16).

Pollen Remains (Susan Smith)

Five pollen samples were analyzed from LA 85404. Table 31.17 lists the frequency of identified pollen types. Squash and maize were the only cultigens identified in the assemblage. No other economic resources were identified. A number of potential economic resources were also identified in the assemblage (Table 31.17), and these are described in detail in Smith's chapter in Volume 3 (Chapter 63).

SUMMARY

LA 85404 consists of three rock features. The site is located on the south side of Rendija Canyon adjacent to an intermittent drainage. Only one rock feature, a one-room Early-Middle Classic period fieldhouse, was excavated as part of the Conveyance and Transfer Project. Burned maize cupules with maize and squash pollen were recovered during the sire excavation; therefore, the one-room structure was presumably occupied during the growing season. Maize remains provided a radiocarbon date of circa AD 1460. The diagnostic ceramics corroborate an Early-Middle Classic period occupation.

CHAPTER 32
RENDIJA TRACT (A-14): LA 85407 (SERNA HOMESTEAD)

Gregory D. Lockard

INTRODUCTION

LA 85407 is the historic Serna Homestead located on a gently sloping bench immediately north of Rendija Canyon. The site is located in a cleared, grassy area surrounded by a mixed piñon-juniper and ponderosa pine woodland. The site is situated at an elevation of 2097 m (6880 ft).

LA 85407 was first recorded on August 16, 1991, by David Hill (1991) during a survey for the Bason Land Exchange Project. According to Hill, architecture on the site at the time of his visit consisted of a habitation structure with an iron and asphalt roof, a circular rock feature (possibly a hearth or horno), an amorphous pile of cut logs, and an animal pen. A trash scatter located along the canyon edge on the southeastern side of the site contained lard, coffee, sardine, kerosene, and condensed milk cans. Other artifacts at the site that were noted by Hill included an enamelware wash basin, galvanized metal, a stove pipe, the base of a kerosene lamp of purple glass, and a Kapo Black sherd. Four obsidian flakes found near the trash scatter indicated a prehistoric presence in the site area.

On July 20, 1992, Archaeological Research, Inc., was awarded the contract to conduct archaeological testing of the Bason Land Exchange sites. John Peterson and Christian Nightengale (1993) supervised the excavations, which took place between July 27 and August 23 of 1992. Peterson and Nightengale recorded seven architectural features at LA 85407 (1993:99–103). These features included a rectangular alignment/concentration of logs and dimension lumber (Feature 1), the remains of an horno (Feature 2), an L-shaped alignment of cobbles and boulders (Feature 3), a log structure (Feature 4), a large corral (Feature 5), another L-shaped rock alignment (Feature 6), and a small pile of cobbles (Feature 7).

Peterson and Nightengale also recorded two trash concentrations (designated Trash Areas 1 and 2) near the southeastern edge of the site. Two 1- by 1-m test pits (Units A and B) were excavated at the site (Peterson and Nightengale 1993:103–104). Unit A was located within the horno. The unit was excavated to a sterile Pleistocene soil at a maximum depth of 43 cm below ground surface. Historic artifacts were recovered from all four excavation levels. Two courses of rock that formed the feature's northwest edge were encountered below the surface. A layer of burned clay was uncovered beneath these rocks. The burned clay formed a low cone at the bottom of the feature. The clay consisted of a layer of reddish (i.e., oxidized) clay on top of a layer of bluish (i.e., reduced) clay. Unit B was placed adjacent to one of the L-shaped rock alignments (Feature 6). The unit was excavated to sterile Pleistocene soil at a maximum depth of 20 cm below ground surface. The excavations revealed no clearly defined walls and no cultural materials were recovered. As a result, Peterson and Nightengale argued that the feature probably represented a concentration of large rocks removed from a field.

In order to learn more about the homestead, Archaeological Research, Inc., also conducted historical research on the site. This research included a review of historical documents and two interviews conducted by Ada González-Peterson (Peterson and Nightengale 1993:46–82). The most important document was the Homestead Entry Survey No. 394, Santa Fe National Forest, State of New Mexico (1916). The first interview was of Annie Lujan and her husband Bernardo Lujan. Annie Lujan was the daughter of José María Serna, who was the owner of the homestead when it was seized by the U.S. government in 1943. She had visited her father's homestead on numerous occasions as a child. The second interview was of Severo and Aurora González, who provided first-hand accounts of life in Los Alamos before the Manhattan Project.

According to the historical documents, Andres Martinez applied for homestead certification in 1913, and the Homestead Entry Survey No. 394 was performed in October of 1916. The homestead was patented in 1922 and subsequently sold to José and Fidel Serna (of unknown relations), who had probably occupied the homestead since 1913. According to the survey, 40 acres of beans, corn, and vegetables were under cultivation on the homestead in 1916. Improvements included a 12- by 30-ft log house, a 12- by 20-ft pole shed, and one mile of brush fence. According to Annie Lujan, the cabin included three rooms and a sun porch. The Serna family made seasonal use of the homestead. They traveled by wagon to the site three times a year and stayed for about two weeks during each visit. In the spring, they traveled to the homestead to plant their crops. They returned to tend the fields once during the summer and to harvest the crops in the fall. Crops grown on the homestead by the Serna family included pinto beans, corn, wheat, pumpkins, and other "soft vegetables."

FIELD METHODS

Before excavation, the site was cleared of trees and large undergrowth, and an arbitrary site datum (designated 100N/100E, 10.00 m elevation) was set up in the northern portion of the site (Figure 32.1). The area was then covered with a 5- by 5-m grid that extended 15 m north, 65 m south, 45 m east, and 80 m west of the site datum. The site was then divided into excavation areas. These areas included the cabin (Area 1), the horno (Area 3), a small concentration of rocks (Area 4), the shed (Area 5), the corral (Area 6), and the reservoir (Area 7) (Figure 32.2). All other areas of the site were designated Area 2. Surface collection of the site began during the 2003 field season, and was completed during the 2005 field season. Surface artifacts were collected by 1- by 1-m grid unit. The grid unit of the collected artifacts was determined by tape measures extended from the 5- by 5-m grid stakes.

The 5- by 5-m grids were divided into 1- by 1-m grid units and subdata were set up for taking elevations in the areas to be excavated. The entire cabin (Area 1) was covered with a 1- by 1-m grid that measured 6 m north-south (60N-65N) by 11 m east-west (90E-100E). Three subdata (A-C) were set up for taking elevations. The horno (Area 3) was covered with a grid that measured 3 m north-south (69N-71N) by 3 m east-west (94E-96E), and a single subdatum (D) was set up for taking elevations. The small concentration of rocks (Area 4) was covered with a grid that measured 2 m north-south (45N-46N) by 2 m east-west (91E-92E), and a subdatum (E) was set up for taking elevations.

Figure 32.1. View of the cabin area before excavation.

The shed (Area 5) was covered with a grid that measured 5 m north-south (61N-65N) by 5 m east-west (90E-94E), and a subdatum (F) was set up for taking elevations. Two non-contiguous 1- by 1-m grid units (105N/130E and 108N/126E) were set up and excavated in the corral (Area 6), and a subdatum (G) was set up for taking elevations. The entire corral was mapped, however, and surface artifacts recovered from anywhere within the corral were designated Area 6. Two auger holes were the only excavations in the reservoir (Area 7). These auger holes were excavated for the sole purpose of recovering pollen samples from the reservoir. Before excavation, Areas 1 and 3 were mapped and Areas 1, 3, and 4 were photographed. Excavations proceeded by strata and did not terminate until a cultural feature (e.g., a floor or wall) or sterile soil was encountered. Soil samples were taken from select locations, and all other soil was passed through screens with 1/8-in. mesh to aid in the recovery of artifacts. After excavation, Areas 1, 3, 4, 5, 6, and 7 were mapped and photographed.

The 2003 surface collection at LA 85407 was performed by Hannah Lockard and Mia Jonsson. During the 2005 field season, work at the site was supervised by Greg Lockard. Excavators on the 2005 field crew included Michael Dilley, Alan Madsen, Kari Schmidt, Jennifer Nisengard, Brian Harmon, Joseph (Woody) Aguilar, Sandi Copeland, and Bettina Kuru'es. Surface collectors and screeners included Ellen McGehee, Kari Garcia, Timothy Martinez, Aaron Gonzalez, Jeremy Yepa, Rhonda Robinson, Sherrie Sherwood, and Marwin Shendo.

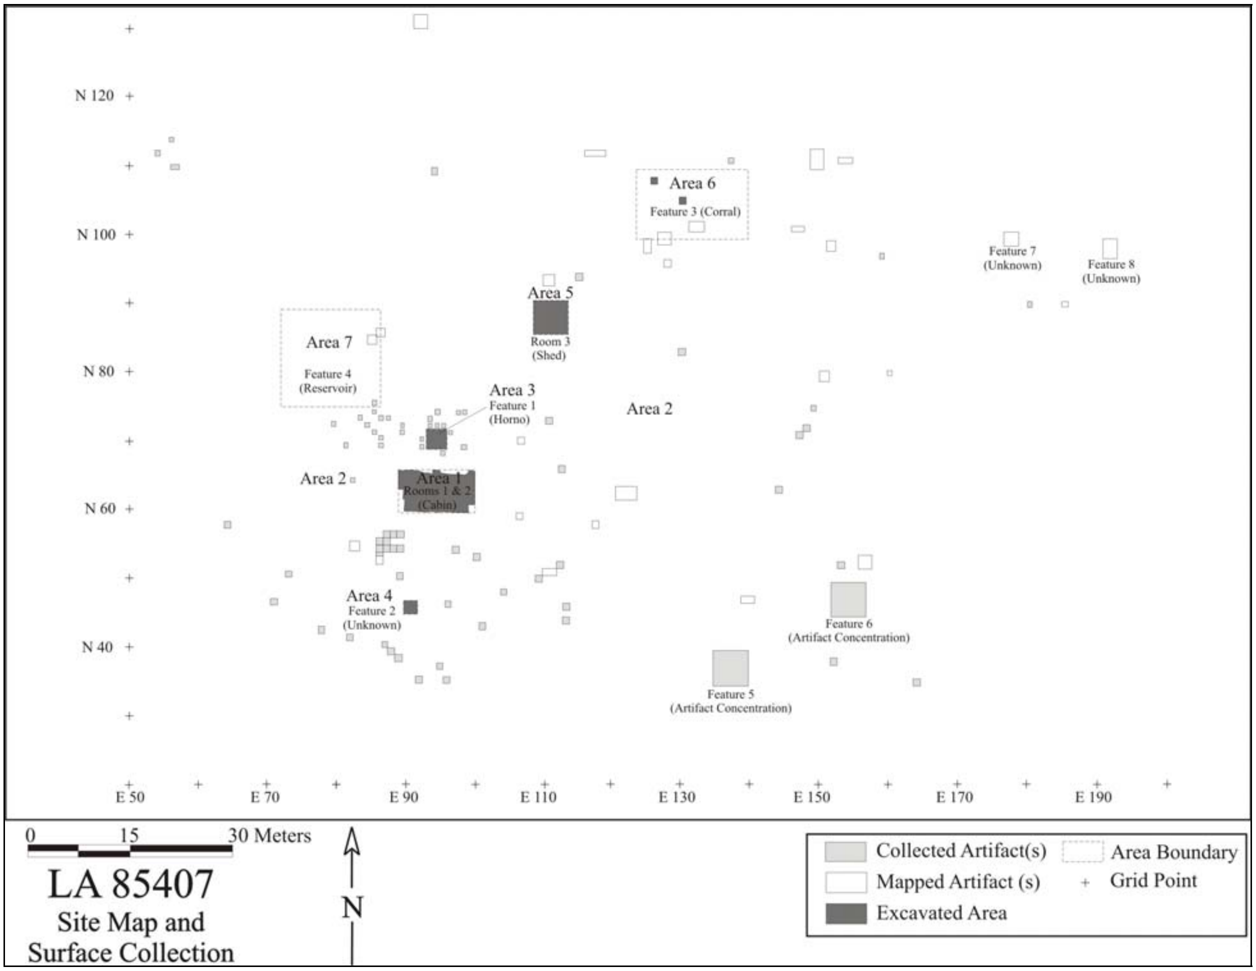

Figure 32.2. Site map and surface collection at LA 85407.

STRATIGRAPHY

Three strata were identified at LA 85407 (Figure 32.3). Stratum 1 is composed of loose, surface sediment. It is uniformly 2 to 7 cm thick across the site. Stratum 2 is post-occupational fill and ranges from 5 to 40 cm in thickness in the areas excavated. The fill was thickest (i.e., >25 cm) in Areas 3 and 5. The backfill from Peterson and Nightengale's Unit A, located in Area 3, was excavated separately. No artifacts, however, were recovered from this backfill. As a result, the backfill was not designated as a separate stratum. Due to the fact that the site's occupation has been well established by historical documents and interviews, the site's stratigraphy was not analyzed by geologists. Strata from LA 85407 are summarized in Table 32.1. Artifact counts from strata and areas at the site are listed in Tables 32.2 and 32.3. Table 32.4 lists the average artifact count per grid unit by area from LA 85407.

SITE EXCAVATION

Area 1 (Rooms 1 and 2 – Cabin)

Sequence of Excavation. Area 1 consists of the remains of a historic log cabin and the area immediately adjacent to the cabin (Figures 32.4 and 32.5). According to Homestead Entry Survey No. 394, the cabin measured 12 by 30 ft in 1916 (Peterson and Nightengale 1993:51). According to Annie Lujan, who frequented the homestead as a child, the cabin contained three interior rooms and included an exterior sun porch (Peterson and Nightengale 1993:62, 71). Excavation of the room began with an east-west trench (63N/90-100E) followed by a north-south trench (60-65N/95E), both of which extended across the entire cabin (see Figure 32.3). The trenches were excavated in 1- by 1-m grid units, and intersected in the approximate center of the cabin. The excavation of the trenches served to define the room's stratigraphy, as well as to locate the room's perimeter walls. The rock foundation of the cabin's east wall was encountered in 63N/99E of the east-west trench. Unit 63N/100E is therefore completely outside of the cabin. No evidence of the cabin's west wall was encountered in the east-west trench.

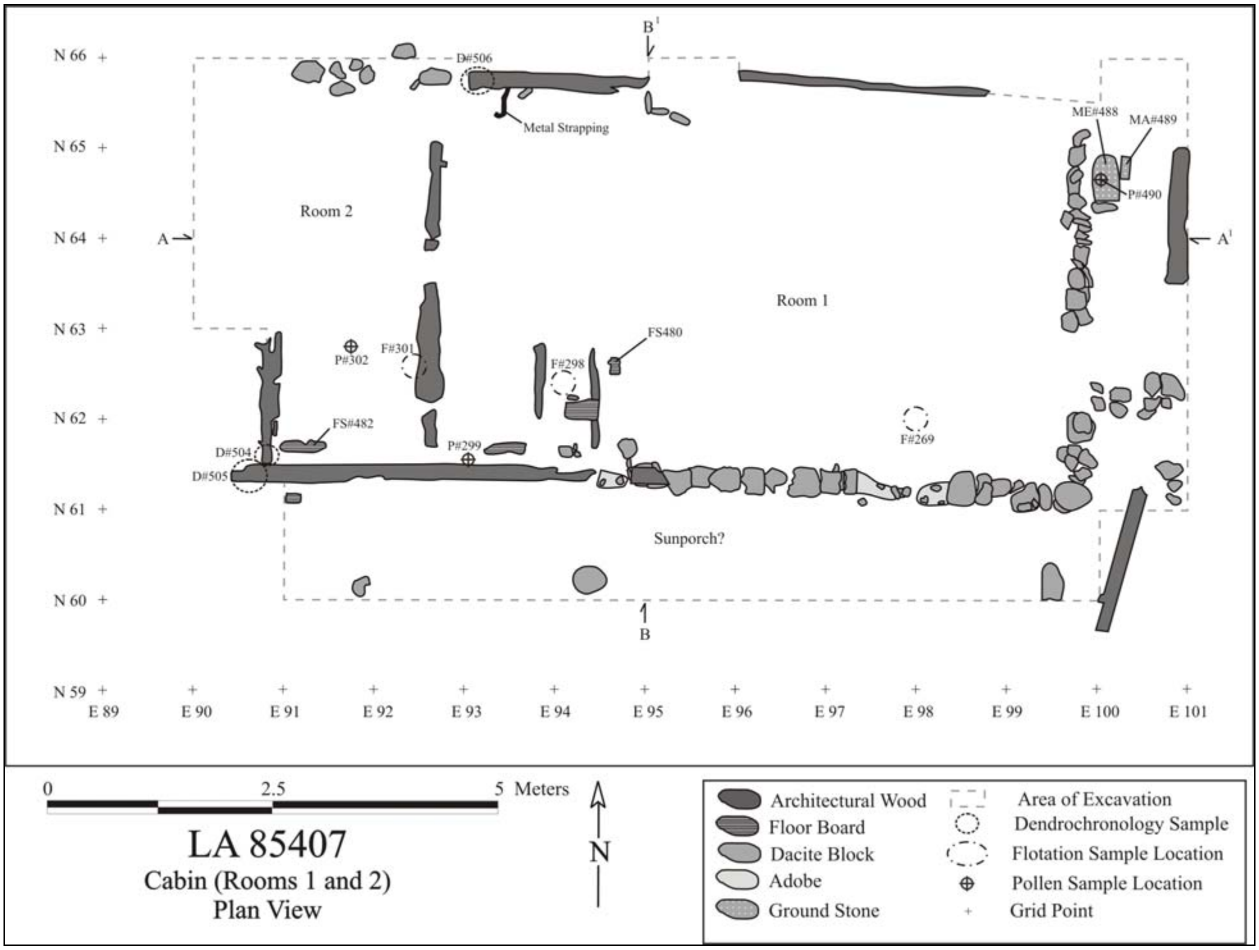

Figure 32.4. Plan view of cabin (Rooms 1 and 2).

Surface wood beams to the south of the trench, however, indicated that the wall passed through the easternmost portion of unit 63N/90E. Most of this unit is therefore also outside of the cabin. The rock foundation of the cabin's south wall was encountered in unit 61N/95E of the north-south trench. Unit 60N/95E is therefore located outside of the cabin. The only evidence encountered in the north-south trench of the cabin's north wall was a few displaced rocks in unit 65N/95E. Coping of the sterile soil beneath the cabin's post-occupational fill and surface wood beams to the east and west of the trench, however, indicated that the north wall passed through the northern half of this grid unit.

The excavation of the trenches also served to divide the cabin into four quadrants of roughly the same size. The initial excavation strategy for the cabin was for each of these quadrants to serve as a large excavation unit. During the excavation of the east-west trench, however, a wood beam was encountered in unit 63N/92E. This beam extended from north to south across the unit and was roughly parallel to the structure's east and west walls. It was originally thought that this beam was the remains of a wall that divided the cabin's interior into separate rooms. As a result, the cabin's western quadrants were each divided by the wood beam into two excavation units.

Figure 32.5. Post-excavation photo of Area 1, the cabin.

The area to the east of the wood beam (including the cabin's two eastern quadrants) was designated Room 1, and the area to the west of the wood beam was designated Room 2. The cabin's interior, excluding the trench units, was therefore excavated in six large units. During the excavation of these units, other wood beams were encountered that were parallel to the beam that divided the areas designated Rooms 1 and 2. A small piece of floorboard was still nailed to the top of one of these beams. As a result, the wood beam that divided the areas that were designated Room 1 and Room 2 most likely was not part of an interior wall. Instead, it appears to have been the best preserved of many support beams for the cabin's floorboards. The room designation of the various areas within the cabin, and consequently the room designation of the artifacts recovered from the cabin, is therefore almost certainly inaccurate. The cabin probably was divided into two or three rooms, as suggested by the informant Annie Lujan. The location and extent of these rooms, however, could not be determined through excavation.

After the excavation of the cabin's interior, units were excavated to the east and south of the cabin. The purpose of these excavations was to locate the sun porch noted by the informant Annie Lujan, as well as to determine the prevalence and distribution pattern of artifacts in the area immediately surrounding the cabin. The area to the east of the cabin was excavated in two 1- by 2-m units (61-63N/100-101E and 64-66N/100-101E). These units were located on either side of the easternmost 1- by 1-m unit in the east-west trench (63N/100E). A mano and a single-footed metate were discovered side by side just outside the cabin's east wall (Figure 32.6). The mano is located completely within unit 64N/100E, while the metate extends slightly into unit

64N/99E. A pollen sample (Field Specimen [FS] 490) was taken from directly beneath the metate, which was upside down. Taxa identified in the sample included prickly pear (*Opuntia*), beeweed (*Cleome*), grass family (Poaceae), cheno-ams (*Chenopodium/Amaranthus*), sunflower family (Asteraceae), ragweed/bursage (*Ambrosia*), fir (*Abies*), unidentified pine (*Pinus*), piñon pine (*Pinus edulis*), juniper (*Juniperus*), Mormon tea (*Ephedra*), and sagebrush (*Artemisia*).

The area to the south of the cabin was also excavated in two units, which were located on either side of the southernmost 1- by 1-m unit in the north-south trench (60N/95E). The unit to the east measured 1 by 4 m (60-61N/96-100E), and the unit to the west measured 1.3 by 4 m (60-61.3N/91-95E). A small portion of the area to the west of the cabin was also excavated. This includes most of the westernmost 1- by 1-m unit in the east-west trench (63N/90E) and the westernmost portion of the Room 2 section (i.e., western half) of the cabin's northwest quadrant (64-66N/90-92.6E). No evidence of the cabin's west wall was found in either of these excavation units. For this reason, the fill from inside the cabin could not be distinguished from the fill just outside of the cabin. Because most of the smaller excavation unit (63N/90E) was located outside of the cabin, the artifacts recovered from it were not given a room designation. Since most of the larger excavation unit (64-66N/90-92.6E) was located inside the cabin, however, the artifacts from this unit were designated from Room 2.

Figure 32.6. *In situ* mano and metate recovered just outside the cabin.

The cabin's floor was composed of wooden boards (see below). As a result, no sedimentary living surface of any kind was encountered in Area 1. The vertical distribution of cultural materials was fairly uniform throughout the area. This cultural debris terminated rather suddenly at the top of a layer of sterile, clay-rich soil that predates the site's occupation. The excavation of all of the units in Area 1 terminated at the top of this soil horizon.

Fill. The interior of the cabin was filled with 2 to 7 cm of surface sediment on top of 5 to 25 cm of fill. The fill probably began to accumulate during the site's occupation in the form of sediment, and artifacts fell through the cracks between the boards that formed the cabin's floor. Most of the fill, however, is probably post-occupational. The fact that the fill is uniform down to the sterile, clay-rich soil probably indicates significant mixing of pre-occupational and post-occupational Holocene sediments as a result of rodent bioturbation. A number of rodents were in fact still living and constructing tunnels within the cabin during its excavation.

The cabin fill was extremely rich in charcoal. Most if not all of this charcoal is probably the burned remains of the beams and boards that formed the cabin's walls and floor. According to Peterson and Nightengale (1993), little remained of the cabin's walls when they performed their testing at the site in 1992. An inspection of the site shortly after the Cerro Grande fire on October 4, 2000, however, indicates that at least some of the cabin's remains burned during this fire. At least some of the charcoal may therefore date to this time. Flotation (FS 269 and FS 298) and pollen (FS 299) samples were analyzed from the post-occupational fill from the southeast (FS 269) and southwest (FS 298 and FS 299) corners of Room 1.

Carbonized taxa identified in the flotation samples include pigweed (*Amaranthus*), goosefoot (*Chenopodium*), beeweed, maize (*Zea mays*), grass family (Graminae), sage (*Salvia*), vervain (*Verbena*), grape (*Vitis*), sedge family (Cyperaceae), unidentified pine, ponderosa pine, and unknown conifer (Gymnospermae). Taxa identified in the single analyzed pollen sample include sunflower type (*Helianthus*), rose family (Rosaceae), grass family, cheno-ams, sunflower family (Asteraceae), fir, unidentified pine, piñon pine, juniper, oak (*Quercus*), and sagebrush. A flotation sample (FS 301) and a pollen sample (FS 302) were also taken from the post-occupational fill from the southern half of Room 2. Charred taxa identified in the flotation sample include goosefoot, stickseed (*Lappula*), groundcherry (*Physalis*), grass family, juniper, unidentified pine, and ponderosa pine. Taxa identified in the pollen sample include grass family, cheno-ams, sunflower family, evening primrose (Onagraceae), unidentified pine, piñon pine, juniper, oak, and sagebrush.

Floor. Excavation revealed that the cabin's floor was formed by wooden boards oriented east to west placed on top of and nailed to wooden beams oriented north to south. The floorboards also presumably rested on top of the foundations of the cabin's south, east, and west walls. To the north, the floorboards probably extended to the sterile, clay-rich soil that functioned as the foundation for the cabin's north wall (see below). Floor board fragments were preserved in four locations. All of these fragments were oriented from east to west. The largest fragment was located in the southwest quadrant of unit 62N/94E (Figure 32.7). This unit is located in the southwest corner of Room 1. The floorboard fragment, which was 1 in. thick and 6 in. wide, was still nailed to a wood beam below that was oriented north to south. The board was very poorly preserved and fragmented. As a result, it was not kept as a sample.

Figure 32.7. ***In situ*** **remnants of the cabin floor**.

A smaller floorboard fragment was encountered in the northeast quadrant of the same grid unit (see Figure 32.7). The board was also one inch thick, but was four inches wide. Due to its poor state of preservation, however, it fractured into two pieces during removal. The last floorboard fragment encountered within the cabin was located in the far southwest corner of Room 2, in the northwest quadrant of unit 61N/91E. Due to its poor state of preservation, however, it fractured into three pieces during removal. No artifacts were encountered in direct association with any of the floorboard fragments within the cabin.

The fourth floorboard fragment encountered in Area 1 was located just outside the cabin. It was located just south of the cabin's southwest corner, in the southwest corner of grid unit 61N/91E (Figure 32.8). This floorboard fragment may be the remains of the sun porch described by the informant Annie Lujan (Peterson and Nightengale 1993:71). This interpretation is supported by the presence of three large dacite cobbles to the south of the cabin. These rocks may have functioned as the porch's foundation. All three rocks were located approximately 1 m from the cabin's south wall. The central rock was located approximately twice as far from the east rock as the west rock. This suggests that there was a fourth rock located between the central and east rocks. If this is the case, the four rocks would have been roughly equidistant from one another in addition to being approximately the same distance from the south wall. The location of the rocks, in addition to the fact that large dacite cobbles do not occur naturally in the area, therefore indicates that even if the rocks did not function as the porch's foundation, they were at least intentionally placed in the area to the south of the cabin.

Figure 32.8. ***In situ*** **floorboard located just outside the cabin**.

Wall and Roof Construction. The cabin utilized three types of wall foundations. The foundation of the entire east wall, the eastern two-thirds of the south wall, and the western quarter of the north wall were composed of irregularly shaped dacite cobbles. In most locations, the wall is only a single course high. In a few locations, the wall foundation is composed of two courses of shorter rocks. An almost complete lack of rock wallfall in the excavated area indicates that the masonry was probably never higher than the extant remains. Wall dimensions are provided in Table 32.5.

Table 32.5. Room 1/2 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	8.80	0.09–0.18 (rock) 0.05–0.25 (wood)	0.14–0.35 (rock) 0.06–0.12 (wood)	1 (rock) 1 to 2 (wood)
South	8.80	0.05–0.17 (rock) 0.01–0.15 (wood)	0.05–0.33 (rock) 0.08–0.18 (wood)	1 (rock) 1 (wood)
East	4.20	0.07–0.25 (rock)	0.08–0.38 (rock)	1 to 2 (rock)
West	4.20	0.05–0.17 (wood)	0.07–0.20 (wood)	2 (wood)

The sediment between the rocks was slightly more compact than the surrounding sedimentary matrix, especially in the south wall. This suggests that simple mud was utilized as mortar for the rocks. The rock foundation of the south wall appears to be almost completely intact. Most of the rock foundation in the east wall is also intact. The most notable exception is within unit 62N/99E. None of the rocks that formed this section of the wall's foundation were found *in situ*. A number of loose rocks, however, were found in the area to the east. These rocks most likely formed the wall foundation's missing section. The northernmost portion of the east wall also appears to be disturbed. It is impossible to determine to what extent, however, as the north wall is poorly defined in this area of the cabin. The rock foundation of the north wall is very poorly preserved. All of the rocks appear to be present, but slightly displaced.

The foundation of the western third of the south wall and the southern third of the west wall was composed of wooden beams. Presumably, the foundation of the northern two-thirds of the west wall was also composed of wooden beams, as no rocks were found in this location. If this is the case, however, the wooden beams were no longer preserved in this location. The foundation of the eastern three-quarters of the north wall was composed of compact sediment. The sediment is a sterile, clay-rich soil. This soil slopes upward to the north, forming a near vertical surface below the lowest wood beams in the north wall. Presumably, some of the compact, clay-rich soil was excavated in the northern, uphill portion of the cabin's interior during its construction to create a level surface. The sloped surface to the north thereby represents the northern extent of these excavations. The cabin's floorboards probably rested on top of this highly compact surface, as the base of the north wall is considerably higher than the floorboard fragments found within the cabin. The sloped surface of the compact soil probably formed coping between the floorboards and the base of the north wall. Most of the base of the north wall is composed of two wood beams. These wood beams are located approximately 1 m apart. No wood beams were encountered in the area of the north wall within grid unit 65N/95E. Three small dacite cobbles, however, were encountered to the south of this area. These rocks may be the displaced remains of the base of the central section of the north wall.

The upper portions of all four walls were most likely composed of large wood beams. Unfortunately, very little of the cabin's superstructure was preserved at the time of excavation. The cabin's roof was probably composed of sheet metal and asphalt, as argued by Hill (1991). Several small pieces of asphalt were in fact recovered during the excavation of the cabin, and several large pieces of sheet metal were found within and around the cabin. The sheet metal was concentrated in the area to the south of the cabin. These materials are most likely the remains of the cabin's roof.

Three dendrochronology samples were taken from *in situ* wood beams in Area 1. The first sample (FS 504) was taken from the south end of the southernmost log in the cabin's west wall. The second sample (FS 505) was taken from the west end of the westernmost log in the cabin's south wall. The last sample (FS 506) was taken from the end of a log in the western half of the north wall. In addition, three dendrochronology samples (FS 291, FS 303, and FS 406) were taken from logs that were not *in situ* but were almost certainly part of the cabin's walls. All three wood beams were located just south of the cabin. All of the samples were identified as ponderosa pine and are discussed in the chronology section near the end of the chapter.

Artifact Distribution. Due to the fact that several excavation units contained multiple grid units, as well as portions of grid units in some cases, the exact distribution of artifacts in Area 1 could not be calculated. Artifact counts for each grid unit were mathematically calculated, however, using the following technique. First, the average number of artifacts per 1 m^2 was calculated for each excavation unit. If an entire grid unit was within a single excavation unit, the artifact count of the former is the average number of artifacts per 1 m^2 of the latter. If only part of the grid unit was excavated, but all of the excavated portion was within a single excavation unit, the artifact count of the grid unit is the area of that grid unit multiplied by the average number of artifacts per 1 m^2 of the excavation unit. If the grid unit contained portions of more than one excavation unit, the artifact count for the grid unit is the sum of the area of that portion of the grid unit that is within each excavation unit multiplied by the average artifacts per 1 m^2 of the respective excavation units. As Table 32.6 demonstrates, the distribution of artifacts was fairly uniform throughout the excavated portion of Area 1. The grid unit with the highest density of artifacts was 63N/95E, which was located in the center of the cabin. There was also a slightly higher density of artifacts in the southwest corner of Room 1. Interestingly, this is also the area in which the cabin's floor was best preserved. The reason for this artifact distribution pattern is unclear.

Table 32.6. Artifact counts from Area 1 by grid unit.

Note: All but the trench units (63N/90-100E and 60-65N/95E) are mathematical calculations based on the averages from the excavation unit(s) in which each grid unit is located; lightly shaded grid units were partially excavated; bold numbers indicate grid units that are located completely or partially within the cabin (Rooms 1 and 2).

Area 2

Area 2 consists of the entire site except for Area 1 (the cabin), Area 3 (the horno), Area 4 (a circular rock alignment), Area 5 (the shed), Area 6 (the corral), and Area 7 (the reservoir). No excavations were conducted in Area 2. Artifacts from the surface of the area, however, were collected during two surface collections. The first surface collection was performed by Hannah Lockard and Mia Jonsson during the 2003 field season. During this collection, all artifacts visible on the surface of grid units 69-74N/80-100E were collected. This area includes Area 3 (69-71N/94-96E).

The second surface collection was performed during the 2005 field season. There were two stages in this collection. The first stage was performed by Ellen McGehee and Kari Garcia and involved a survey of the entire site and the flagging of diagnostic artifacts. The survey extended from 35-113N and from 54-180E, although the survey area was not completely rectangular. During the survey, diagnostic artifacts were marked for collection or mapping by labeled pin flags. Artifacts marked for mapping were mostly large pieces of sheet metal.

The second stage of the surface collection was performed by Gregory Lockard, Kari Schmidt, and Jennifer Nisengard. Artifacts marked for collection were collected by 1- by 1-m unit. The grid unit of the artifacts was determined by tape measures extended from the 5- by 5-m grid stakes. A single piece of metal (FS 222) was collected from a grid unit (74N/99E) within the area of the first surface collection. Artifacts marked for mapping were photographed with a board labeled with the artifact's grid unit(s). The labels were later utilized to mark the location of the artifacts on a map of the site (see Figure 32.1). The locations of the collected artifacts (from both surface collections) were marked on the same map. Area 2 includes two dense artifact scatters located along the southeast margin of the site. These scatters were comprised almost entirely of metal cans. Due to their association and artifact density, the scatters were collected in 5- by 5-m units rather then 1- by 1-m units. The first scatter, designated Feature 5 (Peterson and Nightengale's Trash Area 1), extended from 35-40N and 135-140E. The second scatter, designated Feature 6 (Peterson and Nightengale's Trash Area 2), extended from 45-50N and 152-157E.

Area 3 (Feature 1 – Horno)

Feature 1 is the remains of a rock feature (Figures 32.9 and 32.10) located approximately 3 m north of the cabin.

Figure 32.9. Rock feature (Feature 1) located north of the cabin.

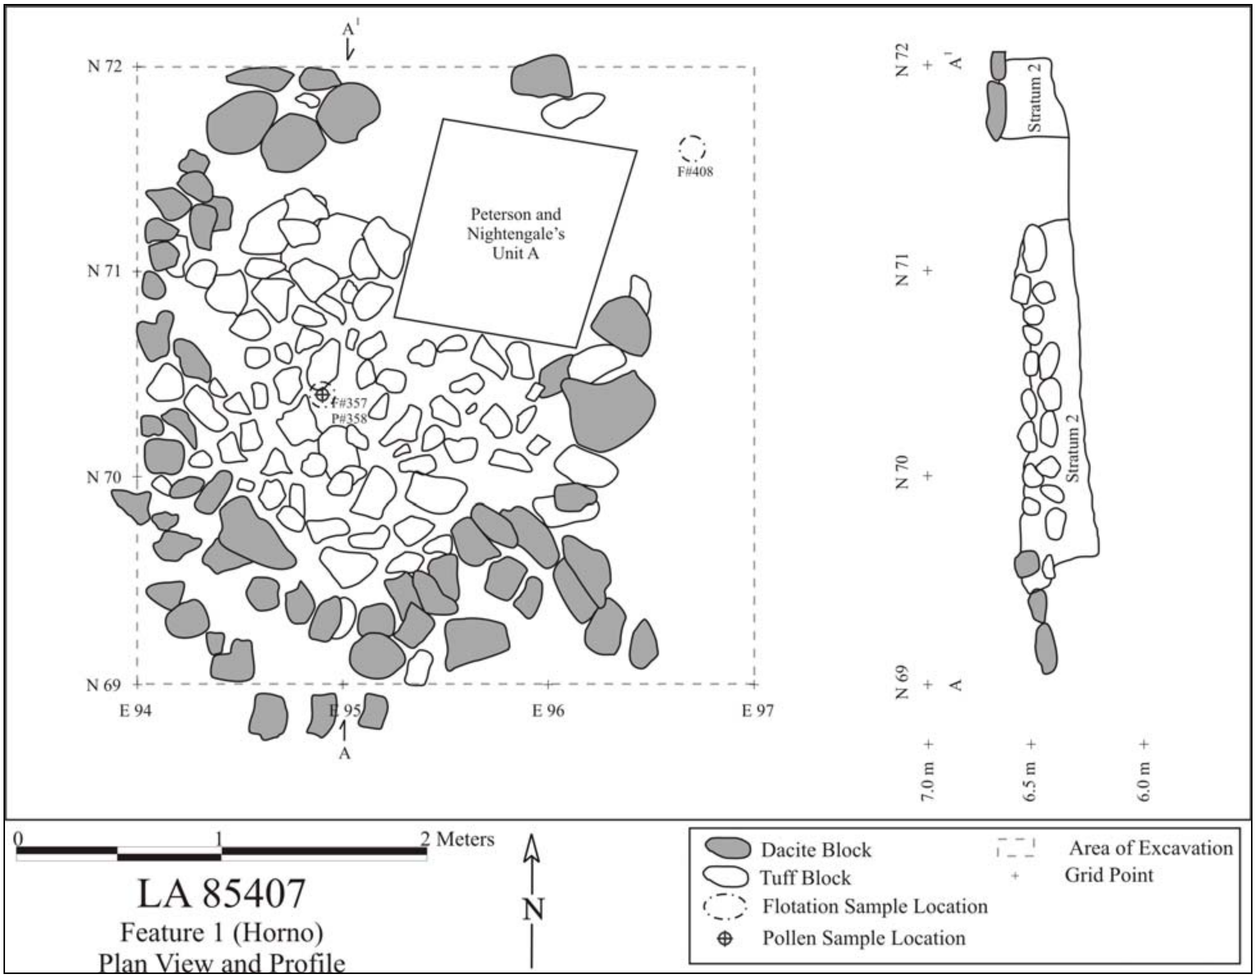

Figure 32.10. Plan view and profile of Feature 1 (horno).

According to Peterson and Nightengale (1993:103), the excavation of their Unit A and informant interviews confirmed that the feature was a horno. The entire feature (excluding the portion removed by Peterson and Nightengale during the excavation of their Unit A) was excavated during the Conveyance and Transfer (C&T) Project. The excavations confirmed that the feature was C-shaped, with the open end facing northeast. The feature was approximately 3 m in diameter. The feature's outer perimeter was composed of a single course of large dacite cobbles. A dense concentration of tuff rocks was found within the feature's perimeter. These rocks appeared to be the collapsed remains of the feature's superstructure. The rocks appeared to be oxidized, most likely as a result of thermal activity. During the excavation of their Unit A, Peterson and Nightengale encountered a layer of burned adobe at the base of the feature. During the C&T Project excavations, only a small patch of this burned surface was encountered. It is a patch of oxidized soil located in the northeast corner of grid unit 69N/95E (Figure 32.11). Beneath the oxidized soil was a dark layer that appeared to be a charcoal lens. Alternatively, it could have been the layer of bluish (i.e., reduced) clay described by Peterson and Nightengale (1993:103). A fairly high concentration of charcoal was encountered throughout the area near the base of the feature. The charcoal was especially dense near the open end of the feature to the northeast. This charcoal concentration probably represents a dump zone.

Figure 32.11. Patch of oxidized soil associated with a burned adobe surface in Feature 1.

A flotation sample (FS 357) and a pollen sample (FS 358) were taken from near the base of the west-central portion of Feature 1. Charred taxa identified in the flotation sample included unknown conifer and ponderosa pine. Taxa identified in the pollen sample included buckwheat, grass family, cheno-ams, sunflower family, fir, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush. A flotation sample (FS 408) was taken from the charcoal concentration in the northeast portion of the feature. Carbonized taxa identified in the flotation sample included goosefoot, juniper, unidentified pine, piñon pine, and ponderosa pine.

The grid unit in Area 3 with the highest number of artifacts was 70N/95E, located in the center of the feature (Table 32.7). The next highest concentration of artifacts was in the grid unit to the southwest (69N/96E), followed by the grid units to the northeast (71N/96E) and north (71N/95E). The higher concentration of artifacts to the north and especially northeast is probably a result of the fact that the open end of the horno was located in this area. The higher concentration of artifacts in this area therefore most likely represents a dump zone. The reason for the higher concentration of artifacts to the southeast is unknown.

Table 32.7. Area 3 (horno) artifact counts by grid unit.

Area 4 (Feature 2 – Circular Rock Alignment)

Feature 2 was a small rock feature (Figures 32.12 and 32.13) located approximately 14 m south of the western end of the cabin.

Figure 32.12. Post-excavation photo of Feature 2 (possible privy).

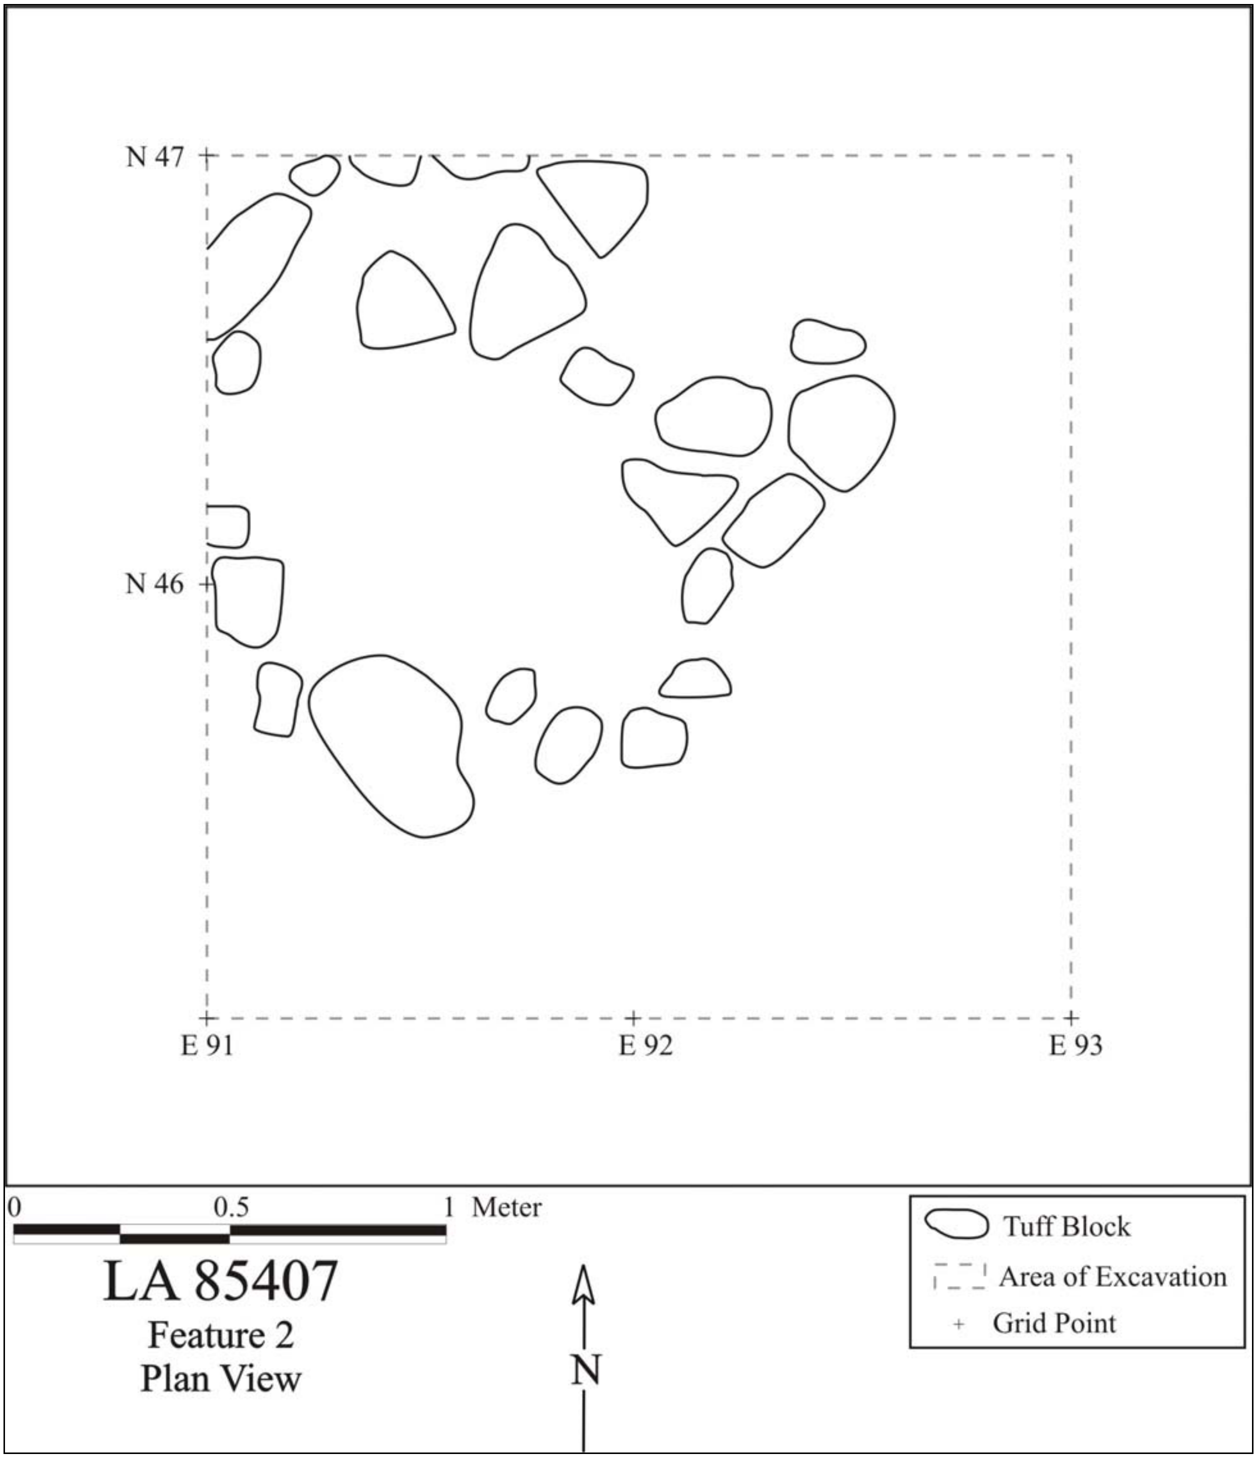

Figure 32.13. Plan view of Feature 2, a circular rock feature identified as a possible privy.

Before excavation, the feature appeared to be a small, circular concentration of rocks. The feature was excavated because it was believed to be the remains of a privy. The entire extant portion of the feature was excavated in four 1- by 1-m units (45-46N/91-E92E). The excavations revealed that the feature was a circular rock alignment. The eastern and westernmost portions of the feature were not encountered *in situ*. There were a number of disturbed rocks, however, that were encountered in the eastern half of the feature. These are probably the disturbed remains of the eastern portion of the circular alignment. The westernmost portion of the feature may have been open. A layer of sterile, clay-rich soil was encountered 15 to 20 cm below the surface. The feature was therefore superficial and could not have been a privy. The feature's function is unknown.

The grid unit in Area 4 with the highest number of artifacts was 45N/92E, followed by 46N/92E (Table 32.8). Much fewer artifacts were recovered from the two grid units to the west (45N/91E and 46N/91E). This indicates that there was a higher concentration of artifacts outside of the feature than within it.

Table 32.8. Area 4 artifact counts by grid unit.

	E91	E92
N46	7	27
N45	9	62

Area 5 (Room 3 – Shed)

Sequence of Excavation. Room 3 is the remains of a wood structure (Figures 32.14 and 32.15) located approximately 21.5 m north-northeast of the cabin.

Figure 32.14. Post-excavation photo of Room 3, the shed.

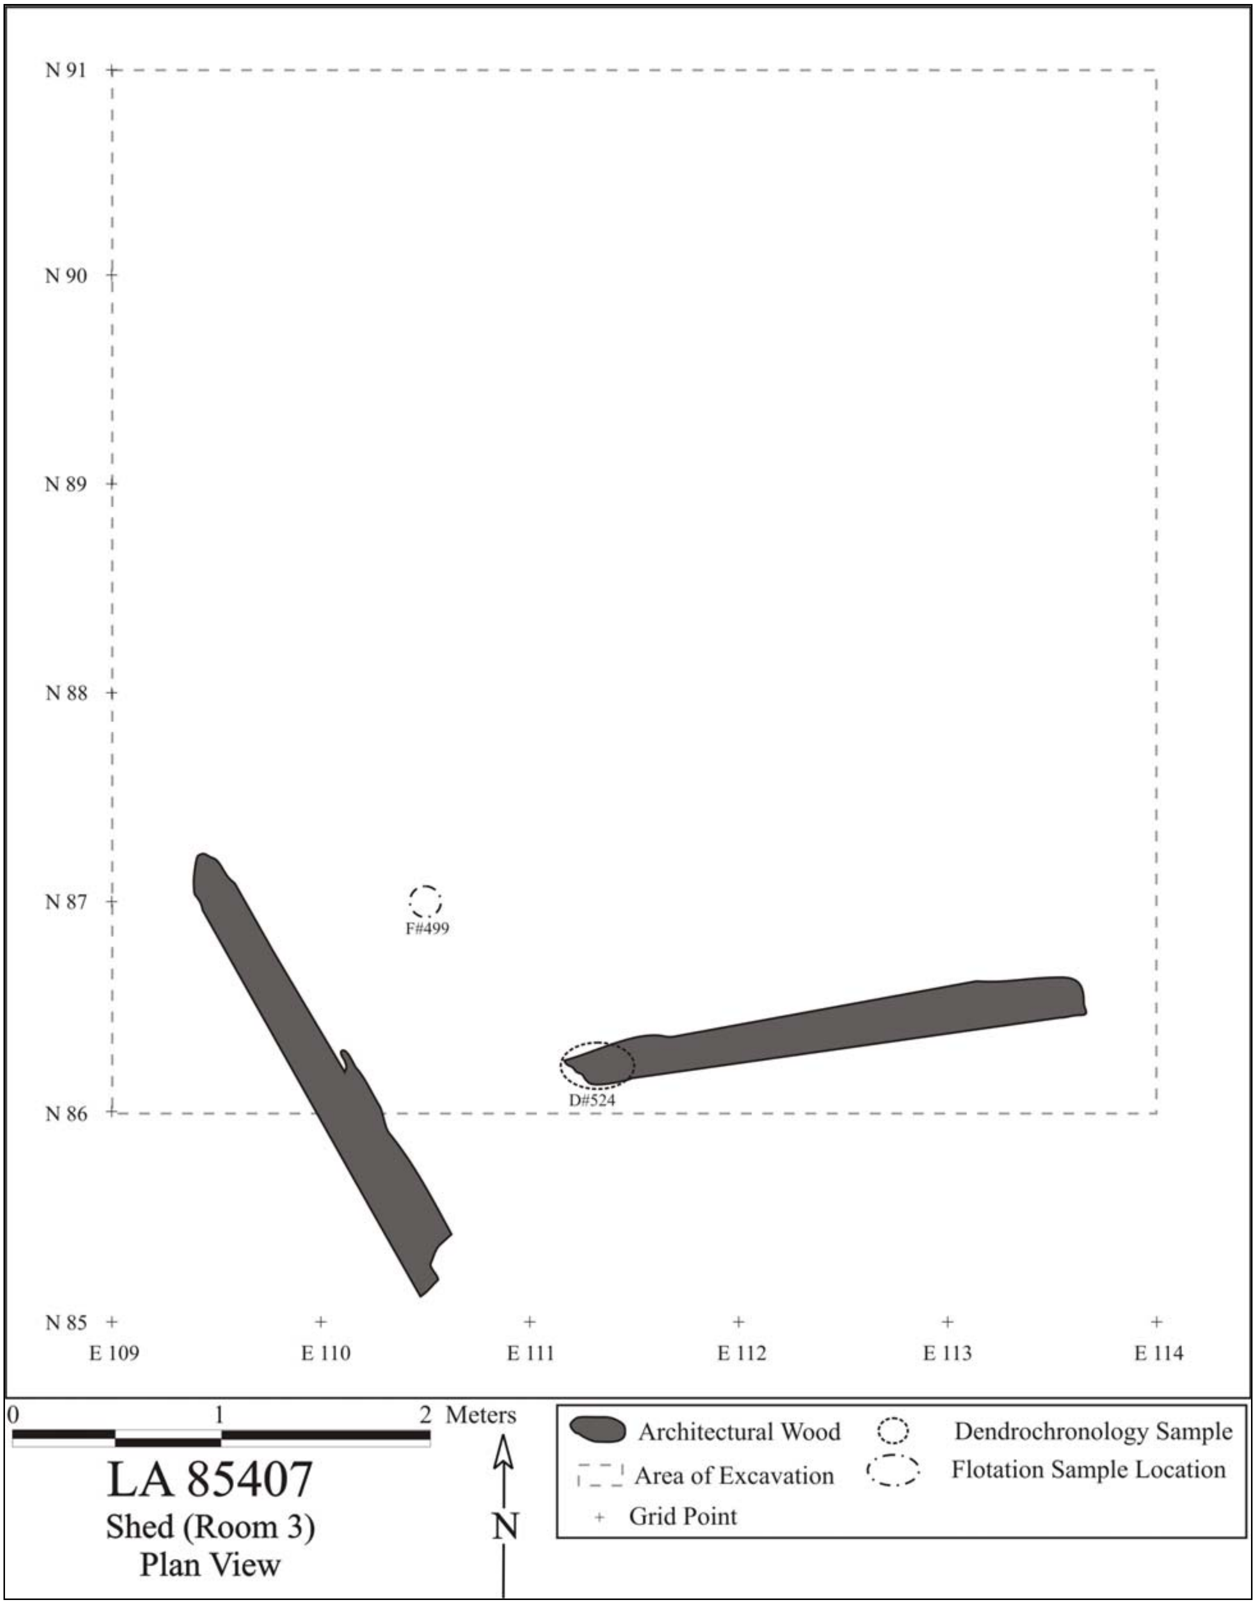

Figure 32.15. Plan view of Room 3, the shed.

Two large wood beams were the only remains of this structure visible on the surface before excavation. These wood beams appeared to have been part of the structure's south wall. Room 3 is most likely the pole shed described in Homestead Entry Survey No. 394. According to this document, the shed measured 12 by 20 ft (Peterson and Nightengale 1993:51). A 5- by 1-m east-west trench was initially excavated to the north of the wood beams. The trench was excavated in 1- by 1-m units. The trench was excavated to expose a profile of the area's stratigraphy, as well as to determine the location of the room's east and west walls. Unfortunately, no wall remains were encountered in the trench units, suggesting that the shed lacked a firm foundation. In addition, no living surfaces were encountered, nor were there any obvious changes in the structure's fill. As a result, the trench's profile was not drawn or photographed. The excavation of the trench units terminated at a sterile, clay-rich soil.

After the excavation of the trench, the structure's extent was estimated based on the dimensions provided in Homestead Entry Survey No. 394. According to this document, the shed was 12 by 20 ft, with the long side oriented east to west (Peterson and Nightengale 1993:51). Based on these dimensions, it was decided that the excavations should extend 2 m north and 2 m south of the east-west trench. The southern extension included the entire eastern wood beam and the northern half of the western wood beam of the shed's south wall. The excavations therefore extended to the approximate location of the shed's southern boundary. By extending the excavations 2 m north and south of the east-west trench, the excavations in Area 5 measured 5 by 5 m. Provided that the center of the excavations was located more or less in the center of the shed, the excavations therefore included the shed's entire width (12 ft, or approximately 3.66 m) and most of its length (20 ft, or approximately 6.10 m). The excavations to the north and south of the east-west trench were each divided into two large excavation units. The eastern excavation units (86-88N/112-114E and 89-91N/112-114E) measured 2 by 2 m, and the western excavation units (86-88N/109-112E and 89-91N/109-112E) measured 2 by 3 m. No additional wall remains or living surfaces were encountered in any of the excavations. The excavations terminated at the top of the layer of sterile, clay-rich soil encountered in the east-west trench.

Fill. Room 2 contained 2 to 7 cm of surface sediment (Stratum 1) on top of 25 to 40 cm of relatively undifferentiated post-occupational fill (Stratum 2). Only one flotation sample (FS 499) was taken of the shed's post-occupational fill. This sample was taken from a concentration of burned soil and charcoal in the southwest quadrant of the room. Charred taxa identified in the sample included goosefoot, cheno-ams, beeweed, doveweed (*Croton*), groundcherry (*Physalis*), sedge family (Cyperaceae), juniper, piñon pine, and ponderosa pine.

Floor. No living surface of any kind was encountered during the excavation of Room 3. The shed probably had an unprepared dirt floor.

Wall and Roof Construction. All that remained of the shed's walls at the time of excavation was two wood beams lying on the surface. These wood beams are believed to have been part of the shed's south wall. The quantity and nature of the artifacts recovered from the excavations to the north of the wood beams suggest that this area was in fact the shed's interior. The shed's walls were probably composed of wood beams and/or boards and the roof of sheet metal, although no evidence was found to support these suppositions. A dendrochronology sample (FS 524) was taken from the west end of the east wood beam in the south wall of the shed. It was identified as ponderosa pine and results are presented in the chronology section later in this chapter.

Artifact Distribution. Due to the fact that several excavation units contained multiple grid units, the exact distribution of artifacts in Area 5 could not be calculated. Artifact counts for each grid unit in the four large excavation units, however, were mathematically calculated. The artifact counts for the grid units are the average number of artifacts per 1 m^2 of the excavation unit in which they were located. As Table 32.9 demonstrates, the distribution of artifacts was surprisingly uniform throughout the excavated portion of Area 5. The number of artifacts recovered from the trench units ranges from 5 to 14. The artifact density was slightly higher in the room's northwest quadrant (16.67), but nearly identical in the room's other three quadrants (8.17 to 9.50).

Table 32.9. Artifact counts by grid unit in Area 5.

	E109	**E110**	**E111**	**E112**	**E113**

N88	11	14	5	6	14
N87	8.17	8.17	8.17	9.00	9.00
N86	8.17	8.17	8.17	9.00	9.00

Note: All but the trench units (N88 E109-113) are averages from the excavation units in which the grid units are located.

Area 6 (Feature 3 - Corral)

Feature 3 is the remains of a corral (Figure 32.16) located approximately 14 m northeast of the shed. Judging from Peterson and Nightengale's map and description of the corral, it was in a much better state of preservation when they worked at the site in 1992 than it was during the C&T Project. Some of the structural remains appear to have burned in the Cerro Grande fire, which is probably the most important contributing factor to the corral's recent degradation (Nisengard et al. 2002). According to Peterson and Nightengale, the remains of the corral in 1992 measured approximately 11 by 12 m in area (1993:103). The feature's walls formed an irregular polygon and consisted of stacked logs that were wired together for support. No upright posts were evident. A partially intact, covered area that measured 3 by 4 m was located in the southwest corner of the corral.

During the C&T Project, the corral measured approximately 15 m east-west by 9.5 m north-south. The discrepancy between these measurements and those of Peterson and Nightengale are most likely the result of the feature's recent degradation. The C&T Project measurements are approximations, as the feature's structural remains are sparse and quite possibly partially scattered. Therefore, the Peterson and Nightengale measurements probably more accurately reflect the original size of the feature. The partially intact, covered area in the southwest corner of the corral no longer existed during the C&T Project, and was presumably destroyed by the Cerro Grande fire. In fact, the best-preserved portion of the corral during the C&T Project was the northwest corner. In this location, the remaining logs were mostly unburned.

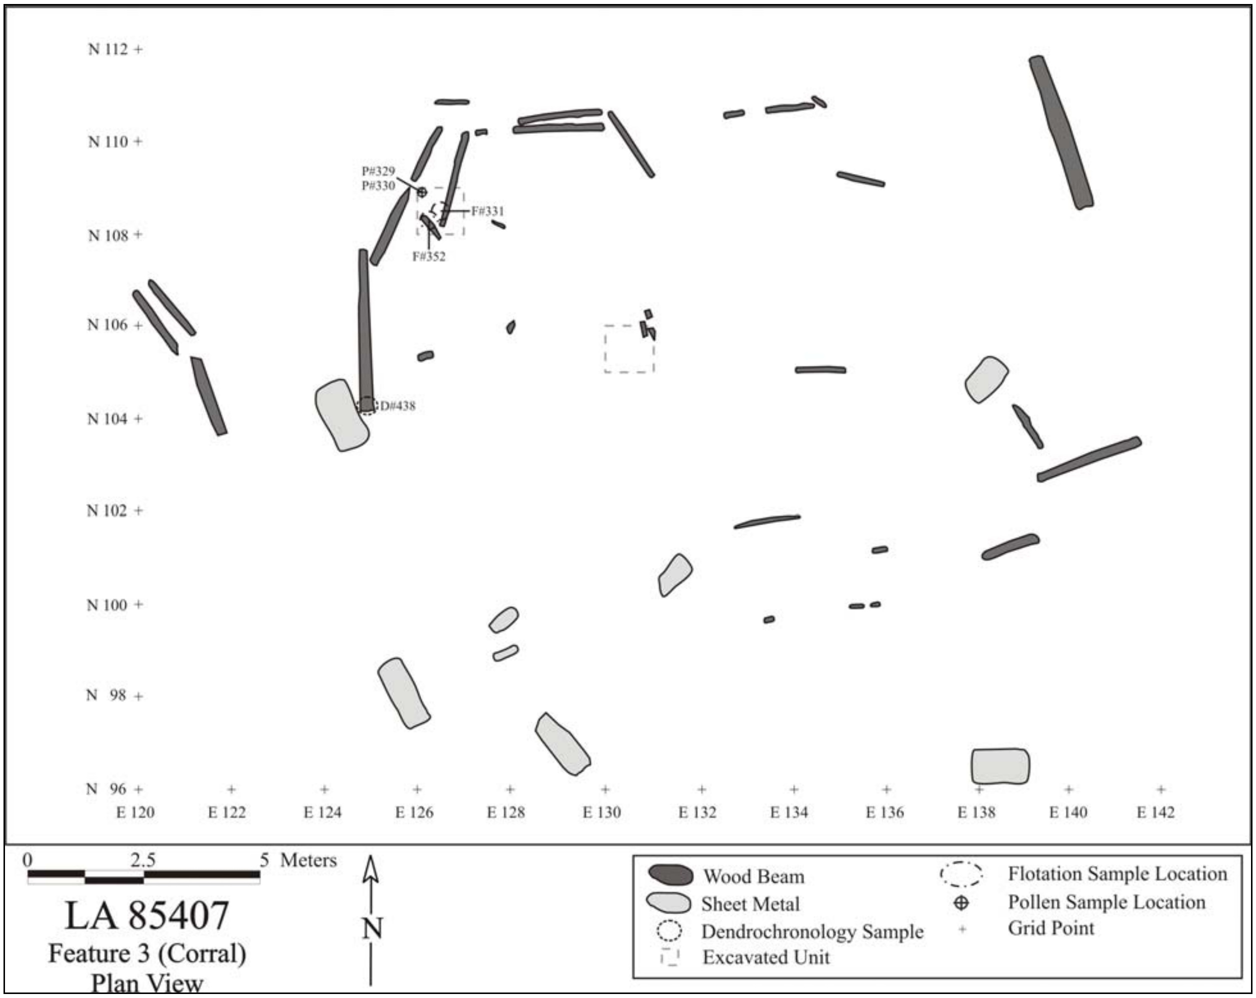

Figure 32.16. Plan view of Feature 3, the corral.

Most of the feature's logs that were extant during the C&T Project varied from 10 to 20 cm in thickness and 1 to 3.5 m in length. The logs are in such poor condition, however, that it is impossible to tell if any of them are still of their original length. The best preserved log was located in the northeast corner of the corral. This log was 40 cm wide and 3.6 m long. Both ends of the log appeared to have been cut, indicating that it probably retained its original length. All of the logs appear to be juniper, and no notches were observed. A dendrochronology sample (FS 438) was taken from the end of one of the logs, which was located in the corral's west wall. It was identified as ponderosa pine and dendro results are presented later in this chapter. Although no logs remained wired together, lengths and loops of wire were present in and around the corral. Large fragments of corrugated sheet metal were also found in and around the feature. The highest concentration of sheet metal was in the southwest corner of the feature. This metal probably functioned as the roof for the covered area in the southwest corner of the corral described by Peterson and Nightengale (1993:103). The extent of the corral was also marked by the presence of tumbleweed, which was not present in any other location of the site. Presumably, the tumbleweed reflects the fact that the soil within the corral was different from that of the rest of the site as a result of being fertilized by the manure of the animals that it housed.

Two 1- by 1-m test pits were excavated in Feature 3 to recover the remains of manure for analysis to determine what types of animals were housed in the corral. For this reason, numerous soil samples were taken from the test pits. The first test pit was grid unit 108N/126E, which was located in the northwest corner of the corral. Four flotation samples (FS 331, FS 332, FS 333, and FS 352) and five pollen samples (FS 329, FS 330, FS 354, FS 355, and FS 356) were collected from the fill in several different locations and at different elevations within the unit. FS 331 was the only flotation sample analyzed from this unit. Carbonized taxa identified included goosefoot, summer cypress (*Kochia scoparia*), dropseed grass (*Sporobolus*), piñon pine, and ponderosa pine. FS 329 and FS 330 were the only pollen samples analyzed, and the taxa identified in these samples included maize grass family, cheno-ams, sunflower type (Asteraceae), globemallow (Sphaeralcea), spurge family (Euphorbiaceae), spruce (*Picea*), fir (*Abies*), penstemon family (Scrophulariaceae), unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush.

The second test pit was unit 105N/130E, which was located just west of the center of the corral. Three flotation samples (FS 398, FS 399, and FS 400) and three pollen samples (FS 395, FS 396, and FS 397) were taken of fill from different locations and at different elevations within the unit, but none of these samples were analyzed. The excavation of the test pits terminated at a layer of sterile, clay-rich soil approximately 20 to 25 cm below the surface. The fill above was fairly uniform, and no living surface of any kind was encountered. The soil in the test pits, however, was highly disturbed by rodent bioturbation. Extensive rodent activity was also evident on the surface throughout much of the rest of the corral.

Area 7 (Feature 4 – Reservoir)

Feature 4 is a small reservoir located approximately 9.5 m north-northwest and uphill from the cabin and 22 m west of the shed (Figure 32.17). The reservoir is also located directly east of a small arroyo. The reservoir is roughly circular, with a diameter of approximately 14 m. The reservoir presumably functioned as a catchment basin for rainwater. A human-made berm formed the south and west borders of the reservoir. This berm reaches a height of between 1.5 and 2 m as measured from the basin. The northern edge of the reservoir is formed by the natural ground surface, which slopes up to the north. The eastern edge of the reservoir is formed by only a slight mound, as the natural ground surface also slopes upward (although not as steeply) to the east. The depth of the basin is approximately 1 m as measured from the slight mound to the east.

Two auger holes were excavated in Feature 4. The purpose of these excavations was to recover pollen samples from different elevations in two separate locations of the feature. Auger Hole 1 was located on the slope between the basin and the berm to the south, at 82.70N/82.50E. Auger Hole 2 was located within the basin, at 81.00N/82.00E. The sediment removed from Auger Hole 2 (within the basin) was rich in silt, while the sediment removed from Auger Hole 1 was rockier and had a higher clay content. The former presumably reflects the accumulation of alluvial sediments within the reservoir, while the latter represents the cultural fill used to construct the berms. No artifacts were observed in either auger hole.

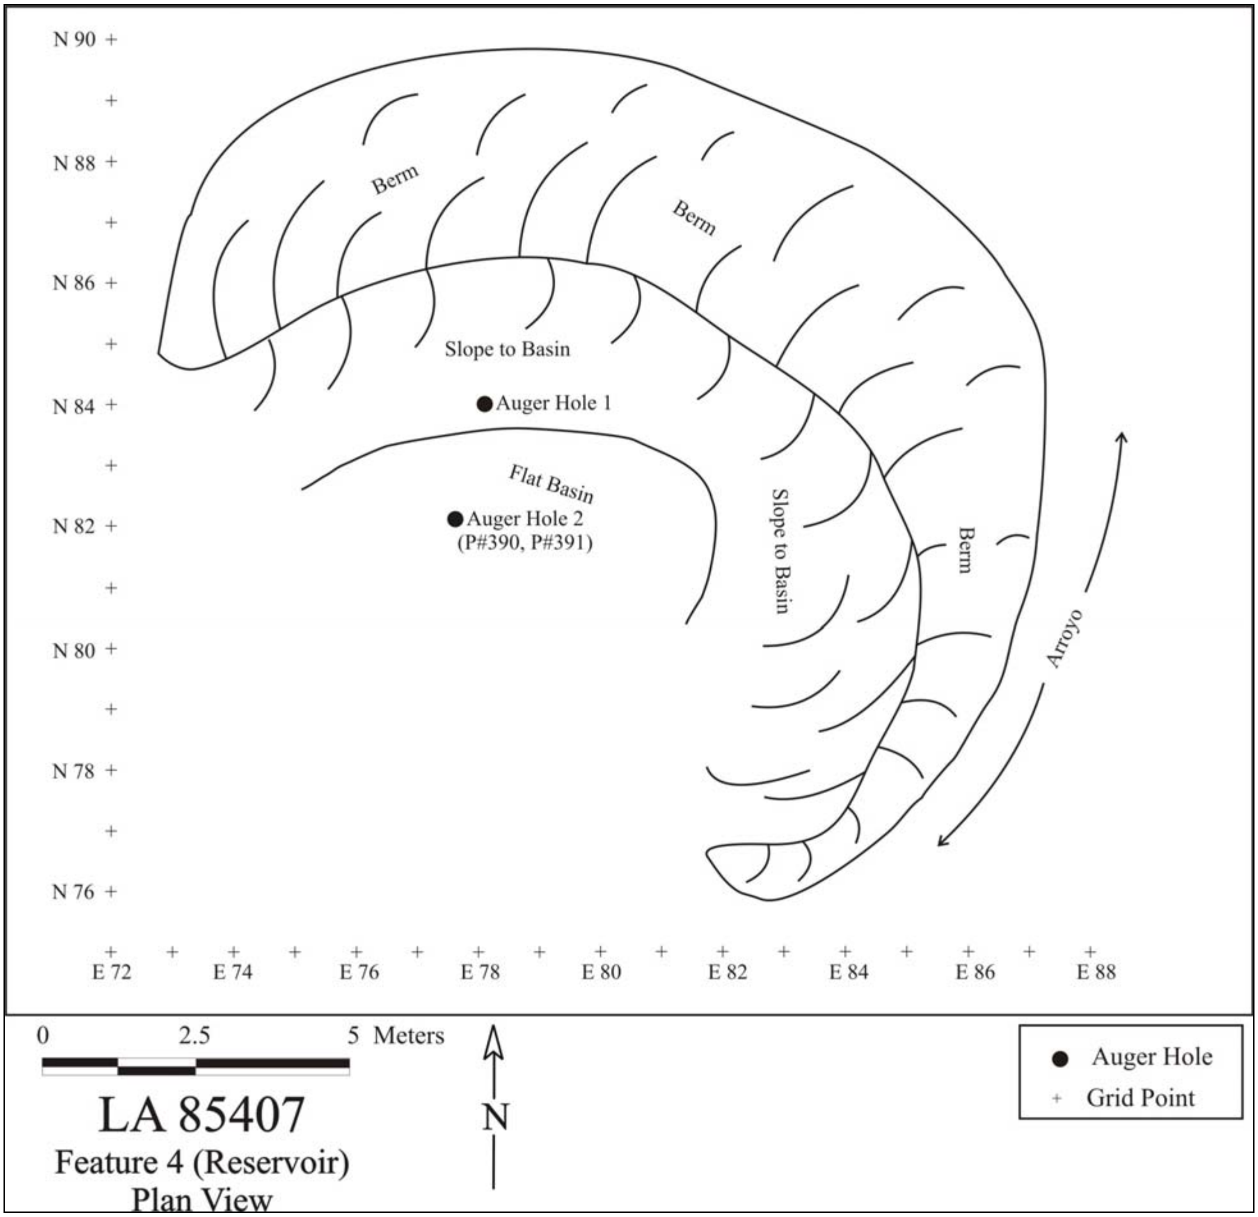

Figure 32.17. Plan view of Feature 4, the reservoir.

Pollen samples were taken from 5 (FS 385), 10 (FS 386), 15 (FS 387), and 20 (FS 388) cm below ground surface in Auger Hole 1, and from 5 (FS 389), 10 (FS 390), 20 (FS 391), and 30 (FS 392) cm below ground surface in Auger Hole 2. Only FS 390 and FS 391 were analyzed and identified taxa included prickly pear, cheno-ams, sunflower family, ragweed/bursage, spurge family, spruce, fir, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 5591 artifacts were analyzed from the excavations conducted at LA 85407. Flotation and pollen samples were selected for analysis from the post-occupation fill (Stratum 2). Architectural wood was also submitted for tree-ring dating. The results of the artifact and sample analyses are presented in the following sections. Table 32.10 lists the samples that were selected for analysis.

Table 32.10. Samples selected for analysis from LA 85407.

Stratum	Sample Type			
	Flotation	Pollen	Macrobot.	Tree-ring

1				
2	269, 298, 301, 331, 352, 357, 408, 499	299, 302, 329, 330, 358, 390, 391, 490	41, 64, 95	

Chronology

Tree-Ring Dating

Eight wood construction elements from LA 85407 were submitted to the Dendrochronology Laboratory at the University of Arizona (Table 32.11). Ron Towner reported that all the samples were ponderosa pine, with five of the eight yielding dates. However, none provided cutting dates due to the poor preservation of the outside rings, leading to a couple of interpretations. The simplest is that the entire structure was built sometime after 1900, based on the 1900+vv date from NM-27 (Room 2). Alternatively, the mini-cluster of noncutting dates in the late 1860s to 1870 (NMI-29, 31, 33) might indicate construction of Rooms 1 and 3 and the corral in the late 1800s. Given that the cabin was built as a single unit, it appears that the former interpretation is probably more accurate.

Ceramic Artifacts (Dean Wilson)

A total of 193 ceramics were analyzed from LA 85407. The majority of the pottery consists of Athabaskan plainware, with fewer biscuitwares, micaceous utilitywares, and historic utilitywares (Table 32.12). A more detailed analysis of the Athabaskan plainware sherds was conducted by Sunday Eiselt (see Chapter 75, Volume 4; Appendix O). Eiselt's analysis also identified the presence of two Tewa blackware sherds, four Tewa micaceous slipped sherds, and four Hispanic/Tewa Buff sherds. Two of the Tewa micaceous sherds could have been derived from a vessel produced at nearby San Ildefonso or Santa Clara pueblos, while the other two sherds could have been derived from a vessel produced at Nambe, Tesuque, or Pojoaque. Eiselt suggests a post-1913 date for the historic ceramic assemblage at the Serna Homestead. Information on ceramic tradition by ware, temper by ware, and vessel form by ware are provided in Tables 32.13 to 32.15 and in Chapter 75.

Table 32.12. Ceramic types from LA 85407.

Ceramic Type	Frequency	Percent

The Analysis of the Historic Artifacts from the Serna Homestead (Charles M. Haecker and Louanna L. Haecker)

A total of 5325 historic artifacts were collected from the LA 85407. All of these artifacts were coded using a material type classification and functional typology. In this system, each artifact is analyzed both in terms of its material type and method of manufacture. Determination of the probable function of each artifact was the goal of the analysis. An artifact was assigned to 1 of 10 functional categories based on expected domestic household activities. These categories derive from classificatory schemes used in other studies of 20th century rural habitation sites in New Mexico (Haecker 1999, 2006; Maxwell 1983; McKeown 1983; Seaman n.d.; Ward et al. 1977; Wilson 1979). The basic assumption is that the activities that took place in the historic household are basically similar to those in a present-day household.

The 10 categories represent generalized domestic activities and permit quantification of those artifacts assigned within each category. It is important to note that simple quantification of artifacts within a category does not necessarily reflect a direct correlation with its relative importance within a household. For example, a high percentage of beverage bottle fragments are often represented within collections of artifacts derived from 19th and 20th century homesteads. These glass fragments, however, may be the result of the breakage of only a relatively few bottles over the lifetime of the homestead. Conversely, complete tools within the same collection typically are a rare occurrence; it would be a mistake to interpret their sparse numeric count in an archaeological collection as reflecting unimportance in the day-to-day activities that once took place at the homestead. Several other factors prevent an artifact assemblage from unambiguously reflecting the period(s) of occupation of a site, or from replicating the inventory of items used or consumed on the site. Non-cultural processes include decay and weathering.

Cultural processes include dumping of trash off-site, scavenging, relic collecting, and archaeological excavation.

The function of an artifact and its date of manufacture and use can infer changes in production and subsistence. To obtain this information, artifacts recovered from the Serna Homestead assemblage are classified in terms of *functional categories* and *material types.* Other than a few fragments of adobe, the Serna assemblage consists of mass-produced items; therefore, the functions of most items, as intended by the manufacturers, can be identified. We assume that the site occupants used most of the manufactured items for the purpose intended by the manufacturers. Items used otherwise will show evidence of modification or re-use.

As with prehistoric artifacts, functional artifact identification can be divided into three categories: descriptive, chronological, and functional. Descriptive variables provide information about the physical properties of the artifact (e.g., maker's mark and brand contents). Chronological variables place the artifact in a temporal framework. Maker's techniques (e.g., wire nails and sanitary seal cans) are useful in this regard. Functional categories provide information about the use(s) of the artifact. The relevant variables are artifact type, primary function, reuse function, and contents. The artifacts from the Serna Homestead were initially classified into the general material categories of glass, metal, ceramic, and miscellaneous. The majority of artifacts fall into the first three categories. The miscellaneous group contains an assortment of artifacts of different materials, no one of which is sufficiently common to warrant placing the artifact into a separate group. Examples of materials in the miscellaneous category are leather, rubber, wood, and adobe. The artifacts were then described in terms of more specific physical properties. Each artifact was also classified in the general and specific functional categories. Dates were recorded for each artifact when possible, and any evidence for reuse modification/function was also noted.

Definitions

<u>Primary Function</u>: This variable describes the use or function of an artifact in broad terms. For example, a can that is known to have once contained food has a primary function of household in that it provided subsistence; a nail has a primary function of construction.

<u>Secondary Function</u>: This variable indicates the presence or absence of modification of the artifact. If modified, there is a determination as to the function other than that intended by the manufacturer.

<u>Manufactured Technique</u>: This variable indicates how the artifact was made by the manufacturer, and what specific material type(s) was used. For example, a can is made of rolled steel; a wood stove part is made of cast iron.

<u>Artifact Identification</u>: This variable indicates the artifact type (e.g., wire nail, window glass, whiteware, or shoe leather).

Condition: This variable identifies the overall physical state of the artifact at the time of its analysis. For example, from a list of coded identifiers, the artifact could be described as bent, crushed, melted, or a combination of any coded identifier.

Color: A determination of artifact color is provided only for glass, since glass color is an essential attribute that can provide information regarding chronology and function.

Measurements: Measurements were taken, where appropriate, and expressed in the standard United States system, that is, inches for linear measurements and ounces for volume (if known).

Comments: Specific information not identified by the above-stated coded identifiers are provided in written format. A sketch of the artifact is also done if such illustration would assist in better describing the artifact.

Results of the Analysis

The functional assemblages monitored for analysis are described below:

Construction

This assemblage is composed of hardware and building materials used in the fabrication and upkeep of site structures. Artifact types include nails, barbed wire, window glass, caulking, mortar, milled lumber, adobe, and bricks. As discussed by Maxwell (1983) and Seaman (n.d.), the diversity of articles in construction is indicative of varied building techniques as well as loss probabilities. Small easily carried items such as nails can be expected to have a higher loss probability, but that probability decreases as relative size and weight increases. Loss probability is also affected by the relative monetary value and availability of the item in the market. Through destruction, deterioration, scavenging, or even a subsequent occupation, all the materials that comprise a structure could enter the archaeological record. For most situations, these objects are expected to be abundant and concentrated within the location of the structure.

From their number alone, the most significant type of artifacts found in the construction assemblage is nails. Nail form is dictated by technological transitions that occurred during the late 19th century. American wire nail machinery was perfected during the 1860s and 1870s and wire nails replaced cut nails very gradually. The relative cheapness and ease of handling made wire nails more acceptable.

Wire nails were manufactured in standardized pennyweights and performed the same functions as their cut counterparts. All of the nails recovered from the Serna Homestead are the wire variety, which is appropriate given the period of site occupation: 1913–1943. Nail size categories were arranged and ranked according to the most frequent nail sizes recovered. Only whole nails, including both bent and unbent nails, were measured. The most common nail size measures 3.0 in. long (n = 153), followed by 2.5 in. (n = 86), 4.0 in. (n = 42), 3.5 in. (n = 41), 2.0 in. (n = 10), 5.0 in. (n = 10), 4.5 in. (n = 8), 1.5 in. (n = 3), 6.0 in. (n = 2), 5.5 in. (n = 1), 1.2 in. (n = 1), 1.0 in. (n = 1), and 3.25 in. (n = 1). Approximately 88 percent of the nails were recovered in the immediate vicinity of the cabin, and it is assumed that these nails are representative of what nail sizes were used to construct and maintain the cabin.

The two most commonly found nails sizes, that is, 3.0 in. and 2.5 in. long, are termed “box” nails. These nails are typically used for light framing, such as joining planks to floor and ceiling joists. The 3.5-in. and 4.0-in. nails may have joined together wider-dimensioned lumber such as floor joists to joist board spacers (Jurney 1991). Only one 1.2-in. nail was recovered. The evident paucity of this nail size, intended for roof shingles, reflects the fact that roofing of the Serna cabin consisted of sheet steel.

Approximately 750 fragments of window glass were recovered. Four concentrations of window glass occurred in the immediate vicinity of the cabin. Several window glass fragments are melted or else show crazing and these conditions may be the result of the cabin having been destroyed by burning; however, evidence of burning is minimal as opposed to what was found within the McDougall cabin, a homestead located in Technical Area 55 at Los Alamos National Laboratory (McGehee et al. 2006).

Several large pieces of sheet steel were recovered from testing the site. According to informants regarding the Serna Homestead, the cabin roof was sheathed with sheet steel. In fact, nail holes are positioned either at the corners of sheet steel or along the edges. Some of the sheet steel sheets have been cut or modified to accommodate the placement of, for example, a stove or vent pipe. One segment of stove pipe was recovered in the vicinity of the cabin.

Tools

This assemblage typically is included with construction activities in the analysis of historic artifacts; however, in this present study it is identified as its own assemblage to facilitate comparison between the Serna and McDougall homesteads (Haecker 2006). Tools include hammers, wrenches, and files. Being relatively expensive, large tools are typically curated and usually discarded only when damage is irreparable. Since the loss probability is low, a discard pattern is expected for broken tools, assuming no reuse or recycling. Usable tools found in the interior of a structure or activity area represent what Schiffer (1977:24) terms *de facto* archaeological refuse. This results from rapid destruction of the area or structure, or abandonment under conditions that allow belongings to be taken only as time or subsequent space availability permits.

Testing of the Serna Homestead recovered several undamaged and presumably still serviceable tools, including three sizes of bastard files, two pairs of scissors, a hacksaw blade, a box wrench, and a shovel blade. Fragments of a pocket compass and a gear wheel to what is believed to be a pocket watch were also recovered. All of these items were discovered either within or in the immediate vicinity of the cabin. The presence of these items in the archaeological record suggests that the cabin was destroyed or abandoned before the occupants could remove them along with all their other possessions.

Household

This category consists of common household artifacts used to store, prepare, and serve foods including furniture, lighting, washing, writing, and so on. Major components of the household category are the containers and other closures for commercially prepared foods. Items such as egg shells and peach pits are assigned to this group. Archaeological finds recovered from homesteads rarely indicate the inhabitants' dependence on bulk staples such as flour and dried beans. These types of important food items are typically packaged in perishable materials, which leave little or no trace of their former presence. In contrast, empty food cans deposited in an arid environment may remain largely intact for decades. It is usually the case that cans lack labels and are deteriorated in varying degrees, thereby preventing identification of the original can contents. Fortunately, some can shapes and dimensions are representative of the contents, such as sardine cans, lard buckets, tapered cans intended for meat, and condensed milk cans. Slide-off lid containers held products such as baking powder, coffee, and lard. All of the key strip-opened cans recovered from the Serna Homestead once contained coffee.

Of the 1561 can remains that were recovered, only 9 percent (n = 165) could provide accurate dimension measurements. The measurable cans indicate that the homestead inhabitants depended on canned fruits, juices, vegetables, and baked beans. Sardine cans also were present but represented less than 3 percent of the total number of food cans. It is presumed, then, that sardines were consumed on an occasional basis and likely eaten as a serving for one individual, as indicated by the small sizes of the entire sardine cans. Canned sardines, a possible luxury purchase, may have been consumed only on a non-meat fast day such as Friday. The excavations recovered only one meat can, which would have contained approximately one pound of commercially prepared meat such as corned beef.

Seventeen lard pails were identified in the assemblage. These pails typically contained lard, but the same type of container may have also held peanut butter, fruit jam, honey, or axle grease. A number of the pails have non-manufactured baling wire handles and presumably were attached to these pails by an occupant of the homestead. Pail opening diameters are 10 in., 9 in., 7.5 in., 6 in., and 5 in. Once empty of its packaged food content, lard-type pails sometimes were recycled for a variety of other purposes including use as lunch pails, water buckets, and collection receptacles for rendered fat. The collection includes a 4-in. diameter pail, which may have once contained hard candy. This unusually small-sized pail also has a non-commercial bailing wire handle. Its opening has been pinched shut and the base of the pail has eight small nail holes. Perhaps this object had been recycled by a child to hold a "pet" animal or insect.

Coffee was definitely the beverage of choice at the homestead, as indicated by the numbers of coffee cans and coffee can strip keys in the collection. Only two condensed milk cans and one cocoa can were identified in the artifact collection. The seeming paucity of condensed milk cans may reflect the fact that the Sernas brought a milk cow with them when on their seasonal visits to the homestead (Peterson and Nightengale 1993:61).

Glass containers that once contained food and condiments were also identified in the collection; however, the small-fragment conditions of the glass shards recovered from the homestead prevents diagnostic identification for virtually all of these types of artifacts. It was possible to identify one glass container that once contained a pickle-type relish. This jar is similar in shape and size to commercially packed glass jars of pickle relish recovered at a World War II Japanese-American internment camp (J. Burton 1996:746, Figure B.12b). A fragment of a catsup bottle, three glass stoppers of a type used on various types of bottled pickles and other preserves, a fragment of a bottle that once contained chili pepper sauce comparable to Tabasco Sauce, and a fragment of a bottle that once contained Karo-brand syrup were also identified.

A few fragments of canning jars were also identified in the collection. Canning jars are intended to be used over and over again, thus representing multiple years of usage. Also, since the Sernas only seasonally occupied the homestead, it is possible that home canning at that location was not a worthwhile task. One informant recalled that his mother canned a great amount of home-grown vegetables and fruits, but it was not noted if this task was performed at both the Serna primary residence in Nambe and at the homestead (Peterson and Nightengale 1993:66). According to Jansen (1982:362 in Akins 1995:36), Hispanic women in New Mexico relied mostly on drying rather than canning as their principal method of food preservation into the 1930s. Drying is inexpensive and efficient while jars and caps are expensive, and cold-pack canning required considerable time and effort. Corn, chile, onions, beans, squash, and meat were traditionally dried. Agricultural extension agents made little effort to teach Spanish-speaking women the art of canning before 1929 (Jansen 1982:365).

A total of 84 ceramic fragments were recovered, representing a minimum of 24 vessels, including plates, saucers, bowls, cups/mugs, and a decorative vase. Vessel forms were recognized by rims, bases, or distinctive curvature. Other fragments were labeled as indeterminate in form. Paste type is the primary criterion by which historic, commercially manufactured ceramics are categorized; however, it can be difficult in distinguishing white earthenware paste types from harder, fired ironstone or graniteware paste types. Since the separation of these types on the basis of hardness may be invalid, Majewski and O'Brien's approach of combining these types into one 'refined whiteware' was used (1987).

Refined whitewares were favored by the occupants of the Serna Homestead. Vessels of this durable, inexpensive type were used to serve meals and represent over 90 percent of the recovered ceramic fragments. A number of the whiteware sherds are decorated using the decal method. One pattern design consists of sprigs of small flowers, which was a ceramic motif popular during the early 20th century and prior ceramic designs inspired by the Art Deco period of design (circa 1920–1940). There is not an overall ceramic design pattern in the collection of decorated whiteware sherds. It may be the case, therefore, that vessels were bought one at a time at local stores, rather than buying complete matching sets. Only one fragment of a porcelain bowl was recovered. This vessel, which would have been significantly more expensive than domestic whitewares, was made in either Japan or China during the late 19th or early 20th century. The presence of a few fragments of stoneware crockery is indicative of food storage and/or food preparation. One fragment of a whiteware vase was also recovered, as well as a Kapo Black sherd.

Indulgences

This category is represented by objects that are not essential for human survival but instead provide pleasure or satisfy a superfluous desire. These items include glass fragments of alcoholic and non-alcoholic beverages and toys. Several clay and glass marbles were found, as were one fragment of a bisque-fired doll's head and several plastic beads. All of these objects are indicants that children lived at the homestead. A fragment of a harmonica reed plate was also identified in the assemblage. A harmonica can be in the possession of a child or an adult.

Only a few diagnostic glass fragments of wine and beer bottles are in the collection, and none of these fragments appear to date to 1913–1943. Likewise, there is only one identifiable fragment of a soda pop bottle (probably Coca-Cola) and three crown bottle caps in the collection. FS 431 consists of a concentration of fragments of wine and beer bottles, located approximately 50 m (152 ft) to the northwest of the Serna cabin. The few identifiable closures for the wine bottles are screw-tops, which would date these bottles to post-1970. Also, the few diagnostic beer bottle fragments are dated to post-1960, suggesting that the site area has recently been used by hunters, hikers, or others using the area for various forms of recreation. The collection also does not contain tobacco cans; however, there is one cigarette holder made of plastic.

Personal Possessions

This category includes individually owned items such as shoes, clothing, coins, jewelry, or those related to personal hygiene. These items would have variable use-lives such as shoes and clothing that were eventually discarded when worn out, and jewelry that was carefully safeguarded and entered the archaeological record only when lost. Smaller items, such as buttons and clothing rivets may be either discarded or lost. The artifact collection contains several buttons that are made of milk glass, bone, and shell. Most of these buttons are typically found on work shirts and work jackets. There are two mother-of-pearl buttons that may have been attached to a woman's dress blouse, and one button for a woman's dress coat. Several pieces of jewelry are present in the collection, including a possible broach made of carved mother-of-pearl with a cupreous decorative inset and several glass beads from a probable necklace. Fragments of shoe leather and fragments of a rubberized cloth Wellington-type boot are present. The remains of a man's shoe heel made of rubber and a woman's or child's rubber shoe heel were also found.

Firearms and ammunition were also included in the personal possessions category. A concentration of nine .22-caliber cartridge cases was found in the area between the cabin and horno. This suggests that occasional target practice and/or shooting of varmints took place at this location. Also discovered in the vicinity of the cabin are one .38-caliber rifle cartridge case and one .50-caliber rifle cartridge case.

Other personal items include the remains of a clasp knife, the needle of a pocket compass, a brass gear wheel that probably came from a pocket watch, a plastic comb, the above-mentioned cigarette holder, a five-cent coin that dates to 1902, and a fragment of a cold cream jar. Two pennies that date to post-1958 are also in the collection and reflect casual visitation to the Serna Homestead long after it was abandoned in 1943.

Animal Husbandry

Four horseshoes and one horseshoe nail were also identified in the collection, as were fragments of what is believed to be a leather harness. The presence of several fence staples in the collection suggests that the homestead included a wire fence compound, presumably for penning livestock.

Transportation

An informant described how he, as a child, rode a horse on the Serna Homestead during their seasonal visits. He also recalled how the Serna family made the trips in a covered wagon (Peterson and Nightengale 1993:63). In fact, four horseshoes, a horseshoe nail, and possible metal brace fittings for a wagon were also identified in the collection. A leaf spring that could have been part of a wagon or automobile, a cam shaft that presumably derived from an automobile, truck, or tractor, and fragments of a worn-out automobile tire were also identified. It should be kept in mind that, during the early to mid-20th century, it was common for rural inhabitants to collect metal scrap both for their recycling possibilities and/or for selling to dealers in scrap metal (Buckles et al. 1986:354). It should not be assumed, therefore, that the discovery of automobile or truck parts is an indication that the site inhabitants actually owned such vehicles. The hubcap of a circa-1948 Plymouth automobile is in the collection; therefore its deposition post-dates abandonment of the Serna Homestead. We suspect that the Sernas did not own an internal combustion conveyance because motor oil cans are notably absent from the collection. Such cans are usually present on a 20th century rural habitation site where various types of internal combustion engines were maintained.

Health and Hygiene

Fragments of a paneled bottle(s) were identified in the collection. These bottles are of a type that were typically used for non-prescription patent medicines during the late 19th and early 20th centuries. There is little else to suggest that the Serna Homestead depended on commercially manufactured medicines.

Summary of Findings

Oral interviews and documents research indicate that, beginning in 1913 and up to 1942, the Serna family occupied the homestead on a seasonal basis. They traveled by wagon to the homestead, lived in a log cabin that had sheet metal roofing, and cultivated 40 acres of beans, corn, wheat, pumpkins, and various vegetables. Artifacts collected from this site are supportive of these findings. They occupied the homestead approximately six weeks a year, which would have generated significantly less refuse when compared to the refuse generated by those families who lived year-round on the Pajarito Plateau. Non-staple foods consumed at the homestead include commercially canned vegetables and baked beans and, perhaps, canned fruits and/or juices. Canned meats likely were not regular items on the menu, and neither were home-canned foods. An informant recalled that his family regularly ate fresh beef (Peterson and Nightengale 1993:66), which would explain the virtual absence of meat cans. It is likely that, at least during the harvest season, the Sernas were consuming at least some of what they were harvesting (e.g., onions, beans, squash, chili, and corn). There is little to suggest that the inhabitants treated themselves to even the occasional culinary luxury.

Ceramic plates, saucers, cups, and mugs are of types that are utilitarian and inexpensive. Cooking and lighting is appropriate for the time and place, that is, dependence on kerosene lamps and wood used for heating. Indulgences are minimally represented in the collection, and what few indulgences that are represented are mostly children's toys. The Sernas apparently were not imbibers of alcoholic beverages or tobacco, at least not during their seasonal visits to the homestead.

Comparison of the Serna and McDougall homesteads (see McGehee et al. 2006) indicate not-surprising idiosyncratic differences between the daily routines of the two households (Table 32.16). As examples, the McDougall household indulged in alcoholic beverages and tobacco, whereas these indulgences were virtually absent at the Serna Homestead. Extensive food can refuse is present at the McDougall homestead, but significantly fewer cans are present at the Serna Homestead. This difference, however, may be misleading since the Sernas occupied their homestead on a seasonal basis. In contrast, the McDougalls lived on their homestead year-round, thus generating significantly more domestic refuse.

Table 32.16. Comparison of artifacts from the McDougall and Serna homesteads by primary functions.

Primary Functions	McDougall Homestead	Serna Homestead
	Construction	
Nails	3621 nails, mostly within the cabin; light framing nail is the most common type	354 nails, mostly within or near the cabin; light framing nail is the most common type
Sheet steel	Present but sparse	Present; used for roofing
Window glass	Present in cabin area; many fragments are melted, crazed	Present in cabin area; few fragments are melted, crazed
Tools	One hammer head	Files, scissors, wrench, hacksaw blade, shovel blade
	Domestic Routine	
Food cans	Two extensive can dumps; most of cans once contained fruits, vegetables, juices; single-serving potted meats and sardine cans present; condensed milk cans are common	Can dump absent; most cans once contained fruits, vegetables, juices; only one meat can; only two condensed milk cans; single-serving sardine cans present
Commercial food jars	Condiments, sauces, pickles	Condiments, sauces, pickles
Canning jars	Present	Present, but scarce

Primary Functions	**McDougall Homestead**	**Serna Homestead**
Ceramics	Inexpensive whitewares are common; one Limoges porcelain sherd; stoneware storage vessels; local Native American ceramics present	Inexpensive whitewares are common; one Asian porcelain sherd, one vase sherd; stoneware storage vessels; local Native American ceramics present
Kerosene lamp chimney glass	Present	Present but scarce
Lard pails	Present; two sizes. Recycling not evident	Present, five sizes; possible recycling for other use(s)
	Indulgences	
Alcohol bottles	Present	Absent from the period of homestead occupation
Soda bottles	Present but scarce	Possibly absent from the period of homestead occupation
Tobacco cans	Present	Absent
Toys	One marble	Marbles, doll fragment, plastic beads
Personal possessions	Shirt and blouse buttons, glass beads	Glass beads, brooch fragment, harmonica fragment, clasp knife fragment, pocket compass fragment, shirt, blouse, jacket buttons, shoe and boot fragments, comb, cold cream jar
	Transportation	
Auto/truck	Oil-can, post-1947 spark plug	Cam shaft, leaf spring; circa 1948 car hub cap
Horse/wagon	One horseshoe	Four horseshoes, possible hardware for a wagon
	Health	
Medicine	Patent medicine bottle fragments	Patent medicine bottle fragments

There is some physical evidence of different ethnic backgrounds at the two homesteads. The Sernas utilized an horno, used adobe as a building material, and employed a Mexican-style metate. There are no indications of comparable Hispanic architecture or ethnic-identity artifacts recovered at the McDougall homestead. What are more notable are the strong similarities. Both homesteads utilized building materials such as logs and stones to a large extent. Recycling of commercially manufactured building materials occurred. Food items were limited in variety and simple to prepare, and the plates and bowls that contained the food were as basic as the food itself. It is clear that both families operated on minimal cash income, which restricted discretionary spending on indulgences. It is possible that the McDougall's possessed a bit more discretionary income, judging by their evident consumption of alcoholic beverages, tobacco, and (perhaps) owning an automobile. These differences, however, are marginal.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 75 artifacts were analyzed from LA 85407, consisting of 54 pieces of debitage, 12 retouched tools, six ground stone items, two hammerstones, and a manuport. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 32.17 presents the data on lithic artifact type by material type. The debitage is primarily made of obsidian, with less chalcedony, Pedernal chert, and general chert. The presence of cortex on 14.8 percent of the debitage indicates that these materials were collected from waterworn (*n* = 6) and nodule (*n* = 2) sources. The chalcedony, Pedernal chert, and chert are available from local Rio Grande Valley gravels and the obsidian from nearby sources in the Jemez Mountains. The manuport is an unmodified piece of schist that could also have been obtained from local gravel sources. The ground stone igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the Pajarito Plateau.

Table 32.17. Lithic artifact type by material type.

Nine pieces of obsidian and one biface were submitted for X-ray fluorescence analysis. Most of the artifacts are made from the Cerro Toledo source, but fewer from the Valle Grande and El Rechuelos sources (Table 32.18). The Cerro Toledo (Obsidian Ridge/Rabbit Mountain) and the Valle Grande (Cerro del Medio) source areas are located about 19 km (12 mi) and 17 km (11 mi) as the "crow flies" to the southwest and west of the site. Although obsidian is present at these nearby sources in the Jemez Mountains, it is also present in the area of the site as small pebbles. These pebbles compose part of the secondary deposits associated with the Cerro Toledo interval and are scattered along the mesa top. Lastly, the El Rechuelos (Polvadera Peak) source area is located approximately 27 km (17 miles) to the northwest.

Table 32.18. Obsidian source samples.

FS #	Artifact	Color	Source
96	Debitage	Black dusty	El Rechuelos
215	Debitage	Translucent	Valle Grande rhyolite
380	Debitage	Black dusty	El Rechuelos

Lithic Reduction

The debitage consists primarily of core flakes, with fewer angular debris, biface flakes, microdebitage, and an undetermined flake fragment. The overall cortical:non-cortical ratio of 0.28 reflects an emphasis on the later stages of core reduction and tool production/maintenance. The flakes mostly have single-faceted (n = 10), with fewer cortical (n = 2), and crushed (n = 4) platforms. Four of the platforms exhibit evidence of preparation and were abraded/crushed. The majority of the core flakes are whole (n = 9) or distal (n = 8) fragments, with fewer proximal (n = 4), midsection (n = 3), and undetermined (n = 2) fragments. The whole core flakes have a mean length of 26.3 mm (*std* = 10.8), the single whole biface flake a length of 13.0 mm, and the angular debris a mean weight of 3.9 g (*std* = 6.2).

The retouched tools primarily consist of retouched pieces with two bifaces and a projectile point (Figure 32.18). Four of the retouched pieces exhibit bidirectionally retouched lateral edges that include a projection. In contrast, the other five flakes have unidirectionally retouched lateral edges with angles of 65 degrees. The bifaces are fragments with edge angles of 60 to 65 degrees that presumably reflects that they were broken during the middle reduction stage. The projectile point is the midsection of a possible stemmed Late Archaic dart point.

Tool Use

None of the flakes and all of the retouched pieces exhibit evidence of edge damage that could be attributed to use. The retouched pieces that include projections have rounding/polish on their points, whereas the other retouched pieces exhibit some rounding and/or micro-scarring along their lateral edges. The projectile point has a broken tip and base that presumably occurred during use.

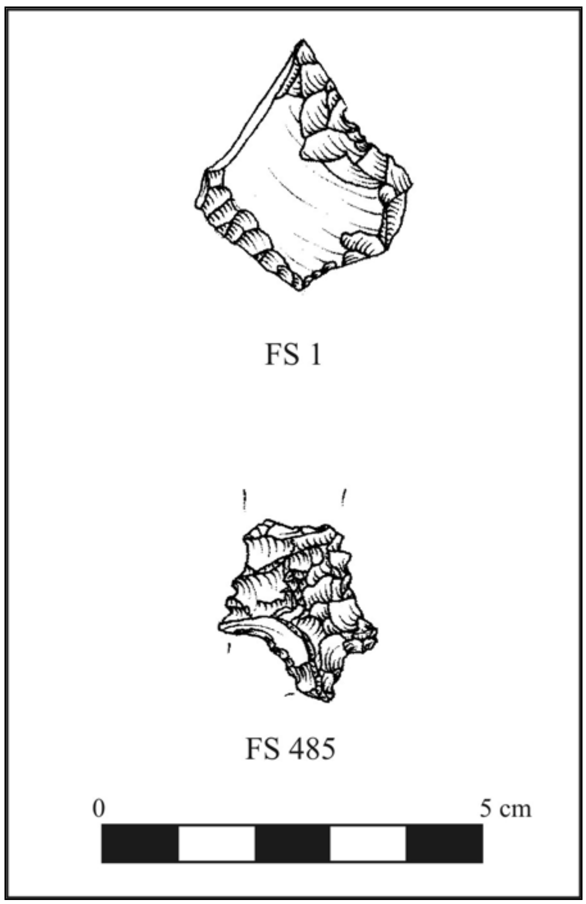

Figure 32.18. Retouched flake and projectile point.

The ground stone artifacts include manos, a metate, a grinding slab, and a whet stone. The one-hand mano is a flat dacite cobble that exhibits some grinding on both opposing surfaces. In contrast, the two-hand mano is a formal basalt, wedge-shaped mano that is heavily ground on all three sides. This mano was found in association with a formal basalt slab metate. It is a Mexican-style metate with one rear leg (see Figure 32.6). The grinding slab consists of a rectangular-shaped tuff slab with rounded corners and an oval grinding surface. Lastly, the whet stone is a small tabular piece of sandstone with a very smooth and striated surface. This artifact was presumably used to sharpen metal knives.

Faunal Remains (Kari Schmidt)

Twenty-seven pieces of bone were recovered during excavations at LA 85407. The site consists of the remains of a historic log cabin and various features in the surrounding area.

Cabin (Area 1)

The cabin was divided into Rooms 1 and 2. Ten bones were recovered in Room 1 and included one unfused kangaroo rat (*Dipodomys* sp.) femur, a fragment of a mule deer (*Odocoileus hemionus*) rib, a horn fragment from a domestic cow (*Bos taurus*), a fragment of an elk (*Cervus elaphus*) thoracic vertebra, two medium/large-sized mammal bones (one burned), two large-sized mammal rib fragments that both contained butcher saw marks, one large-sized mammal unidentified burned bone, and one unidentified piece of unburned bone. One bone, an unidentified medium/small-sized mammal long bone fragment, was identified in the Room 2 deposits.

Four bones were identified in the fill around the cabin and included a complete human premolar, a burned unidentified medium/large-sized mammal bone, an unidentified large-sized mammal bone, and a large-sized mammal rib fragment that contained evidence of butchery from a large saw.

Horno (Area 3)

Three bones were identified in the area around the horno, but no bones were recovered directly from the feature fill. Analyzed bones included one medium/large-sized mammal bone fragment and two domestic cow vertebral body fragments. None of the bones were burned, and all contained evidence of old breaks.

Area 4 (Feature 2, Circular Rock Alignment)

Feature 2 was a small rock feature located approximately 14 m south of the western end of the cabin (see Figure 32.13). The excavations revealed that the feature was a circular rock alignment. One bone was recovered from the circular alignment and it was identified as a fragment of a domestic cow axis vertebra. It was not burned, but did contain evidence of some butchering activities.

Shed (Area 5, Room 3)

Room 3 is the remains of a wood structure located approximately 21.5 m north-northeast of the cabin. Two large wood beams were the only remains of this structure visible on the surface prior to excavation. These wood beams appeared to have been part of the structure's south wall. Room 3 is most likely the pole shed described in Homestead Entry Survey No. 394. Six bones were recovered from this feature and included one unidentified bone, one blue grouse axis vertebra (*Dendragapus obscurus*), a domestic goat (*Capra hircus*) cervical vertebra and rib fragment, and a domestic cow distal metatarsal fragment. None of these bones were burned or otherwise altered.

Corral (Area 6, Feature 3)

Feature 3 is the remains of a corral located approximately 14 m northeast of the shed. Two bones were identified in the feature: one was an unidentified small/medium-sized mammal bone and one was a medium/large-sized mammal bone fragment.

Archaeobotanical Remains (Pamela McBride)

The contents of samples from post-occupational fill in the log cabin, a test pit in the corral, and an area of burned soil and charcoal in the shed produced a similar assemblage of burned conifer duff, native annual seeds, grass seeds, grass stems, and other disturbance-loving plants like groundcherry and vervain (Table 32.19). Burned sedge family seeds from the cabin and the shed together with unburned bulrush seeds from the corral attest to the proximity of the homestead to the creek just below in Rendija Canyon. Burned seeds that resembled summer cypress were recovered from the corral. Summer cypress is a weed introduced from Eurasia that is widespread in New Mexico and flourishes in waste places and open fields. The corral and some of the cabin burned during the Cerro Grande fire. Because of this and the similarity of the wild plant assemblages, the majority of wild floral remains probably represent weeds burned in the conflagration rather than debris from food preparation or animal feed.

Evidence for domesticates was restricted to the inside of the cabin and included maize cupules and one burned and one unburned grape seed. Interviews with Annie Lujan, the daughter of José María Serna, owner of the homestead, reported that crops grown included pinto beans, corn, wheat, pumpkins, and other "soft vegetables" (see site excavation section in this chapter). There is no mention of grapes or vineyards, but two peach pit fragments were identified in the vegetal sample from Room 1 post-occupational fill, and Mrs. Lujan did not mention that they grew at the homestead either. Wild grapes grow on canyon walls, in canyon bottoms, and piñon-juniper woodland (Foxx et al. 1998:40). While there are no gnaw marks on the specimens, the possibility that rodents deposited them cannot be ruled out. The grape seeds and peach pits could also be remnants of fruit "brought up from the valley (valley here refers to the Pojoaque-Española valley) orchards and vineyards" (Foxx and Tierney 1999:22) or orchards were present on the homestead, but were either not mentioned by Ms. Lujan.

A broken bean cotyledon from the same context and a piece of ponderosa pine wood were also identified in vegetal samples (Table 32.20). Interviews with residents or descendants of residents of the area document beans as the primary cash crop that was grown on the Pajarito Plateau (Tierney 1999c:15–23). With only one fragment recovered, it seems difficult to fathom the huge volume of beans grown on the Pajarito Plateau by homesteaders. One informant said that in 1915, he harvested about 2100 pounds of beans (Tierney and Foxx 1999:10) and this was not unusual before the drought of the late 1930s. The paucity of physical evidence is related to the fragility of beans and threshing and preparation methods. Beans may be removed from the pods elsewhere than the house interior and preparation does not usually involve parching or frying. Beans have no protective seed coat, as the pod acts as a container before harvest, leaving them vulnerable to consumption by animals or insects.

Ponderosa pine		1/<0.1 g	

Wood charcoal from the majority of contexts is overwhelmingly ponderosa pine (Table 32.21). Exceptions are the samples from inside the horno and the burned soil/charcoal concentration in the shed. Fuel used for cooking seems to have been primarily juniper, although piñon and ponderosa were also present. Wood from the shed context is a mixture of juniper, piñon, and ponderosa, but here ponderosa was the most common wood identified. This could reflect the use of ponderosa for construction and juniper for fuel in the horno.

The Serna family grew corn and beans among other crops documented in interviews and the Homestead Entry Survey. The family traveled to the homestead three times a year by wagon and stayed for about two weeks during each visit. The burned beeweed, goosefoot, pigweed, and groundcherry seeds could be evidence that the family ate the fruits of groundcherry and encouraged and collected annual greens from the fields, a practice documented in several interviews of Spanish residents of the region (Tierney 1999c:15-23). Local wood resources were used for fuel and construction.

Pollen Remains (Susan Smith)

Eight pollen samples were analyzed from LA 85407. Table 32.22 lists the frequency of identified pollen types. Maize was the only cultigen identified in the botanical assemblage. Prickly pear was the only other economic resource that was identified. A number of potential economic resources were also identified in the assemblage (Table 32.22).
