SUMMARY

LA 85407 is the historic Serna Homestead that is located on a gently sloping mesa immediately north of Rendija Canyon. The site is composed of several different areas including the main cabin (Area 1), the horno (Area 3), a small concentration of rocks (Area 4), the shed (Area 5), the corral (Area 6), and the reservoir (Area 7) (see Figure 32.2). Samples of wood submitted for tree-ring analysis returned a construction date for the cabin of around 1900. According to the historical documents, Andres Martinez applied for homestead certification in 1913, and the Homestead Entry Survey No. 394 was performed in October of 1916. The homestead was patented in 1922, and subsequently sold to José and Fidel Serna (of unknown relations), who had probably occupied the homestead since 1913. According to the survey, 40 acres of beans, corn, and vegetables were under cultivation on the homestead in 1916. Improvements included a 12- by 30-ft log house, a 12- by 20-ft pole shed, and one mile of brush fence. According to Annie Lujan, the cabin included three rooms and a sun porch, but the archaeological evidence neither supported nor refuted this information. Portions of the wood cabin floor were, however, identified. The Serna family made seasonal use of the homestead, as supported by the historic artifacts. In addition, the remains of maize, beans, peach and grapes were recovered during the site excavation.

CHAPTER 33
RENDIJA TRACT (A-14): LA 85408

Gregory D. Lockard

INTRODUCTION

LA 85408 is the remains of a small Middle Classic period fieldhouse located on the east-facing slope of a narrow ridge on the mesa between Rendija and Guaje canyons. The site is located near the northern boundary of the eastern portion of the Rendija Tract, a few m north of a two-track dirt road. Vegetation on the site consists of piñon-juniper woodland with some oak and ponderosa pine trees and a grass understory. The site is situated at an elevation of 2124 m (6970 ft).

LA 85408 was first recorded on August 16, 1991, by David Hill (1991) during a survey for the Bason Land Exchange Project. Hill believed the site to be a fieldhouse with at least two rooms. Surface Biscuit A (Abiquiu Black-on-gray) sherds indicated that the site was most likely occupied during the Classic period (AD 1325–1600). On July 20, 1992, Archaeological Research, Inc., was awarded the contract to conduct archaeological testing of the Bason Land Exchange sites. John Peterson and Christian Nightengale (1993) supervised the excavations, which took place between July 27 and August 23 of 1992. A single 1- by 1-m test pit (Unit A) was excavated at LA 85408. The unit was excavated to bedrock at a maximum depth of 42 cm below the ground surface. No convincing floor surface was encountered during the excavation of the unit. Artifacts recovered during the excavation of Unit A and a surface collection of the site include 16 pieces of chipped stone, two fragments of a single slab metate, and 19 ceramic sherds (11 Biscuit A, two Biscuit B, two undifferentiated Biscuitware, one White Mountain Redware, and two utilityware sherds). Most of the surface artifacts were collected from the areas to the northeast and southeast of the structural remains.

FIELD METHODS

Before excavation, the site and surrounding area were cleared of trees and large undergrowth. The site was then visible as a rubble mound approximately 5 by 6 m in area (Figure 33.1). An arbitrary site datum (designated 100N/100E, 10.00 m elevation) was set up in the southwest corner of the site. The site was then covered with a 1- by 1-m grid that extended 8 m north and 8 m east of the site datum. Two subdata (A and B) were set up for taking elevations. The site was then photographed. No artifacts were visible on the surface, most likely due to the fact that it had been previously surface collected by Peterson and Nightengale (1993). A 7- by 1-m east-west trench (104N/101-107E) was initially excavated across the middle of the rubble mound. The purpose of this trench was to expose a profile of the site stratigraphy, as well as to determine the location of the structure's east and west walls. Units were excavated by strata, and thicker strata were excavated in arbitrary 10-cm levels.

Figure 33.1. Photo of the mound at LA 85408 before excavation.

Within the structure, the trench units were excavated to a compact surface that may have been the room's living surface. Outside of the structure, the trench units were excavated to the top of a sterile layer of weathered Cerro Toledo bedrock. The westernmost unit in the trench (unit 104N/101E) was chosen to serve as a test pit for geological analysis. Excavation in this grid unit therefore continued until intact bedrock was encountered. The northern profile of the trench was then drawn and photographed. The rest of the site was subsequently excavated, again by strata and arbitrary levels for thicker strata. In all, 40 units were excavated. Within the structure, excavation proceeded to the compact surface encountered while excavating the trench. Outside of the structure, excavation terminated at the sterile layer of weathered bedrock. Excavation focused on defining the structure's walls, removing wallfall, and locating features. Soil samples were taken from select locations, and all other soil was passed through screens with 1/8-in. mesh to aid in the recovery of artifacts. The excavation area extended at least 1 m beyond the structure in all directions to locate external features and/or outdoor activity areas. The site was mapped (Figure 33.2) and photographed (Figure 33.3).

The excavation of the site was supervised by Greg Lockard. The field crew included Michael Dilley, Alan Madsen, Joseph (Woody) Aguilar, Kevin Hanselka, Brandon Gabler, Margaret Dew, and Samuel Duwe. Timothy Martinez and Aaron Gonzalez served as site monitors from San Ildefonso Pueblo and as screeners. Jeremy Yepa served as site monitor from Santa Clara Pueblo and as an additional excavator.

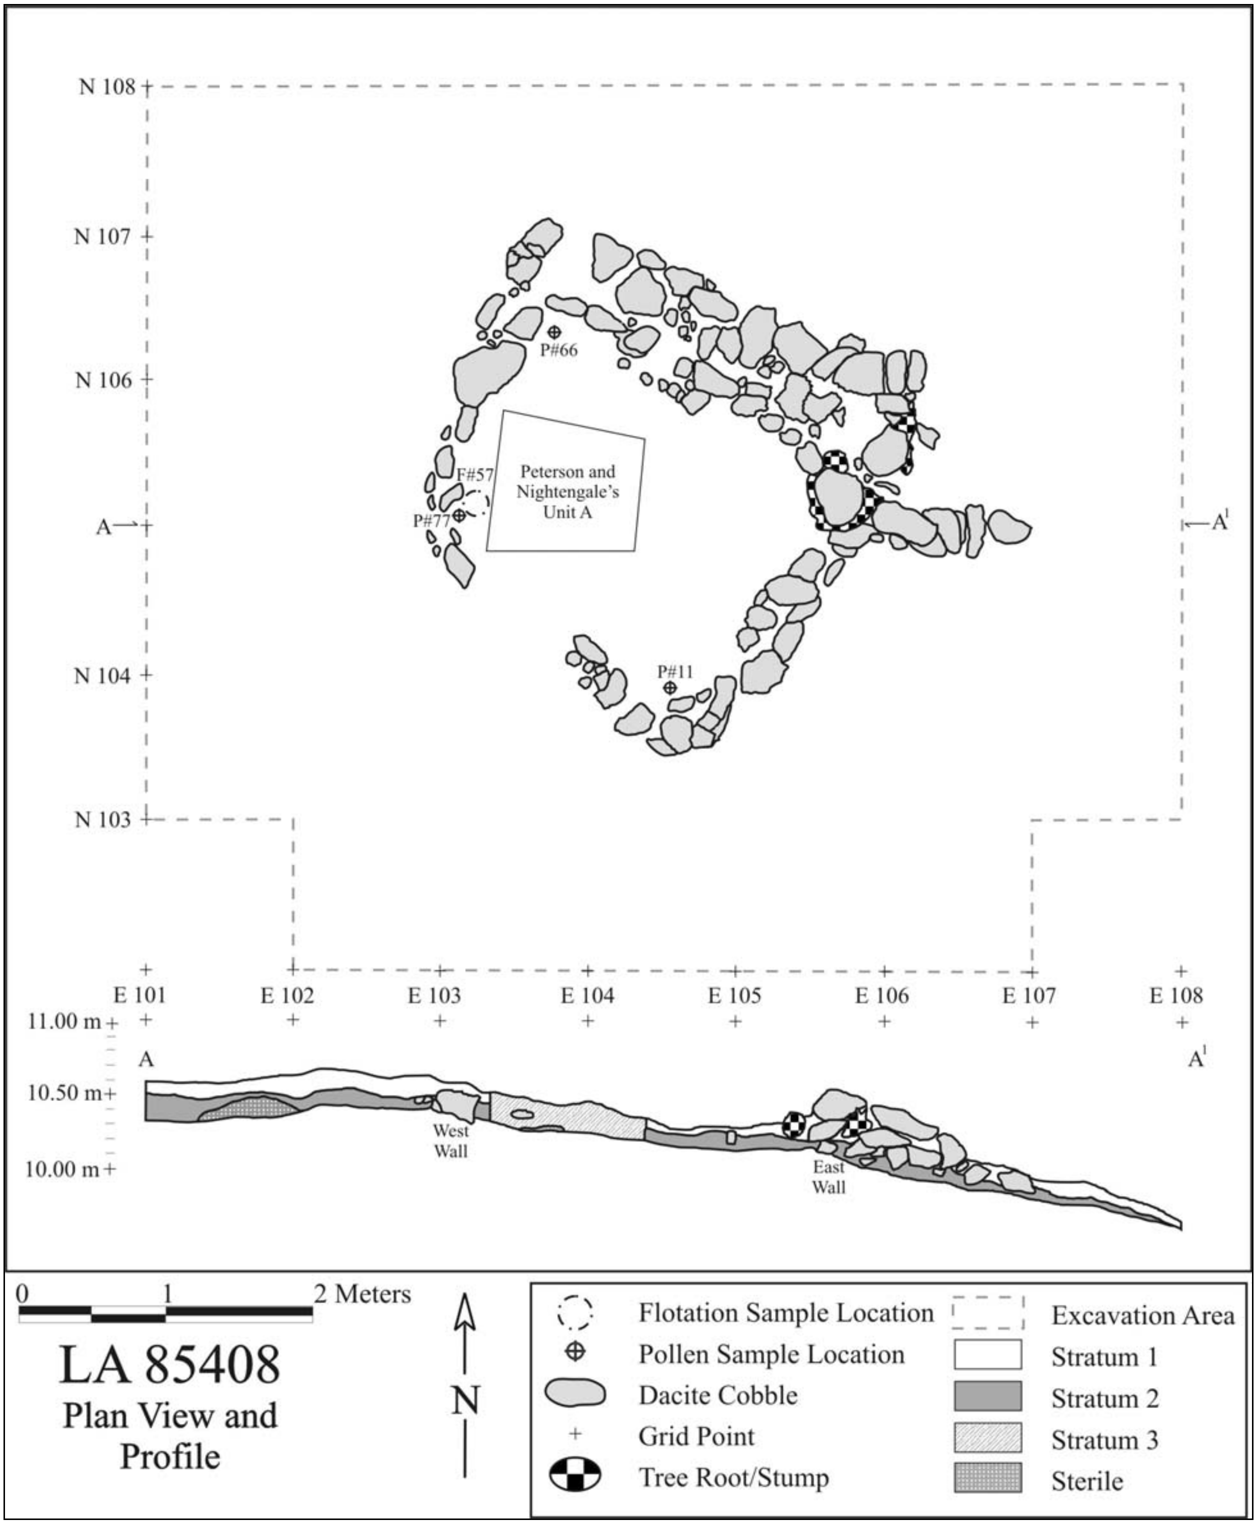

Figure 33.2. Plan view and profile of the fieldhouse at LA 85408.

Figure 33.3. Post-excavation of the fieldhouse at LA 85408.

STRATIGRAPHY

Stratum 1 is composed of loose, surface sediment. It is uniformly 1 to 8 cm thick across the site and is part of the A horizon (topsoil). Stratum 2 is post-occupational fill and ranges from 5 to 30 cm in thickness in the area excavated. This fill was thickest in and around the collapsed walls of the structure and thinned away from the walls and towards the center of the room. In the west profile of the geological test pit (unit 104N/101E), Stratum 2 is part of the A horizon. In other locations, however, the lower portion of Stratum 2 may have been part of a thin Bw horizon. Stratum 3 is the backfill removed from Peterson and Nightengale's Unit A. Stratum 3 is therefore a disturbed context. Tables 33.1 through 33.3 describe the strata at the site.

Table 33.1. LA 85408 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10YR 4.5/3	Sandy loam	1–8	Surface sediment
2	10YR 4.5/3	Sandy loam	5–30	Post-occupational fill
3	10YR 4.5/3	Sandy loam	20	Back fill from P & N test pit

Table 33.2. LA 85408 soil horizon descriptions from the west profile of the geological test pit (104N/101E).

Horizon	Color	Texture	Depth (cm)	Description
A	10YR 4.5/3	Sandy loam	0–9	Topsoil
Rk	-	-	9–20	Weathered Cerro Toledo bedrock
R	-	-	20+	Cerro Toledo bedrock

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is a small structure that probably functioned as a fieldhouse. The fieldhouse is slightly trapezoidal in shape, with the northeast wall being approximately 20 cm longer than the southwest wall. The northeast wall is also significantly thicker than the other walls. The room measures 2.25 m in length (northwest to southeast) by 1.80 m in width (northeast to southwest), with approximately 4.05 m^2 of interior space. Excavation of the room began with an east-west trench that extended across the site (104N/101-107E). The excavation of this trench served to define the room's stratigraphy, as well as to locate the structure's southeast wall and an entryway in the southwest wall. A compact surface was encountered just above the base of the rocks that formed the foundation of the room's southeast and southwest walls. This surface was most likely the room's living surface. After the excavation of the trench, the rest of the room was excavated to the compact surface encountered in the trench. The backfill within Peterson and Nightengale's Unit A was removed as a separate stratum (Stratum 3). This test pit, which is located entirely within the western half of the room, was excavated to intact bedrock. An examination of the pit's profile indicated that there were no discernible living surfaces below the compact surface noted above. After the excavation of the site was complete, the room was mapped, photographed, and documented (see Figures 33.2 and 33.3).

Fill. The interior of Room 1 was filled with 2 to 8 cm of surface sediment on top of 10 to 30 cm of post-occupational fill. The fill was thickest in and around the room's collapsed walls, and thinned away from the walls and towards the center of the room. Flotation (Field Specimen [FS] 57) and pollen (FS 58) samples were taken of the Room 1 fill. The pollen sample was not analyzed, but charred taxa identified in the flotation sample included unknown conifer (Gymnospermae), piñon pine (*Pinus edulis*), and ponderosa pine (*Pinus ponderosa*).

Floor. No prepared floor was encountered during the excavation of Room 1. A compact surface was encountered, however, that was most likely the room's living surface. This surface was distinguishable from the post-occupational fill above in that it was slightly more compact, relatively devoid of rocks, and had a slightly higher clay content. The Room 1 living surface was most likely formed by excavating the loose sediment within the room to expose the compact layer of weathered bedrock below. A thin layer of clay was then most likely placed on top of this naturally compact surface. The relative flatness of the surface compared to the same surface outside of Room 1 (which slopes down from east to west as well as to the north and to the south) indicates that the layer of weathered bedrock was probably leveled to create a flat living surface.

Pollen samples were taken from directly on top of the presumed living surface in the southeast (FS 11), northwest (FS 66), and southwest (FS 77) corners of the room. Identified taxa included maize (*Zea mays*), sedge (Cyperaceae), rose family (Rosaceae), grass family (Poaceae), cottonwood/aspen (*Populus*), cheno-ams (*Chenopodium/Amaranthus*), sunflower family (Asteraceae), ragweed/bursage (*Ambrosia*), spurge family (Euphorbiaceae), spruce (*Picea*), fir (*Abies*), unidentified pine (*Pinus*), piñon pine, juniper (*Juniperus*), oak (*Quercus*), Mormon tea (*Ephedra*), and sagebrush (*Artemisia*). A flotation sample (FS 56) was taken from directly on top of the presumed living surface in the northeast corner of the room, but was not analyzed (see below). The flotation sample was taken from a concentration of fine, light gray sediment. At first, this sediment was believed to be organic ash, possibly from a hearth. Further examination of the site's stratigraphy, however, indicated that it was more likely naturally occurring, pulverized pumice. No artifacts were encountered in direct association with the presumed living surface.

Wall Construction. The extant portions of the Room 1 walls indicate that the wall foundations were composed of dacite cobbles and upright dacite slabs. These rocks were placed into a shallow trench dug into the compact layer of weathered bedrock that most likely served as the room's living surface. What little remains of a second course of rocks indicates that it was composed of oblong dacite cobbles. The rocks that formed the Room 1 walls varied in size from fist-sized cobbles to small boulders. The northeast wall is composed of two rows of rocks separated by a thin space filled in with loose sediment and a few rocks, and is considerably thicker than the other walls. The southwest, southeast, and northwest walls are composed of a single row of large rocks in some places, and two rows of small rocks or thin upright slabs in other places. The southwest wall is divided into southeast and northwest sections by a wide (80 cm) entryway. The southeast section is considerably longer than the northwest section, which is just long enough to form the room's west corner.

Judging from the amount of wallfall removed during the excavation of LA 85408, the room's masonry was originally considerably higher than it was at the time of excavation. In order to estimate the original height of the masonry, all of the rocks removed as wallfall during the site's excavation were placed in five stacks, which were then measured. The stacks measured 0.85 by 1.10 by 0.62 m, 0.86 by 1.85 by 0.78 m, 0.82 by 1.29 by 0.74 m, 1.10 by 1.56 by 0.43 m, and 1.04 by 1.63 by 0.52 m, for a total of approximately 4.22 m^3 of wallfall. Based on this volume of wallfall and the overall length, average thickness, and average height of the extant masonry, the room's masonry was originally approximately 2.01 m in height. This figure is probably too high, however, due to the fact that dacite cobbles occur naturally, albeit sporadically, in the area where the fieldhouse was built. In other words, some of the rocks removed during the site's excavation were probably never part of the room's walls. Nevertheless, the volume of rocks removed during the excavation of the site indicates that the room's masonry was originally quite high (Table 33.4). The uppermost portions of the walls, as well as the ceiling, were most likely composed of wattle and daub. These materials are rarely preserved at archaeological sites on the Pajarito Plateau. In fact, no adobe was recovered from the site.

Table 33.4. Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
Northeast	2.00	0.04–0.46	0.61–0.70	1 to 2
Southwest	1.00 (1.80)	0.15–0.36	0.15–0.38	1
Southeast	1.70	0.19–0.50	0.24–0.48	1 to 2
Northwest	1.64	0.15–0.47	0.20–0.34	1 to 2

Note: The length of the southwest wall including the possible entryway is given in parentheses.

Geological Test Pit

Geologists Paul Drakos and Steven Reneau utilized the west profile of the geological test pit (unit 104N/101E) to reconstruct the natural soil horizons at the site (see Table 33.2). This profile contained a soil sequence consisting of an A horizon (topsoil), a Rk horizon (weathered Cerro Toledo bedrock), and a R horizon (intact Cerro Toledo bedrock) (Figure 33.4).

Artifact Distribution

As Table 33.5 demonstrates, the distribution of artifacts recovered during the excavation of LA 85408 is fairly uniform. There is a slight increase in the artifact distribution within and to the northeast of the room. The former most likely represents artifacts found in their primary context. The increased artifact distribution to the northeast of the room, on the other hand, is most likely the result of post-depositional processes. The natural surface slopes down to the northeast. Many of the artifacts to the northeast of the room have therefore probably washed down into this area. The most dramatic deviation from this pattern of artifact distribution is unit 102N/104E. Twenty-one artifacts were recovered from this unit. Of these, however, 20 are biscuitware sherds recovered from a single excavation level (Stratum 2, Level 2). These sherds most likely represent a pot drop or a large sherd or sherds that were further fragmented after the site was abandoned.

Table 33.5. LA 85408 artifact counts by grid unit.

	E101	E102	E103	E104	E105	E106	E107

Note: Bold numbers indicate grid units that are located completely or partially within Room 1.

Figure 33.4. West profile of the geological test pit (unit 104N/101E).

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 151 artifacts were analyzed from the excavations conducted at LA 85408. In addition, flotation and pollen samples were selected for analysis from the post-occupation fill (Stratum 2). The results of the artifact and sample analyzes are presented in the following sections. Samples taken from the site are listed in Table 33.6.

Table 33.6. Samples selected for analysis from LA 85408.

Ceramic Artifacts (Dean Wilson)

A total of 80 ceramics were analyzed from LA 85408. The majority of the pottery consists of Biscuit B/C (Biscuit B?), Biscuit A, and Biscuit B (Table 33.7). These types, in addition to the two glazeware sherds, would seem to indicate a Middle Classic period (15th century) occupation. Information on ceramic tradition by ware, temper by ware, and vessel form by ware are provided in Tables 33.8 to 33.10. The graywares and whitewares appear to have been locally made from tuff temper; however, a single grayware sherd does exhibit granite with mica temper. This latter sherd is presumably associated with the Classic period occupation. The redware sherd also differs by exhibiting non-local sherd and sand temper. All of the grayware ceramics consist of jar vessel forms whereas the whiteware and redware sherds derived from bowls.

Table 33.7. Ceramic types from LA 85408.

Ceramic Type	Frequency	Percent

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 71 artifacts were analyzed and consisted of three cores, 62 pieces of debitage, four retouched tools, and two ground stone artifacts, which represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 33.11 presents the data on lithic artifact type by material type. The debitage is primarily made of chalcedony, with less Pedernal chert, obsidian, silicified wood, and other materials. The presence of cortex on 19.3 percent of the debitage indicates that these materials were collected from waterworn (n = 11) and nodule (n = 1) sources. The chalcedony, Pedernal chert, and silicified wood are available from local Rio Grande Valley gravels and the obsidian from nearby sources in the Jemez Mountains. A piece of obsidian was the only artifact with nodule cortex. The igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the Pajarito Plateau.

Three pieces of obsidian and two pieces of basalt debitage were submitted for X-ray fluorescence analysis. The obsidian artifacts were made from Cerro Toledo and Valle Grande materials (Table 33.12). The Cerro Toledo (Obsidian Ridge/Rabbit Mountain) and the Valle Grande (Cerro del Medio) source areas are located about 19 km (12 mi) and 17 km (11 mi) to the southwest and west of the site. Although obsidian is present at these nearby sources in the Jemez Mountains, it is also present in the site area as small pebbles. These pebbles compose part of the secondary deposits associated with the Cerro Toledo interval and are scattered across the mesa top. The X-ray fluorescence analysis also indicates that the two basalt pieces of debitage are probably basalt and not dacite.

Table 33.12. Obsidian source samples.

FS #	Artifact	Color	Source
45	Debitage	Translucent	Cerro Toledo rhyolite
63	Debitage	Translucent	Cerro Toledo rhyolite
78	Debitage	Translucent	Valle Grande rhyolite

Lithic Reduction

The two cores were reduced using a single-directional, single, and multi-face technique. Flakes were removed from an unprepared cortical platform on a cobble uniface (Figure 33.5). The two cores were discarded due to material flaws and extensive hinging/stepping, whereas the cobble uniface was considered still useable. Table 33.13 presents the metric information on the cores.

Table 33.13. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Single-directional	54	46	59	154.5
Single-directional	53	79	64	274.6
Cobble Uniface	48	86	102	553.9

The debitage consists primarily of core flakes, with fewer angular debris and undetermined flake fragments. The overall cortical:non-cortical ratio of 0.41 reflects an emphasis on the later stages of core reduction. The flakes mostly have single-faceted platforms (n = 19), with fewer cortical (n = 5) and collapsed (n = 8) platforms. None of the platforms exhibit any obvious evidence of preparation. The majority of the core flakes are whole (n = 24), with fewer proximal (n = 8), midsection (n = 4), distal (n = 12), and lateral (n = 1) fragments. The whole core flakes have a mean length of 27.4 mm (*std* = 9.7) and the angular debris a mean weight of 2.2 g (*std* = 4.5).

The retouched tools consist of retouched pieces and a biface. The retouched pieces consist of two small flakes with retouch along a distal end and a lateral side. This is unidirectional retouch with edge angles of 65 degrees. The other retouched piece was made on a large flake with unidirectional dorsal retouch along two lateral sides and edge angles of 60 degrees. The biface is a small base fragment that could have been broken during the late-stage reduction process (i.e., a projectile point preform).

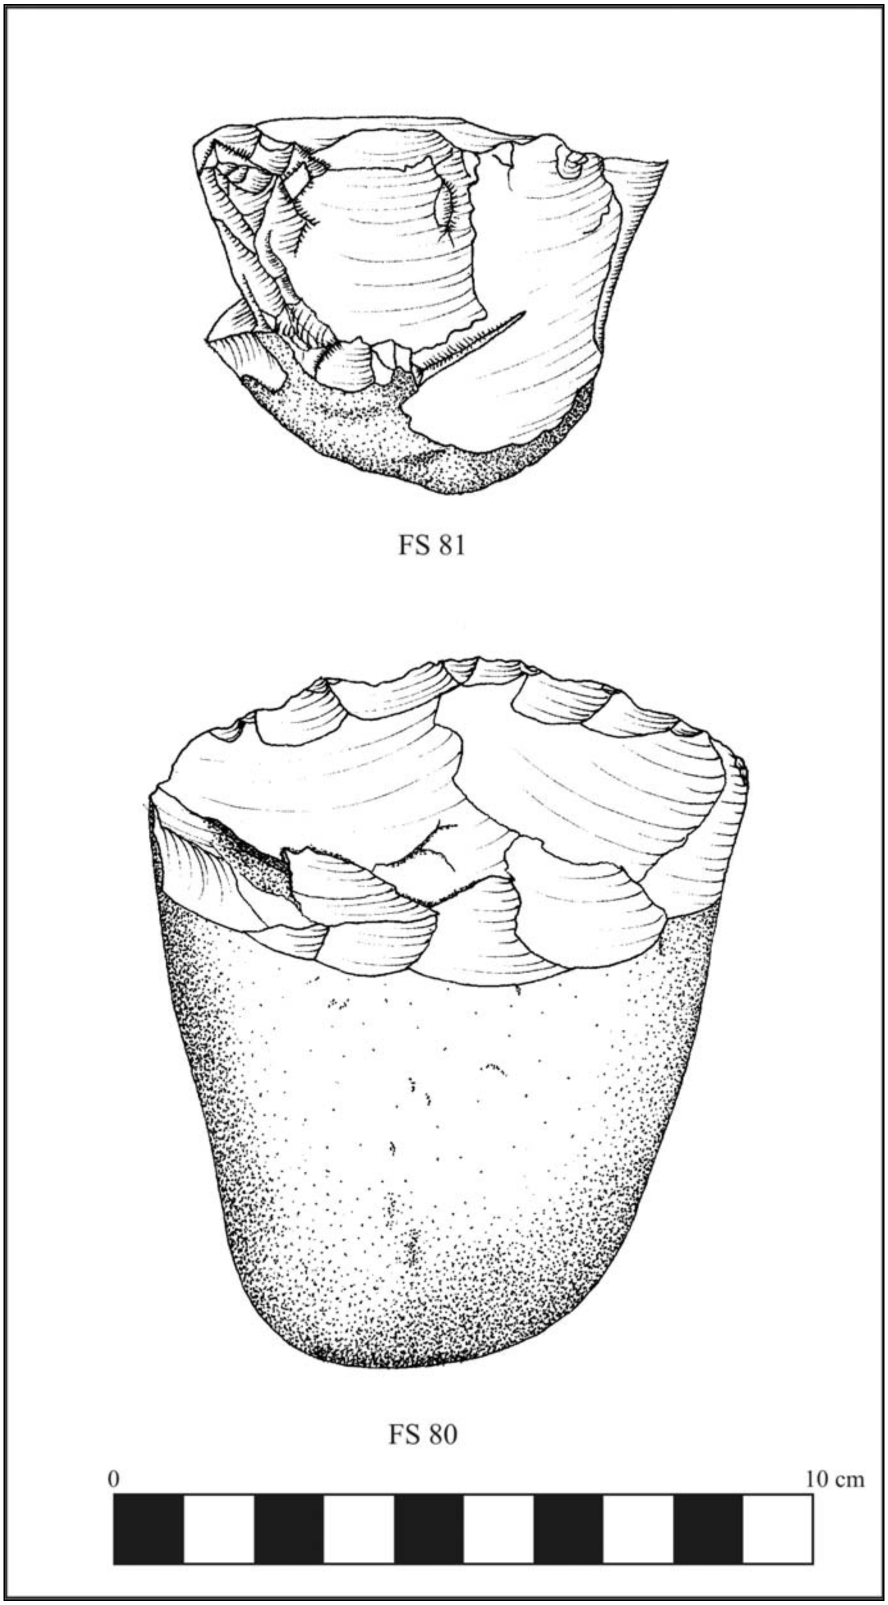

Figure 33.5. Cobble uniface and single-directional core.

Tool Use

Two of the retouched pieces exhibit evidence of edge damage that could be attributed to use. One of the small retouched flakes has a slight projection with rounding/polish, whereas, the large retouched flake exhibits rounding/polish wear along both retouched edges. None of the flakes exhibited similar use damage.

The ground stone consists of a grinding slab and polishing stone. The grinding slab is a large tuff rock with a concave surface that appears to be natural with little or no obvious grinding or striations. Therefore, it might actually represent site furniture rather than a grinding slab. The polishing stone is a small dacite pebble with a flat polished surface.

Faunal Remains (Kari Schmidt)

One piece of bone was recovered from 107N/105E (Stratum 2, Level 2). The bone was an unidentified piece of medium/large-sized mammal bone. The bone was unburned and contained an old break.

Archaeobotanical Remains (Pamela McBride)

Possible piñon nutshell was the only cultural plant material not directly related with firewood use that was found in the fieldhouse (Table 33.14). A total of five pieces of unknown conifer wood, four from the middle fill of the pit and one from post-occupational fill were also recovered. Modern debris included unburned goosefoot, prickly pear, and sedge seeds, grass florets, piñon nutshell, and conifer twigs and needles.

Pollen Remains (Susan Smith)

Three pollen samples were analyzed from LA 85408. Table 33.15 lists the frequency of identified pollen types. Maize was the only cultigen identified in the botanical assemblage. Sedge was the only other economic resource that was identified. A number of potential economic resources were also identified in the assemblage (Table 33.15).

SUMMARY

LA 85408 is a one-room Middle Classic period fieldhouse that was constructed from both shaped and unshaped tuff blocks. The site is situated on a ridge to the north of Rendija Canyon. Maize pollen was recovered during the site excavation, therefore, the one-room structure was presumably occupied during the growing season.

CHAPTER 34
RENDIJA TRACT (A-14): LA 85411

Gregory D. Lockard

INTRODUCTION

LA 85411 consists of the remains of a small Early/Middle Classic period structure and a possible feature. The site is located on a south-facing ridge on the mesa between Rendija and Guaje canyons. The structure is located a few m south of a two-track dirt road. The possible feature is located approximately 30 m to the south of the structure, at the southern edge of the ridge. Vegetation on the site consists of piñon-juniper woodland with a grass understory. The site is situated at an elevation of 2134 m (7000 ft).

The LA 85411 structure was first recorded on August 16, 1991, by David Hill (1991) during a survey for the Bason Land Exchange Project. Hill believed the structure was a one-room fieldhouse. Surface Biscuit A sherds indicated that the structure was most likely occupied during the Classic Period (AD 1325–1600). On July 20, 1992, Archaeological Research, Inc., was awarded the contract to conduct archaeological testing of the Bason Land Exchange sites. John Peterson and Christian Nightengale (1993) supervised the excavations, which took place between July 27 and August 23 of 1992. A single 1- by 1-m test pit (Unit A) was excavated within the LA 85411 structure. In addition, Peterson and Nightengale recorded and excavated a single 1- by 1-m test pit (Unit B) within the possible feature. Unit A was excavated to a sterile Pleistocene soil at a maximum depth of 36 cm below the ground surface. Artifacts recovered during the excavation of Unit A included one obsidian flake and eight sherds (one Biscuit A, one brown utilityware, and seven smeared-indented corrugated sherds).

Unit B was excavated to a maximum depth of 35 cm below the ground surface. No distinct rock alignments or living surfaces were encountered during the excavation. However, two pieces of chipped stone and two ceramic sherds (an unidentified Biscuitware sherd and a micaceous utilityware sherd) were recovered from the excavation. In addition, seven pieces of chipped stone, a small piece of ground stone (a mano fragment), and 21 ceramic sherds (one smeared-indented, four Biscuit B, and 16 Biscuit A sherds) were recovered during a surface collection of the site. Peterson and Nightengale (1993) concluded that the area in and around Unit B was either not a cultural feature or was an ephemeral construction that was no longer intact. As a result, they argued that the research potential of this area of the site was exhausted by the excavation of Unit B. This area of the site was therefore not excavated during the Conveyance and Transfer (C&T) Project.

FIELD METHODS

The excavation of LA 85411 began during the 2004 field season and was completed during the 2005 field season of the C&T Project. In 2004, the LA 85411 structure and surrounding area

(Area 1) were cleared of trees and large undergrowth. The structure was then visible as a rubble mound approximately 5 m across (Figure 34.1).

Figure 34.1. Pre-excavation photo of the mound at LA 85411.

An arbitrary site datum (designated 100N/100E, 10.00 m elevation) was set up in the southwest corner of the site. The site was then covered with a 1- by 1-m grid that extended 7 m north and 9 m east of the site datum. Two subdata (A and B) were set up for taking elevations. The site was then photographed. A single piece of ground stone (Field Specimen [FS] 1) was the only artifact visible on the surface, most likely due to the fact that the site had been previously surface collected by Peterson and Nightengale (1993). An 8- by 1-m east-west trench (units 103N/100-107E) was initially excavated across the center of the rubble mound. The excavation of the trench was begun in 2004 and completed in 2005. The purpose of this trench was to expose a profile of the site stratigraphy, as well as to determine the location of the structure's east and west walls.

Units were excavated by strata, and thicker strata were excavated in arbitrary 10-cm levels. The trench passed through a single room, designated Room 1. The east and west walls of Room 1 were encountered just below the surface. Within the structure, the trench units were excavated to the room's living surface, which was well-preserved in several patches in the eastern half of the room. Outside of the structure, the trench units were excavated to the top of a sterile Bwb1 horizon. The easternmost unit in the trench (103N/107E) was chosen to serve as a test pit (Test Pit 1) for geological analysis. This unit was excavated to intact Cerro Toledo bedrock. The northern profile of the trench was then drawn and photographed. The rest of the site was subsequently excavated, again by strata and arbitrary levels for thicker strata. In all, 48 units were excavated. Within Room 1, excavation proceeded down to the living surface encountered while excavating the trench. During the excavation of units to the east of Room 1, a second, adjacent room was encountered. This smaller room was designated Room 2. Within Room 2, excavation proceeded down to a similar, although lower and less-well-preserved, living surface.

Outside of the structure, excavation terminated at the top of the sterile Bwb1 horizon. Excavation focused on defining the structure's walls, removing wallfall, and locating features. Soil samples were taken from select locations, and all other soil was passed through screens with 1/8-in. mesh to aid in the recovery of artifacts. The excavation area extended at least 1 m beyond the structure in all directions to locate external features and/or outdoor activity areas. The site was then photographed (Figure 34.2) and mapped (Figure 34.3).

Figure 34.2. Post-excavation photo of the fieldhouse at LA 85411.

A second, smaller test pit (Test Pit 2) was excavated beneath the living surface in Room 1. Test Pit 2 comprises the northernmost 35 cm of that portion of unit 103N/101E that is within Room 1. The purpose of excavating this test pit was to determine the nature of the subfloor stratigraphy in Room 1, as well as to determine the depth of the room's wall foundations.

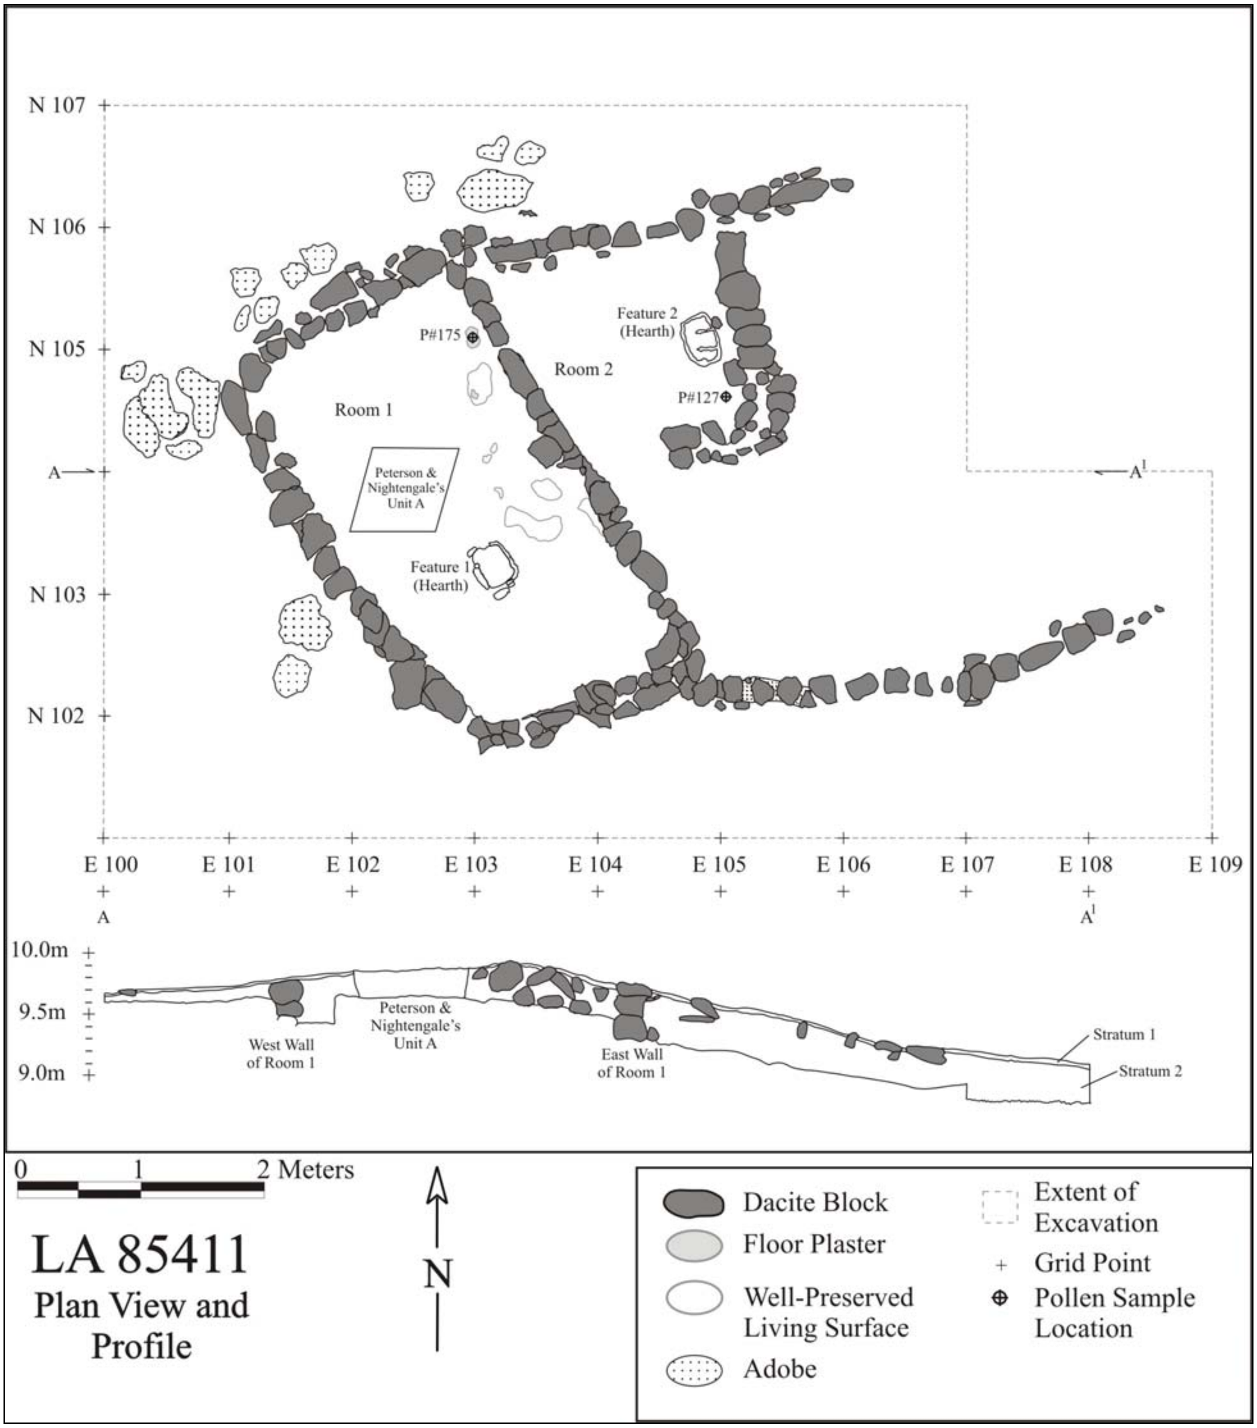

Figure 34.3. Plan view and profile of LA 85411.

During the 2004 field season, the excavation of the site was supervised by Michael Dilley. The field crew included Alan Madsen, Sandi Copeland, and Hannah Lockard. During the 2005 field season, the excavation of the site was supervised by Gregory Lockard. The field crew included Michael Dilley, Joseph (Woody) Aguilar, Kevin Hanselka, Brandon Gabler, Margaret Dew, and Samuel Duwe. Timothy Martinez and Aaron Gonzalez served as site monitors from San

Ildefonso Pueblo and as screeners. Jeremy Yepa served as site monitor from Santa Clara Pueblo and as an additional excavator.

STRATIGRAPHY

Stratum 1 is composed of loose, surface sediment. It is uniformly 1 to 5 cm thick across Area 1 and is roughly equivalent to the A horizon (i.e., topsoil) documented in Test Pit 1. Stratum 2 is post-occupational fill and ranges from 5 to 45 cm in thickness in Area 1. This fill was thickest in and around the collapsed walls of the structure, and thinned away from the walls and towards the center of the rooms. Stratum 2 is roughly equivalent to the Bw horizon documented in Test Pit 1. Stratum 3 is the fill from the hearth in Room 1 (Feature 1), Stratum 4 is the Room 2 living surface, Stratum 5 is the fill from the hearth in Room 2 (Feature 2), and Stratum 6 is the Room 1 living surface. Stratum 7 is the subfloor sediment excavated in Test Pit 2 (i.e., the Btjb1 horizon). This horizon is slightly more developed but otherwise similar to the Bwb1 horizon in documented in Test Pit 1. Tables 34.1 through 34.4 describe and summarize the strata at the site.

Table 34.1. LA 85411 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10YR 4/3	Loamy sand	1–5	Surface sediment
2	10YR 4/3	Sandy loam	5–45	Post-occupational fill
3	10YR 4/2	Sandy loam	10	Feature 1 (hearth) fill
4	10YR 4/3	Clay loam	-	Room 2 living surface
5	10YR 4/2	Sandy loam	10	Feature 2 (hearth) fill
6	10YR 4/3	Clay loam	10	Room 1 living surface
7	-	-	20	Middle/late-Holocene soil

Table 34.2. LA 85411 soil horizon descriptions from the north profile of Geological Test Pit 1 (103N/107E).

Horizon	Color	Texture	Depth (cm)	Description
A	10YR 4/3	Loamy sand	0–4	Topsoil
Bw	10YR 4/3	Sandy loam	4–14	Late-Holocene soil
Bwb1	7.5YR 5/3	Sandy loam	14–30	Middle/late-Holocene soil
R	-	-	30+	Cerro Toledo bedrock

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is a fairly large, rectangular room in a two-room structure that probably functioned as a fieldhouse or small hamlet. The room measures 3.60 m in length (northwest to southeast) by 1.95 m in width (northeast to southwest), with approximately 7.02 m^2 of interior space (Figure 34.4).

Figure 34.4. Room 1 after excavation.

Excavation of the room began with an east-west trench that extended across the site (103N/100-107E). The excavation of this trench served to define the room's stratigraphy as well as to locate the room's east and west walls. A compact living surface was encountered between the east and west walls. The living surface was well-preserved in several patches within units 103N/103-104E (i.e., the eastern half of the room). In addition, a slab-lined hearth (Feature 1) was discovered in unit 103N/103E. After the excavation of the trench, the rest of the room was excavated to the living surface. Additional patches of well-preserved living surface, as well as two patches of floor plaster, were encountered in the northeast corner of the room.

Excavation of the Room 1 fill included the backfill from Peterson and Nightengale's Unit A. No artifacts were recovered from the backfill, which was excavated separately from the surrounding post-occupational fill. After the entire Room 1 living surface was exposed, Feature 1 was excavated. Room 1 was thereafter mapped, photographed, and documented. Test Pit 2 (the northernmost 35 cm of that portion of unit 103N/101E that is within Room 1 was then excavated below the room's living surface. The purpose of excavating this test pit was to determine if there were additional floors or living surfaces below, as well as to ascertain the depth of the room's wall foundations. The test pit reached a maximum depth of 23 cm below the living surface. No additional living surfaces were encountered.

Fill. The interior of Room 1 was filled with 1 to 5 cm of surface sediment (Stratum 1) on top of 15 to 35 cm of post-occupational fill (Stratum 2). The fill was thinnest in the easternmost portion of the room and thickened to the west (i.e., downhill). Flotation (FS 66) and pollen (FS 67) samples were taken of the Room 1 fill, but these samples were not analyzed.

Floor. A fairly well-preserved living surface was encountered throughout most of Room 1. The only location where the living surface was not well-preserved was in the southeast corner of the room. In this area, the living surface was badly disturbed by roots. The living surface was best preserved in several patches in the northeast corner and east-central portion of the room. Two patches of floor plaster were in fact encountered in the northeast corner of the room (Figure 34.5). Excavation of Test Pit 2 revealed a 10-cm-thick layer of clay-rich mud that functioned as the floor's foundation. The reason for the considerable thickness of the floor foundation is unclear. It may have at least partially functioned to level the Room 1 living surface. The floor foundation was then capped by a thin layer of plaster, which was only preserved in two small patches at the time the room was excavated.

Pollen samples were taken from directly on top of the living surface in the southwest corner (FS 81, not analyzed), northeast corner (FS 63 [not analyzed] and 175), and along the eastern edge (FS 31) of the room. One of these samples (FS 175) was scraped from directly on top of a patch of floor plaster. Taxa identified in this sample included rose family, grass family, cheno-ams, sunflower family, ragweed/bursage, fir, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush. Taxa identified in FS 31 included maize, cheno-ams, pea family, sunflower family, fir, unidentified pine, piñon pine, juniper, oak, and sagebrush. In addition, flotation (FS 33) and pollen (FS 34) samples were taken from a clump of adobe located directly on top of the living surface in the northwest corner of the room, but were not analyzed. This adobe was most likely the partially dissolved remains of a piece of wall or rooffall. Similar clumps of adobe were found just outside of the room to the north and west.

Figure 34.5. Living surface identified in Room 1.

Wall Construction. The extant portions of the Room 1 walls indicate that the wall foundations were composed of dacite cobbles. These rocks were placed into a shallow trench dug into the compact Btjb1 or Bwb1 horizons that predate the site's occupation. What remains of the second and third courses of the walls indicate that they were composed mostly of oblong dacite cobbles. In most places, the walls were composed of a single row of rocks. Most of the south wall and part of the north wall, however, were composed of two rows of smaller rocks. There was no break in any of the walls to indicate the location of the room's entryway. The room's entryway therefore had a substantial doorsill. The living surface in Room 2 sloped up to the level of the Room 1 living surface in the northwest corner of Room 2. This suggests that there may have been an entryway that led from the northwest corner of Room 2 into the northeast corner of Room 1. If this is the case, the doorsill was up to 20 cm tall on the Room 1 side of the entryway.

A substantial auxiliary wall extended approximately 2 m due east from the southeast corner of Room 1. The wall then gently curved northwards. The wall measured 3.30 m in total length and had similar width and height dimensions to the extant portions of the Room 1 perimeter walls. The wall most likely functioned to define the southern border of an outdoor activity area (see below). If this is the case, the wall was most likely only a single course high. This interpretation is supported by the fact that increasingly smaller amounts of wallfall were encountered away from Room 1 (i.e., to the east) on either side of the auxiliary wall.

Judging from the amount of wallfall removed during the excavation of the area in and around Room 1, the room's masonry was originally considerably higher than it was at the time of excavation. In order to estimate the original height of the masonry, all of the rocks removed as wallfall during the site's excavation were placed in seven stacks, which were then measured. The stacks measured 2.05 by 0.33 by 0.43 m, 2.35 by 0.37 by 0.43 m, 1.40 by 0.40 by 0.47 m, 3.25 by 0.42 by 0.45 m, 2.30 by 0.67 by 0.40 m, 1.60 by 0.60 by 0.58 m, and 2.30 by 0.40 by 0.67 m, for a total of approximately 3.33 m^3 of wallfall. Based on this volume of wallfall and the overall length, average thickness, and average height of the extant portions of the walls, the Room 1 wall masonry was originally approximately 1.03 m in height (Table 34.5). This figure assumes that the Room 1 auxiliary wall and the eastward extension of the north wall of Room 2 were only one course high. It also assumes that the Room 1 and Room 2 masonry were the same height. The uppermost portions of the walls, as well as the ceiling, were most likely composed of wattle and daub. Several large clumps of adobe, which were most likely the partially dissolved remains of wallfall from this section of the walls and/or rooffall, were discovered both within and just outside to the north and west of Room 1. These clumps of adobe were sampled. They were not collected, however, due to the fact that they were partially dissolved, which made it difficult to clearly distinguish them from the surrounding sedimentary matrix.

Table 34.5. LA 85411 Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	1.87	0.08–0.22	0.12–0.44	1 to 2
South	1.75	0.10–0.27	0.20–0.40	1 to 2
East	3.65	0.10–0.25	0.14–0.33	2 to 3
West	3.32	0.04–0.32	0.15–0.34	2 to 3
Auxiliary	3.30	0.20–0.38	0.15–0.32	1

Feature 1

Feature 1 is a small, elliptical pit hearth located in the south-central portion of Room 1 (Figures 34.6 and 34.7). Most of the north, south, and west walls of the hearth were formed by upright dacite slabs or small dacite cobbles. There was only a single small dacite cobble along the hearth's eastern margin. The remainder of the hearth's perimeter may have been formed by an adobe collar. If this is the case, however, nothing remained of the collar. The interior of the hearth was lined with a fairly thick layer of adobe plaster that was hardened by the heat associated with the hearth's use. The entire hearth measured 60 cm north to south by 44 cm east to west. The interior of the hearth was 41 cm north to south by 34 cm east to west. The hearth was 22 cm deep as measured from the top of the highest perimeter rock to the base of the hearth, and contained approximately 10 cm of ashy fill. Three flotation samples were taken of the ashy fill from the northern (FS 76, FS 77, and FS 78) and southern (FS 111, FS 112, and FS 118) halves of the hearth. Charred taxa identified in the northern half included mountain mahogany, piñon pine, ponderosa pine, oak, goosefoot, maize, unknown conifer, and unidentified pine. Charred taxa identified in the southern half included mountain mahogany, unknown conifer, piñon pine, ponderosa pine, unidentified pine, and maize. In addition, a pollen sample was taken from the base of the hearth's northern (FS 180) and southern (FS 174) halves. Taxa identified in the sample from the northern half included grass family, cheno-ams, sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon pine, juniper, oak, and sagebrush, while those identified in the southern half included rose family, cheno-ams, grass family, sunflower family, ragweed/bursage, spurge family, fir, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush.

Figure 34.6. Pit hearth (Feature 1) in Room 1 at LA 85411.

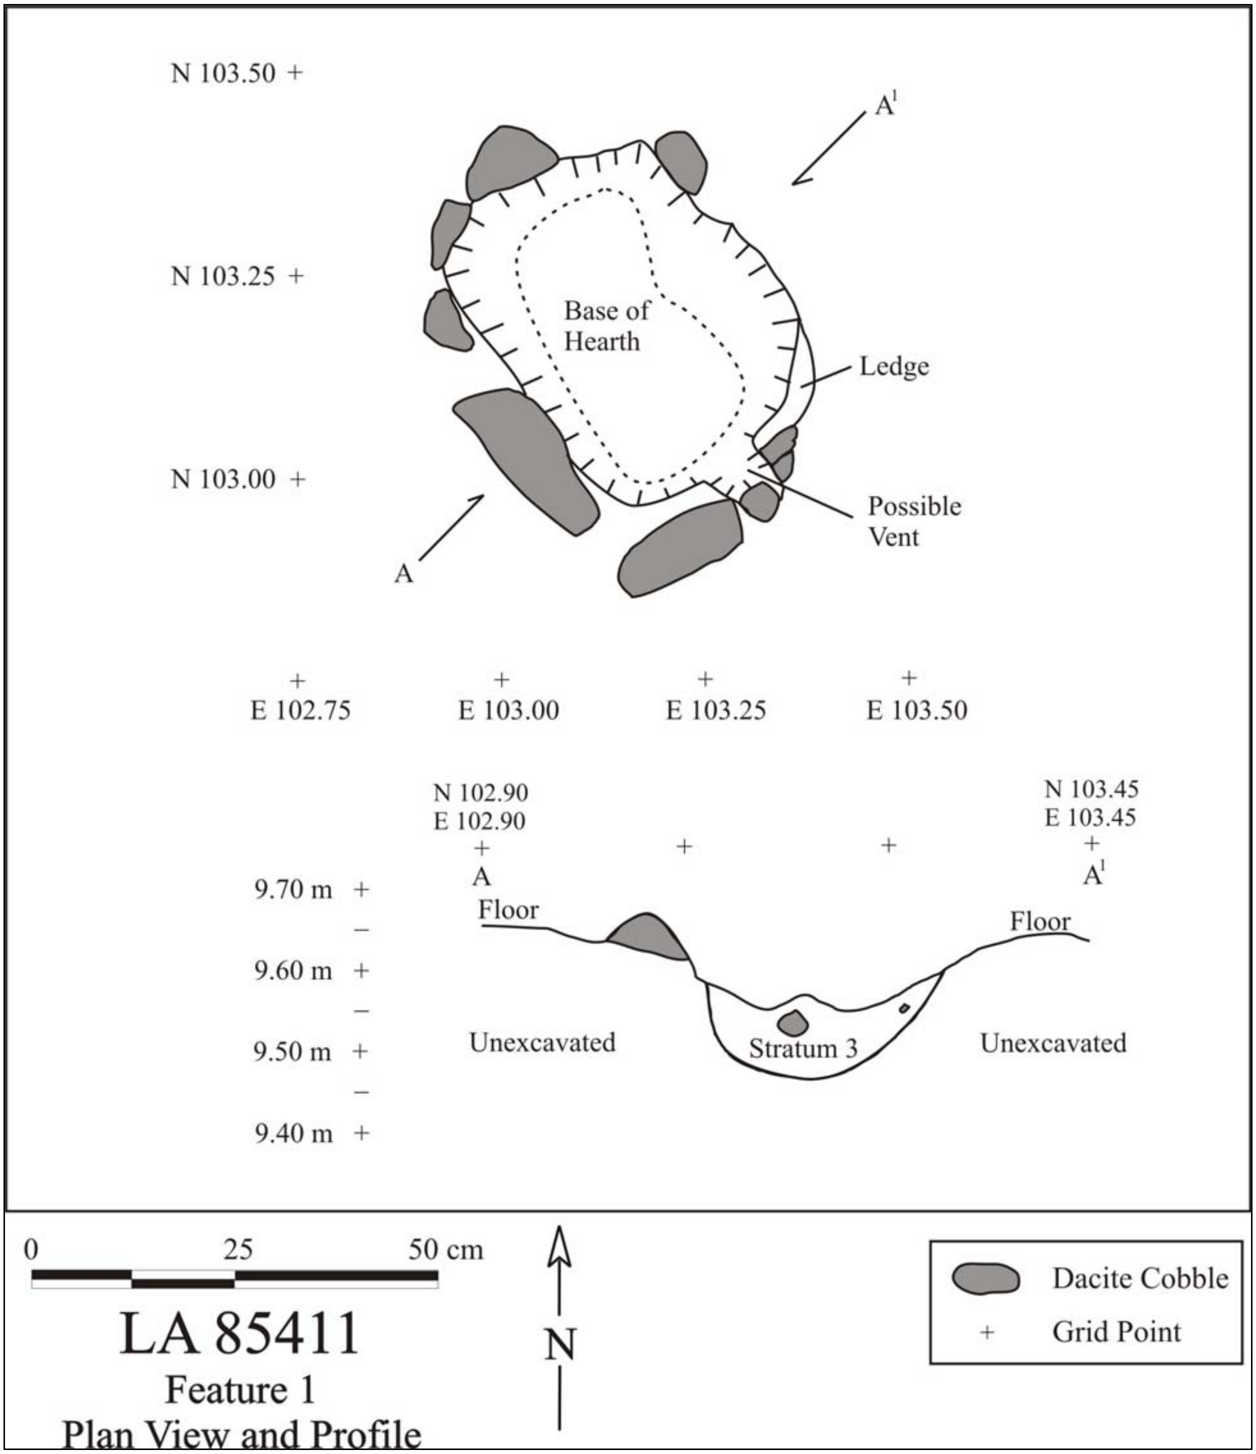

Figure 34.7. Plan view and profile of Feature 1.

Room 2

Sequence of Excavation. Room 2 is a small room that shares a wall with Room 1 (Figure 34.8). The room's north, east, and south walls have a slightly different orientation than the Room 1 walls, including the wall that the two rooms share (i.e., the west wall of Room 2). This strongly suggests that Room 2 was constructed at a later time than Room 1, and was therefore an addition. The room measured 1.58 m north to south by 1.55 m east to west, with approximately 2.45 m^2 of interior space. Room 2 was not visible as a separate room before the excavation of the site. In addition, the east-west trench excavated across the site did not pass through any portion of the room. As a result, Room 2 was only discovered while excavating the exterior of Room 1. During the excavation of the units surrounding Room 1, several walls were encountered to the east of the room. These walls were eventually identified as the walls of a separate room. Once the extent of the room was defined, excavation within proceeded to a compact surface similar, although less well preserved, to the Room 1 living surface. During the excavation of the interior of Room 2, a small hearth was encountered. This hearth was designated Feature 2, and excavated only after the excavation of the rest of the room was complete.

Figure 34.8. Post-excavation photograph of Room 2 at LA 85411.

Fill. The interior of Room 2 was filled with 1 to 3 cm of surface sediment (Stratum 1) on top of 20 to 40 cm of post-occupational fill (Stratum 2). The fill was thickest in and around the room's collapsed walls, and thinned away from the walls and towards the center of the room. No samples were taken of Room 2 fill. This is because much of the room's interior had already been excavated by the time it was identified as a separate room.

Floor. The Room 2 living surface was a compact surface composed of rocks, sand, and clay from a Pleistocene soil. There was a thin layer of blackened, ash-stained sediment in much of the eastern half, and especially the southeast corner, of the room. This thin layer of ashy sediment was the best evidence of a floor, and was designated Stratum 4. Much of the living surface in Room 2 appears to have been leveled. The eastern half and west-central portion of the room are relatively flat compared to the surrounding surface, which slopes down to the east and south. In the northwest corner of the room, the surface slopes up to the wall that divides Rooms 1 and 2. The living surface in this area forms a slight ramp that leads to a possible entryway between Rooms 1 and 2. If this is an entryway between the rooms, it had a doorsill that was up to 27 cm tall on the Room 2 side. The living surface is also sloped in the southwest corner of the room. In this location, the living surface slopes downward to the south through an entryway into the room from outside. This entryway is located in the western half of the room's south wall.

A pollen sample (FS 127) and a charcoal sample (FS 128) were taken from the ashy surface in the room's southeast corner. Taxa identified in the pollen sample included rose family, grass family, cheno-ams, sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon pine, oak, and sagebrush, while the charcoal sample was not analyzed. Pollen samples were also taken from the northwest (FS 176) and northeast (FS 177) corners of the room. These samples were designated Stratum 2, however, because there was no clearly definable living surface in this area. Only FS 177 was analyzed and identified taxa included squash, grass family, cheno-ams, sunflower family, ragweed/bursage, unidentified pine, piñon pine, oak, and sagebrush. No artifacts were recovered from directly on top of the Room 2 living surface.

Wall Construction. The north, south, and east walls of Room 2 do not share the same orientation as the wall that divides Rooms 1 and 2 and the other walls in Room 1. The former are more closely oriented with the cardinal directions. The fact that the common wall shares the orientation of the other walls of Room 1 and not those of Room 2 indicates that the latter is a later addition to the former. The north wall of Room 2 extends approximately 1 m beyond the room's east wall. The function of this eastward extension is unknown. The south wall of Room 2 is essentially a short, right-angle continuation of the east wall. The room's north, east, and west walls were constructed of a single row of upright dacite slabs and dacite cobbles. The south wall, on the other hand, was composed of two rows of smaller dacite cobbles (Table 34.6).

The entryway into Room 2 from outside is located in the western half of the south wall. There does not appear to have been any doorsill. The living surface slopes down to the south as it passes through the entryway. There may have been an entryway between Rooms 1 and 2 in the northernmost portion of the rooms' common wall. This possible entryway is indicated by the fact that the living surface in the northwest corner of Room 2 slopes up towards the common wall. If there was an entryway in this location, it had a doorsill that was up to 27 cm tall on its Room 2 side. Small rocks line both the interior and exterior faces of the Room 2 walls, especially the north wall (including the eastward extension). The small rocks along the room's interior wall faces probably served as foundations for floor coping.

Based on the volume of wallfall removed during the excavation of LA 85411 and the overall length, average thickness, and average height of the extant portions of the walls, the Room 2 masonry was originally approximately 1.03 m in height (see above). The uppermost portion of the walls and ceiling were most likely composed of wattle and daub. Several large but amorphous clumps of adobe were in fact encountered in the area directly north of Room 2. These clumps of clay are most likely the partially dissolved remains of wall or roof fall from Room 1 and/or Room 2.

Table 34.6. LA 85411 Room 2 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	1.80 (3.00)	0.08–0.22	0.16–0.28	1
South	0.83 (1.35)	0.08–0.16	0.20–0.34	1
East	1.50	0.09–0.18	0.16–0.35	2
West	~1.75	0.15–0.45	0.12–0.34	1 to 2

Note: The length of the north wall including its eastward extension and the length of the south wall including the entryway are given in parentheses.

Feature 2

Feature 2 is a small pit hearth located just inside the east wall of Room 2 (Figures 34.9 and 34.10). The remains of an adobe collar were encountered in the northwest corner of the hearth. Presumably, this collar originally encircled the entire hearth. Two small dacite cobbles were encountered between the eastern border of the hearth and the east wall of Room 2. These rocks most likely functioned to further define the hearth's eastern border. No rocks, however, were found along the hearth's northern, southern, or western boundaries. The hearth's interior was originally lined with a thin layer of adobe plaster that was burned during the hearth's use. This plaster has been significantly disturbed, however, most recently by a number of roots. What remains of this plaster lining is extremely thin and friable. As a result, it was not possible to take archaeomagnetic samples from the hearth.

Geological Test Pits

Geologists Paul Drakos and Steven Reneau utilized two profiles to reconstruct the natural soil horizons at the site. The first was the north profile of Test Pit 1 (unit 103N/107E). This profile contained a soil sequence consisting of an A horizon (topsoil), a Bw horizon (a late-Holocene soil), a Bwb1 horizon (a middle/late-Holocene soil), and an R horizon (Cerro Toledo bedrock) (see Table 34.2 and Figure 34.11). The second profile examined was the west profile of Test Pit 2. Test Pit 2 is the subfloor excavation of the northernmost 35 cm of that portion of grid unit 103N/101E that is within Room 1. The purpose of excavating this test pit was to determine whether or not there were additional living surfaces below, as well as to determine the depth of the Room 1 wall foundations. The west profile of Test Pit 2 contained a soil sequence consisting of a Bw2 horizon on top of a Btjb1 horizon (see Table 34.3 and Figure 34.12). The Bw2 horizon is a culturally constructed layer of clay-rich sediment that is approximately 10 cm thick. This layer functioned as the foundation of the Room 1 floor. It is unknown why the floor foundation was made so thick. The Btjb1 horizon is slightly more developed than, but otherwise similar to, the Bwb1 horizon encountered in Test Pit 1.

Artifact Distribution

As Table 34.7 demonstrates, the highest concentration of artifacts at LA 85411 was in the area to the east of Rooms 1 and 2, to the south of the eastward extension of the north wall of Room 2, and to the north of the Room 1 auxiliary wall. This area, which is circumscribed on all but its eastern border, most likely functioned as an outdoor activity area for the site's residents. A higher concentration of artifacts was also encountered in the units to the south of the easternmost section of the Room 1 auxiliary wall (101N/107-108E). This is most likely the result of site formation processes (i.e., the artifacts are washed down from the area to the west). There is also a slightly higher concentration of artifacts in the northern half of Room 2 (105N/103-104E), and a significantly higher concentration in the unit directly north of the eastern half of Room 2 (106N/104E). The reason for the increased concentration of artifacts in these areas is unknown.

Table 34.7. LA 85411 artifact counts by grid unit.

	E100	E101	E102	E103	E104	E105	E106	E107	E108
N106	0	3	0	0	40	13	2	--	--
N105	0	**0**	**1**	***12***	*14*	*9*	29	--	--
N104	1	**3**	**4**	***3***	*4*	*50*	47	--	--
N103	1	**11**	**5**	**9**	**4**	16	13	3	9
N102	4	4	**6**	**7**	**6**	30	8	2	4
N101	0	2	1	**2**	1	7	0	25	19

Note: One artifact was collected from the surface of a grid unit that was not excavated (107N/95E); bold numbers indicate grid units that are located completely or partially within Room 1, and italic numbers indicate grid units that are located completely or partially within Room 2.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 429 artifacts were analyzed from the excavations conducted at LA 85411. In addition, flotation and pollen samples were selected for analysis from the post-occupation fill (Stratum 2), Feature 1 hearth fill (Stratum 3), Room 2 living surface (Stratum 4), and Feature 2 hearth fill (Stratum 5) (Table 34.8). Maize was submitted for radiocarbon dating, two Biscuit A sherds were selected for thermoluminescence (TL) dating, pieces of the floor plaster of the hearth in Room 1 were submitted for archaeomagnetic dating, and five pieces of obsidian were submitted for hydration dating. The results of the artifact and sample analyzes are presented in the following sections.

Table 34.8. Samples selected for analysis from LA 85411.

Stratum	Sample Type				
	Flotation	Pollen	Archaeomag	Radiocarbon	TL
1					
2		31, 177			30, 68

4		127			
5	136, 137, 138, 178	173			
6		175			
7					

Chronology

Radiocarbon Dating

One maize sample was submitted for accelerator mass spectroscopy dating. This specimen was derived from a flotation sample taken of the Feature 1 hearth fill (FS 78). The sample provided a date of 630±40 BP (Beta-221840), with calibrated intercepts of AD 1310, AD 1370, and AD 1380 and a two-sigma range of AD 1290 to 1410.

Archaeomagnetic Dating

Nine specimens were collected as a set (ADL 1282) from a hearth (Feature 1) in Room 1. No specimens could be collected from the hearth walls or rim, and all were collected from the plaster lining of the hearth floor. Table 34.9 shows the single archaeomagnetic result. Blinman and Cox's chapter (Volume 3, Chapter 66) should be consulted for additional information.

Table 34.9. Archaeomagnetic (AM) results from LA 85411.

Sample	Site	Feature	Inc.	Dec.	VGP* Lat.	VGP Long.	$\forall_{95}$	$*_p$	$*_m$	N	De-mag level	AM Date ranges (AD)	
												Wolfman or *DuBois*	SWCV2000
1282	LA85411	Room 1, Feature 1	-9.724	317.3	32.882	127.31	13.623	6.696	13.772	9/8	NRM	N/A	N/A

*VGP is virtual geomagnetic pole

Thermoluminescence Dating

Two Biscuit A sherds were submitted for TL dating from LA 85411 (Table 34.10). All derived ages are given in years BP, which refers to years before 2003. The 14th century date appears to correspond with the radiocarbon dates and the 13th century date does have a large sigma that includes the early 14th century. The ages did not differ at two sigma, and the weighted average is AD 1371±40.

Table 34.10. TL dates from Biscuit A ceramics at LA 85411.

FS#	Lab #	Context	Burial depth (cm)	Years BP	% error	Years AD
30	UW1502	Sherd, Room 1, Stratum 3	20	611	7.1	1395±43
68	UW1503	Sherd, Room 1, Stratum 2	25	801	14.2	1205±114

Obsidian Hydration Dating

Five obsidian artifacts from LA 85411 were submitted for age determination using the obsidian hydration dating method. In order to calculate the absolute date for an obsidian artifact, three analytical procedures were completed. First, the amount of surface hydration, or the thickness of the hydration rim, was measured. Second, the high-temperature hydration-rate constants for each artifact were determined from the composition of the glass. Lastly, the soil temperature and relative humidity at the archaeological site was estimated in order that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. Using these methods, a hydration rate for the obsidian artifacts was calculated (Table 34.11).

Table 34.11. Obsidian hydration dates for LA 85411.

FS No.	Lab No.	Source	Rim (um)	AD/-BC	1 S.D.
24	2006-59	Valle Grande	3.55	488	84
44	2006-60	Valle Grande	5.80	221	60
91	2006-61	Valle Grande	2.07	325	161
145	2006-62	Cerro Toledo	5.26	1018	36
148	2006-63	Cerro Toledo	5.82	1154	28

Relative to other dating methods conducted at the site, the obsidian hydration dates seem to be the least accurate. Radiocarbon and TL dates indicate a 14th century date, while the obsidian samples indicate Late Archaic and Developmental period dates.

Ceramic Artifacts (Dean Wilson)

A total of 320 ceramics were analyzed from LA 85411. The majority of the pottery consists of Sapawe Micaceous, with Biscuit A, Biscuit B, and Biscuit B/C (Biscuit B?) sherds (Table 34.12). This assemblage indicates a late 14th century or early 15th century occupation for the site, which is commensurate with the radiocarbon date. Information on ceramic tradition by ware, temper by ware, and vessel form by ware are provided in Tables 34.13 to 34.15. The graywares and whitewares appear to have been locally made from local tuff temper. This contrasts with the Sapawe Micaceous pottery, which appears to have been derived from a non-local and local source. The former is represented by a micaceous temper and the latter by a tuff temper with a micaceous slip. All of the grayware and micaceous ceramics consist of jar vessel forms while the whiteware sherds were solely derived from bowls.

Table 34.12. Ceramic types from LA 85411.

Ceramic Type	Frequency	Percent
Northern Rio Grande Whiteware

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 109 artifacts were analyzed from LA 85411, consisting of four cores, 95 pieces of debitage, four retouched tools, and six ground stone artifacts. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 34.16 presents the data on lithic artifact type by material type. The debitage is primarily made of obsidian, with less Pedernal chert, chalcedony, and other materials. The presence of cortex on 38.9 percent of the debitage indicates that these materials were collected from waterworn (n = 18) and nodule (n = 19) sources. The chalcedony, Pedernal chert, quartzite, and greenstone are available from local Rio Grande Valley gravels and the obsidian from nearby sources in the Jemez Mountains. Nodule cortex is solely present on obsidian artifacts. Otherwise, the igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the plateau.

Table 34.16. Lithic artifact type by material type.

Eight pieces of obsidian and one piece of basalt debitage, an obsidian tested pebble, an obsidian biface, and a basalt projectile point were submitted for X-ray fluorescence analysis. The obsidian artifacts are made from the Cerro Toledo and Valle Grande materials (Table 34.17). The Cerro Toledo (Obsidian Ridge/Rabbit Mountain) and the Valle Grande (Cerro del Medio) source areas are located about 19 km (12 mi) and 17 km (11 mi) as the "crow flies" to the southwest and west of the site. Although obsidian is present at these nearby sources in the Jemez Mountains, it is also present in the area of the site as small pebbles. These pebbles compose part of the secondary deposits associated with the Cerro Toledo interval and are scattered across the mesa top. Indeed, the test pebble is probably derived from this local source. The X-ray fluorescence analysis also indicates that the basalt flake is actually made of dacite from a local source and the projectile point from a non-local dacite source at San Antonio Mountain. San Antonio Mountain is located about 115 km (70 mi) north of Rendija Canyon.

Table 34.17. Obsidian source samples.

FS #	Artifact	Color	Source
6	Debitage	Translucent	Cerro Toledo rhyolite
24	Debitage	Translucent	Valle Grande rhyolite
84	Debitage	Translucent	Cerro Toledo rhyolite
91	Debitage	Translucent	Valle Grande rhyolite
93	Debitage	Translucent	Valle Grande rhyolite
106	Tested pebble	Translucent	Cerro Toledo rhyolite
145	Debitage	Translucent	Cerro Toledo rhyolite
148	Biface	Translucent	Cerro Toledo rhyolite
163	Debitage	Translucent	Valles Grande rhyolite

Lithic Reduction

Two cores were reduced using a bi-directional, bifacial technique. Flakes were also removed from an unprepared cortical platform on a cobble uniface (Figure 34.13) and a local obsidian pebble had a single flake removed. One of the cores was broken and thought to be discarded due to a culturally induced fracture, whereas, the other core and cobble uniface were considered still useable. Table 34.18 presents the metric information on the cores.

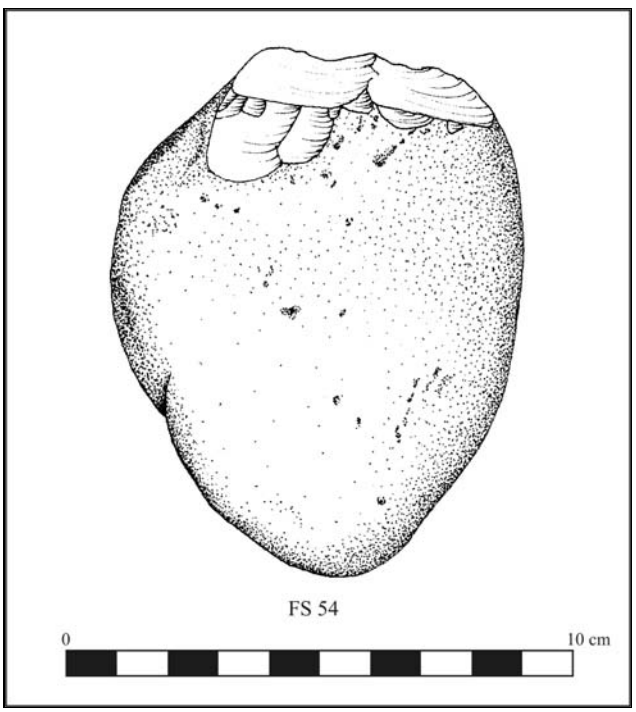

Figure 34.13. Cobble uniface.

Table 34.18. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Bi-directional	77	70	44	291.9
Cobble Uniface	37	83	104	458.8

The debitage primarily consists of core flakes, with fewer angular debris, biface flakes, and other items. The overall cortical:non-cortical ratio of 1.0 reflects an even distribution between early stage core reduction and late stage core reduction and tool production/maintenance. The flakes mostly have single-faceted platforms (*n* = 27), with fewer cortical (*n* = 8), multi-faceted (*n* = 1), collapsed (*n* = 13), and crushed (*n* = 4) platforms. Only two of the platforms exhibit any obvious evidence of preparation and are abraded/crushed. The majority of the core flakes are whole (*n* = 31), with fewer proximal (*n* = 15), midsection (*n* = 3), and distal (*n* = 19) fragments. The biface flakes consist of whole (*n* = 2), proximal (*n* = 3), midsection (*n* = 1), and distal (*n* = 2) fragments. The whole core flakes have a mean length of 25.3 mm (*std* = 7.9), the whole biface flakes a mean length of 44.0 (*std* = 5.6), and the angular debris a mean weight of 3.4 g (*std* = 2.5).

The retouched tools consist of an endscraper, two biface fragments, and a projectile point. The endscraper and the projectile point are depicted in Figure 34.14.

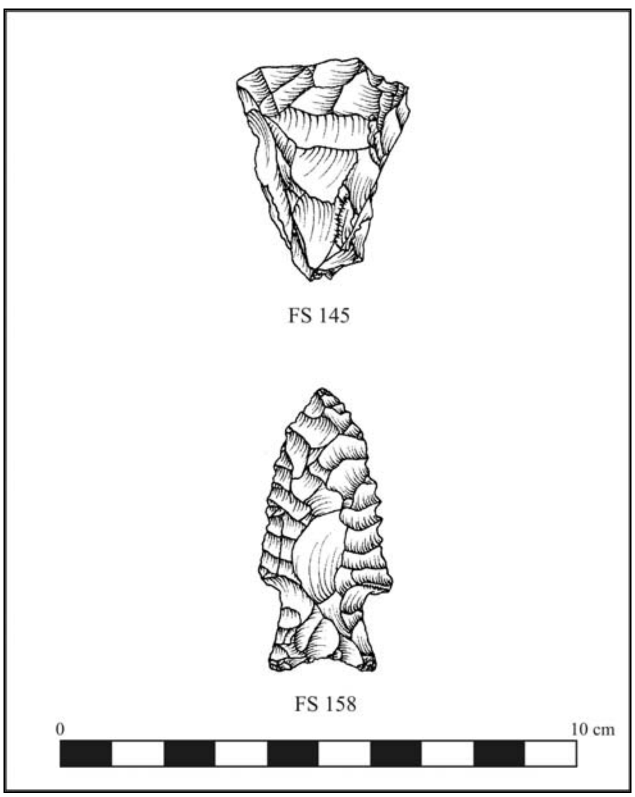

Figure 34.14. Endscraper (top) and San Jose dart point (bottom).

The endscraper is a flake that has been retouched along three edges, creating a steep-angled (80 degrees), triangular-shaped tool with a convex working edge. The two biface fragments consist of a midsection and an undetermined fragment that broke during the early-middle stage of the reduction process. The projectile point is a whole San Jose style dart point. Metrical and descriptive information on the projectile point is presented in Table 34.19.

Table 34.19. Projectile point metrical (mm) and descriptive data.

FS #	Material	Condition	Overall Length	Blade Length	Neck Width	Stem Length	Stem Width	Thickness	Weight (g)	Haft Type	Blade Shape	Base Shape
158	Basalt (Dacite)	Whole	54	38	15	16	20	6	8.9	Stemmed	Serrated	Con-cave

Tool Use

None of the flakes or retouched pieces exhibit evidence of edge damage that could be attributed to use. The ground stone includes manos, a millingstone, and an axe. The manos are both fire-cracked quartzite cobbles with a single flat surface that is heavily ground. The millingstone is a tabular piece of dacite with some grinding on one surface. The axe appears to have a refurbished bit that had originally broken off and was subsequently resharpened along one face (Figure 34.15).

The area around the bit also exhibits evidence of rounding, scarring, and use-striations. The surface of the axe has been well ground and polished with numerous striations along the long axis of the tool. It is notched with a shallow-pecked central groove. The butt also exhibits heavy use with battering wear.

Faunal Remains (Kari Schmidt)

Four pieces of bone were recovered during excavations of this Early/Middle Classic period fieldhouse. One bone was recovered in 104N/106E and was identified as a fragment of a mule deer (*Odocoileus hemionus*) atlas vertebra. Three bones were identified in 105N/106E and were all identified as part of a mule deer sacrum. None of the bones were burned and the pieces of the sacrum all contained recent breaks suggesting these bones may have come from a single animal.

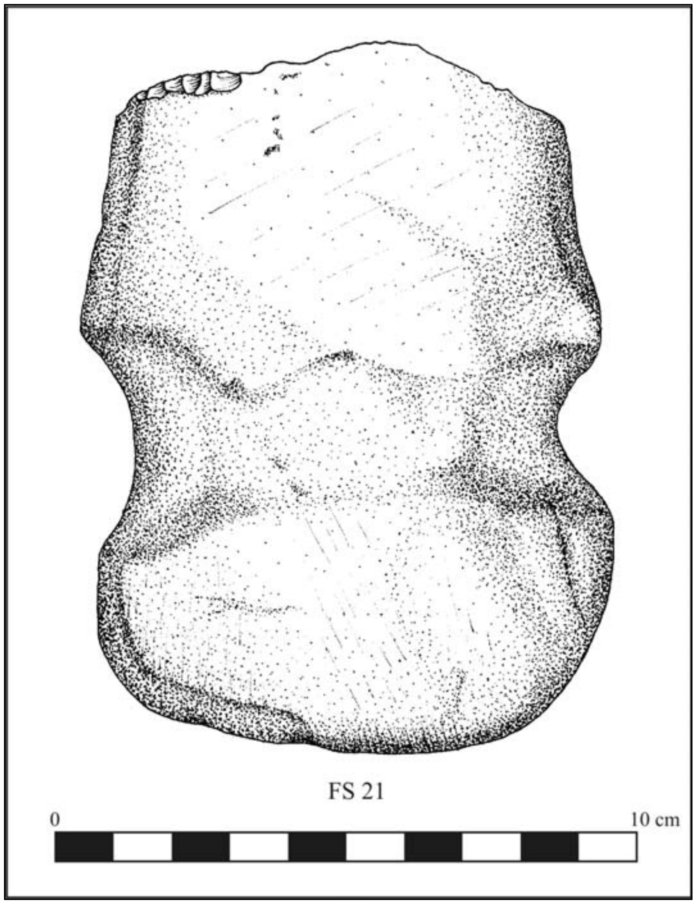

Figure 34.15. Axe from LA 85411.

Archaeobotanical Remains (Pamela McBride)

Tobacco was found in the small pit hearth (Feature 2) in Room 2 along with pigweed and purslane seeds (in upper and middle fill) and the ever present conifer needles and cone fragments (Table 34.20). Unlike the hearth in Room 2, it was only the lower fill of the Feature 1 hearth in Room 1 that yielded floral remains unrelated to wood use (maize and one goosefoot seed). Ponderosa pine and mountain mahogany were the two most frequently encountered wood taxa (Table 34.21). Unknown conifer, pine, and oak were also present. A single vegetal sample from post-occupational fill just outside Room 1 contained a pine umbo and six pieces of ponderosa pine weighing a tenth of a gram.

Pollen Remains (Susan Smith)

Seven pollen samples were analyzed from LA 85411. Table 34.22 lists the frequency of identified pollen types. Squash and maize were the only cultigens identified in the botanical assemblage, and each were found in only one sample. Sedge and lily family were the only other economic resources that were identified. A number of potential economic resources were also identified in the assemblage (Table 34.22), and these are discussed in detail in Smith's chapter in Volume 3.

SUMMARY

LA 85411 is a two-room Early/Middle Classic period fieldhouse that was constructed from both shaped and unshaped tuff blocks. Two internal hearths were identified at the site, and the ceramic assemblage and chronometric dates indicate a probable 14th century occupation. The site is located on a ridge north of Rendija Canyon. The presence of two rooms with internal hearths indicates that the site was occupied for extended period(s) of time, possibly during the winter. The presence of maize kernels, with maize and squash pollen indicates that the site was also occupied during the growing season.

CHAPTER 35
RENDIJA TRACT (A-14): LA 85413

Gregory D. Lockard

INTRODUCTION

LA 85413 is the remains of a small Early Classic period structure located on a south-facing slope on the mesa between Rendija and Guaje canyons. The site is located in the northeast corner of the Rendija Tract, a few tens of m north of a two-track dirt road. Vegetation on the site consists of piñon-juniper woodland with a grass understory. The site is situated at an elevation of 2109 m (6920 ft).

LA 85413 was first recorded on August 16, 1991, by David Hill (1991) during a survey for the Bason Land Exchange Project. Hill believed the site was a two-room fieldhouse. Surface Biscuit A, Glaze-on-Red, and Glaze Polychrome sherds indicated that the site was most likely occupied during the Early Classic period (AD 1325–1600). On July 20, 1992, Archaeological Research, Inc., was awarded the contract to conduct archaeological testing of the Bason Land Exchange sites. John Peterson and Christian Nightengale (1993) supervised the excavations, which took place between July 27 and August 23 of 1992. Two 1- by 1-m test pits (Units A and B) were excavated at LA 85413. Units A and B were both excavated to a maximum depth of 60 cm below the ground surface. No floor or other features were encountered during the excavation of the units.

Artifacts recovered during the excavation of the units and a surface collection of the site include 37 pieces of chipped stone and 57 ceramic sherds (29 Biscuit A sherds, 11 smeared-indented sherds, five small Black-on-red sherds that could be Glaze A, three sherds tentatively identified as Wiyo Black-on-white, four decorated sherds too badly eroded to identify, and five utilityware sherds). In addition to the excavations and surface collection, Peterson and Nightengale documented two small rock alignments (designated Features 2 and 3) at the site that they interpreted as check dams. The check dams are located approximately 16 m northeast of the structure. Feature 2 measures 1.5 m and Feature 3 measures 2 m in length.

FIELD METHODS

Before excavation, the site and surrounding area were cleared of trees and large undergrowth. The site was then visible as a mound of rubble measuring approximately 5 by 7 m in area. The northern half of the rubble mound contained clearly definable rock alignments that appeared to be the remains of a small, rectangular room (Figure 35.1). Immediately to the south, there was a wider, less clearly defined rock alignment that extended southward and terminated at an amorphous concentration of rocks that extended a few m to the east. Hill (1991) and Peterson and Nightengale (1993) believed that the rocks in this southern area were the remains of a second room. An arbitrary site datum (designated 100N/100E, 10.00 m elevation) was set up in the southwest corner of the site. The site was then covered with a 1- by 1-m grid that extended 9 m north and 8 m east of the site datum. Three subdata (A-C) were set up for taking elevations. The site was then photographed. Artifacts visible on the surface were collected by grid unit.

Figure 35.1. Pre-excavation photograph of the mound at LA 85413.

An 8- by 1-m east-west trench was initially excavated across the room (designated Room 1) in the northern half of the rubble mound (grids 106N/100-107E). The purpose of this trench was to expose a profile of the site stratigraphy, as well as to determine the location of the room's east and west walls. Units were excavated by strata, and thicker strata were excavated in arbitrary 10-cm levels. A fairly large patch of burned floor was encountered in the east corner of the room in unit 106N/105E. In the grid units to the west, the room's living surface took the form of a compact surface relatively devoid of rocks. Within the structure, the trench units were excavated to the floor or compact living surface.

Outside of the structure, the trench units were excavated to the top of a sterile layer of weathered Cerro Toledo bedrock. The easternmost unit in the trench (unit 106N/107E) was chosen to serve as a test pit for geological analysis and was therefore excavated to intact bedrock. Ultimately, however, the profiles of other areas were chosen for geological analysis (see below). The northern profile of the trench was then drawn and photographed. The rest of the site was subsequently excavated, again by strata and arbitrary levels for thicker strata. In all, 44 units were excavated. Within the structure, excavation proceeded to the floor or compact living surface encountered while excavating the trench. Outside of the structure, excavation terminated at the top of the sterile layer of weathered bedrock in the northern portion and the top of a Btk1b1 horizon in the southern portion of the excavated area.

Excavation focused on defining the structure's walls, removing wallfall, and locating features. During the excavation of the area to the south of Room 1, no convincing walls or other features were defined. The rock alignment and concentration visible on the surface appear to have been natural, or at the very least non-structural and of unknown function. Soil samples were taken from select locations, and all other soil was passed through screens with 1/8-in. mesh to aid in the recovery of artifacts. The excavation area extended at least 1 m beyond the structure in all directions to locate external features and/or outdoor activity areas. The site was then photographed (Figure 35.2) and mapped (Figure 35.3).

The excavation of the site was supervised by Greg Lockard. The field crew included Michael Dilley, Alan Madsen, Brian Harmon, Joseph (Woody) Aguilar, Bettina Kuru'es, Kevin Hanselka, Brandon Gabler, Margaret Dew, and Samuel Duwe. Timothy Martinez and Aaron Gonzalez served as site monitors from San Ildefonso Pueblo and as screeners. Jeremy Yepa was the site monitor representing Santa Clara Pueblo, as well as an additional excavator.

Figure 35.2. Post-excavation photograph of LA 85413.

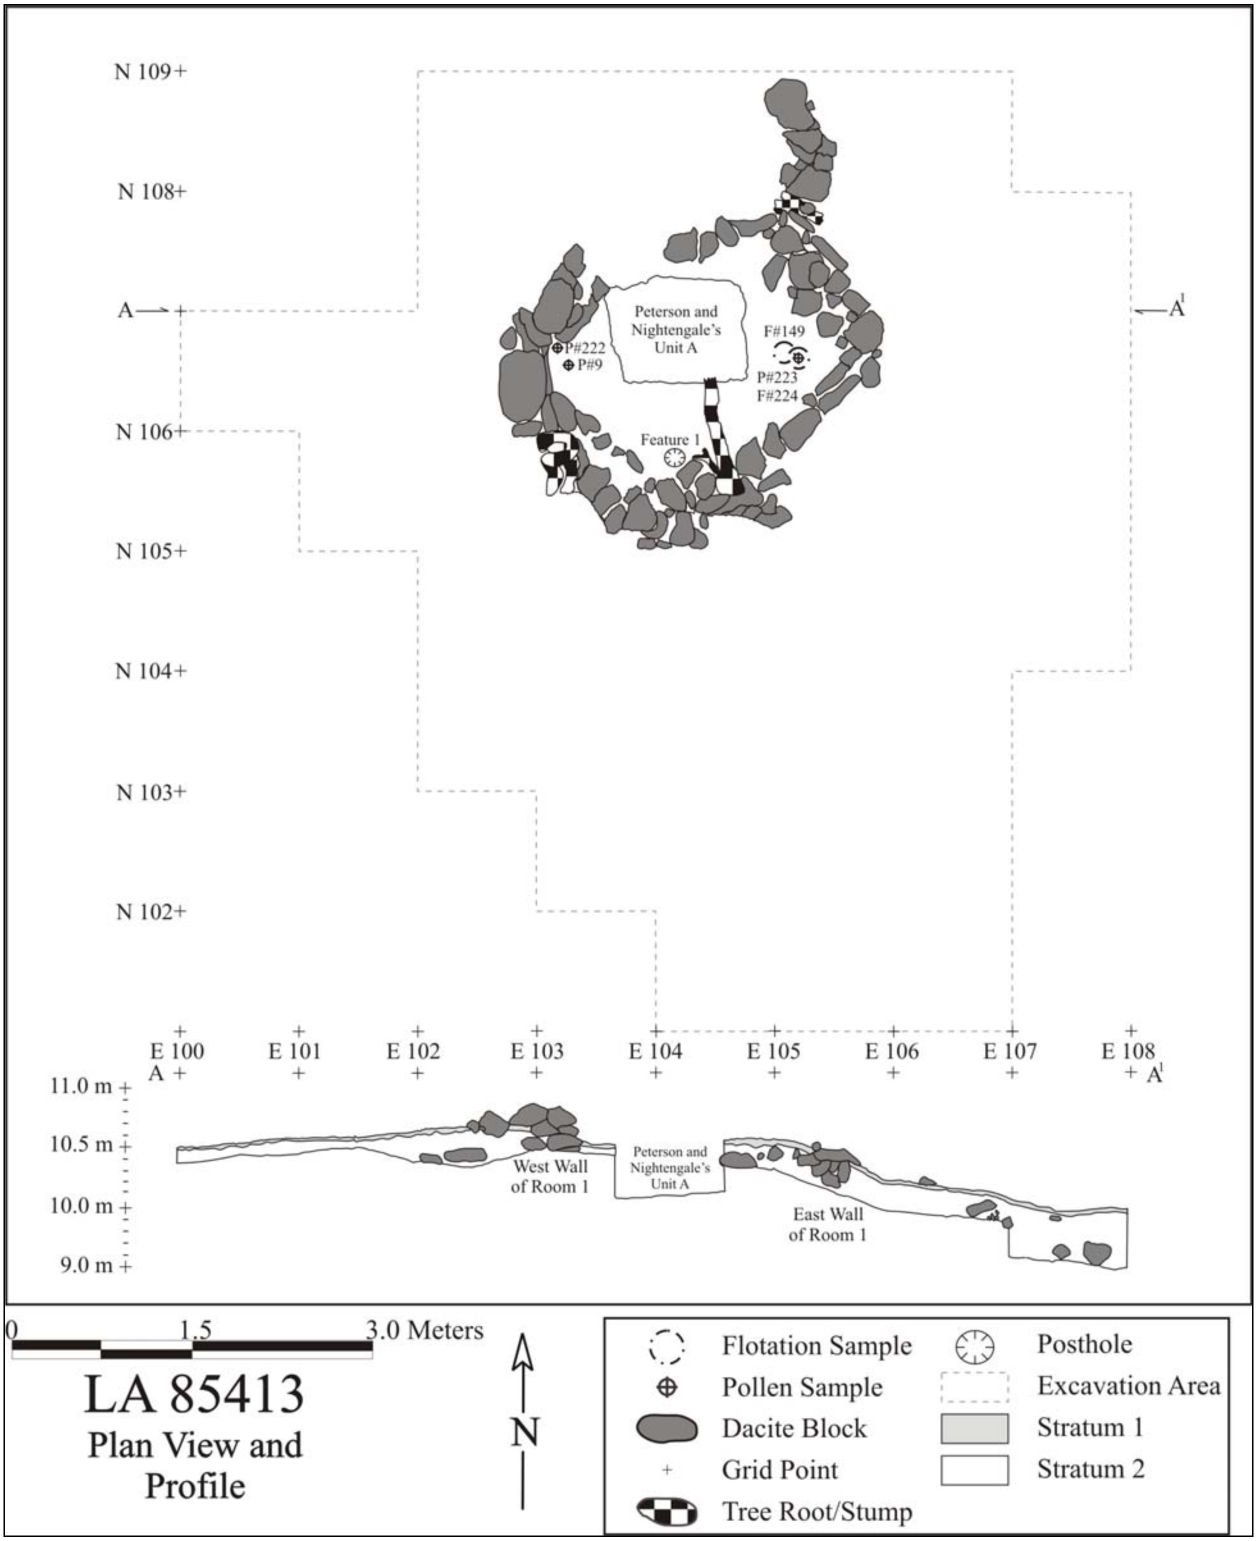

Figure 35.3. Plan view and profile of LA 85413.

STRATIGRAPHY

Stratum 1 is composed of loose, surface sediment. It is uniformly two to six cm thick across the site and is part of the A horizon (topsoil). Stratum 2 is post-occupational fill and ranges from 10 to 40 cm in thickness in the area excavated. This fill was thickest in and around the collapsed walls of the structure and thinned away from the walls and towards the center of the room. It was also considerably thicker in the downhill (i.e., southern) half of the site. Stratum 2 is more or less equivalent to the Bw horizon. Stratum 3 is weathered Cerro Toledo bedrock excavated in the grid unit originally chosen for geological analysis (106N/107E). Stratum 4 is the backfill removed from the test pits excavated by Peterson and Nightengale. Stratum 4 is therefore a disturbed context. Stratum 5 is the Room 1 floor/living surface, and Stratum 6 is the fill removed from Feature 1 (posthole). Tables 35.1 through 35.4 summarize and describe the strata excavated at the site.

Table 35.1. LA 85413 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10YR 3/3	Loamy sand	2–6	Surface sediment
2	10YR 4/4	Sandy loam	10–40	Post-occupational fill

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is a small structure that probably functioned as a fieldhouse. The fieldhouse is roughly rectangular in shape. The room measures 2.30 m in length (northeast to southwest) by 1.83 m in width (northwest to southeast), with approximately 4.21 m^2 of interior space. Excavation of the room began with an east-west trench that extended across the site (units 106N/100-107E). The excavation of this trench served to define the room's stratigraphy, as well as to locate the walls that formed the east and west corners of the room. A large patch of burned floor was encountered in the east corner of the room. To the west, the room's living surface took the form of a compact surface relatively devoid of rocks. After the excavation of the trench, the rest of the room was excavated to the floor or compact living surface encountered in the trench. One of the test pits excavated by Peterson and Nightengale (Unit A) is located completely within the northern half of the room. The backfill within this test pit was removed as a separate stratum (Stratum 4). Unit A was excavated to intact Cerro Toledo bedrock. An examination of the pit's profile indicated that there were no floors or living surfaces below the floor discussed above. After the excavation of the site was complete, the room was mapped, photographed, and documented.

Fill. The interior of Room 1 was filled with 2 to 6 cm of surface sediment on top of 20 to 35 cm of post-occupational fill. The fill was thickest in and around the room's collapsed walls and thinned away from the walls and towards the center of the room. Flotation (Field Specimen [FS] 119) and pollen (FS 120) samples were taken of the Room 1 fill, but were not analyzed.

Floor. A large patch of burned floor was encountered in the east corner of the room. The floor was composed of a thin layer of clay. In the rest of the room, the living surface took the form of a compact surface relatively devoid of rocks. This surface was presumably the foundation upon which the clay floor was constructed. Throughout the room, the living surface (including the patch of floor) had been disturbed by tree roots. The source of these roots included two trees that were growing within the Room 1 walls before being cut done shortly before the excavation of the site. The living surface was particularly disturbed in the northernmost portion of the room. In fact, no compact surface at all was encountered in this area. The Room 1 living surface was associated with a single feature. This feature, designated Feature 1, was a probable posthole (see below).

A pollen sample (FS 9) and a flotation sample (FS 10) were taken from beneath a rock near the level of the floor. The flotation sample was not analyzed, but taxa identified in the pollen sample included maize, cheno-ams, sunflower family, ragweed/bursage, fir, unidentified pine, piñon pine, juniper, and sagebrush. A flotation sample (FS 149) was also taken of a concentration of ash and charcoal on top of the burned floor in the east corner of the room. Carbonized taxa identified in this sample included maize, mountain mahogany, unidentified pine, piñon pine, and ponderosa pine. In addition, a pollen sample (FS 223) was taken of sediment that was scraped from the burned floor surface, and a flotation sample (FS 224) was taken of the burned floor matrix. Taxa identified in the pollen sample included beeweed, prickly pear, buckwheat, grass family, walnut, cheno-ams, sunflower family, ragweed/bursage, spurge family, spruce, unidentified pine, piñon pine, juniper, oak, and sagebrush. Charred taxa identified in the flotation sample included goosefoot, mountain mahogany, unknown conifer, piñon pine, oak, and ponderosa pine. Finally, a pollen sample (FS 222) was taken from directly on top of a fairly well-conserved patch of living surface in the west corner of the room. Taxa identified in this sample include beeweed, grass family, cheno-ams, sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush.

Wall Construction. The extant portions of the Room 1 walls indicate that the wall foundations were composed of unshaped dacite cobbles and a few upright slabs. These rocks appear to have been placed directly on top of the Bw horizon. Unlike at most of the other Rendija Canyon fieldhouses excavated during the Conveyance and Transfer Project, the wall foundations do not appear to have been placed in a trench. In some places, the wall was composed of a single row of large rocks. In other places, the wall was composed of two rows of upright slabs or two to three rows of small cobbles (Table 35.5). There is a short rock alignment that extends north from the room's north corner. This alignment may have been a short auxiliary wall. If this is the case, the function of the wall is unknown. There is a break of approximately 56 cm in the northwest wall. This may have been the room's entryway. This area of the site, however, has been significantly disturbed by several large roots. Two trees growing within the room's walls were cut down just before the site was excavated. One of these is located in the room's southwest wall, and the other is located in the southwestern half of the southeast wall (see Figure 35.2). The stumps and roots of these trees have contributed to the overall poor state of preservation of the Room 1 walls.

An alignment of rocks extending southward from the room's south corner was visible on the surface before the site was excavated. This alignment terminated to the south at an amorphous concentration of rocks that extended to the east. Originally, the alignment and concentration of rocks were believed to be the remains of a second room. Excavation of this area of the site, however, failed to reveal any clearly definable walls. If the rock alignment is cultural, it most likely took the form of a linear mound of rocks. The rock concentration to the south is most likely natural. Excavation revealed that the rock concentration is located within a prehistoric gully. The gully, which originally ran from the northwest to the southeast, has been filled in with small to medium-sized rocks and colluvial sediment.

Judging from the amount of wallfall removed during the excavation of the area in and around Room 1, the room's masonry was originally considerably higher than it was at the time of excavation. Due to the substantial number of rocks removed from the alignment and concentration to the south of the room, which could not be distinguished from wallfall, the original height of the room's masonry could not be estimated with any degree of certainty. For this reason, the volume of wallfall removed during the excavation of LA 85413 was not calculated. The uppermost portions of the walls, as well as the ceiling, were most likely composed of wattle and daub. These materials are rarely preserved at archaeological sites on the Pajarito Plateau. In fact, no adobe was recovered from the site.

Table 35.5. LA 85413 Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
Northwest	1.50 (2.06)	0.04–0.07	0.08–0.32	1
Southeast	1.80	0.11–0.33	0.14–0.65	1 to 3
Northeast	1.30	0.26–0.42	0.21–0.53	1 to 2
Southwest	1.30	0.23–0.43	0.23–0.46	1 to 3

Note: The length of the northwest wall including the possible entryway is given in parentheses.

Feature 1

Feature 1 is a small posthole located just inside the southeast wall in the southernmost portion of the room. The compactness of the base and interior walls of the hole, as well as its verticality and circular shape, preclude the possibility of it being caused by a root and make it unlikely that it was created by an animal. The posthole measured 9 by 8 cm in area and was 10 cm deep. A pollen sample (FS 158) was taken of the fill removed from the posthole, but it was not analyzed.

Geological Analysis

The grid unit originally chosen for geological analysis (106N/107E) was excavated below the surface of the layer of weathered Cerro Toledo bedrock encountered in the northern portion of the site. The excavation proceeded only a few cm before intact Cerro Toledo bedrock was encountered. No artifacts were encountered in this level of the unit. Ultimately, the exposed profiles in this unit were not chosen for geological analysis. Instead, geologists Paul Drakos and Steven Reneau analyzed two different profiles. The first was the east profile of grid unit 101N/106E (see Table 35.2). This profile contained a soil sequence consisting of an A horizon (topsoil), a Bw horizon (a late-Holocene soil), and two Btkb1 horizons (late-Pleistocene soils). The second profile that was examined was below the exterior face of the northeast wall of Room 1 (within unit 107N/105E) (see Table 35.3). This profile contained a soil sequence consisting of an A horizon (topsoil), a Bw horizon (a late-Holocene soil), and a Rk horizon (weathered Cerro Toledo bedrock).

Artifact Distribution

As Table 35.6 demonstrates, an increasingly higher number of artifacts were recovered from grid units to the south and east within the excavated area. This pattern is almost certainly due to site formation processes, as the natural hillside slopes downward in this direction. The only deviation from this pattern is the 109 artifacts recovered from unit 105N/106E. This is by far the highest number of artifacts recovered from any unit. Of the 109 artifacts, however, 104 are sherds recovered from Stratum 2. Most of these sherds are of the same type and were concentrated in a single location. They therefore most likely represent a pot drop or the fragmentation of a very large sherd.

Table 35.6. LA 85413 artifact counts by grid unit.

	E100	E101	E102	E103	E104	E105	E106	E107

N104	--	--	4	11	21	20	38	18
N103	--	--	2	18	28	28	43	--
N102	--	--	--	9	27	29	31	--
N101	--	--	--	--	17	25	38	--

Note: Does not include eight artifacts recovered from the surface of unexcavated grid units and four unprovenienced artifacts recovered while cleaning the site for photographs; bold numbers indicate grid units that are located completely or partially within Room 1.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 740 artifacts were analyzed from the excavations conducted at LA 85413. In addition, flotation and pollen samples were selected for analysis from the post-occupation fill (Stratum 2) and the Room 1 living surface (Stratum 5) (Table 35.7). The results of the artifact and sample analyzes are presented in the following sections.

Table 35.7. Samples selected for analysis from LA 85413.

Ceramic Artifacts (Dean Wilson)

A total of 494 ceramics were analyzed from LA 85413. The majority of the pottery consists of Sapawe Micaceous and Biscuit A (Table 35.8) types. These types, in addition to the Cieneguilla Glaze-on-yellow sherd, would seem to indicate an Early Classic period (14th century) occupation. Information on ceramic tradition by ware, temper by ware, and vessel form by ware are provided in Tables 35.9 to 35.11. The graywares and whitewares appear to have been locally made from tuff temper; however, the glazeware and micaceous pottery are made from non-local tempers. All of the grayware and micaceous ceramics consist of jar vessel forms while the whiteware and glazeware sherds were derived solely from bowls.

Table 35.8. Ceramic types from LA 85413.

Ceramic Type	Frequency	Percent

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 246 artifacts were analyzed from LA 85413. The assemblage consists of nine cores, 224 pieces of debitage, one retouched tool, 11 ground stone artifacts, and a hammerstone. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 35.12 presents the data on lithic artifact type by material type. The debitage is primarily made of chalcedony, with less Pedernal chert, obsidian, and other materials. The presence of cortex on 36.6 percent of the debitage indicates that these materials were collected from waterworn (n = 62) and nodule (n = 20) sources. The chalcedony, Pedernal chert, quartzite, and silicified wood are available from local Rio Grande Valley gravels and the obsidian from nearby sources in the Jemez Mountains. Nodule cortex is solely present on obsidian artifacts. The igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the plateau.

Seven pieces of debitage, a core, and two tested pebbles were submitted for X-ray fluorescence analysis. The obsidian artifacts are made solely from Cerro Toledo obsidian (Table 35.13). The Cerro Toledo (Obsidian Ridge/Rabbit Mountain) source area is located about 19 km (12 mi). Although obsidian is present at these nearby sources in the Jemez Mountains, it is also present in the area of the site as small pebbles. These pebbles compose part of the secondary deposits associated with the Cerro Toledo interval and are scattered across the mesa top. Indeed, two tested pebbles and an obsidian pebble core are probably derived from this local source.

Lithic Reduction

Five cores, one cobble uniface, and three tested pebbles were identified during the analysis. The cores were reduced using a single-directional, single face, a bidirectional, change-of-orientation, and a multi-directional opposed/90 degrees and opposed-same-and-different-face technique. Flakes were removed from an unprepared cortical platform on the cobble unifaces and tested pebbles (Figure 35.4). Two of the cores were discarded because they were broken along a material flaw and due to extensive stepping/hinging, while the other two were exhausted. Table 35.14 presents the metric information on the cores.

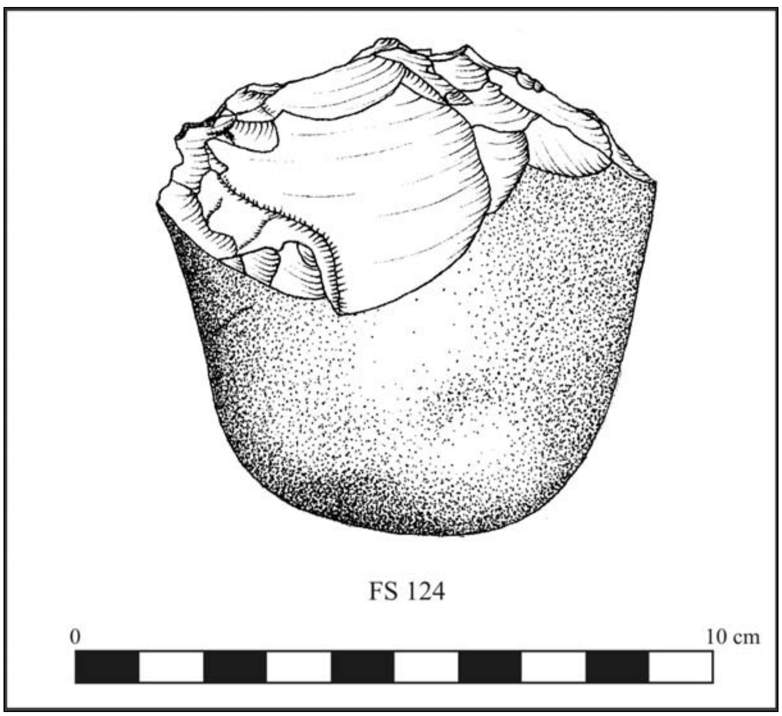

Figure 35.4. Cobble uniface from LA 85413.

Table 35.14. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Single-directional	21	26	24	15.3
Single-directional	37	71	65	198.9
Bi-directional	32	46	33	59.9
Multi-directional	68	50	43	140.3
Multi-directional	74	73	57	237.2
Cobble Uniface	60	82	80	464.2

The debitage consists primarily of core flakes with fewer angular debris, microdebitage, and other items. Table 35.15 summarizes the various stages of reduction represented by the whole core flakes. The debitage assemblage is composed primarily of secondary non-cortical, with less secondary cortical and a few primary flakes. The overall cortical:non-cortical ratio of 0.77 reflects this slight emphasis on the later stages of core reduction. However, this varies by material type. Obsidian is primarily represented in the early stages of core reduction, presumably due to the use of locally available pebbles. In contrast, Pedernal chert is a mix of early- and late-stage reduction and chalcedony emphasizes the late stage of core reduction.

Table 35.15. Debitage reduction stages.

Material	Primary	Secondary Cortical	Secondary Non-cortical	Tertiary	Cortical: Non-cortical ratio
Basalt	0	0	1	0	---
Obsidian	3	6	2	0	4.5
Chalcedony	0	12	25	0	0.48
Pedernal chert	0	10	12	0	0.83
Total	**3**	**28**	**40**	**0**	**0.77**
Percentage	4.2	39.4	56.3	0	---

The flakes mostly have single-faceted platforms (n = 56), with fewer cortical (n = 24), multi-faceted (n = 1), collapsed (n = 17), and crushed (n = 11) platforms. None of the platforms exhibit any obvious evidence of preparation. The majority of the core flakes are whole (n = 80), with fewer proximal (n = 29), midsection (n = 9), distal (n = 54), and undetermined (n = 1) fragments. The whole core flakes have a mean length of 29.3 mm (*std* = 11.9) and the angular debris a mean weight of 7.5 g (*std* = 8.5).

The retouched tools consist solely of a drill. The tool is a midsection fragment, bifacially retouched and with a diamond-shaped cross-section.

Tool Use

A single flake exhibits evidence of edge damage that could be attributed to use. This flake has a ground and polished area along the dorsal cortical surface of the artifact. It was presumably removed from a ground stone tool.

The ground stone includes manos, metates, polishing stones, abrading stones, and an axe. The manos are all the one-hand variety and consist of dacite and quartzite cobbles with one to two ground surfaces. One of these artifacts was also used as a hammerstone. The millingstone is a large piece of andesite with a single concave grinding surface, whereas, the undetermined metate consists of a broken tabular piece of dacite with a flat, heavily ground surface. The polishing stone is a dacite pebble that is polished over most of its surface. It also appears to exhibit some staining. In contrast, the abrading stone is an irregular-shaped dacite cobble with a single heavily polished edge and ground surface with unidirectional striations. The axe is a thin quartzite cobble fragment that was unifacially flaked along one lateral side and the ends. The other lateral side consists of a clean broken face (Figure 35.5). Each of the four edges of the artifact are notched so that it could be hafted. There is some rounding/scarring on the bit, but the item was probably resharpened. Several quartzite flakes were observed in the site assemblage that could have been removed from the artifact during shaping and/or resharpening. Lastly, the undetermined ground stone item is a small fragment of dacite with a ground surface that might represent a broken mano.

Figure 35.5. Axe from LA 85413.

Faunal Remains (Kari Schmidt)

Twelve pieces of bone were recovered during excavations of this Classic period fieldhouse. The majority of the bones were recovered in Stratum 2 (post-occupational fill), but two bones were identified in Stratum 5, which was the living surface identified in the fieldhouse. The bones identified on the living surface were unidentified to the level of class and were both heavily calcined. The bones identified in Stratum 2 included two pocket gopher (*Thomomys* sp.) elements (right humerus, left mandible), five mule deer (*Odocoileus hemionus*) bones, one small/medium-sized mammal remain, one medium/large-sized mammal remain, and one unidentified remain. The mule deer elements included three rib fragments, one right calcaneus, and one right astragalus. None of the bones were burned.

Archaeobotanical Remains (Pamela McBride)

Cultural plant remains consisted of one goosefoot seed and one possible maize cupule fragment (Table 35.16). Charred and partially charred plant part fragments were not identified and conifer needles are probably a product of firewood use. Wood charcoal was primarily mountain mahogany and pine with piñon, ponderosa pine, oak, and unknown conifer occurring in smaller numbers (Table 35.17).

Pollen Remains (Susan Smith)

Four pollen samples were analyzed from LA 85413. Table 35.18 lists the frequency of identified pollen types. Maize was the only cultigen identified in the botanical assemblage and was found in only one sample. Prickly pear and beeweed were the only economic resources that were identified in the assemblage. A number of potential economic resources were also identified in the assemblage (Table 35.18), and these are discussed in detail in Smith's chapter in Volume 3.

SUMMARY

LA 85413 is a one-room Early Classic period fieldhouse that was constructed from both shaped and unshaped tuff blocks. A single feature (a posthole) was identified at the site. The site is situated on the mesa north of Rendija Canyon and just south of Guaje Canyon. The presence of maize cupules and pollen indicates that the one-room structure was presumably occupied during the growing season.

CHAPTER 36
RENDIJA TRACT (A-14): LA 85414

Gregory D. Lockard

INTRODUCTION

LA 85414 is the remains of a small Middle Classic period structure located on a southeast-facing ridge slope on the mesa between Rendija and Guaje canyons. The site is located in the far northeast corner of the Rendija Tract, approximately 30 m north of a two-track dirt road. Vegetation on the site consists of piñon-juniper woodland with a grass understory. The site is situated at an elevation of 2109 m (6920 ft).

LA 85414 was first recorded on August 16, 1991, by David Hill (1991) during a survey for the Bason Land Exchange Project. Hill believed that the site was a one-room fieldhouse. Two chalcedony flakes were the only artifacts noted on the surface. On July 20, 1992, Archaeological Research, Inc., was awarded the contract to conduct archaeological testing of the Bason Land Exchange sites. John Peterson and Christian Nightengale (1993) supervised the excavations, which took place between July 27 and August 23 of 1992. Two 1- by 1-m test pits (Units A and B) were excavated at LA 85414. Unit A was located in the center of the rubble mound, and Unit B was located just west of the mound. Units A and B were excavated to a maximum depth of 62 and 20 cm below the ground surface, respectively. No clear rock alignments or living surfaces were encountered in either unit. Artifacts recovered during the excavation of the units and a surface collection of the site include 16 pieces of chipped stone and 11 ceramic sherds (nine smeared-indented sherds, one plain brownware body sherd, and two other utilityware sherds).

FIELD METHODS

Before excavation, the site and surrounding area were cleared of trees and large undergrowth. The site was then visible as a mound of rubble measuring approximately 5 by 4 m in area (Figure 36.1). An arbitrary site datum (designated 100N/100E, 10.00 m elevation) was set up in the southwest corner of the site. The site was then covered with a 1- by 1-m grid that extended five m north and eight m east of the site datum. Two subdata (A and B) were set up for taking elevations. The site was then photographed. Artifacts visible on the surface were collected by grid unit. A 6- by 1-m east-west trench (102N/102-107E) was initially excavated across the remains of the one-room structure, which was designated Room 1. The purpose of this trench was to expose a profile of the site stratigraphy, as well as to determine the location of the room's east and west walls. Units were excavated by strata, and thicker strata were excavated in arbitrary 10-cm levels.

Much of Peterson and Nightengale's Unit A was located within unit 102N/105E. The eastern edge of three aligned rocks that were most likely part of the room's west wall (see below) formed the western border of Unit A. The unit extends eastward across much of the narrow room. Unit A was excavated to bedrock. The room's living surface was therefore only encountered in thin strips just north of Unit A (the northernmost portion of grid unit 102N/105E) and just inside the room's east wall (the westernmost portion of unit 102N/106E) during the excavation of the east-west trench. Outside of the room, the trench units were excavated to the top of a sterile Btb1 horizon. Peterson and Nightengale's Unit A was chosen to serve as a sub-floor test pit for geological analysis. The northern profile of the trench was then drawn and photographed. The rest of the site was subsequently excavated, again by strata and arbitrary levels for thicker strata. In all, 29 units were excavated. Within the structure, excavation terminated at the compact living surface encountered while excavating the trench.

Figure 36.1. Pre-excavation photograph of LA 85414.

Outside of the structure, excavation terminated at the top of the Btb1 horizon. Excavation focused on defining the structure's walls, removing wallfall, and locating features. Soil samples were taken from select locations, and all other soil was passed through screens with 1/8-in. mesh to aid in the recovery of artifacts. The excavation area extended at least 1 m beyond the structure in all directions to locate external features and/or outdoor activity areas. The site was then mapped (Figure 36.2) and photographed (Figure 36.3).

During the excavation of Area 1, an obsidian projectile point fragment was discovered in association with a small concentration of rocks. The rock concentration, which is located approximately 35 m southwest of Room 1, was designated Area 2. The Area 1 grid was extended to Area 2, and a 2- by 2-m grid was placed over the rock concentration. All four grid units (73-75N/82-84E) were then excavated. Excavation revealed that the rocks were superficial and did not form any clear pattern (Figure 36.4). In addition, very few artifacts were recovered from the excavations. As a result, it is highly unlikely that the rock concentration was a cultural feature.

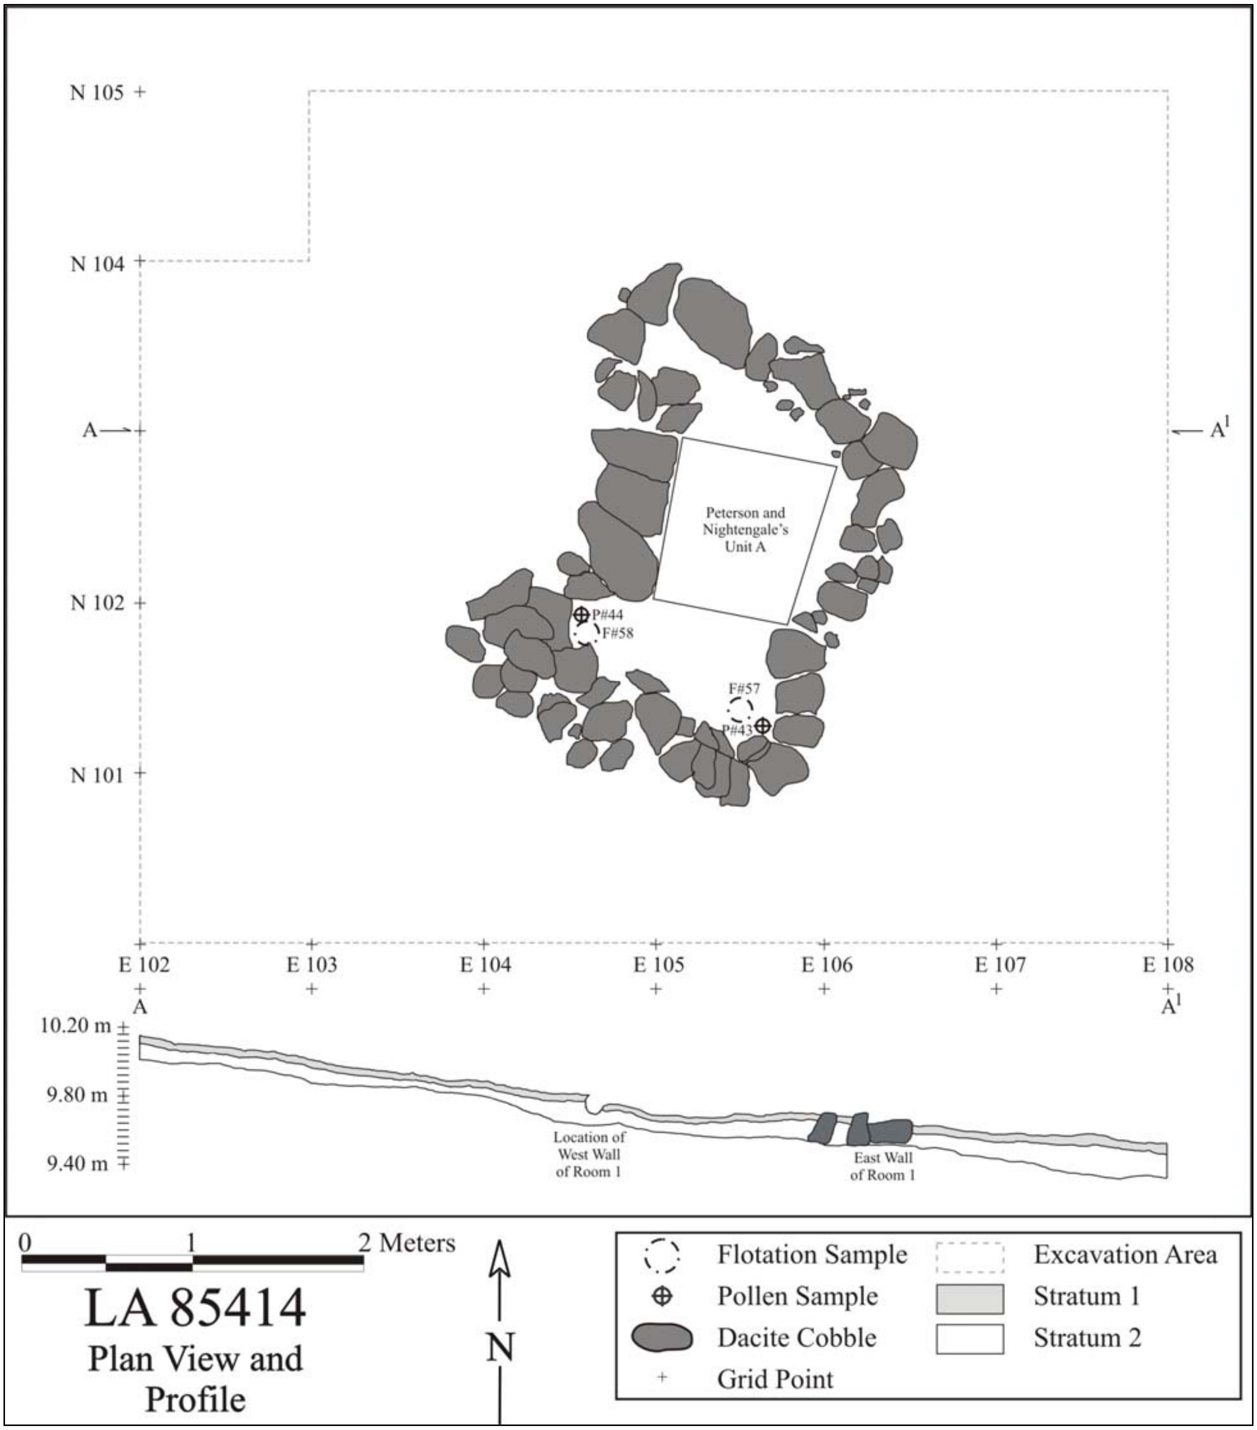

Figure 36.2. Plan view and profile of LA 85414.

Figure 36.3. Post-excavation photograph of the fieldhouse at LA 85414.

Figure 36.4. Area 2, a rock concentration located southwest of Room 1.

The excavation of the site was supervised by Greg Lockard. The field crew included Michael Dilley, Alan Madsen, Brian Harmon, Bettina Kuru'es, and Margaret Dew. Timothy Martinez and Aaron Gonzalez served as site monitors from San Ildefonso Pueblo and as screeners. Jeremy Yepa was the site monitor representing Santa Clara Pueblo, as well as an additional excavator.

STRATIGRAPHY

Stratum 1 is composed of loose, surface sediment. It is uniformly 2 to 6 cm thick across the site and is part of the A horizon (topsoil). Stratum 2 is post-occupational fill and ranges from 5 to 20 cm in thickness in Area 1 and 7 to 8 cm in Area 2. In Area 1, the post-occupational fill was thickest in and around the collapsed walls of the structure and thinned away from the walls and towards the center of the room. It was also considerably thicker in the downhill (i.e., eastern) half of the site. Stratum 2 is more or less equivalent to the Bw horizon. Stratum 3 is the backfill removed from Peterson and Nightengale's Unit A. Stratum 3 is therefore a disturbed context. Peterson and Nightengale's Unit B could not be located. Judging from their map of the site, however, it was most likely located within the excavated area. The back fill in this shallow (20 cm) excavation was therefore indistinguishable from the surrounding post-occupational fill, and therefore could not be excavated as a separate stratum. Stratum 4 is the Room 1 living surface. Tables 36.1 through 36.4 summarize and describe the strata excavated at the site.

Table 36.1. LA 85414 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10YR 5/3	Loamy sand	2–6	Surface sediment
2	10YR 5/3	Sandy loam	5–20	Post-occupational fill
3	10YR 5/3	Sandy loam	60	Backfill from P & N test pit
4	10YR 5/2	Clay loam	-	Room 1 living surface

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is a small structure that probably functioned as a fieldhouse. The fieldhouse is roughly rectangular in shape, although the west wall does appear to curve significantly inward (see below). Room 1 measures 2.05 m in length (north to south) by 1.40 m in width (east to west), with approximately 2.87 m^2 of interior space. Excavation of the room began with an east-west trench that extended across the rubble mound in Area 1 (102N/102-107E). The excavation of this trench served to define the room's stratigraphy, as well as to locate the room's east and west walls. Peterson and Nightengale's Unit A, which was excavated to bedrock, covers much of that portion of the trench that is within Room 1. As a result, the room's living surface was only encountered in thin strips to the north and east of Unit A during the excavation of the trench. An excavation of the test pit's profiles indicated that there were no additional floors or living surfaces below. After the excavation of the trench, the rest of the room was excavated down to the compact living surface encountered in the trench.

Fill. The interior of Room 1 was filled with 2 to 6 cm of surface sediment on top of 7 to 11 cm of post-occupational fill. The fill was thickest in and around the room's collapsed walls and thinned away from the walls and towards the center of the room. Flotation (Field Specimen [FS] 39) and pollen (FS 40) samples were taken of the Room 1 fill, but were not analyzed.

Floor. No prepared floor was encountered in Room 1. There is a compact surface just above the Btb1 horizon, however, that was most likely the room's living surface. This surface is relatively flat, devoid of rocks, and slightly stained in the area south of Peterson and Nightengale's Unit A. To the north of Unit A, there were several large rocks embedded in the presumed living surface. These rocks may be wallfall. The fact that they are deeply embedded in the presumed living surface and Btb1 horizon below, however, indicates that this may not be the case. The rocks do not present a discernible pattern. If they are not wallfall, their function is therefore unknown. The tops of the rocks may have been at floor level, in which case the floor was slightly higher than the excavated surface in this area of the room. A thin strip of living surface was encountered to the east of Unit A, which was poorly preserved.

Pollen samples were taken at the level of the presumed living surface in the northeast (FS 47), northwest (FS 42), southeast (FS 43), and southwest (FS 44) corners of the room. FS 43 and FS 44 were analyzed and identified taxa included grass family, sunflower family, ragweed/bursage, cheno-ams, spurge family, spruce, fir, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush. Flotation samples were taken of the fairly well-preserved living surface matrix in the southeast (FS 57) and southwest (FS 58) corners of the room. Carbonized taxa identified in these samples included unidentified pine and piñon pine.

Wall Construction. In general, the Room 1 walls were constructed of dacite cobbles of various sizes (Table 36.5). The people who constructed the walls do not appear to have selected for any particular size or shape of rock. The foundation of the walls was formed by placing dacite cobbles in a shallow trench dug into the Btb1 horizon, which is a late-Pleistocene soil. The north wall was composed of a single row of irregularly shaped dacite cobbles. One rock remained of the wall's second course. It was located in the westernmost portion of the wall. Small dacite cobbles were placed in the crevices between the wall's larger rocks. The south wall was a double wall of irregularly shaped dacite cobbles. The cobbles were also irregularly placed, which may indicate that the wall was partially disturbed. A few rocks of the second course remained in the westernmost portion of the wall. The east wall was only one course high and was largely composed of a single row of irregularly shaped dacite cobbles. These rocks tend to be rounder, however, than those of the other walls. The west wall was quite unusual. The northernmost 55 cm of the wall extended southward from the west end of the north wall.

Table 36.5. LA 85414 Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	1.45	0.10–0.30	0.25–0.35	1 to 2
South	1.40	0.08–0.42	0.26–0.53	1 to 2
East	1.72	0.08–0.15	0.20–0.35	1
West	1.65	0.14–0.22	0.20–0.50	1

Note: The west wall measurements include the large rocks in the central portion of the wall that are lower and offset to the east.

There was also a short section of the wall that extended northward from the west end of the south wall. In between were three very large rocks that extended down into the Btb1 horizon. The central of the three rocks was especially large and extended at least 10 cm into the Btb1 horizon. All three of the rocks extended eastward into the room. If the rocks were part of the east wall, the wall curved significantly inward, making the central portion of the room extremely narrow. For this reason, the rocks may instead have been a slightly raised platform or stair just inside the room's entryway. A small upright cobble extended from the southernmost of the three large rocks diagonally to the northern end of the west wall's south section. There were several cobbles that similarly extended from the northernmost of the three large rocks diagonally to the southern end of the west wall's north section. The location of these rocks suggests that the three large rocks were indeed *in situ*. If this is the case, the room was rectangular only if the three large rocks were part of an internal feature (i.e., a platform or stair just inside the room's entryway).

Judging from the amount of wallfall removed during the excavation of the area in and around Room 1, the room's masonry was originally considerably higher than it was at the time of excavation. In order to estimate the original height of the masonry, all of the rocks removed as wallfall during the site's excavation were placed in three stacks, which were then measured. The stacks measured 0.35 by 4.00 by 0.58 m, 0.65 by 1.20 by 0.70 m, and 0.35 by 2.7 by 0.50 m, for a total of approximately 1.83 m^3 of wallfall. Based on this volume of wallfall and the overall length, average thickness, and average height of the extant portions of the walls, the room's masonry was originally approximately 1.08 m in height. The uppermost portions of the walls, as well as the ceiling, were most likely composed of wattle and daub. These materials are rarely preserved at archaeological sites on the plateau. In fact, no adobe was recovered from the site.

Geological Analysis

Geologists Paul Drakos and Steven Reneau utilized two profiles to reconstruct the natural soil horizons at the site. The upper strata were described from the east profile of unit 103N/107E, and the lower strata were described from the east profile of Peterson and Nightengale's Unit A (within unit 102N/105E). The east profile of unit 103N/107E contained a soil sequence consisting of an A horizon (topsoil), a Bw horizon (a late-Holocene soil), a Btb1 horizon (a late-Pleistocene soil), and a R horizon (weathered Cerro Toledo bedrock). The east profile of Peterson and Nightengale's Unit A contained a soil sequence consisting of a Bw horizon, a Btb1 horizon, and a Rk horizon (Cerro Toledo bedrock).

Artifact Distribution

The number of artifacts encountered during the excavation of LA 85414 (*n* = 73) is small compared to other Rendija Canyon fieldhouses excavated during the Conveyance and Transfer Project. This may indicate that the site was occupied for only a short period of time. As Table 36.7 demonstrates, the number of artifacts in Area 1 increases slightly in grid units to the south and east. This artifact distribution is most likely the result of site formation processes, as the natural hillside surface slopes downward in this direction. No other patterns are discernible in the artifact distribution at the site. Only three artifacts were recovered from Area 2 (Table 36.8). This supports the conclusion that the concentration of rocks in the area was not a cultural feature.

Table 36.6. LA 85414, Area 1 artifact counts by grid unit.

	E102	E103	E104	E105	E106	E107

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 70 artifacts were analyzed from the excavations conducted at LA 85414. In addition, flotation and pollen samples were selected for analysis from the Room 1 living surface (Stratum 4) (Table 36.8). The results of the artifact and sample analyzes are presented in the following sections.

Table 36.8. Samples selected for analysis from LA 85414.

Ceramic Artifacts (Dean Wilson)

A total of 35 ceramics were analyzed from LA 85414. The majority of the pottery consists of Sapawe Micaceous, with Biscuit A, and glazeware sherds (Table 36.9). This would indicate a Middle Classic (14th century) occupation for the site. Information on ceramic tradition by ware, temper by ware, and vessel form by ware are provided in Tables 36.10 to 36.12. The graywares and whitewares appear to have been locally made from local tuff temper. This contrasts with the Sapawe Micaceous pottery that appears to have been derived from a non-local and local source. The former is represented by a micaceous temper and the latter by a tuff temper with a micaceous slip. All of the grayware, micaceous, and glazeware ceramics consist of jar vessel forms while the whiteware sherds were derived solely from bowls.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 35 artifacts were analyzed from LA 85414. The assemblage consists of 28 pieces of debitage, two retouched tools, four ground stone artifacts, and a hammerstone. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 36.13 presents the data on lithic artifact type by material type. The debitage is primarily made of chalcedony and Pedernal chert with less obsidian, silicified wood, and basalt materials. The presence of cortex on 14.2 percent of the debitage indicates that these materials were collected from waterworn (*n* = 4) sources. The chalcedony, Pedernal chert, and silicified wood are available from local Rio Grande Valley gravels and the obsidian from nearby sources in the Jemez Mountains. The igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the plateau.

Table 36.13. Lithic artifact type by material type.

Artifact Type		Material Type

Three pieces of obsidian debitage, a biface, and a projectile point, and a single basalt flake were submitted for X-ray fluorescence analysis. The obsidian artifacts are mostly made from Cerro

Toledo obsidian; however, the projectile point is made from the El Rechuelos source (Table 36.14). The Cerro Toledo (Obsidian Ridge/Rabbit Mountain) source area is located about 19 km (12 mi) as the "crow flies" to the west of the site. Although obsidian is present at these nearby sources in the Jemez Mountains, it is also present in the area of the site as small pebbles. These pebbles compose part of the secondary deposits associated with the Cerro Toledo interval and are scattered across the mesa top. The El Rechuelos (Polvadera Peak) source area is situated about 27 km (17 mi) northwest of the site. The single basalt flake is actually dacite, which is derived from the San Antonio Mountain area located approximately 115 km (70 mi) north of Rendija Canyon.

Table 36.14. Obsidian source samples.

FS #	Artifact	Color	Source
23	Debitage	Translucent	Cerro Toledo rhyolite
34	Projectile point	Black dusty	El Rechuelos
35	Debitage	Translucent	Cerro Toledo rhyolite
36	Biface	Translucent	Cerro Toledo rhyolite
55	Debitage	Translucent	Cerro Toledo rhyolite

Lithic Reduction

The debitage consists solely of core flakes and angular debris. The overall cortical:non-cortical ratio of 0.28 reflects a slight emphasis on the later stages of core reduction. The flakes mostly have single-faceted platforms (n = 5), with fewer collapsed (n = 4) and crushed (n = 11) platforms. None of the platforms exhibit any obvious evidence of preparation. The majority of the core flakes are distal fragments (n = 11), with fewer whole (n = 9), proximal (n = 1), midsection (n = 1), and undetermined (n = 1) fragments. The whole core flakes have a mean length of 34.5 mm (*std* = 10.3) and the angular debris a mean weight of 1.7 g (*std* = 1.2).

The retouched tools consist of a biface and projectile point. The biface is a proximal fragment with an edge angle of 60 degrees indicating that it was broken during the middle stage of the reduction process. The projectile point is a midsection fragment with a broken tip and base. It was manufactured on a flake and was only partially bifacially retouched. It could represent the broken remains of a corner-notched arrow point.

Tool Use

A single flake exhibits evidence of edge damage that could be attributed to use. This damage consists of some rounding and polish on a distal end with an edge angle of 70 degrees. The ground stone includes a mano, a millingstone, a grinding slab, and a grooved abrader. The mano is a one-hand variety made on a small dacite slab that exhibits a single well-used grinding surface. The millingstone is a large piece of dacite with a single concave-shaped grinding surface. In contrast, the grinding slab is a flat piece of andesite with a single, flat, heavily ground surface that also exhibits slight polish. The polished area includes striations that are oriented along a single direction. Lastly, the grooved abrader is a small dacite cobble with a natural indentation that appears to exhibit some wear along the groove.

Faunal Remains (Kari Schmidt)

One piece of bone was recovered during excavations of this Middle Classic period fieldhouse. The bone was recovered in 102N/105E and was identified as a fragment of the proximal metacarpal of a mule deer (*Odocoileus hemionus*). The bone was identified as a possible awl in the field, but closer inspection suggested that it was not an awl, but was simply shaped and polished. The bone was not burned.

Archaeobotanical Remains (Pamela McBride)

Piñon needles were the only non-wood plant material recovered from the fieldhouse and most likely relate to fuelwood use (Table 36.15). Wood charcoal was limited to five pieces of pine recovered from the southeast corner of the living surface.

+ 1-10/liter.

Pollen Remains (Susan Smith)

Only two pollen samples were analyzed from LA 85414. Table 36.16 lists the frequency of identified pollen types. No cultigens or other economic resources were identified in the assemblage. Other potential economic resources were identified in the assemblage (Table 36.16), and these are discussed in detail in Smith's chapter in Volume 3.

SUMMARY

LA 85414 is a one-room Middle Classic period fieldhouse that was constructed from both shaped and unshaped tuff blocks. The site is situated on a southeast-facing ridge slope on the mesa between Rendija and Guaje canyons. Although no evidence of cultigens was identified, the one-room structure was presumably occupied during the growing season when maize was being cultivated.

CHAPTER 37
RENDIJA TRACT (A-14): LA 85417

Gregory D. Lockard

INTRODUCTION

LA 85417 is a small Classic period site located on a south-facing ridge slope of the mesa between Rendija and Guaje canyons. The site is located near the southern boundary of the Rendija Tract. Vegetation on the site consists of piñon-juniper woodland with a grass understory. The site is situated at an elevation of 2091 m (6860 ft).

LA 85417 was first recorded on August 17, 1991, by David Hill (1991) during a survey for the Bason Land Exchange Project. According to Hill, the site consisted of a burned jacal structure with a rock foundation, two isolated sub-rectangular rooms, a hearth or burned rock midden, and two agricultural terraces. The jacal structure was associated with a few obsidian and chalcedony flakes, a few plain smooth brown sherds, and two indented corrugated sherds. A single black micaceous sherd was found between the two features interpreted as isolated sub-rectangular rooms. On July 20, 1992, Archaeological Research, Inc., was awarded the contract to conduct archaeological testing of the Bason Land Exchange sites. John Peterson and Christian Nightengale (1993) supervised the excavations, which took place between July 27 and August 23 of 1992.

Seven 1- by 1-m test pits (Units A-G) and one test pit extension (Unit E-Ex) were excavated at LA 85417. Unit A is located in the center and Unit B is located just west of the burned jacal structure, which they designated Feature 1. Unit A was excavated to a maximum depth of 41 cm. Several pieces of burned daub, many of which had wattle impressions, were recovered from the unit, as well as a chalcedony flake and a utilityware sherd. An elevated layer of clay was encountered in the unit's northeast quadrant, which was interpreted as a possible living surface. Unit B was excavated to a maximum depth of 30 cm. A high concentration of burned adobe fragments was encountered just below the surface. No additional artifacts were recovered.

Unit C is located in the concentration of rocks that Hill (1991) interpreted as a hearth or burned rock midden. This rock concentration was designated Feature 3. Unit C was excavated to a maximum depth of 30 cm. After the removal of surface rocks, a semi-circular rock alignment was exposed. Several pieces of partially burned wood were recovered during the excavation of the unit, and a charcoal-stained surface was encountered within the semi-circular rock alignment. Peterson and Nightengale (1993) argue that the feature was a hearth that post-dates the occupation of the burned jacal structure (i.e., Feature 1).

Unit D is located in one of the features that Hill (1991) interpreted as an isolated sub-rectangular room. The unit was excavated to a maximum depth of 40 cm. No artifacts were recovered from the excavation, and no rock alignments or cultural surfaces were encountered. Peterson and Nightengale (1993) argue that the feature may have been utilized for soil control.

Unit E is located in the other feature that Hill (1991) interpreted as an isolated sub-rectangular room. The unit was excavated to a maximum depth of 40 cm. Excavation revealed the feature to be the remains of a historic hearth, which was designated Feature 2. The hearth consisted of a firepit lined with small cobbles bounded by upright slabs and surrounded by an outer ring of rocks. Most of the hearth's interior was exposed during the excavation of Unit E. A 0.5- by 0.5-m extension (Unit E-Ex) was excavated to the east of the northern half of Unit E to investigate the extent and function of the outer ring of rocks around the firepit. Unit E-Ex was excavated to a maximum depth of 30 cm. The excavation revealed that the rocks did not continue to the east. Artifacts recovered from within the hearth include three plain gray utilityware sherds (possibly prehistoric), one glazed earthenware sherd, and numerous pieces of rusted metal (possibly the remains of food cans). No artifacts were found outside of the hearth.

Units F and G are located in the rock concentrations that Hill (1991) interpreted as agricultural terraces. These rock concentrations were designated Features 5 and 6. Unit F is located in Feature 5 and was excavated to a maximum depth of 40 cm. Unit G is located in Feature 6 and was excavated to a maximum depth of 35 cm. No cultural materials of any kind were found in either unit. Peterson and Nightengale (1993) argue that both features are probably check dams. In addition to the artifacts described above, five pieces of chalcedony debitage and 57 ceramics were recovered during a surface collection of the site. One of these was identified as a Wiyo Black-on-white sherd. The rest are utilityware sherds. Peterson and Nightengale (1993) argue that the research potential of Features 2 to 6 was exhausted by their excavations. For this reason, only Feature 1, which was re-designated Area 1, was excavated during the Conveyance and Transfer (C&T) Project.

FIELD METHODS

Before excavation, Area 1 was cleared of trees and large undergrowth (Figure 37.1). An arbitrary site datum (designated 100N/100E, 10.00 m elevation) was set up in the southwest corner of the area. The area was then covered with a 1- by 1-m grid that extended 7 m north and 8 m east of the site datum, and three subdata (A-C) were set up for taking elevations. The area was then photographed. Artifacts visible on the surface were then collect by grid unit. A 7- by 1-m east-west trench (units 103N/101-107E) was initially excavated across the remains of the structure, which was designated Room 1. The purpose of this trench was to expose a profile of the site stratigraphy, as well as to determine the location of the room's east and west walls. Units were excavated by strata, and thicker strata were excavated in arbitrary 10-cm levels.

A high quantity of wallfall was removed from the central grid units in the trench (103N/103-106E). This wallfall included rocks of various sizes, as well as countless pieces of burned adobe, many of which contained wattle impressions. All adobe fragments that were the size of a golf ball or larger were kept for analysis. The location of the room's east and west walls could not be determined with certainty until the foundation rocks were exposed. Above the foundation rocks were poorly defined rock alignments. These alignments were the partially disturbed remains of the room's walls. Part of the room's west wall and most of its entryway were encountered in unit 103N/104E. Part of the room's east wall and the entire south wall, excluding the entryway, were encountered in unit 103N/105E.

Figure 37.1. Pre-excavation photograph of LA 85417.

Several patches of a burned plaster floor were encountered in those portions of units 103N/104E and 103N/105E that were within Room 1. In those areas where the plaster floor was not preserved, the floor's foundation (a compact layer of clay-rich sediment) was encountered. Outside of the room, the trench units were excavated down to the top of a sterile Btb1 horizon. Peterson and Nightengale's Unit B occupies much of unit 103N/102E, as well as the east-central portion of unit 103N/101E. The backfill within this test pit was excavated as a separate stratum (Stratum 4). The northern profile of the trench was then drawn and photographed. The rest of the site was subsequently excavated, again by strata and arbitrary levels for thicker strata. In all, 32 units were excavated. Within the structure, excavation proceeded down to the plaster floor or floor foundation encountered while excavating the trench.

Outside of the structure, excavation proceeded down to the top of the Btb1 horizon. Excavation focused on defining the structure's walls, removing wallfall, and locating features. Soil samples were taken from select locations, and all other soil was passed through screens with 1/8-in. mesh to aid in the recovery of artifacts. The excavation area extended at least 1 m beyond the structure in all directions to locate external features and/or outdoor activity areas. The structure was then mapped (Figure 37.2) and photographed (Figure 37.3).

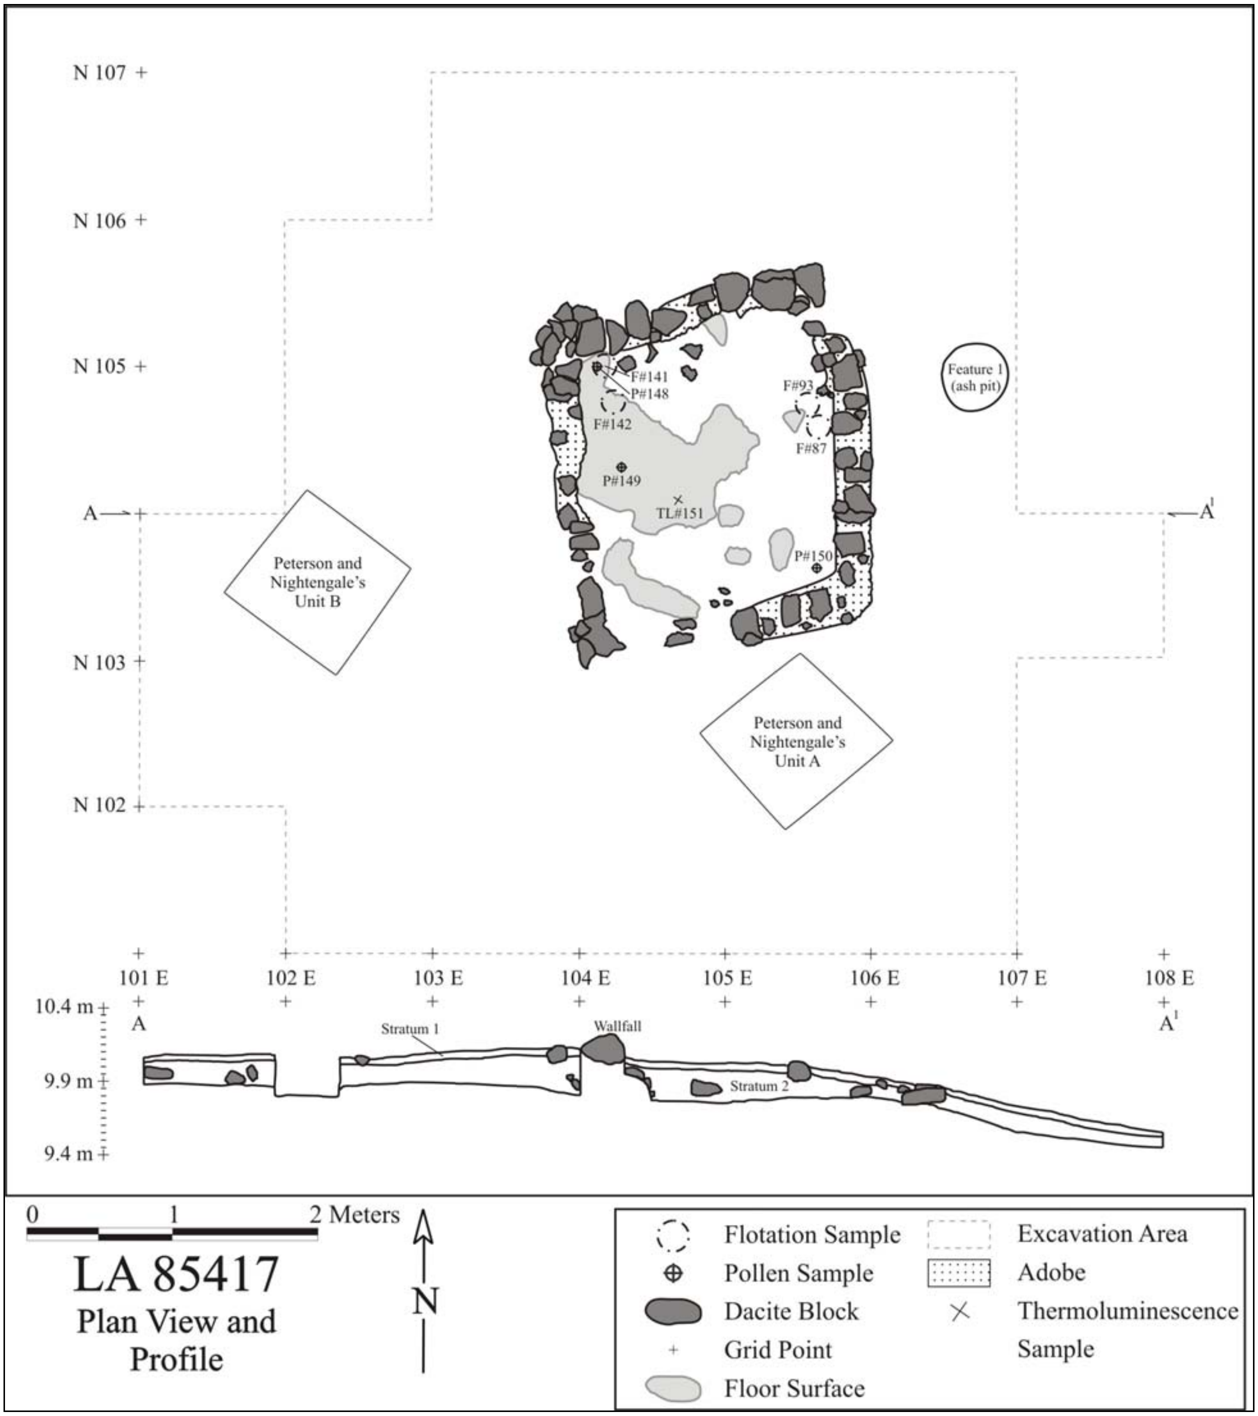

Figure 37.2. Plan view and profile of LA 85417.

Figure 37.3. Post-excavation photograph of the fieldhouse at LA 85417.

The excavation of the site was supervised by Greg Lockard. The field crew included Michael Dilley, Alan Madsen, Brian Harmon, Jennifer Nisengard, Bettina Kuru'es, and Rhonda Robinson. Timothy Martinez and Aaron Gonzalez served as site monitors from San Ildefonso Pueblo and as screeners. Jeremy Yepa was the site monitor representing Santa Clara Pueblo, as well as an additional excavator.

STRATIGRAPHY

Stratum 1 is composed of loose, surface sediment. It is uniformly 2 to 6 cm thick across the site and is part of the A horizon (topsoil). Stratum 2 is post-occupational fill and ranges from 5 to 30 cm in thickness in the area excavated. Stratum 3, which is wallfall, is located between Strata 1 and 2. A separate stratum for wallfall was only utilized in those units in which a high concentration of burned daub was encountered below the surface sediment. This amounted to nine units, all of which are located to the south and west of Room 1. Stratum 3 ranges from 5 to 20 cm in depth. The combined post-occupational fill and wallfall (i.e., Strata 2 and 3) was thickest in and around the structure and thinned away from the room. Strata 2 and 3 are more or less equivalent to the Bw horizon. Stratum 4 is the backfill removed from Peterson and Nightengale's Units A and B. Stratum 4 is therefore a disturbed context. Stratum 5 is the Room 1 floor, and Stratum 6 is the fill removed from Feature 1 (a small, circular firepit). Tables 37.1 through 37.4 summarize and describe the strata excavated at LA 85417.

Table 37.1. LA 85417 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10YR 5/3	Sandy loam	2–6	Surface sediment
2	10YR 5/3	Sandy loam	5–30	Post-occupational fill
3	10YR 5/3	Sandy loam	5–20	Wallfall
4	10YR 5/3	Sandy loam	20–25	Backfill from P & N test pits
5	7.5YR 4/1	Clay	-	Room 1 floor
6	10YR 4/2	Sandy loam	8	Feature 1 (fire pit) fill

Table 37.2. LA 85417 soil horizon descriptions from the west profile of unit 104N/102E.

Horizon	Color	Texture	Depth (cm)	Description
A	10YR 5/3	Loam	0–6	Topsoil
Bw	10YR 5/3	Loamy sand	6–15	Late-Holocene soil
Btb1	7.5YR 4/6	Sandy clay	15–25+	Pleistocene soil

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is a small, rectangular shaped structure that probably functioned as a fieldhouse. It measures 1.95 m in length (north to south) by 1.65 m in width (east to west), with approximately 3.22 m^2 of interior space. Excavation of the room began with an east-west trench that extended across Area 1 (103N/101-107E). The excavation of this trench served to define the room's stratigraphy, as well as to locate the room's east and west walls. The room's entryway and south wall were also encountered while excavating the trench. Within the room, the trench units were excavated down to the room's living surface. After the excavation of the trench, the rest of the room was excavated down to the living surface. In much of the room, this living surface took the form of a plaster floor (see below).

Fill. The interior of Room 1 was filled with 2 to 6 cm of surface sediment on top of 25 to 30 cm of post-occupational fill. The fill was fairly uniform in thickness throughout the room. Flotation (Field Specimen [FS] 80) and pollen (FS 81) samples were taken of post-occupational fill from the center of the room, but the samples were not analyzed.

Floor. A burned plaster floor was encountered throughout much of Room 1 (Figure 37.4). In those areas where the plaster floor was not preserved, an extremely compact layer of clay-rich sediment was encountered.

Figure 37.4. Burned floor in Room 1 at LA 85417.

This layer of sediment is most likely the floor's foundation (i.e., matrix). Only small patches of burned plaster floor were encountered at other fieldhouses in the Rendija Tract that were excavated as part of the C&T Project. Most of these patches of plaster floor were located in the area immediately surrounding a hearth. The fact that the floor in Room 1 at LA 85417 was baked and thus preserved throughout the room indicates that the structure burned down either while the site was occupied or shortly thereafter. This interpretation is supported by the unusually high number of pieces of burned daub that were recovered during the excavation of the site (see below).

As is the case for other fieldhouses in the Rendija Tract in which evidence was available, the plaster floor appears to have been formed by a thin (1 to 2 cm) layer of clay mud spread evenly throughout the room. The floor's foundation is composed of a thicker layer of compact, clay-rich sediment. The best preserved portions of the plaster floor are in the westernmost and central portions of the room. There are also patches of the plaster floor in the eastern half of the room. In those areas where the plaster floor is not preserved, the floor's foundation is well-preserved in all but the north-central portion of the room.

Two flotation samples were taken from post-occupational fill directly on top of the floor in the east-central portion of the room (FS 87 and FS 93). These samples were not analyzed. Additional flotation samples were taken from a concentration of ash and charcoal directly on top of the floor in the far northwest corner (FS 141) and west-central portion (FS 142) of the room. Carbonized taxa identified in these samples included pine, ponderosa pine, cheno-ams, unknown conifer, and juniper. Pollen samples of sediment scraped from the floor were also taken in the far northwest corner (FS 148) and west-central portion (FS 149) of the room. Taxa identified in these samples included maize, buckwheat, grass family, cheno-ams, sunflower family, spurge family, ragweed/bursage, evening primrose, unidentified pine, juniper, and sagebrush. An additional pollen sample was taken of floor matrix from the southeast corner of the room (FS 150), but it was not analyzed. Finally, a large piece of the burned plaster floor was taken from the center of the room as a sample for thermoluminescence (TL) dating (FS 151). The sample dated to 1415±39.

Wall Construction. During the excavation of Room 1, several rock alignments were encountered that were presumed to be the room's walls. Further excavation confirmed that the rock alignments were indeed the remains of the room's walls. The walls were highly disturbed, however, and were no longer in their original position. In other words, the upper courses of the walls were no longer directly on top of the wall foundations. As a result, these rocks were removed, and the wall foundations thus exposed. The wall foundations were constructed of small to medium-sized dacite cobble of irregular shape and adobe mortar. In some locations, the adobe mortar fills in significant space between the rocks. The room's entryway is located in the western half of the south wall. Two small, narrow rocks are located within the entryway. These rocks are most likely the remains of a short doorsill. A fairly large patch of plaster floor is in fact located just inside and terminates at the inner of these two rocks.

During the excavation of the area in and around Room 1, hundreds of pieces of burned daub were recovered. Many of the larger of these contain impressions of branches of varying sizes and/or reed-like vegetal material. The fragments of burned daub are the remains of the upper portion of the room's walls and the roof. No more than a few pieces of burned daub were recovered from any other site in the Rendija Tract. The unusually high number of pieces of burned daub recovered from the site indicates that the structure burned down either while it was occupied or shortly after it was abandoned. This interpretation is supported by the fact that much of the room's plaster floor was burned and thus preserved. Large pieces of burned daub were removed from FS 104 and FS 136 to serve as samples from TL dating. These samples dated to 992±59 and 1277±58, respectively.

Judging from the amount of wallfall removed during the excavation of the area in and around Room 1, the masonry portions of the room's walls were originally considerably higher than they were at the time of excavation. In order to estimate the original height of the walls, all of the rocks removed as wallfall during the site's excavation were placed in three stacks, which were then measured. The stacks measured 1.50 by 1.20 by 0.40 m, 1.40 by 0.70 by 0.30 m, and 9.70 by 0.53 by 0.45 m, for a total of approximately 3.33 m^3 of wallfall. Based on this volume of wallfall and the overall length, average thickness, and average height of the extant portions of the walls, the masonry portions of the room's walls were originally approximately 2.44 m in height (Table 37.5). This number is highly inflated, however, due to the fact that there was a consistent and dense layer of small, naturally occurring rocks just above the Bt horizon across much of the site. This layer of rocks was especially dense in the area to the south of Room 1. There were also quite a few rocks on the surface that appeared to be naturally occurring. The naturally occurring rocks could not be differentiated from the Room 1 wallfall. At least half of the rocks removed during the excavation of the site were therefore probably never part of the Room 1 walls. Based on the analysis of wallfall from other fieldhouses excavated in the Rendija Tract that are located in areas with little or no naturally occurring rocks, the masonry portions of the walls were probably around 1 m tall. As indicated by the numerous fragments of burned adobe with wattle impressions recovered from the site, the upper portions of the walls and roof were composed of wattle and daub.

Table 37.5. LA 85417 Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	1.55	0.10–0.25	0.17–0.30	1 to 2
South	0.85 (1.60)	0.07–0.21	0.20–0.27	1
East	1.90	0.07–0.32	0.22–0.30	1 to 2
West	1.85	0.07–0.31	0.15–0.30	1 to 3

Note: The length of the south wall including the entryway is given in parentheses.

Feature 1

Feature 1 is a small circular depression that was filled with ashy and charcoal-rich sediment (Figures 37.5 and 37.6). It does not appear to have been a formal hearth. Instead, it was most likely an unprepared, limited-use firepit. The pit extends down into the compact, clay-rich Btb1 horizon. The interior of the firepit is fairly well preserved. Only the northeast corner is disturbed. The sides and base of the rest of the pit appear to have been hardened and oxidized by heat. The fill in the southern portion of the pit was removed as two flotation samples (FS 71 and

FS 72) and charred taxa included cheno-ams, juniper, unidentified pine, piñon pine, and ponderosa pine. The fill in the northern portion was removed as a single flotation sample (FS 114) and carbonized taxa included unknown conifer and ponderosa pine. A pollen sample (FS 123) was taken of sediment scraped from the bottom of the hearth and identified taxa included cheno-ams, grass family, sunflower family, unidentified pine, piñon pine, juniper, and sagebrush.

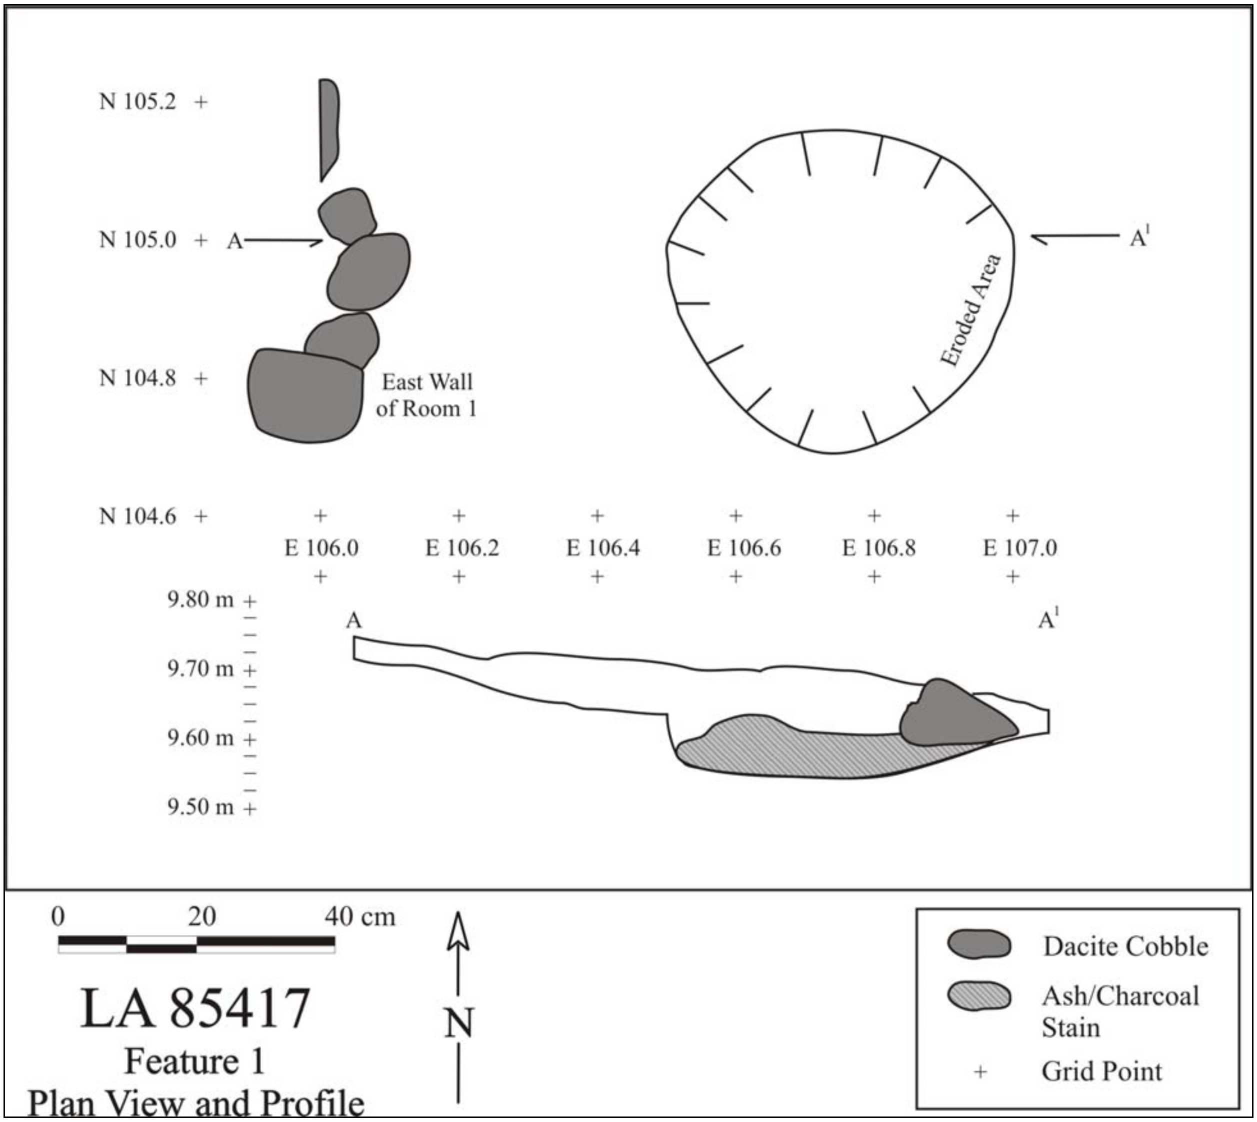

Figure 37.5. Plan view and profile of Feature 1, a small ashpit or hearth.

Geological Analysis

Geologists Paul Drakos and Steven Reneau utilized two profiles to reconstruct the natural soil horizons at the site. In order to reconstruct the soil stratigraphy in the area surrounding the site, they analyzed the west profile of unit 104N/102E. In order to reconstruct the soil stratigraphy in the area of the structure, they analyzed the interior face of the room's west wall (within unit

104N/104E). Both profiles contained a soil sequence consisting of an A horizon (topsoil), a Bw horizon (a late-Holocene soil), and a Btb1 horizon (a Pleistocene soil).

Figure 37.6. Post-excavation of Feature 1, a possible hearth.

Artifact Distribution

Interestingly, the grid units with the highest number of artifacts at LA 85417 are those that are located completely or partially within Room 1 (103-105N/104-105E; Table 37.6). This contrasts with most of the other fieldhouses excavated in the Rendija Tract. At these other sites, the highest concentration of artifacts is located just outside one side of the structure. In those fieldhouses in which the entryway is discernible, the highest concentration of artifacts is usually in the area just outside of the entryway. At LA 85417, the highest concentration of artifacts outside the structure is in the grid units immediately to the east (103-105N/106E). The unit immediately south of the entryway (102N/104E) does also have an elevated number of artifacts (n = 10). Little or no artifacts, however, were encountered in the other units to the south of the room. It should be noted that the entryways and activity areas of many of the Rendija Tract fieldhouses are located to the east. One explanation for this pattern is that this was the best location to take advantage of the heat and light from the early morning sun. At LA 85417, the entryway is located to the south. Feature 1, however, which was most likely an informal firepit, is located to the east. The presence of the firepit, along with the higher concentration of artifacts, indicates that the area immediately to the east of the fieldhouse was an activity area. LA 85417 therefore only deviates from the pattern at other Rendija Tract fieldhouses in that the entryway is located to the south.

Table 37.6. LA 85417 artifact counts by grid unit.

	E101	E102	E103	E104	E105	E106	E107
N106	--	--	2	4	0	0	--

N102	2	0	1	10	0	2	--
N101	--	0	0	0	2	6	--

Note: Bold numbers indicate grid units that are located completely or partially within Room 1.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 146 artifacts were analyzed from LA 85417. Flotation and pollen samples were selected for analysis from the post-occupational fill (Stratum 2), the floor in Room 1 (Stratum 5), and Feature 1 (hearth) fill (Stratum 6) (Table 37.7). A sherd and several burned pieces of adobe from the walls and floor of the structure were also submitted for TL dating. The results of the artifact and sample analyzes are presented in the following sections.

Table 37.7. Samples selected for analysis from LA 85417.

Stratum	Sample Type			
	Flotation	Pollen	Radiocarbon	TL
1				
2	141, 142			47, 136
3				104
4				
5		148, 149		151
6	71, 72, 114	123		

Chronology

Thermoluminescence Dating

Three pieces of burned adobe and a Santa Fe Black-on-white sherd were submitted for TL dating from LA 85417 (Table 37.8). All derived ages are given in years BP, which refers to years before 2003. The 13th century date from the Santa Fe Black-on-white and a piece of burned adobe from the fill appear to be in agreement with the ceramics present on the site; however, the 10th century date seems too early and the 15th century date seems too late.

Table 37.8. TL dates from ceramics at LA 85417.

FS#	Lab #	Context	Burial depth (cm)	Years BP	% error	Years AD
47	UW1504	Sherd from fill	23	722	6.5	1284±47
104	UW1505	Adobe from wall	11	1014	5.8	992±59
136	UW1506	Adobe from fill	30	729	8.0	1277±58
151	UW1507	Adobe from floor	40	591	6.6	1415±39

Archaeomagnetic Dating

Ten specimens were collected as a set (ADL 1281) from a portion of burned floor in the northwest corner of Room 1 at the site. The estimated date range based on the Wolfman curve is AD 1100–1235, whereas the date range based on SWCV2000 is AD 1010–1310. The date range is much bigger for the SWCV2000 curve because of the tightness of the AD 1125 loop represented in that curve and because of the size of the sample error ellipse. The dating implications of the archaeomagnetic pole position are that the structure burned in the early Coalition period, probably before AD 1250 (based on the Wolfman curve) or in the Late Developmental through Early Classic period (based on SWCV2000).

Ceramic Artifacts (Dean Wilson)

A total of 129 ceramics were analyzed from LA 85417. The majority of the pottery consists of smeared plain corrugated, with a single Santa Fe Black-on-white sherd. These types presumably date to the Coalition period, with the dominance of smeared plain corrugated ceramics possibly indicating late 13th century (Table 37.9). On the other hand, the buffware sherds with mica slip appear to be historic in age. These sherds are primarily situated in the upper levels of the excavation, so they may be associated with the historic features present in the area of the site. Information on ceramic tradition by ware, temper by ware, and vessel form by ware are provided in Tables 37.10 to 37.12. The grayware and whiteware pottery appear to have been locally made from smeared-indented sand and tuff temper; however, the micaceous pottery is actually an historic buffware with a mica slip that would have been produced at a nearby pueblo in the Rio Grande Valley. All of the grayware ceramics consist of jar vessel forms. The single whiteware sherd is from a bowl and the micaceous pottery is represented by both jar and bowl forms.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 17 artifacts were analyzed from LA 85417. The assemblage consists of a core, 13 pieces of debitage, two ground stone artifacts, and a hammerstone, which represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 37.13 presents the data on lithic artifact type by material type. The debitage is primarily made of chalcedony and Pedernal chert with a single piece of andesite. Cortex was not identified on any of the debitage artifacts. Nonetheless, the chalcedony and Pedernal chert are available from local Rio Grande Valley gravels. Otherwise, the igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the plateau.

Lithic Reduction

The core was reduced using a single-directional, single-face technique. It was classified as still useable when discarded. Table 34.14 presents the metric information on the core.

Table 37.14. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Single-directional	34	30	35	57.2

The debitage consists of core flakes, biface flakes, a piece of angular debris, and microdebitage. The total absence of cortex indicates an emphasis on the later stages of core reduction and tool production/maintenance. The flakes mostly have single-faceted platforms (n = 5), with fewer collapsed (n = 1) and crushed (n = 3) platforms. None of the platforms exhibit any obvious evidence of preparation. The majority of the core flakes are whole (n = 6), with fewer proximal (n = 1) and distal (n = 4) fragments. The whole core flakes have a mean length of 23.6 mm (*std* = 5.7), the biface flakes have a mean length of 22.0 mm (*std* = 4.2), and the single piece of angular debris a weight of 8.8 g.

Tool Use

None of the debitage exhibit evidence of edge damage that could be attributed to use.

The ground stone includes a mano and a grinding slab. The mano is a two-hand variety made on a piece of dacite (Figure 37.7). It is heavily worn and has a wedge-shaped cross-section. The grinding slab is a tabular dacite fragment with a single heavily ground surface.

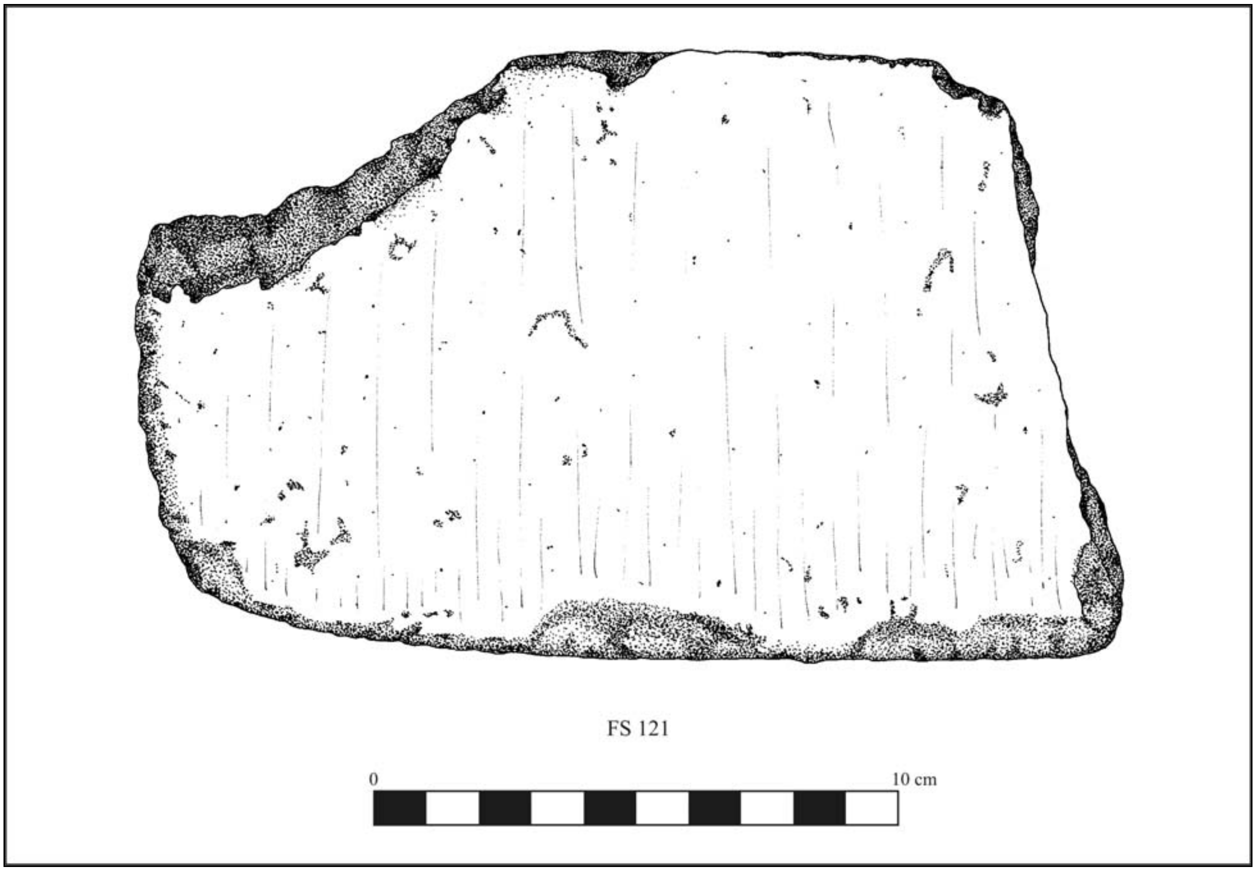

Figure 37.7. Two-hand mano from LA 85417.

Archaeobotanical Remains (Pamela McBride)

Cheno-am seeds were identified in the south half of the ashpit fill and in the ash/charcoal deposit on the floor of the structure (Table 37.15). Piñon seeds (immature, so identification is tentative), juniper cone fragment, and unidentifiable plant parts were also recovered in the south half of the ashpit. Non-cultural material included annual seeds, cactus seeds, and conifer needles. Wood charcoal was entirely coniferous, with ponderosa pine and unknown conifer the most common taxa, followed by pine and juniper (Table 37.16).

Pollen Remains (Susan Smith)

Three pollen samples were analyzed from LA 85417. Table 37.17 lists the frequency of identified pollen types. Maize was the only cultigen identified in the botanical assemblage, and was found in only one sample. No other economic resources were identified in the assemblage. A number of potential economic resources were also identified in the assemblage (Table 37.17), and these are discussed in detail in Smith's chapter in Volume 3.

SUMMARY

LA 85417 is a small one-room Coalition period fieldhouse that was constructed from both shaped and unshaped tuff blocks. The site is situated on the mesa top overlooking Rendija Canyon to the south, near LA 85861 (another Coalition period fieldhouse). One feature, a small ashpit or possible hearth, was identified at the site. However, the site is unique since it appears to have burned and therefore provides evidence of a wattle and daub structure. The presence of maize pollen indicates that the one-room structure may have been occupied during the growing season.

CHAPTER 38
RENDIJA TRACT (A-14): LA 85859

Steven R. Hoagland

INTRODUCTION

LA 85859 is a lithic scatter located on the northeast slope of a knoll situated along the north side of Rendija Canyon (Figure 38.1). The site is situated at an elevation of 2108 m (6910 ft) in an area vegetated by piñon, juniper, and ponderosa pine trees. The artifact scatter covers an area of approximately 368 m^2.

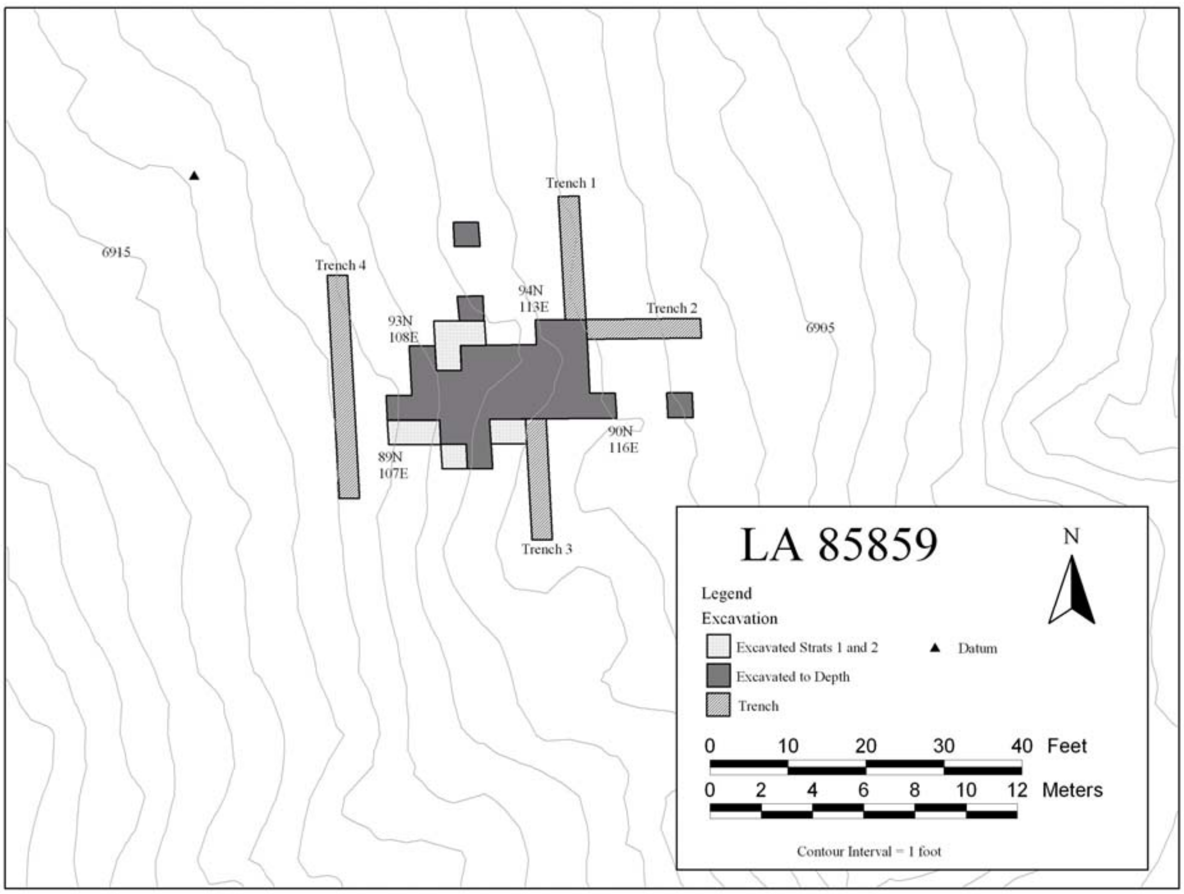

Figure 38.1. Schematic of the excavations at LA 85859.

Soils in the vicinity of LA 85859 are associated with the Sanjue-Arriba Complex. These are deep, well-drained soils that weathered in materials derived from pumice (Sanjue series) or dacites of the Puye Conglomerate (Arriba series) (Nyhan et al. 1978:61). The local stratigraphy consists of a 4- to 23-cm-thick layer of late-Holocene colluvium overlying late-Pleistocene colluvium. Pumice gravels or carbonate cemented pumice underlie the colluvium at depths ranging from 30 to 95 cm from south to north across the site. The pumice gravels are associated with Cerro Toledo Rhyolite deposits, which is "a series of post-collapse rhyolite domes, obsidian, tuffs, and tuff breccias associated with the 1.4-Myr-old Toledo caldera" (Burton 1982).

PREVIOUS INVESTIGATIONS AT LA 85859

LA 85859 was originally documented in September of 1991 by TFA, Inc., during the Basin Land Exchange survey (Hill 1991). It was described as a campsite of unknown cultural affiliation. The campsite was indicated by less than 100 lithics situated within a 225-m² area. The obsidian or chalcedony lithics were either biface thinning flakes or resharpening flakes.

Archeological Research, Inc., subsequently tested LA 85859 for National Register eligibility in August of 1992. The site was described as a small concentration of lithic tools and debitage situated within a 225-m² area. In addition to the lithics, two plain utilityware sherds were observed.

Archeological Research, Inc., excavated two 1- by 1-m test units at the site. Unit A was placed at the edge of the artifact scatter and Unit B was placed upslope. Unit A was excavated to a depth of 60 cm, with obsidian debitage being recovered from all but the first level. Unit B was excavated to a depth of 30 cm and no cultural materials were recovered. In support of the testing, surface artifacts were collected from a 1-m-wide by 15-m-long transect that was laid out across the center of the site. Two San Jose style projectile point bases were also collected as in a grab sample.

A total of 224 pieces of obsidian debitage were recovered from the Unit A excavations and 15 pieces were recovered from the surface collection transect. All of the recovered debitage was the result of secondary or tertiary reduction. This suggested that partially shaped lithic materials (e.g., core or preforms/bifaces) were transported to the site and were further reduced in the course of tool manufacture. Twenty of the flakes found on the site exhibit use wear or retouch. The presence of utilized flakes suggested that some type of processing activity occurred at the site, however, no materials were located that would identify what type, or types, of processing might have been conducted. Based on the diagnostic projectile points, the site dated to the Early Archaic period. Based on this testing, Archeological Research, Inc., recommended that LA 85859 be included as a Register-eligible property.

FIELD METHODS

Fieldwork began with an assessment of the site. The assessment consisted of the crew systematically walking the site at 2 to 3 m intervals. All observed artifacts were pin-flagged to delineate the site boundary and to establish artifact concentrations.

Upon completion of the assessment, the main site datum (Datum A) and baselines for a 1- by 1-m grid system were established. The datum that was placed in the southwest corner of the site was designated as grid point 100N/100E and assigned an elevation of 10.0 m. Several 100-m tapes were used to set up the grid system and to collect all the site surface artifacts. The observed lithics and sherds were collected and provenienced by 1- by 1-m grid units. All collected materials were documented within a Field Specimen (FS) Catalog form. The southwest corner intersection of each grid unit determined its coordinate.

The site excavation involved the hand excavation of 1-m grid units. This technique was used to define the extent, depth, and character of subsurface deposits. Grid level excavation designations started with 0 at the surface, then from 1 to n from the top to bottom of each grid unit (regardless of whether the level is natural or arbitrary). The excavation was conducted by hand using shovels, trowels, and picks when the clay content was high, thus the soil was compact. With the exception of pollen, soil, and macrobotanical samples, all hand-excavated materials were passed through 1/8-in. mesh screens.

A Grid Level Excavation Form was completed for each excavation level. Documented information included the depth of the excavation level, description of the sediment matrix, recovered cultural materials, and the nature and reason for samples collected. A minimum of one pollen sample and one flotation sample was collected from each separate stratum. Macrobotanical samples were also collected from the site.

As the natural stratigraphy had not yet been established, the first excavation units were excavated in arbitrary 10-cm levels. Once established, the remaining grids were excavated by natural stratigraphic units with those being thicker than 10 cm excavated in arbitrary 10-cm levels. Toward the end of the excavation, grids were excavated by natural stratigraphic units regardless of thickness. A stratum is defined as a distinct depositional unit. To facilitate vertical control, subdata containing the same 10-m elevation as Datum A were established close to excavation units and/or blocks. Grid levels were measured from the subdata using string and line levels.

Upon completion of the grid system, a systematic series of auger probe locations were established across the site. The probes were placed at 4-m intervals east to west across the site and every 2 m north to south with each subsequent east to west row offset by 2 m. The 3-in.-diameter auger probes were generally excavated down to the Cerro Toledo pumice horizon or were terminated by rock. The soils extracted from each auger cylinder were described in the Auger Form as were any cultural materials recovered from screening the extracted soil through a 1/8-in. mesh screen. After excavation of a half dozen auger holes, a decision was made to halt further augering until the local stratigraphy could be established from the grid excavation units. The site-wide augering program was continued to completion after the first four grid excavation units were completed.

Geomorphic evaluations were conducted throughout the excavation process with the first assessment conducted after completion of the first four grid units. The assessment for geomorphic context and integrity was conducted by Steve Reneau and Paul Drakos (see Chapter 57, Volume 3).

An overall site map was assembled during the course of excavation. It depicted the site boundary, site datum, subdata, surface collection grids, excavation units, and test trenches. The site map was created with locational information generated by a total station that was backed up with geographic positioning system unit locational points. The final contour map of the site was generated from the geographic information system locational information. The site and its components were photographed with a color digital camera and a 35-mm camera with black-and-white film (ASA 100).

STRATIGRAPHY

The stratigraphy at LA 85859 includes cultural materials bearing pockets of preserved late-Pleistocene to early-Holocene colluvium that has been removed by erosion throughout much of the surrounding area. The site is situated on the northeast-facing slope of a knoll with runoff draining down to the northeast. The site stratigraphy infers that the upper knoll slope contains a thin (less than 25 cm thick) late-Holocene colluvium overlying Cerro Toledo pumice deposits and the lower knoll slope has a thin Holocene colluvium overlying up to 81 cm of late-Pleistocene to early-Holocene colluvium and Cerro Toledo pumice. The upper and lower knoll slopes are separated by an area with bedrock at or near the surface. It is inferred from the stratigraphy that the upper knoll slope was eroded during the late Pleistocene to early Holocene and that colluvium derived from the Cerro Toledo was deposited on the concave portion of the knoll slope situated at and below LA 85859. At the base of this colluvium is a series of dacite clasts, up to small boulder size, that represents a lag left after almost complete erosion of an older alluvial unit. A second period of erosion likely occurred sometime during the middle or late Holocene, during which the upper knoll slope was stripped to bedrock and the late-Pleistocene to early-Holocene soils on the lower slope were truncated. The stripped Cerro Toledo on the upper knoll slope and truncated late-Pleistocene to early-Holocene soils on the lower slope were subsequently buried by a thin late-Holocene colluvium deposit (Drakos and Reneau 2004).

Upper Knoll Stratigraphy. Four stratigraphic units characterize the upper knoll slope. The surface A horizon (AC in places) (Stratum 1) is a loose, light brown, sandy loam that often contains charcoal and ash from vegetation that burned during the May 2000 Cerro Grande fire. Pumice gravels form about 20 percent to 40 percent of the fill matrix. This late-Holocene colluvium ranges from 1 to 12 cm in thickness. The BW (Stratum 2) stratum situated directly below is a soft to slightly hard, grayish-brown to brown, sandy loam with pumice gravels forming about 20 percent to 30 percent of the matrix. This late-Holocene colluvium likely has an age of less than 1000 years. This stratum also contains Cerro Grande fire-derived ash and charcoal flecks and ranges from 1 to 16 cm in thickness.

Underlying the BW stratum is an excessively bioturbated 2Btb1 stratum (Stratum 9). It is a soft to slightly hard, brown, sandy loam to sandy clay loam containing a high percentage of pumice gravels and pebbles (40% to 70%). Colloidal stains are common on the pumice clasts. The gravel and pebbles have weathered out of the upper portion of a pumice bed associated with the Cerro Toledo Rhyolite formation. This stratum ranges from 5 to 30 cm in thickness. The abrupt upper stratum boundary likely records the erosional stripping of overlying younger soils. Situated directly below is a 2Coxb1 stratum (Stratum 6) that is a light brown Cerro Toledo pumice deposit. It is 80 percent to 90 percent oxidized pumice gravels and pebbles loosely intermixed with sand. This upper knoll stratigraphy is present directly above and adjacent to LA 85859.

LA 85859 and Lower Knoll Stratigraphy. The stratigraphy for the site and the lower knoll is different from the upper knoll slope in that there is a deposit of late-Pleistocene to early-Holocene clays situated between the BW soil horizon and the weathered Cerro Toledo pumice bed (2Btb1/2Coxb1). Cultural materials bearing pockets of the late-Pleistocene to early-Holocene clays are situated at the edge of the upper knoll zone. Although truncated, this approximate 65-cm-deep pocket of fill appears to have been protected from additional erosion by an arch-shaped alignment of dacite cobbles and boulders that are part of the lag that accumulated along the lower margin of the upper knoll slope.

As revealed by the block excavation, a small Pleistocene-era drainage had traversed southwest to northeast across the eastern site area, cutting into the Cerro Toledo pumice bed. It is likely that water within this drainage also eroded some of the upslope fill, cutting the depression that subsequently retained the cultural material bearing late-Pleistocene to early-Holocene soil. More recently, erosion protection for the site area has been provided by an approximately 6-ft-deep drainage that trends southwest to northeast about 20 m to the southeast of the site and a shallow southwest-to-northeast-trending drainage located about 4 m to the east of the site.

Situated directly beneath the BW horizon within the site was a Bt1b1 horizon that was composed of silty to sandy reddish clay that contained a low amount of pumice gravel. The hard, well-formed, subangular blocky clay peds tended to be stratified by size with the larger peds (at 3 to 7 cm, Stratum 3A) situated above smaller peds (1 to 3 cm, Stratum 3B). Stratum 3A appeared to have slightly less pumice gravel (5% to 10%) than Stratum 3B (10% to 20%).

Situated beneath strata 3A/B was a Bt2b1 horizon (Stratum 3C). It was a slightly hard to hard, yellowish-brown to brown, silty clay loam that formed into small (<1 cm) subangular blocky peds. Pumice gravel formed about 20 to 30 percent of the horizon matrix. The pumice that tended to occur in small pockets, increased slightly with depth.

Stratum 4 was a Bt3b1 horizon soil. It was a slightly hard to hard, brown to strong brown, silty loam to silty clay loam. The pumice gravel content ranged from about 20 percent to 30 percent. A few dacite and pumice cobbles were present, especially toward the bottom of the horizon. Some of the clasts and peds contained a thin, discontinuous $CaCO_3$ coating, especially along the margins of the site. Rodent borrows were frequent throughout the stratum.

Stratum 5 was classified as a BKb1 or a BCb1 horizon. It was a soft to slightly hard, light to pale brown, sandy loam to sandy clay loam. The pumice gravel content ranges from about 30 percent to 50 percent. Discontinuous CaCo3 coatings were present on clasts and peds. Dacite cobbles were more abundant throughout this stratum. Rodent burrows were frequent. Table 38.1 lists and describes the strata excavated at LA 85859. Table 38.2 lists the artifact counts from each of the strata at the site.

Table 38.1. LA 85859 strata descriptions.

Strat	Horizon	Texture	Munsell Color	Thickness	Description
1	A	Sandy loam	10YR5/3	1 to 12 cm	Young colluvium (<1000 yrs). Loose, single grain with varying amounts of pea sized pumice gravels (20% to 40%); ash and charcoal present from Cerro Grande fire.
2	BW	Sandy loam	10YR6/3 to 10YR4/3; 10YR5/2	1 to 16 cm	Late-Holocene fill (<1000 yrs?). Soft to slightly hard with pea-sized pumice gravels (20% to 30%); some ash and charcoal present from Cerro Grande fire.
3A	Bt1b1	Silty to sandy clay	7.5YR4/4; 7.5YR5/3 to 7.5 YR 4/3	1 to 11 cm	Late-Pleistocene or early-Holocene fill. Hard, well-formed, large subangular blocky peds (3 to 7 cm) with a small amount of pea-sized pumice gravel (5% to 10%).
3B	Bt1b1	Silty to sandy clay	7.5YR4/4	1 to 22 cm	Late-Pleistocene or early-Holocene fill. Hard, well-formed smaller subangular blocky peds (1 to 3 cm) with about 10% to 20% pea-sized pumice gravel.
3C	Bt2b1	Silty clay loam	10YR5/4; 7.5YR5/4 to 7.5YR4/4; 7.5YR5/3	1 to 59 cm	Late-Pleistocene or early-Holocene fill. Slightly hard to hard with small subangular blocky peds (<1 cm) or, less frequently, platy peds. Pea-sized and larger pumice gravels (20% to 30%). Pumice increases with depth and is at times clustered in pockets.
4	Bt3b1	Silty loam to silty clay loam	7.5YR5/4 to 7.5YR4/4 7.5YR5/6 to 7.5YR4/6;	4 to 53 cm	Late-Pleistocene or early-Holocene fill. Slightly hard to soft with depth. Few dacite cobbles and gravel, pebbles, and cobbles of pumice especially toward bottom of stratum. Gravel content ranging from about 20% to 30%. Few thin discontinuous CaCO3 coatings on clasts and peds, especially along margins of site. Rodent burrows abundant.

Strat	Horizon	Texture	Munsell Color	Thickness	Description
5	Bkb1 or BCb1	Sandy loam to sandy clay loam	7.5YR5/4; 7.5YR6/3 to 10YR6/3	1 to 41 cm	Late-Pleistocene fill. Soft to slightly hard with abundant gravels and pebbles of pumice (30% to 50%). Dacite cobbles more abundant. Discontinuous CaCO3 coatings on clasts and peds. Rodent burrows are frequent.
6	2Coxb1 or 2CBkb2	Sand and gravel	7.5YR8/2; 7.5YR5/3; White	6+ cm	1.2 to 1.6 Ma (million years). Toledo Pumice bed. 80 plus percent pumice. Discontinuous to continuous CaCO3 coatings on clasts.
7		Silty clay loam	7.5YR7/4 to 7.5YR5/4; 7.5YR6/3	3 to 28 cm	Late-Pleistocene fill. Lenses of carbonate cemented silt and pumice. 40% to 60% pumice gravels. Generally, a cemented Stratum 5 located along the north side of the excavation block.
8		Silty clay loam	10YR5/3	62 cm	Disturbed soil from previous test pit (Strata 1, 2, and 3A-C).
9	2Btb1	Sandy loam to sandy clay loam	7.5YR5/3 to 7.5Yr4/3; 7.5YR4/4	5 to 17 cm	1.2 to 1.6 Ma. Soft to slightly hard colluvium with abundant pumice gravels and pebbles (40% to 70%). Colloidal stains common on pumice clasts.
10		Sand	7.5YR8/2	2 to 8 cm	Fine-grained sand predominantly formed from pumice. Associated with a SW-to-NE-trending drainage that cuts into the Toledo Pumice within the lower east side of the excavation block.

SITE EXCAVATION

Based on the surface artifact collection where the majority of surface artifacts were located between grids 87 to 95N and 110 to 119E and the results of the testing phase excavation units, it was determined to begin excavations in unit 90N/110E. This grid was located directly east of Test Excavation Unit A that contained 224 pieces of obsidian debitage. Using 90N as an intersite baseline, excavation units were also initiated a few m above and below 90N/110E (90N/101 and 118E) to establish the eastern and western site boundary (Figure 38.2). Unit 90N/110E contained numerous subsurface flakes of obsidian (584) of which 95 percent were recovered from within the upper five soil strata (upper four soil horizons). As the first grid unit was excavated, the fill was removed in arbitrary 10-cm levels. Upon excavation, the soil profile was used to establish the primary soil strata used to stratigraphically excavate all other grid units. Unfortunately, the arbitrary levels did not correspond well with the observed stratigraphy sequence, especially within the upper four strata. A summary of the excavation levels as they correspond to soil strata and artifact content is presented in Table 38.3.

Table 38.3. Excavation levels in 90N/110E.

Level	Stratum	Soil Horizon	No. Lithics	Faunal Remains
1	1/2	A/Bw	123	
2	2/3A	Bw/Bt1B1	205	
3	3A/3B	Bt1b1	81	
4	3B/3C	Bt1b1/Bt2b1	114	
5	3C	Bt2b1	28	
6	4	Bt3b1	4	
7	5	Bkb1	1	
8	5	BkB1	17	10 (rodent)
9	5	Bkb1	11	

The late-Holocene soils (A and Bw) contained at least 123 lithics (21%), while the Bt1b1 and Bt2b1 Bt soils contained up to 428 lithics (73.3%). The lithic totals dropped off drastically within the lower two soil horizons with four lithics recovered from the Bt3b1 horizon (0.7%) and 29 lithics from the BKb1 horizon (5%). All of the lithics were chipped stone debris.

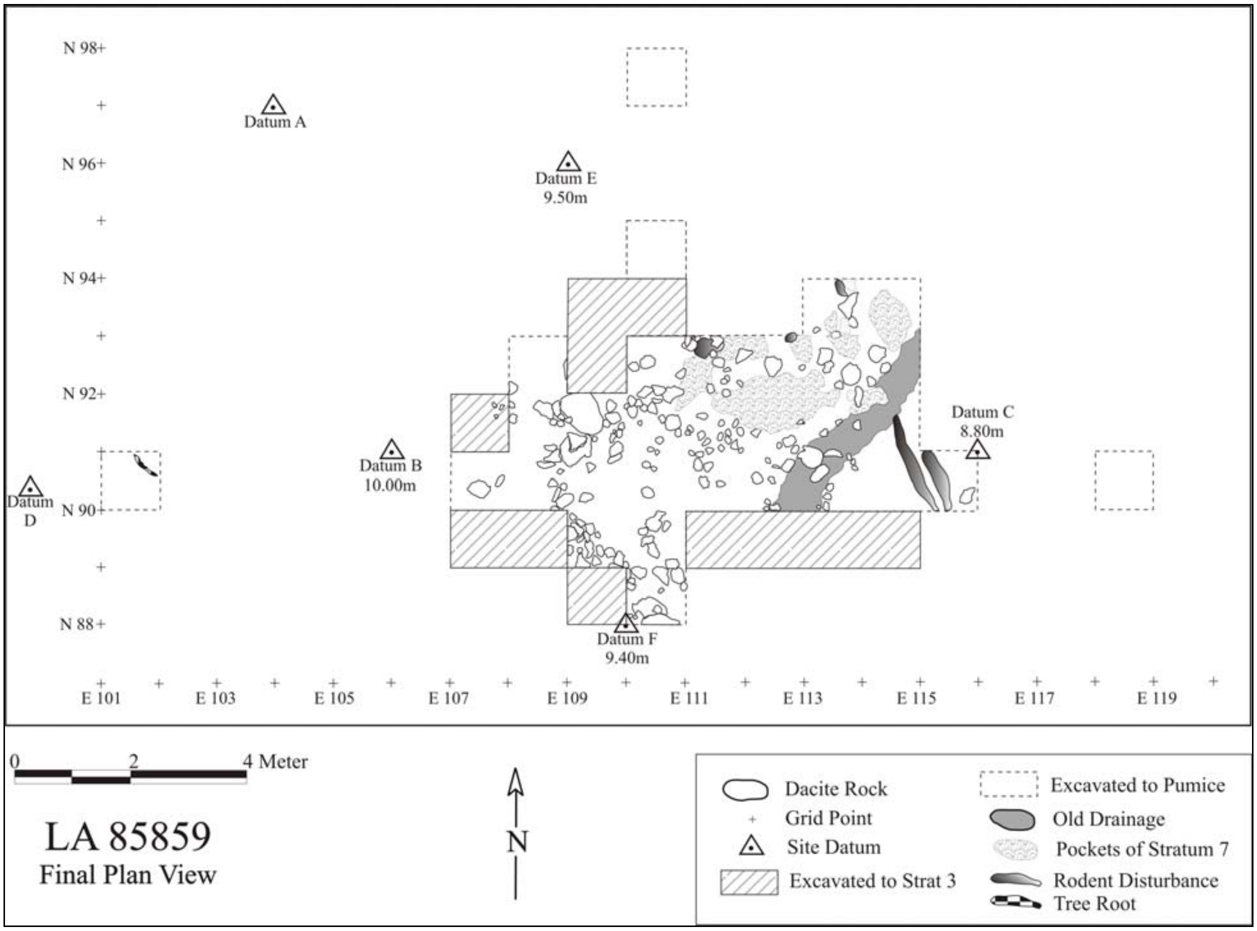

Figure 38.2. Schematic of grid unit excavations at LA 85859.

Conversely, unit 90N/101E contained neither cultural materials nor any of the late-Pleistocene to early-Holocene clays within which approximately 75 percent of the 90N/110E artifacts were located. Cerro Toledo pumice deposits were encountered at a depth of between 4 and 7 cm below the surface. Unit 90N/118E contained a total of 28 lithics with 22 of these (79%) recovered from the late-Holocene soil horizon and six (21%) from the late-Pleistocene or early-Holocene Bt1b1 horizon. The assumption based on these first three grid unit excavations was that 90N/101E was located above the site, 90N/110E was within the heart of the site, and 90N/118E was situated at the lower (eastern) edge of the site.

Based on the above excavations units, 90N/107E and 90N/114E were excavated to provide additional information concerning the eastern and western extent of the site. Although the late-Pleistocene to early-Holocene clays were encountered within 90N/107E (a mixed Strata 3 and Stratum 4), only one lithic was recovered and that was from Stratum 4. Unit 90N/107E was assessed to be located just above or along the upper western margin of the site.

The upper portion of the Bt1b1 horizon (Stratum 3A) was missing from 90N/114E. This grid unit contained a total of 73 lithics and one sherd that was recovered from the A soil horizon. Forty-nine percent of the lithics were recovered from the late-Holocene horizon. Most of the remaining lithics were recovered from the Bt horizons (35, 48%) with about half of these recovered from the Bt1b1 horizon (Stratum 3b). Although the artifact density dropped significantly from upslope (90N/110E), this unit was within the southern site boundary.

Much of the late-Holocene strata (Strata 1 and 2) within the site boundary contained charcoal and ash from the 2000 Cerro Grande fire. As a precautionary measure, the decision was made to excavate these strata in areas surrounding locations proposed for excavation. This measure was intended to prevent Cerro Grande charcoal from contaminating excavations that extended down into the late-Pleistocene or early-Holocene horizons. Most of this soil stripping was conducted in grids located in the vicinity of 90N/110E. Also at this time the disturbed fill from previously excavated Test Unit A was removed.

With the eastern and western site limits becoming clearer, a decision was made to excavate three units out to the north in an attempt to define the site boundary. The excavations were conducted at 92N/108E, 94N/110E, and 97N/110E. At this point, the small drainage located about 4 m to the south of the 90N gridline was assumed to form a natural site boundary. The excavation of 92N/108E ended up being fairly shallow with few lithics present. The 15- to 28-cm-thick late-Holocene horizon overlaid a shallow Bt horizon (7 to 12 cm) that appeared to be a truncated Bt3b1 soil (Stratum 4). Erosion apparently removed any Bt1b1 and Bt2b1 soils before the late-Holocene depositional period. Two lithics were recovered from the late-Holocene soils, one flake from the Bt soil and two lithics from weathered Cerro Toledo Pumice gravels (Stratum 5). The lack of Bt1b1 and Bt2b1 soils that were present only 1 to 2 m to the east infers that the northwestern edge of the site is located in this vicinity.

A truncated lens (3 to 7 cm thick) of late-Pleistocene to early-Holocene soil (Stratum 3B?) was encountered beneath the late-Holocene soil horizons (Strata 1 and 2) in 94N/110E. This horizon rapidly graded into a weathered pumice gravel deposit (2Btb1, Stratum 9). Three flakes were recovered from the early-Holocene deposits and 35 flakes were recovered from the combined 3/9 Stratum. Unit 97N/110E was excavated to an approximate depth of 50 cm below surface. The late-Holocene soils that increased in pumice gravels with depth occupied the upper 20 to 25 cm. Situated below was an approximate 20-cm-thick Bt horizon that appeared to be a highly mixed Bt1b1 through Bt3b1 deposit. This horizon graded into a 2- to 10-cm-thick 2btb1 deposit that in turn overlaid Cerro Toledo pumice deposit (Stratum 6). This grid unit was assessed to be situated beyond the northern site boundary as only six flakes were recovered from the late-Holocene horizons and one flake recovered from the Bt horizon.

The next phase involved excavating the units situated directly east and west of 90N/110E and the unit located directly west of 90N/114E. These grid units were excavated to further establish the cultural context in the eastern and western site areas. All three grids contained the complete soil horizon series as established in 90N/110E (Figure 38.3). Unit 90N/109E contained 330 lithics of which 117 (35.5%) were within the late-Holocene horizon, 203 (61.5%) within the Bt soils (Strata 3A-C and 4), and 10 lithics (3%) within the weathered Toledo pumice deposit (Stratum 5). Within the Bt horizon, 65.5% of the lithics (133) were located within the Bt1b1 horizon (83 in 3A and 50 in 3B). The artifact content within unit 90N/111E was fairly similar with a total of 333 lithics being recovered. The late-Holocene horizon contained 134 lithics (40%) and the Bt horizon contained 199 lithics (60%). Within the Bt horizon, 79 percent of the lithics (158) were in the Bt1b1 horizon (79 in 3A and 79 in 3B). Downslope, unit 90N/113E contained 179 lithics. Nearly 29 percent (51) of these lithics were recovered from the late-Holocene horizon and 66 percent (118) from the Bt horizons. Within the Bt horizons, 96 of the lithics (81%) were recovered from the Bt1b1 horizon (54 in 3A and 42 in 3B) and 8 from within the Bt2b1 horizon (7%).

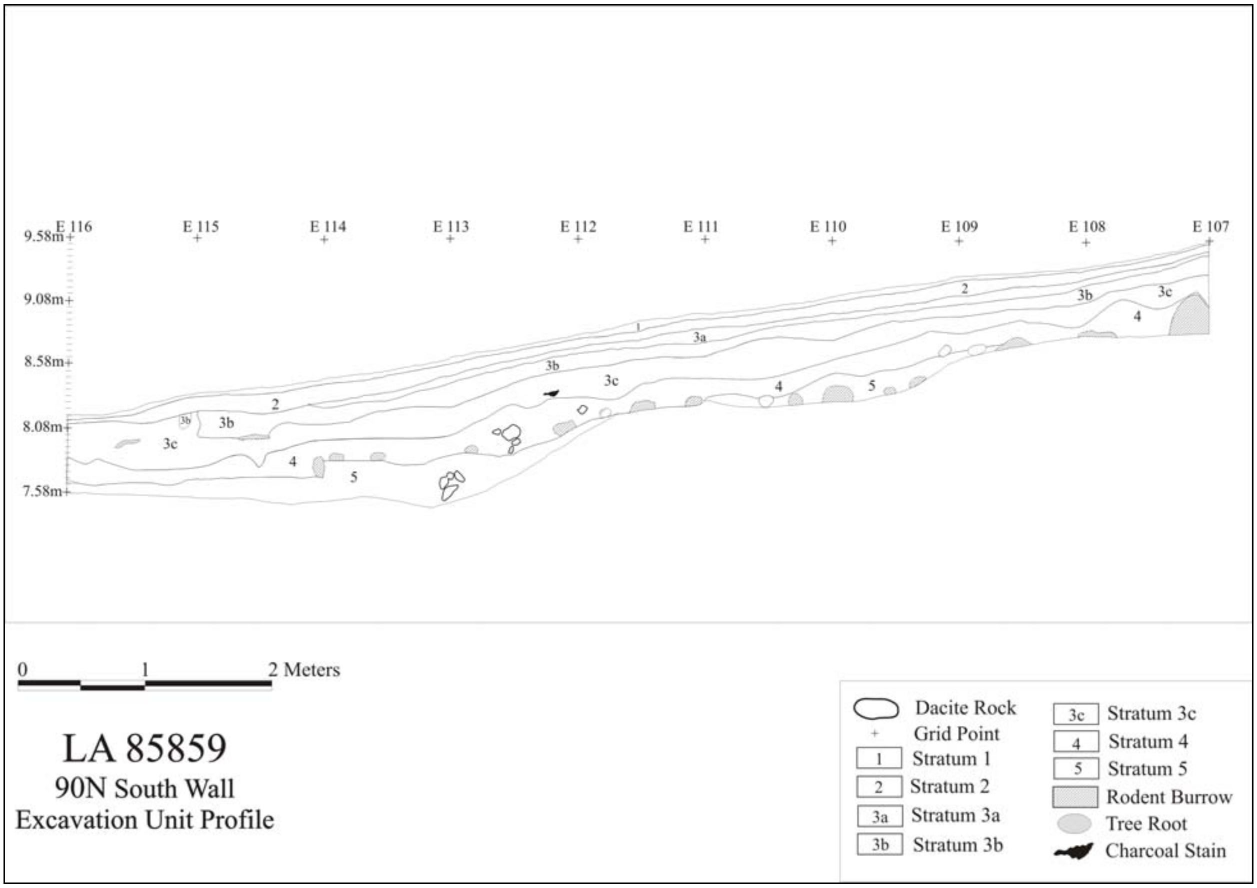

Figure 38.3. Profile of the 90N grid line.

Although the grid units located directly to the east and west of 90N/110E exhibit a 40 percent drop in total lithics, their relatively high artifact count infers that this location is a major activity area associated with the site. The 60 percent increase in total artifacts moving up 1 m from 90N/114E to 90N/113E suggests that this location may be the eastern edge of the same activity area.

Based on the limited number of cultural materials recovered from the two westernmost excavation units (90N/107E and 92N/108) and abundant lithic materials located 1 m to the east and southeast, respectively (90N/109E), a decision was made to excavate the units situated between these two areas in an attempt to understand this discrepancy. As a result, units 90N108E and 91N/108E were subsequently excavated.

Unit 91N/108E contained two distinct stratigraphic sequences. Within the northern half of the unit, a 10-cm-thick late-Holocene deposit directly overlaid a weathered Cerro Toledo pumice gravel deposit (Bkb1). The southern half of the unit contained a 10-cm-thick, undifferentiated Bt horizon that was situated between the Holocene and weathered pumice deposit. All six lithics were recovered from the pumice deposit. About 15 dacite cobbles or small boulders that were set slightly into the Bkb1 soil deposit were scattered across the unit, especially along the eastern edge. Directly south in unit 90N/108E, the Bt horizon was much more intact, ranging in depth from about 8 to 50 cm below surface. All three Bt soil horizons were present. Recovered artifacts included five lithics from the late-Holocene horizon and 14 lithics from the late-Pleistocene to early-Holocene Bt soil horizons. Within the Bt horizon, eight lithics were recovered from the Bt1b1 soil (six in 3A and two in 3B), one lithic from the Bt2b1 soil, and five from the Bt3b1 soil. The cluster of dacite cobbles observed in 91N/108E continued along the eastern edge of this unit. The surface of the Bkb1 soil deposit slopes down 30 to 40 cm between the eastern edge of 91N/108E where the dacite cobbles are concentrated and the eastern edge of 90N/109E and drops 1.2 m between the eastern edge of 90N/108E and 90N/114E.

To gain a better understanding of the site formation process and to explore the potential that the recently encountered dacite cobbles and small boulders were the remains of a cultural feature, unit 91N/109E was excavated. As two shallow boulders that were left in place along the western half of the unit (0 to 25 cm), most of the excavation occurred in the eastern portion. The eastern half of the unit contained the complete range of Bt soils. The Bt soils that were situated between 10 and 50 cm below surface dropped in depth and thickened toward the southeast corner of the unit. Dacite cobbles were also encountered within the eastern half of this unit at depths ranging from 30 to 70 cm. In all, 85 lithics were recovered from 91N/109E. Eighteen of the lithics (21%) were recovered from the late-Holocene horizon, 60 (71%) from the Bt soils, and seven (8%) from the weathered pumice gravels. Within the Bt horizon, 44 lithics (73%) were recovered from the Bt1b1 soil, 11 (18%) from the Bt2b1 soil, and five from the Bt3b1 soil horizon.

A discernable difference exists between the soil stratigraphy located west (upslope) of the dacite cobble and boulder cluster located along the 108E to 109E grid boundary and that located to the east. The excavations conducted upslope from the dacite cluster revealed shallow soils with no or thin, truncated Bt soils. When Bt soils were encountered within this area, they were highly mixed and contained few associated cultural materials. Conversely, directly east of the cobble and small boulder concentration the Bt soils became thicker, well-defined, and contain a relatively high lithic artifact count. The dacite cobble and boulder cluster appears to form a functional western boundary for an activity area located directly to the east (Figure 38.4). The cultural material bearing soils sit on a weathered Toledo pumice deposit that drops in depth and slopes significantly downslope from west to east.

Based on the change in stratigraphy and artifact content observed along the 108E gridline, the decision was made to excavate the undisturbed soils situated below Test Unit A (91N/110E), and to excavate adjacent unit 92N/110E. Test Unit A corresponded well with unit 91N/110E with only a 10-cm-wide soil lens located along the western edge of the grid that was not previously excavated. The undisturbed soils beneath Test Unit A (60 cm below surface) included an approximate 15-cm-thick Bt3b1 (Stratum 4) deposit overlaying a weathered, 10-cm-thick Cerro Toledo pumice deposit (Bkb1). Approximately 10 dacite cobbles were situated within the northwest portion of the unit. The previously noted 224 lithics that were recovered during site testing would have been situated within the late-Holocene A and BW soil horizons and the late-Pleistocene to early-Holocene Bt1b1 and Bt2b1 horizons. An additional 27 lithics were recovered from the back dirt used to refill the test unit and nine lithics were recovered from the unexcavated 10-cm-wide west-side soil lens (Stratum 3). The previously undisturbed Stratum 4 (Bt3b1) deposit contained 19 lithics, and the Bkb1 weathered pumice deposit contained four lithics.

Figure 38.4. Dacite cobble and boulder outcrop forming western site occupation boundary.

Adjacent to the west, unit 92N/110E was excavated down to the Toledo pumice deposit (2CBkb2), which was encountered at depths ranging from 33 cm in the northwest corner to 76 cm in the southeast corner. As the depths indicate, the Cerro Toledo pumice bed, as well as the overlying weathered pumice gravel deposit (Bkb1), slope significantly from northwest to southeast. The upper portion of the Bt1b1 soil horizon is missing, otherwise, the Bt soil formations are similar to the horizon sequence located directly east in the assumed activity area. A total of 312 lithics were recovered from this unit. Of these, 55 (18%) lithics were within the late-Holocene deposit, 251 (80%) within the Bt horizon, and six (2%) in the weathered Cerro Toledo pumice stratum. Within the Bt horizon, 149 lithics (59%) were within the Bt1b1 soil, 91 (36%) within the Bt2b1 soil, and 11 (5%) within the Bt3b1 soil.

These two units provide more information concerning the stratigraphy situated within the northwestern portion of the site. The slope of the Cerro Toledo pumice deposits indicate that there is a low area situated directly east and south of an arching, fairly linear, cluster of dacite cobbles and small boulders (Figure 38.5). This low area or possible hollow has retained late-Pleistocene to early-Holocene soil deposits that appear to have eroded out on the hillslope to the west and north. The hollow soils were likely sheltered from erosional activities by the upslope dacite rock deposit. The vast majority of artifacts associated with this site appear to be situated within Bt1b1 and/or Bt2b1 located within the hollow.

Figure 38.5. Dacite cobble and boulder barrier (upper center) with a hollow situated directly downslope to the east.

The next series of grid units to be excavated were within the southeastern portion of the site. Grids 90N/112E and 90N/115E were excavated to continue defining the soil stratigraphy and associated artifact distribution from west to east, down through the site. Grids 91N/114E and 92N/114E were also excavated to further establish the nature of the cultural remains within the eastern portion of the site. Grid 90N/112E had the same well-developed upper Bt soil horizon as found directly upslope to the west, although the upper portion of the Bt1b1 (Stratum 3A) was fairly thin (2 to 8 cm). The lower portion of this horizon appeared to have much greater disturbance due to bioturbation, as there was no clear boundary between Bt2b1 (Stratum 3C) and Bt3b1 (Stratum 4). A total of 202 lithics were recovered from 90N/112E. Sixty-four of the lithics (32%) were recovered from the late-Holocene horizon, 136 (67%) from the Bt soils, and two from the weathered pumice gravels. Within the Bt horizon, 87 lithics (64%) were recovered from the Bt1b1 soil (42 from 3A and 45 from 3B), 14 (10%) were within the Bt2b1 soil, nine (7%) from a Bt2b1/Bt3b1 mix, and 26 (19%) from Bt3b1.

The Bt horizon appears to have been impacted by erosion in unit 90N/115E as the Bt1b1 soil is not present. This erosion was also apparent in the adjacent upslope unit (90N/114E) where the upper portion of the Bt1b1 soil was missing (Stratum 3A). Ten lithics were recovered from the late-Holocene horizon, 15 from the Bt horizon (Strata 3C and 4), and one from the Cerro Toledo pumice gravels. Thirteen (87%) of the Bt horizon lithics were recovered from the Bt2b1 soil. The Bt horizon in units 91N/114E and 92N/114E had also been impacted by erosion as indicated by the upper Bt1b1 soil being absent and by bioturbation as a fairly thick, mottled, Bt1b1/Bt2b1 (Stratum 3B/3C) deposit overlaid by a pocket of Bt2b1 soil in 92N/114E and the Bt3b1 (Stratum 4) soil deposit throughout the rest of the two units. Lithic debitage was fairly abundant in both units with 220 flakes recovered from 91N/114E and 307 recovered from 92N/114E. Forty-five of the 91N/114E lithics (20%) were recovered from the late-Holocene horizon and 139 (80%) from the Bt soils. Within the Bt horizon, 175 lithics (63%) were recovered from the Bt1b1/Bt2b1 soil stratum and 36 (16%) were within the Bt3b1 soil. Forty-eight of the 92N/114E lithics (16%) were recovered from the late-Holocene horizon, 236 (77%) from the Bt soils, and 23 (7%) from the weathered pumice gravels. Within the Bt horizon, 43 lithics (14%) were recovered from the Bt1b1/Bt2b1 soil stratum, 95 (31%) from the Bt2b1 horizon, and 98 (32%) were within the Bt3b1 soil. Based on the upslope soil stratum artifact densities, it was assumed that the cultural occupation occurred in the Bt1b1 soil horizon and that artifacts within underlying Bt horizons were mixed into these soils by bioturbation. As the Bt1b1 soil has been eroded and/or highly mixed into underlying strata, the potential for encountering undisturbed remains was thought to be poor.

To establish the southern boundary of the site, unit excavations were initiated in 89N/109E and 89N/110E. A small drainage that parallels these grids was located about 3 m to the south. The encountered stratigraphic sequence was similar to the grids located directly to the north with Strata 3A, 3B, and 3C represented. Both units were terminated directly above a dacite rock and Toledo pumice deposit (Stratum 6), which was situated directly below Stratum 3C in Grid 89N/109E and below Stratum 4 in 89N/110E. The associated artifact densities were significantly less than that observed in the units directly to the north. Thirty-eight lithics were recovered from 89N/109E and 95 from 89N/110E. Only one flake was recovered from the late-Holocene horizon, and the rest from the Bt soils in 89N/109E. The Bt horizon artifacts included 14 lithics (37%) from the Bt1b1 horizon and 23 (60.5%) from the Bt2b1 soil horizon. Within 89N/110E, 14 (15%) of the lithics were recovered from the late-Holocene horizon, 73 (77%) from the Bt soils, and eight (8%) from the weathered pumice gravels (Bkb1). Bt horizon artifacts included 65 lithics (89%) from the Bt1b1 horizon, three from the Bt2b1 horizon, and five from the Bt3b1 horizon.

As a good stratigraphic sequence with a fairly large number of associated artifacts was encountered in 89N/110E, the excavation was extended into 88N/110E. Stratum 3A only extended across the northern two-thirds of the unit and Stratum 3B tapered out in the southeast corner. It appears that erosion associated with the small south-side drainage removed portions of the Bt1b1 soil horizon from this unit and is assumed to have also removed it from units further to the south. Although Stratum 3C still extended across the unit, its interface with Stratum 4 was extremely mottled. Rodent disturbance was extensive throughout the lower stratigraphic horizons. Stratum 4 overlaid a culturally sterile, plated clay deposit that appeared to be a water deposited lens of Stratum 3C. This deposit suggests that subsurface water movement has been a factor in forming the south-side site stratigraphy. The reduction in soil-horizon-associated artifacts observed in adjacent north-side units continued into 88N/110E as only 31 lithics were recovered. Nine of the lithics (29%) were recovered from the late-Holocene horizon and 22 (71%) from the Bt soils. The Bt1b1 horizon contained 10 lithics, all from the 3B Stratum. Three flakes were recovered from the Bt2b1 horizon and nine from the Bt3b1 horizon of which all but one were associated with rodent disturbances.

The drainage associated with the removal of Bt1b1 soils and the likely removal of Bt2b1 horizon soils a short distance further to the south, along with the decrease in associated artifacts, led to the conclusion that the potential for intact cultural remains was extremely limited to the south of the 90N grid line.

To continue exploration of the eastern and northeastern site area, units 91N/111E, 91N/112E, and 91N/113E were excavated. Units 92N/111E, 92N/112E, 92N/113E, 93N/113E, and 93N/114E were subsequently excavated. Stratum 3A was present in only two of the eight units (91N/111E and 91N/112E), and lower strata mixing was noted along the 91N grid line with Strata 3B and 3C mottling observed in all three units. Within grids 91N/112E and 91N/113E, the mixing was so severe that Strata 3B and 3C were mottled into one combined stratum (3B/3C). Strata 3B and 3C were present as distinct units within the 92N and 93N grid line units, although they were becoming mottled along the northern half and coexisted as one mottled stratum along the northern edge of the 93N units. The artifact density remained fairly high within the eight grids, primarily ranging from 200 to 300 per unit (Table 38.4). The artifacts were spread throughout the Holocene and late-Pleistocene soil horizons. Increased soil horizon vertical mixing was indicated by the continued high number of artifacts associated with the late-Holocene deposits and a sharp increase in the number of lithics recovered from the Bt3b1 soil horizon (Stratum 4). Rodent burrows were abundant throughout the Bt3b1 and Bkb1 soil horizons (Figure 38.6). Along with the absence of the upper Bt1b1 soil horizon, the lower portion of the horizon (Stratum 3B) exhibited a significant drop in artifact content in the locations where it was still discernable from the Bt2b1 horizon. In three units situated in the northeast corner of the block excavation, artifacts associated with the Bt1b1 soil horizon only numbered in the teens. Conversely, Stratum 3C as well as the Stratum 4 lithics increased in the northeast corner of the excavation. Overall, Stratum 4 lithics increased in number from southwest to northeast across the excavation block.

Table 38.4. East and northeast unit artifact tallies.

Grid	Total No. of Lithics	Strata	Soil Horizon	No. of Lithics	Percent of Lithics
91N/111E	361	1/2	A and Bw	44	12

With the removal of fill overlying the Toledo pumice deposit, it became apparent that a southwest-to-northeast-trending drainage had traversed the hillslope in the site area (Figure 38.7). The drainage is evidenced by a shallow trough that cut into the pumice deposit and by small pockets of almost pure pumice sand (Stratum 10) that occurred within the overlying fill along and slightly above the trough. This drainage cuts across the southeastern corner of the block excavation, entering in units 90N/112E and 90N/113E and exiting in units 92N/114E and 93N/114E. The upslope hollow containing the site focus was likely formed as a channel funneling runoff into this larger southeast-to-northeast-trending drainage. The increase in Strata 3 and 4 lithics that generally increase from southwest to northeast across the block excavation appear to reflect some subsurface soil movement along these old drainages. With the absence of

Stratum 3A, significant reduction of artifacts associated with Stratum 3B, the mottling of Strata 3B and 3C, and the increase in artifact movement down into Stratum 4, the assessed potential for encountering intact cultural remains within additional area units was assessed to be extremely low, thus the excavation was ended.

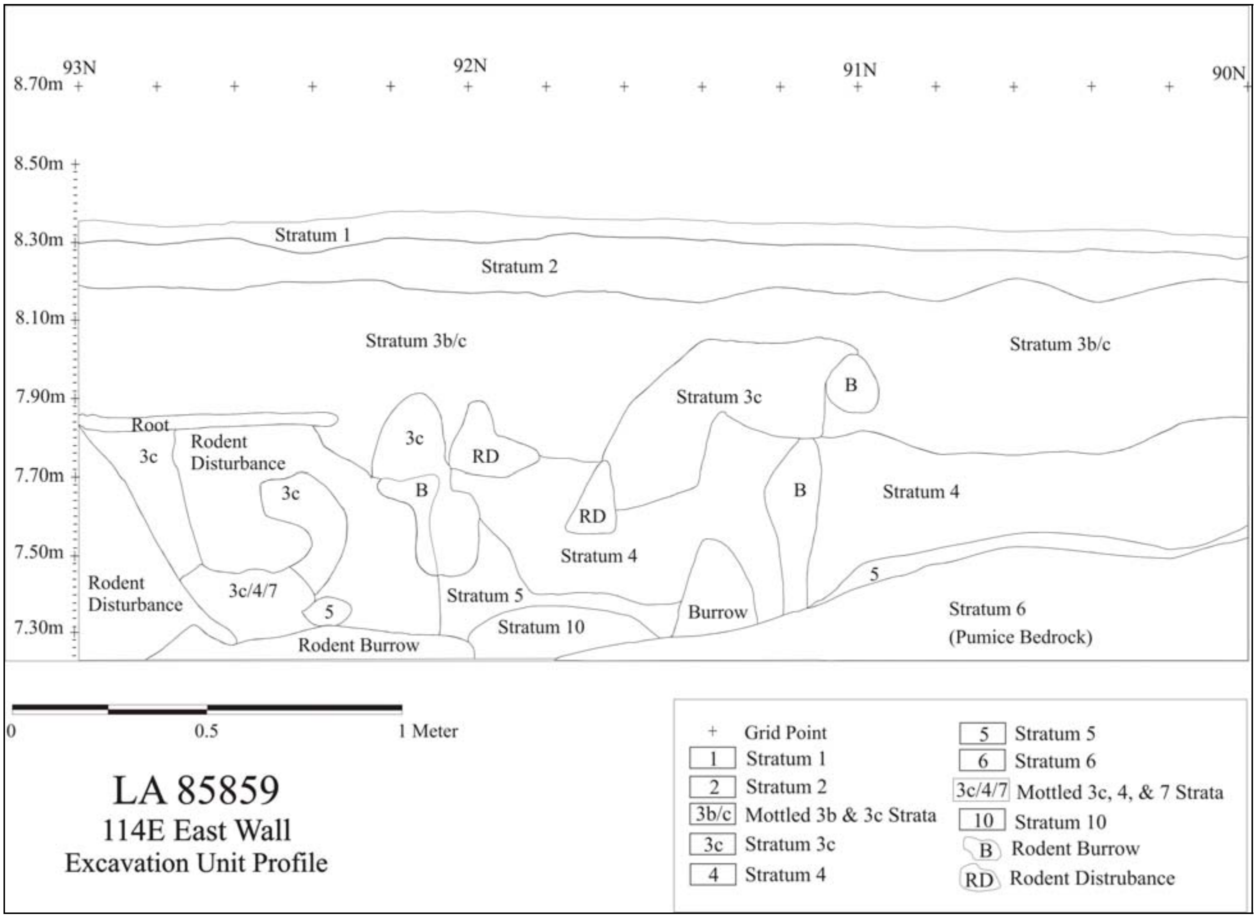

Figure 38.6. Profile of the 114E grid line.

To verify the assumptions concerning the site stratigraphy, four backhoe trenches were excavated. Trenches 1 through 3 were excavated out from the east end of the block excavation and Trench 4 was located above the block excavation. Trench 1 was 5 m long running north from 94N/114.2E through 98N/114.2E, Trench 2 was 4.5 m long running east from 93.16N/115E through 93.16N/119.5E, Trench 3 was 5 m long running south from 89N112.4E through 85N/112.4E, and Trench 4 was a 9-m-long north-to-south-trending trench that ran from 87N/104.9E through 95N/104.9E. The southern 1.7 m of Trench 1 was similar to that observed in the northern edge of 93N/114E where a mottled Bt1b1/Bt2b1 (3B/3C) deposit underlay the late-Holocene horizon soils (see Figure 38.1). The approximate 50-cm-thick Bt1b1/Bt2b1 mix overlaid a Stratum 7 deposit that appeared to be a sandy, water-deposited sediment, likely representing an old drainage channel. From units 94.7N through 95N the trench deposit contained the Bt1b1 through Bt3b1 horizon sequence (Stratum 3B through 4), which transitioned into a Bt1b1/Bt2b1 mix that directly overlaid a Toledo pumice deposit. The upper part of the

Bt1b1 soil horizon was not present within the trench and. other than a 1.3-m-long segment within the central portion of the trench, the Bt soils were highly mixed when present.

Figure 38.7. Grid unit excavation with dacite barrier (center) and southwest-to-northeast-trending drainage channel slightly above.

The first meter heading east out of the block excavation in Trench 2 (93N/114E) also displayed a mottled Bt1b1/Bt2b1 horizon, which overlaid a thick, sandy drainage channel deposit. From 93.16N/116E through to the end of the trench, intact Bt1b1 through Bt3b1 soil horizons (Strata 3B and 3C) were again present. Directly south of 90N/112E, Trench 3 contains a mixed Bt1b1/Bt2b1 stratum that overlays a weathered Toledo pumice deposit (Bkb1). Approximately 1.5 m east of the block excavation, a Bt3b1 horizon soil appears beneath the Bt1b1/Bt2b1 horizon. The Bt3b1 soil continued eastward through the trench, whereas the Bt1b1/Bt2b1 soil pinched out about 2.5 m east of the block excavation. The trench appears to verify that the small drainage situated just south of the block excavation has removed the upper Bt soils from the area. Trench 4 revealed the presence of a pocket of Bt horizon soil between 91.5N and 88N. This pocket included a 3-m-long wedge of Bt1b1 (Stratum 3) overlying a 4-m-long wedge of Bt2b1/Bt3b1 that tapers and likely terminates just beyond the trench in 87N/105.7E.

The large deposit of Stratum 7 colluvial sand in Trenches 1 and 2 supports the assessment that a drainage traversed down through the northeast corner of the block excavation. These trenches also support the assessment that the Bt soils within the northeast corner of the block excavation have been significantly mixed through bioturbation. Trench 3 and the southern end of Trench 4 support the assessment that the small south-side drainage has removed the Bt soils within its vicinity. The lack of the Bt soil series along the north side of Trench 4 also supports the assessment that much of these soils along the upper hillslope above LA 85859 have been removed through erosion. Table 38.5 shows the distribution of artifacts recovered from grid units at LA 85859.

Table 38.5. LA 85859 artifact counts by grid unit.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 2059 artifacts were analyzed from LA 85859. In addition, flotation and pollen samples were selected for analysis from Strata 1 to 7 (Table 38.6). Charcoal was submitted for radiocarbon dating from Strata 3A, 3B, and 3B/C, and 15 pieces of obsidian for hydration dating from Strata 1 to 5. The results of the artifact and sample analyses are presented in the following sections.

Table 38.6. Samples selected for analysis from LA 85859.

Stratum	Sample Type			
	Flotation	Pollen	Radiocarbon	Hydration

6	143, 308			
7	346	329		
10	315	337		

Chronology

Radiocarbon Dating

Four charcoal samples were submitted for accelerator mass spectroscopy dating. Sample FS 360 from Stratum 3A provided a date of 570±40 BP (Beta-183759), with a calibrated intercept of AD 1410 and a two-sigma range of AD 1300 to 1430. FS 225 from Stratum 3B yielded a date of 6010±40 BP (Beta-183757), with calibrated intercepts of 4900 BC, 4890 BC, and 4860 BC, and a two-sigma range of 4990 to 4790 BC. FS 359 was also taken from Stratum 3B and provided a date of 6310±40 BP (Beta-183758), with a calibrated intercept of 5300 BC and a two-sigma range of 5370 to 5220 BC. Lastly, FS 363 was derived from Stratum 3B/C and yielded a date of 6140±40 BP (Beta-221840), with a calibrated intercept of 5050 BC and a two-sigma range of 5220 to 4940 BC. Therefore, the three samples from the lower contexts all provided Early Archaic dates ranging from about 5300 to 4860 BC.

Obsidian Hydration

Ten obsidian artifacts from LA 85859 were submitted to the Diffusion Laboratory for age determination using the obsidian hydration dating method. In order to calculate the absolute date for an obsidian artifact, three analytical procedures were completed. First, the amount of surface hydration, or the thickness of the hydration rim, was measured. Second, the high-temperature hydration-rate constants for each artifact were determined from the composition of the glass. Lastly, the soil temperature and relative humidity at the archaeological site was estimated in order that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. Using these methods, a hydration rate for the obsidian artifacts was calculated (Table 38.7).

Table 38.7. Obsidian hydration dates for LA 85859.

FS No.	Lab No.	Source	Rim (um)	AD/-BC	1 S.D.
40	2006-1	Valle Grande	n/a		
109	2006-2	Valle Grande	3.61	1673	16
118	2006-3	Valle Grande	4.04	1410	27
144-2	2006-4	Valle Grande	3.52	-2880	278
147	2006-5	Valle Grande	3.83	-3673	297
148	2006-6	Valle Grande	4.83	-71	85
166	2006-7	Valle Grande	4.44	-5510	340
169-2	2006-8	Valle Grande	5.29	426	58
172	2006-9	Valle Grande	4.48	-2171	186
285	2006-10	Valle Grande	4.07	-4542	323

The obsidian hydration dates appear to span a 7000-year time span, ranging from AD 1673 to 5510 BC. The earlier part of this range corresponds with the Early Archaic radiocarbon date of 5050 BC; however, the dates continue for several more millennia. The two youngest dates are from a similar context in Stratum 3A, and indeed correspond with the radiocarbon date of circa AD 1410 from the same stratum. Therefore, these upper levels appear to exhibit some recent mixing of materials. On the other hand, the three oldest dates are derived from the lower Strata 3C, 4, and 5, which also correspond with the Early Archaic radiocarbon dates obtained from Strata 3B and 3B/C. Otherwise, the remaining dates are primarily Late Archaic and are situated in the upper levels of the site in Strata 1, 2, 3A, and 3B.

Ceramic Artifacts (Dean Wilson)

Two smeared-indented corrugated sherds were analyzed from the excavations. Both were recovered from the upper levels of the site.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 2057 artifacts were analyzed from LA 85859, consisting of one core, 2046 pieces of debitage, 10 retouched tools, and one mano. This represents a 37 percent sample of the 5595 total lithic artifacts recovered during the site excavations. Table 38.8 presents the data on lithic artifact type by material type. The majority of the debitage is made of obsidian, with a few items of other materials. The presence of cortex on 6.5 percent of the debitage indicates that most of these materials were collected from primary nodular sources (96.9%), with some from secondary waterworn sources. The obsidian and rhyolite is present at nearby sources in the Jemez Mountains, but two obsidian flakes did exhibit waterworn cortex. In contrast, chalcedony, Pedernal chert, and quartzite are available from local Rio Grande Valley gravel sources.

Table 38.8. Lithic artifact type by material type.

Ten pieces of debitage and eight retouched tools were submitted for X-ray fluorescence analysis. All of these artifacts were from the Valle Grande source (Table 38.9). The Valle Grande (Cerro del Medio) source area is located about 17 km (11 mi) as the "crow flies" to the west of the site.

Lithic Reduction

The core consists of a bidirectional, bifacial core made on a chalcedony cobble (Figure 38.8). It exhibits waterworn cortex indicating that it was obtained from secondary gravel sources. The core was classified as still useable when discarded. Table 38.10 presents the metric information on this core.

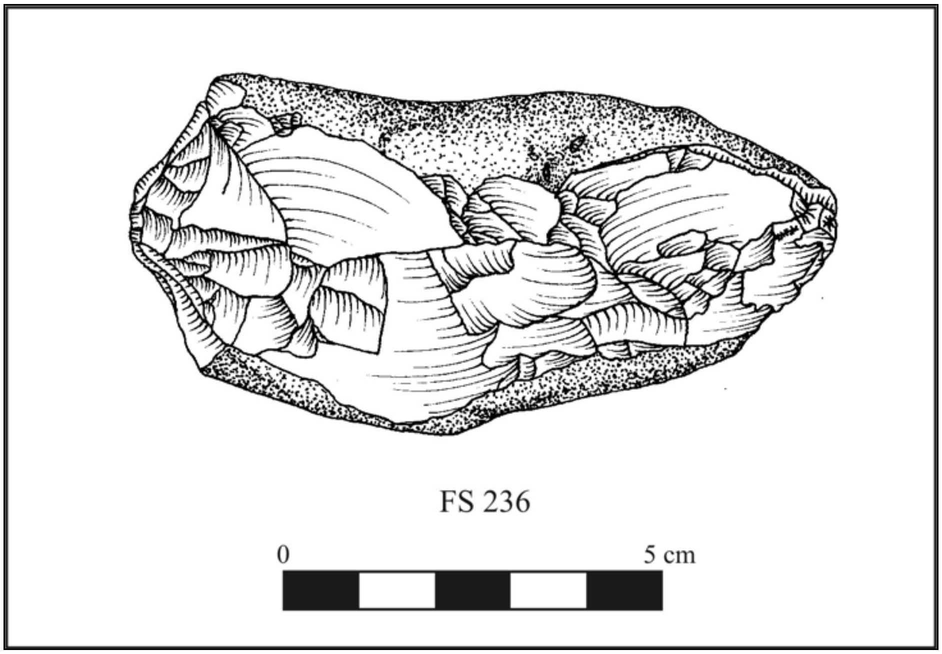

Figure 38.8. Bifacial core from LA 85859.

Table 38.10. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Bi-directional	97	74	48	374.0

The debitage mainly consists of microdebitage (37.7%) and biface flakes (33.2%), with some core flakes (19.9%), undetermined flake fragments (6.3%), and other items. Table 38.11 summarizes the various stages of reduction represented by the whole core and biface (tertiary) flakes. The overall cortical:non-cortical ratio of 0.13 reflects this emphasis on the tool production. The presence of notching and *outrepasse* flakes also indicate the presence of biface production activities at the site.

Table 38.11. Debitage reduction stages.

Material	Primary	Secondary Cortical	Secondary Non-cortical	Tertiary	Cortical: Non-cortical ratio
Rhyolite	0	0	1	0	---
Obsidian	0	16	23	92	0.13
Chalcedony	0	0	1	0	---

Material	Primary	Secondary Cortical	Secondary Non-cortical	Tertiary	Cortical: Non-cortical ratio
Total	**0**	**16**	**25**	**92**	**0.13**
Percentage	0	12.0	18.7	69.1	---

The majority of the flakes exhibit crushed platforms (*n* = 176; 54.1%), with cortical (*n* = 3), single-faceted (*n* = 58), multi-faceted (*n* = 54), and collapsed (*n* = 34) platforms. Ninety six (29.8%) of the flake platforms exhibit evidence of preparation, with most of these being abraded/crushed and only two ground platforms.

The majority of the core flakes consist of distal fragments (*n* = 242; 59.1%), with fewer whole (*n* = 46), proximal (*n* = 35), midsection (*n* = 84), and lateral flake fragments (*n* = 2). Most of the biface flakes are also distal fragments (*n* = 330; 48.4%), with fewer whole (*n* = 92), proximal (*n* = 152), midsection (*n* = 99), and lateral flake fragments (*n* = 8). The whole core flakes have a mean length of 24.2 mm (*std* = 12.7), whereas the whole biface flakes exhibit a mean length of 25.9 mm (*std* = 11.9). Lastly, angular debris have a mean weight of 0.5 g (*std* = 0.5).

The retouched tools consist of a mix of expedient flakes and retouched pieces, while the formal tools consisted primarily of bifaces (Figure 38.9). The retouched pieces exhibit one (*n* = 1), two (*n* = 2), and three (*n* = 1) marginally retouched edges. Table 38.12 presents the information on retouch type by edge outline.

Table 38.12. Retouched pieces.

Retouch Type	Edge Outline						
	Straight	Concave	Convex	Straight/ concave	Straight/ convex	Concave/ convex	Projection
Unid. Ventral	1	0	0	0	0	0	0
Unid. Dorsal	2	0	0	0	0	0	0
Bidirectional	1	0	0	0	0	0	0
Total	**4**	**0**	**0**	**0**	**0**	**0**	

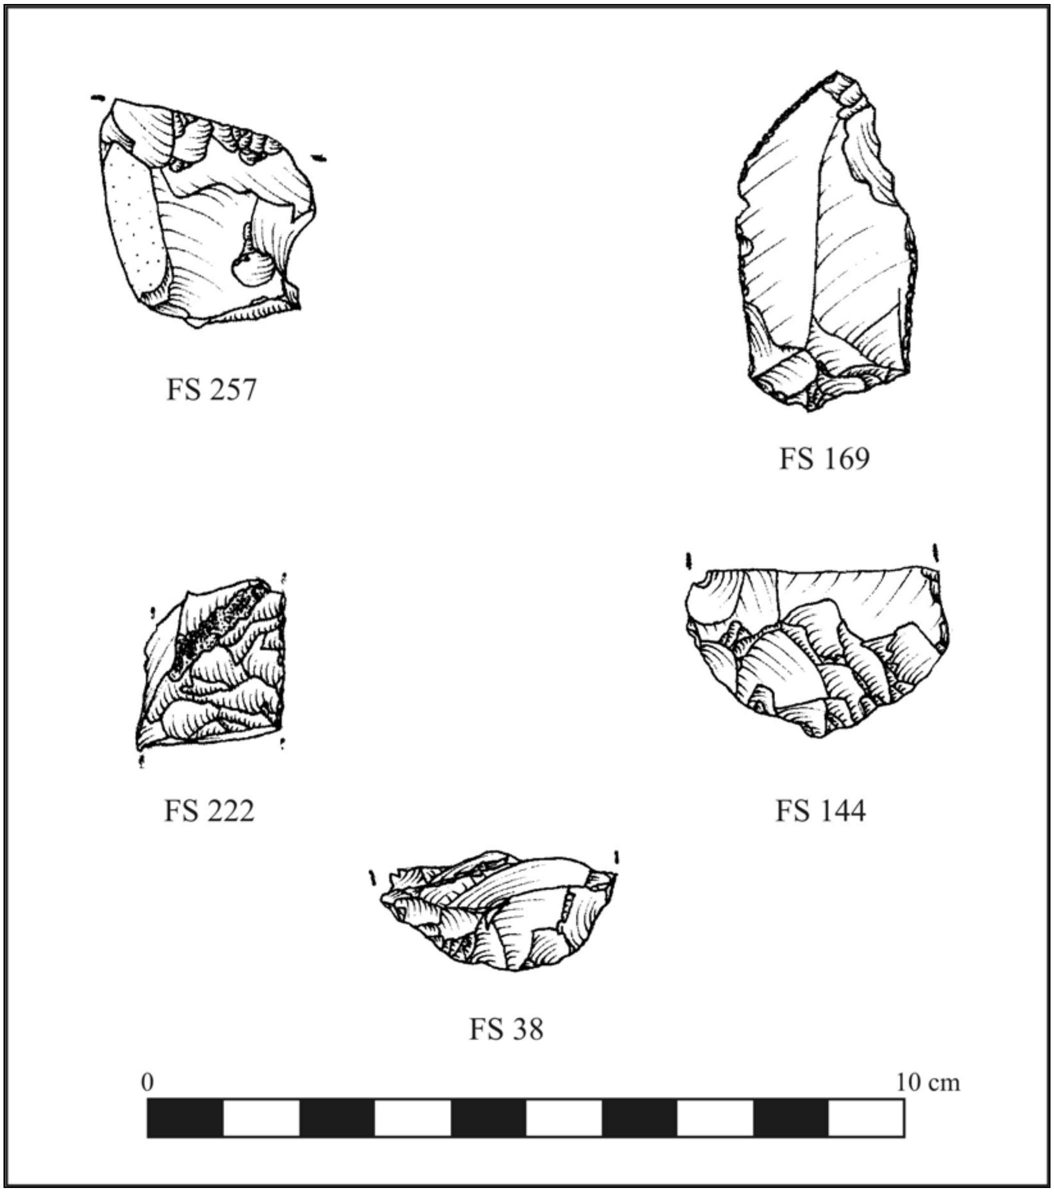

Figure 38.9. Retouched flakes (top) and biface fragments (bottom).

All the retouched edges exhibit straight outlines. The edge angles range from 40 to 50 degrees, with a mean of 42.5 degrees (*std* = 5.0). This reflects an emphasis on the use of more acute edge angles.

All six bifaces are broken, consisting of two distal, one lateral, and three undetermined fragments. Therefore, platform angles were measured on biface flakes (*n* = 82) to provide information on the stages of biface production represented at the site. The angles range from 45 to 85 degrees, with a mean of 65 degrees (*std* = 6.1). However, Figure 38.10 indicates a bimodal distribution with peaks at 75 and 60/65 degrees. This indicates that early-middle stage bifaces, and possibly bifacial cores, were being reduced at the site. This corresponds with the presence of the *outrepasse* flakes.

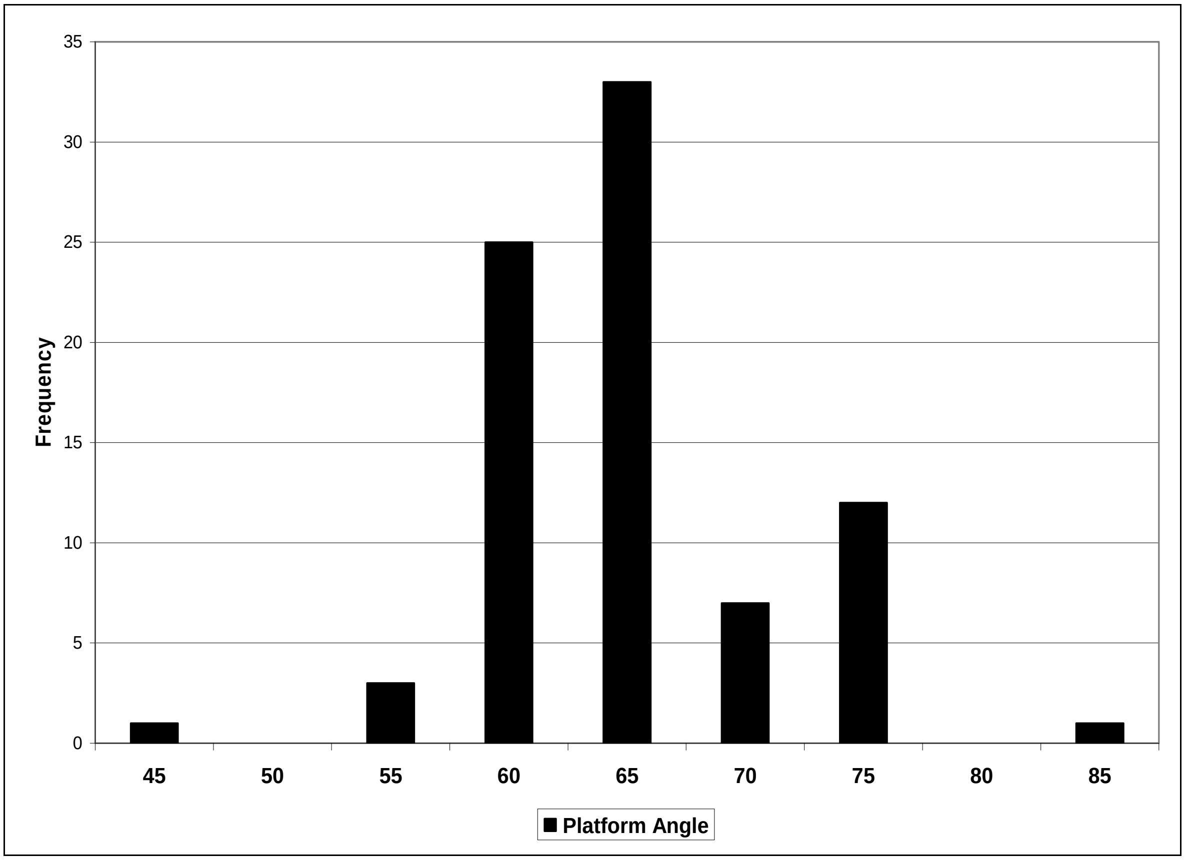

Figure 38.10. Biface flake platform angles.

Tool Use

Only two flakes (0.04%) exhibit evidence of damage that could be attributed to use-wear. These are obsidian biface flakes with damage situated along a straight lateral edge with angles of 40 degrees. They too have an acute angle like that exhibited by the retouched tools and were presumably removed from large bifacial cores.

Two of the retouched flakes exhibit evidence of use-wear, whereas, all the biface fragments appear to have been broken during manufacturing. A composite tool includes two retouched lateral edges with acute angles and a steeply angled edge at the distal end of the flake. Use-wear is present along these edges indicating use as both a cutting and scraping tool (see Figure 38.9).

A single one-hand quartzite cobble mano was analyzed. It exhibits two well-worn opposing surfaces and has some battering along one end (Figure 38.11).

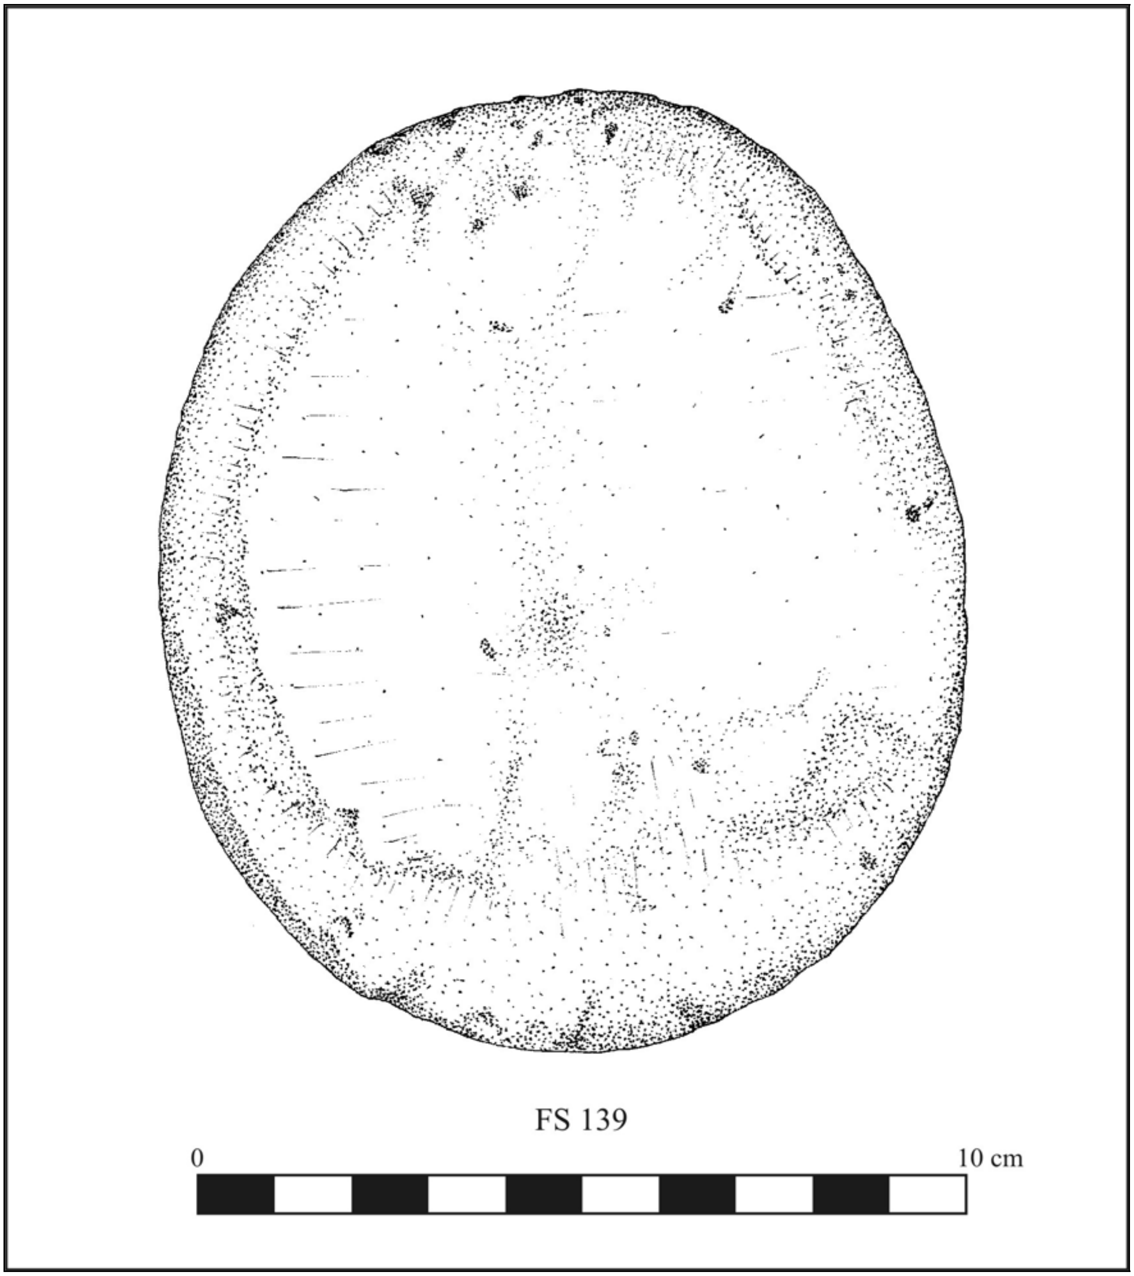

Figure 38.11. One-hand cobble mano.

Faunal Remains (Kari Schmidt)

Fourteen pieces of bone were recovered from this site. All of the bones were modern, and all are pocket gopher (*Thomomys bottae*) remains. None of the bones were burned, and none showed signs of weathering. Bones were recovered throughout the excavated levels. Methods used in the analysis of the bone are detailed in Volume 3 (Schmidt, Chapter 64).

Archaeobotanical Remains (Pamela McBride)

The majority of flotation and vegetal samples were from the center of the main activity area (grid 90N/109E) from strata that yielded the highest number of lithic artifacts. One of these samples produced a goosefoot seed fragment. The remaining assemblage consisted of burned and unburned conifer duff including pine cone fragments, piñon and ponderosa needles, and juniper twigs (Table 38.13). Samples from that part of the site along the upper western margin (FS 353) and from the northeastern portion of the site (FS 310) also contained unburned weed seeds of goosefoot, spurge, bean family, composite family, and the knotweed family.

+ 1-10/liter, pc partially charred.

Wood charcoal was entirely coniferous and piñon was the only taxon identified as charcoal was very fragmented and sparse (Tables 38.14 and 38.15). Unknown conifer and undifferentiated pine were also part of the record. The archaeobotanical remains from LA 85859 could be remnants of vegetation that burned during the Cerro Grande fire, especially those from Strata 1 and 2 that both contained material burned during the fire. Strata 4 and 5 displayed frequent rodent burrows indicating floral material from the fire could have been deposited by bioturbation.

Pollen Remains (Susan Smith)

Nineteen pollen samples were analyzed from LA 85859. Table 38.16 lists the frequency of identified pollen types. No cultigens were identified in the botanical assemblage. Beeweed and lily family were identified as other economic resources in the assemblage. Several other potential economic resources were identified in the assemblage (Table 38.16), and these are discussed in detail in Smith's chapter in Volume 3.

EXCAVATION SUMMARY

LA 85859 is an Early Archaic lithic scatter located on the northeast slope of a knoll situated along the north side of Rendija Canyon. The implemented data recovery plan resulted in a block excavation from which 5595 lithics were recovered. The vast majority of the lithics were debitage made of obsidian, with a few items of other materials also present.

The least disturbed portion of the site is located in the west-central portion of the block excavation, directly east of a dacite cobble outcropping. With removal of the overlying soil, it was apparent that a hollow had formed in the Toledo Pumice deposit directly downslope from a cascade of dacite rocks and cobbles. The bottom of the hollow sloped down to the east for 4 to 5 m until it merged with a drainage that ran from southwest to northeast across the knoll slope. The drainage is evidenced by a shallow trough that was cut into the pumice deposit. It is likely that the hollow originally functioned as a drainage channel that funneled runoff into the lower southwest-to-northeast-trending drainage.

The dacite cobble outcropping apparently formed a barrier that allowed the preservation of soils within the hollow. The stabilized soils included an intact Bt1b1 through Bt3b1 sequence from which the majority of cultural remains were located. As indicated by the systematic site augering and selective test units, the Bt soil horizons are virtually non-existent above (west) and patchy when present out to either side of the hollow. It is inferred from the site stratigraphy that the upper hillslope was eroded during the late Pleistocene or early Holocene and that colluvium derived from Toledo bedrock or Toledo soils was deposited in the concave part of the hillslope (Drakos and Reneau 2004). The complete Bt soil sequence is limited to an approximately 3- by 4-m area located directly east of the dacite rock barrier as the upper Bt1b1 soil horizon is missing from the northern and eastern sides of the block excavation. The lower Bt1b1 and Bt2b1 soils are present throughout the hollow; however they are so heavily mixed that they are indistinguishable through the east-central portion of the excavation. It appears that many of the cultural materials originally retained in the hollow have gradually moved downslope toward the east and northeast in concert with the original hillside drainages. Significant vertical displacement of cultural materials also appears to be a byproduct of this depositional movement and significant bioturbation. Although the artifact density remains fairly high throughout the eastern half of the excavation, the context becomes more blurred with an increase in artifacts in lower soil horizons due to post-occupation mixing.

The maximum artifact concentration at the site was found in unit 90N/110E, and the majority of these artifacts were recovered from the Bt1b1 soil horizon. The lack of artifacts recovered from the Bt soils within 90N/107E provides evidence that the artifacts were not transported from upslope, but were originally deposited in the vicinity of 90N/110E. Although the artifact content in grids to the north and east of 90N/110E decreases somewhat, the similar artifact distribution pattern leads to the assessment that this general area is the focus for site activities.

No occupation surface was encountered during excavations. This lack of a surface is likely due to significant post-occupational mixing of cultural materials between strata as is indicated by the large number of artifacts scattered throughout the soil horizons. The relatively high Bt1b1 artifact content suggests that the site occupation surface was within this upper late-Pleistocene or early-Holocene colluvium, and likely within the upper half of this horizon (Stratum 3A). This infers that the artifacts found in the late-Holocene colluvium were supplied from local bioturbation of the underlying b1 soils. As evidence of extensive burrowing was observed in the Bt3b1 and Bkb1 soil horizons, associated artifacts are assessed to have been transported into these deeper deposits through rodent burrowing. Bioturbation that occurred after abandonment is also the likely source of artifact movement into the Bt2b1 soil horizon. The fact that the maximum artifact density occurs in the best-developed soil horizon (Bt1b1) suggests that most of the bioturbation occurred relatively soon after deposition of the colluvium and site abandonment, before development of these soil horizons. As the peak artifact density occurs in the upper part of the b1 soil, site occupation also apparently occurred late in the period of deposition (Drakos and Reneau 2004).

The drop in artifact totals observed in units 90N/115E and 90N/118E suggests that the site focus is located in the hollow and that several artifacts have eroded east into the area situated below the hollow. The good soil development in the focus area infers that the site has been relatively stable since the period of high bioturbation that occurred shortly after abandonment. Although bioturbation has obliterated the site structure, including the spatial relationship of artifacts and charcoal, the sheltered environment provided by the hollow allowed the majority of cultural remains to be retained in relative proximity to their original setting. The good assemblage composition should facilitate an assessment as to the site function(s) and to establish the general period(s) of site occupation. Charcoal was fairly rare below the late-Holocene deposits that contained charcoal associated with the Cerro Grande fire. Seventeen charcoal samples were recovered from the Bt soils. Approximately half of the charcoal samples were submitted for radiocarbon dating from which four dates were obtained. Three of the samples date to the Early Archaic period and one from the Ancestral Pueblo Classic period, which indicates that some stratigraphic mixing was occurring throughout the history of the site. The Classic period date likely corresponds to use of the area during the Ancestral Pueblo era as indicated by sites LA 85861 and LA 85415 located approximately 150 and 300 ft upslope to the southwest and south-southwest, respectively. The range of obsidian hydration dates for the site tend to support the two distinct periods of site activity with the three oldest dates derived from lower strata corresponding with the Early Archaic radiocarbon dates and the two youngest dates corresponding with the Classic period radiocarbon date. The remaining four obsidian hydration dates suggest that site activities also occurred between the Late Archaic and Classic periods. Unfortunately, with bioturbation obscuring the spatial relationship of the cultural remains, there are no distinct cultural lenses or use surfaces from which to establish a specific occupational sequence at the site, nor to establish the number of occupations that it took to build the site.

CHAPTER 39
RENDIJA TRACT (A-14): LA 85861

Gregory D. Lockard

INTRODUCTION

LA 85861 is the remains of a one-room Late Coalition period fieldhouse located on an east-facing slope on the mesa between Rendija and Guaje canyons. The site is located in the east-central portion of the Rendija Tract. Vegetation on the site consists of piñon, juniper, and ponderosa pines. The site is situated at an elevation of 2103 m (6900 ft).

LA 85861 was first recorded on September 12, 1991, by David Hill (1991) during a survey for the Bason Land Exchange Project. Hill interpreted the site as a campsite or possible fieldhouse. A diffuse artifact scatter at the site included obsidian, chalcedony, and siliceous rhyolite lithics and ceramics. The ceramics in the scatter included Wiyo and Santa Fe Black-on-white sherds, which led Hill (1991) to conclude that the site was occupied during the Late Coalition period. On July 20, 1992, Archaeological Research, Inc., was awarded the contract to conduct archaeological testing of the Bason Land Exchange sites. John Peterson and Christian Nightengale (1993) supervised the excavations, which took place between July 27 and August 23 of 1992.

A single 1- by 1-m test pit (Unit A) was excavated at LA 85861. Unit A was placed within a diffuse scatter of rocks that measured 4 by 5 m, which was designated Feature 1. No clear rock alignments were visible in the scatter of rocks. For this reason, Peterson and Nightengale believed the scatter to be the foundation stones of a structure built primarily of perishable materials. Unit A was excavated to a maximum depth of 55 cm below the ground surface. No clear rock alignments or living surfaces were encountered in the excavation. Ten sherds, however, were recovered from the unit. In addition, six lithics (including a chert core/chopper) and 20 sherds were recovered during a surface collection of the site. The ceramics recovered from the excavation and surface collection consist of one Black-on-red decorated sherd (possibly Glaze A or White Mountain Redware), five Wiyo Black-on-white, three Biscuit B, one Biscuit A, four smeared-indented, and 16 other utilityware sherds. Finally, a rock alignment located a few m to the northeast of Feature 1 was recorded. No excavations were conducted of this rock alignment, which was designated Feature 2.

FIELD METHODS

Before excavation, the site and surrounding area were cleared of trees and large undergrowth. The site was then visible as a diffuse scatter of rocks approximately 4 by 5 m in area, designated Area 1 (Peterson and Nightengale's Feature 1), and a small concentration of rocks to the northeast, designated Area 2 (Peterson and Nightengale's Feature 2) (Figure 39.1). An arbitrary site datum (designated 100N/100E, 10.00 m elevation) was set up in the southwestern portion of the site. The site was then covered with a 1- by 1-m grid that extended 9 m to the north, 7 m to the east, and 3 m to the west of the site datum. Four subdata (A-D) were set up for taking elevations. The site was then photographed. Artifacts visible on the surface were then collected by grid unit. The location of artifacts outside of the grid was determined with tape measures. A 6- by 1-m east-west trench (units 104N/99-104E) was initially excavated across Area 1.

Figure 39.1. Pre-excavation photograph of LA 85861.

Because there were no clear rock alignments on the surface, the primary purpose of this trench was to determine if the rocks in the area were the remains of a structure. The trench also served to expose a profile of the site's stratigraphy. Units were excavated by strata, and thicker strata were excavated in arbitrary 10-cm levels. No living surface was encountered in any of the trench units. Excavation of these units therefore proceeded down to Cerro Toledo bedrock. A concentration of several rocks was encountered in units 104N/100-101E, and two rocks were encountered in unit 104N/99E. These rocks, however, did not form any obvious alignments. It was therefore unclear whether they were part of the walls of a structure. The later excavation of units to the north, however, revealed that they were in fact the remains of the disturbed southernmost portion of a one-room fieldhouse, which was designated Room 1. After the excavation of the trench units, the north profile of the trench was drawn and photographed. The rest of the area was subsequently excavated, again by strata and arbitrary levels for thicker strata.

In all, 36 units were excavated in Area 1. During the excavation of these grid units, the diffuse scatter of rocks in Area 1 was determined to be a one-room fieldhouse, and the walls of the fieldhouse were defined. Patches of a poorly preserved living surface were only encountered in two units (105N/99-100E). The units that were excavated before Room 1 was discovered (105N/103E and 106N/103E and 104E) were excavated to bedrock. Subsequently, units were excavated to the level of the base of the foundation of the room's walls, or the living surface in the case of units 105N/99-100E. Excavation of Area 1 focused on defining the room's walls, removing wallfall, and locating features. Soil samples were taken from select locations, and all other soil was passed through screens with 1/8-in. mesh to aid in the recovery of artifacts. The excavation area extended at least 1 m beyond the structure in all directions to locate external features and/or outdoor activity areas. The small concentration of rocks in Area 2 was excavated in four units (107-108N/105-106E). The excavations revealed the rocks to be superficial, and no clear alignments were detected. If the concentration of rocks was a cultural feature, its function is therefore unknown. After the excavation of Areas 1 and 2 was complete, the site was mapped (Figure 39.2) and photographed (Figure 39.3).

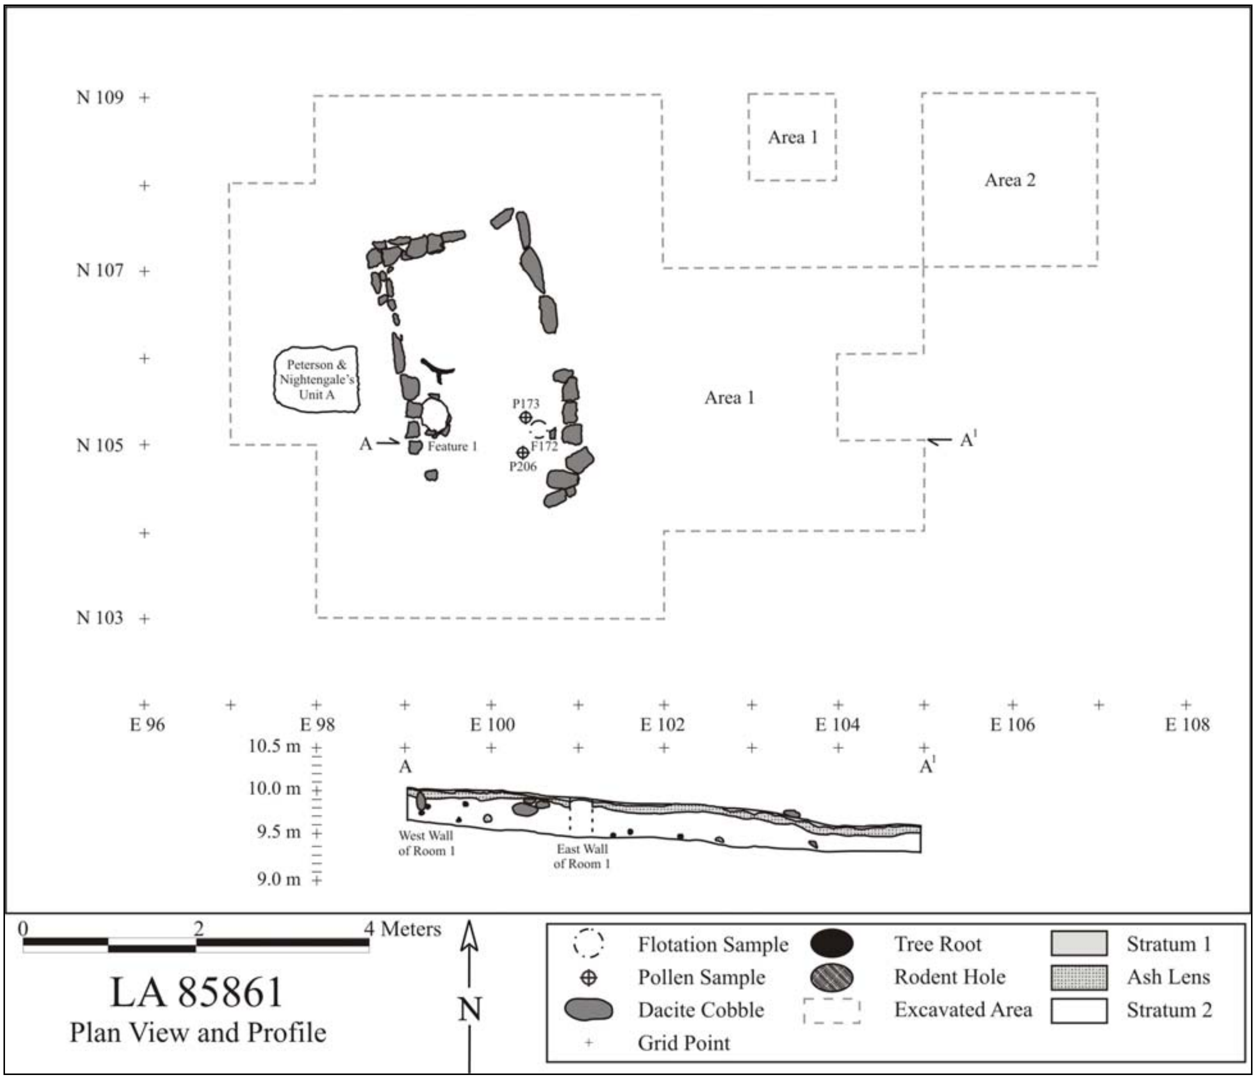

Figure 39.2. Plan view and profile of the fieldhouse at LA 85861.

Figure 39.3. Post-excavation photograph of the fieldhouse at LA 85861.

The excavation of the site was supervised by Greg Lockard. The field crew included Michael Dilley, Alan Madsen, Brian Harmon, Jen Nisengard, Sandi Copeland, and Bettina Kuru'es. Timothy Martinez and Aaron Gonzalez served as site monitors from San Ildefonso Pueblo and as screeners. Jeremy Yepa was the site monitor representing Santa Clara Pueblo, as well as an additional excavator.

STRATIGRAPHY

Stratum 1 is composed of loose surface sediment. It is uniformly 2 to 7 cm thick across the site and is part of the A horizon (topsoil). Stratum 2 is post-occupational fill and ranges from 20 to 40 cm in thickness in Area 1 and 20 to 25 cm in thickness in Area 2. Stratum 2 is more or less equivalent to the Bw and Bwb1 horizons. Stratum 3 is the backfill removed from Peterson and Nightengale's Unit A. Stratum 3 is therefore a disturbed context. Stratum 4 is the ashy fill removed from Feature 1 (hearth). Tables 39.1 through 39.5 summarize and describe the strata excavated at LA 85861.

Table 39.1. LA 85861 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface

Stratum	Color	Texture	Thickness (cm)	Description
1	10YR 5/4	Loamy sand	2–7	Surface sediment
2	10YR 4/4	Sandy loam	20–40	Post-occupational fill
3	10YR 4/4	Sandy loam	20	Backfill from P & N test pits
4	10YR 4/2	Sandy loam	9	Feature 1 (hearth) fill

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is a small rectangular structure that probably functioned as a fieldhouse. The walls in the southernmost portion of the room have been severely disturbed, and many of the rocks are missing in this area. The room measures approximately 3.05 m in length (north to south) by 1.70 m in width (east to west), with approximately 5.19 m^2 of interior space. Excavation of the room began with an east-west trench that extended across the diffuse scatter of rocks visible on the surface of Area 1 (units 104N/99-104E). The excavation of this trench served to define the room's stratigraphy, as well as to locate several rocks that turned out to be the extant portions of the walls that formed the southernmost portion the room. These rocks were not determined to be part of the walls of a structure, however, until grid units to the north of the trench were excavated. No living surface was encountered in any of the trench units. The poorly preserved remains of the room's living surface were encountered, however, in two grid units to the north of the trench (105N/99-100E). The room's only internal feature, a small, stone-lined hearth, was also encountered in unit 105N/99E. No living surface was encountered within Room 1 in the units to the north (106-107N/98-100E). The excavation of these grid units therefore terminated at the base of the foundation of the room's walls.

Fill. The interior of Room 1 was filled with 2 to 7 cm of surface sediment on top of 20 to 35 cm of post-occupational fill. A flotation sample (Field Specimen [FS] 98) and a pollen sample (FS 99) were taken from the Room 1 fill, but these samples were not analyzed.

Floor. During the excavation of unit 105N/99E, a small elliptical hearth was encountered. A few very small patches of a poorly preserved living surface were encountered in the area surrounding the hearth. These small patches of living surface were presumably preserved as a result of being slightly hardened by the heat from the hearth. A compact surface relatively devoid of rocks was also encountered in the unit directly to the east (105N/100E). This surface extends into the northernmost portion of unit 104N/100E. By itself, it was not a convincing living surface. Due to the fact that it was at about the same level as the top of the hearth and the small patches of living surface in unit 105N/99E, however, it probably was in fact the very poorly preserved remains of the Room 1 living surface. A flotation sample (FS 172) and two pollen samples (FS 173 and FS 206) were taken from directly on top of this presumed living surface. The flotation sample was not analyzed, and taxa identified in FS 173 included rose family, cheno-ams, grass family, sunflower family, piñon pine, juniper, oak, and sagebrush. No living surface of any kind was encountered in other areas of the room. For this reason, these areas were excavated to the base of the foundation of the room's walls.

Wall Construction. The extant portions of the Room 1 walls were composed of dacite rocks, many of which are tall, thin, upright slabs (Table 39.6). The elevation of the living surface encountered in the southern half of the room, as well as staining on some of the rocks, indicates that the room's foundation was placed in a trench approximately 15 cm deep. The remains of a second course of rocks were preserved in all but the west wall. The rocks that form this second course tend to be tabular dacite cobbles placed flat on top of the foundation rocks. There is a 30-cm gap in the eastern half of the northern wall. This gap is most likely the result of a missing foundation rock. There is also a gap in the east wall, which is 55 cm wide. Due to its width and the fact that the fieldhouses excavated in the Rendija Tract during the Conveyance and Transfer Project tend to have entryways to the east, this gap was most likely the room's entryway. Just south of the entryway, a patch of burned daub was encountered on the east wall's exterior face. A piece of this burned daub was collected as a thermoluminescence (TL) sample (FS 249) and dated to 1193±53. Much of the walls that form the southernmost portion of the room have been severely disturbed. Several rocks appear to be missing from the southernmost portion of the west wall, and all but the easternmost 35 cm of the south wall is missing. It is therefore possible that the room's entryway was located in the south wall instead of the east wall.

Judging from the amount of wallfall removed during the excavation of the area in and around Room 1, the masonry portions of the room's walls were originally considerably higher than they were at the time of excavation. In order to estimate the original height of the walls, all of the rocks removed as wallfall during the site's excavation were placed in two stacks, which were then measured. The stacks measured 1.60 by 0.88 by 0.60 m and 1.80 by 0.55 by 0.37 m, for a total of approximately 1.21 m^3 of wallfall. Based on this volume of wallfall and the overall length, average thickness, and average height of the extant portions of the walls, the masonry portions of the room's walls were originally approximately 1.10 m in height. The uppermost portions of the walls, as well as the ceiling, were most likely composed of wattle and daub. A number of pieces of burned adobe were in fact recovered from the site.

Table 39.6. LA 85861 Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	1.70	0.18–0.32	0.10–0.26	1 to 2
South	~1.60	0.25–0.30	0.10–0.26	1 to 2
East	2.45 (3.00)	0.08–0.35	0.10–0.23	1 to 2
West	>2.56	0.15–0.25	0.10–0.20	1

Notes: The exact prehistoric length of the south and west walls could not be determined; the length of the east wall including the possible entryway is given in parentheses; the wall height measurements for the north, south, and east walls were measured from the base of the walls instead of from a living surface.

Feature 1

Feature 1 is a shallow, elliptical hearth located just inside the west wall of Room 1 (Figures 39.4 and 39.5). A large, flat rock forms the base of the hearth. Much of the perimeter of the southern half of the hearth is formed by three small rocks. A fourth rock defines the northern edge of the hearth. Three of the rocks are dacite, and the fourth is tuff. The rest of the hearth's perimeter appears to have been formed by an adobe lining. This lining, however, is now only preserved on the east wall and in a small patch on the west wall of the hearth. The adobe lining on the east wall extends down and partially covers the rock at the base of the hearth. This indicates that the adobe lining probably originally covered the entire interior of the hearth, including the base. The hearth was filled with ashy sediment. A medium- to large-sized mammal bone awl (FS 196) and a lithic (FS 197) were recovered from the upper portion of this fill. The rest of the fill was collected in four flotation samples (FS 191, FS 192, FS 193, and FS 194). Carbonized taxa from these samples included beeweed, unknown conifer, piñon pine, cheno-ams, mint family, unidentified pine, ponderosa pine, and maize. Three additional faunal remains were recovered from the heavy fraction of two of these samples. In addition, a pollen sample (FS 195) was taken from the base of the hearth. Identified taxa included maize, buckwheat, grass family, cheno-ams, sunflower family, evening primrose, ragweed/bursage, unidentified pine, piñon pine, and sagebrush.

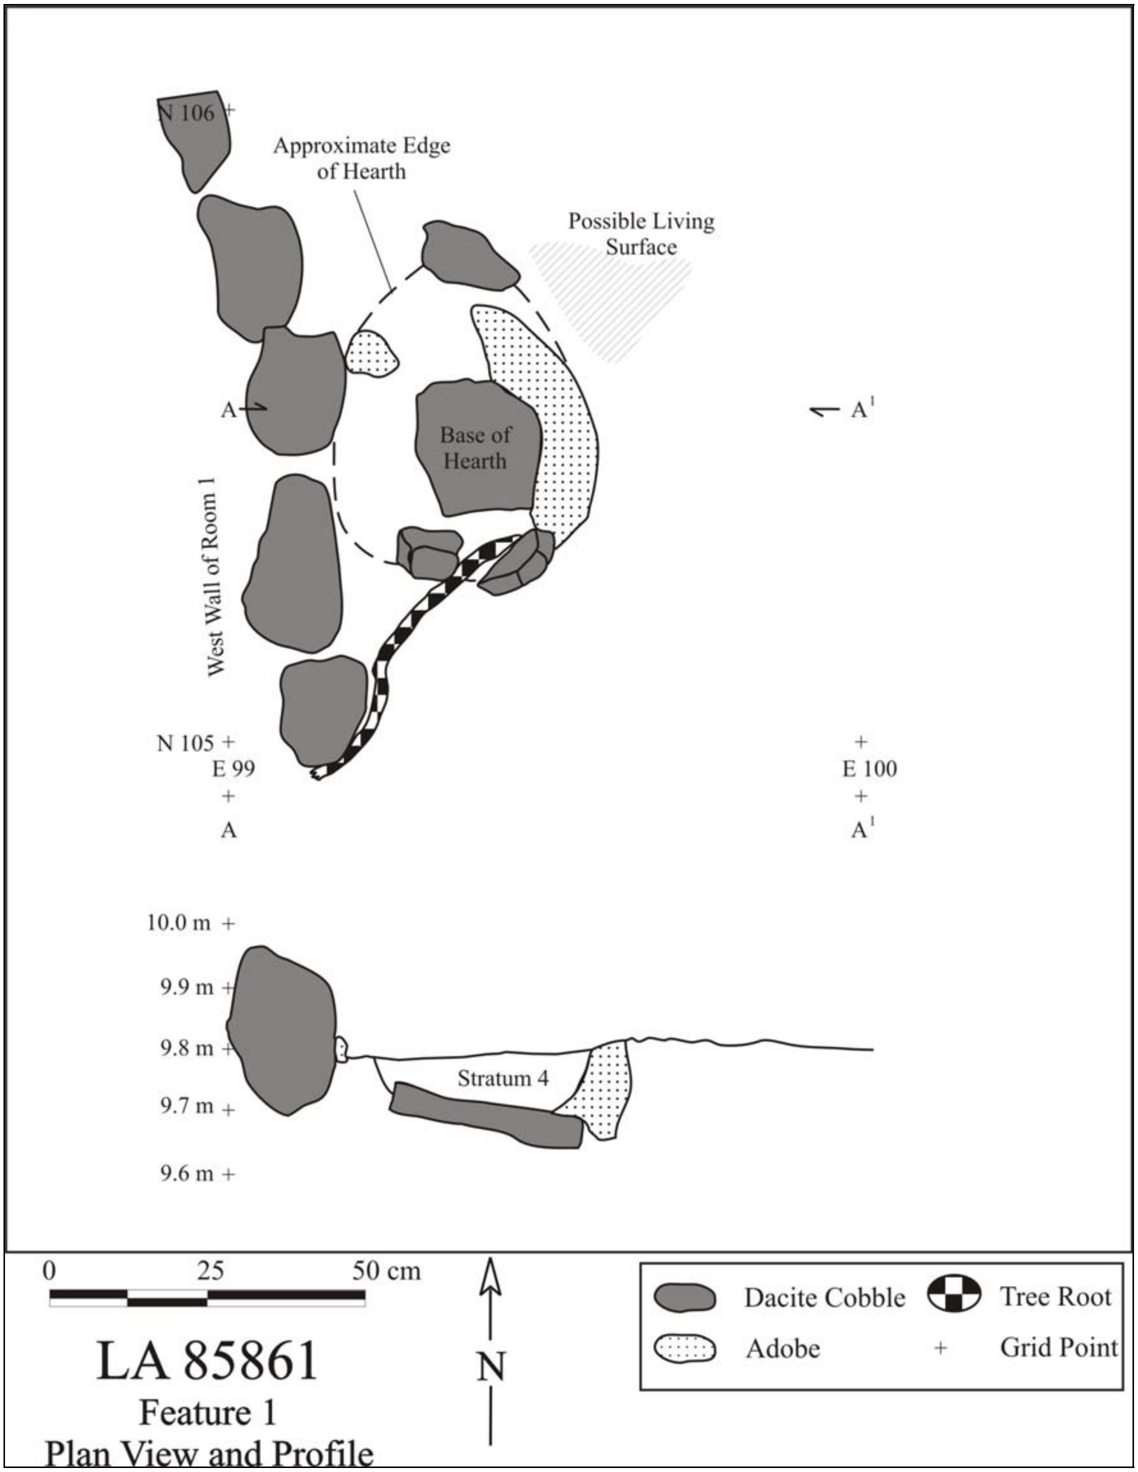

Figure 39.4. Plan view and profile drawing of Feature 1, a hearth.

Figure 39.5. Post-excavation photograph of Feature 1, a hearth.

Geological Analysis

Geologists Paul Drakos and Steven Reneau conducted a full analysis on three profiles (see Tables 39.2 through 39.4) and a partial analysis on a fourth profile at LA 85861. The profiles that were fully analyzed were the north profile of unit 106N/104E, the north profile of unit 108N/106E, and the exterior face of the north wall of Room 1 (within unit 107N/99E). The partially analyzed profile was the north profile of unit 108N/99E. All four profiles contained a soil sequence consisting of an A horizon (topsoil), a Bw horizon (a late Holocene soil), a Bwb1 horizon (a middle- to late-Pleistocene soil), and a Rk horizon (Cerro Toledo bedrock).

Artifact Distribution

The grid units with the highest number of artifacts in Area 1 at LA 85861 include the unit in which Feature 1 is located (105N/99E) and the unit immediately to the east (105N/100E) (Table 39.7). The high number of artifacts in these units is therefore most likely due to activities that took place around the hearth. The other units with a high number of artifacts in Area 1 are located to the east of Room 1 (104-106N/101-104E). This indicates that the area to the east of the room was most likely an outdoor activity area. This conforms to the pattern for most of the fieldhouses excavated in the Rendija Tract during the Conveyance and Transfer Project. Furthermore, it supports the interpretation that the gap in the east wall of Room 1 is the room's entryway, as outdoor activity areas also tend to be located directly in front of the entryway.

Table 39.7. LA 85861 artifact counts by grid unit.

	E97	E98	E99	E100	E101	E102	E103	E104	E105	E106

Note: Does not include 10 artifacts found outside of the excavated area during surface collection; bold numbers indicate grid units that are located completely or partially within Room 1.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 537 artifacts were analyzed from the excavations conducted at LA 85861. In addition, flotation and pollen samples were selected for analysis from the post-occupational fill (Stratum 2) and Feature 1 hearth fill (Stratum 4) (Table 39.8). Maize was submitted for radiocarbon dating, and a sherd and piece of burned adobe wall plaster were selected for TL dating. The results of the artifact and sample analyzes are presented in the following sections.

Table 39.8. Samples selected for analysis from LA 85861.

Stratum	Sample Type			
	Flotation	Pollen	Radiocarbon	TL
1				
2		173, 184		142, 249
3				
4	191, 192, 193, 194	195	193	

Chronology

Radiocarbon Dating

One maize sample was submitted for accelerator mass spectroscopy dating. This specimen was derived from a flotation sample taken from the Feature 1 hearth fill (FS 193). The sample provided a date of 930±40 BP (Beta-221842), with calibrated intercepts of AD 1050, AD 1100, and AD 1140 and a two-sigma range of AD 1020 to 1200.

Thermoluminescence Dating

A single smeared plain corrugated sherd and a piece of burned adobe wall plaster were submitted for TL dating from LA 85861 (Table 39.9). All derived ages are given in years BP, which refers to years before 2003. Both TL dates correspond to the two-sigma range of the radiocarbon dates.

Table 39.9. TL dates from LA 85861.

FS#	Lab #	Context	Burial depth (cm)	Years BP	% error	Years AD
142	UW1508	Sherd, Room 1, Stratum 2	33	795	9.2	1211±73
249	UW1509	Burned plaster, Room 2, Stratum 2	30	813	6.6	1193±53

Archaeomagnetic Dating

A single surface room with a hearth was the only candidate for archaeomagnetic sampling at this site. The surface room was a fieldhouse, and associated pottery suggested an Early Classic period occupation to the field excavators. The hearth itself was rock lined, and the interstitial plaster was too weakly burned and too disturbed for normal sample definition and collection. Four specimens were prepared and were submitted for measurement as ADL 1307. An experimental approach was used during the collection of this sample, and although these results are not helpful for the dating of the LA 85861 structure, they do validate the experimental field sampling approach used in this case (see Blinman and Cox, Volume 3 for further details).

Ceramic Artifacts (Dean Wilson)

A total of 439 ceramics were analyzed from LA 85861. The majority of the pottery consists of smeared plain corrugated and Santa Fe Black-on-white sherds. These types, in conjunction with the presence of Wiyo Black-on-white, would indicate a Late Coalition period date during the 13th century (Table 39.10). However, the radiocarbon date reflects an Early Coalition period occupation dating to the 12th century, and the TL dates overlap both the 12th and 13th centuries. Information on ceramic tradition by ware, temper by ware, and vessel form by ware are provided in Tables 39.11 through 39.13. The graywares and whitewares appear to have been locally made from tuff temper while the Sapawe Micaceous sherds contained a non-local micaceous temper. All of the grayware and micaceous ceramics were jars while the whiteware sherds consisted solely of bowl sherds.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 108 artifacts were analyzed from LA 85861, consisting of two cores, 79 pieces of debitage, 10 retouched tools, 14 ground stone artifacts, and three hammerstones. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 39.14 presents the data on lithic artifact type by material type. The debitage is primarily made of chalcedony, with less Pedernal chert, obsidian, and other materials. The presence of cortex on 10.1 percent of the debitage indicates that these materials were collected from waterworn (n = 7) and nodule (n = 1) sources. The chalcedony, Pedernal chert, and quartzite are available from local Rio Grande Valley gravels and the obsidian from nearby sources in the Jemez Mountains. Otherwise, the igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the plateau.

Nine pieces of obsidian debitage, an obsidian biface, and a single basalt flake were submitted for X-ray fluorescence analysis. The obsidian artifacts are mostly made from Valle Grande obsidian, however, two artifacts are made of Cerro Toledo obsidian (Table 39.15). The Valle Grande (Cerro del Medio) and Cerro Toledo (Obsidian Ridge/Rabbit Mountain) source areas are located about 17 km (11 m) and 19 km (12 mi) to the west and southwest. Although obsidian is present at these nearby sources in the Jemez Mountains, it is also present on the mesa as small pebbles. These pebbles compose part of the secondary deposits associated with the Cerro Toledo interval. The single basalt flake is actually dacite derived from a local source.

Lithic Reduction

The cores were reduced using a bidirectional, bifacial, and 90 degrees reduction technique (Figure 39.6). They were classified as still useable and discarded due to extensive hinging/stepping. Table 39.16 presents the metric information on the cores.

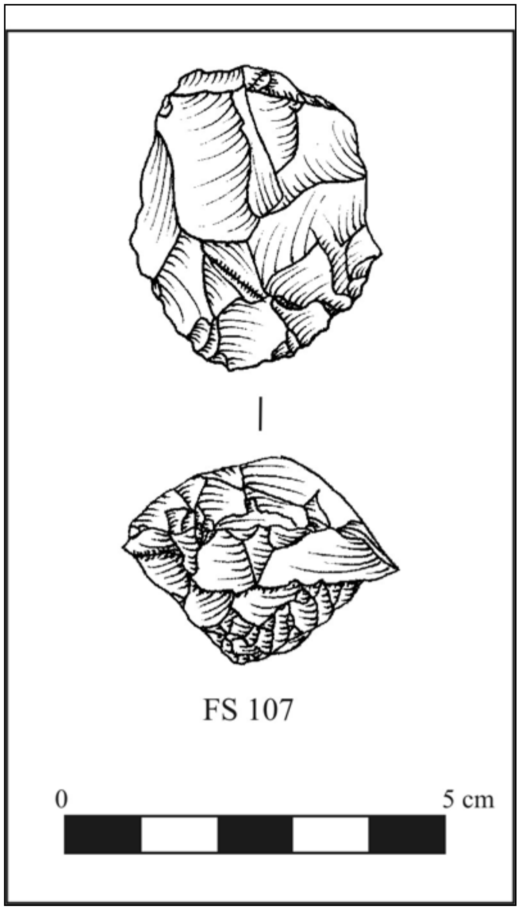

Figure 39.6. Bifacial core.

Table 39.16. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Bi-directional	41	52	95	196.7
Bi-directional	42	35	26	30.1

The debitage consists of core flakes, with fewer biface flakes, angular debris and other items. The overall cortical:non-cortical ratio of 0.14 reflects a slight emphasis on the later stages of core reduction and biface production/maintenance. The flakes mostly have single-faceted platforms (*n* = 19), with fewer cortical (n = 1), multi-faceted (n = 1), collapsed (*n* = 5), and crushed (*n* = 8) platforms. Four of the platforms exhibit obvious evidence of preparation by abrading/crushing. The majority of the core flakes are whole (*n* = 20), with fewer proximal (*n* = 6), midsection (*n* = 3), and distal (*n* = 18) fragments. Most of the biface flakes are also whole (*n* = 7), with fewer proximal (*n* = 1), midsection (*n* = 2), and distal (*n* = 4) fragments. The whole core flakes have a mean length of 20.2 mm (*std* = 8.9), the biface flakes a mean length of 28.7 mm (*std* = 7.6), and the angular debris a mean weight of 4.0 g (*std* = 5.7).

The retouched tools consist of retouched pieces, bifaces, and unifaces (Figure 39.7). The retouched pieces can be differentiated between small and large retouched flakes. The small flakes include a fragment with unidirectional dorsal retouch along two edges that produces a slight project where the edges intersect. Another retouched piece is a wedge-shaped flake fragment that also exhibits unidirectional dorsal retouch along a lateral edge. The three large flakes are made of dacite, chalcedony, and quartzite and exhibit marginal unidirectional dorsal or ventral retouch along their lateral sides or ends with edge angles of 65 to 75 degrees.

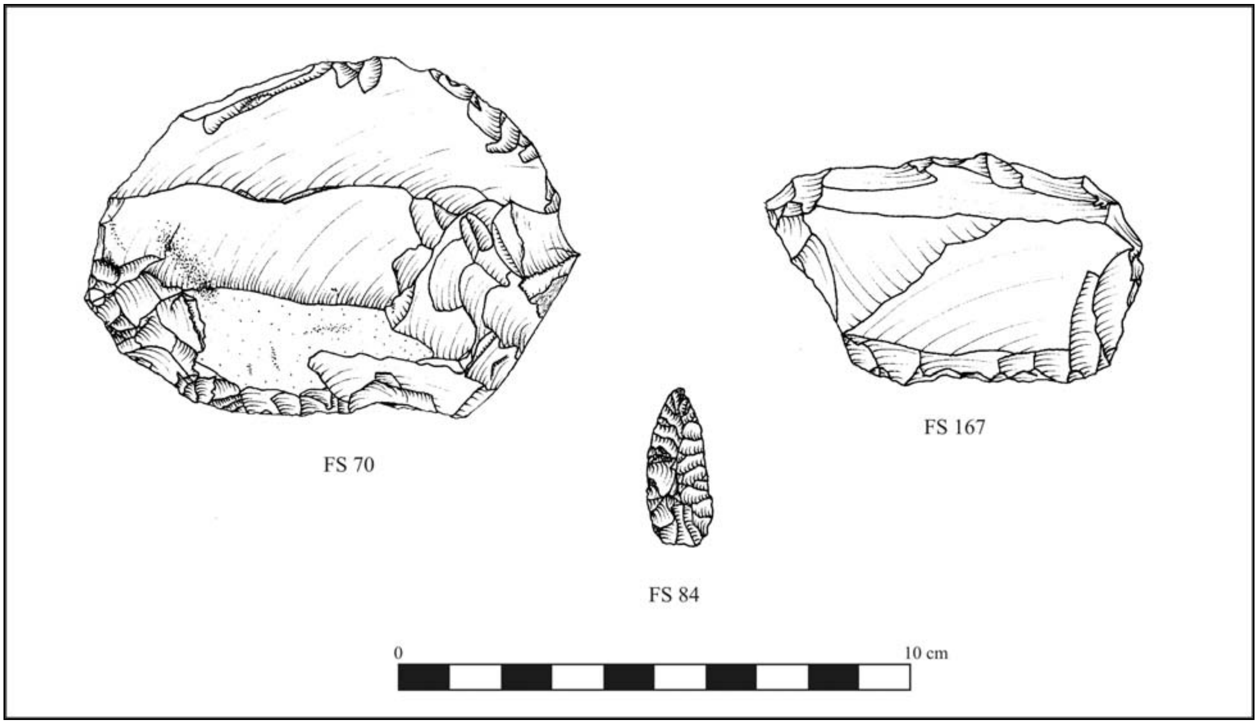

Figure 39.7. Retouched flake, biface, and uniface from LA 85861.

The bifaces include a whole lanceolate-shaped late-stage biface. This item presumably represents a preform with a thickness of 5 mm and edge angle of 50 degrees. The other biface is a distal fragment. The unifaces are flakes with unidirectional dorsal retouch along most of their perimeters, with steep edge angles of 70 and 75 degrees. One has a slightly denticulated edge that could represent both a scraper and graving tool.

Tool Use

A single flake exhibits evidence of edge damage that could be attributed to use. This flake has some rounding and microscarring on its lateral edge with an edge angle of 55 degrees. Three of the five retouched pieces exhibit some round, polish, or microscarring that could be attributed to use and both unifaces also exhibit use-wear consisting of microscarring.

The ground stone includes manos, a metate, a polishing stone, a grooved abrader, and a hoe (Figure 39.8).

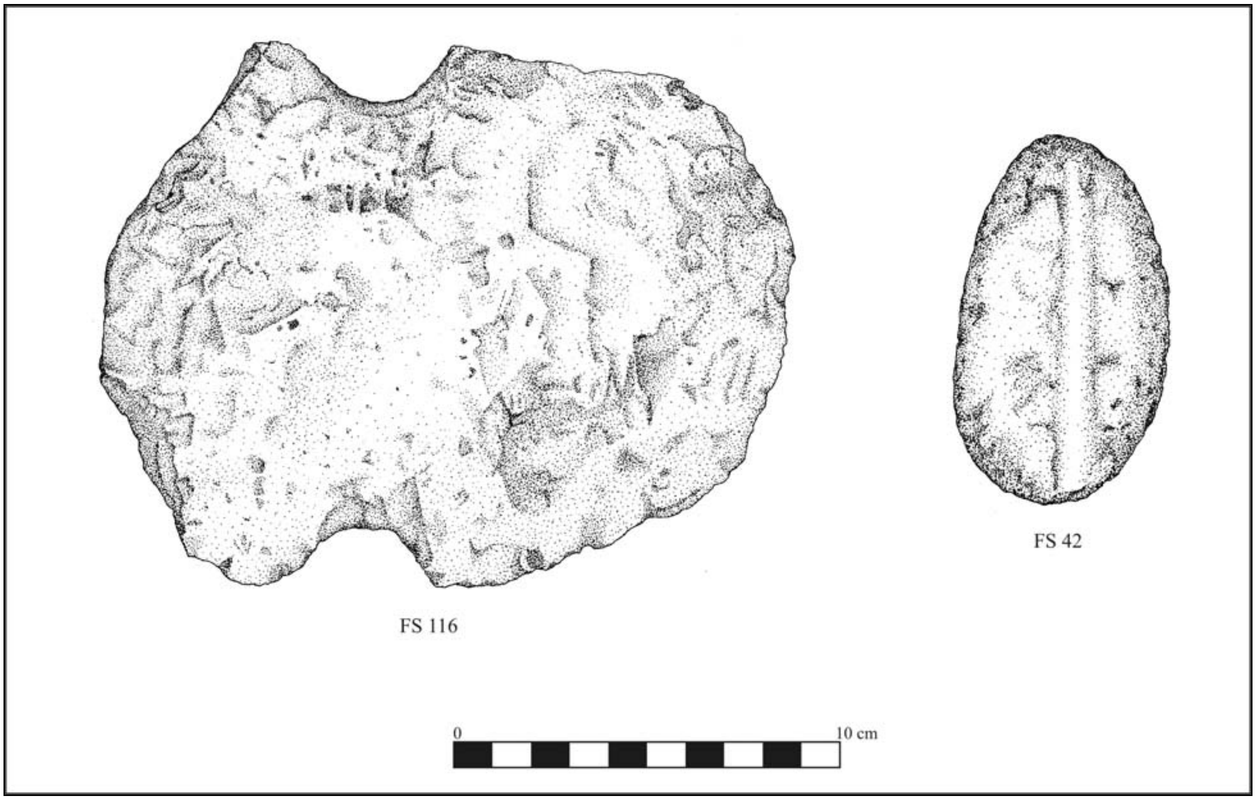

Figure 39.8. Hoe and grooved abrader from LA 85861.

The manos consist of a one-hand cobble with two opposing ground surfaces and a cobble fragment with a single ground surface. The metate is a large piece of dacite with a single flat ground surface. This item could represent a millingstone. The polishing stone is a small basalt pebble that is highly polished and exhibits multiple striations. The grooved abrader is a tuff cobble with a ground central groove**.** The hoe is a large thin piece of basalt that has been notched along both sides for hafting and the bit has been slightly shaped into a convex outline. It seems more likely that the artifact represents a hoe rather than an axe because it does not exhibit scarring along the edge, but polish on the high spots of both opposing blade surfaces. The undetermined ground stone consists of a dacite cobble fragment with a single ground surface and battered end. It could represent a mano that was also used as a hammerstone. The second ground stone item is a tuff slab fragment with a flat ground surface that could be part of a metate.

Lastly, the other two fragments are pieces of dacite that refit and have a single slightly concave grinding surface.

Faunal Remains (Kari Schmidt)

Five pieces of bone were recovered during excavations of this Late Coalition/Early Classic period fieldhouse. One piece of bone was recovered from Stratum 2 (post-occupational fill). This bone was identified as an unidentified mule deer (*Odocoileus hemionus*) second phalanx. The remaining four bones were recovered from the hearth (Feature 1, Stratum 4) and included a leporid molar and small-sized, small/medium-sized, and medium/large-sized mammal long bone fragments. None of the remains were burned. The medium/large-sized mammal long bone fragment was manufactured into an awl fragment.

Archaeobotanical Remains (Pamela McBride)

Although lacking the diversity of some of the other Rendija Canyon fieldhouses, the hearth in this fieldhouse contained beeweed seeds. A cheno-am seed fragment, a mint family seed, and unidentifiable plant part fragment, piñon needles, and two maize cupules comprise the balance of the cultural plant material recovered (Table 39.17). Unburned piñon needles were the only modern plant parts present. Small quantities of pine, piñon, ponderosa pine, and unknown conifer charcoal were also identified (Table 39.18).

Pollen Remains (Susan Smith)

Three pollen samples were analyzed from LA 85861. Table 39.19 lists the frequency of identified pollen types. Maize was the only cultigen identified in the botanical assemblage and was found in only one sample. Beeweed, which is also an economic resource, was identified in the assemblage. A number of potential economic resources were also identified in the assemblage (Table 39.19), and these are discussed in detail in Smith's chapter in Volume 3.

SUMMARY

LA 85861 is a small one-room Late Coalition period fieldhouse that was constructed from both shaped and unshaped tuff blocks. The site is situated on the mesa above Rendija Canyon near LA 85417 (another Coalition period fieldhouse). One feature, a small hearth, was identified at the site. The presence of maize cupules and pollen indicates that the one-room structure may have been occupied during the growing season. Unlike most the fieldhouses which emphasize core reduction activities, this site also included evidence of biface production/maintenance.

CHAPTER 40
RENDIJA TRACT (A-14): LA 85864

Steven R. Hoagland

INTRODUCTION

LA 85864 is a tipi or wickiup ring situated on the tip of a ridge finger situated between two 2- to 3-m-deep, narrow arroyos. The site is located at an elevation of 2127 m (6980 ft) in an area dominated by piñon-juniper woodland. The site has been severely impacted by erosion with the east side and most of the north side tipi ring rocks apparently having washed down into the adjacent arroyos. The north side arroyo, which has a 30-degree side slope, has cut into the tipi ring, and the south-side arroyo is located from 2 to 3 m south of the tipi ring. Most of the remaining site surface slopes down toward the south-side arroyo. This southern slope is subject to sheet washing. The two arroyos intersect approximately 12 m east of the site. The extensive erosion along the northern and eastern sides of the site is estimated to have washed away about 40 percent of the rock ring. The site has also been impacted by five trees growing in the northern half of the tipi ring.

PREVIOUS INVESTIGATIONS

The site was originally documented in 1991 for the Bason Land Exchange Project as a curvilinear alignment of large rocks spaced between 0.4 and 0.75 m apart (Hill 1991). The rocks that originally formed the eastern half of the tipi ring had eroded down into the site-cutting arroyos before its recordation. The original tipi ring was assumed to have measured 4.5 m in diameter. Two sherds were found near the structure; one was located in the arroyo south of the cobble ring and the other located on the ridge approximately 8 m west of the tipi ring. One sherd had a micaceous black paste and the other had a gray paste and tuff temper. A chalcedony core was also observed near the structure. A rhyolitic tuff slab with a grounded surface was located 20 m east of the structure.

A 1- by 1-m test unit (Unit A) and two shovel tests were excavated in 1992 during testing conducted for the Bason Land Exchange Project (Peterson and Nightengale 1993). Unit A, which was placed within the rock ring, was excavated to a depth of 22 cm. The southwest quadrant of a hearth was exposed at a depth of 16 cm. The hearth was represented by a concentration of ash and charcoal with burned clay beneath. It appeared that the hearth was built on the ground surface with no pit or enclosing rock ring. Charcoal submitted for radiocarbon analysis was dated to 130±60 BP (AD 1820/AD 1740 to 1900). Five small unidentified pieces of burned bone were recovered from a flotation soil sample collected from the hearth. No cultural materials were located in the shovel tests that were placed just beyond the tipi ring rocks to the west and south.

During site testing, four surface artifacts were observed and collected (Peterson and Nightengale 1993). The sherds included a Biscuit A decorated sherd and two utilitywares (one broken into two pieces). One of the utilityware ceramics was a smeared-indented sherd. The remaining artifact was a chalcedony core/chopper. With the exception of the Biscuit A sherd, these artifacts were found in eroded areas of the site.

Before the 2003 excavations, the site consisted of a semi-circular alignment of 11 dacite rocks spaced from 0.1 to 1.7 m apart. The rocks that appeared to form the western half of a tipi ring ranged from about 15 to 40 cm in diameter. Based on the location of the existing rocks, the tipi ring would have been 4.5 to 5 m in diameter.

FIELD METHODS

Fieldwork at LA 85864 began on December 8, 2003, with an initial assessment of the site. The crew, which initially consisted of Steve Hoagland, Bettina Kuru'es, Michael Kennedy, Mark Hungerford, and Aaron Gonzales, walked over the site area and delineated the site boundary. As the fieldwork progressed, Alan Madsen, Greg Lockard, and Mia Jonsson aided in the excavations. The assessment consisted of the crew systematically walking the site at 2- to 3-m intervals. No surface artifacts were located close to the tipi ring.

After the site assessment was completed, the main site datum (Datum A) and baselines for a 1- by 1-m grid system were established. The datum was placed 2 m west of the western edge of the tipi ring on top of the ridge finger. It was designated as grid point 100N/100E and assigned an elevation of 8.0 m. One-hundred-meter tapes were used to set up the grid system. The southwest corner intersection of each grid unit determined its coordinates. Before initiation of the site excavation, the grid system was used to complete a comprehensive metal detector survey of the site (see Appendix N for results).

The site excavation involved the hand excavation of 1- by 1-m grid units. This technique was used to define the extent, depth, and character of the subsurface deposits. Grid level excavation designations started with zero at the surface, then from 1-n from the top to bottom of each grid unit (regardless of whether the level was natural or arbitrary). The excavation was conducted using shovels and hand trowels. With the exception of pollen, soil, and macrobotanical samples, all hand-excavated materials were screened through 1/8-in. mesh screens. All collected materials were documented within a Field Specimen (FS) Catalog form.

A Grid Level Excavation Form was completed for each completed excavation level. Documented information included the depth of the excavation level, description of the sediment matrix, recovered cultural materials, and the nature and reason for samples collected. Pollen and flotation samples were collected from selected strata. Macrobotanical samples were also collected from the site.

Grids were excavated by natural stratigraphic units. Those units thicker than 10 cm were excavated in arbitrary 10-cm levels. A stratum was defined as a distinct depositional unit. To facilitate vertical control, subdata containing the same 8-m elevation as Datum A were established close to the excavation units. Grid levels were measured from the datum or subdata using string and line levels. An assessment for geomorphic context and integrity was conducted by Steve Reneau and Paul Drakos, and results can be found in Chapter 57 in Volume 3.

An overall site map was assembled during the course of excavation (Figure 40.1). It depicted the site boundary, site datum, subdata, and excavation units. The site map was created with 100-m tapes. The site and components that make up the sites were photographed with a color digital camera and a 35-mm camera with black-and-white film (ASA 100).

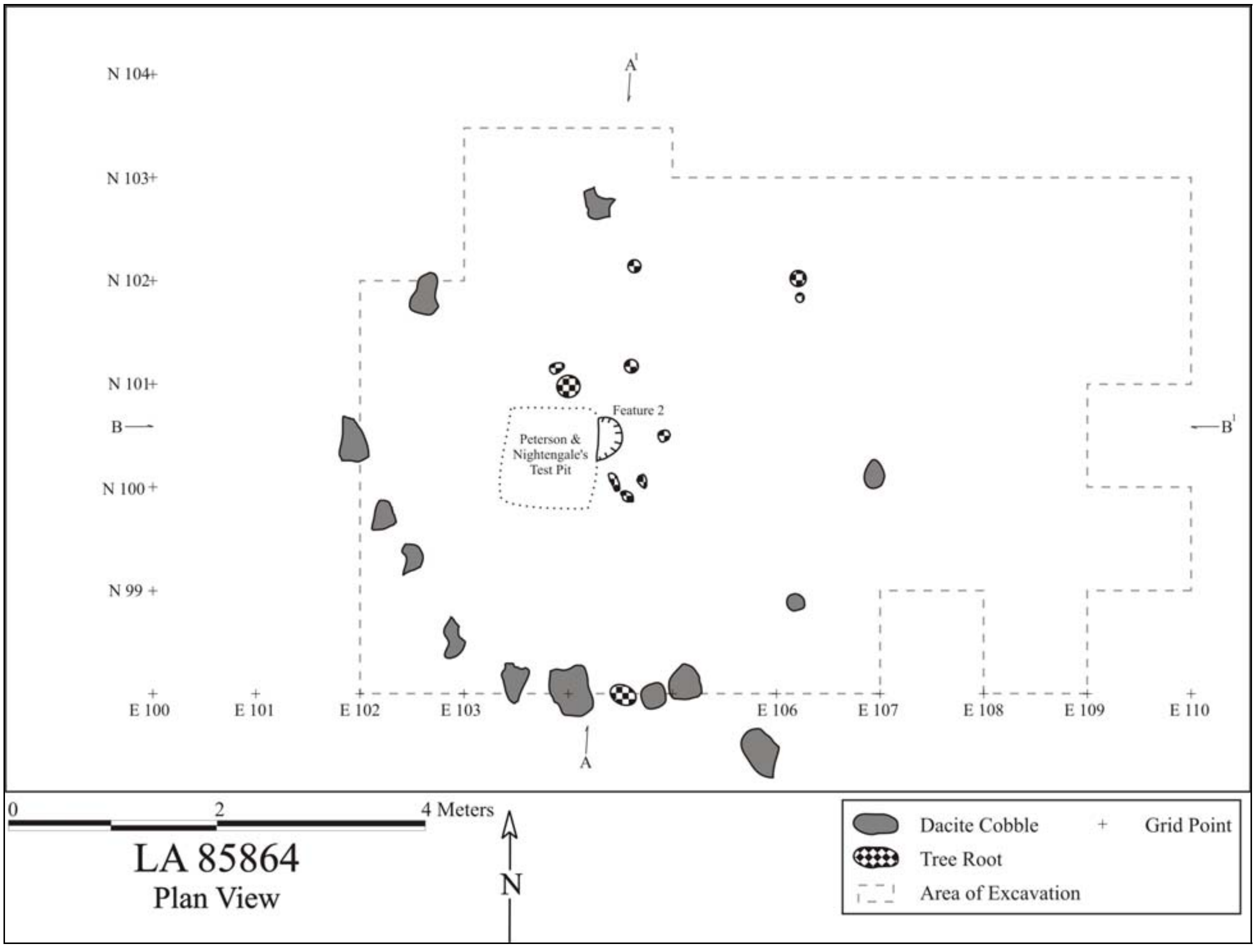

Figure 40.1. Post-excavation plan view of the structure at LA 85864.

STRATIGRAPHY

LA 85864 is situated on a preserved valley bottom remnant between two 2- to 3-m-deep southeast-sloping gullies. The soil at the site includes a 1- to 18-cm-thick A horizon overlying a 10-plus-cm-thick Ab1 horizon. The tipi ring rocks are set on top of or slightly within the Ab1 horizon. No distinct occupational surface was encountered during the excavation, however, based on the stratigraphy, it was likely established on top of the Ab1 horizon. The A horizon post-dates construction of the tipi ring.

The A horizon soil is a loose to lightly compact sandy to silty loam (10YR 4/4) that was divided into and excavated in two distinct stratums. Stratum 1 was the upper loose surface component that contained varying amounts of duff. Stratum 2 was the lightly compacted lower A horizon component that ranged in thickness from 0 to 15 cm. The compaction of Stratum 2 increases slightly with depth. The areas of greater A horizon thickness were located adjacent to trees growing out of the center of the tipi ring. The trees tended to minimize erosion and stabilize the adjacent soil. A few small pockets of A horizon soil containing from 10 percent to 40 percent pumice gravels were noted along the south side of the block excavation.

The Ab1 horizon (Stratum 4) is a fairly compact and often friable silty clay loam (10YR3/4). The Ab1 soil texture became friable where it had apparently been impacted by water erosion. The horizon boundary between A and Ab1 is abrupt and smooth within the west-central portion of the excavation (in the vicinity of the tree cover) and patchy elsewhere. The patchy nature of the deposit suggests that post-occupational erosion cut into and around sections of the Ab1 deposit with A horizon soils filling the resulting voids. As a result, the remaining Ab1 deposits extend up into the lower portion of the A horizon. The abrupt horizon boundary noted in the west-central portion of the tipi ring suggests that the horizon surface was subject to erosion before the occupational episode. Stratum 3 was the charcoal and ash fill located in the remainder of the hearth that was partially excavated in 1992 during the Bason Land Exchange Project. Table 40.1 summarizes the stratigraphic blocks that were excavated at LA 85864.

Table 40.1. Stratigraphic summary for LA 85864.

Prov	Strat	Hori-zon	Texture	Munsell Color	Thickness	Description
Area 1	1	A	Sandy to silty loam	10YR4/4	1 to 5 cm	Post-occupation late-Holocene loose surface deposit with pea-sized pumice gravels (10% to 40%), increasing in content toward the eastern end of the ridge finger. Surface and upper few cm contained varying amounts of duff.

Prov	Strat	Hori-zon	Texture	Munsell Color	Thickness	Description
	2	A	Lightly compact sandy to silty loam	10YR4/4	0 to 15 cm	Late-Holocene soft to slightly hard deposit with pea-sized pumice gravels (20% to 30%), increasing in content toward the eastern end of the ridge finger. Compaction increased slightly with depth. A few flecks of charcoal presumably associated with the site hearth were scattered throughout the deposit. Stratum 2 has been removed through erosion along the northern edge of the site. Other than degree of compaction, stratum is extremely similar to Stratum 1.
	3	Hearth deposit	Slightly compact ash and charcoal deposit	7.5YR3/4	1 to 5 cm	Charcoal and ash mix concentrated within a 40- by 25-cm basin-shaped area. Western third of hearth previously removed during testing phase.
	4	Ab1	Compact silty clay loam	10YR6/3	1 to 8+ cm	Pre-occupation late-Holocene deposit. The boundary between Strata 2 and 4 is abrupt and smooth, suggesting that erosion occurred between depositional episodes.

SITE EXCAVATION

The excavation at LA 85864 was initiated along the south and west edges of the tipi ring, which was the area that appeared to have minimal erosional damage. It was anticipated that the outlining tipi ring rocks could be used as an aid in locating an associated occupational surface. The excavation revealed that the majority of outlining rocks had been set on the top of the Ab1 soil horizon; however, no occupational surface was encountered. As a result, unit 100N/104E, which contained the remaining portion of the test phase that encountered hearth, was excavated to determine its relationship to the soil deposition and to ascertain whether an occupation surface was associated.

Remnants of the hearth were encountered at the interface of the A and Ab1 soil horizon, although the hearth was not clearly defined until 1 to 2 cm of the upper Ab1 soil were removed (Figure 40.2). Post-occupational erosion apparently impacted the upper level of the hearth. The top of the hearth was situated at a depth of 17 to 19 cm below the surface with charcoal flecking first noted at a depth of 14 cm below the surface. Concentrated charcoal flecking extended out into a 70-cm-diameter area surrounding the hearth. A few small charcoal chunks and flecks were also noted sporadically throughout the excavation, suggesting that erosion spread some of the upper hearth remains after the site was abandoned.

The hearth was evidenced by a 40- by 25-cm area with a 1- to 5-cm-deep deposit of charcoal and ash (Figure 40.3). Before the testing phase excavation, the hearth would have been approximately 40 cm in diameter. The shape and the fact that the charcoal and ash extended down into the pre-occupational Ab1 soil horizon indicated that the hearth was situated within a shallow basin that would have been scooped out during construction. The surface sediment of the basin exhibited alteration due to a significant amount of heat with the clay content having been partially oxidized (Figure 40.4).

Figure 40.2. Feature 2 (hearth) exposed with 1993 test pit located directed to the west.

Up to 6 cm of Ab1 soil was excavated from within and around unit 100N/104E to explore for an occupation surface associated with the hearth. The Stratum 4 excavations indicated that the soil within the Ab1 horizon was culturally sterile. As both the outlining rocks and the hearth appeared to have been situated on top of the Ab1 soil horizon, it was assumed to be the occupational surface associated with the tipi ring. However, no evidence of cultural modification or use was encountered to support this assumption. The excavation was then continued to the north and south with the remaining units terminated at the A/Ab1 soil horizon. The continued excavation resulted in the exploration of most of the grid units in a 5- by 8-m area situated around the tipi ring (Figure 40.5). The excavation extended to the east about 3 m beyond the assumed eastern edge of the rock ring and continued to the north to include about 1 to 1.5 m of the drainage slope that has cut into the site to check for eroding cultural materials (Figure 40.6). A compact lens of A horizon soil was situated directly above the Ab1 soil horizon in the excavated units located to the west and immediately north of the hearth (Figure 40.7). It was also speculated that this lens was the occupation surface associated with the tipi ring. However, as with the top of the Ab1 horizon, no evidence of cultural modification or use was encountered. The Ab1 soil situated in the eastern half of the excavation became friable and softer, suggesting that the area was affected by water erosion (Figure 40.8). The east-side excavation resulted in the uncovering of two previously buried dacite cobbles that appear to extend the circular cobble alignment out to form the southeastern section of the tipi ring.

Figure 40.5. Post-excavation photo of LA 85864 looking east.

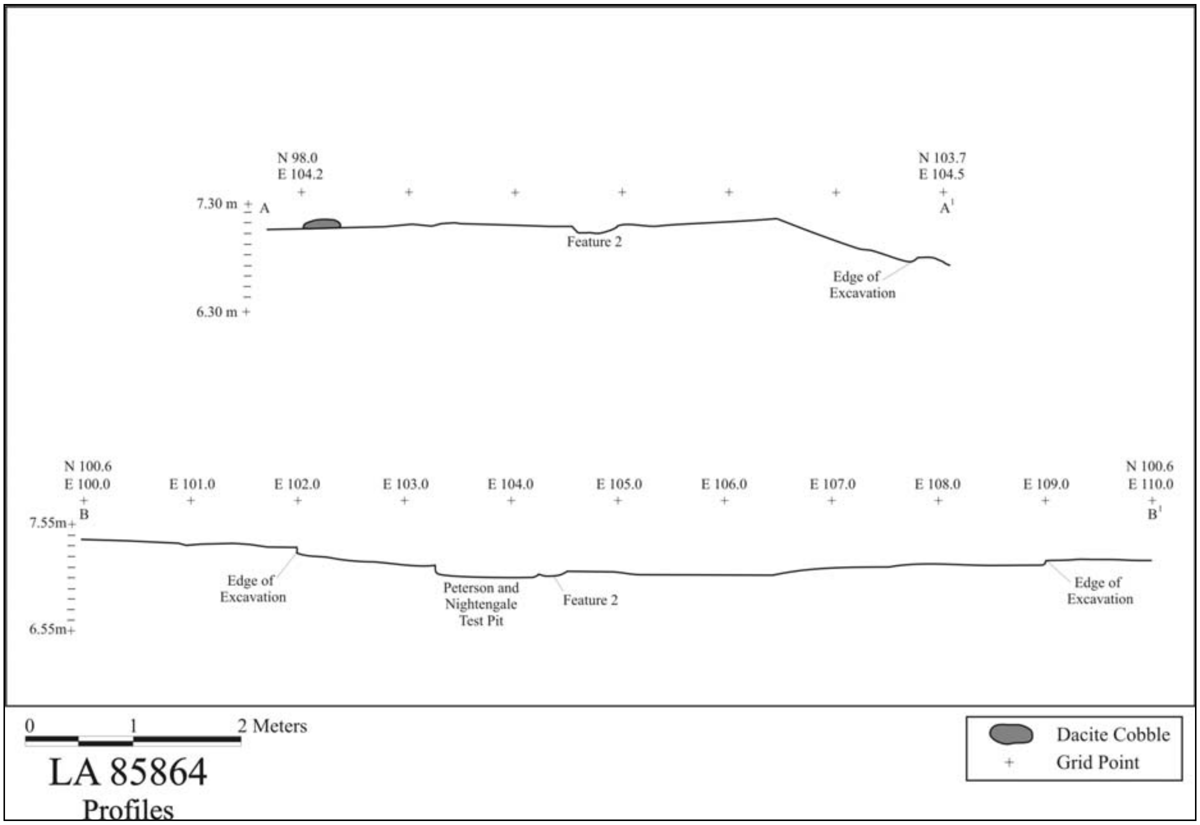

Figure 40.6. LA 85864 site excavation surface profiles.

Only six artifacts were recovered from the excavation phase at LA 85864. These included two ceramics and four heavily burned and unidentified pieces of bone (FS 11) that were recovered from the hearth. A smeared-indented corrugated utilityware sherd (FS 1) was collected from the surface of unit 97N/95E, which is located about 9 m west-southwest of the southwestern outer edge of the tipi ring. The other ceramic was a Santa Fe Black-on-white sherd (FS 16) located in Stratum 2 of 100N/102E, which would be about 1 to 2 m west of the hearth. Stratum 2 in this area was situated between 1 and 3 cm below the surface and was from 2 to 7 cm thick. No metallic artifacts were recovered. The only other potential cultural item recovered during the excavation was a badly eroded possible wheat seed recovered from a flotation sample collected from the hearth (FS 10). Table 40.2 lists the artifacts by stratum.

Table 40.2. Artifact count by stratum.

Stratum	Ceramics	Chipped Stone	Ground Stone	Faunal Remains	Total
0	1	0	0	0	1
1	0	0	0	0	0

Total	**2**	**0**	**0**	**4**	**6**

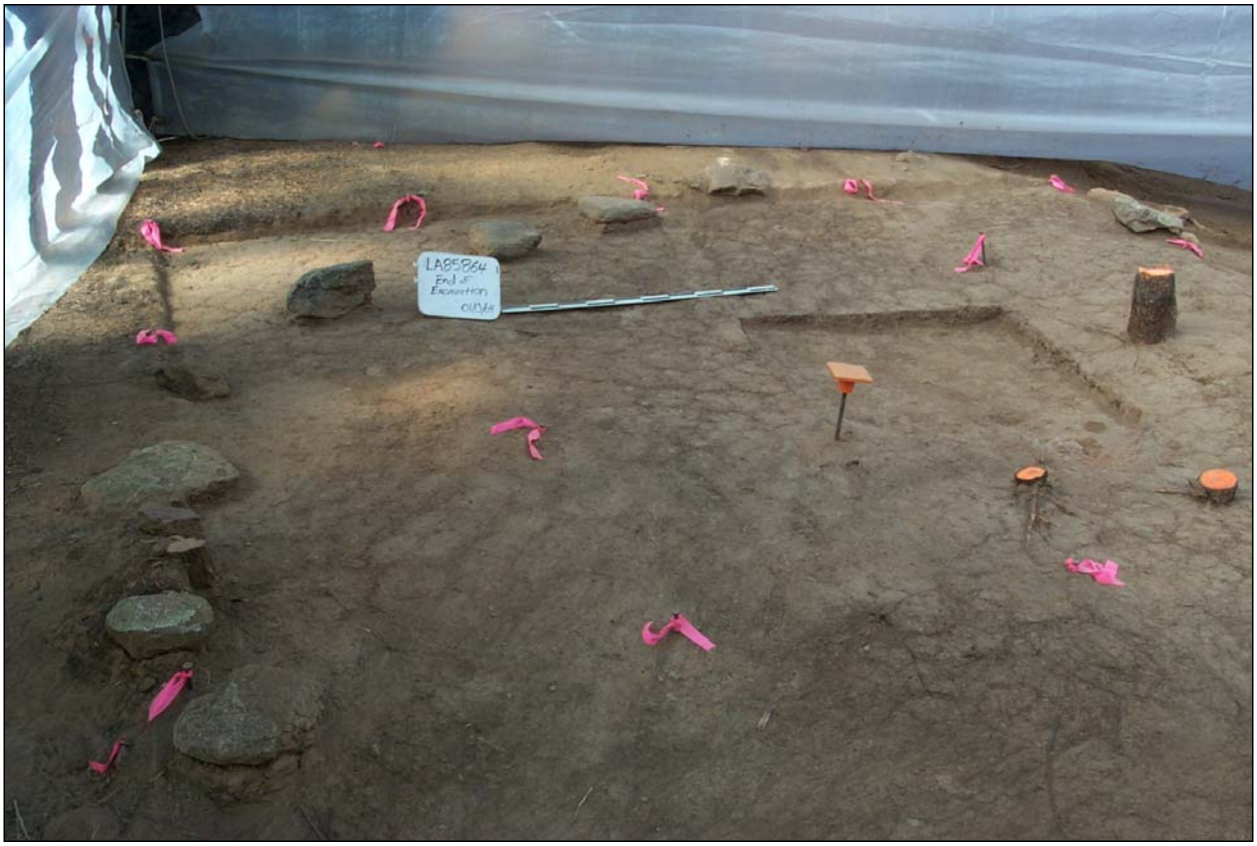

Figure 40.7. Post-excavation photo of the western end of LA 85864.

Other than rocks forming the tipi ring, the fairly well-preserved hearth at the center of the rock ring, the sherd situated in Stratum 2 of 100N/102E, and the four burned bone fragments recovered from the hearth, no cultural materials were encountered during the excavation. The lack of cultural materials is likely due to the extensive erosion that has impacted the site. Several small juniper trees in the vicinity of the hearth have reduced the amount of erosion in the immediate vicinity and upslope to the north and west. Although erosional activity could explain the lack of cultural materials from the southern and eastern portions of the tipi, the area to the west and within 1.5 m to the north of the hearth retain two surfaces that could be associated with the occupation. One potential occupation surface is the compact A horizon lens situated directly on top the Ab1 soil horizon that also could have been the occupation associated surface. As the soil deposition in this area appears to be intact, it seems likely that cultural materials located within the area would still be present if they were ever deposited. It therefore is speculated that the site represents a very short occupation from which very few cultural materials were discarded or lost.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of five artifacts (ceramics) were analyzed from the excavations conducted at LA 85864. In addition, flotation, and pollen samples were selected for analysis from Strata 2 and 3 (Table

40.3). Charcoal was submitted for radiocarbon dating from Stratum 3 and an archaeomagnetic sample was taken from the hearth (Feature 2). The results of the artifact and sample analyses are presented in the following sections.

Figure 40.8. Post-excavation photo of the eastern end of LA 85864.

Table 40.3. Samples selected for analysis from LA 85864.

Stratum	Sample Type		
	Flotation	Pollen	Radiocarbon
1			
2	4, 5, 6, 14	3	
3	10	8	10

Chronology

Radiocarbon Dating

A single charcoal (piñon pine) sample was submitted for radiocarbon dating. It yielded several possible intercepts that range from AD 1680 to 1950 (Table 40.4).

Table 40.4. Radiocarbon data from LA 85864.

FS	Laboratory (Beta)#	Conventional radiocarbon age	Intercept of radiocarbon age	Two-sigma calibrated result
10	199371	170±40 BP	AD 1680 AD 1770 AD 1800 AD 1940 AD 1950	AD 1650 to 1890 or AD 1910 to 1950

Archaeomagnetic Dating

A single archaeomagnetic sample was taken from the hearth in the tipi ring. Blinman (see Chapter 66, Volume 3) indicates that the sample likely dates to the late 19th century, although the date estimates provide a range from AD 1730 to the present.

Table 40.5. Archaeomagnetic date for LA 85864.

Sample Number	Feature	VGP Curves and Date Estimates (AD)	
		Wolfman	SWCV2000
1234	Hearth	AD 1600–1820 1730–present	ca. 1675–1840 ca. 1850–present

Ceramic Artifacts (Sunday Eiselt)

The four ceramics collected during the testing and excavation phases were analyzed by Sunday Eiselt. Three of the ceramics were micaceous sherds representing two vessels (one sherd apparently broke into two pieces some time after collection) and one was a Biscuit A body sherd. The two sherds from the same vessel displayed characteristics most similar to a Jicarilla Apache Cimarron Micaceous ceramic dating from AD 1730 to present. The moderate amount of mica along with rosy quartz and magnetite temper indicate a Cordova-Truchas Source District origin for the clay. The exterior and interior sherd surfaces were burnished and compacted, unlike Tewa vessels. The other sherd appeared to be made from alluvial clay containing mica rather than primary micaceous clay. The origin of the clay is unknown, although micaceous clays are present north of Abiquiu. The ethnic affiliation for the ceramic could not be determined.

Although the type identifications are tentative, the three micaceous sherds likely represent Cimarron Micaceous vessels based on paste characteristics and surface finish. The Cordova-Truchas source district was used extensively by the Jicarillas (Eiselt 2006). The vessel surfaces are also highly compacted through burnishing and polishing; traits that are likewise commonly found 19th century Cimarron Micaceous sherds (Eiselt 2005). The Biscuit A sherd and the Santa Fe Black-on-white and smeared-indented corrugated sherds recovered during the excavation may represent earlier activities conducted in the site vicinity.

Faunal Remains (Kari Schmidt)

Four unidentified pieces of bone (FS 11) were recovered from this site. The bones were heavily burned (calcined) and were recovered in Stratum 3 in Feature 2.

Archaeobotanical Remains (Pamela McBride)

The sample from the base of the informal central hearth in the tipi ring produced charred conifer duff (juniper twigs, pine needles, and bark) along with an unusual find: a badly eroded possible wheat caryopsis (or seed). The caryopsis appeared to have two attributes characteristic of wheat: a crease running longitudinally for the length of the grain and the germ. The distal end of the seed was the most eroded and the general condition of the seed led to a tentative identification. As wheat had been around a long time before the occupation of LA 85864, it would not be unusual for it to have been part of the Jicarilla Apache diet. The Mescalero Apache would obtain wheat from raids in Mexico or from early settlers; wheat was planted in sandy loam, harvested by beating it with a stick, and subsequently used to make bread (Castetter and Opler 1936). Aside from wood, the remainder of the archaeobotanical assemblage consisted of unburned goosefoot seeds and burned and unburned conifer duff (Table 40.6).

Flotation and vegetal sample wood charcoal was primarily piñon, present in 84 percent and 89 percent respectively by weight (Tables 40.7 and 40.8). Juniper, pine, cf. ponderosa pine, and unknown conifer were also recovered. The occupants of LA 85864 were probably incorporating the Old World grain wheat into their diet and burning local conifers for fuel.

Pollen Remains (Susan Smith)

Two pollen samples were analyzed from LA 85864. Table 40.9 lists the frequency of identified pollen types. No cultigens were identified in the botanical assemblage. Beeweed and sunflower type were the only other taxa identified as other economic resources in the assemblage. Several other potential economic resources were also identified in the assemblage (Table 40.9), and these are discussed in detail in Smith's chapter in Volume 3 (Chapter 63).

SUMMARY

The site contained an approximate 5-m-diameter tipi ring that was located on a narrow ridge finger between two deep drainages. The tipi ring had been significantly affected by erosional processes. Other than the rock tipi ring and an associated hearth, one ceramic, four burned bone fragments, and a possible wheat seed were recovered during the excavation. The lack of cultural materials is likely due somewhat to the extensive erosion that has impacted the site with several small juniper trees in the vicinity of the hearth having reduced the amount of erosion in the immediate vicinity. Although erosional activity could explain the lack of cultural materials from the southern and eastern portions of the tipi, the area to the west and within 1.5 m to the north of the hearth retain remnants of two stratigraphic lenses, either one of which may represent the occupation surface. One potential surface is the compact A horizon lens situated directly on top of the truncated Ab1 soil horizon that also could have been the occupation surface. As the soil deposition in this area appears to at least be partially intact, it seems likely that cultural materials located within the area would still be present if they were ever deposited. It is therefore speculated that the site represents a very short occupation from which very few cultural materials were discarded or lost.

Based on the site type, the three micaceous ceramics, and the cultural history of the area, the tipi ring is assessed to be associated with a Jicarilla Apache occupation dating to the 19th century. As wheat had been around a long time before the occupation of LA 85864, it would not be unusual for it to have been part of the Jicarilla Apache diet (Chapter 62, Volume 3).

CHAPTER 41
RENDIJA TRACT (A-14): LA 85867

Gregory D. Lockard

INTRODUCTION

LA 85867 is the remains of a one-room Classic period fieldhouse and several small features located on a south-facing slope on the mesa between Rendija and Guaje canyons. The site is located in the eastern quarter of the Rendija Tract. A two-track dirt road passes through the site. Vegetation consists of piñon-juniper woodland with a grass understory. The site is situated at an elevation of 2114 m (6935 ft).

LA 85867 was first recorded on September 14, 1991, by David Hill (1991) during a survey for the Bason Land Exchange Project. According to Hill, the site consisted of two one-room fieldhouses. The first fieldhouse was located within and adjacent to a modern roadbed. A chalcedony core, two eroded biscuitware sherds, and a micaceous sherd with black paste were the only artifacts observed in the area. The presence of the biscuitware sherds led Hill to tentatively date the site to the Classic period. The second fieldhouse was located 35 m to the northeast of the first. A micaceous sherd with black paste and an eroded whiteware sherd were the only artifacts observed in the area. Hill also noted the presence of two smaller rock concentrations that he interpreted as possible hearths located halfway between the fieldhouses.

On July 20, 1992, Archaeological Research, Inc., was awarded the contract to conduct archaeological testing of the Bason Land Exchange Project sites. John Peterson and Christian Nightengale (1993) supervised the excavations, which took place between July 27 and August 23 of 1992. Three 1- by 1-m test pits (Units A-C) were excavated at LA 85867.

Unit A was placed within the fieldhouse by the road, which was designated Feature 1. A floor was encountered 27 cm below the surface in this unit. The floor was described as "a very hard packed clay surface" (1993:184). Several smeared-indented sherds and two Biscuit A sherds were recovered from the floor surface. A sample of charcoal was taken from the floor and submitted to Beta Analytic for radiocarbon analysis. The sample produced a date of 430 ±60 BP. The excavation of the unit continued below the floor to a maximum depth of 72 cm below the ground surface. No features or artifacts were encountered below the floor.

Unit B was located in one of the small rock concentrations noted by Hill. According to Peterson and Nightengale, the concentration, which they designated Feature 3, was 21 m northwest of Feature 1. The unit was excavated to a maximum depth of 20 cm below the ground surface. The excavation revealed that the rock concentration was a single course of stones, and no cultural materials were recovered. According to Peterson and Nightengale, the only other rock concentration in the area was a recent firepit, which they did not test.

Unit C is located in the remains of the second structure that Hill interpreted as a fieldhouse. The unit was excavated to a maximum depth of 30 cm below the ground surface. No living surface or cultural materials of any kind were encountered. As a result, Peterson and Nightengale suggest that any structural remains that may have existed in this location have been eroded down slope. Due to the fact that they found no cultural materials of any kind in Units B and C, Peterson and Nightengale argue that the research potential of Features 2 and 3 was exhausted by their excavations. As a result, only Peterson and Nightengale's Feature 1, which was re-designated Room 1, was excavated during the Conveyance and Transfer (C&T) Project.

FIELD METHODS

Before excavation, the site and surrounding area were cleared of trees and large undergrowth. Area 1 was then visible as a small rubble mound approximately 4 by 4.5 m in area and approximately 30 cm in height (Figure 41.1). An arbitrary site datum (100N/100E, 10.00 m elevation) was set up in the southwest corner of the area. The area was then covered with a 1- by 1-m grid that extended 6 m north and 5 m east of the site datum. Two subdata (A and B) were set up for taking elevations, and the site was photographed. Artifacts visible on the surface were collected by grid unit, and the location of artifacts outside of the grid was determined with tape measures. A 5- by 1-m east-west trench (103N/100-104E) was initially excavated across the structure in Area 1. The purpose of this trench was to expose a profile of the site stratigraphy, as well as to determine the location of the room's east and west walls. Units were excavated by strata, and thicker strata were excavated in arbitrary 10-cm levels.

Figure 41.1. Pre-excavation photograph of LA 85867.

Peterson and Nightengale's Unit A was encountered while excavating the trench. Unit A occupies all but the westernmost 30 cm of unit 103N/102E. It extends eastward approximately 25 cm into unit 103N/103E and northward approximately 5 cm into units 104N/102-103E. The backfill within Unit A, which was excavated to a maximum depth of 72 cm, was removed as a separate stratum (Stratum 3). A poorly preserved living surface was encountered to the east and west of Unit A within the trench. The room's east wall was encountered in unit 103N/103E, and the west wall was encountered along the border between units 103N/100-101E. After the excavation of the trench units, the north profile of the trench was drawn and photographed. The rest of the area was subsequently excavated, again by strata and arbitrary levels for thicker strata.

In all, 23 units were excavated. Within the structure, excavation proceeded down to the living surface encountered while excavating the trench. Outside the structure, excavation proceeded down to the top of the sterile Bw2 horizon. Excavation focused on defining the room's walls, removing wallfall, and locating features. Soil samples were taken from select locations, and all other soil was passed through screens with 1/8-in. mesh to aid in the recovery of artifacts. The excavation area extended at least 1 m to the south, east, and west of the structure to locate external features and/or outdoor activity areas. The excavation area extended to the north of only the eastern half of the structure. The area to the north of the western half of the structure was not excavated because it had been severely impacted by the presence of a two-track dirt road. The structure was then mapped (Figure 41.2) and photographed (Figure 41.3).

The excavation of the site was supervised by Greg Lockard. The field crew included Michael Dilley, Alan Madsen, Brian Harmon, Bettina Kuru'es, Margaret Dew, and Rhonda Robinson. Timothy Martinez and Aaron Gonzalez served as site monitors from San Ildefonso Pueblo and as screeners. Jeremy Yepa was the site monitor representing Santa Clara Pueblo, as well as an additional excavator.

STRATIGRAPHY

Stratum 1 is composed of loose surface sediment. It is uniformly 1 to 6 cm thick across the site and is more or less equivalent to the A horizon (topsoil). Stratum 2 is post-occupational fill and ranges from 3 to 25 cm in thickness. The post-occupational fill was thickest in and around the collapsed walls and thinned away from the walls and towards the center of the room. It was particularly thin (in fact, almost non-existent) in the grid units to the north of Room 1 that are located within and/or near the two-track dirt road. Stratum 2 is more or less equivalent to the Bw1 horizon. Stratum 3 is the backfill removed from Peterson and Nightengale's Unit A. Stratum 3 is therefore a disturbed context. Stratum 4 is the Room 1 living surface. Tables 41.1 through 41.3 summarize and describe the strata that were excavated at LA 85867.

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is a small rectangular structure that probably functioned as a fieldhouse. The room measures approximately 1.25 m in width (north to south) by 2.27 m in length (east to west), with approximately 2.84 m^2 of interior space. Excavation of the room began with an east-west trench that extended across Area 1 (units 103N/100-104E). The excavation of this trench served to define the room's stratigraphy, as well as to locate the room's east and west walls. Most of Peterson and Nightengale's Unit A was located within the trench (units 103N/102-103E). To the east and west of Unit A, a poorly preserved living surface was encountered. After the excavation of the trench, the rest of the room was excavated down to the living surface. This living surface was slightly burned and thus better preserved in the northwest corner of the room (see below).

Fill. The interior of Room 1 was filled with 1 to 4 cm of surface sediment on top of 15 to 25 cm of post-occupational fill. Flotation (Field Specimen [FS] 3 and FS 26) and pollen (FS 4 and FS 27) samples were taken of the Room 1 fill, but they were not analyzed.

Floor. The Room 1 living surface is a poorly preserved layer of compact, clay-rich sediment. This surface takes the form of a fairly large patch of burned floor in the northwest corner of the room. Even in this location, however, there is no evidence that the floor was plastered. Elsewhere, the living surface is marked by black staining and charcoal inclusions, as well by an absence of rocks. As noted above, Peterson and Nightengale reportedly found a well-preserved clay floor in Unit A, upon which they recovered several sherds, many of which appear to have come from the same vessel (a possible pot drop). The living surface encountered during the C&T Project does not appear to have been as well preserved as that described by Peterson and Nightengale. The living surface, however, is located at about the same depth as the floor reported by Peterson and Nightengale. In addition, several sherds were encountered near Unit A at about the same level. None of these sherds, however, were in direct contact with the living surface. It is possible that the Room 1 living surface was best preserved in the area where Unit A was excavated. Because the excavation of this unit continued well below floor level, nothing remains of the floor described by Peterson and Nightengale.

A pollen sample (FS 66) was taken from below a masonry block that was sitting directly on top of or just above the living surface in the north-central portion of the room. Taxa identified in this sample included maize, beeweed, locoweed, grass family, cheno-ams, sunflower family, ragweed/bursage, chicory tribe, spurge family, evening primrose, unidentified pine, piñon pine, juniper, oak, and sagebrush. Additional pollen samples were scraped from directly on top of the living surface in the southwest (FS 75), southeast (FS 76), and northeast (FS 77) corners of the room. Taxa identified in these samples included prickly pear, cactus family, beeweed, sunflower type, purslane, rose family, buckwheat, mustard family, locoweed, grass family, willow, cheno-ams, sunflower family, globemallow, evening primrose, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush. Flotation samples were taken of the living surface matrix in the northwest (FS 78) and southeast (FS 79) corners of the room. Charred taxa identified in these samples included unknown conifer and ponderosa pine.

Wall Construction. The walls in Room 1 are constructed of dacite cobbles and upright slabs. The rocks that form the foundation of the walls appear to have been placed in a shallow trench excavated into the Bw2 horizon, which is a compact, reddish, clay-rich soil that predates the site's occupation. Some of the foundation stones are upright slabs, and others are cobbles. In some places, the walls are formed by a single row of large dacite cobbles. In other places, the wall is formed by two rows of rocks. When this is the case, one or both of the rocks are usually upright slabs. In the western half of the south wall, there are three rows of rocks. This portion of the wall, however, is probably at least partially disturbed.

The western half of the north wall has been disturbed by the two-track dirt road. Some dacite cobbles were encountered in this area of the site. It is highly unlikely, however, that these rocks are *in situ*. One of these is a thin, flat rock located just east of the northernmost rock in the west wall. This rock appears to have been an upright slab that was pushed over to the south during the grading or subsequent use of the road. If this is the case, the northwest corner of the rock defines the far northwest corner of the room. The other rocks that formed the western half of the north wall appear to have been pushed to the north of their original location. The foundation of the eastern half of the north wall appears to be largely intact. The western half of this section of the wall is formed by a large, linear concentration of compact adobe. This adobe may have been a doorsill. If this is the case, the entryway into Room 1 was located in the center of the north wall. A thin, flat rock was encountered directly south of the adobe. This rock may be an upright slab that was pushed over onto its side. Alternatively, it could be a southward extension of the adobe doorsill.

Judging from the amount of wallfall removed during the excavation of the area in and around Room 1, the masonry portions of the room's walls were originally considerably higher than they were at the time of excavation (Table 41.4). In order to estimate the original height of the walls, all of the rocks removed as wallfall during the site's excavation were placed in three stacks, which were then measured. The stacks measured 1.57 by 1.42 by 0.47 m, 1.93 by 1.05 by 0.53 m, and 1.74 by 1.05 by 0.50 m, for a total of approximately 3.04 m^3 of wallfall. Based on this volume of wallfall and the overall length, average thickness and average height of the extant portions of the walls, the masonry portions of the room's walls were originally approximately 1.63 m high. This is considerably higher than wall heights calculated for other fieldhouses excavated in the Rendija Tract during the C&T Project, excluding those in areas that are naturally rocky. Although at least some of the rocks recovered during the excavation of LA 85867 probably do not represent wallfall, the site does not appear to be located in an area with a lot of naturally occurring rocks. Some of the rocks may have been pushed onto the excavated portion of the site during the grading and/or use of the two-track dirt road. These factors, however, do not appear to fully account for the wall height presented above. The masonry portions of the walls were therefore probably at least a little bit higher than those of the average fieldhouse in the Rendija Tract. The uppermost portions of the walls, as well as the ceiling, were most likely composed of wattle and daub. These materials are rarely preserved at archaeological sites on the Pajarito Plateau. In fact, only two pieces of burned adobe (FS 20 and FS 54) were recovered from the site.

Table 41.4. LA 85867 Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	2.22	0.02–0.29	0.14–0.33	1 to 2
South	2.30	0.12–0.27	0.25–0.55	1 to 2
East	1.24	0.15–0.26	0.19–0.40	1
West	~1.25	0.06–0.25	0.17–0.35	1

Geological Analysis

Geologists Paul Drakos and Steven Reneau utilized a single profile to reconstruct the natural soil horizons at the site (see Table 41.2). The profile that they utilized was the south profile of Peterson and Nightengale's Unit B, located in about the same location as the south profile of unit 103N/102E. The profile includes the interior face of the south wall of Room 1, as well as significant sub-floor deposits. The profile contained a soil sequence consisting of an A horizon (topsoil) and three Bw horizons (a late-Holocene soil and two Holocene soils).

Artifact Distribution

The grid units with the highest number of artifacts are those located within and to the east of Room 1 (Table 41.5). The artifacts within Room 1 are concentrated in the western half of the room. This is almost certainly a result of the fact that many of the artifacts in the eastern half of the room were recovered during the excavation of Peterson and Nightengale's Unit A. In fact, 32 sherds (30 smeared-indented and two Biscuit A sherds) were recovered from Unit A. The higher concentration of artifacts to the east of the fieldhouse follows a pattern observed at many of the fieldhouses in the Rendija Tract excavated during the C&T Project. Presumably, the people who utilized the fieldhouses tended to choose the area to the east as a work area to best take advantage of the warmth and/or sunlight from the morning sun. The room's entryway, however, appears to be located in the north wall, rather than the east wall. Although there is a slight tendency for entryways to be located in the east wall, it is not as strong as the tendency for activity areas (indicated by a higher concentration of artifacts) to be located in the area to the east of the fieldhouse.

Table 41.5. LA 85867 artifact counts by grid unit.

	E100	E101	E102	E103	E104
N105	--	--	1	2	9
N104	0	**6**	**7**	**7**	11

N102	0	1	5	4	5
N101	3	2	5	1	16

Note: Does not include two artifacts found outside of the excavated area during surface collection; bold numbers indicate grid units that are located completely or partially within Room 1.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 122 artifacts were analyzed from the excavations conducted at LA 85867. In addition, flotation and pollen samples were selected for analysis from the post-occupation fill (Stratum 2) and the Room 1 living surface (Stratum 4) (Table 41.6). The results of the artifact and sample analyses are presented in the following sections.

Table 41.6. Samples selected for analysis from LA 85867.

Stratum	Sample Type			
	Flotation	Pollen	Radiocarbon	TL*

Ceramic Artifacts (Dean Wilson)

A total of 68 ceramics were analyzed from LA 85867. The majority of the pottery consists of Sapawe Micaceous and Biscuit A sherds, which presumably date to the Early Classic period (14th century) (Table 41.7). Information on ceramic tradition by ware, temper by ware, and vessel form by ware are provided in Tables 41.8 through 41.10. The grayware and whiteware pottery appear to have been locally made from tuff temper, however, the micaceous pottery is a non-local type. Otherwise, all of the grayware and micaceous ceramics consist of jar vessel forms, whereas the whiteware sherds are derived from bowls.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 54 artifacts were analyzed from LA 85867, consisting of six cores, 45 pieces of debitage, one retouched tool, and two ground stone artifacts. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 41.11 presents the data on lithic artifact type by material type. The debitage is primarily made of chalcedony, with less Pedernal chert, greenstone, obsidian, and other materials. The presence of cortex on 26.6 percent of the debitage indicates that these materials were collected from waterworn (*n* = 11) and nodule (*n* = 1) sources. The chalcedony, Pedernal chert, and greenstone are available from local Rio Grande Valley gravels and the obsidian from nearby sources in the Jemez Mountains. Otherwise, the igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the Pajarito Plateau.

Three pieces of obsidian and three pieces of basalt debitage were submitted for X-ray fluorescence analysis. The obsidian artifacts are solely made from Cerro Toledo obsidian (Table 41.12). The Cerro Toledo (Obsidian Ridge/Rabbit Mountain) source area is situated about 19 km (12 mi) to the southwest. Although obsidian is present at these nearby sources in the Jemez Mountains, it is also present on the mesa as small pebbles. These pebbles compose part of the secondary deposits associated with the Cerro Toledo interval. One of the basalt flakes appears to be made of basalt, however, the other is dacite, which is derived from a local source.

Table 41.12. Obsidian source samples.

FS #	Artifact	Color	Source
23	Debitage	Translucent	Cerro Toledo rhyolite
35	Debitage	Translucent	Cerro Toledo rhyolite
39	Debitage	Translucent	Cerro Toledo rhyolite

Lithic Reduction

Four of the five cores were reduced using a single-directional reduction technique that involved either a single or multiple faces; whereas, the fifth core was reduced using a bidirectional, bifacial technique (Figure 41.4). Otherwise, flakes were also removed from a cortical platform on a cobble uniface. Three of the cores were classified as still having been discarded due to a break along a material flaw, whereas, the other cores were considered exhausted and the cobble uniface as still useable. Table 41.13 presents the metric information on the cores.

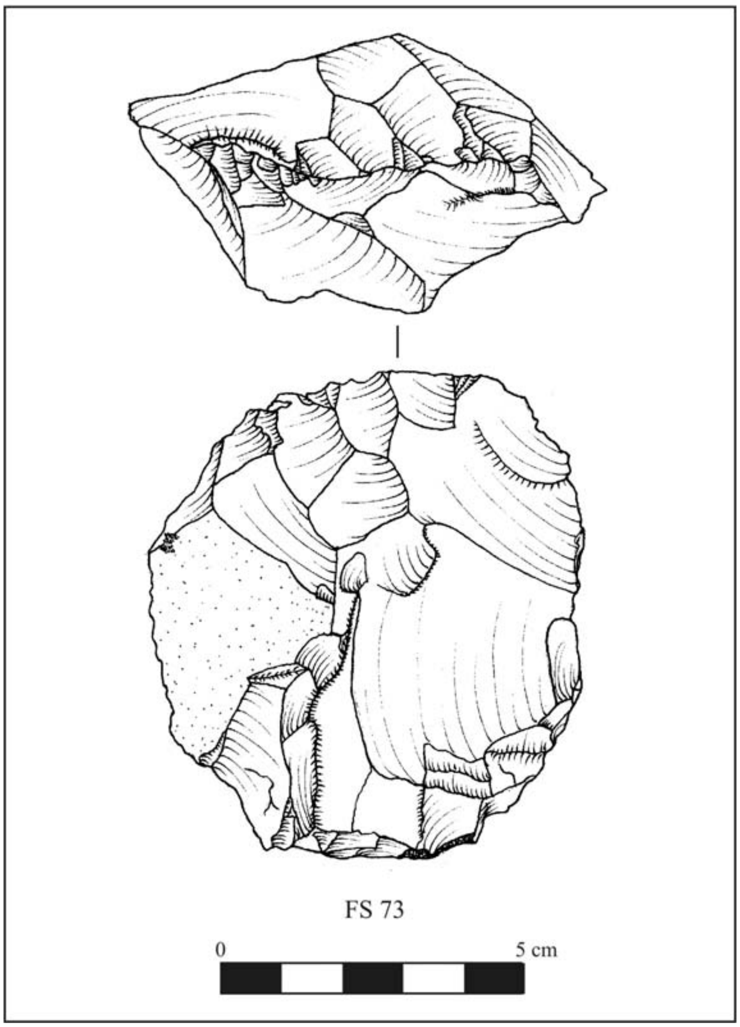

Figure 41.4. Bifacial core from LA 85867.

Table 41.13. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Single-directional	106	91	60	600.9
Single-directional	34	68	52	124.6
Single-directional	48	58	74	182.3
Single-directional	41	77	73	268.7
Bidirectional	79	72	43	243.7
Cobble Uniface	51	103	99	544.1

The debitage mostly consists of core flakes, with a few other items. The overall cortical:non-cortical ratio of 0.50 reflects an emphasis on the later stages of core reduction. The flakes mostly have single-faceted platforms (*n* = 14), with fewer cortical (*n* = 7), multi-faceted (*n* = 1), collapsed (*n* = 2), and crushed (*n* = 3) platforms. Only one of the platforms exhibits abrading/crushing. The majority of the core flakes are whole (*n* = 21), with fewer proximal (*n* = 5), midsection (*n* = 3), and distal (*n* = 9) fragments. Most of the biface flakes are also whole (*n* = 7), with fewer proximal (*n* = 1), midsection (*n* = 2), and distal (*n* = 4) fragments. The whole core flakes have a mean length of 27.8 mm (*std* = 16.2) and the angular debris a mean weight of 6.5 g (*std* = 7.6).

The retouched tools consist of a single retouched piece of angular debris. It has a bidirectionally retouched edge with an angle of 75 degrees.

Tool Use

A single flake exhibits evidence of edge damage that could be attributed to use. It exhibits rounding and polish at the distal end, with an edge angle of 50 degrees. The retouched piece also exhibits some rounding and scarring along a lateral edge with an angle of 75 degrees.

The ground stone assemblage consists solely of manos. The two-hand mano is a loaf-shaped, elongated tuff cobble with a single flat grinding surface (Figure 41.5). The undetermined mano fragment is a quartzite cobble fragment on one surface and appears to be fire-cracked.

Faunal Remains (Kari Schmidt)

One piece of bone was recovered during excavations of this Classic period fieldhouse. This bone was identified as an unburned, unidentified large-sized mammal rib fragment.

Archaeobotanical Remains (Pamela McBride)

Two samples from the living surface of this one-room fieldhouse yielded charred ponderosa pine needles and uncharred hedgehog cactus seeds. Fourteen pieces of ponderosa pine and 12 pieces of unknown conifer, weighing 0.5 g round out the cultural plant material recovered.

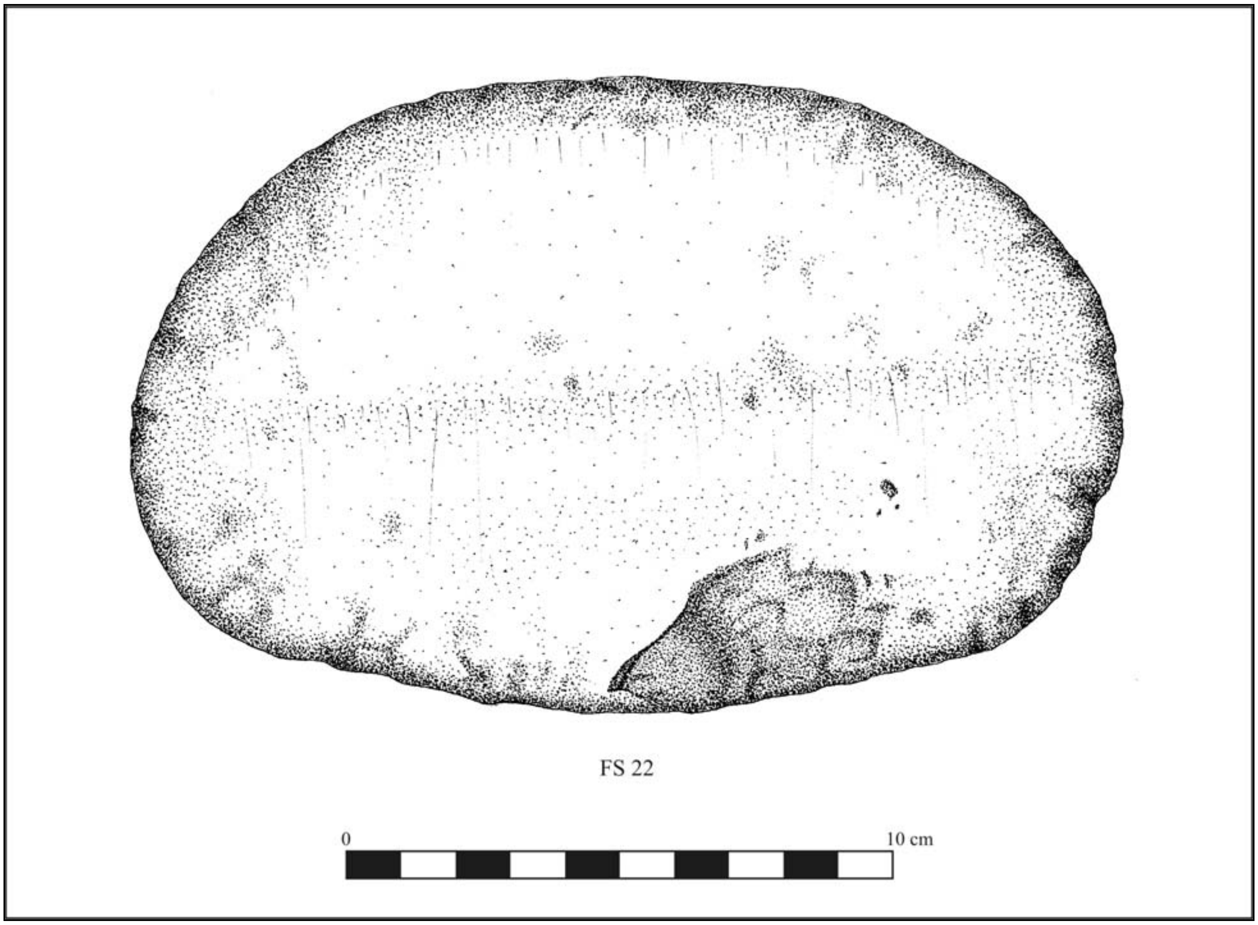

Figure 41.5. Two-hand mano.

Pollen Remains (Susan Smith)

Four pollen samples were analyzed from LA 85867. Table 41.14 lists the frequency of identified pollen types. Maize was the only cultigen identified in the botanical assemblage and was found in only one sample. Prickly pear, cactus family, beeweed, sunflower type, and purslane were all identified as economic resources in the assemblage. A number of potential economic resources were also identified in the assemblage (Table 41.14), and these are discussed in detail in Smith's chapter in Volume 3.

SUMMARY

LA 85867 is a small one-room Classic period fieldhouse that was constructed from both shaped and unshaped tuff blocks. The site is located on a south-facing slope on the mesa between Rendija and Guaje canyons. No features, other than the fieldhouse, were identified at the site. The presence of maize pollen indicates that the one-room structure may have been occupied during the growing season.

CHAPTER 42
RENDIJA TRACT (A-14): LA 85869

Brian C. Harmon

INTRODUCTION

LA 85869 is a late 19th/early 20th century Jicarilla Apache tipi ring site situated on the northeast-facing slope of a narrow ridge. A small intermittent drainage is located to the north of the site. The site is located in piñon-juniper woodland and is at an elevation of 2132 m (6994 ft). In May of 2000 the Cerro Grande fire burned 195 ha (480 ac) in the Rendija Canyon Tract. The severity of the burn at LA 85869 was low; much of the duff in the central portion of the site was burned off and some ladder fuels were consumed. LA 85869 covers and area of approximately 1500 m^2 (Figure 42.1).

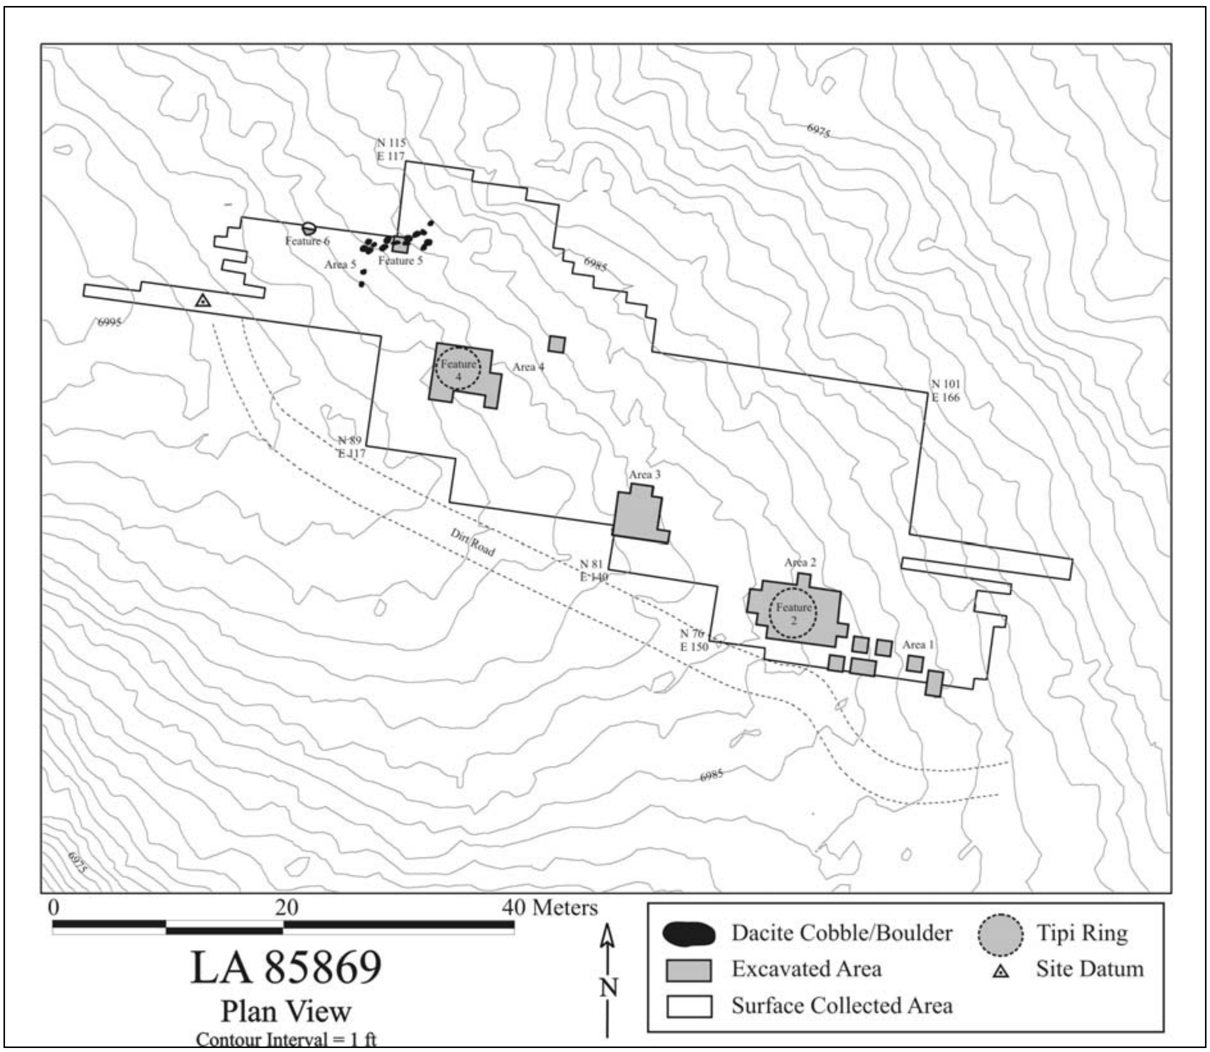

Figure 42.1. Plan view of the excavations at LA 85869.

The soil around LA 85869 is part of the Rendija-Bayo complex; a complex that "contains deep, well-drained soils weathered from materials derived from tuff (Rendija series) or pumice (Bayo series)" (Nyhan et al. 1978:54). The local stratigraphy consists of 10 to 15 cm of late-Holocene colluvium overlying Pleistocene colluvium. At the eastern edge of the site there are outcrops of dacite cobbles and small boulders.

A light scatter of modern garbage (several small automotive parts, pieces of plastic, several fragments of concrete, scraps of clothing, and bullet shells) is present across the site. A dirt road runs along the ridge top and defines the southern boundary of the site.

SITE DESCRIPTION

LA 85869 consists of two rock rings (Features 2 and 4) that mark the former locations of conical tipis. The rocks were used to weight down hides or canvases that were wrapped around a framework of interlocking poles. Both rings are approximately 4 m in diameter and are 33 m apart. Each contained a central, shallow, ash/charcoal deposit (Features 9 and 4, respectively). There is an obsidian debitage concentration immediately east of Feature 4 (the western tipi ring), and a diffuse scatter of obsidian debitage is found across the entire site. Four ceramic sherds from a single micaceous vessel were found 65 m northwest of Feature 4.

Fifteen m northwest of Feature 4 there are two rock features: an uneven alignment of boulders (Feature 5) and a small ring of cobbles (Feature 6). Feature 5 is modern in origin; Feature 6 could not be assigned a date.

PREVIOUS INVESTIGATIONS

LA 85869 was first recorded in 1991 by David Hill (1991:19–20) for the Bason Land Exchange Project. The site was described as consisting of a tipi ring (our Feature 2) and the remains of a possible rock structure (our Feature 5). Between these two features Hill observed a diffuse obsidian debitage scatter. One year later, as part of the same project, Peterson and Nightengale (1993:187–191) revisited the site to conduct more detailed recording. Their work consisted of mapping, in-field analysis, surface collection, and shovel testing. They could not relocate the obsidian scatter mentioned by Hill.

The tipi ring was described as a 4- to 5-m diameter rock ring composed of a surface alignment of large cobbles spaced 40 to 60 cm apart. Peterson and Nightengale excavated a 1- by 1-m unit in the center of this feature and exposed a concentration of burned soil and ash with small flecks of charcoal (our Feature 9) on the western edge of the unit.

The possible rock structure was described as a boulder concentration about 6.5 m long located in an area of erosion. No clear alignments of the boulders were discerned, and several appeared to have been moved in the not too distant past. Recent trash, including a car mirror bracket, pieces of plastic, and several fragments of concrete, had been dumped near this feature. Peterson and

Nightengale placed a 1- by 1-m unit in this feature and found only one retouched flake of Jemez obsidian. This was the only artifact Peterson and Nightengale recovered from the site. They concluded that the boulder concentration was probably not cultural in origin.

The Los Alamos National Laboratory Cultural Resources Management Team revisited LA 85869 in October 2000 as part of the Cerro Grande Fire Assessment Project (Nisengard et al. 2002) at which time the fire impacts discussed above were recorded.

FIELD METHODS

Most of the work reported here took place on September 18, 22, 23, and 30, and between November 10 to December 23, 2003; however, the site was sporadically visited until January 15, 2004. The crew consisted of Steven Hoagland (crew chief), Brian Harmon (assistant crew chief), Sandi Copeland, Michael Dilley, Aaron Gonzales, Mark Hungerford, Maria Jonsson, Bettina Kuru'es, Greg Lockard, Alan Madsen, and Bradley Vierra.

Inspection of the site before excavation revealed seven potential features, including the two that Hill and Peterson and Nightengale had previously recorded. A possible tipi ring at the east end of the site was identified as Feature 1, the original tipi ring was identified as Feature 2, two addition potential tipi rings to the west were identified as Features 3 and 4, the possible rock structure was identified as Feature 5, a possible hearth at the west end of the site was identified as Feature 6, and a possible grid garden at the east end of the site was identified as Feature 7. The obsidian scatter was relocated during the surface collection.

Based on the pre-excavation inspection at LA 85869, the site was divided into six areas. Area 1 is an area of dacite cobbles and boulders in the southeast part of the site. It encompasses Features 1 and 7. Area 2 is just west of Area 1; it encompasses Feature 2. Area 3 is located in the south central part of the site; this area encompasses Feature 3. Feature 4 and the adjacent lithic concentration define Area 4. Area 5 encompasses Features 5 and 6. The rest of the site is Area 6.

After the initial inspection at the site, most of the trees within the site boundary were cut down and cleared. This was done to facilitate the laying out of a grid based on magnetic north. Once the grid was in place, a collection of 100 percent of the surface artifacts was made. The boundaries of the surface collection coincide with the drop off of surface artifact density while also encompassing all potential features. Artifacts were collected in 1- by 1-m grid units and the surface collection consisted of 1448 units.

Two remote sensing surveys were conducted before excavation: a ground penetrating radar (GPR) survey and a metal detector survey. The GPR survey was performed by John Isaacson and Jennifer Nisengard on September 23, 2003. A 96-m^2 area (corners at 76N/150E, 84N/150E, 84N/162E, and 76N/162E) encompassing Feature 2 was surveyed. No subsurface anomalies were observed.

Since this site was known to date to the historic period and since it was large enough that only a portion of it would be excavated, a metal detector survey was carried out on September 30, 2003, to find metal artifacts that would otherwise be missed (Appendix N). The area between the dirt road and the northern boundary of the surface collection was surveyed from approximately the 105E line to the 175E line. When metal was signaled it was excavated with a hand trowel and its location marked with a pin flag. The horizontal coordinates of these artifacts were recorded with a transit. Unfortunately, this method of excavation made it impossible to determine the vertical provenience. However, it was clear that all metal artifacts were found above Stratum 5.

A second class of artifacts expected to be encountered at the site was trade beads. Some of these beads are quite small, so nearly all fill was sifted through two-level screens. The upper screen consisted of 1/8-in. mesh; the lower screen consisted of 1/16-in. mesh. Due to problems with these screens during the first days of excavations, only 20 percent of the fill from units 84N/144E, 94N/127E, 95N/122E, 100N/132E, and 107N/117E was screened through the fine mesh. One hundred percent of the fill from all other units was screened through the fine mesh.

Excavation began by focusing on Features 2, 3, and 4. The interiors and immediately adjacent exteriors of the potential tipi rings were excavated to the top of Stratum 4, the probable occupation surface. After 19 units had been excavated at Feature 3, it was apparent that this was not a cultural feature and the area was abandoned. After the interiors of Features 2 and 4 were exposed and the central ash/charcoal deposits were excavated, focus shifted to the east of the tipi rings since large, formal, thermal features are often found to the east of Jicarilla tipi rings (Anschuetz 2000:23). Eleven square meters were excavated to the east of Feature 2 and 7 m^2 were opened to the east of Feature 4. By the time excavations began outside of Feature 4, much of the ground had frozen, limiting the amount of area that could be excavated. No exterior hearths were found within 2 m of either ring. Later, units to the west of Feature 2 and to the south of Feature 4 were opened. Finally, three units inside each tipi ring were excavated down to Stratum 5 to investigate Stratum 4.

Excavation units in Features 1 and 7 were placed so as to straddle the most promising alignments, and one unit was placed in the approximate center of Feature 1. Five units placed in Feature 1 and three in Feature 7 sufficed to determine that these features were, in fact, natural deposits.

Pre-excavation observations of Feature 5 suggested that this feature is of modern origin. Nevertheless, one excavation unit was placed at the center of the feature to see several boulders in profile. Nothing in this unit suggested anything other than a modern origin and no further excavations were performed.

The southern half of Feature 6 was excavated. As no ash, charcoal, oxidized sediments, or artifacts were found, the northern half was not excavated (however, a small amount of charcoal was recovered from flotation samples).

A single excavation unit (100N/132E) was placed at the edge of the debitage concentration. This unit was excavated into Stratum 5.

STRATIGRAPHY

The stratigraphic sequence at LA 85869 consists of late-Holocene deposits overlaying Pleistocene deposits. Dacite boulders and cobbles outcrop on the eastern edge of the site. Table 42.1 summarizes the strata at the site; it, and the following discussion, draw heavily on the geomorphic descriptions in Drakos and Reneau (Chapter 57, Volume 3).

Table 42.1. Stratigraphic sequence used during excavation at LA 85869.

Provenience	Stratum	Color	Texture	Thickness (cm)	Description
Entire site	0	7.5-10 YR 4-6/3-4	sandy loam, loamy sand	0	Surface
Entire site	1	7.5-10YR 4-6/3-4	sandy loam, loamy sand	1–13	A horizon, contains organics, 10%–50% gravel
Entire site	2	7.5-10 YR 6/2-3	sandy to silty loam	1–11	Bw horizon, very fine, loose, sometimes gravelly
Entire site	3	10YR 3-5/3-5	sandy clay loam	1–17	Bw horizon, some organics, 20%–30% gravel
Entire site	4	7.5-10YR 6/2-3	sandy to silty loam	1–13	Bw horizon, similar to Stratum 2 but more consolidated
Entire site	5	7.5YR 4/4	silty clay	13+	Btb1 horizon
Feature 4	6	10YR 6/3	sandy loam	NA	Feature 4, habitation surface
Feature 8	7	7.5YR 4/3	silt loam	4	Feature 8, fill, ash/charcoal
Feature 9	8	7.5 YR 3/2	silty clay	4	Burned soil below Feature 9
Feature 10	9	7.5YR 5/3	sandy loam	7	Feature 10, fill

The A horizon (Stratum 1) is up to 13 cm deep, although it is rarely deeper than 6 cm. Stratum 1 post-dates the construction of the tipi rings. Most of the sub-surface artifacts were found in this stratum. A Bw horizon underlies Stratum 1. During excavation, three strata (Strata 2, 3, and 4) were distinguished within the Bw horizon. Strata 2 and 4 are similar; they both consist of sandy to silty loam and are light in color. What distinguished these strata from each other is their consistency and stratigraphic position; Stratum 2 is loose and when it is present it always overlays Stratum 4. Stratum 4 is soft to slightly hard. Several of the tipi ring stones and two ground stone artifacts were found on top of Stratum 4. The top of this stratum is interpreted as the surface of the site at the time of habitation. Stratum 2 and 4 are present in Areas 2, 3, and 4. Additionally, a small deposit of Stratum 4 was found in unit 107N/117E. Stratum 3 is a more clayey and darker variation within the Bw horizon. It often overlies Stratum 4 although in a few excavation units it was the only Bw horizon stratum present. Stratum 3 is found in Areas 1 and 4 and in units 100N/132E and 107N/117E. A Btb1 horizon (Stratum 5) underlies the Bw horizon. Stratum 5 is inferred to date to the Pleistocene and is culturally sterile. The other strata are discussed below in the context of the features with which they are associated. Table 42.2 gives the total artifacts recovered from each stratum.

Table 42.2. Artifact count by stratum at LA 85869.

Stratum	Ceramics	Chipped Stone	Ground Stone	Beads	Metal	Bone	Total
0	5	334	3	0	12	1	355

Total	**8**	**370**	**5**	**158**	**29**	**3**	**573**

[1]The provenience information was lost.

SURFACE COLLECTION

The surface collection covered 1448 m^2 and 334 chipped stone artifacts were recovered. Figure 42.2 shows that there is an obsidian debitage concentration to the east of Feature 4 and only a handful of debitage elsewhere at the site. This concentration is discussed in greater detail below (see Feature 4).

SITE EXCAVATION

Area 1

Dacite cobbles in this area suggested the outlines of a tipi ring (Feature 1) centered at 77N/162E and a grid garden (Feature 7) centered at 76N/169E. Units 75N/161E, 75N/163E, 75N/164E, and 77N/165E were placed to explore parts of the cobble arc thought to compose the tipi ring. Additionally, units 77-80N/159-160E and 78N/161E, which were excavated to explore the eastern exterior of Feature 2, covered an area potentially inside Feature 1. Unit 77N/163E was dug to explore the central part of the potential ring. Units 74-75N/170E and 76N/168E straddled likely alignments in the potential grid garden. All units were excavated to the top of Stratum 5. None of the potential alignments appeared to have a cultural origin once excavation was complete, and no evidence of a surface or heating feature was found in the possible tipi ring.

The stratigraphy of Area 1 consists of 1 to 13 cm (4 cm on average) of Stratum 1 overlaying 1 to 17 cm (8 cm on average) of Stratum 3. Stratum 3, in turn, overlies Stratum 5. All the strata in these units contain a great many dacite cobbles. Only three artifacts were found in this area: a .50-caliber lead rifle ball (Field Specimen [FS] 215) was recovered from Stratum 1 and two glass seed beads (FS 276) were recovered from Stratum 4. These artifacts are probably associated with Feature 2. Three pollen samples (FS 307, FS 308, and FS 314) from this area were analyzed. Taxa identified in these samples included rose family, buckwheat, grass family, cheno-ams, sunflower family, ragweed/bursage, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush.

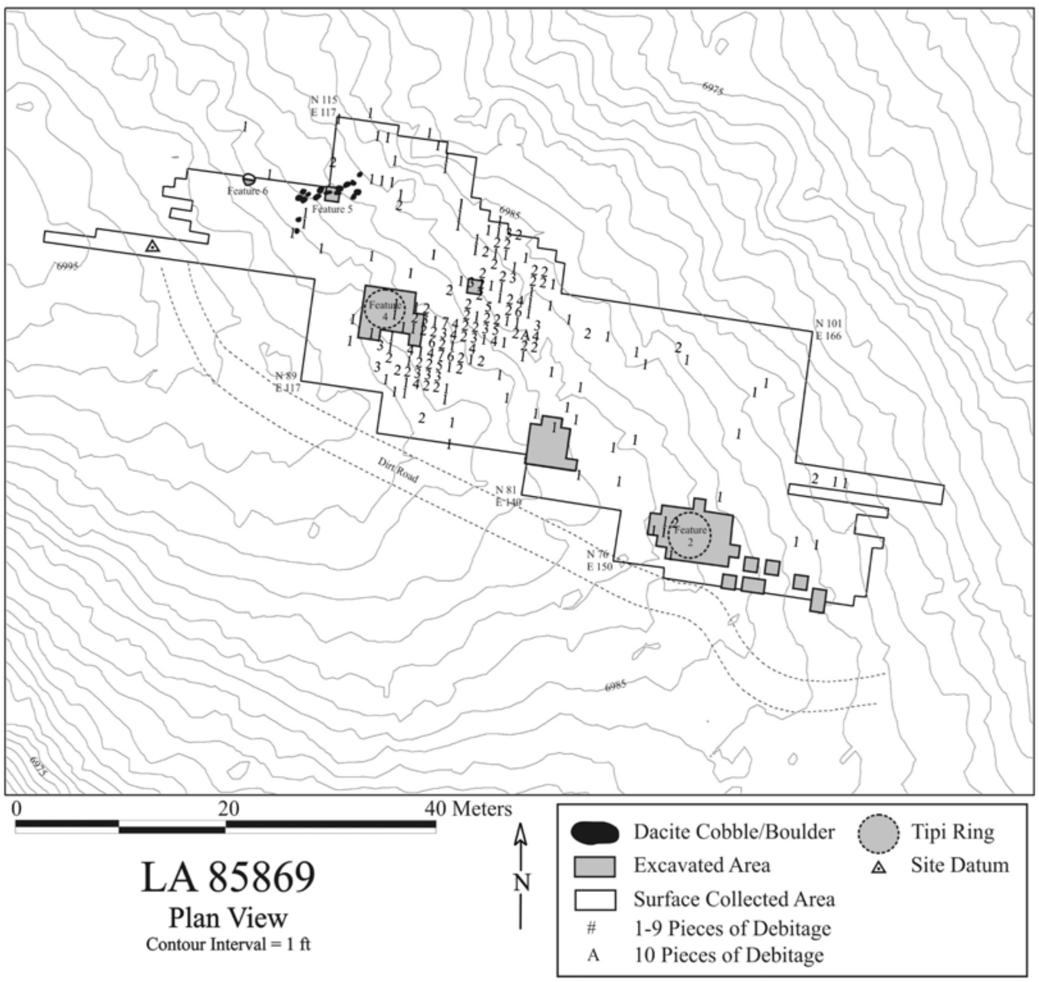

Figure 42.2. Surface debitage distribution at LA 85869.

Area 2

Area 2 was defined as Feature 2 (a tipi ring) and the area immediately around the feature. The stratigraphy outside of the feature to the west consisted of 1 to 8 cm (2.5 cm on average) of Stratum 1 overlaying 1 to 3 cm (1.5 cm on average) of Stratum 2. Stratum 4 underlies Stratum 2.

In the east, Stratum 1 is no different than has been previously noted. In units 77N/159E, 77N/160E, and 80N/159E, Stratum 1 is underlain by Stratum 3. In unit 79N/159E, Stratum 1 is underlain by Stratum 4. In all other units, Stratum 1 directly overlies Stratum 5.

Feature 2

This feature is the tipi ring identified by Hill and tested by Peterson and Nightengale (Figures 42.3 and 42.4). The tipi ring is composed of 22 dacite cobbles arranged in a circle with interior dimensions of 4.23 m north-south and 3.92 m east-west. The remains of a heating feature (Feature 9) are present in the center of the ring, and a possible posthole (Feature 10) is located outside to the southwest.

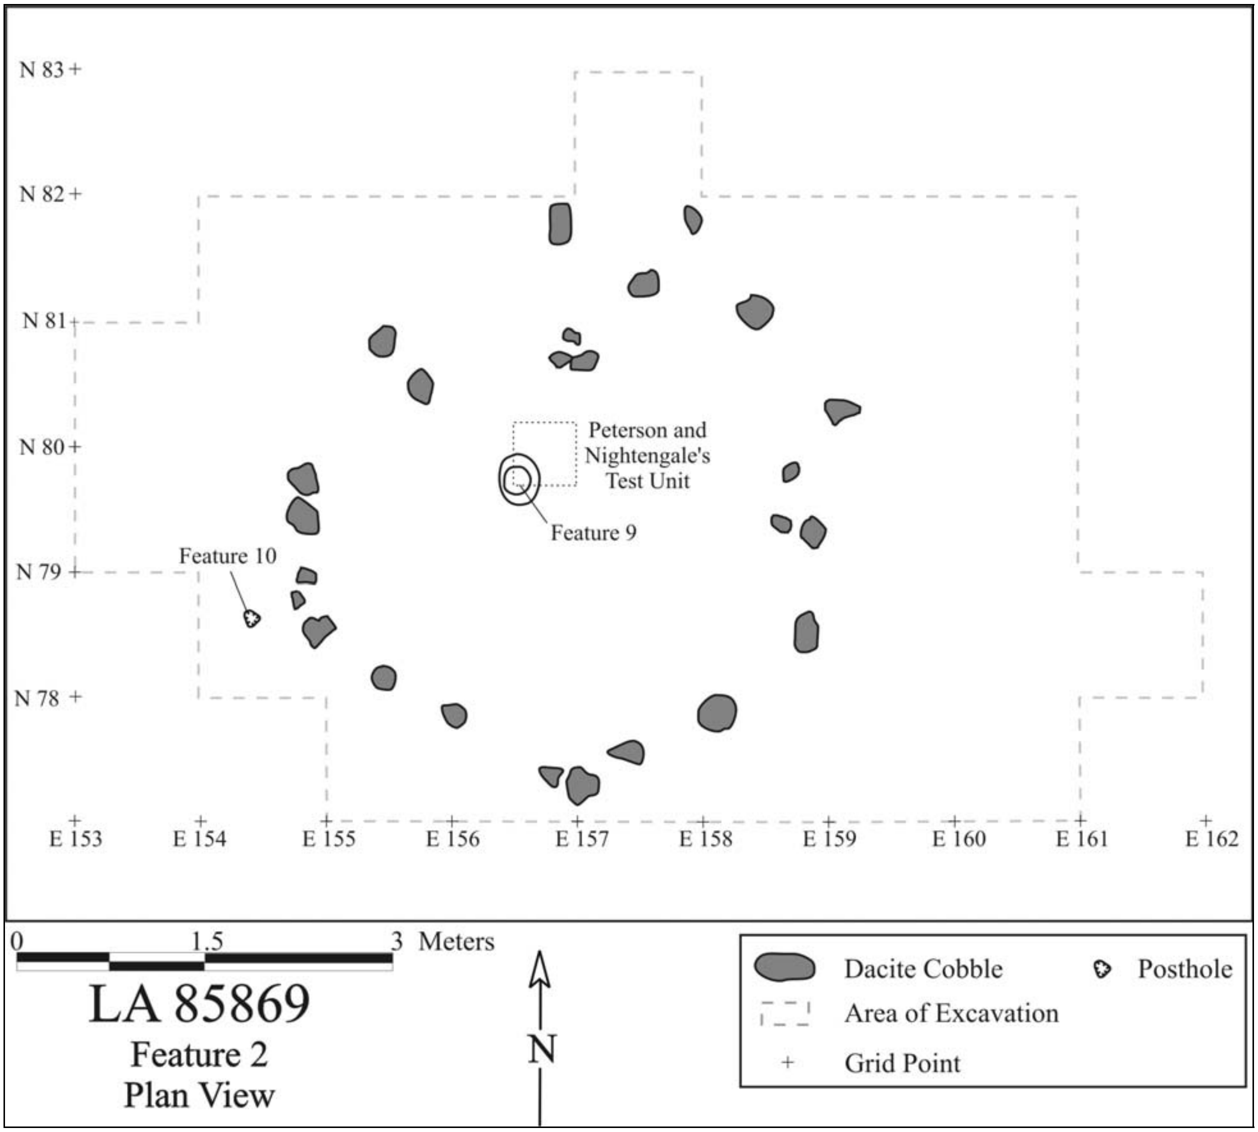

Figure 42.3. Plan view of Feature 2, a tipi ring.

Figure 42.4. Post-excavation photograph of Feature 2, a tipi ring.

Peterson and Nightengale placed a 1- by 1-m test unit in the center of Feature 2. This unit covers about 40 percent of units 79N/156E and 79N/157E and about 10 percent of units 80N/156E and 80N/157E. The test unit was excavated down to, and in places into, Stratum 5.

The stratigraphy of Feature 2 is straightforward. One to 5 cm (2.5 cm on average) of Stratum 1 overlies 1 to 4 cm (2 cm on average) of Stratum 2. Below Stratum 2 a compacted surface at the top of Stratum 4 is present in most places. The top of Stratum 4 is interpreted as the living surface at the time Feature 2 was inhabited. Stratum 4 was excavated in units 78-80N/158E. In this area Stratum 4 is 4 to 6 cm thick in most places save the western edge of 78N/158E where it is between 8 and 13 cm thick. Stratum 5 underlies Stratum 4.

Seventeen of the tipi ring cobbles were partially buried in Strata 1 and 2 and their upper surfaces were covered with lichen; the other five cobbles were completely buried. Most of the cobbles rest directly on top of Stratum 4. Three additional cobbles are located in the north-central portion of the tipi ring (80N/156E and 80N/157E). The base of these rocks is in Stratum 2 and it is not clear if these rocks were associated with the occupation of the tipi.

Since all the non-modern artifacts found in Area 2 are probably associated with Feature 2, Table 42.3 combines the artifact counts for both Area 2 and Feature 2.

Table 42.3. Area 2 and Feature 2 artifact counts by stratigraphic units.

Stratum	Ceramics	Chipped Stone	Ground Stone	Beads	Metal	Total
0	1/0/1[1]	5/1/6	0/0/0	0/0/0	0/1/1	6/2/8
1	2/0/2	2/4/6	0/0/0	54/94/148	1/0/1	59/98/157
2	0/0/0	0/0/0	0/0/0	0/5/5	0/1/1	0/6/6
3	0/0/0	0/0/0	0/0/0	0/0/0	0/0/0	0/0/0

9	0/0/0	0/0/0	0/0/0	0/0/0	0/0/0	0/0/0
Total	**3/0/3**	**7/6/13**	**0/0/0**	**54/99/156[2]**	**1/2/3**	**65/107/175[1]**

[1] 1/0/1: 1 = outside Feature 2, 0 = inside Feature 2, 1 = total; [2] The provenience information for three beads was lost.

The three ceramic sherds (FS 129 and FS 309) are micaceous jar sherds from a single vessel. The chipped stone artifacts consist of angular debris, core fakes, and flake fragments. The material is approximately evenly divided between black translucent obsidian, Pedernal chert/chalcedony, and unspecified chert. The metal artifacts from inside Feature 2 consist of a 4.5-cm-long, 1-cm-wide tin/zinc alloy strip (FS 135) and a metal (possibly lead alloyed with tin or antimony) flake (FS 238). The metal artifact from outside the feature is a lead fishing line weight (FS 310). For a discussion of the bead artifacts see the 'Artifacts and Sample Analysis' section below.

Flotation samples were taken from Stratum 1 (FS 283) and Stratum 2 (FS 288) of Feature 2. The samples were 2.0 and 1.8 liters, respectively. The only charred material recovered was a piñon pine needle fragment from FS 283. A pollen sample from Stratum 1 (FS 282) and a pollen sample from Stratum 2 (FS 287) were analyzed. Taxa identified in these samples included grass family, cheno-ams, sunflower family, ragweed/bursage, fir, unidentified pine, piñon pine, juniper, oak, and sagebrush.

Feature 9

Feature 9 is either a small firepit or a place where heated charcoal and rocks were deposited. It is located near the center of Feature 2 at 79.75N/156.55E. Peterson and Nightengale's excavations removed most of Feature 9. Peterson and Nightengale (1993:190) describe the feature as consisting of "a concentration of burned soil and ash with small flecks of charcoal…The burned area was first hit at a depth of about 5 cm bgs [below ground surface] and the burned clay associated with the hearth [i.e., Stratum 5] extended down to a depth of about 15 cm." Stratum 5 was excavated in the northwestern part of the test unit to determine if a firepit was present. No evidence of a depression in the Btb1 horizon was found, although the soil was burned to a depth of 4 cm from the top of the stratum. Peterson and Nightengale (1993:190) concluded that, "the fire was situated on the surface that formed the floor of the structure."

During excavation, no ash or charcoal were found. However, Strata 2 and 4 were absent in the north-central portion of unit 79N/156E, just west of Peterson and Nightengale's test unit. Here Stratum 1 directly overlays Stratum 5, suggesting that a shallow depression had been dug into Stratum 4. It was also in this area that Stratum 5 was burned. The burned area measures 42 cm north-south and 11 cm east-west (truncated by the test unit). Stratum 5 was burned to a depth of 4 cm (i.e., from the top of Stratum 5 at 6.74 m to 6.70 m). The base of the burned area is about 20 cm in diameter. The burned portion of Stratum 5 was taken as a flotation sample (FS 318). No charred macrobotanical remains were recovered from this sample.

Feature 10

Feature 10 is a possible posthole located at 78.65N/154.43E (about 40 cm from the edge of Feature 2). The hole is 10 cm by 9 cm across, 7 cm deep, and triangular in shape. The upper 2 or 3 cm of the feature were filled with small pebbles and sediment that was slightly darker than the surrounding Stratum 2 matrix. The rest of the fill (Stratum 9) was collected as a pollen sample (FS 320). Taxa identified included plantain, grass family, cheno-ams, sunflower family, ragweed/bursage, spurge family, fir, unidentified pine, piñon pine, juniper, oak, and sagebrush.

Area 3

Before excavation began it seemed possible that a tipi ring (Feature 3) was present and centered on unit 86N/142E. Nineteen excavation units were dug in this area. No alignment of cobbles was found that suggested any part of a tipi ring arch, and no evidence of a heating feature was observed. The stratigraphy in Area 3 is uniform and similar to that in Area 1. Stratum 1 overlies Stratum 2 and both are usually 1 to 4 cm thick, occasionally they are up to 9 cm thick. Stratum 4 is present everywhere beneath Stratum 2. The strata and cobble deposits in Area 3 do not have a cultural origin.

The only artifacts found in Area 3 were two pieces of chipped stone debitage from Stratum 0 and four pieces of chipped stone debitage Stratum 1. A pollen sample (FS 249) from Stratum 2 was analyzed. Taxa identified included grass family, cheno-ams, sunflower family, fir, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush.

Area 4

Area 4 is defined as Feature 4 (a tipi ring) and the concentration of chipped stone debitage to the immediate east. As there is no stratigraphic difference between the interior and the exterior of the feature, the stratigraphy of Area 4 is given in the discussion of Feature 4.

The concentration of lithic debitage to the east of Feature 4 covers an area about 10 m wide (east-west) and 20 m long (north-south). The north-south dimension is parallel to the slope of the ground surface, so the length of this dimension is due, at least in part, to the movement of artifacts downslope. A single test unit (100N/132E) was placed at the edge of this artifact scatter. The stratigraphy consisted of 4 cm of Stratum 1, which contained one piece of chipped stone debitage, and 5 to 10 cm of Stratum 3, which contained two pieces of chipped stone debitage. Stratum 5 was encountered below Stratum 3. Juniper charcoal (FS 244) from Stratum 3 was submitted for accelerator mass spectroscopy analysis. FS 244 returned a post-AD 1950 date (Beta-199372).

Feature 4

This tipi ring consists of 11 dacite cobbles arranged in a circle with interior dimensions of 3.25 m north-south and 3.75 m east-west (Figure 42.5). The cobbles are unshaped and range in size from 17 by 12 cm to 30 by 25 cm. The remains of a heating feature (Feature 8) were found in the center of the ring.

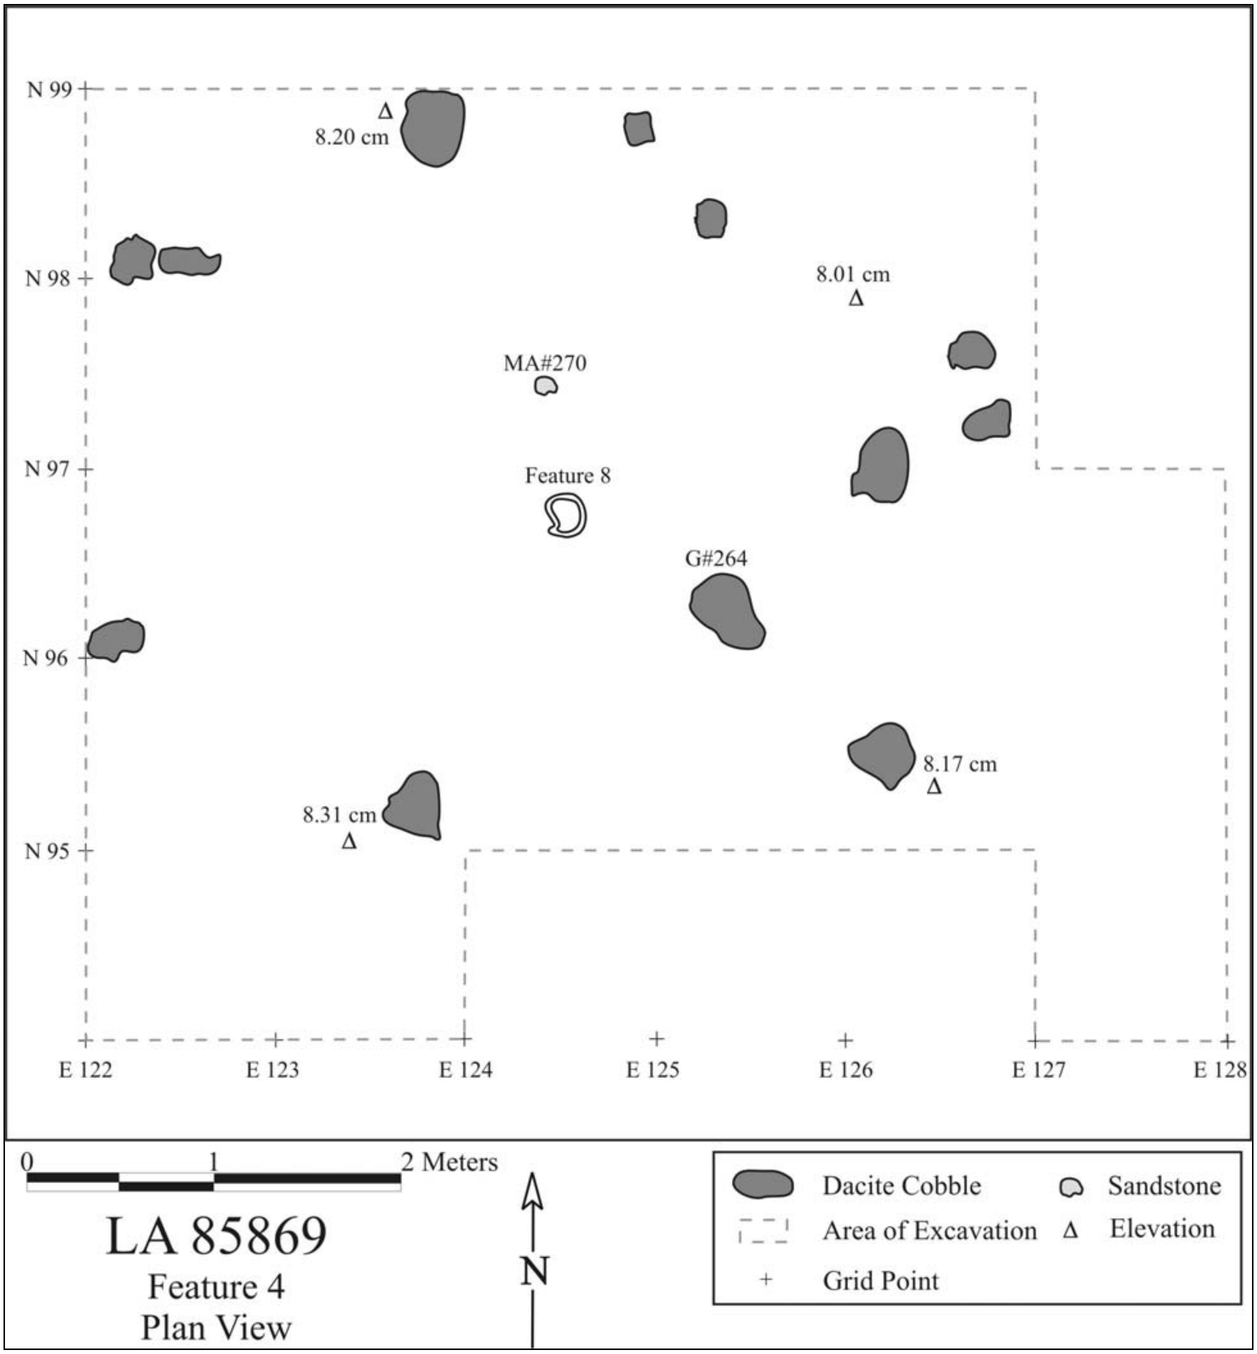

Figure 42.5. Plan view of Feature 4, a tipi ring.

Stratum 1 (1 to 6 cm) covers the entire area, but below this there is some variation. In the central and southwestern part of the tipi ring the stratigraphic sequence consists of Strata 1, 2, and 4. The sequence in the eastern part of the ring and the immediate exterior is Strata 1, 3, and 4. At the extreme east and southwest edges of the area, Stratum 1 directly overlays Stratum 4. In the northernmost units, Strata 2 and 4 are absent. Here Stratum 3 overlays Stratum 5. All of the cobbles were partially buried in Strata 1 and 2 and their upper surfaces were covered with lichen. Most of the cobbles composing the tipi ring were resting on top of Stratum 4; on this basis the top of Stratum 4 is interpreted as the living surface (the actual living surface is designated as Stratum 6). Stratum 4 was excavated in units 95N/123E and 95N/124E and 96N/124E. The stratum was 1 to 11 cm deep (3 to 5 cm deep on average). Stratum 5 underlay Stratum 4 in all three units. Since all the non-modern artifacts found in Area 4 are probably associated with Feature 4, Table 42.4 combines the artifact counts for both Area 4 and Feature 4.

Table 42.4. Area 4 and Feature 4 artifact counts by stratigraphic units.

Stratum	Ceramics	Chipped Stone	Ground Stone	Beads	Metal	Total
0	0/0/0[1]	263/2/265	0/0/0	0/0/0	0/0/0	262/2/265
1	0/0/0	4/11/15	0/0/0	0/0/0	3/7/10	7/18/25
2	0/0/0	1/1/2	0/0/0	0/0/0	0/0/0	1/1/2

[1]0/0/0: 0 = outside Feature 2, 0 = inside Feature 2, and 0 = total

The ceramic artifact (FS 325) is an unidentified plainware sherd. The metal artifacts from inside the feature consist of a straight pin or round wire fragment (FS 210), two possible cone tinkler fragments or pieces of tinkler manufacturing debris (FS 211 and FS 212), a can fragment cut into a 3.0-cm-long strip (FS 213), a .50-caliber lead/alloy rifle ball with an impact surface (FS 214), three joined segments of a *coscojo* (FS 220), and a 4.0-cm-long rolled steel strip (FS 268). Metal artifacts from outside of the feature consist of a *coscojo* fragment (FS 209), two joined *coscojo* segments (FS 221), and a possible cone tinkler fragment (FS 219). The two ground stone artifacts consist of a sandstone mano fragment (FS 270) at 97.2N/124.55E and a dacite millingstone (FS 264) at 96.30N/125.40E. Both of these artifacts were found on the habitation surface of the tipi ring. A pollen sample (FS 263) was taken from below the millingstone. Taxa identified in the sample included grass family, cheno-ams, sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon pine, juniper, oak, Mormon tea, sagebrush, and greasewood. The chipped stone artifacts from Area 4 account for most of the chipped stone artifacts recovered from the site. Instead of being discussed here they are analyzed in the 'Artifact and Sample Analysis' section below.

Feature 8

A concentration of charcoal and charcoal-stained soil was found in the center of Feature 4 at 96.75N/124.52E. This charcoal concentration is 13 cm in diameter and 4 cm deep and is situated in a very shallow depression in Stratum 4. No burning or oxidation was present in the surrounding matrix. The contents of this feature were taken as a flotation sample (FS 272) and a pollen sample (FS 271). Charred taxa identified in the flotation sample included goosefoot and piñon pine. Taxa identified in the pollen sample included mustard family, grass family, cheno-ams, sunflower family, unidentified pine, piñon pine, juniper, and oak. Feature 8 is interpreted as a locale that served as the receptacle for heated rocks and/or charcoal from an external hearth or as a small fire pit.

Material from FS 272 was submitted for accelerator mass spectroscopy analysis. The sample returned an age of 260±40 (Beta-199373) and a date of cal AD 1650 with a two-sigma date range of cal AD 1520–1590, cal AD 1620–1670, cal AD 1770–1800, and cal AD 1940–1950. As the artifacts associated with LA 85869 indicate, the late 19^{th}/early 20^{th} century habitation date returned by this radiocarbon sample is interpreted as reflecting the use of old wood.

Area 5

Area 5 encompasses Features 5 and 6. In addition to the artifacts found in these two features, four chipped stone artifacts were found in Area 5 during the surface collection.

Feature 5

Feature 5 was the second feature tested by Peterson and Nightengale. It is a rough line of unshaped dacite boulders about 8.5 m long and 0.5 to 3.0 m wide (Figure 42.6). The boulders range in size from 25 by 20 by 15 cm to 45 by 25 by 14 cm. Lichen was observed on the bottom of several of the boulders of this feature. Additionally, $CaCO_3$ was found on the top of two other boulders. The modern trash observed by Peterson and Nightengale is still present. An excavation unit (107N/117E) was placed in the center of this feature. The only artifacts recovered were three pieces of chipped stone debitage from Stratum 3.

The upper stratum in unit 107N/117E is Stratum 1, which was about 2 cm deep. This is underlain by Stratum 3 (6 to 8 cm deep) except in the northwest and northeast corners of the unit. In these corners, Stratum 4 (4 to 6 cm deep) is immediately below Stratum 1. As Stratum 4 is only found downslope from and behind the boulders, it was probably present over a greater area in the past, but has since eroded away. The boulders of the feature sit on top of Stratum 3 or are partially buried in it (up to 5 cm in depth). Stratum 5 underlies Strata 3 and 4, and it was here that excavation stopped. A small amount of shallow rodent or root disturbance was observed at the top of this stratum. Two pollen samples (FS 252 and FS 254) from Stratum 3 were analyzed. Taxa identified in these samples included sedge, grass family, cheno-ams, sunflower family, fir, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush.

The presence of modern trash coupled with the inverted location of lichen and calcium carbonate on some boulders indicates that this feature is most probably a push pile or dump of modern origin.

Figure 42.6. Feature 5, an alignment of dacite cobbles.

Feature 6

Feature 6 consists of 12 small cobbles arranged into a rough circle 75 cm by 90 cm (Figure 42.7). Four additional cobbles are present inside the ring. A shallow rill runs north-south along the western edge of the feature. The rill may have removed a few cobbles and deposits from the western part of the feature, particularly from the northwest corner. The southern half of the interior of the ring was excavated to a depth of 10 cm. The fill consisted entirely of Stratum 1 and excavation ended at the top of Stratum 5. No artifacts were found. It was originally thought that Feature 6 was a hearth but no ash and very little charcoal was found. No evidence of burning, such as oxidation, was observed.

Three of the rocks that make up the feature were identified as ground stone artifacts: a dacite polishing stone (FS 286), a basalt one-hand mano (FS 286), and a dacite one-hand mano (FS 319). No other artifacts were found.

Three flotation samples were analyzed from Feature 6 (FS 295, FS 296, and FS 297). Each sample contained less than 0.1 g of wood charcoal. Charred taxa identified included unknown conifer, juniper, piñon pine, ponderosa pine, and unidentified pine. A pollen sample (FS 294) from this feature was analyzed and identified taxa included sunflower type, cheno-ams, grass family, sunflower family, ragweed/bursage, spurge family, spruce, fir, unidentified pine, piñon pine, juniper, oak, and sagebrush.

Figure 42.7. Feature 6, a cobble circle.

Material from FS 295 and FS 297 were submitted for accelerator mass spectroscopy delivery analysis. FS 295 returned an age of 1040±40BP (Beta-199374) and a date of cal AD 1000 with a two-sigma date range of cal AD 910–920 and cal AD 960–1030. FS 297 returned an age of 500±40 BP (Beta-199375) and a date of cal AD 1420 with a date range of cal AD 1400–1450. Given the small amount of charred material present and the disparate radiocarbon dates, it is unclear how to interpret Feature 6.

Area 6

Area 6 includes all the other unaffiliated areas of the site that have not already been discussed. A light scatter of chipped stone debitage is present in this area, and a total of 58 chipped stone artifacts were recovered from the surface. Four sherds from a single Cimarron Micaceous vessel (FS 328) were found 65 m northwest of Feature 4. Due to the paucity of artifacts and absence of cultural features, no excavation took place in this area.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 566 artifacts were analyzed from the excavations conducted at LA 85869 (Table 42.5). In addition, flotation and pollen samples were selected for analysis from Strata 1, 2, 7, and 8 (flotation) and Strata 1, 2, 3, 4, 6, 7, and 9 (pollen). Charcoal was submitted for radiocarbon dating from Strata 1, 3, and 7, and six pieces of obsidian were submitted for hydration dating from Strata 1 and 4. The results of the artifact and sample analyses are presented in the following sections.

Table 42.5. Samples selected for analysis from LA 85869.

Stratum	Sample Type			
	Flotation	Pollen	Radiocarbon	Hydration
1	283, 295, 296, 297	282, 294	295, 297	265, 266, 267, 277, 322

6		263		
7	272	271	272	
8	318			
9		320		

Chronology

Radiocarbon Dating

Four radiocarbon samples were submitted to Beta Analytic for analysis. Table 42.6 gives the results of the radiocarbon analysis. Only FS 272 is clearly associated the Apachean occupation of the site. This sample probably represents the use of old wood.

Table 42.6. Radiocarbon dates from LA 85869.

FS	Context of sample	Laboratory (Beta)#	Conventional radiocarbon age	Intercept of radiocarbon age	Two-sigma calibrated result
244	100N 132E Stratum 3	199372	155.5±0.8 pMC[1]	NA	post-AD 1950
272	Feature 8 (heating feature)	199373	260±40	AD 1650	AD 1520–1590 AD 1620–1670 AD 1770–1800 AD 1940–1950
295	Feature 6	199374	1040±40	AD 1000	AD 910–920

FS	Context of sample	Laboratory (Beta)#	Conventional radiocarbon age	Intercept of radiocarbon age	Two-sigma calibrated result
	(possible hearth)				AD 960–1030
297	Feature 6 (possible hearth)	199375	500±50	AD 1420	AD 1400–1450

[1]Percent modern carbon; results that post-date AD 1950 can only be reported in pMC.

Thermoluminescence Dating

One micaceous ceramic sherd (FS 328) was submitted for thermoluminescence dating. Table 42.7 presents the results generated from this analysis.

Table 42.7. Thermoluminescence dating.

FS	Lab #	Context	Burial depth (cm)	Age (ka)	% error	Years AD
328	UW1245	65 m NW of Feature 4	0	0.146±0.021	9.1	1859±13

Obsidian Hydration Dating

Six obsidian artifacts from LA 85869 were submitted to the Diffusion Laboratory for age determination using the obsidian hydration dating method. In order to calculate the absolute date for an obsidian artifact, three analytical procedures were completed. First, the amount of surface hydration, or the thickness of the hydration rim, was measured. Second, the high-temperature hydration-rate constants for each artifact were determined from the composition of the glass. Lastly, the soil temperature and relative humidity at the archaeological site were estimated so that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. Using these methods, a hydration rate for the obsidian artifacts from LA 85869 was calculated (Table 42.8).

Table 42.8. Obsidian hydration dates for LA 85869.

FS No.	Lab No.	Source	Rim (um)	AD/-BC	1 S.D.
265	2006-11	Valle Grande	3.26	-869	176
266	2006-12	Valle Grande	2.95	-1408	231
267	2006-13	Valle Grande	3.27	-2146	254
277	2006-14	Valle Grande	2.94	-1417	233
322	2006-15	Valle Grande	2.99	-1711	249
324	2006-16	Valle Grande	3.43	1393	33

Only the 14th century obsidian hydration dates correspond with any of the radiocarbon dates. Otherwise, they appear to be too old.

Historic Artifact Dating

Analysis of the beads and metal artifacts (Appendix N) from LA 85869 suggests that the site dates to the late 19th or early 20th century. Artifacts with known temporal associations include a .50-caliber unalloyed lead ball (FS 215), *coscojos* fragments (FS 209, FS 220, and FS 221), a pony bead (FS 304), and seed beads (multiple FS numbers). The following is summarized from Appendix N. Unalloyed lead is characteristic of firearm projectiles before circa AD 1870. *Coscojos* have been found at Apache and Ute sites in New Mexico dating to between AD 1840 and 1900+, and pony beads entered the west in quantity around AD 1800 and remained popular in some areas until the early AD 1880s. Many of the seed beads from LA 85869 are of the smallest size category (0.5 to 0.7 mm in diameter). Additionally, 11 beads are tan in color and five are pink. This size and these colors of beads did not become readily available to the Jicarilla Apache until the early AD 1880s.

The presence of 12 “sanitary seal” can fragments (FS 197 and FS 199) may indicate a post-1897 date for the site. However, these fragments were found in units 103N/114E and 104N/114E. These units are within the light scatter of modern trash around Feature 5. It is unlikely that the can fragments are associated with the Apachean occupation of the site.

Four Cimarron Micaceous sherds from a single vessel (FS 328) were identified by Eiselt (Volume 4, Chapter 75). This type dates to between circa AD 1750 and the 1900s (Gunnerson 1969:33).

Ceramic Artifacts (Sunday Eiselt)

Seven micaceous sherds (FS 129, FS 309, and FS 328) that represents two vessels and one non-micaceous plainware sherd (FS 325) were found at LA 85869. Six of the micaceous sherds were analyzed by Eiselt (Volume 4, Chapter 75) and the results are briefly summarized. Inclusions in the paste of the three jar sherds from a single vessel found near Feature 2 (FS 129 and FS 309) suggest that the clay came from Picuris, Cordova, or Guadalupita, all of which are located in New Mexico. The surface finish, which was compacted with no wipe or scrape marks visible and a mica slurry application, indicates that the vessel may be attributed to Taos, Picuris, or Jicarilla makers. Inclusions in the paste of the four jar sherds from a single vessel found to the northwest of the site (FS 328) suggest that the clay came from Petaca. The probable clay source and surface finish, which was compacted with wipe-marks present and vessel walls sanded or burnished before mica slip or slurry application, indicate that the vessel was probably made by Jicarilla Apaches and is of the Cimarron Micaceous type.

Metal Artifacts (Charles Haecker)

The metal artifacts from LA 85869 were analyzed by Haecker and are summarized in Appendix N. Table 42.9 summarizes the results of Haecker’s analysis.

Table 42.9. Metal artifacts from LA 85869.

FS	Artifact Type	No.	Provenience	Description	Dates
135	metal strip	1	Feature 2	tin/zinc alloy, 1 cm wide, 4.2 cm long, ends bent together, oxidized	unknown
197	can fragments	10	Area 5	"sanitary seal" can fragments	post-AD 1897
199	can fragments	2	Area 5	"sanitary seal" can fragments	post-AD 1897
209	*coscojo*	1	Area 4	two joined parts	circa AD 1840–1900+
210	straight pin or round wire fragment	1	Feature 4	ferrous, 3.0 cm long	19th century to present
211	trapezoidal white metal sheet	1	Feature 4	tin(?), folded, cut edges, 4.0 by 2.5 cm, possible cone tinkler or cone tinkler manufacturing debris	19th century to present
212	white metal fragment	1	Feature 4	tin(?), cut on all sides, oxidized, possible cone tinkler manufacturing debris	19th century to present
213	metal strip	1	Feature 4	can fragment, possible fastener hole, wavy in profile, 3.0 by 1.0 cm	19th century to present
214	.50-caliber lead/alloy rifle ball	1	Feature 4	cast seams visible, impact surface present	Mid/late 19th century to present
215	.50-caliber lead rifle ball	1	Area 1	mold-cast, apparently unfired, more oxidized (older) than FS 214	before circa AD 1870
216	.30-caliber brass pistol shell casing	1	Area 6	rim-fired	post-AD 1871
217	lead (bullet?) fragment	1	Area 6	possibly from a fired bullet, slightly oxidized	19th century to present
218	brass rifle shell fragment	1	Area 6	unknown caliber	20th century to present
219	white metal fragment	1	Area 4	tin(?), cut on two sides, oxidized, possible cone tinkler manufacturing debris	19th century to present
220	*coscojo*	1	Feature 4	three joined parts	circa AD 1840–1900+
221	*coscojo*	1	Area 4	two joined parts	circa AD 1840–1900+
238	metal flake	1	Feature 2	possibly lead alloyed with tin or antimony, 0.5 by 0.7 cm	unknown

FS	Artifact Type	No.	Provenience	Description	Dates
268	rolled steel strip	1	Feature 4	3.81 by 1.9 cm, three sides cut, one side showing fatigue from back-and-forth bending, wavy in profile	unknown
310	split-shot lead sinker	1	Area 2	out-of-round, 0.30-in.-diameter	unknown

While 29 metal artifacts were recovered, only the three *coscojo* fragments (FS 209, FS 220, and FS 221) can be unambiguously assigned to the Jicarilla occupation of the site, although it is likely that the .50-caliber lead ball (FS 215) was also deposited at this time. If the white metal fragments (FS 211, FS 212, and FS 219) are, in fact, cone tinkler fragments, then they are almost surely associated with the Apachean occupation. The temporal affiliation of the rest of the metal artifacts cannot be determined given that a light scatter of modern trash is present. However, the spatial association of FS 135, FS 238, and FS 310 with Feature 2, and FS 210, FS 213, FS 214, and FS 268 with Feature 4, may be indicative of a temporal association.

Beads (Charles Haecker)

All 158 glass beads from LA 85869 were analyzed; Table 42.10 summarizes the results of this analysis.

Table 42.10. Glass beads from LA 85869.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 374 artifacts were analyzed from LA 86869, consisting of 364 pieces of debitage, four retouched tools, five ground stone artifacts, and a piece of fire-cracked rock. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 42.11 presents the data on lithic artifact type by material type. The majority of the debitage is made of obsidian, with lesser amounts of chalcedony, Pedernal chert, and other materials. The presence of cortex on 23.0 percent of the debitage indicates that these materials were collected from mostly nodule (n = 75) and fewer waterworn (n = 9) sources. Most of the nodule cortex was observed on the obsidian artifacts. Although obsidian is present at nearby primary sources in the Jemez Mountains, it is also present in the area of the site as small pebbles. These pebbles compose part of the secondary deposits associated with the Cerro Toledo interval and are scattered across the mesa top. The chalcedony and Pedernal chert are available from local Rio Grande Valley gravel sources and the basalt from local bedrock outcrops and stream gravels. The ground stone artifacts are made of igneous materials, which are available both as bedrock outcrops and in stream gravels that cross-cut the plateau.

Table 42.11. Lithic artifact type by material type.

Artifact Type		Basalt	Vesic. Basalt	Rhyolite	Andesite	Dacite	Tuff	Obsidian	Chalcedony	Chert	Pedernal	Sil. Wood	Sandstone	Total

Six pieces of debitage and four retouched tools were submitted for X-ray fluorescence analysis. All but one of the artifacts was from the Valle Grande source, with a single biface from the Cerro Toledo source (Table 42.12). The Valle Grande (Cerro del Medio) source area is located about 17 km (11 mi) and the Cerro Toledo (Rabbit Mountain/Obsidian Ridge) source area about 19 km (12 mi) to the west and southwest of the site. However, as previously noted, there are pebbles of Cerro Toledo obsidian that are also present in the area of the site.

Table 42.12. Obsidian source samples.

322	Debitage	Translucent	Valle Grande rhyolite
324	Debitage	Translucent	Valle Grande rhyolite

Lithic Reduction

Although no cores were recovered at the site, the presence of a bipolar flake indicates that both platform cores and bipolar cores were reduced at the site. The bipolar reduction technique was presumably used to reduce a small obsidian pebble that was present at the site.

The debitage mainly consists of core flakes (52.1%), with some biface flakes (14.0%), angular debris (13.1%), undetermined flake fragments (12.0%), and microdebitage (8.2%). In addition, a single bipolar flake and *outrepasse* flake were also identified. Table 42.13 summarizes the various stages of reduction represented by the whole core and biface (tertiary) flakes. The overall cortical:non-cortical ratio of 0.63 reflects an emphasis on the later stages of core reduction and tool production/maintenance, although there is relatively more cortex present on the small obsidian sample.

Table 42.13. Debitage reduction stages.

Material	Primary	Secondary Cortical	Secondary Non-cortical	Tertiary	Cortical: Non-cortical ratio
Basalt	0	0	0	0	---
Obsidian	0	6	2	2	1.5
Chalcedony	0	1	2	0	0.50
Pedernal chert	0	0	4	1	---
Total	**0**	**7**	**8**	**3**	**0.63**
Percentage	0.0	38.8	44.4	16.6	---

The majority of the flakes exhibit single-faceted platforms (32.8%; n = 22), with cortical (n = 12), multi-faceted (n = 1), collapsed (n = 14), and crushed (n = 18) platforms. Only five (7.4%) of the flake platforms exhibit evidence of preparation and all of these were abraded/crushed.

The majority of the core flakes consist of distal fragments (n = 90; 47.6%), with fewer whole (n = 17), proximal (n = 35), midsection (n = 43), lateral (n = 1), and undetermined fragments (n =

3). Most of the biface flakes are midsection (*n* = 17) and distal fragments (*n* = 17), with fewer whole (*n* = 3) and proximal (*n* = 14) fragments. The whole core flakes have a mean length of 20.1 mm (*std* = 6.5), whereas the whole biface flakes exhibit a mean length of 18.6 mm (*std* = 3.1). Lastly, angular debris have a mean weight of 2.1 g (*std* = 2.4).

The retouched tools consist of both expedient flakes tools (i.e., retouched pieces) and formal tools (i.e., bifaces and projectile points). Both retouched pieces exhibit a single marginally retouched edge. One of these items has unidirectional dorsal retouch and the other has bidirectional marginal retouch with edge angles of 55 and 65 degrees, respectively. The biface consists of a proximal fragment with an edge angle of 45 degrees. This acute angle indicates that the artifact was probably broken late during the manufacturing process. The projectile point is an undetermined fragment that probably represents a dart point.

Tool Use

Only one flake (0.2%) exhibits evidence of damage that could be attributed to use-wear. The damage is located along the lateral edge of the flake with a concave outline and angle of 40 degrees. One of the retouched pieces does exhibit microflaking; however, this was interpreted as being the result of preparation for further reduction and not use-wear.

Five ground stone artifacts were identified during the analysis, including manos, a millingstone, and a polishing stone. The manos consist of basalt, dacite, and sandstone cobbles. Two of these are one-hand manos with single flat ground surfaces. The other is an undetermined fragment that probably represents a one-hand mano, but is ground on both sides. The millingstone is a large fragment of dacite with a single flat ground surface. Lastly, the polishing stone consists of a small dacite pebble that exhibits polish and grinding on a single surface.

Faunal Remains (Kari Schmidt)

One elk (*Cervus elaphus*) scapula (FS 161) and two small, unidentified mammal fragments (FS 241) were recovered from LA 85869. Based on their general appearance, all of the faunal material appears to be modern in origin.

Archaeobotanical Remains (Pamela McBride)

Seven of nine flotation samples and four of nine macrobotanical samples were submitted for analysis. Table 42.14 shows that little charred material was recovered from the site.

Table 42.14. Charred macrobotanical remains from LA 85869.

Two Jicarilla Apache tipi rings and a ring of cobbles were sampled for floral material at LA 85869. A charcoal concentration in the center of the Feature 4 tipi ring was the only context where carbonized plant material that was not associated with firewood use was recovered, represented by a single goosefoot seed (Table 42.15). The balance of the recognizable plant remains consisted of charred and uncharred conifer duff. Aside from conifer twigs, needles, and cone parts, non-cultural plant material included weedy annual, dock, sweet clover, and hedgehog cactus seeds, as well as unknown dicot and oak leaves. Rodent activity was especially evident in the vegetal sample from the Feature 4 tipi ring, where sample taxa and rodent feces suggested the remains of a rodent nest (unburned juniper twigs and seeds, pine cone parts, and piñon needles). Rodent feces were also present in FS 297 from the Feature 6 cobble ring.

Wood from flotation and vegetal samples was entirely coniferous, with the most significant amount of charcoal (piñon 1.4 g and unknown conifer 0.1 g) occurring in the Feature 8 charcoal concentration (Tables 42.16 and 42.17). The site occupants were using locally available wood for fuel and kindling and possibly processing goosefoot seeds as food. However, it is unknown if the goosefoot seed represents accidental charring from food processing or of a wind blown seed.

Pollen Remains (Susan Smith)

Thirteen pollen samples were analyzed from LA 85869. Table 42.18 lists the frequency of identified pollen types. No cultigens were identified in the botanical assemblage. Sunflower type and sedge were the only other economic resources identified in the assemblage. A number of potential economic resources were also identified in the assemblage (Table 42.18), and these are discussed in detail in Smith's chapter in Volume 3.

SITE SUMMARY

LA 85869 consists of two late 19th/early 20th century Jicarilla Apache tipi rings. Most of the artifacts recovered from LA 85869 were found in the vicinity of Features 2 and 4. The artifact assemblages associated with each tipi ring are distinct. The artifacts in and around Feature 2 consist of glass beads, a few pieces of chipped stone debitage, three ceramic sherds from a single vessel, a .50-caliber rifle ball, a split-shot lead sinker, and a small fragment of metal. The artifacts in and around Feature 4 consist of two ground stone artifacts, an obsidian debitage scatter to the east of the feature, *coscojo* fragments, possible cone tinkler fragments, and several other miscellaneous metal fragments. The nearby tipi ring site at LA 85864 may be contemporaneous with LA 85869.

CHAPTER 43
RENDIJA TRACT (A-14): LA 86605

Michael J. Dilley and Bradley J. Vierra

INTRODUCTION

LA 86605 is a small one-room Late Classic period fieldhouse situated on the broad, gently sloping, east-facing shoulder of the terrace about 150 m south of the ephemeral creek in Rendija Canyon. The area is covered by a ponderosa pine forest at an elevation of 2110 m (6920 ft). The fieldhouse is located at the end of the Los Alamos Sportsmen's Club rifle range, but did not appear to have been impacted by these activities.

The site was originally recorded by Stolpe, Hoagland, and McGehee in 1991 and given the temporary site number of M-49. Stolpe et al. described the site as a one- to two-room masonry structure that was constructed from both shaped and unshaped tuff blocks within a 50-m^2 area. A total of eight pieces from a polychrome glaze bowl, four Pedernal chert flakes, and a flake made of Jemez obsidian were identified during this visit. Based on the ceramic evidence, they surmised the site dated to the Classic period.

FIELD METHODS

Fieldwork began with a reconnaissance of the area around the fieldhouse to define the nature and extent of the surface remains. The site datum was set at the southwestern corner of the site and was designated as 100N/100E and 10.00 m elevation. A 1- by 1-m grid system was laid in around the surface architecture with grid corners at 100N/100E, 100N/1007E, 107N/100E, and 107N/107E. Subdata were subsequently shot in along each of the four sides of the excavation block (A-D). The site was photographed and surface collected (Figure 43.1), and a total of 14 chipped stone and four ceramic artifacts were recovered.

An east-west trench was excavated along the 103N grid line from 101 to 105E to expose and define the walls of the structure and the site stratigraphy. The east and west walls were identified, as was a possible unprepared living surface about 35 cm below the present surface. The block excavation was, therefore, expanded to include the area bounded by 101N/101E, 101N/104E, 104N/101E, and 104N/104E, in addition to grids 102-104N/105E. A total of 19 grids were excavated in and around the one-room fieldhouse.

Excavations within the structure involved removing post-occupational fill down to the level of the possible unprepared floor surface. This surface was situated at the top of the Btb1 soil horizon. Excavations outside the structure were also conducted to the top of the Btb1 soil horizon, but the soil was much shallower in this area (ca. 20 cm). Obvious wallfall was removed so that the structure's walls and any internal or external features could be identified. The context of this wallfall was also used to help expose the level of the unprepared floor surface.

Figure 43.1. Pre-excavation photograph of LA 86605.

Pollen and flotation samples were taken from each stratigraphic unit and various locations on the possible floor surface. All excavated soil was sieved through a 1/8-in. mesh to aid in the recovery of cultural remains. The excavation area was extended approximately 1 m around the structure to locate external features and to identify outside activity areas. This actually included 2 m to the east of the structure to help isolate any activity areas. No internal or external features were identified. After the excavations were complete, the site was mapped (Figure 43.2) and photographed (Figure 43.3).

The excavation of the site was supervised by Michael Dilley. Crew members included Joseph (Woody) Aguilar, Greg Lockard, Kari Schmidt, and Bradley Vierra. Aaron Gonzalez, Timothy Martinez, and Michael Chavarria served as site monitors, representing both San Ildefonso and Santa Clara pueblos.

STRATIGRAPHY

Five stratigraphic units were defined during the excavations. These are illustrated in the profile provided in Figure 43.2 and are listed in Table 43.1. Stratum 1 is the loose topsoil that covered the site and represents most of the A soil horizon. Some of the surface organic material had been burned by the Cerro Grande fire. Stratum 2 consists of a silty loam that characterizes the post-occupational fill. This stratum is situated within the structure and represents the Bw soil horizon.

Stratum 3 is an unprepared occupational surface (upper and lower). Stratum 4 is similar to Stratum 2 except that it represents the Bw soil horizon situated outside of the structure. Lastly, Stratum 5 is the basal stratigraphic unit at the site and is composed of silty loam clay.

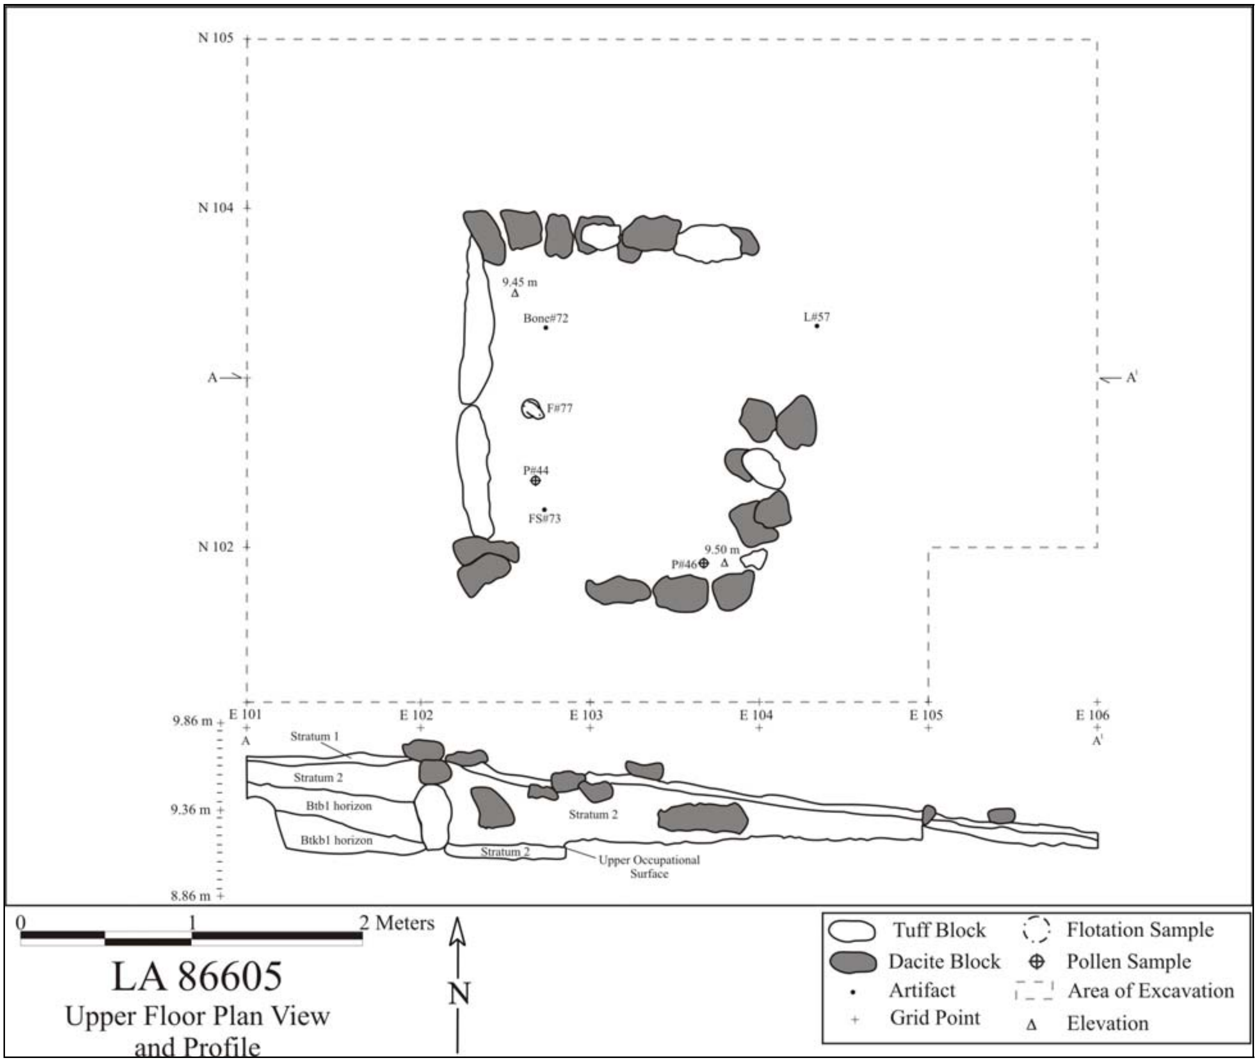

Figure 43.2. Plan view and profile map of LA 86605.

Table 43.1. LA 86605 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10YR 4/4	Loamy sand	2–6	Surface sediment
2	7.5YR 4/4	Silty loam	5–40	Post-occupational fill within the structure
3	7.5YR 4/4	Silty loam	0	Living surface (upper and lower)
4	7.5YR	Silty loam	10–15	Post-occupational fill outside the

Stratum	Color	Texture	Thickness (cm)	Description

5	7.5 YR 5/4	Silty loam clay	35+	Pre-occupational fill outside of structure, but below the floor level

Figure 43.3. Post-excavation photograph of LA 86605.

A geomorphic test pit was excavated adjacent and outside the west wall of the structure in unit 103N/101E (see Drakos and Reneau, Volume 3). The pit was excavated to a depth of about 1 m, and five separate soil horizons were identified (Table 43.2). From top to bottom these consist of A, Bw, Btb1, and Btkb1. The characterization of the soil profile continued within the structure at 103N/102E. In contrast to the outside profile, the inside profile did not include the Btb1 soil horizon, but rather an upper A and a middle Bw, which laid on top of the Btkb1 soil (Table 43.3). The Bw horizon could be separated into upper and lower sections that were approximately 30 and 10 cm thick, respectively. These differences became important once the inside fill of the structure had been excavated. Table 43.4 provides the artifact count information by stratigraphic unit at the site, with a total of 189 artifacts being recovered.

Table 43.2. LA 86605 soil horizon descriptions from the south profile of the geological test pit located outside the structure (103N/101E).

Horizon	Color	Texture	Depth (cm)	Description
A	10YR 4/4	Loamy sand	0–7	Topsoil
Bw	7.5YR 4/4	Silty loam	7–19	Late-Holocene soil
Btb1	7.5YR 5/4	Silty loam	19–35	Late-Pleistocene/early-Holocene soil
Btkb1	7.5YR 5/4	Silty loam	35–50+	Late-Pleistocene/early-Holocene soil
Btkb1	-	-	54–93+	Late-Pleistocene/early-Holocene soil

Table 43.3. LA 86605 soil horizon descriptions from the south profile of grid unit 103N/102E located inside the structure.

2	85	50	3	1	**139**
Total	**109**	**74**	**3**	**1**	**187**

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is a single room in a small fieldhouse (see Figure 43.3). The room measures 2.0 m north-south by 1.75 m east-west, with about 3.5 m^2 of interior space. Excavation of the room began with the east-west trench that extended across the rubble area along the 103N grid line. This excavation defined the east and west walls of the structure, the internal stratigraphy, and a possible unprepared floor surface. After the trench was completed, the remainder of the room fill was removed down to the level of the possible floor.

The geologic test pit was subsequently excavated adjacent to the west wall of the structure to define the stratigraphic context of the walls and occupational surfaces. As previously noted, separate soil profiles were identified within and outside of the structure.

Floor. Approximately 20 to 30 cm of post-occupational fill was removed before exposing a possible unprepared living surface within the structure. It was difficult to discern, being mostly disturbed in the western section of the room. However, it was defined by isolating charcoal bits, burned daub, a few blocks of wallfall, and a couple of artifacts along a horizontal break in the soil profile. This break was defined between the upper Bw(1) and lower Bw(2) soil horizons within the room fill.

A flotation sample (Field Specimen [FS] 77) was taken from under a tuff block in the middle of the room. Charred taxa identified in this sample included ponderosa pine, piñon pine, maize, and unknown conifer. Two pollen samples (FS 44 and FS 46) were taken from areas adjacent to the west and south walls. Identified taxa included maize, cholla, prickly pear, beeweed, lily family, grass family, cheno-ams, sunflower family, ragweed/bursage, spurge family, spruce, fir, unidentified pine, piñon pine, juniper, oak, squawbush, Mormon tea, and sagebrush. In addition, three artifacts were found lying on the floor surface. These consist of a Pedernal chert flake (FS 57), a mule deer bone fragment (FS 72), and a piece of burned adobe (FS 73).

A second lower occupational surface was identified. This floor also consisted of an unprepared living surface that was situated about 20 cm lower than the upper floor. However, the lower floor was located at the break between the Bw and Btkb1 soil horizon. That is, the upper floor was located near the bottom of the masonry wall, whereas the lower floor was located below the level of the walls. Nonetheless, additional wallfall, bits of charcoal, and a few artifacts were also recovered from the fill between the two floors. A flotation (FS 107) and pollen (FS 106) sample were taken from the lower floor. Ponderosa pine was the only charred taxon identified in the flotation sample, while grass family, cheno-ams, sunflower family, unidentified pine, piñon pine, juniper, oak, and sagebrush were all identified in the pollen sample. In addition, a single chalcedony flake was recovered from the same level and grid (103N/103E).

The identification of these two possible floor surfaces is tentative, but do appear to correlate with breaks in the stratigraphic profile and architectural remains. Drakos and Reneau (see Volume 3, Chapter 57) suggest that these represent two distinct occupations at the site, with the later occupants reusing the building stone from the previous occupation. In addition, Drakos and Reneau relate the upper occupation to the top of the exterior Bw soil horizon and the lower occupation to the top of the Btb1 soil horizon. They speculate as to whether the lower occupation might date to the Coalition period and the upper occupation to the Classic period.

Wall Construction. The walls in Room 1 were composed of tuff blocks and dacite cobbles. The tuff is available from outcrops in the canyon and the dacite from the gravels in the nearby ephemeral drainage. Most of the north, east, and west walls are composed of dacite cobbles that are resting near the upper floor level. Some adobe was observed below the central part of the north wall, which could represent foundation; however, no other evidence of adobe was observed below or within the other wall sections. Most of the building stones were set horizontally, with a few being upright in the north, east, and south walls. These appear to be dry-laid walls, with one to two courses remaining. Two very large tuff blocks are all that represent the western wall segment. These blocks have been set into a trench that cuts down into the lower Bw(2) soil horizon inside the room and the Btkb1 soil horizon outside of the room. The trench was filled with nearby soil that contained a few artifacts.

Based on the amount of wallfall removed during the excavation (1.2 m^3), it is speculated that the original walls were only three courses high. Wall measurement information is provided in Table 43.5. The remaining sections of the north, west, and south walls appear to be *in situ*; however, the nature of the east wall is unclear. This wall only partially extends along the east side of the room, leaving an opening in the northeast corner. The remainder of the wall does not appear to be *in situ* and may actually represent a cluster of building stones. If so, then the opening may not reflect a doorway, and there may not have been any standing masonry along this side of the room.

Table 43.5. Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	1.74	0.09–0.25	0.17–0.30	1 to 2
South	1.60	0.13–0.40	0.13–0.17	1
East	1.15 (1.65)	0.12–0.26	0.18–0.33	1 to 2
West	2.08	0.28–0.43	0.11–0.31	1

Note: The length of the east wall including the entryway is given in parentheses.

Artifact Distribution

Table 43.6 graphically illustrates the distribution of artifacts recovered during the site excavations (i.e., ceramics, chipped stone, ground stone, and faunal remains). However, this does not include the 18 artifacts found outside of the excavated area during surface collection. The bold numbers indicate grid units that are located completely or partially within Room 1, which indicates that the majority of the artifacts were recovered from within the structure or directly to the east of the room. The latter may reflect an outside activity area that was situated in front of the fieldhouse, or possibly reflects material removed from inside the structure during cleaning episodes.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 189 artifacts were analyzed from the excavations conducted at LA 86605. In addition, flotation and pollen samples were selected for analysis from the post-occupational fill (Stratum 2) and the upper and lower floors (Stratum 3) in the structure. Maize that was recovered from the flotation sample on the upper floor (FS 77) was submitted for radiocarbon dating (Table 43.7).

Table 43.7. Samples selected for analysis from LA 86605.

2	94	39, 93, 95	77	
3 (upper)	77	44, 46		
3 (lower)	107	106		

*thermoluminescence

Chronology

Radiocarbon Dating

A single maize sample was submitted for accelerator mass spectroscopy dating. The sample provided a date of 360±40 BP (Beta-215551), with a calibrated intercept of AD 1500 and a two-sigma range of AD 1440 to 1640. The sample was recovered from the upper floor of the structure.

Ceramic Artifacts (Dean Wilson)

A total of 105 ceramics were analyzed from LA 86605. The majority of the pottery represents local Rio Grande decorated ceramics, with a few utilityware types (Table 43.8). These include Biscuit B, Biscuit C, Sankawi Black-on-cream, and Sapawe Micaceous. The whitewares are primarily tempered with local fine tuff or ash and the utilitywares with non-local granite and mica (Table 43.9). Most of the whitewares are represented by jar vessel forms, while all the utilitywares are jars (Table 43.10). Given the presence of Biscuit C and Sankawi Black-on-cream, the site probably dates to the Late Classic period. This corroborates the potential 16th century occupation represented by the radiocarbon date. It seems unlikely that the lower floor dates to the Coalition period given the absence of any earlier ceramic types.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 72 artifacts were analyzed from LA 86605, consisting of 67 pieces of debitage, four retouched tools, and a ground stone artifact. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 43.11 presents the data on lithic artifact type by material type. The debitage is primarily made of chalcedony, with less Pedernal chert and other materials. The presence of cortex on 23.8 percent of the debitage indicates that these materials were collected from waterworn (n = 14) and nodule (n = 2) sources. The chalcedony, Pedernal chert, silicified wood, and quartzite are available from local Rio Grande Valley gravels and the obsidian from nearby sources in the Jemez Mountains. Otherwise, the igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the plateau.

*Change-of-Orientation Flake

Three obsidian flakes, three basalt flakes, and a retouched piece were submitted for X-ray fluorescence analysis. The obsidian artifacts are made from Valle Grande, Cerro Toledo, and El Rechuelos obsidian (Table 43.12). The Valle Grande (Cerro del Medio) and Cerro Toledo (Obsidian Ridge/Rabbit Mountain) source areas are situated about 17 km (11 mi) and 19 km (12 mi) to the west and southwest. Although obsidian is present at these nearby sources in the Jemez Mountains, it is also present on the mesa to the northeast of the site as small pebbles. These pebbles compose part of the secondary deposits associated with the Cerro Toledo interval. In contrast, the El Rechuelos (Polvadera Peak) source area is located about 27 km (17 mi) northwest of the site. Both of the basalt flakes appear to be made of dacite; however, one of these is derived from a local source and the other from the San Antonio Mountain source.

Table 43.12. Obsidian source samples.

FS #	Artifact	Color	Source
1	Debitage	Black dusty	El Rechuelos
27	Debitage	Translucent	Cerro Toledo rhyolite
41	Debitage	Translucent	Valle Grande rhyolite
59	Tool	Translucent	Valle Grande rhyolite

Lithic Reduction

The debitage mostly consists of core flakes, with a few other items. The overall cortical:non-cortical ratio of 0.37 reflects an emphasis on the later stages of core reduction. The flakes mostly have single-faceted platforms (*n* = 16), with fewer cortical (*n* = 2), collapsed (*n* = 7), and crushed (*n* = 9) platforms. None of the platforms exhibit any obvious evidence of preparation. The majority of the core flakes are proximal fragments (*n* = 22), with fewer whole (*n* = 13), midsection (*n* = 6), and distal (*n* = 9) fragments. The whole core flakes have a mean length of 23.5 mm (*std* = 6.9) and the angular debris a mean weight of 1.3 g (*std* = 8.8).

The retouched tools consist solely of retouched pieces. They exhibit both unidirectional dorsal and bidirectional marginal retouch along the lateral sides of the flake, with one situated at the distal end of the flake. These edge angles range from 55 to 70 degrees.

Tool Use

None of the flakes exhibit evidence of edge damage that could be attributed to use. In contrast, three of the four retouched pieces exhibit rounding and scarring that appears to be the result of use. The only ground stone artifact was a grinding slab fragment with a single ground surface. The ground surface is slightly concave and ovoid shape, with some of the high spots being smoothed and polished.

Faunal Remains (Kari Schmidt)

One piece of bone was recovered from Room 1 (Stratum 2, Level 5). The bone was a mule deer (*Odocoileus hemionus*) distal humerus (right) that was fairly weathered and may have been exposed to the elements for quite some time before deposition. The bone was unburned, and its location in the fieldhouse was point-plotted (103.35N/102.72E).

Archaeobotanical Remains (Pamela McBride)

Corn cupules, a grass seed fragment, and ponderosa pine needles were recovered from the two samples analyzed from the fieldhouse floor and post-occupational fill (Table 43.13). With the exception of four fragments of ponderosa pine charcoal (Table 43.14), the sample from the lower living surface contained only unburned plant material. In comparison, the wood assemblage from post-occupational fill was quite diverse, including mountain mahogany, piñon pine, ponderosa pine, cottonwood/willow, and sagebrush.

Pollen Remains (Susan Smith)

Six pollen samples were analyzed from LA 86605. Table 43.15 lists the frequency of identified pollen types. Maize and cholla were the only cultigens identified in the botanical assemblage. Prickly pear, beeweed, and lily family were all identified as economic resources in the assemblage. A number of potential economic resources were also identified in the assemblage (Table 43.15), and these are discussed in detail in Smith's chapter in Volume 3.

SUMMARY OF SITE EXCAVATIONS

LA 86605 consists of a one-room fieldhouse. The north, west, and south walls are clearly defined, but it is unclear as to whether the east wall is *in situ* or simply represents a cluster of building stones. Excavations revealed the presence of possibly two unprepared floors that correspond to changes in the soil profile. The upper floor was situated at the base of the masonry walls, whereas the lower floor was located below the walls. No features and only a few artifacts were present on either floor, with bits of charcoal and adobe. The project geomorphologists suggested that the upper floor might date to the Classic period and the lower floor to the Coalition period; however, the radiocarbon and ceramic evidence indicates that the site was probably occupied during the Late Classic period. The presence of maize and the prevalence of storage jars reflect the agricultural function of the site, with limited core reduction and grinding activities also being represented.

CHAPTER 44
RENDIJA TRACT (A-14): LA 86606

Gregory D. Lockard

INTRODUCTION

LA 86606 is the remains of a small structure located on the tip of an east-facing ridge finger in Cabra Canyon, which is located in the northwest extension of the Rendija Tract. The site is located a few tens of m to the west and directly uphill from the end of a two-track dirt road and the Pajarito Trail (Trail #286). Vegetation on the site consists of ponderosa pine with some juniper and scrub oak. The site is situated at an elevation of 2122 m (6960 ft).

LA 86606 was first recorded on March 16, 1992, by Binzen, Hoagland, and Manz as part of the Environmental Restoration Program (McGehee et al. 1992) and given the temporary site number of B-19. The site was believed to be the remains of a one-room structure and an associated rock alignment located approximately 6 m to the west. No artifacts were visible on the surface due to the presence of a thick layer of pine duff.

FIELD METHODS

The excavation of LA 86606 began during the 2004 field season and was completed during the 2005 field season of the Conveyance and Transfer Project. In 2004, the site and surrounding area were cleared of trees and large undergrowth. The site was then visible as a mound of rubble (designated Area 1) and a short rock alignment a few m to the west (designated Area 2) (Figure 44.1). The rubble mound measured 3 by 3.5 m in area and was approximately 20 cm tall. An arbitrary site datum (designated 100N/100E, 10.00 m elevation) was set up in the southwestern portion of Area 1. The entire site was then covered with a 1- by 1-m grid that extended 4 m north, 2 m south, 7 m east, and 3 m west of the site datum. Four subdata (A-D) were set up for taking elevations. The site was then photographed. The site was not surface collected because no artifacts were visible on the surface.

Excavation of a 5- by 1-m east-west trench (units 101N/102-106E) across the structural remains in Area 1 was begun during the 2004 field season and completed during the 2005 field season. The purpose of this trench was to expose a profile of the site stratigraphy, as well as to determine the location of the room's east and west walls. Grid units were excavated by strata, and thicker strata were excavated in arbitrary 10-cm levels. The room's west wall was encountered in the western half of unit 101N/103E, and the east wall was encountered in unit 101N/105E. Within Room 1, excavation of the trench units proceeded down to a poorly preserved living surface. Outside of the room, the trench units were excavated down to the top of a sterile Bw horizon. The westernmost unit in the trench was chosen to serve as a test pit for geological analysis. Excavation of this unit therefore continued for approximately 90 cm below the top of the sterile soil horizon. No artifacts were recovered during the excavation of this stratum (Stratum 4). The northern profile of the trench was then drawn and photographed.

Figure 44.1. Pre-excavation photograph of LA 86606.

The rest of Area 1 was subsequently excavated, again by strata and arbitrary levels for thicker strata. In all, 23 units were excavated. Within the structure, excavation proceeded down to the poorly preserved living surface encountered while excavating the trench. Outside of the structure, excavation proceeded down to the top of the sterile soil horizon. Excavation focused on defining the structure's walls, removing wallfall, and locating features. Soil samples were taken from select locations, and all other soil was passed through screens with 1/8-in. mesh to aid in the recovery of artifacts. The excavation area extended at least 1 m beyond the structure in all directions to locate external features and/or outdoor activity areas. Area 1 was then mapped (Figure 44.2) and photographed (Figure 44.3). Lastly, the geological test pit was extended to the exterior face of the west wall of Room 1. The purpose of this excavation was to determine the depth of the foundation of the room's walls.

The rock alignment in Area 2, located a few m to the southwest of Room 1 in Area 1, was fully excavated in six units (98-100N/97-98E). Grid units were excavated by strata, and thicker strata were excavated in arbitrary 10-cm levels. Excavation revealed that the rock alignment was a wall, which was designated Feature 1. This wall most likely functioned as a wind break for a possible hearth (see below). After the excavation of the feature was complete, Feature 1 was photographed (Figure 44.4) and mapped (Figure 44.5).

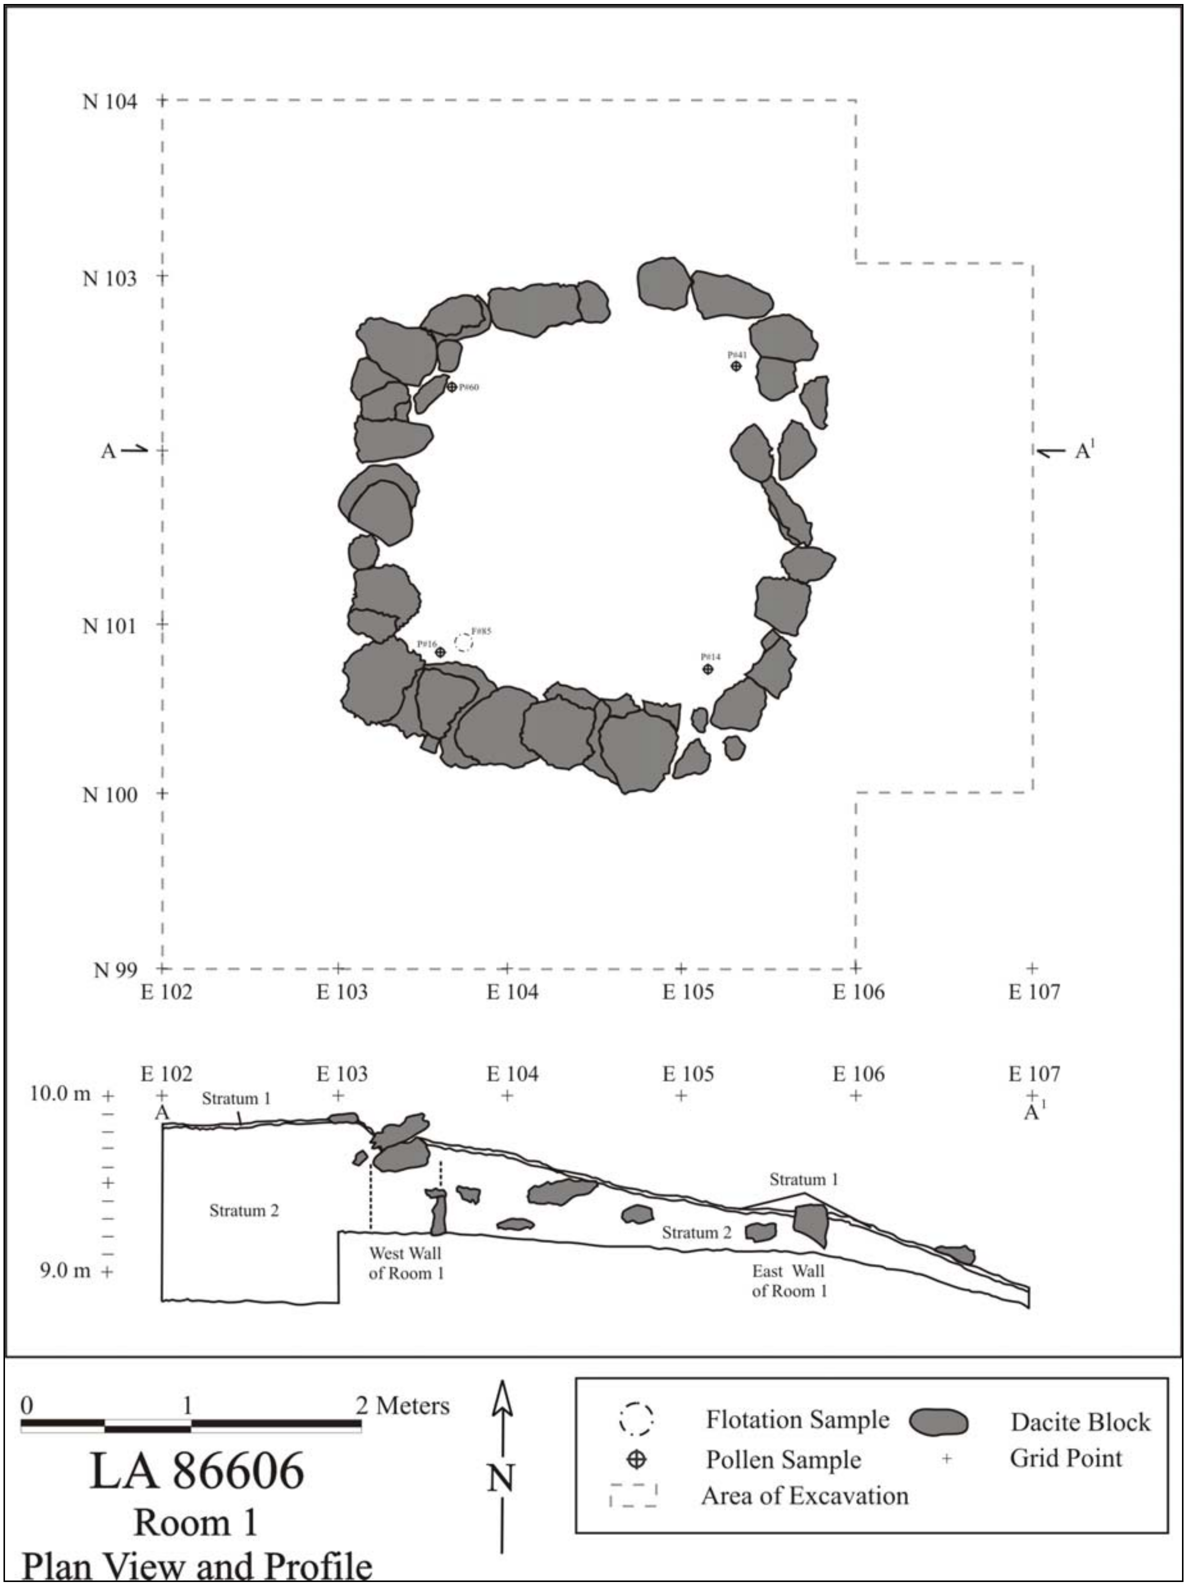

Figure 44.2. Post-excavation plan view and profile map of LA 86606.

Figure 44.3. Post-excavation photograph of the fieldhouse at LA 86606.

Figure 44.4. Post-excavation photograph of Feature 1, a rock alignment.

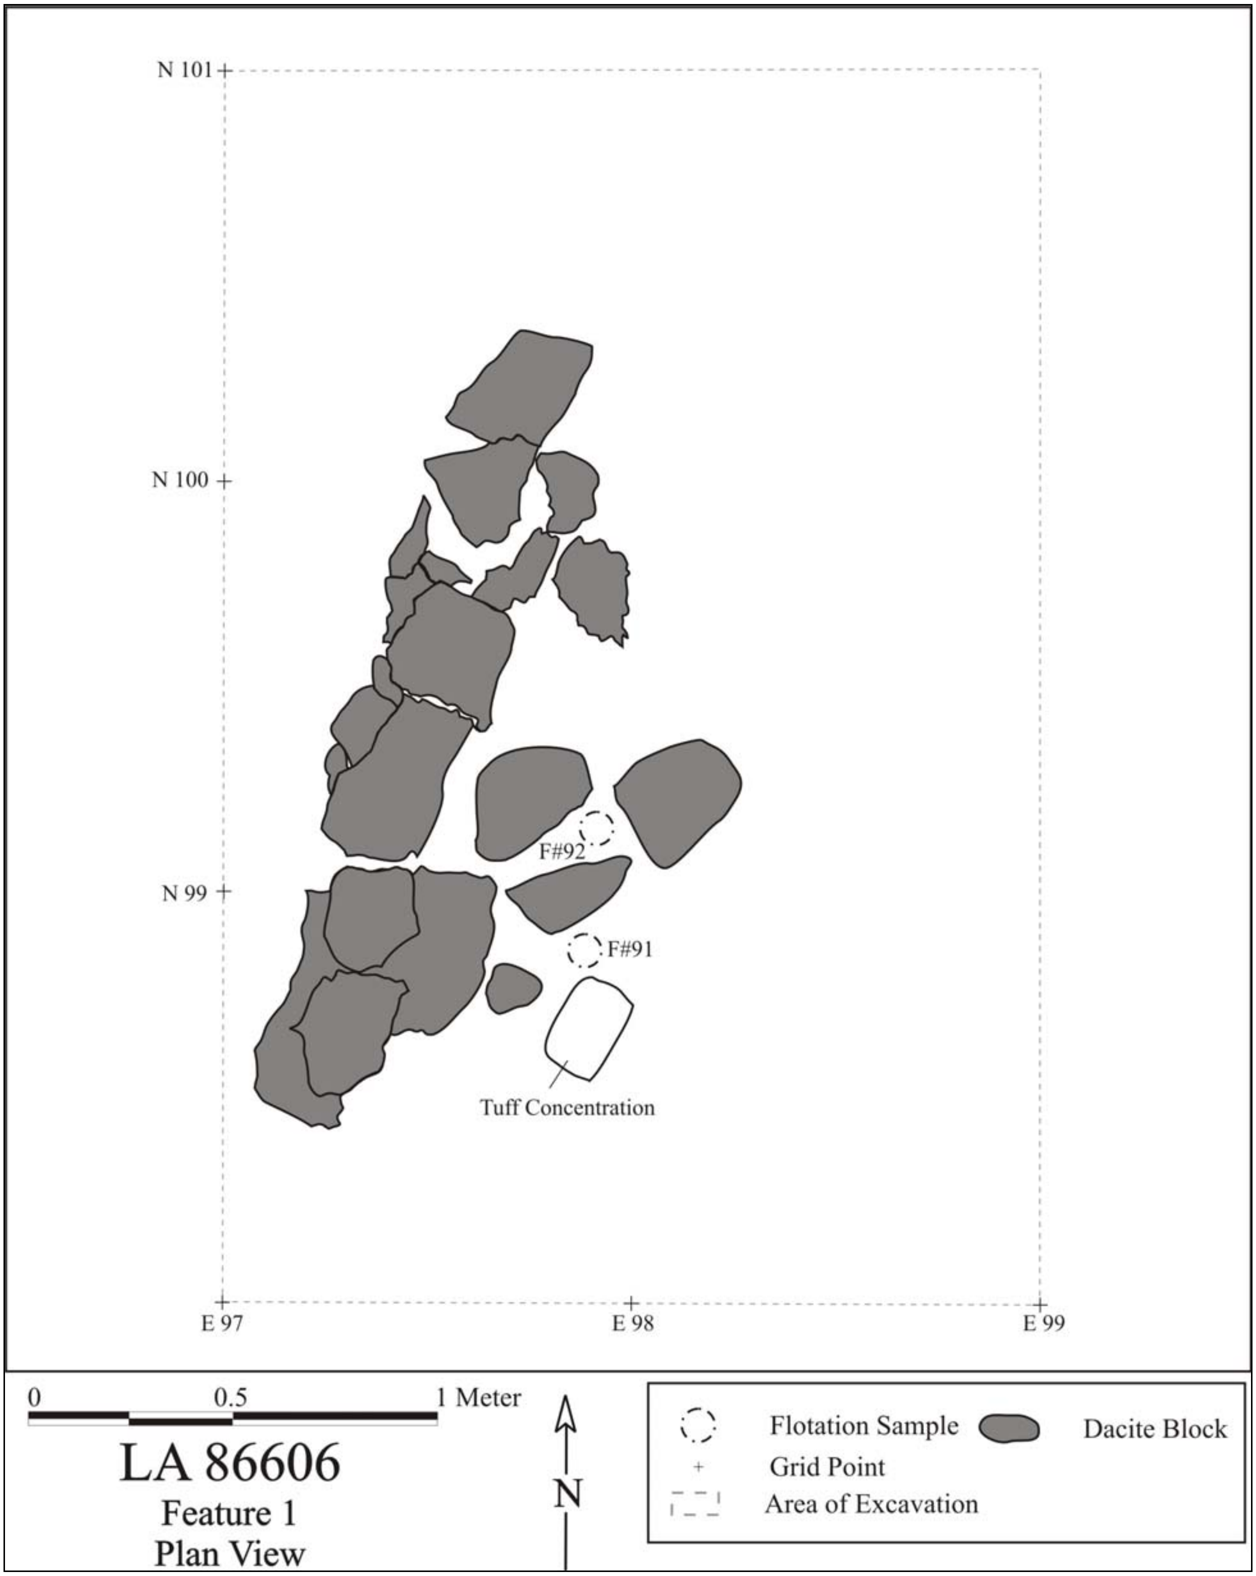

Figure 44.5. Plan view drawing of Feature 1, a rock alignment.

During the 2004 field season, the excavation of the site was supervised by Michael Dilley, and the field crew included Alan Madsen, Sandi Copeland, and Hannah Lockard. During the 2005 field season, the excavation of the site was supervised by Greg Lockard, and the field crew included Michael Dilley, Joseph (Woody) Aguilar, Brandon Gabler, and Samuel Duwe. Timothy Martinez and Aaron Gonzalez served as site monitors from San Ildefonso Pueblo and as screeners during both field seasons.

STRATIGRAPHY

Stratum 1 is composed of loose surface sediment. It is uniformly 2 to 5 cm thick across the site and is part of the A horizon (topsoil). Stratum 2 is post-occupational fill and ranges from 10 to 50 cm in thickness in Area 1 and 10 to 30 cm in Area 2. In Area 1, the post-occupational fill became progressively thinner in the eastern, downhill portion of the area. This was due to erosion of the eastern edge of the ridge finger upon which Area 1 is located. The post-occupational fill was still thicker in the western, uphill portion of Area 1, however, than it was in Area 2 to the west. This was most likely the result of aeolian sediments becoming trapped in the Room 1 wallfall. Stratum 2 corresponds with the upper substrata of the Bw horizon. Stratum 3 is the Room 1 living surface, which was very poorly preserved in all but the southwest corner of the room. Stratum 4 is the sterile soil horizon excavated in the geological test pit (unit 101N/102E) and corresponds with the lower substrata of the Bw horizon. Tables 44.1 through 44.3 describe and summarize the strata excavated at the site.

Table 44.1. LA 86606 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10YR 4.5/3	Loamy sand	2–5	Surface sediment
2	10YR 5/3	Loamy sand	10–50	Post-occupational fill

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is a small structure that probably functioned as a fieldhouse. The shape of the fieldhouse is square with slightly rounded corners. Room 1 measures 2.05 m in length (north to south) by 1.85 m in width (east to west), with approximately 3.79 m^2 of interior space. Excavation of the room began with an east-west trench that extended across the rubble mound in Area 1 (101N/102-106E). The excavation of this trench served to define the room's stratigraphy, as well as to locate the room's east and west walls. The room's east wall was encountered in unit 101N/105E, and the west wall in unit 101N/103E. A poorly preserved living surface was encountered between the walls. After the excavation of the trench, the rest of the room was excavated down to the living surface encountered in the trench.

Fill. The interior of Room 1 was filled with 2 to 5 cm of surface sediment on top of 25 to 40 cm of post-occupational fill. The fill was thickest just inside the room's west wall and was progressively thinner to the east. A flotation sample (Field Specimen [FS] 45) and a pollen sample (FS 44) were taken from the Room 1 fill, but were not analyzed.

Floor. No prepared floor was encountered during the excavation of Room 1. Excavation of the interior of the room proceeded to a few centimeters above the base of the room's walls. At this level, a compact surface was encountered throughout most of the room. In some locations, the compact surface took the form of a thin layer of dark, ashy sediment. This was most likely the remains of an informal (i.e., not plastered) living surface. A layer of reddish, clay-rich soil was encountered just beneath and surrounding the patches of compact, ashy sediment. When the room was first constructed, this natural surface most likely functioned as the room's living surface. The thin layer of compact, ashy sediment is therefore most likely sediment that accumulated and became compacted during the site's occupation. The flatness of the room's living surface compared to the slope of the surrounding natural hillside indicates that the living surface was most likely leveled to some degree during the room's construction. The living surface therefore appears to have been constructed by first clearing the entire surface of loose sediment and exposing the layer of reddish, clay-rich sediment beneath. Additional sediment was then removed from the western, uphill side of the room to create a level surface.

A flotation sample (FS 17) and a pollen sample (FS 16) were taken from just above the living surface in the southwest corner of the room. The flotation sample was not analyzed, but taxa identified in the pollen sample included rose family, grass family, cheno-ams, sunflower family, ragweed/bursage, fir, unidentified pine, piñon pine, juniper, oak, and sagebrush. Additional pollen samples were taken from about the floor level in the southeast (FS 14), northeast (FS 41), and northwest (FS 60) corners of the room. Taxa identified in these samples included maize, rose family, grass family, birch, cheno-ams, sunflower family, ragweed/bursage, spruce, fir, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush. Flotation samples were also taken from about floor level in the north-central portion (FS 54) and northwest corner (FS 59) of the room, but these were not analyzed. A well-preserved patch of living surface in the southwest corner of the room was also removed as a flotation sample (FS 85). Charred taxa identified in this sample included purslane, grass family, unidentified pine, and ponderosa pine.

Wall Construction. The extant portions of the Room 1 walls were composed of dacite rocks of various shapes and sizes (Table 44.4). The foundations of the north, south, and west walls were composed of large upright slabs. The base of the interior faces of these walls was formed by the flat surfaces of these slabs. Slabs with flat faces in fact appear to have been specifically chosen as foundation rocks. Almost all of the slabs are sloped slightly outwards, forming an obtuse angle between the living surface and the wall faces. The rocks in the courses above are more irregular in size and shape. Some are long rocks placed on their sides across the top of two or more foundation slabs. The base of the exterior wall faces was composed of adobe that was placed within the acute angle formed by the outward sloping foundation slabs. The east wall was considerably shorter than the other walls. The east wall may simply have been more poorly preserved than the other walls because of its location along the edge of the eroding slope to the east. It is more likely, however, that the east wall of the structure was open. If the site's occupant was farming the land at the base of Cabra Canyon, an opening to the east would have provided an ideal view of this land. If the east wall was not completely open, the room's entryway was most likely located in this wall. The extant portion of the east wall, or at least some portion thereof, therefore most likely represents a short doorsill.

Judging from the amount of wallfall removed during the excavation of the area in and around Room 1, the masonry portions of the room's walls were originally considerably higher than they were at the time of excavation. In order to estimate the original height of the walls, all of the rocks removed as wallfall during the site's excavation were placed in two stacks, which were then measured. The stacks measured 3.25 by 0.50 by 0.6 m and 3.25 by 0.40 by 0.558 m, for a total of approximately 1.69 m^3 of wallfall. Based on this volume of wallfall and the overall length, average thickness, and average height of the extant portions of the walls, the masonry portions of the room's walls were originally approximately 1.06 m in height. The uppermost portions of the walls, as well as the ceiling, were most likely composed of wattle and daub. These materials are rarely preserved at archaeological sites on the Pajarito Plateau. In fact, only three pieces of burned adobe were recovered from Area 1 (FS 9, FS 74, and FS 77).

Table 44.4. LA 86606 Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	1.70	0.28–0.43	0.17–0.40	1 to 2
South	1.80	0.18–0.52	0.28–0.55	2
East	1.97	0.12–0.30	0.17–0.32	1
West	1.92	0.40–0.67	0.30–0.43	3 to 4

Feature 1 (Area 2)

Feature 1 is a short wall composed of unshaped dacite blocks of varying sizes. The wall was approximately 2 m in length and was two to three courses high. The foundation rocks were placed in a shallow trench dug into the sterile Bw2 horizon. The wall most likely functioned as a wind break. Five large rocks were encountered directly east of the wall. One of these is a dacite block that was placed directly adjacent to the wall. This rock was most likely a later addition that functioned to provide additional support for the base of the wall. Three of the remaining rocks formed a circular alignment. These rocks were most likely a pot rest or the remains of a hearth. A concentration of ash and charcoal was in fact encountered to the south of the three rocks.

In addition, several pieces of burned adobe were recovered from throughout Area 2. The entire area to the east of the wall has been heavily disturbed by rodents, however, and none of the burned adobe was found *in situ*. As a result, the exact location of any hearth that may have existed within Area 2 could not be determined. It may have been in the center of the three rocks. Alternatively, it may have been in the ash concentration to the south, in which case the three rocks were an adjacent pot rest. It could have even been located to the north, between the three rocks and the fifth rock encountered to the east of the wall. If there was a hearth in Area 2, it was almost certainly located to the east of the wall. The wall, therefore, appears to have functioned as a wind break to protect the hearth from easterly winds. A concentration of decomposing, laminar, soft tuff was also encountered along the northern edge of the ash concentration and to the south of the three rocks. This concentration of soft tuff was completely surrounded by post-occupational fill. In addition, nothing of its kind was found elsewhere at the site. As a result, the soft tuff was most likely brought to the site by the person who built and/or last utilized Feature 1. One possible explanation as to its function is that it was meant to be used as temper for ceramics. Lastly, several biscuitware ceramics were recovered from Area 2. This indicates that Feature 1 was contemporaneous (and thus most likely associated) with Room 1.

Two flotation samples and a pollen sample were taken from Feature 1. One of the flotation samples (FS 92) was taken from between the three rocks to the east of the wall. Charred taxa identified in the sample included unknown conifer, mountain mahogany, unidentified pine, ponderosa pine, and oak. The other flotation sample (FS 91) was taken from the area to the south of the three rocks and to the north of the concentration of soft tuff. Charred taxa identified in this sample included mountain mahogany, piñon pine, ponderosa pine, and oak. The pollen sample (FS 93) was taken from the narrow area between the wall and the three rocks, but it was not analyzed. Finally, a sample of the soft tuff (FS 89) was also taken.

Geological Test Pit

Geologists Paul Drakos and Steven Reneau analyzed the north profile of the geological test pit (unit 101N/102E) and its eastward extension (within unit 101N/103E) to reconstruct the natural soil horizons at the site. This profile contained a soil sequence consisting of an A horizon (topsoil), four Bw horizons (a late-Holocene soil and three middle/late-Holocene soils), and a BCk horizon (a middle/late-Holocene soil). The rocks that form the foundation of the west wall of Room 1 extend down into the Bw4 horizon. Just inside the west wall, the room's living surface is at or just above the top of the Bw4 horizon.

Artifact Distribution

The distribution of artifacts within Room 1 is fairly uniform. A greater number of artifacts were recovered from the units to the north and especially west of the room (Table 44.5). This is fairly surprising, as most of the fieldhouses in the Rendija Tract excavated during the Conveyance and Transfer Project had the highest concentration of artifacts to the east of the structure. There is also a tendency for there to be a higher concentration of artifacts on the side of the structure in which the entryway is located. In Room 1, the entryway appears to have been to the east. The lack of artifacts to the east of the structure is most likely the result of site formation processes. The site is located on the tip of a ridge finger. Just east of the structure, the downward slope of the natural surface becomes increasingly steep. As a result, there was very little post-occupational fill to the east of the structure. Most of the artifacts that once existed to the east of the structure have most likely eroded downhill to the east. An additional factor that helps explain the higher concentration of artifacts to the west of the structure is the location of Feature 1. If this feature was indeed a wind break for an outdoor hearth, the area surrounding the hearth was most likely an activity area. More artifacts were recovered from the units to the east of the Feature 1 wall (Table 44.6). The number of artifacts recovered from these units, however, was still smaller than the number of artifacts recovered from the units just west of Room 1 in Area 1.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 153 artifacts were analyzed from the excavations conducted at LA 86606. In addition, flotation and pollen samples were selected for analysis from the post-occupational fill (Stratum 2) and the Room 1 living surface (Stratum 3) (Table 44.7). The results of the artifact and sample analyses are presented in the following sections.

Table 44.7. Samples selected for analysis from LA 86606.

Ceramic Artifacts (Dean Wilson)

A total of 143 ceramics were analyzed from LA 86606. The majority of the pottery consists of smeared plain and smeared-indented corrugated, with some Santa Fe Black-on-white and Biscuitware sherds (Table 44.8). All of the Santa Fe Black-on-white and the single Wingate Black-on-red sherds were derived from Area 1 and the fieldhouse. In contrast, the biscuitwares are present in both Area 1 and Area 2. Therefore, it appears that the site is multi-component, with a Coalition period fieldhouse and a Classic period feature (Feature 1). Information on ceramic tradition by ware, temper by ware, and vessel form by ware are provided in Tables 44.9 to 44.11. The graywares and whitewares appear to have been locally made from tuff temper; however, a single grayware sherd does exhibit granite with mica temper. This latter sherd is presumably associated with the Classic period occupation. The redware sherd also differs by exhibiting non-local sherd and sand temper. All of the grayware ceramics consist of jar vessel forms, while the whiteware and redware sherds derived only from bowls.

Table 44.8. Ceramic types from LA 86606.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 28 artifacts were analyzed from LA 86606, consisting of a core, 17 pieces of debitage, nine ground stone artifacts, and a hammerstone. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 42.12 presents the data on lithic artifact type by material type. The debitage is primarily made of chalcedony, with other materials. The presence of cortex on 23.5 percent of the debitage indicates that these materials were collected from waterworn (*n* = 4) sources. The chalcedony and Pedernal chert are available from local Rio Grande Valley gravels and the obsidian from nearby sources in the Jemez Mountains. Otherwise, the igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the plateau.

Table 44.12. Lithic artifact type by material type.

(Material Type columns: Basalt through Total.)

Two pieces of obsidian and a piece of basalt debitage were submitted for X-ray fluorescence analysis. The obsidian artifacts are made from Cerro Toledo and Bear Springs Peak obsidian (Table 44.13). The Cerro Toledo (Obsidian Ridge/Rabbit Mountain) and Bear Springs source areas are situated about 19 km (12 mi) and 38 km (24 mi) to the southwest. Although obsidian is present at these nearby sources in the Jemez Mountains, it is also present on the nearby mesa as small pebbles. These pebbles compose part of the secondary deposits associated with the Cerro Toledo interval. The single basalt flake appears to be made of basalt and not dacite.

Table 44.13. Obsidian source samples.

FS #	Artifact	Color	Source
47	Debitage	Translucent	Bear Springs Peak
73	Debitage	Translucent	Cerro Toledo rhyolite

Lithic Reduction

The single core was reduced using a bidirectional, discoidal reduction technique. Table 44.14 presents the metric information on the core.

Table 44.14. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Bidirectional	49	54	27	65.4

The debitage mostly consists of core flakes, with a few other items. The overall cortical:non-cortical ratio of 1.00 reflects an equal emphasis on the early and later stages of core reduction. The flakes mostly have single-faceted platforms (n = 4), with fewer cortical (n = 1) and collapsed (n = 2) platforms. None of the platforms exhibit evidence of preparation. The majority of the core flakes are distal fragments (n = 5), with fewer whole (n = 4), proximal (n = 3), and midsection (n = 1) fragments. The whole core flakes have a mean length of 28.5 mm (*std* = 7.5) and the angular debris a mean weight of 2.9 g (*std* = 2.3).

Tool Use

None of the debitage exhibit evidence of edge damage that could be attributed to use. The ground stone items included a mano, metate, and axe. The two-hand mano is a loaf-shaped, elongated tuff cobble with a single flat grinding surface (Figure 44.6). The undetermined metate is a broken fragment of tuff with a single grinding surface. In contrast, the grinding slab is a small piece of dacite with grinding present on the high spots of a single surface. The axe consists of a butt fragment from a full-grooved polished axe (Figure 44.7). The butt does exhibit some battering. Three fragments of a rhyolite slab were classified as the remnants of a possible shaped slab. The undetermined ground stone artifacts are two small pieces of fire-cracked dacite slabs. They both exhibit some grinding on the high spots of a single surface and could be parts of the same artifact (a millingstone?).

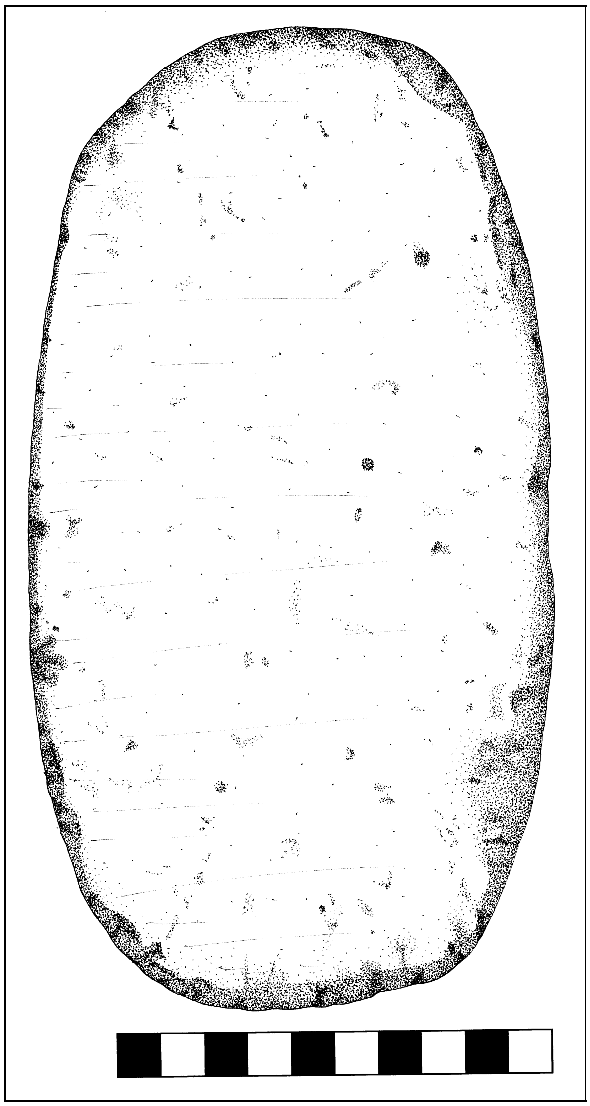

Figure 44.6. Two-hand mano from LA 86606.

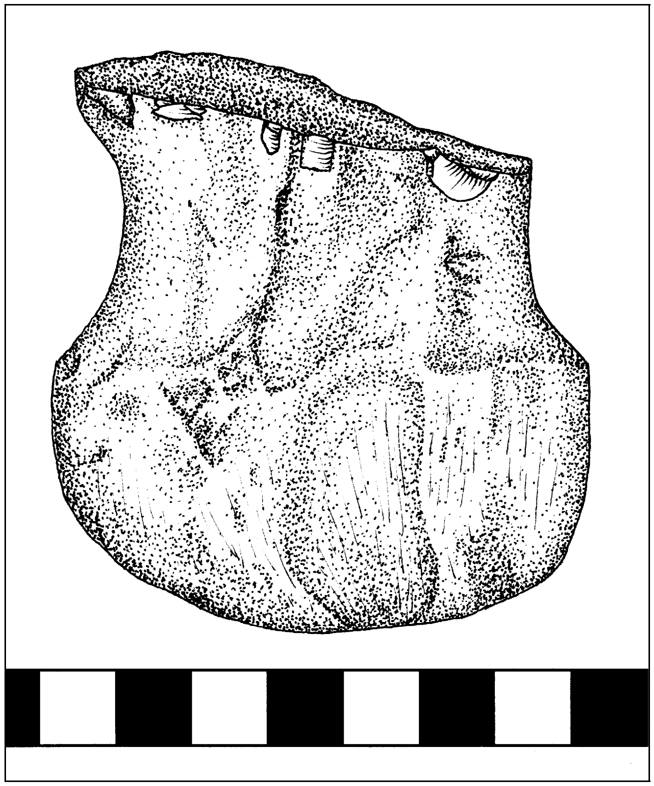

Figure 44.7. Axe fragment from LA 86606.

Faunal Remains (Kari Schmidt)

One piece of bone was recovered from this Classic period fieldhouse. The bone was identified as a heavily burned medium/large-sized mammal long bone fragment and was recovered in the post-occupational fill level (102N/104E).

Archaeobotanical Remains (Pamela McBride)

Carbonized purslane seeds, grass stems, conifer duff, and unidentifiable plant parts were found on a well-preserved patch of the living surface in the southwest corner of the fieldhouse (Table 44.15). An unidentifiable plant part and ponderosa pine needles were recovered from the fill between three rocks that may have been the remnants of an exterior hearth or pot rest next to a hearth. Ashy sediment found south of the three rocks yielded ponderosa pine needles. Ponderosa pine was the only taxon identified from the structure living surface, possibly indicating the identity of a ceiling element. Mountain mahogany was the dominant wood taxon in the ashy sediment and the possible hearth (Table 44.16). Logically, the ashy sediment (possible dump from the hearth) was the most diverse, containing ponderosa pine, piñon, mountain mahogany, and oak.

Pollen Remains (Susan Smith)

Four pollen samples were analyzed from LA 86606. Table 44.17 lists the frequency of identified pollen types. Maize was the only cultigen identified in the botanical assemblage. No other economic resources were identified in the assemblage. A number of potential economic resources were also identified in the assemblage (Table 44.17), and these are discussed in detail in Smith's chapter in Volume 3.

SUMMARY OF SITE EXCAVATIONS

LA 86606 consists of a one-room fieldhouse and a rock alignment located on a ridge in Cabra Canyon. All four walls were intact and appeared to contain an opening to the east. No floors or prepared surfaces were identified in the fieldhouse. A single linear rock alignment just outside the fieldhouse was the only feature identified. Bits of charcoal and adobe were identified at the site. Ceramic evidence indicates that the fieldhouse was probably occupied during the Late Coalition period and that the rock alignment (Feature 1) likely dates to the Classic period. The presence of maize and the prevalence of storage jars reflect the agricultural function of the site, with limited core reduction and grinding activities also being represented. The site is situated near another Coalition period fieldhouse (LA 86607).

CHAPTER 45
RENDIJA TRACT (A-14): LA 86607

Gregory D. Lockard

INTRODUCTION

LA 86607 is the remains of a one-room Coalition period fieldhouse located on top of a ridge in Cabra Canyon to the northwest of Rendija Canyon. The site is located less than 100 m to the northwest of LA 86606, in the northwest extension of the Rendija Tract. A leg of the Pajarito Trail (Trail #286) passes through and has significantly impacted the site. Vegetation on the site consists of ponderosa pine with some piñon, juniper, and scrub oak. The site is situated at an elevation of 2146 m (7040 ft).

LA 86607 was first recorded on March 16, 1992, by Manz, Hoagland, and Binzen as part of the Environmental Restoration Program (McGehee et al. 1992) and given the temporary site number of B-20. The site was believed to be the remains of a two- to four-room structure. Two indented corrugated utilityware jar sherds and a basalt interior flake were the only artifacts visible on the surface. As Manz, Hoagland, and Binzen note, additional surface artifacts may have been collected by hikers utilizing the Pajarito Trail.

FIELD METHODS

Before excavation, the site and surrounding area were cleared of trees and large undergrowth. The site was then visible as a mound of rubble measuring 5 by 4 m in area (Figure 45.1). The mound appeared to be the remains of a one-room structure. An arbitrary site datum (designated 100N/100E, 10.00 m elevation) was set up in the southwest corner of the site. The site was then covered with a 1- by 1-m grid that extended 6 m north and 5 m east of the site datum. Two subdata (A and B) were set up for taking elevations. The site was then photographed. The site was not surface collected because no artifacts were visible on the surface (although one sherd was later recovered from the surface of an excavated grid unit). As mentioned, the paucity of artifacts on the surface of the site may be the result of the collection of artifacts by hikers utilizing the Pajarito Trail, which passes through the site.

A 5- by 1-m east-west trench (units 103N/100-104E) was initially excavated across the remains of the structure, which was designated Room 1. The purpose of this trench was to expose a profile of the site stratigraphy, as well as to determine the location of the room's east and west walls. Grid units were excavated by strata, and thicker strata were excavated in arbitrary 10-cm levels. The room's west wall was encountered in the eastern half of unit 103N/101E, and the remains of the east wall were encountered in the eastern half of unit 103N/103E. Within Room 1, excavation of the trench units proceeded down to a poorly preserved living surface. Outside of the room, the trench units were excavated down to the top of a sterile Btb1 horizon. The westernmost grid unit in the trench was chosen to serve as a test pit for geological analysis.

Excavation of this unit therefore continued for approximately 30 cm below the top of the Btb1 horizon. The northern profile of the trench was then drawn and photographed.

Figure 45.1. Pre-excavation photograph of LA 86607.

The rest of the site was subsequently excavated, again by strata and arbitrary levels for thicker strata. In all, 23 units were excavated. Within the structure, excavation proceeded down to the poorly preserved living surface encountered while excavating the trench. Outside of the structure, excavation proceeded down to the top of the Btb1 horizon. Excavation focused on defining the structure's walls, removing wallfall, and locating features. Soil samples were taken from select locations, and all other soil was passed through screens with 1/8-in. mesh to aid in the recovery of artifacts. The excavation area extended at least 1 m beyond the structure in all directions to locate external features and/or outdoor activity areas. The site was then mapped (Figure 45.2) and photographed (Figure 45.3). Lastly, the geological test pit was extended to the exterior face of the west wall of Room 1. The purpose of this excavation was to determine the depth of the foundation of the room's walls.

The excavation of the site was supervised by Greg Lockard. The field crew included Michael Dilley, Joseph (Woody) Aguilar, Brandon Gabler, Margaret Dew, and Samuel Duwe. Timothy Martinez and Aaron Gonzalez served as site monitors from San Ildefonso Pueblo and as screeners. Jeremy Yepa was the site monitor representing Santa Clara Pueblo, as well as an additional excavator.

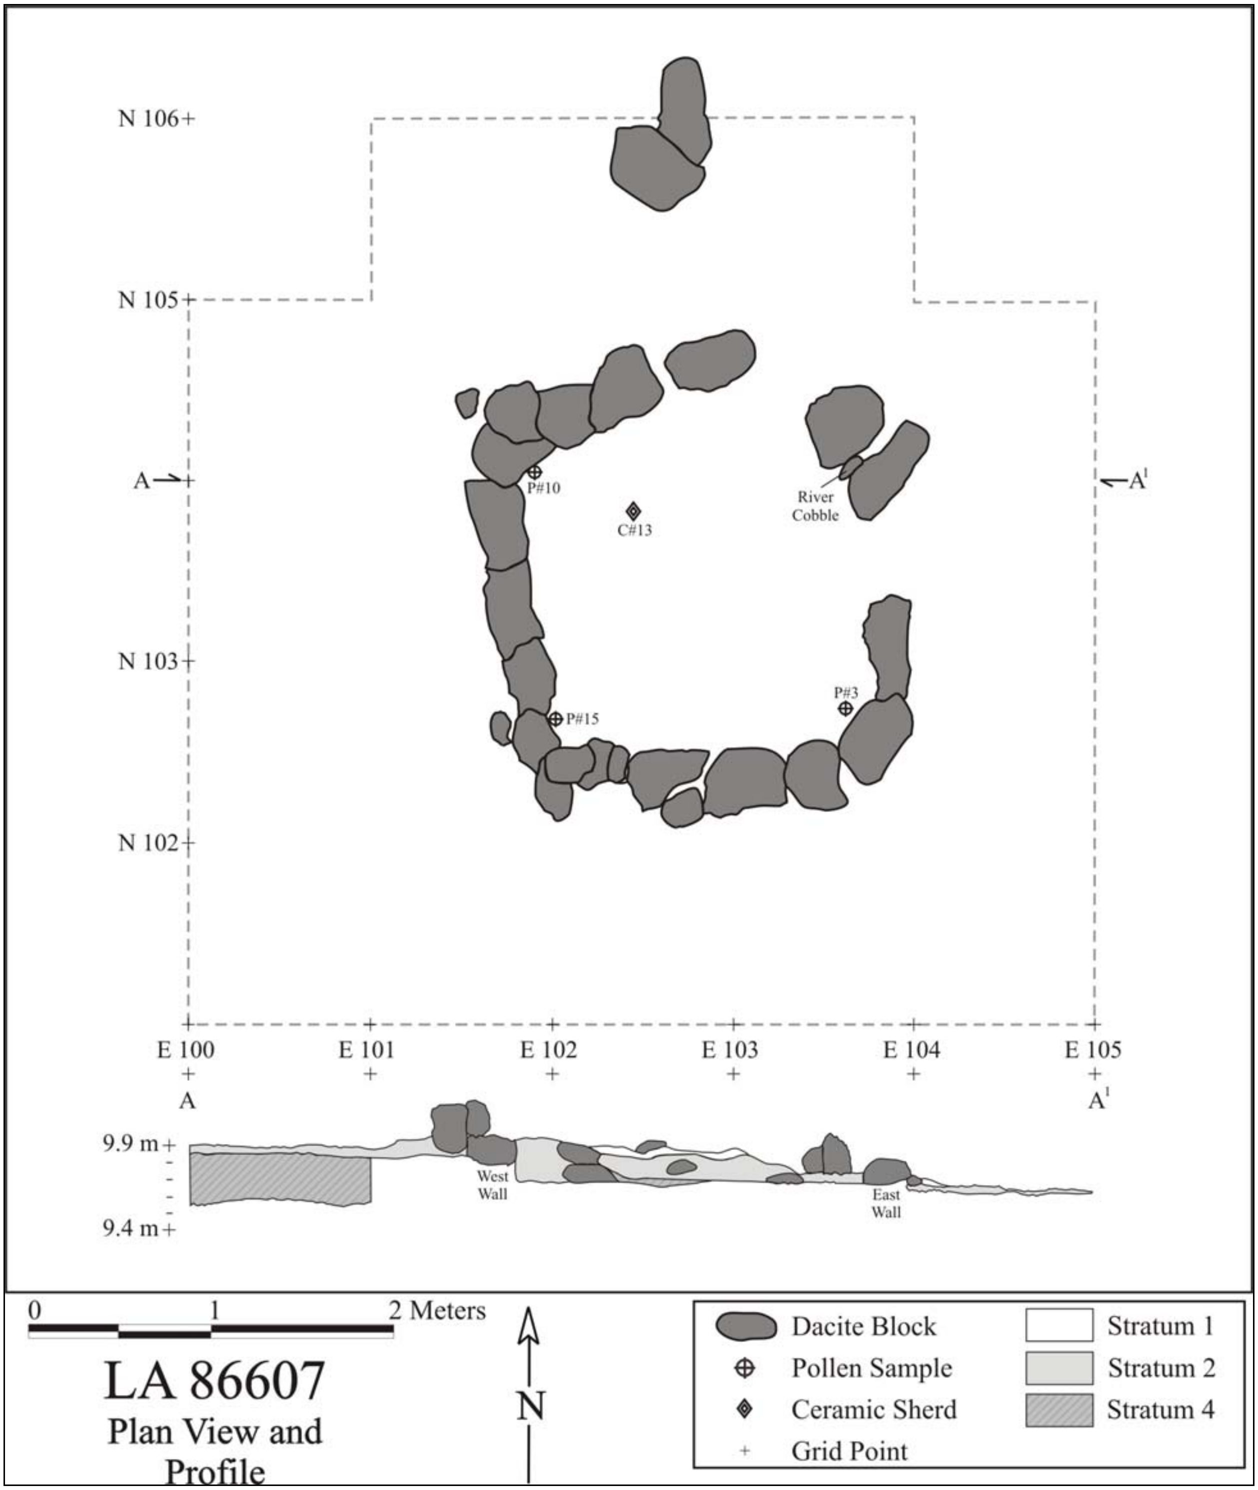

Figure 45.2. Plan view and profile of the fieldhouse at LA 86607.

Figure 45.3. Post-excavation photograph of the fieldhouse at LA 86607.

STRATIGRAPHY

Stratum 1 is composed of loose surface sediment. It is uniformly 1 to 4 cm thick across the site and is part of the A horizon (topsoil). Stratum 2 is post-occupational fill and ranges from 2 to 30 cm in thickness. The post-occupational fill was thickest just inside of the south wall of Room 1 and thinned to the north. Stratum 2 is also part of the A horizon. Stratum 3 is the Room 1 living surface. Stratum 4 is the sterile soil horizon excavated in the geological test pit (unit 103N/100E) and corresponds with the Btb1 horizon. Tables 45.1 through 45.3 summarize and describe the strata that were excavated at LA 86607.

Table 45.1. LA 86607 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10YR 4/3	Sandy loam	1–4	Surface sediment
2	10YR 4/3	Sandy loam	2–30	Post-occupational fill
3	7.5YR 5/4	Clay	-	Room 1 living surface
4	7.5 YR 5/4	Clay	30	Pleistocene soil

Table 45.2. LA 86607 soil horizon descriptions from the north profile of the geological test pit (unit 103N/100E).

Horizon	Color	Texture	Depth (cm)	Description
A	10YR 4/3	Sandy loam	0–4	Topsoil
Btb1	7.5YR 5/4	Clay	4–33+	Pleistocene soil

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is a small structure that probably functioned as a fieldhouse. Most of the room's northeast quadrant has been disturbed, presumably by the construction and use of the trail that passes through this area of the site. Nevertheless, it was possible to determine that the room was roughly square in shape. The room measures 2.10 m in length (north to south) by approximately 1.80 m in width (east to west), with approximately 3.78 m^2 of interior space. Excavation of the room began with an east-west trench that extended across the room (103N/100-104E). The excavation of this trench served to define the room's stratigraphy, as well as to locate the room's east and west walls. The room's east wall was encountered in unit 103N/101E and the west wall in unit 103N/103E. A poorly preserved living surface was encountered between the walls. After the excavation of the trench, the rest of the room was excavated down to the living surface encountered in the trench.

Fill. The interior of Room 1 was filled with 1 to 4 cm of surface sediment on top of 10 to 30 cm of post-occupational fill. The fill was thickest just inside the room's south wall and thinned to the north. A flotation sample (Field Specimen [FS] 5) and a pollen sample (FS 6) were taken of the Room 1 fill, but these samples were not analyzed.

Floor. No prepared floor was encountered during the excavation of Room 1. Instead, the people who constructed the room appear to have utilized the Btb1 horizon as a living surface. The Btb1 horizon is a layer of highly indurated, clay-rich soil that would have made an ideal natural living surface. The top of the Btb1 horizon is fairly flat within the room, despite the fact that it slopes upward to the west outside of the room. The surface is 20 to 25 cm lower just inside of the room's west wall as it is just outside of the wall. The surface is at about the same level, on the other hand, on either side of the east wall. This indicates that the living surface was leveled by excavating into the Btb1 horizon in the uphill (i.e., western) half of the room. The living surface is slightly convex. It is between 5 and 10 cm lower in the middle of the room than it is along the edges. The living surface is lower than the base of the walls in the western half of the room and significantly lower than the base of the west wall. In addition, there is significant coping between the living surface and the interior wall faces, especially in the northwest and southwest corners of the room. The walls therefore appear to have been constructed before the room's living surface was leveled. At the very least, the rocks that form the base of the walls were not placed on top of the excavated living surface.

A single Santa Fe Black-on-white sherd (FS 13) was encountered directly on top of the living surface in the northwest quadrant of the room. This was the only floor-contact artifact recovered from the site. A pollen sample (FS 3) was taken from near the level of the living surface in the southeast corner of the room, but was not analyzed. Additional pollen samples were taken from directly on top of the living surface in the northwest (FS 10) and southwest (FS 15) corners of the room. Taxa identified in these samples included rose family, mustard family, grass family, cheno-ams, sunflower family, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush.

Wall Construction. The Room 1 walls were constructed of unshaped dacite cobbles. The foundation rocks were placed in a shallow trench dug into the Btb1 horizon. These rocks tended to have flat surfaces that formed the interior wall faces. This was also characteristic of the foundation rocks in Room 1 at LA 86606, which is located nearby. The foundation of the south and west walls was well preserved. The foundation rocks in the western half of the north wall and the southernmost portion of the east wall also appeared to be *in situ*. The walls that form the northeast corner of the room, however, were significantly disturbed by the construction and/or use of a hiking trail that passes through this part of the site. There were two large cobbles in the approximate location of the northeast corner of the room. These rocks probably formed the northernmost portion of the east wall. The location of floor coping in this area indicated that the northern rock was probably *in situ*, while the southern rock was slightly east of its original location. A small, rounded river rock was encountered between these two rocks. This rock was unlike any other rock in the Room 1 walls. It may have therefore been deposited between the rocks after the site's occupation. Alternatively, it may have been utilized as a chinking stone.

There is a gap to the south of the two rocks in the east wall. This gap, which is 70 cm wide, was most likely the room's entryway. There is also a gap of approximately 45 cm to the west of the two rocks in the north wall. This portion of the north wall was probably disturbed by the people who constructed the trail just north of the room. There is in fact an alignment of four large dacite cobbles just north of Room 1 (the two southern rocks in this alignment appear in Figure 45.2). These rocks were placed across the trail as erosion control. It is likely that the rocks were either wallfall or *in situ* foundation rocks removed from the north wall of Room 1. The easternmost rock in the extant portion of the north wall also appeared to have been moved slightly to the north of its original location.

Judging from the amount of wallfall removed during the excavation of the area in and around Room 1, the masonry portions of the room's walls were originally considerably higher than they were at the time of excavation (Table 45.4). In order to estimate the original height of the walls, all of the rocks removed as wallfall during the site's excavation were placed in two stacks, which were then measured. The stacks measured 2.50 by 0.35 by 0.55 m and 1.70 by 0.40 by 0.50 m, for a total of approximately 0.82 m^3 of wallfall. Based on this volume of wallfall and the overall length, average thickness, and average height of the extant portions of the walls, the masonry portions of the room's walls were originally approximately 0.68 m in height. This is significantly less than the height calculated for most of the Rendija Tract fieldhouses excavated during the Conveyance and Transfer Project.

There are several possible explanations for this lower wall height. First, some of the rocks that formed the room's walls appear to have been removed by the people who constructed the nearby hiking trail. Some even appear to have been utilized in the construction of alignments across the trail designed to reduce erosion. Second, some of the rocks from LA 86607 may have been utilized in the construction of the fieldhouse at LA 86606. The latter is located nearby to and clearly postdates the former. Lastly, the masonry portions of the Room 1 walls at LA 86607 may have simply been shorter than those of the average Ancestral Pueblo fieldhouse in Rendija Canyon. Unfortunately, there is no way to test any of these hypotheses. The uppermost portions of the walls, as well as the ceiling, were most likely composed of wattle and daub. These materials are rarely preserved at archaeological sites on the Pajarito Plateau. In fact, no adobe was recovered from LA 86607.

Table 45.4. LA 86607 Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	1.76	0.08–0.25	0.16–0.32	1 to 2
South	1.76	0.12–0.25	0.13–0.35	1 to 2
East	~1.65	0.08–0.31	0.13–0.30	1
West	1.66	0.04–0.15	0.17–0.28	1

Geological Test Pit

Geologists Paul Drakos and Steven Reneau analyzed the north profile of the geological test pit (unit 103N/100E) and its eastward extension (within unit 103N/101E) to reconstruct the natural soil horizons at the site. This profile contained a soil sequence consisting of an A horizon (topsoil) and a Btb1 horizon (a Pleistocene soil). The profile indicates that the foundation rocks were set approximately 5 cm into the Btb1 horizon.

Artifact Distribution

Very few artifacts were recovered during the excavation of LA 86607. One possible explanation for the lack of artifacts is that many, especially those visible on the surface, were collected by hikers utilizing the trail that passes through the site. The fact that very few subsurface artifacts were recovered, however, indicates that the collection of artifacts by hikers does not completely account for the lack of artifacts at the site. Another possible explanation is that the site was only used for a short period of time. Because of the small number of artifacts recovered from the site, very little can be said about the artifact distribution. There does appear to be a slight tendency for a greater number of artifacts in the grid units to the southeast, but given the small sample size, this could be incidental. Table 45.5 shows the distribution of artifacts at the site.

Table 45.5. LA 86607 artifact counts by grid unit.

	E100	E101	E102	E103	E104
N105	--	0	0	0	--
N104	0	**0**	**0**	**0**	0

N102	0	**0**	**0**	**2**	0
N101	0	0	1	2	0

Note: Does not include one artifact found outside of the excavated area during surface collection; bold numbers indicate grid units that are located completely or partially within Room 1.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of nine artifacts were analyzed from the excavations conducted at LA 86607. In addition, flotation and pollen samples were selected for analysis from the post-occupational fill (Stratum 2) and the Room 1 living surface (Stratum 4) (Table 45.6). The results of the artifact and sample analyses are presented in the following sections.

Ceramic Artifacts (Dean Wilson)

A total of nine ceramics were analyzed from LA 86607. The majority of the pottery consists of Santa Fe Black-on-white and smeared-indented corrugated sherds, which presumably date to the Coalition period (Table 45.7). Information on ceramic tradition by ware, temper by ware, and vessel form by ware are provided in Tables 45.8 through 45.10. The grayware and whiteware pottery appear to have been locally made from tuff temper. All of the grayware sherds consist of jar vessel forms, whereas the whiteware sherds are derived from bowls.

Table 45.7. Ceramic types from LA 86607.

Ceramic Type	Frequency	Percent

Archaeobotanical Remains (Pamela McBride)

One fragment of ponderosa pine charcoal weighing less than a tenth of a gram was the sole floral material from post-occupational fill in the structure. The paucity of remains is not surprising considering the impact of trail building (Pajarito Trail #286 passes through the site); some of the rocks that were originally part of the structure walls were probably used to construct the trail and rock alignments that cross the trail, built to control erosion.

Pollen Remains (Susan Smith)

Three pollen samples were analyzed from LA 86607. Table 45.11 lists the frequency of identified pollen types. No cultigens or other economic resources were identified in the botanical assemblage. A number of potential economic resources were also identified in the assemblage (Table 45.11), and these are discussed in detail in Smith's chapter in Volume 3.

SUMMARY OF SITE EXCAVATIONS

LA 86607 consists of a one-room fieldhouse located in Cabra Canyon. The south and west walls were intact, while the other walls appear to have been disturbed by the trail that runs through the site. No floors or prepared surfaces were identified in the fieldhouse. Ceramic evidence indicates that the fieldhouse was probably occupied during the Coalition period, with a second Coalition period fieldhouse (LA 86606) being situated nearby. Although no cultigens were recovered, the site was presumably occupied during the growing season when maize was cultivated.

CHAPTER 46
RENDIJA TRACT (A-14): LA 87430

Gregory D. Lockard

INTRODUCTION

LA 87430 is a small one-room Classic period fieldhouse located on the edge of an approximately 15-m-high terrace to the immediate south of the creek in Rendija Canyon. The site is situated less than 100 m east of the western boundary of the Rendija Tract, on a slope of approximately five degrees. The surrounding area is covered with ponderosa pine trees, many of which were severely burned in the Cerro Grande fire. The understory is dominated by several grass and wildflower species. The site is situated at an elevation of 2111 m (6925 ft).

The site was first surveyed on August 7, 1991, by Manz, Parish, Wallace, and Jandacek and given a temporary site number of M37. In the Site Survey Form, they interpret the site as a one-room fieldhouse. A charcoal stain visible in a nearby trail was thought to indicate the possible presence of a hearth. Artifacts encountered during a surface survey included plainware and glazeware sherds and obsidian flakes. On the basis of architecture and the artifacts present, the site was argued to be Ancestral Pueblo (AD 1200–1600).

FIELD METHODS

Before excavation, the site and surrounding area were cleared of trees and large undergrowth (Figure 46.1). An arbitrary site datum (designated 100N/100E, 10.00 m elevation) was then set up. The site datum could not be placed in the southwest corner of the site, which was common practice, because of the steep escarpment just to the northwest of the site. The site datum was therefore placed in the center of the southern edge of the site. The site was then covered with a 1- by 1-m grid system that extended 7 m north and 8 m east of the site datum, and three subdata (A-C) were set up for taking elevations. Three additional subdata (D-F) were set up at later times. The site was then photographed and surface collected. Two ceramic sherds and a lithic were the only artifacts encountered in the surface collection.

A 5- by 1-m east-west trench was initially excavated across the middle of the rock alignments and wallfall visible on the surface of the site (103N/98-102E). The purpose of this trench was to define and present a profile of the stratigraphy both within and outside of the structure, as well as to determine the location of the east and west walls of the structure. Units were excavated by strata, and thicker strata were excavated in arbitrary 10-cm levels. During the excavation of grids 103N/98E and 103N/99E, a compact surface was encountered. Excavation within the structure thereafter proceeded down to the level of this compact surface, which was presumed to be a living surface. In the area of the trench to the east of the structure, excavation proceeded down to the top of the sterile Btb1 horizon. The north profile of the trench was then drawn (Figure 46.2) and photographed. The rest of the site was subsequently excavated. In all, 18 units were excavated in their entirety and three additional units were partially excavated.

Figure 46.1. Pre-excavation photograph of LA 87430.

Within the structure, excavation proceeded down to the compact surface encountered in the western portion of the trench, when present. When this compact surface was not encountered, excavation proceeded down to either the top of the sterile Btb1 horizon or the level of the structure's nearest perimeter wall. Outside of the structure, excavation proceeded down to the top of the Btb1 horizon except in the southeast corner of the area excavated. The stratigraphy in this area of the site has been badly disturbed by an uprooted tree. Excavation in this area proceeded down to the level of the top of the Btb1 horizon in the nearest, undisturbed area. Excavation included the removal of rocks that could be clearly identified as wallfall to define the structure's walls and locate any internal or external features.

Soil samples were taken from select locations, and all other soil was passed through screens with 1/8-in. mesh to aid in the recovery of artifacts. The excavation area was extended approximately 1 m to the north, south, and east of the structure to locate external features and identify outside activity areas. The area to the west of the structure could not be excavated because the steep escarpment is directly adjacent to the structure's west wall. The excavations were extended 2 m to the east of the structure to investigate a charcoal lens that turned out to be associated with an external, slab-lined hearth (Feature 1). This area also contained the highest concentration of artifacts at the site. The high concentration of artifacts, coupled with the presence of an external hearth, indicates that the area to the east of the structure was an outdoor activity area. After the excavations were complete, the site was mapped (Figure 46.2) and photographed (Figure 46.3).

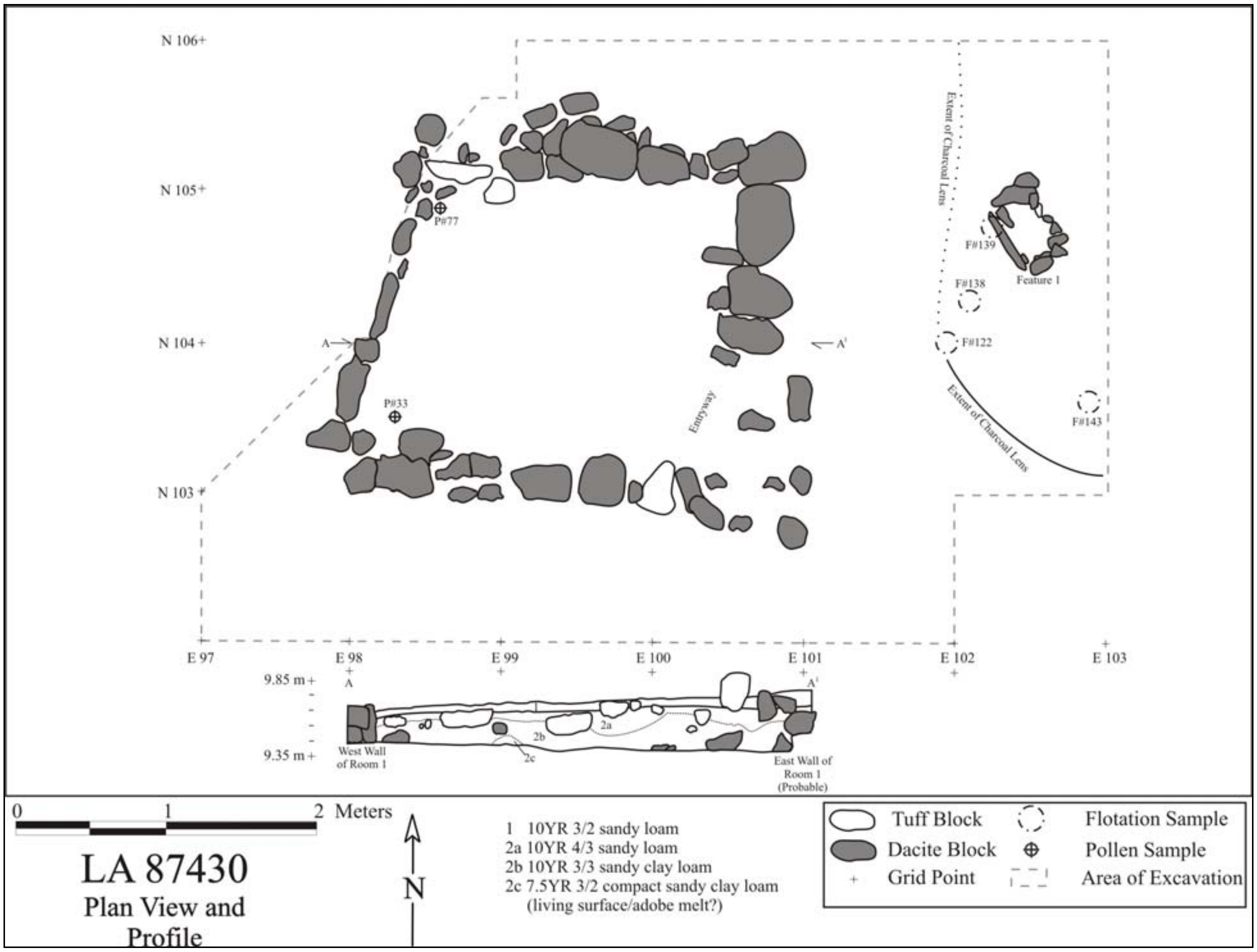

Figure 46.2. Plan view and profile drawing of the fieldhouse at LA 87430.

The excavation of the site was supervised by Greg Lockard. Crewmembers included Joseph (Woody) Aguilar, Brian Harmon, Bettina Kuru'es, and Jennifer Nisengard. Aaron Gonzalez and Michael Chavarria served as site monitors, representing San Ildefonso and Santa Clara pueblos, respectively.

Figure 46.3. Post-excavation photograph of the fieldhouse at LA 87430.

STRATIGRAPHY

Stratum 1 is composed of loose surface sediment. It is uniformly 3 to 5 cm thick across the site and is roughly equivalent to the top half of the A horizon (topsoil). Stratum 2, which ranges from 5 to 20 cm thick in the area excavated, is post-occupational fill. This fill was thickest in and around the structure, especially in the area just south (downhill) of its north wall. Stratum 2 is roughly equivalent to the lower half of the A horizon and the Bw horizon. Stratum 3 is a charcoal lens associated with a slab-lined hearth located to the east of the structure. This lens, along with the hearth, is designated Feature 1. Stratum 4 is the oxidized soil encountered directly beneath some areas of the Stratum 3 charcoal lens. Stratum 5 is the Feature 1 hearth fill. Strata 3, 4, and 5 are cultural strata. Stratum 6 is the unconsolidated soil excavated beneath the Stratum 3 charcoal lens in grid 104N/102E. Stratum 6 is part of the Bw horizon. Beneath the Bw horizon (Strata 2 and 6) is the Btb1 horizon. This horizon is a terrace that most likely dates to the middle Holocene. Beneath the Btb1 horizon is the Bcb1 horizon, which is transitional between the B and C horizons. Tables 46.1 through 46.3 summarize and describe the excavated strata at LA 87430.

Table 46.1. LA 87430 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10YR 3/2	Sandy loam	3–5 (25–45)	Surface sediment (and organic matter and tree throw)
2	10YR 4/3	Sandy loam	15–35	Post-occupational fill
3	10YR 3/2	Sandy loam	8–10	Feature 1 charcoal deposit
4	10YR 4/4	Sandy clay loam	3	Feature 1 oxidized soil below charcoal deposit
5	10YR 4/3	Sandy loam	10	Feature 1 hearth fill
6	10YR 4/3	Sandy loam	10	Below occupation level, east of the Feature 1 hearth

Table 46.2. LA 87430 soil horizon descriptions from the south profile of 103N/102E.

horizon	Color	Texture	Depth (cm)	Description
"C"	-	-	+22–0	Organic material and tree throw
A	10YR 3/2	Sandy loam	0–6	Topsoil
Bw	10YR 4/3	Sandy loam	6–18	Late-Holocene soil
Btb1	10YR 4/4	Sandy clay loam	18–41	Middle-Holocene soil

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is the only room in a small fieldhouse (see Figure 46.3). The room measures 1.85 m north to south by 2.10 m east to west, with approximately 3.885 m^2 of interior space. Excavation of the room began with the east-west trench that extended across the site (103N/98-102E). The excavation of this trench served to define the stratigraphy and locate the east and west walls and floor of the room. After the excavation of the trench, the rest of the room was excavated. In the western half of the room, excavation proceeded down to the level of a compact surface presumed to be the room's living surface. In the western half of the room, where this compact surface was not encountered, excavation proceeded down to the top of the Btb1 horizon or to the level of the base of the foundation of the nearest wall. The room was then photographed (see Figure 46.3). The portion of unit 104N/98E was subsequently excavated as a test pit below the presumed living surface. The purpose of this test pit was to determine whether or not there were any floors or additional living surfaces below, as well as to ascertain how deep the foundation of the west wall extends in that location. No floor or additional living surface was encountered, and the wall foundation was found to extend only a few centimeters into the Btb1 horizon.

Fill. The room was filled with 3 to 5 cm of surface sediment and 15 to 30 cm of post-occupational fill. A flotation sample (FS 26) and a pollen sample (FS 25) were taken of Room 1 fill. Charred taxa identified in the flotation sample included ponderosa pine and unknown conifer. Taxa identified in the pollen sample included grass family, cheno-ams, sunflower family, spurge family, unidentified pine, piñon pine, juniper, and sagebrush.

Floor. Room 1 does not appear to have had a prepared floor (i.e., a purposefully constructed layer of adobe and/or plaster). Nevertheless, a compact surface was encountered in much of the western half of the room. This compact surface appears to be the remains of the room's living surface. When present, it is located directly or only a few centimeters above the top of the sterile Btb1 horizon. This presumed living surface was not encountered in the eastern half of the room. In most of this area of the room, excavation proceeded down to the top of the Btb1 horizon, which is considerably more compact than the room fill. In the far southeast corner of the room, both the living surface and the integrity of the Btb1 horizon have been severely disturbed by an uprooted tree.

No artifacts were found in direct association with the presumed living surface. Two pollen samples (FS 33 and FS 77), however, were taken from directly on top of the surface. One of these (FS 33) is from the southwest corner and other (FS 77) is from the northwest corner of the room. Taxa identified in these samples included maize, grass family, cheno-ams, sunflower family, fir, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush.

Wall Construction. The walls in Room 1 are composed mostly of dacite cobbles and upright slabs. There are also a few tuff blocks, but only in the upper courses of the walls. All of the foundation rocks are dacite. The foundation rocks are mostly upright slabs in the western half of the room and mostly large cobbles in the eastern half. In most places, the wall is formed by a single row of rocks. In two locations, however, walls are formed by two rows of rocks (i.e., a double wall). In a small section of the western half of the south wall, a large, upright slab backed by two small, flat cobbles form a double wall. In the northwest corner of the room, several rocks form a double wall. A small, flat, upright rock backed by a large upright slab forms the westernmost portion of the north wall, and several small cobbles form the northernmost portion of the west wall.

The west wall of Room 1 is oriented at a slight angle to what it should be if the room was rectangular. If the wall extended northward at a right angle from the southwest corner of the room, however, it could not continue to the north wall because of the escarpment to the northwest of the site. Instead, it is angled inward such that the northwest corner of the room is located just east of the escarpment. This suggests that the escarpment was more or less in the same location when the room was built as it is today. Room 1 was therefore built right on the edge of a significant drop off, presumably to provide a good view of the Rendija Canyon arroyo below.

As mentioned, the southeast corner of the room has been severely disturbed by an uprooted tree. As a result, the rocks that presumably formed the foundation of the eastern half of the south wall have been slightly displaced. The foundation of southern half of the eastern wall may also have been disturbed. No *in situ* rocks were found in this area, despite the fact that the northern half of the east wall is fairly well preserved. The 73-cm-long gap in the southern half of the east wall could alternatively be an entryway. In fact, the usual pattern for prehistoric architecture on the Pajarito Plateau is for entryways to be placed in the east wall of residential rooms, presumably to take advantage of the light from the rising sun. If the gap encountered in the east wall of Room 1 is an entryway, it is almost identical in form to that of the fieldhouse (Room 1) at LA 85403. The entryway to both fieldhouses is in the southern half of the east wall. In addition, the northern boundary of both entryways is marked by a small, short rock. At LA 85403, the entryway's southern border is marked by a rock that forms a very short southern section of the east wall, as well as the southeast corner of the room. Although the southeast corner of the room is disturbed, this also appears to have been the case for Room 1 at LA 87430. Additional upright slabs and dacite cobbles were encountered in the area just east of the presumed entryway. Three of these form a north-south alignment. A fourth is an upright slab oriented east to west. These rocks may be part of an elaborate entryway (similar to that of LA 127634), but are probably wallfall disturbed by the uprooted tree.

The high quantity of wall encountered during the excavation of Room 1 indicates that the masonry portion of the walls were originally considerably higher than they are today (Table 46.4). In order to estimate how much higher, all of the rocks removed as wallfall during the excavation were placed into two stacks for measurement. One of these stacks measured 2.00 by 1.00 by 0.45 m, for a total of 0.90 m^3. The second stack measured 1.80 by 0.80 by 0.40 m, for a total of 0.576 m^3. Based on the combined volume of these stacks of wallfall (1.476 m^3) and the overall length, average thickness, and average height of the extant portions of the walls, the masonry portion of the Room 1 wall was originally only about 107 cm in height (116 cm if the possible entryway is excluded from the wall length total). The upper part of the walls and ceiling were most likely composed of vegetal material and adobe. These materials are rarely preserved at archaeological sites on the Pajarito Plateau. Two small pieces of burned adobe (FS 50 and FS 148) were the only evidence found of such a superstructure.

Table 46.4. LA 87430 Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	1.90	0.17–0.40	0.22–0.40	1 to 3
South	~2.15	0.12–0.35	0.13–0.28	1 to 2

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
East	1.37 (2.10)	0.03–0.28	0.14–0.32	1 to 2
West	1.70	0.01–0.30	0.04–0.22	1 to 2

Note: The length of the east wall including the possible entryway is given in parentheses.

Feature 1

Feature 1 is an external slab-lined hearth (Figures 46.4 and 46.5) and associated charcoal lens. The interior of the hearth measures 40 cm northwest to southeast by 26 cm northeast to southwest and is 22 cm deep. Upright slabs form the north, south, and west walls of the hearth. No upright slab was encountered along the eastern border of the hearth.

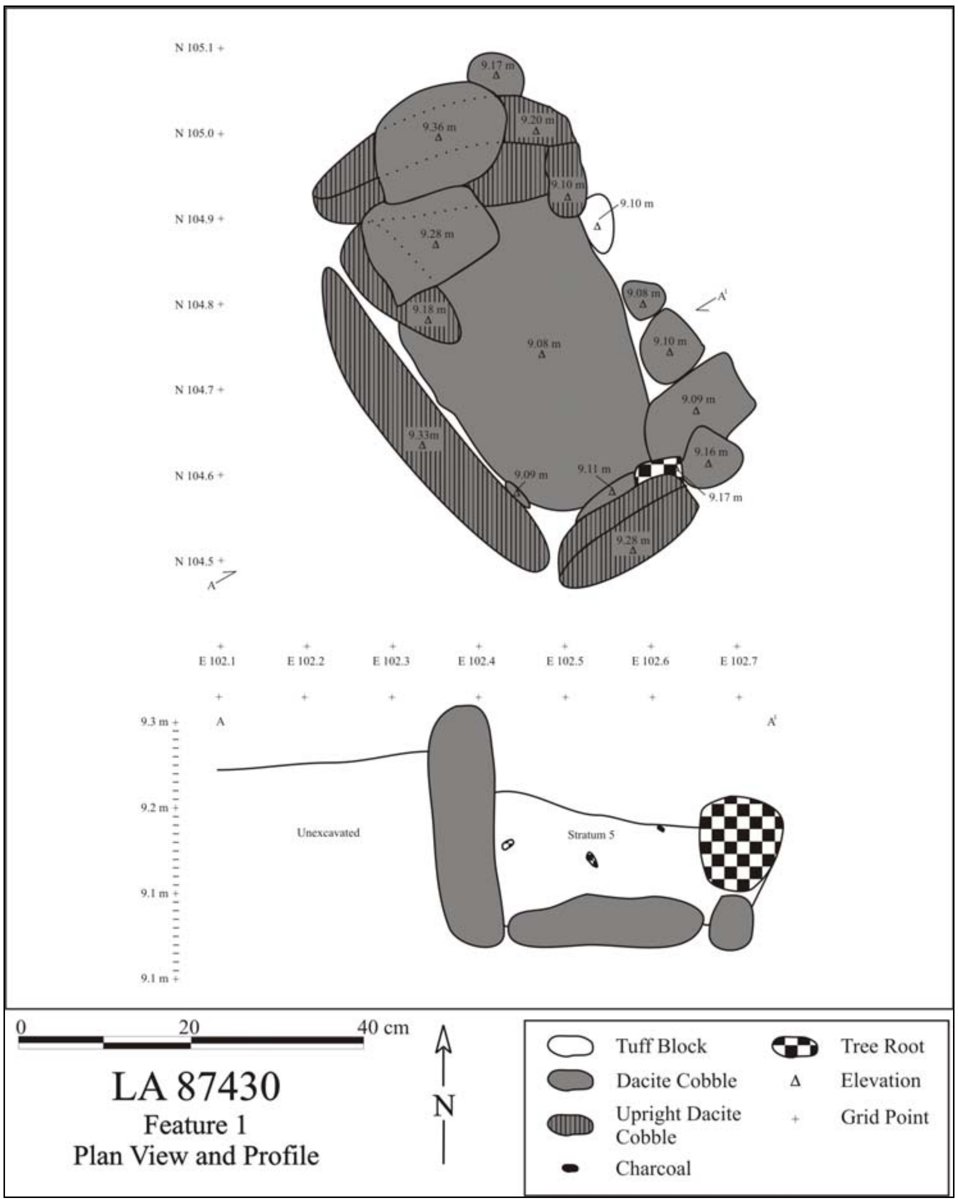

Figure 46.4. Plan view and profile drawing of Feature 1, a slab-lined hearth.

Figure 46.5. Post-excavation photograph of Feature 1, a slab-lined hearth.

The eastern border of the hearth is defined by five small cobbles. The tops of these rocks, however, are significantly lower than the tops of the upright slabs that form the other sides of the hearth. Originally, the cobbles probably functioned as a foundation for an upright slab, or at least a larger rock, that formed the east wall of the hearth. The cobbles are in fact similar in size and elevation to rocks found at the base of the slabs that form the south and west walls of the hearth. The stone that originally formed the east wall of the hearth was probably either removed by someone or displaced by root activity, which has significantly disturbed much of the surrounding area of the site. Several rocks were removed from the fill just above the hearth. Several medium-sized rocks and small cobbles were also recovered from within the hearth. Some or all of these rocks may have once formed the east wall of the hearth. None of the rocks, however, are large slabs similar to those that form north and west walls of the hearth. Some are similar, however, to the smaller slab that forms the south wall of the hearth. A large, flat slab forms the base of the hearth. No adobe or plaster was encountered within or around the hearth. All of the rocks that form the hearth walls and base and the rocks found at lower elevations within the hearth are dacite and show evidence of burning (i.e., a darkened color). The surrounding soil has not been hardened by the burning, however, suggesting that the soil has a low clay content.

Although the hearth fill contained charcoal, it appears to have contained very little ash. More ash and charcoal were encountered in the area surrounding the hearth. This charcoal deposit was present in a lens as thick as 10 cm directly around the hearth. This charcoal lens was considered to be part of Feature 1 due to its association with the slab-lined hearth. This charcoal lens (Stratum 3) was encountered in the northeast half of grid 103N/102E, all of grids 104-105N/102E, and small portions of grids 103-104N/101E. The charcoal lens also extends into unexcavated areas to the north and east. Its full extent is therefore unclear. Small patches of oxidized soil (Stratum 4) were encountered in some areas beneath the charcoal lens.

All of the fill removed from the hearth (Stratum 5) was kept as flotation (FS 170 to FS 173 and FS 175 to FS 177) and pollen (FS 169 and FS 178) samples. Charred taxa identified in the flotation samples included ponderosa pine, piñon pine, sagebrush, mountain mahogany, maize, beeweed, unknown conifer, unidentified pine, oak, purslane, and Douglas fir. Taxa identified in FS 169, which was taken from near the top of the hearth, included grass family and sagebrush. The other pollen sample (FS 178) was taken from directly on top of the rock that forms the base of the hearth. Taxa identified in this sample included maize, beeweed, grass family, cheno-ams, pea family, sunflower family, spurge family, unidentified pine, piñon pine, juniper, and sagebrush. Flotation samples (FS 138, FS 139 and FS 143) were also taken from the charcoal lens (Stratum 3) surrounding the hearth. Charred taxa identified in these samples included ponderosa pine, beeweed, unknown conifer, maize, unidentified pine, and piñon pine. Lastly, a flotation sample (FS 122) was taken of the oxidized soil (Stratum 4) directly below the charcoal lens and charred taxa included ponderosa pine and oak.

Geological Analysis

No specific unit was excavated as a geological test pit at LA 87430. Instead, geologists Paul Drakos and Steven Reneau analyzed the south profile of grid 103N/102E, the south profile of the sub-floor excavation in grid 104N/98E, and the profile of the escarpment located just to the northwest of the site (see Figure 46.3). Their analysis indicates that the upper portion of the terrace upon which the site was built is composed of a Btb1 horizon overlaying a Bcb1 horizon. As mentioned above, the sub-floor excavation in grid 104N/98E also indicates that the rocks that form the foundation of the Room 1 walls do not extend more than a few centimeters into the Btb1 horizon. Most of the foundation rocks are in fact lying directly on top of this surface.

Artifact Distribution

There are two noticeable trends in the artifact distribution at LA 87430 (Table 46.5). One of these is the result of cultural formation processes, while the other is most likely due to natural formation processes. The first trend is a higher concentration of artifacts to the east of the fieldhouse. By far the highest number of artifacts from any unit was from grid 104N/102E. This unit, located over a meter to the east of the fieldhouse, also contains the Feature 1 slab-lined hearth. Most of the artifacts from this unit are from the charcoal lens that surrounds the hearth (Stratum 3), although a large number of artifacts were also encountered in the post-occupational fill directly above. A high number of artifacts were also recovered from Strata 2 and 3 in the units directly to the north and south. The high number of artifacts and the presence of a hearth and associated charcoal lens to the east of Room 1 suggest that it was an activity area, a midden, or possibly both. Activity areas are often encountered to the east and/or directly outside the entryways of prehistoric Native American residences. If it was an activity area, the vertical distribution of artifacts into several strata is most likely the result of bioturbation. Tree roots in particular appear to have significantly affected this area of the site. If it was a midden, the depth of the deposits could instead indicate that the site was occupied for a significant period of time. The second trend in artifact distribution at LA 87430 is a higher concentration of artifacts in the northern, downslope half of the site compared to the southern, upslope half. This is most likely the result of erosion, which is a natural formation process.

Table 46.5. LA 87430 artifact counts by grid unit.

	E102	E103	E104	E105	E106	E107
N104		1	41	68	50	48
N103		**23**	**41**	**29**	30	91
N101	2	**8**	**17**	**18**	18	51
N100	12	4	6	4	28	

Note: Does not include one artifact found outside of the excavated area during surface collection; lightly shaded grid units were partially excavated; bold numbers indicate grid units that are located completely or partially within Room 1.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 583 artifacts were analyzed from the excavations at LA 87430. In addition, flotation and pollen samples were selected for analysis from the post-occupational fill (Stratum 2) and the floor (Stratum 3) (Table 46.6). The results of the artifact and sample analyses are presented in the following sections. In addition, a maize sample was submitted for radiocarbon dating.

Table 46.6. Samples selected for analysis from LA 87430.

Stratum	Sample Type			
	Flotation	Pollen	Radiocarbon	TL*
1				
2	26	25, 33, 77		123
3	138, 139, 143		139

Chronology

Radiocarbon Dating

Two maize samples were submitted for accelerator mass spectroscopy dating. The sample from Stratum 3 provided a date of 370±40 BP (Beta-215552), with a calibrated intercept of AD 1490 and a two-sigma range of AD 1440–1640. It was taken from a charcoal lens that surrounded the Feature 1 hearth. The second sample was taken from the fill of the hearth (Stratum 5). It yielded a date of 390±40 BP (Beta-215553), with a calibrated intercept of AD 1470 and a two-sigma range of AD 1430–1630.

Thermoluminescence Dating

A single Biscuit B sherd was submitted for TL dating from LA 87430 (Table 46.7). All derived ages are given in years BP, which refers to years before 2003. The TL date is about 100 years earlier than the radiocarbon dates, but overlaps at two-sigma.

Table 46.7. TL date from ceramics at LA 87430.

FS#	Lab #	Context	Burial depth (cm)	Years BP	% error	Years AD
123	UW1416	North wall Room 1	16	623	6.2	1384±39

Ceramic Artifacts (Dean Wilson)

A total of 487 ceramics were analyzed from LA 87430. The majority of the pottery consists of Sapawe Micaceous, Biscuit B, and Biscuit B/C (Biscuit B?), which presumably reflects a Middle Classic period occupation (Table 46.8). This corresponds with the 15th century radiocarbon date, but not the TL date. Information on ceramic tradition by ware, temper by ware, and vessel form by ware are provided in Tables 46.9 through 46.11. The graywares and whitewares appear to have been locally made from smeared-indented sand or tuff, in contrast to Sapawe Micaceous, which contained a non-local micaceous temper. All of the grayware and most of the micaceous ceramics consist of jar vessel forms. Several micaceous sherds were derived from a bowl(s). The whiteware sherds include mostly bowls, but some jars are present.

Table 46.8. Ceramic types from LA 87430.

Ceramic Type	Frequency	Percent

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 96 artifacts were analyzed from LA 87430, consisting of four cores, 80 pieces of debitage, five retouched tools, and seven ground stone artifacts. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 46.12 presents the data on lithic artifact type by material type. The debitage is primarily made of chalcedony and Pedernal chert with other materials. The presence of cortex on 13.7 percent of the debitage indicates that these materials were collected from waterworn (*n* = 11) sources. The chalcedony, Pedernal chert, and silicified wood are available from local Rio Grande Valley gravels and the obsidian from nearby sources in the Jemez Mountains. The igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the plateau.

Table 46.12. Lthic artifact type by material type.

Five pieces of obsidian and a piece of basalt debitage were submitted for X-ray fluorescence analysis. The obsidian artifacts are Valle Grande and Cerro Toledo obsidian (Table 46.13). The Valle Grande (Cerro del Medio) and Cerro Toledo (Obsidian Ridge/Rabbit Mountain) source areas are situated about 17 km (11 mi) and 19 km (12 mi) to the west and southwest. Although obsidian is present at these nearby sources in the Jemez Mountains, it is also present on the nearby mesa as small pebbles. These pebbles compose part of the secondary deposits associated with the Cerro Toledo interval. The single basalt flake appears to be made of dacite from the Newman Dome source.

Table 46.13. Obsidian source samples.

FS #	Artifact	Color	Source
69	Debitage	Translucent	Valle Grande rhyolite
107	Debitage	Translucent	Valle Grande rhyolite
127	Debitage	Translucent	Valle Grande rhyolite
131	Debitage	Translucent	Cerro Toledo rhyolite
145	Debitage	Translucent	Valle Grande rhyolite

Lithic Reduction

All four cores were reduced using a single-directional, single-face technique (Figure 46.6). Three of these were classified as still useable when discarded and one as discarded due to a culturally induced fracture. Table 46.14 presents the metric information on the cores.

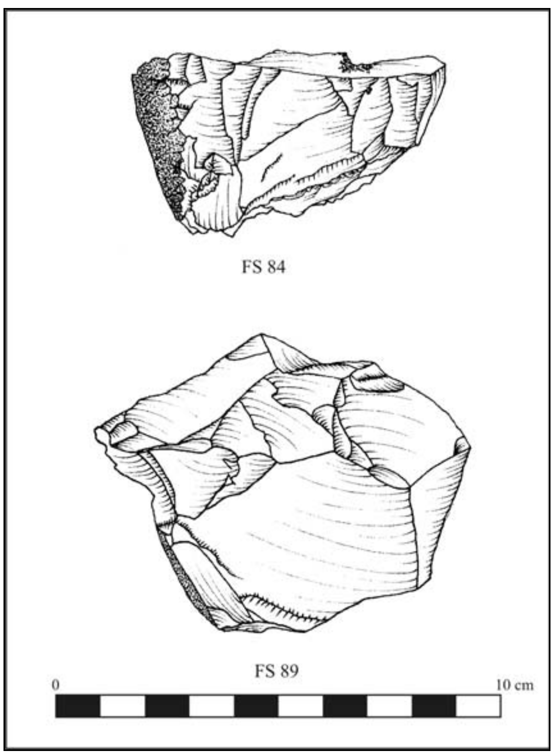

Figure 46.6. Single-directional, single-face cores.

Table 46.14. Core type dimensions (mm) and weight (g).

Core Type	Length (*std*)	Width (*std*)	Thickness (*std*)	Weight (*std*)
Single-directional	42	62	71	222.9
Single-directional	55	53	59	245.9
Single-directional	50	83	65	288.9
Single-directional	60	78	49	255.6

The debitage mostly consists of core flakes, with a few biface flakes and angular debris. The overall cortical:non-cortical ratio of 23.5 reflects an emphasis on the later stages of core reduction and tool production/maintenance. The flakes mostly have single-faceted platforms ($n = 29$), with fewer cortical ($n = 3$), multi-faceted ($n = 3$), collapsed ($n = 11$), and crushed ($n = 5$) platforms. Four of the platforms exhibit evidence of preparation by abrasion/crushing. The majority of the core flakes are proximal fragments ($n = 24$), with fewer whole ($n = 21$), midsection ($n = 2$), and distal ($n = 15$) fragments. In contrast, the biface flakes consist of six proximal and two distal fragments. The whole core flakes have a mean length of 28.6 mm (*std* = 9.4) and the angular debris a mean weight of 4.5 g (*std* = 4.6).

The retouched tools consist of retouched pieces, bifaces, and a projectile point (Figure 46.7). The retouched pieces are two flakes with unidirectional dorsal retouch along a lateral edge with angles of 70 degrees. One of the bifaces was rejected during the early stages of the reduction process with a thickness of 12 mm and edge angle of 70 degrees. It is triangular-shaped with alternate beveled edges. The other biface is a proximal fragment of a knife or spear point. Most of the blade is missing and it appears that the base was being thinned because one side is ground and the other exhibits a series of small retouch flakes. Small notches are present at the shoulder that could have been an attempt to haft the artifact. Lastly, the projectile point is the base fragment of a side-notched arrow point. Metrical and descriptive information on the point is presented in Table 46.15.

Table 46.15. Projectile point metrical (mm) and descriptive data.

146	Obsidian	Proximal	--	--	7	7	14	3	0.6	Side-notched	Und.	Straight

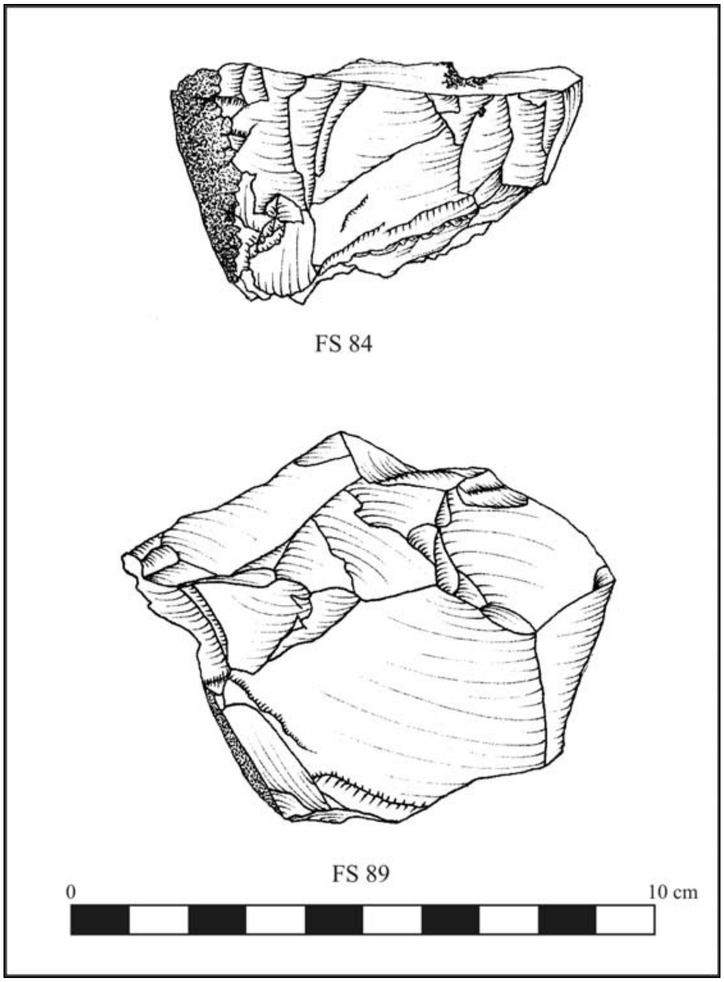

Figure 46.7. Projectile point and bifaces from LA 87430.

Tool Use

None of the debitage exhibit evidence of edge damage that could be attributed to use. Both retouched pieces exhibit rounding and scarring that reflect use and the biface fragment has rounding and polish along the remaining portion of the blade. The ground stone artifacts include a mano, millingstones, and grooved abrader. The manos consist of fire-cracked cobbles with a single grinding surface that probably represent broken one-hand manos. The millingstones are fragments of dacite and andesite with a single flat ground surface. The abrading stone is an odd-shaped dacite cobble with a flat ground surface that exhibits unidirectional striations. It could have been used as a mano, but was classified as an abrading stone due to the irregular shape and wear.

Archaeobotanical Remains (Pamela McBride)

Burned pine needles were the most common plant materials recovered from this Classic period fieldhouse, followed by corn parts (Table 46.16). Besides corn, samples from the hearth yielded charred goosefoot, purslane, and beeweed seeds. A seed that compares favorably to beeweed was also identified from the charcoal concentration in Room 1. Young beeweed plants were used as greens, eaten much like spinach. The seeds were also dried, ground, and mixed with cornmeal. The leaves of older plants were cooked down until they formed a paste, sun-dried, and made into cakes that could later be eaten with cornmeal mush or fried with fat. Another, more unusual and important use of the reconstituted cakes was as a black pigment for decorating pottery and baskets (Dunmire and Tierney 1995:182–184).

Piñon and ponderosa pine dominated the wood assemblage, while mountain mahogany was the most common non-conifer with small amounts of sagebrush and oak also occurring (Table 46.17). Corn, grown in nearby fields, was probably cooked on the hearth, possibly along with goosefoot, purslane, and beeweed. Locally available woods were used as fuel.

Pollen Remains (Susan Smith)

Five pollen samples were analyzed from LA 87430. Table 46.18 lists the frequency of identified pollen types. Maize was the only cultigen identified in the botanical assemblage. Beeweed was the only other economic resource that was identified in the assemblage. A number of potential economic resources were also identified in the assemblage (Table 46.18), and these are discussed in detail in Smith's chapter in Volume 3.

SUMMARY OF SITE EXCAVATIONS

LA 87430 consists of a one-room fieldhouse and a slab-lined hearth. All four walls were intact and appeared to contain an opening to the east. A formal floor was not identified, but the fieldhouse did contain a compact surface. The slab-lined hearth contained bits of charcoal. Ceramic and radiocarbon evidence indicate that the fieldhouse was probably occupied during the Middle Classic period. The presence of maize and the prevalence of storage jars reflect the agricultural function of the site. This is supported by the limited core reduction represented in the lithic assemblage and by the grinding activities.

CHAPTER 47
RENDIJA TRACT (A-14): LA 99396

Brian C. Harmon

INTRODUCTION AND SITE SETTING

LA 99396 is a multicomponent site consisting of an Archaic period lithic artifact scatter and a Coalition period one-room fieldhouse. The site is situated on the broad, open southeast-facing slope of a saddle (Figure 47.1). The site covers an area of about 1385 m^2 and is at an elevation of 2110 m (6925 ft). Headwater cutting of several small washes has created an area of shallow erosion across much of the southeast portion of the site. While located within piñon-juniper woodland, the site itself is relatively clear of trees. The Cerro Grande fire did not impact this site.

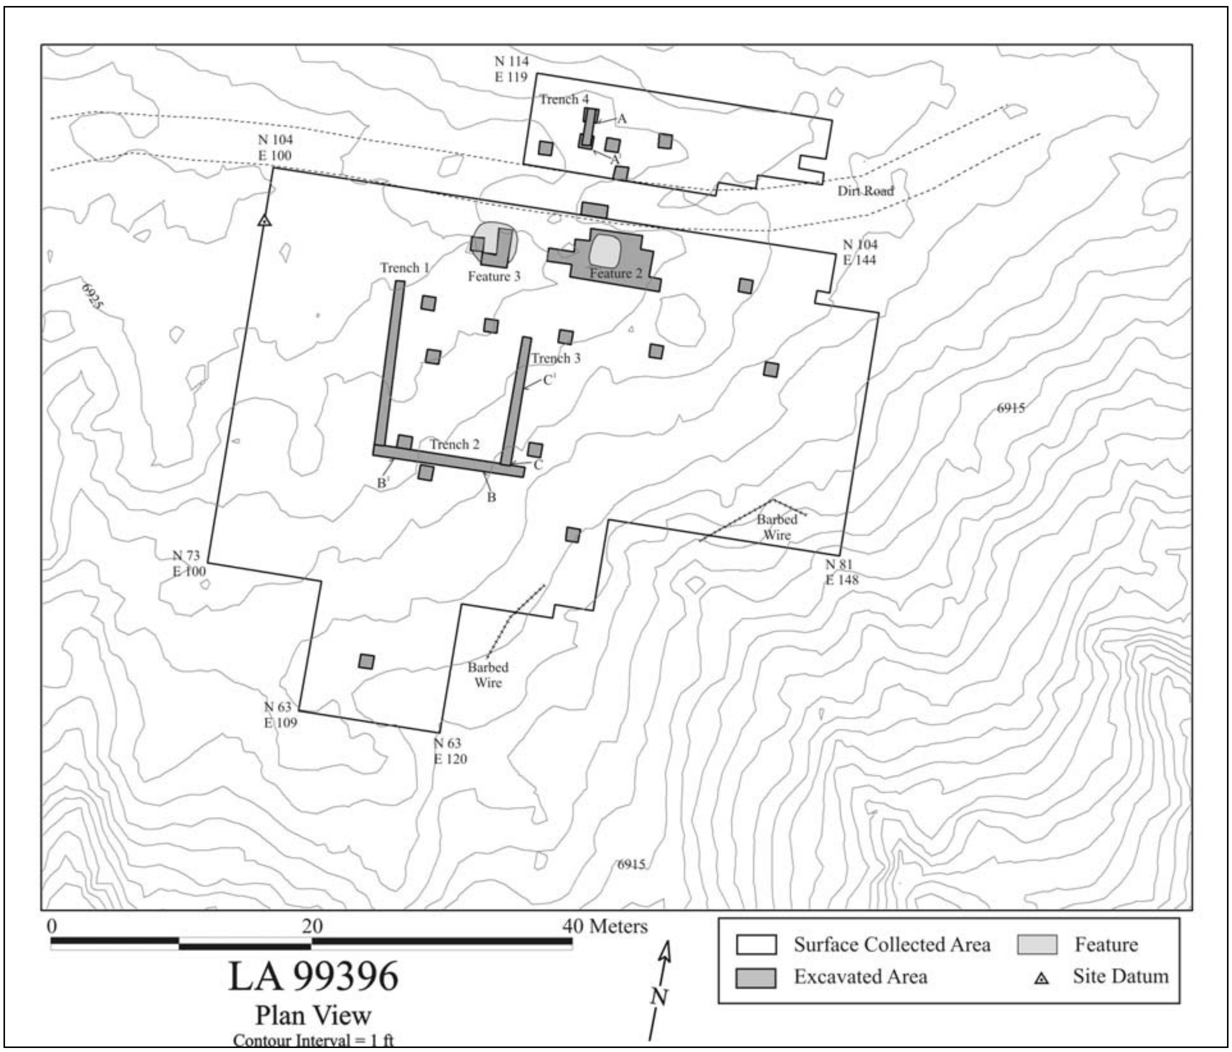

Figure 47.1. Plan view drawing of LA 99396.

The soil at LA 99396 is part of the Rendija-Bayo complex; a complex that "contains deep, well-drained soils weathered from materials derived from tuff (Rendija series) or pumice (Bayo series)," (Nyhan et al. 1978:54). The local stratigraphy consists of 2 to 37 cm of late-Holocene eolian and colluvial deposits overlying late-Pleistocene or early-Holocene eolian deposits. At the northern end of the site, Cerro Toledo or Guaje pumice (Qct or Qbog) underlies the Pleistocene deposits at about 120 cm below the surface. In the southern and central parts of the site, pumice is found 8 to 24 cm below the surface.

A dirt road runs through the northern portion of the site. This road appears to have been bladed in areas and is cut into the late-Pleistocene/early-Holocene deposits. A dirt bike track is present on the slope and valley north of the site. The edge of an old open-pit pumice mine defines the southern and southeastern boundaries of the site. In recent years the site has been used as an informal shooting range; many bullet cartridges, skeet fragments, metal and plastic fragments, and other debris are found within several meters of the dirt road. This site is located within the boundaries of the Serna Homestead patent (see Chapter 32, this volume).

SITE DESCRIPTION

The lithic artifact scatter covers an area of approximately 1385 m^2 and consists mostly of obsidian debitage. Several biface fragments, including four projectile point bases, and ground stone artifacts were also recovered. These artifacts are in a reworked context.

The one-room structure (Feature 2) is partially subterranean: a shallow pit was excavated into the late-Pleistocene/early-Holocene deposits and this forms the living surface of the structure. The walls were built of unshaped dacite and tuff cobbles. None of the walls are standing but the cobbles are still present in the form of two low mounds; one (Feature 1) directly overlays the excavated portion of the structure and the second (Feature 3) is located 7 m to the west. A light scatter of ceramic sherds and ground stone artifacts is present in and around Feature 2.

No homestead era artifacts were recovered during excavation, but the remains of a barbed wire fence, which probably marked the Serna Homestead patent boundary, is present along the southeast edge of the site.

PREVIOUS INVESTIGATIONS

LA 99396 was first recorded in 1992 by Peterson and Nightengale (1993:208–212) for the Bason Land Exchange Project. Their work consisted of mapping, infield analysis, surface collection, and shovel testing. Hoagland et al. (2000:7–38) summarized Peterson and Nightengale's results:

> Testing included 10 shovel tests, a 1- by 23.5-m-long artifact collection transect across the center of the site, plus a site-wide infield analysis of 157 [lithic] artifacts. Ceramics, all from surface finds, amounted to only three sherds: one Biscuit A, one Pajarito smeared-indented, and one gray utilityware. The majority of lithic materials

> collected from this site consisted of obsidian debitage including 15 [sic, 16] flakes recovered from [six of] the shovel tests. The few pieces of debitage that were not obsidian include a tertiary flake of a gray opaque material as well as four tertiary flakes, two secondary flakes, and two angular pieces of chalcedony. In addition to this, a broken basalt point base, that was thought to be from a Bajada projectile point, was collected. All but one of the pieces of debitage are the result of secondary or tertiary reduction suggesting that partially reduced materials were transported to the site where they were further reduced in the course of chipped stone tool manufacture and/or to obtain flakes as expedient tools. Utilized or retouched flakes comprise about 4 percent of the site debitage.

Peterson and Nightengale also recorded two small rock concentrations immediately south of the dirt road. The westernmost concentration (our Feature 3) was recorded as being approximately 3 m in diameter, and the other (our Feature 1) as approximately 1.5 m in diameter. One test unit was placed immediately south of Feature 3 and encountered the Btb1 horizon 5 cm below surface. No artifacts were found. A second test unit was placed in the center of the eastern concentration and encountered the Btb1 horizon at 20 cm below surface. One obsidian flake was found. On the basis of these tests Peterson and Nightengale (1993:208) concluded that the concentrations "were probably formed in the course of road construction and maintenance". The Los Alamos National Laboratory Cultural Resources Management Team visited LA 99396 in 2000 during the Cerro Grande Fire Assessment Project (Nisengard et al. 2002).

FIELD METHODS

Most of the work reported here took place between September 29 and December 10, 2003, although the site was sporadically visited until January 15, 2004. The crew consisted of Steven Hoagland (crew chief), Brian Harmon (assistant crew chief), Maria Jonsson, Michael Kennedy, Bettina Kuru'es, and Alan Madsen. Aaron Gonzales was the San Ildefonso tribal monitor. Leo Martinez operated the bobcat during trenching operations.

A grid was laid out at the site based on magnetic north. Investigations began with a ground penetrating radar (GPR) survey with the goal of locating potential cultural deposits associated with the lithic artifact scatter. The area between 77 to 100N and 111 to 130E was surveyed. Several anomalies were found and, in the course of excavation, four units (81N/127E, 82N/115E, 91N/114E, and 99N/124E) were dug to investigate these anomalies. No cultural features were encountered in these excavations and additional anomalies were not investigated. The GPR anomalies are interpreted to be variations in pumice depth, variability in soil characteristics, etc.

After the GPR survey, a surface collection was made of 100 percent of the artifacts within the estimated site boundaries. Collection did not take place in the dirt road. Artifacts were collected in 1- by 1-m grid units and 1566 units were included in the surface collection.

Significant erosion has occurred in the southeastern part of LA 99396. For this reason, initial excavations focused on the high areas of the site, where it was thought that intact cultural deposits would most likely be encountered. The high areas are 84-102N/113-118E and 106-

110N/120-130E. No intact cultural deposits were found. Later, several units were placed in the eroded area. Intact cultural deposits were not found here, either. Additional excavations focused on the two rock piles south of the road. Five excavation units placed in the western rock pile (Feature 3) demonstrated that it was not associated with any subsurface cultural deposits. However, the subterranean remains of a one-room structure (Feature 2) were found below the eastern rock pile (Feature 1). Initially, Feature 2 was thought to be the remains of an Archaic structure unassociated with Feature 1 (hence the separate feature numbers). The entire fill of Feature 2 was saved as flotation and pollen samples. When several ceramic sherds were encountered in the fill of the hearth, it became obvious that this was a Puebloan structure.

While Feature 2 was being excavated, an ashy deposit was observed in the road just north of the structure. Units 104N/124-125E were opened and a hearth (Feature 5) was discovered. The remains of a possible post (Feature 4) were found immediately north of Feature 2. These discoveries suggested the possibility of additional exterior features, so a 24-m^2 area was opened around the structure. No additional features were found.

After excavation, four trenches (Table 47.1.) were dug by backhoe to make long profiles of the site stratigraphy visible. Trenches 1 to 3 were placed to explore the west-central portion of the site. Trench 4 was dug to explore the high area north of the road.

Table 47.1. Trench dimensions.

4	109.2N 123.2E	112N 123.2E	2.8	0.80

STRATIGRAPHY

The general stratigraphic sequence at LA 99396 consists of late-Holocene eolian and colluvial deposits overlaying late-Pleistocene or early-Holocene eolian deposits that, in turn, overlay Qct or Qbog pumice (see Chapter 57, Volume 3). During excavation, variations within soil horizons were given different stratum numbers. Table 47.2 summarizes the strata at LA 99396. Table 47.3 lists the artifact count by stratum.

Table 47.2. Stratigraphic sequence used during excavation.

Provenience	Stratum	Color	Texture	Thickness (cm)	Description

The uppermost soil horizon across the site is a late-Holocene A horizon consisting of eolian and colluvial deposits. During excavation, the A horizon was divided into two strata based on consistency: Stratum 1 consisted of loose surface sediments and Stratum 2 consisted of underlying soft sediments. Although there is considerable variation in the thickness of these two strata, Stratum 1 was usually about 3 cm thick and Stratum 2 was usually about 8 cm thick. Strata 1 and 2 were probably deposited within the last 1000 years.

In most places, the A horizon is underlain by late-Pleistocene or early-Holocene eolian deposits. The uppermost of these deposits is a truncated Bt1b1 horizon. This truncation indicates erosion at LA 99396 some time during the Holocene before the deposition of Strata 1 and 2. In the field, this horizon was divided into two strata (Stratum 3 and Stratum 10) based on textual, structural, and consistency differences. In Drakos and Reneau (Volume 3, Chapter 57 and Appendix L), the Bt1b1 horizon in LA 99396-1 is an example of Stratum 3; the Bt1b1 horizon in LA 99396-4 is an example of Stratum 10. Stratum 3 was encountered south of 108N, while Stratum 10 was found north of 108N. Strata 3A and 10A are Bt2b1 horizons.

Stratum 3 and 10 are underlain by sterile Bk and Btk horizons (Volume 3, Chapter 57). The deepest of these late-Pleistocene or early-Holocene deposits occur on the northern part of the site (Figure 47.2). A piece of wood charcoal (Field Specimen [FS] 774) from the Btkb1 horizon (Stratum 18) in Trench 4 was submitted for radiocarbon analysis. This sample returned an age of 33660±320 BP (Beta-199381). In the southern portion of the site, sterile horizons are considerably shallower (Figures 47.3 and 47.4). Across the site, the late-Pleistocene or early-Holocene soils are underlain by Cerro Toledo or Guaje pumice deposits.

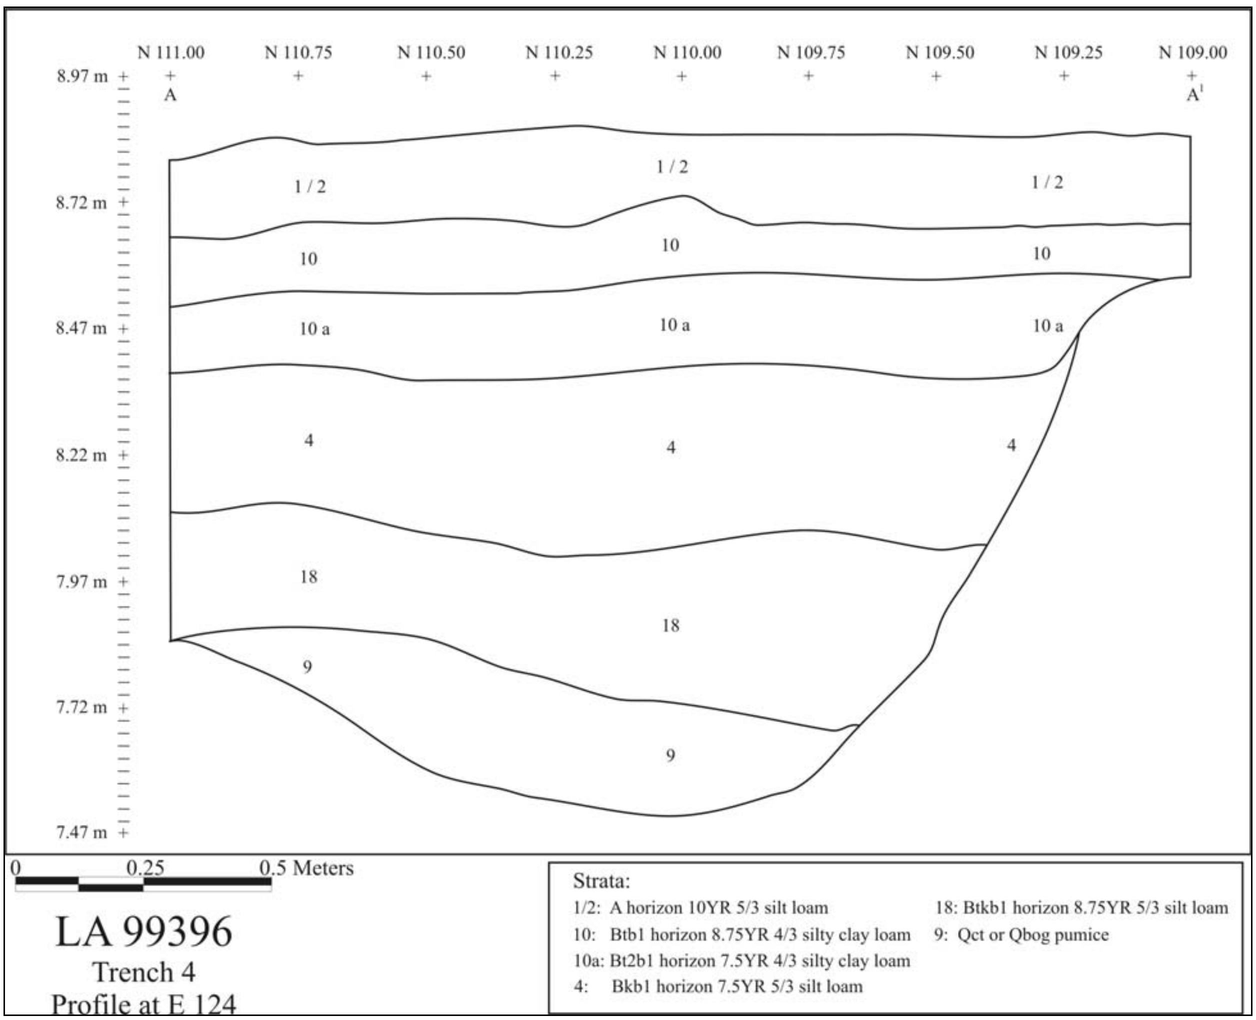

Figure 47.2. Profile of Trench 4 at LA 99396.

Swale fill (Strata 6 and 7) was observed in unit 84N/113E and in Trenches 2 and 3. Deposits are present between 114.4 to 121E and between 83.2 to 88N. The swale fill consists of a sandy clay loam Bwb1 horizon (Stratum 6) overlying a sandy loam Bkb1 horizon (Stratum 7). The swale fill deposits were likely derived from the reworking of older upslope soils some time in the middle to late Holocene. These strata are overlain by the A horizon and underlain by Stratum 4 and Stratum 9.

A piece of wood charcoal (FS 775) from Stratum 6 was submitted for radiocarbon analysis. The sample returned an age of 1000±40 BP (Beta-199382) and a date of cal AD 1020 with a two-sigma date range of AD 980–1060 and AD 1080–1150.

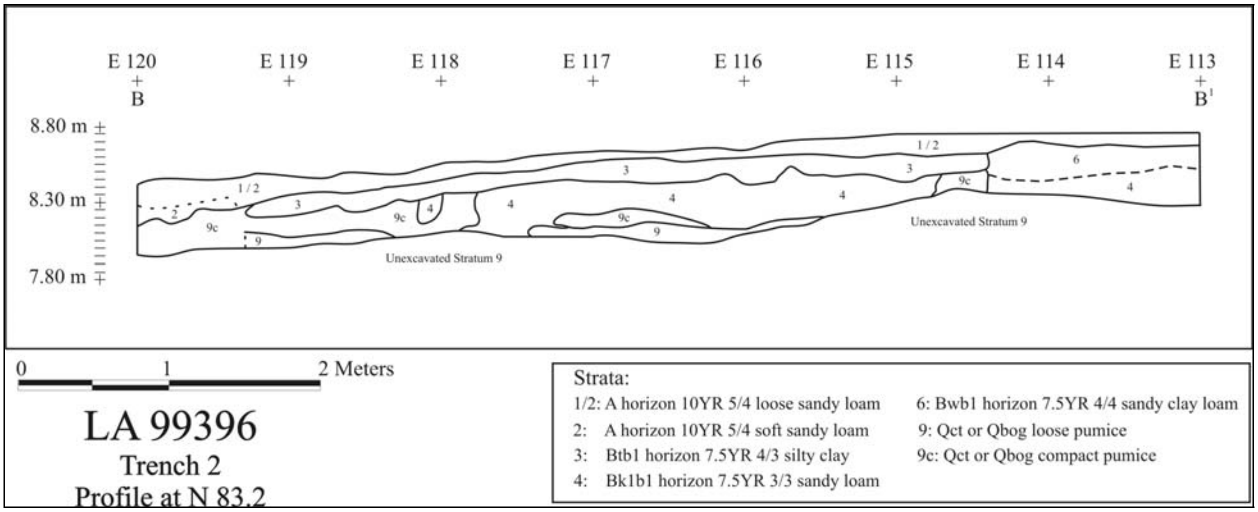

Figure 47.3. Profile of Trench 2 at LA 99396.

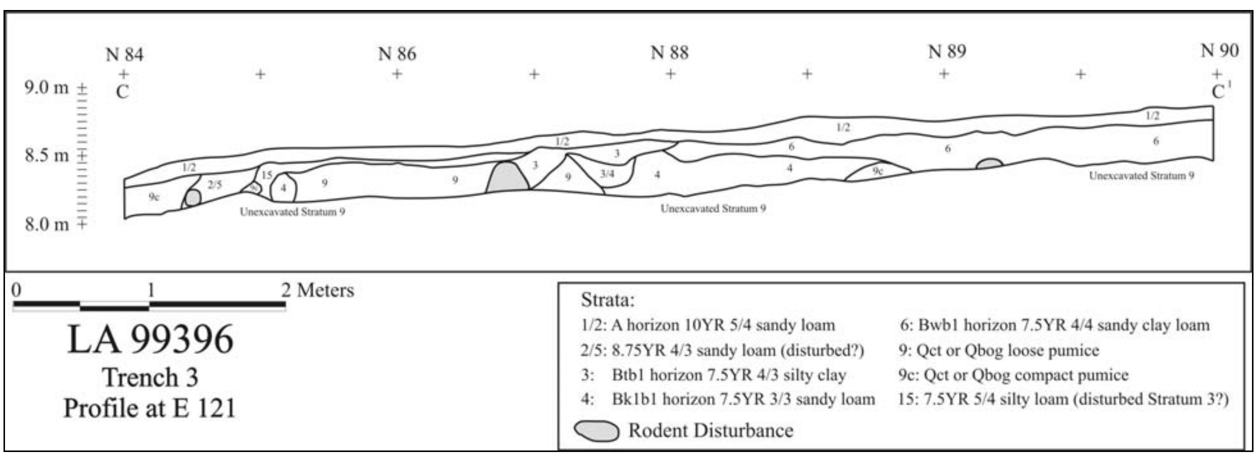

Figure 47.4. Profile of Trench 3 at LA 99396.

SURFACE COLLECTION

An area of 1566 m^2 was surface collected and 659 artifacts were recovered. Figures 47.5 and 47.6 show the distribution of surface artifacts. Most of the chipped stone debitage is found on the southeast-facing slope of the site. Headwater cutting of several small washes has created an area of shallow erosion across much of this area. In contrast to the chipped stone debitage, nearly all of the surface ceramic artifacts are found immediately east of Feature 2.

SITE EXCAVATION

Archaic Component. The Archaic component of the site consists of a moderately dense scatter of chipped stone debitage and a few stone tools. Most of these artifacts are located on a shallowly eroded southeast-facing slope. Given that the A horizon is probably not older than 1000 years and that the underlying truncated Btb1 horizon dates to the late Pleistocene or early Holocene, it is unlikely that any Archaic period habitation surface is still intact. All of the Archaic period artifacts are in a reworked context.

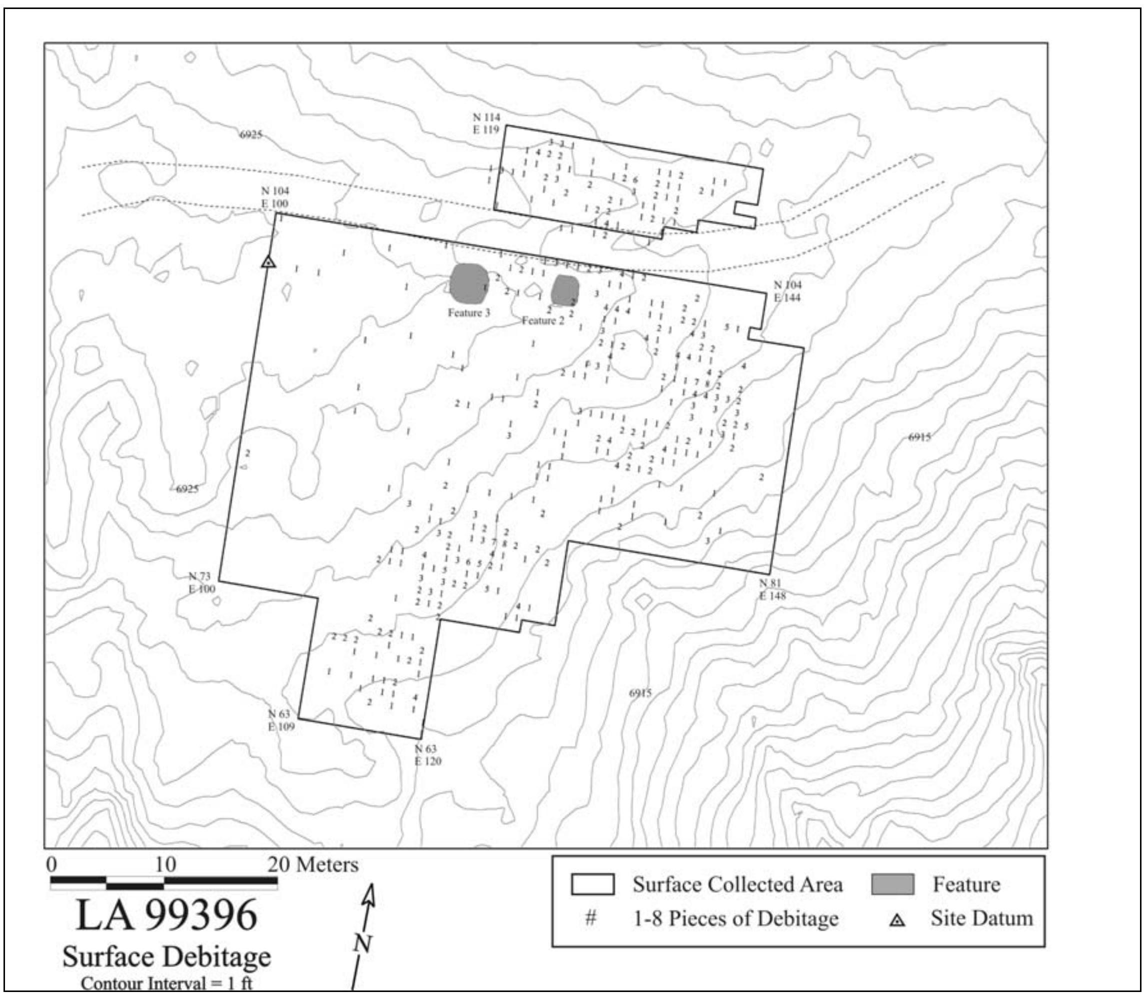

Figure 47.5. LA 99396 surface chipped stone debitage.

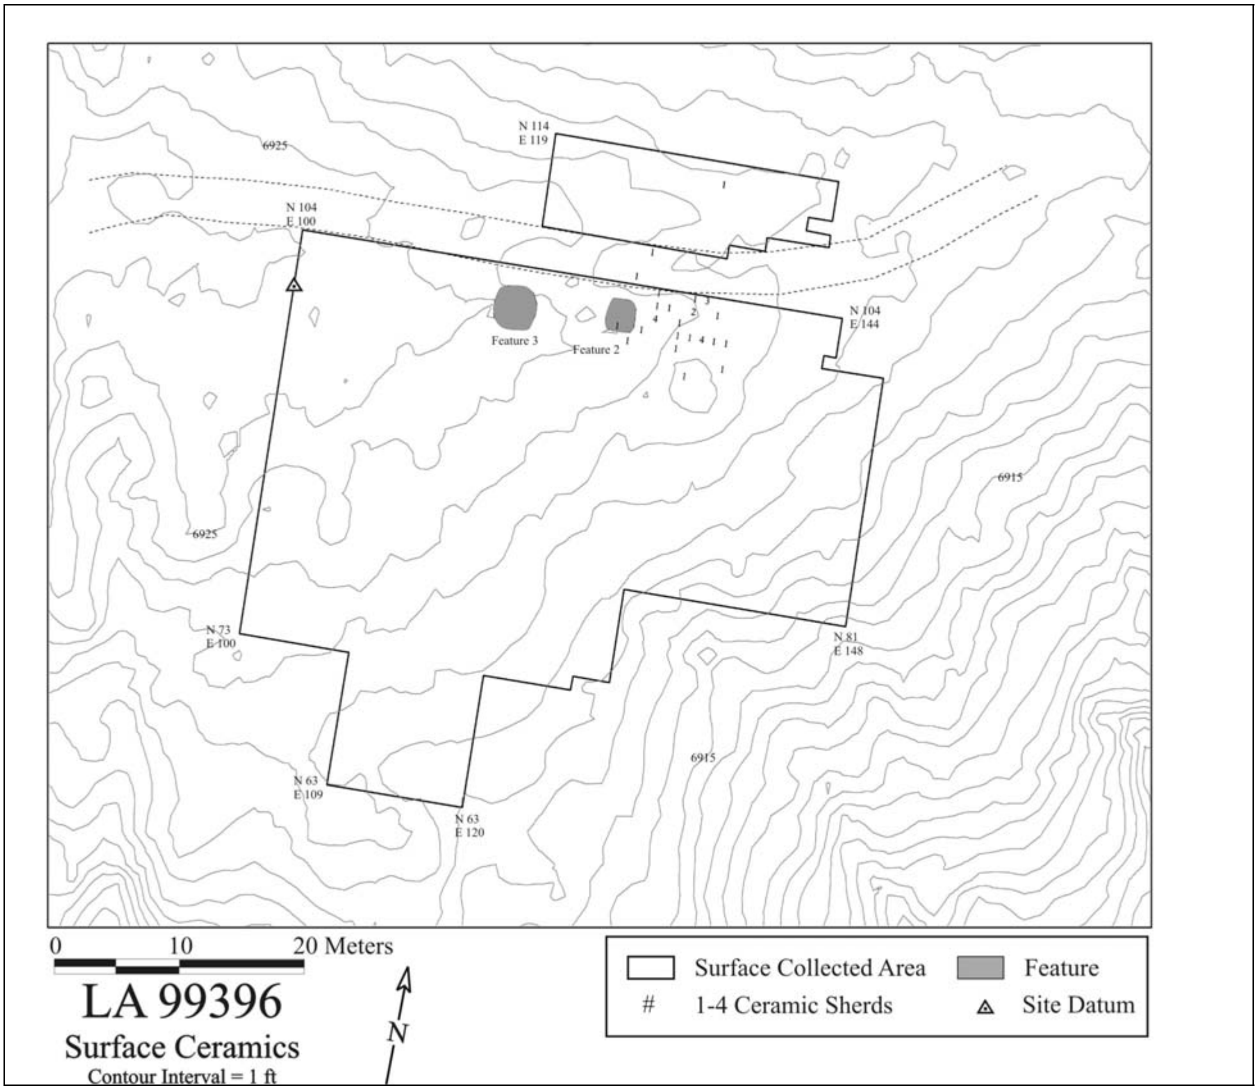

Figure 47.6. LA 99396 surface ceramic artifacts.

Coalition Period Component. This component consists of a one-room structure and associated features and artifacts.

Features 1 and 2

Feature 1 is a low mound of approximately 100 unshaped dacite cobbles and several unshaped tuff cobbles (Figure 47.7). It is approximately 3 m north-south by 2 m east-west. The cobbles range in size from 9 by 9 by 8 cm to 33 by 21 by 11 cm. The most common size is 16 by 14 by 10 cm. The matrix around these cobbles consists of Strata 1 and 2, although some cobbles extended down into Stratum 11 and two or three cobbles rested on the floor of the structure. These cobbles (and those of Feature 3) were the aboveground walls of Feature 2.

Figure 47.7. Feature 1, partially excavated.

Feature 2 (Figures 47.8 and 47.9) is the subterranean portion of a one-room structure that was excavated into Stratum 3. The structure is oriented approximately north-south. It is rectangular in shape, although the corners are rounded. The interior dimensions at the level of the floor are 2.3 m north-south by 2.1 m east-west. A hearth (Feature 7) is present at the center of the structure, and outside, to the north, a second hearth (Feature 5) and a post fragment (Feature 4) are present. In the discussion that follows, Feature 2 is used to refer to the one-room structure as a whole while Feature 1 is used to refer specifically to the cobble concentration (which is treated as a sub-feature of Feature 2).

Five (originally six) strata are associated with Feature 2. Strata 1 and 2 are associated with Feature 1, Stratum 11 (and Stratum 17, see Table 47.1) is the fill of the structure, Stratum 12 is the living surface, and Stratum 16 is the fill of the interior hearth (Feature 7) (Figure 47.10).

Strata 1 and 2 are described above. Stratum 11 is a Bw soil horizon consisting of 6 to 15 cm of sandy loam. Given the paucity of cobbles in Stratum 11, it appears that this stratum was deposited before the walls collapsed. The living surface of Feature 2 (Stratum 12) consists of smooth and compacted Stratum 3. A light scatter of ash and charcoal flecks is embedded in this surface, giving it a grayish color. No artifacts were found on the living surface.

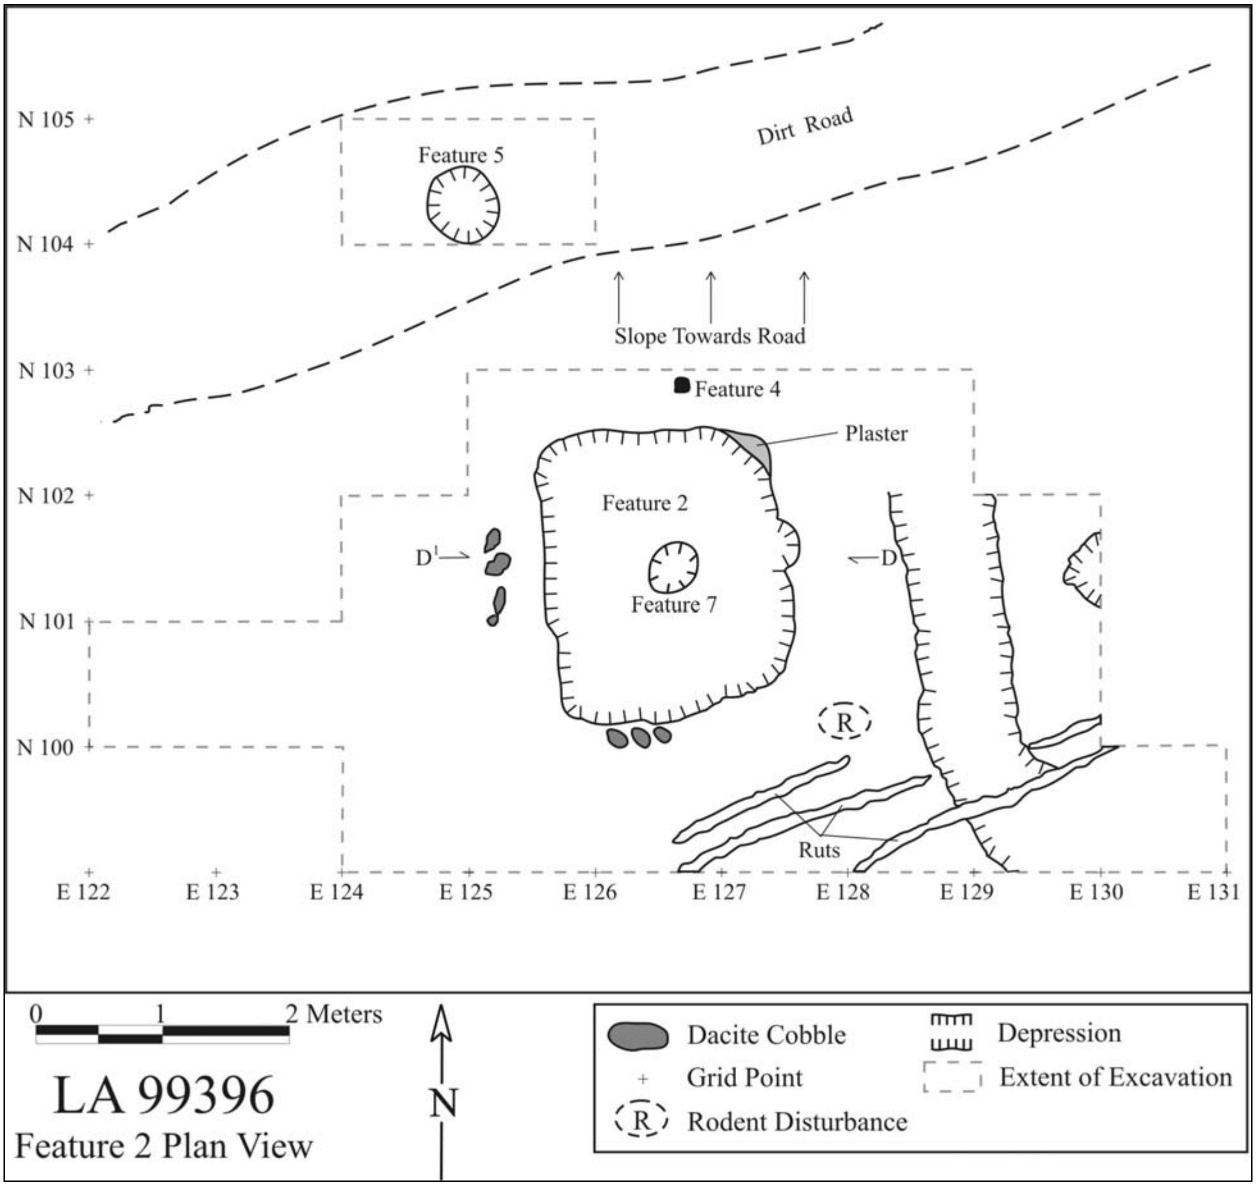

Figure 47.8. Plan view of Feature 2.

Figure 47.9. Photograph of Feature 2 at LA 99396.

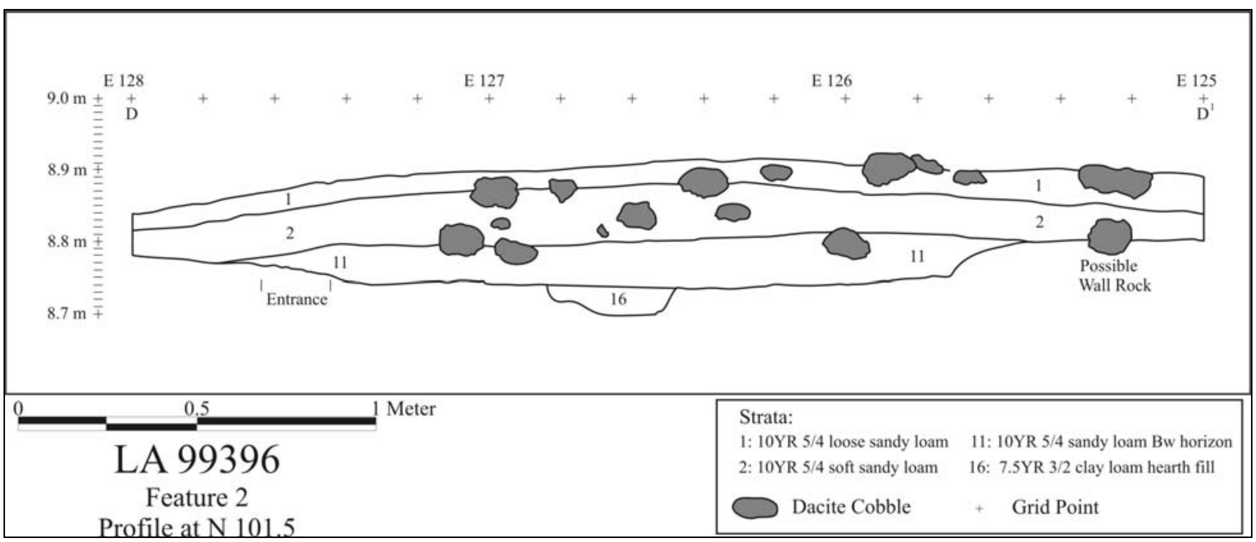

Figure 47.10. Profile of Feature 2 at LA 99396.

The subterranean walls are 5 to 12 cm high and are outwardly sloped. The western wall is slightly longer than the eastern wall; their respective lengths are 2.2 m and 1.9 m. All the walls are straight except for the east wall, which is slightly concave. A thin coat of plaster is present in the northeast corner of Feature 2. Near the center of the east wall (101.6N/127.5E), a 40-cm-wide gentle slope extends from the floor to the top of Stratum 3. The soil along this slope is highly compacted. This is the entrance of the structure.

No standing walls were encountered, but several unshaped dacite cobbles were found set into Stratum 3 just outside the subterranean portion of Feature 2. A set of three adjacent cobbles is present to the south, and a second three-cobble set is present on the west. These cobbles probably formed the base of the structure's above-ground walls, although they are separated from the subterranean walls by 5 to 30 cm.

About 1 m east of Feature 2, there is a narrow, shallow depression running roughly north-south. The depression is 70 to 80 cm wide and up to 8 cm deep. The depression runs from about 102N to 99N, and at both the north and south ends the top and base of the depression gradually converge to a single surface. Three roughly parallel narrow furrows cut across the depression, from about 100N/130E to 99.2N/126.7E. These furrows are 5 to 10 cm wide and 3 to 5 cm deep. It is not know if the depression is the result of natural or cultural activities. The furrows appear to be cultural in origin, but it is unclear if they are associated with homesteading activities (e.g., plow scars), with the creation of the road (e.g., marks from a backhoe), or with some other activity. Table 47.4 summarizes the artifacts found in Features 1, 2, and 7.

Table 47.4. Features 1, 2, and 7 artifact counts by stratigraphic units.

Stratum	Ceramics	Chipped Stone	Ground Stone	Total
0	2	6	0	8
1	7	56	0	63
2	13	179	2	194
11	0	75	2	77
16	15	12	0	27
Total	**37**	**328**	**4**	**369**

Four ground stone artifacts were found in Feature 2: a dacite two-handed mano (FS 420), a dacite ground stone fragment (FS 461), a welded tuff grinding slab (FS 697), and a dacite grinding slab (FS 723). A dacite one-handed mano (FS 467) was found just west of Feature 2 in unit 101N/124E. A small piece of mica schist (FS 380) was found just north of Feature 2 in unit 103N/125E.

Three flotation samples (FS 438, FS 493, and FS 712) were analyzed from Feature 2. Charred taxa identified in the samples included unknown conifer, piñon pine, unidentified pine bark, and juniper wood.

Feature 3

Feature 3 (Figure 47.11) is a low circular mound approximately 10 cm high and 3 m in diameter. The northern side of the feature is slightly truncated by the dirt road. The tops of about two dozen unshaped dacite cobbles were visible on the surface of the mound before excavation. Five units were excavated to explore this feature (99N/117E, 99N/118E, 100N/116E, 100N/118E, and

101N/118E). Excavation revealed a loose jumble of about 60 unshaped cobbles. Most of the cobbles are dacite; a few are tuff. The cobbles are similar in size to those in Feature 1. The stratigraphy of Feature 3 consists of 1 to 2 cm of Stratum 1 overlaying 10 to 15 cm of Stratum 2. Excavation ended at the top of Stratum 3 where considerable rodent disturbance was visible. All of the cobbles were found in Strata 1 and 2. The bases of most of the cobbles are about 10 cm above the top of Stratum 3, although a few cobbles are within 2 cm of the Btb1 horizon.

Figure 47.11. Post-excavation photograph of Feature 3.

Only six artifacts were found in or near Feature 3: a sandstone mano fragment (FS 487) and five pieces of debitage.

The cobbles of this feature formed no discernable alignments and no cultural deposits were found beneath the cobbles. The Feature 3 cobbles were probably once part of the Feature 1 walls. Feature 3 was probably formed by field clearing associated with the Serna Homestead or during road construction activities.

Feature 7

Feature 7 is a circular hearth at the center of Feature 2 (101.38N/126.66E). It measures 51 cm north-south and 44 cm east-west and is 8 cm deep. The hearth is not plastered or rock-lined, although a small rock was found at its base. The walls and base are simply exposed Stratum 3 sediment. The north wall is well-baked and a sample was taken from it for archeaomagnetic dating. In contrast, the south wall and the base of the hearth are not well defined; consequently the north-south and vertical dimensions given above may be several centimeters too large. The fill of the hearth (Stratum 16) is clay loam mixed with charcoal flecks. No ash was present. Excavation of the hearth ended at 8.53 m, but artifacts were found only as deep as 8.55 m. The artifacts recovered from Feature 7 are discussed above as part of Feature 2.

The error ellipse of the archaeomagnetic sample overlaps two segments of the Wolfman calibration curve: AD 1020–1085 and AD 1175–1260. Based on the archaeomagnetic result and on the ceramic assemblage, the later age range is the most likely (Chapter 66, Volume 3).

Two pieces of wood charcoal from flotation samples (FS 753 and FS 758) taken from Feature 7 were submitted for radiocarbon analysis. FS 753 returned an age of 930±40 BP (Beta-199379) and a date of cal AD 1050, cal AD 1000, and cal AD 1140 with a two-sigma date range of cal AD 1020–1200. FS 758 returned an age of 870±40 BP (Beta-199380) and a date of cal AD 1180 with a two-sigma date range of cal AD 1040–1260.

Two flotation samples (FS 753 and FS 758) were analyzed from Feature 7. Charred taxa identified in these samples included unknown conifer, piñon pine, and ponderosa pine.

Feature 4

Feature 4 is located just north of Feature 2 at 102.88N/126.77E. It is a chunk of charcoal that appears to be the remains of a burned post. The charcoal is roughly a half-cylinder 12 by 6 cm wide and 10 cm tall. Most of this charcoal was buried in Stratum 3; only a few fragments stuck up into Stratum 2. The wood was identified as cf. piñon pine.

A portion of this feature (FS 472) was submitted for radiocarbon analysis. The sample returned an age of 810±60 BP (Beta-199376) and a date of cal AD 1240 with a two-sigma date range of cal AD 1050–1100 and cal AD 1140–1290.

Feature 5

Feature 5 is an oval-shaped hearth located north of Feature 2 in the middle of the dirt road (Figure 47.12). The hearth is centered at 104.40N/125.00E and measures 80 cm north-south and 60 cm east-west and is 7 cm deep. A 1-cm-thick layer of Stratum 1 covered the feature.

The hearth consists of a shallow depression excavated into Stratum 3. Twenty-six unshaped dacite cobbles ranging in size from 3 by 3 cm to 20 by 9 cm were found throughout the fill of the hearth. Some of the cobbles are fire-cracked. It is not clear if all these cobbles are part of the base of the hearth, or if some of them once lined the walls. The top several centimeters of Feature 5 were destroyed when the road was created.

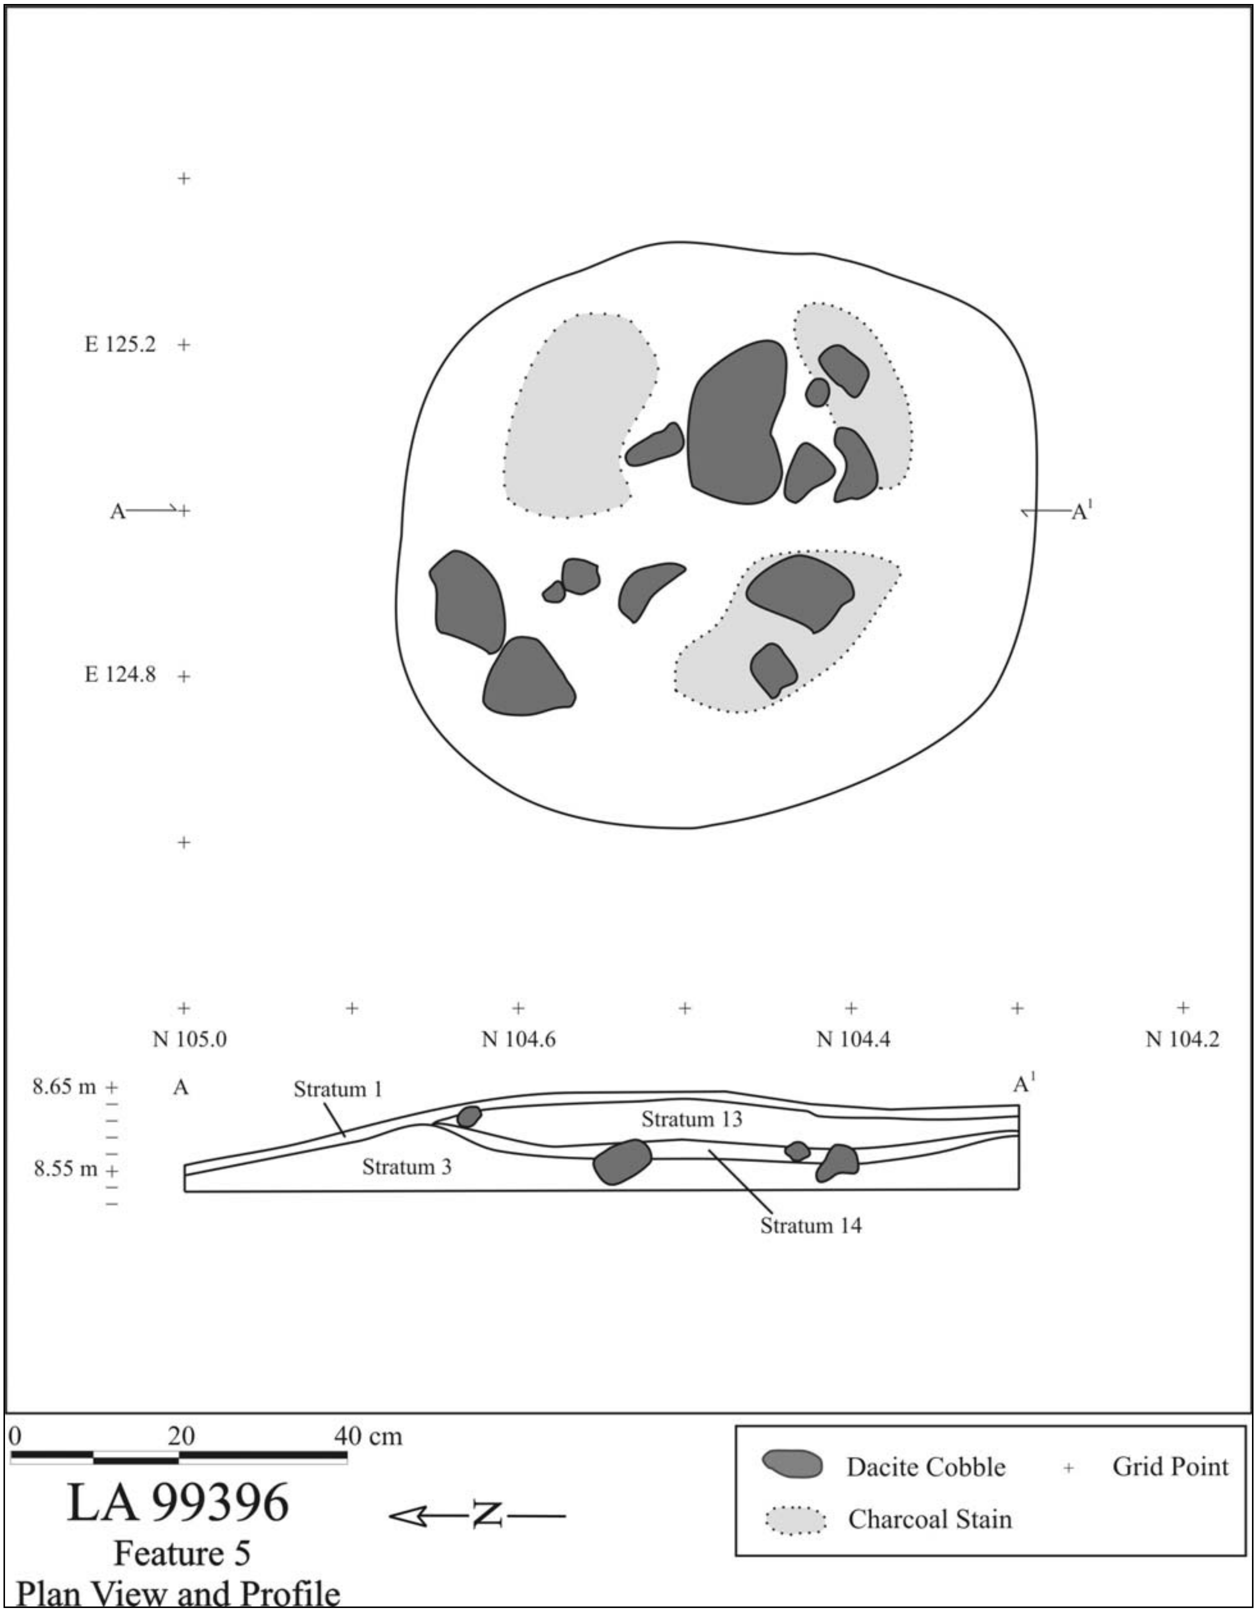

Figure 47.12. Feature 5 plan view and profile.

The upper fill of the hearth (Stratum 13) consists of 2 to 5 cm of silty clay loam. Below is a 1- to 2-cm deep deposit of sandy loam (Stratum 14). Both of these strata are charcoal-stained and contain charcoal fragments. These soils are oxidized, as is the Stratum 3 matrix surrounding the hearth. No ash was found in the hearth, nor was there evidence of a living/use surface around the feature. Two plain gray jar sherds (FS 614) were recovered from the hearth.

A piece of wood charcoal identified in a flotation sample (FS 608) from the hearth was submitted for radiocarbon analysis. The sample returned an age of 890±40 BP (Beta-199378) with a date of cal AD 1170 and a two-sigma date range of cal AD 1030–1240.

One flotation sample (FS 608) was analyzed from Feature 7. Charred taxa identified in the sample included purslane, unknown conifer, juniper, unidentified pine, and piñon pine.

Homestead Component. Approximately 20 m of several lengths of barbed wire form a rough northeast-to-southwest alignment near the southeast corner of the site. Most of the barbed wire is on the ground but occasionally it is wrapped around tree trunks. In these cases the barbed wire has been partially enveloped by the tree. The line defined by the barbed wire is parallel to the homestead patent boundary and is within 20 m of it. Since most of the southeastern patent boundary is located on a slope, it is not surprising that the fence-line is located on the nearest level ground. No other Homestead Era artifacts were found.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 1488 artifacts were analyzed from the excavations conducted at LA 99396. In addition, flotation and pollen samples were selected for analysis from Strata 1, 2, 11, 13/14, and 16. Charcoal was submitted for radiocarbon dating from Features 1, 4, 5, and 7 and Strata 6 and 18. A burned piece of the hearth was submitted for archaeomagnetic dating, two sherds were submitted for thermoluminesence (TL) dating, and 14 pieces of obsidian were submitted for hydration dating (Table 47.5). The results of the artifact and sample analyses are presented in the following sections.

Table 47.5. Samples selected for analysis from LA 99396.

Stratum	Sample Type			
	Flotation	Pollen	Radiocarbon	TL
1	438	439		
2	493	411, 450, 506, 532, 555	493	414, 612
3			472	
6			775	
11	712	562, 676		
13/14	608	615	608	
16	753, 758	769	753, 758	
18			774	

Chronology

Radiocarbon Dating

Five burned piñon pine samples and two burned juniper samples were submitted for radiocarbon dating (Table 47.6). Most of the dates are associated with the occupation of the one-room structure (Feature 2); however, two samples were also submitted from geologic contexts (Strata 6 and 18). The calibrated intercepts are between circa AD 1140 to 1240, reflecting an Early to Middle Coalition period occupation. Geologic dates were derived from Stratum 6 (a swale fill Bwb1 soil horizon) and Stratum 18 (a Btkb1 soil horizon).

Table 47.6. Radiocarbon dates from LA 99396.

FS	Context of sample	Laboratory (Beta)#	Conventional radiocarbon age	Intercept of radiocarbon age	Two-sigma calibrated result
472	Feature 4 (Post)	199376	810±60	AD 1240	AD 1050–1100 AD 1140–1290
493	Feature 1, Stratum 2	199377	860±40	AD 1190	AD 1040–1260
608	Feature 5 (Hearth)	199378	890±40	AD 1170	AD 1030–1240
753	Feature 7 (Hearth)	199379	930±40	AD 1050 AD 1100 AD 1140	AD 1020–1200
758	Feature 7 (Hearth)	199380	870±40	AD 1180	AD 1040–1260
774	Stratum 18	199381	33660±320	N/A	N/A
775	Stratum 6	199382	1000±40	AD 1020	AD 980–1060 AD 1080–1150

Archaeomagnetic Dating

A single archaeomagnetic sample was taken from the hearth (Feature 7) in the one-room structure (Feature 2). Blinman and Cox (Volume 3, Chapter 66) state that the best date for the last burning of the hearth is AD 1175–1260, which corresponds with the radiocarbon dates (Table 47.7).

Table 47.7. Archaeomagnetic date from LA 99396.

Sample Number	Feature	VGP* Curves and Date Estimates (AD)	
		Wolfman	**SWCV2000**
1233	Feature 7, Hearth	1175–1260 1020–1085	1010–1125 1155–1320

*Virtual Geomagnetic Pole

Thermoluminescence Dating

A Santa Fe Black-on-white (FS 414) and incised corrugated sherd (FS 612) were submitted for TL dating (Table 47.8). Both sherds came from within the one-room structure. The age for the Santa Fe Black-on-white sherd seems quite early, whereas, the corrugated sherd fits the range provided by the radiocarbon and archaeomagnetic dates.

Table 47.8. Thermoluminescence dates from LA 99396.

FS	Lab #	Context	Burial depth (cm)	Age (ka)	% error	Years AD
414	UW1246	Feature 1, Stratum 2	10	1.169±0.134	11.5	836±134
612	UW1247	Feature 1, Stratum 2	22	0.847±0.062	7.4	1158±63

Figure 47.13 shows all the dates derived from within and around Feature 2. The radiocarbon dates, the archaeomagnetic date, and one of the TL dates are in agreement.

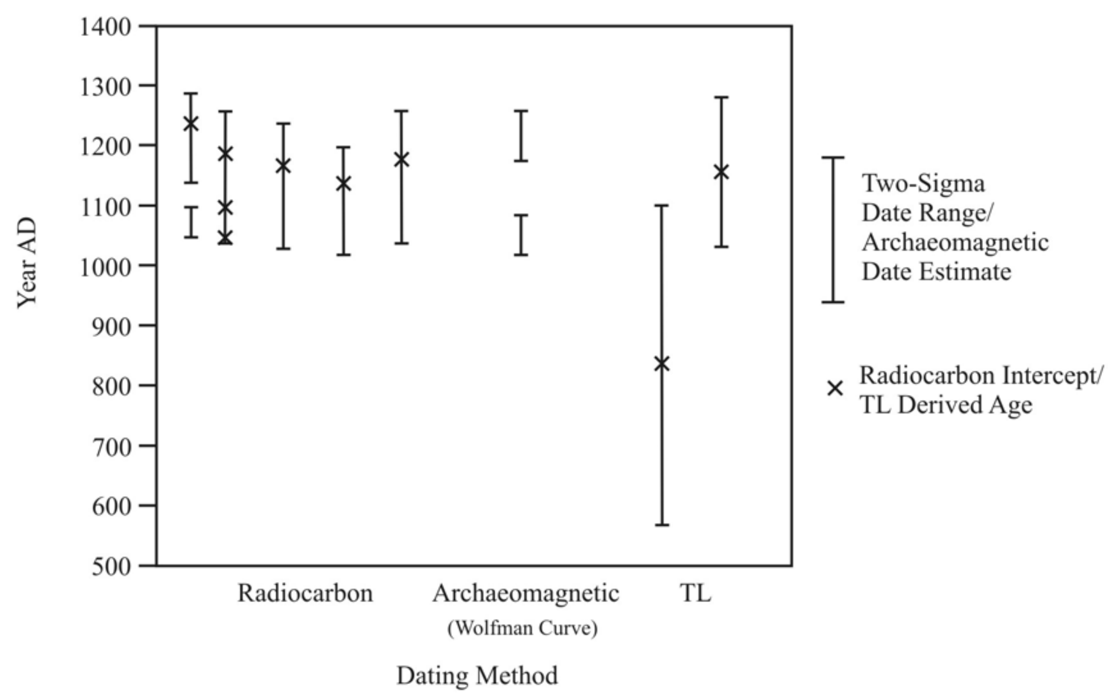

Figure 47.13. Dating methods comparison from LA 99396.

Obsidian Hydration Dating

Fourteen obsidian artifacts from LA 99396 were submitted for age determination using the obsidian hydration dating method. In order to calculate the absolute date for an obsidian artifact, three analytical procedures were completed. First, the amount of surface hydration, or the thickness of the hydration rim, was measured. Second, the high-temperature hydration-rate constants for each artifact were determined from the composition of the glass. Lastly, the soil temperature and relative humidity at the site were estimated so that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. Using these methods, a hydration rate for the obsidian artifacts was calculated (Table 47.9).

Table 47.9. Obsidian hydration dates from LA 99396.

FS No.	Lab No.	Source	Rim (um)	AD/-BC	1 S.D.
38	2006-17	Cerro Toledo	5.56	-10,245	443
48	2006-18	Cerro Toledo	3.95	-4244	317
54	2006-19	Cerro Toledo	3.88	-4009	311
126	2006-20	Cerro Toledo	4.44	-5599	344
186	2006-21	Cerro Toledo	3.32	-2228	256
289	2006-22	Valle Grande	4.16	-4803	328
318	2006-23	Valle Grande	3.30	-365	143
354	2006-24	El Rechuelos	n/a		
385	2006-25	Cerro Toledo	2.88	-1350	233
397	2006-26	El Rechuelos	n/a		
402	2006-27		3.75	-3646	302
430	2006-28	El Rechuelos	2.95	-1422	233
501	2006-29	Valle Grande	3.39	-2610	273
546	2006-30	El Rechuelos	2.13	187	169

The obsidian artifacts were selected from the surface scatter on the site. The obsidian hydration dates range from 10,245 BC to AD 187; however, most are distributed between from 5599 to 1350 BC. Excluding the 10,000 BC date, the remainder consists of four Early Archaic, three Middle Archaic, and four Late Archaic dates. This corresponds with the presence of several Archaic projectile point bases that were recovered from the same area of the site. This includes a possible Bajada point recovered during the initial test excavations by Peterson and Nightengale.

Ceramic Artifacts (Dean Wilson)

Eighty-five ceramic artifacts were analyzed from LA 99396; most of these artifacts were found near or in the one-room structure (Feature 2). The majority of the pottery consists of smeared-indented corrugated and Santa Fe Black-on-white sherds, which indicate a Coalition period occupation (Table 47.10). The utilitywares and whitewares are primarily tempered with anthill sand and tuff, respectively, and most of the utilitywares are jars and all the whitewares are bowls. One of the utilityware sherds is classified as a bowl rim and two sherds are from a miniature pot (Tables 47.11 and 47.12).

Table 47.10. Ceramic types from LA 99396.

Ceramic Type	Frequency	Percent
Northern Rio Grande Whiteware		
Unpainted undifferentiated	12	14.1

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 1401 artifacts were analyzed from LA 99396, consisting of two cores, 1366 pieces of debitage, 23 retouched tools, nine ground stone artifacts, and a hammerstone. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Tables 47.13

and 47.14 present the data on lithic artifact type by material type. Table 47.13 represents the surface artifact assemblage at the site, and Table 47.14 consists of the lithic artifacts recovered during the excavation of Features 2 and 7. In both cases, the majority of the debitage is made of obsidian, with lesser amounts of chalcedony, Pedernal chert, and other materials. The retouched tools are also primarily made of obsidian. The presence of cortex on 6.4 percent of the debitage indicates that these materials were collected from mostly nodule (*n* = 80) with some waterworn (*n* = 8) sources. Most of the nodule cortex was observed on the obsidian artifacts. Although obsidian is present at nearby primary sources in the Jemez Mountains, it is also present on the mesa to the north of the site as small pebbles. These pebbles compose part of the secondary deposits associated with the Cerro Toledo interval. For example, the obsidian core is a pebble that might have been obtained from this local source. On the other hand, the chalcedony and Pedernal chert are available from local Rio Grande Valley gravel sources. Otherwise, the igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the plateau.

Fourteen pieces of debitage, a core, and nine retouched tools were submitted for X-ray fluorescence analysis. The artifacts represent a mixture of Valle Grande, Cerro Toledo, and El Rechuelos obsidian types (Table 47.15). The Valle Grande (Cerro del Medio) source area is located about 17 km (11 mi) and the Cerro Toledo (Rabbit Mountain/Obsidian Ridge) source area about 19 km (12 mi) as the "crow flies" to the west and southwest of the site. However, as previously noted, there are pebbles of Cerro Toledo obsidian that are also present on the mesa top, and the pebble core is made of Cerro Toledo obsidian. The El Rechuelos (Polvadera Peak) source area is located approximately 27 km (17 mi) to the northwest.

Lithic Reduction

The two cores were reduced using a bidirectional, multi-face technique. One is a small obsidian pebble core and the other is a large rhyolite cobble core. The presence of an obsidian bipolar flake indicates that this technique was also being used to reduce small pebbles. Table 47.16 presents the metric information on these cores.

Table 47.16. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Bi-directional	36	27	17	18.2

Core Type	Length	Width	Thickness	Weight
Bi-directional	86	98	52	376.9

The debitage mainly consists of core flakes, biface flakes, and microdebitage, with less angular debris and undetermined flake fragments. In addition, a single bipolar flake, core trimming flake, *outrepassé* flake, and uniface flake were also identified. Table 47.17 summarizes the various stages of reduction represented by the whole core and biface (tertiary) flakes. The overall cortical:non-cortical ratio of 0.30 reflects the emphasis on the later stages of core reduction and tool production/maintenance. However, the presence of primary and secondary cortical obsidian flakes corroborates the possible use of local pebbles.

Table 47.17. Debitage reduction stages.

Material	Primary	Secondary Cortical	Secondary Non-cortical	Tertiary	Cortical: Non-cortical ratio
Obsidian	1	5	8	9	0.35
Chalcedony	0	0	2	2	---
Pedernal chert	0	2	5	0	0.40
Total	**1**	**7**	**15**	**11**	**0.30**
Percentage	2.9	20.5	44.1	32.3	---

The majority of the flakes exhibit crushed platforms (n = 94; 56.9%), with cortical (n = 9), single-faceted (n = 7), multi-faceted (n = 31), and collapsed (n = 24). The large number of crushed and collapsed platforms is associated with the reduction of obsidian. Forty-six (27.8%) of the flake platforms exhibit evidence of preparation. Most of these are abraded/crushed, with two ground and a single abraded/ground platform.

The majority of the core flakes consist of distal fragments (n = 167; 42.0%), with fewer whole (n = 23), proximal (n = 51), midsection (n = 131), lateral (n = 6), and undetermined fragments (n = 19). Most of the biface flakes are proximal (n = 112) and midsection (n = 103) fragments, with fewer whole (n = 11), distal (n = 71), lateral (n = 1), and undetermined (n = 5) fragments. The whole core flakes have a mean length of 18.6 mm (*std* = 5.6), and the whole biface flakes exhibit a mean length of 18.5 mm (*std* = 6.8). Lastly, angular debris have a mean weight of 1.8 g (*std* = 3.9).

The retouched tools primarily consist of formal tools like bifaces and projectile points, with fewer informal tools such as retouched pieces. Three of the retouched pieces exhibit a single marginally retouched edge, whereas two exhibit double retouched edges. The former consist of unidirectional ventral retouch along straight edge outlines with angles ranging from 55 to 65 degrees. The other two artifacts have unidirectional ventral, unidirectional dorsal, and alternate retouch along straight, straight/concave, and a projection with angles ranging from 60 to 75 degrees. Two uniface/scrapers were also identified during the analysis (Figure 47.14). Both are distal fragments with all or a portion of the working edge present and angles of 60 and 75 degrees.

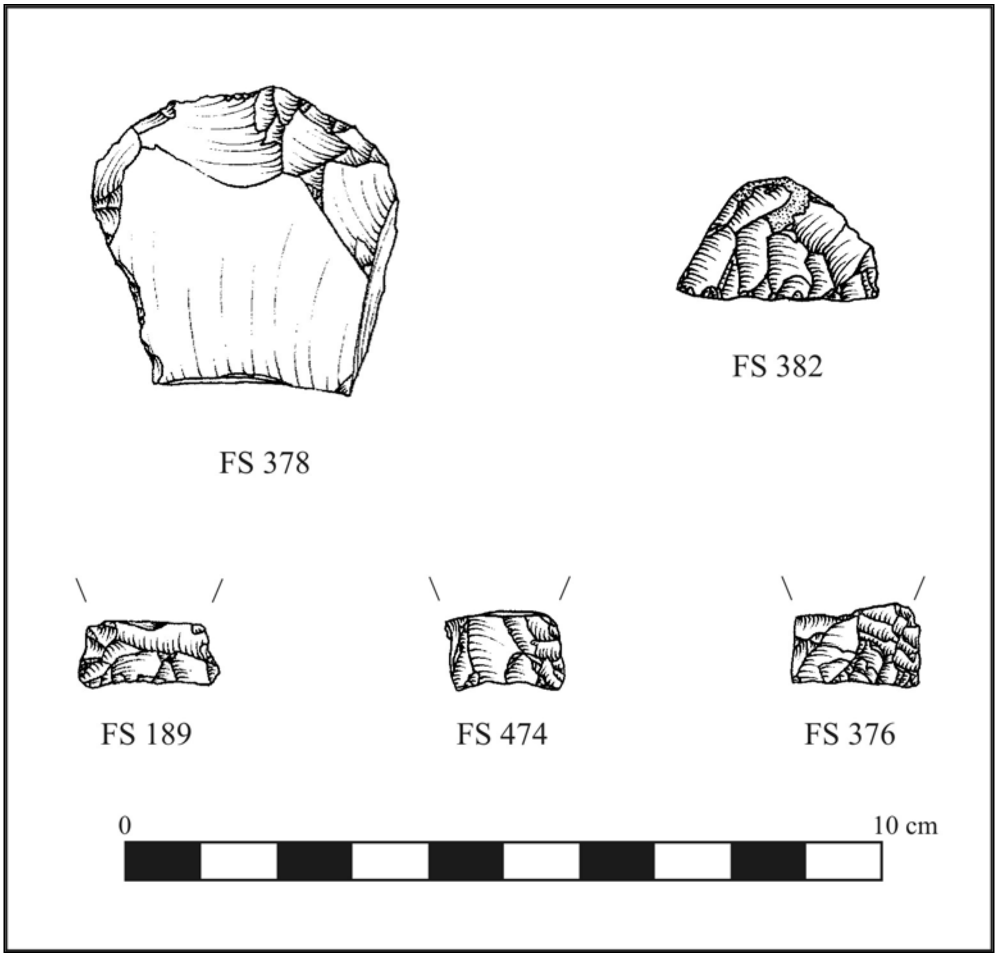

Figure 47.14. Uniface, endscraper, and projectile points.

The bifaces primarily consist of undetermined fragments, with a single piece being identified as distal fragment. Most of these appear to be early- to middle-stage bifaces that were presumably broken during manufacturing and therefore have edge angles ranging from 45 to 65 degrees. All four of the projectile points are proximal fragments with stems that contract towards the neck and have slightly concave bases that could represent either Middle or Late Archaic dart points (see Figure 47.14).

Tool Use

Only three flakes (0.8%) exhibit evidence of damage that could be attributed to use-wear. Two are flakes with damaged lateral edges and angles of 50 and 55 degrees. The other is a utilized projection on flake. Four of the five retouched pieces exhibit edge damage that could reflect use-wear and both of the scrapers have rounding and polish along the working edge. These lateral items were presumably broken during use. On the other hand, the biface fragments appear to have been broken during manufacturing, and the projectile points due to use.

Nine ground stone artifacts were identified during the analysis, including manos, a grinding slab, and undetermined fragments. The one-hand manos consist of a dacite cobble with a single ground surface and what appears to be a metate fragment that had been reworked into a mano. The possible two-hand mano consists of a broken dacite cobble with opposing grinding surfaces. The grinding slabs are made of tabular tuff and a large piece of dacite. The former item is rectangular-shaped with striations along the long axis and a slightly concave grinding surface. The latter artifact also has a slightly concave surface with evidence of grinding and polish. The undetermined metate fragment is also a large piece of dacite, but with a well-worn and slightly concave grinding surface. Lastly, the single undetermined piece of ground stone is a tabular piece of dacite with grinding and polish present along several high spots of one surface.

Archaeobotanical Remains (Pamela McBride)

Evidence from the use of the one-room structure, an extramural hearth, and the central hearth of the structure consisted of pine bark, piñon and ponderosa pine needles, an unidentifiable plant part, and one purslane seed (Table 47.18). Non-cultural plant material included weedy annual and dropseed grass seeds and juniper duff. The charred bark and needles are probably artifacts of firewood use. Piñon dominated the wood assemblage (present in 70% of samples by weight; Table 47.19). Small amounts of juniper, unknown conifer, and unknown non-conifer were also present. The post fragment from the structure was most likely piñon (Table 47.20). Economic activity at the site is reflected in the use of locally available wood taxa for fuel and building materials and the possible use of purslane for food although one charred seed could have been burned in the exterior hearth after being deposited there by vectors other than humans. Samples were not taken from the Archaic component.

Pollen Remains (Susan Smith)

Ten pollen samples were analyzed from LA 99396. Table 47.21 lists the frequency of identified pollen types. No cultigens were identified in the botanical assemblage. Prickly pear and lily family were the only other economic resources that were identified in the assemblage.

SITE SUMMARY

LA 99396 is a multicomponent site consisting of an Archaic period lithic artifact scatter and a Coalition period one-room fieldhouse. The artifact scatter probably represents a Middle to Late Archaic period campsite. The Coalition period fieldhouse was inhabited some time between the late 12th century and middle 13th century AD; however, evidence for cultigens is lacking from the site.

CHAPTER 48
RENDIJA TRACT (A-14): LA 99397

Brian C. Harmon

INTRODUCTION, SITE SETTING, AND SITE DESCRIPTION

LA 99397 is a Middle to Late Archaic period chipped stone debitage scatter that may have been a habitation site. The site may have been reused in the Classic period. LA 99397 is situated on the gentle east-facing slope of a narrow ridge at an elevation of 2136 m (7008 ft). The site covers an area of approximately 1500 m^2 (Figure 48.1) and is centered on a small clearing surrounded by dense piñon-juniper woodland. In May of 2000 the Cerro Grande fire burned 195 ha (480 ac) in the Rendija Tract. The central portion of LA 99397 was unburned, but severe burning occurred on the northern and northwestern periphery of the site. A dirt road runs east-west through the site.

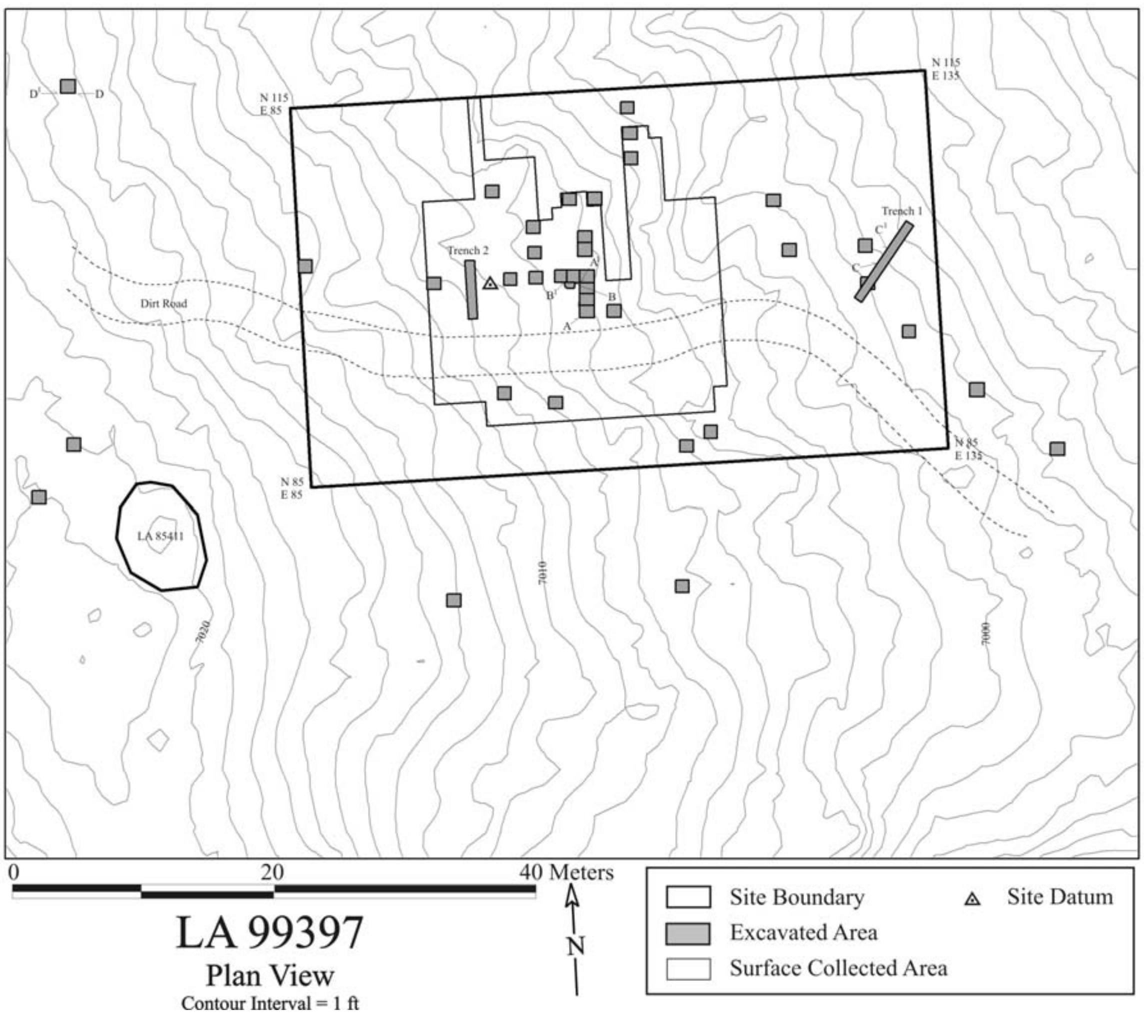

Figure 48.1. Plan view map of LA 99397.

The soil around LA 99397 is part of the Rendija-Bayo complex; a complex that "contains deep, well-drained soils weathered from materials derived from tuff (Rendija series) or pumice (Bayo series)," (Nyhan et al. 1978:54). The sediment consists of late-Holocene colluvial and eolian deposits, sporadically capped by surface gravel or a weak desert pavement. In most places, the late-Holocene deposits are 10 to 20 cm thick and overlay truncated late-Pleistocene or early-Holocene colluvium. Cerro Toledo gravels (Qct) underlie the soil on the ridge top just west of the site. Bedrock was not encountered within the site boundary.

Several large rills run through the site, generally trending to the east. The largest of these is in the eastern half of the site. It runs northeast from the dirt road for about 10 m before turning to the east. The north-running portion of the drainage is about 4.5 m wide and 0.4 to 0.5 m deep. Peterson and Nightengale (1993:212) defined this as the eastern boundary of the site.

Nearly all of the artifacts at LA 99397 were recovered from strata that post-date the Archaic period, indicating that they are in a reworked context. No cultural features were encountered and it is unlikely that any aspects of culturally derived site structure are present.

A Classic period fieldhouse (LA 85411) is located upslope and to the southwest of the site (Chapter 34, this volume). It is possible that some of the artifacts at LA 99397 are derived from this site.

PREVIOUS INVESTIGATIONS

LA 99397 was first recorded in 1992 by Peterson and Nightengale (1993:212–215) for the Bason Land Exchange Project. The initial site recording consisted of mapping, in-field analysis, surface collection, and shovel testing. Hoagland and Vierra (2002:5-18) summarize Peterson and Nightengale's testing as follows:

> The site covers an area of about 900 m^2. Fourteen shovel tests were dug at the site, with 10 pieces of debitage being recovered from six of the tests. These were located in the central area of the site with the highest surface artifact densities. These items were recovered from depths of up to about 40 cm. Artifacts were also collected from a 1- x 38-m transect laid out across the center of the site; [a total of 31 pieces of debitage were collected from the surface, and in-field observations were made on an additional 104 pieces of debitage]. Except for one metate fragment, all of the lithic artifacts observed were either debitage or chipped stone tools. Obsidian constituted 76 percent of the lithics with chalcedony forming the remaining 24 percent. A dusty obsidian similar to Polvadera Peak obsidian was most abundant (75%). The vast majority of the lithic debitage were tertiary flakes. In addition, three formal tools or tool fragments were collected from the site. They consist of a retouched Polvadera Peak obsidian tertiary flake, a crude lanceolate chalcedony biface, and the distal fragment of a Polvadera Peak obsidian biface or projectile point. A fragment of a metate was also observed on the site. Based on the high percentage of obsidian tertiary flakes and the lack of ceramics at the site, it presumably represents an Archaic period occupation.

The Los Alamos National Laboratory Cultural Resources Management Team visited LA 99397 in October of 2000 as part of the Cerro Grande fire Assessment Project (Nisengard et al. 2002).

FIELD METHODS

Most of the work reported here took place between August 12 and September 17, 2003; however, the site was sporadically visited until January 15, 2004. The crew consisted of Steven Hoagland (crew chief), Brian Harmon (assistant crew chief), Hannah Dodd, Mark Hungerford, Maria Jonsson, Michael Kennedy, Bettina Kuru'es, and Alan Madsen. Aaron Gonzales was the San Ildefonso tribal monitor. Leo Martinez operated the bobcat during trenching operations.

Work began at LA 99397 by establishing a grid based on true north (in actuality, the grid is about four degrees west of north). Once the grid was in place, a surface collection was made of 100 percent of the artifacts in the area that was clear of pine duff and trees. Artifacts were collected in 1- by 1-m grid units, and 457 units were included in the surface collection. Surface artifacts extend outside of the surface collection area, but the heavy duff and tree cover prevented collection in these areas. Excavation units were used to assess artifact densities in these areas.

Excavation units were initially placed in non-drainage areas that had the highest density of surface artifacts. Unit placement proceeded to move outwards, ending when units yielded two or fewer artifacts. Three units (85N/63E, 89N/66E, and 117.1N/67.3E) were not placed according to this strategy. During excavation it became apparent that many of the artifacts had likely been reworked into the A and Bw horizons, so the higher elevation to the west was investigated to determine if any *in situ* Archaic deposits were present. After the three units mentioned above failed to produce any artifacts, excavation in this area was discontinued. Excavation of the first several units indicated that while Stratum 3 (the Bt1b1 horizon) contained artifacts, Stratum 4 (the Bt2b1 horizon) did not. For this reason later excavation units were ended once Stratum 4 was reached.

After the site boundaries had been determined by excavation of 1- by 1-m units, two 0.80-m-wide trenches were dug by backhoe to expose long profiles of the site stratigraphy. Trench 1 was excavated to more clearly define the stratigraphy at the eastern end of the site. The western wall of Trench 1 was 7.15 m long and ran from 97.50N/128.50E to 103.25N/132.75E. The high density of the trees in this area prohibited the trench from being aligned with the grid. Trench 2 was located to expose the stratigraphy of the central portion of the site. It was 4.75 m long and ran from 97.50N/98E to 102.25N/98E.

STRATIGRAPHY

This section draws on Drakos and Reneau's geomorphological summary of the site (Chapter 57, Volume 3). Table 48.1 summarizes the stratigraphy at LA 99397; the individual strata are discussed in more detail below. Table 48.2 lists the artifact count by stratum.

Table 48.1. Stratigraphic summary of LA 99397.

Stratum	Provenience	Thickness (cm)	Color	Texture	Comment
0	Entire site	0	10YR 5/3	loam, sandy loam, loamy sand	Modern surface, sporadic gravel cap or weak desert pavement
1	Entire site	1–18	10YR 5/3	loam, sandy loam, loamy sand	A to Av horizon, late Holocene
2	Entire site	1–29	10YR 5/3	loamy sand, sandy loam	Bw horizon, late Holocene

[1]No cultural material was found below Stratum 3A.

The stratigraphy of LA 99397 consists of late-Holocene colluvial and eolian deposits (A and Bw horizons, Strata 1 and 2, respectively) with a discontinuous cover of desert pavement. Below the late-Holocene deposits are strata of late-Pleistocene or early-Holocene colluvium (Btb and Btk horizons). Stratum 3 (a Bt1b1 horizon) is truncated, indicating erosion at the site some time during the Holocene, before the deposition of the late-Holocene deposits (see Drakos and Reneau 2003; Figure 23). Artifacts were not found below Stratum 3.

The stratigraphic column of the west and central portions of the site (between 85E and 120E) consists of Strata 1 (mean thickness of 6 cm), 2 (mean thickness of 6 cm), 3 (mean thickness of 13 cm), and 4 (mean thickness of 20 cm), and 10 (40+ cm thick). In a few places, Stratum 3A is present above Strata 3. In this area, both Strata 1 and 2 are soft loamy sands and are approximately 20 percent and 5 percent gravel, respectively. Figure 48.2 shows the profile to the base of Stratum 3 along the 107E line.

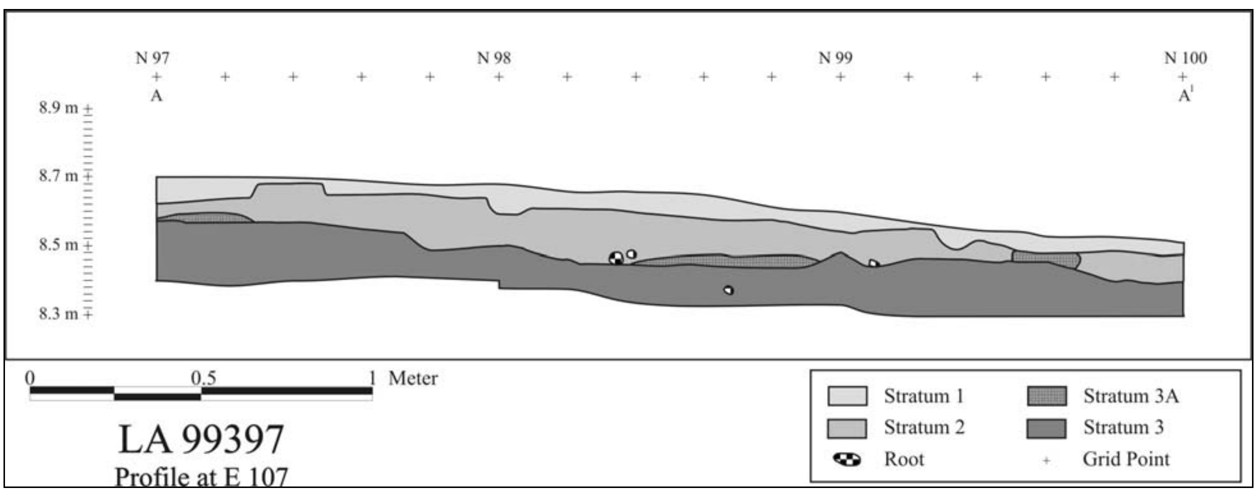

Figure 48.2. 107E profile at LA 99397.

The remains of a burned stump, consisting of fragments of charcoal and charcoal stained soil, were found at 100N/106.2E (Figure 48.3). Analysis of the charcoal indicated that the tree was likely a ponderosa pine (Chapter 62, Volume 3). The tree grew after the deposition of Stratum 3 and before the deposition of Stratum 1. The stump hole of the tree was filled with Stratum 2.

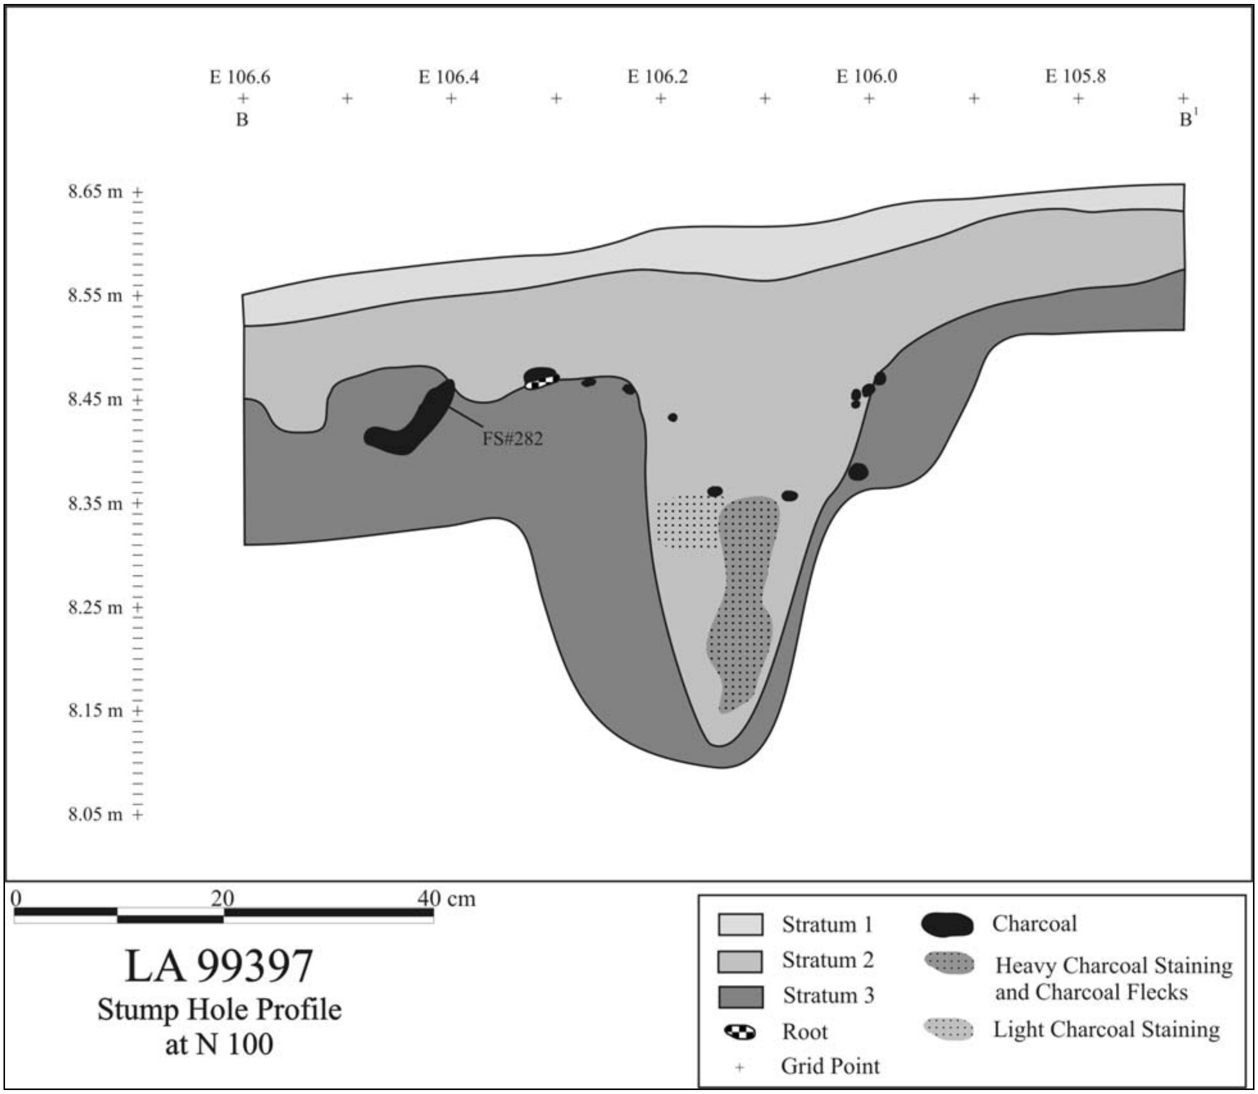

Figure 48.3. Profile of the stump hole at 100N.

One piece of wood charcoal from the burned stump (Field Specimen [FS] 282) and two pieces of wood charcoal (FS 211 and FS 214) from Stratum 3 were submitted for radiocarbon analysis. FS 211 was taken from unit 100N/95E and FS 214 was taken from unit 91N/100E; both samples were taken at an elevation between 9.60 and 9.50 m. FS 282 appears to be a sample of root wood. It returned an age of 880±40 BP (Beta-202213) and a date of cal AD 1180 with a two-sigma age of cal AD 1030–1250. This date supports the geomorphological interpretation that Strata 1 and 2 were formed within the last 1000 years. FS 211 returned an age of 2110±60 BP (Beta-199383) and a date of cal 160 BC with a two-sigma date range of cal 360–280 BC and cal 240 BC–AD 20. FS 214 returned an age of 2280±40 BP (Beta-199384) and a date of cal 380 BC with a two-sigma date range of 400–350 BC and 310–210 BC. Both of these dates are younger than the inferred late-Pleistocene/early-Holocene date of Stratum 3. The presence of this later material is probably the result of bioturbation and/or infiltration.

East of 120E, there is a subtle change in the stratigraphy. Strata 1 and 2 are present as sandy loams. Stratum 2 is generally thicker (mean thickness of 17 cm) and slightly harder than in the west. Stratum 1 consists of about 5 percent gravel and Stratum 2 is approximately 30 percent gravel. Strata 3, 4, 10, and 11 underlie Strata 1 and 2 (Figure 48.4).

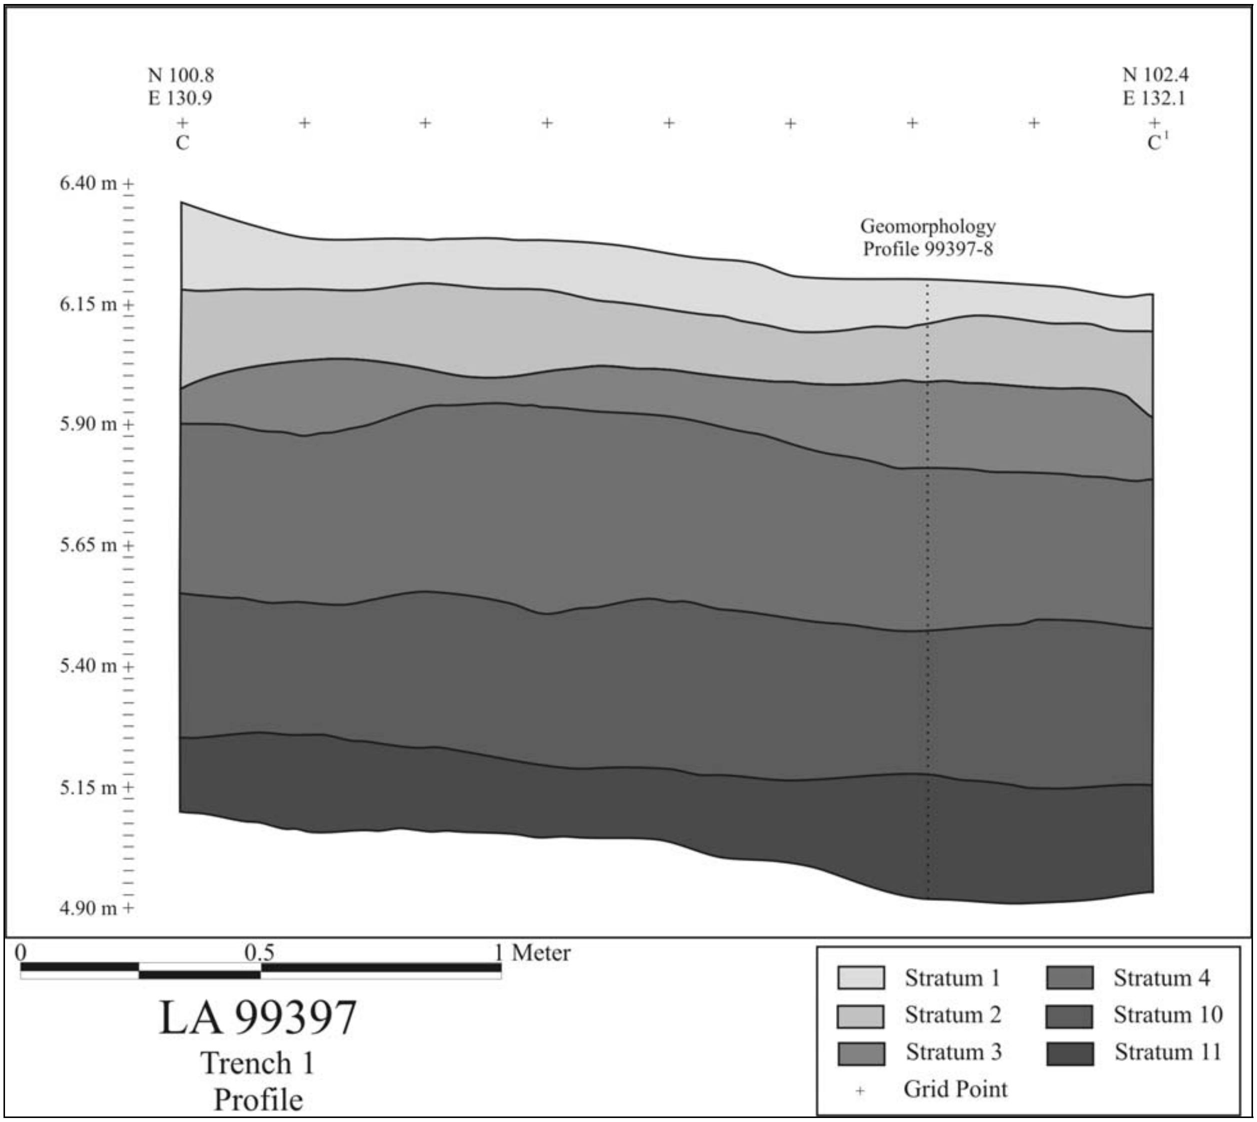

Figure 48.4. Profile of Trench 1.

Excavation in unit 98N/129E revealed swale fill deposits (Strata 8 and 9) underlying Strata 1 and 2. The presence of these deposits indicates the development of shallow drainages in the area and their subsequent filling by episodic deposition in the middle to late Holocene.

A piece of wood charcoal (FS 292) from Stratum 2 in unit 98N/129E was submitted for radiocarbon analysis. The sample returned an age of 530±40 BP (Beta-199385) and a date of cal AD 1420 with a two-sigma date range of AD 1320–1350 and AD 1390–1440.

The stratigraphy from the two units on the ridge top and near LA 85411 (85N/63E and 89N/66E) is similar to that from within the LA 99397 boundaries, although the Bw horizon (Stratum 2) is absent. Unit 117.1N/67.3E, however, represents a different stratigraphic pattern (Figure 48.5). This unit is capped by a 4-cm-thick AC horizon (Stratum 5) of fine pumice gravel. This is underlain by a 10-cm-thick A horizon (Stratum 1). The underlying Bw horizon (Stratum 7) is composed of soft to loose sand. Cerro Toledo (Qct) gravel bedrock (Stratum 6) was encountered approximately 25 cm below the surface.

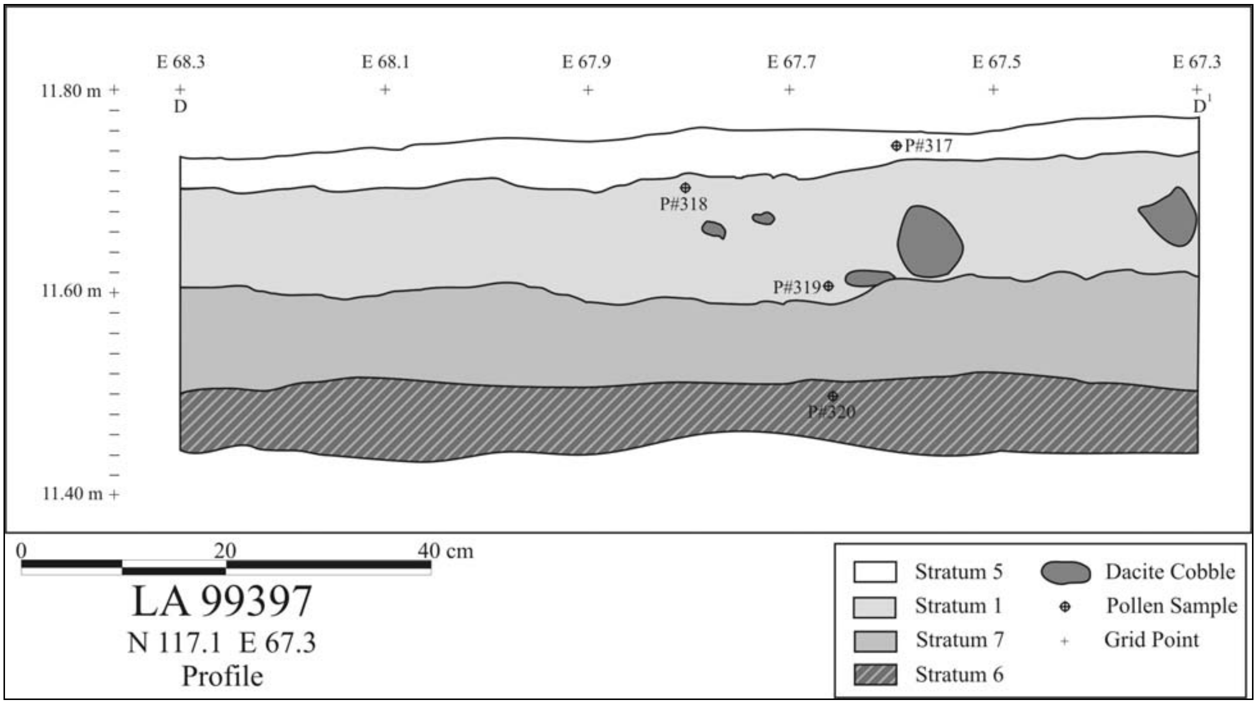

Figure 48.5. Profile of 117.1N/67.3E.

In summation, Stratum 3 and the underlying strata were deposited during the late Pleistocene or early Holocene. The parent material of these strata may be bioturbated Qct deposits and eolian fines. During the early to middle Holocene, the upper portion of Stratum 3 was removed by erosion. Sometime in the middle to late Holocene, shallow drainages developed in the site area and were subsequently episodically filled (Strata 8 and 9). Strata 1 and 2 were deposited during the late Holocene, probably within the last 1000 years.

SURFACE COLLECTION

The surface collection covered 453 1- by 1-m units in the center of the site. Outside of this area pine duff cover was too thick to undertake a meaningful collection. The distribution of the ground stone and lithic debitage collected from the surface is shown in Figure 48.6.

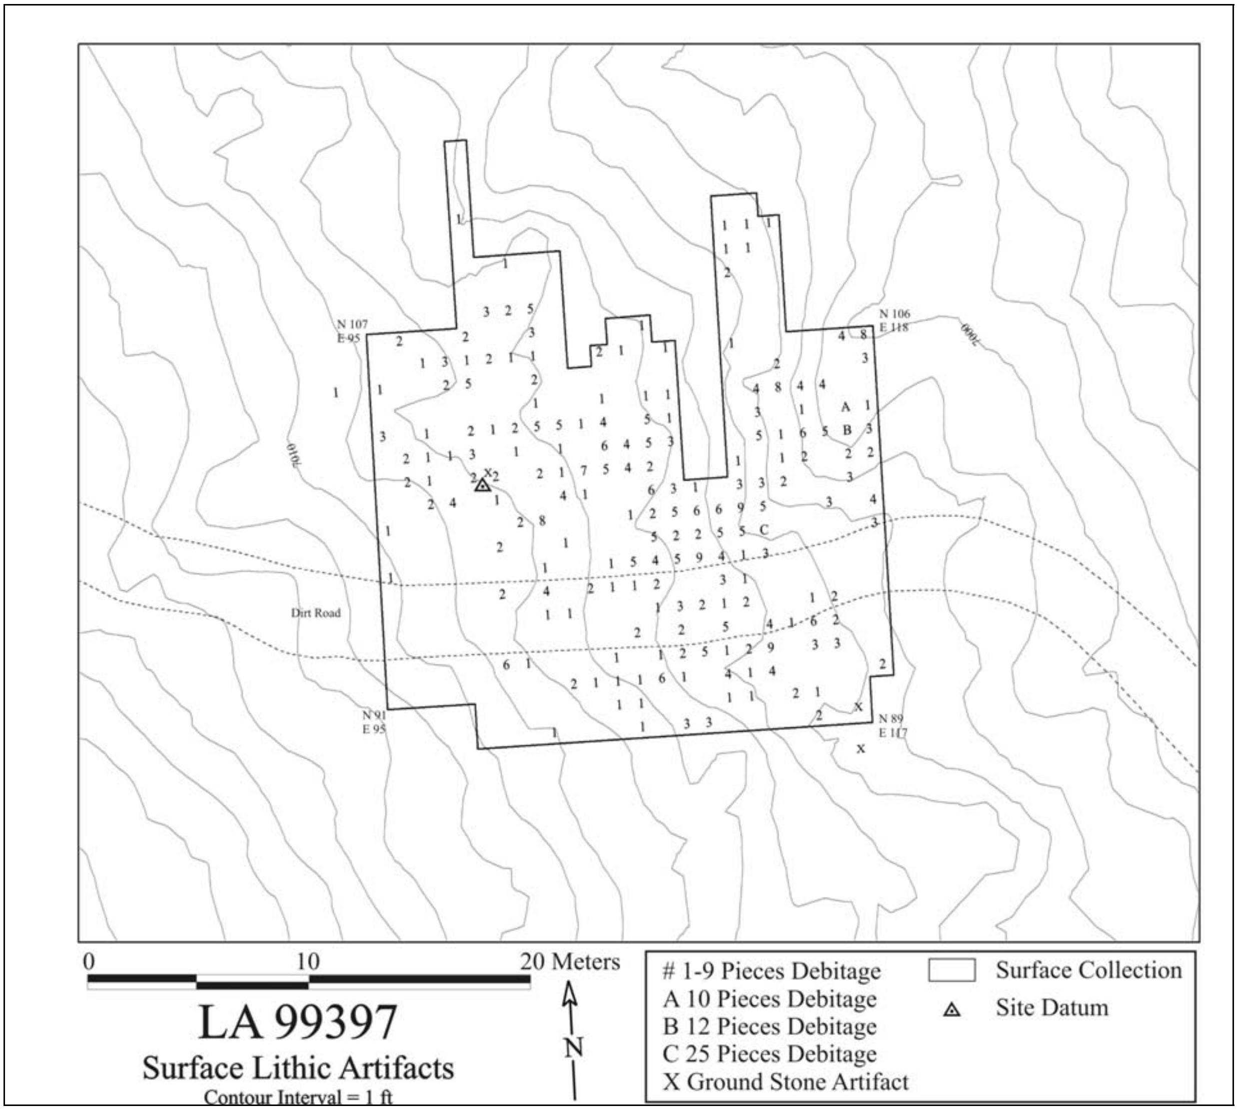

Figure 48.6. Surface artifact distribution.

Figure 48.6 shows that the densest concentration of artifacts is located just north of the road near the center of the surface collection area. Part of this concentration lies within a shallow rill and at the head of a larger erosional channel. Two smaller concentrations are also present; both are located in and near erosional channels. One is centered at 102N/115E, the other at 92N/112E. Note the area along the 103N line where there are few artifacts. A small erosional channel runs through this area, emptying into the northern "drainage concentration." In general, the distribution of the surface artifacts appears to have been shaped by erosional activity.

SITE EXCAVATION

One dozen excavation units were placed in the central artifact concentration (i.e., between 95 to 104N and 101E to 110E). Not surprisingly, subsurface artifact density was higher here than on the rest of the site (Table 48.3). Subsurface artifact density was moderately high in the five excavation units between 118E and 135E. Everywhere else artifact densities were very low. No artifacts were found in the three units west of 85E and east of 135E, and only four artifacts (including one ceramic sherd) were found in the two units south of 85N.

Table 48.3. Artifact density: chipped stone/m^3 by area.

	Central Concentration			East Area			Periphery[1]		
Stratum	Volume	Debitage	Density	Volume	Debitage	Density	Volume	Debitage	Density
1[2]	0.5225	158	302.4	0.3050	55	180.3	1.0675	65	61.0
2[3]	0.4650	122	262.4	0.6450	58	89.9	0.6275	22	35.1
3[4]	1.3575	50	36.8	0.2000	1	5.0	1.9100	6	3.1

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 1093 artifacts were analyzed from the excavations conducted at LA 99397. In addition, flotation and pollen samples were selected for analysis from Strata 1 to 4 and 9 (flotation) and Strata 1 to 7 and 9 (pollen) (Table 48.4). Charcoal was submitted for radiocarbon dating from Strata 2 and 3, and 10 pieces of obsidian were submitted for hydration dating from Stratum 0. The results of the artifact and sample analyses are presented in the following sections.

Table 48.4. Samples selected for analysis from LA 99397.

	Sample Type			
Stratum	**Flotation**	**Pollen**	**Radiocarbon**	**Hydration**
0				5, 12, 32, 43, 50, 60, 66, 67, 76, 77

Chronology

Radiocarbon Dating

Four charcoal samples were submitted for radiocarbon analysis (Table 48.5). Two of these are piñon pine wood (FS 211 and FS 214) and two are ponderosa pine wood. Although none of the samples can be associated with cultural activities they help refine the stratigraphic chronology.

Table 48.5. Radiocarbon dates from LA 99397.

FS	Context of Sample	Laboratory (Beta)#	Conventional radiocarbon age	Intercept of radiocarbon age	Two-sigma calibrated result
211	100N/95E, Stratum 3	199383	2110±60 BP	160 BC	360–280 BC 240 BC–AD 20
214	91N/100E, Stratum 3	199384	2280±40 BP	380 BC	400–350 BC 310–210 BC
282	100.00N/106.42E, burned tree stump (root)	202213	880±40 BP	AD 1180	AD 1030–1250
292	98N/129E, Stratum 2	199385	530±40 BP	AD 1420	AD 1320–1350 AD 1390–1440

Obsidian Hydration Dating

Ten obsidian artifacts from LA 99397 were submitted to the Diffusion Laboratory for age determination using the obsidian hydration dating method. All of these artifacts came from Stratum 0. In order to calculate the absolute date for an obsidian artifact, three analytical procedures were completed. First, the amount of surface hydration, or the thickness of the hydration rim, was measured. Second, the high-temperature hydration-rate constants for each artifact were determined from the composition of the glass. Lastly, the soil temperature and relative humidity at the archaeological site were estimated so that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. Using these methods, a hydration rate for the obsidian artifacts was calculated (Table 48.6).

Table 48.6. Obsidian hydration dates for LA 99397.

FS No.	Lab No.	Source	Rim (um)	AD/-BC	1 S.D.
5	2006-31	Valle Grande	3.15	-1914	249
12	2006-32	Valle Grande	2.71	-1029	224
32	2006-33	Valle Grande	3.46	-2715	274
43	2006-34	Valle Grande	2.98	1527	29

60	2006-36	Valle Grande	2.80	1492	33
66	2006-37	Valle Grande	3.43	-2778	280
67	2006-38	Valle Grande	2.69	-903	216

FS No.	Lab No.	Source	Rim (um)	AD/-BC	1 S.D.
76	2006-39	Valle Grande	3.02	-1656	243
77	2006-40	Valle Grande	3.59	-3156	288

The obsidian hydration dates range from 3156 BC to AD 1527; however, they tend to cluster into two groups: 3156 to 903 BC (Middle to Late Archaic) and AD 1492 to 1527 (Middle to Late Classic).

Ceramic Artifacts (Dean Wilson)

Only three ceramic artifacts were recovered from LA 99397. All of these artifacts were identified as smeared-indented corrugated jar sherds; two came for Stratum 0 (FS 105 and FS 111) and one came from Stratum 1 (FS 230).

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 1090 lithic artifacts were analyzed from LA 99397, consisting of one core, 1068 pieces of debitage, 18 retouched tools, and three ground stone artifacts. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 48.7 presents the data on lithic artifact type by material type. The majority of the debitage and retouched tools are made of obsidian, with some chalcedony and other materials. The presence of cortex on 8.1 percent of the debitage indicates that most of these materials were collected from primary nodular sources (74.7%), with some from secondary waterworn sources. The obsidian is present at nearby sources in the Jemez Mountains. In contrast, the chalcedony and Pedernal chert are available from local Rio Grande Valley gravel sources.

Table 48.7. Lithic artifact type by material type.

Ten pieces of debitage were submitted for X-ray fluorescence analysis. All of these artifacts were identified as being obtained from the Valle Grande source (Table 48.8). The Valle Grande (Cerro del Medio) source area is located about 17 km (11 mi) as the "crow flies" to the west of the site.

Table 48.8. Obsidian source samples.

Lithic Reduction

The core consists of a bidirectional, bifacial core made on a chalcedony cobble. It exhibits waterworn cortex indicating that it was obtained from secondary gravel sources. The core was classified as exhausted when discarded. Table 48.9 presents the metric information on this core.

Table 48.9. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Bi-directional	51	36	18	29.5

The debitage mainly consists of biface flakes, core flakes, and microdebitage, with some undetermined flake fragments and angular debris. Table 48.10 summarizes the various stages of reduction represented by the whole core and biface (tertiary) flakes. The debitage assemblage is primarily composed of tertiary flakes, with less secondary non-cortical and cortical flakes. No primary flakes were identified. The overall cortical:non-cortical ratio of 0.41 reflects an emphasis on the later stages of core reduction and tool production.

Table 48.10. Debitage reduction stages.

Material	Primary	Secondary Cortical	Secondary Non-cortical	Tertiary	Cortical: Non-cortical ratio
Obsidian	0	9	8	13	0.42
Chalcedony	0	1	2	1	0.33
Total	**0**	**10**	**10**	**14**	**0.41**
Percentage	0	29.4	29.4	61.1	---

The majority of the flakes exhibit crushed platforms (*n* = 90), with cortical (*n* = 9), single-faceted (*n* = 38), dihedral (*n* = 4), multi-faceted (*n* = 26), and collapsed (*n* = 38) platforms. Fifty-six (27.3%) of the flake platforms exhibit evidence of preparation, with most of these being abraded/crushed and a few ground, abraded/ground, retouched, and retouched/abraded.

The majority of the core flakes consist of distal fragments (*n* = 145; 46.2%), with fewer whole (*n* = 21), proximal (*n* = 45), midsection (*n* = 86), lateral (*n* = 3), and undetermined (*n* = 14) fragments. Most of the biface flakes are also proximal fragments (*n* = 127; 38.6%), with fewer whole (*n* = 14), midsection (*n* = 99), distal (*n* = 85), lateral (*n* = 2), and undetermined (*n* = 2) fragments. The whole core flakes have a mean length of 20.4 mm (*std* = 8.2), whereas the whole biface flakes exhibit a mean length of 16.0 mm (*std* = 6.9). Lastly, angular debris have a mean weight of 1.4 g (*std* = 1.8).

The retouched tools consist of a mix of expedient flakes tools (i.e., retouched pieces) while the formal tools consist primarily of bifaces and projectile points (Figure 48.7). All the retouched pieces exhibit a single modified edge. The edges are unidirectional ventral (*n* = 1), unidirectional dorsal (*n* = 3), and bidirectional (*n* = 1) retouched, with straight (*n* = 5), concave/convex (*n* = 1), and undetermined outlines (*n* = 1). The edge angles range from 40 to 70 degrees, with a mean of 52.1 degrees (*std* = 11.1).

All eight bifaces are broken, consisting of three proximal, one lateral, and four undetermined fragments. Edge angles range from 35 to 65 degrees, with a mean of 52.5 degrees (*std* = 8.4). Most of these appear to have been broken during manufacture, with the range of edge angles indicating middle- to late-stage reduction. A review of Figure 48.8 indicates a modal distribution for biface platform angles, with peaks at 55 to 65 degrees, but an overall range from 40 to 80 degrees. This indicates that early-, middle-, and late-stage bifaces, and possibly bifacial cores, were being reduced at the site.

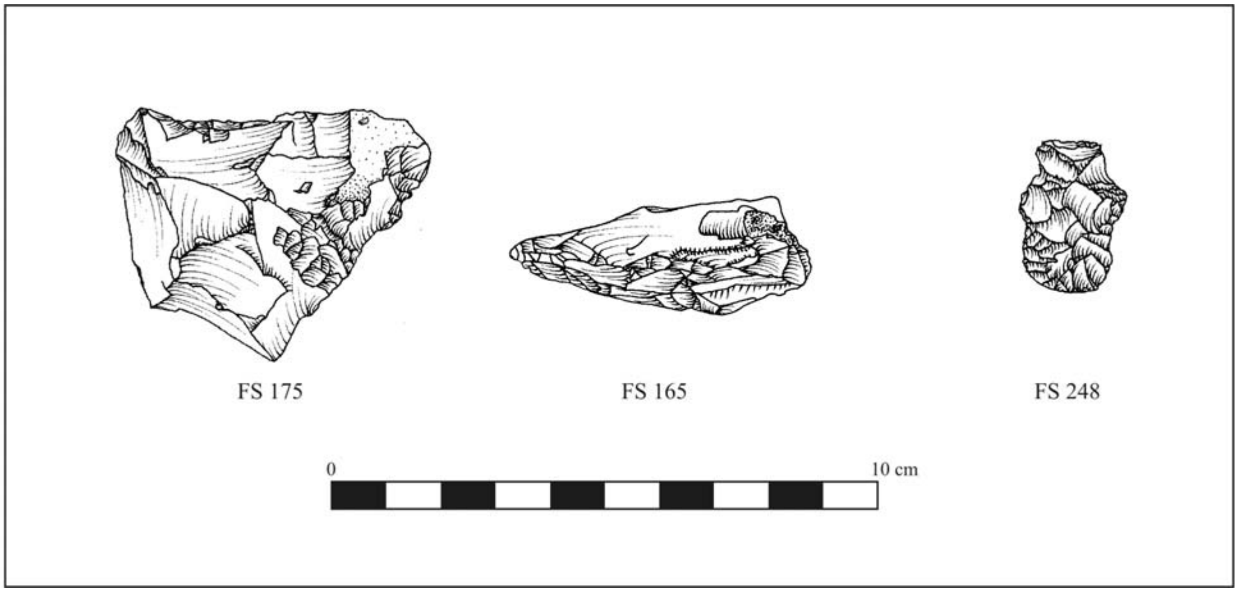

Figure 48.7. Retouched flake, biface fragment, and projectile point.

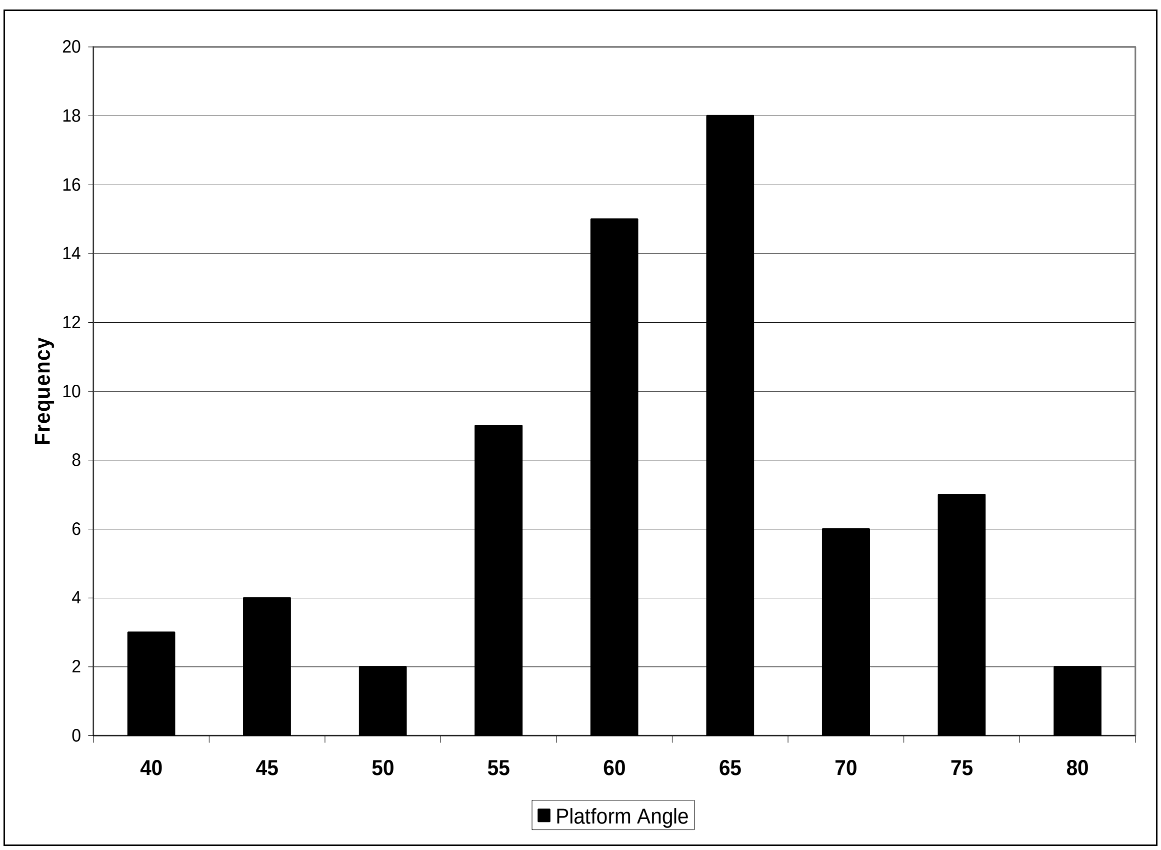

Figure 48.8. Biface platform angles.

The three projectile points consist of proximal, midsection, and distal fragments. The base fragment is a possible Late Archaic dart point with a snap break at the tip (see Figure 48.7). It exhibits marked tangs and was manufactured on a flake blank with a marked ventral curvature. Metric and descriptive information on the projectile points is presented in Table 48.11.

Table 48.11. Projectile point metric (mm) and descriptive data.

FS #	Material	Condition	Overall Length	Blade Length	Neck Width	Stem Length	Stem Width	Thickness	Weight (g)	Haft Type	Blade Shape	Base Shape
248	Obsidian	Proximal	--	--	11	7	--	4.9	2.7	Stemmed	Und.	Con-cave

Tool Use

None of the debitage exhibit evidence of damage that could be attributed to use-wear. In contrast, two marginally retouched flakes do exhibit evidence of edge damage consisting of rounding and scarring. One of these is a biface flake that is 25 mm long and the other is a large core flake that is 57 mm long (see Figure 48.7). In addition, two of the projectile points appear to have impact breaks.

Three millingstones were identified during the analysis. All three items are broken dacite fragments that have oval-shaped grinding surfaces that are concave in cross-section.

Archaeobotanical Remains (Pamela McBride)

Very little wood charcoal or other charred macrobotanical remains were found at LA 99397 and none of the remains could be linked to cultural activities. Seven flotation samples and six macrobotanical samples were submitted for analysis. Table 48.12 reflects the paucity of charred macorbotanical items at the site.

Table 48.12. Charred macrobotanical remains from LA 99397.

Pollen Remains (Susan Smith)

Thirteen pollen samples were analyzed from LA 99397. Table 48.13 lists the frequency of identified pollen types. Maize was the only cultigen identified in the botanical assemblage. Prickly pear, beeweed, and sunflower type were the only other economic resources that were identified in the assemblage. A number of potential economic resources were also identified in the assemblage (Table 48.13), and these are discussed in detail in Smith's chapter in Volume 3.

SITE SUMMARY

Obsidian hydration dates suggest Middle to Late Archaic period occupation of LA 99397. A Late Archaic projectile point fragment (FS 248) lends additional support to a Late Archaic period occupation. Two charcoal samples returned Late Archaic dates (FS 211 and FS 214); however these dates are several hundred years younger than the youngest obsidian hydration date and there is no evidence that these samples are the result of cultural activity. Nearly all of the artifacts recovered from LA 99397 come from Strata 0, 1, and 2. These strata do not appear to be older than AD 1000; consequently it seems likely that the LA 99397 Archaic assemblage is in a reworked context and that no culturally derived site structure patterns remain. Analysis of the lithic artifacts indicates that a wide range of core reduction and tool production/maintenance activities were performed at the site. LA 99397 may therefore represent a habitation site. All of the sourced obsidian is from the Valle Grande source, implying that the site inhabitants had geared up with obsidian from the caldera and then moved into the Rendija Canyon area.

Two obsidian hydration samples and a single radiocarbon sample returned Classic period dates. These dates may represent a Puebloan use of the site; specifically, this use may be associated with the nearby fieldhouse, LA 85411.

CHAPTER 49
RENDIJA TRACT (A-14): LA 127627

Michael J. Dilley and Bradley J. Vierra

INTRODUCTION

LA127627 is a small one-room Classic period fieldhouse situated on a northwest-facing slope of a terrace about 110 m south of the ephemeral creek in Rendija Canyon. The area is covered by a ponderosa pine forest at an elevation of 2117 m (6940 ft). The fieldhouse is located to the immediate north of the Los Alamos Sportsmen's Club, but did not appear to have been impacted by these activities.

The original survey identified alignments of unshaped dacite blocks, one to two courses in height, within a 3- by 3-m area that incorporated naturally occurring bedrock boulders. The alignments were situated in a section of the forest that was heavily burned by the Cerro Grande fire, including burned pine duff and ponderosa pine trees. No surface artifacts were observed.

FIELD METHODS

Fieldwork began with the cutting and removal of several burned ponderosa pine trees that were partially covering the site. A reconnaissance was subsequently conducted of the area around the fieldhouse to define the nature and extent of the surface remains. No artifacts or any other features were identified. The site datum was set at the southwestern corner of the site and designated as 100N/100E and 10.00 m elevation. A 1- by 1-m grid system was laid in around the surface architecture with grid corners at 101N/101E, 105N/101E, 105N/107E, and 101N/107E. Subdata were shot in along the north, east, and south sides of the excavation (A-C). The site was photographed and excavations begun (Figure 49.1).

An east-west-oriented trench was excavated across the site through grids 103N/101-106E. It was excavated to define the walls within the structure and identify the stratigraphic sequence. Upon completion, it was determined that the alignments represented a one-room structure. Excavations proceeded to expose the remaining walls of the structure and removal of the interior fill by stratigraphic layers and 1- by 1-m grids. A block excavation including grids 101-106N/103-106E was excavated around the room.

Pollen and flotation samples were taken from each stratigraphic unit and various locations on the floor of the structure. All excavated soil was sieved through 1/8-in. mesh to aid in the recovery of cultural remains. The immediate area bounding the structure was exposed to locate external features or outside activity areas. After excavations were complete, the site was mapped and photographed (Figure 49.2).

The excavation of the site was supervised by Michael Dilley. Crew members included Sandi Copeland, Maggie Dew, Alan Madsen, and Aaron Lenihan. Timothy Martinez, Aaron Gonzales, and Michael Chavarria served as site monitors representing both San Ildefonso and Santa Clara pueblos.

Figure 49.1. LA 127627 before excavation.

STRATIGRAPHY

Four stratigraphic units were defined during the excavations. These are illustrated in the profile provided in Figure 49.2 and are listed in Table 49.1. Stratum 1 is the loose topsoil that covered the site and represents the A soil horizon. Some of the surface duff had been burned by the Cerro Grande fire. Stratum 2 consists of a sandy loam that characterizes the post-occupational fill. This stratum is situated within and outside the structure and represents the Bw soil horizon. Stratum 3 is an unprepared occupational surface that is situated inside the structure.

A geomorphic test pit was excavated outside and adjacent to the structure in grid 103N/106E (see Chapter 57, Volume 3). It was excavated to a depth of about 1 m and four separate soil horizons were identified (Table 49.2). From top to bottom these horizons consisted of A, Bw, Bt1b1, and Bt2b1. The site is buried in a weakly developed soil in a colluvial deposit, but the Bw horizon has a hard consistency. The occupation surface at the site is situated at the top of the Bt1b1 horizon. Table 49.3 provides the artifact count information by stratigraphic unit at the site. A total of 173 artifacts were recovered.

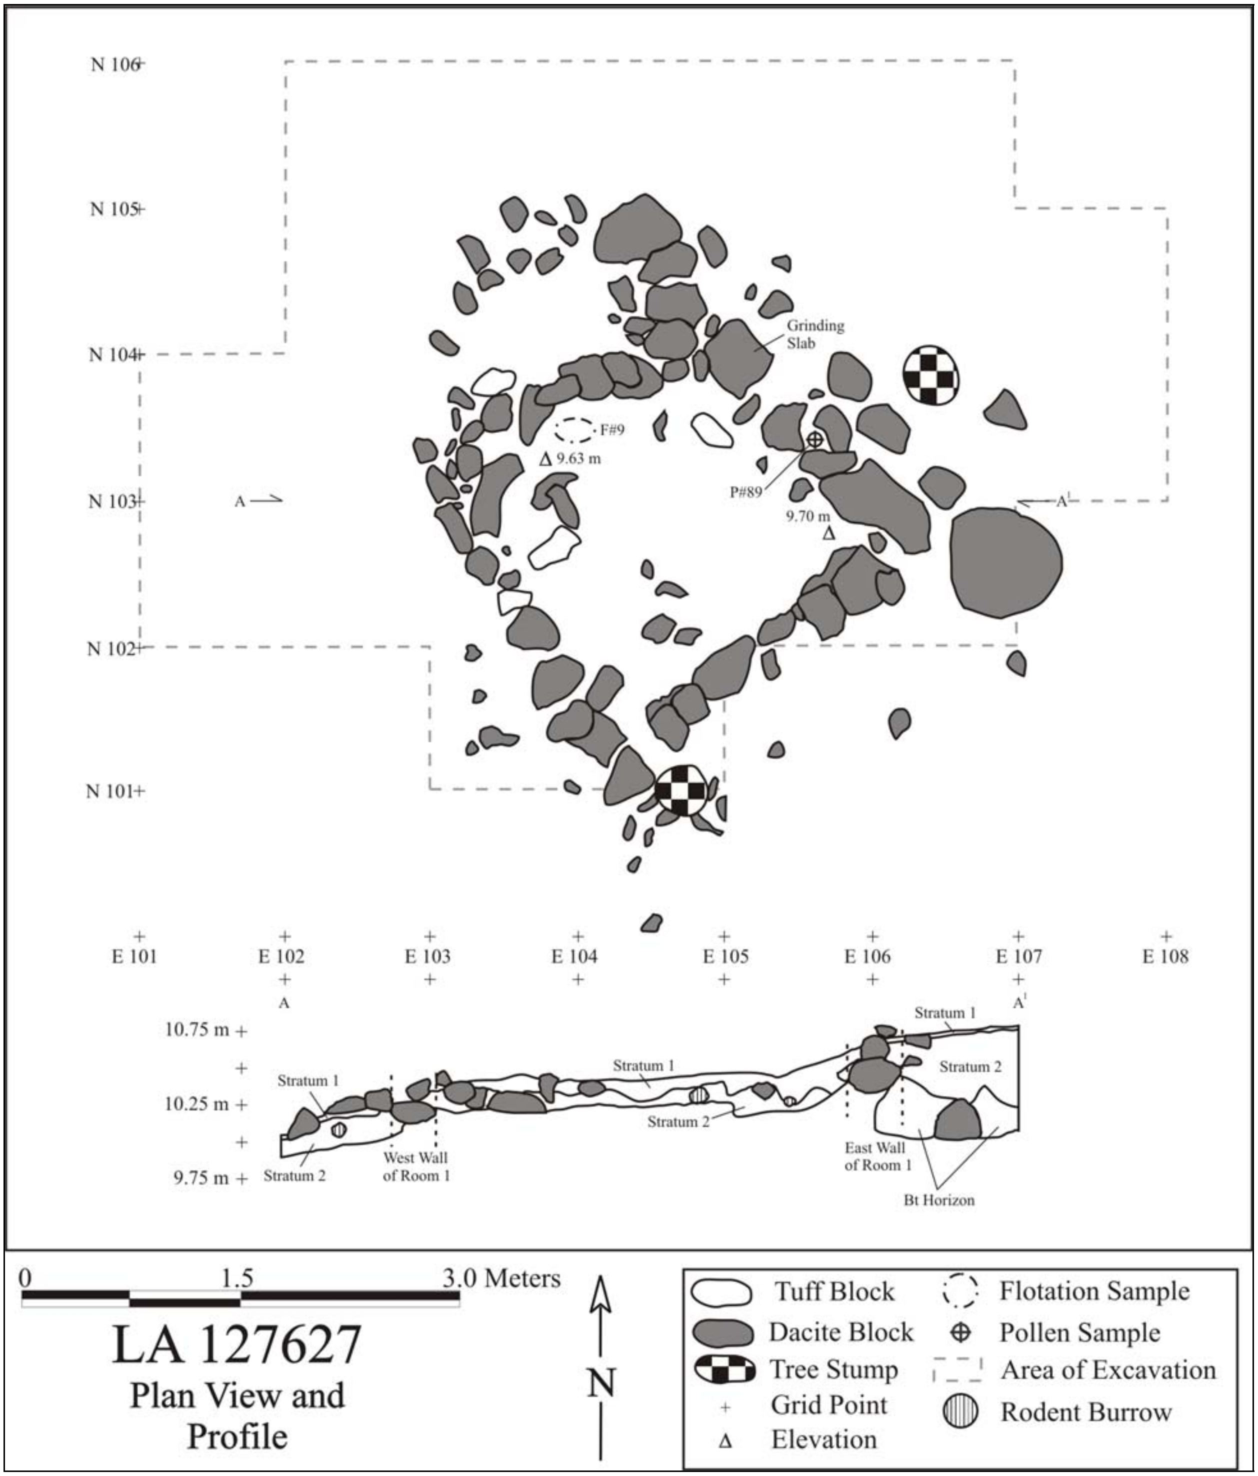

Figure 49.2. LA 127627 plan view and profile.

Table 49.1. LA 127627 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10YR 3/3	Sandy loam	1–6	Surface sediment
2	10YR 4.5/3	Sandy loam	5–30	Post-occupational fill
3	10YR 4.5/3	Sandy clay loam	0	Floor/living surface

Table 49.2. LA 127627 soil horizon descriptions from the south profile of the geological test pit.

Horizon	Color	Texture	Depth (cm)	Description
A	10YR 3/3	Sandy loam	0–5	Topsoil
Bw	10YR 4.5/3	Sandy loam	5–21	Late-Holocene soil
Bt1b1	7.5YR 4/4	Sandy clay loam	21–48	Late-Pleistocene soil
Bt2b1	7.5YR 4/5	Sandy clay loam	48–72+	Late-Pleistocene soil

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is a single room in a small fieldhouse (Figure 49.3). The room is oriented along a northwest-southeast line, with the northern side situated downslope. The room measures 1.87 m north-south by 1.66 m east-west, with about 3.1 m^2 of interior space. The excavation of the room began with the east-west trench that extended across the rubble area along the 103N grid line. This excavation defined the east and west walls of the structure, the internal stratigraphy, and a possible unprepared floor surface. After the trench was completed, the remainder of the room fill was removed down to the level of the possible floor. The geomorphic test pit was subsequently excavated adjacent to the southeastern walls of the structure to define the stratigraphic context of the walls and occupational surface.

Floor. Approximately 5 to 30 cm of post-occupational fill was removed before exposing a possible unprepared living surface within the structure. It was difficult to discern as it was heavily disturbed by rodent activity and slope wash. Nonetheless, patches were preserved in the northeastern and southern sections of the room. These were defined by a buff color and the presence of ashy adobe melt that was situated on top of the Bt1b1 soil horizon. The portion of the floor in the northeastern corner of the room also contained some adobe plaster that extended onto the floor from the adjacent wall. Since the fieldhouse was constructed on a northwest-facing slope, the floor appears to have been leveled by cutting into the slope above and filling on the downslope side; however, the floor still sloped about 10 cm down. No features or artifacts were associated with the floor. A single pollen sample (Field Specimen [FS] 89) was taken from the better-preserved northeastern area of the room. Taxa identified in this sample included cheno-ams, sunflower family, ragweed/bursage, spruce, unidentified pine, piñon pine, juniper, oak, Mormon tea, sagebrush, and greasewood. A flotation sample (FS 9) was also taken from directly on top of the floor in the northwestern corner of the room. Charred taxa identified in this sample included unidentified pine, piñon pine, ponderosa pine, cheno-ams, maize, and unknown conifer.

Figure 49.3. LA 127627, Room 1.

Wall Construction. The walls in Room 1 were primarily composed of dacite cobbles, with a few tuff blocks. In addition, some *in situ* dacite boulders were also integrated into the construction of the fieldhouse, as was a dacite grinding slab. The dacite is available from the nearby ephemeral drainage and the tuff from outcrops in the canyon. The walls are resting on top of the floor and Bt1b1 soil horizon. There is no evidence of a foundation, and adobe plaster was only observed on a few cobbles located in the eastern section of the room. Otherwise, the building's stones appear to be dry-laid walls, with one to two courses remaining. A possible doorway is situated at the northeastern corner of the room, where a grinding slab is located. Wall measurement information is provided in Table 49.4. Most of the standing walls had collapsed and the original walls were estimated at approximately 1 m high.

Table 49.4. LA 127627 Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
West	1.87	0.07–0.33	0.17–0.31	1 to 2
East	1.87	0.21–0.43	0.15–0.29	1 to 2
North	1.56	0.12–0.42	0.24–0.49	1 to 2
South	1.75	0.12–0.46	0.17–0.34	1 to 2

Artifact Distribution

Table 49.5 illustrates the distribution of artifacts that were recovered during the site excavations. These totals do not include one artifact that was recovered outside of the excavated area during the surface collection. The bold numbers indicate grid units that were located completely or partially within Room 1, which indicates that most of the artifacts were recovered from within the structure or directly north of the room. However, since the room and hill slope is oriented to the northwest, the higher levels of artifacts located in grids 105N/104-105E may reflect an outside activity area that was located in front of the fieldhouse.

Table 49.5. Artifact distribution by grid unit.

	101E	102E	103E	104E	105E	106E	107E
105N		0	3	11	16	0

101N			1	1			

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 173 artifacts were analyzed from the excavations of LA 127627. In addition, flotation and pollen samples were selected for analysis from the post-occupational fill (Stratum 2) and the living surface (Stratum 3). Maize recovered from the flotation samples was submitted for radiocarbon dating (Table 49.6).

Table 49.6. Samples selected for analysis from LA 127627.

Chronology

Radiocarbon Dating

Maize that was recovered from two separate contexts at LA 127627 were submitted for radiocarbon dating. The first sample was recovered from the floor of the structure (FS 9). It provided a date of 380±40 BP (Beta-215554), with a calibrated intercept of AD 1480 and a two-sigma range of AD 1440–1640. The second sample was recovered from under a rock in the northeast corner of the room (FS 52). This sample provided a date of 400±40 BP (Beta-215555), with a calibrated intercept of AD 1460 and a two-sigma range of AD 1430–1530. Both dates indicate a 15th century occupation at the site.

Ceramic Artifacts (Dean Wilson)

A total of 82 ceramics were analyzed from LA 127627. The majority of the pottery represents local Rio Grande utilityware ceramics, with a few decorated wares (Table 49.7), including Biscuit B and Sapawe Micaceous. The whitewares are primarily tempered with local fine tuff or ash, whereas the utilitywares are tempered with non-local granite and mica and tuff with phenocrysts (i.e., smeared-indented sand) (Table 49.8). The differences in utilityware temper reflect the non-local production of Sapawe Micaceous (and plain gray) versus the local production of smeared-indented corrugated ceramic vessels. All of the utilitywares are represented by jar vessel forms, whereas the whitewares are mostly bowls with a single jar sherd (Table 49.9). The glazeware sherds appear to be from the same jar. Based on these assemblage characteristics (i.e., Biscuit B and Sapawe Micaceous), it is likely that LA 127627 dates to the Middle Classic period. This corroborates the potential 15th century occupation represented by the radiocarbon dates.

Table 49.7. Ceramic types from LA 127627.

Ceramic Type	Frequency	Percent

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 74 artifacts were analyzed from LA 127627, consisting of three cores, 68 pieces of debitage, two retouched tools, and four ground stone artifacts. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 49.10 presents the data on lithic artifact type by material type. The debitage is primarily made of Pedernal chert and chalcedony with other materials. The presence of cortex on 8.8 percent of the debitage indicates that these materials were collected from waterworn (n = 6) sources. The Pedernal chert and chalcedony are available from local Rio Grande Valley gravels and the obsidian from nearby sources in the Jemez Mountains. Otherwise, the igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the plateau.

One piece of obsidian and a piece of basalt debitage were submitted for X-ray fluorescence analysis. The obsidian artifact is derived from the El Rechuelos (Polvadera Peak) source area located about 27 km (17 mi) northwest of the site (Table 49.11). The basalt artifact was determined to be basalt and not dacite.

Table 49.10. Lithic artifact type by material type.

Lithic Reduction

Two of the cores are a platform and flake core that were reduced using a single-directional, multi-face technique. The other artifact is a core fragment. All were still useable and broken on a material flaw when discarded. Table 49.12 presents the metric information on the cores.

The debitage mostly consists of core flakes, with a few other debitage types. The overall cortical:non-cortical ratio of 16.0 reflects an emphasis on the later stages of core reduction and tool production/maintenance. The flakes mostly have single-faceted platforms (*n* = 31), with fewer cortical (n = 1), collapsed (*n* = 4), and crushed (*n* = 5) platforms. None of the platforms exhibit evidence of preparation. The majority of the core flakes are whole (*n* = 28), with fewer proximal (*n* = 10), midsection (*n* = 6), distal (*n* = 13), and undetermined flake (*n* = 1) fragments. In contrast, the biface flakes consist of a whole and proximal fragment. The whole core flakes have a mean length of 31.7 mm (*std* = 11.1), the single whole biface a length of 23.0 mm, and the angular debris a mean weight of 6.7 g (*std* = 5.8).

Table 49.12. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Single-directional	39	43	43	96.9
Single-directional	24	47	39	58.2

The retouched tools consist of a retouched piece and a biface. The retouched piece is a large chalcedony flake fragment with unidirectional dorsal retouch along an edge with an angle of 80 degrees. The biface is a proximal fragment with an edge angle of 80 degrees, indicating that it was broken during the early stage of manufacturing.

Tool Use

One piece of debitage exhibits evidence of edge damage that could be attributed to use. It is a core flake with a concave/convex-shaped damaged lateral edge with an angle of 55 degrees. The retouched flake also exhibits rounding/polish along the edge. This tool could have been broken during the resharpening process.

The ground stone artifacts include manos. One of the manos is a two-hand variety made on an oblong-shaped schist cobble with a single heavily ground flat surface (Figure 49.4). The other two manos are cobble fragments with one and two ground surfaces that are flat and convex-shaped. Lastly, the undetermined piece of ground stone is a piece of dacite with the high points ground on a single side. This artifact could be a mano fragment or a small grinding slab.

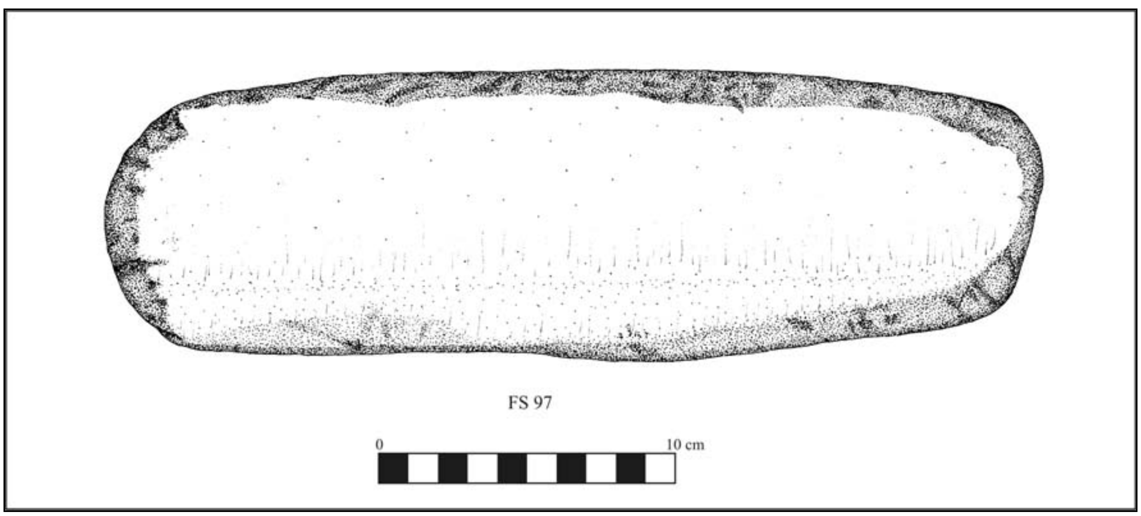

Figure 49.4. Two-hand mano.

Faunal Remains (Kari Schmidt)

Two pieces of unidentified bone were recovered from LA 127627. The bones were both recovered from the same unit (103N/107E), both were burned, and both were very small. Both pieces of bone were recovered from the fill of the fieldhouse, and both contained old breaks.

Archaeobotanical Remains (Pamela McBride)

Cultural plant material consisted of conifer duff, unknown seeds and plant parts, corn cupules, and a goosefoot seed fragment (Table 49.13). More conifer duff was recovered unburned, along with annual seeds and grass parts.

Table 49.13. Flotation plant remains, count, and abundance per liter from LA 127627.

All plant remains are seeds unless indicated otherwise. Cultural plant remains are charred, non-cultural plant remains are uncharred. + 1-10/liter, c cupule, cf. compares favorably, cs cupule segment, pp plant part.

Coniferous woods dominated the wood assemblage; two fragments of oak identified in occupational fill were the only representatives of non-conifer wood (Table 49.14). Ponderosa and pine were the most abundant wood taxa, but may not be cultural in origin as the site area was heavily burned in the Cerro Grande fire. A single fragment of juniper was recovered from under the stone in the northwest corner of the structure. Corncobs and possibly local woods were used for fuel and site occupants may have consumed goosefoot (but considering only a fragment was recovered and the condition of the site, this is equivocal at best).

Pollen Remains (Susan Smith)

Six pollen samples were analyzed from LA 127627. Table 49.15 lists the frequency of identified pollen types. No cultigens or other economic resources were identified in the assemblage. A number of potential economic resources were also identified in the assemblage (Table 49.15), and these are discussed in detail in Smith's chapter in Volume 3.

SUMMARY OF SITE EXCAVATIONS

LA 127627 consists of a one-room fieldhouse. The site was situated on the terrace overlooking the adjacent drainage in Rendija Canyon, with the room constructed to offset the northwest-facing slope. The walls were built from local dacite cobbles and tuff blocks, with several boulders integrated into the architecture. Excavations revealed a single unprepared living surface with no interior features. This surface was situated at the top of the Bt1b1 horizon, with the post-occupational fill being composed of the Bw soil. The majority of the artifacts were recovered from the fill of the structure, with a concentration located to the immediate northeast that could represent an outside activity area. Although no cultigens were recovered, the site presumably was occupied during the growing season with maize being cultivated. The radiocarbon dates and ceramic evidence indicate a Middle Classic period occupation during the 15^{th} century.

CHAPTER 50
RENDIJA TRACT (A-14): LA 127633

Michael J. Dilley and Bradley J. Vierra

INTRODUCTION

LA 127633 is the remains of a rock feature consisting of four upright slabs, with several other blocks eroding downslope. The site is located on a north-south-trending ridge near the bottom of Rendija Canyon. The northern and western (upslope) portion of the site remains intact while the southern and eastern sides of the site have eroded downslope. Vegetation on the site consists of ponderosa pine and various tall grasses, with a heavy pine duff ground cover. The site is situated at an elevation of 2109 m (6900 ft).

The site was first recorded on April 1, 1999, by Hoagland and Campbell during a survey for the Conveyance and Transfer Project and given the temporary site number of Q-195. The site was initially recorded as a rock feature, possibly representing the remains of a structure foundation. No surface artifacts were recorded. The site was partially eroded and some questions were raised about the presence of intact subsurface deposits.

FIELD METHODS

Before excavation proceeded, the slab feature and surrounding area was cleared of fallen trees and underbrush to ensure safe working conditions and to expose the extent of the feature. The feature was visible as four unshaped upright dacite slabs with several other dacite and tuff blocks eroding downslope (Figure 50.1). The slab feature was 1.3 m in length (east-west) and 1 m in width (north-south). An arbitrary site datum was established (designated 100N/100E) and the site was then covered with a 1- by 1-m grid that extended 2 m north and 4 m east of the site datum. Two subdatums (A-B) were established for taking elevations and pre-excavation photographs were taken (see Figure 50.1). A surface survey of the site was conducted, and no artifacts were recovered. A 1- by 3-m east-west trench (101N/101-103E) was then excavated across the feature. The purpose of this trench was to expose the stratigraphy of the site and to determine the extent of the feature. Units were excavated by strata, and thicker strata were excavated in arbitrary 10-cm levels. No living surface was determined, and the excavations were terminated at the base of the upright slabs. Upon completion of the trench excavation, the rest of the feature area was then excavated by grid unit and strata, with thicker units excavated in arbitrary 10-cm levels. Since excavated units outside the feature produced no subsurface deposits, excavations focused on the interior of the structure. A total of seven units were excavated for this feature (Area 1). Grid unit 101N/101E served as a geomorphic test pit and was excavated below the base of the upright slabs into the Btjb1 horizon.

Figure 50.1. Pre-excavation photograph of the feature at LA 127633.

Approximately 10 m downslope to the southwest of the slab feature, a rough alignment of tuff blocks was partially exposed on the surface of the ridge slope (Area 2). The grid was extended to include the possible alignment. A second trench was excavated to investigate this area for possible cultural deposits. The trench was oriented north-south to accommodate the slope and included grids 89-91N/98E. A subdatum (C) was established to take elevations. No cultural deposits were determined for this area, but the trench was utilized for further geomorphological investigations. A total of three units were excavated in Area 2.

Soil and pollen samples were taken from selected locations in both Areas 1 and 2, and all other soil was screened through a 1/8-in. screen to recover any artifacts. Subsequent to excavation, both areas were mapped (Figure 50.2) and photographed (Figure 50.3).

The excavation of the site was supervised by Michael Dilley. The field crew included Sandi Copeland, Hannah Lockard, Rhonda Robinson, and Bradley Vierra. Timothy Martinez represented San Ildefonso Pueblo as site monitor.

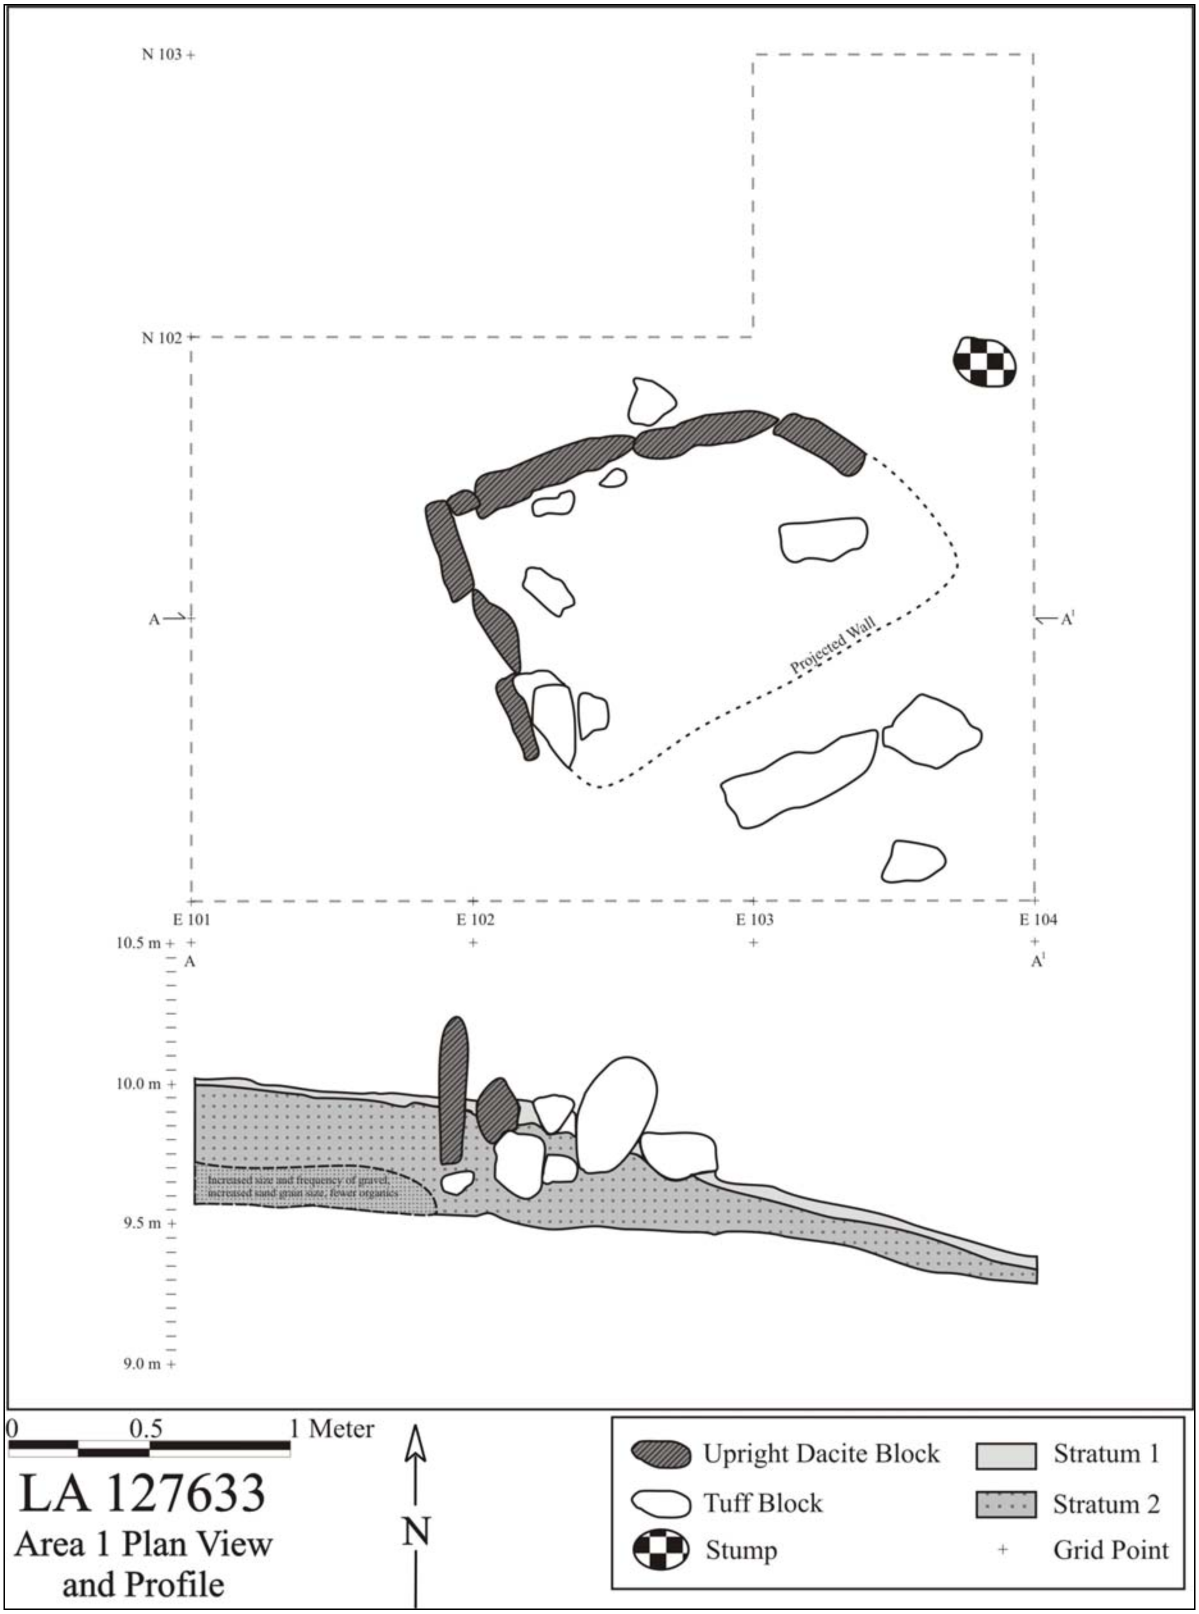

Figure 50.2. Plan view and profile of the excavations in Area 1.

Figure 50.3. Post-excavation photograph of Feature 1.

STRATIGRAPHY

Stratum 1 is the loose surface sediment, consisting of loamy sand and pine duff (Table 50.1). The stratum is 3 to 9 cm thick across Area 1 and 1 to 6 cm thick in Area 2. Stratum 2 is post-occupational fill and semi-consolidated soils consisting of loamy sand with gravel inclusions, ranging from 9 to 56 cm in thickness in Area 1. In Area 2, Stratum 2 was not considered post-occupational fill, but included the semi-consolidated soils, ranging from 6 to 57 cm in thickness (Table 50.2). Excavation below Stratum 2 was limited to geomorphological investigations and included sterile soils.

Table 50.1. Area 1 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10YR 6/3	Loamy sand/ pine duff	3–9	Surface sediment
2	8.75 YR 4/3	Loamy sand w/gravel inclusions	9–56	Semi-consolidated fill
3	10YR 4/3	Sandy soil w/gravels/pumice	56+	Sterile

Table 50.2. Area 2 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10YR 5/3	Loamy sand/pine duff	1–6	Surface sediment
2	10YR 6/3	Loamy sand w/gravel inclusions	6–57	Semi-consolidated fill
3	7.5YR 5/4	Sandy soil w/gravels/pumice	57+	Sterile

SITE EXCAVATION

Area 1, Feature 1

Sequence of Excavation. Area 1 included the slab feature (Feature 1), which consisted of four upright dacite slabs (see Figure 50.3). Feature 1 is considered to be a possible storage bin. The feature measures 1.3 m east-west by 1.0 m north-south. Feature 1 is situated on an eroding south-facing slope and the four upright slabs were all that remained intact. Excavation began with an east-west trench across the feature (101N/101-103E). The trench was excavated in an attempt to define the feature and to determine the extent and condition of the feature. Upon completion of the trench excavation, the remainder of the feature area was excavated by grid down to the base of the upright slabs. Grids surrounding the feature were also excavated, but were determined to contain no additional cultural information and were abandoned in favor of concentrating on excavation of the feature's interior. During the excavation of the interior of Feature 1, several tuff and dacite blocks were recovered as well as several small fragments, these rocks were recorded as possible construction materials. No floor, defined living surface, or additional feature elements were encountered. After the feature excavation was completed, samples were taken and the feature was mapped and photographed.

Fill. The interior of the feature was filled with 1 to 10 cm of loose surface sediment overlying 10 to 56 cm of a semi-consolidated post-occupational fill. The soil below the loose surface sediment was a loamy sand (BC horizon) that contained numerous small gravel inclusions that increased in size and frequency with depth, indicating episodic erosion. Flotation (Field Specimen [FS] 2) and pollen samples (FS 3) were taken from the Feature 1 fill. The flotation sample was not analyzed, but taxa identified in the pollen sample included grass family, cheno-ams, sunflower family, fir, unidentified pine, piñon pine, juniper, and oak.

Floor. No floor or living surface was determined for Feature 1. Due to the feature's location on an eroding slope, a good portion was eroded away, and any interior surface was also eroded away. There also was root and rodent disturbance noted within the interior of the feature. As best as could be determined, the base of the upright slabs was used as an indicator of the living surface. No artifacts were recovered from the interior. Flotation (FS 14 and FS 15) and pollen

(FS 11, FS 12, and FS 13) samples were taken from the interior of the feature. FS 14 was analyzed and the only charred taxon identified was ponderosa pine. Taxa identified in the pollen samples included rose family, buckwheat, mustard family, grass family, cheno-ams, sunflower family, spurge family, fir, unidentified pine, piñon pine, juniper, oak, ash, Mormon tea, and sagebrush.

Wall Construction. Feature 1 was constructed of upright dacite slabs, only four of which remained in place. These slabs made up the north and west walls of the feature. The slabs, as far as could be determined due to the eroded nature of the area, were set into the BC soil horizon. The slabs were apparently held in place, or supported by, smaller rocks that were situated at and against the base of the slabs. Several of these smaller rocks were still noted in place and several more were encountered in the fill during excavation. There was also some evidence of possible mortar still in place. Some hardened clay/adobe was exposed at the base of the large slab in grid 101N/102E. There also were some larger tuff rocks included in the fill of the feature's interior that may represent additional construction material, or were weights used to hold down a cover of the feature. Units excavated outside of Feature 1, immediately to the south, produced additional tuff and dacite rubble (additional dacite slab fragments were also noted on the surface downslope), indicating the possibility that the south and east side of the feature had eroded downslope.

Area 2

Sequence of Excavation. Area 2 consisted of a suspected rock alignment that was located approximately 10 m downslope to the southwest of Feature 1. The alignment included several partially buried tuff blocks transversing a narrow eroding ridge. A test trench was excavated north-south through the suspected tuff block alignment (89-91N/98E).

Fill. Fill from the trench excavation consisted of a loose surface sediment including pine duff (Stratum 1) that was 1 to 6 cm in thickness, a semi-consolidated loamy sand with dacite and pumice inclusions (Stratum 2) that was 6 to 21 cm thick, and a more consolidated, darker fine-grained loamy sand (Stratum 3) that was 21 to 57 cm thick (Figure 50.4). Pollen (FS 8) and flotation (FS 9) samples were taken from the fill, but were not analyzed.

Excavation of the trench produced no subsurface cultural deposits. No actual alignments were exposed and no artifacts were recovered. The area was then abandoned, but the trench was subsequently utilized in a geomorphological profile.

Geomorphic Analysis

A single grid unit was excavated below the BC horizon (Stratum 2) to serve as a geomorphic test pit in Area 1. The profile of this unit was analyzed by geomorphologists Paul Drakos and Steven Reneau. A soil sequence was determined consisting of an A horizon young colluvium topsoil (middle-late Holocene), a BC/IIC young colluvium post-occupation (middle-late Holocene), and a IIIBwb1 horizon (middle-late Holocene).

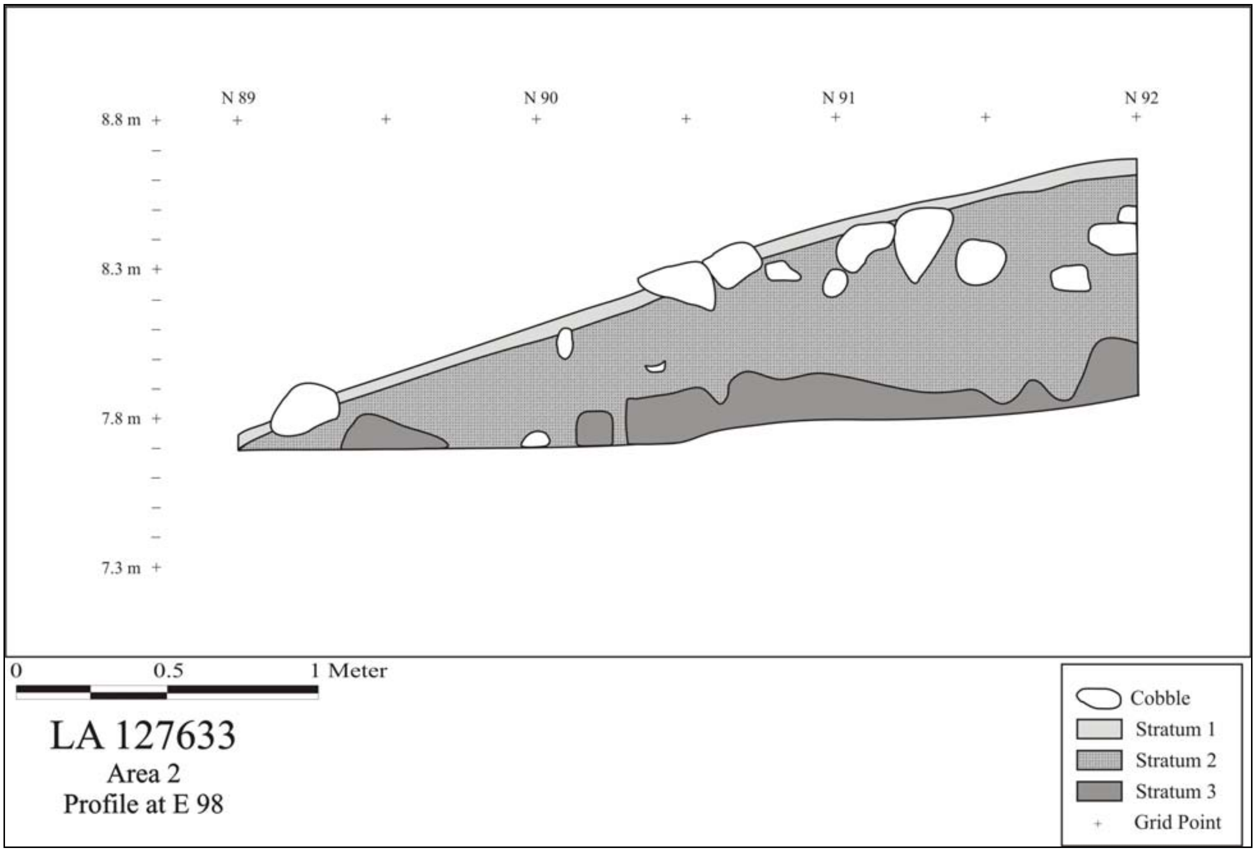

Figure 50.4. Profile of the 98E line in Area 2.

In Area 2, a test trench was excavated (89-91N/98E) into the slope of the ridge 10 m below Area 1. The profile of this trench was also analyzed by Paul Drakos and Steven Reneau. A soil sequence was determined consisting of an A horizon late-Holocene topsoil, a BC horizon late Holocene, and a Btjb1 horizon middle-late Holocene.

The likely occupation surface at LA 127633 is within the upper part or at the top of the BC soil horizon. The weak soil development both above and below the structure indicates a likely Classic period age.

SITE CHRONOLOGY AND ASSEMBLAGE

Only two artifacts were analyzed from the excavations conducted at LA 127633. Flotation and pollen samples were selected for analysis from the post-occupational fill (Stratum 2) (Table 50.3). The results of the artifact and sample analyses are presented in the following sections.

Table 50.3. Samples selected for analysis from LA 127633.

Stratum	Flotation	Pollen	Radiocarbon	TL*
1				
2	2,4,14	3,5,11,13		
3				

*thermoluminescence

Ceramic Artifacts (Dean Wilson)

A single plain gray body sherd was the only ceramic artifact that was recovered from the site. It is a jar body sherd that was tempered with smeared-indented sand.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

A single Pedernal chert core was the only lithic artifact recovered from LA 127633. It was reduced using a bidirectional, 90-degree technique and was classified as being discarded due to extensive hinging/stepping. Table 50.4 presents the metric information on the core.

Table 50.4. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Bidirectional	75	62	33	164.3

Archaeobotanical Remains (Pamela McBride)

Contexts associated with a rectangular feature that could be all that remains of a storage bin or cist, produced carbonized goosefoot seeds, ponderosa pine needles, and unidentifiable plant parts (Table 50.5). The site was extremely compromised, the southern and eastern sides of the site having eroded downslope. Wood taxa were limited to ponderosa pine and unknown conifer (Table 50.6). Considering the poor condition of the site, the charred plant remains are most likely non-cultural.

Pollen Remains (Susan Smith)

Five pollen samples were analyzed from LA 127633. Table 50.7 lists the frequency of identified pollen types. No cultigens were identified in the botanical assemblage. Lily family was the only other economic resource that was identified in the assemblage. A number of potential economic resources were also identified in the assemblage (Table 50.7), and these are discussed in detail in Smith's chapter in Volume 3.

SUMMARY OF SITE EXCAVATIONS

LA 127633 consists of a rectangular feature with upright slabs that could be the remains of a storage bin or cist. The presence of a single plain gray jar sherd could indicate a Classic period occupation. No evidence of cultigens was recovered.

CHAPTER 51
RENDIJA TRACT (A-14): LA 127634

Gregory D. Lockard

INTRODUCTION

LA 127634 is a small one-room Classic period fieldhouse situated on a ridge finger overlooking Rendija Canyon. The site is located 340 m north of the Rendija Canyon bottom and just east of site LA 127635, which is another small one-room fieldhouse (see Chapter 52, this volume). The site is on a slope of approximately four degrees. The surrounding area is covered with ponderosa pine trees, most of which were severely burned in the Cerro Grande fire, and a scattering of juniper trees. The understory is dominated by several grass and wildflower species. The site is situated at an elevation of 2115 m (6940 ft).

The site was first surveyed on April 1, 1999, by Hoagland and Campbell and given a temporary site number of Q196. In the Laboratory of Anthropology Site Record, they interpret the site as a two-room fieldhouse. Nineteen artifacts were discovered in a surface survey of the site and analyzed in the field. Fourteen lithics were encountered. Eleven were Pedernal chert, two were black translucent obsidian, and one was rhyolite. Five biscuitware sherds were encountered, three of which were identified as Biscuit B. The structure was therefore presumed to date to the Classic period (AD 1325–1600).

FIELD METHODS

Before excavation, the site and surrounding area were cleared of trees and large undergrowth. An arbitrary site datum (designated 100N/100E, 10.00 m elevation) was set up in the southwest corner of the site. The site was then covered with a 1- by 1-m grid system that extended 7 m north and 8 m east of the site datum, and four subdatums (A-D) were set up for taking elevations (Figure 51.1). The site was then photographed and surface collected. A ceramic sherd and a lithic were the only artifacts encountered in the surface collection.

A 6- by 1-m east-west trench was initially excavated across the middle of the rock alignments and wallfall visible on the surface of the site (103N/100-105E). The purpose of this trench was to define and present a profile of the stratigraphy both within and outside of the structure, as well as to determine the location of the east and west walls of the structure. Units were excavated by strata, and thicker strata were excavated in arbitrary 10-cm levels. During the excavation of grid 103N/103E, a small patch of burned floor was encountered. Excavation within the structure thereafter proceeded down to the level of this patch of floor. In the areas of the trench to the east and west of the structure, excavation proceeded down to the top of the sterile Btkb1 horizon. The westernmost unit in the trench (103N/100E) was chosen to serve as a test pit for geological analysis. Excavation in this unit therefore continued through the Btkb1 horizon down to the underlying Bandelier Tuff bedrock. The north profile of the trench was then drawn and photographed.

Figure 51.1. Pre-excavation photograph of LA 127634.

The rest of the site was subsequently excavated, again by strata and arbitrary levels for thicker strata. In all, 29 units were excavated. Within the structure, excavation proceeded down to the floor surface where present. In areas where no clearly discernible floor surface was encountered, excavation proceeded down to a compact surface often found at or just below the level of nearby patches of well-preserved floor. This compact sediment is most likely the floor matrix that was once just beneath the floor's smooth surface. Outside of the structure, excavation proceeded down to the top of the sterile Btkb1 horizon. Excavation included the removal of rocks that could be clearly identified as wallfall to define the structure's walls and locate any internal or external features.

Soil samples were taken from select locations, and all other soil was passed through screens with 1/8-in. mesh to aid in the recovery of artifactual remains. The excavation area was extended approximately 1 m outside of the structure in all directions to locate external features and identify outside activity areas. The excavations were extended 2 m to the east of the structure as this area contained the highest concentration of artifacts at the site and may therefore have been an outdoor activity area. The site was then mapped (Figure 51.2) and photographed (Figure 51.3).

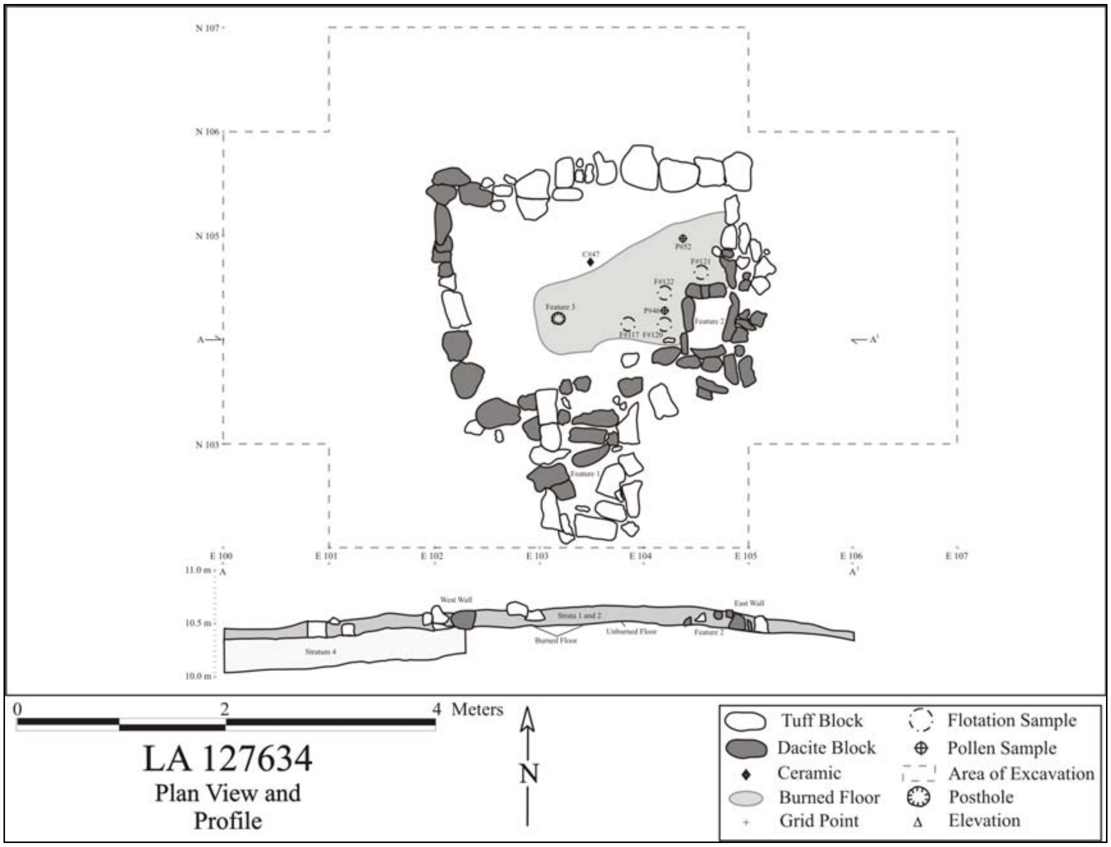

Figure 51.2. Plan view and profile drawing of the fieldhouse at LA 127634.

Figure 51.3. Post-excavation photograph of LA 127634.

The excavation of the site was supervised by Greg Lockard. Crewmembers included Joseph Aguilar, Brandon Gabler, and Jeanine Wood. Aaron Gonzalez and Michael Chavarria served as site monitors, representing San Ildefonso and Santa Clara pueblos, respectively.

STRATIGRAPHY

Stratum 1 is composed of loose surface sediment. It is uniformly 2 to 10 cm thick across the site and is roughly equivalent to the top half of the A horizon (topsoil). Stratum 2, which ranges from 7 to 25 cm thick in the area excavated, is post-occupational fill. This fill was thickest in and around the structure, especially in the area just south (downhill) of its north wall. Stratum 2 includes the lower half of the A horizon. A thin Bw horizon may have also existed in some areas of the site, although it was not present in the profile analyzed by geologists Paul Drakos and Steven Reneau. Stratum 3 is a prepared floor within the structure and Stratum 4 is the sterile Btkb1 horizon. The Btkb1 horizon, upon which the structure was built, contains discontinuous $CaCO_3$ coatings and is most likely a Pleistocene colluvium. Stratum 5 is the ashy fill from a slab-lined hearth (Feature 2) and Stratum 6 is the fill from a small posthole (Feature 3), both of which are inside the structure. Tables 51.1 through 51.3 summarize and describe the strata excavated at LA 127634.

Table 51.1. LA 127634 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is the only room in a small fieldhouse. The room measures 1.80 m north-south by 2.50 m east-west, with approximately 4.50 m^2 of interior space. Excavation of the room began with the east-west trench that extended across the site (103N/100-105E). The excavation of this trench served to define the stratigraphy and locate the east and west walls and floor of the room. After the excavation of the trench, the rest of the room was excavated down to the floor level and then photographed. A small test pit was subsequently excavated below the floor level in unit 104N/103E. The purpose of this test pit was to determine whether there were any additional living surfaces below. No additional living surface was encountered. In addition, the geological test pit (103N/100E) was extended eastward to the west wall of the room to ascertain how deep the foundation of the west wall extends in that location. The wall foundation was found to extend only a couple of centimeters into the Btkb1 horizon, indicating that the structure was basically built directly on top of this surface.

Fill. The room was filled with 2 to 10 cm of surface sediment and 10 to 20 cm of post-occupational fill. The fill was thickest just south (downhill) of the room's north wall. Two flotation samples were taken of Room 1 fill (Field Specimen [FS] 39 and FS 84), one of which came from directly on top of floor (FS 84). Charred taxa in these samples included piñon pine, ponderosa pine, sagebrush, unidentified pine, maize, mountain mahogany, unknown conifer, cottonwood/willow, and oak. Two pollen samples (FS 40 and FS 72) were also taken of Room 1 fill. One of these (FS 72) is from directly beneath a ground stone metate fragment that was at or near floor level (the floor was badly disturbed in this area). Taxa identified in these samples included maize, cholla, buckwheat, grass family, cheno-ams, sunflower family, ragweed/bursage, spurge family, spruce, fir, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush.

Floor. The first step in the construction of the living surface of Room 1 was to clear the area of loose surface sediment and expose the top of the more compact Btkb1 horizon. The living surface has about the same slope as the surrounding hillside (sloping upward to the northwest), and therefore does not appear to have been leveled. The surface was not plastered. It was, however, covered with a thin layer of clay-rich sediment (i.e., adobe). This layer of adobe was either added to the top of or formed by wetting and packing down the surface of the Btkb1 horizon. This floor is very poorly preserved except where it was burned. This burning is most extensive near Feature 2, which is a slab-lined hearth located in the southeast corner of the room. The floor is best preserved just to the north and especially west of the hearth. In the western third of the structure, the floor is very poorly preserved and in places indiscernible.

Burned, hardened adobe was also encountered on top of the rock slab that defines the northern border of the Feature 2. This adobe is most likely the remains of a collar that covered the stone slab that defines the northern boundary of the hearth. The two slabs that form the western boundary of the hearth were probably also covered by the adobe collar. The slabs to south and east, on the other hand, probably were not covered with adobe as they extend significantly higher above the floor level and directly abut the perimeter wall of the structure. In addition to the hearth (Feature 2), the floor is also associated with a posthole (Feature 3). This posthole, which is located just to the southwest of the center of the room, is 9 cm in diameter and 7 cm deep.

Two pollen samples (FS 46 and FS 52) were taken from directly on top of the living surface. Taxa identified in these samples included maize, prickly pear, beeweed, rose family, buckwheat, grass family, cheno-ams, sunflower family, ragweed/bursage, spurge family, evening primrose, fir, unidentified pine, piñon pine, oak, and sagebrush. Four flotation samples (FS 117 and FS 120-122) were taken of burned floor matrix. Three of these are from areas directly to the west (FS 120 and FS 122) and north (FS 121) of the slab-lined hearth (Feature 2). Charred taxa identified in the samples taken from west of the hearth included piñon pine, ponderosa pine, unidentified pine, maize, oak, squash/coyote gourd, mountain mahogany, and unknown conifer. Charred taxa identified in FS 121 included juniper, piñon pine, ponderosa pine, unidentified pine, maize, beeweed, bugseed, and unknown conifer, while charred taxa identified in FS 117 included ponderosa pine, oak, goosefoot, unknown conifer, sagebrush, piñon pine, and unidentified pine. Two charcoal samples were also taken from these areas (FS 118 and FS 119) to serve as radiocarbon samples if no better botanical samples are recovered from flotation samples, but these samples were not analyzed.

Wall Construction. The rocks that form the perimeter walls of the fieldhouse are mostly long shaped tuff blocks (Table 51.4). Dacite cobbles were also used, especially as foundation rocks. As mentioned above, the geological test pit was extended eastward to the west wall of Room 1 in order to determine how deep the wall foundation is in this location. The wall foundation was found to extend only a few centimeters into the Btkb1 horizon, upon which the Room 1 floor was built. The Room 1 perimeter walls did not therefore have a very deep foundation. The upright slabs that form the perimeter of Feature 2 (slab-lined hearth), on the other hand, were embedded much deeper into the Btkb1 horizon (they extend below the base of the hearth, which is about 15 cm below floor level). The remains of the north and west walls of Room 1 are still two courses high. The east and especially south walls are more poorly preserved. They are only a single course high and contain some small gaps were no *in situ* rocks were encountered. One of the gaps in the south wall, however, may be an entryway (see Feature 1 description below).

Table 51.4. LA 127634 Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	2.60	0.13–0.35	0.17–0.34	1 to 2
South	2.30	0.05–0.15	0.10–0.30	1
East	1.75	0.05–0.11	0.10–0.30	1
West	1.85	0.08–0.25	0.10–0.22	1 to 2

The high quantity of wallfall encountered during the excavation of Room 1 indicates that the masonry portion of the walls were originally considerable higher than they are today. In order to estimate how much higher, all of the rocks removed as wallfall during the excavation were placed into two stacks for measurement. One of these stacks measured 2.95 by 0.58 by 0.25 m, for a total of 0.428 m^3. The second stack measured 3.40 by 0.80 by 0.35 m, for a total of 0.952 m^3. Based on the combined volume of these stacks of wallfall (1.38 m^3) and the overall length, average thickness, and average height of the extant portions of the walls, the masonry portion of the Room 1 wall was originally only about 94 cm in height. The upper part of the walls and ceiling were most likely composed of vegetal material and adobe. These materials are rarely preserved at archaeological sites on the Pajarito Plateau. In fact, four small pieces of burned adobe (FS 10, FS 60, FS 65, and FS 86) were the only evidence found of such a superstructure.

Feature 1 (Staircase/Entryway)

Feature 1 appears to be a staircase leading to the Room 1 entryway (Figures 51.4). It is an external feature located directly south of the central portion of the south wall of Room 1. The feature is composed of dacite cobbles and several shaped tuff blocks. The feature's south, east, and west perimeter walls are mostly composed of the shaped tuff blocks. The south and west perimeter walls are fairly well preserved, while the east perimeter wall appears to have been partially disturbed. The northern boundary of the feature is defined only by a couple of small dacite cobbles that appear to form the threshold (i.e., doorsill) of the entryway into Room 1. The feature measures approximately 1.5 m north-south by 1.0 m east-west.

Figure 51.4. Post-excavation photograph of Feature 2, an entryway/staircase.

Three long, flat dacite rocks are located within the feature. These rocks are oriented east to west and appear to have functioned as steps leading up to the entryway. If this interpretation is correct, the shaped tuff block that forms the south perimeter wall of the feature also functioned as the first step in the staircase. There is a gap of approximately 40 cm between this first step and the southernmost interior step. Originally, this gap was probably filled by another step that is now missing or displaced. If Feature 1 functioned as a staircase, it probably originally had five steps.

Feature 2 (Hearth)

Feature 2 is a rectangular, slab-lined hearth located in the far southeast corner of Room 1 (Figure 51.5).

Figure 51.5. Feature 2, a slab-lined hearth at LA 127634.

All of the slabs that form the perimeter of the hearth are dacite. Two upright slabs form the western border of the hearth and the other three borders are each formed by a single upright slab. The top of the slab that forms the northern border of the hearth has broken off. This area of the slab is covered with burned adobe, however, indicating that it was broken either before or during the occupation of the fieldhouse. The presence of adobe on top of this slab also suggests that an adobe collar once covered the northern border of the hearth. If this is the case, the adobe collar probably also covered the slabs that formed the western border of the hearth. The adobe collar probably did not cover the slabs that formed the southern and eastern borders of the hearth, on the other hand, as they extend significantly higher above the floor level and directly abut the perimeter wall of the structure. The interior of the hearth measures 47 cm north-south by 27 cm east-west and is 15 cm deep. The hearth was filled with very ashy sediment that contained some small pieces of charcoal. Burned, hardened adobe was encountered in the bottom corners of the hearth, especially the northwest corner. This adobe does not appear to be the remains of a hearth lining. Instead, the adobe appears to have been used only to fill in the places in between the slabs that form the hearth's perimeter.

A pollen sample (FS 104) was taken from beneath a rock lying directly on top of the ashy sediment that filled the hearth, at about floor level, but no taxa were identified. The rest of the ashy fill (Stratum 5) removed from the hearth was kept as eight flotation samples (FS 105 through FS 112). Charred taxa identified in these samples included maize, beans, tobacco, oak, banana yucca, goosefoot, sagebrush, ponderosa pine, beeweed, mountain mahogany, and piñon pine.

Feature 3 (Posthole)

Feature 3 is a posthole located just to the southwest of the center of Room 1 (Figure 51.6). The center of the posthole is located at 104.23N/103.16E on the excavation grid.

Figure 51.6. Post-hole (Feature 3).

The posthole is 9 cm in diameter and 7 cm deep. All of sediment excavated from within the posthole (Stratum 6) was kept as a pollen sample (FS 116). Taxa identified in this sample included maize, rose family, mustard family, grass family, cheno-ams, ragweed/bursage, sunflower family, unidentified pine, piñon pine, and sagebrush.

Geological Test Pit

A single unit (103N/100E) was excavated below the top surface of the Btkb1 horizon as a geological test pit. The north profile of this unit, which was analyzed by geologists Paul Drakos and Steven Reneau, contained a soil sequence consisting of A and Btkb1 horizons (see Table 51.2). The Btkb1 horizon rests directly on top of Bandelier Tuff bedrock. After the site was completely excavated and photographed, the northern half of the test pit was extended eastward to the west wall of Room 1 to determine the depth of the wall's foundation. This excavation revealed that the foundation of the west wall of Room 1 extends only a couple of centimeters into the Btkb1 horizon in that location.

Artifact Distribution

The usual pattern for prehistoric architecture on the Pajarito Plateau is for entryways to be placed in the east wall of residential rooms, presumably to take advantage of the light from the rising sun. Artifact density is usually high in the areas directly outside of the entryways, to the east of the rooms. One explanation for the high artifact density to the east of the rooms is that this locale functioned as an activity area. An alternative, or possibly complementary, explanation is that the artifacts were swept into the area from inside the rooms through their doorways. As Table 51.5 demonstrates, the majority of artifacts encountered from LA 127634 are from the area just east of Room 1. The entryway to Room 1, however, appears to be to the south (see Feature 1 description above). The increased artifact density to the east of the room therefore cannot be the result of sweeping artifacts through the doorway, and instead most likely reflects its use as an activity area. Surprisingly, the southern, downhill half of the area excavated did not contain significantly more artifacts than the northern, uphill half. This suggests that erosion was not a significant natural formation process affecting the distribution of artifacts at the site.

Table 51.5. LA 127634 artifact counts by grid unit.

	E100	E101	E102	E103	E104	E105	E106
N106		1	2	9	8		
N105	0	0	**3**	**5**	**7**	25	29
N104	0	1	**2**	**17**	**12**	21	14
N103	1	10	**6**	**7**	**13**	23	13
N102		6	5	2	12		

Note: Does not include six artifacts found outside of the excavated area during surface collection; bold numbers indicate grid units that are located completely or partially within Room 1.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 247 artifacts were analyzed from excavations at LA 127634. Analyses of the ceramics, lithics (chipped and ground stone), pollen, and archaeobotanical materials were conducted (Table 51.6). In addition, samples were submitted for radiocarbon, thermoluminescence (TL), and obsidian hydration dating. The results of these analyses, as well as associated tables, are presented in the following pages.

Table 51.6. Samples selected for analysis from LA 127634.

Stratum	Sample Type			
	Flotation	Pollen	Radiocarbon	TL
1				
2	39, 84	40, 72		43, 95
3	117, 120, 121, 122	46, 52		
4				
5	105, 106, 107, 108, 109, 110, 111, 112	104	105, 108	
6		116		

Chronology

Radiocarbon Dating

Two maize samples recovered from Feature 5 (hearth) were submitted for accelerator mass spectroscopy dating. The first sample provided a date of 350±40 BP (Beta-215556), with calibrated intercepts of AD 1510, AD 1600, and AD 1620, and a two-sigma range of AD 1470–1630. The second sample yielded a similar date of 340±40 BP (Beta-215557), with calibrated intercepts of AD 1520, AD 1590, and AD 1620, and a two-sigma range of AD 1480–1640.

Thermoluminescence Dating

Two Biscuit B sherds were submitted for Optically Stimulated Luminescence (OSL) dating from LA 127634 (Table 51.7). All derived ages are given in years BP, which refers to years before 2003, and both are consistent with a Middle Classic period date.

Table 51.7. Thermoluminescence dates from ceramics at LA 127634.

FS#	Lab #	Context	Burial depth (cm)	Years BP	% error	Years AD
43	UW1417	East wall Room 1	8	542	6.1	1464±33
95	UW1418	East of Room 1	17	512	5.5	1494±28

Obsidian Hydration Dating

Three obsidian artifacts from LA 127634 were submitted to the Diffusion Laboratory for age determination using the obsidian hydration dating method. In order to calculate the absolute date for an obsidian artifact, three analytical procedures were completed. First, the amount of surface hydration, or the thickness of the hydration rim, was measured. Second, the high-temperature hydration-rate constants for each artifact were determined from the composition of the glass. Lastly, the soil temperature and relative humidity at the archaeological site were estimated so that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. Using these methods, a hydration rate for the obsidian artifacts was calculated (Table 51.8).

Table 51.8. Obsidian hydration dates for LA 127634.

FS No.	Lab No.	Source	Rim (um)	AD/-BC	1 S.D.
8	2003-74	Cerro Toledo	4.49	1565	17
19	2003-75	Valle Grande	3.13	-2166	267
99	2003-76	Valle Grande	4.26	-5023	331

Relative to other dating methods conducted at the site, the obsidian hydration dates seem to be the least accurate. Radiocarbon and OSL dates indicate a Middle to Late Classic period date (16^{th} or 17^{th} century), with only one of the three obsidian samples providing a 16^{th} century date. The other two obsidian artifacts might have been scavenged from nearby Early and Middle Archaic sites.

Ceramic Artifacts (Dean Wilson)

One-hundred-forty-nine sherds were recovered from the fieldhouse at LA 127634. These primarily consist of Biscuit B/C (Biscuit B?) and Sapawe Micaceous sherds, which indicate a Middle Classic period date (16^{th} century). This corresponds with the presence of Sankawi Black-on-cream and glazeware ceramics, which also support a Classic period occupation. Tables 51.9 through 51.12 show the summary ceramic data for the site, including general type, types by tradition, temper material by ware type, and ware by vessel form. Most of the graywares and all of the whitewares contain local tempering material like smeared-indented sand to tuff; however, the glazewares and five graywares contain basalt temper and the Sapawe Micaceous sherds a granitic temper with mica. The graywares, micaceous wares, and most of the glazewares represent jar vessel forms. In contrast, the whitewares exhibit mostly bowls, with some jars.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 98 artifacts were analyzed from LA 127634, consisting of 94 pieces of debitage, a retouched tool, and three ground stone artifacts. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 51.13 presents the data on lithic artifact type by material type. The debitage is primarily made of chalcedony and Pedernal chert, with some other materials. The presence of cortex on 17.0 percent of the debitage indicates that these materials were collected from waterworn (*n* = 15) and nodule (*n* = 1) sources. The chalcedony and Pedernal chert are available from local Rio Grande Valley gravels and the obsidian from nearby sources in the Jemez Mountains. The igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the plateau.

Table 51.13. Lithic artifact type by material type.

Three pieces of obsidian and two pieces of basalt debitage were submitted for X-ray fluorescence analysis. The obsidian artifacts are Valle Grande, Cerro Toledo, and El Rechuelos obsidian (Table 51.14). The Valle Grande (Cerro del Medio) and Cerro Toledo (Obsidian Ridge/Rabbit Mountain) source areas are situated about 17 km (11 mi) and 19 km (12 mi) to the west and southwest. Although obsidian is present at these nearby sources in the Jemez Mountains, it is also present on the nearby mesa as small pebbles. These pebbles compose part of the secondary deposits associated with the Cerro Toledo interval. The El Rechuelos (Polvadera Peak) source area is located approximately 27 km (17 mi) northwest of the site. A single basalt flake is actually made of dacite that was derived from local sources, however, the other flake appears to be basalt.

Table 51.14. Obsidian source samples.

FS #	Artifact	Color	Source
8	Debitage	Translucent	Cerro Toledo rhyolite
19	Debitage	Black dusty	El Rechuelos
99	Debitage	Translucent	Valle Grande rhyolite

Lithic Reduction

The debitage mostly consists of core flakes and angular debris, with a few biface flakes and microdebitage. The presence of a single obsidian bipolar flake may reflect the reduction of small nodules that are locally available on the nearby mesa top. The overall cortical:non-cortical ratio of 27.2 reflects an emphasis on the later stages of core reduction and tool production/maintenance. The flakes mostly have single-faceted platforms (n = 20), with fewer cortical (n = 3), dihedral (n = 1), collapsed (n = 3), and crushed (n = 9) platforms. Only one of the platforms exhibit evidence of preparation by abrasion/crushing. The majority of the core flakes are distal fragments (n = 24), with fewer whole (n = 12), proximal (n = 19), and midsection (*n* = 5) fragments. In contrast, the biface flakes consist of two whole, one proximal, and a distal fragment. The whole core flakes have a mean length of 30.8 mm (*std* = 14.8), biface flakes a mean length of 13.0 mm (*std* = 2.8), and the angular debris a mean weight of 5.6 g (*std* = 12.6).

A single retouched flake was identified during the analysis. It exhibits unidirectional ventral retouch that creates a convex-shaped lateral edge with an angle of 70 degrees.

Tool Use

Three pieces of debitage exhibit evidence of edge damage that could be attributed to use. Two of the flakes have rounding/polish along a lateral edge with a straight outline and the third a concave outline. Each exhibits an edge angle of 55, 60, and 70 degrees, respectively.

The ground stone artifacts include a mano and metate. The mano is a fire-cracked cobble fragment with small ground areas on two opposing surfaces. The metate is also fire-cracked, consisting of a dacite fragment with a single ground surface. Lastly, the undetermined ground stone artifact is a black piece of tuff that has been shaped on two sides by abrasion and grinding to create two smooth flat surfaces.

Archaeobotanical Remains (Pamela McBride)

Aside from charred conifer duff, beeweed and corn were the most common taxa identified in flotation samples (Table 51.15). Banana yucca, beans, and tobacco seeds were found in samples from the hearth, while bugseed and possible squash rind were present in floor contexts near the hearth. This is quite a remarkable floral assemblage from a one-room fieldhouse. Carbonized tobacco indicates ritual activities may have taken place here that may have included using beeweed pigment to paint pottery or ritual items (Adams et al. 2002). Beeweed was of course also used extensively as a pot herb and the seeds were ground into a meal for flour or gruel (see Jones 1931 or Lange 1968a) and its presence may have more to do with food preparation rather than pigment manufacture.

The wood assemblage at LA 127634 was composed of piñon, cottonwood/willow, ponderosa pine, mountain mahogany, oak, and sagebrush (Table 51.16). Site occupants probably used corncobs for fuel and the presence of kernels and embryos points to processing of maize. Compared to other fieldhouses in the Rendija Tract, LA 127634 and LA 127635 (see Chapter 52, this volume) yielded the greatest number of wild and domesticated taxa, including ritual plants, indicating that perhaps these sites were in use over a longer period of time.

Pollen Remains (Susan Smith)

Six pollen samples were analyzed from LA 127634. Table 51.17 lists the frequency of identified pollen types. Maize and cholla were the only cultigens identified in the botanical assemblage. Prickly pear and beeweed were the only other economic resources that were identified in the assemblage. A number of potential economic resources were also identified in the assemblage (Table 51.17), and these are discussed in detail in Smith's chapter in Volume 3.

SUMMARY OF SITE EXCAVATIONS

LA 127634 consists of a one-room fieldhouse, a staircase/entryway, a slab-lined hearth, and a posthole. All four walls were intact and appeared to contain an opening to the east. A formal floor was not identified, but the fieldhouse did contain a compact living surface. The slab-lined hearth contained both maize and beans. The ceramic, radiocarbon, and TL evidence indicate that the fieldhouse was probably occupied during the Middle Classic period.

CHAPTER 52
RENDIJA TRACT (A-14): LA 127635

Michael J. Dilley and Bradley J. Vierra

INTRODUCTION

LA 127635 consists of the remains of a one-room early Classic period fieldhouse. The site is located near the southern end of a low north-south trending ridge overlooking Rendija Canyon. Vegetation in the site area is primarily ponderosa pine with scattered junipers and various grasses, with a surface covering of pine duff. The site is situated at an elevation of 2120 m (6950 ft).

The site was first recorded on April 1, 1999, by Hoagland and Campbell during a survey for the Conveyance and Transfer Project and given the temporary site number of Q-197. The site was initially recorded as a one-room fieldhouse with very little remaining rubble but having an intact foundation with potential for subsurface deposits. Surface artifacts consisted of three ceramic sherds identified as a single Biscuit A and two non-micaceous plainware sherds. Based on the surface-identified artifacts, the site was tentatively dated to the Classic period.

FIELD METHODS

Before excavation proceeded, the site and surrounding area was cleared of felled trees and underbrush to ensure safe working conditions and to expose the extent of the structure. The structure was visible as a roughly rectangular outline of shaped and unshaped tuff blocks, roughly 3 m north-south by 2 m east-west in size. An arbitrary site datum was established (designated 100N/100E) and the site was then covered with a 1- by 1-m grid that extended 6 m north of the datum and 3 m east and 3 m west of the datum. Two subdatums (A and B) were set up for taking elevations. Pre-excavation photographs were then taken and the site was surveyed for surface artifacts. A 6- by 1-m trench was initially excavated across the site (grids 103N/97-103E) to determine stratigraphy and to locate the east and west walls of the structure. Units were excavated by strata, and thicker strata were excavated in arbitrary 10-cm levels. The west wall of the structure was encountered in unit 103N/98E, and the east wall was encountered in unit 103N/100E. The alignment of the walls was not oriented exactly north to south. Wall orientation was more along a northeast to southwest axis. Units excavated for the trench were taken down to a compact surface that was ashy with charcoal flecking imbedded. This surface was determined to be the floor (living surface).

Upon completion of the excavation of the trench, the remainder of the site was then excavated by grid unit and strata, with thicker units excavated in 10-cm arbitrary levels. A total of 21 units were excavated. Within the structure, units were excavated to the floor/living surface determined during the excavation of the trench. Outside the structure, units were excavated to the top of a sterile Bwb1 horizon. The focus of excavation was on defining the walls of the structure, removing wallfall, exposing the floor/living surface, and locating any internal or external features. Soil and pollen samples were taken from selected locations, and all other soil removed was screened through a 1/8-in. screen to recover any artifacts. Excavation was extended at least 1 m around the perimeter of the structure to locate any external features or activity areas. Subsequent to excavation the structure was mapped (Figure 52.1) and photographed (Figure 52.2). Grid unit 104N/101E was excavated below the Bw horizon to serve as a geomorphological test pit.

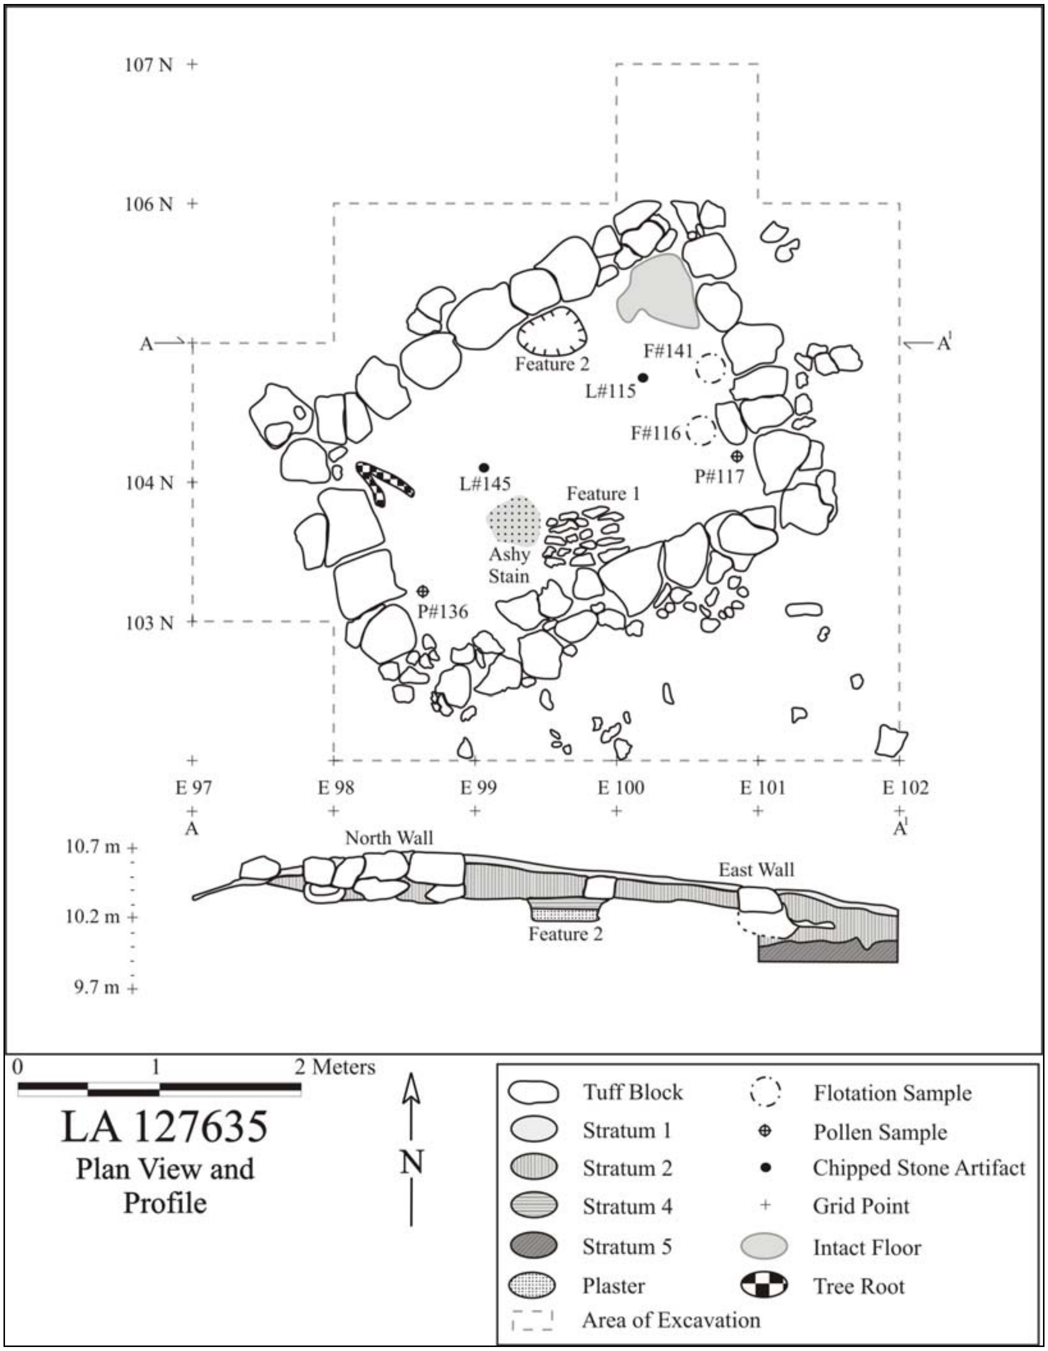

Figure 52.1. Plan view and profile drawing of LA 127635.

Figure 52.2. Post-excavation photograph of LA 127635.

The excavation of the site was supervised by Michael Dilley. The field crew included Sandi Copeland, Hannah Lockard, Aaron Lenihan, and Alan Madsen. Timothy Martinez and Mike Chavarria served as monitors and screeners representing San Ildefonso and Santa Clara pueblos, respectively.

STRATIGRAPHY

Stratum 1 is loose surface sediment and is composed of a loamy sand that is 1 to 7 cm thick across the site (A horizon). Stratum 2 is post-occupational fill ranging from 7 to 19 cm in thickness and is composed of a sandy loam (Bw horizon). Stratum 3 is the living surface and is the top of a soil horizon composed of a sandy clay loam (Bwb1 horizon). Stratum 4 is feature fill from Feature 2 and is composed of an ashy sandy loam. Stratum 5 is soil excavated outside of the structure and is composed of the sandy clay loam below the living surface (Bwb1 horizon). Excavation into this stratum went to depths ranging from 19 to 33 cm. Stratum 6 is composed of the sandy clay loam soil excavated from a subfloor test pit in 103N/98E, which was inside the structure (Bwb1 horizon). Stratum 7 is soil excavated from a bioturbated area outside the south wall of the structure and is composed of loamy sand with charcoal flecking (Bw horizon). Tables 52.1 through 52.3 summarize and describe the strata excavated at LA 127635.

Table 52.1. LA 127635 strata descriptions.

Stratum	Color	Texture	Thick (cm)	Description
0	-	-	-	Surface
1	10yr 5/3	Loamy sand	1–7	Surface sediment
2	10yr 5/3	Sandy loam	7–19	Post-occupational fill
3	8.75yr 5/4	Sandy clay loam	19–33	Living surface and below
4*	10yr 5/2	Ashy sandy loam	17	Feature fill (Feature 2)
5*	10yr 5/3	Sandy loam	7–19	Outside of structure
6*	10yr 5/3	Sandy loam	7–19	Sub floor pit
7*	10yr 5/3	Sandy loam	7–19	Bioturbated area

*Note: Strata are not listed as a strict soil horizon sequence, but rather as an excavation sequence.

Table 52.2. LA 127635 soil horizon descriptions from geomorphic test pit profile.

Horizon	Color	Texture	Depth (cm)	Description
A	10yr 5/3	Loamy sand	0–7	Young colluvium (late Holocene)
Bw	10yr 5/3	Sandy loam	7–19	Young colluvium (late Holocene)
Bwb1	8.75yr 5/4	Sandy clay loam	19–33	Middle to late Holocene
Bkb1	8.75yr 5/4	Sandy clay loam/carbonate	33–43+	Middle to late Holocene

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is a relatively small one-room rectangular structure that probably functioned as a fieldhouse. The room measures 2.75 m north-south by 1.9 m east-west with approximately 5.23 m^2 of interior space. Construction of the room consisted of two courses of shaped and unshaped tuff block. Excavation of the room began with an east-west trench that extended across the structure (units 93N/97-103E). The excavation of this trench served to define the stratigraphy within the room, to locate the east and west walls of the room, and to determine the floor/living surface within the room. After the trench was excavated, the rest of the room was excavated, by grid, down to the presumed living surface (top of the Bwb1 soil horizon). During the excavation of the room, two features were exposed. Feature 1 (103N/99E) consisted of a patterned concentration of tuff rocks and Feature 2 (104-105N/99E) consisted of a formal plastered hearth. The features were excavated, samples were taken, and the features were mapped. Following the completion of the room and feature excavations, photographs of the features, walls, and living surface were taken. A subfloor pit was excavated in the southwest corner of the room (103N/98E) to determine if any living surfaces were below the initial surface and to determine the depth of the wall foundation.

Fill. The interior of the room was filled with 1 to 7 cm of loose surface sediment overlying 7 to 19 cm of a more consolidated post-occupational fill. Flotation (Field Specimen [FS] 45 and FS 53) and pollen (FS 42) samples were taken from the room fill. Charred taxa identified in the flotation samples included unidentified pine, piñon pine, ponderosa pine, unknown conifer, squash/coyote gourd, maize, and mountain mahogany. Taxa identified in the pollen sample included rose family, cheno-ams, grass family, sunflower family, spurge family, evening primrose, unidentified pine, piñon pine, and sagebrush.

Floor. Although no formal plastered floor was encountered, patches of a prepared surface were exposed during excavation of Room 1 in 104-105N/100E. This surface consisted of a compact clay-rich mud that was 1 to 2 cm thick, ashy gray in color, and contained imbedded charcoal pieces and flecking. Within these grid units some evidence of coping was also encountered, where the mud was smoothed and curved upwards to the base of the wall. There was also some evidence for an episode of remodeling, or an earlier occupation. The top layer of the smoothed surface (1 to 2 cm) popped off when it was scraped with a trowel, revealing another surface. This lower surface (an additional 2 to 3 cm thick) was a very compact ashy/burned surface, exhibiting oxidation and discoloration. Other areas across the living surface within Room 1 exhibited ashy staining and charcoal flecking, but no other patches of the smoothed mud were encountered. It is likely that the top of the compact Bwb1 horizon served as a foundation for the floor. The living surface was disturbed by roots and insect and rodent activity.

Feature 2, a formal hearth, was exposed in unit 104-105N/99E and was situated at floor level adjacent to the north wall of the room (see feature description). Two chipped stone artifacts (FS 115 and FS 145) were recovered from floor context. Flotation (FS 116) and pollen (FS 117) samples were taken from the floor context. Charred taxa identified in the flotation sample included piñon pine, mountain mahogany, unidentified pine, and unknown conifer. Taxa identified in the pollen sample included cheno-ams and unidentified pine.

Additional samples were taken from wall and floor contexts along the west wall (FS 136, pollen) and east wall (FS 141, flotation). Taxa identified in the pollen sample included maize, cheno-ams, grass family, sunflower family, ragweed/bursage, spruce, fir, unidentified pine, piñon pine, oak, Mormon tea, and sagebrush. Charred taxa identified in the flotation sample included maize and ponderosa pine. A pollen (FS 134) and flotation sample (FS 135) were taken from underneath soil that a tuff rock concentration (Feature1) was resting on, which was located 10 cm above the floor (see feature description). Taxa identified in the pollen sample included maize, rose family, grass family, cheno-ams, sunflower family, unidentified pine, piñon pine, juniper, and sagebrush. No charred specimens were identified in the flotation sample.

An area of ashy staining was also observed in unit 103N/99E just to the west of Feature 1. This ashy stain contained charcoal flecking and small pieces of charcoal. A flotation sample (FS 53) was taken from this stain and identified charred taxa included ponderosa pine, squash/coyote gourd, maize, mountain mahogany, and unknown conifer. Several small chipped stone flakes were also recovered from this area. Although the south wall of the structure appeared to be complete, it is possible that this area may have served as an entryway. The ashy staining, chipped stone flakes, and the presence of the rock concentration (Feature 1) may indicate this area was an entryway. Additionally, the wall block encountered in grids 102-103N/99E appear to be smaller and more jumbled than the rest of the wall.

Wall Construction. All that remained of the walls of Room 1 are two courses, in a single row, of shaped and unshaped tuff blocks that formed the foundation of the structure. Very little wallfall was observed during the excavation of Room 1 and it is possible that wall block from this site was scavenged and utilized elsewhere either during prehistoric times or more recently. What remained of the walls formed a well-preserved rectangular foundation. There were areas within the wall block where there was some remnant mortar, consisting of chunks of clay adhering to the block. Chinking stones were also present, some still in place between larger wall blocks, and these smaller rocks were also the most common rubble in the post-occupational fill.

It is possible that the walls of the structure were not very high to begin with and the foundation blocks may have had a stick and adobe superstructure (Table 52.4). Several pieces of burned adobe were recovered from the room fill. Very compact clay (wall slump?) was noted in areas along the base of the walls inside the room. As described briefly above, wall/foundation blocks along the west end of the south wall were of a somewhat different nature than the rest of the wall. Rocks were smaller and appeared to be in a double row. This could have been intentional or could represent either wallfall or a purposeful closing off of this section of wall. Just inside the room, an area of ashy staining and a light concentration of small chipped stone flakes, which could possibly represent a limited work, were noted on the floor. Excavation to the base of the wall blocks showed that, for the most part, the foundation of the structure was set into the Bwb1 horizon by means of a shallow, narrow trench, not more than 8 to 10 cm in depth.

Table 52.4. LA 127635 Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	2.75	0.35	0.35	2
South	2.65	0.36	0.38	2
East	1.82	0.20	0.36	2
West	1.90	0.29	0.35	2

Feature 1

Feature 1 is a concentration of 18 small tuff rocks located next to the south wall of Room 1 in units103N/99-100E. The rocks appear to be in rows, in a rough alignment. These rocks were not resting on the living surface. Two ceramic sherds and two chipped stone artifacts were recovered from the fill underneath the rocks and it was determined that this fill was part of the post-occupational fill. It is possible these rocks were originally part of the wall construction and fell into the structure subsequent to abandonment. Though there is no direct supportive evidence for it, these rocks could possibly represent the walling up of the entry way to the structure, the concentration was located adjacent to an area of the south wall where the foundation rocks differed from the rest of the wall. Wall blocks in this section were smaller and appeared to be in a double row, whereas in the rest of the wall and the structure, wall block was only a single row in width. Additionally, just inside the room, there was an area of ashy staining on the living surface that contained several small chipped stone artifacts, suggesting a possible activity area that may have been situated by the entryway. This area of ashy staining was located immediately to the west of the rock concentration. A flotation sample (FS 135) and pollen sample (FS 134) were taken from the fill below the rock concentration. No charred taxa were identified in the flotation sample, and taxa identified in the pollen sample included maize, rose family, grass family, cheno-ams, sunflower family, unidentified pine, piñon pine, juniper, and sagebrush.

Feature 2

Feature 2 consists of a prepared plaster hearth located against the north wall and inside of Room 1 (Figures 52.3 and 52.4). The top of the feature was roughly level with the living surface. Feature 2 is roughly ovoid in shape with plastered sides and bottom.

Figure 52.3. Post-excavation photograph of Feature 2 (hearth).

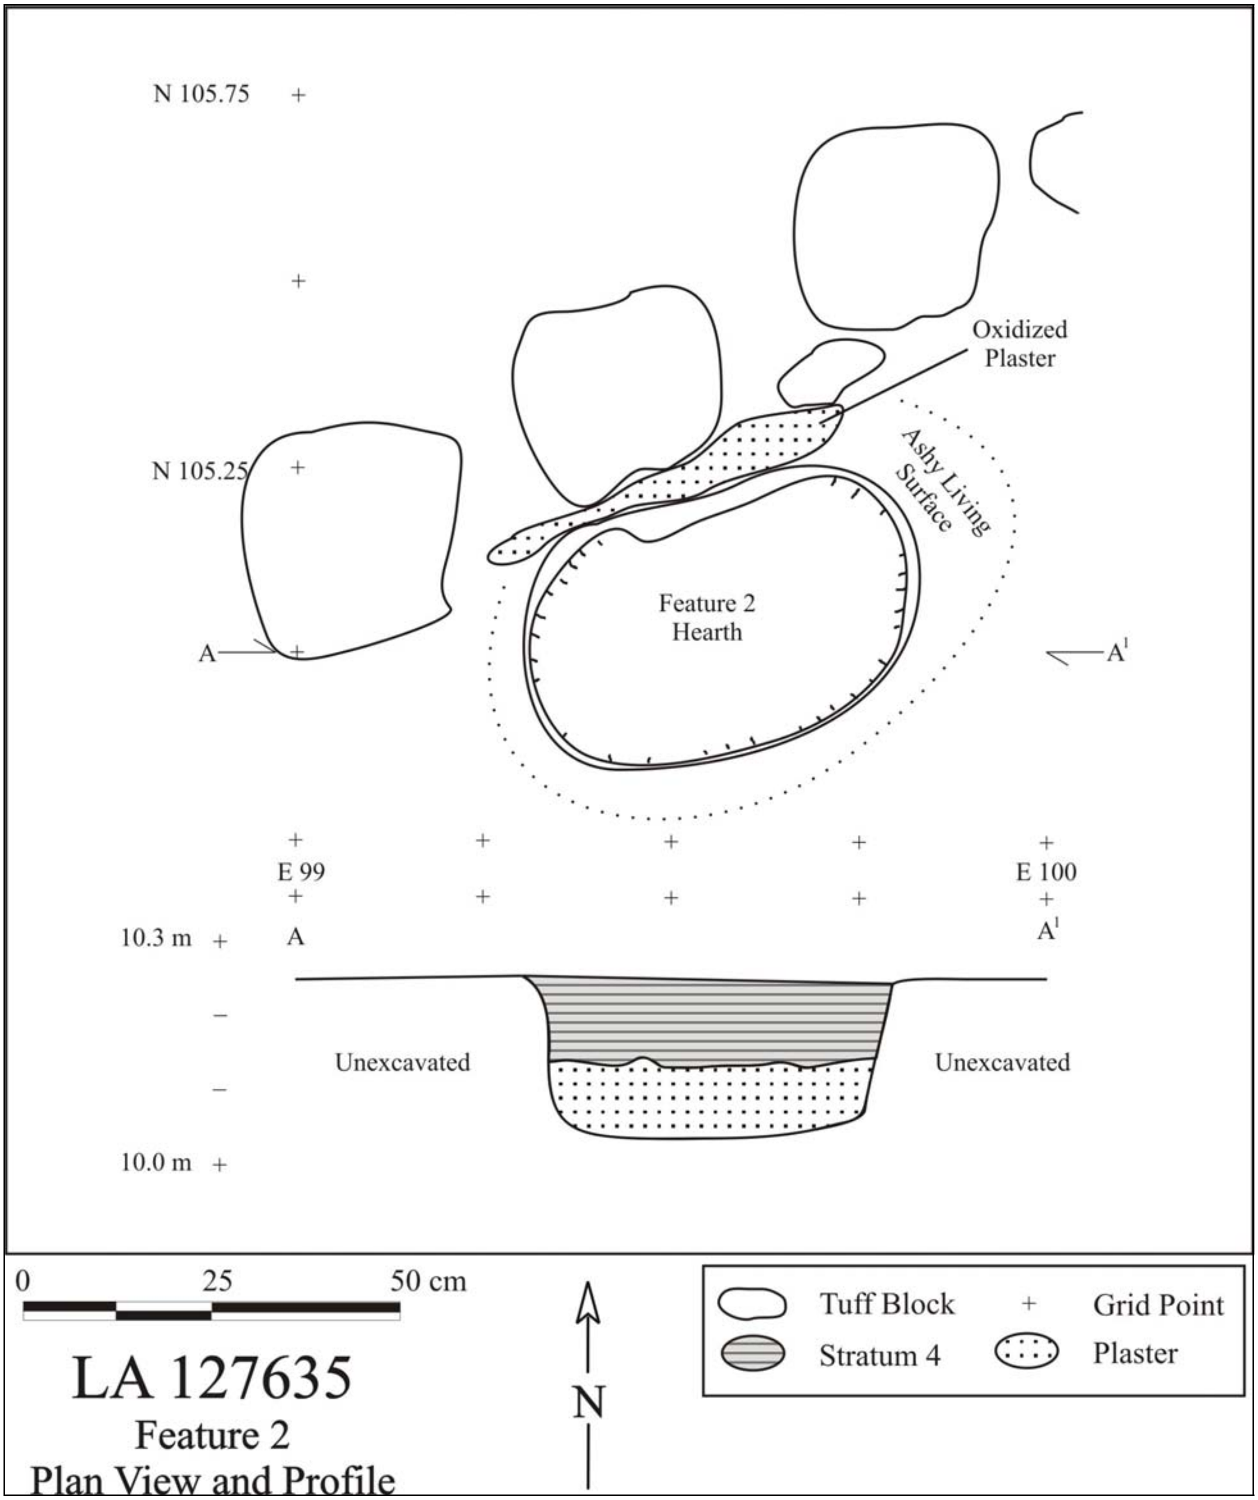

Figure 52.4. Plan view and profile drawing of the hearth (Feature 2) at LA 127635.

Feature 2 is heavily oxidized on the plaster surfaces, and the wall behind the feature also exhibited oxidation, indicating some fairly heavy use. Feature fill consisted of solid ash with some charcoal flecking. Although rootlets were observed growing in the bottom of the hearth, it was basically intact. The plaster on the upper sides of the hearth was somewhat damaged and crumbling, but the sides were also intact. There was no prepared collar noted but there was evidence of a small lip around the perimeter at the top of the hearth. The space between the feature and the north wall of the room was filled in with reddish dirt that also may be oxidized. The dirt fill appeared to be intentional as it was of a different color and texture and was looser than the surrounding compacted dirt of the living surface. Pollen (FS 109 and FS 127), flotation (FS 105, FS 123, FS 124, FS 125, and FS 126), charcoal (FS 107), and macrobotanical/corn (FS 108) samples were all collected from the hearth. No identifiable taxa were recovered from the pollen sample (FS 109). Charred taxa identified in the flotation samples included unknown conifer, unidentified pine, mountain mahogany, maize, tobacco, sagebrush, cheno-ams, ponderosa pine, oak, juniper, bugseed, cottonwood/willow, hedgehog cactus, and beeweed. The charcoal sample was not analyzed, but the maize sample was submitted for radiocarbon dating (see Chronology section below).

Geomorphic Analysis

A single grid unit (104N/101E) was excavated below the Bwb1 horizon to serve as a geomorphic test pit. The profile of this unit was analyzed by geomorphologists Paul Drakos and Steven Reneau. A soil sequence was determined consisting of an A horizon topsoil young colluvium (late Holocene), a Bw post-occupation colluvium with wallfall (late Holocene), a Bwb1 level, the top of which was the likely living surface (middle to late Holocene), and a Bkb1 sterile soil with carbonate development (middle to late Holocene).

Artifact Distribution

A total of 465 artifacts were recovered from the excavation of LA 127635, including 83 pieces of chipped stone, 381 ceramics, and one piece of ground stone. A total of 37 chipped stone artifacts were recovered from inside Room 1. The majority of these artifacts were recovered from units 103-104N/99E, located between Feature 2 and Feature 1 (including the ashy stain next to the feature) (Table 52.5). Both of these units were in direct line with the possible entry way (grid 102N/99E). Three chipped stone artifacts were recovered from the fill beneath Feature 1. Two chipped stone artifacts were recovered from the Feature 2 fill. As stated previously, several small chipped stone flakes (n = 17) were recovered from the ashy area next to Feature 1, suggesting the possibility of a limited activity area. These artifacts constituted almost half of the chipped stone recovered from inside the room.

Most of the chipped stone artifacts were recovered from Stratum 2, Level 2 (post-occupational fill), with fewer artifacts recovered from the ash stain area (Level 4) and the feature fill. The remaining 46 chipped stone artifacts were recovered from outside of Room 1. Located just outside of the south wall of Room 1 (102N/99E) there was a heavily bioturbated area from which 12 chipped stone artifacts were recovered. This unit was in line with the grids inside the room with the highest artifact concentration, suggesting the possibility of an activity area associated with the entryway of the structure. However, a large burrow continued from the unit outside the structure up under the wall and just inside the structure, which could have resulted in the loss of integrity of *in situ* artifacts due to rodent activity. If not for the rodent disturbance it could be suggested that artifacts recovered from the grid line 102-104N/99E represented a possible limited activity area, or was the result of sweeping out the structure. The remainder of the chipped stone artifacts was fairly evenly distributed across the site with no apparent concentrations.

Of the 381 ceramic sherds recovered from the excavation, 154 were recovered from inside Room 1. The majority were recovered from the post-occupational fill, with only three sherds recovered from the living surface (Stratum 3). Additionally, two sherds were recovered from the fill beneath Feature 1 and six sherds were recovered from the Feature 2 fill. As with the chipped stone artifacts, the highest concentration of ceramics was recovered from grids 103-104N/99E. A total of 227 ceramic sherds were recovered from units excavated outside of Room 1. The highest concentrations were recovered from units just to the east of the structure (104-105N/101E) and from the bioturbated area just outside the structure to the south (102N/99E). A total of 57 ceramic sherds were recovered from 104-105N/101E, all of which were from Stratum 2, Level 2. Thirty-one sherds were recovered from the bioturbated area in grid 102N/99E.

A single ground stone artifact, a two-hand mano, was recovered in an area located less than 1 m from the southeast corner of the structure. The mano was not associated with any activity area or features.

Table 52.5. LA 127635 artifact counts by grid unit.

	97E	**98E**	**99E**	**100E**	**101E**
102N	0	6	39	32	23
103N	12	25	43	17	10
104N	6	29	65	22	50
105N	0	14	16	7	41

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 448 artifacts were analyzed from the excavations conducted at LA 127635. In addition, flotation and pollen samples were selected for analysis from the post-occupational fill (Stratum 2), the floor (Stratum 3), the hearth fill (Stratum 4), and outside the structure (Stratum 5) (Table 52.6). Two maize samples were submitted for radiocarbon dating, a micaceous sherd for thermoluminescence (TL) dating, and three pieces of obsidian for hydration dating. The results of the artifact and sample analyzes are presented in the following sections.

Table 52.6. Samples selected for analysis from LA 127635 by FS#.

Stratum	Flotation	Pollen	Radiocarbon	TL
1				
2	135	134,136		
3	116,141	117		106
4	105, 123–126	109,127	105, 125	

Stratum	Flotation	Pollen	Radiocarbon	TL
5	100	99		

Chronology

Radiocarbon Dating

Two maize samples were submitted for accelerator mass spectroscopy dating. Both of the maize specimens were derived from flotation samples taken from the Feature 2 hearth fill. The first sample provided a date of 800±40 BP (Beta-215558), with a calibrated intercept of AD 1250 and a two-sigma range of AD 1180–1280. The second sample yielded a similar date of 760±40 BP (Beta-215559), with a calibrated intercept of AD 1270 and a two-sigma range of AD 1210–1290. Both dates indicate a Coalition period occupation dating to the 13th century.

Thermoluminescence Dating

A single Sapawe Micaceous sherd was submitted for TL dating from LA 127635 (Table 52.7). All derived ages are given in years BP, which refers to years before 2003. The TL date corresponds with the two radiocarbon dates, indicating a 13th century occupation.

Table 52.7. Thermoluminescence date from ceramics at LA 127635.

FS#	Lab #	Context	Burial depth (cm)	Years BP	% error	Years AD
106	UW1419	Stratum 3	40	753	14.3	1253±108

Obsidian Hydration Dating

Three obsidian artifacts from LA 127635 were submitted to the Diffusion Laboratory for age determination using the obsidian hydration dating method. In order to calculate the absolute date for an obsidian artifact, three analytical procedures were completed. First, the amount of surface hydration, or the thickness of the hydration rim, was measured. Second, the high-temperature hydration-rate constants for each artifact were determined from the composition of the glass. Lastly, the soil temperature and relative humidity at the archaeological site were estimated so that the rate of hydration determined at high temperature may be adjusted to reflect ambient hydration conditions. Using these methods, a hydration rate for the obsidian artifacts was calculated (Table 52.8).

Table 52.8. Obsidian hydration dates for LA 127635.

FS No.	Lab No.	Source	Rim (um)	AD/-BC	1 S.D.
6	2003-77	Valle Grande	1.37	1732	33
43	2003-78	Cerro Toledo	n/a		
103	2003-79	Valle Grande	4.11	-4556	321

Relative to other dating methods conducted at the site, the obsidian hydration dates seem to be the least accurate. Radiocarbon and TL dates indicate a Late Coalition period date (13th century), with neither of the two obsidian samples providing results.

Ceramic Artifacts (Dean Wilson)

A total of 371 ceramics were analyzed from LA 127635. The majority of the pottery consists of smeared-indented corrugated and Biscuit A sherds. In addition, the presence of Santa Fe Black-on-white, Wiyo Black-on-white, Galisteo Black-on-white, and Sapawe Micaceous would seem to reflect an Early Classic period occupation (Table 52.9). This would, however, represent a 14th century and not an earlier 13th century occupation as indicated by the radiocarbon dates. On the other hand, it would fit the two-sigma range of the TL date. Therefore, this site may have been occupied early in the 14th century or circa AD 1300. Information on ceramic tradition by ware, temper by ware, and vessel form by ware is provided in Tables 52.10 through 52.12. The graywares and whitewares appear to have been locally made from smeared-indented sand or tuff, in contrast to Sapawe Micaceous, mica utility, seven smeared-indented, and one plain gray sherd, which contained a non-local micaceous temper. Most of the grayware and all of the micaceous ceramics consist of jar vessel forms, while several grayware sherds were derived from a bowl(s). In contrast, the whiteware sherds include mostly bowls, with some jars.

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 77 artifacts were analyzed from LA 127635, consisting of two cores, 71 pieces of debitage, three retouched tools, and one ground stone artifact. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 52.13 presents the data on lithic artifact type by material type. The debitage is primarily made of chalcedony and Pedernal chert, with other materials. The presence of cortex on 12.6 percent of the debitage indicates that these materials were collected from waterworn (*n* = 9) sources. The chalcedony and Pedernal chert are available from local Rio Grande Valley gravels and the obsidian from nearby sources in the Jemez Mountains. Otherwise, the igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the plateau.

Three pieces of obsidian and a piece of basalt debitage were submitted for X-ray fluorescence analysis. The obsidian artifacts are Valle Grande and Cerro Toledo obsidian (Table 52.14). The Valle Grande (Cerro del Medio) and Cerro Toledo (Obsidian Ridge/Rabbit Mountain) source areas are situated about 17 km (11 mi) and 19 km (12 mi) to the west and southwest. Although obsidian is present at these nearby sources in the Jemez Mountains, it is also present on the nearby mesa as small pebbles. These pebbles compose part of the secondary deposits associated with the Cerro Toledo interval. A single basalt flake is actually made of dacite that was derived from a local source.

Table 52.14. Obsidian source samples.

FS #	Artifact	Color	Source
6	Debitage	Translucent	Valle Grande rhyolite
43	Debitage	Translucent	Cerro Toledo rhyolite
103	Debitage	Translucent	Valle Grande rhyolite

Lithic Reduction

The platform core was reduced using a bidirectional, 90 degree technique, whereas the cobble uniface represents the removal of flakes from an unprepared cortical platform. The core was classified as exhausted and the cobble uniface as still useable when discarded. Table 52.15 presents the metric information on the core and cobble uniface.

Table 52.15. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Bidirectional	27	44	30	39.3
Cobble Uniface	42	94	103	526.0

The debitage mostly consists of core flakes, with a few other items. The overall cortical:non-cortical ratio of 33.3 reflects an emphasis on the later stages of core reduction and tool production/maintenance. The flakes mostly have single-faceted platforms (n = 11), with fewer cortical (n = 1), dihedral (n = 1), collapsed (n = 4), and crushed (n = 3) platforms. Only one of the platforms exhibited evidence of preparation by abrasion/crushing. The majority of the core flakes are distal fragments (n = 20), with fewer whole (n = 11), proximal (n = 8), and midsection (n = 2) fragments. In contrast, the biface flakes consist of a whole and distal fragment. The whole core flakes have a mean length of 25.0 mm (*std* = 10.5), the single whole biface flake a length of 16.0 mm, and the angular debris a mean weight of 2.3 g (*std* = 3.1).

Two retouched pieces and a notch were identified during the analysis. One of the retouched pieces is an obsidian flake with alternate retouch that creates a rounded end that could have been used as perforator or drill. The other item is a flake with bidirectional retouch along a lateral edge with an angle of 55 degrees. The notched tool is actually a double notch with an edge angle of 40 degrees.

Tool Use

None of the debitage and two of the retouched tools exhibit evidence of edge damage that could be attributed to use. The obsidian retouched tool has rounding along the end, which indicates possible use as a perforator or drill. The retouched flake also exhibits rounding and scarring along the lateral retouched edge.

The ground stone artifacts solely consist of a two-hand mano. The mano is a well-worn loaf-shaped piece of tuff with flat and convex-shaped grinding surfaces (Figure 52.5).

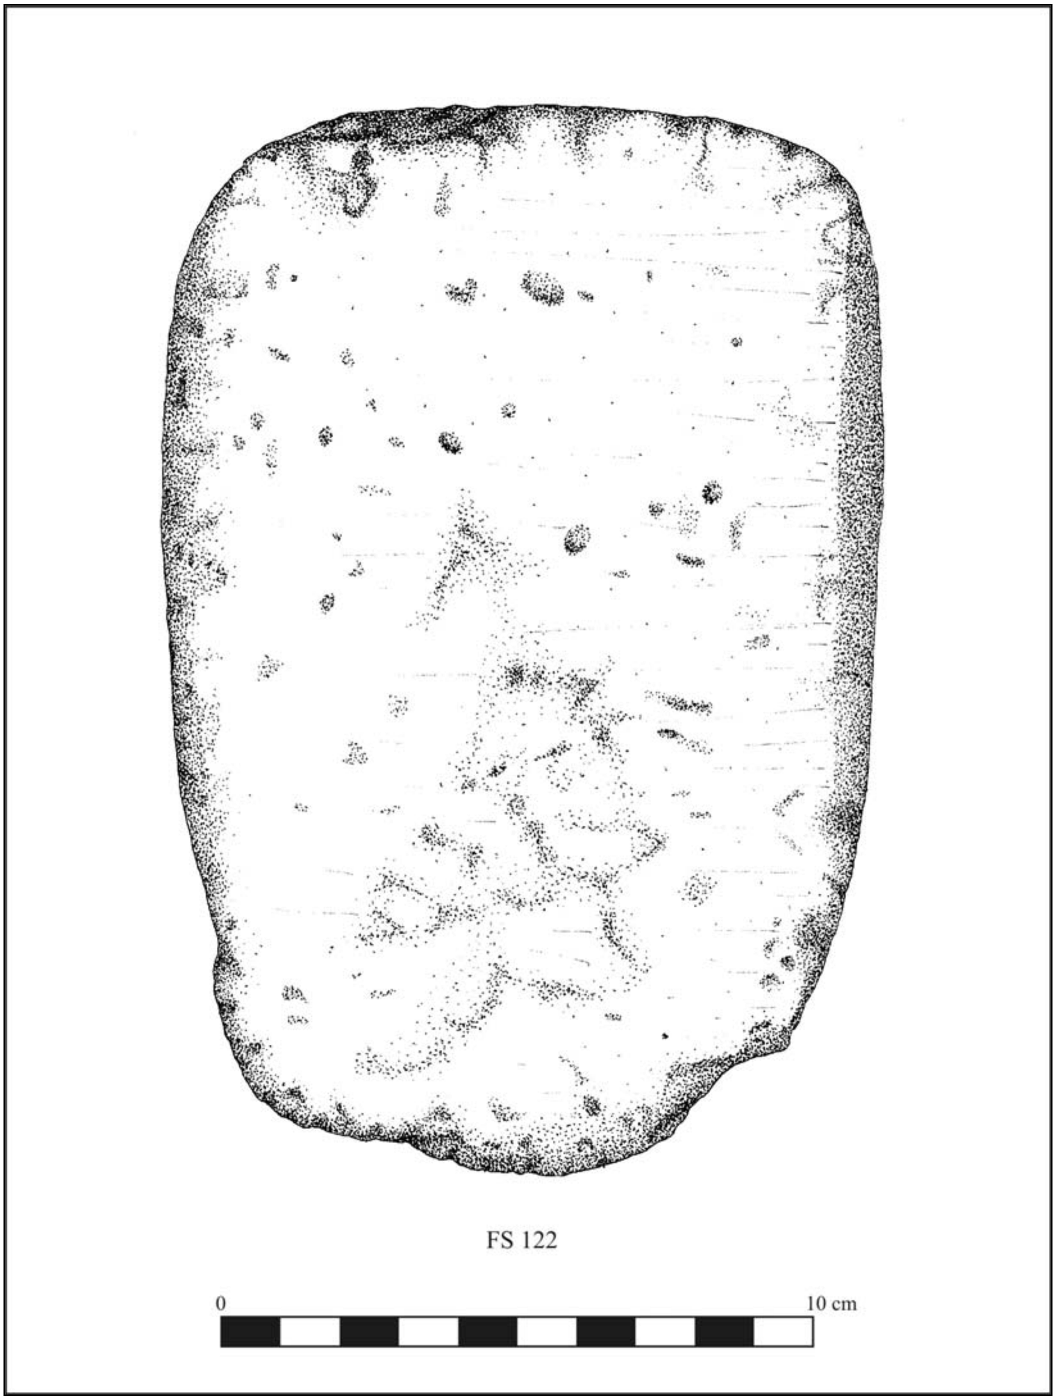

Figure 52.5. Two-hand mano from LA 127635.

Archaeobotanical Remains (Pamela McBride)

Floral remains from this Classic period fieldhouse resemble those from the neighboring fieldhouse, LA 127634, to the east. Beeweed and maize were the most common taxa from both fieldhouses. While tobacco was found in hearths at both sites, only one sample out of 14 at LA

127634 yielded tobacco, whereas tobacco was present in 56 percent of samples from LA 127635. Beans were present at LA 127634 and not at LA 127635. Aside from conifer needles and bark, evidence for perennial plant use was represented by a hedgehog cactus seed fragment from the upper fill of the hearth, while at LA 127634, a banana yucca seed in the hearth was the only non-conifer perennial plant part recovered. Possible squash rind was identified from both structures.

LA 127635 floor scrape and floor samples (FS 116 and FS 141) yielded very similar taxa to those encountered in post-occupational fill samples (FS 45 and FS 53), including corn cupules and charred conifer duff (Table 52.16). The exception was possible squash rind identified in the general fill sample. Only unburned material was recovered from under the patterned rock concentration (Feature 1). Lower and upper fill of the hearth (Feature 2) yielded cheno-ams, tobacco, beeweed, maize, and conifer duff; bugseed and hedgehog cactus seeds were restricted to the upper fill. One sample from the upper fill of the hearth consisted almost entirely of kernel fragments. In general, much higher concentrations of maize kernels were present at LA 127635 than at LA 127634. The sample taken from under the concentration of tuff rocks adjacent to the south wall of the structure (Feature 1) contained only unburned plant material. It was suggested earlier in this chapter that this rock concentration may represent the deliberate walling up of the entrance to the structure. Two ceramic sherds and two chipped stone artifacts were found in the fill under Feature 1 and it was determined that this was post-occupational fill. However, if this were the case, the sample would be more likely to contain similar remains to those found in FS 45 that included conifer needles, bark, and charcoal.

Wood charcoal from the floor scrape was very different from the floor sample; ponderosa pine was the only wood type identified in the floor scrape sample, while pine, piñon, and mountain mahogany were identified in the floor sample (Table 52.17). Charcoal from the two general fill samples was also very different. Fill above the living surface produced only coniferous woods, while the majority of charcoal from the general fill sample was mountain mahogany with a small amount of unknown conifer. The Feature 2 wood assemblage was much more diverse than other contexts, yielding coniferous (including juniper), cottonwood/willow, mountain mahogany, oak, and sagebrush.

Feature 2 was the best-preserved hearth that was excavated in Rendija Canyon (Lockard, personal communication), and the preservation of plant material certainly confirms this observation. Plant remains indicate that the occupants of LA 127635 were utilizing several annual species (including ritual use of tobacco), hedgehog cactus, maize and possibly squash, and wood species from the riparian, mountain foothills, and ponderosa pine forest zones.

Pollen Remains (Susan Smith)

Five pollen samples were analyzed from LA 127635. Table 52.18 lists the frequency of identified pollen types. Maize was the only cultigen identified in the assemblage. No other economic resources were identified. A number of potential economic resources were also identified in the assemblage, and these are discussed in Smith's chapter in Volume 3.

SUMMARY OF SITE EXCAVATIONS

LA 127635 consists of a one-room fieldhouse with plaster-lined heath. All four walls were intact, with evidence for two possible floors. This evidence, in conjunction with the ceramic, radiocarbon, and TL data, indicates that the fieldhouse was probably occupied during the Late Coalition and Early Classic period. Maize pollen was recovered during the site excavations indicating that the fieldhouse may have been seasonally occupied during the growing season.

CHAPTER 53
RENDIJA TRACT (A-14): LA 135291

Michael J. Dilley and Bradley J. Vierra

INTRODUCTION

LA 135291 is a small one-room Classic period fieldhouse situated on a north-facing slope of the terrace about 115 m south of the ephemeral creek in Rendija Canyon. The area is covered by a ponderosa pine forest at an elevation of 2108 m (6915 ft). The fieldhouse is located to the east and outside the Los Alamos Sportsmen's Club and to the immediate north of the Rendija Canyon road. Neither of these appear to have impacted the site.

The site was originally identified by Brian Harmon during the Cerro Grande post-fire assessment project and given a temporary number of BCH-1. It was described as a possible fieldhouse consisting of a large cluster of cobbles that covered a 10- by 10-m area; however, most of the rocks were centered in a roughly rectangular-shaped 3- by 4-m area. This locale was severely burned during the Cerro Grande fire, as is evidenced by the remains of two burned junipers on the site. The architectural feature was surrounded by a light scatter of artifacts that included a Wiyo Black-on-white sherd, two Biscuit A sherds, two plainware sherds, a Pedernal flake, and a quartzite cobble fragment. The site was said to date to the Classic period.

FIELD METHODS

Fieldwork began with a reconnaissance of the area around the fieldhouse to define the nature and extent of the surface remains. The site datum was set at the southwestern corner of the site and designated 100N/100E and 10.00 m elevation. A 1- by 1-m grid system was laid in around the surface architectural remains. Subdatums were subsequently shot in along the west and south sides of the excavation block (A and B). The site was photographed and excavations begun (Figure 53.1).

An east-west trench was excavated along the 104N grid line from 100 to 106E to expose and define the walls of the structure and the site stratigraphy. The east and west walls were identified, as was a possible unprepared living surface about 20 cm below the present surface. The block excavation was, therefore, expanded to include the area bounded by 103N/100E, 106N/100E, 106N/106E, and 103N/106E. A total of 26 grids were excavated in and around the one-room fieldhouse.

Excavations within the structure involved removing the post-occupational fill down to the level of the possible unprepared living surface. This surface was situated at the top of the Btb1 soil horizon and was covered by fill consisting of Bw soil. Obvious wallfall was removed so that the structure's walls and any internal features could be identified. It appeared that the south wall had collapsed within the structure, whereas, the north, east, and west walls had collapsed towards the outside of the structure.

Figure 53.1. Pre-excavation photograph of LA 135291.

Pollen and flotation samples were taken from each stratigraphic unit and various locations on the possible floor surface. All excavated soil was sieved through a 1/8-in. mesh to aid in the recovery of cultural remains. The excavation was extended approximately 1 m around the structure to locate external features and identify outside activity areas. Both internal and external features were found during the excavations. After the excavations were complete, the site was mapped (Figure 53.2) and photographed (Figure 53.3).

The excavation of the site was supervised by Michael Dilley. Crewmembers included Sandi Copeland, Hannah Lockard, Greg Lockard, Alan Madsen, and Bradley Vierra. Timothy Martinez and Mike Chavarria served as monitors and screeners representing San Ildefonso and Santa Clara pueblos, respectively.

STRATIGRAPHY

Four stratigraphic units were defined during the excavations. These are illustrated in the profile provided in Figure 53.2 and are listed in Table 53.1. Stratum 1 is the loose topsoil that covered the site and represents most of the A soil horizon. Some of the surface organic material and two juniper trees burned during the Cerro Grande fire. Stratum 2 consists of the sandy loam that characterizes the post-occupational fill. This stratum is situated within and outside of the structure, consisting of the Bw soil horizon. Stratum 3 is an unprepared occupational surface. Stratum 4 is the ashy clay soil that filled Feature 2, an ashpit.

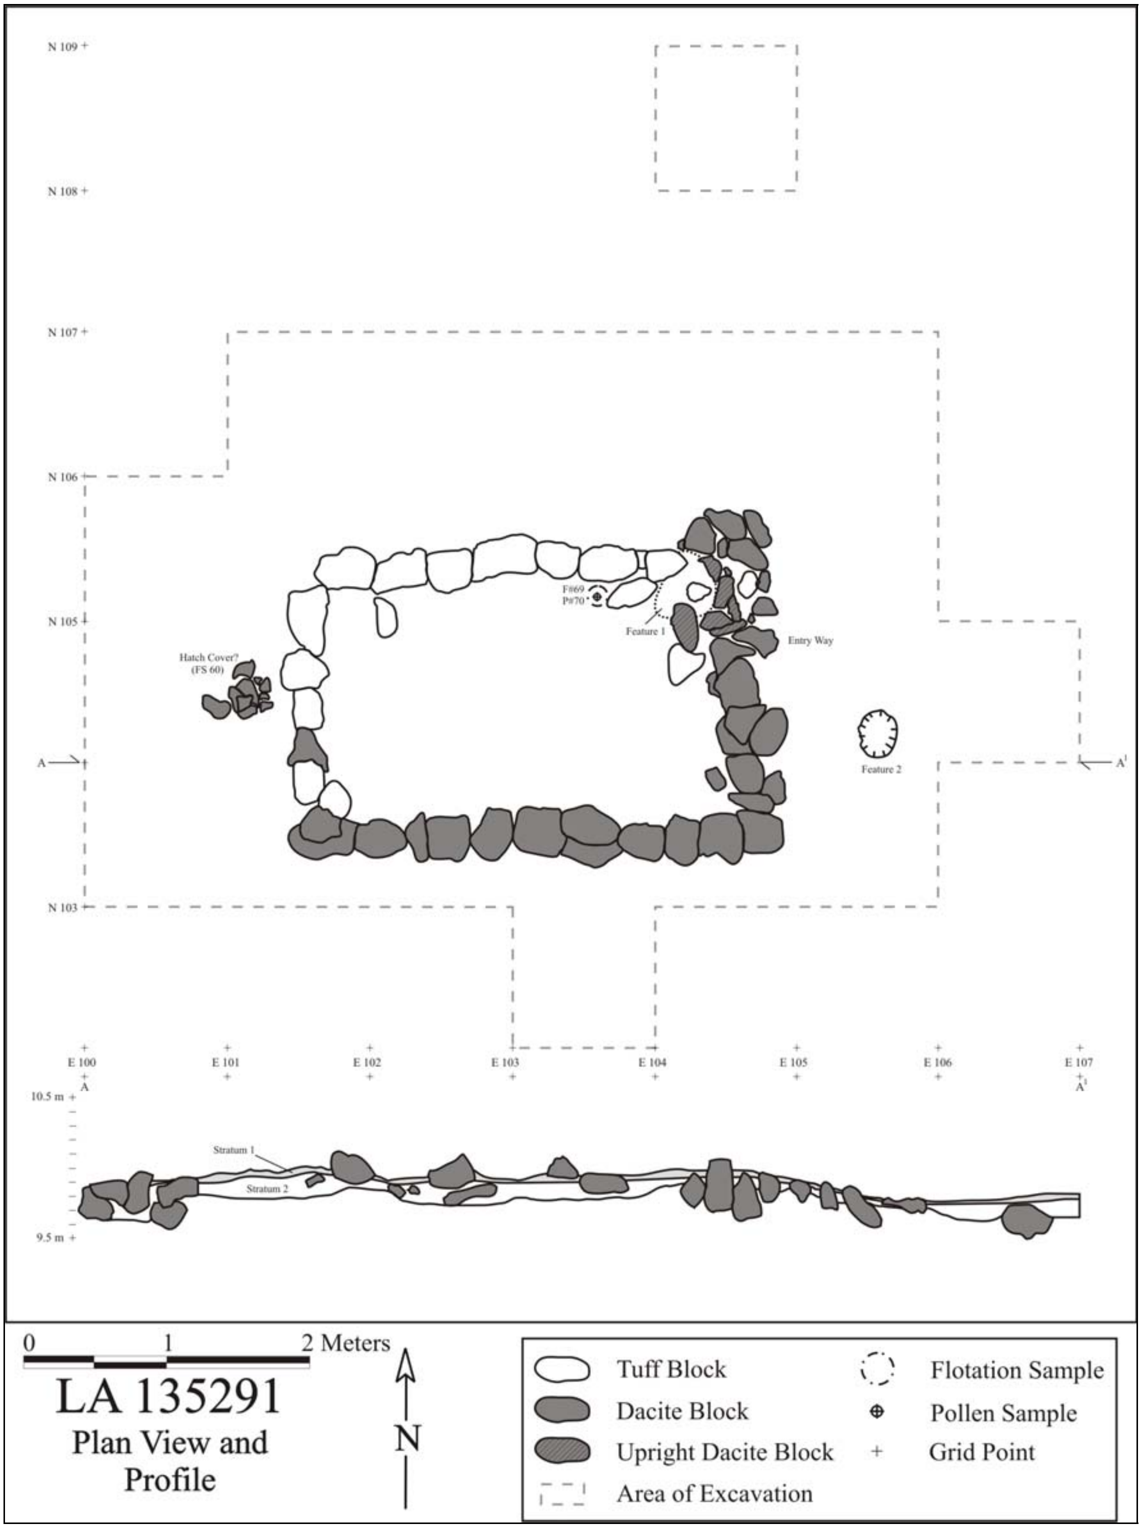

Figure 53.2. Plan view and profile drawing of LA 135291.

Figure 53.3. Post-excavation photograph of the fieldhouse at LA 135291.

Table 53.1. LA 135291 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10YR 3/3	Sandy loam	1–5	Surface sediment
2	10YR 3/4	Sandy loam	10–30	Post-occupational fill
3	7.5YR 3/3	Sandy clay	-	Living surface
4	10YR 7/2	Sandy loam	18	Feature 2 (ash pit) fill

A geomorphic test pit was excavated adjacent and outside the east wall of the structure in grid 103N/105E (see Chapter 57, Volume 3). It was excavated to a depth of about 1 m, and three soil horizons were identified (Table 53.2). From top to bottom these consist of A, Bw, and Btb1. As previously noted, the A and Bw soil horizons relate to Strata 1 and 2; whereas, the site occupation was associated with the top of the Btb1 soil horizon and Stratum 3. Table 53.3 provides the artifact count information by stratigraphic unit at the site, with a total of 113 artifacts recovered.

Table 53.2. LA 135291 soil horizon descriptions from the east profile of unit 103N/105E.

Horizon	Color	Texture	Depth (cm)	Description
A	10YR 3/3	Sandy loam	0–4	Topsoil
Bw	10YR 3/4	Sandy loam	4–11	Late-Holocene soil
Btb1	7.5YR 3/3	Sandy clay	11–30+	Pleistocene soil

Total	**80**	**19**	**14**	**0**	**113**

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is a one-room fieldhouse (see Figure 53.3). The room measures about 1.70 m north-south by 2.85 m east-west, with about 4.8 m^2 of interior space. Excavation of the room began with an east-west trench that extended across the rubble area along the 104N grid line. This excavation defined the east and west walls of the structure, the internal stratigraphy, and a possible unprepared floor surface. After the trench was completed, the remainder of the room fill was removed to the level of the possible floor. The geomorphic test pit was subsequently excavated to the immediate east of the structure to define the stratigraphic context of the walls and occupational surfaces.

Floor. Approximately 20 to 30 cm of post-occupational fill was removed before exposing a possible unprepared living surface within the structure. The floor was poorly defined with no obvious preparation, but was primarily identified by the break in the soil profile and the top of the Btb1 horizon. The surface was not level, but sloped down towards the north. No artifacts were recovered from the floor, but a flotation (Field Specimen [FS] 69) and pollen (FS 70) sample were taken from the southeastern corner of the room. Charred taxa identified in the flotation sample included unknown conifer, mountain mahogany, juniper, unidentified pine, and ponderosa pine. The pollen sample was not analyzed.

Features

Feature 1. Feature 1 consists of a circular set of upright dacite cobbles that bound a 43- by 57-cm area (Figure 53.4). At least one cobble is set in the bottom of the feature, but none exhibit any obvious evidence of burning, nor was any ash or charcoal present as fill. Therefore, it seems unlikely that it represents a hearth, but could be a pot rest. A pollen (FS 57) and two flotation samples (FS 58 and FS 59) were taken from the fill. Taxa identified in the pollen sample included cheno-ams, grass family, sunflower family, ragweed/bursage, globemallow, spurge family, fir, unidentified pine, piñon pine, juniper, oak, Mormon tea, and sagebrush. Charred taxa identified in the flotation samples included juniper, piñon pine, ponderosa pine, and unknown conifer.

Figure 53.4. Post-excavation photograph of Feature 1.

Feature 2. Feature 2 consists of a small ash concentration that is located outside and to the immediate east of the structure (see Figures 53.2 and 53.3). The concentration is ovoid in plan view and is 25 by 30 cm in size and 6 cm in depth (Figure 53.5). The feature could represent a discard pile, since it was not well-preserved, exhibited no evidence of *in situ* burning, and contained no charcoal or artifacts. The feature was situated directly on top of the Btb1 soil horizon. A flotation (FS 61) and pollen (FS 62) sample were taken from the fill of the feature (Stratum 4). Charred taxa identified in the flotation sample included mountain mahogany, unidentified pine, ponderosa pine, Douglas fir, oak, and maize. Taxa identified in the pollen sample included buckwheat, grass family, cheno-ams, sunflower family, ragweed/bursage, unidentified pine, piñon pine, juniper, Mormon tea, and sagebrush.

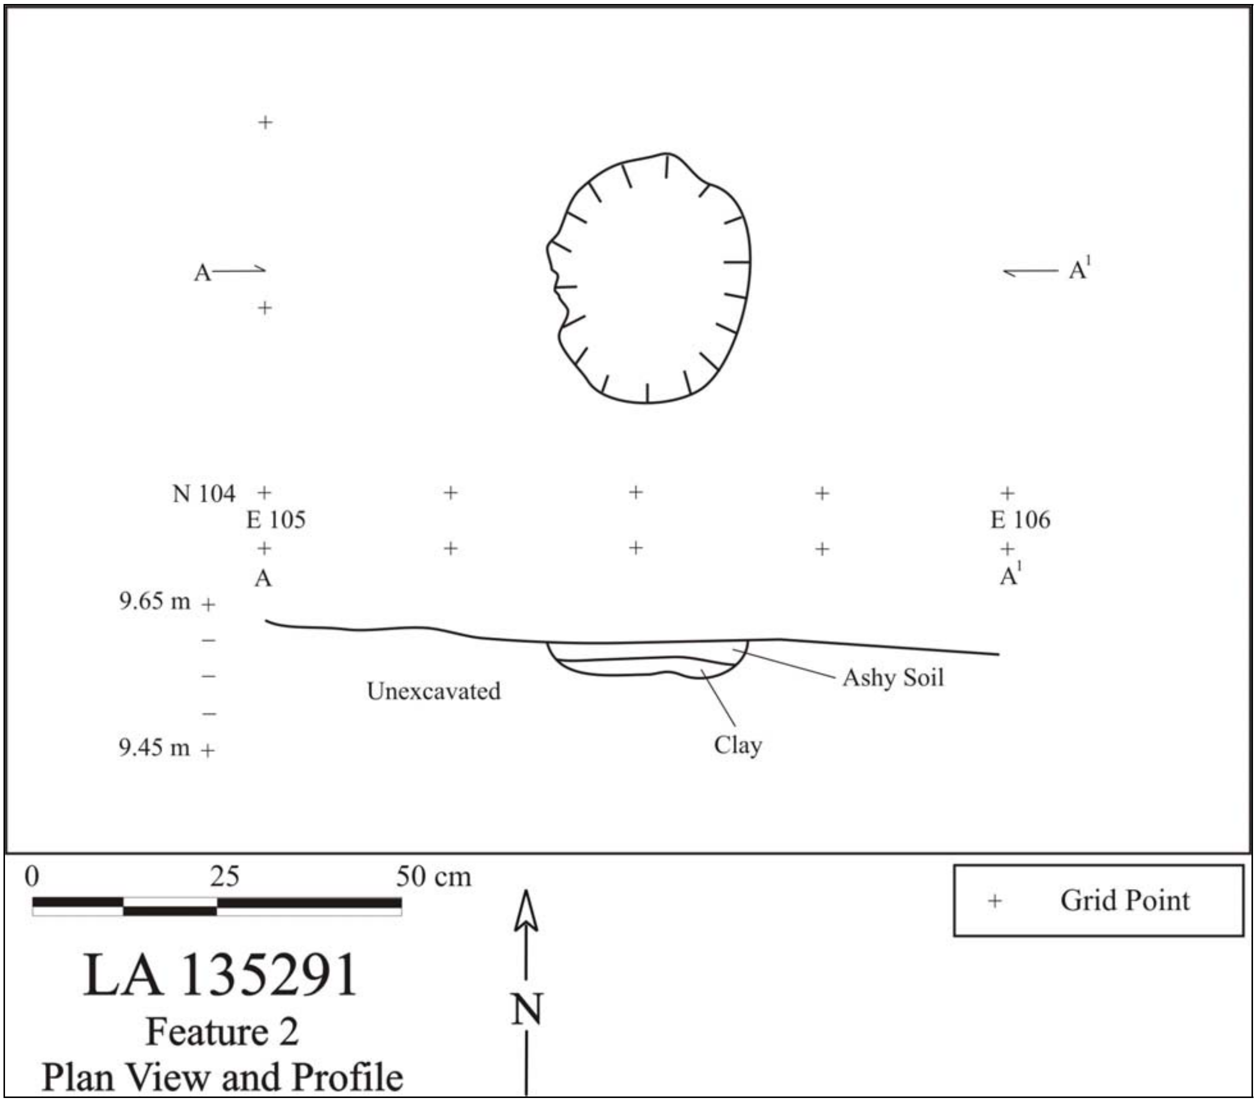

Figure 53.5. Plan view and profile drawing of Feature 2.

Wall Construction. The walls in Room 1 were composed of dacite cobbles with a few tuff blocks. The dacite is available from gravels in the nearby drainage and the tuff from outcrops in the canyon. The existing walls are one to two courses high, with dacite cobbles composing the upper course and more uniform tabular dacite cobbles the lower course. This basal course has been placed a few centimeters below the surface in a foundation trench. There was no evidence of mortar or plaster, indicating that the walls were probably dry laid. A broken dacite slab was embedded in the east wall and could represent a possible doorway into the room. The distribution of wallfall indicates that the north, east, and west walls collapsed towards the outside of the room and the south wall towards the inside of the room. A total of 2.5 m^3 of masonry rubble was removed from the fill of the room, indicating that the original walls may have stood less than 1 m high. Fragments of a broken dacite slab were identified outside the west wall that could be the remains of a hatch cover. Wall measurement information is provided in Table 53.4.

Table 53.4. LA 135291 Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	2.80	0.05–0.25	0.18–0.30	1
South	2.90	0.10–0.25	0.20–0.30	2
East	1.85	0.12–0.24	0.17–0.30	1 to 2
West	1.60	0.05–0.21	0.17–0.34	1 to 2

Artifact Distribution

Table 53.5 illustrates the distribution of artifacts recovered during the site excavation (i.e., ceramics, chipped stone, ground stone, and faunal remains). The bold numbers indicate grid units that are located completely or partially within Room 1, which indicates that the majority of the artifacts were recovered from within the structure; however, there are three grids with numerous artifacts that are located to the north of the fieldhouse.

Table 53.5. LA 135291 artifact distribution by grid unit.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 113 artifacts were analyzed from the excavations conducted at LA 135291. In addition, flotation and pollen samples were selected for analysis from the post-occupation fill (Stratum 2), Feature 1 (Stratum 3), and Feature 2 (Stratum 4) (Table 53.6).

Table 53.6. Samples selected for analysis from LA 135291.

Chronology

Radiocarbon Dating

A single maize sample was submitted for accelerator mass spectroscopy dating from LA 135291. The sample provided a date of 410±40 BP (Beta-229536), with a calibrated intercept of AD 1450 and a two-sigma range of AD 1430 to 1520.

Ceramic Artifacts (Dean Wilson)

A total of 82 ceramics were analyzed from LA 135291. The majority of the pottery represents local Rio Grande decorated ceramics, with a few utilityware types (Table 53.7). These include Biscuit A, smeared-indented corrugated, and micaceous plain gray sherds. The whitewares are primarily tempered with fine ash tuff, the corrugated wares with smeared-indented sand, and the plain gray sherds with granite and mica (Table 53.8). Most of the whitewares are represented by bowl forms and the utilitywares by jar forms; however, two whiteware sherds are from jars and one of the plain gray sherds is from a bowl (Table 53.9). The site probably dates to the early Classic period (14th century) given the presence of Biscuit A.

Table 53.7. Ceramic types from LA 135291.

Ceramic Type	Frequency	Percent
Northern Rio Grande Whiteware		
Biscuit A	12	14.6
Unpainted Biscuit one side slipped	3	3.7
Biscuit paint and slip absent	14	17.1

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 32 artifacts were analyzed from LA 135291, consisting of two cores, 14 pieces of debitage, two retouched tools, and 14 ground stone artifacts. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 53.10 presents the data on lithic artifact type by material type. The debitage is primarily made of Pedernal chert and chalcedony, with a single obsidian artifact. The presence of cortex on 14.2 percent of the debitage indicates that these materials were collected from waterworn (*n* = 2) sources. The Pedernal chert and chalcedony are available from local Rio Grande Valley gravels and the obsidian from nearby sources in the Jemez Mountains. Otherwise, the igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the plateau.

Lithic Reduction

The platform core was reduced using a bidirectional, opposed-same-face technique; whereas, the flake core was reduced using a single-face technique. The platform core was classified as exhausted and the flake core as broken due to a culturally induced fracture when discarded. Table 53.11 presents the metric information on the cores.

Table 53.11. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Single-directional	22	40	31	28.2
Bidirectional	24	40	42	41.7

The debitage consists mostly of core flakes and angular debris, with a few other items. The flakes mostly have collapsed platforms (n = 3), with fewer cortical (n = 1), single-faceted (n = 2), and multi-faceted (n = 2) platforms. Only one of the platforms exhibits evidence of preparation by abrasion/crushing. The majority of the core flakes are whole (n = 8), with fewer proximal (n = 3), midsection (n = 1), and distal (n = 2) fragments. In contrast, the biface flakes consist of a whole and distal fragment. The whole core flakes have a mean length of 36.5 mm (*std* = 6.3), the single whole biface flake a length of 12.0 mm, and the angular debris a mean weight of 2.8 g (*std* = 2.3).

Two retouched pieces were identified during the analysis. One of the retouched pieces is an obsidian flake fragment with bidirectional retouch along a lateral edge with an edge angle of 55 degrees. The other is a Pedernal chert flake fragment that exhibits unidirectional dorsal retouch along a lateral edge with an angle of 65 degrees.

Tool Use

None of the debitage or the retouched tools exhibit evidence of edge damage that could be attributed to use.

The ground stone artifacts include manos and metates. The one-hand mano consists of a piece of dacite with a single ground surface. The two-hand mano consists of a loaf-shaped piece of dacite with flat and convex-shaped grinding surfaces. The undetermined mano fragment is a fire-cracked quartzite cobble with some evidence of grinding on two opposing surfaces. The undetermined metate is a fire-cracked piece of dacite with a single heavily ground flat surface. Lastly, the undetermined ground stone items compose part of a shaped dacite slab.

Archaeobotanical Remains (Pamela McBride)

Maize cupules from the ash concentration found outside the structure just to the east were the only plant remains hinting at the agricultural activities that took place near the fieldhouse (Table 53.12). Juniper twigs and ponderosa pine and piñon needles could be related to fuelwood use or represent residue from the Cerro Grande fire. Unburned juniper twigs, ponderosa pine needles, hedgehog cactus seeds, and weedy annual seeds most likely represent modern intrusives transported into the site by wind or rodents.

+ 1-10/liter.

Wood charcoal from inside the structure consisted of pine, ponderosa pine, and unknown conifer (Table 53.13). The wood may also be the result of the Cerro Grande fire. The site is located in a pine forest that was severely burned during the fire and two burned juniper trees were found inside the feature. In contrast, the wood assemblage from the possible discard pile outside the structure was quite different in composition, including possible Douglas fir, mountain mahogany, and oak. The presence of maize in this feature along with this unique wood assemblage suggests a discrete dumping episode that may be the only intact evidence at the site of fuel use.

Pollen Remains (Susan Smith)

Four pollen samples were analyzed from LA 135291. Table 53.14 lists the frequency of identified pollen types. Maize was the only cultigen identified in the assemblage. No other economic resources were identified. A number of potential economic resources were also identified in the assemblage, and these are discussed in Smith's chapter in Volume 3.

SUMMARY OF SITE EXCAVATIONS

LA 135291 consists of a one-room fieldhouse. Excavations revealed the presence of an unprepared floor that corresponded with the top of the Btb1 soil horizon. No artifacts were exposed on the floor; however, a single feature was identified. The feature consisted of several upright dacite cobbles that enclosed the northeast corner of the room. The cobbles do not appear to be the remains of a hearth given the absence of burning, but may be a pot rest. An ash discard pile was identified outside and to the east of the fieldhouse. The presence of maize and the prevalence of storage jars reflect the agricultural function of the site, with limited core reduction and grinding activities also being represented. The occupation of the site dates to the 14th century (Early Classic) based on the presence of Biscuit A ceramics.

CHAPTER 54
RENDIJA TRACT (A-14): LA 135292

Gregory D. Lockard

INTRODUCTION

LA 135292 is the remains of a one-room Classic period fieldhouse located on a terrace to the south of the Rendija Canyon channel. The site is located a few tens of m north of the Rendija Canyon Road. It is covered with grass, but otherwise contains only a few small bushes that were burned during the Cerro Grande fire. The site is situated at an elevation of 2080 m (6915 ft).

LA 135292 was first recorded on October 19, 2000, by Nisengard, Harmon, and Schmidt as part of the Cerro Grande post-fire assessment project. The site was identified as a possible fieldhouse. Artifacts visible on the surface included an obsidian core flake, a Pedernal chert core flake, a Wiyo black-on-white sherd, a Biscuit B sherd, two indeterminate whiteware sherds, two smeared-indented sherds, and three plainware sherds. Based on these ceramics, the site was likely occupied during the Classic period (AD 1325–1600).

FIELD METHODS

Before excavation, the site and surrounding area were cleared of trees and large undergrowth. The site was then visible as a small rubble mound approximately 2 by 2 m in area (Figure 54.1). An arbitrary site datum (designated 100N/100E, 10.00 m elevation) was set up in the southwest corner of the site. The site was then covered with a 1- by 1-m grid that extended 5 m north and 6 m east of the site datum. Two subdatums (A and B) were set up for taking elevations. The site was then photographed. Artifacts visible on the surface were collected by grid unit, and the location of artifacts outside of the grid was determined with tape measures. A 6- by 1-m east-west trench (102N/100-105E) was initially excavated across the rubble mound. The purpose of this trench was to expose a profile of the site stratigraphy, as well as to determine the location of the structure's east and west walls. Units were excavated by strata, and thicker strata were excavated in arbitrary 10-cm levels. The southwest corner of the structure was encountered in unit 102N/102E. The south wall extends eastward through unit 102N/103E and into the western half of unit 102N/104E.

No discernible living surface was encountered in any of the grid units in the trench. Excavation of the trench units proceeded down to the base of the walls. Unit 102N/101E, located just west of the southwest corner of the room, was selected to serve as a test pit for geological analysis. Excavation in this unit therefore proceeded an additional 50 cm below the surrounding units. After the excavation of the trench units, the north profile of the trench was drawn and photographed. The rest of the area was subsequently excavated, again by strata and arbitrary levels for thicker strata. In all, 18 units were excavated. Excavation revealed that only the structure's southwest corner was preserved. The other corners, along with most if not all of the room's north and east walls, were destroyed, probably by modern machinery. As a result, there was no clear boundary between the inside and outside of the room, except in the southwest corner.

Figure 54.1. Pre-excavation photograph of LA 135292.

Excavation throughout the site therefore terminated at the same level—the base of the extant portions of the room's walls. Excavation focused on defining the room's walls, removing wallfall, and locating features. Soil samples were taken from select locations, and all other soil was passed through screens with 1/8-in. mesh to aid in the recovery of artifacts. The excavation area extended at least 1 m beyond the structure in all directions to locate external features and/or outdoor activity areas. The structure was then mapped (Figure 54.2) and photographed (Figure 54.3).

The excavation of the site was supervised by Greg Lockard. The field crew included Joseph (Woody) Aguilar, Bettina Kuru'es, Brandon Gabler, Margaret Dew, Jeanine Wood, and Aaron Lenihan. Timothy Martinez and Aaron Gonzalez served as site monitors from San Ildefonso Pueblo and as screeners. Michael Chavarria was the site monitor representing Santa Clara Pueblo, as well as an additional screener.

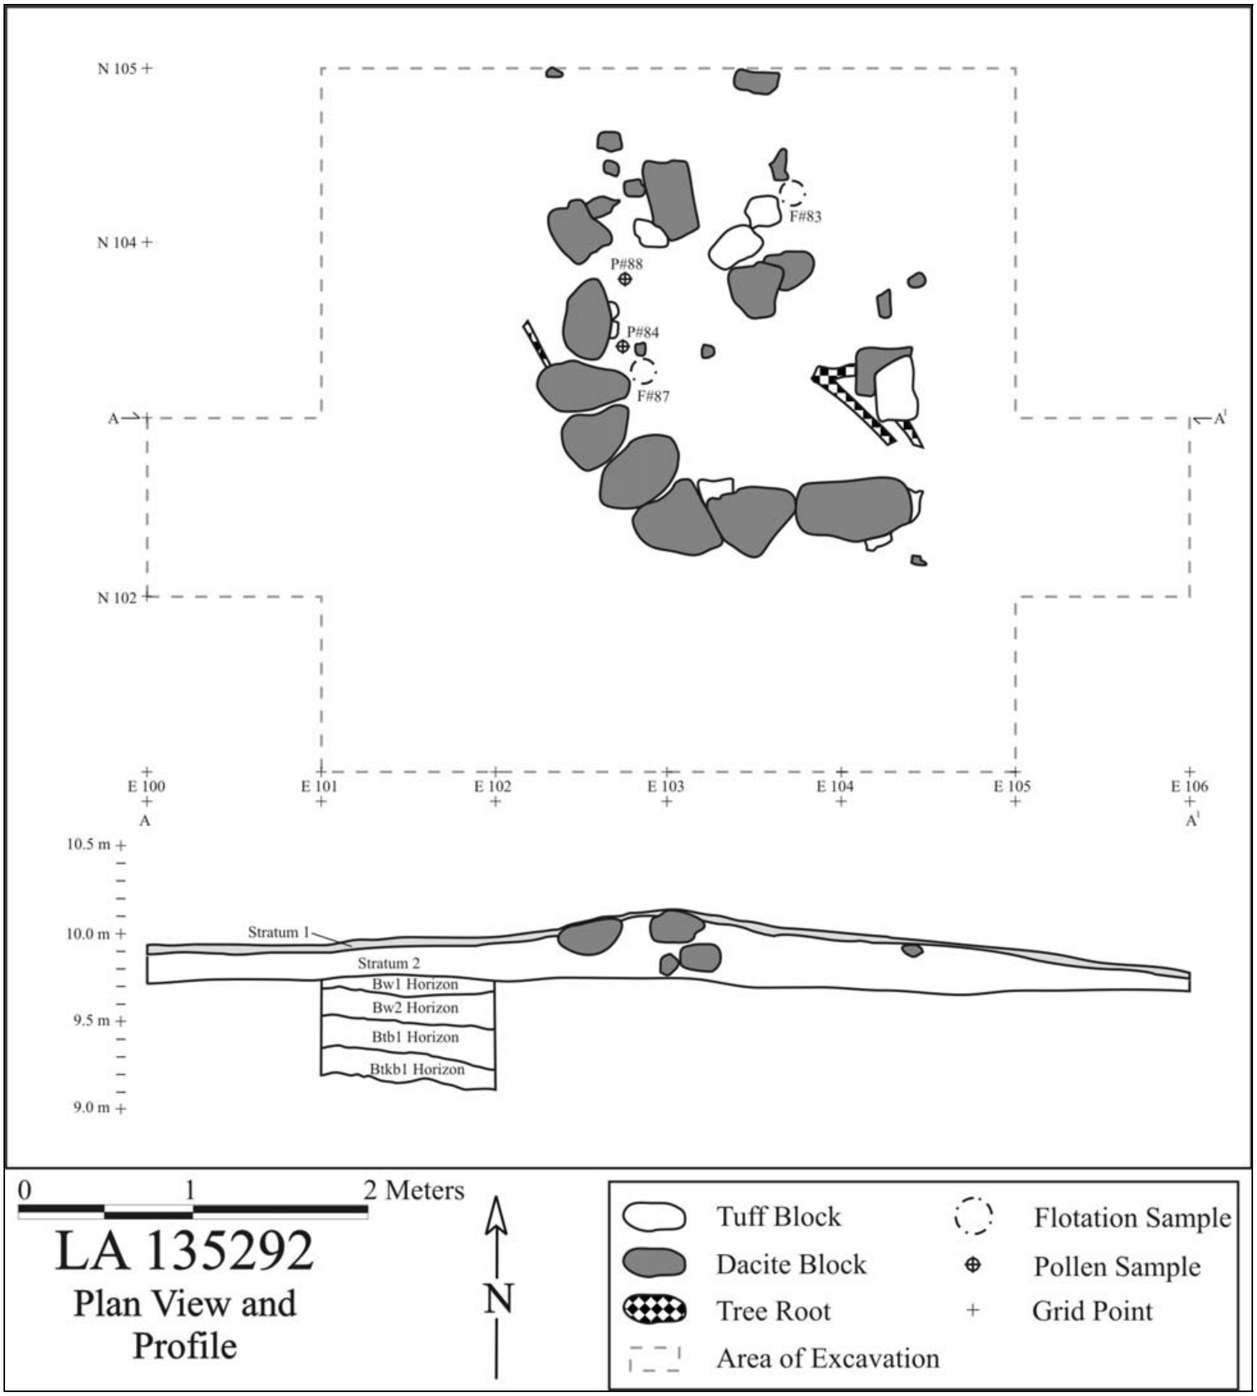

Figure 54.2. Plan view and profile drawing of LA 135292.

STRATIGRAPHY

Stratum 1 is composed of loose surface sediment. It is uniformly 2 to 6 cm thick across the site and is equivalent to the upper portion of the A horizon (topsoil). Stratum 2 is post-occupational fill and ranges from 20 to 35 cm in thickness. The post-occupational fill was thickest in the southwest (i.e., preserved) corner of the room. Stratum 2 includes the lower portion of the A horizon and the upper portion of the Bw1 horizon. Stratum 3 is the sterile sediment excavated in the geological test pit and includes the lower portion of the Bw1 horizon and the Bw2, Btb1, and Btkb1 horizons. Tables 54.1 to 54.4 describe the strata.

Table 54.1. LA 135292 strata descriptions.

Stratum	Color	Texture	Thickness (cm)	Description
0	-	-	-	Surface
1	10YR 4/3	Silty loam	2–6	Surface sediment
2	10YR 4/4	Silty loam	20–35	Post-occupational fill
3	8.75YR 4/4	Silt	45	Pleistocene soil

SITE EXCAVATION

Room 1

Sequence of Excavation. Room 1 is a small structure of unknown shape and dimensions that probably functioned as a fieldhouse. Excavation of the room began with an east-west trench that extended across the site (102N/100-105E). The excavation of this trench served to define the room's stratigraphy, as well as to locate the room's south and west walls. No living surface was encountered in any of the grid units in the trench. The excavations therefore terminated at the base of the room's walls. After the excavation of the trench, the area to the northeast of the south and west walls was excavated down to the level of the base of the room's walls. A small patch of burned earth was encountered in 104N/103E. This patch of burned earth may have been part of the room's living surface.

Fill. Due to the destruction of all but the southwest corner of the room, the room's fill could not be differentiated from the post-occupational fill outside of the room. Nevertheless, three flotation samples (Field Specimen [FS] 75, FS 77, and FS 87) and three pollen samples (FS 76, FS 78, and FS 88) were taken of post-occupational fill in the area to the northeast of the south and west walls. All of these samples are from locations that were most likely within Room 1. The samples may therefore represent room fill. The machinery that disturbed the room's walls, however, most likely also disturbed the post-occupational fill in all but the room's southwest corner. As a result, the samples probably represent mixed deposits rather than pure room fill. Charred taxa identified in the flotation samples included ponderosa pine, unidentified pine, maize, cheno-ams, juniper, unknown conifer, and mountain mahogany. Taxa identified in the pollen samples included maize, beeweed, lily family, rose family, grass family, cheno-ams, sunflower family, ragweed/bursage, spurge family, unidentified pine, piñon pine, juniper, oak, and sagebrush.

Floor. No floor or prepared living surface was encountered during the excavation of LA 135292. A small patch of burned earth was encountered in the southeast quadrant of 104N/103E (Figure 54.4). This patch of burned earth could be part of the room's living surface. It is equally likely, however, that the earth was burned during a forest fire. A small pit was encountered nearby in 103-104N/103E. This pit was most likely the remains of an animal burrow. The pit contained four large rocks. These rocks may have been placed within the pit during the site's occupation. If this is the case, the animal burrow probably post-dates the room's construction, as it is unlikely that a fieldhouse would have been built around such a large hole. The site was thereafter reoccupied, at which time the rocks were placed in the animal burrow to repair the room's living surface. There is no firm evidence, however, that the rocks were placed within the pit prehistorically. In other words, the animal burrow may post-date the site's occupation. If this is the case, the rocks are wallfall that fell into the burrow, or were pushed into the burrow by the modern machinery that destroyed the walls in this area of the site.

Figure 54.4. Burned patch of earth in Room 1 at LA 135292.

A pollen sample (FS 84) was taken from just inside the room at the base of the west wall. Taxa identified in this sample included beeweed, grass family, cheno-ams, ragweed/bursage, sunflower family, spurge family, unidentified pine, oak, and sagebrush. A flotation sample (FS 87) and a pollen sample (FS 88) were also taken from just inside the room's west wall, a few centimeters above the base of the walls (see above for results). At least one of these three samples is from a level that is at least near the Room 1 living surface. A flotation sample (FS 83) was taken of the burned earth in the southeast quadrant of 104N/103E. Charred taxa identified in this sample included juniper, Douglas fir, oak, mountain mahogany, unknown conifer, and ponderosa pine. A great deal of charcoal was encountered during the excavation of the site. Most if not all of the charcoal, however, was produced during the Cerro Grande fire. This modern charcoal could not be distinguished from any possible prehistoric charcoal. As a result, no charcoal was kept from the site as a radiocarbon sample.

Wall Construction. The only walls in Room 1 that were preserved at the time of excavation were the south and west walls. These walls join to form the southwest corner of the room, which is well-rounded. The walls do straighten out, however, away from the corner. The room therefore does not appear to have been elliptical in shape. Instead, it was most likely rectangular with rounded corners. The easternmost two rocks of the south wall are elongated and oriented lengthwise. The cobbles that form the southwest corner and west wall, on the other hand, tend to be rounder and more irregular in shape. Small tuff rocks were utilized as foundations for, and placed in, the spaces between the large dacite cobbles. Because the northwest and southeast corners of the structure were destroyed, the prehistoric lengths of the walls are unknown (Table 54.5). Two stones, one on top of the other, were encountered to the north of the east end of the south wall. The lower rock is not like the cobbles that form the south and east walls and is considerably deeper. It therefore does not appear to have been part of the room's walls. The upper rock, on the other hand, is a shaped tuff block, and therefore probably was part of the room's walls. It is unknown, however, whether the rock is *in situ*. Its north-south orientation suggests that it is *in situ* and was part of the east wall. If this is the case, however, the room was very narrow (about 1.5 m). A large dacite cobble was encountered to the north of the west wall. This rock was most likely part of the west wall and is only slightly displaced. Two tuff blocks were encountered to the northeast of the west wall. These rocks were probably part of the north wall. Their orientation, however, indicates that they are not *in situ*.

Table 54.5. LA 135292 Room 1 wall measurements.

Orientation	Length (m)	Height (m)	Thickness (m)	Number of Courses
North	0	N/A	N/A	0
South	1.42	0.10–0.27	0.18–0.36	1
East	0.36	0.16–0.29	0.18	1 to 2
West	1.21	0.13–0.23	0.10–0.40	1

Note: The lengths are of the extant portions of the walls.

Judging from the amount of wallfall removed during the excavation of the area in and around Room 1, the room's masonry was originally considerably higher than it was when the site was excavated. Due to the fact that the lengths of the room's walls could not be determined, the original height of the masonry could not be determined. All of the rocks removed as wallfall during the site's excavation, however, were placed in a large stack for measurement. The stack measured 4.35 by 0.30 by 0.45 m, for a total of approximately 0.59 m^3 of wallfall. This number is significantly less than the average volume of wallfall removed during the excavation of other fieldhouses in the Rendija Canyon Tract during the Conveyance and Transfer Project. The rest of the rocks that formed the room's walls were probably pushed off of the excavated portion of the site by the modern machinery that destroyed the room's north and east walls. This interpretation is supported by the fact that most of the wallfall removed from the site was from the southwest (i.e., preserved) corner of the room. The uppermost portions of the room's walls, as well as the roof, were most likely composed of wattle and daub. These materials are rarely preserved at archaeological sites on the Pajarito Plateau. In fact, only seven pieces of burned adobe (FS 45, FS 51, FS 55, FS 60, FS 67, FS 82, and FS 86) were recovered from the site.

Geological Analysis

Geologists Paul Drakos and Steven Reneau utilized two profiles to reconstruct the natural soil horizons at the site. The first is the north profile of the geological test pit (102N/101E). The profile contained a soil sequence consisting of an A horizon (topsoil), Bw1 and Bw2 horizons (late-Holocene soils), and Btb1 and Btkb1 horizons (Pleistocene soils) (see Table 54.2; Figure 54.5). The second profile, the north profile of 102N/103E, was examined just after the excavation of the east-west trench across the site. This profile contained a soil sequence consisting of an A horizon (topsoil) and a Bw1 horizon (a late-Holocene soil) (see Table 54.3). An examination of the relationship between the stratigraphy and the extant portions of the Room 1 walls reveals that the foundations were constructed directly on top of the Bw1 horizon.

Artifact Distribution

There are no obvious patterns in the distribution of artifacts at LA 135292 (Table 54.6). Much of the site has been severely disturbed, probably by modern machinery. Even if patterns were evident in the artifact distribution, they would have probably been the result of modern rather than prehistoric site formation processes anyway.

Table 54.6. LA 135292 artifact counts (ceramics, chipped stone, ground stone, and faunal remains) by grid unit.

	E100	E101	E102	E103	E104	E105

N101		11	15	18	9	

Note: Does not include nine artifacts found outside of the excavated area during surface collection.

Figure 54.5. Profile of the north wall in the geologic test pit.

SITE CHRONOLOGY AND ASSEMBLAGE

A total of 178 artifacts were analyzed from the excavations conducted at LA 135292. In addition, flotation and pollen samples were selected for analysis from the post-occupation fill

(Stratum 2) (Table 54.7). The results of the artifact and sample analyzes are presented in the following sections.

Table 54.7. Samples selected for analysis from LA 135292.

Ceramic Artifacts (Dean Wilson)

A total of 89 ceramics were analyzed from LA 135292. The majority of the pottery consists of smeared-indented corrugated and Biscuit A sherds. In addition, the presence of Santa Fe Black-on-white, Wiyo Black-on-white, Galisteo Black-on-white, and Sapawe Micaceous would seem to reflect an Early Classic period occupation (Table 54.8). Information on ceramic tradition by ware, temper by ware, and vessel form by ware are provided in Tables 54.9 to 54.11. The graywares and whitewares appear to have been locally made from smeared-indented sand or tuff, although a single whiteware sherd does exhibit non-local micaceous temper. Most of the grayware ceramics consist of jar vessel forms, however, one sherd was derived from a bowl. In contrast, the whiteware sherds include mostly bowls, with some jars.

Table 54.8. Ceramic types from LA 135292.

Ceramic Type	Frequency	Percent
Northern Rio Grande Whiteware		
Unpainted undifferentiated	1	2.2

Lithic Artifacts (Bradley Vierra and Michael Dilley)

Material Selection

A total of 89 artifacts were analyzed from LA 135292, consisting of a core, 78 pieces of debitage, six retouched tools, and four ground stone artifacts. This represents a 100 percent sample of the total lithic artifacts recovered during the site excavations. Table 54.12 presents the data on lithic artifact type by material type. The debitage is primarily made of chalcedony, Pedernal chert, and obsidian, with a few other materials. The presence of cortex on 12.8 percent of the debitage indicates that these materials were collected from waterworn (n = 7) and nodule (n = 3) sources. The chalcedony, Pedernal chert, and silicified wood are available from local Rio Grande Valley gravels and the obsidian from nearby sources in the Jemez Mountains.

Otherwise, the igneous materials are available both as bedrock outcrops and in stream gravels that cross-cut the plateau.

Four pieces of obsidian debitage, a single piece of basalt debitage, and four obsidian retouched tools were submitted for X-ray fluorescence analysis. The obsidian artifacts are Valle Grande, Cerro Toledo, and El Rechuelos obsidian (Table 54.13). The Valle Grande (Cerro del Medio) and Cerro Toledo (Obsidian Ridge/Rabbit Mountain) source areas are situated about 17 km (11 mi) and 19 km (12 mi) to the west and southwest. Although obsidian is present at these nearby sources in the Jemez Mountains, it is also present on the nearby mesa as small pebbles. These pebbles compose part of the secondary deposits associated with the Cerro Toledo interval. The El Rechuelos (Polvadera Peak) source area is located approximately 27 km (17 mi) northwest of the site. A single basalt flake is actually made of dacite that was derived from a local source.

Table 54.13. Obsidian source samples.

FS #	Artifact	Color	Source
20	Debitage	Translucent	Cerro Toledo rhyolite
30	Biface	Translucent	Cerro Toledo rhyolite
33	Debitage	Translucent	Valle Grande rhyolite
39	Biface	Black dusty	El Rechuelos
63	Debitage	Translucent	Valle Grande rhyolite
73	Debitage	Translucent	Cerro Toledo rhyolite
89	Point	Black Dusty	El Rechuelos

Lithic Reduction

The single core is a flake core that was reduced using opposed-same-face technique. It was classified as still useable when discarded. Table 54.14 presents the metric information on the core.

Table 54.14. Core type dimensions (mm) and weight (g).

Core Type	Length	Width	Thickness	Weight
Flake core	45	44	15	32.0

The debitage mostly consists of core flakes, with fewer biface flakes, angular debris, and other items. The flakes mostly have single-faceted platforms (*n* = 20), with fewer multi-faceted (*n* = 1), collapsed (*n* = 9), and crushed (*n* = 10) platforms. Only two of the platforms exhibit evidence of preparation by abrasion/crushing. The majority of the core flakes are whole (*n* = 16), with fewer proximal (*n* = 15), distal (*n* = 13), and undetermined (*n* = 1) fragments. In contrast, the biface flakes consist of a whole (*n* = 2), proximal (*n* = 7), and midsection (*n* = 2) fragments. The whole core flakes have a mean length of 24.1 mm (*std* = 11.4), the whole biface flakes a mean length of 24.5 mm (*std* = 7.7), and the angular debris a mean weight of 1.5 g (*std* = 1.4).

The retouched tools consist of retouched pieces, bifaces, and projectile points. The retouched pieces are large flakes with laterally retouched edges. One has been retouched along the dorsal surface and the other exhibits alternating retouch (dorsal and ventral), with edge angles of 75 and 70 degrees. The bifaces consist of a distal fragment from a large biface and a whole late-stage biface. The latter may be a reworked point or an unfinished preform (Figure 54.6). The projectile points consist of two base fragments. One appears to be a corner-notched point with a broken blade and tangs. The other is a stemmed point with a concave base. It exhibits an impact fracture that burinated the tip and lateral side of the point. Both of these items could represent Archaic dart points.

Tool Use

Only one piece of debitage and none of the retouched tools exhibit evidence of edge damage that could be attributed to use. The single utilized flake has rounding use along a lateral straight edge with an angle of 45 degrees.

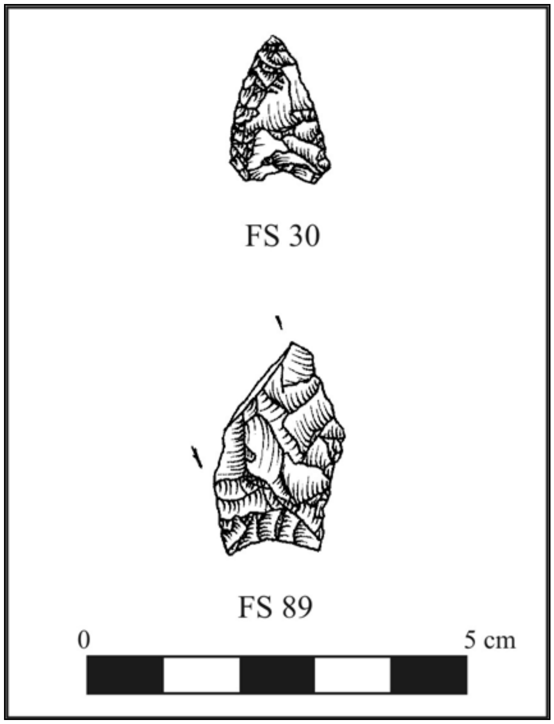

Figure 54.6. Biface and projectile point.

The ground stone artifacts include manos, a polishing stone, and an axe. The two-hand mano is a fragment that appears to have been reworked and continued to be used as a one-hand mano (Figure 54.7). It has two opposing heavily ground surfaces and a wedge-shaped cross-section. The other mano is a fire-cracked quartzite cobble fragment with a single ground surface. The polishing stone consists of a flat andesite pebble with a single ground/polished surface. Lastly, the axe is a butt fragment with a full groove (Figure 54.7). The faces are polished, indicating that the item might have been ground during resharpening, rather that chipped; however, this might also be the by-product of use.

Faunal Remains (Kari Schmidt)

One piece of unidentified bone was recovered from LA 135292. The bone was recovered from unit 102N/103E, was heavily burned, and was a very small fragment of cancellous bone. The bone was recovered from the upper fill of the fieldhouse and contained an old break.

Archaeobotanical Remains (Pamela McBride)

LA 135292 was severely affected by the Cerro Grande fire and all but the southwest corner of the room was destroyed by modern machinery. The sample from room fill contained a charred cheno-am seed, ponderosa pine needles, and a possible cupule fragment (Table 54.15). Unidentifiable plant parts were recovered from the area of burned earth that may represent what remains of the living surface. Modern uncharred grass, annual, and groundcherry seeds were all that was recovered from the sample just inside the room's west wall.

The wood assemblage was much more diverse than that present at LA 135291 and included juniper, ponderosa pine, and mountain mahogany (Table 54.16). Possible Douglas fir and oak were identified in the sample from the burned earth, wood taxa that were absent from general fill samples. Excavators noted that burned wood resulting from the Cerro Grande fire could not be distinguished from possible prehistoric charcoal. Therefore, the cultural origin of wood from flotation samples is doubtful.

Pollen Remains (Susan Smith)

Three pollen samples were analyzed from LA 135292. Table 54.17 lists the frequency of identified pollen types. Maize was the only cultigen identified in the assemblage. Beeweed and lily family were also identified as economic resources. A number of potential economic resources were also identified in the assemblage, and these are discussed in Smith's chapter in Volume 3.

SUMMARY OF SITE EXCAVATIONS

LA 135292 consists of a probable one-room fieldhouse that did not contain a formal floor or a living surface. Ceramic evidence suggests the site was occupied during the Early Classic period. The presence of maize and the prevalence of storage jars reflect the agricultural function of the site, with limited core reduction and grinding activities also being represented. The occupation of the site dates to the 14th century (Early Classic) based on the presence of Biscuit A ceramics.

CHAPTER 55
TESTING FOR SITE ELIGIBILITY IN THE TA-74 AND WHITE ROCK Y TRACTS

Steven R. Hoagland

INTRODUCTION

Portions of two Land Conveyance and Transfer Tracts, that were scheduled to be conveyed to the County of Los Alamos (County), New Mexico, or its designee, contained archaeological sites that were assessed to have an undetermined Register eligibility. Under 36 CFR 800.5(vii), the conveyance of lands to the County is considered an adverse effect to historic properties, if adequate and legally enforceable restrictions or conditions to ensure the long-tern preservation of these properties' historic significance are not established. The original cultural resources evaluation for this project assessed 10 archaeological sites in the TA-74 Tract and two sites in the White Rock Y Tract as having an undetermined potential under Criterion D to yield information important to New Mexico's history and prehistory. As a result, 11 of these 12 sites were tested to determine whether they qualify as historic properties (Register eligible). The sites tested in the TA-74 Tract include LA 21596, LA 86528, LA 86531, LA 110121, LA 110126, LA 110130, LA 110132, LA 110133, and LA 117883, and White Rock Y Tract tested sites include LA 61034 and LA 61035. Prior to testing, an eligibility evaluation was conducted for TA-74 Tract site LA 86532. Upon review, a determination was made to concur with a New Mexico State Historic Preservation Officer (SHPO) assessment that LA 86532 was not eligible to the Register as the information potential had been exhausted through survey recording. As LA 86532 was no longer assessed to have an undetermined eligibility, it was not tested.

TA-74 TRACT

The TA-74 Tract is located east of the Los Alamos town site and below the mesa upon which the town site is built. This tract is comprised of several canyons and mesas. The northern half of the tract is dominated by lower Bayo Canyon and Barrancas Canyon, whereas the southern half includes Pueblo Canyon. The tract that is situated at an elevation between 2013 m and 2333 m (6040 to 7000 ft) is forested by a piñon-juniper woodland with stands of ponderosa pine present along the south side of some canyons. The TA-74 County parcel is located in a relatively broad part of lower Pueblo Canyon. Surficial geologic units within the parcel include the active stream channel and adjacent floodplains of Pueblo Canyon with areas of colluvium and alluvial fans on the side slopes and along tributary drainages. All of the sites with an undetermined Register eligibility are located south of the Pueblo Canyon drainage. The sites and testing are described below by Laboratory of Anthropology (LA) site number order.

LA 21596

LA 21596 is a set of three distinct series of garden plots (A-C) that is associated with Otowi Pueblo (LA 169), a very large multi-room Classic period habitation site located upslope to the east-northeast. LA 21596 is located along the north side of the Pueblo Canyon drainage. The surficial geologic units within the site vicinity include the active stream channel and adjacent floodplains of Pueblo Canyon, higher stream terraces of Holocene and Pleistocene age, and areas of colluvium and alluvial fans on the side slopes and along tributary drainages (Drakos and Reneau 2003). The grid gardens are located at the base of a colluvial slope adjoining floodplains or fluvial terraces in the bottom of Pueblo Canyon. The area is vegetated by a piñon-juniper woodland and ponderosa pine forest. Heavy vegetation obscures the center portion of the site. The site is at an elevation of 1989 m (6460 ft) above sea level.

The Pajarito Archaeological Research Project (PARP) originally recorded LA 21596 in 1978. The site was described as four sets of grid gardens and terraces although it was noted that erosion and rock fall may have erased links between some of them. Running from west to east the gardens were labeled D, A, B, and C. The site area measured 204.5 by 24.5 m with Plot A situated 12 m east of Plot D, Plot B located 52 m east of Plot A, and Plot C situated 26 m east of Plot B. According to the site form, garden plot D measured 24.5 by 19 m, Plot A measured 10 by 23.5 m, Plot B measured 15.5 by 5.0 m, and Plot C measured 56.5 by 4 m. Garden plots A and D were 100 percent collected. No collections were taken at Plots B and C. PARP noted that ceramics on the site most likely washed down from Otowi Pueblo or were deposited during agricultural-related activities.

The current project survey documented three sets of terraced garden plots with associated artifacts. Additional erosion and rock fall apparently has obscured the fourth set documented by PARP. Also, subsequent alluvial and colluvial processes and the schematic nature of the original PARP site sketch make it impossible to correlate the 1978 recorded plots with the 1994 plots. The recent project documentation labeled the garden plots from east to west as Components A, B, and C (Figure 55.1).

Site Setting

Otowi Pueblo is located on the second bench upslope from LA 21596. There is a continuous scatter of artifacts extending down from Otowi, with hundreds of artifacts situated on the first bench. The associated artifact boundaries for Components A through C are relatively arbitrary and restricted to the immediate garden plot vicinity. Within these areas either all of the observed artifacts or a sample of the artifacts were documented.

Site Description

LA 21596A consists of a series of 10 to 12 garden plots outlined by tuff, basalt, and rhyolite rocks. The series of plots cover an area measuring approximately 11 by 16 m in size. Several good linear alignments are visible.

Two-hundred-seventy-three artifacts were recorded near LA 21596A. Most of these were ceramics (*n* = 259) with fewer lithics. Most of the identified ceramics consist of Biscuit A and Biscuit B, with a few Santa Fe Black-on-white, Espinosa Glaze-on-Polychrome, Potsu'ii Incised, and micaceous and non-micaceous plainwares. The chipped stone artifacts consist of Pedernal chert and obsidian chipped stone debitage and a retouched flake.

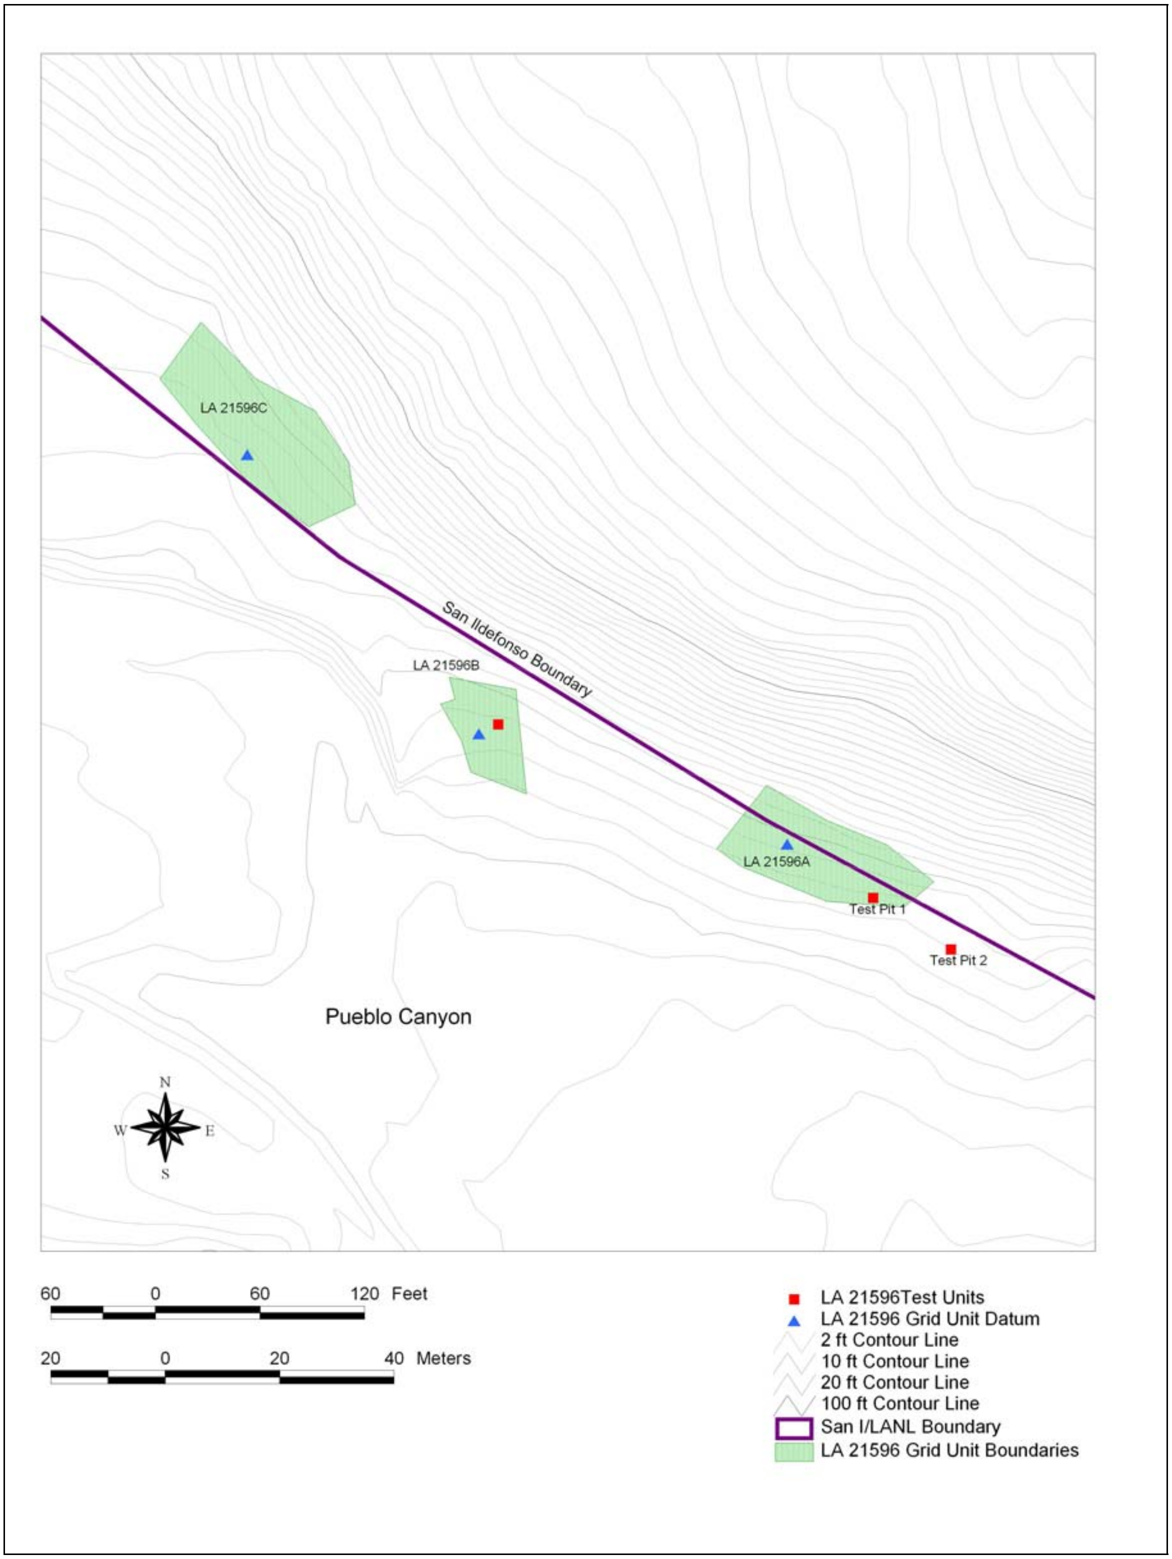

Figure 55.1. LA 21596 geographic positioning system (GPS) differential map.

LA 21596B consists of a series of five to six small garden plots constructed of tuff, basalt, and rhyolite blocks. The rocks range in size from 10 by 6 by 6 cm to 50 by 36 by 25 cm, averaging 35 by 30 by 20 cm. The features cover an area approximately 12 by 15 m in size.

Forty-four artifacts were recorded in this area, with most being ceramics (n = 46). The majority of the ceramics consist of Biscuit A and Biscuit B, with less Santa Fe Black-on-white, Sankawi Black-on-cream, and non-micaceous and micaceous plainwares. The lithic artifacts primarily consist of Pedernal chert and obsidian debitage with two metate fragments.

LA 21596C consists of a series of three small garden plots constructed of tuff, basalt, and rhyolite blocks. The rocks forming the garden plots range in size from 12 by 10 by 8 cm to 60 by 40 by 30 cm, the average being 40 by 35 by 20 cm. The plots are in two rectangular shapes, covering an area of approximately 17 by 15 m. The plots are oriented roughly northwest to southeast.

There is a continuous scatter of artifacts down from Otowi including approximately 200 to 300 items on the first bench near the site. The artifact boundary for LA 21596C is arbitrary and is restricted to a 30- by 40-m area. Within this area, all the lithic artifacts and only a 30 percent sample of the ceramic artifacts were flagged, examined, described, and quantified. Numerous other artifacts were observed and there is good potential for many more to be located under high concentrations of pine duff. Artifacts were also abundant on the slope between the first and second benches.

Ninety-one artifacts were recorded in the garden plot boundary. Most of these are ceramics (n = 76) with fewer lithics. The majority of the ceramics consists of Biscuit A and Biscuit B, with less Santa Fe Black-on-white, Sankawi Black-on-cream, Potsu'ii Incised, smeared-indented, and obliterated corrugated sherds. The lithics consist of Pedernal chert and obsidian debitage with a single obsidian uniface.

Site Excavation

LA 21596 is located in Los Alamos National Laboratory, Technical Area (TA) 74. The boundary between Los Alamos County and San Ildefonso properties runs through the approximate center of LA 21596. Garden plot C and the approximate northern half of Plot A are on land that will be transferred to the Department of the Interior and the southern half of Plot A and Plot B are on land that will be conveyed to Los Alamos County. Garden Plot B and the southern half of Garden Plot A were tested in October and November of 2002 because of their potential to be adversely affected.

One 2- by 1-m test unit was excavated within both Garden Plot A and the southern half of Garden Blot B (Figures 55.2 and 55.3). The two test units were situated where they straddled what appeared to be the lowest (southern) enclosing garden plot wall in hopes of recovering comparative data from within and outside of the features. Also, a 1- by 1-m test unit was placed to the east of Garden Plot A, outside of any garden plot, to use for a comparison. The test units were excavated in arbitrary 10-cm levels with shovel and trowel. With the exception of pollen, soil, and macrobotanical samples, all hand-excavated materials were screened through 1/8-in. mesh.

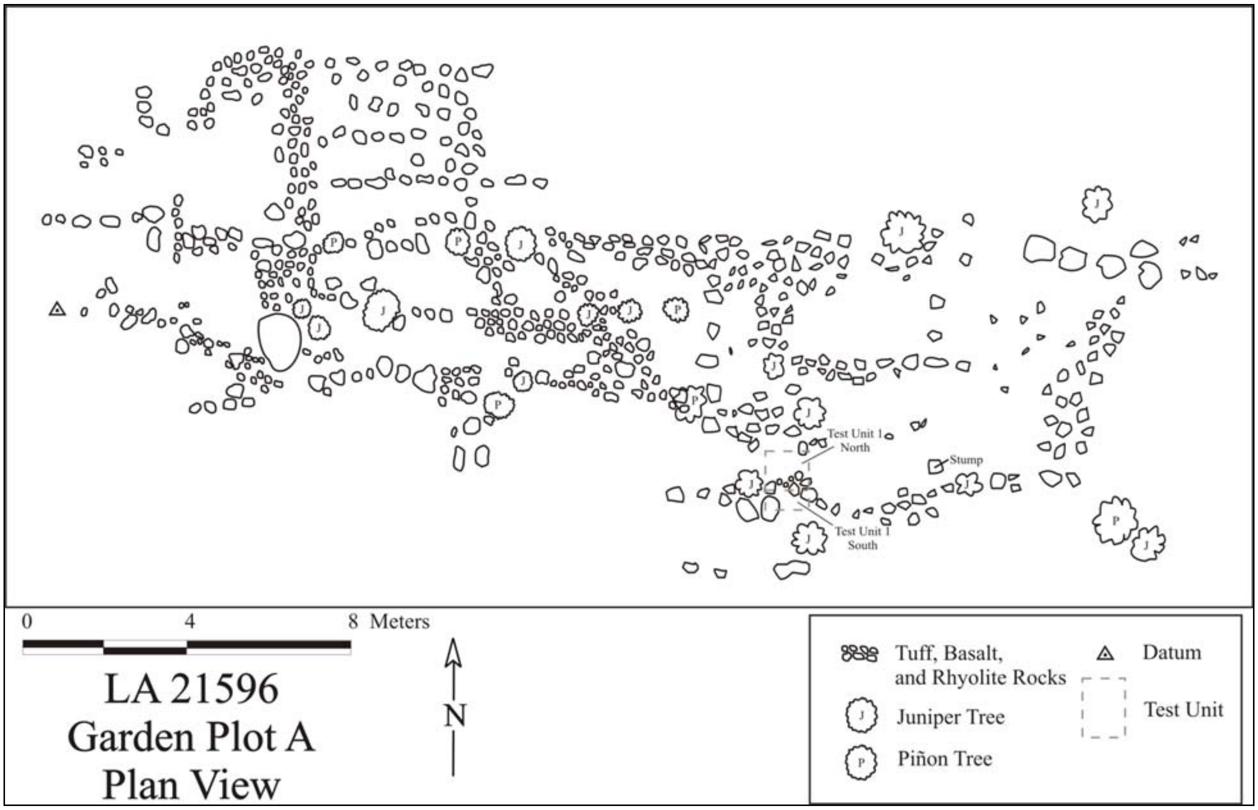

Figure 55.2. Plan view of Garden Plot A at LA 21596.

The 2- by 1-m test unit in Plot A (Test Pit 1) was excavated to a depth of 30 cm below surface. The northern half was assumed to be within the garden plot and the slightly downslope southern half to be outside the garden plot. The fill within the two 1- by 1-m test units was essentially the same. They contained three stratigraphic deposits with the upper 4 cm being an A horizon soil consisting of a soft/loose loamy sand with abundant decomposed organic material. Stratum 2 (4 to 15 cm), a Bw1 horizon soil, consisted of a soft sandy loam with about 30 percent to 40 percent gravel and several tuff and basalt rocks that were generally 10 cm in diameter or less. Stratum 3 (15 to 30 cm), a Bw2 horizon soil, was a soft loamy sand with about 30 percent to 40 percent gravel and several tuff and basalt rocks that tended to become larger with depth (5 cm diameter and larger).

The northern half of the 2- by 1-m test unit placed in Plot B was excavated to a depth of 50 cm below surface (Test Pit 1), while the southern half (Test Pit 2) that was assumed to be outside of the garden plot was excavated to a depth of 30 cm. Fill within Test Pit 1 consisted of three stratigraphic deposits with the upper 5 cm (A horizon) consisting of loamy sand with abundant decomposed organic material. Stratum 2 (5 to 22 cm), a Bw1 horizon soil, consisted of a soft sandy loam containing 20 percent to 30 percent gravel and several fist-sized and smaller tuff, basalt, and rhyolite rocks. Stratum 3 (22 to 50 cm), a Bw2 horizon soil, was a soft sandy loam with about 20 percent to 30 percent gravel.

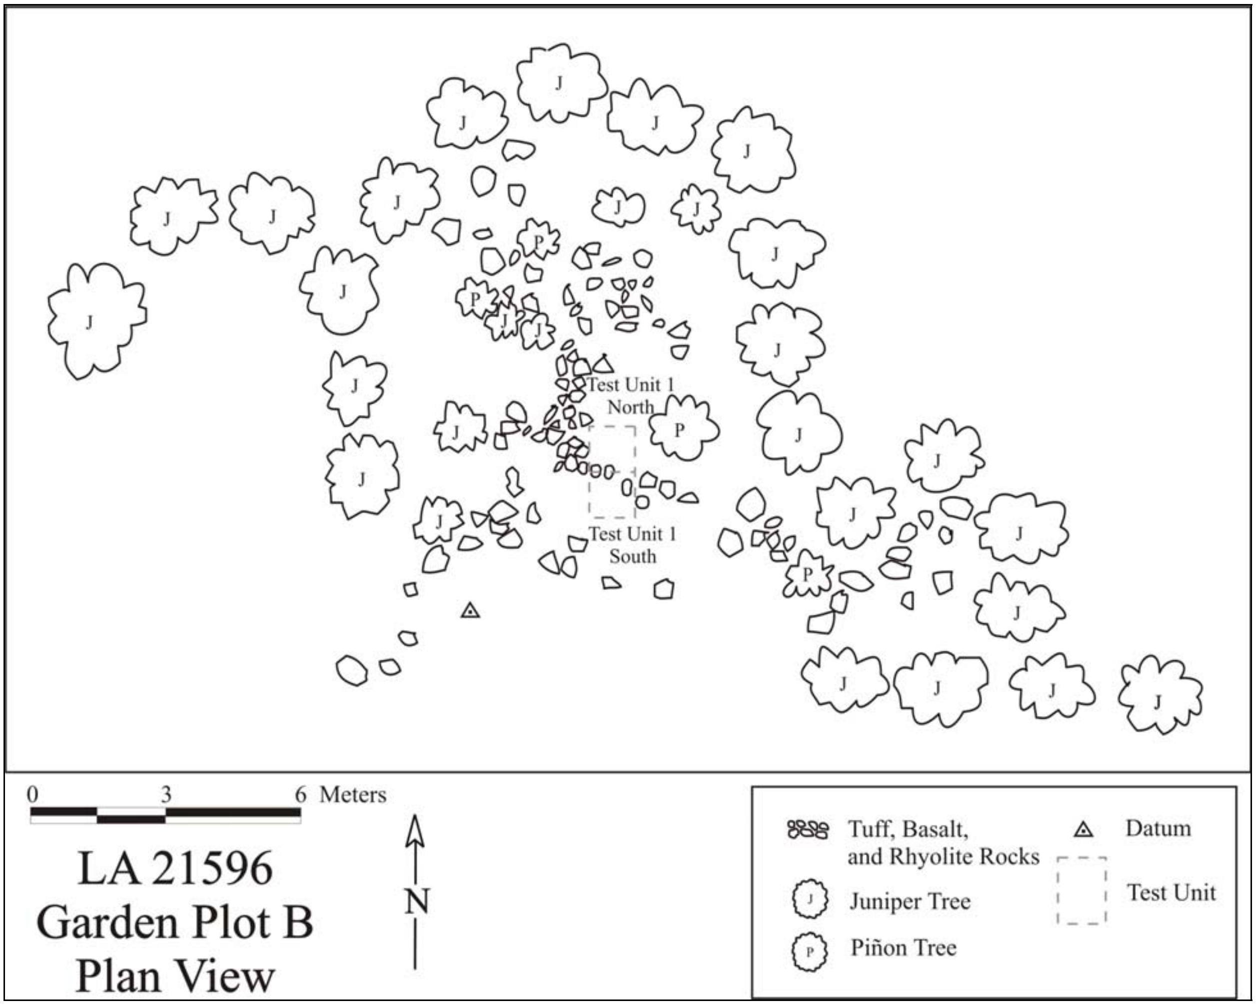

Figure 55.3. Plan view of Garden Plot B at LA 21596.

The southern half of the test unit (Test Pit 2) contained only two soil strata. Stratum 1 (0 to 6 cm) was soft loamy sand with 10 percent to 20 percent gravel (A horizon) and Stratum 2 (6 to 30 cm) was a soft/loose sand with 10 percent to 20 percent gravel (Bw1 horizon). Both strata contained fist-sized and smaller tuff and basalt rocks scattered throughout, although they did become less abundant with depth.

Although excavated at a similar elevation, the 1- by 1-m test unit was placed to the east of the LA 21596A garden plots for comparison (Test pit 2) and was excavated into a relatively open area on the colluvial slope. As such, it did not have the rich organic material that was observed within the garden plot test units. It contained only two soil strata. Stratum 1 (0 to 12 cm), an AC horizon soil, was a loose sandy loam with about 40 percent gravel. Stratum 2 (12 to 30 cm), a C horizon soil, was a loose loamy sand with 40 percent to 50 percent gravel. It contained tuff and basalt rocks ranging from 5 to 10 cm in diameter. Lenses of dry sand were noted throughout the lower portion of Stratum 2. These lenses appeared to be somewhat graded lenses deposited through erosional runoff.

Site Chronology and Assemblage

The test unit in LA 21596A combined with the control test unit located just east of Garden Plot A contained 371 ceramics and 19 chipped stone artifacts, while the LA 21596B test unit contained 264 sherds and four pieces of chipped stone. The ceramics recovered from the testing exhibited combinations of Santa Fe Black-on-white and biscuitware types that may indicate mixed or transitional site utilization between the Ancestral Pueblo Coalition and Classic periods. An even mixture of Biscuit A and Biscuit B ceramics was noted at both LA 21596A and LA 21596B. The presence of Sapawi and Potsuwi may indicate that some of this site dates fairly late in the Classic Period.

The excavations indicated that artifacts are abundant from 0 to 30 cm and present but less abundant from 30 to 50 cm. The excavation also indicates that relatively little sediment has been deposited since construction of the grid gardens. Rocks forming the grid gardens are set on the Bw1 horizon and are buried by only 4 to 6 cm of sediment. Unlike the recovered ceramics, these observations suggest that the gardens were created during a relatively late stage of occupation at Otowi Pueblo and that a significant amount of colluvial deposition occurred at this location concurrent with the Ancestral Puebloan occupation. The control test unit placed to the east of LA 21596A showed that the thickness of young colluvium is greater than 30 cm. It is possible that human traffic or other disturbances on the steep slope between Otowi Pueblo and the grid gardens accelerated the rate of colluvial transport and deposition at this location (Drakos and Reneau 2003). Thus, it is also possible that the Late Coalition and Early Classic ceramics were deposited at LA 21596 before establishment of the grid gardens.

Macrobotanical (flotation samples) and pollen samples were collected and processed from all three LA 21596 test units. These samples were collected from the soil horizons exposed within both the north and south sides of the LA 21596A Test Unit and from the horizons exposed within the control test unit excavated to the east of LA 21596A. Macrobotanical and pollen samples were also collected from each 10-cm arbitrary level (Levels 1-3) excavated within the LA 21596B Test Unit.

The macrobotanical analysis produced charred corn cupules from the test units in both LA 21596A and LA 21596B. One cupule was recovered from Stratum 3 (Bw2 horizon) collected from the north side of LA 21596A, and five cupules were recovered from Level 3 (Bw1 horizon) collected from the south side of LA 21596B. The presence of these charred cupules suggest one of two scenarios: 1) the occupants were cooking nearby and a few cob remains that were used as fuel ended up in the garden plots or 2) the occupants of Otowi Pueblo were throwing garbage over the escarpment and some landed approximately 40 ft below within the grid gardens (Chapter 62, Volume 3).

The charred corn cupules were submitted to Beta Analytical, Inc., for accelerator mass spectrometer radiocarbon dating. The calibration of radiocarbon age to calendar years for the LA 21596 North sample (Beta Number 183768) resulted in a conventional age of 600±40 BP and a two-sigma calibration date range of AD 1290 to 1420 with intercepts of AD 1320, AD 1340, and AD 1390. The calibration of the LA 21596 South sample (Beta Number 183769) resulted in a conventional age of 70±30 BP with two-sigma calibration date ranges of AD 1690 to 1730, AD 1810 to 1920, and AD 1950 to 1960, and an intercept of AD 1950.

The pollen analysis also produced evidence of cultigens as well as some evidence as to the occupational surface. Both the north- and south-side samples recovered from LA 21596A exhibited a trend for decreasing pollen abundance with depth matched by decreasing values of tree pollen and a higher representation of cheno-am (*Chenopdoium/Amaranthus*), sunflower family (Asteraceae), and grass (Poaceae). This observed signature could reflect an agricultural weed signal that would mark Stratum 3 (Bw2 horizon) as the cultural surface. Maize pollen was identified from Strata 2 (Bw1 horizon) and 3 from the north side of the test unit and from Stratum 3 from the south side. There were no observed trends in pollen spectra with increasing depth from either the north- or south-side samples collected from LA 21596B. Two of the three north side samples were sterile (too little pollen for a significant count), although maize was identified in one of the sterile samples. Evidence for cultigens was also documented from the south half of the test unit with maize (*Zea mays*) and squash (*Cucurbita*) pollen recovered from Level 2 and maize pollen recovered from Level 3 (both are from the Bw1 horizon). One of the two samples recovered from the control test unit excavated outside of LA 21596A was sterile. Neither of the test unit stratigraphic samples produced any agricultural pollen evidence (Chapter 63, Volume 3).

Summary

The preservation of corn cupules along with maize and squash pollen from within stratigraphic deposits suggests that the unexcavated portions of the site likely contain potential for additional significant cultural remains. Floral and pollen materials could aid in establishing additional subsistence crops and other crops that may have been utilized by Classic period inhabitants of the area. There is also potential for establishing a chronological sequence that could aid in establishing agricultural changes that may have occurred during the Ancestral Pueblo Classic period and potentially through reuse of the site in later Historical periods. As the research potential at LA 21596 is still assessed to be excellent, it is considered eligible to the Register under Criterion D, likely to yield information important in prehistory or history.

LA 86528

Site LA 86528 (Q-28) is a partially enclosed rock overhang that likely served as a temporary shelter. It is located at the base of the steep talus slope that forms the upper north side of Pueblo Canyon. The local vegetation is transitional between piñon-juniper woodland and ponderosa pine forest. The site is situated at an elevation of 2024 m (6640 ft). This site consists of a large tuff boulder overhang associated with 8 to 10 large rocks representing an enclosed area (Figure 55.4). The overhang, which is 2.55 m wide, 2.25 m deep, and 0.9 m high at the mouth, opens to the south. A small water channel running from southeast to northwest has cut through the overhang and below the large tuff boulder (Figure 55.5).

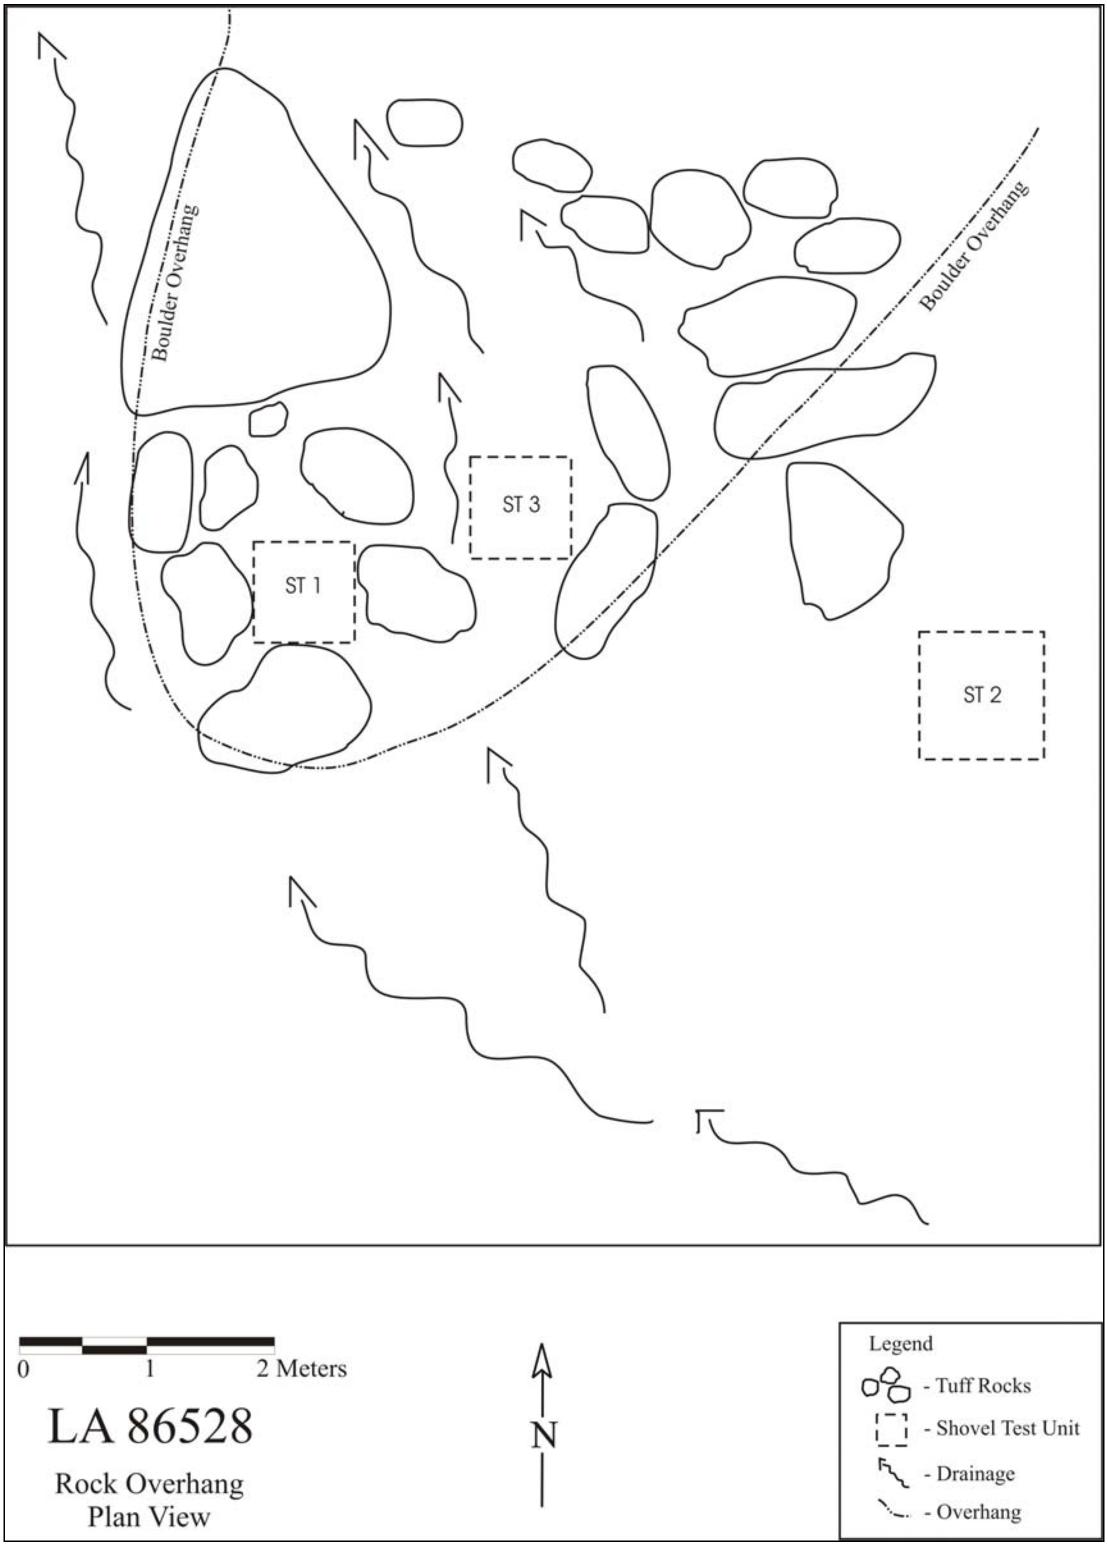

Figure 55.4. Plan view of overhang at LA 86528.

Figure 55.5. Post-testing photo of LA 86528 looking northwest.

During the original site recording, a few small chunks of charcoal were observed just downslope from the overhang. It was assumed that the charcoal could have washed out from the overhang via the small drainage that has cut through the feature. Approximately nine Glaze E sherds (same vessel) were associated with the structure. These sherds were situated within a small drainage running across the front and down along the west side of this shelter. A rhyolite core flake was observed about 8 to 10 m below the overhang. Three grooves measuring 40 by 4 cm, 35 by 2 cm, and 1 by 5 cm were potentially cut into the rock above the overhang. Based on the presence of the Glaze E ceramics, the site likely dates to the Classic period.

Testing

Two test units (referred to as shovel tests) were initially excavated to assess whether there was any potential for intact cultural remains to be present within or adjacent to the overhang. Test Unit 1 was a 40- by 40-cm unit placed between fallen enclosure rocks beneath the overhang. It was situated in the outer southwestern portion of the overhang in the area that displayed the least amount of water erosion. Test Unit 2 was located just over a meter southeast (upslope) of the overhang in an area that displayed less colluvial erosion than that observed within the general area. Test Unit 3 was placed within the overhang, to the east-northeast and beyond the enclosure rocks that surrounded Test Unit 1. This test unit was excavated to further explore a charcoal stain that was encountered within Test Unit 1. All three test units were excavated in arbitrary 10-cm levels. No artifacts were recovered from any of the test units.

Test Unit 1 that exhibited three soil horizons was excavated to a depth of 40 cm below surface. The upper 5 cm of the unit contained an AC horizon sandy loam (Stratum 1). A few charcoal flecks were observed within the upper half of the stratum and a 2- to 3-cm-thick lens with charcoal staining was present at the base of the stratum. Situated from 5 to 21 cm in depth was a late-Holocene Bwb1 horizon sandy loam (Stratum 2) that overlaid a Btb2 horizon sandy clay loam (Stratum 3) that likely dates to the Pleistocene. The boundary between the A/C horizon and the Bwb1 horizon was abrupt and smooth suggesting that an erosional cycle occurred between depositions of the two horizons. The boundary between the Bwb1 and Btb2 horizons was abrupt and irregular, which also may indicate erosional impacts.

Test Unit 2 was excavated to a depth of 30 cm below surface. It contained two soil horizons, a relatively recent (AC horizon) sandy loam from surface to 10 cm and a Pleistocene, Btb1 horizon, sandy, clay loam from 10 to 30 cm. A small chunk of charcoal was recovered from a depth of 4 cm below surface.

Test Unit 3 was excavated within the overhang to clarify the nature of charcoal encountered within Test Unit 1. The unit, which contained four soil horizons, was excavated to a depth of 30 cm. The upper 3 cm was a C horizon with loose sandy loam that overlaid a late-Holocene Ab1 sandy loam (3 to 10 cm). A Bwb1 horizon sandy clay loam (10 to 20 cm), which overlaid a Pleistocene era Btb2 sandy clay loam (20 to 30 cm), was located below. A few chunks and flecks of charcoal were observed throughout the test unit, which indicates that there has been some degree of mixing between strata.

One flotation (Stratum 2), one macrobotancial (charcoal), and two pollen samples (Strata 1 and 2) were collected from Test Unit 1. A macrobotanical charcoal sample from Test Unit 2 and two macrobotanical charcoal samples from Test Unit 3 were also collected. The flotation and macrobotanical samples represented charred and uncharred wood materials that were dominated by oak and unknown conifer. Oak and conifer trees are abundant on the canyon slope in the vicinity of LA 86528. The Stratum 1 pollen sample was dominated by tree pollen and the Stratum 2 sample contained too little pollen for a significant count. Prickly pear pollen was documented from Stratum 1 and maize was identified from Stratum 2.

The test units situated within the overhang exhibit late-Holocene (possibly Puebloan-age) Bwb1 horizons overlying Pleistocene colluvial soils. Test Unit 2, situated on the colluvial slope outside the overhang, exhibits only young colluvium (<500 years) overlying Pleistocene soil. These soil profiles are indicative of a stripped, Pleistocene colluvial hillslope overlain by thin (10 to 20 cm thick) late-Holocene to historic age colluvium (Drakos and Reneau 2003).

Drakos and Reneau (2003) noted that the abrupt, irregular boundary between the Bwb1 and underlying Btb2 Pleistocene soil can be interpreted as resulting from either cultural or non-cultural processes. One explanation is that a pit or similar excavation was dug into the Pleistocene soil during cultural use of the overhang. An alternative explanation is that the irregular boundary between the Bwb1 and the Btb2 horizons was caused by erosion on the fairly steep slope that moved materials down through the overhang with an opening at the downslope end. In this scenario, subsequent partial plugging of the erosional escape hole facilitated colluvial deposition, which was followed by a non-cultural fire. Overall, the geomorphic evidence is ambiguous with respect to whether or not the overhang contained intact cultural deposits. The charcoal stain at the base of the AC horizon in Test Unit 1 may be of relatively recent origin, post-dating the Puebloan occupation (Drakos and Reneau 2003).

The formation of tuff stones situated around the overhanging boulder indicates cultural modification and likely utilization. This assessment is supported by the maize pollen recovered from Stratum 2 in Test Unit 1. However, the lack of artifacts from within the shelter suggests that deposited remains subsequently eroded downslope and out of the shelter or that the original occupation was of such a short duration that few to no cultural remains were discarded or lost.

Summary

The two test units placed within the overhang did not expose any traces of a previous excavation such as a pit dug into the floor of the shelter. There was no patterned concentration of charcoal or charcoal-stained fill that would suggest that it had originated from a hearth. As a result, it is assumed that the second scenario is more likely, that post occupation charred and uncharred wood materials and possibly the maize and prickly pear pollen eroded down into and were subsequently trapped within the overhang as the escape hole was temporally plugged. Erosion again appears to be moving materials downslope through the overhang. The integrity of the fill beneath the overhang has been subjected to bioturbation and likely replacement as colluvial materials have eroded, and are continuing to erode, down through the feature. As a result, the research potential of LA 86528 was likely exhausted during the testing activities and is no longer considered eligible to the Register.

LA 86531

LA 86531 (Q-33) is an artifact scatter located in a 582-m² area on the top and upper northern slope of a narrow ridge situated along the south side of Pueblo Canyon (Figure 55.6). The ridge is a fluvial fill terrace located approximately 30 m above the canyon floor. The deposit underlying the terrace comprises multiple fluvial sequences, with a coarsening upward deposit capped by imbricated boulders at the top (Drakos and Reneau 2003). The site, which is located at an elevation of 2009 m (6590 ft), is in an area that is transitional between a piñon-juniper woodland and ponderosa pine forest. When originally recorded the observed artifacts included approximately 20 ceramic sherds representing five to seven vessels and three pieces of chipped stone debitage.

Identified ceramics represent one or two Wiyo Black-on-white vessels, a Biscuit B vessel, a Sankawi Black-on-cream vessel, and one or two smeared-indented utilityware vessels. Also noted was a bowl sherd that appeared to have remnants of a reddish or orange slip on the interior and an incised line on the exterior. The lithics included a basalt, an obsidian, and a quartzite core flake. Based on the ceramic assemblage, the site likely dates to the Late Coalition/Early Classic period.

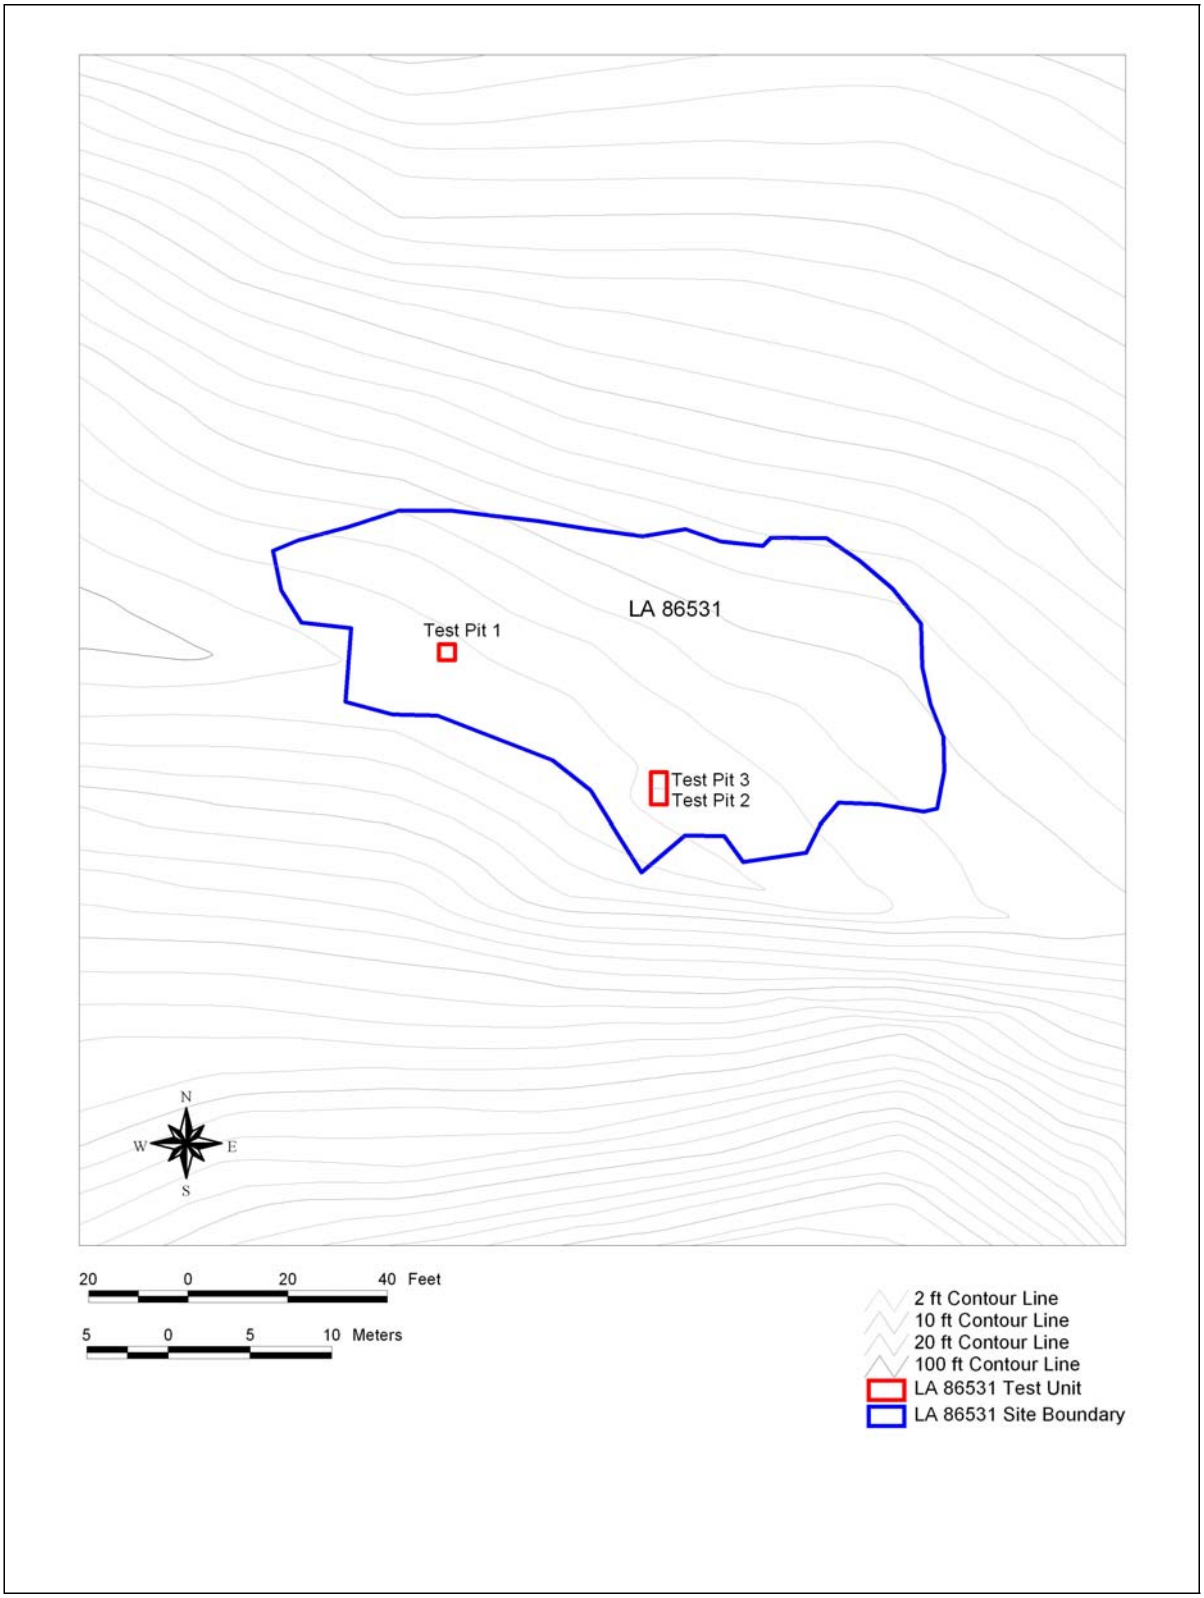

Figure 55.6. LA 86531 GPS differential map.

Testing

In January of 2003, three 1- by 1-m test units were excavated by trowel at LA 86531 in arbitrary 10-cm levels (Figure 55.7). With the exception of pollen, soil, and macrobotanical samples, all hand-excavated materials were screened through 1/8-in. mesh. Test Unit 1 was excavated into the west central portion of the site. It was excavated to a depth of 10 to 20 cm below surface where it was terminated after encountering boulders forming the top of the fluvial terrace. The test unit contained three stratigraphic layers. The upper 3 cm consisted of a C horizon soil that contained a loose sandy clay loam with gravel that formed 20 percent to 30 percent of the deposit (7.5YR4/3 damp). Stratum 2 (3 to 10 cm), an Ab1 horizon soil, was also a sandy clay loam with 20 percent to 30 percent gravel (7.5YR3/3 damp). Stratum 3 (10 to 20 cm) was a Btb2 horizon sandy clay (5YR4/3 damp) containing 20 percent to 30 percent gravel (middle to late Pleistocene). A few charcoal flecks were observed within the Ab1 horizon. Other than the charcoal flecks, which may or may not be cultural, no cultural materials were recovered.

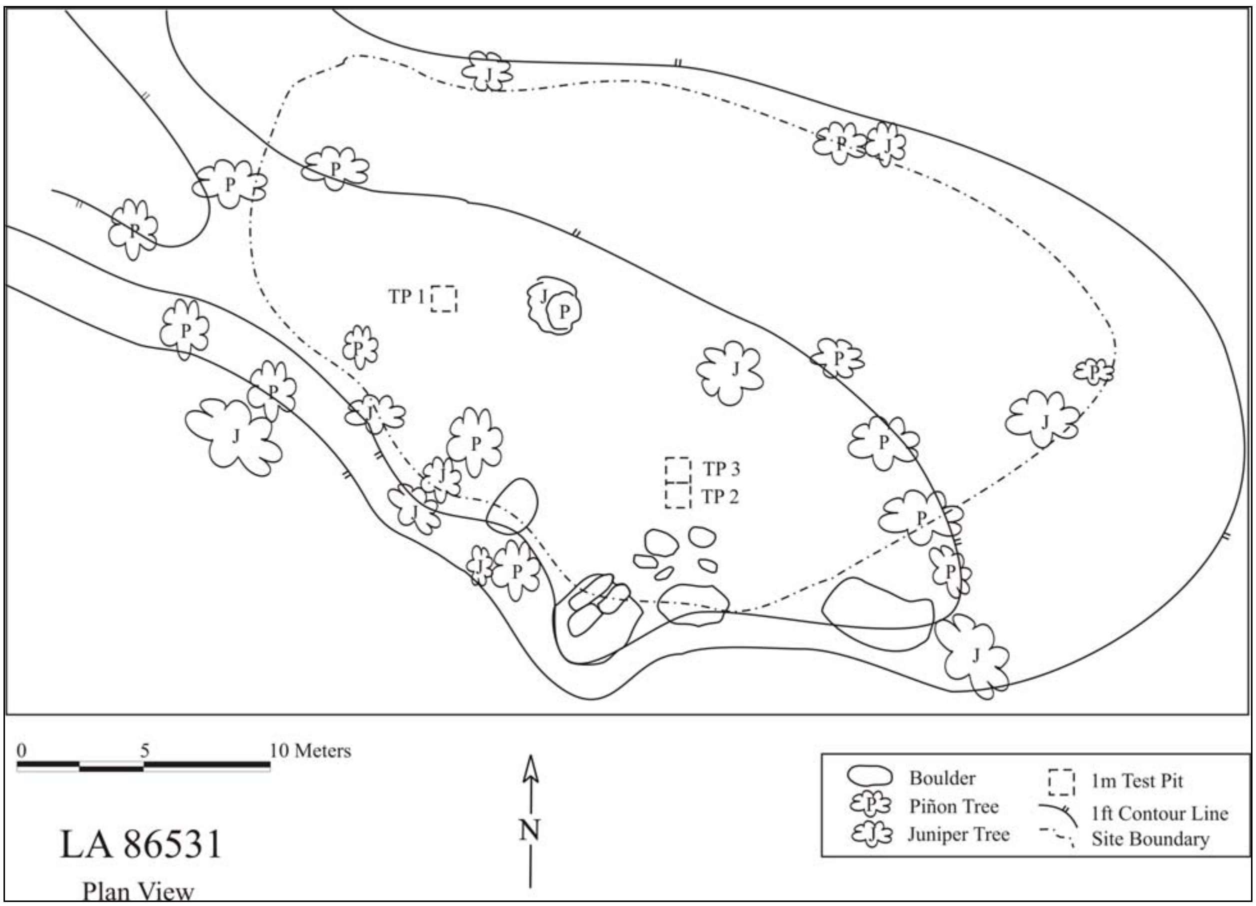

Figure 55.7. Plan view of artifact scatter at LA 86531.

Test Unit 2 was excavated into the east-central portion of the ridge top. It was excavated to a depth of 3 to 17 cm where the underlying boulders were encountered. Two soil strata were encountered within the excavation (Figure 55.8). The upper 3 cm was a C horizon soil consisting of loose silty loam with 20 percent to 30 percent gravel (10YR3/3 damp). This stratum was assessed to be recent slopewash. The underlying stratum was an Ab1 horizon soil consisting of a sandy clay loam with 20 percent gravel (10YR3/2 damp). A small amount of burned soil and charcoal was located within the northwest corner of the unit. As a result, the adjacent 1- by 1-m unit to the north (Test Unit 3) was excavated. It also was terminated at the underlying boulder zone that was encountered at depths ranging from 8 to 23 cm below surface. The stratigraphy was the same as that encountered in Test Unit 2 except that a third potential Bk horizon soil was encountered at depths ranging from 12 to 23 cm (7.5YR6/4 to 10YR6/4). This soil that was a compact silty loam with virtually no gravel was assessed to be a Pleistocene deposit. Charcoal and charcoal-stained fill were situated throughout the southern third of the unit in Strata 2 and 3 (8 to 23 cm). As the charcoal was inset into the Pleistocene soil, the stain was interpreted to be a root burn rather than a cultural feature. One indented corrugated utilityware sherd was recovered from Stratum 2 within Test Unit 3.

Figure 55.8. Photo of LA 86531, Test Units 2 and 3 looking north.

Based on the soils exposed through excavation, the top of the terrace appears to be a stripped surface that is capped by a thin (less than 20 cm thick) young soil overlying a stripped Pleistocene soil or bedrock. Stratum 1 appears to be a 0- to 3-cm-thick (less than 100 years?) slopewash that overlies Stratum 2, a thin 7- to 11-cm-thick late-Holocene/post-Puebloan(?) deposit. Based on the relatively well-developed stripped Bt horizon encountered within Test Unit 1 and the height of the terrace above the canyon floor, the terrace is inferred to be middle Pleistocene in age (Drakos and Reneau 2003).

The likely cultural horizon (Ab1) observed at LA 86531 is thin. The presence of the surficial artifact scatter on an eroded ridge top with thin soils indicates that LA 86531 represents an eroded site situated on the Pleistocene terrace. The observed artifacts may represent a lag and may have only been transported a short distance (Drakos and Reneau 2003).

Macrobotanical (flotation and charcoal) and pollen samples were collected and processed from Test Unit 3, Level 1 (Stratum 2) and Level 2 (Stratum 2/3.). The flotation sample from Level 1 produced two charred corn cupules and five possible charred corn kernel fragments. No cultigens were identified from Level 2. The pollen sample assemblages were characterized by tree pollen although maize pollen was recovered from the Stratum 2/3 sample. The charred corn cupules and kernel fragments were submitted to Beta Analytical, Inc., for accelerator mass spectrometer radiocarbon dating. The results of the two-sigma calibration produced a date range of AD 1180 to 1280 (Cal BP 780 to 670).

Summary

The testing conducted at LA 86531 indicates that most of the surface soils have been stripped from the ridge and that the remaining deposits are quite thin. The upper two soil horizons are assessed to post-date the Ancestral Puebloan area utilization as indicated by the site associated ceramics, and the underlying soil horizon is assessed to date to the middle Pleistocene. The site cultural materials that are situated within the upper 20 cm of soil deposition remaining on the ridge are the result of slopewash colluvium or are surface lag (Drakos and Reneau 2003). Based on this assessment, the cultural materials associated with LA 86531 are not in their original context and there is no potential for intact cultural remains to be situated on the site. As a result, LA 86531 is no longer eligible to the Register.

LA 86532

LA 86532 (Q-34) is the remains of a homestead cabin that was subsequently utilized as Camp Hamilton Boy Scout Camp. It is located within the Pueblo Canyon floodplain directly north of the existing channel. Situated at an elevation of 1987 m (6520 ft), the site area is transitional between a piñon-juniper woodland and ponderosa pine forest.

The site contains the foundation and some wall and roof remains of an approximately 7- by 7-m log cabin mortared with concrete. The foundation consists of stacked rock slabs. Although deteriorated, portions of standing walls form a 3- by 3-m two-room area. Two window openings remain within the structure: one in the south wall of the southernmost room and one in the west wall of the northernmost room. Roof beams are located on the ground within and near the northeast corner of the structure. A 12-m-long stacked masonry wall built against a dirt bank is located about 2 to 3 m north (upslope) of the cabin. Outhouse material remains are located several meters northwest of the structure.

Historic trash is scattered throughout a 12- by 112-m area surrounding the cabin. Some observed items include a car seat, brick, mortar, milled lumber, a silver knife blade, assorted broken bottle glass, and a 1944 New Mexico license plate from a truck.

The cabin was originally constructed by a Santa Fe resident named Coomer. Coomer, who leased the land from the Forest Service, conducted guided tours ("Tent Cities of the Rockies") in Pueblo Canyon during the early 1920s. In 1923, S. C. Hamilton bought the lease and improved the cabin. Hamilton was the father of Ranch School student Samuel Hamilton. Upon renovation, the cabin was used as a base for schoolboy outings. These outings, which were frequently conducted during the winter months, continued for two decades. When the cabin reached a state of disrepair, some of the original timbers were used to construct the National Historic Registry Landmark shelter on Trinity Drive just south of Ashley Pond in Los Alamos, NM (Hoard 1981:47). Based on documented history, this Homestead Era site was occupied from the early 1920s to 1943.

Upon completion of a review conducted for the Land Conveyance and Transfer Project site eligibility testing program, LA 86532 was re-evaluated and deemed ineligible to the Register. The re-evaluation was based upon the SHPO opinion that the information potential of LA 86532 had been exhausted through survey recording. As the decision was made to concur with the SHPO eligibility evaluation, and as LA 86532 is not eligible under other criteria, it was reassessed as not eligible to the Register. As LA 86532 is no longer assessed to be a potentially eligibility property, it was not tested for site eligibility.

LA 110121

LA 110121 (V-117) is located on the eroding slope of an eastern-trending ridge in the bottom of Pueblo Canyon. The site is situated between two east-west-running drainages (Figure 55.9). The area is dominated by a piñon-juniper woodland. The site slopes five degrees to the east and is at an elevation of 1967 m (6450 ft).

The site consists of a light artifact scatter situated within a 25- by 43-m area. Observed surface artifacts included 56 ceramic sherds and 12 pieces of lithic debitage. Decorated ceramics included 11 Santa Fe Black-on-white, two Santa Fe/Wiyo Black-on-white, three Wiyo Black-on-white, and nine unidentified black-on-white sherds. Utilityware ceramics included 11 indented corrugated, 10 smeared-indented-corrugated, eight obliterated, and two non-micaceous plainware sherds. Lithic debitage consisted of 10 Pedernal chert core flakes, one piece of Pedernal chert angular debris, and one obsidian core flake.

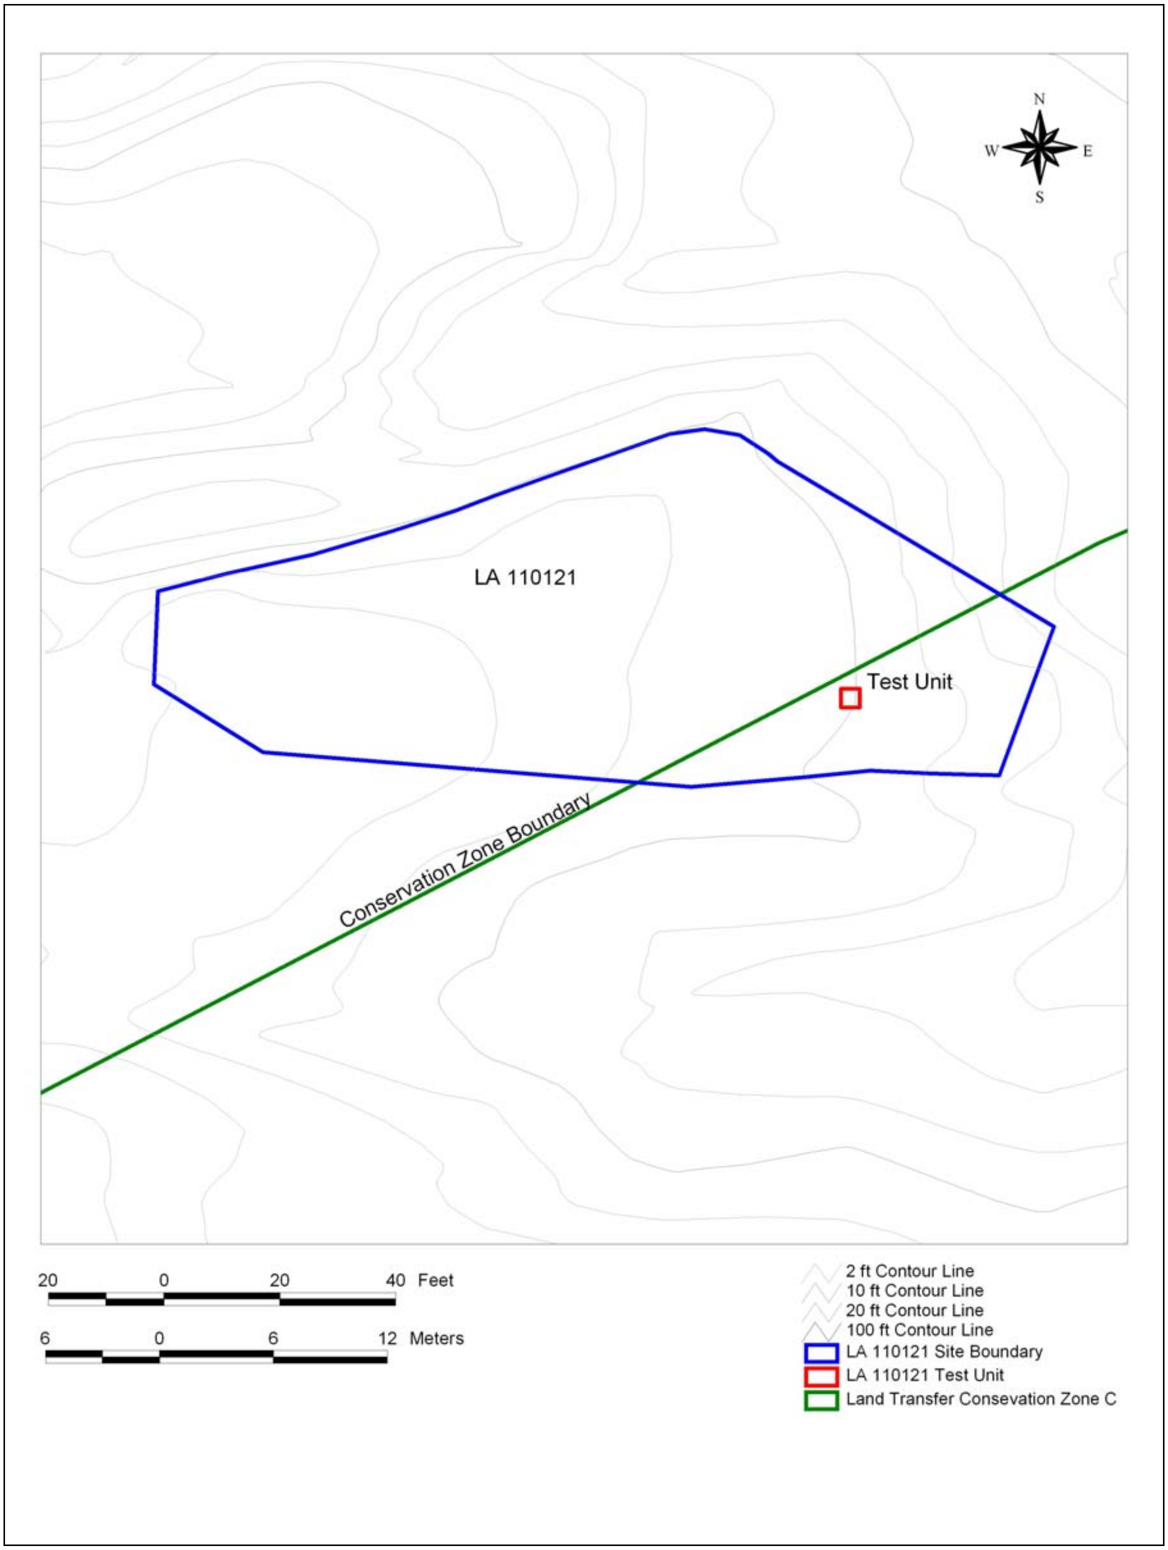

Figure 55.9. LA 110121 GPS differential map.

Testing

The eastern quarter of LA 110121 was tested to establish whether there were any intact cultural remains that could be adversely affected by the land conveyance. As the eastern end of LA 110121 appeared to have been impacted by erosion, a 1- by 1-m test unit was established outside the conservation zone boundary in the area that appeared to have the most potential for retaining surface soils and cultural remains (Figure 55.10). The test unit was excavated in arbitrary 10-cm levels by trowel. With the exception of pollen, soil, and macrobotanical samples, all excavated materials were screened through 1/8-in. mesh.

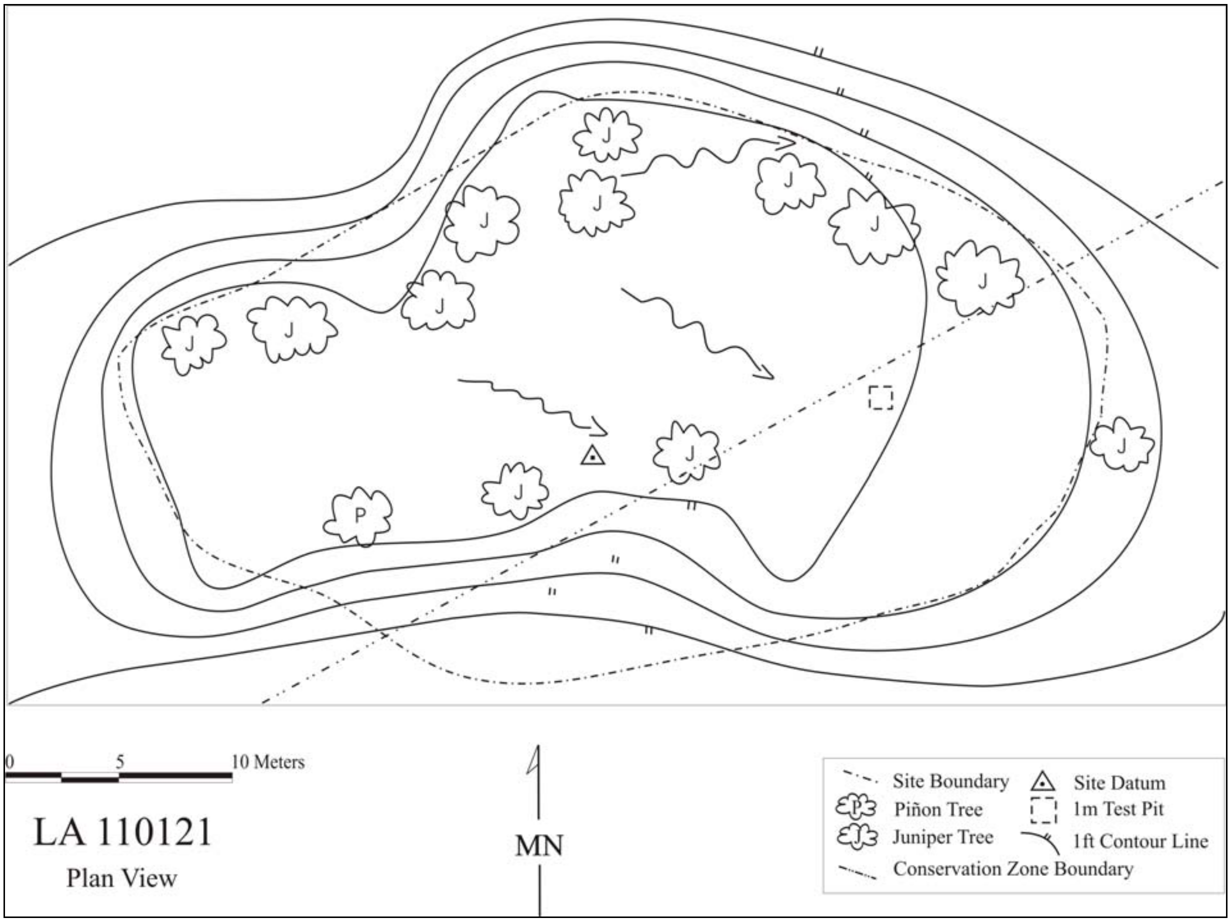

Figure 55.10. Plan view of artifact scatter at LA 110121.

Test Unit 1 was excavated to a depth of 20 cm below surface. The upper 11 cm contained an A horizon sandy clay loam with a pumice gravel content that increased with depth (10YR5/4). The upper 2 to 3 cm of the deposit contained about 5 percent pumice gravels, which increased to about 60 percent by the base of the stratum. Underlying the A horizon soil was a Bw horizon sand and pumice deposit. Pumice clasts formed approximately 90 percent of this deposit. At a depth of 19 cm below surface, a Guaje pumice bed deposit (C horizon) was encountered (Drakos and Reneau 2003). No cultural materials were encountered during the excavation.

As the post-Guaje sediment was only 11 cm thick at the test unit location, the artifact scatter that is apparently part of the thin overlaying colluvium is not in cultural context (Drakos and Reneau 2003). The testing indicated that the western quarter of LA 110121 contains no intact cultural deposits and as such should be removed from the site. As testing was not conducted in the western 3/4 of the site, although unlikely, there is some potential that intact cultural deposits could still be present. A few piñon and juniper trees have facilitated the retention of soil along the west side ridge edges. Until such time as these ridge edge locations can be tested, LA 110121 is still assessed to have an undetermined Register eligibility.

LA 110126

LA 110126 (V-123) consists of a highly eroded one-room structure situated on a north facing ridge finger that formed between two small drainages on the south side of Pueblo Canyon (Figure 55.11). The site was recorded in October of 1994 by Los Alamos National Laboratory Cultural Resources Team archaeologists during fieldwork conducted for the Environmental Restoration Canyon Bottom Project. This area is dominated by piñon-juniper and ponderosa pine. The site area slopes 10 degrees to the north and is at an elevation of 1960 m (6430 ft).

The structure was constructed of shaped and unshaped tuff blocks. An average tuff block measured 15 by 10 by 8 cm. The limited number of blocks located in the vicinity suggests that they originally formed the foundation of a one-room structure. In the least disturbed northern area of the site, an alignment of four tuff rocks is still present (Figure 55.12). Most of the remaining blocks are located downslope to the north and east from this alignment. A juniper tree is located directly south of the four rock alignment and a piñon and a juniper tree are located just northeast of the northern end of the alignment. These trees have partially stabilized the tip of the ridge finger containing the structural remnants. Defining the original size and shape of the structure was impossible due to the high degree of erosion (Figure 55.13).

The surface artifact assemblage, which was located in a 270-m² area situated within and downslope from the structural remains, consists of both chipped stone debris and ceramics. Decorated ceramics include three Biscuit A sherds (one is worked), nine Biscuit B sherds, one Santa Fe Black-on-white sherd, and two indeterminate black-on-white sherds. Utilityware ceramics included seven obliterated, one smeared-indented sherd, and one Sapawe Micaceous sherd. Chipped stone debitage included one obsidian biface flake, four chalcedony core flakes, one chalcedony core, and one piece of chalcedony angular debris. These surface artifacts indicated an Ancestral Pueblo Classic period affiliation for the site.

Testing

Site testing that resulted in the excavation of four 0.5- by 0.5-m test units, was conducted from October 18 through the 22, 2002. Although the test units were termed shovel tests to denote that they were smaller than a 1- by 1-m test unit, they were excavated by trowel in arbitrary 10-cm levels. Shovel Test 1 was placed 2 m east of the juniper located south of the four-rock alignment along the eastern edge of the tree-supported knoll. Shovel Test 2 was positioned at the northern edge of the knoll just above the slope where many of the structural tuff rocks have been redeposited by erosion. Shovel Test 3 was sited approximately 1 m east of the rock alignment within what appeared to be a stabilized portion of the structure interior. Shovel Test 4 was located just south of the juniper located south of the rock alignment in an area that did not appear to be impacted by erosion.

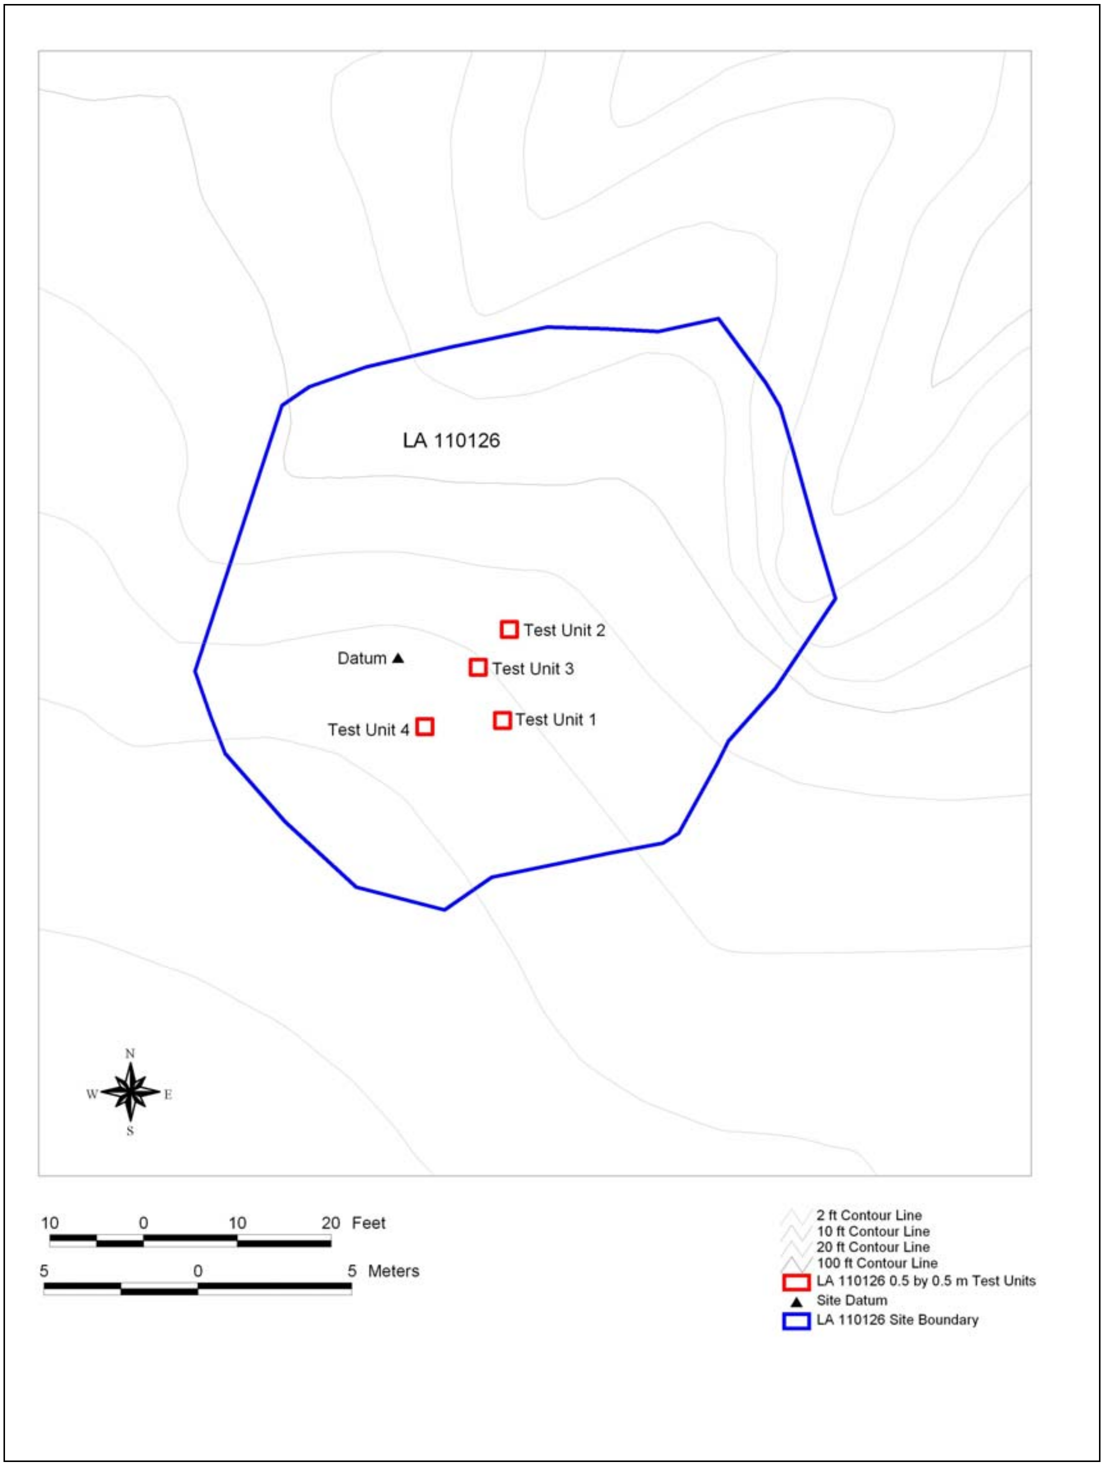

Figure 55.11. LA 110126 GPS differential map.

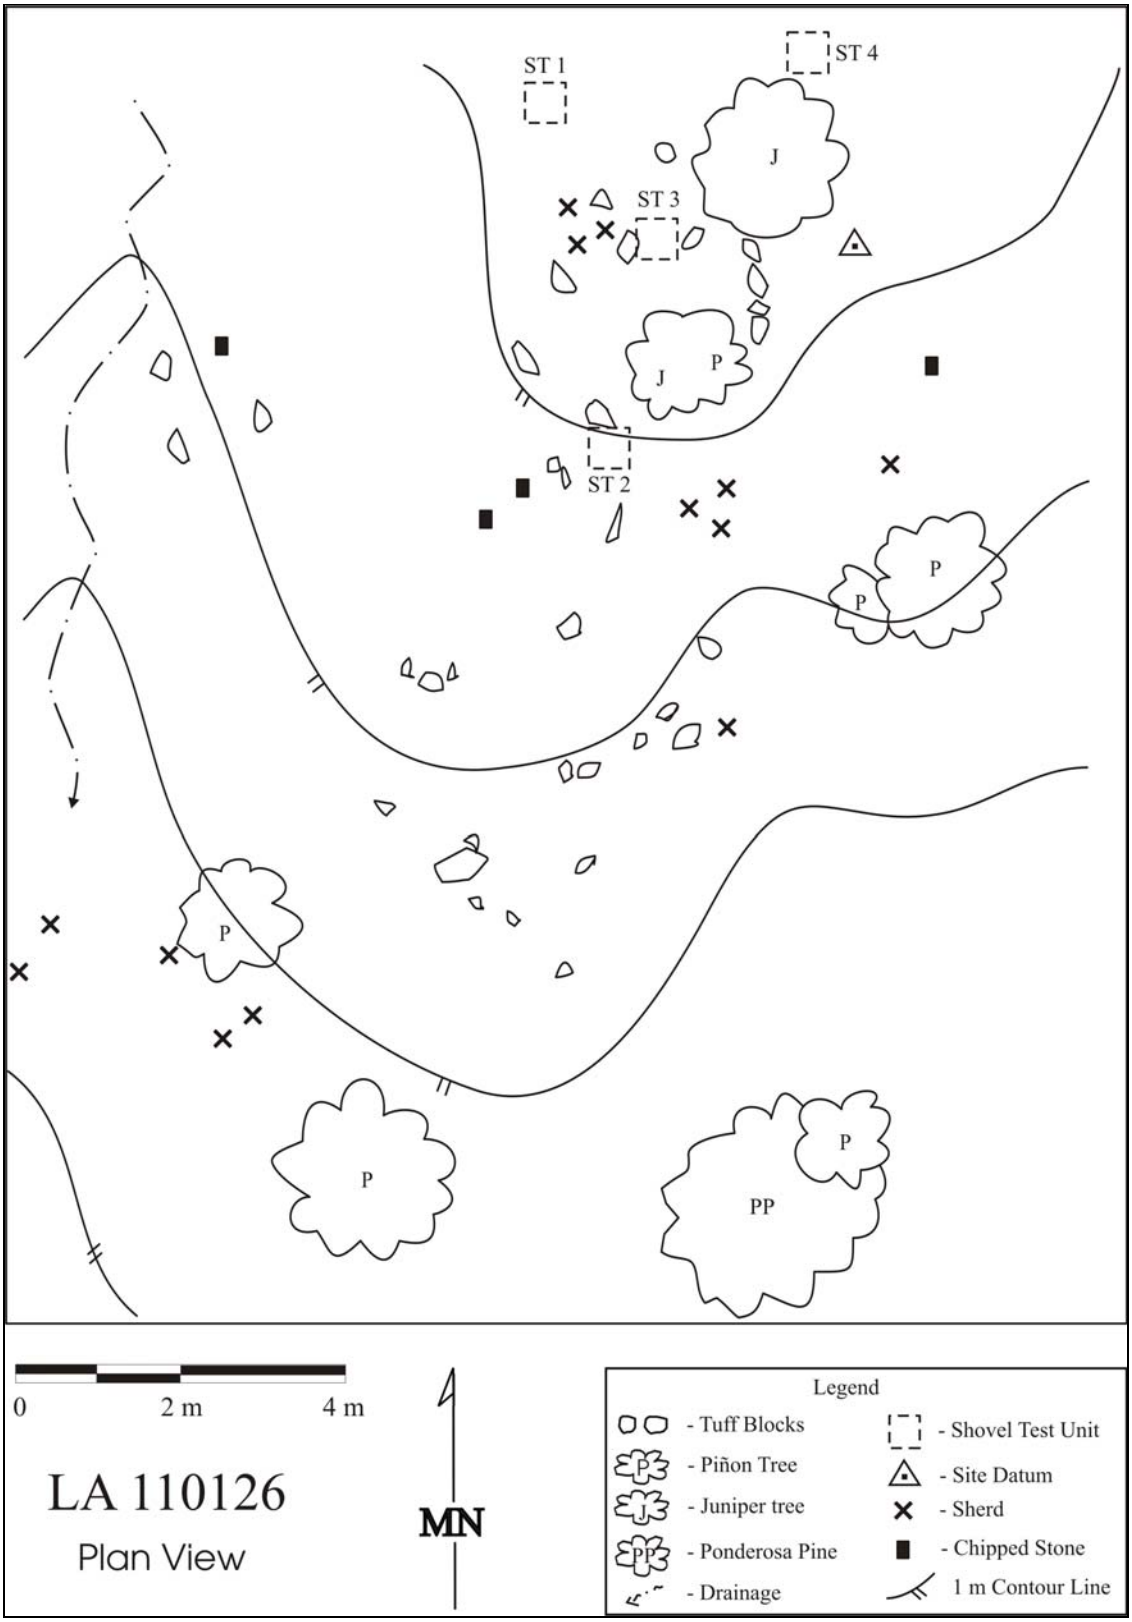

Figure 55.12. Plan view of the one-room structure at LA 110126.

Figure 55.13. Photo of LA 110126 looking southeast.

The stratigraphy was similar across the site with only the depth of deposits varying. Stratum 1 was a silty sandy loam ranging from 8 to 13 cm in depth. The upper 1 to 3 in. was loose with light to abundant duff. The soil below was lightly compacted. The Munsell color of the loam ranged form 7.5 to 10Y4/3. Stratum 1 was distinguished from Stratum 2 primarily on the level of compactness, color mottling, and the presence of decomposed tuff blocks and gravels (5% to 10%). The soil was a semi-compact silty sandy loam with 5 percent to 10 percent gravel. Also present were a few decomposing tuff blocks within ST 1 through 3. Although the soil was assessed to be Munsell color 7.5 to 10YR4/3, it visually ranged from a light brown to a grayish or reddish brown. Charcoal-stained fill was noted within the northwest quadrant of Shovel Test 1 and a few chunks and flecks of charcoal were observed within Shovel Tests 2 and 3. The charcoal chunks noted in Shovel Test 3 were assessed to be associated with a burned root, and it is likely that the other charcoal remains were associated with a tree fire. Stratum 3 consisted of compact clay with some well developed peds (7.5 to 10 YR 5/4).

Shovel Test 4 was apparently positioned beyond the original site activity area as no cultural materials were encountered or any materials that were present subsequently eroded downslope into the structural remains. Eleven ceramics and four pieces of chipped stone debris were recovered from Strata 1 and 2 within Shovel Tests 1 through 3. The ceramics recovered from the test unit excavations included seven Biscuit B sherds, two unpainted biscuitwares that were slipped on one side, and two Sapawe Micaceous sherds. The chipped stone included a chalcedony core flake recovered from Level 1 in Shovel Test 2 and core flake, a piece of microdebitage and a piece of Pedernal chert angular debris recovered from Level 3 in Shovel Test 3.

Macrobotanical and pollen samples were taken from Stratum 2 and 3 from Shovel Test 2. No culturally significant remains were recovered from either sample.

No evidence of an occupational surface or intact cultural deposit was encountered. Both Strata 1 and 2 are assessed to be post-occupational deposits with Stratum 3 being a late-Pleistocene culturally sterile soil. Many of the cultural remains associated with the structure have eroded downslope, primarily to the north and east. The remaining subsurface cultural materials have been mixed into Strata 1 and 2. The localized erosion has destroyed the original site context with only the four-tuff-rock alignment still assumed to be intact due to its location between trees that have reduced the amount of soil movement. As erosional processes have destroyed the site integrity, LA 110126 is no longer considered eligible to the Register.

LA 110130

LA 110130 (V-127) consists of a one-room structure located on the north edge of an eroded, gently east-sloping fluvial terrace (Figure 55.14). The terrace is situated above the Pueblo Canyon floodplain. It is situated within the transition zone from piñon-juniper woodland to ponderosa pine forest, at an elevation of 1954 m (6410 ft).

The structure is represented by partial alignments of tuff blocks with additional blocks deposited downslope to the north and east (wallfall?) (Figure 55.15). Based on the partial alignments, the masonry structure roughly measured 4 by 3 m with an associated earthen mound measuring approximately 0.2 m in height. The masonry blocks are relatively small, averaging about 15 by 10 by 6 cm in size. The overall extent of the site, including artifacts and eroded building material, is approximately 15 by 35 m.

About 10 m to the west of the one-room structure is another rough alignment of tuff rocks. It is unclear what the function of this feature might have been. The 1.1-m-long eight-stone alignment is oriented in an east to west direction.

Testing

Two 1- by 1-m test units and two 0.5- by 0.5-m units termed shovel tests were excavated into the masonry block concentration in November of 2002 (Figure 55.16). All four test excavations were excavated in arbitrary 10-cm levels using a trowel. With the exception of pollen, soil, and macrobotanical samples, all excavated materials were screened through 1/8-in. mesh.

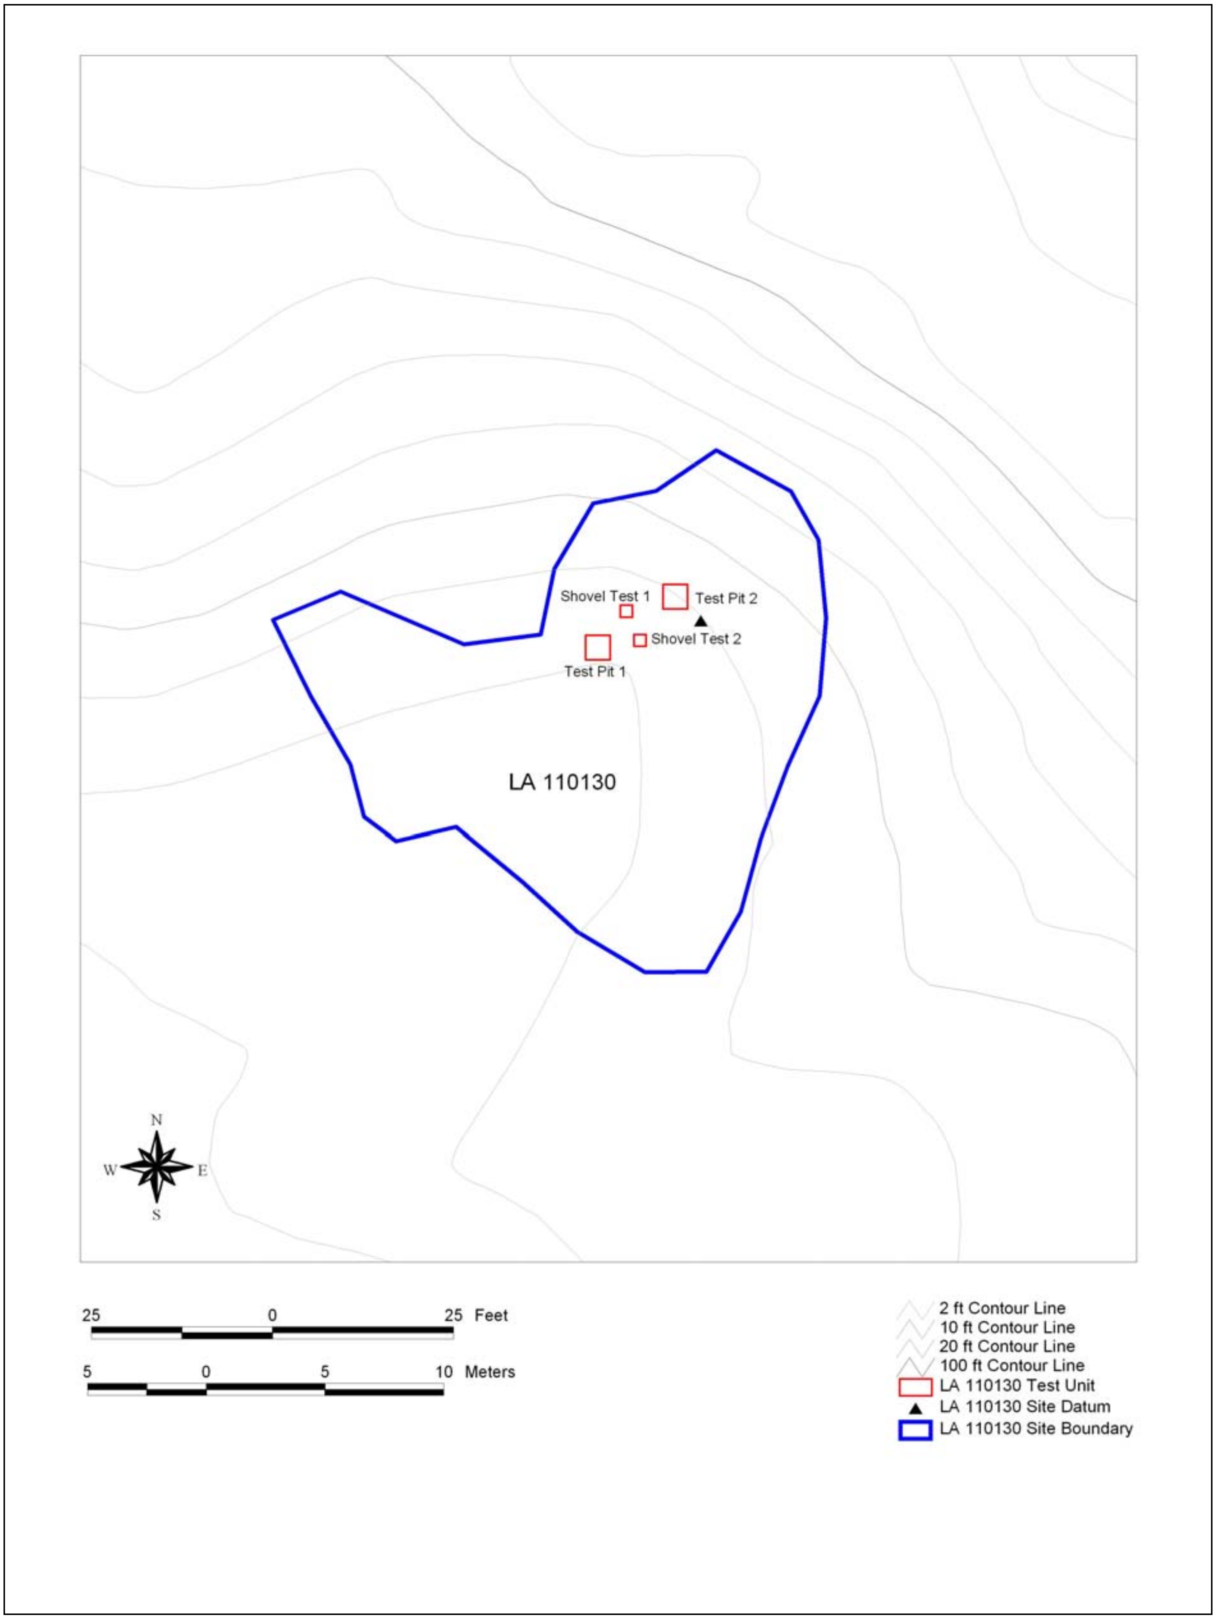

Figure 55.14. LA 110130 GPS differential map.

Figure 55.15. Plan view of structure at LA 110130.

Test Unit 1 was situated to straddle the apparent southwest corner of the masonry structure, while Test Unit 2 was placed within the rubble concentration located in the southeastern portion of the structure. Both test units were terminated at a depth of 20 cm after approximately 3 to 4 cm of culturally sterile soil was encountered. There was essentially no difference in the encountered stratigraphy between Test Unit 1 and Test Unit 2 except that there was a pocket of lightly charcoal-stained soil located within the southwest quadrant of Unit 2. The charcoal-stained soil that was encountered at a depth of 12 to 15 cm below the surface was 20 cm in diameter. There was also virtually no stratigraphic variability between the assumed interior and exterior of the structure as defined by the rock alignment in Test Unit 1. As a result, the two shovel tests were placed between Test Unit 1 and Test Unit 2 into what was assumed to be the interior of the structure to ascertain whether an activity surface was present. Shovel Test 1 was located about 1 m to the north-northeast, and Shovel Test 2 was located about 0.75 m to the east-northeast of Test Unit 1. Shovel Test 1 was excavated to a depth of 20 cm while Shovel Test 2 was excavated to a depth of 30 cm. No activity surface was encountered within either shovel test. The stratigraphy in both shovel tests was virtually the same as that encountered in the two test units, although an additional 10 cm of culturally sterile soil was removed from Shovel Test 2 (20 to 30 cm). Twenty Sapawe Micaceous and two smeared-indented utilityware sherds were recovered from Levels 1 and 2 and a quartzite core flake from Level 1 in Shovel Test 2. Other recovered artifacts included one Wiyo Black-on-white sherd from the surface and a plain non-micaceous utilityware sherd from Level 1 in Test Unit 1; two rhyolite core flakes, two Pedernal chert core flakes, and one piece of Pedernal chert angular debris from Level 1; one plain non-micaceous utilityware sherd from Level 2 in Test Unit 2; one Sapawe Micaceous sherd from Level 1; and one rhyolite core flake from Level 2 in Shovel Test 1.

Figure 55.16. Post-testing photo of LA 110130 looking east.

As the soil stratigraphy within all four test excavations was very similar, only the Test Unit 1 profile is described. The upper 5 cm was an A horizon soil consisting of loose sandy loam with about 5 percent gravel content. Stratum 2, a Bw soil, ranged from about 5 to 17 cm below surface. It consisted of soft to slightly hard sandy clay loam with about 10 percent gravel content. Stratum 3 (17 to 20+ cm) is a Btb1 horizon soil consisting of soft/loose sandy clay loam with a 40 percent to 50 percent gravel content.

The test excavations revealed approximately 17 cm of sediment overlying a buried Bt horizon interpreted to likely represent a stripped or eroded late-Pleistocene soil. The tuff blocks associated with the partial structural alignments are set slightly into or on top of the Btb1 horizon. The tuff block alignments are not clearly walls, but may represent the foundation of a structure. The additional tuff blocks to the north and east likely represent the fall and downslope erosion of upper course wall blocks. An alternative assessment is that the partial tuff block alignments may represent the remnants of a rock-lined grid garden.

The A and Bw horizons likely represent slopewash colluvium that includes reworked older soil in the Bw horizon that has partially buried the rock alignments. The artifacts observed within the A and Bw horizons are likely part of the slopewash colluvium although their presence does suggest an association with the alignments and a Classic period affiliation for the structure. The artifacts may also represent locally bioturbated material that is in reasonably good archaeological context (Drakos and Reneau 2003).

Strata 2 and 3 macrobotanical (flotation) and pollen samples were collected and processed from both the assumed interior and exterior of the structure as defined in Test Unit 1. A flotation sample collected from the charcoal stain observed in Test Unit 2 was also collected. The flotation sample from Test Unit 1, Stratum 2 produced one charred *Amaranthus* seed while the charcoal stain in Test Unit 2 produced a corn cupule and a corn cupule fragment. The corn cupule was submitted to Beta Analytical, Inc., for accelerator mass spectrometer radiocarbon dating (Beta Number 183767). The calibration of radiocarbon age to calendar years resulted in a conventional age of 360±30 BP, a two-sigma calibration date range of AD 1450 to 1640, and an intercept date of AD 1500.

Pollen samples from the assumed exterior of the structure were more productive, exhibiting a gradient from the shallow to the deeper samples of decreased tree pollen and increased cheno-am. No cultigen pollen was recovered from any of the samples.

Summary

Although likely bioturbated, the artifacts and corn cupule remains suggest that the cultural material is in reasonably good archaeological context. As a result, there is still potential that LA 110130 contains cultural materials that could aid in establishing the nature of the structural remains (i.e., is the site the remains of a fieldhouse or grid garden). With the establishment of the site type, there is additional potential to address regional and site-specific research questions concerning the Classic period adaptation on the Pajarito Plateau such as establishing land and resource utilization patterns. As LA 110130 is assessed to retain research potential that could better establish the Ancestral Pueblo Classic period cultural adaptation on the Pajarito Plateau, it is considered eligible to the Register under Criterion D, likely to yield information important in prehistory or history.

LA 110132

LA 110132 (V-129) contains two adjoining partial rock alignments that, based on the apparent association of artifacts, were assessed to be potential masonry structure foundation or garden plot enclosure alignments (Figures 55.17 and 55.18). The site is located on a ridge situated along the south side of Pueblo Canyon. It is situated at an elevation of 1955 m (6415 ft), within an area that is transitional between piñon-juniper woodland and ponderosa pine forest.

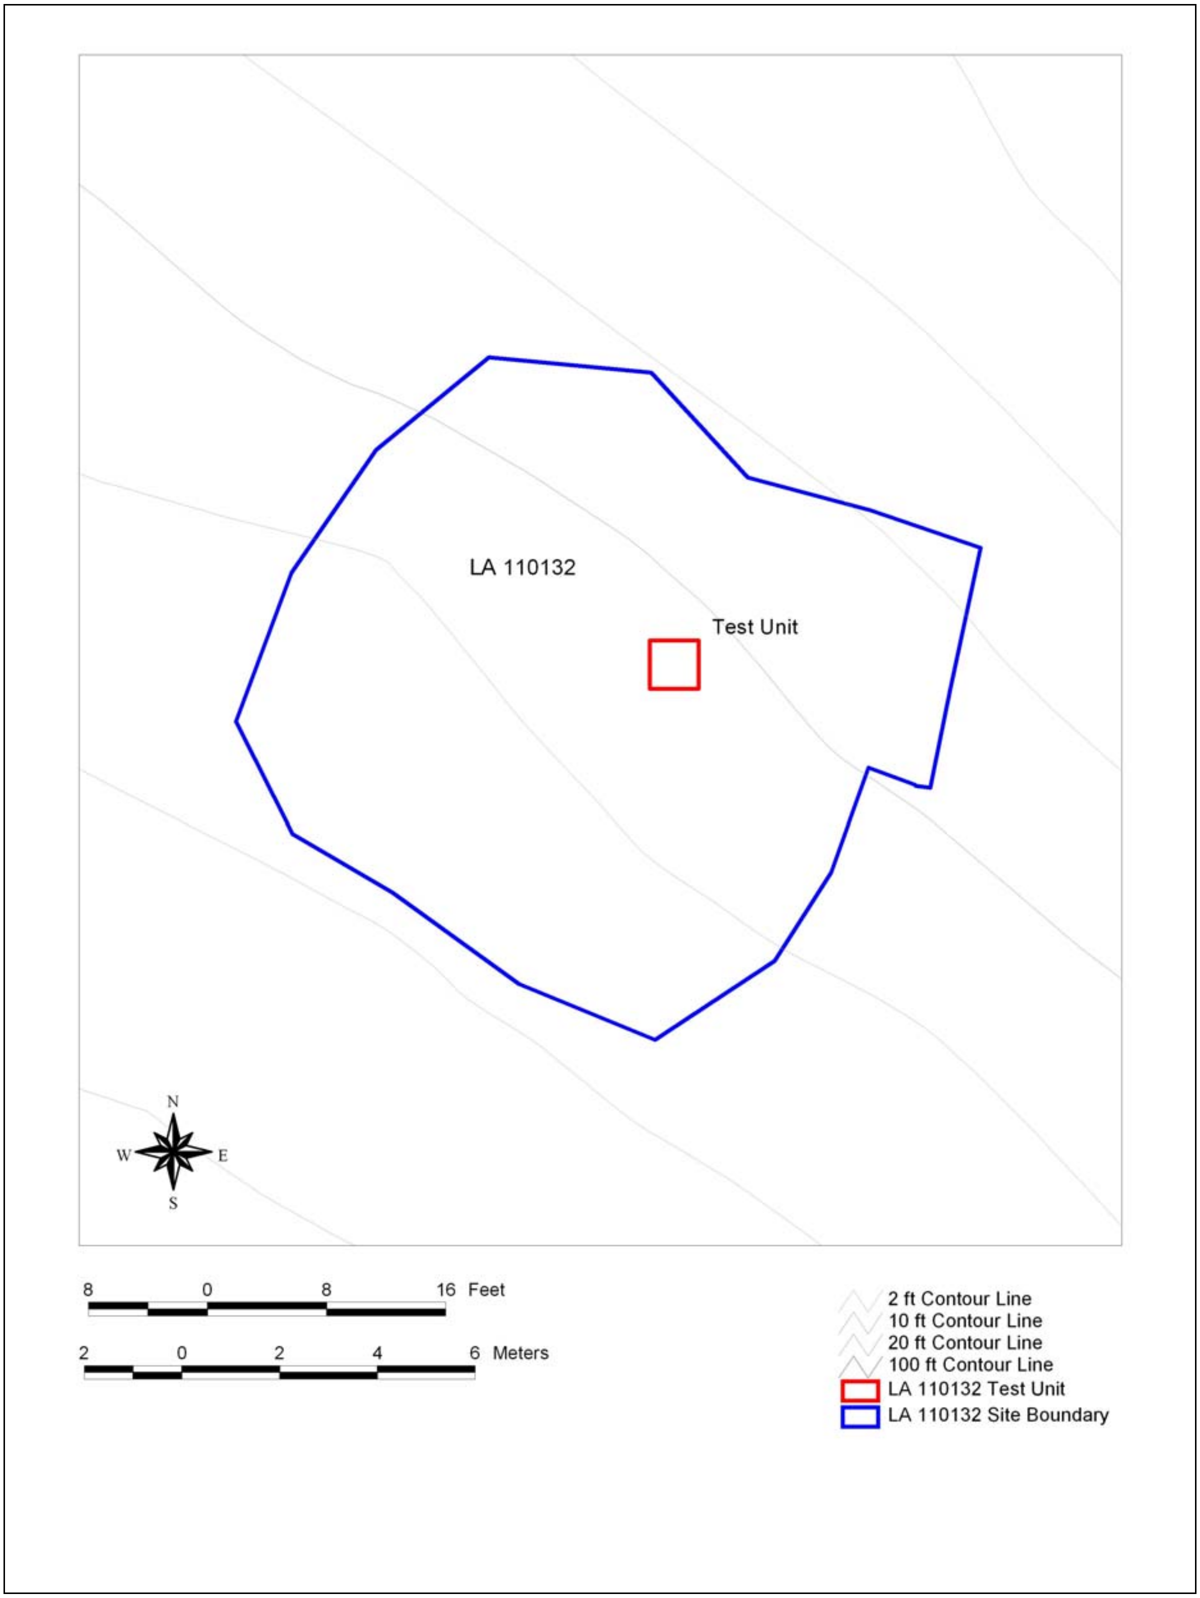

Figure 55.17. LA 110132 GPS differential map.

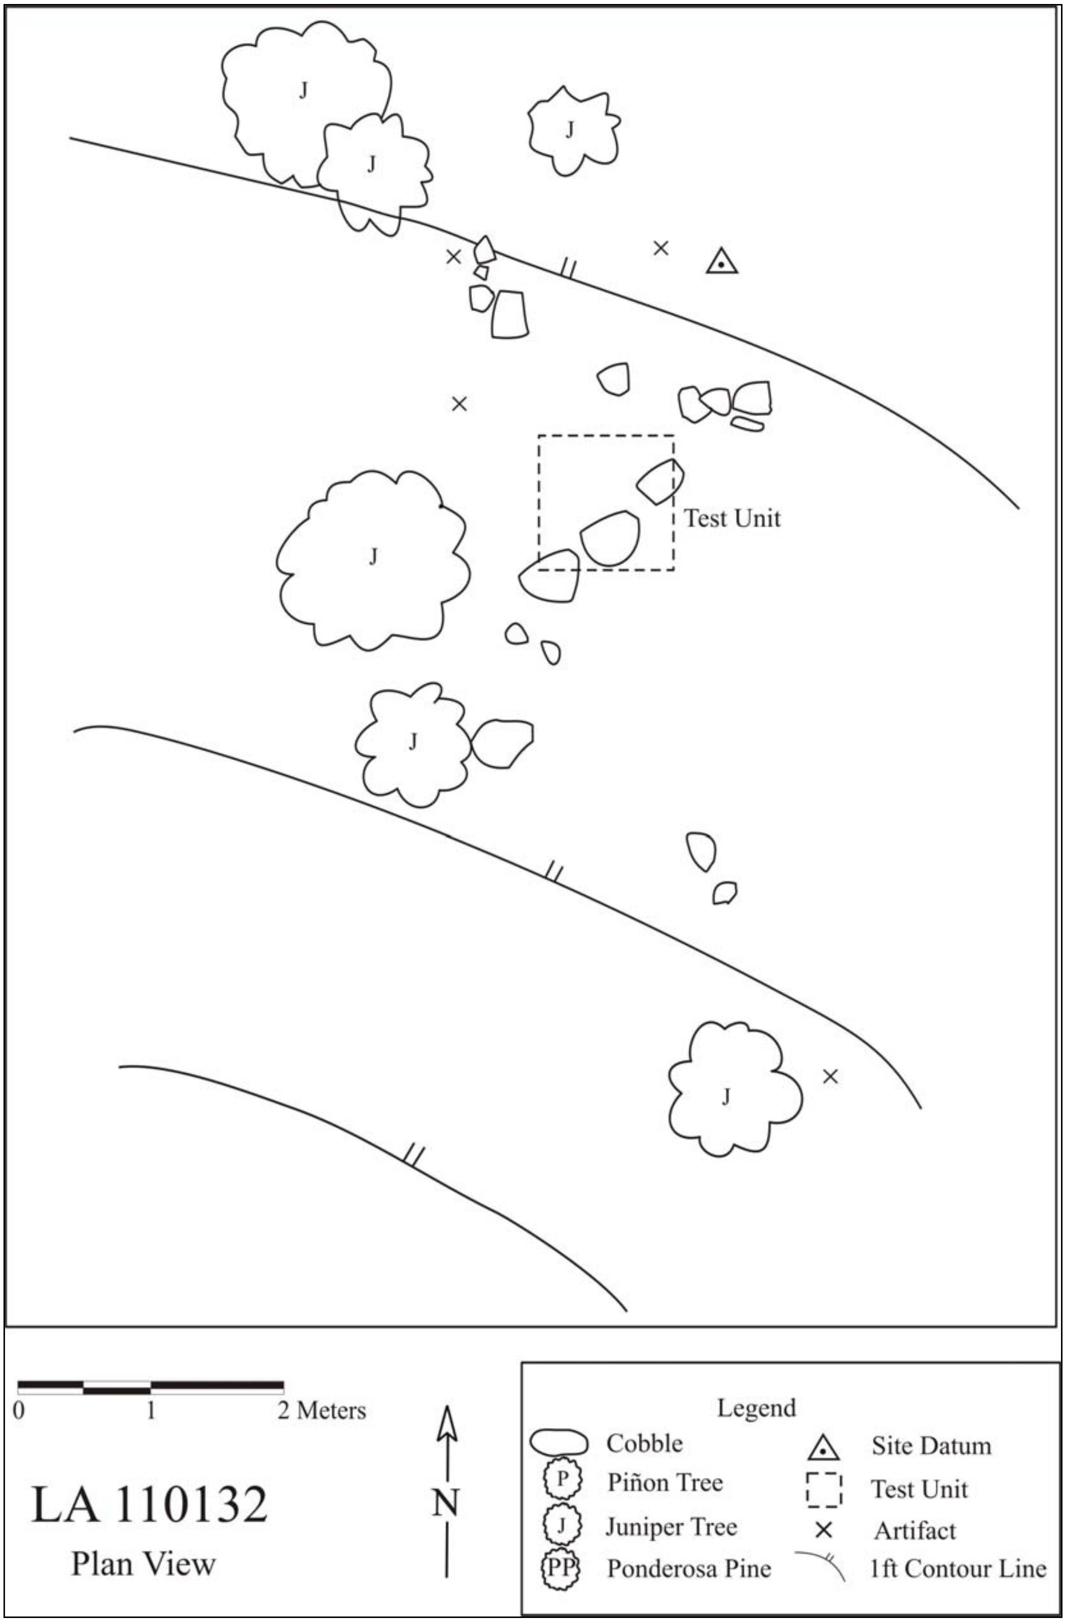

Figure 55.18. Plan view of potential structure at LA 110132.

The partial alignments are one course wide, with the north-south alignment measuring 2.4 m and the east-west alignment measuring 2.1 m in length. These intersecting alignments appear to form the northeast corner of a feature. The overall site area, including associated artifacts, is about 36 m^2. The rocks forming the potential cultural alignments average about 25 by 15 by 10 cm.

Four artifacts were observed within the site perimeter. The two ceramics consisted of a Santa Fe Black-on-white bowl sherd and a Biscuit A bowl sherd. The two lithics include an obsidian biface fragment, possibly a knife tip, and a broken quartzite cobble, possibly a mano fragment.

Testing

One test unit (A) was positioned over the east-side alignment to assess any stratigraphic differences from the inside to the outside of the structure. The test unit was excavated to a maximum depth of 10 cm with a trowel. All excavated materials were screened through 1/8-in. mesh.

The surface of a terrace boulder(s) was encountered between 2 cm (southwest corner) and 10 cm (southeast corner) below surface in the test unit. The fill above the terrace boulder was a sandy loam colluvium, which included reworked terrace gravels. There was no discernable difference in the colluvium from one side of the cobble alignment to the other. Based on the test unit, the potential structural alignments were assessed to be naturally occurring terrace cobbles and not of cultural origin. Other than the four surface artifacts, no cultural materials were associated with LA 110132. As no intact cultural materials were present, LA 110132 is no longer assessed to be eligible to the Register.

LA 110133

LA 110133 (Q-199) consists of a sparse ceramic and lithic artifact scatter. It is located on a north-facing colluvial slope situated below the mesa cliff face, along the southern edge of Pueblo Canyon (Figure 55.19). The site abuts the north side of the Pueblo Canyon dirt road. It is situated at an elevation of 1995 m (6540 ft) within a piñon-juniper woodland.

The artifact scatter is situated within an area that measures 2803 m^2. The 27 observed surface artifacts were dominated by ceramics. The decorated ceramics included four Santa Fe Black-on-white, one Wiyo Black-on-white, one Wingate Black-on-white, two unidentified redwares, two Biscuit A, one Biscuit B, and one Potsuwi'i Incised sherd. Utilityware ceramics included one indented corrugated, eight smeared-indented corrugated, one obliterated, and three unidentified sherds. The lithics consist of a chert biface flake and a ground quartzite cobble fragment.

Testing

Two 1- by 1-m test units were excavated into light artifact concentrations, one just below a two-track dirt road in the lower southern quarter of the site (Test Unit 1) and the other in the upper southeast corner of the site (Test Unit 2). Both test units were excavated in arbitrary 10-cm levels with shovel and trowel. With the exception of pollen, soil, and macrobotanical samples, all hand-excavated materials were screened through 1/8-in. mesh.

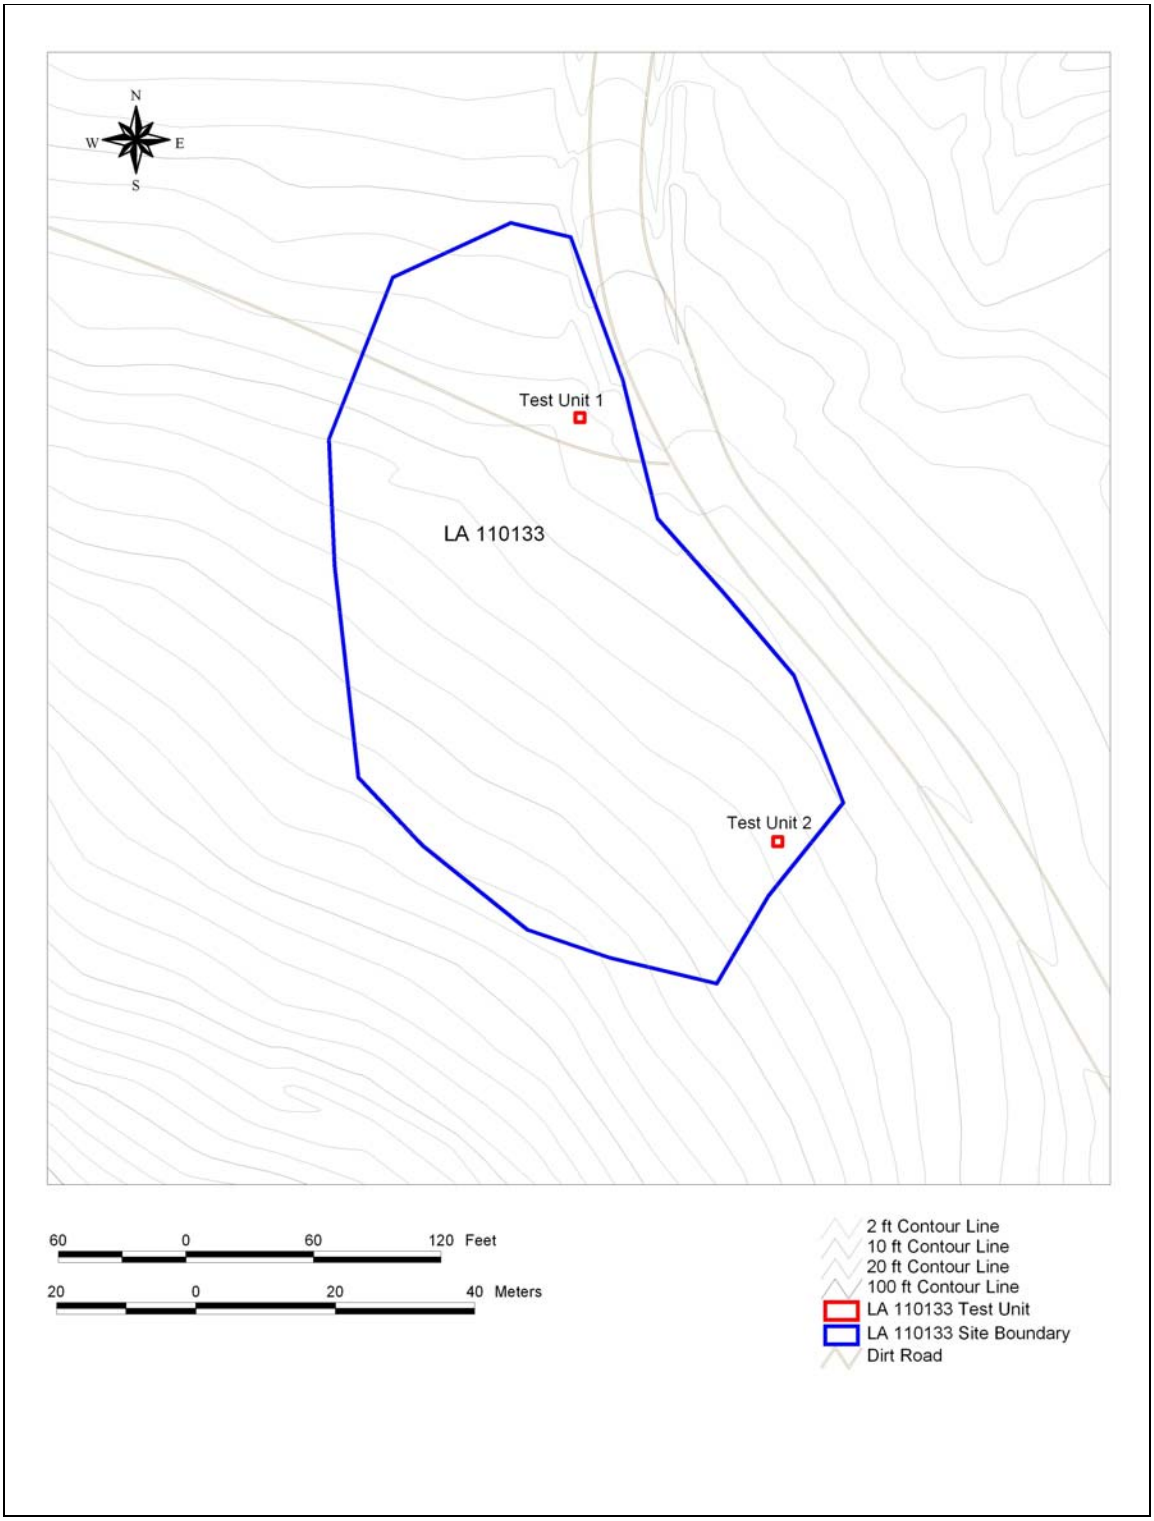

Figure 55.19. LA 110133 GPS differential map.

Test Unit 1 was excavated to a depth of 1 m and Test Unit 2 was excavated to a depth of 0.7 m below surface. Both test units were extremely similar in that they contained young colluvium throughout. The upper 16 to 19 cm contained a loose sand to loamy sand (10YR5/4) AC horizon soil that was assessed to be less than 100 years in age. The underlying fill was a loose to soft sandy loam (7.5YR5/4) BC or CB horizon soil exhibiting very weak soil development that was assessed to be less than 500 years in age (Drakos and Reneau 2003). Test Unit 1 was terminated within the colluvium, whereas Test Unit 2 was terminated at a change in the soil stratigraphy. At a depth of about 65 cm below surface, the colluvium in Test Unit 2 became extremely compact although pockets of loose sandy loam were still present. The hardening of the soil may have been produced by silica cement.

One ceramic was recovered from the upper 10 cm within both test units, and two ceramics were recovered from depths of 40 to 70 cm below surface in Test Unit 1. A plain gray utilityware sherd was recovered from the upper 10 cm (level 1), while smeared-indented utilityware sherds were recovered from Levels 5 (40 to 50 cm) and 7 (60 to 70 cm) in Test Unit 1. An unpainted, undifferentiated sherd was recovered from Level 1 in Test Unit 2. Other than theses four ceramics, no cultural materials were observed from within the two test units.

The test unit profiles indicated that LA 110133 is located on a very active colluvial slope with 70 cm or greater of post-Ancestral Pueblo colluvial deposition. The artifacts observed at LA 110133 appear to be part of the colluvium and are not in archaeological context (Drakos and Reneau 2003). As there appears to be no intact cultural deposits associated with LA 110133, it is no longer assessed to be eligible to the Register.

LA 117883

LA 117883 (Q-39) consists of a sparse lithic scatter situated within an area measuring 1410 m². The site is located on a north-side colluvial slope that forms a bench situated 3 m above the current drainage channel within Pueblo Canyon (Figure 55.20). The south and west sides of the site have been exposed to recent channel cutting. The area is vegetated by a piñon-juniper woodland and a ponderosa pine forest. The site is situated at an elevation of 1969 m (6460 ft).

During the initial recording, 62 lithic artifacts and four ceramics that were thought to be intrusive were documented during infield analysis. The chipped stone tools include the proximal end of an obsidian dart point with a concave base, an obsidian uniface, and a chert biface fragment. The debitage consisted of 39 pieces of obsidian, 14 pieces of Pedernal chert, and two pieces of basalt. The obsidian included 24 core flakes, 14 biface flakes, and one piece of angular debris. The Pedernal chert consisted of 10 core flakes and three biface flakes. The basalt included one core flake and one biface flake. The ceramics were identified as one unidentified biscuitware and three smeared-indented corrugated utilityware sherds.

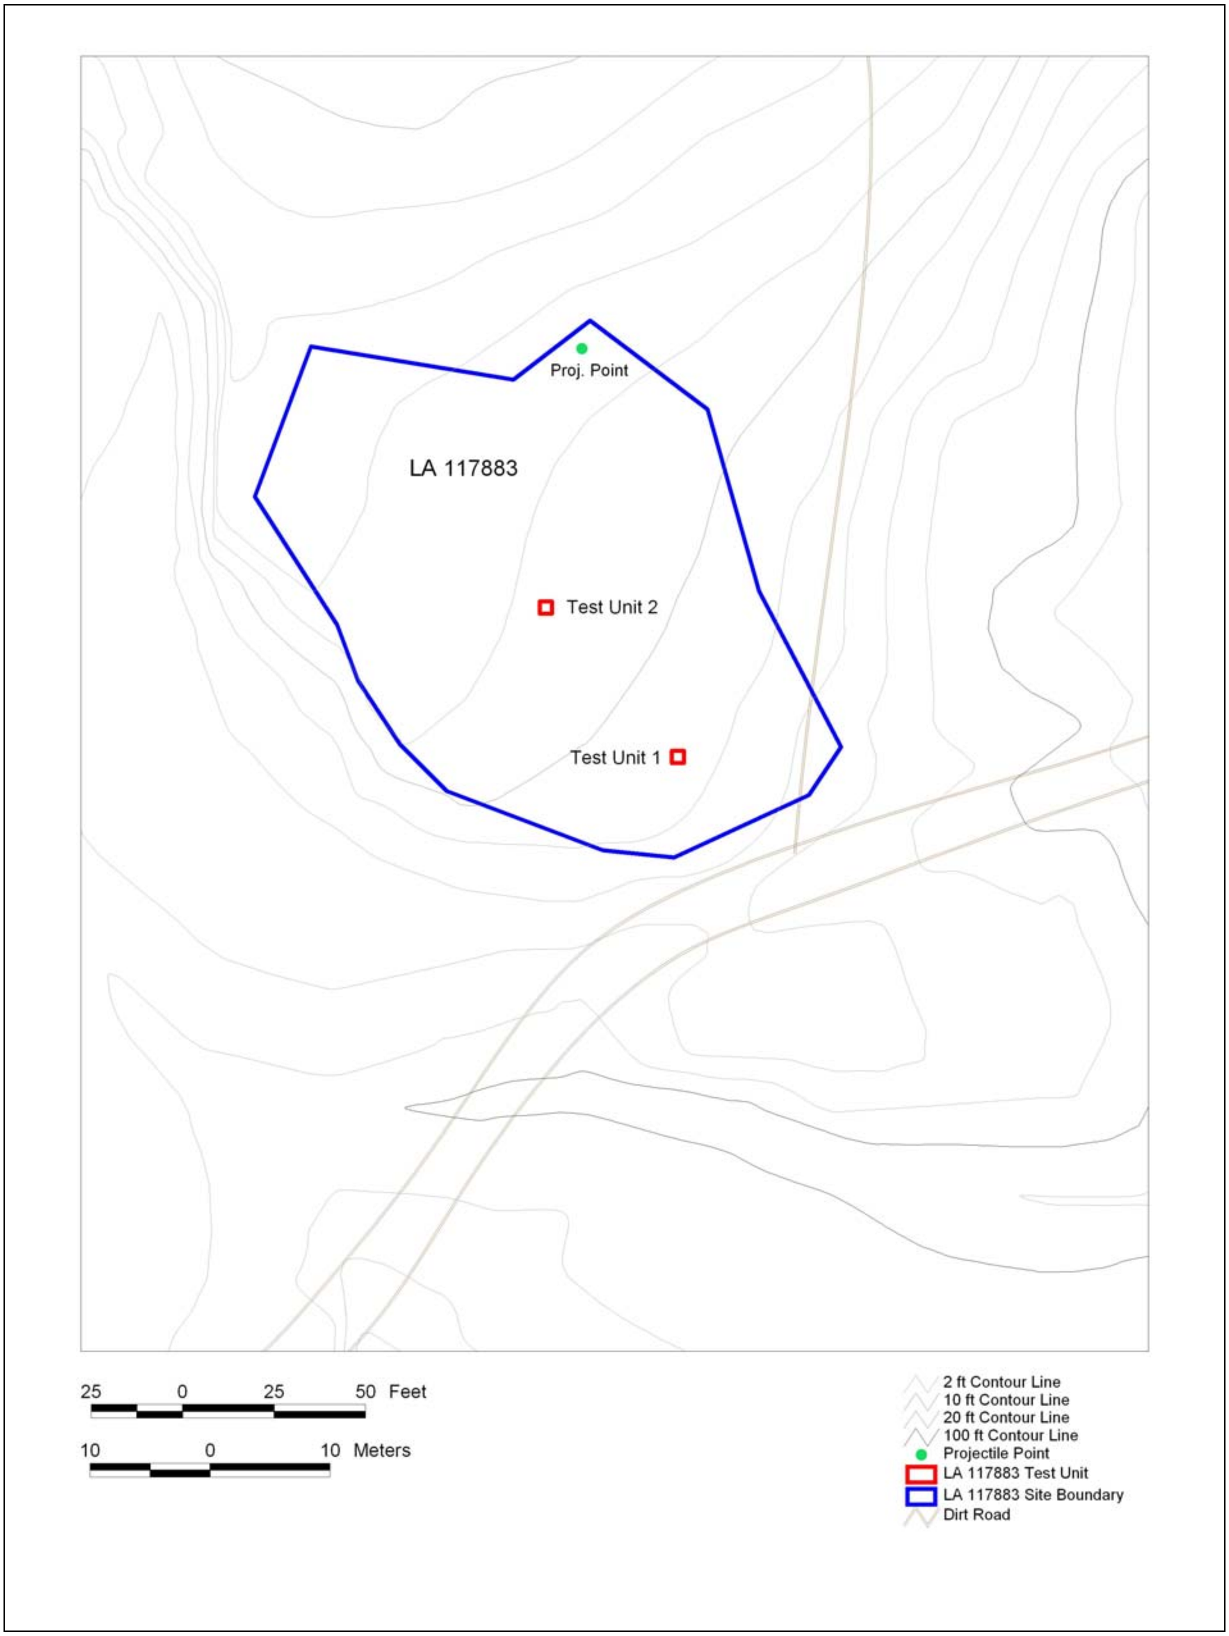

Figure 55.20. LA 117883 GPS differential map.

One ground stone artifact that was identified as a possible spade-shaped, tabular, polishing stone was also documented. It showed evidence of polishing along one rounded and one angled edge. It measured 12 by 7.5 by 5 cm and appeared to be made from a slate-like material.

Testing

Before the initiation of test unit excavations, an infield analysis was conducted on all observed surface artifacts located on LA 117833 (Table 55.1). The infield analysis resulted in the documentation of 75 lithics, including a projectile point, a biface fragment, a core, and 71 pieces of chipped stone debitage. Obsidian artifacts formed 81 percent of the surface lithics and Pedernal chert formed 13.5 percent. Biface flakes formed 51 percent of the lithic debitage while core flakes and flake fragments formed 28 percent and 10 percent, respectively. Also noted during the infield analysis were a Biscuit A ceramic and a Biscuit B ceramic sherd.

Table 55.1. Lithic artifact type by material type from LA 117833.

Artifact Type		**Obsidian**	**Pedernal**	**Basalt**	**Chert**	**Chalce-dony**	**Total**

Total		**60**	**10**	**2**	**1**	**1**	**74**

Two 1- by 1-m test units were excavated into light artifact concentrations. Test Unit 1 was located on a terrace situated 20 m north of the Pueblo Canyon channel and Test Unit 2 was situated upslope approximately 32 m north of the Pueblo Canyon channel. Both test units were excavated in arbitrary 10-cm levels with shovel and trowel. With the exception of pollen, soil, and macrobotanical samples, all hand-excavated materials were screened through 1/8-in. mesh.

Test Unit 1 was excavated to a depth of 0.67 m and Test Unit 2 was excavated to a depth of 1 m below surface. Both test units were similar in that they contained colluvium overlying buried terrace gravels. The upper 9 to 15 cm contained a loose sand (10YR4/3 to 10YR4/2) AC horizon soil that was assessed to be less than 500 years in age. Underlying the AC soil horizon was a 25- to 28-cm-thick C horizon soil deposit of loose sand (10YR5/3 to 10YR4/3) that was also assessed to be less than 500 years in age. Situated between the C horizon and the gravel terrace was an 18- to 23-cm-thick Bwb1 horizon soft sand deposit (10YR5/3) that was assessed to be less than 1000 to 2000 years in age. In Test Unit 2, a 60-cm-thick BCb1 horizon deposit of soft sand (10YR5/3) was situated between the C horizon soil and the terrace gravels. The test unit deposits suggest that there were two depositional events, with older colluvium, less than 1000 to 2000 years, overlain by young colluvium, less than 500 years (Drakos and Reneau 2003).

The buried soil in with the gravels in Test Unit 2 includes a Stage I carbonate suggesting a late-Pleistocene to early-Holocene age for the terrace. In contrast, the buried terrace gravels in Test Unit 1 lack carbonate, soil structure, or other indicators of soil development, suggesting that this terrace is late Holocene in age. These differences suggest that two terraces of different age are buried beneath the colluvium, with the terrace below Test Unit 1 inset into the terrace situated beneath Test Unit 2 (Drakos and Reneau 2003).

Lithic debitage was recovered from every level of both test units (Table 55.2) with 42 collected from Test Unit 1 and 105 from Test Unit 2. Also recovered was an undetermined biscuitware sherd from Level 3 (20 to 30 cm below surface) in Test Unit 1. Chunks of charcoal were also recovered from Level 6 in Test Unit 1 and Level 8 from Test Unit 2. The presence of lithics throughout the colluvium in the test units suggests that the artifacts have been transported from upslope and are not in place (Drakos and Reneau 2003).

Table 55.2. Excavation recovered artifacts from LA 117883.

Test Unit	Depth of Test Unit (cm)	Level (depth in cm)	No. of Lithics	No. of Sherds	Ground Stone	Faunal Bone	Charcoal	Total Arti-facts

Summary

The testing at LA 117883 indicated that there are no intact cultural deposits associated with the site. Although several artifacts and a few chunks of charcoal were recovered, they were all mixed in with colluvium, and as such, lack cultural context. As there appears to be no intact cultural deposits associated with LA 117883, it is no longer eligible to the Register.

WHITE ROCK TRACT

As originally defined, the White Rock Y Tract was located south of State Road (SR) 502 and west of SR 4 and included the interchange between the two. Sandia Canyon ran through the southern portion and Los Alamos Canyon, including its confluence with Pueblo Canyon, ran through the northern portion of the tract. Elsewhere, the tract was dominated by several small mesas that are dissected by narrow valleys. The tract, which is lightly forested with a piñon-juniper woodland and ponderosa pine forest, ranged in elevation from 2107 m to 2267 m (6320 to 6800 ft).

The U.S. Department of Energy (DOE), National Nuclear Security Administration (NNSA) made a decision after the cultural resource survey phase to remove most of the White Rock Y Tract from the proposed conveyance. The remaining areas proposed for conveyance include the highway right-of-way surrounding the interchange and the SR 4 and 502 corridors. The SR 4 and 502 interchange is located just west of the confluence of Los Alamos and Pueblo canyons. The two sites with an undetermined Register eligibility are located directly south of Los Alamos Canyon, which is situated a short distance south of SR 502. Within the cultural site vicinities, Los Alamos Canyon is incised into basalt bedrock and contains an adjacent stream terrace that is overlain by colluvium derived from a higher terrace.

LA 61034

LA 61034 is an artifact scatter situated on a colluvial bench slope located directly south of the Los Alamos Canyon drainage (Figure 55.21). The site is at an elevation of 1922 m (6305 ft) in an area that is dominated by piñon-juniper woodland. The several hundred artifacts are situated in an area measuring 2190 m². When originally recorded, no formal artifact analysis was conducted. Observed ceramics included Potsuwi'i Incised, Sankawi Black-on-cream, red-slipped ware, Jemez Black-on-white, and smeared-indented corrugated sherds. The lithic assemblage was not detailed. The presence of Sankawi Black-on-cream and Potsuwi'i Incised ceramics dated this site to the Classic period.

Testing

Before initiating the excavation of test units, infield analysis was conducted on 100 percent of the observed surface artifacts. The infield analysis resulted in the documentation of 32 ceramics (Table 55.3) and 147 pieces of lithic debitage (Table 55.4). The four decorated ceramics are associated with the Classic period. The three micaceous plainware sherds and the Potsuw'ii Incised sherd support the Classic period assessment.

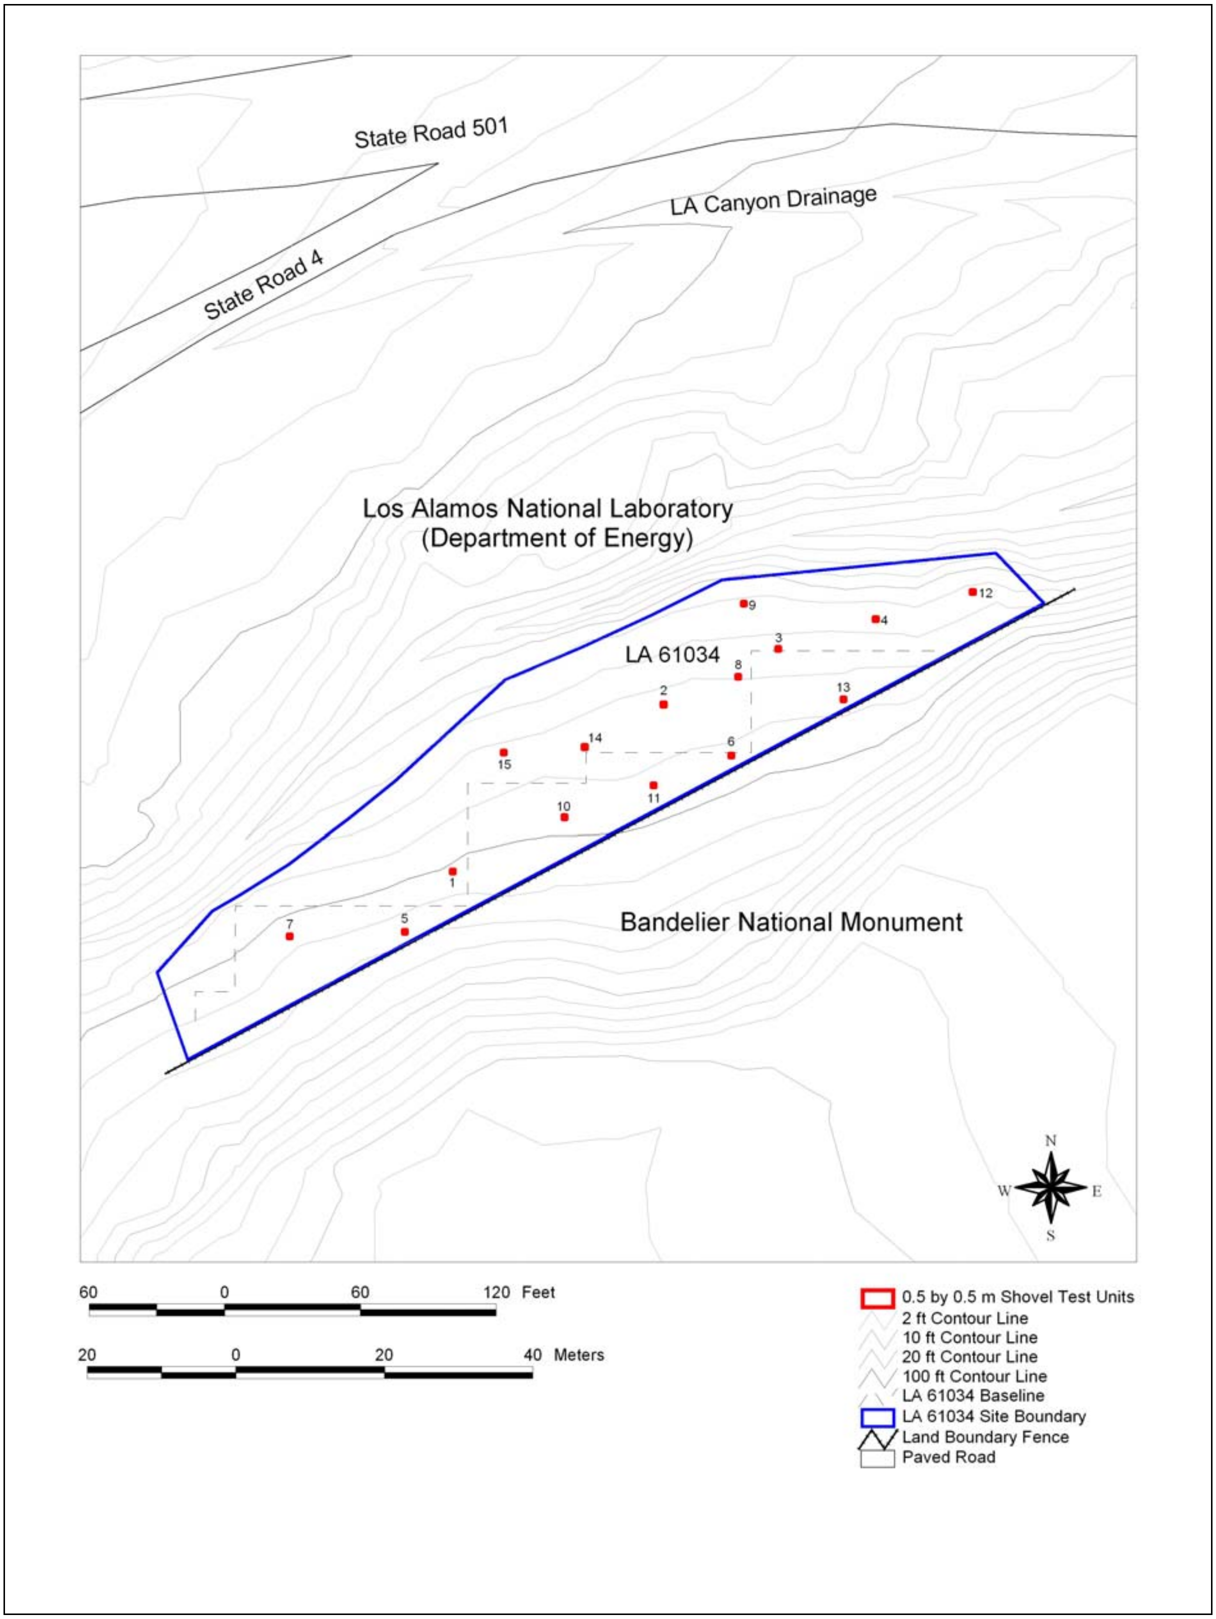

Figure 55.21. LA 61034 GPS differential map.

Table 55.3. LA 61034 infield ceramic analysis.

Ceramic Type		Total
Decorated	Wiyo Black-on-white	1
	Biscuit B	1
	Sankawi Black-on-cream	1
	Unidentified red glazeware	1

Excavation

Fifteen 50- by 50-cm test units, termed shovel tests, were excavated into the site. The test units were excavated with a trowel in arbitrary 10-cm levels. With the exception of pollen, soil, and macrobotanical samples, all hand-excavated materials were screened through 1/8-in. mesh. The test units were positioned across the site with a larger number placed in the northeastern portion where the surface artifact density was higher (Table 55.5). The shovel tests varied in depth from 10 cm near the Los Alamos Canyon drainage (Shovel Test 9) that runs along the northwestern edge of the site to 70 cm in an upslope location near the Bandelier National Monument Boundary Fence where colluvial deposits are much deeper (Shovel Test 6).

Although depths and thickness varied, the soil stratigraphy was similar throughout all of the test units. The upper 4 to 6 cm was a loose sandy to silty loam (10YR5/3). Directly below this A horizon was a 10- to 16-cm-thick Bw Soil horizon deposit consisting of lightly compacted sandy clay loam (7.5YR5/4). At depths ranging from 18 to 32 cm below surface, a compact sandy clay loam was encountered (7.5YR5/4). This Btj1(b1?) soil horizon that was approximately 10- to

15-cm-thick, overlaid a 10- to 30-cm-thick Btj2(b1?) soil horizon, which was also a compact sandy clay loam that contained cicada burrows forming hard peds (7.5YR5/4). When present, the Btj2 horizon soils overlaid a sandy clay loam deposit containing numerous (60% to 70%) rounded stream cobbles (IIBC horizon). In test units that were situated closer to Los Alamos Canyon, the stream cobble deposit was encountered at fairly shallow depths (10 to 28 cm below surface), often situated directly below the Bw Soil horizon. An exception to this general soil stratigraphy sequence occurred in Shovel Test 4 where basalt bedrock was encountered from 5 to 20 cm below surface.

Lithic debitage and a few ceramic sherds were recovered from several of the test units and charcoal fragments and/or flecks were present in three of the units (Table 55.5). The lithics were recovered from throughout the soil sequence, whereas the ceramics were recovered from the upper 20 cm. The vast majority of excavation-recovered artifacts were located in the central and northern end of the site.

Table 55.5. Artifacts recovered during excavation of LA 61034.

Total Artifacts				**118**	**4**		**122**

The presence of artifacts situated throughout the site colluvium suggests that the artifacts have been transported from upslope and are not in place. An Archaic period site is located on a terrace situated upslope between 18 and 30 m to the southeast of LA 61034. The stratigraphic sequence suggests that Ancestral Puebloan or post-Puebloan colluvium (A and Bw horizons) overlays Archaic period colluvium (Btj1 and Btj2 horizons) that buries Holocene terrace gravel (IIBCb2 horizon). This interpretation is supported by the distribution of artifacts with ceramics and lithics found in excavation depths corresponding to the A and Bw horizons, whereas only lithics were found in excavation depths corresponding to the Btj1 and Btj2 horizons (Drakos and Reneau 2003). The artifacts observed and recovered from LA 61034 also support the presence of two cultural manifestations. The high percentage of obsidian debitage and lithic debris that indicates a biface manufacturing strategy suggests that many of the lithics are affiliated with an Archaic period area utilization, while the diagnostic ceramics suggest a Classic period utilization.

Summary

LA 61034 is located on a colluvial slope that overlies a Los Alamos Canyon stream terrace of probable Holocene age. The colluvium appears to have been deposited from an adjacent, higher Pleistocene terrace (Drakos and Reneau 2003). The test units excavated into LA 61034 indicate that the site-associated artifacts are intermixed within the colluvium and are not in a cultural context. As there are no intact cultural remains located at LA 61034, it is no longer considered eligible to the Register.

LA 61035

LA 61035 is a sparse artifact scatter situated in a 327-m² area. The site is situated on a small, narrow, fairly flat bench situated between a terrace to the south and the Los Alamos Canyon drainage to the north (Figure 55.22). The site is at an elevation of 1916 m (6285 ft) in an area that is dominated by piñon-juniper woodland. Dirt piles, assumed to have been deposited during the construction of SR 501, which is located directly north of the Los Alamos Canyon drainage, were observed on both the east and west ends of the site.

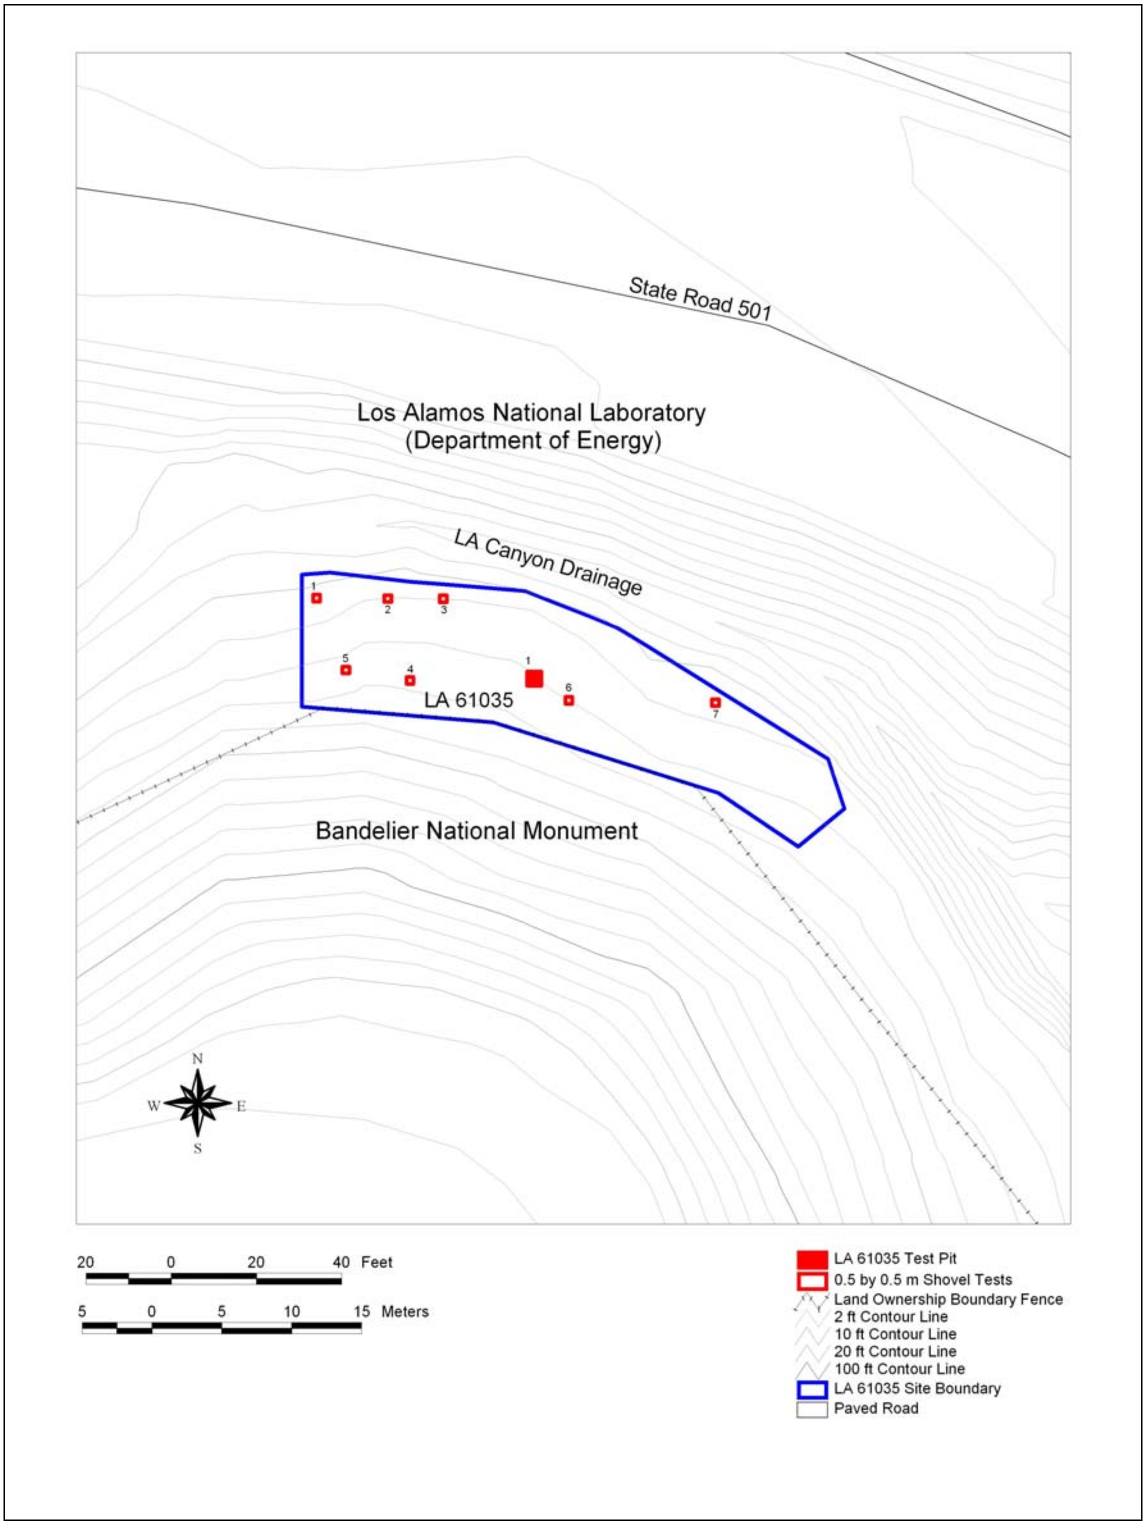

Figure 55.22. LA 61035 GPS differential map.

When originally recorded, no formal analysis was conducted on the artifacts that were assessed to number in the tens. Observed diagnostic ceramics included Sankawi Black-on-cream sherds. Lithics were mostly obsidian with a small percentage of chalcedony also present. Based on the ceramics, this site dated to the Classic period.

Testing

Before excavation of the test units, an infield artifact analysis was conducted on 100 percent of the observed surface artifacts. The infield analysis resulted in the documentation of seven ceramics (Table 55.6) and 146 lithics (Table 55.7). The four decorated ceramics are associated with the Classic period.

Table 55.6. Infield ceramic analysis from LA 61035.

Ceramic Type		**Total**
Decorated	Wiyo Black-on-white	1

	Unidentified biscuitware	1
	Unidentified redware	1
	Subtotal	**4**
Utilitywares	Smeared-Indented Corrugated	2
	Obliterated	1
	Subtotal	**3**
Total		**7**

The analyzed lithics included one chalcedony biface and 145 pieces of chipped stone debitage. Obsidian artifacts formed 83 percent of the lithic debitage and Pedernal chert formed 9 percent. Biface flakes formed 56 percent of the lithic debitage, while core flakes and flake fragments formed 26 percent and 7.5 percent, respectively.

Excavation

One 1- by 1-m test unit and seven 50- by 50-cm test units called shovel tests were excavated into the site. The 1- by 1-m test unit was excavated by shovel and trowel and the shovel tests were excavated by trowel. The units were excavated in arbitrary 10-cm levels unless a distinct stratigraphic change was encountered. With the exception of pollen, soil, and macrobotanical samples, all hand-excavated materials were screened through 1/8-in. mesh.

Although depths and thickness varied, the soil stratigraphy was similar throughout all of the test units with three colluvial soil horizons situated above a gravel and cobble stream terrace. The upper 8 to 12 cm of soil was loose loamy sand (A horizon) that overlaid lightly compacted loamy sand (Bw horizon). The Bw soil horizon that increased in compaction with depth extended down to depths of 40 to 45 cm below surface in locations where the terrace deposits were deeply buried. A C horizon soil that contained hard peds formed from cicada burrows intermixed with lightly compacted to loose loamy sand was situated below the Bw horizon.

The depth of colluvial deposits increased rapidly upslope to the south with increased distance away from the Los Alamos Canyon drainage channel. In the northwest corner of the site, Shovel Tests 1 and 2 were terminated at depths of 18 to 40 cm below surface, respectively, as terrace deposits of rounded stream gravels and cobbles were encountered. Shovel Tests 5 and 7 that extended down into the C horizon were also terminated at or just below contact with the gravel and cobble terrace deposit. All other test units were terminated within the C soil horizon with Test Unit 1 excavated to a depth of 1.4 m below surface (Figure 55.23).

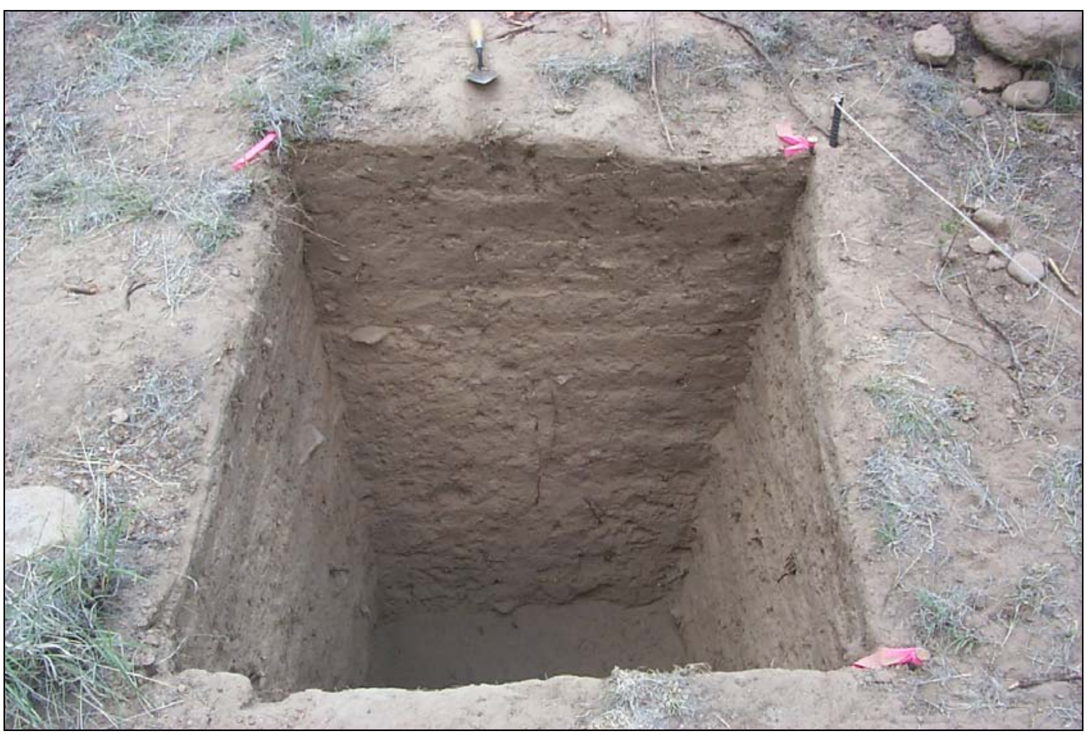

Figure 55.23. Post-excavation photo of Test Pit 1 at LA 65035.

Cultural materials were situated throughout the site colluvial deposits. Lithic debitage and ceramic sherds were recovered from the upper 40 cm, while only lithics were recovered from depths greater than 40 cm below surface. Charcoal flecks and/or fragments were noted in all of the test units except for Shovel Test 4. The charcoal was intermixed throughout the colluvial deposits, ranging from 0.05 to 1.0 m in depth. It is not known whether the charcoal was associated with a cultural occupation or whether it resulted from an area wildfire.

The presence of artifacts throughout the entire colluvial deposit suggests that the cultural materials have been transported from upslope and are not *in situ* (Table 55.8). The presence of ceramics in the upper 40 cm indicates significant colluvial deposition since the Ancestral Pueblo occupation of the site area. Although the sample of recovered ceramics is extremely small, the two diagnostic sherds recovered from test units indicate a Coalition period cultural affiliation, whereas the surface ceramics indicate a Classic period affiliation. The presence of lithic debitage and the lack of ceramics at depths greater than 40 cm below surface suggest that colluvial deposition began before the Ancestral Pueblo area utilization, likely during the Archaic cultural period (Drakos and Reneau 2003). Much of the debitage located at LA 61035 was likely derived from upslope erosion of a nearby Archaic period site. The high percentage of obsidian debitage and lithic debris that indicates a biface manufacturing strategy supports the assumption that many of the lithics are affiliated with an Archaic period area utilization.

Summary

LA 61035 is located on a colluvial slope that overlies a Los Alamos Canyon stream terrace of probable Holocene age. The colluvium appears to have been deposited from an adjacent, higher Pleistocene terrace (Drakos and Reneau 2003). The test units excavated into LA 61035 indicate that the site-associated artifacts are intermixed within the colluvium and are not in a cultural context. As there are no intact cultural remains located at LA 61035, it is no longer considered eligible to the Register.

CONCLUSION

Ten archaeological sites with an undetermined eligibility were tested to establish whether they were eligible to the Register and LA 86532, the remains of a Homestead Era structure, was re-evaluated as not eligible based on previous consultation with the SHPO. LA 110121 was only partially tested. The western three-quarters of LA 110121 is situated in a conservation zone being established by DOE, NNSA to provide protection for Historic Properties. As a result, only the eastern quarter of LA 110121 that is situated outside the conservation zone and subject to potential impacts, was tested. The testing indicated that the artifacts associated with LA 110121 lacked spatial integrity as they were mixed in with a thin colluvial deposit. It is therefore recommended that the LA 110121 site boundary be re-established along the outer edge of the conservation zone and that the site retain its undetermined eligibility status.

Of the remaining 10 tested sites, two were assessed to be eligible and eight were assessed as not eligible to the Register. LA 21596 and LA110130 retain information important to New Mexico's history and prehistory and as such are eligible to the Register under Criterion D. All of the sites assessed as not eligible to the register lack site integrity. Ceramic and/or lithic scatter sites LA 61034, LA 61035, LA 110133, and LA 117883 are located on active colluvial slopes where the associated artifacts are part of the colluvium and lack any spatial integrity. Sites LA 86528, LA 110121, and LA 110126 are situated on eroded colluvial slopes. Artifacts associated with ceramic and lithic scatter site LA 110121 are part of the colluvium and lack spatial context. The cultural remains associated with LA 86528, a potential rockshelter, and LA 110126, a one-to- three room structure, have been severely impacted by erosional processes and the associated cultural remains are mixed in with slopewash colluvium or a surface lag. Testing revealed that the structural remains assumed to be associated with LA 110132 were natural exposed terrace cobbles and not cultural materials. As LA 110132 is no longer assessed to be a cultural site, it is not eligible to the Register.

CHAPTER 56
INTRODUCTION TO ANALYSES

Bradley J. Vierra

An array of artifacts and samples were collected during the course of the four-year excavation of 39 archaeological sites and the testing of 11 sites. These sites include Archaic lithic scatters, Ancestral Pueblo habitations and fieldhouses, Jicarilla Apache tipi rings, and an Hispanic homestead dating from circa 5000 BC to AD 1943. Over 150,000 artifacts and about 3500 samples were collected. The detailed results of these artifact and sample analyses are presented in this volume. Together, they provide an excellent database from which to address the project research questions presented in the data recovery plan (Vierra et al. 2002).

Table 56.1 presents the artifact and sample totals for the excavated sites. Artifact totals range from 37 to 761 for fieldhouses, from 49 to 5412 for artifact scatters, and from 12,192 to 86,304 for Ancestral Pueblo roomblock sites. The original field survey conducted for the Land Conveyance and Transfer (C&T) Project tracts identified a range of activities and intensity of site occupations (Vierra 2000). This was in part reflected in artifact density values that ranged from 0.01 to 200 artifacts per m^2. This pattern is illustrated as a continuous sequence in Figure 56.1. The greatest break is at about 150 artifacts per m^2. All but one of the sites above this value were Coalition period roomblocks, with a single Coalition period plaza pueblo. Otherwise, the highest density exhibited by the Late Coalition/Early Classic period plaza site is Little Otowi with 134 artifacts per m^2 and the Classic period plaza site of Otowi with 116 artifacts per m^2. Overall, garden plots, cavates, and one- to three-room structures exhibited the lowest artifact densities, with 0.1, 3.2, and 4.6 artifacts per m^2, respectively. Lithic and lithic/ceramic scatters have the next highest densities of 12.4 and 18.6, respectively. Lastly, roomblocks and plaza pueblo sites have the highest densities with 61.6 and 62.3 artifacts per m^2, respectively. As previously noted, this follows the general pattern as observed in Table 56.1.

INTRA-SITE SAMPLING

One-hundred percent of the collected artifacts were submitted for analysis on most of the excavated sites. However, intra-site sampling was implemented on four sites with extremely large collections. Sampled sites consist of the three Ancestral Pueblo roomblocks (LA 12587, LA 86534, and LA 135290) and a lithic scatter (LA 85859). On the other hand, the sampling strategy at LA 12587 (Area 8) was focused on the area of the scatter that represented the Late Archaic occupation and not the section that was a continuation of the surface scatter from the nearby pueblo roomblock.

Table 56.1. Artifact and sample totals by tract and archaeological site.

Tract	LA #	Ceramics	Chipped Stone	Ground Stone	Bone	Shell	Flotation	Pollen	Macrobot.	TL*	Ornament	Minerals	Adobe (other)	Metal	Glass

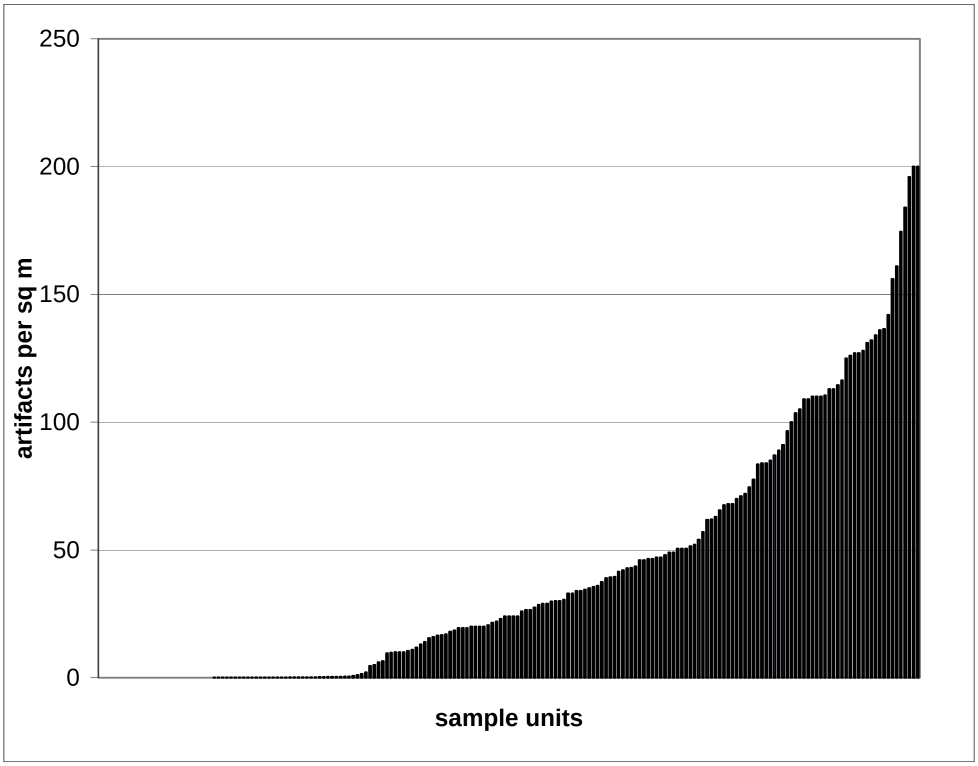

Figure 56.1. Artifacts per m^2 illustrated as a continuous sequence for the C&T Project survey data.

The sampling strategy implemented for the Ancestral Pueblo roomblocks consisted of selecting two or more 1- by 1-m grids within each room and analyzing all the artifacts from the stratigraphic column. This also included the collection of a set of flotation and pollen samples from each stratum represented within the column. All floor artifacts were analyzed and a selection of flotation and pollen samples from the floor, as well as all artifacts and samples from floor features. Exterior activity areas and middens were also systematically sampled based on the overall areal extent of the deposits. This was done primarily at LA 12587, which was the only site that contained a midden deposit. The result was that lithic samples ranged from 16 percent to 18 percent at LA 12587 and LA 86534 to 35 percent at LA 135290. In contrast, ceramic samples ranged from 15 percent to 17 percent at LA 12587 and LA 86534 to 38 percent at LA 135290. Lastly, a sample of lithic artifacts was also selected from the early Archaic lithic scatter site at LA 85859. Artifacts and samples were only analyzed from a central section of the excavation, which provided the best example of the site stratigraphy. The result was that a 38 percent sample of the lithic artifacts from the site was studied.

CHRONOMETRIC DATING

Samples were taken to derive absolute dates from several chronometric techniques. Maize was selected whenever available for Accelerator Mass Spectrometer (AMS) dating by Beta Analytic, Inc. Archaeomagnetic samples were obtained from burned features by Eric Blinman at the Office of Archaeological Studies. Ceramic and burned adobe samples were submitted to James Feathers at the University of Washington for luminescence dating. Lastly, obsidian that was sourced by Steve Shackley (University of California) was provided to Chris Stevenson (Diffusion Laboratory) for obsidian hydration dating.

Attempts were made to obtain samples of each chronometric technique from similar contexts at each site. For example, a hearth might provide maize for AMS, burned adobe for archaeomagnetic, ceramics within or adjacent to the feature for luminescence, and obsidian artifacts on the nearby floor for hydration dating. The point was to evaluate the accuracy and precision of the various dating techniques by collecting samples from similar contexts whenever possible, while dating the occupational sequence at the site.

CHAPTER 57
SURFICIAL UNITS AND PROCESSES ASSOCIATED WITH ARCHAEOLOGICAL SITES IN LAND CONVEYANCE AND TRANSFER TRACTS AT LOS ALAMOS NATIONAL LABORATORY

Paul G. Drakos and Steven L. Reneau

INTRODUCTION

Geomorphic studies were conducted in selected land conveyance parcels at Los Alamos National Laboratory (LANL) in support of archaeological investigations preceding transfer of these tracts from the Department of Energy to Los Alamos County, San Ildefonso Pueblo, or the New Mexico Highway Department. This work included mapping and description of surficial geologic units to help define the geomorphic context of archaeological sites. This investigation also focused on identification of surficial processes associated with potential erosion or burial of cultural features. Fieldwork was conducted during the 2002, 2003, 2004, and 2005 field seasons in support of excavations within the Airport (A-3, A-7, and A-5-1), White Rock (A-19), Technical Area (TA) 74 (A-18a), White Rock Y (C-2), and Rendija Canyon (A-14) land transfer parcels.

GEOMORPHIC SETTING

LANL is located on the Pajarito Plateau, east of the Jemez Mountains (the Sierra de los Valles), and west of White Rock Canyon of the Rio Grande (see Figure 3.2 in Reneau and Drakos, Volume 1). The Pajarito Plateau includes gently east-sloping mesas and numerous narrow canyons that are between approximately 1900 and 2300 m in elevation. The modern climate is semiarid, and vegetation is dominated by ponderosa pine forest to the west and piñon-juniper woodlands to the east (Allen 1989; Bowen 1990; Reneau et al. 1996a). This area has a complex geomorphic history over the last 10 to 15 thousand years, the time scale relevant to archaeological investigations (e.g., Reneau and Drakos, Volume 1; Reneau and McDonald 1996; Reneau et al. 1996a). At various times, large parts of the landscape experienced deposition of alluvial, colluvial, or eolian sediments, with an associated potential to bury and help preserve archaeological sites. The landscape has also experienced significant erosion, with the associated potential to erode archaeological sites. Mesa top settings preserve several widespread eolian events, including one event that post-dates the Middle Coalition period and a smaller eolian event that post-dates the Classic period. Periodic eolian deposition also helped provide sediment that was reworked into colluvial deposits.

Archaeological sites examined during this investigation are located on mesa tops, hillslopes, fluvial terraces, and valley bottoms. Five separate tracts of land were the focus of this investigation (see Figure 3.2 in Reneau and Drakos, Volume 1), and geomorphic maps were compiled based on original field mapping for each tract. The five tracts are the White Rock Tract, the Airport Tract, the Rendija Tract, the TA-74 Tract, and the White Rock Y Tract. The total area encompassed by the five tracts is 799 ha (1973 acres).

METHODS

Surficial geologic maps of selected land transfer tracts were prepared at a scale of 1:1200. The White Rock, Airport, and TA-74 tracts geologic maps were completed during the 2002 field season (Drakos and Reneau 2003). The Rendija Tract geologic map was completed during the 2003 field season and included an area mapped previously by Reneau (Reneau and McDonald 1996:102). The White Rock Y Tract geologic map was completed in 2006. The mapping was focused on units with potential archaeological significance. Soil descriptions were made at profiles both inside and outside of identified archaeological sites following methods discussed in Birkeland (1999). Soil horizon nomenclature is from Birkeland (1999) and Soil Survey Staff (1999). An explanation of soil horizon nomenclature, soil properties utilized in field soil descriptions, and a key to symbols used in descriptions of soil morphology are included in Appendix K. Soil descriptions are included in Appendix L. Carbonate stage for soils follows nomenclature developed by Gile et al. (1965, 1966). Preliminary age estimates for deposits were made based on soil descriptions and comparison of the general degree of soil development to previously dated sites on the Pajarito Plateau and to soils described during the present investigation where radiocarbon dates were obtained.

Radiocarbon dates, age calibrations, and additional stratigraphic data are included in Appendix M. General age estimates based on carbonate stage development are also based on rates of carbonate development described by Machette (1985). Small charcoal samples were collected for radiocarbon analysis from soil profiles at sites LA 85859, LA 99396, and LA 99397 in Rendija Canyon and from LA 135290 in the Airport Tract. A cal 5 ka (ka = thousands of years before present) radiocarbon age colluvial deposit in Fence Canyon (Stop 1-4c, Reneau and McDonald 1996:62–64), at the same general elevation as the White Rock parcel, was used as a key reference for the degree of soil development in a mid-Holocene unit on that part of the plateau (Figure 57.1; Table M.1). A cal 4.5 ka radiocarbon age valley fill deposit in "EG&G gully" on the mesa east of the Airport Tract sites (Longmire et al. 1996:48–49), at the same general elevation as the Airport Tract, was used as a key reference site for the degree of soil development in a mid-Holocene unit within the Airport Tract (Figure 57.2; Table L.1). The presence of the ca. 50 to 60 ka El Cajete pumice (age from Reneau et al. 1996b; Toyoda et al. 1995) interbedded with or overlying colluvial sediments, provided additional age control in some areas. The relation of deposits with varying soil characteristics to cultural material (e.g., potsherds and lithics) provided additional information on the age of some layers. Remnants of a Pleistocene soil with 5YR color and moderately thick clay films that has an estimated age of at least 100 to 200 ka (McFadden et al. 1996), underlying cultural deposits at some locations, provided a clear demarcation of cultural versus archaeologically sterile sediments.

Age estimates for soils in Airport Tract sites are also based on comparison with soils and stratigraphic units described in paleoseismic trenches on Pajarito Mesa (Kolbe et al. 1995; Reneau et al. 1995). Age constraints for the Pajarito Mesa eolian and colluvial slopewash deposits are provided by numerous radiocarbon dates and by stratigraphic position relative to the El Cajete pumice. The Pajarito Mesa trenches also exposed 10 inferred buried archaeological sites, including seven Ancestral Puebloan sites and three Paleoindian sites (Reneau et al. 1995), that are utilized to help define the soil stratigraphic context of mesa top archaeological sites.

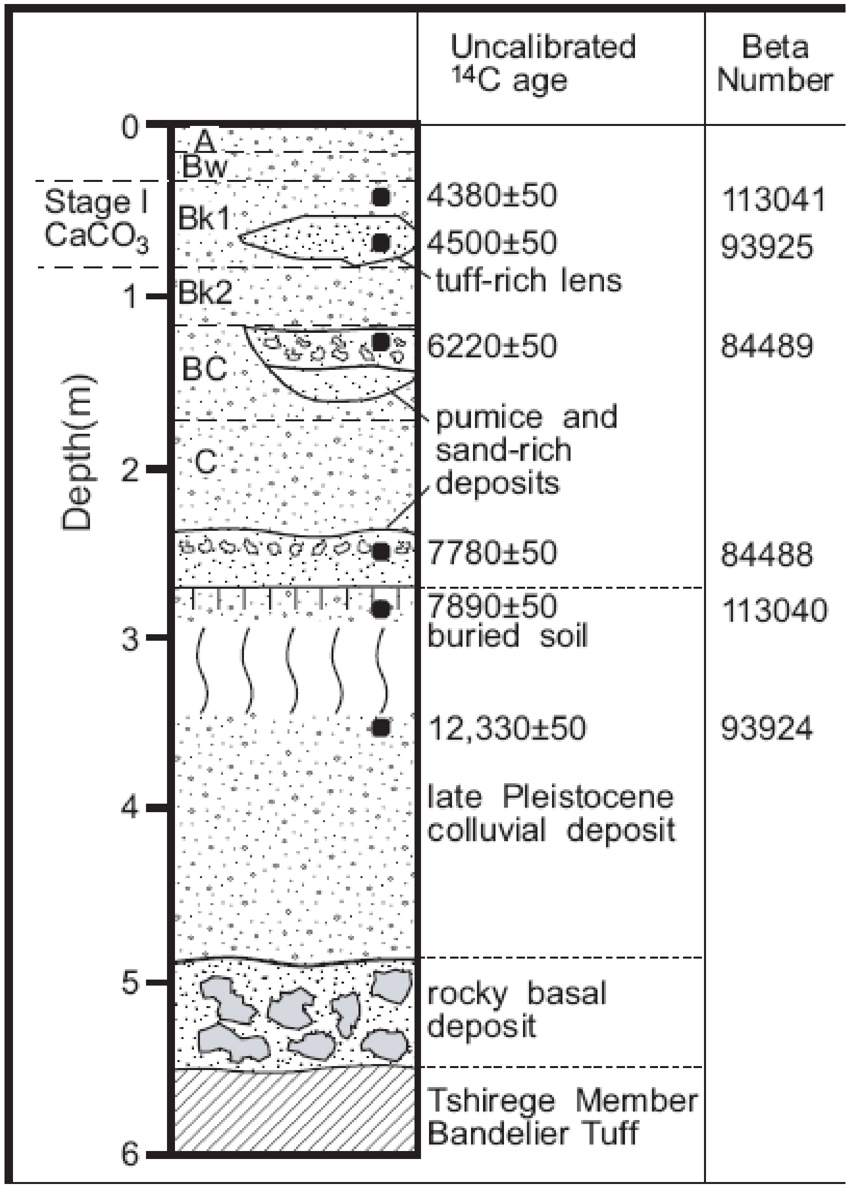

Figure 57.1. Stratigraphic section at Fence Canyon reference site, showing uncalibrated radiocarbon dates (see Appendix M, Table M.1 for radiocarbon data). Upper colluvium was deposited between ca. 8 and 4 ka 14C BP, with the surface stabilizing at ca. 4 ka. Modified from Reneau and McDonald, Figure 1-22).

Preliminary age estimates for soils in Rendija and Pueblo canyons are based on comparison with a chronosequence of Pleistocene and Holocene soils developed on a terrace sequence in Rendija Canyon (McDonald et al. 1996; Phillips et al. 1998; Reneau and McDonald 1996). Age constraints for the Rendija Canyon fluvial terraces are provided by 13 radiocarbon dates for Holocene terraces, two radiocarbon dates for Pleistocene terraces, and cosmogenic ^{21}Ne age estimates for three terraces. Additional data for Rendija Canyon soil age estimates are based on comparison with soils described in paleoseismic trenches in Chupaderos Canyon, northwest of the Rendija Tract (Gardner et al. 2003).

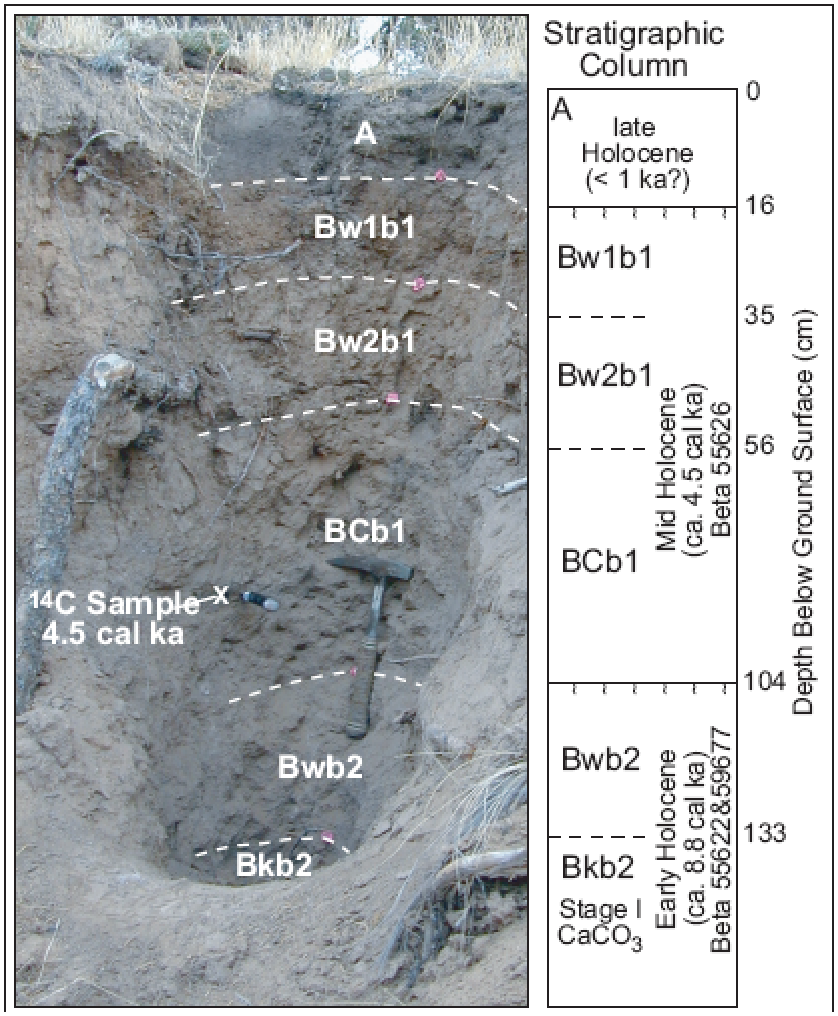

Figure 57.2. Soil stratigraphy and charcoal sample location, EG&G Gully site (see Appendix M for radiocarbon data).

The topographic profiles at individual sites were surveyed using a hand level, tape measure, and stadia rod.

WHITE ROCK TRACT

Surficial Geologic Units

The White Rock Tract (A-19) is within the Cañada del Buey watershed and includes part of the active stream channel and adjacent floodplains, colluvial slopes, and alluvial fans (Figure 57.3). Bedrock beneath most of the parcel is basalt of the Cerros del Rio volcanic field (unit Tb). The

Tshirege Member of the Bandelier Tuff (unit Qbt), which overlies the Cerros del Rio basalt, is also present along the northern margin, and as an isolated mesa in the western part of the parcel (Figure 57.4). Large parts of the parcel are covered by locally derived colluvial, alluvial fan, or slopewash deposits of a variety of ages. Geologic maps of this area have been prepared by Griggs (1964), Rogers (1995), and Dethier (1997). A detailed geomorphic map of the part of the parcel along the Cañada del Buey stream channel was previously prepared by Drakos et al. (2000). In this investigation, a surficial geologic map at a scale of 1:1200 was prepared of the White Rock Tract, focused on units with potential archaeological significance (Figure 57.3).

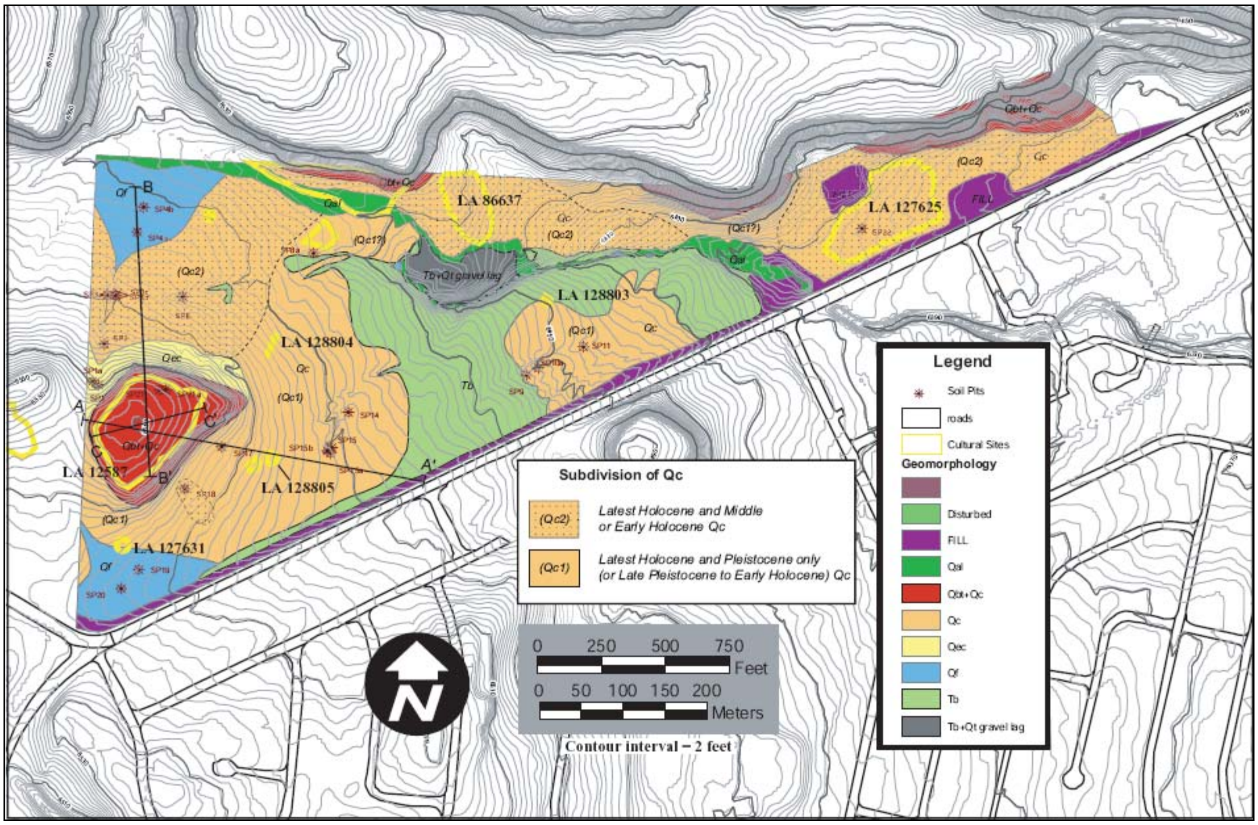

Figure 57.3. Geomorphology, cross-section, and soil pit locations in the White Rock Tract.

Unit Qal consists of young alluvium in the main stream channel of Cañada del Buey and tributary drainages and adjoining floodplains and stream terraces. Sediment ranges in size from silt to coarse sand and gravel and is dominated by coarse sand in the main channels and very fine sand on the floodplains (Drakos et al. 2000). The upper sediment layers along the main channel and floodplains (approximately 0.5 to 2.0 m thick) are largely historic in age, although older sediment may be locally present at depth. Higher stream terraces along Cañada del Buey are generally above the level of historic flooding and are inferred to be late Holocene to Pleistocene in age. The stream terraces are in part overlain by colluvium (unit Qc). These areas could have been used for agriculture.

Unit Qf consists of young alluvial fans that emanate from side drainages, typically below eroding areas of colluvium. Qf is dominated by stratified fine to very fine sand and also includes coarse sand and fine gravel layers. The upper parts of these deposits are historic in age, and older deposits are commonly present at depth. Greater than 1 m of late Holocene sediment can be present in Qf units. There is potential for burial of archaeological sites in these areas. A buried Pleistocene soil was observed at a depth greater than 1 m in one Qf soil profile. Soil descriptions of sites in Qf are presented in Appendix L (Tables L.1. and L.2) (locations 4a, 4b, 19, and 20).

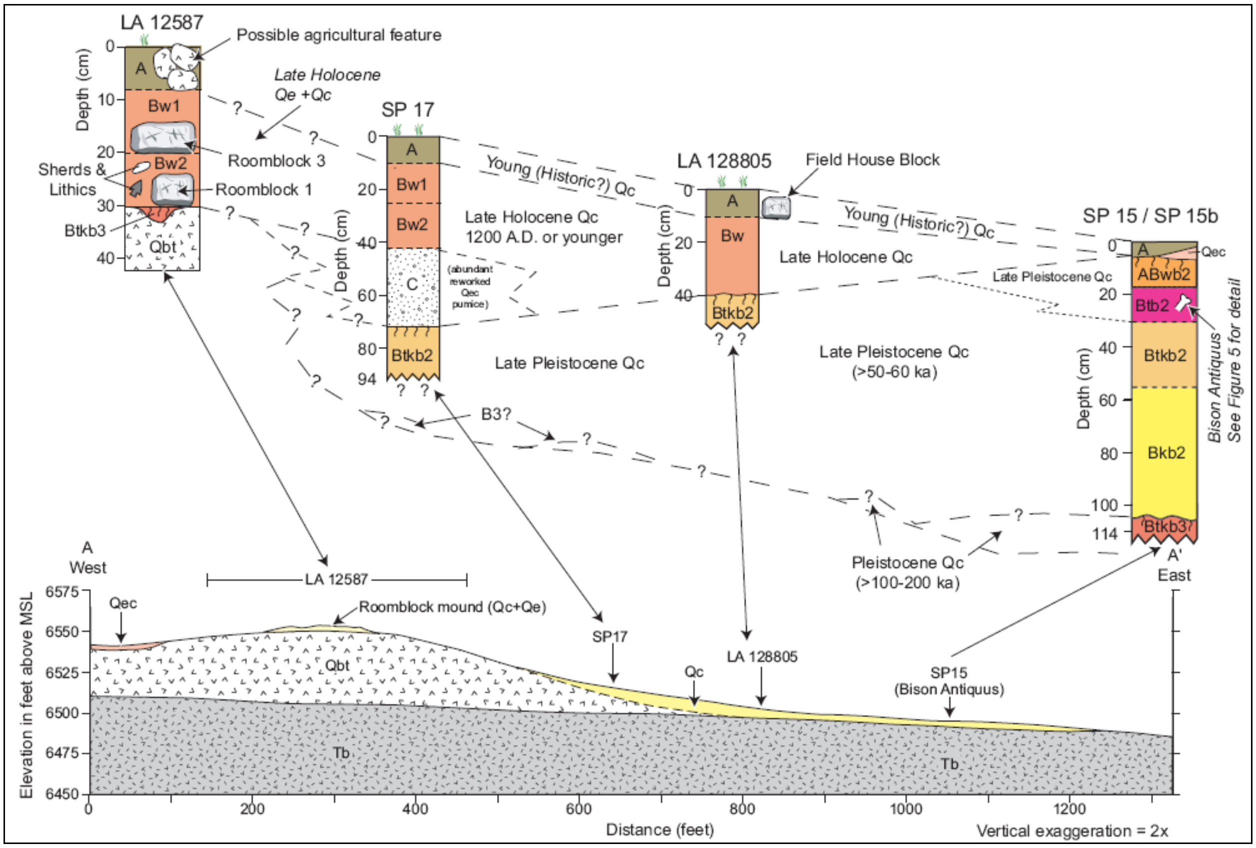

Figure 57.4. Cross-section (bottom), soil profiles, and correlations (top) through selected sites in the White Rock Tract. See Figure 57.3 for cross-section and soil description locations.

Unit Qc is dominated by relatively fine-grained (fine to very fine sand) slopewash colluvium deposited by overland flow, and also includes rocky colluvium on hillslopes below mesas. Qc likely includes alluvial fan surfaces and underlying deposits and eolian deposits and/or locally reworked eolian sediment. Qc deposits have a wide range in age and typically have buried soils that indicate pauses in deposition, in part accompanied by local erosion. Several soil profiles include surficial and buried deposits that indicate at least two episodes of colluvial deposition since mid-Holocene time, with a lower colluvial layer likely deposited around 2 to 4 ka and an upper colluvial layer that was likely deposited within the past 1000 years, possibly during post-Puebloan time (locations 3a, 6, 18, 3b, 3c, and 19; Appendix L, Tables L.1 and L.2). However, in many locations, the upper colluvial layer overlies late Pleistocene or early Holocene to latest Pleistocene deposits. The early Holocene to latest Pleistocene deposits could potentially contain buried archaeological sites, although no buried sites were observed in gullies that cross many parts of this unit. In other areas Qc is older than 50 to 60 ka. Upper layers in many areas are probably latest Holocene in age.

Although unit Qc is characterized by spatial complexity in its depositional history, as indicated by soil descriptions (Tables L.1 and L.2), an attempt was made to subdivide Qc into Qc1 and Qc2. Unit Qc1 is characterized by latest Holocene (<1 ka?) Qc overlying Pleistocene or late Pleistocene to early Holocene Qc (Figure 57.4). In the area east of the Bandelier Tuff mesa and LA 12587, the late Holocene Qc thins downslope from 0.7 m thick at the base of the mesa to less than 0.1 m thick at SP15 (see Figure 57.4). Unit Qc2 is characterized by latest Holocene (<1 ka?) Qc overlying middle or early Holocene Qc. Middle Holocene deposits in Unit Qc2 are approximately 1 m thick at SP6 and are overlain by approximately 0.2 to 0.7 m of late Holocene deposits (Figure 57.5). In general, Qc1 underlies east- and southeast-facing slopes in areas of relatively thin colluvial deposits overlying bedrock units Tb (Cerros del Rio basalt) and Qbt (Bandelier Tuff) (Figures 57.3 and 57.4). Unit Qc2 underlies aggrading toe slopes below embayments in the Qbt mesa north of the tract and the north-facing slope between the small Qbt mesa and Cañada del Buey within the western part of the White Rock Tract (Figure 57.5).

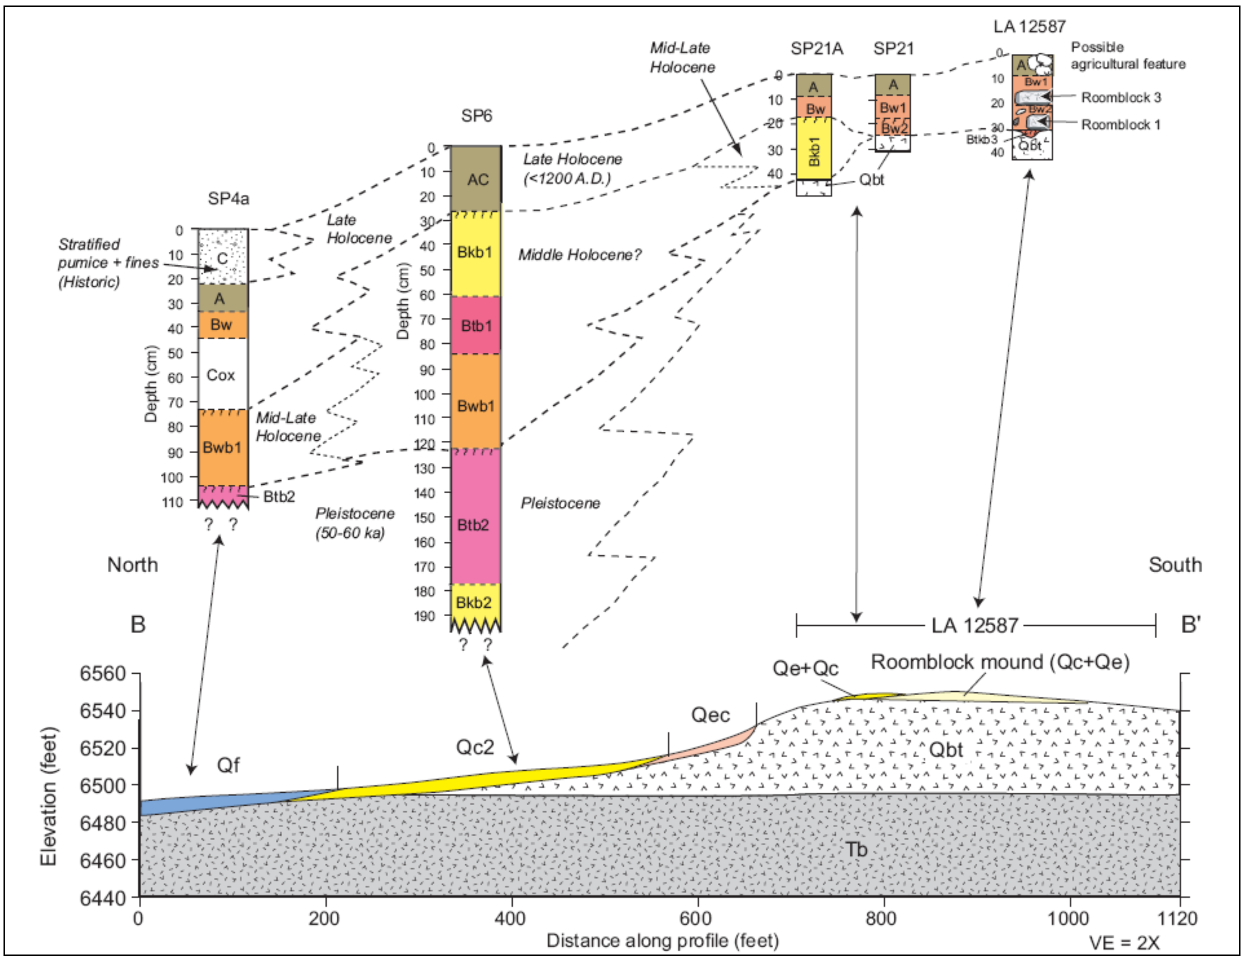

Figure 57.5. Cross-section (bottom), soil profiles and correlations (top) showing stratigraphic relationships between alluvial fan (Unit Qf), hillslope (Unit Qc2), and mesa top (Unit Qe+Qc) deposits in the White Rock Tract.

Sediment in unit Qc with estimated ages younger than ca. 5 ka, based on comparison with the Fence Canyon reference section, ranges in thickness from 6 cm to >1 m (soils lack Stage I carbonate or Bt horizons). The thickest deposit was recorded in the eastern parcel, where greater than 1.1 m of late Holocene colluvium is present at location 22, within site LA 127625. Farther west, 70 to 80 cm of colluvium younger than ca. 4 ka is present on the south side of an isolated mesa of Bandelier Tuff (locations 17 and 18). The total thickness of Holocene or possibly latest Pleistocene sediment (<~10 to 15 ka) reaches about 1.7 m in a gullied area in the northwestern part of the parcel (location 3a).

At one location in the south-central parcel (location 15), a piece of fossilized bone was found at a depth of about 20 to 30 cm eroding out of a gully wall stratigraphically below the ca. 50 to 60 ka El Cajete pumice. This bone was collected by Gary Morgan, New Mexico Museum of Natural History, who identified it as part of a humerus of an extinct species of bison, *Bison antiquus* (Figure 57.6, catalogue number NMMNH 37623, locality number L-5214). Notably, this is apparently the first recorded Pleistocene fossil from Los Alamos County and is also one of very few bison records in New Mexico with dates older than about 20 ka (G. Morgan, per. comm.).

Figure 57.6. Left distal humerus of the extinct species of bison, *Bison antiquus* (lower image). Humerus of a modern bison, *Bison bison* (upper image) shown for comparison. New Mexico Museum of Natural History catalog number NMMNH 37623 and NMMNH locality number L-5214. Photograph and fossil identification by Gary Morgan, NMMNH.

Unit Qc includes areas that presently experience dispersed overland flow and either local erosion or deposition. Qc also includes gullied areas where significant erosion presently occurs. Agricultural potential probably varies significantly within Qc. The areas with the highest probability of agricultural use are inferred to be at locations with relatively thick loose soils situated below long slopes and/or below mesa tops. These sites therefore receive overland flow from nearby highlands (e.g., locations 17 and 18, Tables L.1 and L.2) and are likely areas of active deposition and cumulic soil profiles. Location 17 has approximately 0.7 m of late Holocene (younger than 1 to 2 ka?) sediment overlying a Pleistocene soil. Areas with older, more consolidated soils present at shallow depths are inferred to have a lower probability of agricultural use. A grid garden is present at one location near the boundary between Qc and Tb (LA 128803), and several sites are located on Qc (LA 86637, LA 127631, and LA 128805).

Unit Qec is the ca. 50 to 60 ka El Cajete pumice. It is present in a relatively thick (≥50 cm) layer within Qc on the north side of the isolated Bandelier Tuff mesa in the western parcel (locations 1 and 1a, Table L.2), and thin remnants were observed within Qc farther east (site 15b, Table L.1). This unit may have a high agricultural potential associated with well-drained soils.

Unit Qbt is the Tshirege Member of the Bandelier Tuff. There are no soils or only thin soils present in much of this unit, particularly along the edges of mesas, and consequently there is a high potential for erosion of cultural material. Thin, discontinuous, fine-grained deposits dominated by very fine sand occur on the isolated mesa top in the western parcel (locations 21 and 21a, Tables L.1 and L.2) and represent either eolian or locally reworked eolian sediment. These thin deposits overlying Qbt are in part late Holocene in age (likely less than 1 ka) based on the degree of soil development. The largest set of roomblocks in the parcel is located on this unit (LA 12587).

Unit Tb is basalt of the Cerros del Rio volcanic field. There are no soils or only thin soils present throughout the area of exposure of this unit, and consequently there is a high potential for erosion of cultural material in such locations. In other areas discontinuous colluvial or eolian sediments overlie unit Tb. Bedrock metates or grinding slicks were observed at one location in this unit along Cañada del Buey.

LA 12587 (Ancestral Puebloan Roomblock and Archaic Lithic Scatter)

Site Geomorphology and Stratigraphy

LA 12587 is a multi-component Ancestral Puebloan roomblock site situated on a small isolated Bandelier Tuff mesa and a separate lithic scatter located south of the roomblocks. Component 1 includes Roomblock 1, which is built either directly on Bandelier Tuff or on remnants of Pleistocene soils preserved in depressions in the undulating tuff surface. Component 2 consists of a second, younger roomblock (Roomblock 3) located west of Roomblock 1. Some sections of Roomblock 3 are built on colluvium derived from the Roomblock 1 (Figure 57.7). In other areas, Roomblock 3 is built either directly on Bandelier Tuff or on remnants of Pleistocene soils. Component 3, the most recent, includes a fieldhouse (Roomblock 2) constructed on top of the

Roomblock 1 rubble (Figure 57.8) and rock alignments north of the roomblocks that may represent agricultural features. The rock alignments overlie aligned shaped blocks that may represent Roomblock 3.

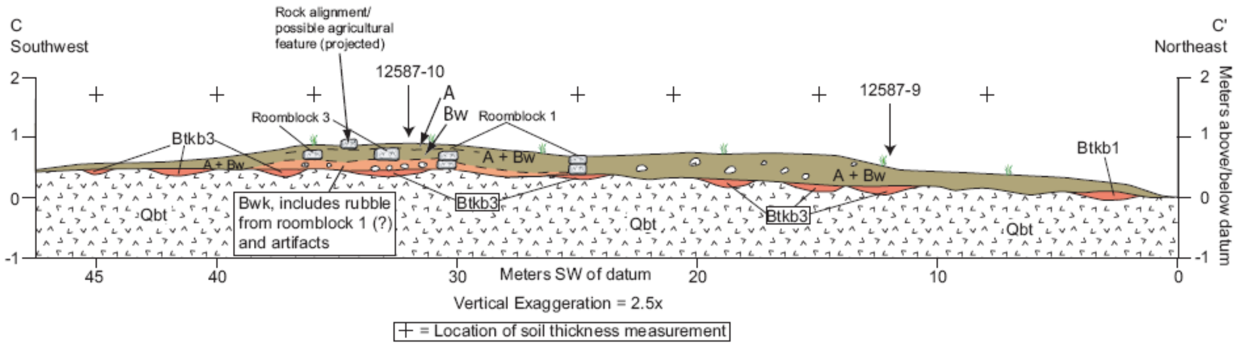

Figure 57.7. Cross-section through LA 12587. Location of line of section shown in Figure 57.3.

The discontinuous Pleistocene soil underlying LA 12587 consists of an eroded Btk horizon (Bt horizon with Stage I carbonate) (Table L.3). Pleistocene soil thickness in the site vicinity ranges from 0 to 16 cm. The remnant Pleistocene soil is inferred to be 100 to 200 ka or older, based on correlation with soils described by McFadden et al. (1996) and Reneau et al. (1995). The Pleistocene soil at LA 12587 is a polygenetic soil in which the Bt horizon formed during the Pleistocene, and the Stage I carbonate formed later, probably during the Holocene.

In the vicinity of the roomblocks, the Bt horizon is overlain by Bw horizons formed in eolian or reworked eolian sediment plus colluvium derived in part from the roomblock. In areas where roomblocks are located close to one another, the Component 2 walls (Roomblock 3) are built on top of a lower Bwk or Bw horizon (typically a Bw2), that is overlain by an A-Bwk1 or A-Bw1 profile (e.g., Table L.3, profiles 12587-10, 12587-11, and 12587-12; see Figure 57.7). These soils are formed in eolian or reworked eolian sediment plus colluvium derived in part from the roomblock. Total thickness of post-occupational soils in the vicinity of the roomblocks ranges from 10 to 54 cm. Greater sediment thickness corresponds in general to the roomblock locations, except for a mound of relatively thick sediment located immediately east and north of Roomblock 1 (Figure 57.9). Outside of the colluvial mound surrounding the roomblocks, post-occupational soil thickness ranges from 0 cm on stripped bedrock surfaces east, north, and west of the roomblocks (Figure 57.9), to 17 cm at Location 21A (Table L.1). The 17-cm A-Bw profile at Location 21 overlies a stripped Btk horizon and likely represents eolian deposition that occurred both during the Late Coalition period and that post-dates the Puebloan occupation.

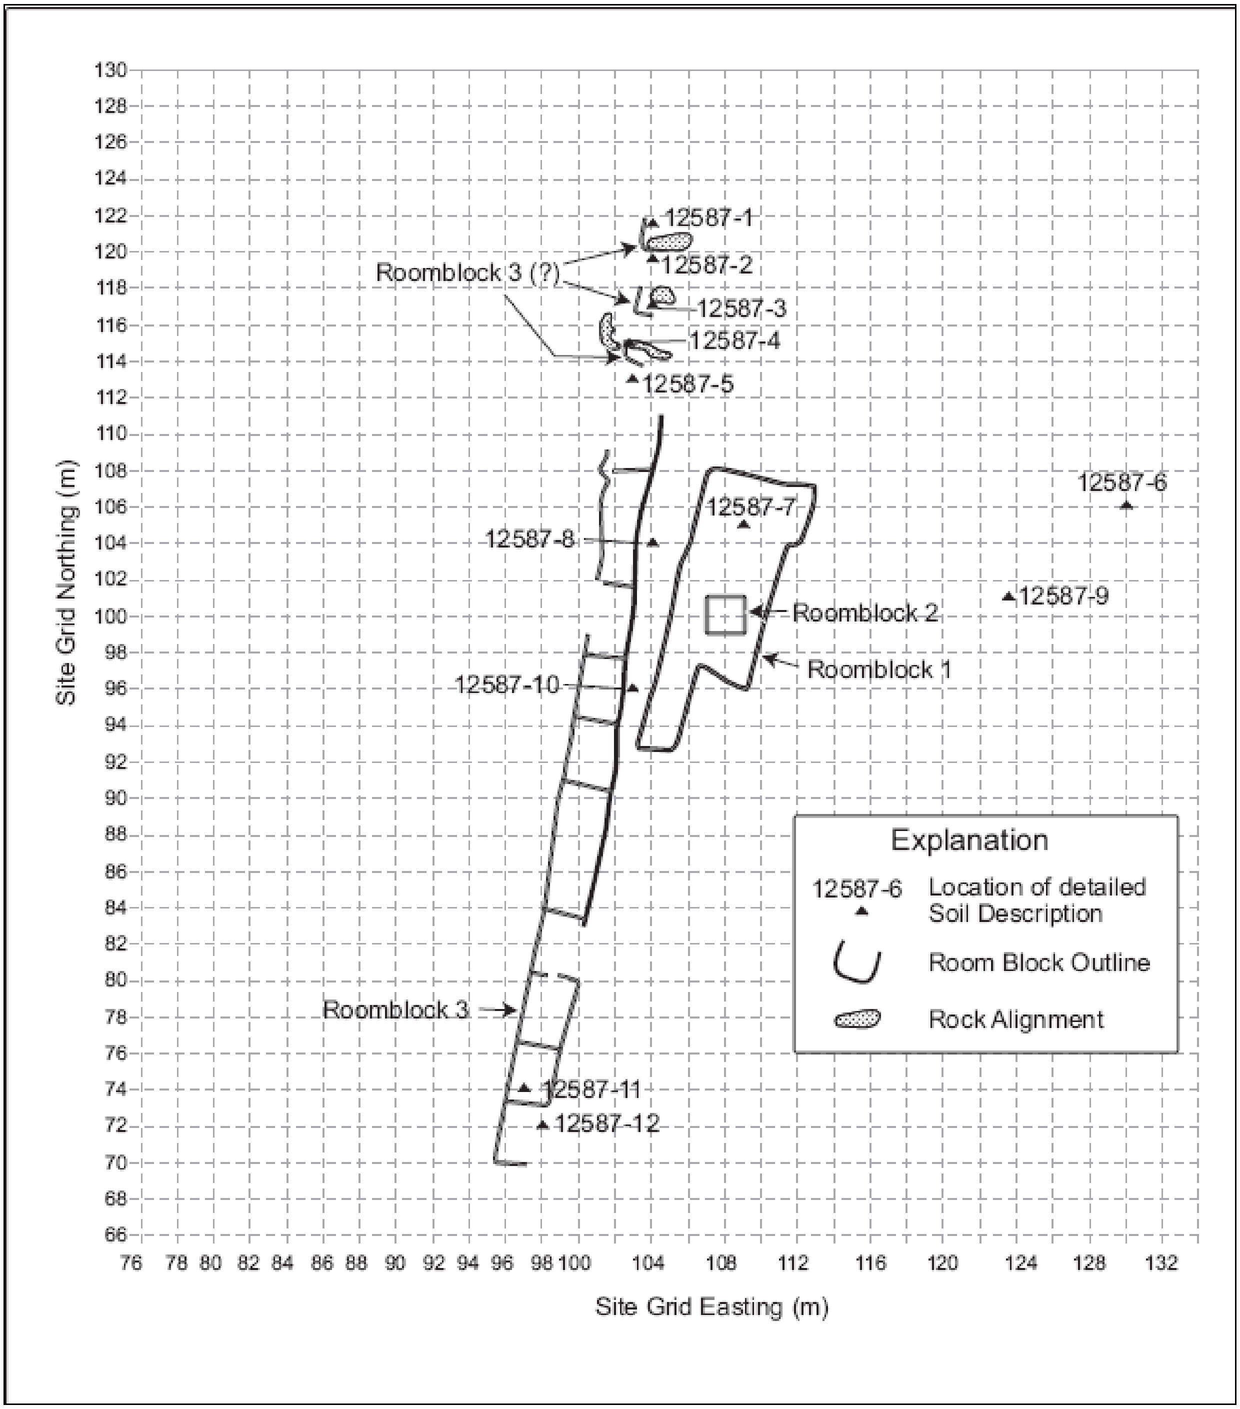

Figure 57.8. LA 12587 site map showing soil description locations, roomblocks, and rock alignments.

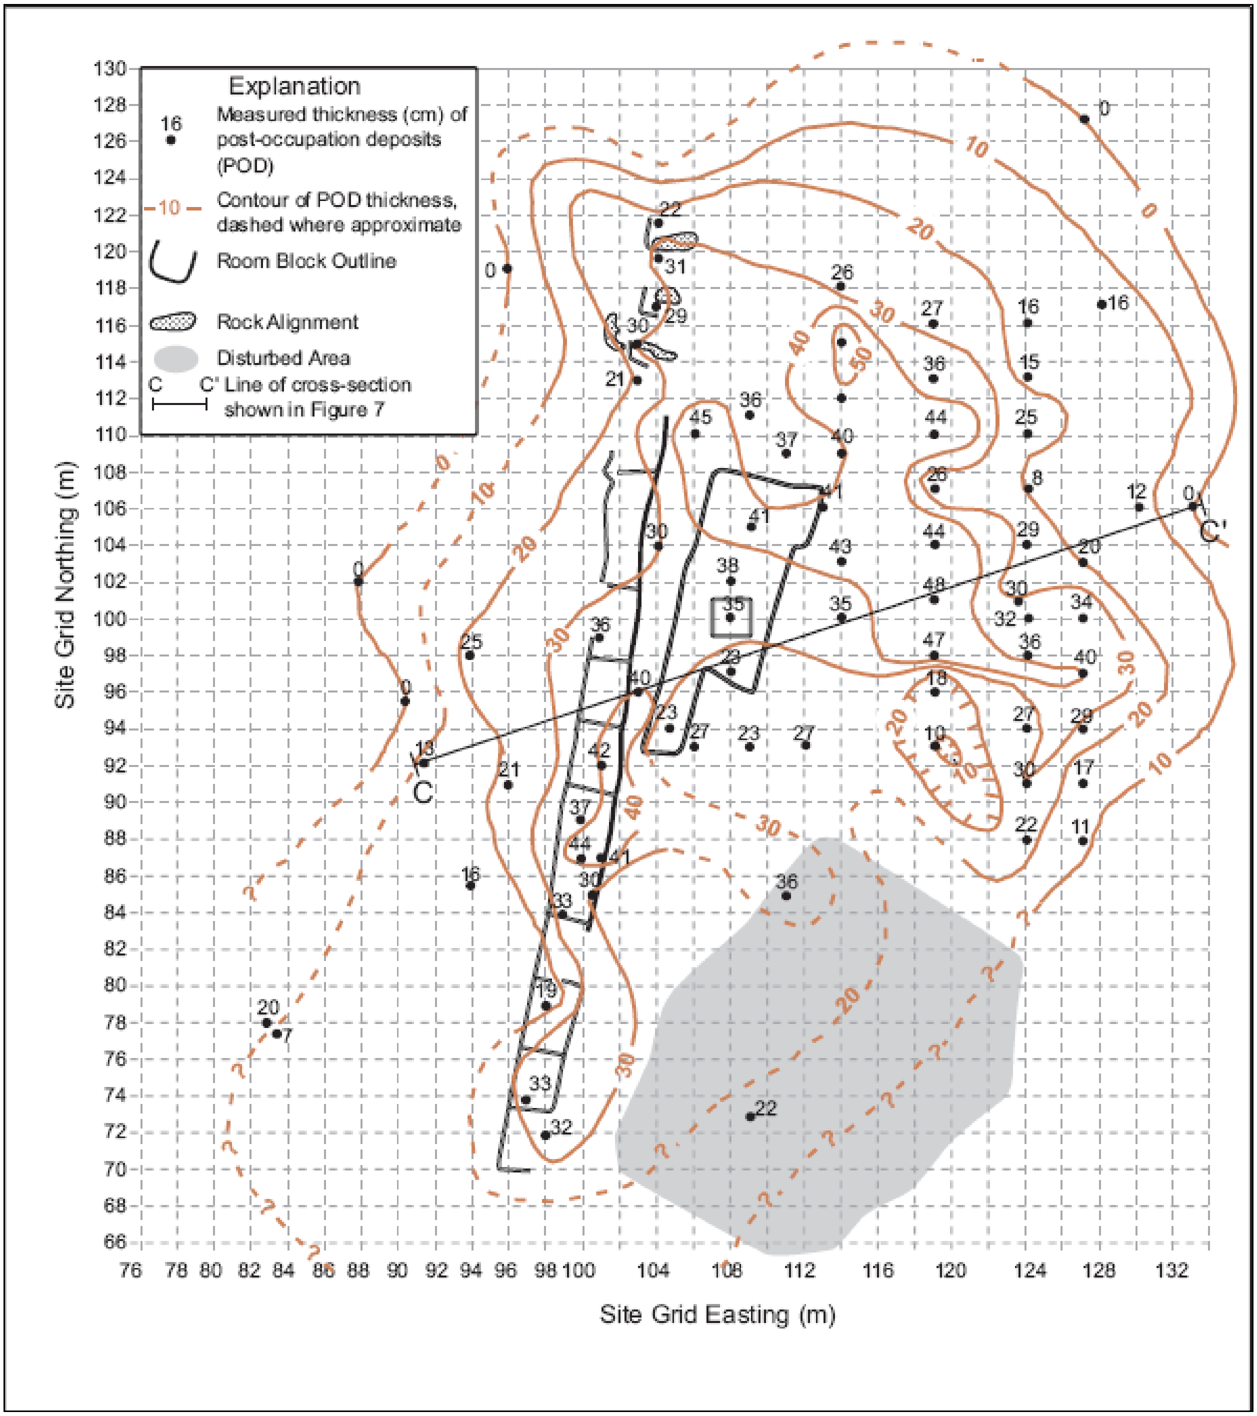

Figure 57.9. Isopach map showing the thickness of post-occupational deposits at LA 12587.

Component 1 (Roomblock 1 and Sheet Trash Deposits)

Roomblock 1 is an Ancestral Puebloan roomblock built either directly on Bandelier Tuff or on the remnant stripped Pleistocene soil (Figure 57.10 – example from Roomblock 3). Eolian or reworked eolian sediment is interpreted to largely comprise the upper soil that partially buries blocks of tuff derived from wall collapses. The upper soil also includes clasts of tuff derived from the roomblocks and a variety of ceramic and lithic artifacts, and is inferred to also contain the dissolved remnants of mortar and roofing material. The different soil components are well mixed, which indicates extensive bioturbation of the post-occupational soil by burrowing and other processes. Roomblock 1 is typically buried by 30 to 40 cm of young material that overlies the former floor, the underlying Btk horizon, or Bandelier Tuff. The upper soil layers that post-date occupation are anomalous in that Bw or Bwk horizons typically strongly effervesce, indicating the presence of calcium carbonate, (soil description 12587-7, 8, 9, and 10, Table L.3), whereas other young soils nearby do not effervesce (Table L.1, Location 21A). The reason for this is not certain. One hypothesis is that calcium carbonate was present in the mortar used in wall construction, and that this material is weathered out of the mortar and concentrated in the post-occupation soil. A soil profile with post-occupational A-Bw horizons described in sheet trash deposits approximately 17 m east of Roomblock 1 also strongly effervesce, indicating that sediments derived from the roomblock contain significant calcium carbonate (Table L.3, description 12587-9). A isopach map of post-occupational deposits at the site shows that sediments derived from the roomblock have been reworked east and north of the ruin, forming a colluvial apron at least 30 cm thick extending approximately 21 m east and 16 m north of the center of the roomblock (Figure 57.9).

Figure 57.10. Roomblock 3 wall at LA 12587 constructed directly on top of Bandelier Tuff (Qbt) and remnant Pleistocene soil (Btk horizon).

Component 2 (Roomblock 3)

Roomblock 3 is an Ancestral Puebloan roomblock that is younger than Roomblock 1. In some areas, wall blocks are set on top of a lower (Bw2 or Bwk2) horizon that contains rubble and artifacts inferred to be derived from Roomblock 1 (e.g., profiles 12587-10, 11, and 12, Table L.3). In other areas, Roomblock 3 walls are built either directly on Bandelier Tuff or on the remnant stripped Pleistocene soil (Figures 57.10 and 57.11). Roomblock 3 is typically buried by 20 to 30 cm of young soil that overlies the former floor, underlying soil horizons, or Bandelier Tuff. Post-occupational soils in Roomblock 3 also contain calcium carbonate. The isopach map shows a much smaller colluvial apron emanating from Roomblock 3 (the 30-cm-thick deposit extends approximately 4 m east of Roomblock 3) than is associated with Roomblock 1 (Figure 57.9), suggesting that Roomblock 3 walls were not built as high as were the walls forming Roomblock 1. These data support the hypothesis that Roomblock 3 was not completed.

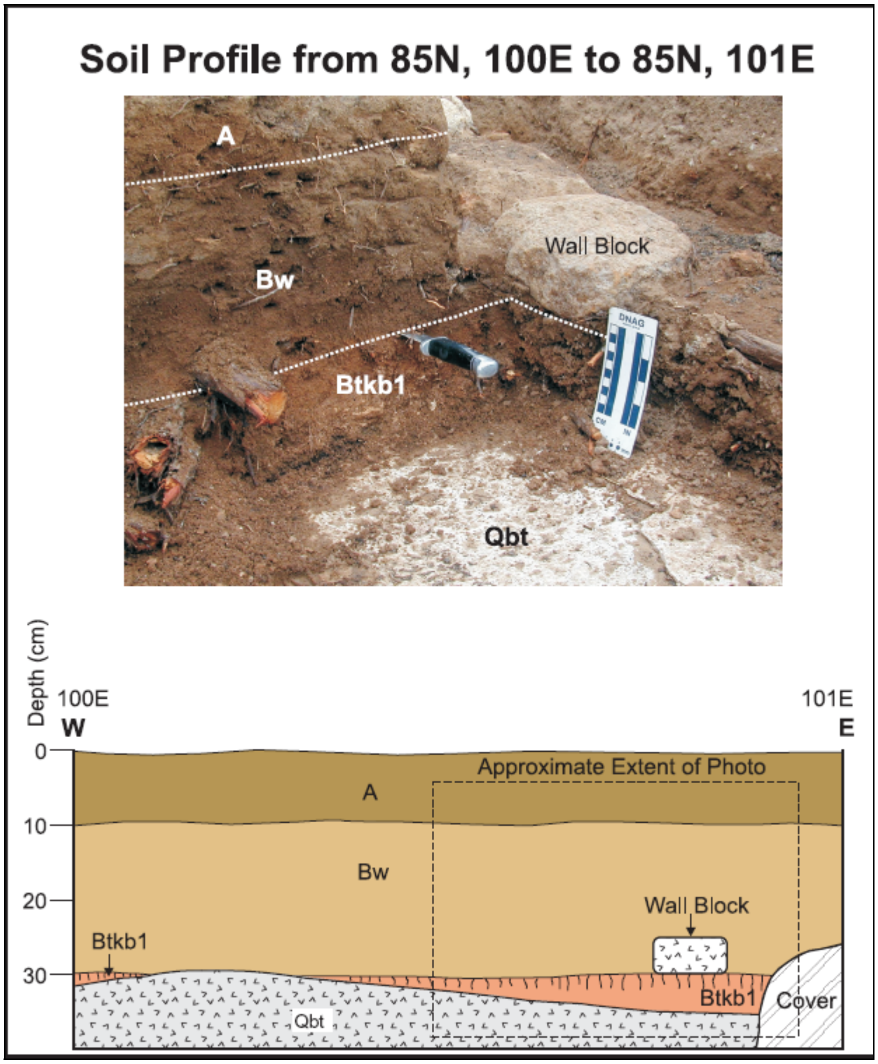

Figure 57.11. Photograph and sketch of Roomblock 3 wall at LA 12587, which is built on a remnant Pleistocene soil (Btkb1) and buried by post-Puebloan soil (A-Bw profile).

Component 3 (Roomblock 2 and Possible Agricultural Rock Alignments)

Roomblock 2 is a fieldhouse constructed on top of Roomblock 1. Soils were not described inside of Roomblock 2. A series of five soil descriptions were completed in the vicinity of the rock alignments located north of Roomblock 2 (see Figure 57.8). The rock alignments were constructed on top of a post-occupational Bw horizon 16 to 23 cm thick and lie within or are partly buried by an A or AC horizon that was 9 to 15 cm thick (Figures 57.12 and 57.13). Shaped blocks, inferred to be part of the Roomblock 3 construction, occur within the Bw horizon and below the rock alignments (Figure 57.12).

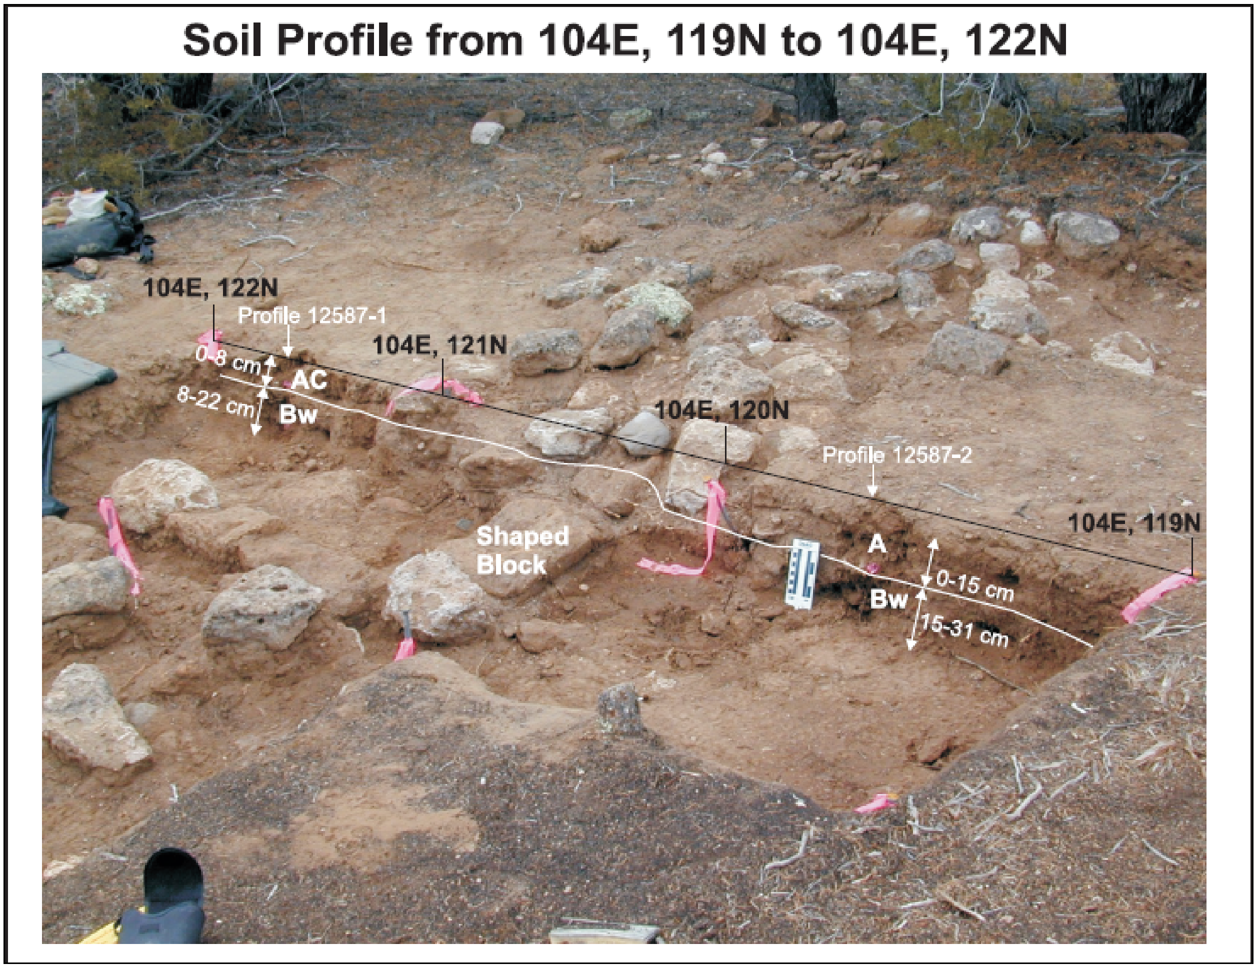

Figure 57.12. Photograph of excavation through LA 12587 northern rock alignment showing soil profiles.

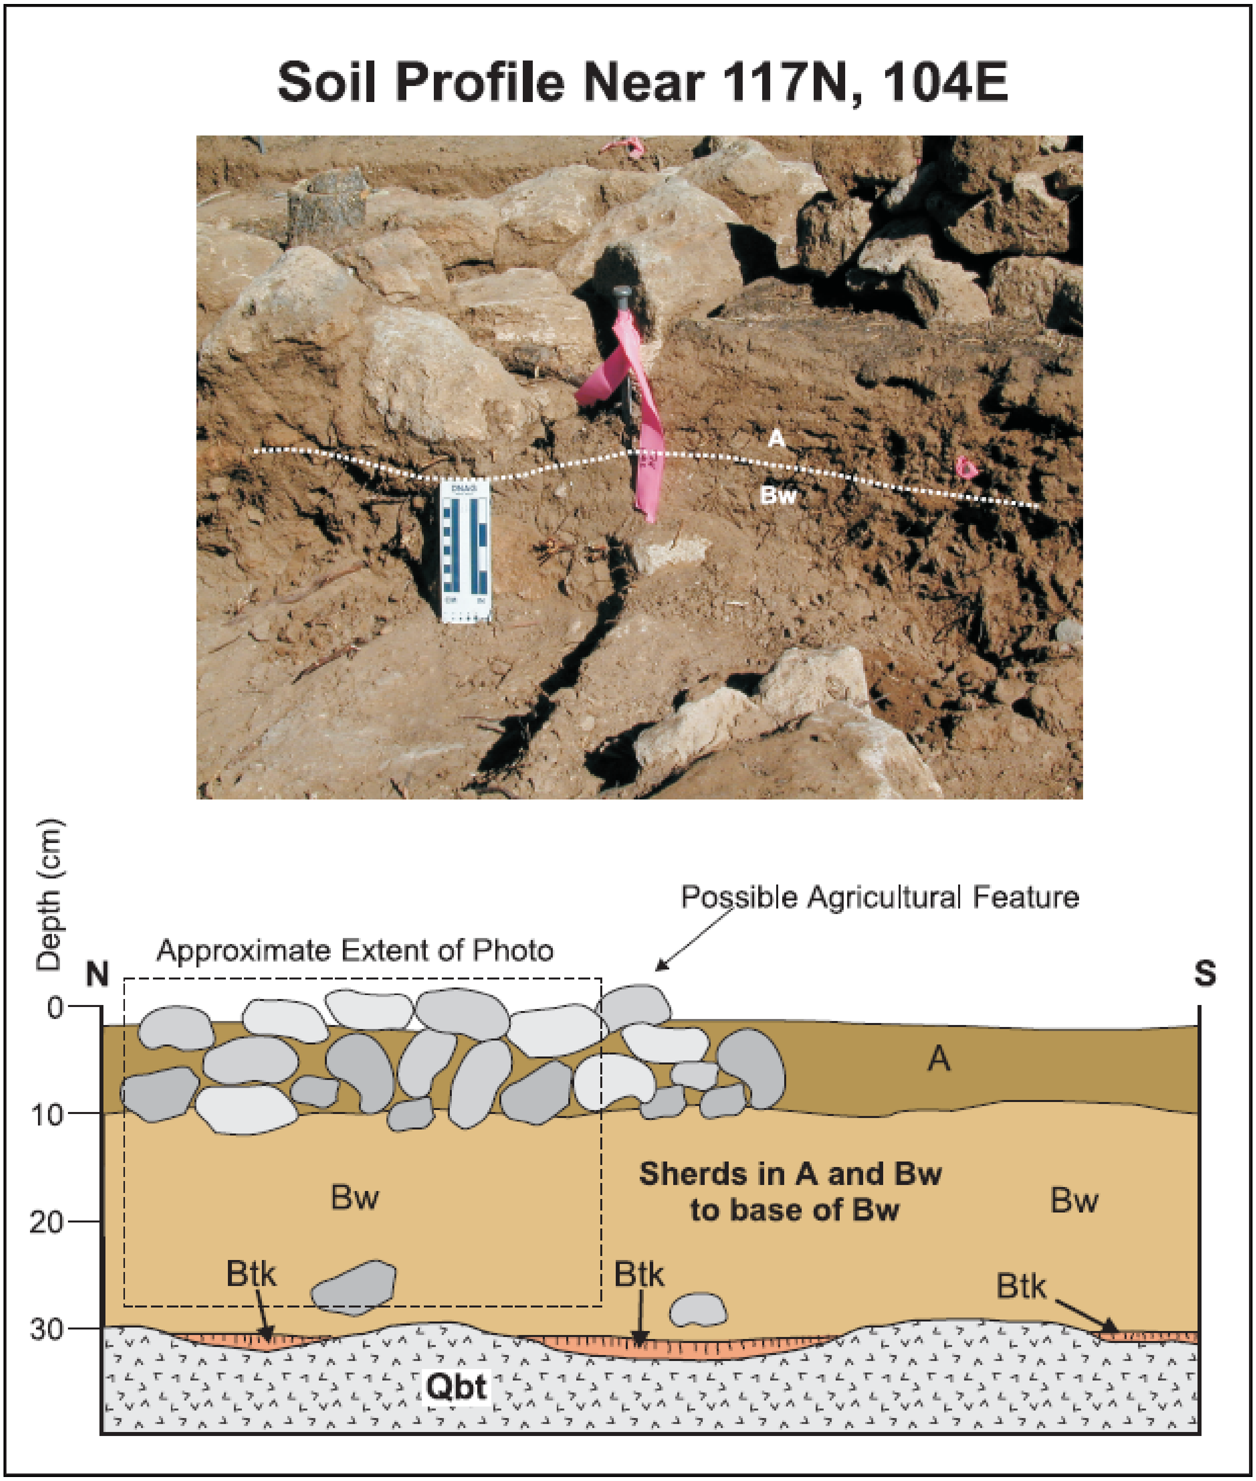

Figure 57.13. Photo and sketch of profile across the middle rock alignment at LA 12587.

Two profiles (12587-1 and 12587-5) were described outside and three profiles (12587-2, 12587-3, and 12587-4) were described inside the rock alignments (Table L.3). No textural differences were observed between profiles described inside versus outside the rock alignments. Soils described inside the rock alignments have a greater thickness (average 30 cm versus average 22 cm) than do the soils described immediately outside the rock alignments, due to generally thicker A horizons (Table L.3). This is observed most clearly in comparing profiles 12587-2 and 12587-1, where the A or AC horizon thins from 15 cm inside to 8 cm outside the northern rock alignment (see Figure 57.12). These observations indicate that the rock alignments are either acting to preferentially trap eolian or slopewash sediment, or that dirt was placed inside the alignments. The placement of dirt inside the rock alignments is suggested by the greater A horizon thickness and the absence of textural differences inside versus outside the rock alignments and by the orientation of the alignments oblique to a slope with a relatively shallow gradient.

The presence of a 16- to 23-cm-thick Bw horizon formed in sediment composed predominantly of eolian or reworked eolian sediment underlying the agricultural (?) rock alignments is evidence for significant eolian deposition during the Coalition (likely Late Coalition) period. Roomblock 1 was built on a stripped bedrock surface with remnant Pleistocene soils; therefore, deposition of sediment underlying the possible agricultural rock alignments occurred subsequent to construction of Roomblock 1. In contrast, eroding roomblocks provided a source for coarse colluvium, the predominantly fine-grained nature of upper Bw horizons indicates an eolian source for most of the sediment burying Component 2 features. Additional, thinner (9 to 15 cm) sediment partially buries the rock alignments, indicating smaller inputs of eolian sediment or reworked eolian sediment following the Component 3 occupation. This sediment deposition could date to the latest Coalition period, the Classic period, or the Historic period.

Lithic Scatter (Area 8)

LA 12587 also includes an Archaic lithic scatter at the south part of the mesa. This material is in an area of thin soils over tuff bedrock where significant erosion has occurred. The lithic scatter may in part represent a lag left following erosion of an unknown thickness of mesa top soils. Excavation into relatively thick pockets of soil (up to 28 cm thick) inside the main artifact scatter revealed the presence of both ceramics and obsidian flakes to the base of a weakly developed soil (Table L.3, profile 12587-13). An excavation completed outside the main artifact scatter revealed a young colluvial deposit of similar thickness (20 cm) and a weakly developed soil (Table L.3, profile 12587-14). Soils in the vicinity of the lithic scatter lack the Bw horizons typically observed in older post-occupational soils and instead exhibit A-BC or A-C horizons. This weak soil development is consistent with a post-occupational, possibly less than 500-year, age for the colluvium. This observation is consistent with the interpretation that this is an actively eroding surface with minimal potential for preserving an intact archaeological record.

LA 86637 (Fieldhouse and Lithic/Ceramic Scatter)

LA 86637 includes a fieldhouse with large tuff blocks on a deeply eroded colluvial slope. The fieldhouse is situated on a pedestal >0.5 m high between channels incised into the colluvial slope. The site also includes a lithic and ceramic scatter, which is inferred to represent reworked material transported down the colluvial slope. Because of the extensive erosion in this area, there is considered to be minimal potential for the preservation of an intact archaeological record.

Soils were described in two test pits at the site. Soil profile 86637-1 has an AC-Bw1b1-Bw2b1-Btkb2 horizon sequence interpreted to represent very young colluvium from 0 to 6 cm, overlying post-Coalition period colluvium that was observed to a depth of 43 cm (Table L.3). The young colluvium overlies a Pleistocene colluvial soil. Artifacts (lithics and ceramics) scattered throughout the AC, Bw1b1, and Bw2b1 horizons are interpreted to be part of the young colluvial package and therefore are not in archaeological context.

Soil profile 86637-2 has an AC-Bwk1b1-Bwk2b1-Bkb2 horizon sequence interpreted to represent deposition of young colluvium from 0 to 10 cm, overlying 2 to 4 ka colluvium with Stage I carbonate from 10 to 46 cm (Table L.3). The age estimate for the Bwk horizons with Stage I carbonate is based on comparison with the Fence Canyon borrow pit description (Table L.1), which exhibits a Stage I carbonate with a surface age of approximately 4 ka and an 8 ka age at depth (Reneau and McDonald 1996). The Holocene colluvium overlies a Pleistocene colluvial soil. Ceramics and lithics observed in the upper 10 cm are part of the young colluvial package and are not in archaeological context. Only lithics were observed in the Bwk1b1 horizon and are interpreted to be part of an older (middle to late Holocene) colluvial package. The lithics in the Bwk1b1 horizon were apparently reworked from an Archaic site upslope and are therefore likely not in archaeological context at this location.

LA 127625 (Lithic and Ceramic Scatter)

LA 127625 includes scattered sherds and lithic fragments in an area of thick late Holocene colluvium with little soil development (Table L.2, Location 22; see Figure 57.3). The colluvium here may post-date Ancestral Puebloan occupation of this area, and the cultural material was likely transported to the site in runoff from nearby slopes. The cultural material is therefore not in archaeological context at this location.

LA 127631 (Fieldhouse)

LA 127631 is a fieldhouse at the base of a low gradient colluvial hillslope, with an area of fan deposition to the southwest. Excavations at the site show the hillslope is mantled by a thin (<25 cm) layer of young colluvium overlying a Pleistocene soil (Table L.3, description 127631-1). Colluvium is a fine to very fine sand and may be composed primarily of reworked eolian sediment. The fieldhouse is buried by 10 to 19 cm of colluvium, with blocks set within a Bw horizon, at the boundary between a Bw1 and Bw2 horizon (Table L.3, description 127631-2). The site stratigraphy is consistent with the fieldhouse construction corresponding to the time of construction of Component 2 (Roomblock 3) at LA 12587. Scattered lithics and sherds occur on the surface in this area and may largely represent a lag or may consist of material transported by surface runoff.

LA 128803 (Grid Gardens)

LA 128803 consists of a grid garden in an area of discontinuous thin colluvial soils over basalt bedrock. There is a long colluvial slope west of LA 128803 that provides surface runoff to the site. The grid gardens may be partially buried by slopewash colluvium. Northeast of here the soils thin and the slope steepens above an incised channel of Cañada del Buey.

Four soil profiles were described upslope, in, and downslope of the rock alignments forming the grid garden (Figure 57.14). Soils were moist when described, and therefore weakly developed soil structure, if present, was difficult to discern. However, two trends are apparent in the soils described in the immediate vicinity of the grid garden. One trend is that the thickness of post-occupational soil is greater upslope and within the grid garden, ranging from 16 to 21 cm (Table L.3, descriptions 128803-1, 128803-2, and 128803-3), than was observed downslope of the grid garden, where the post-occupational soil thickness was 10 cm (Table L.3, description 128803-4). A second trend is that upper-horizon post-occupational soils are finer-grained (a silt loam) within and immediately downslope of the grid garden (Table L.3, descriptions 128803-2, 128803-3, and 128803-4), than was observed upslope of the grid garden (a sandy loam; Table L.3, description 128803-1). Both trends are consistent with the rock alignments acting to retain surface runoff and fine-grained slopewash and are consistent with the rock alignments functioning as a grid garden.

An additional observation was the absence of remnant Pleistocene soils in relatively deep pockets in the basalt within the rock alignments (Table L.3, descriptions 128803-2, and 128803-3), although such soils were present outside the rock alignments (Table L.3, description 128803-4, and in a test pit south of the alignments). This observation suggests that the area inside the alignments may have been prepared by first excavating the relatively dense, clay-rich Pleistocene soils and replacing this material with looser soil. Soils at LA 128803 are very weakly developed and apparently lack development of Bw horizons observed in Coalition period soils. It is therefore inferred that LA 128803 is likely a Classic period feature.

LA 128804 (Check Dam)

LA 128804 is an apparent 6-m-long check dam consisting of tuff clasts up to 60 cm long aligned across a shallow drainage on a colluvial slope. The dam has been partially breached by an incised channel, and some of the tuff has been transported downslope. Additional tuff blocks are scattered down a gradient along this same channel to the east and may represent the eroded remnants of similar structures.

Profile 128804-1 was described at Test Pit #1 and shows that the check dam was constructed on top of young stratified alluvium, possibly less than 100 years old, deposited in an aggrading stream channel (Table L.3). Deposition of approximately 16 cm of young alluvium has occurred at Test Pit #1 and behind the west part of the dam, with minimal deposition apparent elsewhere. Soils and geomorphic data indicate that LA 128804 is a recent structure, post-occupational in age, and likely less than 100 years old.

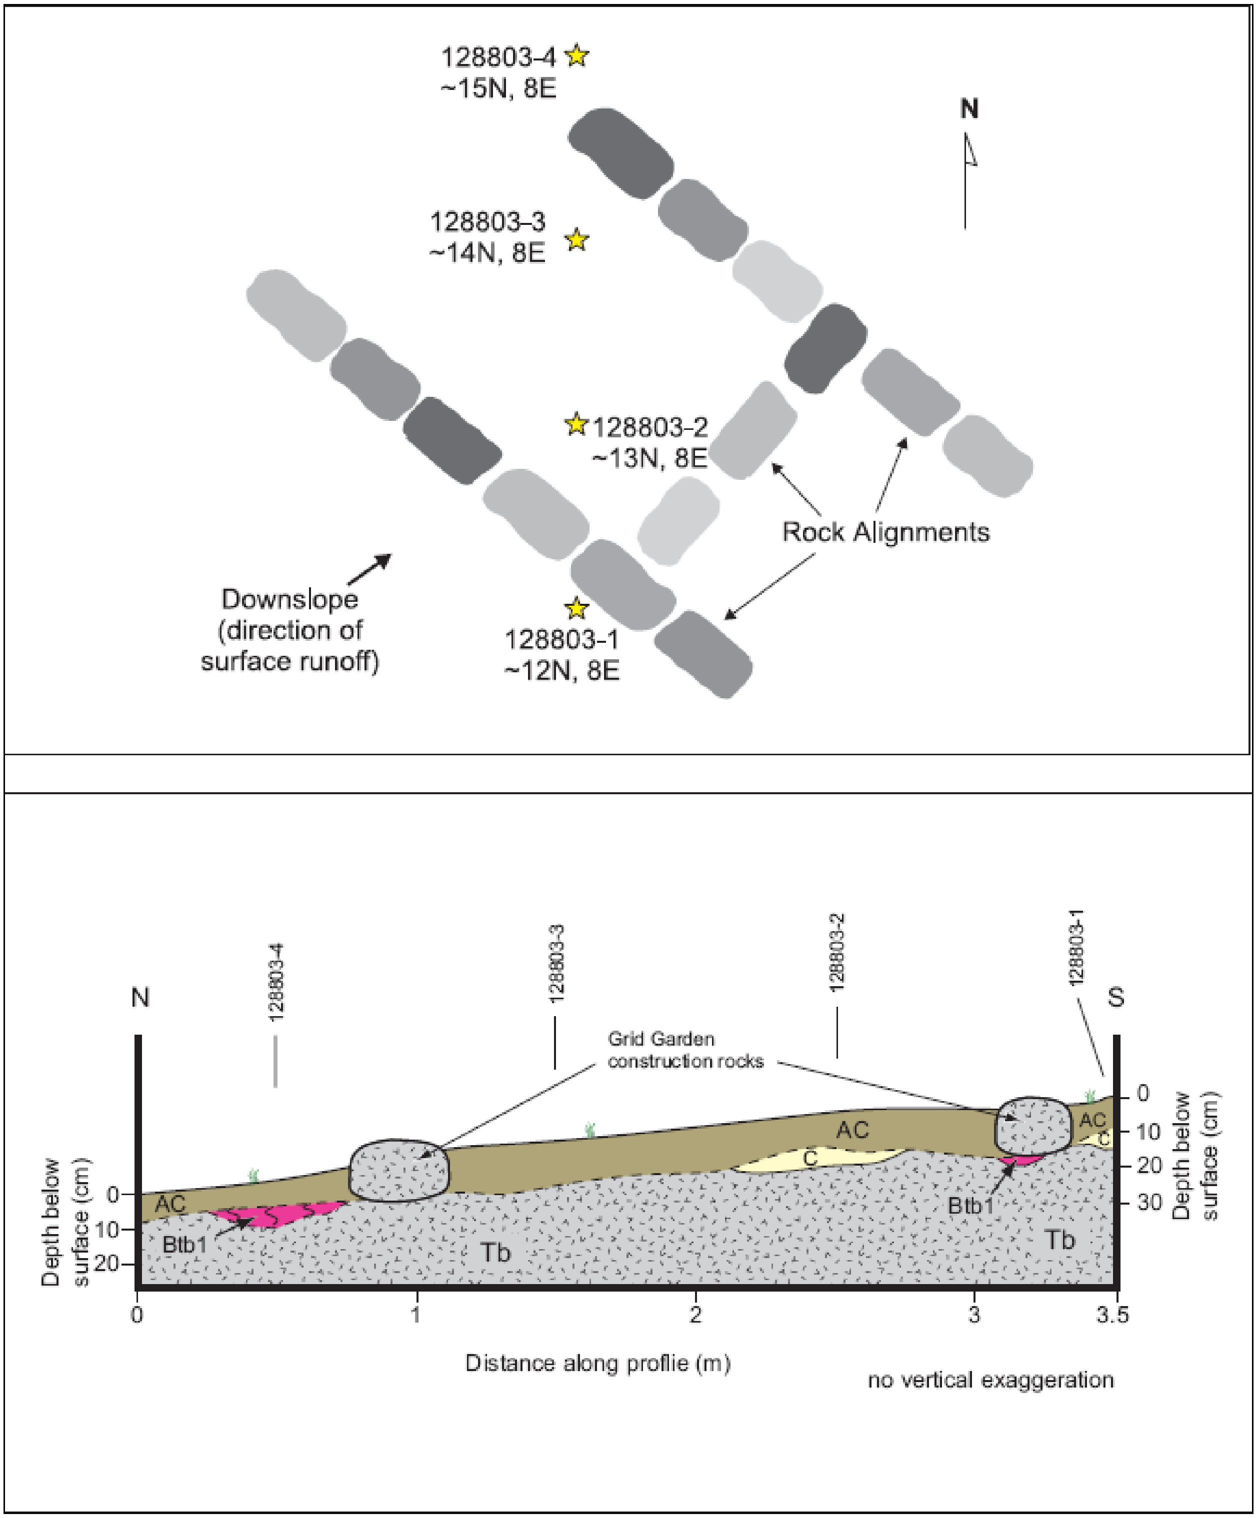

Figure 57.14. Schematic plan view (top) and cross-section (bottom) showing soil stratigraphy at LA 128803.

LA 128805 (Fieldhouse)

LA 128805 includes a Classic period fieldhouse on a broad colluvial slope that displays abundant evidence for active erosion. The fieldhouse is at the upslope end of eroding channels that extend to the east, with about 0.5 m of recent erosion estimated on the southeast side. Eroded channels also wrap around the northwest side of the structure. The tuff blocks in the fieldhouse appear to be acting as a local armor, protecting the area occupied by the fieldhouse from erosion while surrounding slopes are stripped. There is potential for some deposition of slopewash colluvium on the upslope (west) side of the fieldhouse, whereas other adjacent areas are experiencing erosion.

An examination of soils in a test pit located 1 m southeast of the southeast corner of the structure suggests that LA 128805 was constructed on an aggrading colluvial slope that experienced post-occupational deposition before the recent erosion that occurred at the site. A thin (10-cm-thick) A horizon is inferred to post-date occupation of the site (i.e., less than 500 yrs old). The A horizon overlies a buried (Bwb1) horizon, with soil structure development similar to that observed for older post-Coalition period soils and is inferred to be 500 to 800 years old (Table L.3, description 128805-1; Figure 57.15). The Bwb1 horizon overlies a buried Pleistocene soil formed in colluvium. The sequence of buried soils at this site suggests rapid deposition of colluvium, possibly during the Coalition period, with continued aggradation after abandonment of this Late Classic period fieldhouse, followed by recent erosion.

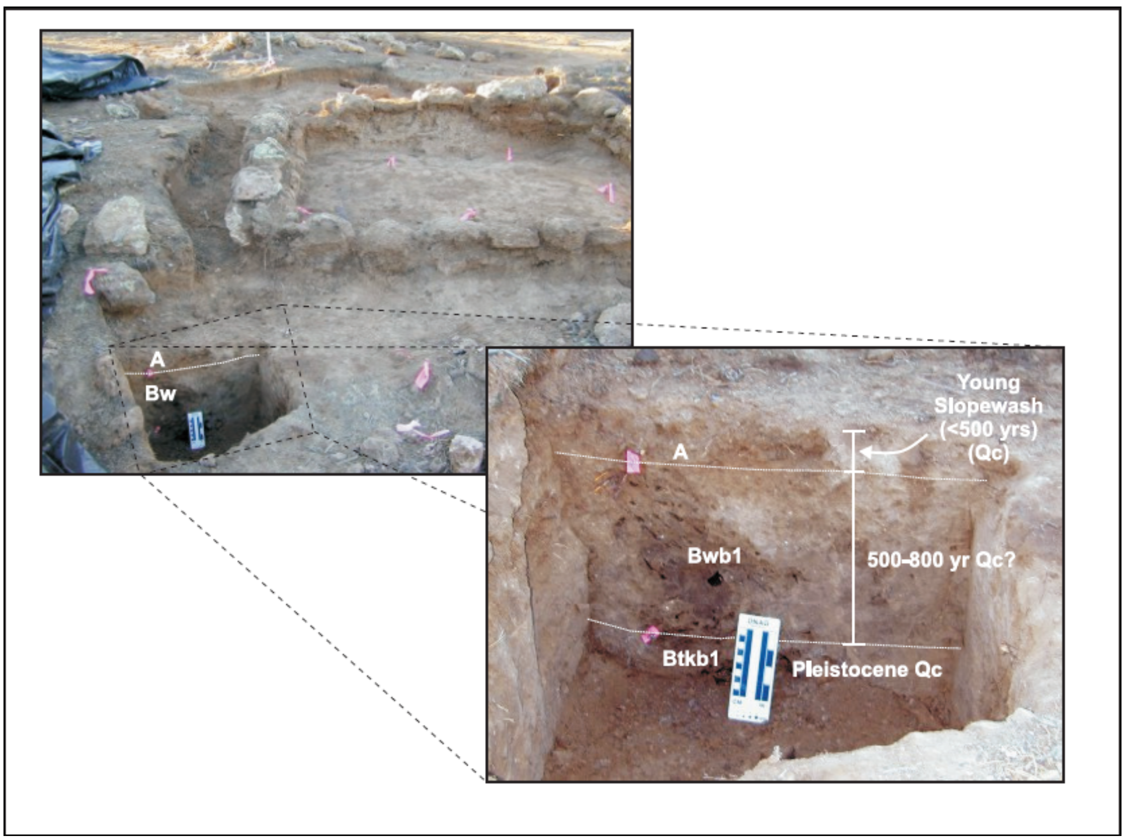

Figure 57.15. Photo of LA 128805 showing soil profile adjacent to the fieldhouse.

Geomorphic Summary of White Rock Tract

Hillslopes in the White Rock Tract are underlain by a sequence of truncated Pleistocene and Holocene soils that are inferred to represent colluvial deposition and soil formation followed by erosion in the mid-Pleistocene (buried soil "b3"), the late Pleistocene (buried soil "b2"), and the middle to late Holocene (buried soil "b1") (see Figures 57.4 and 57.6). The presence of middle to late Holocene deposits in several areas of the White Rock Tract indicates that there is potential for the preservation of buried Archaic sites.

An examination of colluvial stratigraphy at sites throughout the parcel indicates that there have been two episodes of relatively widespread colluvial deposition in the area since the middle Holocene. An episode or several episodes of colluvial deposition occurred during the middle to late Holocene (Archaic time), likely around 2 to 5 ka (e.g., buried soil b1, see Figure 57.6), and a second period of colluvial deposition occurred within the past 800 years, likely contemporaneous with and/or post-dating Puebloan occupation (A-Bw surficial soil profiles, see Figures 57.4 and 57.6). Many sites also exhibit a thin (typically less than 10 cm thick), very young colluvial layer, likely deposited within the past 100 years. In addition, a less extensive middle (?) Holocene colluvial deposit was locally preserved (e.g., SP6, see Figure 57.6). Areas of the White Rock Tract where middle to late Holocene colluvial deposits were preserved are mapped as Qc2 (see Figure 57.3). Areas of the White Rock Tract where middle to late Holocene colluvial deposits are not preserved are mapped as Qc1. Archaic sites are unlikely to be preserved in the Qc1 map unit area.

Two episodes of widespread Pleistocene colluvial deposition were recorded as buried soils b2 and b3 (see Figure 57.4). The b2 soil is overlain by El Cajete pumice (Figure 57.4, SP15 and SP17) and is therefore older than 50 to 60 ka. The b3 soil is discontinuously preserved, often as remnant stripped soils in bedrock depressions. The b3 soil exhibits 5YR color and moderately thick clay films and, based on comparison with previous soils investigations on the Pajarito Plateau, has an estimated age of at least 100 to 200 ka (McFadden et al. 1996). Evidence for the polygenetic nature of Pleistocene soils in the White Rock Tract is shown by several profiles where peds in Btk horizons exhibit translocated clay in ped interiors but are coated with carbonate.

Although a depositional record is recorded on many colluvial slopes, other slopes have experienced recent erosion. As a result of active transport and deposition on colluvial slopes, artifact scatters on colluvial slopes are typically part of the colluvial deposit and are not in archaeological context.

Mesa top locations in the White Rock Tract are characterized by Bandelier Tuff bedrock overlain by thin, discontinuous remnant Pleistocene soils and recent eolian or reworked eolian deposits typically less than 20 to 30 cm thick (see Figures 57.6 and 57.7). Similar thin, discontinuous deposits not greater than 20 to 30 cm thick were noted during archaeological excavations on the Mesita del Buey mesa top approximately 1 km west of LA 12587 (Steen 1982). Before the Coalition period, mesa top surfaces were characterized by stripped surfaces with remnant eroded

Pleistocene (b3) soils and exposed bedrock. Although erosion and some colluvial transport has occurred across mesa top surfaces, roomblocks and associated artifacts are in relatively good archaeological context. Roomblocks were an effective trap for eolian sediment, and the eroding walls were a local source of coarse colluvium after site abandonment. Two eolian events are recorded in the vicinity of the mesa top sites. At LA 12587, the older Coalition period roomblocks are buried by eolian deposits with Bw horizon development, whereas Classic period rock alignments are constructed on top of the Bw horizon (see Figure 57.7). Classic period features are partially buried by a younger eolian deposit. The earlier eolian event likely occurred during the Late Coalition period (AD 1250 to 1325), and the latter eolian event could date to the latest Coalition period, the Classic period, and/or the Historic period.

Sites investigated within the White Rock Tract include a multi-component ancestral Puebloan roomblock site situated on a small isolated Bandelier Tuff mesa (LA 12587), fieldhouse sites, lithic scatters, a grid garden site, and a check dam. The mesa top roomblock site is buried by eolian deposits and is in good archaeological context. As a result of active transport and deposition on colluvial slopes, artifact scatters on unit Qc are typically part of the colluvial deposit (e.g., LA 127625, LA 86637, and LA 12587) and are not in archaeological context. LA 128805, LA 127631, LA 86637, and LA 128803 are also located on colluvial slopes. LA 128805 and LA 86637 are fieldhouses situated on eroded hillslopes that do not preserve a geomorphic record that would allow correlation with other sites in the area. Soil-stratigraphic relationships observed at LA 128803 indicate that the rock alignments there were acting to retain surface runoff and fine-grained slopewash and are consistent with the rock alignments functioning as a grid garden. Soils at LA 128803 are very weakly developed and are consistent with interpretation of LA 128803 as a Classic period feature. Soil and stratigraphic context indicates that the LA 127631 construction corresponds approximately to the time of construction of Roomblock 3 at LA 12587. The check dam at LA 128804 is likely less than 100 years old.

AIRPORT TRACT (A-3, A-7, A-5-1)

Surficial Geologic Units

The Airport land transfer tract includes a gently east-sloping mesa between a tributary to Pueblo Canyon on the north and DP Canyon, a tributary to Los Alamos Canyon, on the south (see Figure 3.2, Volume 1). Bedrock beneath the mesa consists of the Tshirege Member of the Bandelier Tuff (unit Qbt). Here, Bandelier Tuff is designated as Qbt, undifferentiated. At the Airport site location, the Bandelier Tuff has been mapped as unit Qbt-3 by Goff (1995). The mesa is capped by colluvium that thins to exposed bedrock near the mesa edge (Figure 57.16), overlain by fine-grained soils that likely constitute either eolian sediments or locally reworked eolian sediments. Recent (Holocene) soils and sediments unconformably overly thin Pleistocene soils. Eolian deposits located in the approximate center of the mesa top include latest Holocene and middle or early Holocene deposits overlying Pleistocene soils and bedrock (map unit Qc2), whereas deposits near the edge of the mesa top consist of latest Holocene deposits overlying Pleistocene soils and bedrock (map unit Qc1) (Figure 57.16). A tributary drainage to Pueblo Canyon that heads in the tract is shallowly incised, to a depth of up to 20 m below the mesa top. The tributary drainage contains a narrow strip of young (historic in age) alluvium consisting of gravelly medium to coarse sand. Geologic maps of this area have been prepared by Griggs (1964), Smith et al. (1970), Goff (1995), and Rogers (1995).

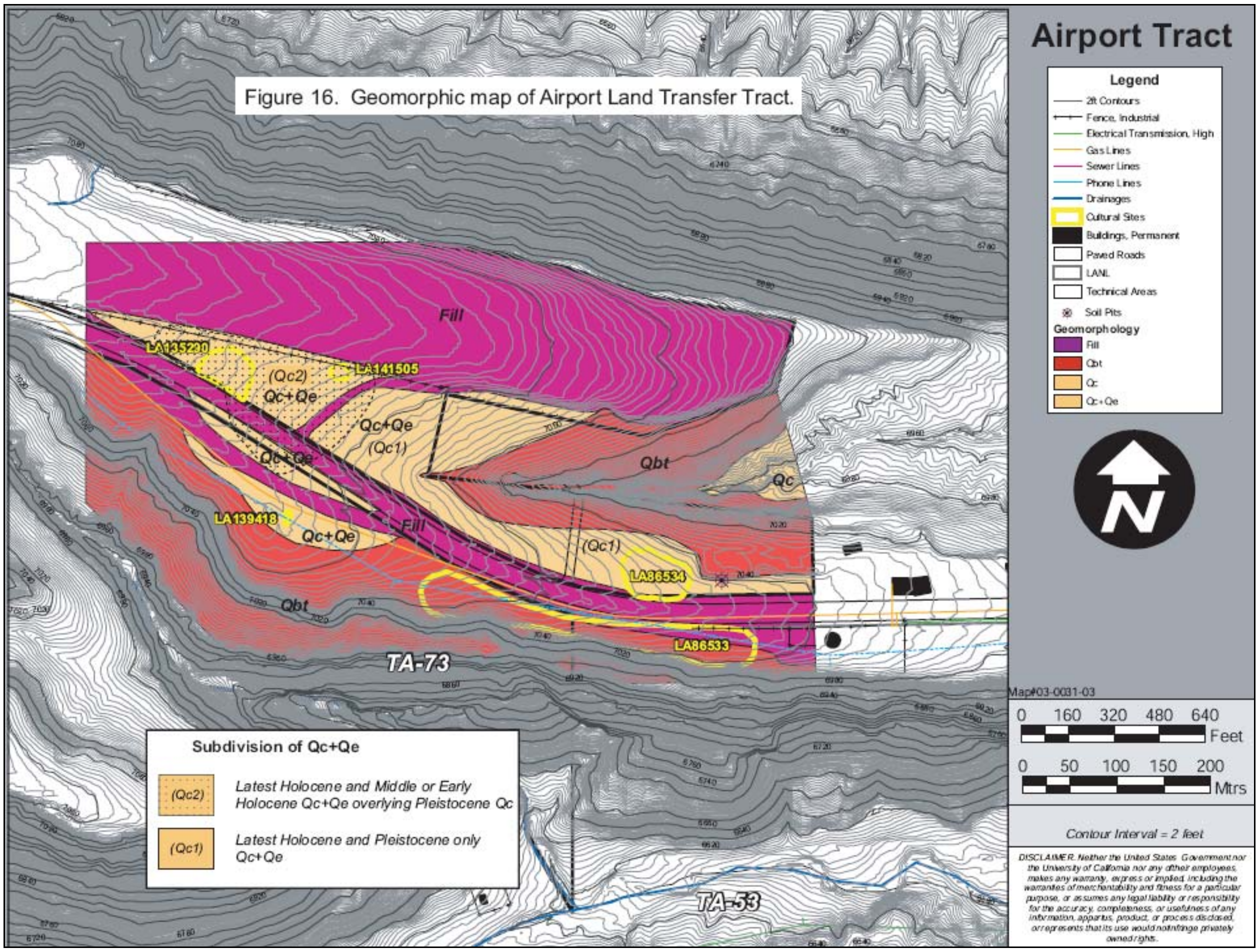

Figure 57.16. Geomorphic map of Airport Tract.

Soils were described at four archaeological sites within the Airport Tract. Soils were also described in a ca. 4.5 cal ka valley fill deposit overlying a ca. 8.8 cal ka deposit in "EG&G gully" east of the Airport Tract sites (Figure 3.2, Volume 1). These ages are based on three radiocarbon dates from charcoal collected from an upper and a lower soil at the site (see Figure 57.2; Longmire et al. 1996). The age of the upper soil, with an A-Bw1b1-Bw2b1-BCb1 profile, is constrained by one sample that yielded an age of 4020±80 BP (Beta-55626) and a date of cal 4543 BP with a two-sigma date range of cal 4297 to 4824 BP (Table M.1; calibrated ages for all samples discussed in this report from CALIB 5.01, Stuiver et al. 2005). The age of the lower soil, with a Bwb2-Bkb2 profile and Stage I carbonate horizon (see Figure 57.2), is constrained by two samples statistically the same at the 95 percent confidence level (Beta-55622 and Beta-59677) that were combined to yield an age of 7949±72 BP and a date of cal 8810 BP with a two-sigma date range of cal 8607 to 8997 BP (Table M.1).

LA 86533 (Coalition Lithic and Ceramic Scatter)

LA 86533 is a probable Coalition period site consisting of a dispersed lithic and ceramic scatter. LA 86533 is situated near the mesa edge on top of shallow soils in a highly eroded area with exposed bedrock (see Figure 57.16). Sparse artifacts are part of a thin colluvial cover overlying Bandelier Tuff bedrock. The archaeological context at the site is poor, and the lithics appear to represent a lag deposit.

LA 86534 (Middle Coalition Period Roomblock)

Site Geomorphology and Stratigraphy

LA 86534 is an Ancestral Puebloan roomblock that dates to the Middle Coalition period. The site is underlain by a thin (15- to 20-cm-thick) Pleistocene Bt horizon inferred to be 100 to 200 ka or older, based on correlation with soils described by McFadden et al. (1996). The Bt horizon is a reddened (5YR) silty to sandy clay that is a potential clay source, and is correlated with remnant Btb3 soils described at other Airport Tract sites. Roomblocks were apparently built on top of the Bt horizon. Close to the roomblock, the Bt horizon is overlain by Bw horizons formed in colluvium derived in part from the roomblock. Outside of the rubble mound surrounding the roomblock, the Bt horizon is overlain by a 20- to 25-cm eolian deposit that apparently post-dates the Puebloan occupation. The Bt horizon appears to be the lower part of an originally thicker Pleistocene soil that has been partially stripped by erosion. The presence of only a thin Pleistocene soil underlying young eolian deposits in the vicinity of LA 86534 suggests that erosional processes predominated in this area before the Coalition period.

Approximately 3 m northeast of the roomblock, two episodes of mixed colluvial and eolian deposition are recorded in soil profile 86534-2 (Table L.4). A 5-cm-thick AC horizon that is inferred to be less than 200 years old overlies a 27-cm-thick buried soil (Bw1b1-Bw2b1) formed in sediments derived in part from erosion of the roomblock. The Bw1b1-Bw2b1 soil is therefore less than 750 to 850 years old and overlies the Pleistocene Bt horizon. The Bw2-Bw1 horizon sequence is developed in a colluvial deposit derived from erosion of the roomblock, with fines representing likely eolian deposition. The greater abundance of tuff clasts (60% to 70% gravel) in the lower (Bw2b1) horizon is indicative of sediment derived primarily from the roomblock, whereas a decrease in gravel content to 10 percent in the Bw1b2 horizon suggests eolian deposition in the rough surface created by wall remnants and the rubble mound surrounding the ruin.

Scattered tuff blocks were observed on the surface to the west and north of the roomblock. These tuff blocks were originally thought to represent the location of a structure. However, the tuff blocks occur within or on top of an A horizon that overlies fine-grained deposit dominated by silt and very fine sand with little soil development (Bw horizon, location 86534-1, approximately 8 m west and 3 m north of the roomblock). This deposit, extending to a depth of 25 cm, apparently post-dates Puebloan occupation here. The presence of tuff blocks overlying a fine-grained, post-occupational soil lacking colluvium derived from the roomblock indicates that the surficial tuff blocks are not in place. These blocks may have been moved during highway construction. Beneath the post-occupational deposit is the reddish, clay-rich Pleistocene Btb3 soil horizon that directly overlies tuff bedrock. The contact between the two soil horizons is abrupt and probably records stripping of part of the older soil followed by fairly recent burial of the horizon by eolian sediments.

The mesa top soil described outside of the roomblock rubble mound (86534-3) comprises a non-gravelly AC horizon overlying an eroded Bt horizon (Table L.4). The AC horizon consists of well-sorted fine sand and extends to a depth of 21 cm. This horizon likely represents eolian deposition, possibly mixed with fine-grained colluvium. Based on the relative absence of soil structure, the AC horizon is inferred to post-date site occupation. The 21-cm-thick AC horizon and eolian deposit at 86534-3 is roughly correlated to the 25-cm-thick A-Bw profile and eolian deposit at 86534-1 and is similar to the thickness of other post-Coalition period eolian deposits throughout the Airport Tract (Figure 57.17). Based on soil-stratigraphic relationships observed at other Airport Tract sites (discussed below) and at the White Rock Tract mesa top site LA 12587, most of the eolian deposition likely occurred soon after abandonment of the LA 86534 roomblock or during the Late Coalition period (AD 1250 to 1325).

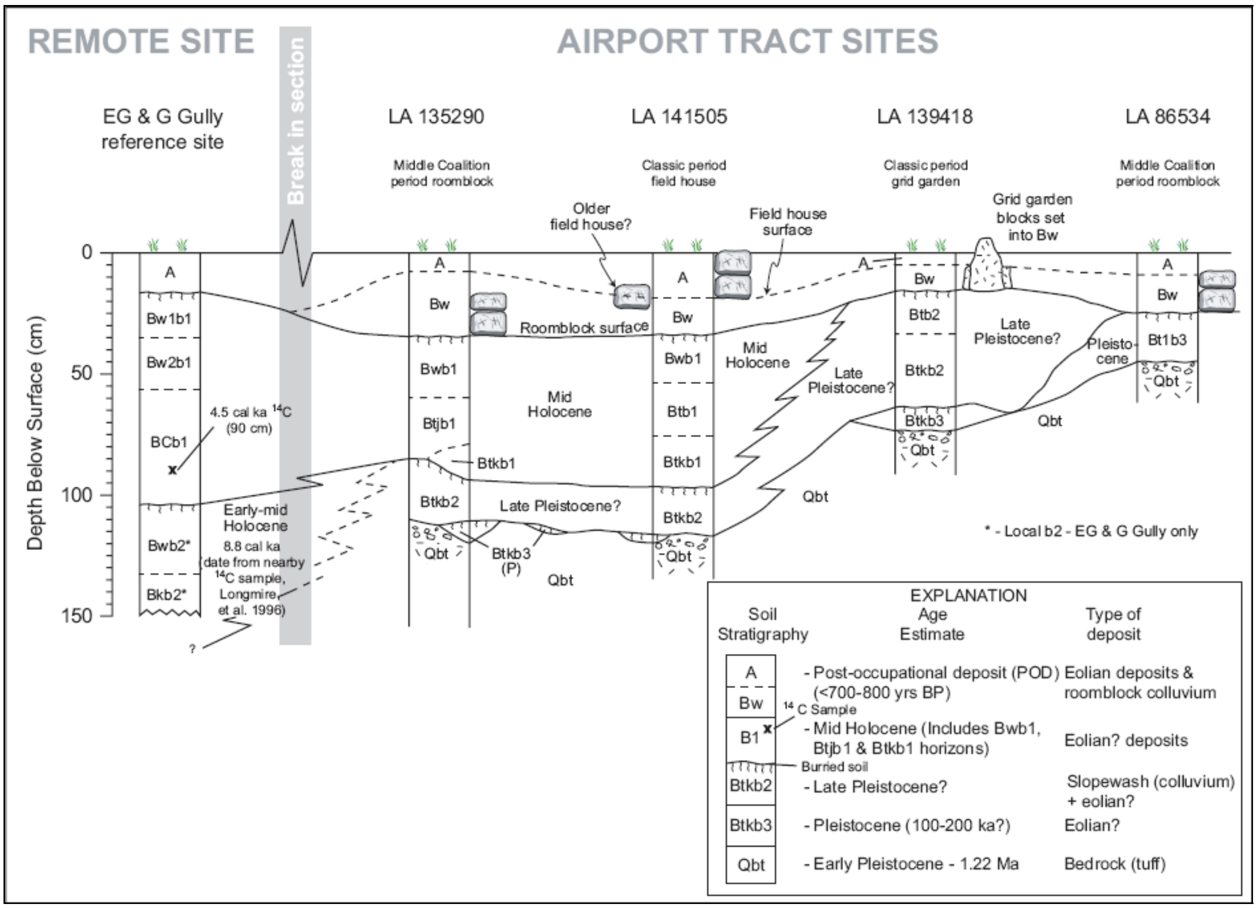

Figure 57.17. Stratigraphic correlation of the Airport Tract sites.

LA 135290 (Middle Coalition Period Roomblock)

LA 135290 is an Ancestral Puebloan roomblock on the mesa top that dates to the Middle Coalition period. The site is underlain by a sequence of stacked Holocene and Pleistocene soils (Figure 57.18; Table L.4). The older (b2 and b3) soils of inferred Pleistocene age are present as remnant soils that were eroded and subsequently buried by swale fill and/or eolian deposits (Figure 57.18). Thickness of buried Pleistocene deposits ranges from 0 to approximately 35 cm (see Figure 57.3; Table L.4). The inferred mid-Holocene (b1) soil formed in fine-grained silty deposits of likely eolian origin (Table L.4). An increase in gravel percentage from less than 2 percent in the overlying b1 soil to approximately 5 percent in the underlying b2 soil is suggestive of a stone line or erosion of the underlying bedrock by biological or slopewash processes during the late Pleistocene.

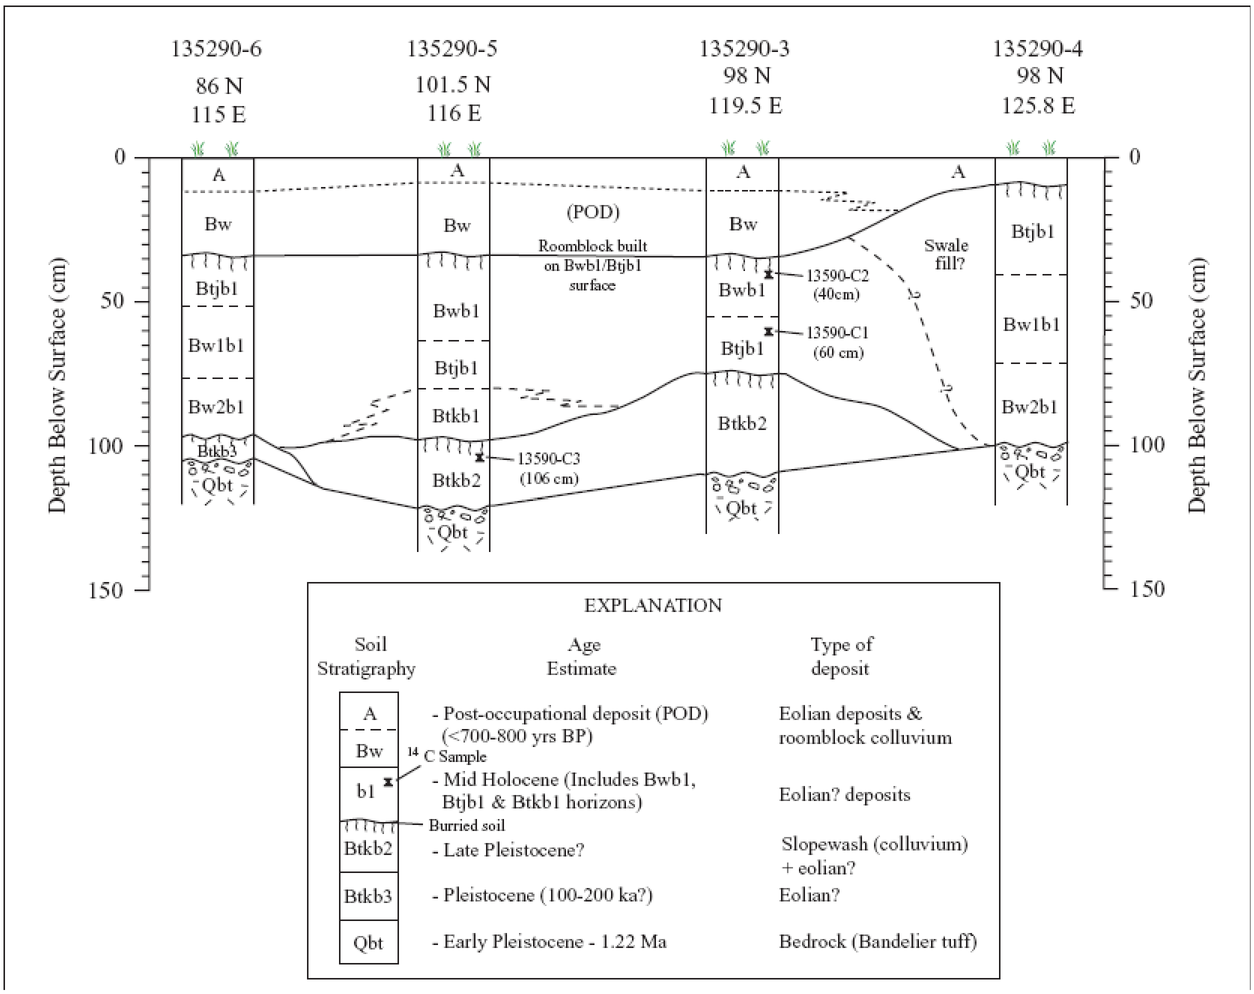

Figure 57.18. Correlation chart for LA 135290.

Burial of an undulating Bandelier Tuff surface and alternating periods of erosion and deposition have resulted in variable thicknesses of Pleistocene and Holocene sediments underlying the site (Figures 57.19 and 57.20). A buried swale trends west-northwest to east-southeast, east of the roomblock (Figure 57.20). Pleistocene soils are discontinuously preserved, indicating extensive erosion of the mesa top between the late Pleistocene and the mid-Holocene (Figures 57.18, 57.19, and 57.20). The 40- to 90-cm-thick mid-Holocene eolian deposit comprising the b1 soil was partially stripped (truncated) before occupation of LA 135290. Pleistocene and possibly Holocene soils are likely reworked and deposited as a swale fill sequence in the vicinity of profile 4 (Figure 57.18). The top of the mid-Holocene eolian deposit and the upper surface of Holocene swale fill deposits comprise the occupation surface for LA 135290. The mid-Holocene deposits are overlain by mixed colluvium derived from the roomblock and eolian deposits less than 700 to 800 years old, referred to herein as post-occupation deposits.

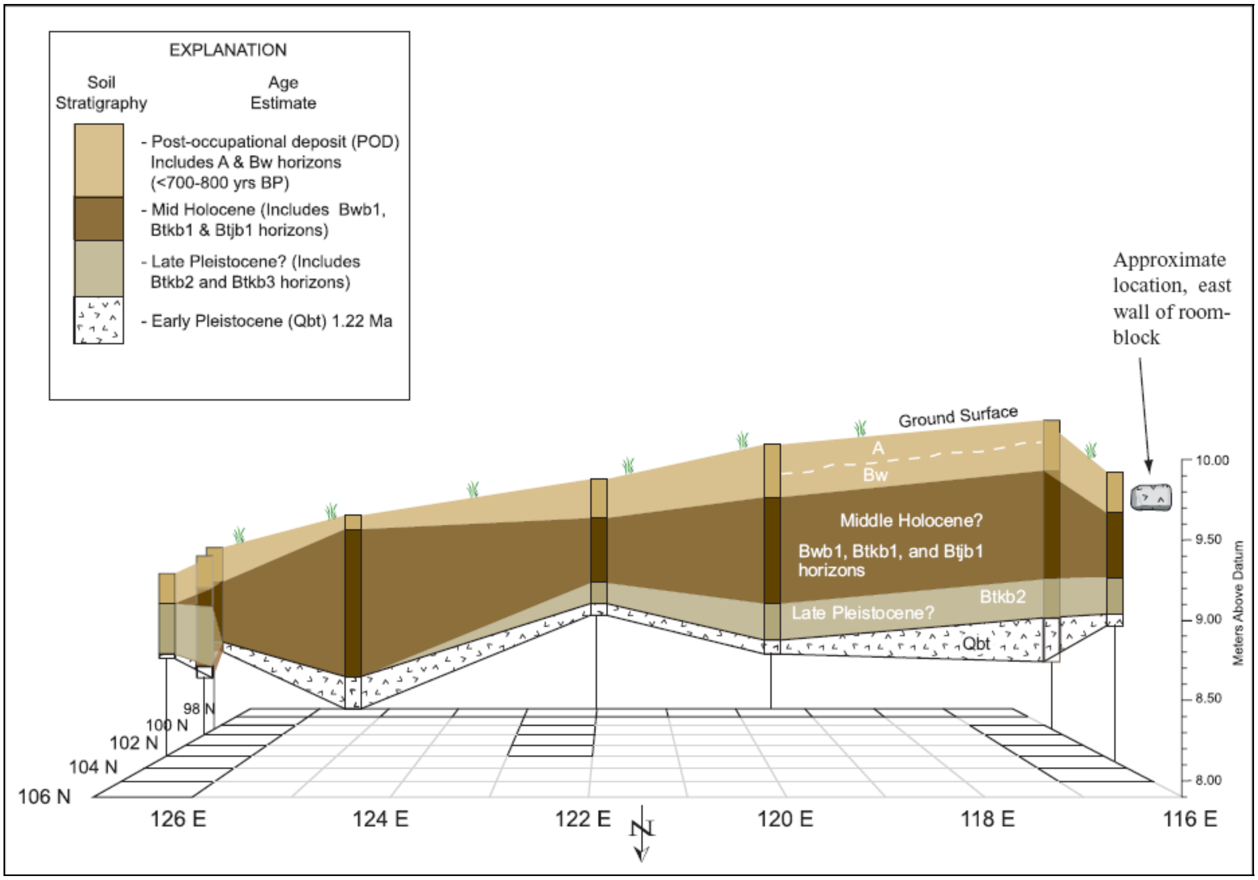

Figure 57.19. LA 135290 soil profile fence diagram east of roomblock (looking south).

Age estimates for soils underlying the roomblock are based on correlation with soils on the Pajarito Plateau for which age control is available. Although three charcoal samples were collected from soils underlying the occupation surface (Figure 57.18), due to their small sample size these samples have been unsuitable for analysis. Based on the estimated age of the roomblock, the A-Bw post-occupational deposit is less than 700 to 800 years old. The buried soil (b1) underlying post-occupational deposit includes Bw, incipiently developed Btj, and Btk horizons with Stage I carbonate (Figure 57.18; Table L.4, profiles 135290-3, 4, 5, and 6). The b1 soil has an inferred mid-Holocene age (4 to 6 ka BP), based on correlation with profile EG&G-1, described in "EG&G gully" east of the Airport Tract sites (Table L.4; Longmire et al. 1996). EG&G-1 has Bw1 and Bw2 horizons developed in a ca. 4.5 cal ka deposit and a Bk horizon with Stage I carbonate developed in an underlying 8.8 cal ka deposit (Figure 57.2, Table L.4). The mid-Holocene b1 soil is underlain at some locations by a Btkb2 soil of inferred late Pleistocene age, based on the age of the overlying soil and the additional time required to develop a Bt (argillic) horizon with 7.5YR color and common, moderately thick clay films. The Btkb2 soil exhibits clay films and color similar to the Rendija Canyon Qt4 soil that has an estimated age of 63±8 ka based on ^{21}Ne analyses and 68 to 78 ka based on soils (McDonald et al. 1996; Phillips et al. 1998; Reneau and McDonald 1996), and may correlate with the Pajarito Mesa pre-El Cajete (greater than 50 to 60 ka) unit 3b soil (Reneau et al. 1995). The underlying thin (0 to 8 cm thick) Pleistocene Btkb3 horizon is inferred to be 100 to 200 ka or older, based on correlation with soils described by Reneau et al. (1995) and McFadden et al. (1996). The Btkb3 horizon is a reddened (5YR) silty clay, likely of eolian origin, which is a potential clay source for making ceramics.

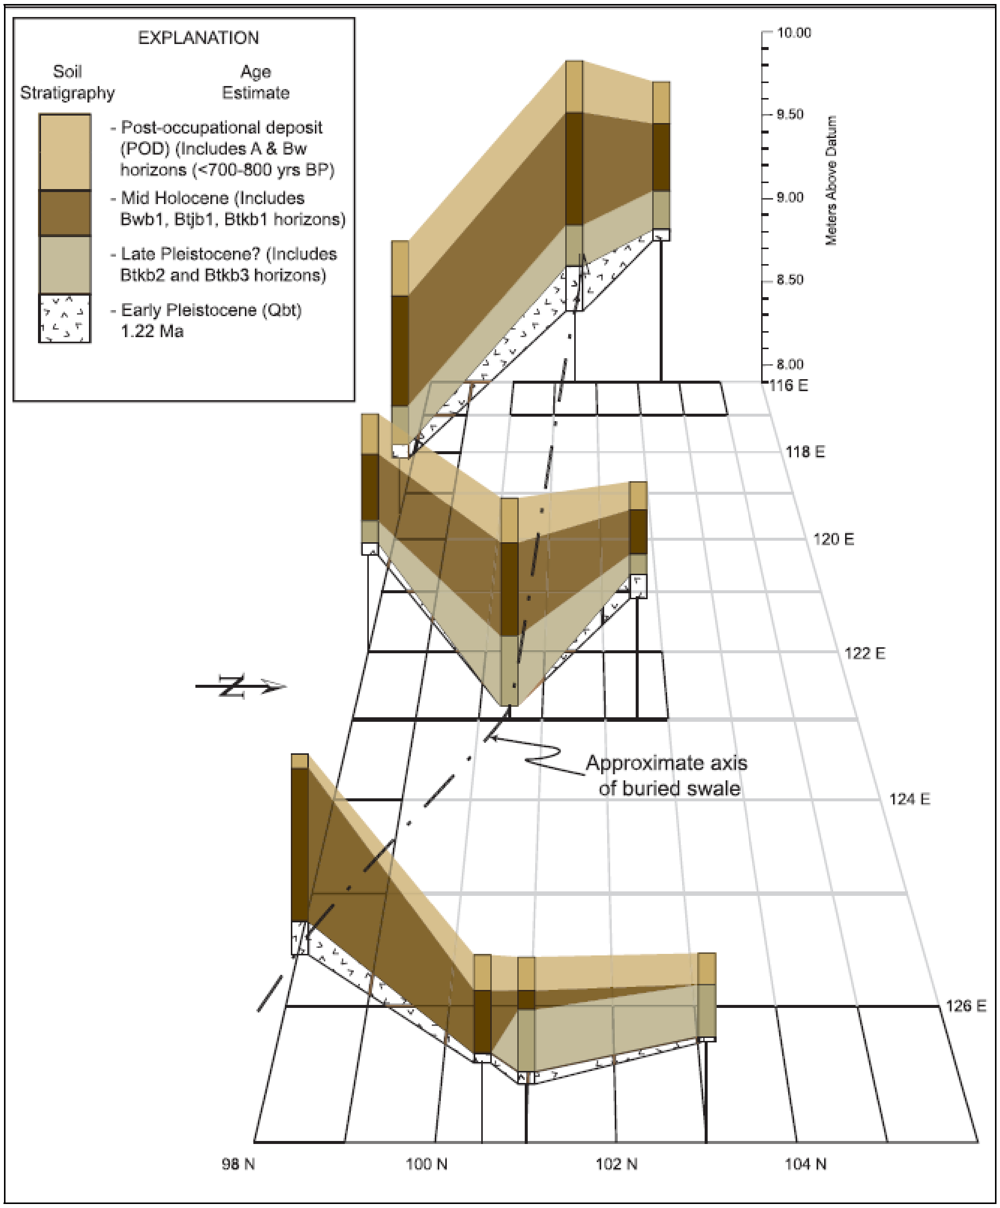

Figure 57.20. LA 135290 soil profile fence diagram east of roomblock (looking west).

Roomblocks were apparently built on top of the b1 soil (either on top of the Bwb1 or Btjb1 horizon) (Figure 57.18). Soils formed in and surrounding the roomblock (post-occupational deposit) typically exhibit A-Bw1-Bw2 profiles developed in silty eolian sediment mixed with roomblock-derived colluvium (Figure 57.21, Table L.4, profiles 135290-1 and 2). The A and Bw horizons include a variety of ceramic and lithic artifacts. Eolian or reworked eolian sediment is interpreted to largely comprise the A horizon that partially buries blocks of tuff derived from wall collapses. The different soil components are well-mixed, which indicates extensive bioturbation of the post-occupational soil by burrowing and other processes.

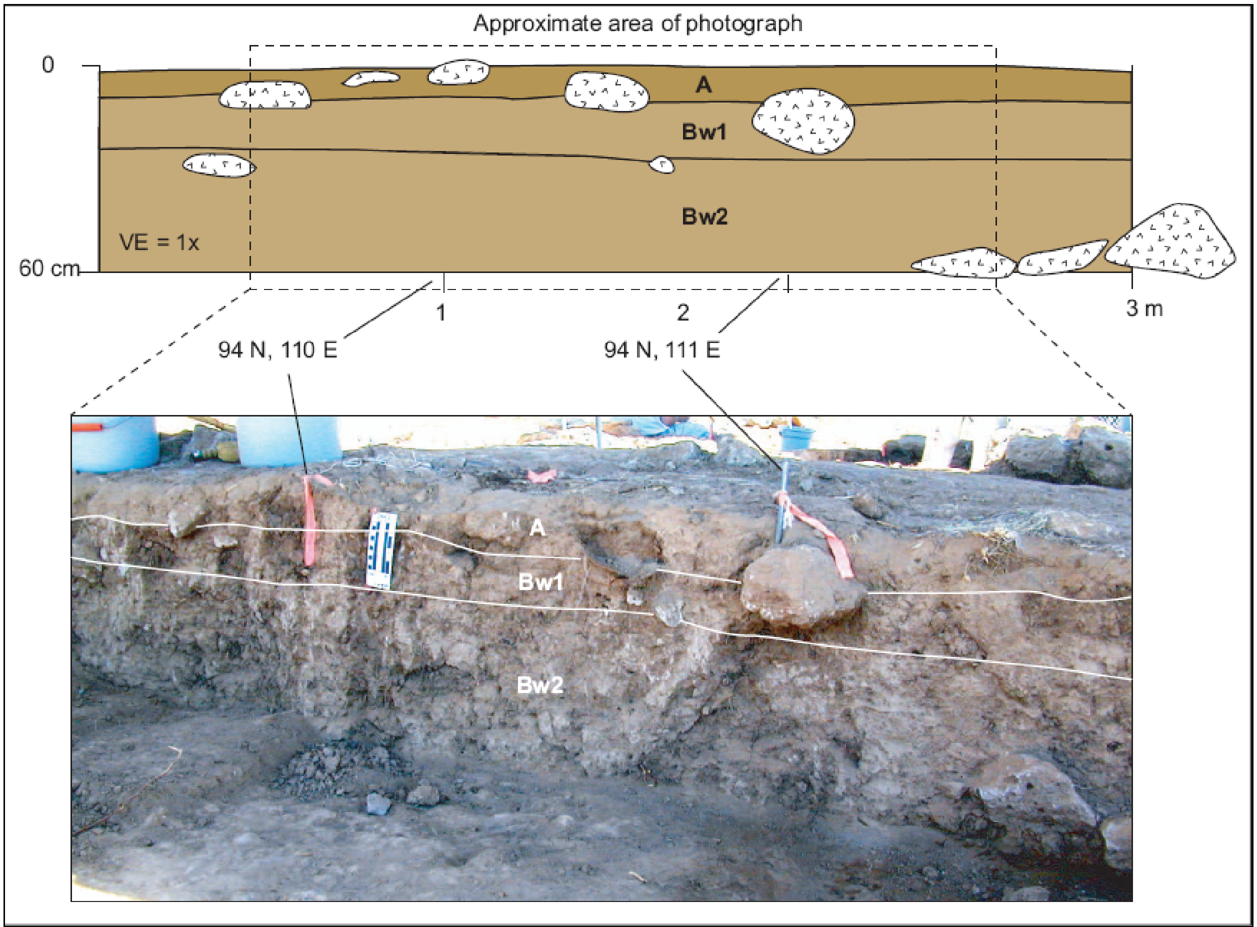

Figure 57.21. Photograph and sketch through the LA 135290 roomblock showing soil developed in the roomblock fill.

The presence of pockets of reddened (7.5YR) soil with minor gravel immediately underneath the roomblock floor (e.g., 135290-7, 135290-8, and 135290-9; Table L.4) suggests that the roomblock is underlain by imported fill at some locations. At locations 135290-7 and 135290-9, the 7.5YR soil immediately underneath the roomblock floor overlies a less reddened Bwb1 horizon, suggesting that an older, more reddened soil was used as fill material. The slight increase in gravel percentage in the Bw versus the Bwb1 horizon at 135290-7 suggests that some gravel was also utilized in the fill material, possibly picked up from the mesa edge, or that the soil used for the fill contained more gravel than the original soil at the site. The thickness of the fill below the roomblock floor in the three soil profiles where the fill material was observed ranges from 11 to 14 cm.

Total thickness of post-occupational deposits in the vicinity of the roomblocks ranges from 40 to 70 cm (Figure 57.22). The colluvial mound surrounding the roomblock (defined by the location of the 20-cm isopach) extends approximately 10 to 12 m east-southeast and approximately 4 m west and north of the roomblock (Figure 57.22), illustrating the transport of roomblock colluvium to the east-southeast by slopewash processes. Outside of the colluvial mound surrounding the roomblocks, post-occupational soil thickness ranges from 5 to 10 cm or more (Figure 57.22), to 16 cm on the south side of the mesa top near the LA 139418 grid garden (see profile 139418-4, Table L.4). Non-cultural sediments post-dating the Ancestral Puebloan sites within the Airport Tract appear to be primarily eolian in origin, are up to 20 cm thick, and likely represent at least two separate eolian depositional events (discussed below). The thicker post-occupational deposits inside the roomblocks than outside is probably due to a combination of enhanced eolian deposition in the roomblock, erosion of roomblock walls, and contributions to the soil from adobe at the site.

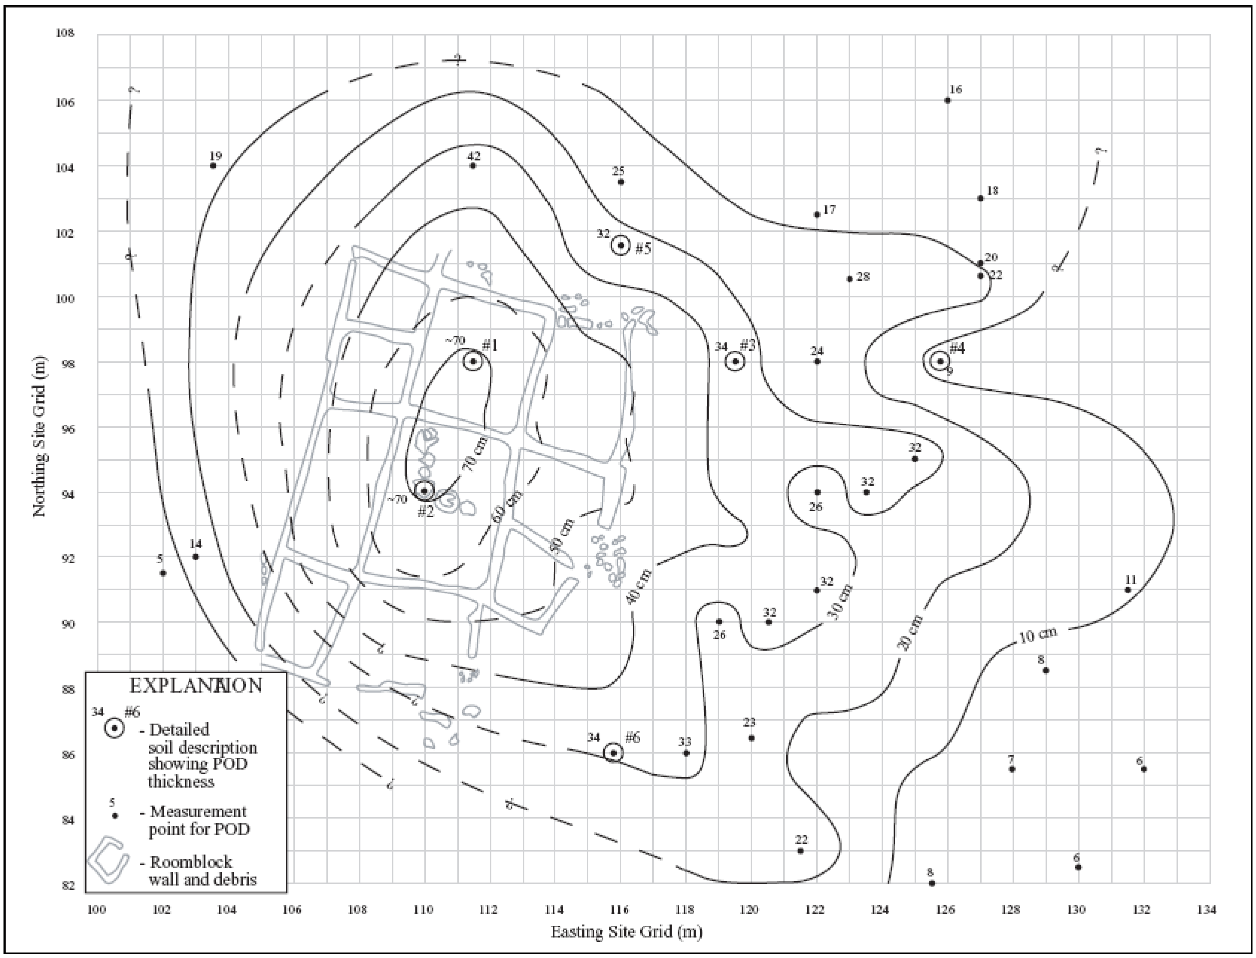

Figure 57.22. Isopach map showing thickness of post-occupation deposits at LA 135290.

LA 139418 (Grid Garden)

LA 139418 consists of a grid garden on the mesa top in an area of stripped Pleistocene soils overlain by thin, weakly developed soils inferred to be less than 600 to 700 years old (Figure 57.23). Depth to Bandelier Tuff bedrock, observed 15 m east of the grid garden, was less than 1 m. The grid garden is located on a gently southeast-sloping area of the mesa that affords minimal surface runoff to the site.

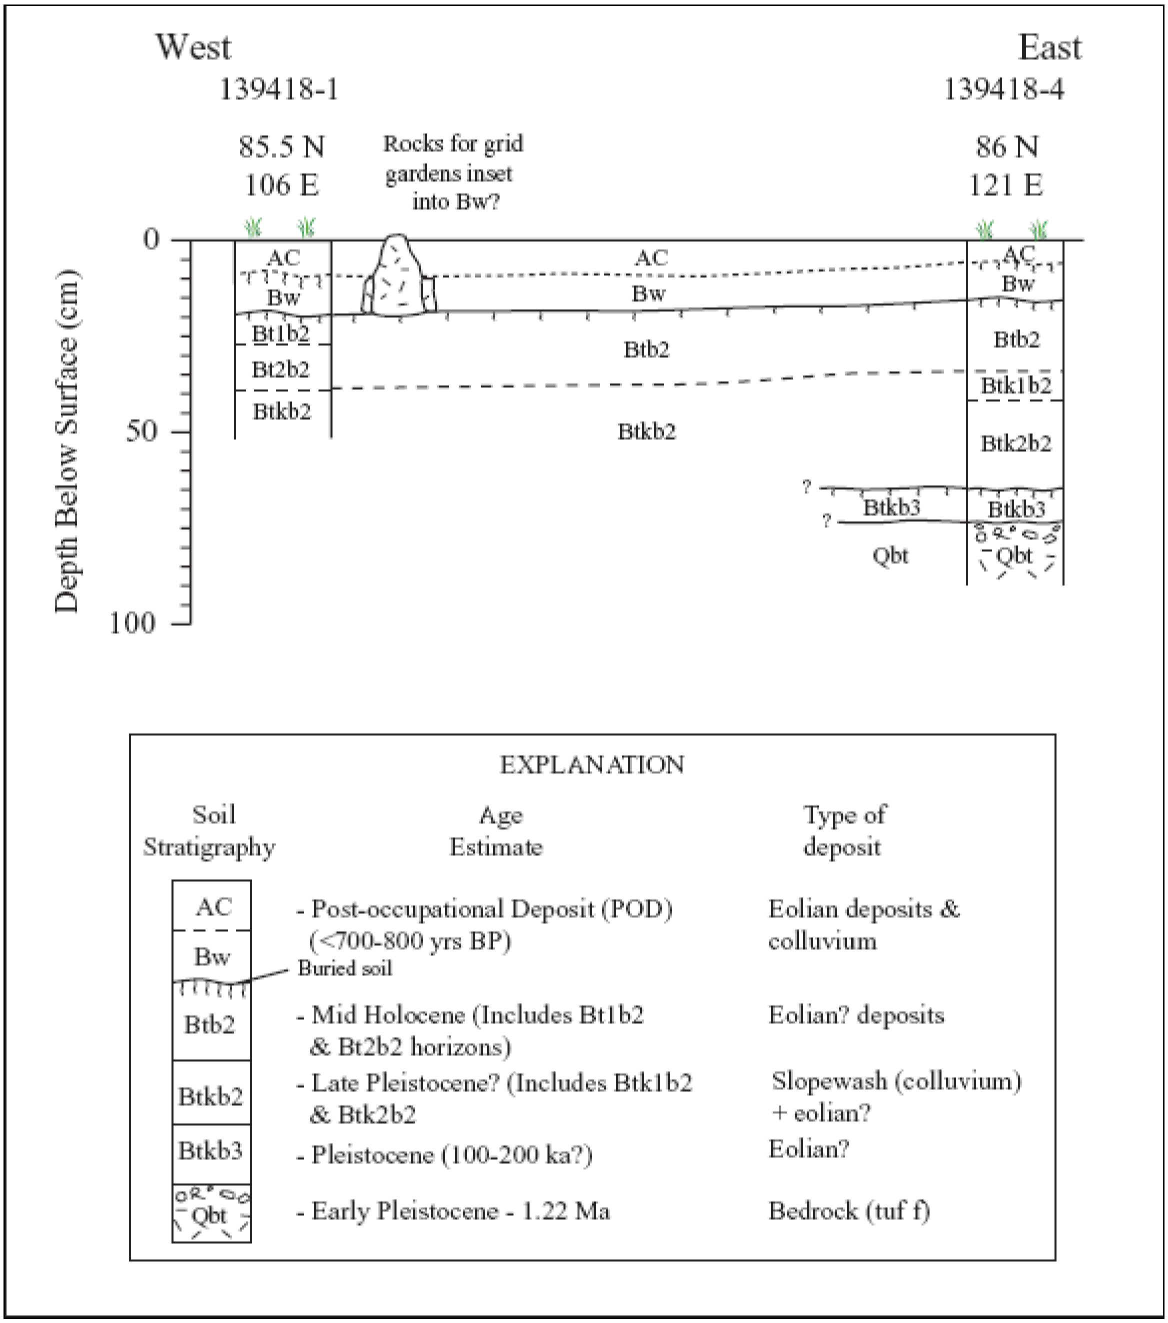

Figure 57.23. Schematic cross-section showing soil stratigraphy at LA 139418.

Two soil profiles (139418-1 and 2) were described within the rock alignments forming the grid garden, one profile (139418-3) was described just outside, slightly downslope, and one profile (139418-4) was described well outside of the rock alignments (Figure 57.24). Rocks forming the grid garden appear to have been set into the Bw horizon, with the smaller rocks that faced larger rocks set to the top of the Bw horizon (Figures 57.23 and 57.24). Soils described inside and outside of the grid garden have similar texture, color, structure, and consistence (Table L.4). AC horizons described inside the grid garden have a slightly greater thickness (1 to 3 cm) than do the AC horizons described outside the grid garden, suggesting that the rock alignments trapped some relatively minimal additional eolian silt, either acting as dust traps or by capturing some overland flow, relative to deposition outside the grid garden.

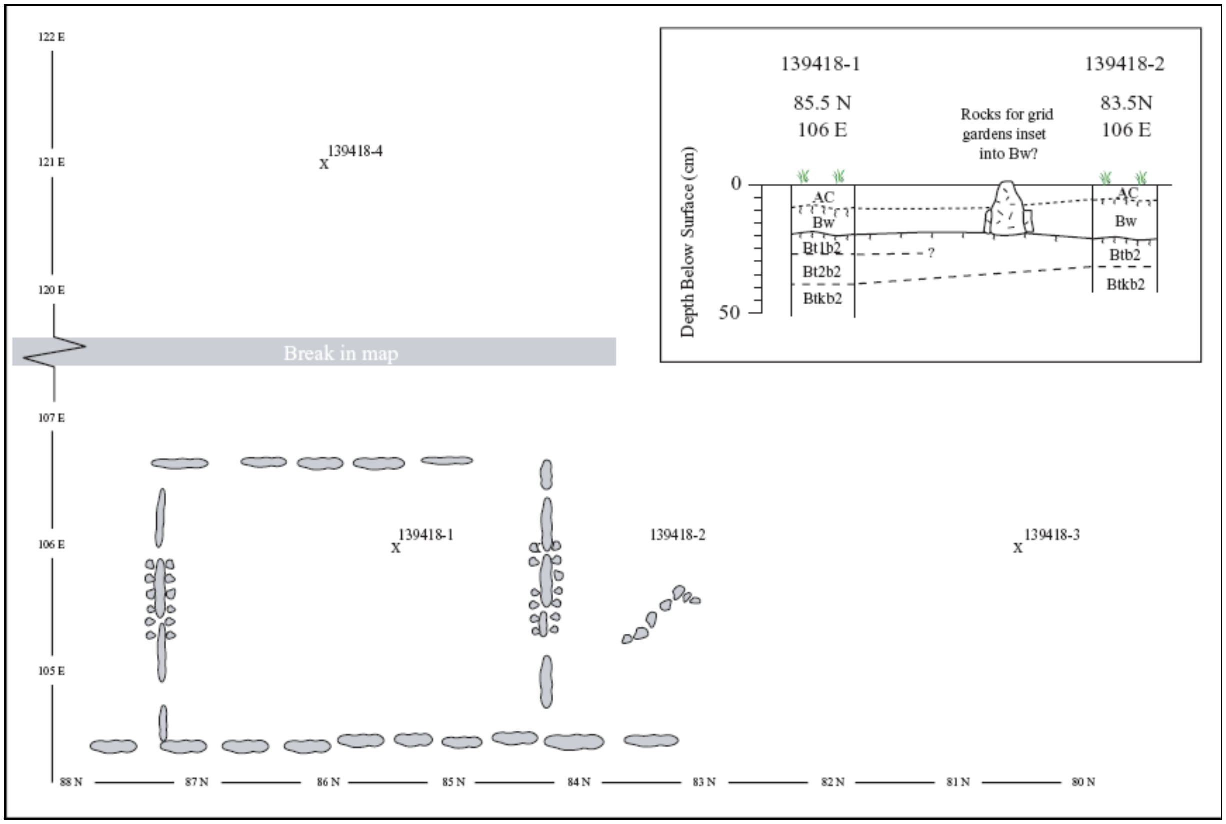

Figure 57.24. Grid garden schematic sketch map and cross-section from LA 139418.

Based on soil characteristics, the AC-Bw horizons at LA 139418 are interpreted to be correlative with post-occupational deposits at LA 135290. It is inferred from the site stratigraphy that approximately 10 cm of sediment was deposited after occupation of the LA 135290 roomblock but before construction of the LA 139418 grid garden. Based on stratigraphic relationships, LA 139418 is a more recent site than is LA 135290 (see Figure 57.17). Soils burying LA 139418 are very weakly developed, have developed only an AC horizon, and apparently lack development of Bw horizons observed in Coalition period soils. The soils and related stratigraphy are therefore consistent with interpretations that LA 139418 is a Classic period feature.

LA 141505 (Fieldhouse)

LA 141505 includes two partially overlapping fieldhouse structures (Rooms 1 and 2) and associated large tuff blocks grouped into Features 2, 3, 4, and 5 on the mesa top east of LA 135290 (Figure 57.25). Soils were described in two test pits at the site. Site stratigraphy is similar to that observed at LA 135290 and includes post-occupational deposits overlying a sequence of buried mid-Holocene and stripped late Pleistocene soils (Figures 57.17 and 57.26; Table L.4). Depth to Bandelier Tuff bedrock, observed below the west wall of the structure, is approximately 1.2 m (Figure 57.26).

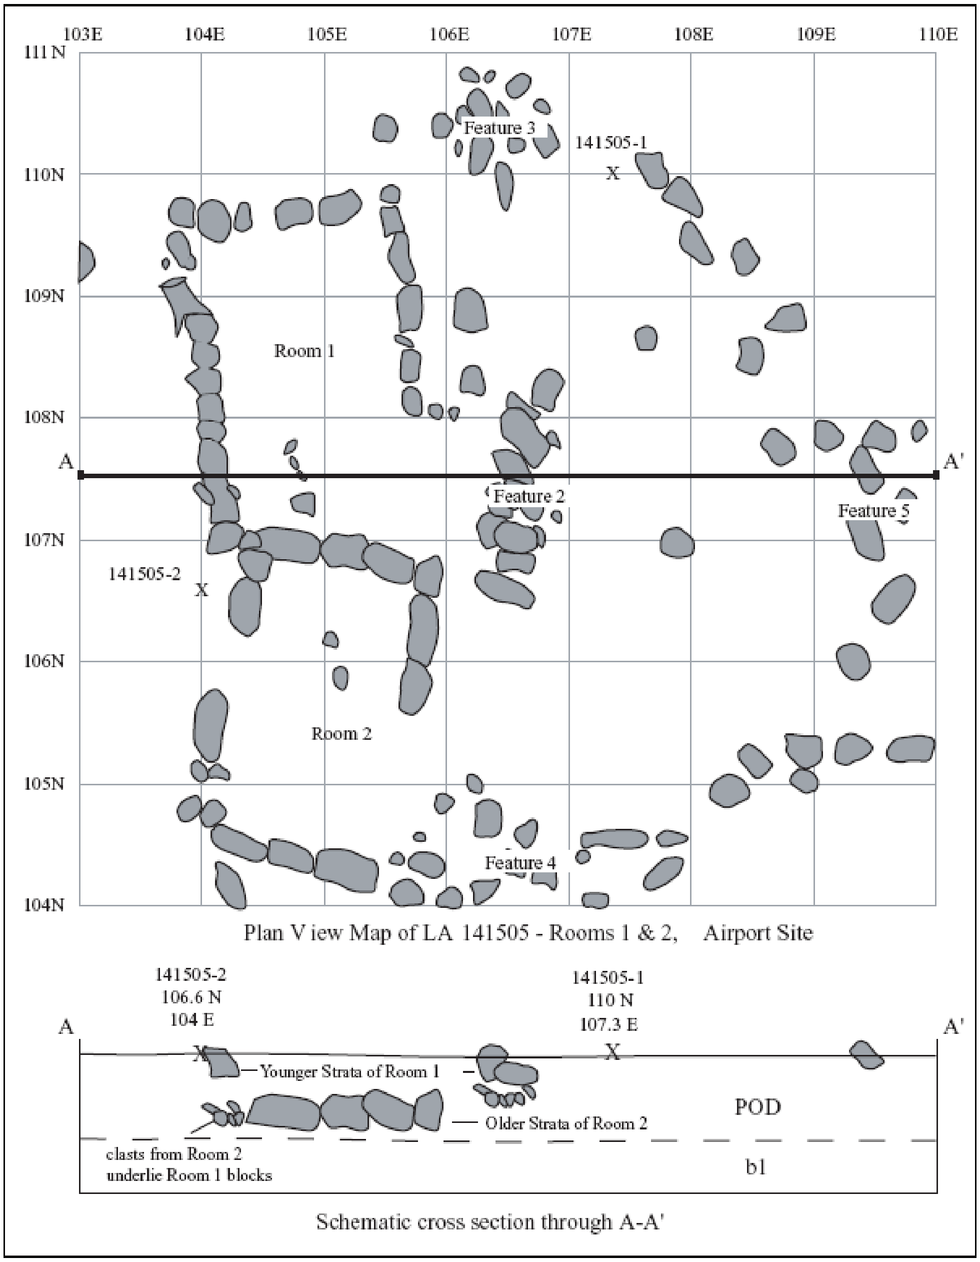

Figure 57.25. Schematic site map and cross-section of LA 141505.

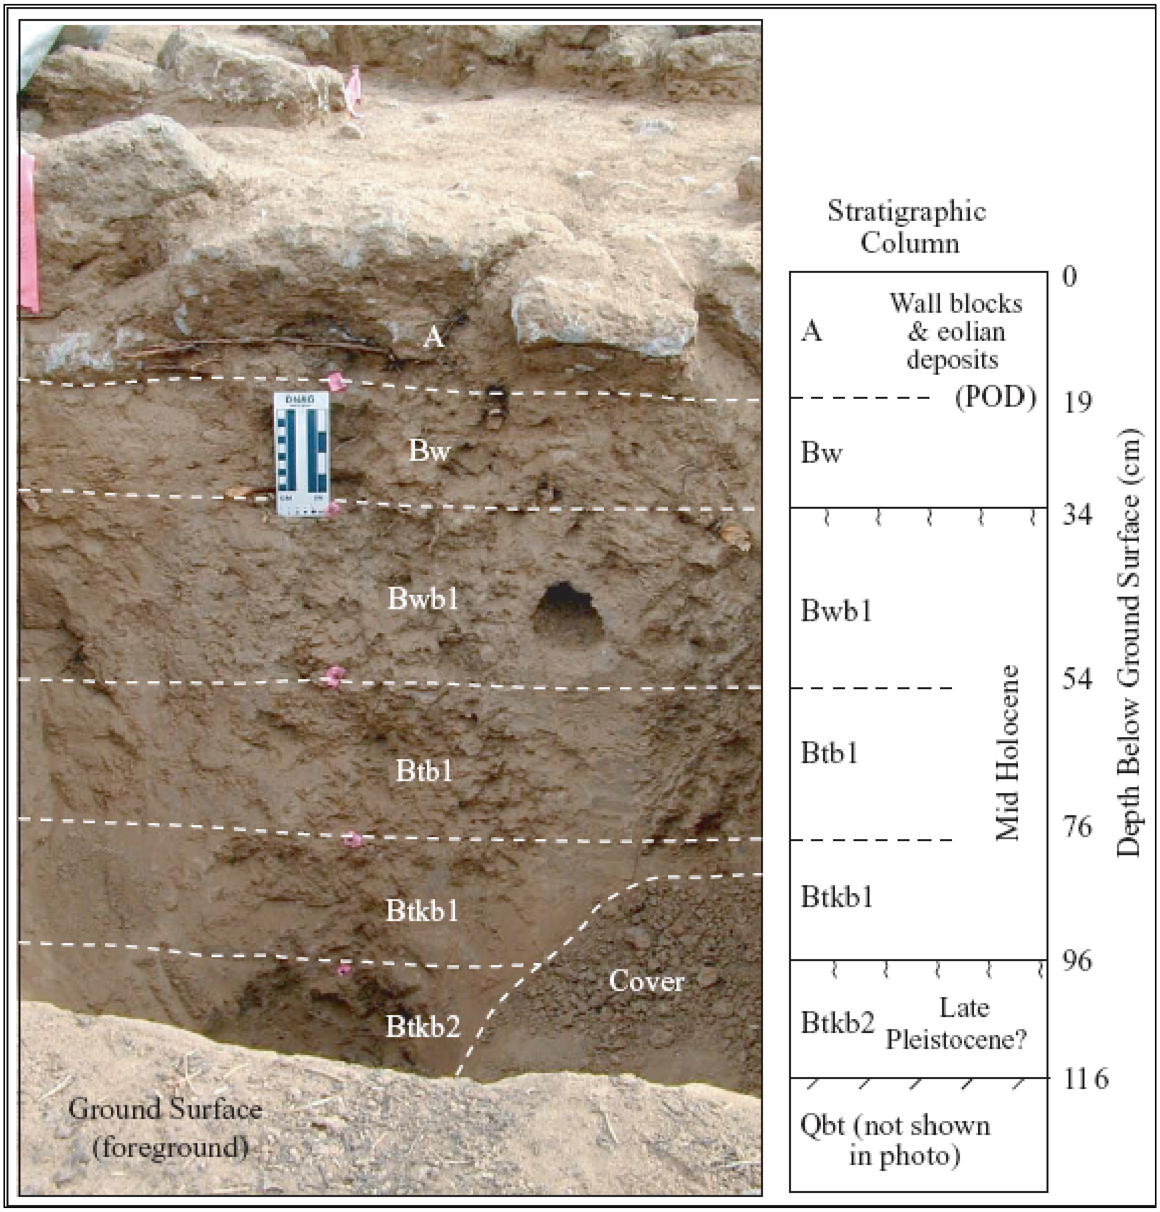

Figure 57.26. Site stratigraphy and wall blocks at LA 141505.

Blocks for the southeastern one-room structure (Room 2) are set into the Bw horizon, whereas blocks for the northwestern one-room structure (Room 1) are set on top of the Bw horizon. Tuff clasts inferred to be derived from Room 2 also lie underneath Room 1 (see Figure 57.25). The soil-stratigraphic relations therefore indicate that Room 2 is older than Room 1. Soil-stratigraphic relationships also indicate that Features 2 through 5 are associated with the later construction of Room 1. In addition, based on their stratigraphic position set into or on top of the Bw horizon, which is inferred to be correlated with post-occupational deposits, the LA 141505 fieldhouses are more recent features than the LA 135290 roomblock (see Figure 57.17). It is inferred from the soil stratigraphy that Room 1 is roughly correlated with the LA 139418 grid garden and that Room 2 may be slightly older than the grid garden. Thin, weakly developed soils burying features at LA 141505, including an A horizon at profile 141505-2 comprising 80 percent to 90 percent tuff blocks with minor eolian sediment, are consistent with a Classic period site.

Airport Tract Summary

A total of four Coalition to Classic period Ancestral Puebloan sites and one Late Archaic dispersed artifact scatter were investigated within the Airport Tract during the 2002 and 2003 field seasons. The sites are situated on a Bandelier Tuff mesa top north of Los Alamos Canyon. Results of the site investigations show that Airport Tract Ancestral Puebloan sites are partially buried, primarily by recent (less than 700- to 800-year-old) eolian deposits and are underlain by less than 1.5 m of Pleistocene and Holocene deposits overlying 1.22 Ma Bandelier Tuff bedrock (see Figure 57.17). The total thickness of Pleistocene deposits ranged from 0.2 to 0.6 m.

The Airport Tract sites are underlain by a sequence of truncated Pleistocene and Holocene soils that are inferred to represent deposition and soil formation followed by erosion in the mid-Pleistocene (buried soil “b3”), the late Pleistocene (buried soil “b2”), and the mid-Holocene (buried soil “b1”) (see Figure 57.17). It is inferred that the mid-Holocene b1 soil is correlated to the cal 4.5 ka b1 soil at EG&G gully. Locally, relatively thick gully fill deposits include an early Holocene stratigraphic record (e.g., the 4-m-thick early Holocene deposit at EG&G gully; see Longmire et al. 1996:49). The thickness of deposits is likely controlled by geomorphic position, with thicker deposits filling mesa top swales and shallow valleys (e.g., LA 135290 and EG&G gully) and stripped surfaces located near the mesa edges or mesa top (e.g., LA 86534 and LA 139418). The presence of mid-Holocene deposits underlying unit Qc2 in the west-central part of the Airport Tract indicates that there is potential for the preservation of buried Archaic sites in this area.

Stratigraphic relationships indicate that LA 141505 and LA 139418 are more recent than LA 135290 and LA 86534. LA 141505 and LA 139418 are constructed on top of the lower section (Bw horizon) of post-Coalition age deposits, which bury LA 135290 and LA 86534 (see Figure 57.17). Soils burying LA 141505 and LA 139418 are very weakly developed, exhibiting thin A or AC horizons but apparently lacking development of Bw horizons observed in Coalition period soils. It is therefore inferred that LA 139418 and LA 141505 are likely Classic period sites. In contrast, Coalition period sites LA 135290 and LA 86534 are built on mid-Holocene to Pleistocene soils, or directly on Bandelier Tuff, and are buried by a thicker soil with an A-Bw profile (Figure 57.17).

It is inferred that most of the recent eolian deposition observed at the Airport Tract sites occurred sometime after the Middle Coalition period but before the Classic period; e.g., during the Late Coalition period (ca. AD 1250 to 1325). This corresponds to "The Great Drought" of AD 1276–1299 and a locally drier period from AD 1250–1255, inferred from tree-ring data, and a major regional event associated with the abandonment of Mesa Verde (Rose et al. 1981). This is consistent with soil stratigraphic relationships observed at LA 12587 that are also indicative of eolian deposition that occurred during the Late Coalition period. Where it has not been eroded, the Late Coalition period eolian deposit is approximately 15 to 20 cm thick. A second, more recent eolian event, occurred after abandonment of the Early Classic (?) period sites, resulting in deposition of an additional 5 to 10 cm of fine-grained sediment across the mesa top since approximately AD 1500. Eolian deposits are thicker inside and next to roomblocks than elsewhere on the mesa, which is due to the greater trapping efficiency at these sites. Animal burrowing also seems to be more active in the abandoned roomblocks, which results in mixing of material at these sites.

Soil-Stratigraphic Correlations with Pajarito Mesa Deposits

Some soil-stratigraphic correlations may be made between surficial deposits on the Airport Tract mesa top and surficial deposits on Pajarito Mesa, located approximately 2.5 mi (4 km) to the southwest (see Figure 3.2, Volume 1). Surficial deposits on Pajarito Mesa were described in exploratory trenches totaling 1340 m in length as part of a paleoseismic hazards investigation (Kolbe et al. 1994; Reneau et al. 1995). Pajarito Mesa soils are formed in a mixture of Bandelier Tuff, post-Bandelier alluvium and pumice, and eolian fine sand and silt (Reneau et al. 1995). The 50-60 ka El Cajete pumice forms a marker bed within Pajarito Mesa soils that is absent in the Airport Tract soils (see Figures 57.17 and 57.27).

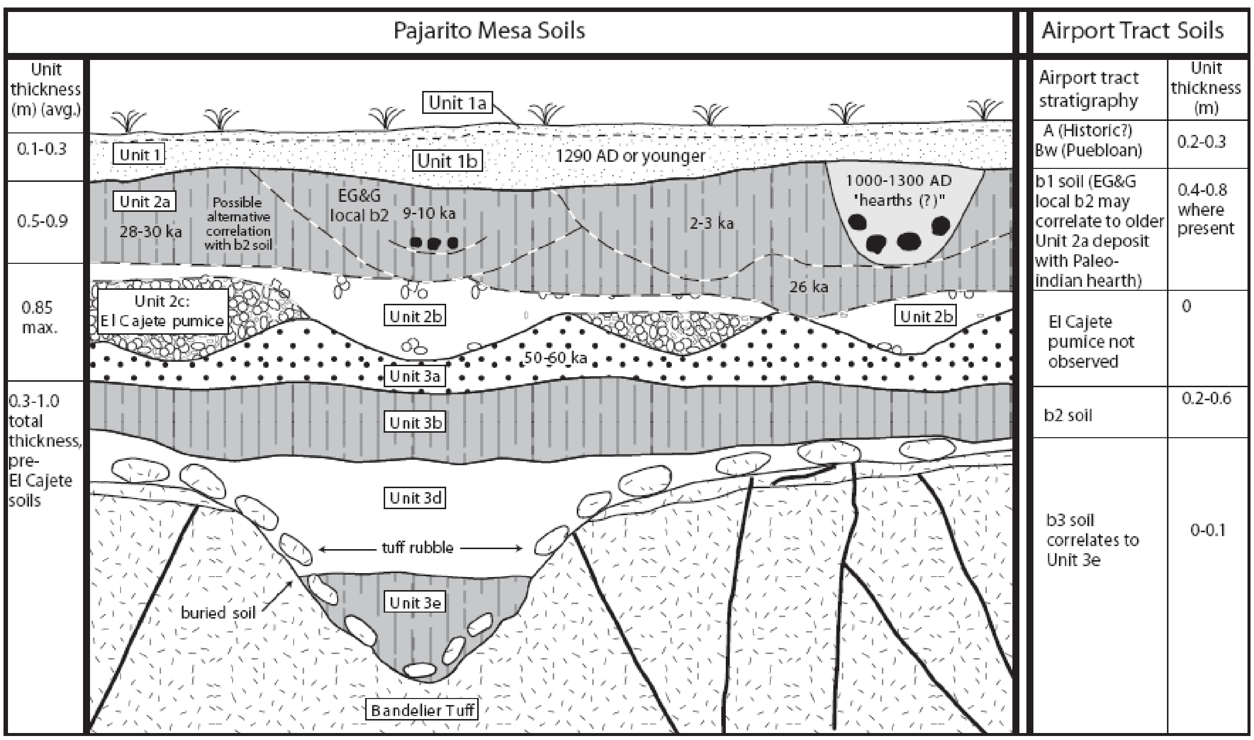

Figure 57.27. Correlation chart showing Pajarito Mesa and Airport Tract stratigraphy.

The Airport Tract late Pleistocene b2 soil is a relatively well-developed soil, although partially eroded, with 7.5YR hue, moderately thick clay films, and Stage I carbonate. The degree of soil development exhibited by the b2 soil, as shown by its color and clay content, is much greater than that observed in the overlying b1 soil and suggests a period of landscape stability and soil development before erosion of the b2 soil. The b1 soil is overlain by a less-than-750-year-old eolian deposit.

The relationships observed in the Airport Tract soils are similar to stratigraphy of Pajarito Mesa units 3b, 2a, and 1 (Reneau et al. 1995). Pajarito Mesa Unit 1 dates to AD 1290 or younger, has a thickness of 0.1 to 0.3 m (Reneau et al. 1995), and is inferred to correlate with the Airport Tract post-Middle Coalition period soils (see Figure 57.27). However, Pajarito Mesa Unit 2a is a composite of deposits dated at 2 to 3 ka, 9 to 10 ka, 26 ka, and 28 to 30 ka in different parts of the trenches (Figure 57.27).

The Airport Tract b1 soil is likely correlated with either the 2 to 3 ka Pajarito Mesa deposit, or is a mid-Holocene deposit not observed or not dated during the Pajarito Mesa investigation. The Airport Tract b2 soil may be correlated with pre-El Cajete Unit 3b, or could be correlated with a Unit 2a Pleistocene or early Holocene deposit. However, unit thickness and soil characteristics are consistent with the interpretation that Airport Tract b1 soil is correlated with a Pajarito Mesa Unit 2a Holocene deposit, and the Airport Tract b2 soil is correlated with Pajarito Mesa pre-El Cajete Unit 3b deposit (Figure 57.27). The early Holocene b2 deposit at EG&G gully may correlate with the Pajarito Mesa Unit 2a 9 to 10 ka deposit. Unit 3b/buried soil b2 and Unit 2a/buried soil b1 include significant components of silt, indicating a common genesis as eolian deposits. The Airport Tract b3 soil and Pajarito Mesa Unit 3e deposit are both characterized by well-developed stripped soils with 5YR to 7.5YR hue formed in part in Bandelier Tuff rubble and preserved in bedrock pockets in the undulating tuff surface and appear to be correlated with one another.

The stratigraphic correlations observed between Pajarito Mesa and the Airport Tract mesa top deposits is consistent with concurrent periods of eolian deposition and erosion in these parts of the Pajarito Plateau since eruption of the Bandelier Tuff. It is significant that the last 750 years have been characterized by net deposition on the crest of both mesas, resulting in the burial and preservation of Ancestral Puebloan and older sites. It is likely that many Pajarito Plateau mesa tops have experienced net deposition over the past 750 years. Previous surveys of Pajarito Plateau archaeological sites, while not explicitly noting net deposition, did note that erosion on the mesa surfaces has been negligible since "pre-Columbian" occupation and that sites are typically buried just below the "sod line" (Steen 1977).

The extensive trenching conducted for the Pajarito Mesa investigation exposed 10 buried cultural sites that had no surface expression (Figure 57.28), including seven Ancestral Puebloan sites (Kolbe et al. 1995; Reneau et al. 1995). Notably, three of the buried sites were inferred hearths that yielded calibrated radiocarbon ages of 8.8 to 9.5 ka (Figure 57.28) that correspond to the Paleoindian period (Vierra et al. 2002). The preservation of latest Holocene and latest Pleistocene/early Holocene eolian deposits on mesa top settings may result in the preservation of Ancestral Puebloan and Paleoindian sites, whereas less extensive preservation of mid-Holocene deposits results in less common preservation of Archaic sites.

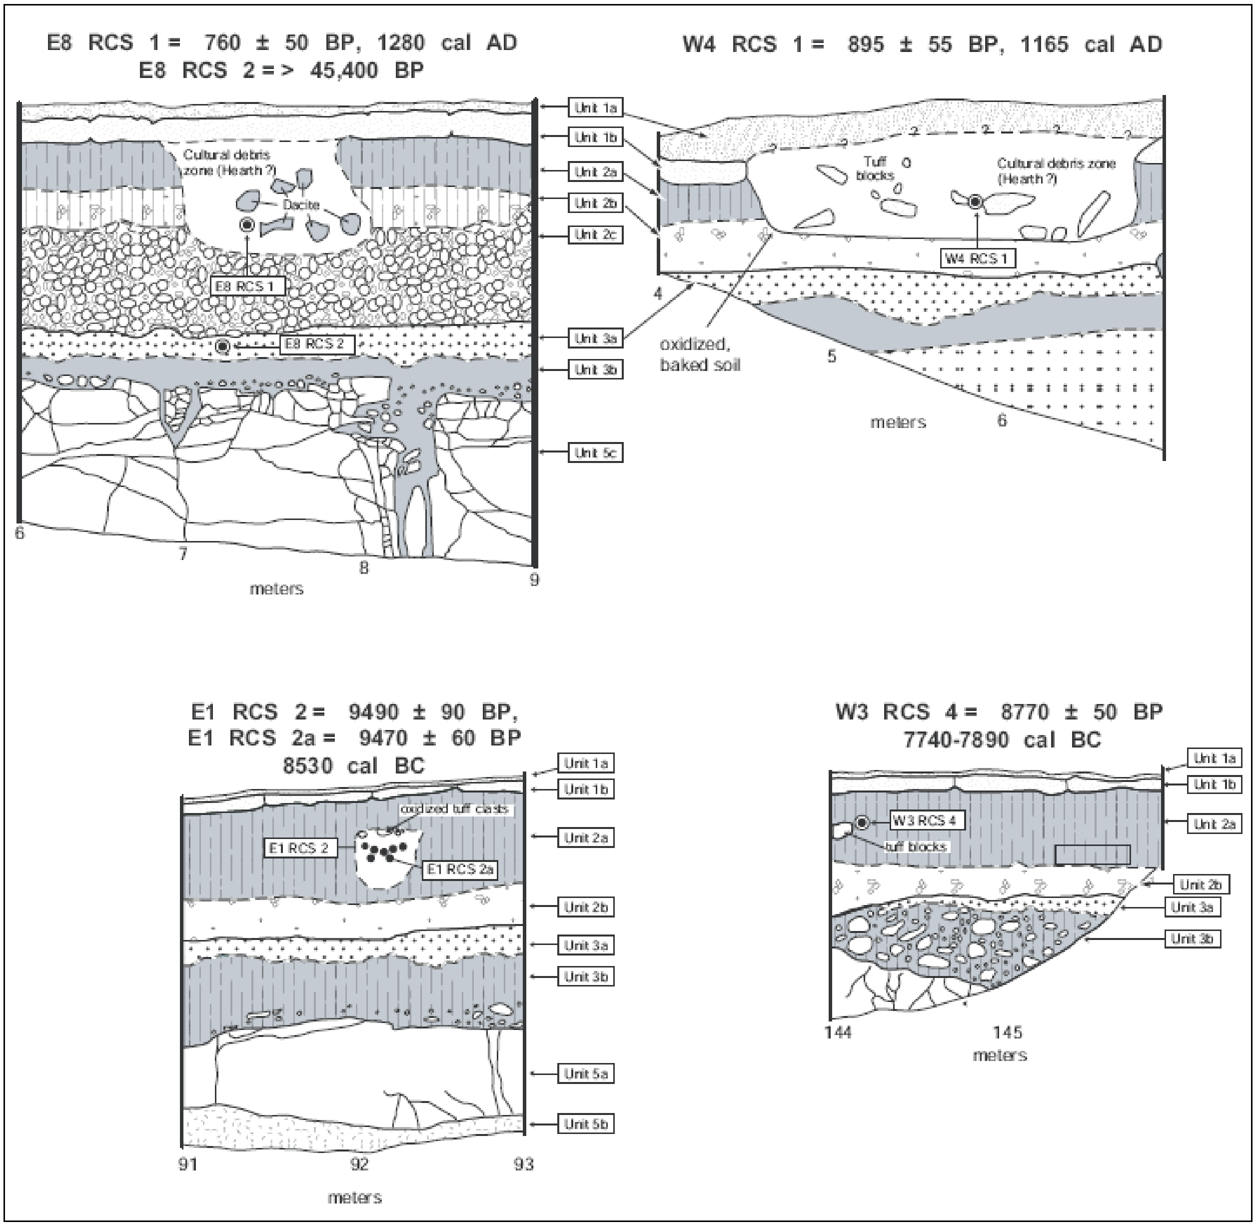

Figure 57.28. Sketches of four archaeological sites exposed in Pajarito Mesa trenches (from Kolbe et al. 1995; Reneau et al. 1995).

RENDIJA TRACT (A-14)

Surficial Geologic Unit

The Rendija Tract is located within the Rendija Canyon watershed and includes part of the active stream channel and adjacent floodplains, tributary drainages, fluvial terraces, colluvial slopes, ridge crests, and mesitas (Figures 57.29 and 57.30).

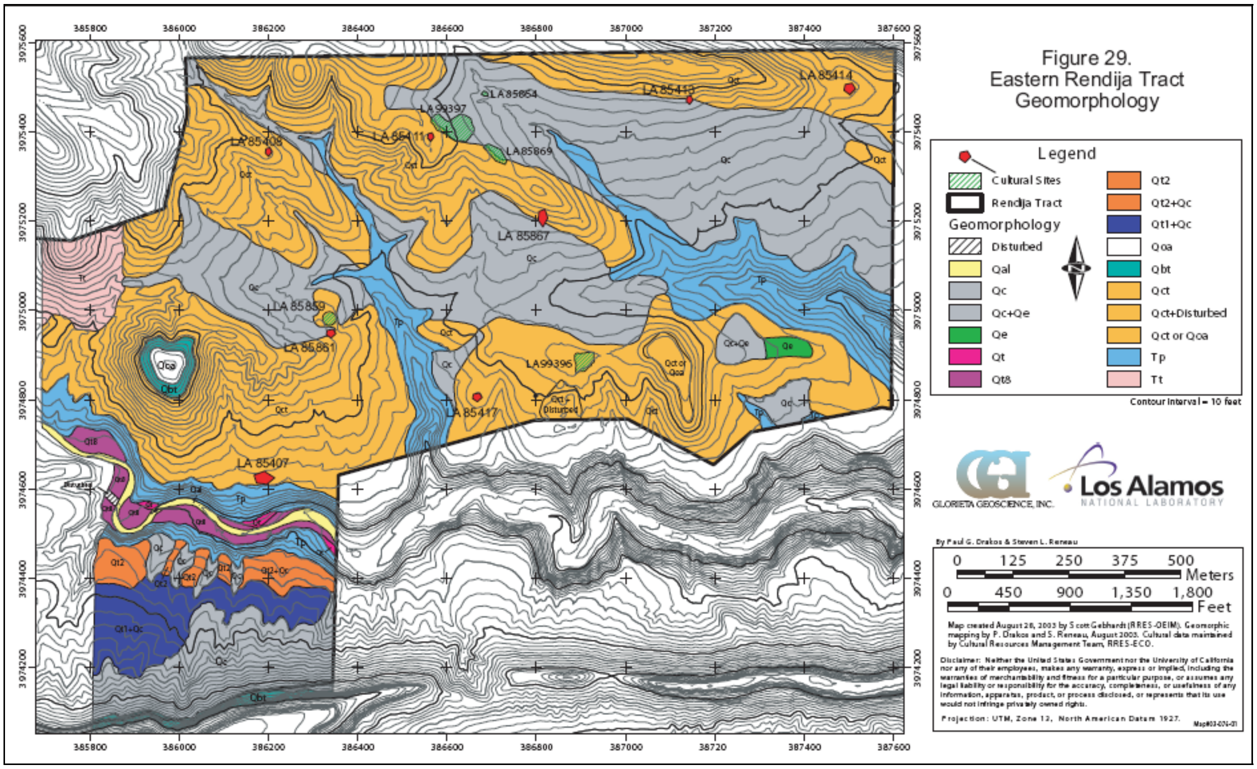

Figure 57.29. Eastern Rendija Tract geomorphology.

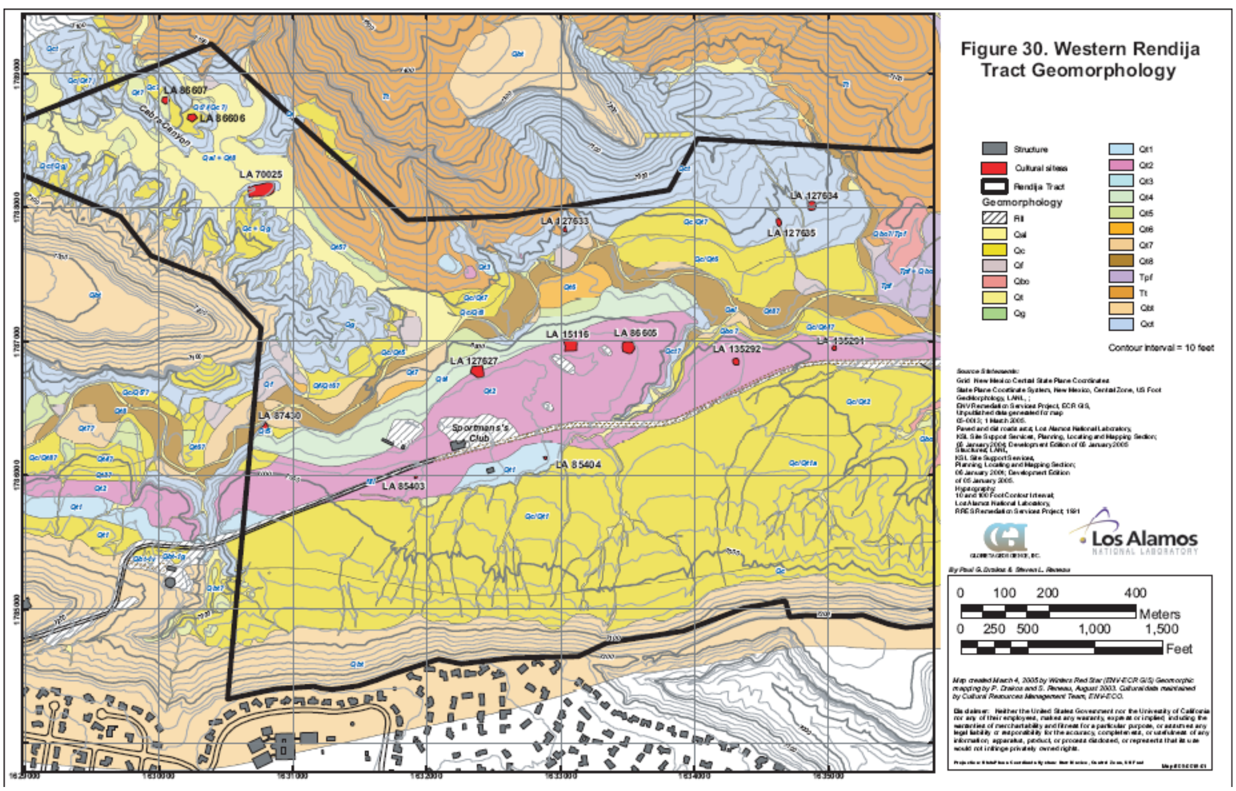

Figure 57.30. Western Rendija Tract geomorphology.

Bedrock units beneath the Rendija Tract include, from oldest to youngest, Tschicoma Formation dacite lavas (unit Tt); Puye Formation (unit Tp), an alluvial fan complex derived from the Tschicoma highlands that includes abundant Tschicoma dacite cobbles; Cerro Toledo interval (unit Qct) pumice beds and dacite-rich alluvium with minor obsidian pebbles; the Tshirege Member of the Bandelier Tuff (unit Qbt), and older alluvium (unit Qoa) (Figure 57.31). Unit Qoa is stratified alluvium deposited on top of the Bandelier Tuff generally before incision of the modern canyons (Kempter and Kelley 2002), possibly within 100,000 years of eruption of Qbt (Reneau and McDonald 1996; Reneau et al. 2002). Unit Qct may include the Guaje Pumice Bed of the Otowi Member, Bandelier Tuff (Qbog).

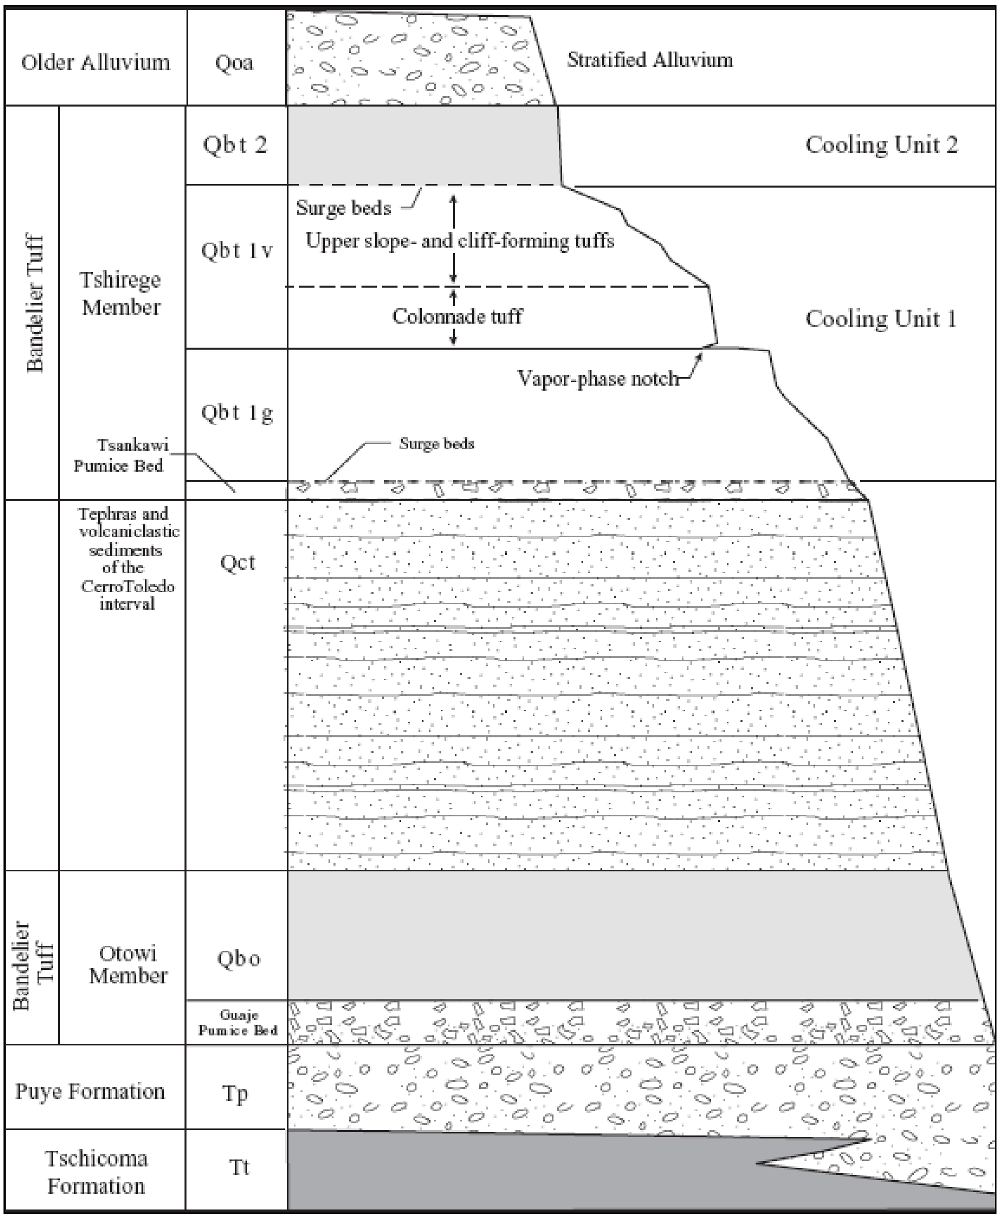

Figure 57.31. Generalized stratigraphic column for the Rendija Canyon area (from Brookton and Reneau 1995).

Bedrock on hillslopes and ridge tops comprising the western half of the tract includes Tschicoma Formation dacite overlain by pumice and alluvium of the Cerro Toledo interval. Tschicoma dacite crops out along a ridge north of the confluence between Rendija and Cabra canyons, forms ridges along the northern tract boundary, and forms the highlands leading up to Guaje Mountain north of the tract (see Figure 57.30; Kempter and Kelley 2002). Puye Formation gravels and the Otowi Member of the Bandelier Tuff crop out in Rendija Canyon and along tributary drainages incised below the Cerro Toledo interval deposits (see Figure 57.12). Bedrock on hillslopes and ridge tops beneath most of the eastern half of the tract is pumice and alluvium of the Cerro Toledo interval. Puye Formation gravels crop out in Rendija Canyon and along tributary drainages incised below the Cerro Toledo interval deposits (see Figure 57.29). Cerro Toledo deposits also crop out in the western half of the tract along the south side of Cabra Canyon, the north side of Cabra Canyon west of the Tschicoma dacite ridge, and along the north side of Rendija Canyon east of the Tschicoma dacite ridge (see Figure 57.30).

The Tshirege Member of the Bandelier Tuff forms the mesa top between Cabra and Rendija canyons west of the Rendija Tract, crops out near the top of an isolated mesa near the western edge of the eastern part of the Rendija Tract, and crops out along the base of the mesa escarpment along the southern boundary of the tract (see Figures 57.29 and 57.30). Remnants of unit Qoa are present on top of the isolated Bandelier Tuff mesa and may cap other ridges in the tract but could not be unequivocally identified. Large parts of the tract are covered by locally derived colluvial or slopewash deposits of a variety of ages. Fluvial terraces are locally preserved near the canyon bottom and are inset into, or interfinger with, colluvial deposits on north-facing slopes south of the Rendija Canyon drainage (see Figure 57.30).

Rendija Canyon possesses what may be the most extensive and best-preserved set of stream terraces on the Pajarito Plateau, locally including at least five Pleistocene surfaces and four Holocene surfaces (Reneau and McDonald 1996; McDonald et al. 1996). Geologic maps of this area have been prepared by Griggs (1964), Smith et al. (1970), and Kempter and Kelley (2002). The Rendija Canyon terrace sequence was first examined by Gonzalez and Gardner (1990) and later by McDonald et al. (1996), Reneau and McDonald (1996), and Phillips et al. (1998). In this investigation, a 1:3000 scale surficial geologic map was prepared that encompasses the eastern half of the Rendija Tract, focused on units with potential archaeological significance (see Figure 57.29). A detailed surficial geologic map of the western part of the tract was previously prepared by Reneau (Reneau and McDonald 1996:102), and is modified for this investigation in Figure 57.30.

Unit Qal consists of young alluvium in the main stream channel of Rendija Canyon. Sediment sources for Rendija Canyon alluvium include Bandelier Tuff and Cerro Toledo beds that provide sand and pumice and Puye Formation beds and Tschicoma Formation dacite outcrops that provide the majority of the pebble to boulder-size gravel (McDonald et al. 1996).

Unit Qt includes several stream terraces flanking the Rendija Canyon stream channel. Stream terraces are labeled Qt1 through Qt8, from oldest to youngest. The Holocene terraces (Qt5 through Qt8) are typically strath terraces, with 0.5 to 2 m channel deposits overlain by fine-grained floodplain sediments (Reneau and McDonald 1996). Pleistocene terraces (Qt1 through Qt4) are typically overlain by more significant aggradational sequences consisting of 4 to 10 m of gravelly deposits. Terraces are in part overlain by colluvium (unit Qc). The older, higher terraces are more extensively buried by colluvium, and many of the Qt1 terraces are completely buried (see Figures 57.29 and 57.30). A high terrace, Qt2, forms a large, relatively flat surface sloping to the east on which several fieldhouse sites are located (see Figures 57.30 and 57.32). Fieldhouse sites excavated during this field investigation are also located on Qt1, Qt4(?), and Qt5 (Figure 57.32).

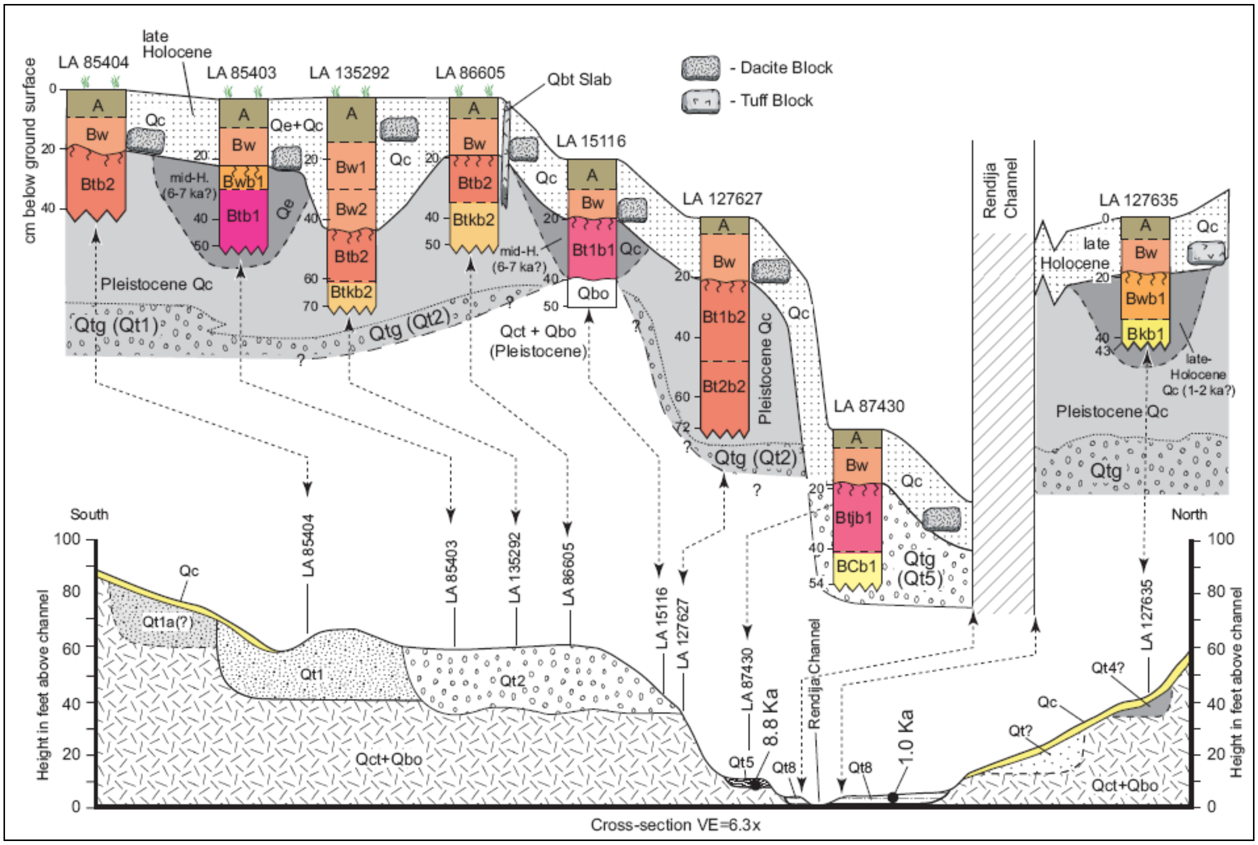

Figure 57.32. Schematic cross-section and soil-stratigraphic correlations between selected Rendija Canyon archaeological sites located on fluvial terraces.

Unit Qc includes a mixture of gravelly and fine-grained (fine to very fine sand and silt) slopewash colluvium deposited by overland flow, and also includes rocky colluvium on hillslopes below mesas and ridge crests. Qc includes valley-filling colluvial deposits that were locally reworked by fluvial processes and eolian deposits and/or locally reworked eolian sediment. Qc includes deposits with a wide age range and typically has buried soils that indicate pauses in deposition, in part accompanied by local erosion. However, at least two relatively widespread episodes of colluvial deposition are inferred from an examination of soil profiles at the Rendija Canyon sites. These depositional events include colluvium of inferred late Pleistocene to middle Holocene age, typically less than 1.5 m thick, overlain by a late Holocene colluvial deposit less than 25 cm thick. Some areas of relatively thin colluvium are mapped as the underlying bedrock or terrace unit. Terraces with a clear geomorphic expression are mapped as terrace units, although they are typically overlain by a thin colluvial deposit (Figure 57.32).

Local swale-fill deposits preserve early to middle Holocene colluvial deposits buried by late Holocene deposits that could potentially contain buried Archaic or Paleoindian sites. LA 85859 provides an example of an Archaic site in a locally preserved 7.4 to 6.7 cal ka colluvial deposit (Figure 57.33). The site is preserved in a hillslope swale in an extensively bioturbated deposit with well-developed soil (Bt) horizons (see site description section for a more detailed description of soils and radiocarbon data). Local middle to late Holocene swale-fill deposits are preserved in colluvial deposits overlying fluvial terraces (see Figure 57.30) and at hillslope sites LA 99396 and LA 99397 (Figures 57.34 and 57.35). Relatively thick (greater than 1 m) early to middle Holocene colluvium is locally preserved as gully-fill deposits (Figure 57.35).

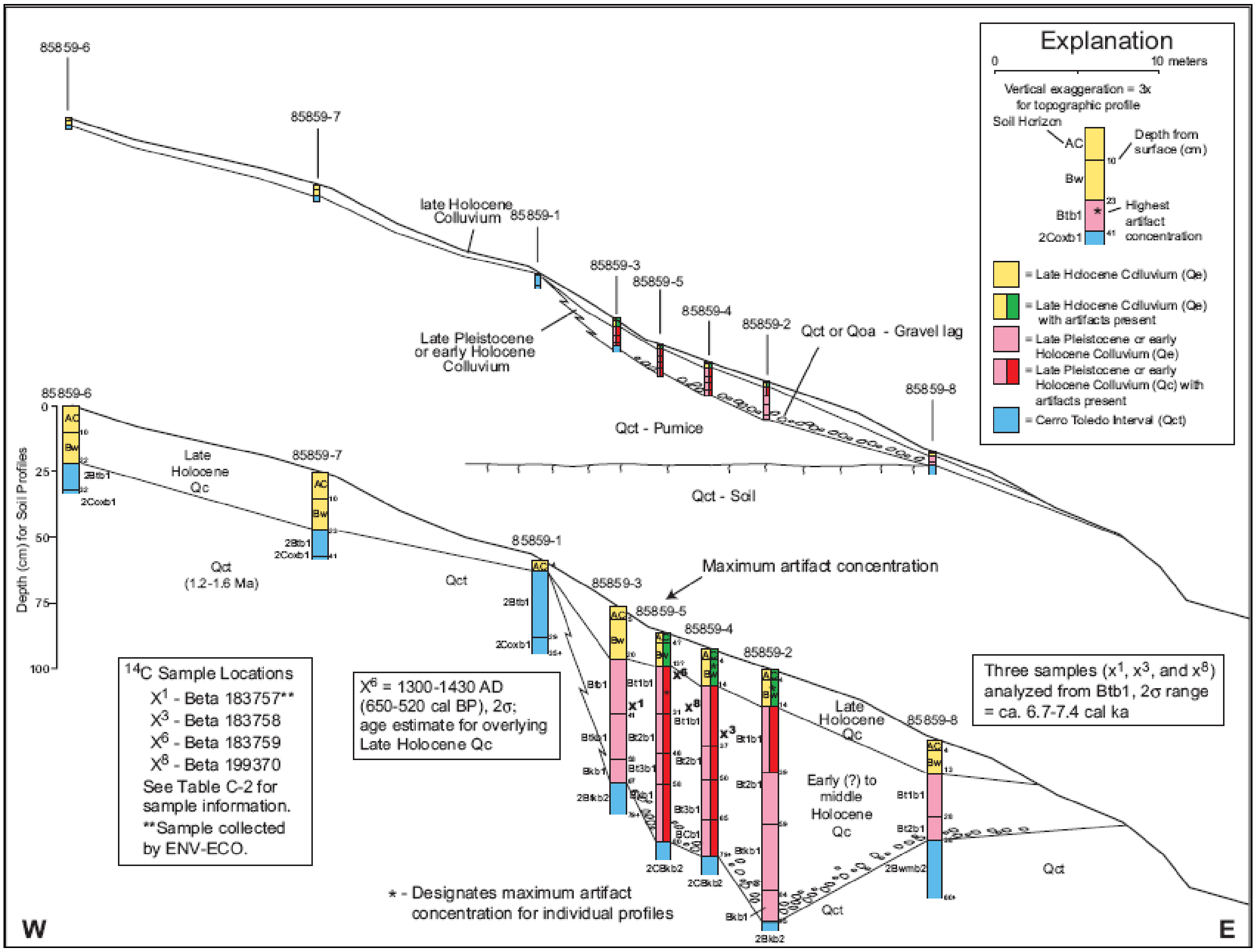

Figure 57.33. Hillslope profile and catena showing artifact distribution, location of charcoal samples, and radiocarbon dates at LA 85859.

Unit Qe is restricted to one small ridge top area near the eastern boundary of the Rendija Tract (see Figure 57.29). Unit Qe is situated east of, and presumably on the leeward side of, a hill capped by Qct gravels or Qoa. Unit Qe appears to be a relatively young deposit and has the potential to preserve buried archaeological sites.

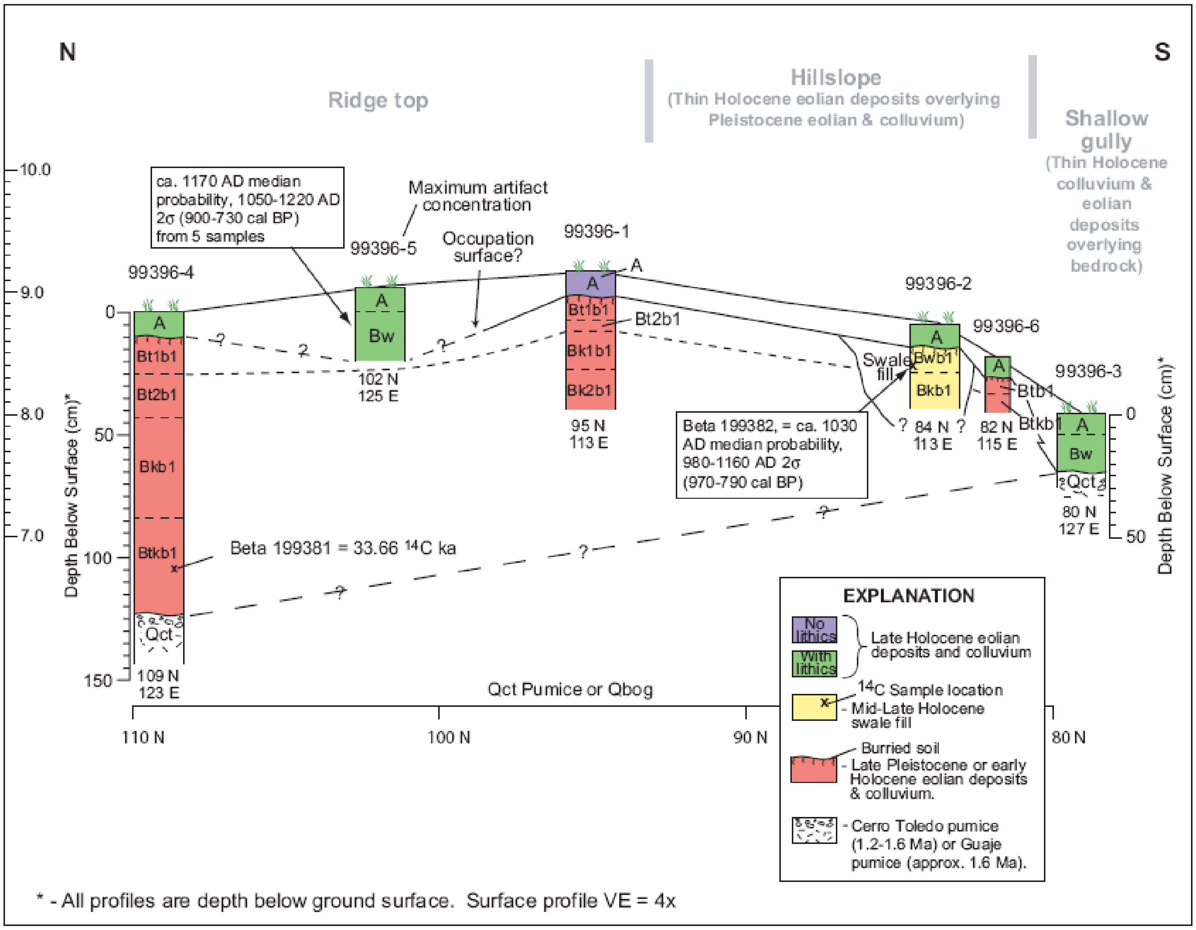

Figure 57.34. LA 99396 stratigraphic correlation, radiocarbon dates, and artifacts.

Age of Colluvial and Eolian Deposits

Age estimates for colluvial and eolian deposits are based on calibrated radiocarbon ages obtained from charcoal samples collected from soils described in Rendija Canyon during this investigation, from stratigraphic relationships with dated cultural materials, and based on comparison with soils described at Coalition and Classic period sites in the Airport and White Rock tracts. Age estimates are also based on comparison with a chronosequence of Pleistocene and Holocene soils developed on a terrace sequence in Rendija Canyon (Reneau and McDonald 1996; McDonald et al. 1996; Phillips et al. 1998). However, parent material for colluvial soils likely includes sediment derived from erosion of older soils that may contain clay-rich horizons. This may lead to more rapid soil development than observed for soils developed in fluvial terrace deposits with lower initial clay contents.

The age of latest Holocene (post-Coalition period) Qc at hillslope sites is constrained by two, statistically indistinguishable radiocarbon dates from charcoal collected at LA 85859 and LA 99397. A charcoal sample from the base of the Bw horizon at LA 99397 yielded an age of 530±40 BP (Beta-199385) and a date of cal AD 1406 with a two-sigma date range of cal AD

1312–1359, and a charcoal sample from the top to the Bt1b1 horizon 3 cm below the base of the Bw horizon at LA 85859 yielded an age of 570±40 BP (Beta-183759) and a date of cal AD 1353 with a two-sigma date range of cal AD 1299–1429 (Table M.2; calibrated ages for all samples discussed in this report from CALIB 5.01, Stuiver et al. 2005). These two radiocarbon dates from charcoal within the soil profiles at different sites suggest the same Rendija Canyon fire event, with a mean probability of AD 1397 with a two-sigma date range of cal AD 1314–1432 and indicate a similar maximum age constraint for the post-Coalition period Qc.

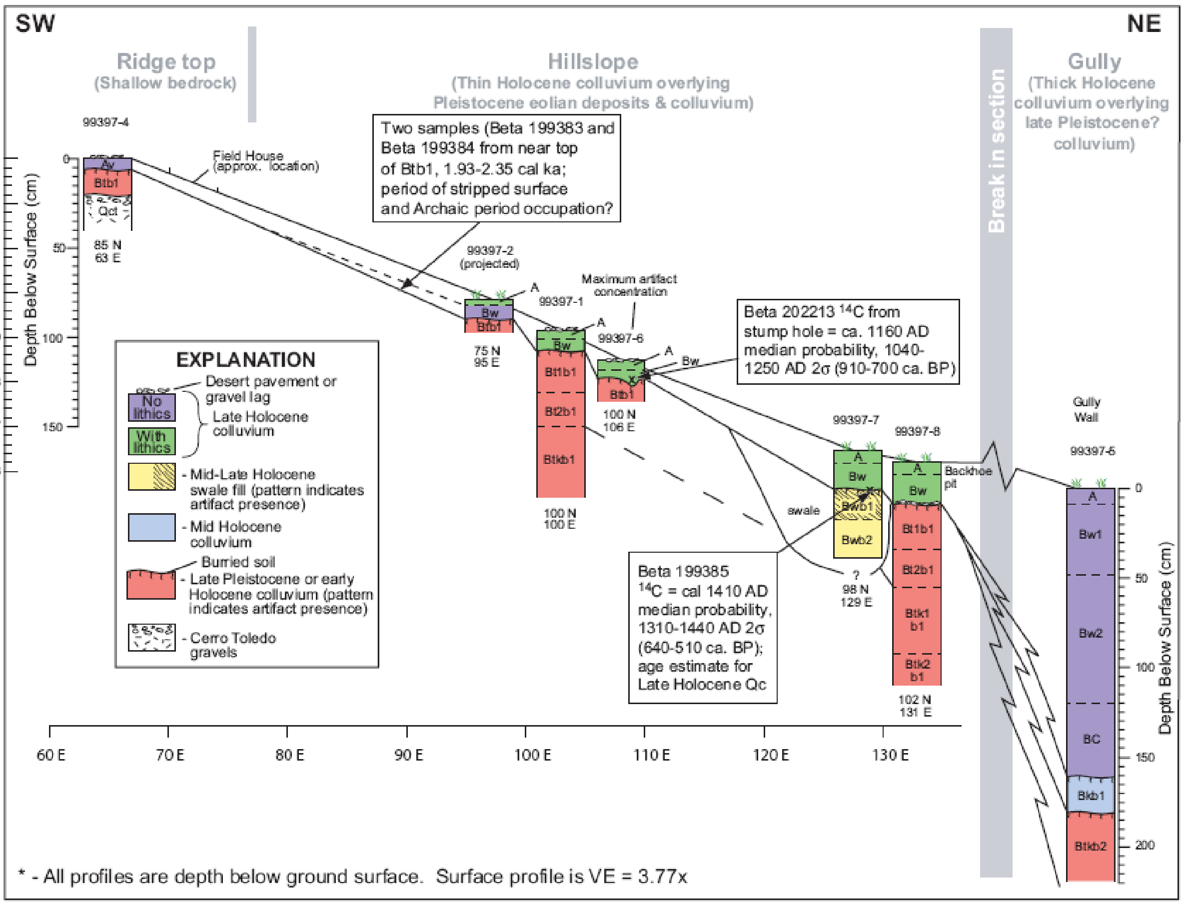

Figure 57.35. LA 99397 stratigraphic correlation, radiocarbon dates, and artifacts.

The age of middle to late Holocene swale fill deposits underlying the younger than cal AD 1400 Qc is constrained by one radiocarbon date from charcoal collected at LA 99396 and by two radiocarbon dates from charcoal collected at LA 99397. A sample collected from the Bwb1 horizon at 99396-2 (Figure 57.34) yielded an age of 1000±40 BP (Beta-199385) and a date of cal AD 1032 with a two-sigma date range of cal AD 975–1155. This provides a minimum age for the Bwb1 soil and the late Holocene swale fill deposits at LA 99396. Two charcoal samples were collected from near the top of the Btb1 horizon at LA 99397. One sample yielded an age of 2110±60 BP (Beta-199383) and a date of cal 2090 BP with a two-sigma date range of cal 1933–2307 BP. A second sample yielded an age of 2280±40 BP (Beta-199384) and a date of cal 2263 BP with a two-sigma date range of cal 2157–2352 BP (Table M.2). These ages are similar but statistically different and are interpreted to date the age of the stripped surface that included the site occupation at LA 99397. The late Holocene swale fill deposit is either contemporaneous or post-dates the age of the stripped surface. Soil description data are interpreted to indicate that the middle to late Holocene swale fill deposits at LA 99396 and LA 99397 are correlative deposits. Therefore, the age of the late Holocene swale fill deposit at LA 99396 and LA 99397 is ca 1 to 2 ka. Based on soil correlations, the middle to late Holocene colluvial/swale fill deposit underlying LA 127635 (Figure 57.32) is likely a correlative 1 to 2 ka deposit.

The colluvial deposit at LA 85859 contained numerous discrete but small charcoal fragments. Dates were obtained from three samples from the Btb1 horizon that yielded the following ages: 6010±40 BP (Beta-183757) and a date of cal 6851 BP with a two-sigma date range of cal 6745–6948 BP; 6310±50 BP (Beta-183758) and a date of cal 7238 BP with a two-sigma date range of cal 7031–7416 BP; and 6140±40 BP (Beta-199370) and a date of cal 7047 BP with a two-sigma date range of cal 6931–7163 BP (Figure 57.33; Table M.2). The ages of these three samples are statistically different, suggesting a period of colluvial aggradation from ca 6.7 to 7.4 ka that included site occupation. Soil characteristics include 7.5YR color, many moderately thick clay films as bridges, colloidal stains, pore fillings, and on ped faces, and maximum Stage II- carbonate (see site description section). Based on soil correlations, the swale fill (?) deposits underlying LA 85403 and LA 15116 (see Figure 57.32) are likely correlative early to middle Holocene deposits.

Age estimates for underlying Pleistocene colluvial and eolian deposits is provided by one radiocarbon date from charcoal collected from an eolian deposit at LA 99396 and by comparison with the Rendija Canyon soil chronosequence. A sample collected from the Btkb1 horizon at 99396-4 (see Figure 57.34) yielded an age of 33,660±320 BP (Beta-199381) that is beyond the range of calibration. Soil characteristics include 7.5YR color, common to many thin clay films as bridges and on ped faces, and maximum Stage II- carbonate (see site description section). Although less-well-developed than soils described at LA 85859, the degree of soil development observed in the 99396-4 b1 soil is similar to that observed in late Pleistocene soils previously described in Rendija Canyon (McDonald et al. 1996; Phillips et al. 1998) and is consistent with the development of Stage II carbonate in warm to temperate semiarid locations in late Pleistocene soils (Machette 1985). This inferred late Pleistocene colluvial soil exhibits much better soil development than the mid Holocene (5.3 to 7.0 ka) Rendija Canyon Qt6 soil, which has 64- to 99-cm-thick Bw horizons, but lacks development of Bt horizons. Incipient Btj horizon development is observed in the early Holocene (8.8 ka) Qt5 soil described at LA 87430, which exhibited 10YR color and few thin clay bridges and pore fillings (Figure 57.32; see site description section for soil description).

The Btb1 and Btkb1 soils described at LA 85859 and LA 99396 exhibit similar field soil properties including 7.5YR color, thin to moderately thick clay films, strong soil structure, and maximum Stage II- carbonate. As discussed above, based on comparison with numerous other soil profiles in the area, these soil properties are typically associated with late Pleistocene soils. However, radiocarbon dates indicate that only the b1 soil at LA 99396 is a late Pleistocene (33.7 ka) soil, whereas the soil at LA 85859 is middle to early Holocene (6.7 to 7.4 ka) soil. The unusually rapid soil formation (based on comparison with other Pajarito Plateau soils for which age control is available) is likely due to site-specific geomorphic factors including erosion of older, clay-rich soils upslope and deposition of clay-rich colluvium in a hillslope depression with clay-formation perhaps enhanced on a northeast-facing hillslope.

LA 15116 (Fieldhouse)

LA 15116 consists of a fieldhouse situated on a north-facing slope below the Qt2 terrace surface (see Figure 57.30). The structure measures approximately 2.5 m north-south by 1.9 m east-west (inside), or 3 m north-south by 2.5 m east-west (outside dimensions). Soils were described in one test pit at the site, located 1 m west of the west side of the fieldhouse. Site stratigraphy consists of an A-Bw soil overlying a buried middle Holocene (?) stripped soil (Btb1 horizon; Figure 57.36, Table L.5). Depth to Otowi tuff (?) bedrock, observed west of the structure, is approximately 0.4 m (Figure 57.36).

Figure 57.36. Photographs showing soil stratigraphy (top) and soil pit next to fieldhouse (bottom), LA 15116.

The fieldhouse was constructed primarily from dacite blocks, with some tuff blocks also utilized. The occupation surface at the site is the top of the Btb1 horizon, and post-occupation colluvial deposits are 20 cm thick at the described profile. Dacite blocks, inferred to be wallfall, were observed in the A and Bw horizons (Figure 57.36). Although intensively burned during the Cerro Grande fire, the site does not show evidence of extensive erosion. Soils burying LA 15116 are relatively weakly developed, but have developed A-Bw horizons. The soils and related stratigraphy are therefore consistent with LA 15116 being a Classic, or possibly a Coalition period, feature, and the site is in relatively good archaeological context.

LA 70025 (Fieldhouse)

LA 70025 consists of a fieldhouse in Cabra Canyon situated on a narrow ridge that forms part of a deeply dissected colluvial slope overlying fluvial terrace or Cerro Toledo gravel. The structure measures approximately 1.8 m by 1.6 m (inside), or 2.2 m by 2 m (outside dimension), situated with the long axis oriented N20°W (Figure 57.37). Soils were described in one test pit at the site, located 2 m west of the west side of the fieldhouse (Figure 57.37; Table L.5). Site stratigraphy consists of an A-Bw1-Bw2 soil overlying a buried middle to late Holocene Btjb1 horizon (Figure 57.37; Table L.5).

The fieldhouse was constructed primarily from tuff blocks, with some dacite blocks also utilized. The occupation surface at the site is the top of the Btjb1 horizon (Figure 57.37). The site is situated in an erosional setting, with the potential for transport of artifacts from the ridgetop to the hillslope below. Soils burying the LA 70025 occupation surface outside the structure are relatively thick in a local low area on the ridge, 29 cm thick at the described soil profile, and include the development of Bw1 and Bw2 horizons. Soils inside the structure on a local topographic high are relatively thin and likely indicate erosion of the site. The soils data and related stratigraphy are consistent with a Coalition or Early Classic period age for LA 70025. The site is in relatively poor archaeological context.

LA 85403 (Fieldhouse)

LA 85403 consists of a fieldhouse situated on a relatively flat Qt2 terrace surface (see Figure 57.30). The structure measures approximately 2.1 m by 1.8 m (inside), or 2.5 m north-south by 2.1 m east-west (outside dimensions), and contains an opening facing east (Figures 57.38 and 57.39). Soils were described in two test pits at the site. A complete soil profile was described 1.4 m west of the west wall of the fieldhouse, and a partial profile was described below the west wall (Figures 57.38 and 57.39; Table L.5). Site stratigraphy consists of an A-Bw soil overlying a buried middle Holocene Bwb1-Btb1 soil (Figure 57.39; Table L.5).

The fieldhouse was constructed primarily from dacite slabs and blocks, with a minor component of tuff blocks also utilized. The wall blocks were partially buried by a fine-grained eolian deposit and were observed to protrude up to 5 to 10 cm above present ground surface. Exposed wall blocks were lichen covered. Based on the absence of evidence of significant surface erosion and the observed burial of the site by eolian material, the site appears to be in good archaeological context.

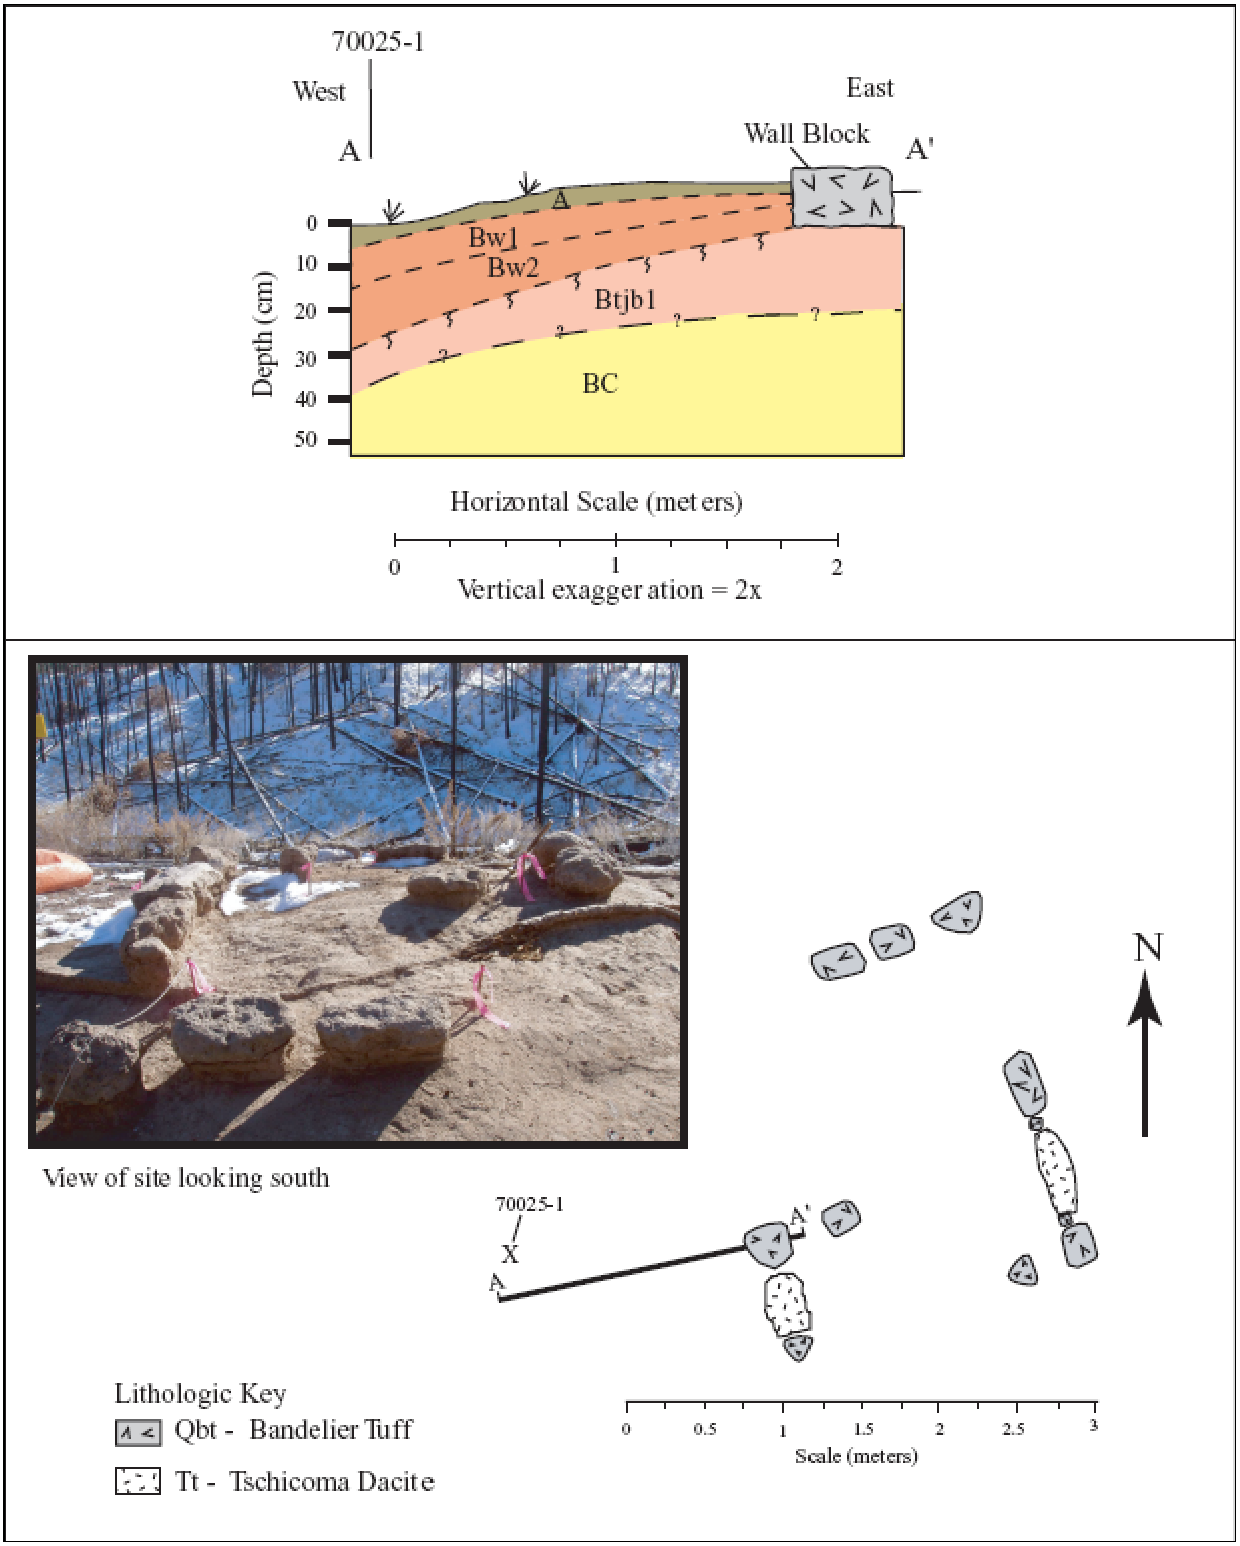

Figure 57.37. Schematic site map, cross-section, and site view looking south, LA 70025.

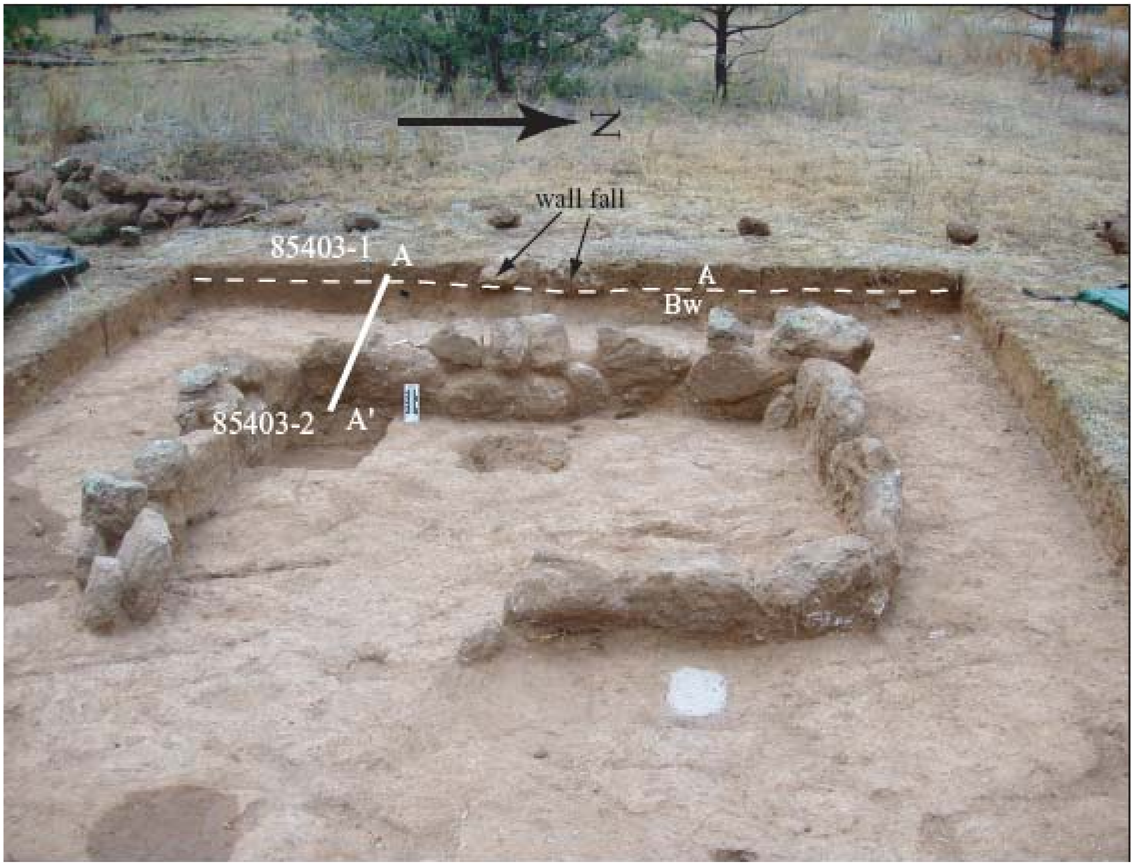

Figure 57.38. Photograph of LA 85403 looking west showing cross-section and soil description locations.

Dacite slabs were set into the Bwb1 horizon and possibly into the Bw horizon (Figures 57.38 and 57.39). Evidence for the actual occupation surface outside the structure was not conclusive, and this surface may have been either the top of the Bwb1 horizon or the top of the Bw horizon. However, the prevalence of wallfall in the A horizon, observed in the excavation wall west of the fieldhouse (Figures 57.38 and 57.39), is evidence that the top of the Bw horizon was the occupation surface. Post-occupation eolian deposition was therefore 9 cm, with the A horizon developing after site abandonment. Based on soil stratigraphy at other sites (Drakos and Reneau 2004), the interpretation that the occupation surface was the top of the Bw horizon is consistent with a Classic period age for the site. A charcoal sample from maize in a prehistoric pit fill at LA 85403 yielded a radiocarbon age of 310±40 BP (Beta-215549) and a date of cal AD 1564 with a two-sigma date range of cal AD 1472–1653 (Table M.2), also indicating a Classic period age for LA 85403.

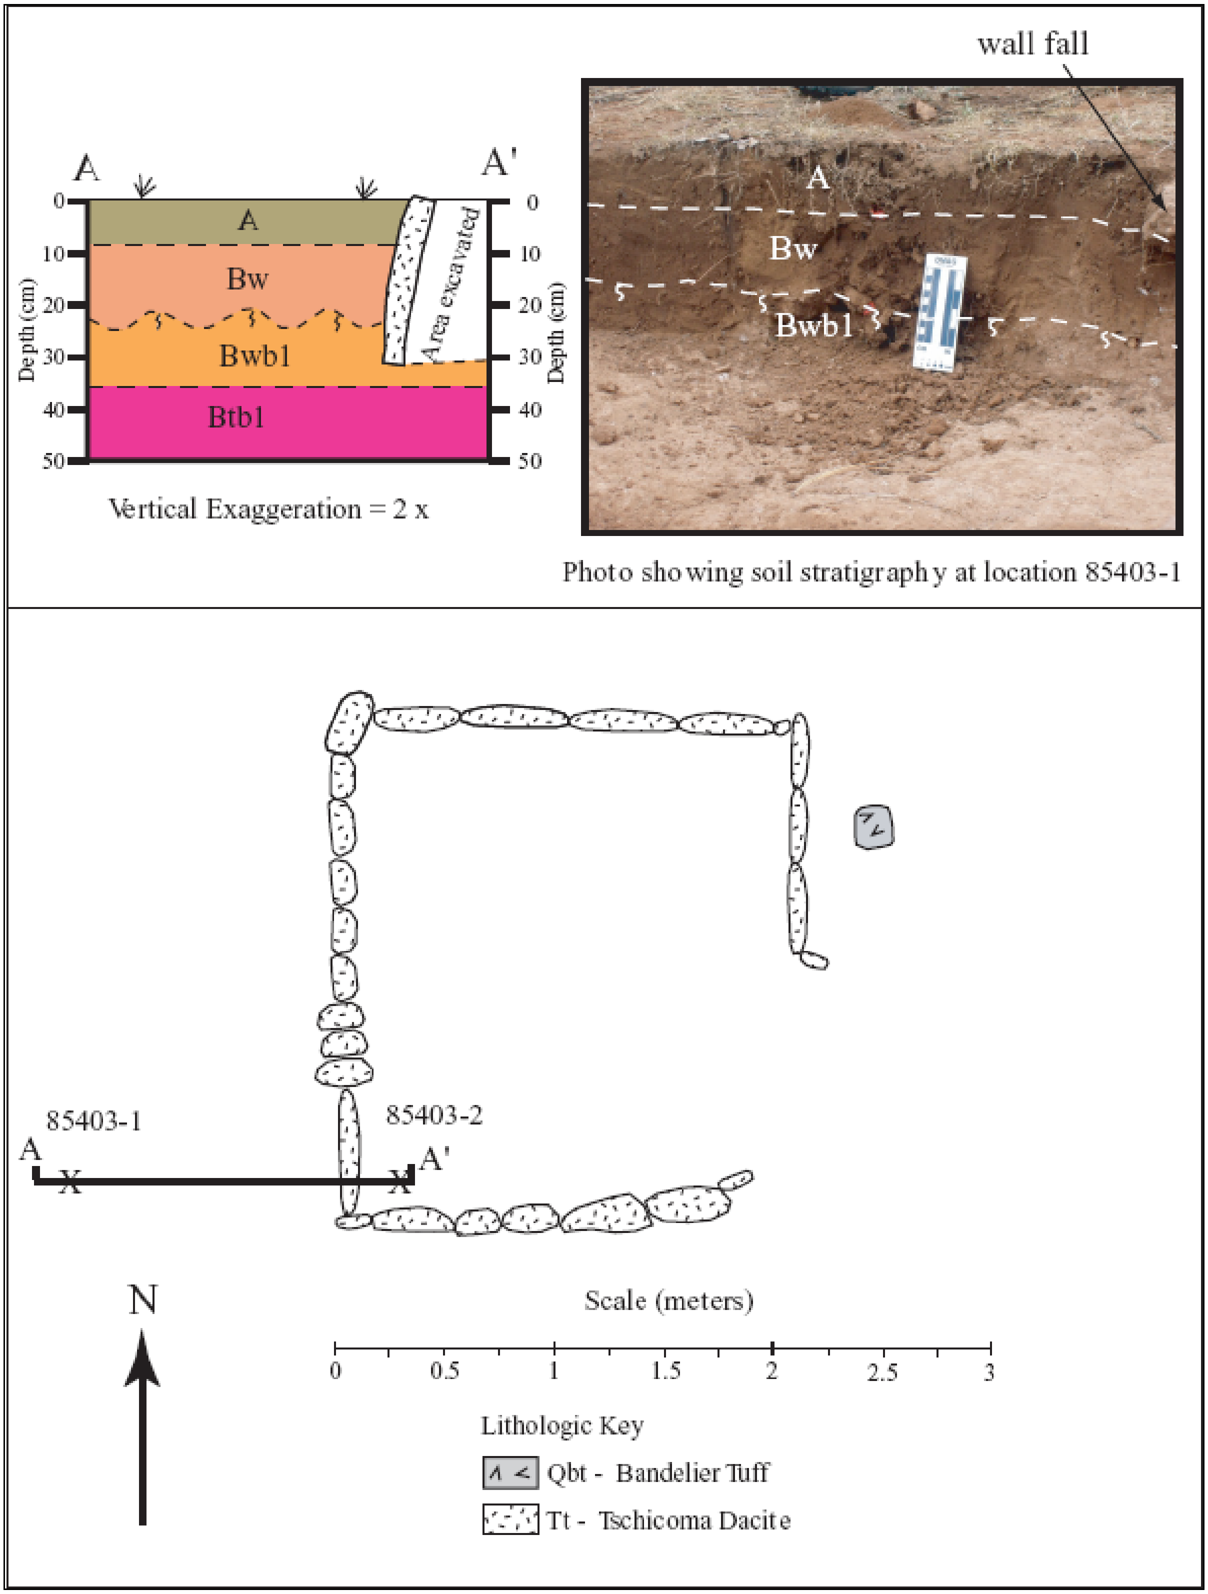

Figure 57.39. Schematic site map (bottom) and cross-section (top) from LA 85403.

LA 85404 (Fieldhouse)

LA 85404 consists of a fieldhouse situated on the gently sloping, east-facing edge of a Qt1 terrace surface (see Figure 57.30). The fieldhouse outside dimensions are approximately 3 m north-south by 2.5 m east-west on the north side of the structure and 1.8 m east-west on the south side of the structure (Figure 57.40).

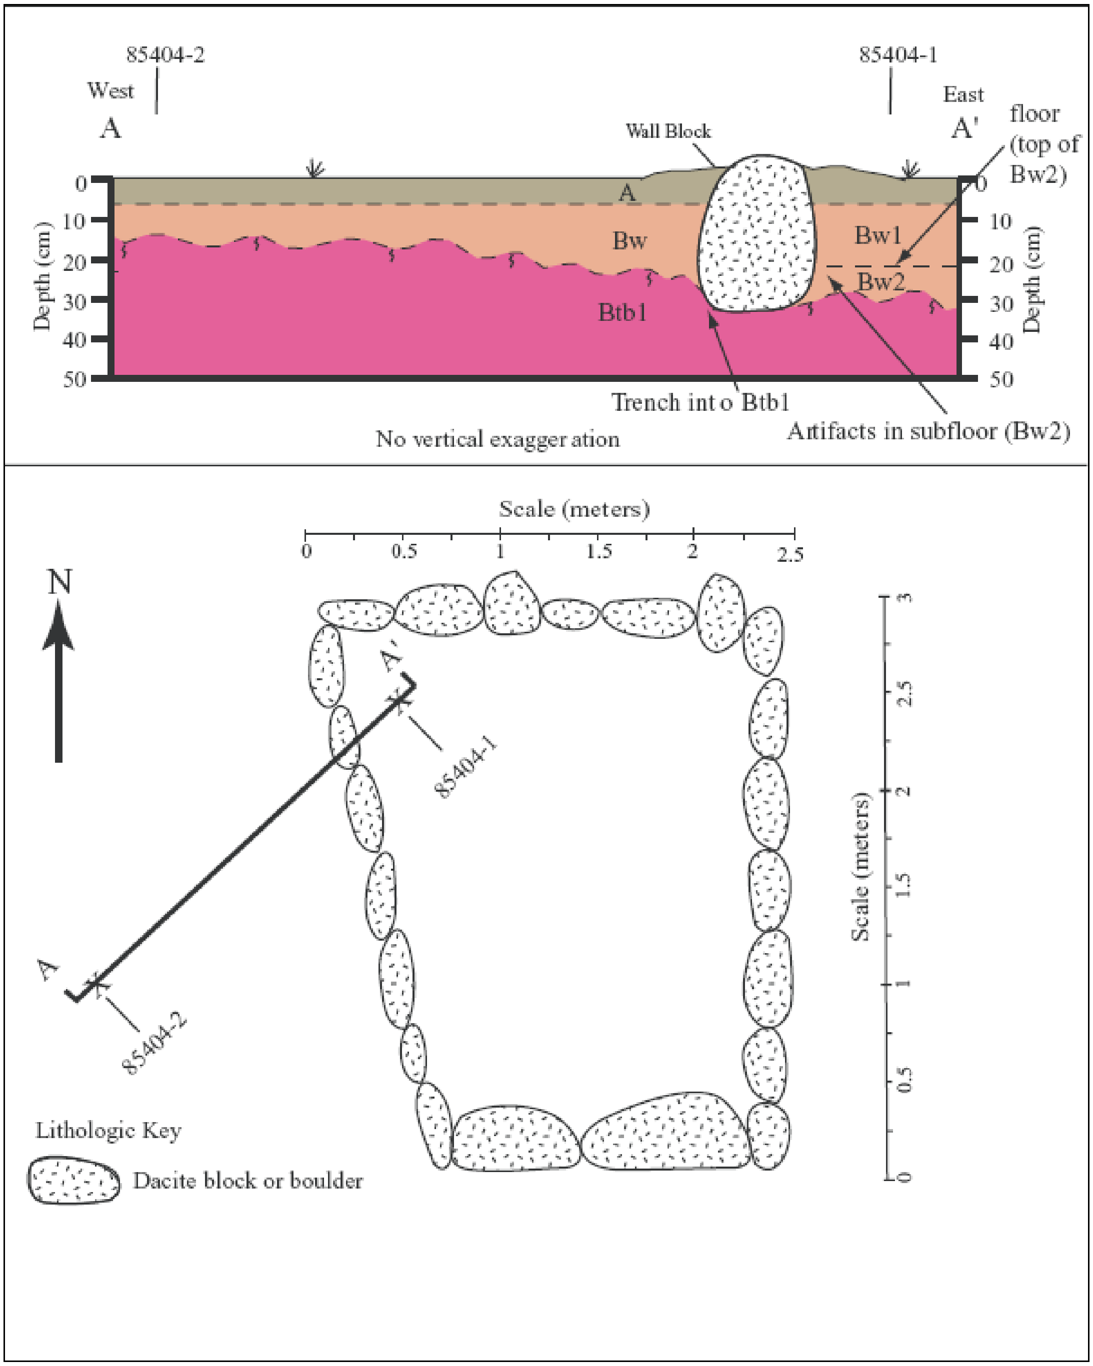

Figure 57.40. Schematic site map and cross-section, LA 85404.

Inside dimensions are approximately 1.2 to 1.7 m east-west by 2.2 m north-south. Soils were described in two test pits at the site; profile 85404-1 was described inside the structure and profile 85404-2 was described 1.5 m west of the west wall of the fieldhouse (Figures 57.40 and 57.41; Table L.5). Site stratigraphy consists of an A-Bw soil overlying a buried Pleistocene Btb1 soil outside the structure and an A-Bw1-Bw2 profile overlying the Pleistocene soil inside the structure (Figure 57.40).

Figure 57.41. Photographs showing fieldhouse constructed of large dacite boulders and soil stratigraphy at LA 85404.

The fieldhouse was constructed from locally derived dacite blocks that appear to have been set into a trench dug into the Btb1 horizon (Figure 57.40). The top of the Btb1 horizon outside the structure and the top of the Bw2 horizon inside the structure constitutes the likely occupation surface. The Bw2 horizon inside the structure contained worked chert with clay films plus possible reworked peds that suggests earlier use of this site and preparation of a sub-floor. The site did not exhibit extensive erosion and appears to be in good archaeological context. The thin colluvial soil observed outside the structure, about 9 cm thick, indicates a relatively young age for this site. The soils and related stratigraphy are therefore consistent with LA 85404 being a Classic period site and are supported by radiocarbon analysis of charcoal sample from maize in the ground floor room level at LA 85404 that yielded an age of 400±40 BP (Beta-215550) and a date of cal AD 1490 with a two-sigma date range of cal AD 1432–1632 (Table M.2).

LA 85407 (Homestead)

This site was only visited during mapping of the Rendija Tract, and the authors did not visit the site during excavation. LA 85407 is situated on a south-facing bench along the contact between Cerro Toledo interval and Puye Formation gravels (see Figure 57.29). The site overlooks the Rendija Canyon channel immediately to the south.

LA 85408 (Fieldhouse)

LA 85408 consists of a fieldhouse situated on a southeast-sloping Qct spur ridge (see Figure 57.29). The structure measures approximately 2.5 m by 1.6 m (inside), or 2.7 m 3.1 m (outside dimensions), situated with the long axis (outside dimension) of the structure oriented N48°E (Figure 57.42). Soils were described in one test pit at the site, located 2 m west of the northwest corner of the fieldhouse. Site stratigraphy includes an A horizon in late Holocene colluvium overlying sandy Qct alluvium with a remnant Qct soil (Figure 57.42, Table L.6). Depth to bedrock in the site vicinity ranges from 9 to approximately 20 cm (Figure 57.42). The absence of early or middle Holocene deposits suggests extensive erosion before deposition of the thin late Holocene colluvium.

The fieldhouse was constructed primarily from dacite blocks, with some tuff blocks and possibly whitish Qct sandstone also utilized. Wall rocks were set into Qct. Shallow, circular pits located approximately 1 m west-southwest of the northwest corner of the fieldhouse were apparently dug into the Qct soil (Figure 57.42). The occupation surface at the site is the top of the Qct soil, and post-occupation colluvial deposits are 9 cm thick at the described profile. The site shows evidence of erosion, as evidenced by a colluvial apron extending 4 to 5 m downslope to the northeast. Soils burying LA 85408 are relatively thin and weakly developed. The soils and related stratigraphy are therefore consistent with a Classic period age for LA 85408. The site is somewhat eroded and is therefore in moderate to poor archaeological context.

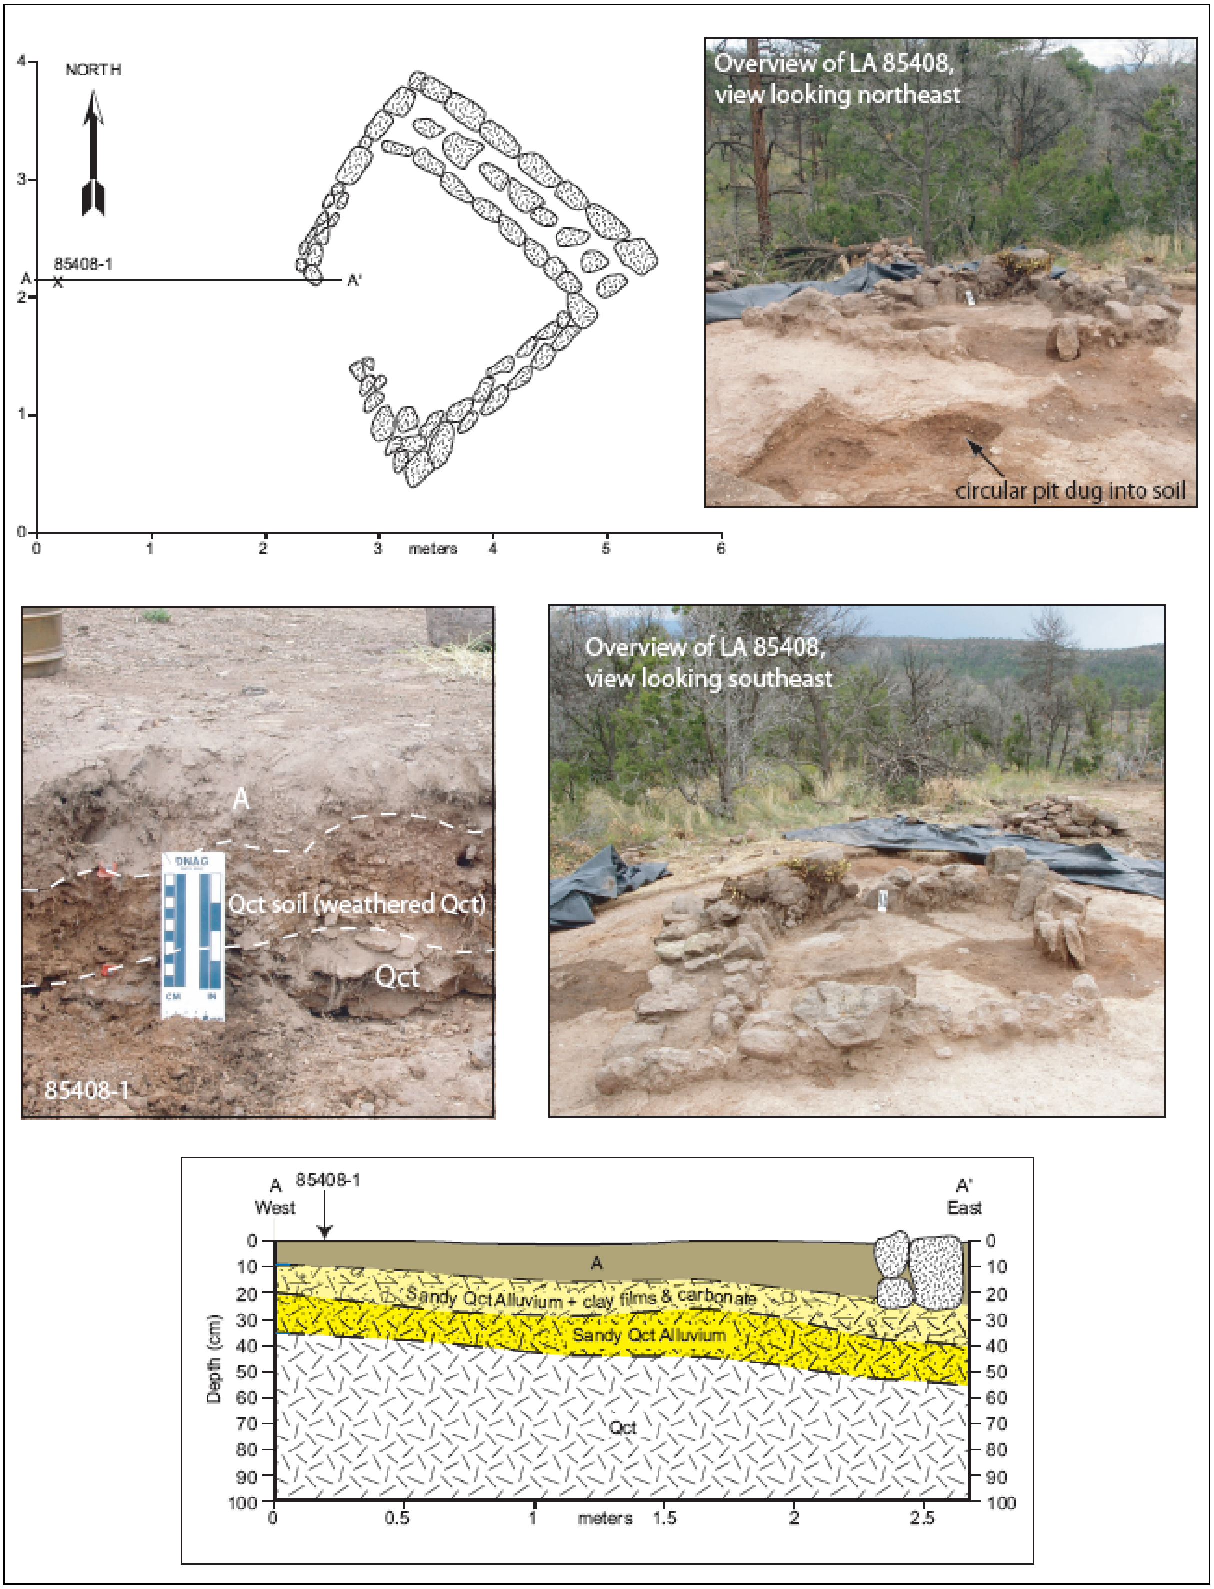

Figure 57.42. Schematic site map, cross-section, and photographs from LA 85408.

LA 85411 (Multi-room structure)

LA 85411 is a two-room (?) structure situated on the northeast-sloping side of a Qct ridge top approximately 7 m northeast of the ridge crest, upslope from LA 99397. The structure measures 7.5 m east-west by 4 m north-south (outside dimensions), with walls of the western room oriented along a northwest-southeast axis (Figure 57.43). Soils were described in two test pits at the site. A detailed soil profile (85411-1) was described 2.3 m east of the southeast corner of Room 2, and a general soil-stratigraphic partial profile (85411-2) was described below the west wall of Room 1 (Figure 57.43; Table L.6). Site stratigraphy consists of an A-Bw soil overlying a buried middle to late Holocene Bwb1 or Btjb1 horizon with variable clay content (Figure 57.43; Table L.6). The buried soil is reddened (7.5YR hue), contains some clasts with clay films, and is possibly reworked from an older soil upslope. Soils are formed in sandy colluvium lacking a significant eolian component. Qct bedrock, consisting of consolidated pumice-rich sandstone, was encountered at a depth of 30 cm at 85411-1. The absence of early Holocene deposits suggests extensive erosion at this site during or before the middle to late Holocene.

The two-room structure was constructed from dacite blocks. Wall rocks were set into the Bwb1/Btjb1 horizon and were locally set directly on Qct bedrock (Figure 57-43). The occupation surface at the site is the top of the Bwb1/Btjb1 horizon, and post-occupation colluvial deposits range from 14 cm thick at 85411-1, outside the structure, to approximately 20 cm thick at 85411-2, adjacent to the west wall (Figure 57.43). The soils and related stratigraphy are consistent with a Classic period age for LA 85411. Although the eastern part of the site appears to be somewhat eroded, the remainder of the site is relatively intact and is in good archaeological context.

LA 85413 (Fieldhouse)

LA 85413 includes a fieldhouse situated on a south-facing slope, at the approximate contact between Qct overlain by thin Holocene colluvium (map unit Qct) and Qct overlain by thicker Pleistocene and Holocene colluvium (map unit Qc) (Figure 57.44). The structure measures approximately 2.0 m by 1.7 m (inside), or 2.9 m by 2.2 m (outside dimensions), situated with the long axis of the structure oriented approximately N75°E (Figure 57.44). Soils were described in two test pits at the site; profile 85413-1 was described 3 m southeast of and downslope from the southeast corner of the structure, and profile 85413-2 was described below the east wall of the fieldhouse (Figure 57.44; Table L.6). Site stratigraphy consists of an A-Bw soil overlying Qct, in the immediate vicinity of the fieldhouse, or an A-Bw soil overlying Btk1b1-Btk2b1 horizons formed in Pleistocene colluvium, south of the fieldhouse (Figure 57.44; Table L.6). Holocene colluvium described at 85413-1 is relatively coarse-grained, with pebble- to cobble-size gravel (Figure 57.44). The absence of middle Holocene deposits suggests extensive erosion at this site during or before the late Holocene.

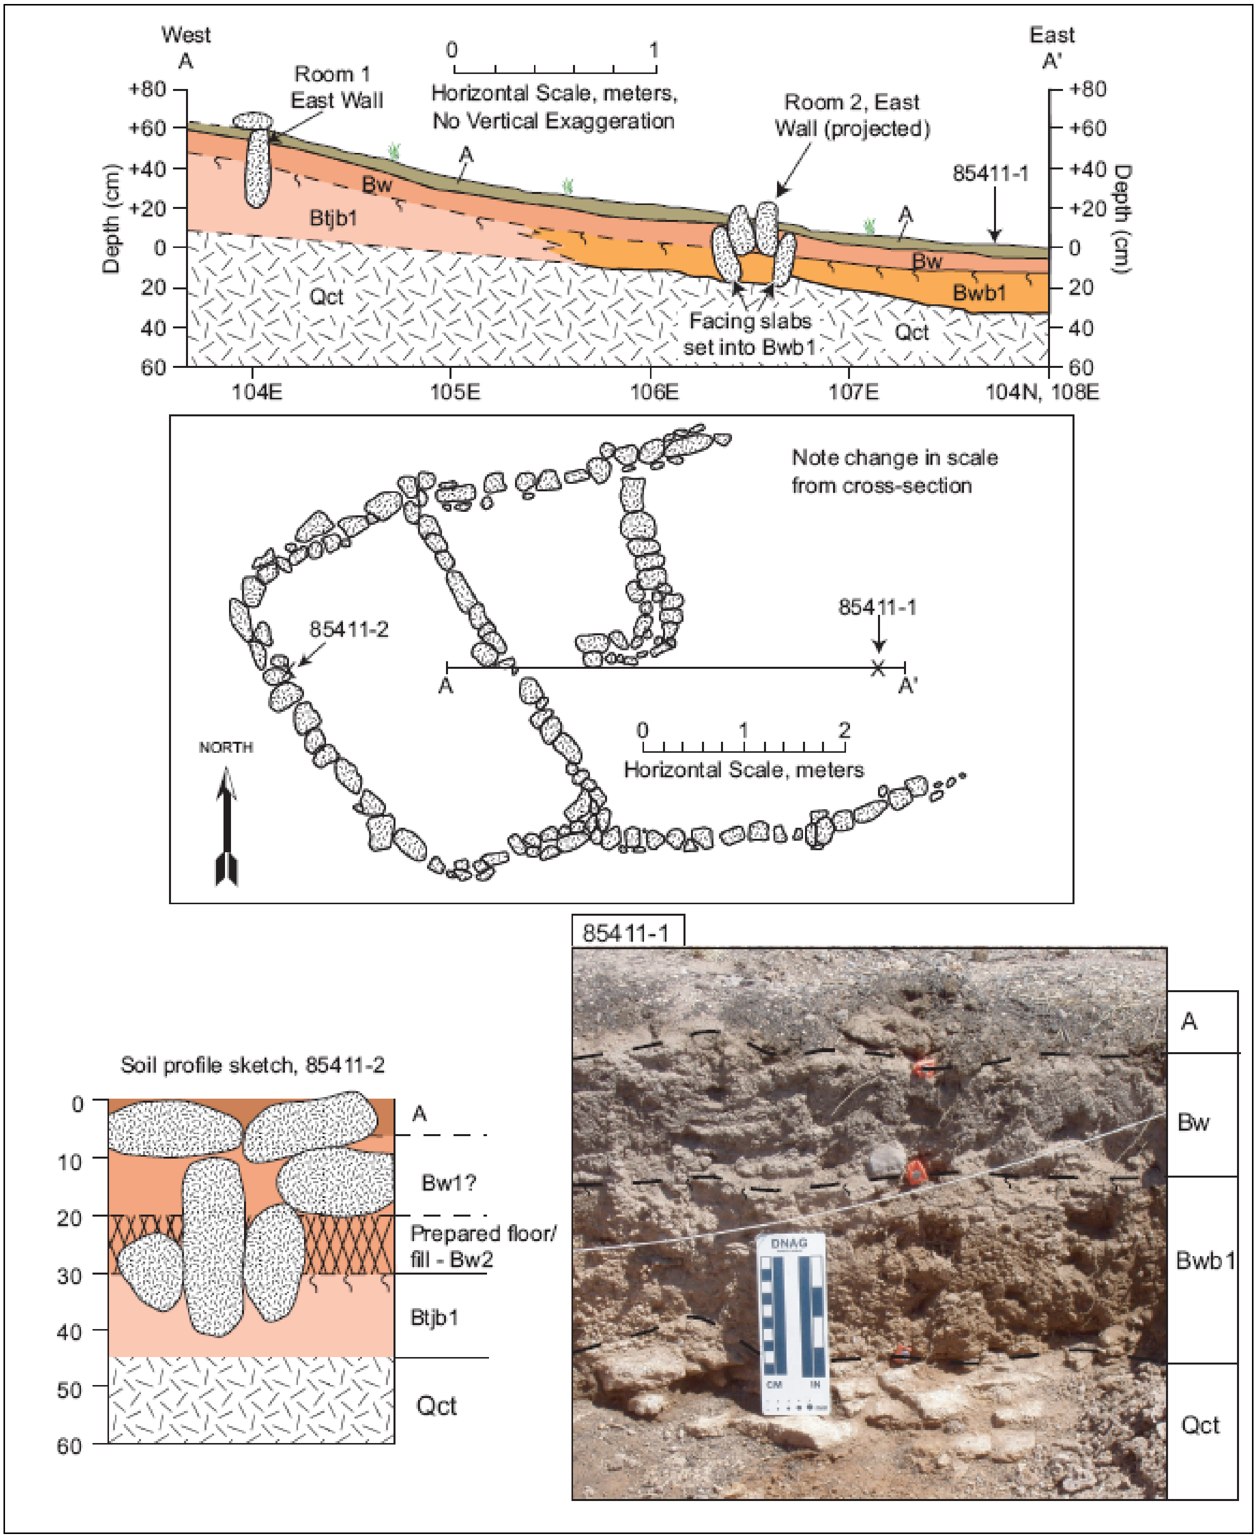

Figure 57.43. Schematic site map, cross-section, and soil stratigraphy from LA 85411.

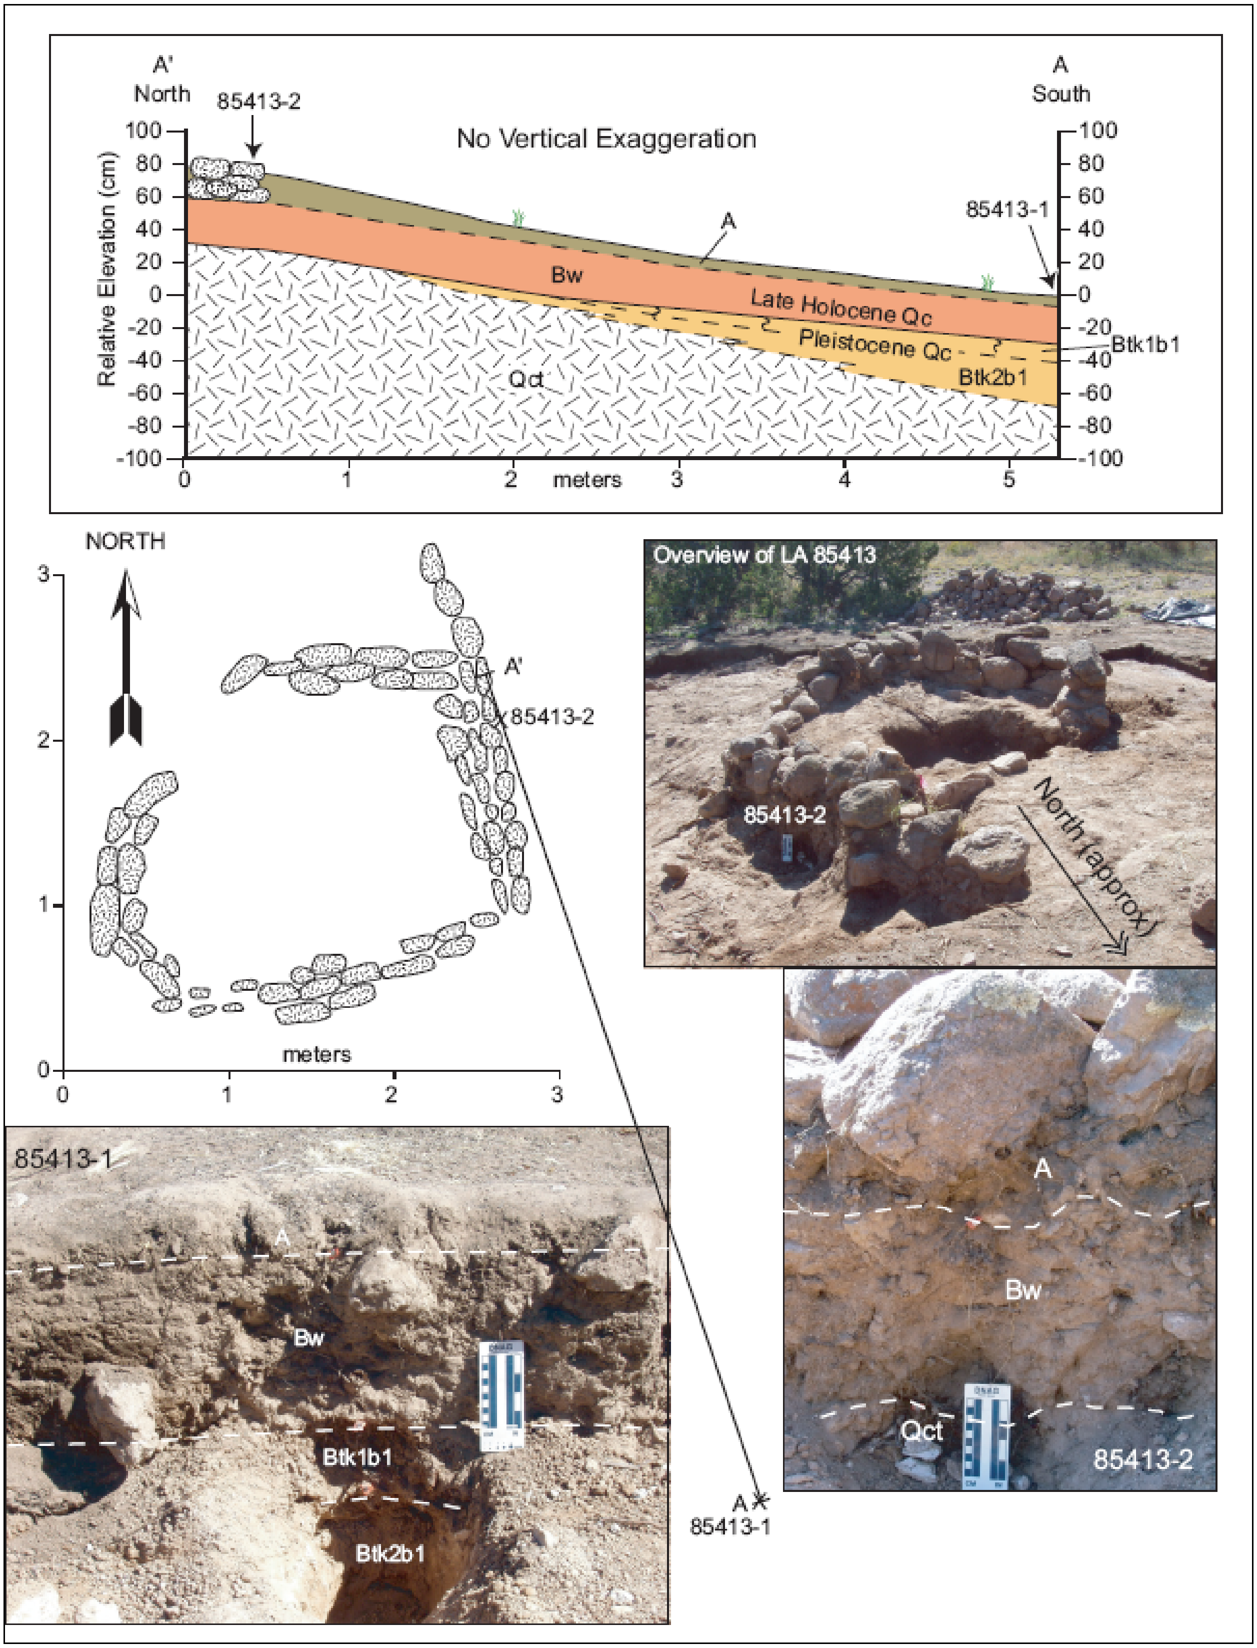

Figure 57.44. Schematic site map, cross-section, and photographs from LA 85413.

The fieldhouse was constructed primarily from dacite blocks. Wall rocks were generally set on top of the Bw horizon (Figure 57.44). The occupation surface at the site is the top of the Bw horizon, and post-occupation colluvial deposits range from 7 cm thick at 85413, outside the structure, to approximately 18 cm thick at 85413-2, adjacent to the east wall (Figure 57.44). The thin, weakly developed soils (A horizon only) that post-date the site and related stratigraphy are consistent with a Classic period age for LA 85413. The site is not extensively eroded and is in good (?) archaeological context.

LA 85414 (Fieldhouse)

LA 85414 is a fieldhouse site situated on an east-facing Qct bench. The structure measures approximately 1.7 m by 1.2 m (inside), and 2.3 to 2.7 m by 1.8 m (outside dimensions), situated with the long axis of the structure oriented approximately N20°E (Figure 57.45). Soils were described in two test pits at the site; profile 85414-1 was described 1.5 m east of the northeast corner of the structure, and profile 85414-2 was described below the east wall of the fieldhouse (Figure 57.45; Table L.6). Site stratigraphy consists of an A-Bw soil formed in late Holocene (both pre- and post-occupation) colluvium overlying a thin Btb1 horizon formed in Pleistocene colluvium (Figure 57.45; Table L.6). The thin Pleistocene colluvial deposits overlie weathered Qct. The absence of early or middle Holocene deposits indicates extensive erosion at this site before deposition of the late Holocene colluvium.

The fieldhouse was constructed primarily from dacite blocks and boulders. Wall rocks were set on top of and into the Bw horizon, with some rocks set to the top of the Btb1 horizon (Figure 57.45). It appears that some large dacite boulders in the Btb1 horizon were left *in situ* and incorporated in the structure (Figure 57.45). The occupation surface at the site is the top of the Bw and top of the Btb1 horizon, and post-occupation colluvial deposits are 8 to 10 cm thick (Figure 57.45). The thin, weakly developed soils (A horizon only) that post-date the site and related stratigraphy are consistent with a Classic period age for LA 85413. The site is not extensively eroded and is in good archaeological context.

LA 85417 (Fieldhouse)

LA 85417 is a fieldhouse site situated on a rocky Qct knob overlain by eolian fines and thin, locally derived colluvium. The structure is oriented north-south by east-west with an east-facing doorway and measures approximately 1.6 m by 1.6 m (inside), and 2 m by 2 m (outside dimensions). Soils were described in two test pits at the site; profile 85417-1 was described 2 m west of the west wall of the structure, and profile 85417-2 was described at the inside of the west wall of the fieldhouse (Figures 57.46 and 57.47; Table L.6). An east-west topographic profile across the site was also constructed, using a hand level and tape, and additional soil-stratigraphic measurements were made along the topographic profile (Figures 57.46 and 57.47). Site stratigraphy consists of an A-Bw soil formed in late Holocene (both pre- and post-occupation) eolian fines and colluvium overlying a thin, discontinuous Btb1 horizon formed in Pleistocene colluvium (Figure 57.47; Table L.6). The soils are exceptionally rocky, with the rocks representing a lag following erosion of overlying units. The thin Pleistocene colluvial deposits overlie a Qct pumice bed, and the absence of early or middle Holocene deposits suggests extensive erosion before deposition of the late Holocene eolian sediment.

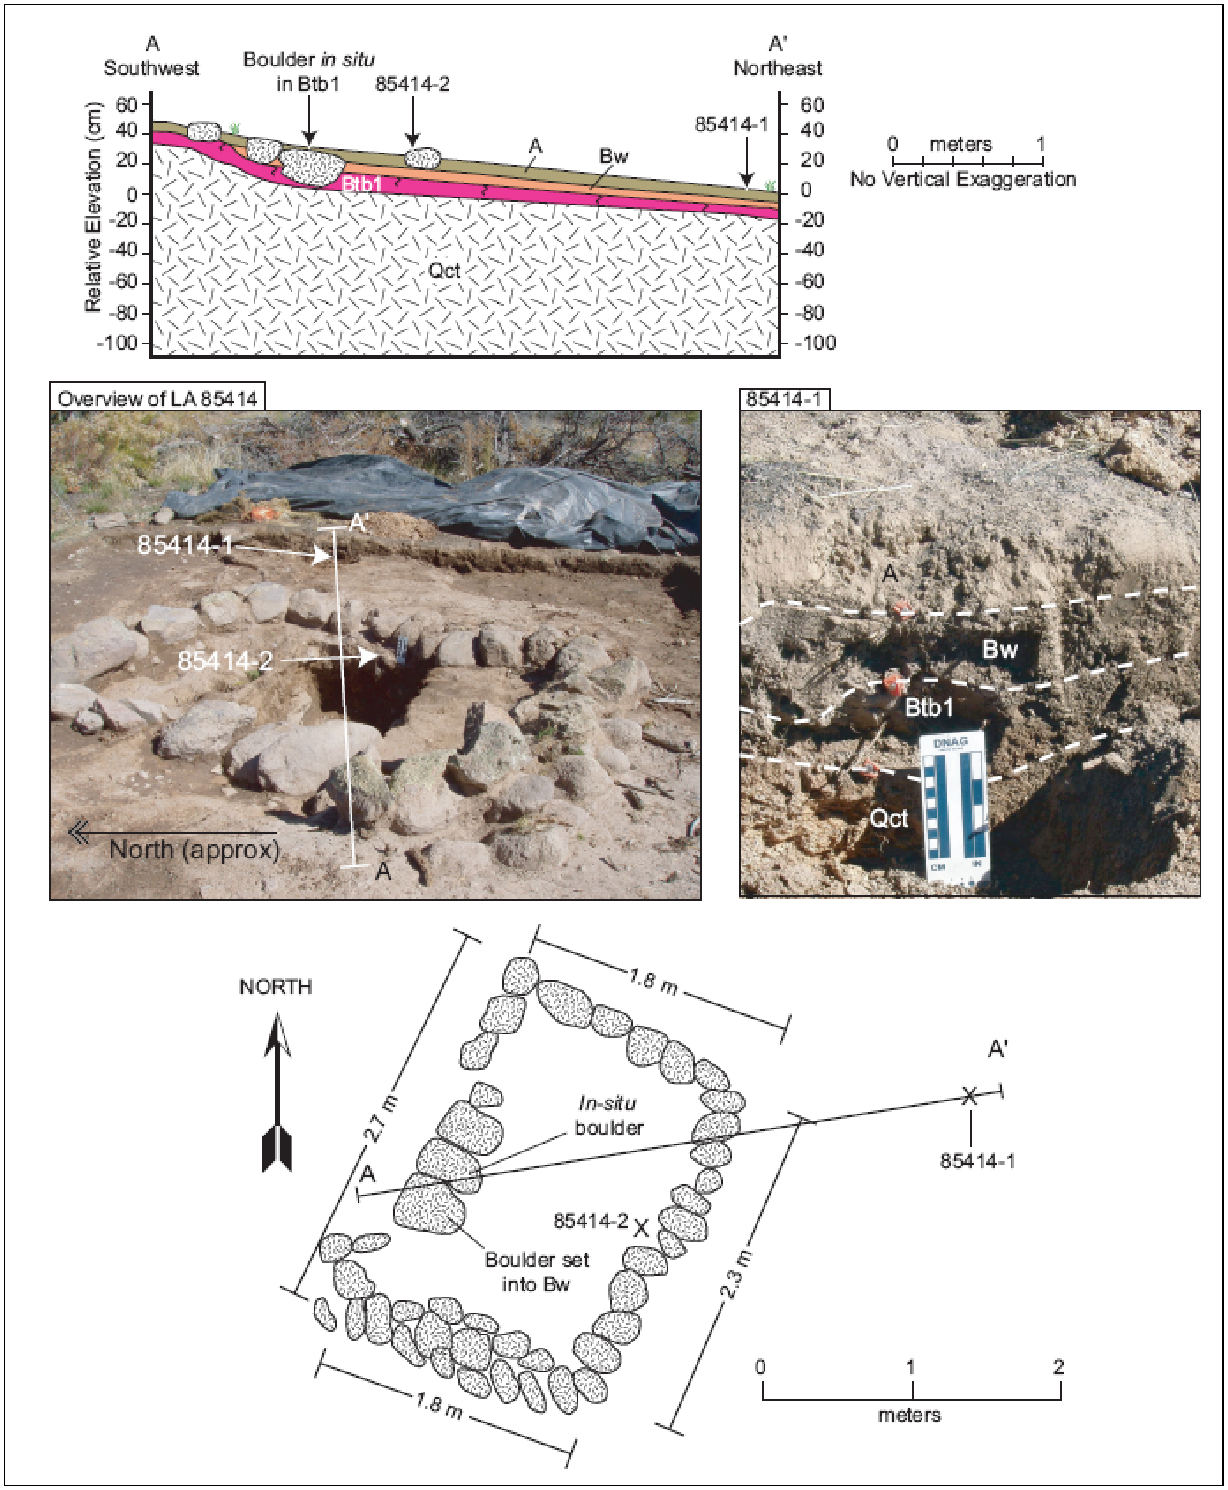

Figure 57.45. Schematic site map, cross-section, and photographs of LA 85414.

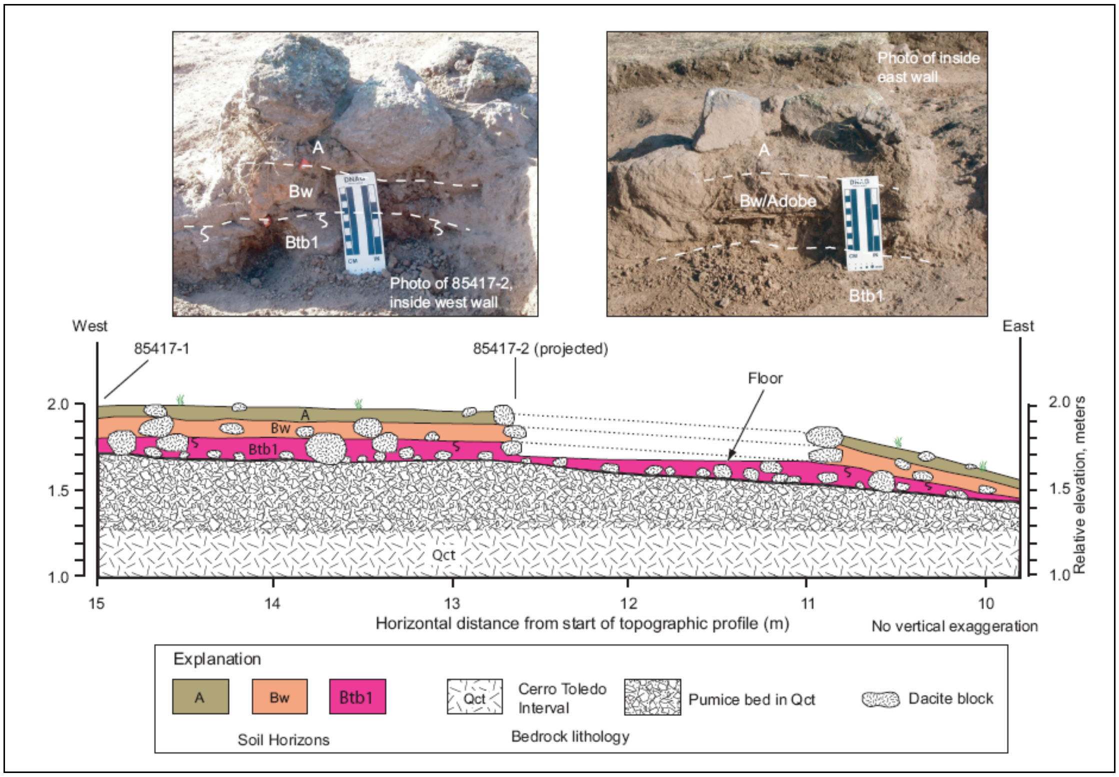

Figure 57.46. Cross-section detail and photographs showing LA 85417 soil stratigraphy.

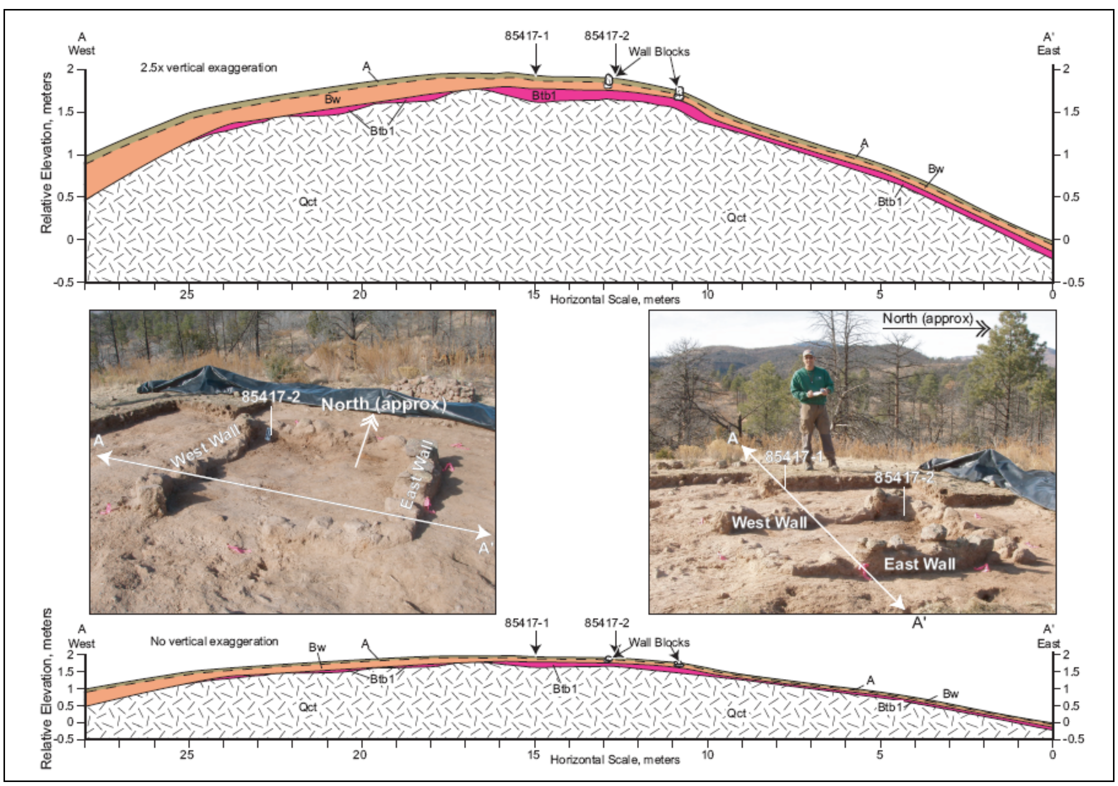

Figure 57.47. Topographic profile, schematic cross-sections, and photographs at LA 85417.

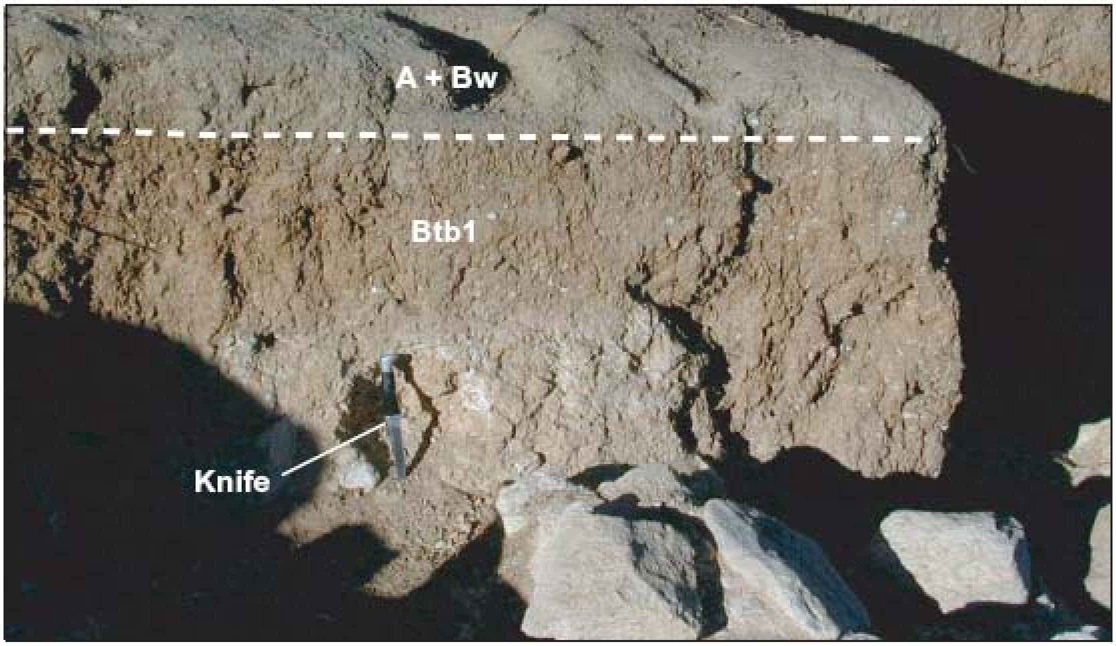
The fieldhouse was constructed primarily from dacite blocks. Wall rocks were set on top of and into the Bw horizon, with some rocks set to the top of the Btb1 horizon (Figure 57.46). The floor was cut into the Btb1 horizon in the northwest corner of the fieldhouse and is coincident with the top of the Btb1 horizon in the east side of the fieldhouse (Figure 57.46). The occupation surface at the site is the top of the Bw and the top of or within the Btb1 horizon, and post-occupation colluvial deposits are less than 10 cm thick (Figure 57.46). Although the thin soils present at the site are likely in part a result of the erosional setting, making age inferences based on soils problematic, the thin, weakly developed soils (A horizon only) that post-date the site and related stratigraphy are consistent with a Classic period age for LA 85417. The site is in good archaeological context.

LA 85859 (Archaic Lithic Scatter)

LA 85859 is an Archaic lithic scatter on a northeast-facing hillslope underlain by Qct pumice and thin colluvial deposits (see Figures 57.29 and 57.33). Qct is overlain by a buried soil in colluvium (b1), up to 80 cm thick, that has an inferred middle Holocene age of 6.7 to 7.4 ka based on three radiocarbon dates from three discrete charcoal fragments (Table M.2). The ages of these three samples are statistically different, suggesting a period of colluvial aggradation from ca. 6.7 to 7.4 ka that included site occupation. The middle Holocene soil profiles are truncated and are overlain by a late Holocene colluvial deposit less than 25 cm thick. An age estimate for the late Holocene colluvium is based on a charcoal sample from the top to the Bt1b1 horizon 3 cm below the base of the Bw horizon at LA 85859 that yielded an age of 570±40 BP (Beta-183759) and a date of cal AD 1353 with a two-sigma date range of cal AD 1299–1429 (Table M.2). Soils described at LA 85859 represent a catena, wherein a series of soil profiles developed in the same parent material that have a similar age, exhibit lateral variability in soil properties that is related to hillslope position. The term catena was proposed by Milne (1935a, 1935b), who emphasized that each soil on a slope bears a relationship to the soils above and below it. Birkeland (1999) discusses catenas at length. At LA 85859, the upper hillslope is underlain by a thin (less than 25 cm thick) late Holocene colluvial deposit overlying Qct (profiles 85859-6 and 7), and a lower hillslope with thin Holocene colluvium overlying up to 81 cm of late Pleistocene or early Holocene colluvium and Qct (profiles 85859-2, 3, 4, 5, and 8; Figures 57.33 and 57.48; Table L.7). The upper and lower hillslopes are separated by an area with bedrock at or near the surface (85859-1; Figure 57.33).

It is inferred from the site stratigraphy that the upper hillslope was eroded during early to middle Holocene time and that colluvium derived from Qct bedrock and/or Qct soils was deposited on the concave part of the hillslope below 85859-1. The base of this colluvial unit includes common dacite clasts, up to small boulder size, that represents a lag left after almost complete erosion of an older alluvial unit (Qoa or a gravel layer within Qct). A second period of erosion likely occurred sometime during the late Holocene, during which the upper hillslope was stripped to bedrock and the middle Holocene soils on the lower hillslope were truncated. The stripped Qct on the upper hillslope and truncated late middle Holocene soils on the lower hillslope were then buried by a thin late Holocene colluvial deposit.



Opposite side of trench wall showing A & Bw horizons (late Holocene colluvium) overlying Btb1 horizon. Dacite gravel lag at base. Knife (length = 22 cm) for scale.

Figure 57.48. Trench wall showing soil horizons at LA 85859. Greatest artifact concentration (obsidian flakes) found in Bt1b1 horizon.

Artifacts are found in both the middle Holocene colluvium and the late Holocene colluvium at LA 85859 (Figure 57.33; Table E-1 of Drakos and Reneau 2004, more than one artifact must be found in a given horizon to confirm artifact occurrence in a particular stratigraphic unit). The maximum artifact concentration at the site was found in the vicinity of 85859-5, and the highest artifact concentration near 85859-5 was in the Bt1b1 horizon. Artifacts were found in the Bt horizons near profiles 85859-2 and -4, downslope from 85859-5, but not near 85859-3, located 3 m upslope from 85859-5 (Figure 57.33; Table E-1 of Drakos and Reneau 2004). Artifacts were also found in the late Holocene colluvium near profiles 85859-2, 4, and 5, with the highest density also near 85859-5. This artifact distribution suggests that the occupation surface was within the upper part of the middle Holocene colluvium, and that the artifacts found in the late Holocene colluvium were supplied from local bioturbation of the underlying b1 soils. Some artifacts were also likely eroded from the upper Bt horizon and redeposited in the late Holocene colluvium. The absence of artifacts upslope near 85859-3 provides evidence that the artifacts found near 85859-5 were not transported from upslope, but that the main occupation area was near 85859-5

Some artifacts were also observed in deeper horizons and immediately above the Qct pumice. Evidence of extensive burrowing was observed immediately above the Qct contact, and it is inferred that these artifacts have been transported to deeper soil horizons by animal burrowing (e.g., the Bkb1 horizon at 85859-5 and the BCb1 horizon at 85859-4; note the occurrence of a rodent bone in the Bkb1 horizon at 85859-5; see Table E-1 of Drakos and Reneau 2004). Additional downward movement of artifacts into other horizons from bioturbation is also inferred to have occurred after site abandonment (e.g., the decrease from 282 artifacts in the Bt1b1 to three artifacts in the Bt3b1 at 85859-5). The dispersion of artifacts through the entire thickness of the soil profile near 85859-4 and 85859-5 provides evidence for substantial bioturbation and vertical transport of artifacts since site abandonment. The precise depth of the occupation surface is therefore not well constrained, but may occur somewhere in the Bt1b1 horizon, at a depth of 13 to 31 cm, where artifact concentrations are highest. Based on the maximum artifact density occurrence in the best-developed soil horizon (Bt1b1), it is inferred that most of the bioturbation occurred relatively soon after deposition of the colluvium and site abandonment, before development of these soil horizons. Because the peak artifact density occurs in the upper part of the b1 soil, site occupation also apparently occurred late in the period of deposition of this unit.

The b1 soil at LA 85859 would have an inferred late Pleistocene age based on comparison with the chronosequence of Pleistocene and Holocene soils developed on a terrace sequence in Rendija Canyon (Reneau and McDonald 1996; McDonald et al. 1996). However, radiocarbon analyses of three charcoal samples collected from Btb1 and Bt1b1 horizons, provided calibrated radiocarbon dates of ca. 6.7 to 7.4 cal ka (Table M.2) that are much younger than age estimates based on soil development. The radiocarbon dates are consistent with the age estimates for two diagnostic points found on the ground surface in the vicinity of LA 85859, providing supporting evidence for the radiocarbon age estimates. Soil properties including development of reddened (7.5YR) Bt horizons with moderately thick clay films reflect rates of soil development that are more rapid on this northeast-facing colluvial hillslope than have been observed in Rendija Canyon terrace deposits or in mesa top deposits at Airport Tract sites, on Pajarito Mesa, or in White Rock Tract sites.

LA 85861 (Fieldhouse)

LA 85861 consists of a large fieldhouse with an internal hearth situated on a broad, gently east-sloping Qct ridge crest below a steeper slope leading to a higher ridge crest south of the site. Due to its location on a bench below a steeper slope, LA 85861 was almost completely buried by slopewash colluvium before excavation. The structure measures approximately 3.0 m by 1.7 m (inside) and 3.3 m by 1.9 m (outside dimensions), situated with the long axis of the structure oriented approximately N10°W (Figure 57.49).

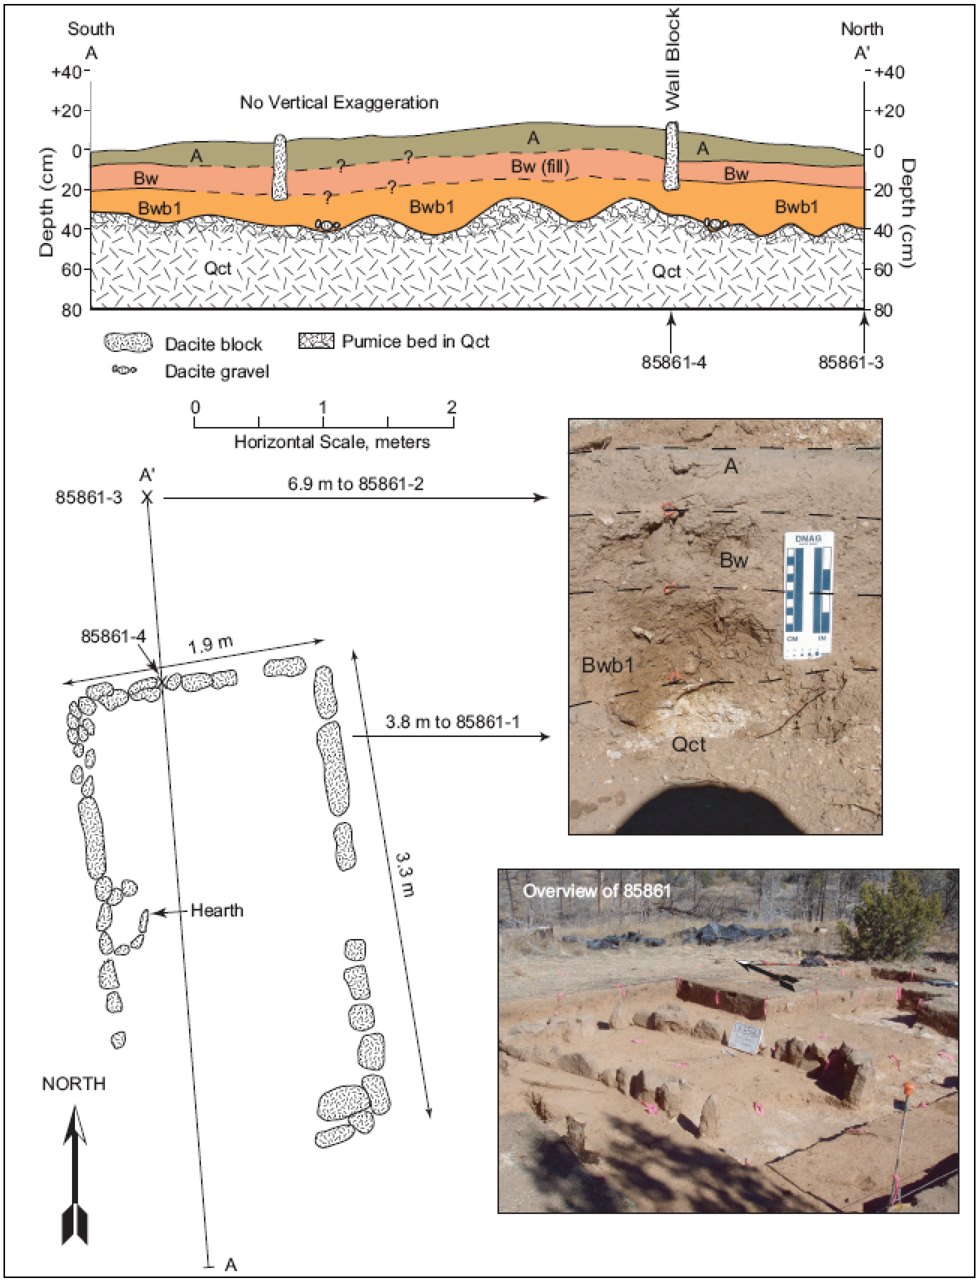


Figure 57.49. Schematic site map, cross-section, and photographs of LA 85861.

Soils were described in four locations at the site; profile 85861-1 was described 4 m east of and downslope from the east wall, profile 85861-2 was described 6.2 m northeast of and downslope from the east wall, profile 85861-3 was described 1.5 m north of the north wall, and profile 85861-4 was described on the north side of the north wall of the structure (Figure 57.49). A north-south topographic profile across the site was also constructed, using a hand level and tape (Figure 57.49). Site stratigraphy consists of an A-Bw-Bwb1 soil formed in sandy Holocene colluvium overlying a Qct pumice bed. Holocene colluvium is 27 to 50 cm thick in the site vicinity and includes a middle to late Holocene deposit (Bwb1 horizon) and an overlying late Holocene deposit (A-Bw horizons). The Bwb1 horizon is reddened (7.5YR4/6 dry color) and may be derived in part from reworking of older soils upslope. The site apparently experienced significant erosion in the early and/or middle Holocene, before deposition of the middle to late Holocene colluvium.

The fieldhouse was constructed primarily from dacite blocks. Wall rocks were generally set into the Bw and Bwb1 horizons, with fill adjacent to wall blocks having the same color as the Bwb1 horizon at profile 85861-4 (Figure 57.49; Table L.6). The occupation surface at the site is the top of the Bwb1 horizon, and post-occupation colluvial deposits are 15 to 31 cm thick (Figure 57.49; Table L.6). The soils (A and Bw horizons) that post-date the site and related stratigraphy are consistent with either a Late (?) Coalition or Classic period age for LA 85861. The site is in very good archaeological context.

LA 85864 (Apache tipi ring site)

LA 85864 is a tipi ring outlined by dacite cobbles located on a gullied Qc valley bottom. The tipi ring is situated on a preserved valley bottom remnant between two 2- to 3-m-deep southeast-sloping gullies (see Figure 57.29). Soil stratigraphy at the tipi ring includes an A horizon from 0 to 9 cm overlying an Ab1 horizon (Table L.6, profile 85864-1). Tipi ring rocks are set on top of or into the Ab1 horizon. The occupation surface may have been on top of the Ab1 horizon or may have been on top of the underlying Bwb1 horizon. The thickness of the A horizon indicates approximately 9 cm of deposition that post-dates construction of the tipi ring during the middle to late 1800s. The deep gully incision in the area apparently post-dates the tipi ring site.

The gullies adjacent to LA 85864 and LA 99397 (discussed below) preserve 1.5- to 2-m-thick middle to late Holocene colluvial deposits (Figure 57.50). The Holocene colluvium buries late Pleistocene to early Holocene colluvium that is exposed near the base of gully walls. The Holocene section exposed in gullies has excellent potential for preservation of Archaic or older sites, but none were observed during mapping or stratigraphic descriptions during the 2003 field season.

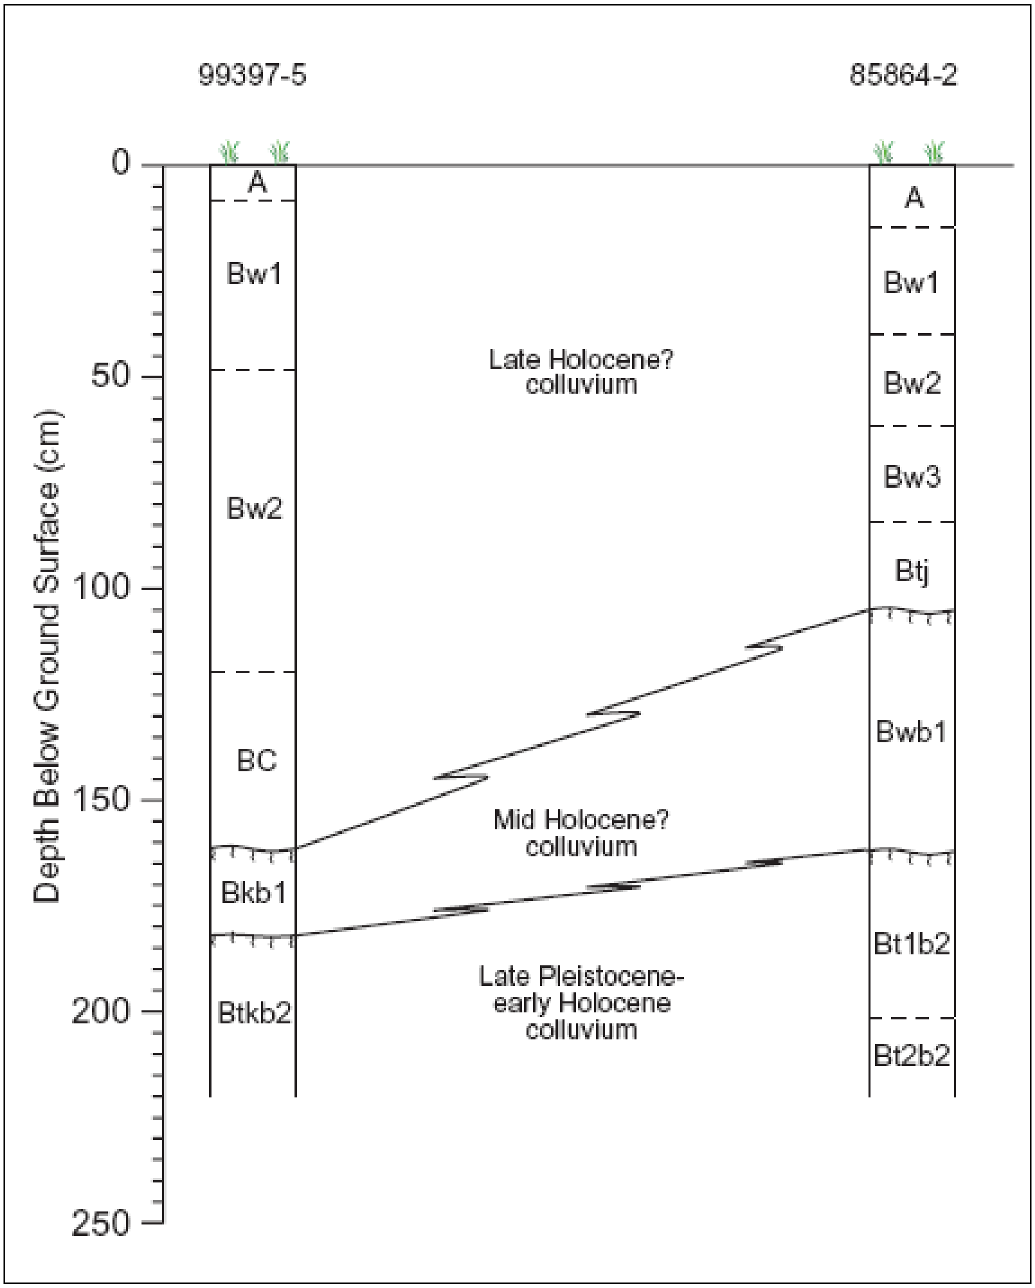

Figure 57.50. Holocene and late Pleistocene stratigraphy exposed in gullies near sites LA 85864 and LA 99397.

LA 85867 (Fieldhouse)

LA 85867 consists of a fieldhouse situated on a south-facing Qc slope below a Qct ridge. The structure is oriented north-south by east-west with a north-facing opening and measures approximately 2.2 m by 1.3 m (inside), or 2.7 m to 3.1 m by 2.0 m (outside dimensions) (Figure 57.51). Soils were described in one test pit at the site, located on the inside of the south wall, 0.8 m west of the southeast corner of the fieldhouse. Site stratigraphy consists of an A-Bw1-Bw2-

Bw3 soil overlying Qct at a depth of greater than 100 cm (Figure 57.51, Table L.6). The soil at this location is a cumulic soil formed in a late (?) Holocene aggradational colluvial deposit.

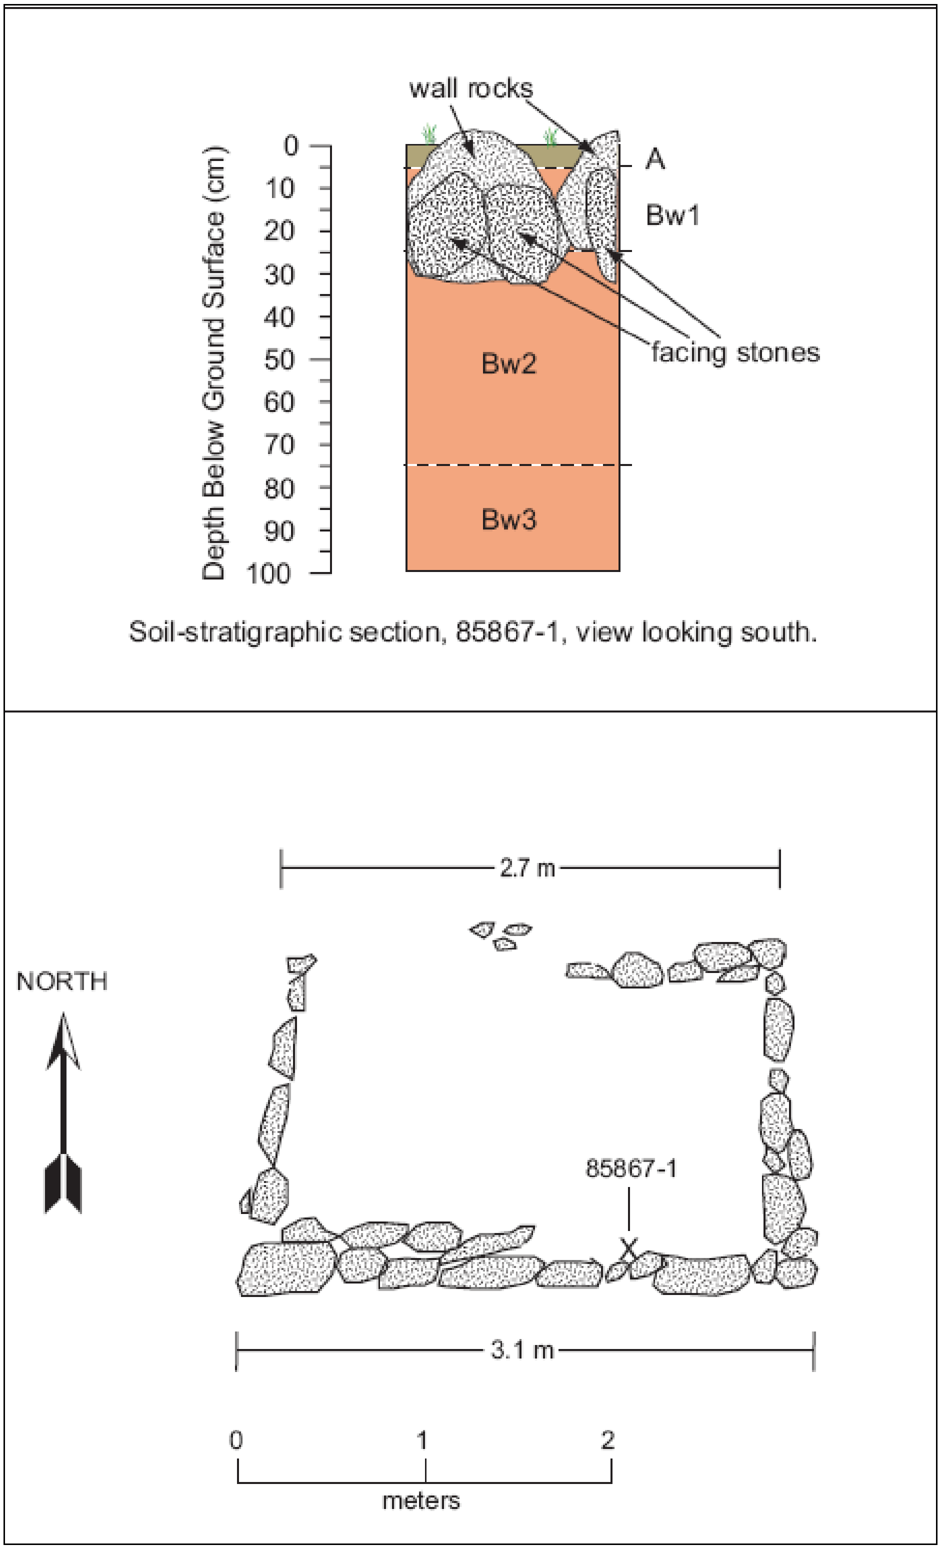

Figure 57.51. Schematic site map and soil-stratigraphic section at LA 85867.

The fieldhouse was constructed primarily from dacite blocks. Wall rocks were set into Bw1 and Bw2 horizons (Figure 57.51). The occupation surface at the site is inferred to be the top of the Bw1 horizon, and post-occupation colluvial and eolian deposits are 5 cm thick at the described profile. Soils burying LA 85408 are relatively thin and weakly developed. The soils and related stratigraphy are therefore consistent with a Classic period age for LA 85867. The north side of the site has been somewhat disturbed due to its proximity to a two-track dirt road, but the remainder of the site has been buried by young colluvium and is apparently in good archaeological context.

LA 85869 (Apache tipi ring site)

LA 85869 includes two tipi rings (Features 2 and 4) defined by dacite cobbles situated on the north shoulder of a northwest-to-southeast-trending ridge, adjacent to the ridge top (see Figures 57.29 and 57.52). Soil stratigraphy at the tipi ring includes an A horizon from 0 to 4 cm that contains beads, chipped stone, ceramics, and metal artifacts overlying a Bw horizon (Figure 57.52; Table L.6). Tipi ring rocks are set on top of the Bw horizon, which corresponds to the occupation surface. The thin A horizon that post-dates construction of the tipi ring indicates minimal deposition has occurred at this site since the middle to late 1800s. The Bw horizon overlies a Btb1 horizon with common to continuous moderately thick clay films. The Btb1 soil is of inferred Pleistocene age. The total thickness of late Holocene deposits in the vicinity of LA 85869 is less than 20 cm (Figure 57.52; Table L.6). The absence of early and middle Holocene deposits suggests extensive erosion at this site before or during the late Holocene.

LA 86605 (Fieldhouse)

LA 86605 consists of a fieldhouse situated on the broad, gently sloping, east-facing shoulder of the Qt2 terrace (see Figure 57.30). The structure measures approximately1.7 m north-south by 1.5 m east-west (inside dimensions), or 2.1 m north-south by 2 m east-west (outside dimensions), and contains an opening facing east (Figure 57.53). Soils were described in two test pits at the site; profile 86605-1 was described 1.1 m west of the west wall of the fieldhouse and profile 86605-2 was described inside the structure, approximately 0.4 m east of the west wall (Figure 57.53; Table L.5). Site stratigraphy consists of an A-Bw soil overlying a buried Pleistocene or early Holocene Btb1-Btkb1 soil outside the structure and an A-Bw1(?)-Bw2(?) profile overlying the buried soil inside the structure (Figure 57.54). The Bw2 horizon inside the structure contains disseminated charcoal and tuff clasts below the level of the bottom of the roomblock walls, providing evidence for an earlier period of occupation at this site.

The fieldhouse was constructed utilizing dacite and tuff blocks and slabs, with two large Bandelier Tuff slabs used to construct most of the west wall (Figure 57.53). The dacite was likely obtained from the local Qt2 terrace gravels, and the tuff may have been obtained from outcrops in a nearby drainage to the east. The slabs are set into a trench dug into the Bw, Btb1 and Btkb1 horizons (Figure 57.54). Sherds were observed in the clayey fill in the trench, providing additional evidence that the structure was built on top of an older site. The top of the

Btb1 horizon (outside the structure) and the top of the Btkb1 horizon (inside the structure) is the likely occupation surface for the first occupation of this site.

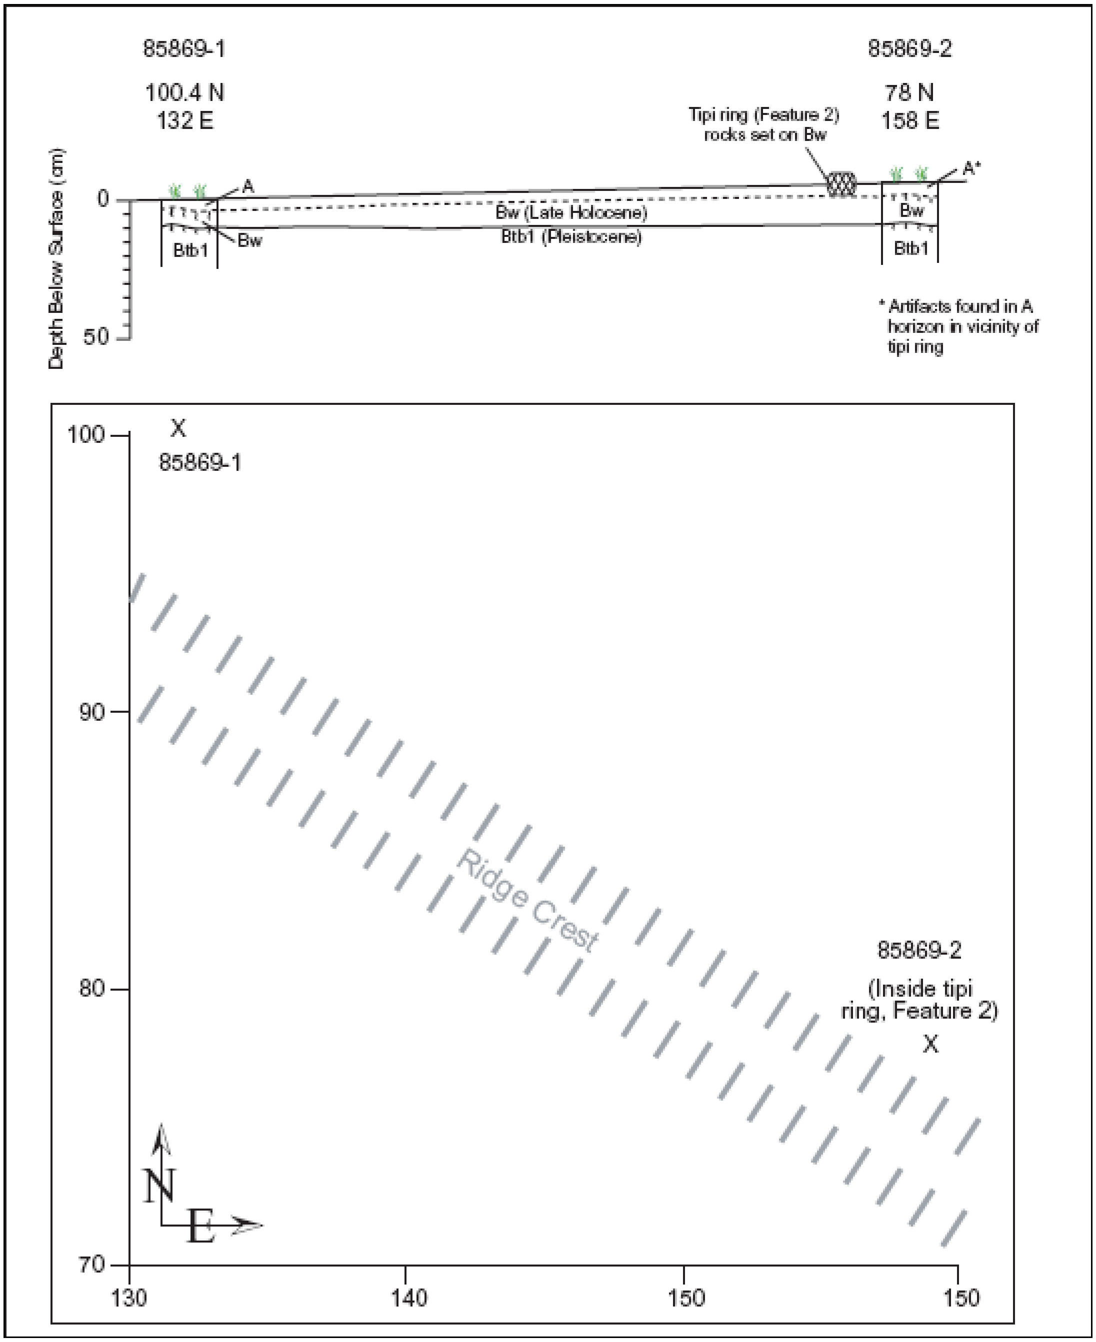

Figure 57.52. Site stratigraphy and sketch map of LA 85869.

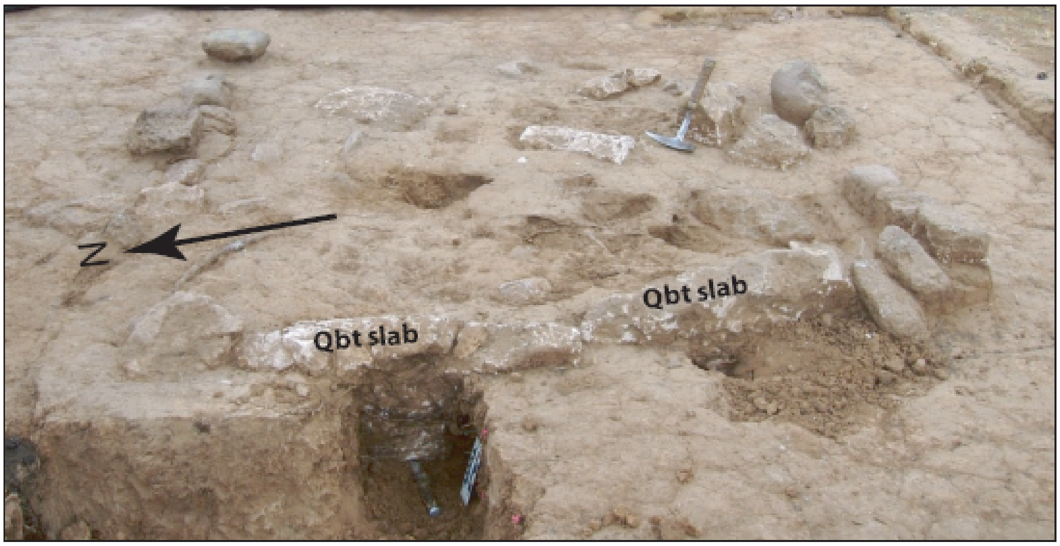
The second period of construction appears to have recycled clasts from the earlier construction phase and built on top of old fill. The top of the Bw2 horizon inside the structure constitutes the likely occupation surface for the latest occupation at this site. Outside the structure the relations are less clear. The occupation surface for the inferred first occupation at this site was likely at the top of the Btb1 horizon, and for the latest occupation could have been at this level but, based on the shallow trench fill next to the slab that appears to extend through the Bw horizon, was likely the top of the Bw horizon. Total deposition outside the structure since initial occupation was about 19 cm and, since the latest occupation, may have been as little as 7 cm.



Photograph of LA 86605 during excavation. Note Qbt slabs, opening in structure facing east.

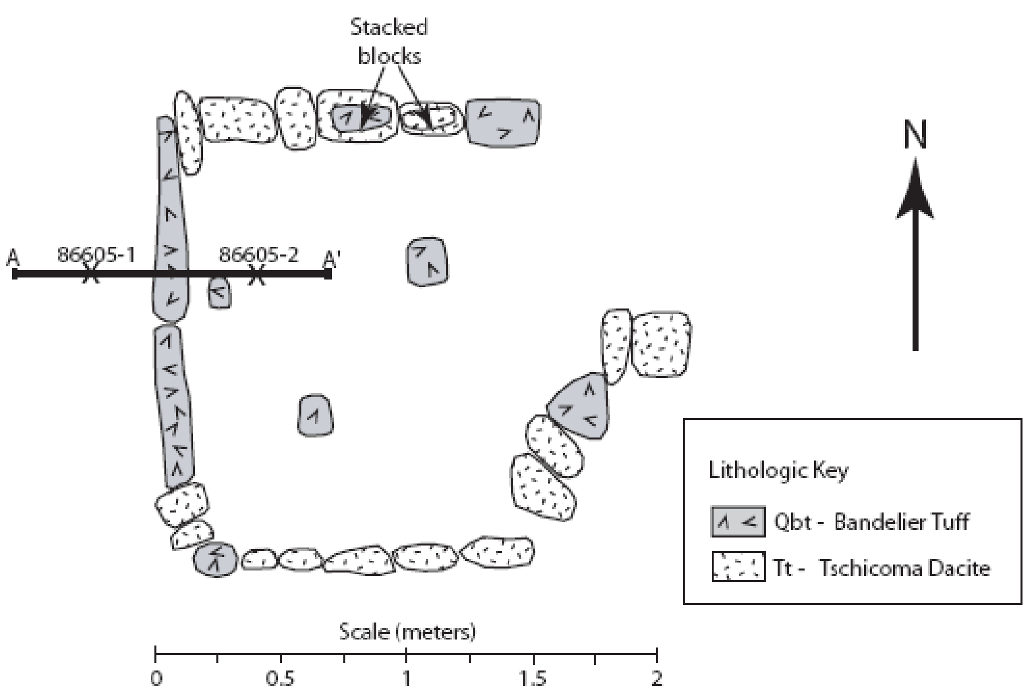


Figure 57.53. Schematic site map and photograph from LA 86605.

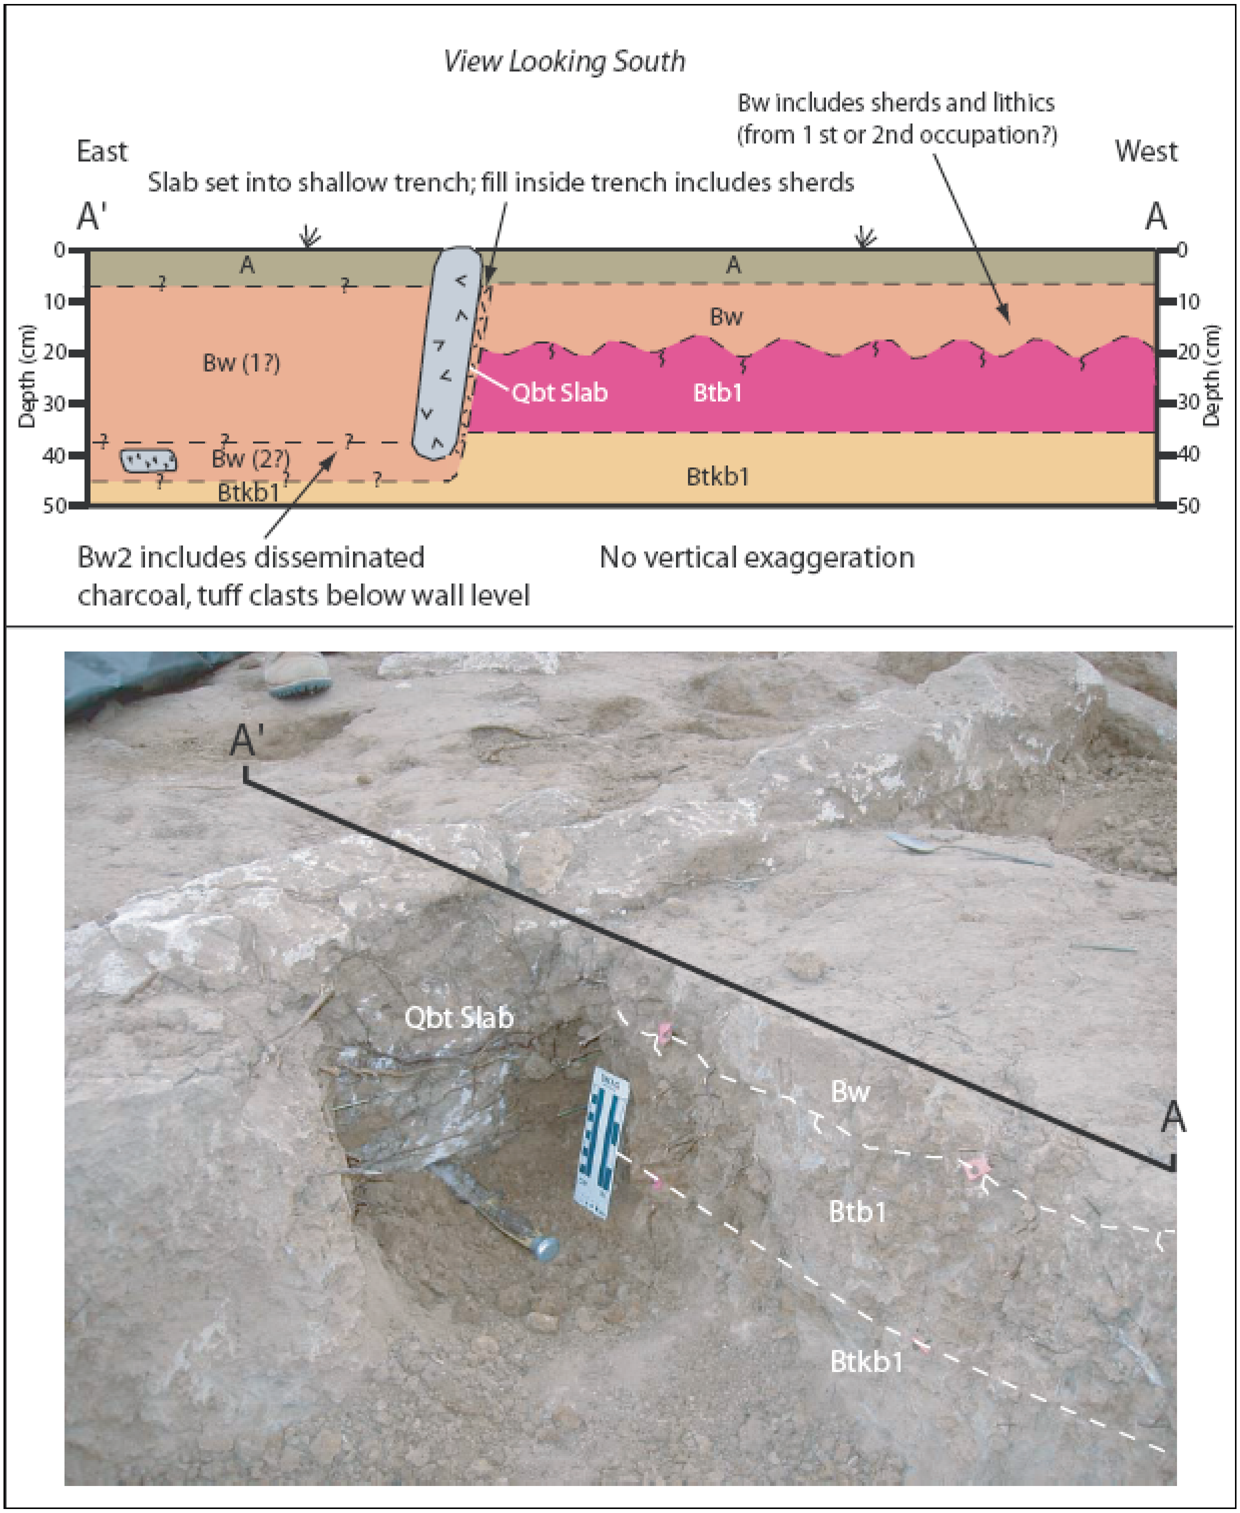

Figure 57.54. Cross-section and photograph showing soil stratigraphy in relation to slabs used in wall construction at LA 86605.

LA 86605 is buried by slopewash colluvium and reworked eolian fine sand, but did not exhibit extensive erosion and appears to be in good archaeological context. The Bw horizon that buries this site is reddened and has a hard consistence, suggesting a relatively older site age for the first occupation, whereas the thin A horizon burying the likely occupation surface at the top of the Bw horizon suggests a relatively young age for the second occupation. The soils and related stratigraphy are therefore consistent with LA 85404 having an earlier Coalition period occupation and a later, likely Classic period, occupation. A maize sample from a possible living surface at LA 86605 yielded a radiocarbon age of 360±40 BP (Beta-215551) and a date of cal AD 1542 with a two-sigma date range of cal AD 1450–1635 (Table M.2), also indicating a Classic period age for the second occupation at LA 86605.

LA 86606 (Fieldhouse)

LA 86606 consists of a fieldhouse and separate wall situated on a prominent gently east-sloping bench overlooking the Cabra Canyon floor. The bench is likely a Cabra Canyon Pleistocene terrace overlain by colluvium derived from the hillslope west of the site. The fieldhouse is oriented north-south by east-west and measures approximately 1.8 m by 1.7 m (inside), or 2.5 m by 2.0 m (outside dimensions) (Figure 57.55).

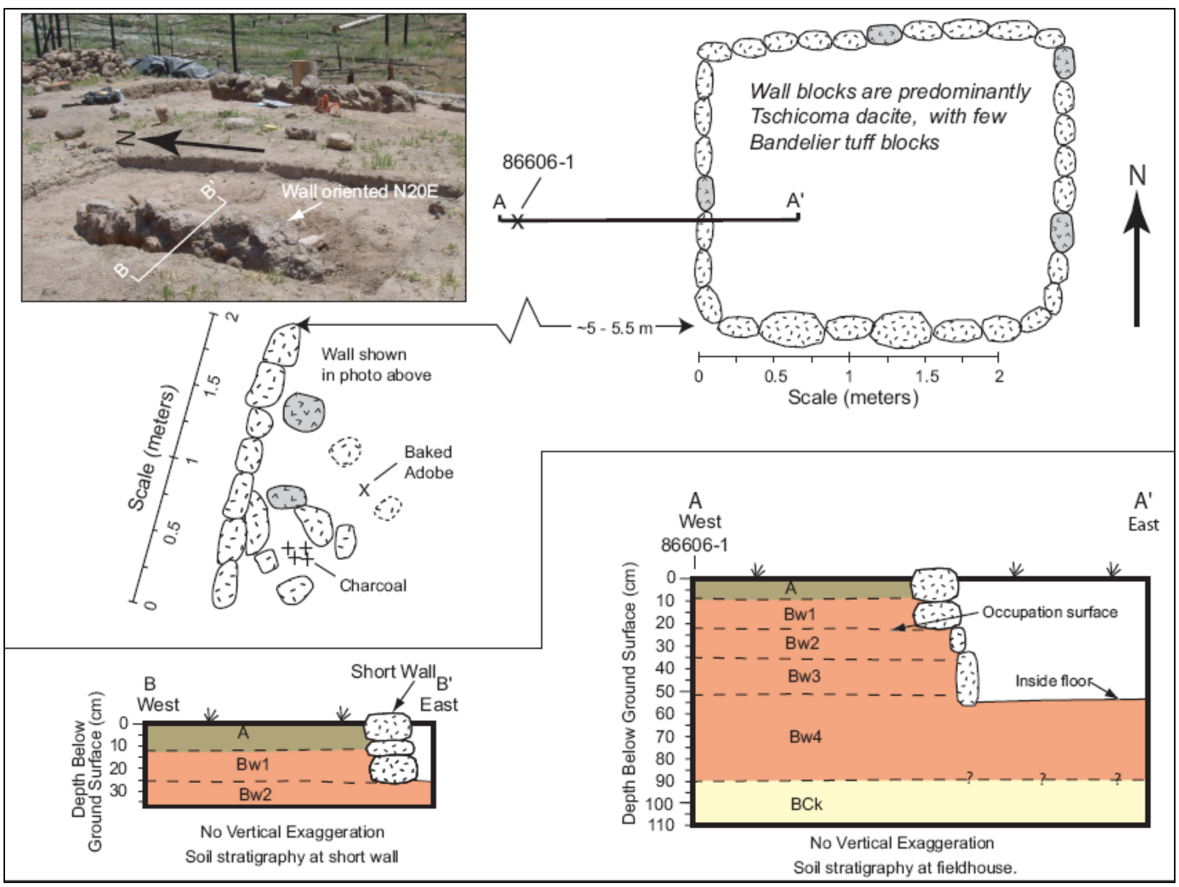

Figure 57.55. Photograph showing fieldhouse and external wall and sketches showing schematic site map and soil stratigraphy at LA 86606.

A separate 2-m-long wall is located 5 to 5.5 m west of the fieldhouse and is oriented N20°E (Figure 57.55). Soils were described in one test pit at the site, located 1.2 m west of the west wall of the fieldhouse. Site stratigraphy consists of an A-Bw1-Bw2-Bw3-Bw4-BCk soil to a depth of 120 cm (Figure 57.55; Table L.6). The soil at this location is a gravelly cumulic soil formed in a middle to late (?) Holocene aggradational colluvial deposit that likely overlies a fluvial terrace deposit. The absence of early Holocene deposits suggests extensive erosion at this site before or during the middle to late Holocene.

The fieldhouse was constructed primarily from dacite blocks, with some (approximately 5%) tuff blocks also utilized. Wall rocks were set to a depth of approximately 25 cm on the outside of the structure, to the top of the Bw2 horizon, and foundation rocks and/or facing slabs were set to a depth of approximately 55 cm inside the fieldhouse, into the Bw4 horizon (Figure 57.55). The occupation surface at the site is inferred to be the top of the Bw2 horizon and inferred post-occupation colluvial deposits are 22 cm thick at the described profile. The separate wall was also set on top of the Bw2 horizon and therefore appears to be contemporaneous with the fieldhouse. Charcoal and baked adobe were present east of the wall (Figure 57.55), suggesting an outside use area. The soils and related stratigraphy are consistent with a Classic period, or possibly (less likely) a Coalition period age for LA 86606. The site is currently in a depositional setting and, with the exception of some minor erosion observed on the east side of the fieldhouse, is in good archaeological context.

LA 86607 (Fieldhouse)

LA 86607 consists of a fieldhouse situated on a ridge spur between Cabra Canyon and a tributary drainage. The ridge spur is a possible high terrace remnant or Qct gravel overlain by thin Holocene colluvium. The fieldhouse is oriented approximately north-south by east-west and measures approximately 2.2 m by 2.0 m (inside), or 2.8 m by 2.6 m (outside dimensions) (Figure 57.56). Soils were described in one test pit at the site, located 1.5 m west of the west wall of the fieldhouse. Site stratigraphy consists of an A horizon formed in late Holocene (post-occupation) colluvium overlying a clay-rich Pleistocene Btb1 horizon (Figure 57.56; Table L.6). The absence of early or middle Holocene deposits suggests extensive erosion before deposition of the late Holocene colluvium sediment.

The fieldhouse was constructed primarily from dacite blocks, with some tuff blocks also utilized. Wall rocks were set to a depth of approximately 5 cm below the top of the Btb1 horizon (Figure 57.56). The occupation surface at the site is inferred to be the top of the Btb1 horizon, and post-occupation colluvial deposits are 4 cm thick at the described profile. Soils burying LA 86607 are thin and weakly developed. The soils and related stratigraphy are consistent with a Classic period age for LA 86607; however, the weak soil development may also be related to the setting of the site. The site is in an erosional setting and is in relatively poor archaeological context.

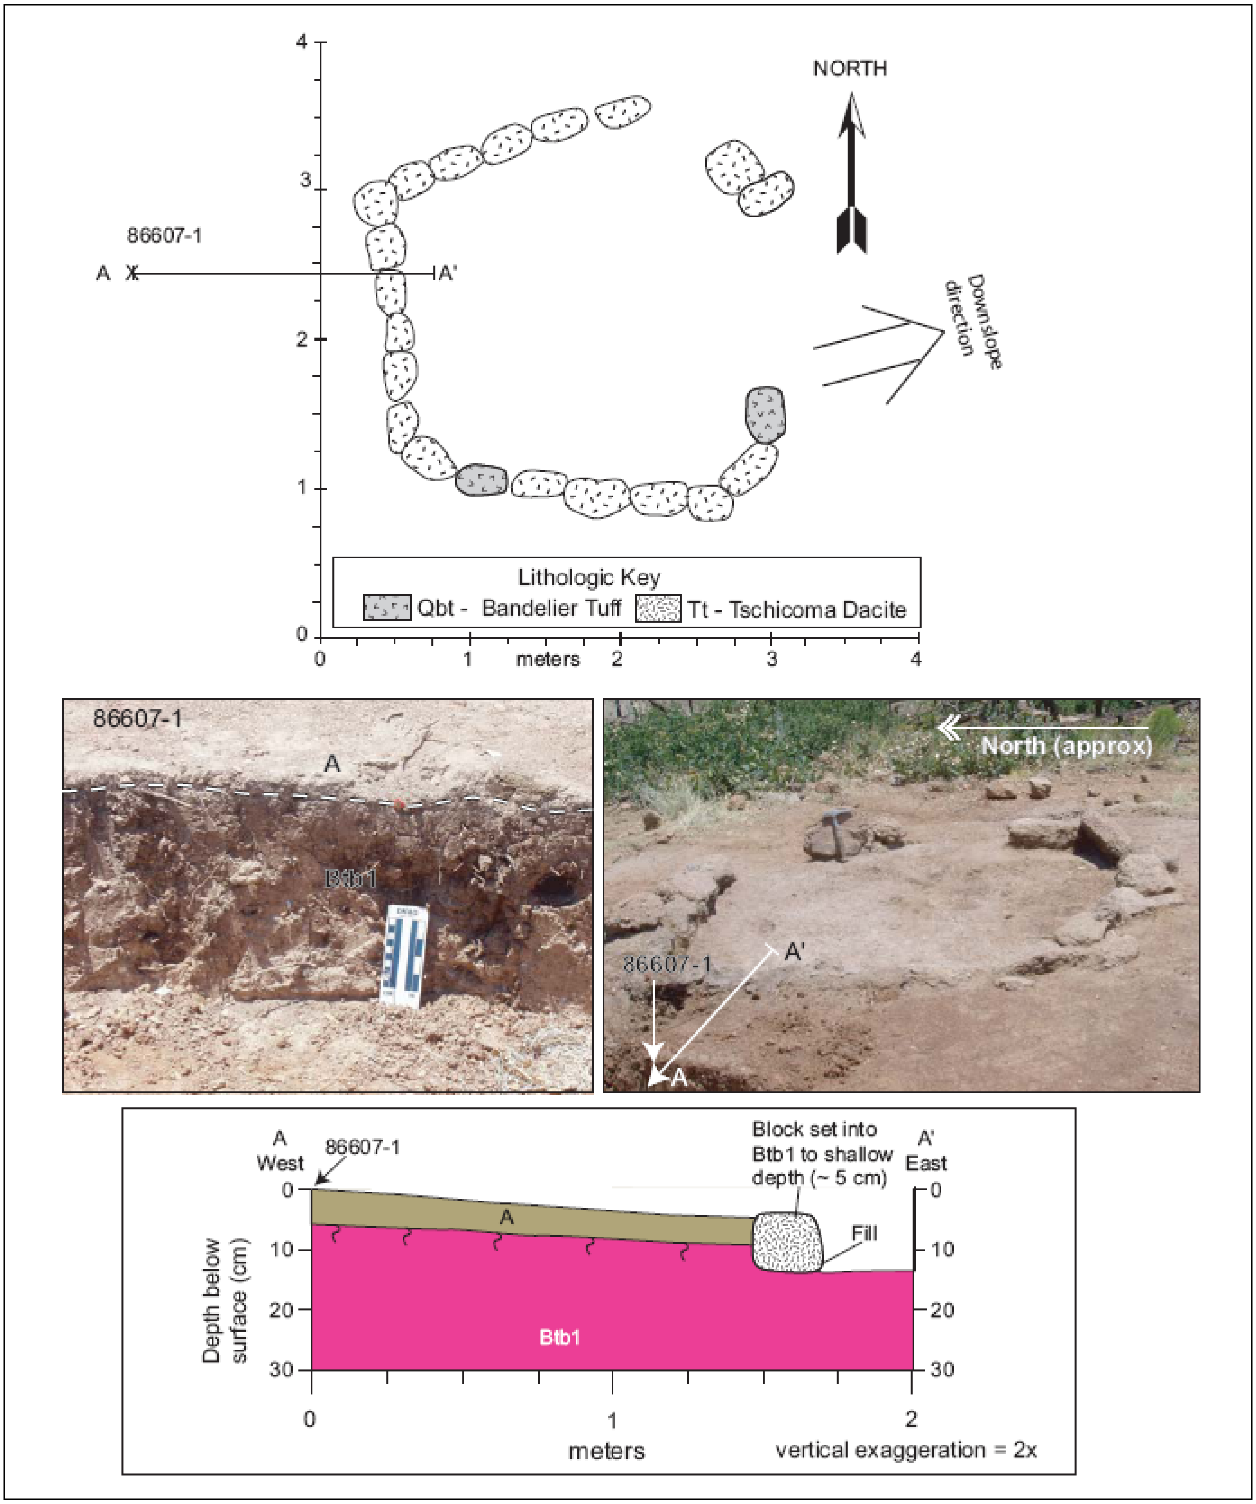

Figure 57.56. Schematic site map, cross-section, and photographs from LA 86607.

LA 87430 (Fieldhouse)

LA 87430 includes a fieldhouse with an external hearth situated on the north edge of a Qt5 terrace overlooking the Rendija Canyon stream channel (Figure 57.57). The structure measures approximately 1.85 m north-south by 2.1 m east-west (inside dimensions), or 2.4 m north-south by 2.4 to 2.8 m east-west (outside dimensions), situated with the short axis of the structure oriented N20°E, and contains an opening facing east-southeast (Figure 57.57). Soils were described in one test pit at the site, located 2 m east of the east side of the fieldhouse (Figure 57.57; Table L.5). Site stratigraphy consists of an A-Bw soil overlying a buried mid Holocene Btb1 horizon (Figure 57.57; Table L.5).

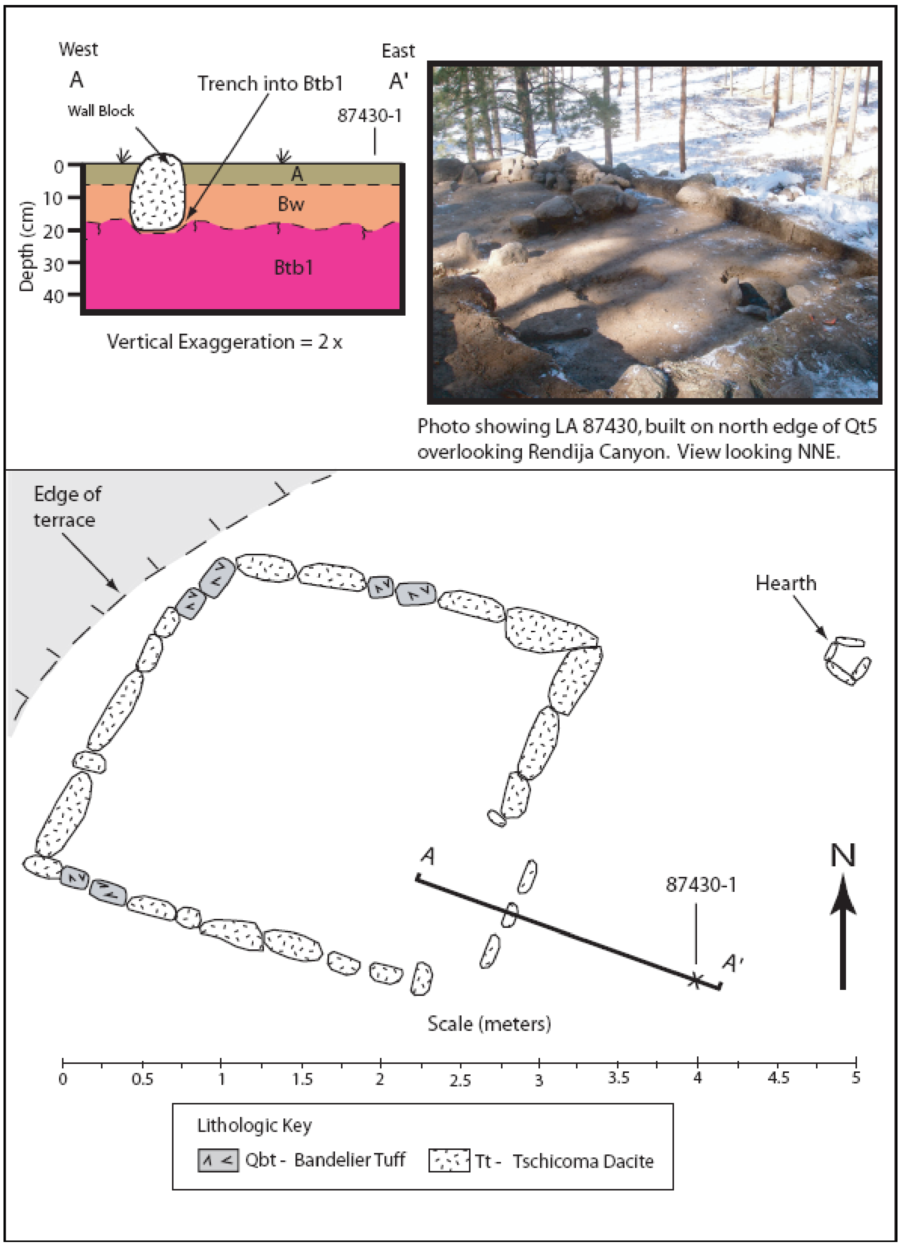

Figure 57.57. Schematic site map and cross-section of LA 87430.

The fieldhouse was constructed primarily from dacite blocks, with some tuff blocks also utilized. The occupation surface at the site is on, or just above, the top of the Btb1 horizon (Figure 57.57). Rocks for wall construction were either set on top of, or in some cases, into a shallow trench into the Btb1 horizon (Figure 57.57). The site has been subject to some erosion on the north side and deposition on the south side of the structure. Although built on the edge of the terrace above a steep streambank, the walls appeared to be relatively well preserved and the site is likely in good archaeological context. LA 87430 is buried by a weakly developed soil in a colluvial deposit that is 18 cm thick where described. The soils data and related stratigraphy are suggestive of a Classic period age for LA 87430. Two samples of maize collected from ash surrounding the external hearth yielded radiocarbon ages of 370±40 BP (Beta-215552) and 390±40 BP (Beta-215553). The dates are statistically indistinguishable, allowing summing of probabilities and a refined age estimate of 380±28 BP and a date of cal AD 1500 with a two-sigma date range of cal AD 1445–1631 (Table M.2), also indicating a Classic period age for LA 87430.

LA 99396 (Multi-component Archaic Lithic Scatter and Puebloan Structure)

LA 99396 includes an Archaic lithic scatter and a one-room Puebloan structure with a hearth and an artifact scatter that includes sherds. The site is situated on a broad, low-relief, approximately east-west-trending ridge crest and on the south-facing hillslope below the ridge and is located just west of a saddle (see Figures 57.29 and 57.58). LA 99396 is underlain by thin eolian and colluvial deposits that overlie Qct or Qbog pumice (Figures 57.34 and 57.59). Many of the soil horizons at the site are fine-grained, silty deposits with less than 2 percent gravel, indicating a significant component of eolian deposition (Table L.7; Figure 57.59).

Site stratigraphy includes late Holocene (younger than AD 1400, based on correlation with radiocarbon dated deposits at LA 85859 and LA 99397) eolian or slopewash deposits generally less than 15 cm thick outside the Feature 2 structure overlying late Pleistocene or early Holocene eolian deposits (99396-1, 99396-4, 99396-5), late Holocene (1 to 2 ka) swale fill deposits (99396-2), or Qct/Qbog pumice (99396-3) (Figures 57.34 and 57.59; Table L.7). A charcoal sample collected from the Bwb1 horizon at 99396-2 yielded a radiocarbon age of 1000±40 BP (Beta-199385) and a date of cal AD 1032 with a two-sigma date range of cal AD 975–1155. This provides a minimum age for the Bwb1 soil and the late Holocene swale fill deposits at LA 99396. The maximum thickness of late Pleistocene or early Holocene eolian deposits observed at LA 99396 was 113 cm at 99396-4 and likely represents a cumulic soil profile. A charcoal sample collected from the Btkb1 horizon at 99396-4 (see Figure 57.34) yielded a radiocarbon age of 33,660±320 BP (Beta-199381) that is beyond the range of calibration. Soil characteristics include 7.5YR color, common to many thin clay films as bridges and on ped faces and maximum Stage II- carbonate. Although less well-developed than soils described at LA 85859, the degree of soil development observed in the 99396-4 b1 soil is similar to that observed in late Pleistocene soils previously described in Rendija Canyon (McDonald et al. 1996; Phillips et al. 1998) and is consistent with the development of Stage II carbonate in warm to temperate semiarid locations in late Pleistocene soils (Machette 1985). Although the 33.7 ka b1 soil at LA 99396 (including Bt, Bk, and Btk horizons) is somewhat similar to the 6.7 to 7.4 ka b1 soil at LA 85859, the different soil ages, based on radiocarbon dates, show the importance of local geomorphic setting on soil development. The late Pleistocene soils are truncated, indicating erosion of the area in the vicinity of LA 99396 some time during the Holocene, before deposition of the late Holocene eolian and colluvial deposits. The development of shallow drainages and their subsequent filling is recorded by the middle to late Holocene swale fill deposit at 99396-2 (Figure 57.34). The swale fill deposits are reddened, exhibiting 8.75YR to 7.5YR color, but lack clay films (Table L.7). From these soil properties it is inferred that the swale fill deposits are derived from reworking of older soils upslope.

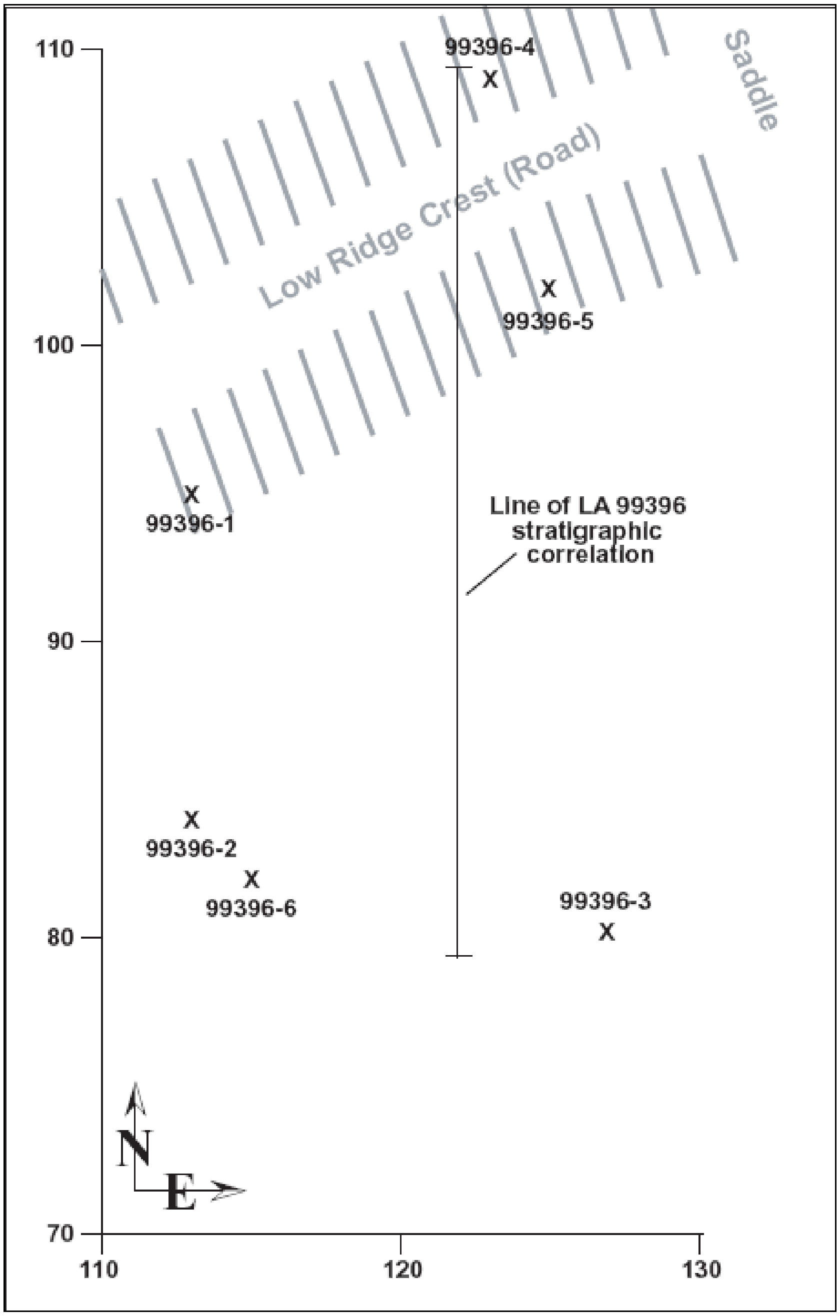

Figure 57.58. Site map showing location of soil pits at LA 99396.

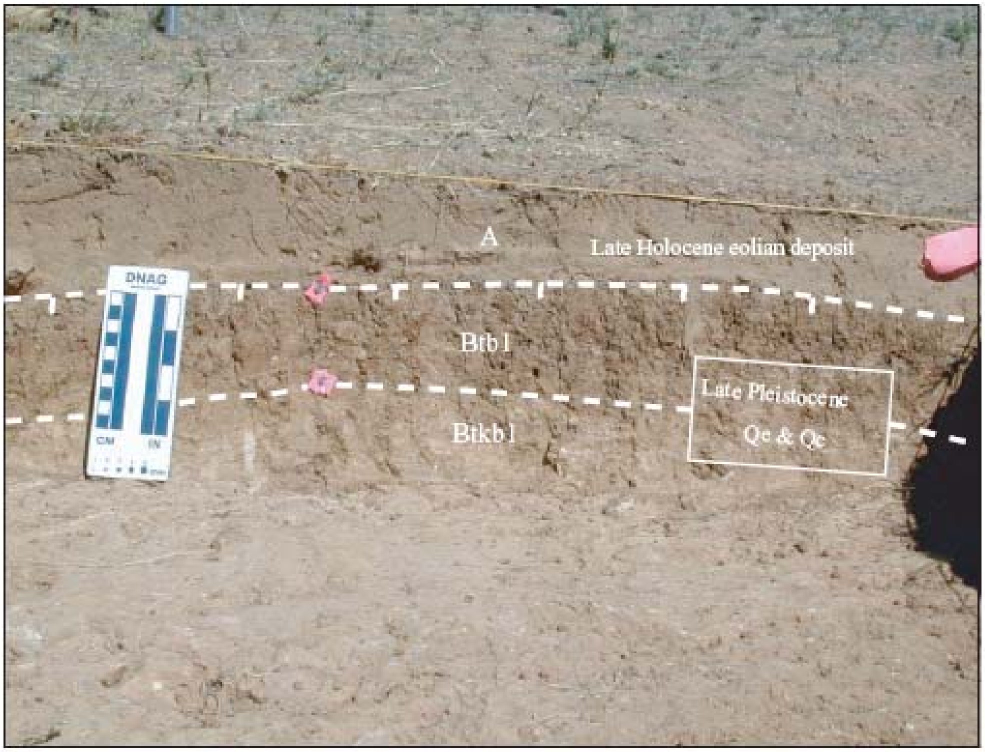

Late Holocene eolian deposit (Qe) over truncated late Pleistocene Btb1 horizon.

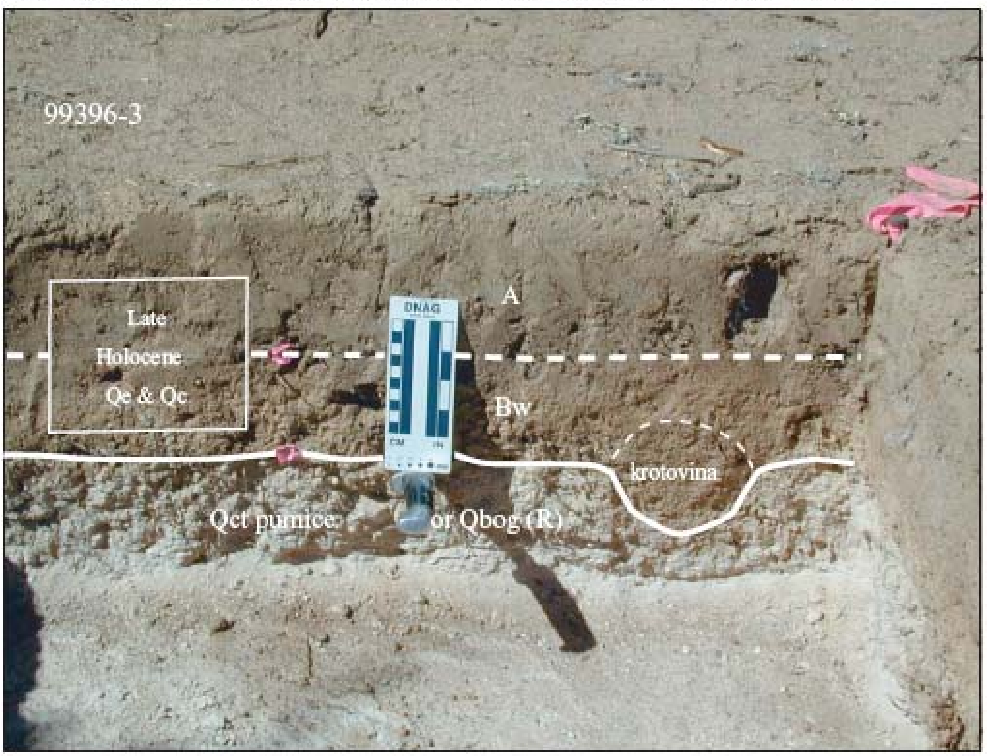

Figure 57.59. Thin soils formed in late Holocene eolian deposits (Qe) and slopewash colluvium (Qc) overlying bedrock (Qct or Qbog pumice) at LA 99396.

Artifacts were found in both the late Holocene deposits and near the top of the upper horizon (Bt1b1) of the late Pleistocene soil at LA 99396 (Figure 57.34; Table E-2 of Drakos and Reneau 2004). The maximum subsurface artifact concentration at the site was observed in the vicinity of 99396-4 and 99396-5, on the ridge crest, and within the one-room structure. Artifacts were observed near the top of the Btlb1 horizon at 99396-4 and at 99396-6 (Table E-2 of Drakos and Reneau 2004). The occupation surface was likely the top of the Btb1 horizon, and some artifacts may have been reworked into the upper Btb1 horizon as a result of bioturbation, anthropogenic, or pedogenic processes. Soil-stratigraphic relationships therefore do not definitively indicate an Archaic component to the site, and the lithic artifacts could be associated with the Puebloan occupation. Artifacts were observed in the late Holocene deposits in several profiles where soils were described, including 99396-2, 99396-3, 99396-4, 99396-5, and 99396-6. These include locations on the ridge crest and on the slopes both to the north and the south. With the exception of one obsidian flake recovered from the Bt1b1 horizon, artifacts were not observed at 99396-1, located west of 99396-5, in a slightly upslope direction (Figure 57.58). The presence of Feature 2, a one-room structure, with a concentration of artifacts including a sherd in the Bw horizon of 99396-5, indicates an Ancestral Puebloan component to the site. The weakly developed soils with thin A-Bw horizons that bury the LA 99396 occupation surface, and within which artifacts occur, is consistent with an Ancestral Puebloan age for Feature 2.

The subsurface artifact distribution at LA 99396 suggests that the Ancestral Puebloan occupation surface was on top of the late Pleistocene eolian deposits and that the site was centered in the vicinity of the one-room structure and LA 99395-5. Artifacts have been transported in late Holocene slopewash colluvium and are concentrated in the shallow gully examined at 99396-3. The site likely extended northward to the vicinity of 99396-4.

The absence of lithics in profile 99396-2, in the 1 to 2 ka swale fill deposit, is consistent with only an Ancestral Puebloan occupation. The subsurface distribution of artifacts suggests that the Archaic site, if present, was likely centered in the vicinity of 99396-4 and possibly also near 99396-6 (Figures 57.34 and 57.58). However, surface lithic density is highest in the vicinity of the shallow gully near 99396-3. These data suggest that much of the Archaic site component has been eroded, with the artifacts transported downslope and concentrated in the shallow gully below the site. In contrast, ceramics associated with Feature 2 are located close to the Ancestral Puebloan structure, both on the surface and in the subsurface, indicating less erosion and downslope transport than for the Archaic components. The concentration of artifacts in the Bt1b1 horizon at 99396-4 and in the Btb1 horizon at 99396-6 (Figure 57.60), near the top of the b1 soil profile, suggests that the Archaic occupation surface was also near the top of the b1 soil, and that the Archaic site was buried by late Holocene eolian deposits.

With the exception of the site disturbance related to development of the two-track road through the site, the Ancestral Puebloan Feature 2 structure and artifacts in its vicinity are in reasonably good context. It is also possible that the Archaic artifacts in the Btb1 horizon at LA 99396 are close to their original location. However, it is likely that the occupation surface has eroded away leaving only a few artifacts in the Btb1 horizon that are not in their precise original location. While not in good archaeological context, the artifacts in the Btb1 horizon are considerably closer to their original context than are those in the late Holocene slopewash colluvium and eolian deposits.

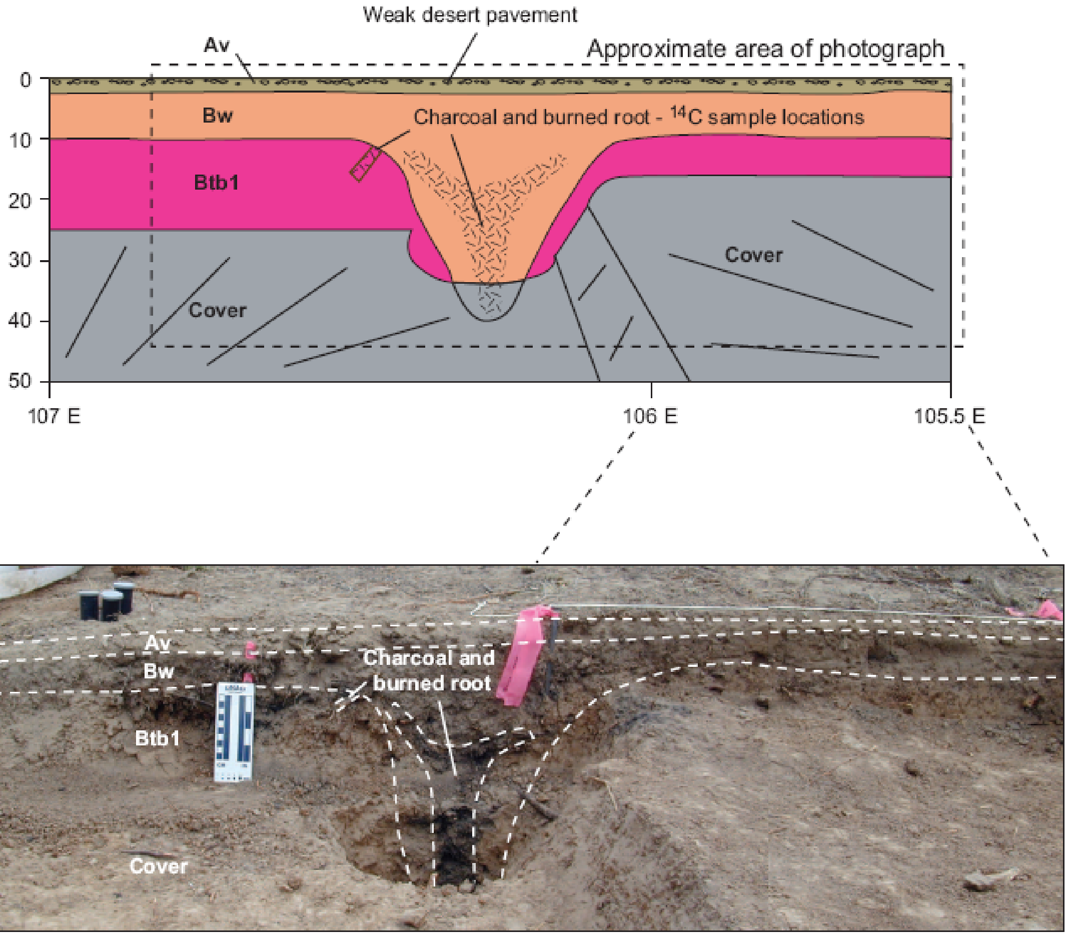

Figure 57.60. Photograph and sketch showing stump hole with charcoal sample location and soil horizons, 99396-6.

LA 99397 (Archaic lithic scatter)

LA 99397 is situated on a northeast-facing hillslope that forms the shoulder of a generally southeast-to-northwest-trending ridge crest, slightly northwest of LA 85869 and southwest of LA 85864 (see Figures 57.29 and 57.61). A fieldhouse (LA 85411) is located just upslope from LA 99397. LA 99397 is underlain by a thin late Holocene colluvial and eolian deposit that overlies Pleistocene colluvium and Qct gravel (see Figure 57.35; Table L.7). Several areas of the site exhibit a surface gravel cap or weak desert pavement, discontinuous Av (vesicular A) horizon, and rubification (reddening) of the underside of surface clasts, all of which indicate a late Holocene eolian influx leading to the formation of a weak desert pavement (Table L.7, 99397-1, 99397-3, 99397-4, and 99397-6; Figure 57.35; see McFadden et al. [1987] for a discussion of eolian dust influx and the formation of desert pavements). Some of the late Pleistocene and

Holocene soil horizons at the site are fine-grained, silty deposits with 5 percent or less gravel, indicating a significant eolian component to the colluvium (Table L.7).

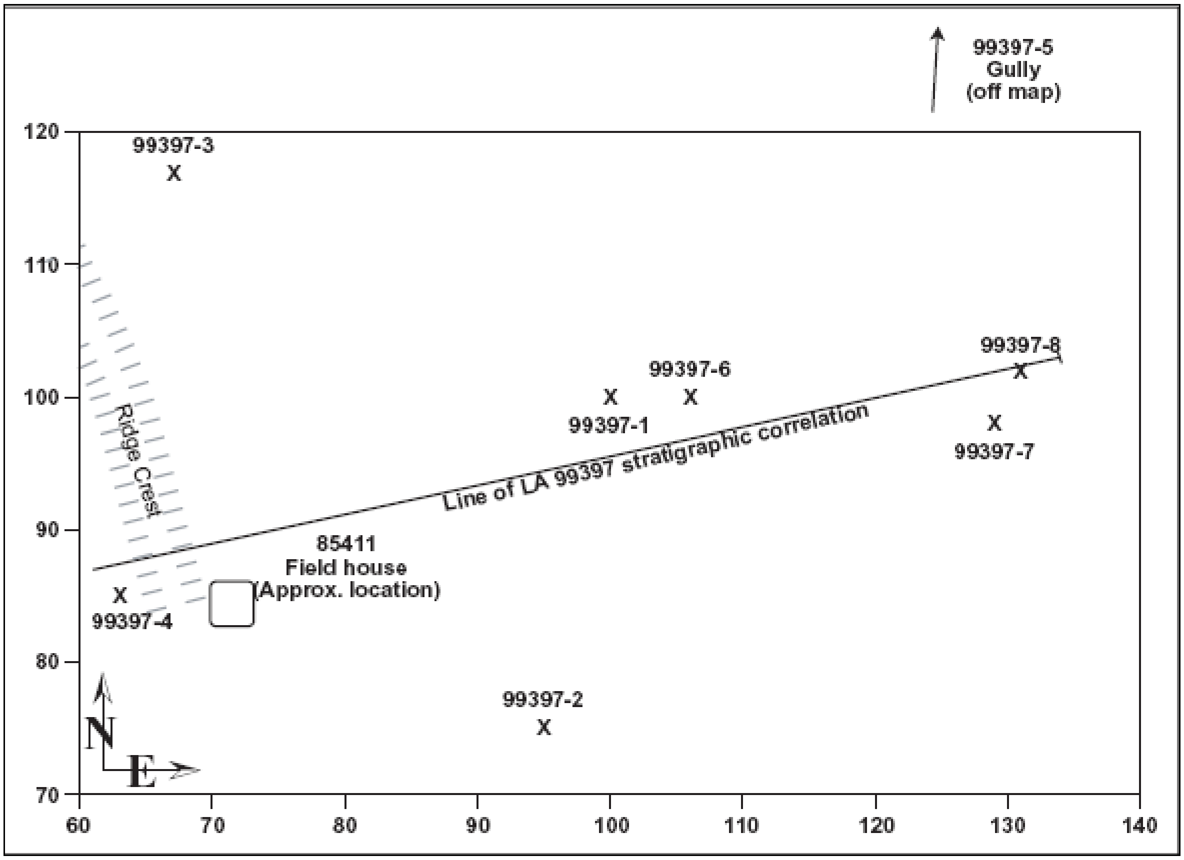

Figure 57.61. Site map showing location of soil pits at LA 99397.

Site stratigraphy includes thin late Holocene colluvial and eolian deposits less than 25 cm thick overlying late Pleistocene to early Holocene colluvial deposits or late Holocene (1 to 2 ka) swale fill deposits (99397-7) (Figures 57.35 and 57.62; Table L.7). The maximum age of the latest Holocene colluvial deposit is constrained by a charcoal sample from the base of the Bw horizon that yielded a radiocarbon age of 530±40 BP (Beta-199385) and a date of cal AD 1406 with a two-sigma date range of cal AD 1312–1359. Late Pleistocene to early Holocene colluvial deposits observed at LA 99397 range in thickness from approximately 15 cm to greater than 114 cm, with deposit thickness generally increasing downslope (Figure 57.35; Table L.7). The late Pleistocene or early Holocene soils are truncated, indicating erosion of the area in the vicinity of LA 99397 sometime during the Holocene, before deposition of the late Holocene colluvium. The development of shallow drainages and their subsequent filling is recorded by the approximately 1 to 2 ka (late Holocene) swale fill deposit at 99397-7 (Figure 57.35). The A-Bw-Bwb1-Bwb2 profile at 99397-7 represents episodic deposition in a swale.

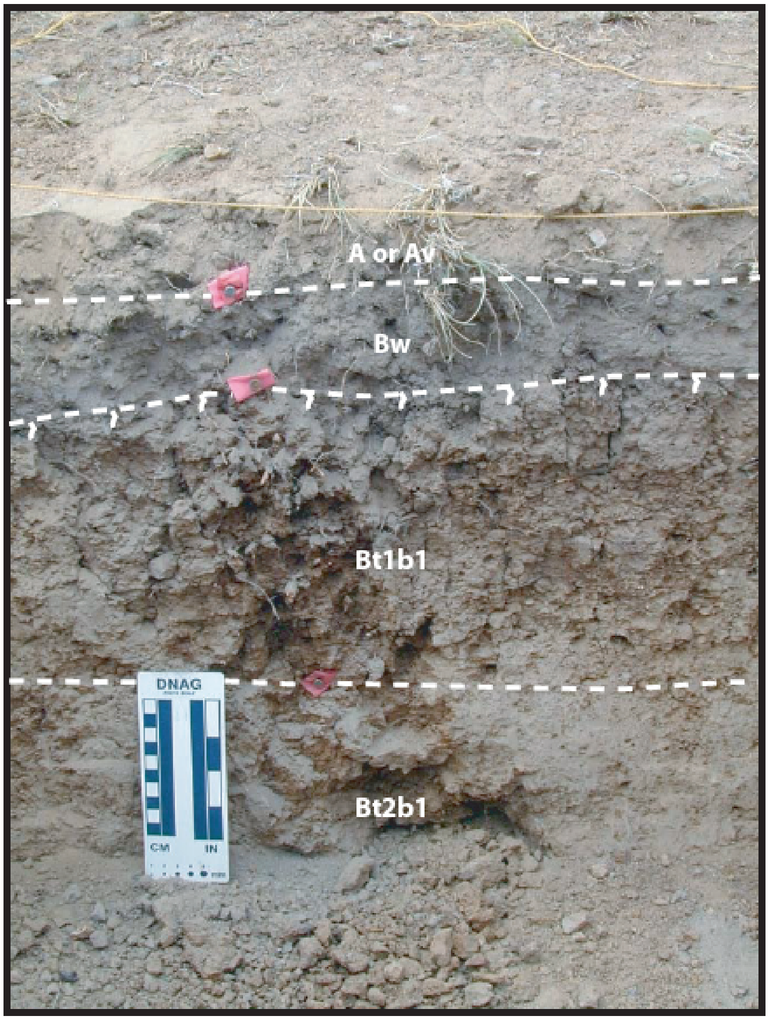

Figure 57.62. Soil profile #1 at LA 99397. Av-Bw horizons formed in late Holocene colluvium and eolian deposits overlying buried Bt horizons developed in late Pleistocene colluvium.

Two charcoal samples were collected from near the top of the Btb1 horizon at LA 99397. One sample yielded a radiocarbon age of 2110±60 BP (Beta-199383) and a date of cal 2090 BP with a two-sigma date range of cal 1933 to 2307 BP. A second sample yielded a radiocarbon age of 2280±40 BP (Beta-199384) and a date of cal 2263 BP with a two-sigma date range of cal 2157 to 2352 BP (Table M.2). These ages are similar but statistically different and are interpreted to date the age of the stripped surface that included the site occupation at LA 99397. The late Holocene swale fill deposit is either contemporaneous or post-dates the age of the stripped surface.

Artifacts including lithics and rare sherds were found concentrated in the late Holocene deposits and locally in the underlying late Pleistocene or early Holocene Btb1 horizon at LA 99397 (Figure 57.35; Table E-3 of Drakos and Reneau 2004). The maximum artifact concentration at the site was observed in the vicinity of 99397-6, where several artifacts were also found in the Btb1 horizon. Artifacts were observed in the A and Bw horizons in 99397-1, 99397-6, and

99397-7 and in the A horizon only in 99397-2. Artifacts were not observed in 99397-3 or 99397-4, located upslope from both the fieldhouse and the artifact concentration at LA 99397. The artifact distribution at LA 99397 suggests that the occupation surface was likely on top of the late Pleistocene or early Holocene colluvial deposits and that usage was centered in the vicinity 99397-6. Artifacts have been transported in late Holocene slopewash colluvium downslope from the vicinity of 99397-6 and are also concentrated in the upper swale fill deposit at 99397-7 (Figure 57.35; Table E-3 of Drakos and Reneau 2004). Artifacts found in the A horizon only at 99397-2 are inferred to have been transported downslope from the fieldhouse (LA 85411).

Several of the b1 soils at LA 99397 (including Bt and Btk horizons) are similar to the b1 soil at LA 99396 and are also inferred to be late Pleistocene in age, based on relative soil development in Rendija Canyon (Reneau and McDonald 1996; McDonald et al. 1996). The Stage II- carbonate horizon observed at 99397-1 and 99396-8 suggests an early Holocene age for these deposits, based on the development of Stage I carbonate in 4 to 8 ka deposits at the Fence Canyon site and the development of Stage II+ carbonate in a greater than 50 to 60 ka colluvial deposit on the White Rock Tract, Location 6 (Drakos and Reneau 2002; Reneau and McDonald 1996), and on carbonate soils described in Machette (1985). However, as discussed above, radiocarbon ages from LA 85859 indicate an age of ca. 6.7 to 7.4 ka, and an age of either late Pleistocene or early to middle Holocene is considered possible for the b1 soil at LA 99397 based on available data.

The remnant truncated mid-Pleistocene (?) soil with 5YR color and continuous, moderately thick clay films on the ridge crest at 99397-4 indicates that older, clay-rich soils are present in locations above LA 99397 where they could have been sources for clay in downslope colluvial deposits. Deposition of clay derived from the erosion of old soils with clay-rich Bt horizons could possibly result in accelerated Bt horizon development in the b1 soil underlying the site, as was observed at LA 85859.

Most of the artifacts at LA 99397 appear to have been reworked into the younger than AD 1312–1444 colluvium and the ca 1 to 2 ka late Holocene swale fill deposits and are not in good archaeological context. It is possible that the Archaic artifacts in the Btb1 horizon at LA 99397 are close to their original location. However, it is likely that the occupation surface has eroded away leaving only a few artifacts in the Btb1 horizon that are not in their precise original location. While not in good archaeological context, the artifacts in the Btb1 horizon are considerably closer to their original context than are those in the late Holocene slopewash colluvium and eolian deposits. Artifacts found in the A horizon only at 99397-2 are inferred to have been transported downslope from the fieldhouse (LA 85411) and are not in good context.

LA 127627 (Fieldhouse)

LA 127627 consists of a fieldhouse situated on a northwest-facing slope below the Qt2 terrace surface (see Figure 57.30). The structure measures approximately 1.9 m by 1.7 m (inside dimensions), or 2.3 m by 2.1 m (outside dimensions), situated with the long axis of the structure oriented approximately N40°W, and contains an opening in the northeast corner (Figure 57.63).

Soils were described in one test pit at the site, located 0.5 m east of the east corner of the fieldhouse (Figures 57.63 and 57.64; Table L.5). Site stratigraphy consists of an A-Bw soil overlying a buried Pleistocene Btb1 soil (Figure 57.63; Table L.5).

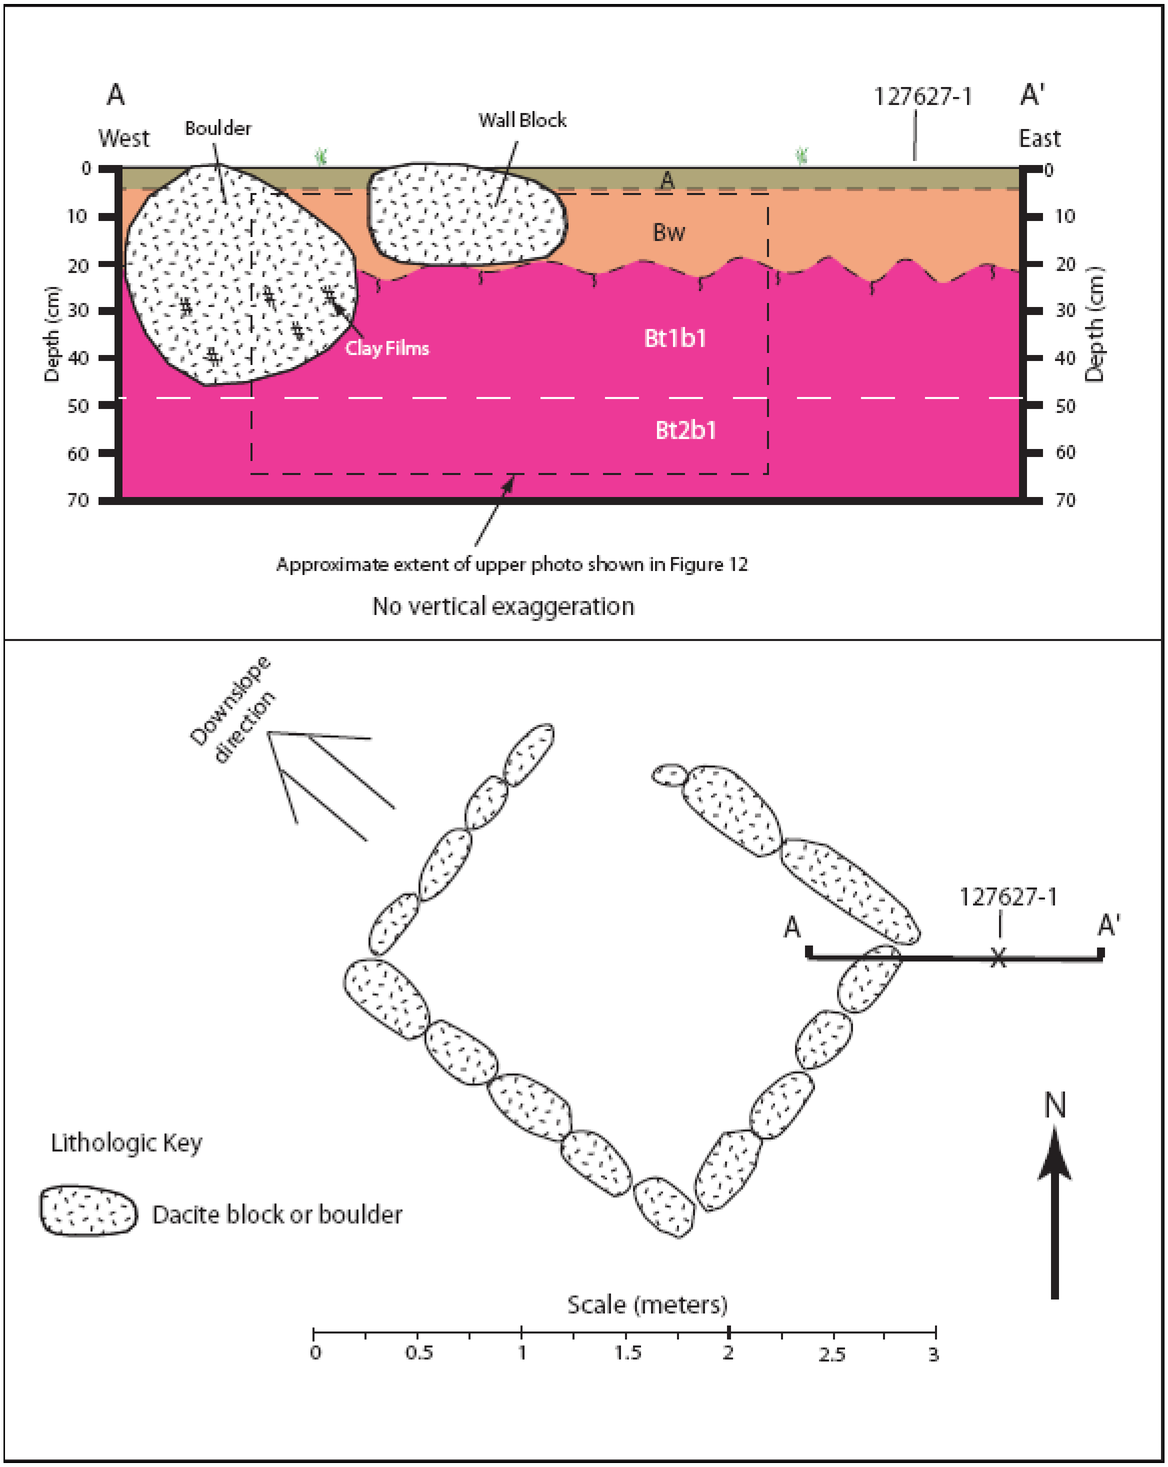

Figure 57.63. Schematic site map (bottom) and cross-section (top) at LA 127627.

Figure 57.64. Photographs showing soil stratigraphy at LA 127627.

The fieldhouse was constructed primarily from dacite blocks, presumably obtained from the Qt2 terrace deposit. Some *in situ* dacite boulders were utilized for fieldhouse construction, as evidenced by the presence of clay films on the lower half of the boulders (Figure 57.63). The LA 127627 structure was constructed on a slope, and the floor appears to have been leveled by cutting into the slope above and filling on the downslope side of the fieldhouse. The occupation surface at the site is the top of the Bt1b1 horizon (Figures 57.63 and 57.64). LA 127627 is buried by a relatively weakly developed soil in a colluvial deposit, but the Bw horizon has a hard consistence. Post-occupation colluvial deposits are 21 cm thick at the described profile near the east wall. The soils data and related stratigraphy are suggestive of a Classic period or possibly Coalition period age for LA 127627. Two samples of maize, collected from the top of the living surface and from under a rock in the room, yielded radiocarbon ages of 380±40 BP (Beta-215554) and 400±40 BP (Beta-215555). The dates are statistically indistinguishable, allowing summing of probabilities and a refined age estimate of 390±28 BP and a date of cal AD 1486 with a two-sigma date range of cal AD 1441–1629 (Table M.2), also indicating a Classic period age for LA 127627. The site has been subject to some erosion and transport of wall blocks as part of the colluvium but still has relatively intact walls, and site preservation has been aided by colluvial deposition. The site is in poor to moderate archaeological context.

LA 127633 (Storage Bin or Fieldhouse)

LA 127633 consists of a slab-lined storage bin on a sloping, south-southeast-facing colluvial hillslope that may be graded to the middle to late Holocene Qt7 terrace. The storage bin is located near the top of a 25° hillslope below a ridge spur. This small structure measures approximately 1.0 m by 0.7 m (inside dimensions), or 1.3 m by 1 m (outside dimensions), situated with the long axis of the structure oriented N77°E (Figure 57.65). Soils were described in two test pits at the site; profile 127633-1 was described several meters southwest of the structure, and profile 127633-2 was described outside of the west wall of the structure (Figure 57.65; Table L.5). Site stratigraphy consists of an A-BC or A-BC-C soil overlying a buried middle (?) Holocene Bw or Btjb1 soil (Figure 57.65; Table L.5).

The storage bin was constructed utilizing dacite slabs and tuff blocks (Figure 57.65). The dacite slabs were likely obtained from a dacite outcrop located a short distance upslope from the site. The slabs were set into a young aggrading colluvial deposit, with some additional burial of the slabs occurring after construction of the storage bin. The likely occupation surface at LA 127633 is within the upper part or at the top of the BC horizon. The dark staining on the slabs (see Figure 57.65) was caused by subsurface weathering and suggests a greater than historic age for this structure. The dark staining may indicate burial of the structure soon after abandonment, or may have occurred subsequent to the slabs having been emplaced in the subsurface. If the slabs were emplaced in the subsurface, the storage bin only experienced partial burial in the last 100 years. The weak soil development both above and below the structure indicates a likely Classic period age. The upper 5 to 10 cm of colluvium buries a small (17-cm-diameter) ponderosa pine with an estimated age of less than 100 years, indicating 5 to 10 cm of post-AD 1900 colluvial deposition at the site. This approximately corresponds to the thickness of the A horizon and of the “no lichen” band on the slabs (Figure 57.65), indicating that the A horizon formed in very young colluvium and that the staining likely requires more than 100 years for formation.

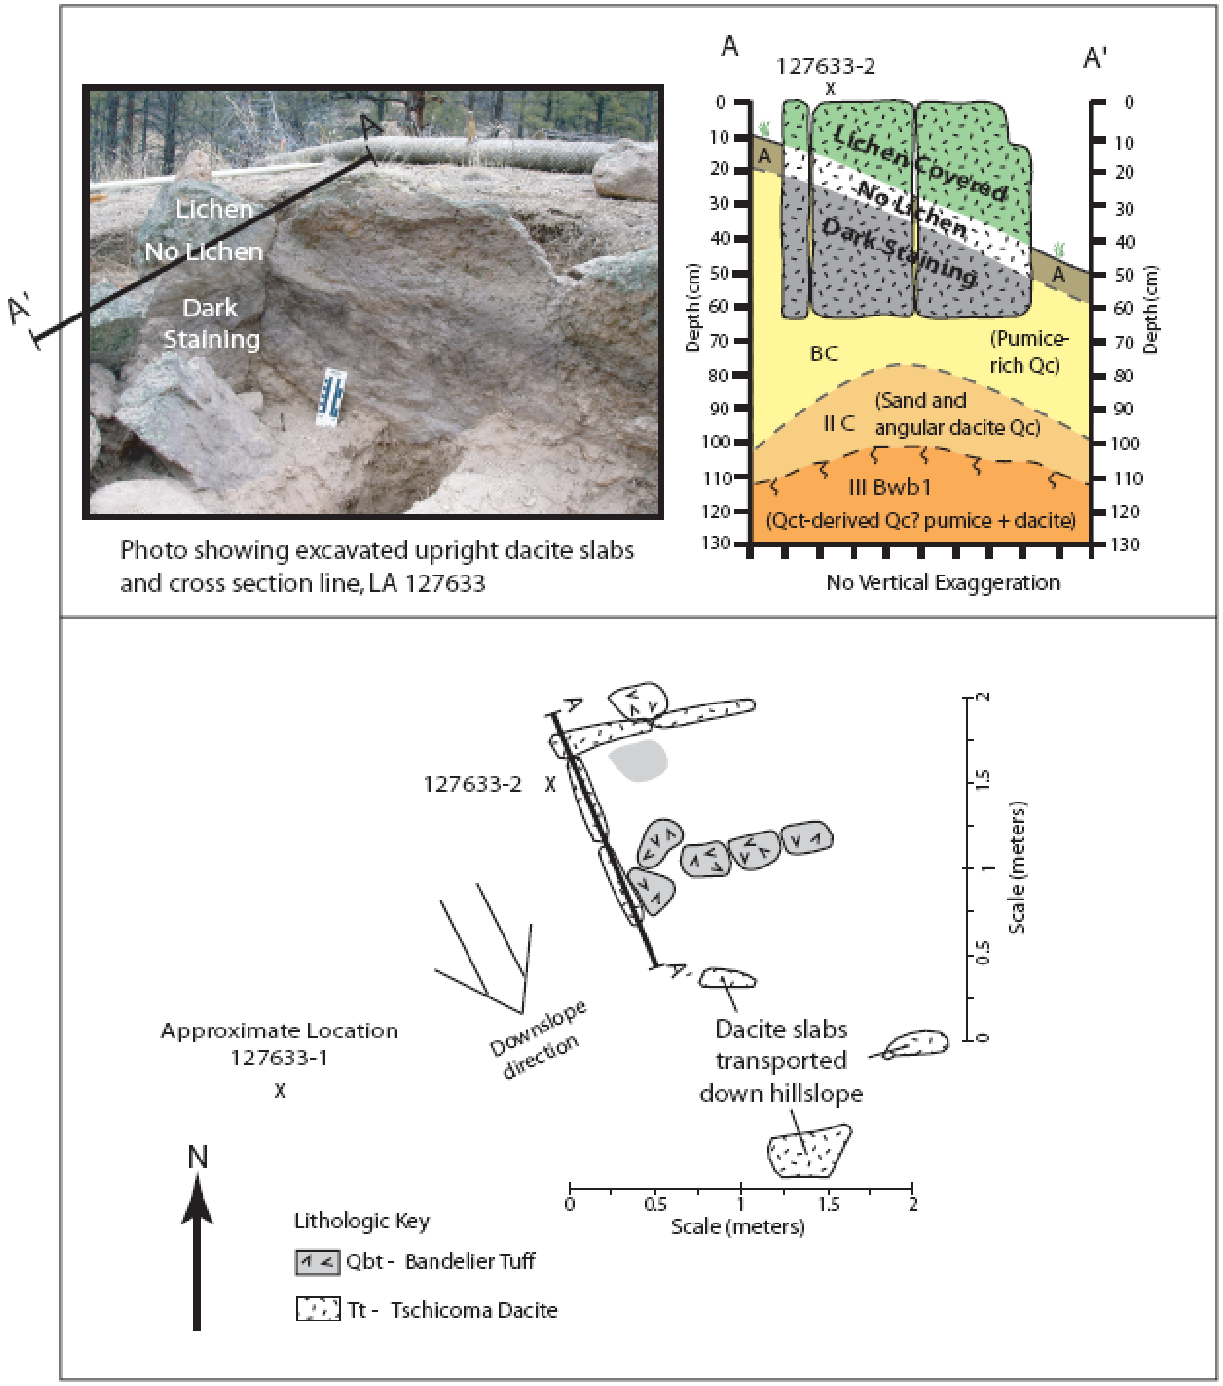

Figure 57.65. Schematic site map and cross-section from LA 127633.

The site is relatively steep and has been subject to some erosion and downslope transport of archaeological materials, including several dacite slabs as part of the colluvium. The site is therefore in moderate to poor archaeological context.

LA 127634 (Fieldhouse)

LA 127634 consists of a fieldhouse situated on a south-facing Qct or Qbog hillslope (see Figure 57.30). The structure measures approximately 2.5 m east-west by 1.8 m north-south (inside dimensions), or 3 m east-west by 2 m north-south (outside dimensions), and contains a south-facing entryway and a hearth in the southeast corner (Figure 57.66). Soils were described in one test pit at the site, located 2 m west of the northwest corner of the fieldhouse (see Figure 57.15; Table 57.1). Site stratigraphy consists of an A horizon overlying a buried late Pleistocene or Holocene Btkb1 soil (Figure 57.66; Table L.5). The Btkb1 horizon is developed in a thin colluvial deposit overlying a Qct or Qbog pumice deposit.

The fieldhouse was constructed from a mixture of dacite and tuff blocks. The occupation surface at the site is a prepared clay floor constructed on top of the Btkb1 horizon (Figure 57.66). LA 127634 is buried by a thin, weakly developed soil in a colluvial deposit, with only an A horizon. Post-occupation colluvial deposits are 6 cm thick at the described profile 2 m west of the west wall. The soils data and related stratigraphy are consistent with a Classic period age for LA 127634. Two samples of maize, collected from fill in the lower and upper part of the hearth, yielded radiocarbon ages of 350±40 BP (Beta-215556) and 340±40 BP (Beta-215557). The dates are statistically indistinguishable, allowing summing of probabilities and a refined age estimate of 345 ± 28 BP and a date of cal AD 1559 with a two-sigma date range of cal AD 1466–1636 (Table M.2), also indicating a Classic period age for LA 127634. The site is buried by a thin colluvial deposit and is not extensively eroded and therefore appears to be in relatively good archaeological context.

LA 127635 (Fieldhouse)

LA 127635 is a fieldhouse situated on a colluvial wedge on the back (south) side of a pre-Qt6 terrace remnant on the north side of Rendija Canyon (see Figure 57.30). The terrace remnant buried by colluvium forms a small spur between drainages. The structure measures approximately 3 m east-west by 2 m north-south (outside dimensions), situated with the long axis of the structure oriented approximately N75°E, and contains an opening facing east-northeast (Figure 57.67). A hearth is located adjacent to the north wall on the inside of the structure. Soils were described in one test pit at the site, located 0.5 m east of the east side of the fieldhouse. Site stratigraphy consists of an A-Bw soil overlying a buried middle to late Holocene Bwb1-Bkb1 soil (Figure 57.67; Table L.5).

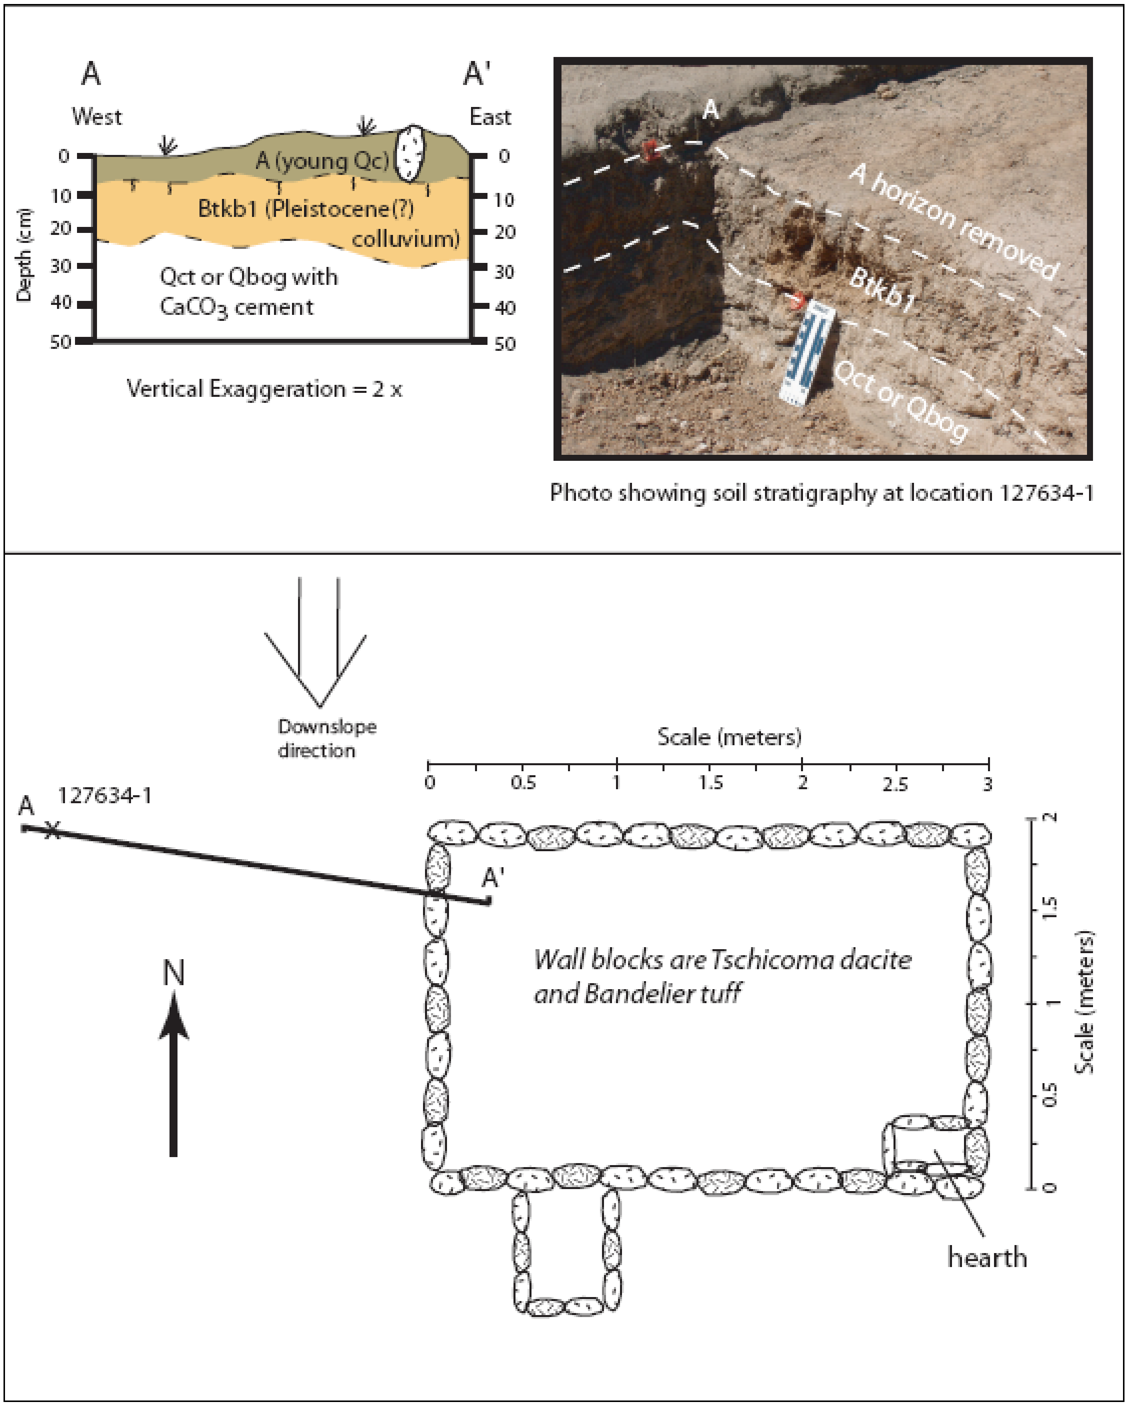

Figure 57.66. Schematic site map (bottom) and cross-section (top) from LA 127634.

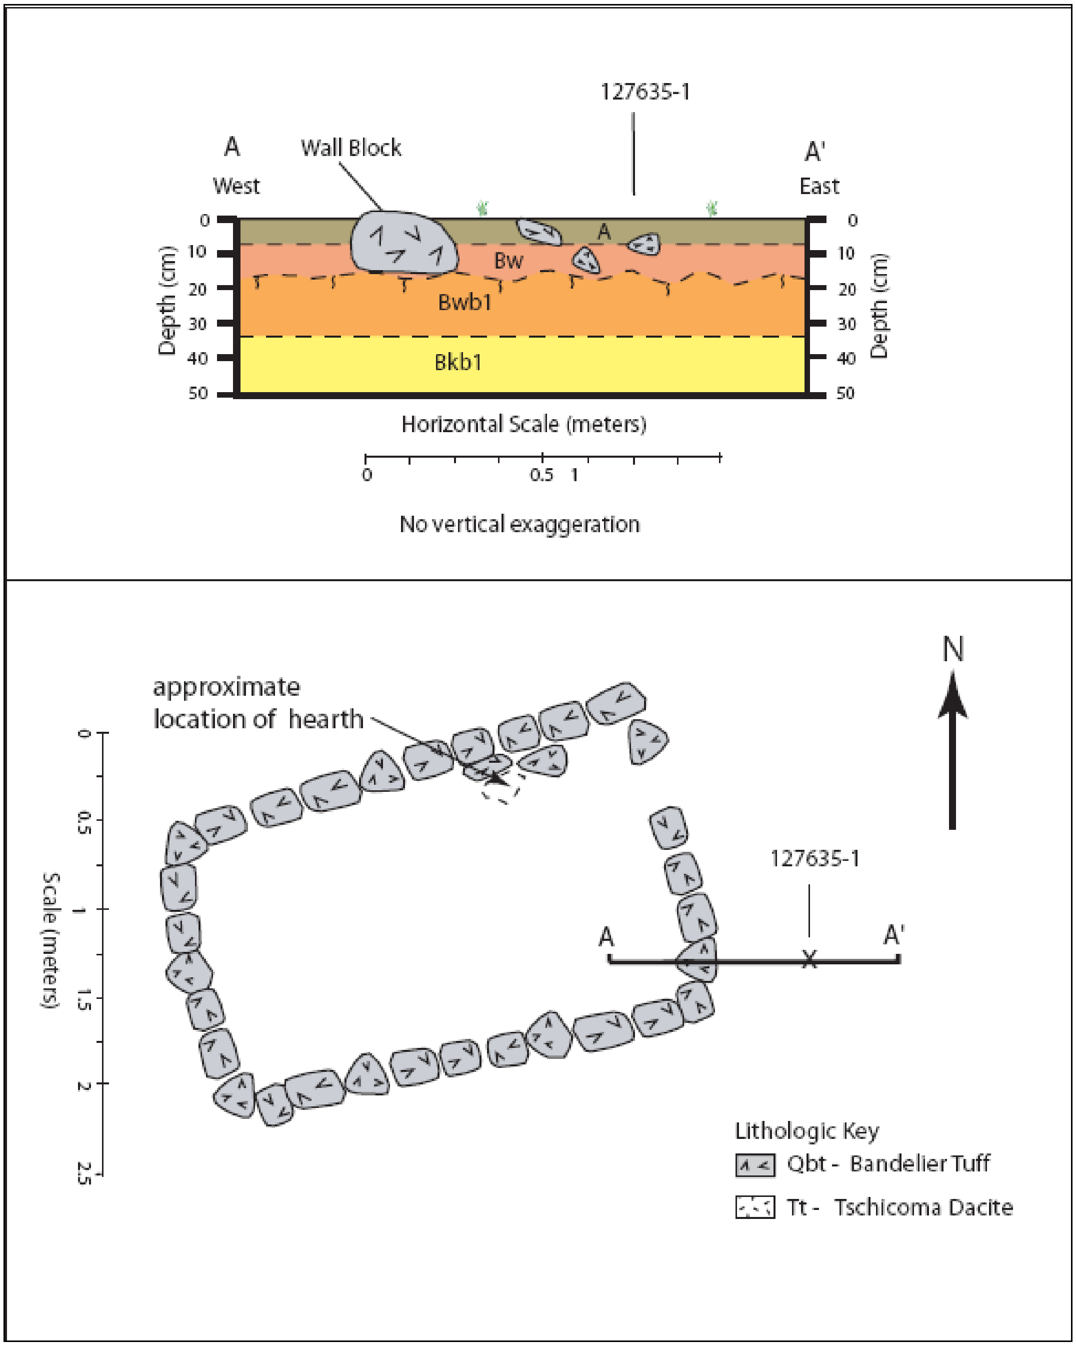

Figure 57.67. Schematic site map and cross-section from LA 127635.

The fieldhouse was constructed from Bandelier tuff blocks. The occupation surface at the site is the top of the Bwb1 horizon (Figure 57.67). LA 127635 is buried by a weakly developed, though relatively thick, colluvial soil with an A-Bw profile that includes wallfall in the deposit. Post-occupation colluvial deposits are 19 cm thick at the described profile near the east wall. The soils data and related stratigraphy are suggestive of a Coalition period or Classic period age for LA 127635. Two samples of maize, collected from fill in the lower and upper part of the hearth, yielded radiocarbon ages of 800±40 BP (Beta-215558) and 760±40 BP (Beta-215559). The dates are statistically indistinguishable, allowing summing of probabilities and a refined age estimate of 780±28 BP and a date of cal AD 1247 with a two-sigma date range of cal AD 1215–1278 (Table M.2), therefore indicating a Coalition period age for LA 127634. The walls are well preserved and colluvial deposition has aided site preservation and the site is likely in good archaeological context.

LA 135291 (Fieldhouse)

LA 135291 is a fieldhouse site situated on a north-facing slope below the top of the Qt2 terrace (see Figure 57.30). The structure measures approximately 2.8 m east-west by 1.7 m north-south (inside dimensions), or 3.3 m east-west by 2.3 m north-south (outside dimensions). A possible feature is located in the northeast corner of the structure. Soils were described in one test pit at the site, located 1.6 m east of the east side of the fieldhouse. Site stratigraphy consists of an A-Bw soil overlying a buried Pleistocene Btb1 soil (Figure 57.68; Table L.5).

The fieldhouse was constructed predominantly from Tschicoma dacite blocks, with a few Bandelier tuff blocks set on top of the Btb1 horizon. The occupation surface at the site is the top of the Btb1 horizon (Figure 57.68). LA 135291 is buried by slopewash colluvium and/or an eolian deposit, measuring 11 cm thick where described. This deposit has a weakly developed soil with an A-Bw profile with artifacts including biscuitware ceramics. The soils data and related stratigraphy are consistent with a Classic period age for LA 135291. With the exception of a few blocks scattered across the surface, the walls are well preserved, and the site is in moderate to good archaeological context.

LA 135292 (Fieldhouse)

LA 135292 is a fieldhouse site situated on the gently northeast-sloping Qt2 terrace surface (see Figure 57.30). The two remaining wall segments of the partially intact structure measure approximately 1.8 m north-south by 1.8 m east-west (Figure 57.69). The structure appears to have been partially disturbed by machinery. Soils were described in two test pits at the site; profile 135292-1 was described 1.3 m west of the west wall of the fieldhouse and profile 135292-2 was described inside the structure (Figure 57.69; Table L.5). Site stratigraphy consists of a relatively thick A-Bw1-Bw2 soil overlying a buried Pleistocene Btb1-Bkb1 soil (Figure 57.69). The upper soil is formed in eolian and reworked eolian silty loam mixed with slopewash colluvium and is 44 cm thick where described.

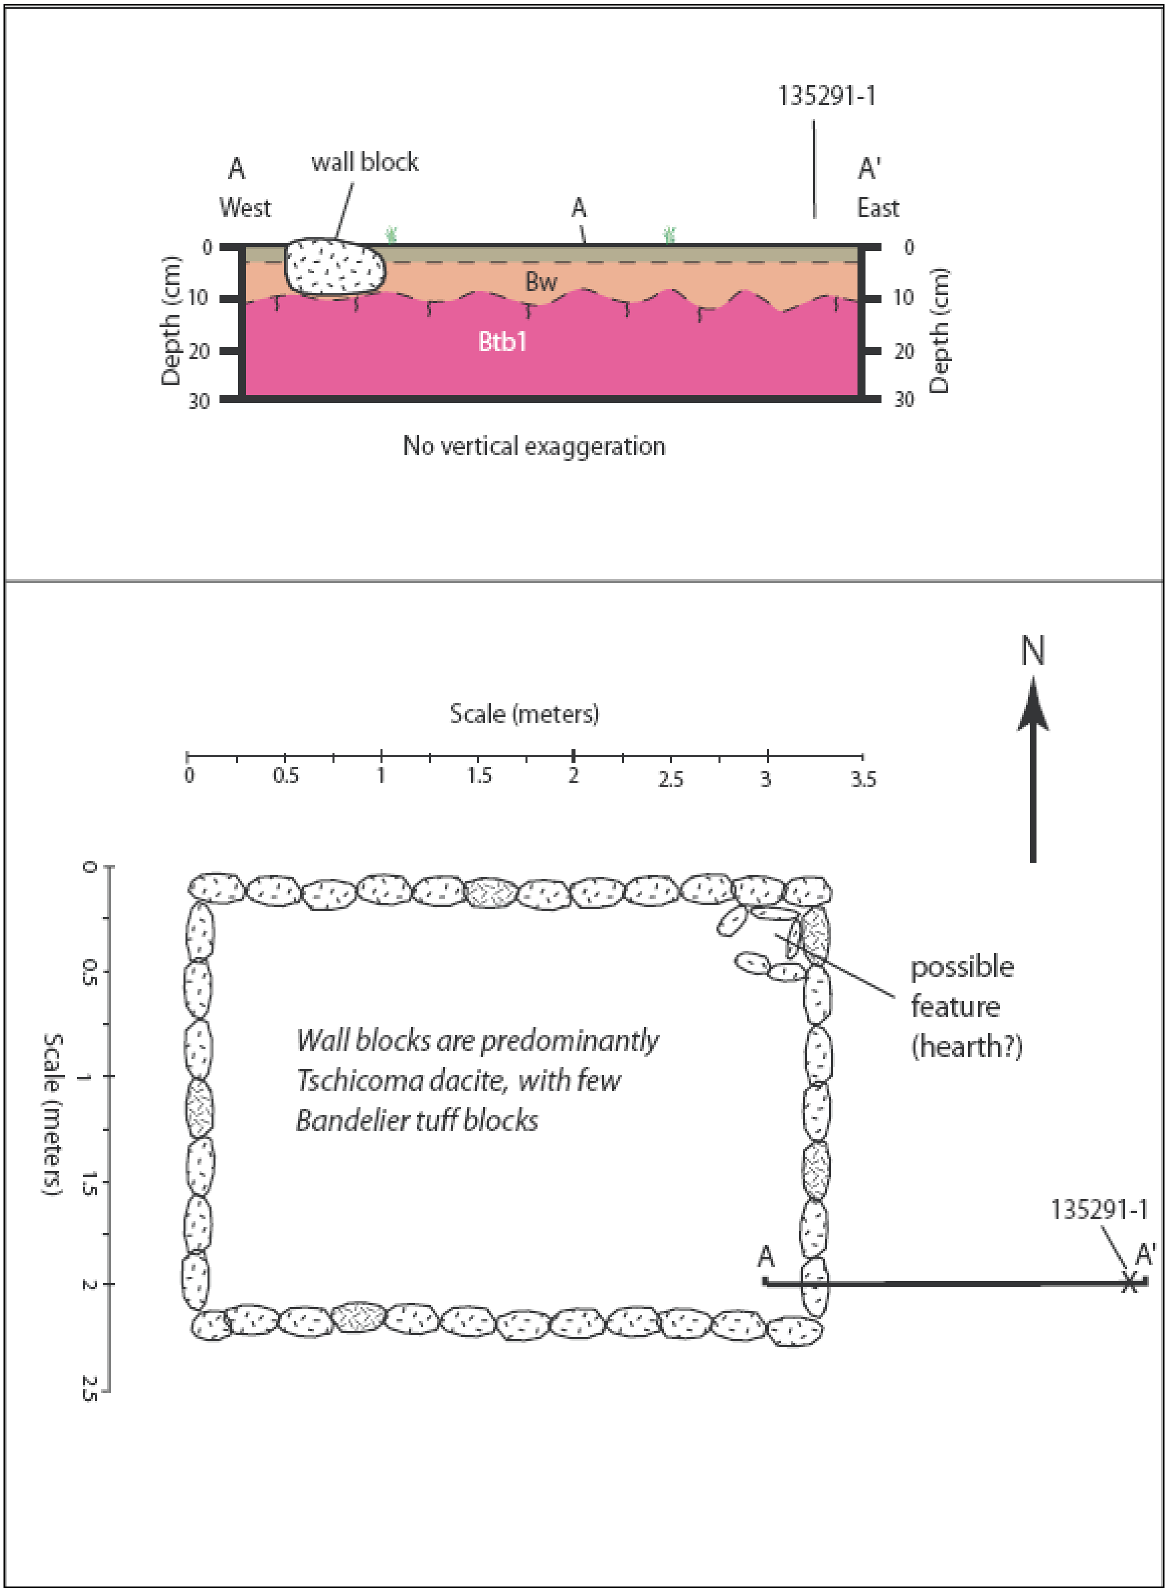

Figure 57.68. Schematic site map and cross-section from LA 135291.

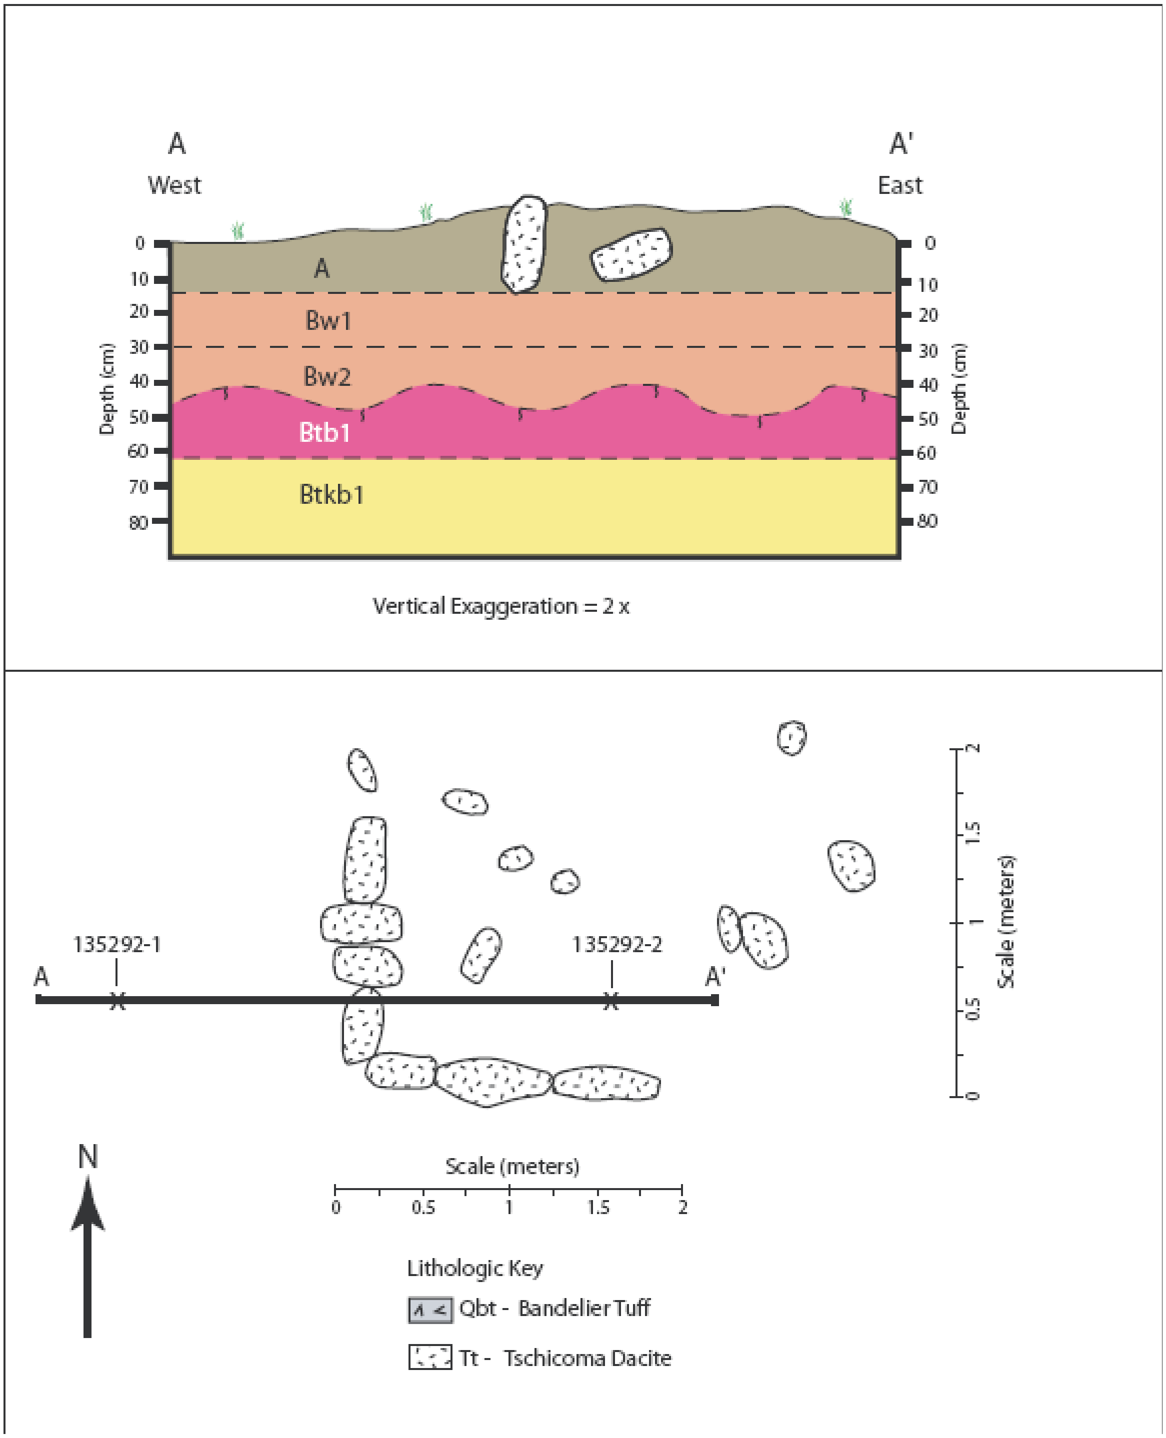

Figure 57.69. Schematic site map (plan view, bottom) and cross-section (top) at LA 135292.

The fieldhouse was constructed from dacite blocks that appear to have been set on top of the Bw1 horizon (Figure 57.69). The top of the Bw1 horizon, which is similar to the post-Coalition deposits observed at the Airport and White Rock tract sites (Drakos and Reneau 2003, 2004), is the likely occupation surface. The site is buried by the A horizon deposit that is mounded inside the structure and is 14 cm thick where described (Figure 57.69; Table L.5). The soils and related stratigraphy are consistent with a Classic period age for LA 135292. Due to apparent disturbance of the north and east walls of the site, LA 135292 is in moderate to poor archaeological context.

Rendija Tract Summary

Sites investigated within the Rendija Tract include three Archaic or multi-component sites on hillslopes and ridge top settings with generally thin colluvium and eolian deposits overlying Qct or Qbog pumice or Qct gravel Twenty-one fieldhouse sites were investigated; nine sites were located on fluvial terraces, eight sites were located on colluvial slopes, three sites were located on ridge crests, and one fieldhouse site was located on a Qct knob (Table 57.1). Two tipi ring sites were investigated, one on a ridge top and one in a valley bottom setting.

Surficial stratigraphy includes thin late Holocene colluvial and eolian deposits less than 25 cm thick (typically 10 to 20 cm thick) overlying late Pleistocene colluvial and eolian deposits or middle Holocene (6.8 to 7.4 ka) to late Holocene (1 to 2 ka) swale fill deposits less than 1.5 m thick (Figure 57.70). Late Pleistocene soils are truncated, indicating erosion some time during the Holocene, before deposition of the late Holocene colluvium. The development of shallow drainages and their subsequent filling is recorded by the ca 1 to 2 ka and ca 6 to 7 ka swale fill deposits (Figures 57.32 and 57.70). Valley bottoms preserve 1.5- to 2-m-thick middle to late Holocene colluvial deposits and an unknown thickness of underlying early Holocene and/or late Pleistocene deposits (see Figure 57.50). The Holocene and Pleistocene sections exposed in gullies have excellent potential for preservation of Archaic or older sites, although no buried sites were observed in this setting during mapping or stratigraphic descriptions for this investigation. Valley-bottom sediments partially bury the Apache tipi ring site LA 85864, and, therefore, the deep gully incision in the area apparently post-dates occupation, occurring sometime after the middle to late 1800s. The ridge top tipi ring site LA 85869 has experienced 0 to 4 cm of eolian deposition since occupation in the middle to late 1800s.

All twenty-one fieldhouse sites excavated within the Rendija Tract during this investigation have experienced some deposition of eolian sediment and/or colluvium since abandonment, which has aided site preservation. The evidence for net deposition at these sites is consistent with evidence from most other Coalition and Classic period sites examined within the land transfer tracts. Although there is also evidence for erosion at some sites, particularly on the steeper slopes, the apparent predominance of deposition has created conditions of relatively good site preservation.

The fieldhouses were constructed utilizing Tschicoma dacite blocks likely obtained from the terrace deposits and Bandelier Tuff blocks and slabs likely obtained from nearby colluvial deposits or outcrops, or possibly taken from surrounding mesas. Some dacite slabs may have been quarried from nearby outcrops. In individual fieldhouses, some were constructed predominantly or solely utilizing one lithology of building materials, whereas other fieldhouses utilized a mixture of lithologies (Table 57.1). Clear relationships between type of building material, relative site age, and/or geomorphic position were not observed.

Table 57.1. Fieldhouse site summaries and relative age estimates for Rendija Canyon land transfer sites.

Site	Buried by (soil horizons and type of deposit overlying site)	Occupation surface and type of deposit	Depth of burial inside structure (cm)	Depth of burial outside structure (cm) and distance from wall (m)	Geomorphic setting/ comments	Estimated relative site age based on soils: 1 = youngest, 2 = intermediate, 3 = oldest	Notes on relative age estimates
LA 15116	A-Bw soil; Qc includes wall fall	Btb; Qc	7	20 cm, 1 m W	North-facing slope below Qt2 surface	2	intermediate age inferred based on A-Bw profile
LA 70025	A-Bw1-Bw2 soil; Qc	Btjb1; Qc	8	29 cm, 2 m W	On dissected Qc slope over Qt ridge (?); Cabra Canyon	3? (2?) (1?)	relatively old age based on relatively thick post-occupation soil and A-Bw1-Bw2 profile outside; but thin eroded soil inside
LA 85403	A horizon only or A-Bw soil; Qe + Qc lag(?)	Bw or Bwb1; Qe	31	9 cm or 22 cm, 1.4 m W	On Qt2 surface	1	young age inferred if Bw horizon is occupation surface
LA 85404	A-Bw soil outside; A-Bw1-Bw2 soil inside; Qc	Btb1;Qtg	32	12 cm, 1.5 m W	East-facing edge of Qt1	1? (2?)	young age inferred based on relatively thin Bw profile outside structure, but possibly old age based on thicker A-Bw1-Bw2 profile inside
LA 85408	A horizon only; Qc	Qct soil	20 to 25	9 cm, 2 m W	Qct ridge spur	1	young age inferred based on thin and very weak post-occupation soil (A horizon)

Site	Buried by (soil horizons and type of deposit overlying site)	Occupation surface and type of deposit	Depth of burial inside structure (cm)	Depth of burial outside structure (cm) and distance from wall (m)	Geomorphic setting/ comments	Estimated relative site age based on soils: 1 = youngest, 2 = intermediate, 3 = oldest	Notes on relative age estimates
LA 85411	A-Bw soil; Qc	Bwb1 or Btjb1; thin Qc over Qct	20	14 cm, 2.3 m E	NE-sloping side of Qct ridge	2	intermediate age inferred based on A-Bw profile
LA 85413	A horizon only; Qc	Bw; Qct	18	7 cm, 3 m SE	North-facing slope at Qc/Qct contact	1	young age inferred based on thin and very weak post-occupation soil (A horizon)
LA 85414	A horizon only; Qc	Bw or Bwb1; thin Qc over Qct	n.a.	8 cm, 1.5 m E	East-facing Qct bench	1	young age inferred based on thin and very weak post-occupation soil (A horizon)
LA 85417	A horizon only; Qe + Qc lag	Bw or Bt b1; thin Qc over Qct	<10	6 cm, 2 m W	Qct knob	1	young age inferred based on thin and very weak post-occupation soil (A horizon)
LA 85861	A-Bw soil; Qc	Bwb1; thin Qc over Qct	31	15 cm, 4 m E	East-sloping Qct ridge	2	intermediate age inferred based on A-Bw profile
LA 85867	A horizon only; Qc	Bw1; Qct	5	n.a.	South-facing Qc slope below Qct ridge	1	young age inferred based on thin and very weak post-occupation soil (A horizon)
LA 86605 *first occupation*	A-Bw soil outside, A-Bw1-Bw2 soil inside; Qc (+ Qe?)	Btb1 (outside), Btkb1 (inside); Qc?	45	19 cm, 1.1m W	On east-sloping shoulder of Qt2; good evidence for two	3? (2?)	relatively old age inferred based on reddened color and relatively hard dry consistence of

Site	Buried by (soil horizons and type of deposit overlying site)	Occupation surface and type of deposit	Depth of burial inside structure (cm)	Depth of burial outside structure (cm) and distance from wall (m)	Geomorphic setting/ comments	Estimated relative site age based on soils: 1 = youngest, 2 = intermediate, 3 = oldest	Notes on relative age estimates
					occupations; Includes Qbt slabs		Bw horizon, possibly intermediate age based on A-Bw profile outside structure
LA 86605 *second occupation*	A horizon outside, A-Bw1 soil inside; Qc (+ Qe?)	Bw (outside), Bw2 (inside); Qc	38	7 cm, 1.1m W		1	relatively young age inferred based on trench for slab apparently cutting Bw horizon(?); thin overlying A horizon
LA 86606	A-Bw1 soil; Qc	Bw2; Qc	n.a.	22 cm, 1 m. W	East-sloping Cabra Canyon Qt overlain by Qc	2? (1?)	intermediate age inferred based on A-Bw profile
LA 86607	A horizon only; Qc	Btb1; Qtg or Qct	10 to 12	4 cm, 1.5 m W	Qct ridge spur or Qt remnant	1?	young age inferred based on thin and very weak post-occupation soil (A horizon); possibly influenced by location in erosional setting
LA 87430	A-Bw soil; Qc	Btb1; Qtg	23	18 cm, 1.8 m E	On north-edge of Qt5 above Rendija Canyon drainage	1? (2?)	young age inferred base on weakly developed colluvial soil; intermediate age inferred based on A-Bw profile

Site	Buried by (soil horizons and type of deposit overlying site)	Occupation surface and type of deposit	Depth of burial inside structure (cm)	Depth of burial outside structure (cm) and distance from wall (m)	Geomorphic setting/ comments	Estimated relative site age based on soils: 1 = youngest, 2 = intermediate, 3 = oldest	Notes on relative age estimates
LA 127627	A-Bw soil; Qc	Bt1b1; Qtg	13	21 cm, approx. 0.5 m E	On north-facing slope below Qt2	2?	intermediate age inferred based on A-Bw profile
LA 127633	A - BC soil; Qc slopewash	IIC; Qc	31	57 cm, hillslope profile SW of site	On relatively steep SE-facing slope; Qc overlying Qct? (storage bin)	1	young age inferred based on weak A-BC soil profile
LA 127634	A horizon; Qc slopewash	Btkb1; Qc	10	6 cm, 2 m W	On Qct or Qbog slopewash Qc	1	young age inferred based on thin and very weak post-occupation soil (A horizon)
LA 127635	A-Bw soil; Qc + wall fall	Bwb1; Qc	29	19 cm, 0.5 m E	On Qc wedge on back side of pre-Qt6 terrace	2? (3?)	intermediate age inferred based on A-Bw profile; possibility of relatively old age suggested by slightly hard dry consistence of Bw horizon, thick soil
LA 135291	A-Bw soil; Qc+Qe	Btb1;Qtg	17	11 cm, 1.6 m E	North-facing slope below/on edge of Qt2 surface	2? (1?)	intermediate age inferred based on A-Bw profile; possibility of relatively young age suggested by thin post-occupation soil on gentle terrace

LA 135292	A horizon; Qc slopewash	Bw1; Qc over Qtg	28	14 cm, 1.3 m W	On flat Qt2 surface overlain by slopewash Qc	1	young age inferred based on weak post-occupation soil profile (A horizon)

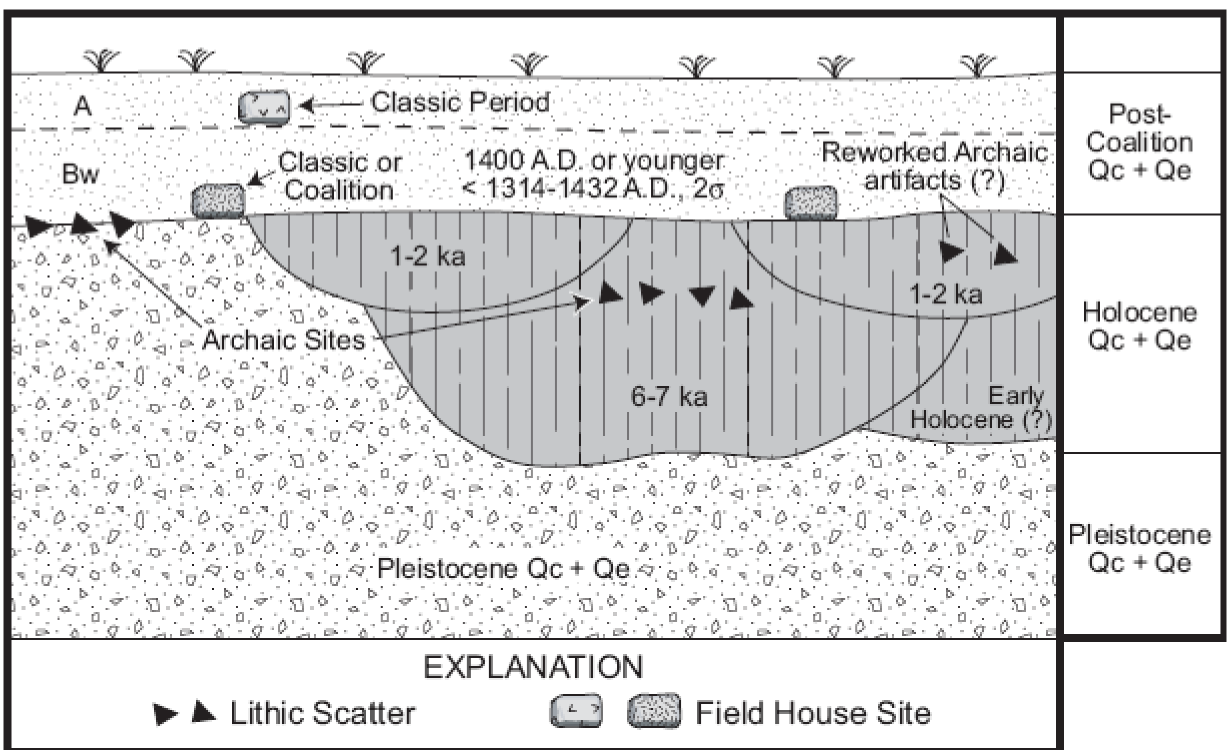

Figure 57.70. Composite soil stratigraphic correlation chart for Rendija Canyon colluvial and eolian deposits.

Based on soil stratigraphy of deposits burying the sites and comparison with soils described at Coalition and Classic period sites in the Airport and White Rock tracts (Drakos and Reneau 2003, 2004), the fieldhouses in the Rendija Tract may have been constructed from Coalition through Classic period time. An attempt was made to provide relative age estimates of fieldhouse sites based on soil characteristics and depth of burial (Table 57.1). Sites overlain by thin soils with only an A horizon or A-BC horizon development, appear to be the youngest sites investigated (relative age = 1 in Table 57.1) and based on soil characteristics are Classic period sites. Sites overlain by slightly thicker soils, typically with A-Bw horizon development, appear to be intermediate in age (relative age = 2 in Table 57.1) of the sites investigated. The intermediate-age sites may be older Classic period sites, or are sites located in a depositional setting. Sites overlain by thicker soils with A-Bw1-Bw2 profiles, or A-Bw profiles with reddened or hardened Bw horizons, are inferred to be the oldest sites investigated (relative age = 3 in Table 57.1). Soil characteristics suggest that the "oldest"-age sites may be Coalition period sites, although soils data do not preclude a Classic period age. However, radiometric ages and evidence provided by dated cultural materials demonstrate that most of the fieldhouses are Classic period sites and in some cases are inconsistent with relative ages inferred from the soils data. These discrepancies could be due to more colluvial-versus-eolian origin for sediments burying Rendija Canyon Ancestral Puebloan sites and may indicate that the main pulse of colluvial deposition has occurred later than the AD 1250–1325 eolian event, likely after AD 1500.

The orientation of fieldhouse structures can be related to geomorphic position. Where building sites are relatively flat, expansive surfaces, structures are oriented with walls aligned along north-south and east-west axes and, if openings are present, have east-facing doorways (Table 57.2). These sites include LA 85403, LA 85417, LA 86605, LA 86606, LA 135291, LA135292, and possibly LA 85404. Where building sites are located on hillslopes, the structure is typically oriented perpendicular to the hillslope (Table 57.2). Doorways, if present, generally face downslope. Structures built on hillslopes with walls shifted off of a north-south/east-west axis include LA 85411, LA 85413, LA 127627, and LA 127633. Structures built on north- or south-facing hillslopes with walls aligned on a north-south/east-west axis include LA 15116, LA 85867, and LA 127634. Structures built on east-facing hillslopes with walls also aligned approximately north-south/east-west include LA 85404, LA 85861, and LA 86607. In other cases, structures are built to fit on small terrace remnants or ridge spurs and are rotated off of a north-south/east-west axis. These fieldhouses include LA 70025, LA 85408, LA 87430, and LA 127635 (Table 57.2).

Table 57.2. Geomorphic position, slope, and fieldhouse orientations, Rendija Tract sites.

Site	Lithology of Blocks	Geomorphic setting/slope	Orientation of Structure	Comments
LA 15116	Tt dacite dominates; minor Qbt tuff	North-facing gentle slope below Qt2 surface	N-S by E-W	possible opening in E wall; structure oriented perpendicular to slope
LA 70025	Qbt tuff+ Tt dacite	On dissected Qc slope over Qt ridge (?); Cabra Canyon	N20°W	Structure oriented to fit small ridge top
LA	Tt dacite	On broad, flat Qt2	N-S by E-W	East-facing doorway

Site	Lithology of Blocks	Geomorphic setting/slope	Orientation of Structure	Comments
85403		surface		
LA 85404	Tt dacite	East-facing gently-sloping edge of Qt1	N-S by E-W	Non-rectangular structure; no obvious doorway
LA 85408	Tt dacite, minor tuff, Qct sandstone?	Qct ridge spur	N48°E	Southwest-facing opening
LA 85411	Tt dacite	NE-sloping side of Qct ridge	NW	Structure oriented perpendicular to slope; two-room fieldhouse
LA 85413	Tt dacite predominates; minor Qbt tuff	N-facing slope at Qc/Qct contact	N75°E	Structure oriented perpendicular to slope (?); NW-facing opening
LA 85414	Tt dacite	East-facing Qct bench	N20°E	Structure oriented to utilize large Tt boulders in place on slope?
LA 85417	Tt dacite	Qct knob	N-S by E-W	East-facing doorway
LA 85861	Tt dacite	Broad, gently east-sloping Qct ridge crest	N10°W	Openings in east and south walls
LA 85867	Tt dacite	South-facing Qc slope	N-S by E-W	North wall disturbed; no other openings in walls
LA 86605	Qbt tuff+ Tt dacite	On broad, gently-sloping east-sloping Qt2 surface	N-S by E-W	East-facing doorway
LA 86606	Tt dacite predominates; minor Qbt tuff	East-sloping Qt overlain by Qc	N-S by E-W	No obvious doorway
LA 86607	Tt dacite predominates; minor Qbt tuff	East-sloping Qct or Qtg ridge spur	approx. N-S by E-W	Non-rectangular structure; opening to east
LA 87430	Tt dacite + Qbt tuff	On north-edge of Qt5 above Rendija Canyon drainage	N20°E	Structure oriented to fit small terrace remnant; SSE-facing doorway
LA 127627	Tt dacite	On northwest-facing slope below Qt2	N40°W	Structure oriented perpendicular to slope; door in NE corner
LA 127633	Tt dacite slabs + Qbt tuff blocks	On relatively steep (25°) SE-facing slope	N77°E	Structure oriented perpendicular to slope
LA 127634	Tt dacite + Qbt tuff	On south-facing Qct or Qbog slope	N-S by E-W	Structure oriented perpendicular to slope; south-facing entryway
LA 127635	Qbt tuff	On Qc wedge on back side of pre-Qt6 terrace	N75°E	Structure oriented to fit small terrace remnant; NNE-facing doorway
LA 135291	Tt dacite dominates; minor Qbt tuff	N-facing slope below/ on narrow top of Qt2 surface	N-S by E-W	No obvious doorway

Site	Lithology of Blocks	Geomorphic setting/slope	Orientation of Structure	Comments
LA 135292	Tt dacite	On flat Qt2 surface overlain by slopewash Qc	N-S by E-W	Structure not intact; doorway unknown

TA-74 SOUTH TRACT

Surficial Geologic Units

The TA-74 South land transfer parcel is located in a relatively broad part of lower Pueblo Canyon. A generalized geologic map of the western and central part of the parcel is shown in Figure 57.71. Surficial geologic units within the parcel include the active stream channel and adjacent floodplains of Pueblo Canyon (unit Qal), higher stream terraces of Holocene and Pleistocene age (unit Qt), and areas of colluvium and alluvial fans on the side slopes and along tributary drainages (unit Qc). Bedrock units within the parcel include Pliocene fanglomerates of the Puye Formation (unit Tpf) and non-welded tuff and pumice beds of the Otowi Member of the Bandelier Tuff (unit Qbo). The latter includes the Guaje pumice bed (unit Qbog). The Tshirege Member of the Bandelier Tuff (unit Qbt) is exposed along the margins of the canyon but is not exposed within the parcel, although erosion of this unit is a major source for colluvium within the parcel. Geologic maps of this area have been prepared by Griggs (1964) and Rogers (1995), and detailed geomorphic maps of parts of the canyon bottom are presented in Reneau et al. (2002) and Tardiff et al. (2002). Except for a strip of young sediment along the main stream channel, the surficial geologic units in the parcel have not been studied in detail, although their characteristics and history are probably similar to units in other parts of the Pajarito Plateau such as the White Rock and Rendija Canyon parcels.

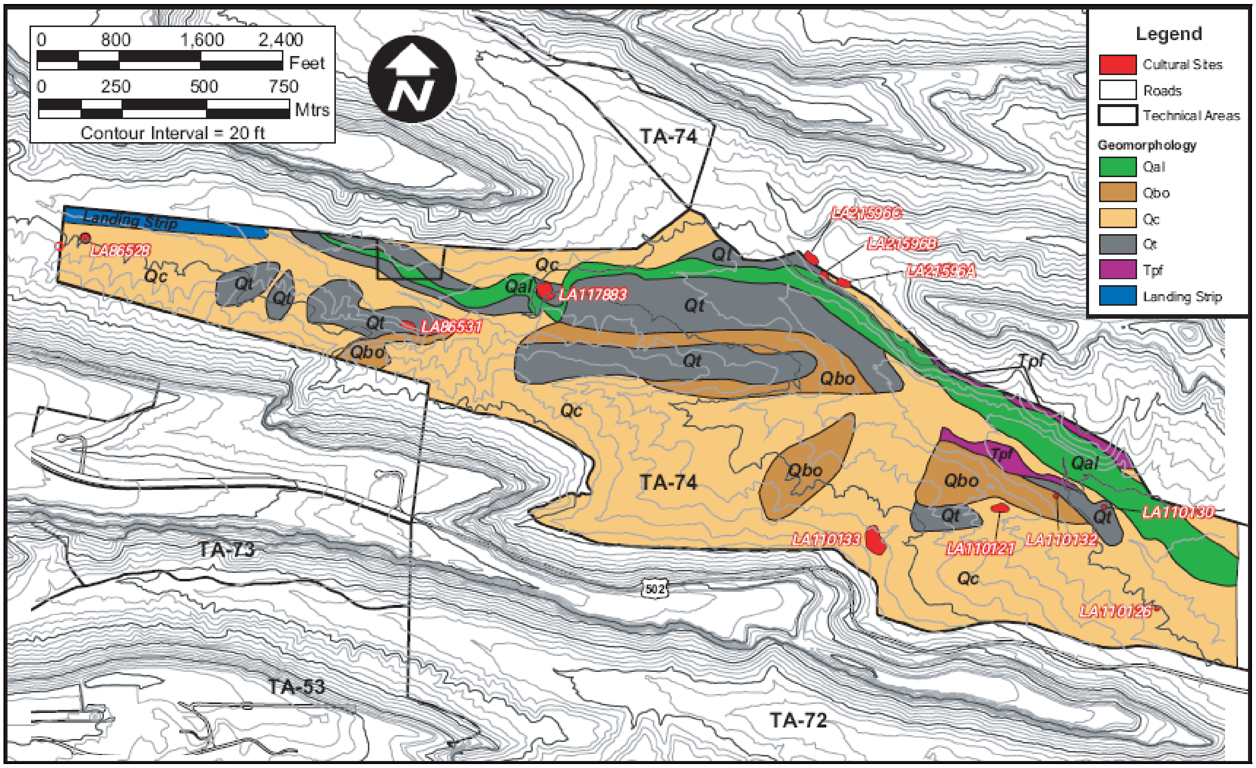

Figure 57.71. TA-74 South Tract (Pueblo Canyon) geomorphology.

Otowi Grid Gardens

The Otowi grid gardens (LA 21592) are located near LA 21596. A description from the Otowi grid gardens is included here for completeness.

LA 21592 (Grid Gardens)

LA 21592 consists of grid gardens on a colluvial slope above the bottom of Bayo Canyon, on the north side of the channel and northwest of the Otowi ruins. The grid gardens are outlined by rock alignments made of locally derived clasts. The upper 8 cm of sediment inside the grid garden has a silt loam texture and exhibits an absence of soil development, indicating a young eolian and/or slopewash layer. The underlying Cbwb1 horizon, 8 to 20 cm deep, is sandier and contains clasts and ceramics and likely represents soil that was present during use of the grid garden. Alternatively, the Cbwb1 horizon could represent a post-occupational deposit, although this interpretation is considered to be less likely.

LA 21596 (Grid Gardens)

LA 21596 consists of grid gardens at the base of a colluvial slope adjoining floodplains or fluvial terraces in the bottom of Pueblo Canyon, below the Otowi ruins. The grid gardens are outlined by rock alignments made of locally derived clasts. Excavations through the grid gardens indicate that ceramics and lithics are present to depths of at least 50 cm and that relatively little sediment has been deposited since construction of the rock alignments. Artifacts are abundant from 0 to 30 cm; artifacts are present but less abundant from 30 to 50 cm. Rocks forming the grid gardens are set on the Bw1 horizons in profiles 21596-1, 21596-2, and 21596-3 and are buried by only 4 to 6 cm of sediment (Table L.8). These observations suggest that the grid gardens were created during a relatively late stage of occupation of Otowi Pueblo and that a significant amount of colluvial deposition occurred at this location concurrent with Puebloan occupation. Based on profile 21596-4, described on the colluvial slope outside the grid garden, the thickness of young colluvium is greater than 34 cm. It is possible that human traffic or other disturbances on the steep slope between the grid gardens and the Otowi ruins accelerated the rate of colluvial transport and deposition at this location.

LA 86528 (Possible Rockshelter)

LA 86528 consists of a possible rockshelter site situated next to and under a large boulder on a north-facing colluvial slope, downslope from the base of a Bandelier Tuff cliff (see Figure 57.71). The site is on the upslope side of the boulder and extends from the colluvial slope to beneath the overhanging lip of the boulder. Three soil profiles were described within, near the edge of, and outside the overhang. Profiles 86528-1 and 86528-3 each have a thin (3 to 5 cm) AC or C horizon formed in young (less than 500 years old, possibly less than 100 years old) colluvium that buries older soil horizons (Table L.8). Profiles described next to and beneath the overhang have late Holocene (possibly Puebloan-age) Bwb1 horizons 10 to 15 cm thick overlying Pleistocene colluvial soils. Profile 86528-2, described on the colluvial slope outside the overhang, exhibits only young (less than 500 years old) thin (10 cm thick) colluvium overlying Pleistocene soil. Profile 86528-1, in Test Pit #1, at the edge of the overhang, included a charcoal stain at the base of the AC horizon and a Bwb1 horizon formed in late Holocene colluvium (Table L.8). The abrupt, irregular boundary between the Bwb1 and underlying Pleistocene Btb2 horizon can be interpreted as due to either cultural or non-cultural processes. One explanation is that a pit or similar excavation was dug into the Pleistocene soil, during the time the overhang was used as a rock shelter. A differing explanation, consistent with the interpretation that the overhang was not used as a rock shelter, is that the irregular boundary between the Bwb1 and underlying Bwb2 horizon was caused by erosion on the fairly steep slope projecting beneath the overhang, with an opening at the downslope end. In this scenario, subsequent partial plugging of the escape hole facilitated colluvial deposition, which was followed by a non-cultural fire.

The profiles described in the vicinity of LA 86528 are indicative of a stripped, Pleistocene colluvial hillslope overlain by thin (10 to 20 cm thick) late Holocene to historic age colluvium. Overall, the geomorphic evidence is ambiguous with respect to whether or not the overhang was used as a rockshelter. The charcoal stain at the base of the AC horizon may be of relatively recent origin, post-dating the Puebloan occupation, in which case there may be very little evidence that the overhang was used as a rockshelter.

LA 86531 (Lithic/Ceramic Scatter)

LA 86531 is a lithic and ceramic scatter situated on top of a Pleistocene fluvial fill terrace located approximately 30 m above the canyon floor (see Figure 57.71). The deposit underlying the terrace comprises multiple fluvial sequences, capped by a coarsening upward deposit with imbricated boulders (Figure 57.72).

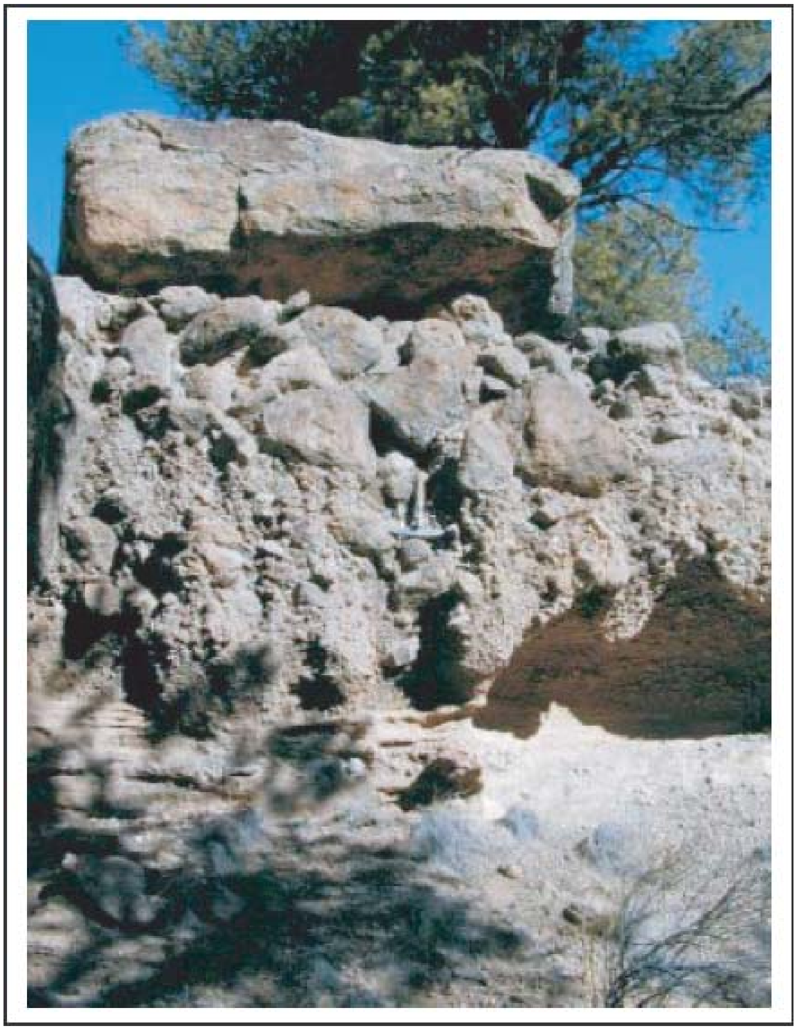

Figure 57.72. Coarsening-upward gravel underlying Pleistocene fluvial terrace at LA 86531.

Gravels include abundant Bandelier Tuff and Tschicoma dacite clasts. The gravel overlies fine-grained fluvial deposits and the Otowi Member of the Bandelier Tuff. The top of the terrace appears to be a stripped surface that is capped by thin (less than 20 cm thick) young soils overlying stripped Pleistocene soils or bedrock (Table L.8, profiles 86531-1 and 86531-2). Based on the relatively well-developed stripped Bt horizon observed in profile 86531-1 and the height of the terrace above the canyon floor, the terrace is inferred to be mid-Pleistocene in age.

Soil descriptions completed at LA 86531 are indicative of young (less than 100 years?) slopewash from 0 to 3 cm overlying a thin (7 to 11 cm thick) late Holocene/post-Puebloan (?) deposit (Table L.8). Charcoal (a fire stain) was observed in Test Pit #2 (profile 86531-2). Test Pit #2 was therefore expanded northward into Test Pit #3, which revealed a Pleistocene compacted silt horizon, likely an eolian unit (profile 86531-2). The fire stain was inset into the Pleistocene soil, suggesting that the fire stain was a root burn, rather than a cultural feature.

The likely cultural horizon (the Ab1 horizon) observed in profiles 86531-1 and 86531-2 is thin. However, the presence of a surficial artifact scatter on an eroded ridge top with thin soils is consistent with the interpretation that the LA 86531 artifact scatter represents erosion of a site situated on the Pleistocene terrace. Artifacts may represent a surface lag and may have only been transported a short distance. The presence of a carved boulder (zig zag patterns carved on the north side of a boulder) directly below the artifact scatter on the north side of the terrace shows the presence of other cultural elements at this location.

LA 110121 (Lithic/Ceramic Scatter)

LA 110121 is a lithic and ceramic scatter situated on the eroding slope of a low ridge that is part of a dissected Guaje pumice landscape (Figure 57.71). The Guaje pumice bed is the base of the Otowi Member of the Bandelier Tuff and overlies the Puye Formation. The thickness of post-Guaje sediment is minimal (11 cm) at this location (Table L.8, profile 110121-1; Figure 57.73). The artifact scatter is apparently part of the thin colluvium overlying the Guaje pumice and is therefore not in archaeological context.

LA 110126 (Fieldhouse)

LA 110126 is a fieldhouse situated on a heavily eroded north-facing colluvial slope (see Figure 57.71). Due to the extensive erosion, there is minimal potential for a preserved archaeological record outside of the structure. Excavation inside the fieldhouse revealed 29 cm of post-Puebloan soil that probably constitutes eolian sediment and/or colluvial sediment mixed with tuff clasts derived from wall collapse (Table L.8, profile 110126-1). An older (Pleistocene) buried Bt soil horizon is present beneath the structure.

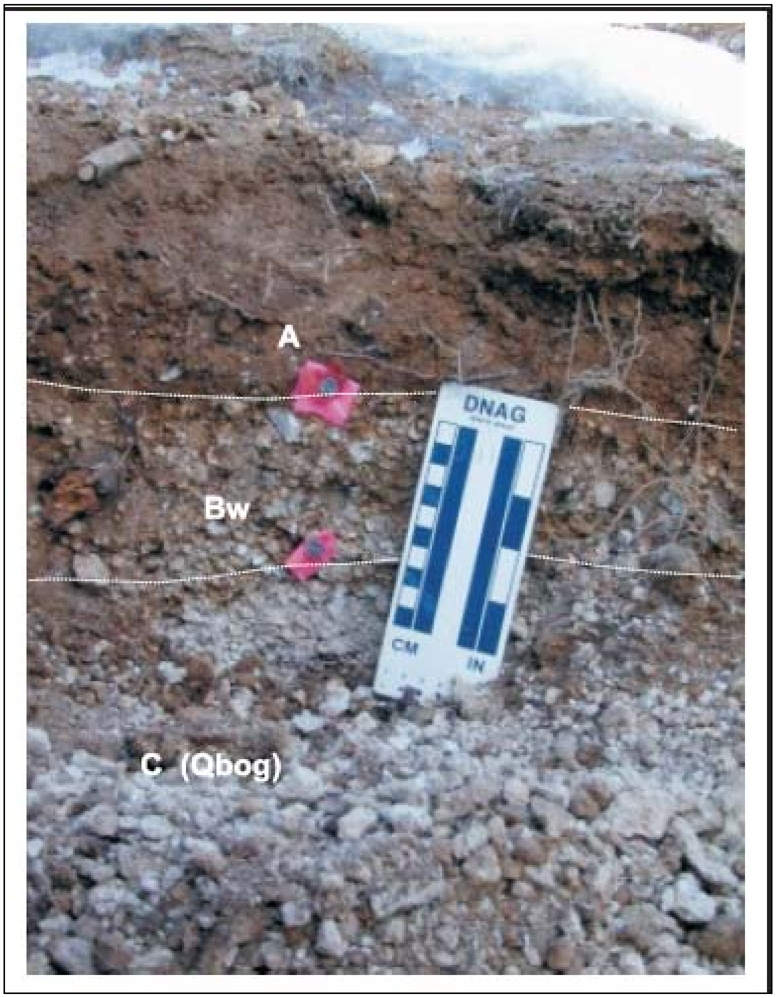

Figure 57.73. Soil formed in Guaje pumice at LA 110121.

LA 110130 (Fieldhouse)

LA 110130 includes rock alignments, sherds, and minor lithics, situated on the north edge of an eroded, gently east-sloping fluvial terrace above the Pueblo Canyon floodplain (see Figure 57.71). Excavation through the rock alignments revealed 17 cm of sediment overlying a buried Bt horizon interpreted to represent a stripped or eroded late (?) Pleistocene soil (Table L.8, profile 110130-1). The rock alignments include large (approximately 10- to 30-cm diameter) rocks set into or on top of the Btb1 horizon (Figure 57.74). The rock alignments are not clearly walls, but may represent the foundation of a structure. Alternatively, the rock alignments may represent a grid garden. Some smaller rocks were observed within the Bw horizon, but the smaller rocks do not appear to be part of the rock alignments.

Classic period sherds were observed in the post-Pleistocene soil horizons and were present in greatest abundance in the Bw horizon. The A and Bw horizons likely represent slopewash colluvium that includes reworked older soil in the Bw horizon and has partially buried the rock alignments. The artifacts observed within the A and Bw horizons are likely part of the slopewash colluvium although their presence does suggest an association with the alignments, and a Classic age for the site. The artifacts may represent locally bioturbated material that is in reasonably good archaeological context.

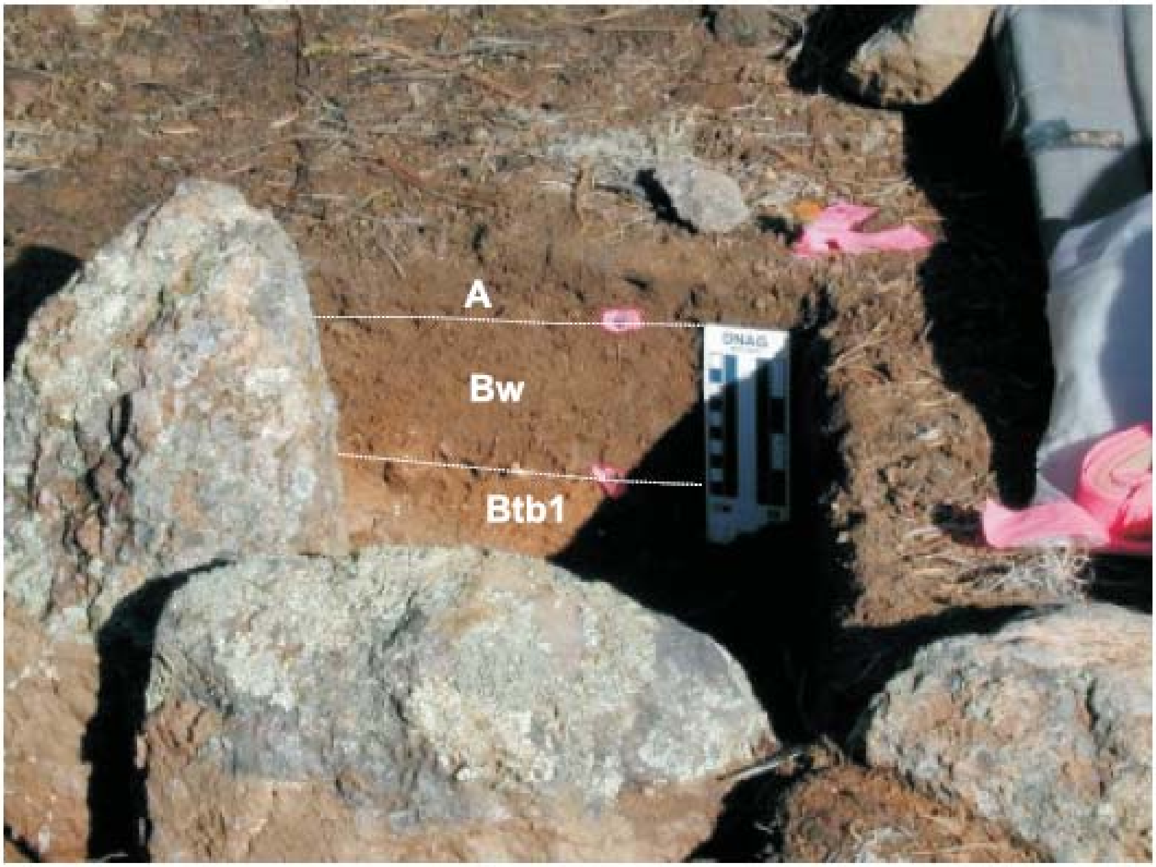

Figure 57.74. Soil stratigraphy at LA 110130; rock alignment set into/on Btb1 horizon.

LA 110132 (Possible Fieldhouse)

LA 110132 consists of a possible rock alignment and surficial artifact scatter in thin, bouldery colluvium overlying the Guaje pumice bed (see Figure 57.71). The colluvium includes reworked terrace gravels with boulders. An examination of the possible rock alignment indicated that it is probably a natural occurrence of large cobbles that are reworked terrace gravels that are part of the colluvium, and not of cultural origin.

LA 110133 (Lithic/Ceramic Scatter)

LA 110133 consists of a light scatter of lithics and ceramics situated on a north-facing colluvial slope on the south side of Pueblo Canyon (see Figure 57.71). LA 110133 is situated where colluvial slopes begin to steepen to the south below the Bandelier Tuff cliffs that form the canyon walls. Two profiles were examined at LA 110133. In profile 110133-1 (Test Pit #1), artifacts were observed at depths of around 30 cm and from 50 to 60 cm. In profile 110133-2 (Test Pit #2), sparse concentrations of artifacts were observed on the surface and from 0 to 10 cm. Both profiles include AC horizons overlying BC or CB horizons with very weak soil development (Table L.8). Profiles 110133-1 and 110133-2 exhibit 16 to 19 cm of very young (likely less than 100 years old) colluvium overlying post-Puebloan age colluvium to a depth of 70 cm or greater (Table L.8). These profiles indicate that LA 110133 is located on a very active colluvial slope with greater than 70 cm of colluvial deposition in post-Puebloan time. The artifacts observed at this location appear to be part of the colluvium and are not in archaeological context.

LA 117883 (Archaic Site)

LA 117883 is an archaic site comprising a lithic scatter on a colluvial slope that overlies a stream terrace or pair of terraces (see Figure 57.71). Two profiles were described at LA 117883. Profile 117883-1 (Test Pit #1) was located on a terrace 20 m north of the Pueblo Canyon channel, and profile 117883-2 (Test Pit #2) was located approximately 32 m north of the Pueblo Canyon channel and upslope from 117883-1. Both soil profiles exhibit an AC-C-Bwb1 or AC-C-BCb1 horizon sequence suggesting two colluvial depositional events, with older colluvium (less than 1000 to 2000 years) overlain by young colluvium (less than 500 years) (Table L.8). The presence of artifacts through the entire thickness of the colluvial layer in profile 117883-1 suggests that the artifacts have been transported from upslope and are not in place. Thickness of colluvium overlying the terrace gravels thins downslope, from 101 cm at profile 117883-2 to 55 cm at profile 117883-1 (Table L.8).

The buried soil developed in the buried terrace gravels at profile 17883-2 includes a Stage I+ carbonate suggesting a late Pleistocene to early Holocene age for the terrace. In contrast, the soil formed in buried terrace gravels at profile 17883-1 lacks carbonate, soil structure, or other indicators of soil development. Soil characteristics of the horizons described in the terrace gravels at the two locations therefore suggest that the buried terrace at 117883-2 is late Pleistocene to early Holocene in age, whereas the buried terrace at 117883-1 is late Holocene in age, based on comparison with the Qt8 soil described by McDonald et al. (1996). These data suggest that two terraces of different age are buried beneath the colluvium, with the profile 117883-1 terrace inset into the profile 117883-2 terrace.

TA-74 Tract Summary

Sites investigated in the TA-74 South Tract include two grid garden sites, three lithic/ceramic scatters, two fieldhouse sites, one possible rock shelter, and one Archaic lithic scatter. Six of the sites in TA-74 are located on active colluvial slopes, two sites are located on Pleistocene terraces, and one site is located on a colluvial slope overlying a late Pleistocene to early Holocene and a late Holocene (?) fluvial terrace (Figures 57.71 and 57.75).

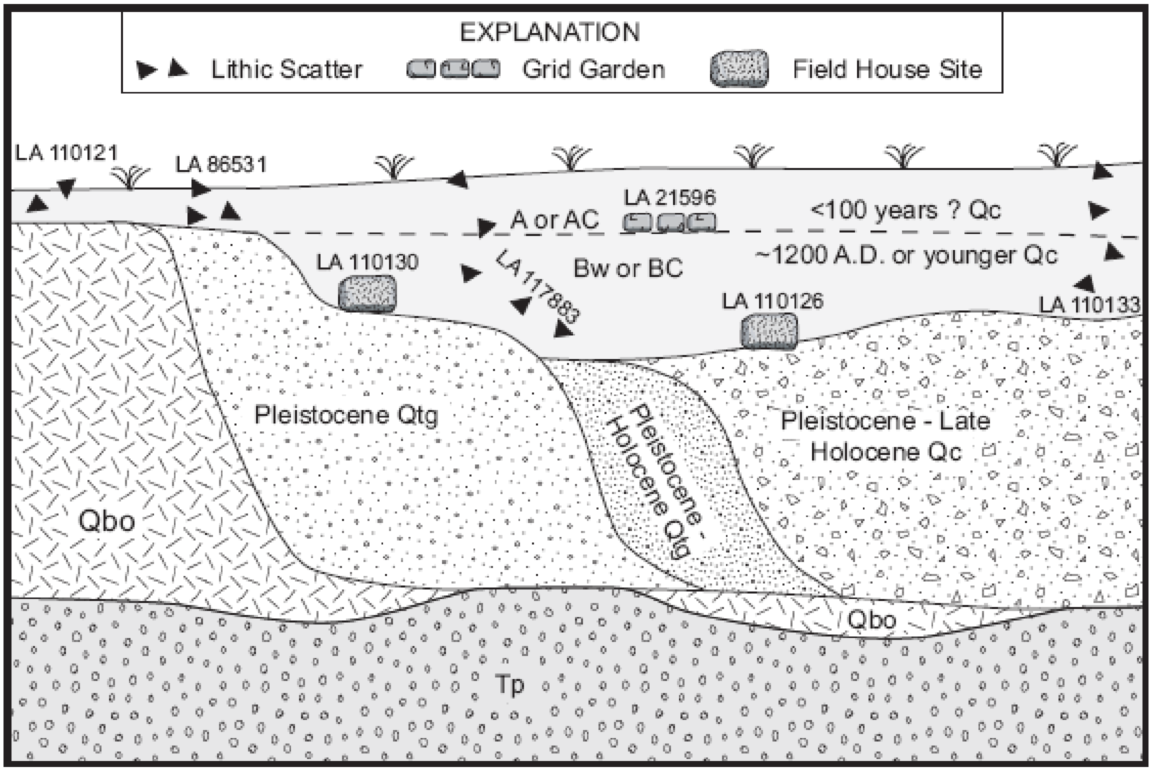

Figure 57.75. Pueblo Canyon schematic stratigraphic correlations chart showing context of archaeological sites.

Recent (less than 750 years old), relatively thick (greater than 50 cm) colluvial deposits were observed at LA 21596b and LA 21596c (Classic period grid garden site), LA 110133 (Coalition/Classic period lithic/ceramic scatter), and LA 117883 (Archaic lithic scatter). Sites LA 110133 and LA 117883 are artifact scatters where the artifacts are part of the colluvium and lack archaeological context (Figure 57.75). LA 21596 includes a series of grid gardens that were a relatively late-stage feature relative to the occupation of Otowi Pueblo, built on top of Puebloan-age colluvium (Figure 57.75). Three sites, LA 110126 (Classic period fieldhouse), LA 86528 (possible Classic/Historic period rock shelter), and LA 110121 (Coalition period lithic/ceramic scatter) are situated on eroded colluvial slopes. At LA 110121, thin (10 cm thick) late Holocene colluvial deposits overlie the Guaje pumice bed (Figure 57.75). The LA 110121 artifact scatter is part of the colluvium and lacks archaeological context. At LA 86528, thin (11 cm thick) late Holocene colluvial deposits overlie Pleistocene colluvium. LA 110130 (fieldhouse) and LA 86531 (lithic scatter) are located on the surface of somewhat dissected Pleistocene fluvial terraces (Figure 57.75). Both sites have artifacts present in the upper 20 cm that are part of slopewash colluvium or are a surface lag, but are likely to have been transported a relatively short distance from their original locations, and therefore may be in moderate to good archaeological context.

Stratigraphy of surficial units includes thin late Holocene colluvial deposits overlying late Pleistocene colluvial deposits or Pleistocene and Holocene fluvial terrace deposits (Figure 57.75). Late Pleistocene soils are truncated, indicating erosion some time during the Holocene, before deposition of the late Holocene colluvium. Soil stratigraphic relationships and artifact context at many of the sites in the TA-74 South Tract are indicative of one colluvial deposit with an age of less than 800 years and a second colluvial deposit that has an estimated age of 100 years or less. Before Coalition period time, large areas of the Pueblo Canyon landscape were characterized by stripped, erosional surfaces. In contrast, most of the landscape in the TA-74 South Tract has experienced net deposition since Coalition period time. With the exception of Holocene terrace deposits, the pre-Coalition period Holocene record in this part of Pueblo Canyon is apparently very poorly preserved. In this geomorphic setting, colluvial processes have reworked many of the artifacts across low-gradient colluvial slopes. Low fluvial terraces buried by young colluvium may have the best potential for preserving an intact archaeological record.

WHITE ROCK Y TRACT

Surficial Geologic Units

Surficial geologic units within the parcel include young alluvium in the main stream channel and tributary drainages of Los Alamos Canyon (unit Qal), higher stream terraces of Holocene and Pleistocene age (units Qt3, Qt2, and Qt1)), and areas of colluvium on side slopes (unit Qc). The White Rock Y parcel includes the channel of Los Alamos Canyon, incised into basalt bedrock (unit Tb), and an adjacent stream terrace, Qt3, that is overlain by colluvium derived from a higher, Pleistocene-age terrace, Qt1 (Figure 57.76).

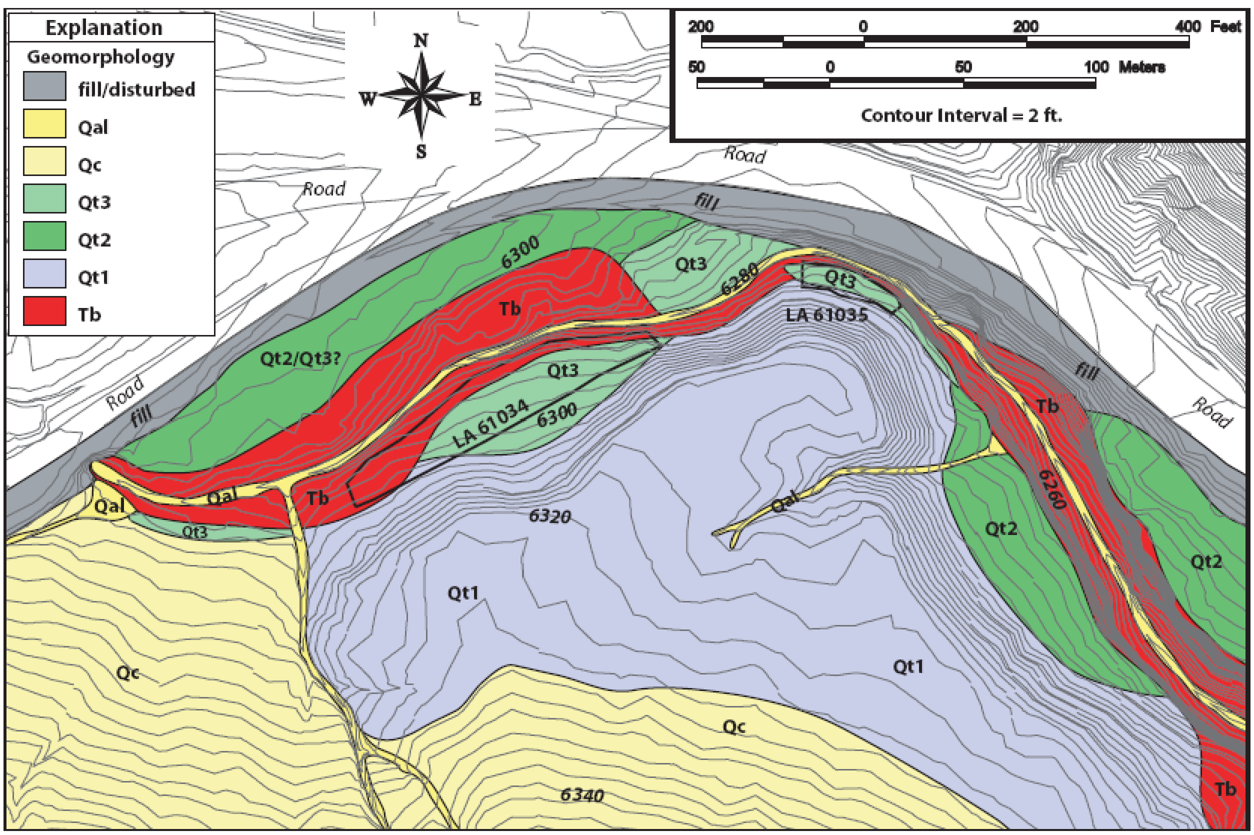

Figure 57.76. Geomorphic map of White Rock Y Tract.

An intermediate, inferred Pleistocene-age terrace, Qt2, is also present above the basalt cliffs in the bottom of the canyon. Terrace gravels exposed on the edge of the Qt3 terrace, below the elevation of the bottom of archaeological test pits, have Stage I calcium carbonate coatings on the undersides of clasts, suggesting an early to middle Holocene deposit (Figure 57.77). The inferred Holocene terrace is 3 to 4 m above the modern stream channel, and the higher Pleistocene terrace is 12 to 13 m above the modern channel (Figure 57.77). Qt1 is bordered on the south by colluvial slopes that lead up to a Bandelier Tuff-capped mesa south of the tract. In the western end of the tract, the Qc slope is continuous from the Bandelier Tuff-capped mesa to basalt bedrock (Figure 57.76).

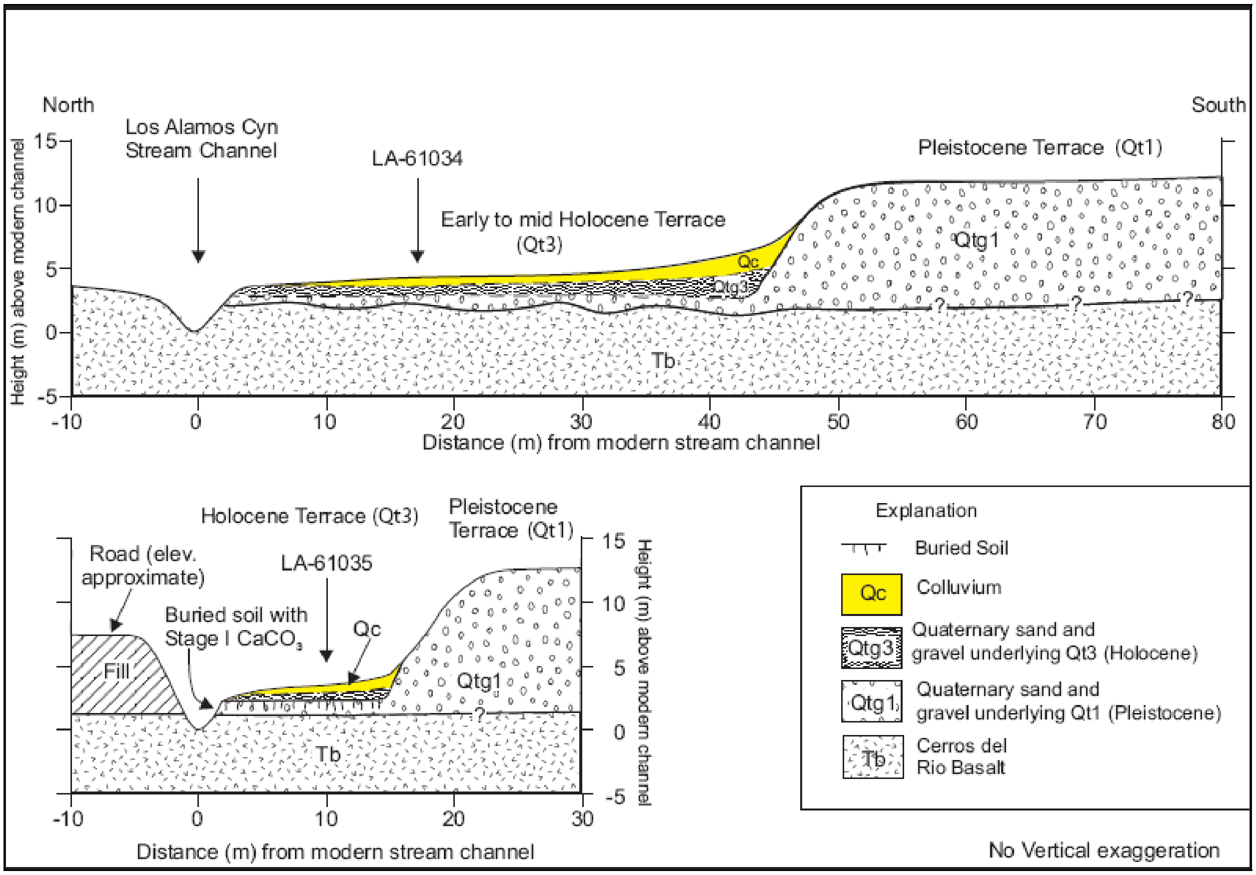

Figure 57.77. Cross-sections through archaeological sites at White Rock Y Tract.

LA 61034 (Lithic/Ceramic Scatter)

LA 61034 consists of lithic and ceramic scatter on a colluvial slope that overlies a stream terrace. The presence of artifacts through the entire thickness of the colluvial layer is consistent with the interpretation that the artifacts have been transported from upslope and are not in place. The horizon sequence, consisting of an A-Bw-Btj1(b1?)-Btj2(b1?)-IIBCb2 profile, is suggestive of Puebloan or post-Puebloan colluvium (the A-Bw horizons) overlying Archaic colluvium (the Btj1(b1?)-Btj2(b1?) horizons), burying Holocene terrace gravel (the IIBCb2 horizon). This interpretation is supported by the distribution of artifacts throughout the colluvial profile. Ceramics and lithics were found in excavation depths corresponding to the A and Bw horizons, whereas lithics only were found in excavation depths corresponding to the Btj1(b1?) and Btj2(b1?) horizons (Table L.9). Total thickness of colluvium at LA 61034 is 40 cm.

LA 61035 (Lithic/Ceramic Scatter)

LA 61035 consists of a lithic and ceramic scatter on a colluvial slope that overlies a stream terrace. The presence of artifacts through the entire thickness of the colluvial layer is consistent with the interpretation that the artifacts have been transported from upslope and are not in place. The presence of ceramics in the upper 30 to 40 cm indicates significant colluvial deposition since Puebloan occupation of this area. Total thickness of colluvium at LA 61035 exceeds 140 cm. The presence of an underlying section of colluvium with obsidian flakes but without ceramics is interpreted to indicate that colluvial deposition here began before Puebloan occupation, likely during Archaic time, and that the obsidian flakes were derived from erosion of an Archaic site upslope. The section of colluvium observed at LA 61035 has a greater thickness than the colluvial section at LA 61034. This is a result of their relative positions on the terrace; with LA 61035 located much closer to the back edge of the terrace than is LA 61034 (Figure 57.77).

White Rock Y Tract Summary

Two sites were investigated in the White Rock Y Tract. LA 61034 and LA 61035 are both lithic/ceramic scatters located on a Los Alamos Canyon stream terrace (Qt3) of probable Holocene age overlain by colluvium derived from an adjacent, higher Pleistocene terrace (Qt1). Artifacts occur in colluvial deposits that overlie the terrace gravel and are not in archaeological context, having been transported here from upslope. Two episodes of colluvial deposition are inferred, with a total thickness of colluvium ranging from 40 cm at LA 61034 to greater than 140 cm at LA 61035. The upper colluvial layer includes both ceramic and lithic artifacts, was deposited during Puebloan time or later, and ranges in thickness from 14 to 45 cm at the two sites. The lower colluvial layer contains only lithic artifacts, was likely deposited during Archaic time, and ranges in thickness from16 to greater than 95 cm at the two sites.

CONCLUSIONS

Archaeological sites examined during this investigation are located on mesa top, colluvial slope, fluvial terrace, valley bottom, and ridge top settings. The record of eolian and colluvial deposition on mesa tops and within canyons indicates periods of widespread deposition during the latest Holocene (generally <1 ka deposits) and during the late Pleistocene to early Holocene. middle Holocene (approximately 6 to 8 ka) and late Holocene (approximately 1 to 2 ka) colluvial deposits are less extensively preserved. Similarly, early Holocene (9 to 10 ka), middle Holocene (approximately 4 to 6 ka), and late Holocene (approximately 2 to 3 ka) eolian deposits are less extensively preserved than late Pleistocene and latest Holocene deposits. Of a total of 59 archaeological sites and stratigraphic profile locations described during this investigation for which pre-Puebloan information is available, 32 (54%) have only latest Holocene and Pleistocene deposits, 23 (39%) have latest Holocene and middle or early Holocene deposits, and 4 (7%) have latest Holocene and late Pleistocene to early Holocene deposits. The net aggradation recorded by nearly all locations with young (post-Coalition period) deposits demonstrates recent aggradation across the Pajarito Plateau landscape following a period dominated by erosion during the middle to late Holocene. This sequence of surficial processes has resulted in good preservation of many Ancestral Puebloan sites in a variety of geomorphic settings, but has resulted in the preservation of relatively few Archaic sites in the land transfer parcels.

Preliminary regional correlation of eolian stratigraphic units have been developed during investigation of sites located on mesa top settings in the Airport Tract and White Rock Tract and, by comparison, with the stratigraphic record exposed in paleoseismic trenches on Pajarito Mesa. A post-Puebloan age eolian deposit is present in each of the mesa top locations; therefore, Ancestral Puebloan sites are typically buried and are generally in good archaeological context. It is inferred that 15 to 20 cm of eolian deposition occurred sometime after the middle Coalition period but before the Classic period (i.e., ca AD 1250–1325), and in many cases Coalition and Classic period sites can be differentiated based on soil stratigraphic relationships. The timing of this eolian event corresponds to "The Great Drought" of AD 1276–1299 and a locally drier period from AD 1250–1255, inferred from tree ring data, and a major regional event associated with the abandonment of Mesa Verde (Rose et al. 1981).

A second, more recent eolian event occurred after abandonment of the Early Classic (?) period sites, resulting in deposition of an additional 5 to 10 cm of fine-grained sediment in mesa top settings since approximately AD 1500. Up to 4 cm of eolian deposition has occurred since the middle to late 1800s at one site. Post-Middle Coalition period deposits are typically underlain by 0 to 1.5 m of Pleistocene and Holocene deposits overlying the 1.22 Ma Bandelier Tuff, recording a sequence of discontinuous, truncated late Pleistocene through middle to late Holocene soils that represent episodic eolian deposition and soil formation followed by erosion. The Airport Tract b1 soil is likely correlative with either the 2 to 3 ka Pajarito Mesa deposit, or is a mid-Holocene deposit not observed during the Pajarito Mesa investigation. The Airport Tract b2 soil may be correlative with pre-El Cajete Pajarito Mesa unit 3b, or could be correlative with a unit 2a Pleistocene or early Holocene deposit. The local early Holocene b2 deposit at EG&G gully may correlate with the Pajarito Mesa unit 2a 9 to 10 ka deposit. The Airport Tract b3 soil and Pajarito Mesa unit 3e deposit are both characterized by well-developed stripped soils with 5YR to 7.5YR hue formed in part in Bandelier Tuff rubble and preserved in bedrock pockets in the undulating tuff surface and appear to be correlative with one another. The presence of late Pleistocene to early Holocene eolian deposits in mesa top settings preserves a record of Paleoindian occupation on the Pajarito Plateau, as shown by the three Paleoindian sites exposed on Pajarito Mesa.

In canyon settings, early to middle Holocene deposits are less extensively preserved, except in some canyon bottoms, recording net erosion during the Holocene across most of the landscape. Late Pleistocene soils are truncated, indicating erosion some time during the Holocene, before deposition of the late Holocene colluvium. In Rendija Canyon, the development of shallow hillslope drainages and their subsequent filling is recorded by the ca 1 to 2 ka and ca 6 to 7 ka swale fill deposits. Valley bottoms preserve 1.5 to 2 m thick middle to late Holocene colluvial deposits and an unknown thickness of underlying early Holocene and/or late Pleistocene deposits. Pre-Coalition period colluvial deposits are apparently preserved over a larger part of the Cañada del Buey landscape, but are apparently very poorly preserved in Pueblo Canyon within the TA-74 South Tract. Use of soil stratigraphic characteristics to differentiate between Coalition and Classic period sites in hillslope settings has not been as reliable as has been found for mesa top sites. This may indicate that the main pulse of recent colluvial deposition has occurred later than the AD 1250–1325 eolian event, likely after AD 1500.

Use of soils to correlate between colluvial and eolian deposits is complicated by variable rates of soil development in different geomorphic settings. This proved problematic in the case of site LA 85859, where a 6.7 to 7.4 ka soil had properties typically observed in late Pleistocene soils found on the Pajarito Plateau. The unusually rapid soil formation observed at LA 85859 is likely due to site-specific geomorphic factors including erosion of older, clay-rich soils upslope, and deposition of clay-rich colluvium in a hillslope depression. Caution should be used when making relative age estimates based on soil properties in variable geomorphic settings.

Pleistocene-age colluvial deposits are not differentiated in the Rendija and TA-74 South tracts; however, two Pleistocene-age colluvial deposits are described in the White Rock Tract. A younger, greater than 50 to 60 ka (pre-El Cajete) colluvial deposit is preserved throughout the tract, and an older, greater than 100 to 200 ka deposit is discontinuously preserved. At one location in the south-central area of the White Rock Tract, a piece of fossilized bone of *Bison antiquus* was found at a depth of about 20 to 30 cm eroding out of a gully wall in the younger Pleistocene Qc deposit, stratigraphically below the ca 50 to 60 ka El Cajete pumice. This is apparently the first recorded Pleistocene fossil from Los Alamos County and is also one of very few bison records in New Mexico with dates older than about 20 ka.

The episodes of eolian deposition provide a significant source of sediment for the colluvial deposits, and eolian deposits are commonly reworked downslope. Several Holocene periods of widespread eolian and colluvial deposition are roughly coincident, with a short lag time between eolian and colluvial deposition, including the latest Holocene (<1 ka deposits), the late Holocene (approximately 1 to 2 ka colluvial deposits and approximately 2 to 3 ka eolian deposits, and the early to middle Holocene (approximately 6 to 8 ka colluvial deposits and 9 to 10 ka eolian deposits). Although most of the Pleistocene record is likely not preserved, late Pleistocene (post-El Cajete) eolian deposits are preserved on Pajarito Mesa, in Rendija Canyon, and possibly in the Airport Tract. Some colluvial deposits are likely also of a similar age. Pre-El Cajete, late Pleistocene eolian and colluvial deposits are preserved on Pajarito Mesa, the Airport Tract, in Cañada del Buey, and likely in Pueblo and/or Rendija canyons. Older, greater than 100 to 200 ka eolian and colluvial deposits are apparently preserved in all areas visited during this investigation. In between eolian events, erosional processes dominate and much of the sediment is stripped from hillslopes and mesa tops and deposited in valley bottoms, including deposition on fluvial terraces.

As a result of widespread eolian and colluvial deposition during the latest Holocene, Ancestral Puebloan sites are well preserved in a variety of settings including mesa tops, hillslopes, fluvial terraces, and ridgetops. Although older Holocene colluvial and eolian deposits are not extensively preserved, Archaic site LA 85869 is located within and on top of colluvium deposited during a period of aggradation from ca 6.7 to 7.4 ka that apparently included site occupation. Other Archaic sites were in poor archaeological context, and lithics were generally present as part of a younger colluvial package or as a surface lag. Although not extensively preserved, future investigations could target middle and early Holocene deposits on fluvial terraces and in other settings in valley bottoms, along gullies and, when possible, during excavations on mesa top settings, to further investigate the Archaic and Paleoindian record on the Pajarito Plateau. The Pajarito Mesa paleoseismic trenching investigation demonstrated that such sites are present, although they have been relatively poorly investigated to date.

CHAPTER 58
CERAMIC ANALYSIS FOR THE LAND CONVEYANCE AND TRANSFER PROJECT, LOS ALAMOS NATIONAL LABORATORY

C. Dean Wilson

INTRODUCTION

This chapter presents the results of the analysis of 22,618 ceramic artifacts recovered during the Land Conveyance and Transfer (C&T) Project archaeological excavations. This analysis was conducted under the supervision of Dean Wilson, with the assistance Candace Lewis, Rick Montoya, Marlene Owens, and Carol Price of the Office of Archaeological Studies, Museum of New Mexico in Santa Fe. The artifacts were recovered from archaeological sites excavated in the White Rock, Airport, and Rendija tracts, as well as test excavations conducted in the Technical Area (TA) 74 and White Rock Y tracts (Table 58.1). The chapter contains information on the ceramic attributes and types recorded during the analysis and the long-term temporal trends reflected in changing ceramic types, production and exchange patterns, and vessel function.

Total		22,618

Several sites were included in the analysis that were not part of the project excavations, but provided additional information. A total of 10,070 sherds were included from LA 4618, 1056 sherds from LA 4619, and 360 sherds from LA 82601. LA 4618 and LA 4619 are Late Coalition period roomblocks while LA 82601 is a Coalition period fieldhouse and all are located on Mesita del Buey near the White Rock Tract (Wilson 2006, 2007). A limited number of sherds were also analyzed from excavations conducted in the 1950s at the Airport 1 (n = 19) and Airport 2 (n = 129) sites located in the Airport Tract (Steen 1977; Chapter 27, Volume 2). Both of these sites appear to be Coalition period roomblocks. Given the lack of information on the Developmental period, a total of 168 sherds were also analyzed from a Late Developmental site (LA 82601) situated on the mesa overlooking the Rio Grande valley in TA-70 (Acklen 1993).

All of the aforementioned data will be included in the discussions provided in this chapter. The chapter will first discuss analysis strategies, procedures, and typological categories employed during the analysis of the ceramics. Data documented during this study is then used to examine various trends and issues relating to prehistoric occupations on the Pajarito Plateau. These data will then be used to address some of the research issues raised by Vierra et al. (2002) in the project data recovery plan. An initial set of questions relates to chronology and site occupation span. Other issues involve the examination of the nature and organization of subsistence activities, local and regional exchange networks, and the influence of various local conditions, stresses, and pressures on various networks and activities as well as on the eventual abandonment of various sites and locations on the Pajarito Plateau.

Many issues can be examined by using ceramic distributions to determine the time of occupation indicated by assemblages from various sites and contexts as well as the documentation of ceramic distributions relating to the production, area of origin, decoration, and use of ceramic vessels. In order to examine various trends, a range of ceramic traits was recorded in the form of both attribute classes and ceramic type categories.

CERAMIC ATTRIBUTES

Sherds exhibiting a unique combination of traits were separated by group, provenience, and site during the ceramic analysis. Information about the characteristics of a combination of sherds from a particular grouping was recorded on distinct data lines. Each data line from a particular provenience was assigned to consecutive catalog numbers. Sherds assigned to a particular grouping were placed into a separate bag along with a small slip of paper recording the site, field specimen (FS) number, and catalog number. Information recorded during ceramic analysis included associated provenience (or FS) and catalog number, typological assignment, descriptive attribute code, quantity of sherds, and total weight. These procedures allow for the matching of sherds with data lines recorded during ceramic analysis, necessary for locating items for data editing and more detailed analyses.

Ceramics from various sites and proveniences were also assigned to a "segment" category, which refers to the stage or year of analysis, the tract where a site was located, and the type of recovery or sampling of ceramics from a particular context. The recording of this information as a separate category allows for the separation and manipulation of ceramic data from distinct tracts or analysis sets.

Attribute classes recorded during the present study include temper, paint type, surface manipulation, modification, and vessel form. In addition, more detailed studies, such as refiring analysis, petrographic characterization, and stylistic analysis were conducted on small samples of pottery.

Temper

Temper category refers to characteristics of added or naturally occurring aplastic particles. Temper analysis involved examining freshly broken sherd surfaces through a binocular microscope. Such characterizations are limited, although broad temper categories can be recognized based on combinations of color, shape, fracture, and sheen of tempering particles.

‘Indeterminate temper’ refers to cases where temper was examined, but the type of material could not be determined. ‘Self-tempered’ refers to examples where distinct added aplastic inclusions were not present in the clay paste, and inclusions are limited to tiny naturally occurring silt grains. ‘Vitrified’ refers to examples where the temper could not be identified because the particles in the paste had been melted due to exposure to very high temperatures.

The majority of the analyzed ceramics appear to have been tempered with volcanic rock commonly used by potters on the Pajarito Plateau. ‘Fine tuff or ash’ refers to fine volcanic fragments common in whiteware forms made over much of the Rio Grande region. Temper assigned to this category consists of small, clear to light, or dark vitreous, angular to rod-shaped particles with light-colored dull pumice particles. The presence of such particles may reflect either the use of self-tempered clays weathered from ash deposits or the intentional addition of crushed or weathered tuff or ash to the clay. Similar categories were recognized based on the presence of associated sand or mica fragments and were classified as 'fine tuff and sand,' 'mica and tuff,' and 'tuff, mica, and sand.' A few examples displayed large fragments and were coded as large tuff fragments or vitric tuff.

The form of temper usually dominating grayware types at sites on the Pajarito Plateau is referred to here as 'tuff and phenocrysts (anthill sand).' These grains are often transparent or crystalline in structure, and occur in a non-micaceous paste. This temper appears to be common in grayware pottery found over much of the Pajarito Plateau and is represented by fairly rounded quartz phenocrysts along with smaller tuff particles. Such sources are most common on anthills and assorted streambeds in the Pajarito Plateau (Vint 1999). Other examples, with a small but still significant amount of phenocrysts, were assigned to a 'mostly tuff with some phenocryst' category. Another form of this temper is dominated by large tuff fragments and was classified as 'large tuff with anthill sand.'

'Granite with mica' refers to the dominant temper type in grayware forms derived from areas in the northern Rio Grande region, although this temper does not appear to have been available to, nor used by, potters residing on the Pajarito Plateau. This category reflects the use of various combinations of local alluvial clays with rock fragments and crushed igneous river cobbles that may have been derived from porphyries common in mountains and drainages scattered over much of the northern Rio Grande region. Even without microscopic examination, sherds with this temper are usually easy to recognize by the presence of numerous mica fragments that visibly glitter on the vessel surface. Temper fragments are relatively large and sub-angular to sub-rounded. These particles are usually white but are occasionally clear, light gray, or pink. Rock fragments may also contain mica and very occasionally black inclusions. Sherds with similar temper were separated into different categories based on the absence or presence of higher amounts of mica fragments. Sherds with similar temper without mica were assigned to the 'granite without abundant mica' category. Pastes where mica represents the dominant material were assigned to a 'highly micaceous (residual) paste' category. Another granitic temper occurs in late grayware types such as Sapawe micaceous, is distinguished by fine crystalline and dense small mica particles, and was recorded as 'Sapawe micaceous temper.'

Sand refers to rounded or sub-rounded, well-sorted sand grains. These grains are translucent, or white to gray. This category is distinguished from sandstone temper by the presence of large even-sized quartz grains and the absence of a matrix. A few sherds containing sand and mica or dark igneous fragments were separated into other categories. Examples of similar sand with other particles were assigned to the 'sherd and sand' or 'sand and mica' category. Examples consisting of extremely fine sand particles were classified as 'very fine sand (silt).' 'Fine sandstone' exhibits rounded sand grains along with angular matrix fragments. Grains derived from sandstone are usually smaller than those found in sand temper.

Sherd refers to the use of crushed potsherds as temper. Crushed sherd fragments may be white, buff, gray, or orange in color. These fragments are often distinguished from crushed rock tempers by their dull non-reflective appearance. Fragments of tuff, however, may be similar in appearance. Small reflective rock particles may be included inside or outside the sherd fragments.

Temper consisting of similar sand along with rounded white to dull gray fragments, assumed to represent natural inclusions in the clay with sand, was assigned to an 'oblate shale and sand' category. Pastes with shale fragments without other lithic fragments were assigned to a 'shale' category. Others containing similar shale and small tuff categories were classified as 'oblate shale and tuff.'

Gray crystalline basalt refers to the presence of homogenous greenish-, gray-, or black-colored angular rock fragments representing crushed basalt. This temper is mainly associated with glazeware types from the Zia, Cochiti, and Albuquerque areas. Similar material with sand particles was assigned to the 'basalt and sand' category. Scoria refers to similar basalt with red- or orange-colored particles.

Another crushed rock type associated with glazeware types is latite. This temper is characterized by dull buff, light gray, to dark colored dull tuff particles and shiny black and white quartz particles.

'Andesite or diorite' refers to fragments from either crushed andesites or diorites grains. This category represents a temper used by potters in most of the northern San Juan or Mesa Verde region of the Four Corners Ancestral Pueblo (Wilson and Blinman 1995a). Examples of this temper noted during the present study were associated with other materials and thus assigned to either an 'andesite or diorite and sherd' or 'andesite or diorite and sand and sherd' category.

'Mogollon volcanics' or 'sand and Mogollon volcanics' refer to the presence of natural inclusions common in clay sources from the Mogollon Highlands in southwest New Mexico. Previous studies of Mogollon pottery indicate that these reflect the use of pedogenic sources ultimately derived from local volcanic outcrops and volcanic-clastic sandstone in the Mogollon Highlands (Wilson 2000). These clay sources usually contain numerous natural igneous and sandstone inclusions, and in most cases the addition of separate tempering material would have been unnecessary.

Other temper categories represent combinations of sherd and distinct crushed rock associated with Chupadero Black-on-white produced in the northern Mogollon region. These temper types include 'dark igneous,' 'dark igneous and sherd,' 'dark igneous and sand,' and 'sherd and calcium carbonate.'

Pigment Type

Pigment categories were identified based on the presence, surface characteristics, and color of painted surface decorations. Most pigments were divided into organic (or carbon) and mineral pigment groups based on previously described characteristics (Shepard 1963).

The presence, type, and color of paint pigments were recorded for all sherds examined. Sherds without evidence of painted decorations were simply placed into a 'none' category. Those, for which the paint type could not be determined, were classified as 'indeterminate and indeterminate burned out.'

Mineral paint refers to ground minerals such as iron oxides used as pigments. These decorations are applied as powdered compounds, usually along with an organic binder. Mineral pigment represents a distinct physical layer and rests on the vessel surface. Such pigments are usually thick enough to exhibit visible relief. Mineral pigments usually obscure surface polish and irregularities. The firing atmospheres to which mineral pigments were exposed affects color. Mineral pigment categories identified during the present study include 'mineral black,' 'mineral brown,' and 'mineral red.'

Organic paint refers to the use of vegetal pigment only. Organic paint is soaked into rather than deposited on the vessel surface. Thus, streaks and polish are often visible through the paint. The painted surface is generally lustrous, depending on the degree of surface polishing. The pigment may be gray, black, bluish, and occasionally orange in color. The edges of the painted designs are often fuzzy. Sherds with the light remnants of organic paint that had been mostly fired off were classified as 'organic diffuse.'

Glaze paint refers to the use of lead as a fluxing agent to produce vitreous decorations. Glaze pigments are often very thick and runny, and bubbles may protrude through the surface. The glaze may weather off, leaving a thin organic layer. Pigment color ranges from brown, black, and orange to green.

Surface Manipulation

Attributes relating to surface manipulations reflect the presence and type of surface texture, polish, and slip treatments. Surface manipulation categories were recorded for both interior and exterior vessel surfaces. Categories identified during the present study include 'plain unpolished,' 'plain polished,' 'polished white slip,' 'polished red slip,' 'polished smudged,' 'plain striated,' 'micaceous slip,' 'surface missing,' 'narrow coil,' 'wide coil,' 'narrow coil,' 'clapboard,' 'indented corrugated,' 'indented plain corrugated,' smeared-indented corrugated,' 'smeared plain corrugated,' 'wide wiped undulated,' 'wide banded incised indented alternating wide fillet-indented corrugated,' 'unpolished white slip,' 'polished thin white slip,' 'basket impressed,' 'polished cream-red slip,' 'polished cream slip,' 'unpolished red slip,' 'parallel incised,' 'fingernail incised,' 'neck corrugated indented,' 'alternating plain indented corrugated,' 'smeared plain corrugated with mica slip,' and 'incised with mica slip.'

Vessel Form

Observations about sherd shape and surface manipulation provide clues concerning the use of the vessels from which they derived. Vessel form classification is usually dependant on sherd size, manipulation, and vessel portion. It is usually possible to assign rim sherds to more specific categories than body sherds. Categories identified during the present study include ’indeterminate,’ ‘bowl rim,’ ‘bowl body,’ ‘seed jar,’ ‘olla rim,’ ‘jar neck,’ ‘jar rim,’ ‘jar body,’ ‘jar body with strap or coil handle,’ ‘jar body with lug handle,’ ‘dipper with handle,’ ‘gourd dipper,’ ‘dipper rim,’ ‘indeterminate coil strap handle,’ ‘canteen rim,’ ‘miniature jar,’ ‘miniature pinch pot rim,’ ‘miniature pinch pot body,’ ‘jar rim with strap handle,’ ‘cloud blower,’ ‘appliqué,’ ‘jar rim with lug handle,’ ‘effigy,’ ‘fired coil,’ ‘body sherd polished interior-exterior,’ ‘body sherd unpolished,’ ‘body sherd polished interior unpolished exterior,’ ‘indeterminate rim,’ ‘dipper handle,’ ‘plate or tray,’ ‘flared bowl rim,’ and ‘indeterminate lug handle.’

Modification

Modification refers to evidence of post-firing alteration including abrasion, drilling, chipping, or spalling. Data concerning such treatments provide information about use, repair, and shaping of sherds and vessels. Modification categories combine information concerning the size, shape, and associated wear patterns of a modified sherd. Modification categories recorded during the present study include ‘none,’ ‘drill hole complete,’ ‘ceramic scraper,’ ‘beveled edge,’ ‘punched hole,’ ‘interior worn from cooking,’ ‘interior spall erosion,’ ‘abraded surface exterior,’ ‘drill hole incomplete,’ ‘interior surface partially worn,’ ‘abraded surface interior,’ ‘exterior firing shall,’ ‘rim wear,’ ‘interior-exterior erosion,’ ‘sooted interior-exterior,’ ‘sooted interior,’ ‘exterior partially exfoliated erosion,’ ‘sooted exterior,’ ‘shaped all sides,’ ‘reshaped rim,’ ‘pendant,’ ‘pigment residue,’ ‘interior chipping,’ ‘intentional chipping,’ ‘unknown residue,’ and ‘single groove incised.’

Stylistic Analysis

While information relating to surface texture and design style were documented through typological categories, a range of stylistic attributes was recorded for a subset of grayware and whiteware rim sherds. Stylistic attributes recorded for painted whiteware types include ‘rim thickness,’ ‘design orientation from the rim,’ ‘design motifs,’ ‘number of motifs,’ ‘rim decoration,’ ‘rim shape,’ and ‘degree of surface polish.’ Attributes recorded for grayware types include ‘evidence of type of finish,’ ‘presence and thickness of top rim fillet,’ and ‘interior finish.’ These attributes provide additional information concerning the characteristics of Rio Grande types. Information relating to the distribution of various attributes from dated types may be compared to studies from other areas to better determine the nature of temporal changes and regional influences.

Refired Color

Refiring analysis provides data for paste comparisons based on mineral impurities in clay and ceramic pastes. This technique involved firing samples in oxidizing conditions to temperatures of 950°C. Such firings standardize the oxidation of iron compounds in clays and fire out organic material. This allows for the common comparison of color of samples and reflects types and amounts of mineral impurities (particularly iron). Sample color was recorded using the Munsell color categories. During the present study, sherds exhibiting hues of 2.5YR were described as red, those exhibiting hues of 5Y as yellow red, hues of 7.5YR as pink, and hues of 10YR, 2.5Y, and 5Y as buff.

Petrographic Analysis

In order to further examine issues relating to local production and exchange, a small sample of sherds were selected for petrographic analysis. The detailed results of the petrographic analysis are presented by Miksa (Chapter 59, this volume). These data will be used to discuss issues pertaining to ceramic production and exchange on the Pajarito Plateau.

CERAMIC TYPE DESCRIPTIONS

Ceramics examined from the project sites were assigned to typological categories based on combinations of traits with spatial, functional, and temporal implications. Ceramics were assigned to different type categories based on a series of decisions that involved the recognition of associated ceramic tradition, ware, and defined pottery types. The determination of associated ceramic tradition involved the separation of ceramics into broad groups indicative of postulated area of origin or "cultural" association. Ceramics were placed into ceramic traditions defined for the northern Rio Grande and surrounding regions based on characteristics of temper, paste, and paint of pottery known to have been produced in various regions. Sherds were then assigned to ware groups based on technological attributes and surface manipulation. Finally, sherds were assigned to ceramic types based on temporally sensitive painted decorations or textured treatments.

Indeterminate Tradition Types

Types assigned to an 'indeterminate tradition' refer to sherds that could not be placed into previously defined regional traditions. The 'indeterminate tradition' category was seldom used and was limited to rare situations where sherds were tempered with material or inclusions not attributed to specific traditions. 'Indeterminate utilityware' refers to grayware pottery of indeterminate tradition or origin. Whiteware pottery was assigned to two types within this tradition including 'unpainted undifferentiated white' and 'indeterminate painted ware.' 'Indeterminate blackware' refers to pottery of unknown origin that is sooted or smudged over a polished surface.

Northern Rio Grande Pottery Tradition

The majority of the ceramics analyzed from the C&T Project sites exhibited styles, technologies, and temper indicative of pottery produced on the Pajarito Plateau or in surrounding areas of the northern Rio Grande region. Both grayware and whiteware ceramics that exhibited these characteristics were assigned to northern Rio Grande tradition types, although low frequencies of intrusive prehistoric types were also identified. Many of the types defined for the northern Rio Grande pottery were first named and described by Kidder or Mera based on excavations in the early 20th century (Kidder 1915; Kidder and Amsden 1931; Kidder and Shepard 1936; Mera 1933, 1934, 1935). The various Rio Grande pottery types defined and described during these investigations were first compiled by Hawley (1936), and these categories have long been used as the basis for the description and examination of pottery data from sites in the northern Rio Grande region (Habicht-Mauche 1993; Honea 1968; Lambert 1954; Lang 1997; Powell 2002; Stubbs and Stallings 1953; Vint 1999; Warren 1976).

Northern Rio Grande Graywares

Northern Rio Grande Grayware refers to the dominant gray or grayware found over wide areas of the Rio Grande region (Habicht-Mauche 1993; Wendorf 1953). Two basic paste groups with strong area implications commonly occur in northern Rio Grande grayware pottery. The majority of grayware forms examined contained temper previously described as "anthill sand" in non-micaceous pastes. This temper appears to reflect tuff sources with unusually high frequencies of quartz phenocryst particles in tuff. The abundance of these particles appears to have resulted from sorting action reflected in both anthills and streambeds found on the Pajarito Plateau. The other paste commonly noted in grayware pottery from sites in the northern Rio Grande region is represented by pottery with numerous mica fragments (Warren 1979). The earliest "micaceous" types appear to reflect the use of crushed local mica-bearing granite cobbles as temper along the Rio Grande and associated drainages (Warren 1979). This temper does not appear to have been commonly used by potters on the Pajarito Plateau, and its presence is assumed to reflect the exchange of vessels produced in other areas such as along the Rio Grande Valley where micaceous granite sources were common.

A range of exterior surface manipulations has been noted on pottery exhibiting both paste groups and resulted in the identification of a number of different prehistoric grayware types. Similar criteria were used to assign northern Rio Grande grayware pottery to types based on exterior surface texture. While formal types have been defined for various surface treatments (for example Tesuque Smeared Corrugated), the definition of many of these types is somewhat vague and confusing, and the types commonly defined often do not cover the full range of manipulation encountered within these assemblages. Thus, the strategy employed here involved the utilization of descriptive types associated with a range of surface textures (Bice 1997).

Plain grayware vessels with completely smoothed surfaces occur at Rio Grande sites dating to all ceramic periods, although their relative frequency within ceramic assemblages changed significantly through time. Plain gray body sherds may be derived from plain surface vessels or from the lower portion of neck banded or corrugated vessels. Rim sherds that appear to have derived from completely smoothed vessels were classified as ‘plain gray rim’ (Figures 58.1 and 58.2). Rim sherds that were too small to indicate the surface texture of the vessel were classified as ‘unknown gray rim.’ Smoothed body sherds that could have originated from plain vessels or smoothed portions of neck banded or corrugated vessels were classified as ‘plain gray body.’ Grayware types assigned to other pottery forms not exhibiting distinct coils include ‘polished gray,' 'basket impressed gray' (Figure 58.3), 'plain incised,' 'wiped scored gray,' and 'mudware' (Figure 58.4).

Figure 58.1. Plain gray rim sherd from LA 86534 (FS 958-1).

Figure 58.2. Plain gray olla rim from LA 4618 (FS 171.1).

Figure 58.3. Basket impressed sherds from LA 86534 (left, FS 1555-1 and FS 1593-1) and LA 12587 (right, FS 4183-1).

Figure 58.4. Mudware vessel from the Pajarito Plateau.

Other grayware sherds display textures created by incompletely obliterated coil junctures along the exterior of vessel necks. Given the absence of sites dating before the Coalition period in the present sample, neck banded sherds are very rare. ‘Wide neckbanded’ refers to sherds with wide coils or fillets. These coils are clearly separated by distinct junctures that rest vertically to each other and usually do not overlap. ‘Wide neckbanded smeared’ is similar to the previously described type except the juncture between the coils has been partially obliterated. The area between these coils is visible but reflected by an undulating or ribbed surface. Similar forms with rounded coils were assigned to a ‘coiled necked’ category. Those with overlapping coils were classified as ‘clapboard neck.’

Other grayware sherds displayed corrugated textures resulting from incompletely obliterated coil junctures on exterior surfaces. Corrugated grayware vessels have thin overlapping coils, which often have regularly spaced indentations. These coils usually cover the entire exterior surface, although corrugated treatments are sometimes limited to the vessel neck. In some cases, corrugated types were further distinguished by other temporally sensitive attributes such as the type and pronouncement of coiled treatment.

‘Indented corrugated’ (Figures 58.5 through 58.7) includes grayware sherds with narrow coils, regularly spaced indentations, and moderate to high contrast between coils. This represents the dominant corrugated type during the Late Developmental period and the very early part of the Classic period.

Figure 58.5. Indented corrugated sherd from LA 12587 (FS 3908-38).

Figure 58.6. Indented corrugated sherd from LA 12587 (FS 4092-16).

Figure 58.7. Indented corrugated jar sherd from LA 135290 (FS 2106-2).

Grayware sherds with similar textures, but with distinct incised decorations, were classified as 'incised corrugated' (Figure 58.8). 'Plain corrugated' refers to grayware forms with similar coil treatment and relief described for indented corrugated but without regularly spaced indentations. Sherds with both rows of indented and coiled treatments were classified as 'alternating corrugated.' 'Patterned corrugated' refers to combinations of corrugated and coiled treatments that form distinct patterns or designs on the vessel. 'Neck corrugated' refers to indented corrugated limited to the neck area. Sherds assigned to this category usually exhibit corrugations with high relief as well as a plain lower area.

Figure 58.8. Incised corrugated sherd from LA 12587 (FS 3110-8).

'Smeared-indented corrugated' and 'smeared-plain corrugated' (Figures 58.9 through 58.12) display indented corrugations that have subsequently been smeared, resulting in the partial obliteration of indentations and coil junctures. Rio Grande grayware types exhibiting these treatments have been previously classified as 'Tesuque Smeared' (Mera 1935). In the Rio Grande region, smeared-indented corrugated was the most common grayware form during most of the Coalition period as well as the very early part of the Classic period.

Figure 58.9. Smeared-indented corrugated sherds from LA 4618 (left, FS 684-8) and LA 12587 (right, FS 1265-4).

Figure 58.10. Smeared-indented corrugated vessel from LA 4712.

Figure 58.11. Smeared-indented corrugated rim sherd from LA 86534 (FS 1248-1).

Figure 58.12. Smeared-indented corrugated rim sherds from LA 135290 (FS 1328-3, FS 1003-3, FS 1254-18b, and FS 2106-3).

'Sapawe micaceous washboard' represents the dominant grayware type at some Classic period sites in the northern Rio Grande region (Figures 58.13 and 58.14). 'Sapawe micaceous washboard' is commonly associated with other Classic period sites such as biscuitware types (Gauthier 1987a). Surfaces may be covered with a micaceous slip and are tan to dark brown to gray in color. Paste cross-section is dark gray, black, to dark brown. Pastes tend to be silty in appearance and are often vitrified. Sherds tend to be hard and dense. This type is almost always represented by jar forms, which tend to be thin. 'Sapawe micaceous washboard' is tempered with micaceous schist or granite that is most likely a natural constituent in the clay (Gauthier 1987a). Slightly obliterated coils are evident on the exterior surface. This creates a series of parallel ridges without distinct junctures between the coils. Other sherds with similar pastes and temper as described for 'Sapawe micaceous' but with plain surfaces were classified as 'mica utility undifferentiated' and 'unpolished micaceous.' A few very thin sherds with characteristics of late occupations were assigned to the 'thin plain non-micaceous' category.

Figure 58.13. Sapawe micaceous sherds from LA 128804 (left, FS 148-1) and LA 21596C (right, FS 11-16).

Figure 58.14. Two Sapawe micaceous vessels excavated from sites on the Pajarito Plateau.

Another type, which contains combinations of attributes noted in Classic period Rio Grande whiteware and plain grayware types, is Potsuwi'i Incised (Mera 1932). This type is represented by jars with very smoothed or polished exterior surfaces (Figures 58.15 and 58.16). Vessels tend to be thin and exterior surfaces are sometimes covered with a micaceous slip. Exterior surfaces are dull and gray. Pastes tend to be cream or tan and contain a fine tuff or ash similar to that noted in biscuitware types. A thin layer of mica was sometimes applied to the surface. Sherds are often thin and are almost always represented by jars. Decorations consist of fine incised lines. Designs are variable but often consist of combinations of parallel horizontal and vertical lines. Punctated decorations are sometimes represented.

The only other grayware pottery assigned to the prehistoric Rio Grande tradition was represented by a few brown-colored, polished sherds classified as 'local brownware.'

Northern Rio Grande Whiteware

Most of the decorated types are represented by black-on-white pottery with distinct pastes and temper indicative of northern Rio Grande whiteware types. The sequence of types assigned here to the northern Rio Grande tradition is similar to that attributed to the Tewa series as defined for areas of the northern Rio Grande (Gauthier 1987a; Harlow 1973; Wendorf 1953). Part of the sequence is also reflected in the Pajarito series as employed during the Arroyo Hondo Project (Habicht-Mauche 1993). This tradition reflects a long sequence of production of black-on-white vessels using distinct resources employed over wide areas of the northern Rio Grande Valley. The production of distinctive Rio Grande tradition pottery began with Pueblo II mineral-painted pottery in areas of the northern Rio Grande during the 10^{th} century and continued with a long sequence of changes that persists with pottery produced by Tewa Pueblo potters today.

Figure 58.15. Potsuwi'i incised sherds from LA 21596C (FS 9-1, left, and FS 11-2, right).

Figure 58.16. Potsuwi'i incised vessel from LA 170 (Tsirege).

Rio Grande whiteware types on the Pajarito Plateau are mainly represented by types associated with the Coalition and Classic periods. Unpainted whiteware sherds with temper indicative of the Rio Grande tradition were placed into an ‘unpainted undifferentiated’ category. This category generally refers to white exhibiting characteristics common in forms produced before the Classic period, as it is often possible to distinguish earlier (Late Developmental and Coalition period) unpainted whiteware sherds from those derived from biscuitware types and other later forms.

The earliest Rio Grande or Tewa series whiteware types identified during the present study is Kwahe'e Black-on-white, which dominates sites occupied during the last part of the Late Developmental period. This type reflects the first use of clays from volcanic ash or alluvial deposits common in areas of the Rio Grande Valley. Temper fragments in Kwahe'e Black-on-white usually consist of fine volcanic rock such as tuff or fine silt. The fineness of these tempers contrasts with that noted for pottery from areas of the Colorado Plateau to the west.

Kwahe'e Black-on-white displays a range of surface characteristics and design styles. Some sherds assigned to this type display surfaces that are not slipped that range from green to gray. Other examples display thin streaky thin white slip applied over a gray paste. Painted surfaces range from poorly to moderately polished, while well-polished examples are rare.

Kwahe'e Black-on-white is always decorated with iron oxide pigment. Pigments are usually black, although brown and red examples are common and may result from a poorly controlled firing atmosphere. Examples of this type are commonly decorated with designs similar to those found in pottery produced at contemporaneous sites in the Colorado Plateau. Execution, however, is sometimes poorer on Kwahe'e Black-on-white, although well-executed examples are occasionally encountered. Rims are usually tapered and may be either unpainted or painted with a solid line.

Most of the pottery assigned to Kwahe'e Black-on-white exhibited painted styles roughly equivalent to various Pueblo II types produced in the Cibola region to the west such as Gallup Black-on-white and Escavada Black-on-white. Sherds were also placed into distinctive stylistic groups defined for Kwahe'e Black-on-white based on the presence of different design styles. Early painted sherds without distinct styles were assigned to the ‘mineral paint undifferentiated’ category. Stylistic groups into which local mineral-painted whiteware sherds were placed include Kwahe'e Black-on-white.

Pottery produced during the Coalition period occupation is in many ways very similar to earlier Rio Grande whiteware types but is easily distinguished from these by decorations in organic rather than mineral paint. Some organic-painted pottery without distinct styles or forms was assigned to an ‘indeterminate organic paint’ category. One sherd with manipulations and paste similar to that noted on Coalition period pottery such as Santa Fe Black-on-white but with red slip was classified as ‘organic paint slipped red.’

Santa Fe Black-on-white represents the earliest organic-painted type described for the northern Rio Grande tradition and dominates most Coalition period assemblages (Figures 58.17 to 58.23).

Figure 58.17. Santa Fe Black-on-white ladle from LA 86534 (FS 1872-1).

Figure 58.22. Santa Fe Black-on-white bowl sherd from LA 135290 (FS 1254-6).

Figure 58.23. Santa Fe Black-on-white bowl from LA 4634.

Painted decorations on Santa Fe Black-on-white reflect a widespread shift to Pueblo III design styles decorated in organic paint (Lambert 1954; Lang 1982; Mera 1935; Stubbs and Stallings 1953; Sundt 1984). Some of the varieties such as Pindi and Pogi variety of Santa Fe Black-on-white, which are recognized based on temper variation (Habicht-Mauche 1993; Stubbs and Stallings 1953), were not used during the present study. In retrospect, the presence of low frequencies of Santa Fe Black-on-white containing vitric tuff temper indicates the presence of Pindi Black-on-white variety.

Vessel walls of Santa Fe Black-on-white are relatively thin and straight and are similar in shape and thickness to Kwahe'e Black-on-white. Pastes are often fairly dense and hard and can be vitreous. Pastes are usually very fine in texture and fracture along an even plain. Paste color is usually light gray to blue gray. Decorated surfaces are usually polished and often slipped. Surfaces are moderately to well-polished and often slipped. Surfaces range from white, light gray, and greenish to tan. Bowls are by far the dominant vessel form in this type. Undecorated exterior bowl surfaces are often unslipped and unpolished and may occasionally display unobliterated coils, striations, or basket impressions. Tempering materials include fine sand or finely crushed volcanic rock temper, fine sand, and, in some cases, sherd (Habicht-Mauche 1993; Stubbs and Stallings 1953).

Painted decorations are executed in organic pigment, which is sometimes faded and translucent. Paint color ranges from dark-gray, blueish-black to black. Rims are usually tapered and undecorated, while ticked rims, similar to those noted in contemporaneous pottery from regions on the Colorado Plateau are extremely rare. In bowls, decoration is oriented in a band on the interior surfaces. Decoration consists of banded panels on bowl interiors and the upper portions of jars. These banded panels are often framed by a pair of single lines that is separated by very short spaces between the line and top and bottom of the panels. Similar lines are also commonly directly incorporated into the top and bottom edges of the panels. These designs are occasionally framed by a series of similar-sized parallel lines or a combination of thick and thin lines. Santa Fe Black-on-white was first produced during the middle to late AD 1100s and continued to dominate assemblages until the middle AD 1300s and may occur as late as the early AD 1400s (Habicht-Mauche 1993; Stubbs and Stallings 1953; Sundt 1987).

Pottery exhibiting designs executed in organic paint, characteristic of Rio Grande whiteware types but with distinct pastes, were assigned to Galisteo Black-on-white. During the present study, Galisteo Black-on-white was differentiated from Santa Fe Black-on-white by the presence of a coarser white paste with added sherd and/or sand temper (Lambert 1954; Stubbs and Stallings 1953). The classification of Galisteo Black-on-white using previously defined criteria presents several dilemmas. Galisteo Black-on-white has been previously defined anywhere from a type reflecting a very distinct technology derived from Mesa Verde Black-on-white from the San Juan region (Stubbs and Stallings 1953) to an areal variation of Santa Fe produced in areas where low-iron geological clays were available (Wilson 1999).

Definitions of Galisteo Black-on-white as employed in some studies imply strong technological and stylistic similarities and relationships between Galisteo Black-on-white and Mesa Verde Black-on-white from the San Juan region (Habicht-Mauche 1993; Stubbs and Stallings 1953). Similarities include the use of sherd and volcanic rock temper, thick crazed slips, square rims, and similar designs (Abel 1955; Stubbs and Stallings 1953). Galisteo Black-on-white appears to have been the dominant decorated type in some areas south of Santa Fe after AD 1300 and is postulated to have reached its widest distribution in the late 14^{th} century (Habicht-Mauche 1993). The most commonly noted form of Galisteo Black-on-white is characterized by white pastes that contrast markedly with the darker and finer Santa Fe pastes. Temper is generally described as a crushed sherd that appears as coarse gray to black angular fragments, although a wide variety of lithic and mineral inclusions may be present (Habicht-Mauche 1993). Surfaces are covered by a well-polished slip that sometimes displays fine crackling. Organic-painted designs can appear on both interior and exterior surfaces.

Designs are usually organized in paneled bands of oblique and horizontal solids, oriented from multiple or single framing lines. Design elements are usually solid, as hatched elements are uncommon. In some assemblages squared rims are present. Rims are sometimes ticked and may be rounded or tapered. Design styles on Galisteo Black-on-white are sometimes characterized as having derived from McElmo and Mesa Verde Black-on-white types (Mera 1935; Lang 1982), although there are definite differences in the range of styles and treatments occurring in these regional types. Sherds exhibiting pastes similar to those described for Galisteo black-on-white but lacking painted decorations were classified as ‘unpainted Galisteo paste.’

Wiyo Black-on-white appears to have developed directly out of Santa Fe Black-on-white (Figures 58.24 through 58.27). (Note: Reconstructible vessel analyses are presented in Appendix P.) Wiyo Black-on-white was originally referred to as "biscuitoid" to indicate pottery with pastes and treatments thought to be transitional between Santa Fe Black-on-white and the biscuitware types (Kidder and Amsden 1931; Mera 1935; Stubbs and Stallings 1953). Wiyo Black-on-white exhibits organic-painted designs similar to Santa Fe Black-on white, but often has softer pastes that are tan, buff, orange, or greenish (Hibben 1937; Stubbs and Stallings 1953). Wiyo Black-on-white is consistently tempered with finely crushed volcanic rock. Forms are usually represented by bowls, although jars, dippers, and other forms have been noted. Interior bowl surfaces are usually well-polished and are evenly smoothed with thin slips that are often tan or brown. Bowl exteriors tend to be unslipped and unpolished and may exhibit a series of small striations. Vessel walls of Wiyo Black-on-white tend to be slightly thicker and more porous than those noted in Santa Fe Black-on-white.

Figure 58.24. Wiyo Black-on-white bowl sherds from LA 12587.

Figure 58.25. Wiyo Black-on-white bowl sherd from LA 4618 (FS 417-4).

Figure 58.26. Wiyo Black-on-white bowl rim sherd from LA 86534 (FS 1206-1).

Figure 58.27. Wiyo Black-on-white vessel from LA 169 (Otowi).

Pigments in Wiyo Black-on-white tend to be darker and denser than those noted in earlier pottery types. Design styles are similar to those described for Santa Fe Black-on-white, although they are sometimes described as heavier (Stubbs and Stallings 1953). Solid designs tend to be more common and lines are thicker. Panel designs are also common on Wiyo Black-on-white.

The temporal range of Wiyo Black-on-white overlaps that for Santa Fe Black-on-white, and the two types occur together in some assemblages in the northern Rio Grande region. Wiyo Black-on-white may date from AD 1250 to 1400, but tends to be most common in assemblages dating between AD 1300 and 1350 (Breternitz 1966; Smiley et al. 1953; Sundt 1987) and is most common at about AD 1300 (Habicht-Mauche 1993). The relative frequency of Wiyo Black-on-white in Coalition period assemblages decreases with distance from the Tewa Basin and Pajarito Plateau, and it is rare at sites south of Santa Fe.

Biscuitware forms are the dominant decorated pottery at Classic period sites in the Tewa Basin, Chama Valley, and Pajarito Plateau (Mera 1934). Biscuitware types refer to the distinctive whiteware pottery produced in areas of the northern Rio Grande during the Classic period. Pastes of biscuitware types reflect the use of bentonite clays and vitric tuff temper (Kidder and Amsden 1931). Vessels have a soft gray to yellow paste, with finely crushed tuff or pumice. Biscuitware forms are distinguished from other organic-painted Rio Grande whiteware types by their porous textures. Surfaces are often white, light gray, tan, or buff. Vessel walls tend to be very thick, particularly when compared to earlier Rio Grande whiteware types. Vessels also tend to be extremely lightweight compared to their overall size because of the porous paste texture. Bowl rims often exhibit a distinct flare or eversion, and thickness may vary considerably from the rim.

Biscuitware types are decorated with sharp, clear, and black organic paint. Plain bowl rims are generally ticked, and standing rims are often embellished with repeating dashes or zigzag lines on the interior below the lip (Gauthier 1987a). Painted designs are often organized in banded patterns with panels of repeating hatched or solid geometrical elements. These include ticked edges, parallel or rectilinear lines, and stylized Awanyu motifs.

Descriptions of some of the biscuitware forms discussed here have been presented in terms of both descriptive names, which include the term biscuitware, and sometimes a type name as well. For example, early forms of biscuitwares that could be assigned to a specific type can be described as either Biscuit A or Abiquiu Black-on-gray. While previous descriptions often employ the term Abiquiu Black-on-gray or Bandelier Black-on-gray (McKenna and Miles 1991), I chose to describe this pottery as Black-on-white. This decision stems from the observation that many of the surface colors noted in the biscuitware types also occur in earlier Rio Grande whiteware types. Since biscuitware forms are definitely part of the continuum associated with the Rio Grande whiteware pottery tradition, the implication that they might be more closely related to grayware could be misleading. Thus, I have chosen to use the terms Abiquiu Black-on-white or Bandelier Black-on-white in the present report as well as other reports where I have described similar forms. It should be noted that the pottery described here in these terms is identical to that described in other studies as Black-on-gray types.

Biscuit A (Abiquiu Black-on-white) is distinguished only for bowl forms and is defined by the presence of slipped or painted manipulations on interior surfaces only (Figures 58.28 through 58.30). Biscuit B (Bandelier Black-on-white) is distinguished from Biscuit A by the presence of slipped surfaces usually with painted decorations on both the exterior and interiors of bowls (Figures 58.31 through 58.37). An additional distinction made for rim sherds otherwise exhibiting characteristics described for Biscuit B was Biscuit C (Cuyamunge Black-on-tan). This type was defined to differentiate later high rimmed tan colored biscuitware bowls (Harlow 1973).

Figure 58.28. Biscuit A bowl sherd from LA 86534 (FS 1748-1).

Figure 58.29. Biscuit A bowl sherd from LA 86637 (FS 176-1).

Figure 58.30. Biscuit A bowl rim sherd from LA 12587 (FS 4034-1).

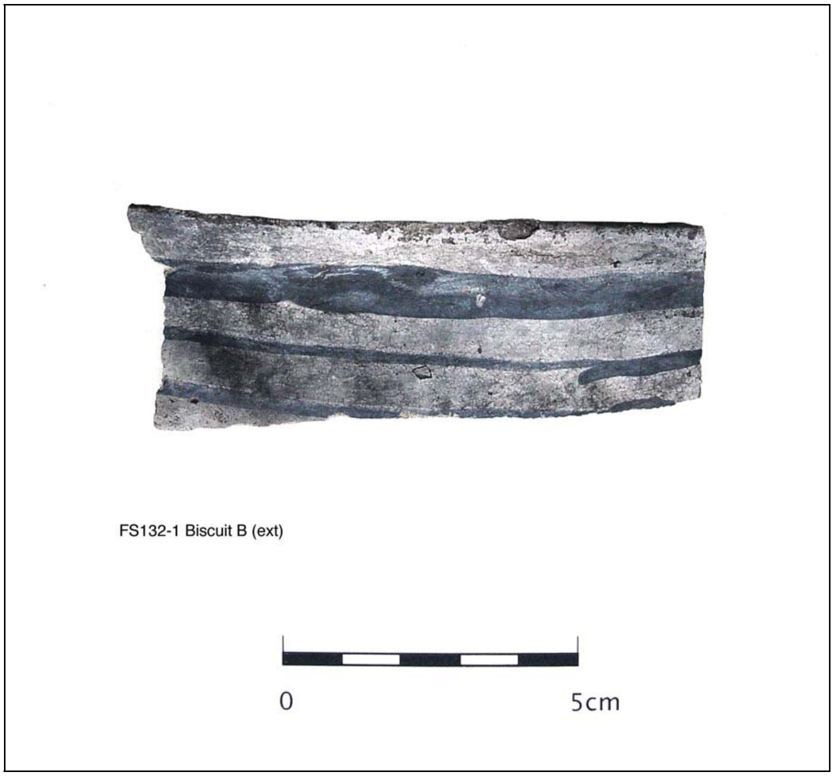

Figure 58.31. Biscuit B sherd from LA 87430 (FS 132-1).

Figure 58.32. Biscuit B sherd from LA 21596C (FS 4-14).

Figure 58.33. Biscuit B sherd from LA 86637 (FS 153-1).

Figure 58.34. Biscuit B sherd from LA 128804 (FS 41-1).

Figure 58.35. Biscuit B interior sherd from LA 87430 (FS 132-1).

Figure 58.36. Biscuit B bowl (Vessel 3) from LA 170 (Tsirege).

Figure 58.37. Biscuit B bowl (Vessel 4) from LA 170 (Tsirege).

In some cases, it was not possible to assign a specific type to pottery exhibiting characteristics clearly indicative of biscuitware types. Unpainted sherds exhibiting pastes, shapes, and thickness characteristic of biscuitware types were assigned to several categories based on evidence of slipping including ‘biscuitware unpainted slipped both sides,’ ‘unpainted biscuitware slipped one side,’ and ‘biscuitware slip, and paint absent.’ All painted jars as well as some bowls where it was not possible to determine the nature of decoration on different sides were assigned to a ‘biscuitware unspecified painted’ category (Figures 58.38 and 58.39).

Figure 58.38. Biscuitware jar sherd from LA 86637 (FS 82-1).

Figure 58.39. Biscuitware jar sherd from LA 128804 (FS 93-3).

While biscuitware forms are found over an area that includes the Tewa Basin, Pajarito Plateau, and Chama Valley (Mera 1934), this area is much smaller than that over which Santa Fe Black-on-white is the dominant decorated type. The temporal range for Biscuit A is estimated from about AD 1375 to 1450, while that for Biscuit B lasted from about AD 1400 to 1550 (Breternitz 1966; Gauthier 1987a; Wendorf 1953).

Sankawi Black-on-cream is very similar to biscuitware types, but exhibits pastes and surface characteristics that may be transitional to later historic forms including Tewa Polychrome types (Figures 58.40 through 58.43). Pastes are often pink to orange and indicate a higher degree of oxidation than biscuitware types. Surfaces tend to be more consistently light cream or tan in color and are often crackled or streaky. Vessel walls tend to be thinner, denser, and harder than biscuitware types. Another change is reflected in Sankawi Black-on-cream jar forms with longer necks. Designs are executed in bands similar to those noted in biscuitware types although execution is simpler and uses less line work. Design motifs include thin parallel and zig-zag lines with pendant dots, solid or hatchured triangles, narrow checkerboards, and awanyus.

Figure 58.40. Sankawi Black-on-cream sherd from LA 128805 (FS 83-1).

Jemez (Vallecitos variety) Black-on-white represents a regional variant of organic-painted whiteware types produced along the Jemez drainage. This type is characterized by a dark paste with fine ash and thick, flat, pearly white slip (Reither 1938). The use of similar clay and manipulations by potters along the Jemez drainage spans the Coalition to Historic periods (about

AD 1300 to 1750). Designs on earlier forms resemble those noted on Santa Fe Black-on-white. Those on later forms appear to have been derived from late glaze vessels and exhibit ticked lips, wide lines, and solid dots. Both jars and bowls were slipped and painted on both sides.

Figure 58.41. Sankawi Black-on-cream vessel from LA 170 (Tsirege).

Figure 58.42. Sankawi Black-on-cream vessel from LA 170 (Tsirege).

Figure 58.43. Sankawi Black-on-cream vessel from LA 170 (Tsirege).

Gallina Black-on-white was assigned to sherds exhibiting design styles, manipulations, and pastes characteristic of pottery produced in the Gallina region and, as defined here, is identical to Gallina Black-on-gray as defined by others (Hibben 1949; Mera 1935; Seaman 1976). Gallina Black-on-white appears to have been produced in the Gallina region between AD 1000 and 1300. Gallina Black-on-white is usually smoothed, may be unpolished or slightly polished, and is never slipped. The surface of Gallina Black-on-white vessels is often bumpy and sometimes striated. Decorations are executed in organic paint and are often faded and gray in color. Designs are usually simple and poorly executed, particularly when compared to Pueblo III types found in other regions. Motifs may be oriented in simple banded or all-over patterns. The simplicity of the execution and patterns is often reminiscent of earlier types in this area such as Rosa Black-on-white. The most common design motifs include parallel and intersecting lines, although triangle, hourglass, checkered, and hatchured patterns may be present. Rims are usually rounded or tapered and undecorated. Pastes are white to gray in color and may contain a distinct core.

Glazeware Types

Glazeware types reflect a distinct pottery class known to have been produced in areas of the middle and southern Rio Grande region. Glazeware types refer to pottery exhibiting painted decorations either with glaze or to unpainted sherds assumed to have been derived from vessels decorated with glaze paint. Glazeware types are defined by the use of lead glaze paint or paste reflecting pottery produced in the middle Rio Grande from about AD 1325 to the early 1700s (Franklin 1997; Kidder and Shepard 1936; Mera 1933; Snow 1982, 1997).

The basic system of classification of glaze rim sherds presented by Mera (1933) is still utilized. This classification system, however, is only applicable to rim sherds. Thus, body sherds that could not be assigned to a specific type were assigned to types based on surface treatments using similar conventions as used in other recent studies in the Middle Rio Grande (Franklin 1997). Unpainted body sherds exhibiting combinations of temper, paste, and surface characteristics indicate probable derivation from glazed painted vessels and were assigned to descriptive type categories based on the presence or type of slip and painted decorations. Categories employed during the present study include 'glaze red body unpainted' and 'glaze yellow body unpainted.' Painted body sherds were also assigned to a series of descriptive glazeware types based on slip and paint characteristics and include 'glaze unslipped body,' 'glaze red body' (Figures 58.44 and 58.45), 'glaze yellow body,' glaze polychrome body,' and 'glaze unslipped body.'

Figure 58.44. Glaze-on-red sherd from LA 128804 (FS 135-3).

Figure 58.45. Glaze-on-red sherd from LA 128804 (FS 88-1).

Bowl rim forms with straight even walls were assigned to Glaze A types (Mera 1933). Pottery exhibiting characteristics of these types appears to be similar to early glazeware pottery recovered over a wide area (Franklin 1997; Habicht-Mauche 1993; Kidder and Shepard 1936). A single Glaze A rim bowl with a well-polished red slip was assigned to Agua Fria Red-on-glaze. Painted decoration associated with Agua Fria Glaze-on-red is usually black paint with limited evidence of vitrification to a distinct glaze. Applications of the paint pigment tend to be well-executed as compared to later glaze forms and often resemble earlier matte pigment. In addition, designs are usually even and well-executed as compared to later glaze forms. Another sherd with similar characteristics as those described for Agua Fria Glaze-on-red with the addition of white clay paint was assigned to Los Padillas Glaze Polychrome.

Cieneguilla Glaze-on-yellow is similar to Agua Fria Glaze-on-red in form and style, but exhibits a light-slipped background. Cieneguilla Glaze-Polychrome is also the first Rio Grande glazeware to incorporate red matte paint into the design field.

Largo Glaze-on-yellow is differentiated from Cieneguilla Glaze-on-yellow by thickened rim forms that developed out of the straight Glaze A rim forms. Largo glaze forms are estimated to have been produced from AD 1400 to 1450 and appear to represent a short-lived form transitional between Glaze A Yellow and Glaze C (Espinosa Glaze Polychrome). Rim forms vary slightly with some rims showing a prominent change in thickness while others have a more gradual thickening.

Puaray Polychrome is characterized by light or red-slipped backgrounds with dark glaze designs, sometimes with red matte interiors. Rim forms are also highly variable. Puaray glaze types are distinguishable by an elongated rim form with some thickening above the base and a shift back to lighter slips. The rim is clearly differentiated from the bowl walls by a curve in the angle of the rim (Mera 1933).

Cibola Types

Pottery exhibiting combinations of white paste and sand or sherd temper indicative of that produced over a wide area to the west were assigned to types of the Cibola tradition (Windes 1977). Grayware assigned to this tradition includes sherds assigned to 'smeared-plain corrugated' and 'polished gray.'

Unpainted sherds exhibiting Cibola Pastes were assigned to 'unpainted white undifferentiated.' Those with similar pastes with indistinct decorations in mineral paint were assigned to 'mineral paint undifferentiated.' Sherds with pastes and manipulation typical of Pueblo II Cibola whiteware with hatchured designs decorated in mineral paint were assigned to Gallup Black-on-white. Those with manipulations, pastes, and solid or hatchured designs typical of Pueblo III forms produced in the southern Cibola region were assigned to Tularosa Black-on-white (Figure 58.46).

Figure 58.46. Tularosa Black-on-white sherds from LA 12587 (FS 3140-1 and 3736-2).

White Mountain Redware

White Mountain redware refers to a specialized pottery that was produced within a fairly limited area in west-central New Mexico and east-central Arizona, but was also widely traded throughout much of the southwest (Carlson 1970). Pottery assigned to this tradition is characterized by white, gray to orange paste, sherd temper, and a dark red slip. Surfaces are well-polished and painted decorations are usually executed in a black mineral or organic paint. A polychrome effect was sometimes achieved through the additional use of white clay paint.

'White Mountain redware unpainted' refers to White Mountain redware pottery not displaying painted decorations, while 'White Mountain red painted undifferentiated' refers to those with indistinct painted decorations. Wingate Black-on-red contains dark red to bright red slips (Figure 58.47). Designs consist primarily of hatchured elements sometimes with opposed solid elements. Painted sherds with a lighter orange paste characteristic of pottery produced during the 13th century were classified as St Johns Black-on-red. Pottery exhibiting similar characteristics but with decorations in white clay paint were classified as St Johns Polychrome.

Figure 58.47. Wingate Black-on-red sherd from LA 128805 (FS 57-1).

San Juan Whiteware

San Juan Whiteware refers to the very small number of sherds exhibiting light pastes and andesite/diorite temper indicating origin within the San Juan or Mesa Verde region of the Four Corners area (Breternitz et al. 1973; Wilson and Blinman 1995a). The number of sherds placed into San Juan types during the present was surprisingly low given modeled widespread migrations from the San Juan region to the Pajarito Plateau. Whiteware types not exhibiting designs of a specific type were assigned to 'unpainted whiteware undifferentiated' or 'indeterminate organic San Juan white.'

Mesa Verde Black-on-white was the last whiteware type produced in the Mesa Verde region and dates from about AD 1180 to 1300 (Wilson and Blinman 1995a). Mesa Verde Black-on-white vessels are usually well-polished, and slipped vessels are common, usually with a pearly white surface. Vessel walls, especially bowls, are thick and bowl rims are flat and are usually decorated with ticks, dots, or lines. Designs are usually complex and well-executed and include banded and all-over forms. Banded designs are commonly bracketed by framing lines both above and below. Single framing lines are usually thick and, if more than one framing line is present, are usually of different thicknesses. Design elements include straight hatchured, triangles, stepped triangles, dots, diamonds, and ticked lines, but elements are often smaller and combinations are more complex. Exterior designs on bowls are common both as isolated elements and as bands, usually without framing lines.

Jornada Mogollon Whiteware

A very small number of whiteware sherds identified during the present study represent Chupadero Black-on-white (Figure 58.48) produced in the Northern Mogollon region (Farwell et al. 1992; Hayes et al. 1981; Kelley 1984; Mera 1931; G. Vivian 1964). Chupadero Black-on-white was first manufactured circa AD 1050 to 1100 and continued to have been produced until about 1550. Chupadero Black-on-white found over a wide area exhibits similar characteristics. Chupadero Black-on-white sherds usually have dense light gray to white pastes reflecting the use of low iron clay firing to buff colors and a low-oxidizing or neutral atmosphere. The undecorated surfaces of Chupadero Black-on-white are often unpolished with striated or scored treatments resulting from scraping. Most Chupadero sherds are tempered with dark igneous rock and sherd, although a wide variety of tempers are represented and may indicate Chupadero vessels were derived from a number of sources.

Painted designs on Chupadero Black-on-white vessels often consist of combinations of hatchured and solid motifs. Designs were executed in a series of panels where the basic design was repeated every one or two sections. At least four, and as many as eight panels, may be represented. During the present study, sherds thought to have derived from Chupadero Black-on-white were assigned to a series of categories based on the presence or style of painted decoration (Figure 58.48). Categories of this type recognized during the present study include 'unpainted Chupadero Black-on-white,' 'Chupadero Black-on-white, solid design,' and 'Chupadero Black-on-white indeterminate design.'

Figure 58.48. Chupadero Black-on-white sherd from LA 86534 (FS 1686-1).

Socorro Black-on-white refers to whiteware forms produced in an area that appears to have been roughly bounded by the roads that today connect Socorro, Albuquerque, Grants, and Quemado, New Mexico. Socorro Black-on-white is distinguished from other whiteware types by distinctive paste, surface characteristics, and painted designs (Mera 1935; Sundt 1979). Surfaces are unslipped and gray in color. Pastes are gray, hard, and often vitrified. Paint is usually black and is often dense and vitrified. The result of these high-fired mineral pigments often contains a sub-glaze appearance. Temper usually consists of a dark igneous rock that may occur along with crushed sherd. The petrographic analysis indicates these dark fragments reflect basalt and rhyolitic tuff. Designs include fine lines, hatchured, dots, lines appended with dots, checkered squares with and without dots, and triangles. Hatched lines are closely spaced. Motifs tend toward opposed solid and hatched combinations. Design layout consists of paneled bands for bowls and wide bands or all-over patterns on jars.

Mogollon Brownware

A very small number of sherds examined displayed pastes, temper, and surface characteristics indicative of utility brownware types produced in the Mogollon Highlands to the west and southwest of the plateau (Wilson 1999). Temper consists of volcanic-clastic rock sometimes with sand and reflects the use of self tempered clays weathered from surrounding volcanic rocks.

Pastes tend to be dark gray, brown, or yellow-red. Brownware sherds were assigned to types based on combinations of smudged interiors and exterior textures. Those with plain exteriors and smudged interiors were classified as 'Reserve smudged.' Those exhibiting exterior corrugations were classified as either 'Reserve indented corrugated' or 'Reserve plain corrugated smudged.'

Historic Pottery Types

A very small number of sherds examined during the present study represent types thought to have been manufactured by Tewa Pueblo potters. This pottery is associated with Hispanic or Anglo homesteads dating from the late 19th to early 20th century and probably reflects trade with nearby Pueblos such as San Ildefonso and Santa Clara. Identified historic Tewa types include 'Tewa Polychrome,' 'San Juan Red-on-tan,' 'Tewa buff undifferentiated,' 'Tewa polished gray,' 'buffware with mica slip,' and 'unpolished mica slip.'

TEMPORAL TRENDS

The first step in the documentation of various trends reflected by ceramic distributions involves the assignment of temporal dates to pottery assemblages from various contexts and sites, based on observations about the distribution of ceramic types and attributes. Many of the assigned dating periods used are based on observations from context in the northern Rio Grande region that have been dated by tree-ring samples or techniques (Creamer 2000; Franklin 1997; Habicht-Mauche 1993; Harlow 1973; Honea 1968; Hubbell and Traylor 1982; Lang 1982, 1993, 1997; McKenna and Miles 1991; Mera 1935; Powell 2002; Smiley et al. 1953; Sundt 1987; Vint 1999; Warren 1976). Information regarding the dating of various contexts has often been organized in terms of periods or phases that are recognized based on the presence, combination, and frequency of different ceramic types.

The Pecos Classification system represented the first systematic attempt to define and document temporal periods across the Southwest (Kidder 1927). Subsequent investigations resulted in the utilization of a classification and phase system distinct to the northern Rio Grande region (Wendorf 1954; Wendorf and Reed 1955). These periods were defined by changes in pottery technology and architecture and include Developmental (AD 600 to 1200), Coalition (AD 1200 to 1325), Classic (AD 1325 to 1600), and Historic (AD 1600 to present) (Wendorf 1954; Wendorf and Reed 1955).

Occupations on the Pajarito Plateau are usually described as beginning during the Early Coalition period and placed circa AD 1150 to 1200 (Kohler 2004; Orcutt 1999), although there is some evidence for an extremely small occupation in this area dating to the Late Developmental period. The Late Developmental period was originally defined as dating from AD 900 to 1200 (Wendorf 1954; Wendorf and Reed 1955) and reflects a time span and material culture roughly equivalent to that noted for the Pueblo II to early Pueblo III period occupations on the Colorado Plateau (Cordell 1978). While Late Developmental sites are not well-documented on the Pajarito Plateau, they are more common and better described for areas in the Tewa Basin to the east, where they may date from about AD 900 to 1200 (McNutt 1969; Mera 1935; Wendorf 1954; Wiseman 1989). Pan-regional stylistic trends have been used to assign Late Developmental components into two distinct phases (McNutt 1969; Wendorf 1954). Assemblages dating to the Red Mesa phase are identified by the presence of Red Mesa Black-on-white as the dominant whiteware type, and grayware assemblages dominated by plain gray and neck banded sherds, and occasionally contain extremely low frequencies of corrugated pottery. Assemblages dating to the later Kwahe'e phase are identified by the presence of local (Kwahe'e Black-on-white) and intrusive black-on-white pottery mostly assigned to Gallup Black-on-white and Escavada Black-on-white. These whiteware types are easily distinguished from those associated with the later Coalition period by decorations in mineral rather than organic pigments (Lang 1982; McKenna and Miles 1995; McNutt 1969). Grayware pottery from Kwahe'e phase assemblages also display a wide range of treatments including neckbanded and corrugated textures, although plain forms often dominate these assemblages.

Almost all the prehistoric ceramic-period occupations on the Pajarito Plateau date to the Coalition or Classic periods (Orcutt 1999). The assignment of dates to assemblages based on ceramic distributions from Coalition and Classic period components is based on pottery distributions from a series of tree-ring-dated contexts from sites in a number of areas, including those east of the Pajarito Plateau such as Pindi Pueblo (Stubbs and Stallings 1953), Arroyo Hondo Pueblo (Habicht-Mauche 1993; Lang 1993), and Pecos Pueblo (Kidder and Amsden 1931; Kidder and Shepard 1936; Powell and Benedict 2002). Assemblages from these and other sites have been used to document changes in the frequency of various pottery types, but are often based on the dominant decorated types noted.

Several studies also provide information relating to various trends from Coalition period sites on the Pajarito Plateau based on comparisons of pottery from sites at or near the Los Alamos area (Curewitz and Harmon 2002; Gray 1990, 1992; Gray and Albaugh 1992; Hendron 1940; Hubbell and Traylor 1982; Kohler 1989, 2004; Larson n.d; Snow 1974; Worman 1967; Worman and Steen 1978). Ceramic seriation studies conducted by Orcutt (1999) as part of the Bandelier Archaeological Survey reviewed data relating to pottery from tree-ring-dated contexts in an area defined by Santa Clara Canyon on the north, Cochiti Pueblo on the south, the Rio Grande on the east, and the Jemez Mountains on the west. The prehistoric occupation was divided into 13 periods, including six defined for the Coalition period and seven for the Classic period (Orcutt 1999). It is, however, difficult to determine how each period was defined from the report, although it is possible to deduce certain changes from this and other studies of sites in the area (Kohler 2004).

The initial occupation of the Pajarito Plateau noted by Orcutt (1999) dates to the earliest part of the Coalition period and is represented by ceramic assemblages in which Santa Fe Black-on-white is the dominant whiteware type, but also contains significant amounts of Kwahe'e Black-on-white, which can make up almost half of the decorated pottery (Hubbell and Traylor 1982; Kohler 2004; Snow 1974; Worman 1967). Grayware types are dominated by indented corrugated sherds. Combinations of these types reflect assemblages dating to the second half of the 12th century (Kohler 2004; Orcutt 1999).

By the early 13th century Kwahe'e Black-on-white may be present but is very rare, and whiteware forms are overwhelmingly dominated by Santa Fe Black-on-white (Bussey 1968a, 1968b; Curewitz and Harmon 2002; Gray 1992; Hubbell and Traylor 1982; Kohler 2004). Decorated types from most sites dating to the 13th century are overwhelmingly represented by sherds derived from Santa Fe Black-on-white vessels, and other decorated types are limited to extremely low frequencies of intrusive pottery, including White Mountain redwares, Cibola whitewares, San Juan whitewares, Chupadero Black-on-white, and Socorro Black-on-white. During the 13th century, grayware assemblages became increasingly dominated by smeared corrugated types.

In the early 14th century, Santa Fe black-on-white is still the dominant decorated type but the overall frequency of this type gradually declines as other types become more common. By AD 1325, Wiyo Black-on-white becomes much more common in the northern Pajarito Plateau, representing a major type occurring along with Santa Fe Black-on-white. The presence of significant frequencies of Wiyo without Biscuit A is a good indicator of occupations dating to the very late part of the Coalition period during the middle of the 14th century. The appearance and increase in Wiyo Black-on-white in the Pajarito Plateau is part of regional trend in the appearance of regionally distinct whiteware types (Habicht-Mauche 1993). At about the same time, Rio Grande glazeware types appear to have been first produced in areas to the south in the middle Rio Grande region (Vint 1999). Changes occurring in the northern Pajarito Plateau and Chama Valley during the Late Coalition are primarily reflected by a gradual increase in Wiyo Black-on-white sherds. Wiyo Black-on-white appears to have developed directly out of, and was closely related to, Santa Fe Black-on-white. This is reflected by the large proportion of Santa Fe Black-on-white sherds with characteristics such as high polish and wide lines, which seem to be transitional between this type and Wiyo Black-on-white (Kohler 2004). Components dating to the entire span of the Coalition period in the Pajarito Plateau are dominated by similar grayware types, which appear to consist of about 80 percent of the total pottery tempered with anthill sand. The only change so far noted in the grayware appears to be an increase in the overall frequency of smeared corrugated as compared to other grayware forms and a decrease in plain and more indented forms (Curewitz and Harmon 2002; Gray 1990, 1992; Stubbs and Stallings 1953).

Biscuit A appears to have replaced Wiyo Black-on-white around AD 1375 at about the same time that Wiyo Black-on-white was no longer produced and the frequency of Santa Fe Black-on-white dramatically diminished. Sites dating to the Early Classic period are identified by the appearance of Biscuit A (Abiquiu Black-on-white) and early glazeware types that were common by the middle of the 14th century (Creamer 2000; Lang 1997). Decorated ceramics at some sites in the southern portions of the Pajarito Plateau are dominated by early glazeware types (Kohler 2004; Vint 1999). During the late 14th century, smeared corrugated appears to have been replaced by plain gray as the dominant utilityware form.

The end date for Biscuit A is some time around AD 1450 and 1500. Biscuit B (Bandelier Black-on-white) may have first been produced at about AD 1400 and lasted until AD 1550 (Lang 1997). This type appears to have been most abundant at sites dating between AD 1500 and 1550. During the last part of the Classic period, a gradual change in firing technology and vessel shape resulted in the appearance of Cuyamunge Black-on-tan (Biscuit C) and Sankawi Black-on cream. Non-local whiteware types are almost completely absent at Classic period sites in the northern Pajarito Plateau, and nonlocal pottery is limited to glazeware types that appear to dominate and may have even been produced in areas of the southern Pajarito Plateau. During the Late Classic period, there was a shift from the total dominance of utilityware forms tempered solely with anthill sand to the additional presence of those containing micaceous granite of schist temper (Vint 1999). This also corresponds with the occurrence of mica-slipped types with smeared-indented corrugated exteriors that include Sapawe Utility and micaceous types with smoothed exteriors. Potsuwi'i Incised also appears during the later part of the Classic period.

Changes noted in glazeware pottery produced at sites in the southern Pajarito Plateau and elsewhere may also provide clues concerning the dating of Classic period sites (Warren 1976). The Glaze-on-red period (AD 1315 to 1425, Group A) was defined by the predominance of glaze-on-red and Glaze A forms. Next in this sequence is the Glaze-on-yellow period (AD 1325 to 1450). Before the end of the 14th century, glaze painted vessels with white, cream, yellow, or pink slips and Glaze B rims are common. The Intermediate Glaze period (AD 1450 to 1600) is characterized by the presence of Glaze C, D, and early E forms and a mixture of slips. The Kotyiti period (AD 1600 to 1750) is characterized by the dominance of Glaze E and F forms.

Another approach that may provide for finer temporal resolution is stylistic analysis. Attempts to subdivide the very long-lived type Santa Fe Black-on-white have so far not been very successful in defining shorter periods within the Coalition period (Ruscavage-Barz 2002), although stylistic analyses from two sites excavated during the Bandelier Archaeological Project indicate a shift from hatchured to solid designs and an increase in the degree of polishing (Gray and Albaugh 1992).

Ceramic Trends for the C&T Project Sites

All sites examined during the present study were assigned to ceramic dating periods based on the combinations and frequencies of pottery types (Table 58.2). Most of the discussions presented here focus on data from sites that were assigned to a dated period, particularly those assigned to the Coalition period, which dominated this analysis. These examinations focus first on using ceramic data to assign sites and components to a particular occupational period or temporal span. Following these evaluations, ceramic data from these dated contexts are used to examine trends relating to the origin, exchange, and uses of this pottery.

Sites of Unknown Age

Assemblages from 10 sites could not be assigned to a particular temporal component based on ceramic distributions (Tables 58.3 and 58.4). Sites not assigned to a particular period based on ceramics include LA 21550, LA 61034, LA 85403, LA 85859, LA 86531, LA 99397, LA 110130, LA 110133, LA 117883, and LA 127633. Because of the small sample size and lack of diagnostic pottery, other trends will not be discussed for these sites.

Late Developmental Period Sites

LA 82601 may contribute extremely important information relating to the timing and nature of what appears to be the earliest ceramic-period settlements on the Pajarito Plateau. This site was excavated in the 1990s by the Ojo Line Extension Project. While this site was not excavated as part of the C&T Project, it is located in TA-70 near White Rock and was analyzed because of the early and distinct nature of the associated pottery (Tables 58.5 and 58.6).

Table 58.5. Distribution of ceramic types from LA 82601, a Late Developmental period site on the plateau.

Ceramic Type	Frequency	Percent
Northern Rio Grande Whiteware		
Unpainted undifferentiated	30	8.3
Mineral paint undifferentiated	1	0.3

Table 58.6. Distribution of ware groups from LA 82601, a Late Developmental period site.

Ware	Count	Percent
Gray	300	83.3
White	60	16.7
Total	360	100.0

The overall proportion of whiteware pottery was high (16.7%) when compared to Late Developmental period sites in the Tewa Basin where types assigned to whiteware types only comprised about 5 percent of the total pottery (Wilson 2006). The majority of the painted pottery from this site exhibits local pastes and decorations in mineral paint and therefore were assigned to Kwahe'e Black-on-white. Other sherds decorated with mineral paint were assigned to Cibola whiteware types based on the presence of sand temper and light pastes. Styles associated with both local and nonlocal whiteware types are similar to those noted in pottery throughout the Southwest dating to the 11th and early 12th centuries. A very small number of sherds were assigned to Santa Fe Black-on-white based on decorations in organic paint, but were otherwise similar to pottery assigned to Kwahe'e Black-on-white. Grayware types consist of a roughly even mixture of plain and corrugated forms. The proportion of corrugated pottery is higher than that noted at Late Developmental period sites in the Tewa Basin (Wilson 2006).

While the combination of pottery types at LA 82601 is similar to that noted at Late Developmental period sites in the Tewa Basin, several observations indicate that this site probably dates to the very end of this period, with a date in the middle of the 12th century being most likely. This site may reflect the initial movement of ceramic-producing groups onto the Pajarito Plateau from areas to the east such as the Tewa Basin some time during the end of the Late Developmental period, and may date just before the occupation of sites previously assigned to the very early span of the Coalition period.

Coalition Period Sites

Assemblages from at least 19 of the sites examined during the present study display some combination of ceramic types indicative of occupations during the Coalition period. These include eight sites from the Rendija Tract, three from the White Rock Tract, four from the Airport Tract, two from the TA-74 Tract, and two from Mesita del Buey. Most of the pottery examined during the present study was recovered from four Coalition period roomblocks and one dating to the Late Coalition/Early Classic period transition. The large ceramic samples from these sites allow for the assignment of fairly specific dating spans to these sites. Distributions noted at these sites will form the basis for discussions of ceramic trends associated with the Coalition period.

Less-specific information is provided in the form of smaller assemblages from four sites, which resulted in their assignment to an Indeterminate Coalition period based on the presence of Santa Fe Black-on-white and smeared corrugated and the absence of later types (Tables 58.7 and 58.8). The small size of these assemblages does not allow for the determination of the specific span of occupation during the Coalition period. Sites assigned to the Indeterminate Coalition period based on ceramic distributions include LA 61035 (n = 11), LA 85864 (n = 2), LA 86607 (n = 9), and LA 99396 (*n* = 85). The small size of these assemblages also makes the determination of other trends difficult to impossible.

Table 58.7. Distribution (count/percent) of ceramics from indeterminate Coalition period sites.

Ceramic Type	61035	85864	86533	86607	99396	Total

Table 58.8. Distribution of ware groups (count/percent) at indeterminate Coalition period sites.

Ware	LA 61035	LA 85864	LA 86533	LA 86607	LA 99396	Total
Gray	7 (63.6)	1 (50.0)	5 (35.7)	3 (33.3)	64 (75.3)	80 (66.1)
White	4 (36.4)	1 (50.0)	9 (64.3)	6 (66.7)	21 (24.7)	41 (33.9)
Total	**11 (100)**	**2 (100)**	**14 (100)**	**9 (100)**	**85 (100)**	**121 (100)**

In addition, the occurrence of Santa Fe Black-on-white and associated grayware types from assemblages at eight sites indicate the presence of Coalition period components as well as ceramics indicating later components dating to the Classic period (Tables 58.9 and 58.10). Sites with assemblages indicating components dating to the Coalition and Classic period include LA 21596B (*n* = 257), LA 21596C (*n* = 382), LA 85404 (*n* = 199), LA 85861 (*n* = 439), LA 86606 (*n* = 143), LA 127631 (*n* = 12), LA 127635 (*n* = 371), and LA 141505 (*n* = 29). In addition, ceramic distributions from another site (LA 85417) indicate pottery derived from both Coalition and Historic period components (Tables 58.11 and 58.12).

Ceramic distributions associated with large assemblages recovered from four roomblock may be used to assign dates to specific spans within the Coalition period, and one within a Coalition/Classic transition period. No sites examined during the present study appear to date to the earliest phase of the Coalition period as defined during the Bandelier Project (Orcutt 1999). A good example of a site representing this phase is located near the sites discussed here, and the phase designation is reflected by distributions from assemblages excavated from Casa del Rito in Bandelier National Monument. Examinations of ceramics from this site indicate that Santa Fe Black-on-white only slightly outnumbers Kwahe'e Black-on-white (Kohler 2004). LA 3852 (Casa del Rito) reflects an occupation dating to the Early Coalition period and probably dates some time between the middle 12th and very early 13th century. The majority of the utilityware is represented by indented corrugated and plain corrugated types. Smeared corrugated is present in very low frequencies and may indicate that this site was abandoned just as smeared corrugated was starting to be produced (Gray 1992).

The next span of occupation is indicated by distributions of pottery types from two sites including LA 86534 (*n* = 3925) and 135290 (*n* = 4921), which are both located in the Airport Tract (Tables 58.13 and 58.14). Examinations of distributions from the large assemblages at these sites provided a good opportunity to examine trends associated with sites dating to the early 12th century or early part of the Middle Coalition period (see Tables 58.13 and 58.14). The majority of pottery from both sites was assigned to grayware types (approximately 80%), with most of the whiteware pottery being derived from Santa Fe Black-on-white vessels. The majority of grayware types represent corrugated and smeared corrugated types that were tempered with anthill sand. Kwahe'e Black-on-white, Wiyo Black-on-white, Galisteo Black-on-white, and White Mountain Redware types are present at both sites in extremely low frequencies. A very small number of sherds from these two sites as reflected by biscuitware and a single glazeware sherd from LA 135290 may reflect a very limited amount of contamination from Classic period components.

Santa Fe Black-on-white is the dominant decorated type at both sites, representing 8 percent of the pottery recorded at LA 86534 and 9 percent from LA 135290. The majority of the pottery from Coalition period sites is represented by grayware forms including combinations of plain, corrugated, and smeared corrugated textures with similar high iron pastes with anthill sand. The dominant grayware pottery at both sites is smeared plain corrugated representing 61.4 percent of the pottery from LA 86534 and 69.7 percent from LA 135290.

Attributes noted for whiteware bowl sherds can also be compared in order to determine their temporal significance. One attribute compared was the frequency of painted and unpainted bowl sherds (Table 58.15). The total frequency of whiteware bowls exhibiting painted decorations are similar at LA 86534 (69.3% of all whiteware bowls) and LA 135290 (69.1%). These frequencies are similar to each other and lower than those noted in later Coalition period assemblages. While the majority of whiteware bowl sherds from both sites exhibit unpolished exteriors, the frequency of Santa Fe Black-on-white sherds with polished exteriors was higher at LA 86534. The frequency of bowl sherds exhibiting plain versus polished exteriors was also compared (Table 58.16). The majority of whiteware bowls from LA 135290 (73.4%) exhibit unpolished and unslipped exteriors, while those from LA 86534 exhibit unpolished exteriors. Frequencies noted on LA 135290 are more similar to those noted for whiteware pottery from other Coalition period sites.

Stylistic analysis of a sample of Santa Fe black-on-white rim sherds indicated a similar range of decorations and manipulations from the Coalition period sites (Tables 58.17 through 58.23). The majority of rim sherds are unpainted and tapered. While other attributes seem to be similar, the small sample size from LA 135290 limits such comparisons.

Table 58.17. Distribution of rim shape (count/percent) by site for Santa Fe Black-on-white sherds.

The dominance of Santa Fe Black-on-white along with low frequencies of Kwahe'e Black-on-white indicates occupations associated with the early part of the Middle Coalition period at both sites. Data from other sites on the Pajarito Plateau indicate a decrease in the frequency of smeared corrugated relative to other grayware forms some time during the early to middle part of the Coalition period (Curewitz and Harmon 2002). The most likely interpretation is that LA 86534 and LA 135290 were both occupied during the early to middle 13th century. This interpretation is supported by archaeomagnetic dates from LA 86534, which support an occupation during the first half of the 13th century.

Further clues concerning occupations during the Middle Coalition period in this area are provided by data from 2985 sherds examined from LA 4624, a site excavated by Los Alamos National Laboratory (LANL) personnel in the early 1990s and analyzed by Curewitz and Harmon (2002). The majority of the pottery at LA 4624 is represented by Santa Fe Black-on-white although Kwahe'e is represented in a low but significant frequency. Wiyo Black-on-white was absent from the assemblage. Nonlocal sherds were limited to Wingate Black-on-red. The majority of all whiteware sherds were painted. Grayware types represent 77.7 percent of all the identified pottery and the assemblage was dominated by smeared-indented corrugated. A small but significant frequency of grayware sherds exhibited plain and indented corrugated exteriors. The presence of Kwahe'e Black-on-white and higher frequencies of grayware forms is similar to trends noted at LA 86534 and LA 135290, although the frequency of Kwahe'e Black-on-white and grayware types other than smeared corrugated is slightly higher at LA 4624. This may indicate an occupation dating slightly earlier than that noted at LA 86534 and LA 135390 (Curewitz and Harmon 2002), and a date in the early 13th century is likely.

A large number of sherds were recovered from LA 12587 (*n* = 10,363) (Tables 58.24 and 58.25). This represents a selected sample, as not all sherds recovered from this site were analyzed. A smaller sub-sample of ceramics includes material from burials as well as special objects selected for analysis. Many aspects of assemblage are similar to those noted for the two Middle Coalition sites just discussed. These include similar frequencies of ware groups, with just over 80 percent representing bowls. Another similarity is that the majority of whiteware sherds are derived from Santa Fe Black-on-white, which represents over 12 percent of all pottery. In addition, as is the case for the other Middle Coalition assemblages, most of the sherds are from smeared corrugated vessels. Frequencies of ware groups are similar to those noted for earlier Coalition period sites with grayware types representing just over 80 percent of the total pottery (Table 58.25).

Table 58.24. Distribution of ceramic types (count/percent) at LA 12587.

Ceramic Type	Total
Indeterminate Whiteware	
Unpainted undifferentiated white	1 (0.0)
Indeterminate painted ware	1 (0.0)
Northern Rio Grande Whiteware	
Unpainted undifferentiated	426 (4.1)

Some differences were noted in ceramic distributions from LA 12587 and those from the other Middle Coalition period sites just discussed. For example, the frequency of Wiyo Black-on-white and Galisteo Black-on-white is slightly higher at LA 12587. The overall frequency of grayware sherds exhibiting smeared corrugated exteriors is also higher at LA 12587. In addition, the total frequency of whiteware sherds exhibiting painted decorations was higher at LA 12587 (79.6% of all whiteware vessels) than at either LA 86534 or LA 135290. This may reflect a broader field of decorations for Santa Fe Black-on-white produced during later periods. The frequency of whiteware bowls from LA 12587 with unpolished exteriors was higher than that noted for LA 86534 and similar to that noted at LA 135290. Stylistic analyses indicate similar trends at the two earlier Coalition period sites including the dominance of unpainted, tapered rims. Differences may include slightly thicker vessel walls, higher polish, and higher frequency of hatchured designs.

The occurrence of Galisteo Black-on-white, St Johns Black-on-red, and higher frequencies of smeared corrugated at LA 12587 (see Tables 58.24 and 58.25) may indicate a slightly later or longer occupation at this site (Curewitz and Harmon 2002; McKenna and Miles 1999). Data from other sites on the Pajarito Plateau indicate a decrease in the frequency of smeared corrugated relative to other grayware forms some time during the early to middle part of the Coalition period (Curewitz and Harmon 2002; Kohler 2004). The most likely interpretation is that while the early part of the occupation of LA 12587 may have overlapped with the previously discussed Coalition period sites, it extended later in time. The later part of the occupation of LA 12587 may have dated from the early to middle 13th century to the beginning of the 14th century. Low frequencies of biscuitware and glazeware types are presumably associated with the later site components (fieldhouse and agricultural features).

The next stage in the ceramic sequence on the Pajarito Plateau for the Coalition period is reflected by ceramic distributions associated with the 10,070 sherds from LA 4618. Almost all the pottery from LA 4618 represents types produced during the Coalition period (Tables 58.26 and 58.27). The only exception was a single San Juan Red-on-tan sherd dating to the Historic period and two glazeware sherds. The majority (84.0%) of the pottery from this site represented gray utilityware types while 15.9 percent represented whiteware types, and 1 percent consisted of redware types (see Table 58.27). Most of the whiteware sherds that could be assigned to a type were classified as Santa Fe Black-on-white, which consisted of 10.9 percent of all pottery. Wiyo Black-on-white was represented in lower frequencies and consisted of 1.3 percent of all pottery. Whiteware types present in very low frequencies include Galisteo Black-on-white and Kwahe'e Black-on-white. Grayware assemblages were dominated by smeared-indented corrugated sherds, which represent 80.6 percent of all pottery. Other sherds, comprising, 1.2 percent of all pottery, were assigned to various corrugated types based on variation in exterior surface treatment or plainware forms exhibiting no exterior surface treatments.

A comparison of the pottery from LA 4618 and the Middle Coalition period sites discussed previously indicate Late Coalition period occupation. A Late Coalition period occupation is not only indicated by the higher frequencies of Wiyo Black-on-white but also by the distinctive range of characteristics noted in Santa Fe Back-on-white from this site, which appear to reflect gradual changes in the technology and decoration of whiteware vessels. This is reflected by a higher degree of polishing on painted whiteware vessels on both Santa Fe Black-on-white and Wiyo Black-on-white sherds at LA 4618. These differences indicate gradational changes associated with the development of Santa Fe Black-on-white into Wiyo Black-on-white. The total frequency of whiteware sherds exhibiting painted decoration is fairly high at LA 4618, with 83.7 percent of all Rio Grande whiteware sherds exhibiting paint. This is slightly higher than the overall frequency noted at other Coalition period sites. The differences in these distributions may reflect broader field of decorations for Santa Fe Black-on-white produced during later periods. The degree of polish appears to be higher for the interior of whiteware bowls as indicated during stylistic analyses. The majority of the whiteware ceramics (83.5%) exhibit a plain, unpolished exterior.

Stylistic analyses indicate similarities in rims noted in painted whiteware sherds from other Coalition period sites. Sherds from this site tend to display wider vessel walls and higher interior polish and reflect the continuation of trends discussed for the previous sites. Hatchured designs appear to be rarer than noted for the previous period.

Distribution of pottery types is somewhat similar to those noted at LA 12587, although the higher frequency of Wiyo Black-on-white reflects a later date. This combination of pottery indicates an occupation dating to some time from the very end of the 13th century to the first part of the 14th century.

Pottery distributions from LA 4618 seem to conform fairly close to pottery described from Area Two of Burned Mesa Pueblo, excavated as part of the Bandelier Project (Gray 1992). Ceramic assemblages from this context were characterized by the dominance of smeared corrugated with Santa Fe Black-on-white and transitional Wiyo Black-on-white. This ceramic assemblage was interpreted as representing an occupation dating some time between AD 1270 and 1335 (Gray 1992).

Pottery distributions associated with the 1056 sherds from LA 4619 are very similar to those noted at LA 4618. As is the case with other Coalition period sites, just over 80 percent of the pottery represents grayware types, with almost all the remaining types representing whiteware forms (Tables 58.28 and 58.29).

Table 58.28. Distribution of ceramic types (count/percent) at LA 4619.

Ceramic Type	LA 4619
Northern Rio Grande Whiteware	
Unpainted undifferentiated	87 (8.2)
Indeterminate organic paint	42 (4.0)

Ware	LA 4619
Gray	848 (80.3)
White	206 (19.5)
Red	2 (0.2)
Total	**1056 (100)**

Slight differences may indicate a somewhat later occupation and the effects of small sherd size on the assignment of pottery types. Similarities include the dominance of Santa Fe Black-on-white along with low but significant frequencies of Wiyo Black-on-white. Biscuitwares also occur in low frequencies. Several of the sherds assigned to biscuitware types as well as those assigned to Wiyo Black-on-white appear to exhibit characteristics transitional between these types. In addition, many of the Santa Fe Black-on-white sherds exhibit pastes that also seemed to be transitional to either Wiyo Black-on-white or biscuitware types. The transitional nature of these whitewares was also noted in many of the sherds from LA 4618, but appears to be even more transitional than noted at LA 4619. The paste of whitewares from LA 4619 tends to be very light (almost white in color) with dense, small tuff particles that are very similar to that noted in biscuitware. Surfaces tend to be highly polished. Almost all the sherds were too small to be included in stylistic analysis. Glazeware types were not present. Intrusive types were limited to very low frequencies of sherds assigned to Cibola Whiteware and White Mountain Redware types.

Utilitywares at the Late Coalition period sites are dominated by smeared corrugated. The main differences are the much higher frequency of sherds assigned to the plain gray body type. This may in part reflect a trend toward increased obliteration of the surface, but may also be a reflection of the much smaller sizes of sherds from LA 4619. The smaller size of many of these sherds may have made it more difficult to identify corrugated treatments, and thus resulted in a higher proportion of sherds being assigned to plain grayware categories.

It is likely that LA 4619 dates to either the same time or to just after the occupational period of LA 4618, with an occupation around the middle of the 14th century. The ceramics from this site exhibit more characteristics described for Coalition period sites and thus are included in the discussion with these sites, although they also exhibit characteristics that are also transitional to those noted in Classic period assemblages.

As part of the present study, ceramics from two sites excavated by LANL personnel during the 1950s were also analyzed. These sites were not given Laboratory of Anthropology (LA) numbers, but consist of the Airport Ruin 1 (n = 19) and Airport Ruin 2 (n = 129) (Tables 58.30 and 58.31). The high frequency of whiteware sherds assigned to specific types may largely be a result of the collection strategy rather than actual behavioral patterns. While Santa Fe Black-on-white is the most common type at both sites, frequencies of Wiyo Black-on-white are also represented higher than noted at other sites examined during the present study. Grayware assemblages are mainly represented by smeared corrugated sherds. Glazeware sherds were noted at Airport Ruin 2. While the number of sherds examined from both sites was small, ceramic distributions appear to most closely resemble those documented from LA 4618 and LA 4619, dating some time during the middle of the 14th century.

Table 58.30. Distributions of ceramic types (count/percent) from non-C&T Project Late Coalition period sites.

Ceramic Type	Airport Ruin 1	Airport Ruin 2	Total

Total	**19 (100)**	**129 (100)**	**148 (100)**

The excavation of Burnt Mesa Pueblo resulted in the examination of ceramics dating to several occupations, most of which dated to the later part of the Coalition period (Gray 1992). Area 2 appears to date to approximately AD 1230 to 1275 and is characterized by the dominance of Santa Fe Black-on-white with relatively few pieces of Wiyo Black-on-white. Dates from the main part of Area 2 indicate an occupation around AD 1270 to 1335. The main occupation was dominated by Santa Fe Black-on-white and transitional or early Wiyo Back-on-white with smeared-indented corrugated. The ceramics characterizing the lower kiva fill is distinct from other areas of the site and is characterized by a high ratio of Wiyo black-on-white to Santa Fe Black-on-white, Galisteo black-on-white, and Biscuit A (Abiquiu Black-on-white) and may indicate an occupation from approximately AD 1350 to 1375.

Thus, while the ceramic distributions from Coalition period sites so far discussed are similar, it is possible to order these sites into a sequence that reflects the gradual nature of change from the Late Developmental period into the Classic period. An analysis of ceramics recovered from LA 82601 indicates that ceramic producing groups had already begun to settle the Pajarito Plateau during the Late Developmental period around the middle of the 12th century. Such sites have rarely been documented on the plateau and are probably limited to extremely sparse habitation and limited activity sites. Sites dating to the next period, which has sometimes been characterized as the earliest phase of the Early Coalition period (Orcutt 1999), are not represented by the LANL assemblages that were examined, although such assemblages are expected to be similar to those described from LA 3852 (Casa del Rito), which was excavated during the Bandelier Archaeological Project (Gray 1992.). The earliest occupation so far examined at LANL is LA 4624 (Curewitz and Harmon 2002), followed by LA 86534 and LA 135290, which exhibit ceramic distributions similar to those noted at Area 2 from Burnt Mesa Pueblo and appear to date to the middle of the 13th century. Later dates are represented by assemblages from LA 12587 and LA 4618, and finally LA 4619, which are similar to those described from Area 1 of Burnt Mesa Pueblo. These occupations appear to reflect occupations dating to the second half of the 13th to the middle of the 14th century. Small ceramic assemblages from two sites (Airport 1 and Airport 2, Steen 1977) also appear to date to the very end of the Coalition period. Thus, ceramic evidence from the C&T Project sites and the surrounding areas dating to the Coalition period reflect continual occupation spanning most of the 13th century into the middle of the 14th century, and may represent a span of about a 150 years.

Dating of Classic Period Sites

Ceramic assemblages were primarily assigned to the Classic period based on the presence of biscuitwares, glazewares, and Sapawe micaceous sherds. Another feature of Classic period ceramic assemblages is the rarity of Santa Fe Black-on-white ceramics as compared to its frequency in Coalition period assemblages. However, it should be pointed out that sherds assigned to the Santa Fe Black-on-white type are hardly ever completely absent in assemblages dating to the Classic period. Assemblages from at least 29 of the sites examined during the present study display a combination of ceramic types indicative of at least some discard of these ceramics during the Classic period. These include 19 sites located in the Rendija Tract, three in the TA-74 Tract, five from the White Rock Tract, and two from the Airport Tract.

Assemblages were usually assigned to different spans within the Classic period based on the relative frequency of different biscuitware types. Of particular importance was the presence of more Biscuit A relative to Biscuit B ceramics at Early Classic period components, and the dominance of Biscuit B in recognizing Late Classic period occupations. The presence of low frequencies of Biscuit C and Sankawi Black-on-cream also played a role in recognizing components associated with the very end of the Classic period.

Five sites were assigned to an indeterminate Classic period based on the dominance of biscuitwares and other late ceramic types, but could not be assigned to specific temporal spans within this period. This inability resulted from difficulties in assigning dates to assemblages with small numbers of ceramics where it was not possible to determine the relative frequencies of Biscuit A and Biscuit B and other important diagnostic types (Table 58.32 and 58.33). Sites assigned to an indeterminate Classic period include LA 85414 (*n* = 35), LA 127625 (*n* = 28), LA 127627 (*n* = 82), and LA 139418 (*n* = 26). Most whiteware sherds from sites assigned to this period were classified to general biscuitware types with the exception of one Biscuit A sherd from LA 85414 and one Biscuit B sherd from LA 127627. The overall frequency of different wares was extremely variable with varying ware groups dominating the assemblages from the sites. Grayware types common at sites assigned to this period include smeared corrugated, Sapawe micaceous, and plain corrugated forms. This variation may reflect both the small size and nature of vessel use at Classic period sites. Despite the small sample size, glazeware types were represented at all of these sites.

Table 58.32. Distribution of ceramic types (count/percent) from indeterminate Classic period sites.

Ceramic Type	85414	127625	127627	139418	Total
Northern Rio Grande Whiteware					
Unpainted undifferentiated	3 (8.6)	3 (10.7)			6 (3.5)

Three sites were assigned to the Early Classic period based on the dominance of Biscuit A in the whiteware assemblages (Tables 58.34 and 58.35). These include LA 85413 (*n* = 494), LA 85867 (*n* = 68), and LA 135291 (*n* = 82). Biscuit B ceramics are absent from these sites. All three sites are dominated by ceramics assigned to grayware types ranging from 64.6 percent at LA 135291 to 85.8 percent LA 85413. The only site assigned to this group from which glazeware sherds were noted is LA 85413, which included one Cieneguilla Glaze-on-yellow sherd.

Table 58.34. Distribution of ceramic types (count/percent) from Early Classic period sites.

Ceramic Type	85413	85867	135291	Total
Northern Rio Grande Whiteware				
Santa Fe Black-on-white	3 (0.6)			3 (0.5)

Table 58.35. Distribution of ware groups (count/percent) at Early Classic period sites.

Ware	85413	85867	135291	Total
Gray	424 (85.8)	54 (79.4)	53 (64.6)	531 (82.5)
White	56 (11.3)	14 (20.6)	29 (35.4)	99 (15.4)
Glaze	14 (2.8)			14 (2.2)
Total	**494 (100)**	**68 (100)**	**82 (100)**	**644 (100)**

Three sites were assigned to a mixed Classic period based on the presence of both Biscuit A and Biscuit B (Tables 58.36 and 58.37). These sites include LA 70025 (n = 185), LA 85411 (n = 320), and LA 86637 (n = 110). Whiteware types from all these assemblages are dominated by biscuitware ceramics but also contain low frequencies of Santa Fe Black-on-white. It is possible these represent a late form of this type rather than a multi-component context. Assemblages from two sites (LA 70025 and LA 85411) are dominated by grayware types (over 70% of the pottery), which is primarily represented by Sapawe micaceous. In contrast, the majority of sherds from LA 86637 are represented by whiteware types. Three glazeware sherds were also recovered from LA 86637.

Table 58.36. Distribution of ceramic types (count/percent) from mixed Classic period sites.

Ceramic Type	70025	85411	86637	Total
Northern Rio Grande Whiteware				
Unpainted undifferentiated	2 (1.1)	8 (2.5)	22 (20.0)	32 (5.2)
Indeterminate organic paint		9 (2.8)	1 (0.9)	10 (1.6)
Santa Fe Black-on-white	2 (1.1)	2 (0.6)	5 (4.5)	9 (1.5)
Biscuitware unpainted slipped both sides	9 (4.9)	2 (0.6)		11 (1.8)
Biscuitware painted unspecified		2 (0.6)	29 (26.4)	31 (5.0)
Biscuit A (Abiquiu Black-on-white)	8 (4.3)	43 (13.4)	3 (2.7)	54 (8.8)
Biscuit B (Bandelier Black-on-white)	5 (2.7)	18 (5.6)	4 (3.6)	27 (4.4)
Unpainted biscuitware slipped one side	5 (2.7)	3 (0.9)	14 (12.7)	22 (3.6)
Biscuitware slip and paint absent	7 (3.8)	1 (0.3)		8 (1.3
Northern Rio Grande Grayware				
Unknown gray rim			2 (1.8)	2 (0.3)
Plain gray body	3 (1.6)	1 (0.3)	11 (10.0)	15 (2.4)
Indented corrugated	4 (2.2)		5 (4.5)	9 (1.5)

Smeared plain corrugated		14 (4.4)	3 (2.7)	17 (2.8)
Smeared-indented corrugated	15 (8.1)		7 (6.4)	22 (3.6)
Sapawe micaceous	125 (67.6	202 (63.1)		327 (53.2)
Sand-Tempered Grayware				
Plain gray body		13 (4.1)		13 (2.1)
Smeared plain corrugated		2 (0.6)		2 (0.3)
Middle Rio Grande Glazeware				
Glaze red body unpainted			2 (1.8)	2 (0.3)
Los Padillas glaze polychrome			1 (0.9)	1 (0.2)
Total	**185 (100)**	**320 (100)**	**110 (100)**	**615 (100)**

Table 58.37. Distribution of ware groups (count/percent) from mixed Classic period sites.

Ware	70025	85411	86637	Total
Gray	147 (79.5)	232 (72.5)	29 (26.4)	408 (66.3)
White	38 (20.5)	88 (27.5)	78 (70.9)	204 (33.2)
Glaze			3 (2.7)	3 (0.5)
Total	**185 (100.0)**	**320 (100)**	**110 (100)**	**615 (100)**

Nine sites were assigned to the Late Classic period based on the dominance of Biscuit B (Tables 58.38 and 58.39). Some of these sites also contain Biscuit C and Sankawi Black-on-cream and may reflect occupations that continued late into the Classic period. This, in conjunction with the small numbers of Biscuit C, influenced the decision to include these types together into a single Late Classic period group. Sites assigned to the Late Classic period based on ceramic assemblages include LA 15116 (*n* = 85), LA 85408 (*n* = 80), LA 86605 (*n* = 105), LA 87430 (*n* = 487), LA 110126 (*n* = 11), LA 127634 (*n* = 149), LA 128804 (*n* = 262), LA 128805 (*n* = 199), and LA 135292 (*n* = 89). While the majority of whiteware types from all these sites are Biscuit B, Biscuit B/C, and Biscuit C or Sankawi Black-on-cream, extremely low frequencies of Santa Fe Black-on-white were also noted at four sites (LA 87430, LA 128804, LA 128805, and LA 135292). While it is possible that some of the pottery assigned to this type could be from earlier Coalition period sites, it is quite likely that at least some are associated with the Classic period. A clue of such association is the unique characteristics of some of the Santa Fe Black-on-white sherds in Classic period sites, including a distinct and highly vitrified paste. While some of the examples of Santa Fe Black-on-white could be from earlier heirloom vessels, it is also possible that some of these represent a very late form of Santa Fe Black-on-white that may have continued to have been produced in certain localities during the Classic period. Such a possibility has previously been suggested for ceramic assemblages from the Arroyo Hondo site (Lang 1993), and it is my experience that low frequencies of Santa Fe Black-on-white continue to occur in northern Rio Grande ceramic assemblages that otherwise seem to date to the Classic period. In addition, some of the pottery assigned to Santa Fe Black-on-white may represent varieties of this type, such as Pindi Black-on-white, which continued to be produced at some localities into the Classic period.

The possibility of components dating to the end of the Classic period at sites with assemblages dominated by Biscuit B is reflected by the additional presence of Sankawi Black-on-cream at three sites (LA 85408, LA 127634, and LA 135292) and the presence of Biscuit C and Sankawi Black-on-cream at two sites (LA 86605 and LA 128805). Sapawe micaceous was present at most sites assigned to this period and the common occurrence of plain corrugated at some of these sites reflects a shift in technology toward fewer manipulations on the surface exterior. Smeared corrugated is present at some Late Classic period sites, but tends to be rarer than in earlier periods. Assemblages from Late Classic period assemblages with glazeware types include those from LA 15116, LA 85408, LA 127634, LA 128804, and LA 128805. Specific types to which glazeware bowl rim sherds from later Classic period sites were assigned include Agua Fria Glaze-on-red and Largo Glaze-on-yellow.

The previous three ceramic groups are the same as defined by Harmon and Vierra in their chronometric chapter (Chapter 69, this volume). That is, Classic 1 is the same as my Early Classic period, Classic 2 is the same as my mixed Classic period, and Classic 3 equals my Late Classic period. Harmon and Vierra's study, therefore, provides independent support for my temporal classification. However, it should also be noted that other chapters in this report series separate the Classic period into Early, Middle, and Late based on ceramics and chronometric dates (e.g., Chapter 1, Volume 1). In this case, Early Classic includes Biscuit A and/or primarily dates to the 14th century, Middle Classic includes Biscuit B and/or primarily dates to the 15th century, and Late Classic includes Biscuit C and Sankawi Black-on-cream and/or primarily dates to the 16th century (also see Orcutt 1999:115). However, mixed Biscuit A/B assemblages were designated as Early-Middle Classic and body sherds lacking rims, but with painted interior and exterior designs, were designated as Biscuit B/C and would have been given a Middle-Late Classic period designation. Therefore, this Middle-Late Classic period designation would simply be lumped together within my Late Classic period group.

Table 58.38. Distribution of ceramic types (count/percent) from Late Classic period sites.

Ceramic Type	15116	85408	86605	87430	110126	127634	128804	128805	135292	Total

The frequency of types assigned to different ware groups is extremely variable in assemblages from sites assigned to the later Classic period. Sites from which the assemblages examined are dominated by grayware types include LA 87430, LA 128804, LA 128805, and LA 135292. Those dominated by whiteware types include LA 15116, LA 85408, LA 86605, LA 110126, and LA 127634. While some of these differences may reflect small sample size, these distributions seem to indicate more variation in the activities for which vessels were used than during earlier periods.

Ceramic distributions from LA 85407 (*n* = 193; the Serna Homestead) indicate the presence of a few sherds dating to the Late Classic period in an assemblage that is otherwise dominated by native historic pottery types (Table 58.40). The prehistoric component was assigned to the Classic period based on the occurrence of Biscuit B and Sapawe micaceous.

Table 58.40. Distribution of ceramic types (count/percent) from LA 85407, the Serna Homestead.

Ceramic Type	Total
Rio Grande Whiteware	
Unpainted undifferentiated	1 (0.5)
Biscuit B (Bandelier Black-on-white)	5 (2.6)
Unpainted biscuitware slipped one side	2 (1.0)
Rio Grande Grayware	
Sapawe micaceous	3 (1.6)
Historic Tewa Plainware	
Tewa buff undifferentiated	2 (1.0)
Tewa polished gray	2 (1.0)
Historic Athabaskan Utilityware	
Unpolished mica slip	2 (1.0)
Athabaskan plain unpolished	176 (91.2)
Total	**193 (100)**

In addition, the frequency of Santa Fe Black-on-white and associated grayware types from assemblages at eight sites indicate the presence of Coalition period components as well as ceramics indicating later Classic period components (see Tables 58.9 and 58.10). Sites with assemblages indicating components dating to the Coalition and Classic period include LA 21596B (*n* = 257), LA 21596C (*n* = 382), LA 85404 (*n* = 199), LA 85861 (*n* = 439), LA 86606 (*n* = 143), LA 127631 (*n* = 12), LA 127635 (*n* = 371), and LA 141505 (*n* = 29). Sites with very small numbers of Late Classic period ceramics but with very few or no distinct biscuitware types include LA 127631 and LA 141505. Thus, the later components from these sites could only be assigned to an indeterminate Classic period group. Biscuitwares from LA 84504 and LA 127635 were dominated by Biscuit A. The later component at these sites appears to date to the Early Classic period. Assemblages from both LA 21596B and LA 21596C exhibit a mixture of Biscuit A and Biscuit B. In addition, the presence of Potsuwi'i Incised at both sites and Biscuit C at LA 21596 indicate some occupation during the Late Classic period, and it is therefore likely that these sites were occupied during both the Early and Late Classic periods. Biscuitwares from LA

85861 and LA 86606 are dominated by Biscuit B, which reflects a later Classic period component at these sites.

Decorated pottery collected in isolated scatters from the White Rock Tract are mainly represented by biscuitware and glazeware types associated with the Classic period, although the frequency of Santa Fe Black-on-white is high enough to indicate the presence of some sherds associated with the Coalition period (Tables 58.41 and 58.42). The dominance of Biscuit B and the presence of Sankawi Black-on-cream also indicate that most of this pottery was deposited during the Late Classic period.

Table 58.41. Distribution of ceramic types (count/percent) for isolated occurrences in the White Rock Tract.

Ceramic Type	Total
Northern Rio Grande Whiteware	
Unpainted undifferentiated	17 (8.9)
Indeterminate organic paint	1 (0.5)
Indeterminate organic Coalition period	3 (1.6)
Santa Fe Black-on-white	8 (4.2)
Biscuitware unpainted slipped both sides	3 (1.6)
Biscuitware painted unspecified	5 (2.6)
Biscuit A (Abiquiu Black-on-white)	7 (3.6)
Biscuit B (Bandelier Black-on-white)	19 (9.9)
Sankawi Black-on-cream	2 (1.0)
Unpainted biscuitware slipped one side	1 (0.5)
Northern Rio Grande Grayware	
Plain gray body	4 (2.1)
Indented corrugated	9 (4.7)

ORGINS AND INFLUENCES OF CERAMICS ON THE PAJARITO PLATEAU

Pottery distributions from these sites may provide information concerning the time and areal origin of ceramic-producing groups on the Pajarito Plateau. Evidence for the presence of a Kwahe'e phase occupation and the gradual and distinctive nature of stylistic development observed during the Coalition period seem to indicate an initial movement of ceramic-producing groups from areas of the northern Rio Grande just to the east. These occupations are followed by a sequence of gradual ceramic changes similar to that occurring in other areas of the northern Rio Grande region. The apparent sudden appearance of populations entering the plateau and other areas of the northern Rio Grande region during the 13th and 14th centuries have sometimes been attributed to the long-distance migration of groups from the San Juan (or Mesa Verde) region in the Four Corners area.

Stylistic analysis indicates that the styles and manipulations noted in Santa Fe Black-on-white are similar to contemporary whitewares from sites in other areas of the Rio Grande region including the Albuquerque area, Santa Domingo Basin, Rio Puerco Valley, Pecos Valley, Santa Fe Valley, Tewa Basin, Chama Valley, and Galisteo Basin. Also of interest is the strong contrast in the nature of decoration and construction of Santa Fe Black-on-white and Mesa Verde Black-on-white from the San Juan region. While certain traits such as the use of organic paint and bold banded styles may reflect influences from the Mesa Verde region, broad stylistic patterns noted in pottery from this region are very different from those noted in Coalition period sites described during the present study (Wilson 1996; Tables 58.17 through 58.23). For example, the majority of the sherds exhibit unpainted, tapered rims in contrast to the flat ticked rims common in Mesa Verde Black-on-white (Breternitz et al. 1974; Wilson 1996; Wilson and Blinman 1995a). In addition, bowl exteriors are usually unpolished and unslipped, and vessel forms other than bowls are extremely rare. This also contrasts with traits noted in Mesa Verde Black-on-white and other 13th century San Juan whiteware types (Breternitz et al. 1974; Wilson and Blinman 1995a). The overall design organization and motifs noted in these Santa Fe Black-on-white sherds also tend to be slightly earlier looking than that from a 13th century site in the San Juan region (Wilson 1996). Thus, a scenario of a full-scale migration of groups to the Pajarito Plateau from the Mesa Verde region seems unlikely.

Instead, the various combinations of traits suggest a local development out of Kwahe'e Black-on-white in areas that were occupied during the Late Developmental period such as the Tewa Basin, along with influences from areas to the west. Characteristics of pottery from the previously discussed Late Developmental site (LA 82601) seem to indicate that the earliest ceramic occupations on the Pajarito Plateau were the result of short-distance migrations from areas such as the Tewa Basin. Recent research also indicates that contemporaneous populations in the Tewa Basin were large enough to have been the source of immigrants onto the Pajarito Plateau (Lakatos 2003). Characteristics described for Early Coalition sites such as LA 3852 (Casa del Rito) investigated during the Bandelier Project indicate a slow and gradual transition from Late

Developmental to Coalition period ceramic forms. Such changes may have resulted from a combination of both local change and continuing migration from areas such as the Tewa Basin. Characteristics described for other Coalition period sites indicate a very gradual transition that was unique to, and occurred over, large areas of the northern Rio Grande region. It has been suggested that population migration onto the Pajarito Plateau from the Mesa Verde region occurred in the form of a series of small population drifts. If this was the case, these individuals had very little influence on ceramic technology and decorative conventions as well as other aspects of the material culture of the regions into which they migrated.

THE TEMPORAL DISTRIBUTION OF SITES BY TRACT

The examination of distributions of sites assigned to different temporal periods within the separate tracts may also provide clues concerning the nature and history of occupations of these various localities of the central Pajarito Plateau. It should be noted, however, that these represent relatively small and not necessarily representative samples of sites dating to the different time periods for these tracts, and characterization of such patterns should be supplemented by data from surveys of these tracts (e.g., see Hoagland et al. 2000).

The majority of the ceramics analyzed from seven sites in the White Rock Tract were recovered from the Late Coalition period roomblock at LA 12587. The extremely small sample of pottery from the fieldhouse at LA 127631 reflects an occupation dating to the Late Coalition and Early Classic periods. Pottery from the other five sites represents Classic period occupations. The artifact scatter at LA 127625 was assigned to an indeterminate span of the Classic period. Ceramics from the artifact scatter at LA 86637 indicate a Middle Classic period occupation. Sites with ceramics dating to the Late Classic period include the check dam at LA 128804 and the fieldhouse at LA 128805.

The majority of ceramics from the five sites excavated in the Airport Tract was recovered from the Middle Coalition period roomblocks at LA 86534 and LA 135290. The very small sample of pottery from the artifact scatter at LA 86533 indicated an occupation during an indeterminate span of the Coalition period. Pottery from the fieldhouse at LA 141505 reflects a Late Coalition and Early Classic period occupation. Pottery from the grid garden and surrounding artifact scatter at LA 139418 suggest a Classic period occupation.

All the 26 ceramic sites examined from the Rendija Tract represent small sites from which relatively few ceramics were recovered. Very small assemblages from the fieldhouses at LA 85403 and LA 127634, the tipi ring at LA 85864, and the artifact scatters at LA 85859 and LA 99397 could not be assigned to a specific time period. Pottery from the artifact scatter and structure at LA 99396 and the fieldhouse at LA 86607 indicate an occupation in an indeterminate span of the Coalition period. Pottery distributions from fieldhouses at LA 85404, LA 85861, LA 86606, and LA 127635 reflects occupations during both the Coalition and Classic periods. Pottery distributions from fieldhouses at LA 85414 and LA 127627 reflect occupations during an indeterminate span of the Classic period. Pottery from the fieldhouses at LA 85413, LA 85869, and LA 135291 reflects an occupation dating to the early part of the Classic period. Pottery from the fieldhouse at LA 85411 indicates possible occupations during the early and late spans of the

Classic period. Pottery from fieldhouses at LA 15116, LA 70025, LA 85408, LA 86605, LA 87430, and LA 135292 indicate occupations dating to the later portion of the Classic period. Distributions of native pottery types from a homestead at LA 85407 indicate an occupation primarily dating to the Historic period, as well as the Classic period. Ceramics recovered in the fieldhouse at LA 85417 suggest both historic and prehistoric occupations of the site area.

All seven of the ceramic assemblages from the TA-74 sites yielded small assemblages. Very small assemblages from fieldhouses at LA 110121, LA 110130, and LA 110133 and the lithic scatter at LA 117883 could not be assigned to a specific time period. Pottery distributions from a grid garden at LA 21596B and a fieldhouse at LA 21596C indicate occupations during both the Coalition and Classic periods. Ceramics recovered from the fieldhouse at LA 110126 indicate an occupation during the later Classic period. Very small ceramic samples from artifact scatters at two sites in the White Rock Y Tract were not assigned to a specific period.

Large ceramic assemblages were recovered from two sites excavated in the early 1990s on Mesita del Buey. Ceramic assemblages from the roomblocks at LA 4618 and LA 4619 indicate occupations dating toward the end of the Coalition period, with those from LA 4619 possibly being slightly later.

A review of dates assigned to sites located in different tracts indicates occupations covering much of the Coalition and Classic periods. The majority of the analyzed pottery was recovered from a small number of Coalition period roomblocks located in the White Rock and Airport tracts. While some seasonal sites (e.g., artifact scatters and fieldhouses) date to the Coalition period, these are relatively rare compared to the Classic period fieldhouse sites. The ceramic assemblages recovered from the Rendija Tract fieldhouses indicate that they date primarily to the Classic period. All the Classic period sites and components identified during this study likely reflect seasonal uses by the occupants of the major Classic period towns in this area of the Pajarito Plateau (e.g., Otowi and Tsirege).

POTTERY TRENDS

The assignment of sites to different time periods based on distributions of ceramic attributes provides evidence for long-term changes in pottery production, exchange, and use of vessels. Many of the spatial and temporal patterns of ceramic distributions previously noted reflect changing factors influencing the production, decoration, exchange, and use of ceramic vessels. Aspects of pottery production, exchange, and function may often represent closely interrelated components of larger economic, technological, and social systems. Thus, the changing characteristics and the range of one aspect of ceramic containers must be considered along with the affect on and influences from others (Blinman 1988; Pool 1992). For example, the characteristics and qualities of clay resources available to potters in a particular area may prevent or encourage the production of certain pottery forms in different regions. This in turn could have facilitated the exchange of specialized pottery forms between areas in which different ceramic resources were available. The types and roles of activities for which pottery containers produced in different areas might have been used would have further influenced the classes and forms of pottery produced. Attempts to produce vessels that would have been desirable or acceptable to groups in various areas would have influenced the decoration and technology of these vessels, as well as contributing to potentially important ties and relationships between groups in separated areas.

This chapter follows recent studies in the northern Rio Grande that have described changing regional systems in the production, distribution, and form of pottery vessels during the Coalition and Classic periods in terms of models of tribalization (Habicht-Mauche 1993; Powell 2002; Vint 1999). While many areas of the northern Rio Grande were first occupied during the Late Developmental period, the Coalition period has often been treated as the starting point in studies of regional trends in relating to settlement, interaction, and exchange in the northern Rio Grande region. In many of these studies, trends noted for Coalition period components are contrasted with those documented for the later Classic period (Habicht-Mauche 1993; Powell 2002; Vint 1999).

Studies framed in terms of tribalization models have largely concentrated on determining how many of the larger communities first appeared in different localities throughout the northern Rio Grande region during the Coalition period, and these were initially organized and integrated into a regional network. These studies have examined evidence relating to the type and nature of social and economic networks between separated communities (Habicht-Mauche 1993; Powell 2002; Vint 1999). During the Coalition period, the widespread sharing of information by separated communities appears to be reflected by the distribution of similar decorative styles and manipulations in pottery found over a very wide area of the northern and middle Rio Grande region (Habicht-Mauche 1993). The high degree of stylistic similarity of Santa Fe Black-on-white produced in the Pajarito Plateau and surrounding areas contrasts with the evidence for paste differences at sites located at a close distance to each other and indicates that vessels produced over a wide area were decorated in a very similar manner (Habicht-Mauche 1993; Kohler et al. 2004; Powell 2002; Ruscavage-Barz 2002; Vint 1999). Other evidence of specialization in the production of whiteware vessels during the Coalition period is reflected by the identification of pit kilns near Santa Fe that were used to produce Santa Fe Black-on-white, but were situated at some distance from village communities (Post and Lakatos 1995). The amount of nonlocal pottery that was clearly produced in regions outside of the northern Rio Grande tends to be very low in Coalition period assemblages.

The widespread homogeneity of locally produced Santa Fe Black-on-white and smeared corrugated at Early Coalition period sites over much of the Rio Grande region has been interpreted as reflecting broad, open, and widespread economic and social networks (Habicht-Mauche 1993). The resulting openness may represent an alternative to the widespread exchange of goods that could have allowed groups in neighboring territories access to information about the availability and distribution of food resources (Habicht-Mauche 1993). This may have represented a strategy that developed to compensate for spatial, seasonality, and annual variability in resources over a wide area.

In contrast, pottery distributions from Classic period components indicate a shift towards a more diverse range of widely exchanged pottery types within restricted production zones (Vint 1999). Regional changes that had begun by the Early Classic period have been interpreted as indicating the emergence, consolidation, and competition between distinct regional alliances (Habicht-

Mauche 1993; Powell 2002). These are thought to reflect alliances supported by formalized reciprocal transactions (Habicht-Mauche 1993). These patterns of economic specialization and regional integration appear to be reflected in the increased differentiation of pottery vessels produced in different areas of the Rio Grande region that began during the late part of the Coalition period. This initial differentiation is represented by the divergence of whiteware types into spatially distinct varieties such as Galisteo Black-on-white in the Galisteo Basin and Wiyo Black-on-white in the Pajarito Plateau, Chama Valley, and Tewa Basin (Habicht-Mauche 1993).

In areas such as the Pajarito Plateau, Chama Valley, and Tewa Basin, the tradition of organic-painted pottery represented in Santa Fe Black-on-white and Wiyo black-on-white types continued with the production of biscuitware types during the Classic period. Distinct glazeware technology was introduced into the southern part of the Pajarito Plateau that replaced earlier organic-painted whitewares (Vint 1999). The technology associated with the production of glazeware pottery did not develop locally in the Rio Grande area region but was introduced by Keres-speaking groups from the Zuni and Little Colorado regions. This new glazeware technology was characterized by a range of styles and techniques indicative of experimentation with this new technology (Snow 1982). By the middle of the 14th century, glazeware pottery had become quite standardized and appears to reflect a level of craftsmanship that surpassed any of preceding decorated pottery forms (Habicht-Mauche 1993). Temper data from sites over a wide area of the northern and middle Rio Grande region indicate that most of the glazeware production occurred at a few production sites in the Rio Grande region (Habicht-Mauche 1993; Kidder and Shepard 1936; Morales 1997; Shepard 1942; 1965; Vint 1999; Warren 1969).

Geology and Resources

Factors resulting in the formation of land forms in the Pajarito Plateau have resulted in the distinct characteristics of clays and tempers available to the potters living in the area. LANL is situated on the central part of the Pajarito Plateau, an east-sloping, dissected tableland bounded by the Jemez Mountains to the west and White Rock Canyon on the east. The geology of this area is the result of a combination of volcanic activity in the Jemez Mountains and surrounding areas and stresses from the Rio Grande rift (see Chapter 2, Volume 1). The Rio Grande rift represents a series of north-south-trending fault troughs spanning from southern Colorado to southern New Mexico. The Pajarito Plateau is located on the southeastern edge of the Jemez Mountains, which represents a huge volcanic landmass that was built over the last 13 million years. The Pajarito Plateau is covered by the gently east-sloping Bandelier tuffaceous materials, which are exposed to depths of several hundred feet. From west to east, canyons are cut progressively deep into the Bandelier tuff, and near the Rio Grande deep canyons expose older igneous and sedimentary rock formations. The Bandelier tuff consists of pyroclastic flows from two extremely large eruptions from the Jemez Mountains, which underwent major eruptions just over a million years ago. These include the Tshierge Member (1.22 million years) and the Otowi Member (1.61 million years). These deposits reflect eruptions that deposited ash and tuff over 300 m thick and that cover much of the Pajarito Plateau (Burton 1982; Woodward 1974). A variety of older formations are exposed in some areas. These include Basalt rocks of the Cerros del Rio Volcanic field and coarse alluvial deposits of the Puye formation including a fanglomerate facies, axial facies, and a lacustrine facies. In some areas this underlies alluvial deposits of the Santa Fe group, as well as igneous bedrock.

Subsequent erosion of these deposits has resulted in land forms dominated by deep canyons that are separated by long narrow mesas that form the Pajarito Plateau. These mostly drain into the eastern mountains as well as the Pajarito Plateau and join the Rio Grande in White Rock Canyon. Recent erosion has resulted in patches of pumiceous soils, which are prominent on surfaces in areas of the Pajarito Plateau. Some of the exposed areas of the Bandelier formation have also eroded into usable clays.

Among the best potential source of clays for pottery are the lacustrine facies of the Puye formation, which include the Culebra Lake deposit in Los Alamos Canyon (see Chapter 2, Volume 1; Lakatos 1995; Warren 1977). This formation consists of extremely light-gray to greenish clays in varied deposits. These clays appear to have accumulated in small lakes formed by the ancient damming of White Rock Canyon (Galusha and Blick 1971). These clays are highly homogeneous and very plastic. These clays contain fine silt fragments and plastic accessory minerals (Lakatos 1995). Clay from the Culebra Lake formation represents a very likely source for at least some of the Santa Fe Black-on-white vessels including those manufactured in locations fairly far from this formation as indicated by paste characteristics of Santa Fe Black-on-white recovered from kilns in the Las Campanas area near Santa Fe (Lakatos 1995).

Tempering material is primarily represented by sources derived from local tuffs (see Chapter 59, this volume). These may represent inclusions that occur naturally in, or material added into, the clay. The very fine size of most of the tuff fragments would be suitable for whiteware vessels. It would have been necessary to add larger particles to grayware pastes. Natural sorting action from alluvial sources and anthills would have resulted in the common occurrence of coarser quartz particles of sufficient size to have been suitable for use in grayware pottery. Such material has been described during this analysis as anthill sand.

Several clay and potential temper sources were collected from the project area (Chapter 59, this volume). Most collected clays appear to represent alluvial formations presumably from the Puye formation including Culebra Lake deposit or pedogenic or alluvial clays near the surface. One of these clays may reflect material weathered from the Bandelier formation. Attempts by Eric Blinman to replicate pottery from these clays were mixed.

Late Developmental Period and the Origins of the Rio Grande System

Evidence from LA 82601, the single Late Developmental period or Kwahe'e phase site included in this analysis, may provide clues concerning factors that influenced the manufacture, distribution, decoration, and use of pottery produced during this period. It may also provide clues to the initial movement of groups into new areas of the Rio Grande region and changing interactions between groups situated in various areas. These changing relationships may have ultimately given rise to the better known regional networks described for the Coalition and Classic periods. While Kwahe'e phase occupations in other areas to the east (e.g., the Tewa

Basin and Santa Fe Valley) appear to have developed directly out of the earlier Red Mesa phase, it is likely that the Pajarito Plateau was unoccupied by ceramic-producing peoples until the very end of the Late Developmental period. Population on the Pajarito Plateau during the Late Developmental period appears to have been extremely small and dispersed and may mainly reflect seasonal use. The Late Developmental period occupation on Pajarito Plateau has gone largely undetected, as the Early Coalition period is still commonly described as the earliest ceramic occupation in this area (Orcutt 1999).

While ceramic assemblages from LA 82601 and other contemporaneous sites in the area exhibit traits and styles similar to those occurring on the Colorado Plateau, they are more similar to those from Late Developmental period complexes occurring in areas along the Rio Grande Valley to the east, with larger population and longer sequences of site occupation. The westward movement of groups to the Pajarito Plateau during the Kwahe'e phase reflects larger trends of movement of people during the very Late Developmental and Early Coalition periods, which also occurred in the Chama Valley, Galisteo Basin, and Pecos Valley. Another interesting aspect of Late Developmental period ceramic assemblages in the northern Rio Grande area is the common occurrence of nonlocal pottery types defined for regions to the west, and is reflected by the occurrence of Cibola and northern San Juan whitewares at LA 82601. A possible area of origin for much of the Cibola pottery is the middle Rio Puerco Valley. Pueblo II period sites in the Rio Puerco Valley contain both Kwahe'e Black-on-white and locally produced Cibola whiteware types and exhibit similar pastes and temper as those occurring on Cibola whiteware types from LA 82601 and other Late Developmental period sites.

In the Rio Puerco Valley, the Kwahe'e period follows a long series of occupational periods dominated by pottery types of the Cibola Ancestral Pueblo tradition. Traits reflecting influences or contacts with areas to the west have sometimes been described in terms of this area being located on the very eastern edge of the vast Chacoan system centered in the San Juan Basin in the Four Corners country (Riley 1995). Contemporary developments in the Four Corners areas, however, are probably best viewed as a distinct regional development that represents responses to pan-regional pressures occurring during the 11^{th} and 12^{th} century. The movement of groups into the northern Rio Grande is followed by the local development of a material culture and interaction system that appears to have represented a distinct regional system in its own right. I have referred to this early network as the Kwahe'e system and it is defined by the widespread production and distribution of similar pottery over wide areas of the northern Rio Grande region (Wilson n.d.). This system is associated with scattered settlements that cover much of the Rio Grande Valley including the middle Rio Grande Valley, Santo Domingo Basin, Rio Puerco Valley, Santa Fe Valley, Tewa Basin, Pecos Valley, and possibly the Taos Valley. Most of the population appears to be concentrated in areas near lower sections of the Rio Grande Valley and adjacent river drainages where Pueblo groups resided historically. Assemblages from most of these locations are dominated by grayware types reflecting a wide range of treatments including plain, incised, neckbanded, and corrugated exteriors and are usually tempered with micaceous granite. Locally produced whiteware forms are decorated with similar designs executed with mineral paint over a lightly slipped surface and are tempered with fine tuff. Characterizations of ceramic assemblages from different areas of the northern Rio Grande do indicate some spatial differences, particularly in the overall frequency of textured treatments on the exterior surface of grayware types.

The boundaries of the Kwahe'e system may reflect both a common ethnicity as well as geographically caused resource constraints on potters participating in this regional economic network. As was the case for contemporaneous Pueblo II regional networks documented elsewhere in the upland Southwest, long-term social and economic ties between separated areas would have provided for the movement of food or other necessary resources between communities in various areas during times of shortages. In addition, the movement of pottery from other regions may have been an important part of this system. Movements onto the Pajarito Plateau may represent the extension of northern Rio Grande groups into new environmental zones as a result of population or climatic pressure.

Characteristics of ceramics at LA 82601 are similar to those noted in Kwahe'e assemblages in areas to the west, although some distinct characteristics may foreshadow traits noted in Early Coalition period ceramic assemblages (see Tables 58.5, 58.6, 58.43, and 58.44). While Cibola whiteware types are present at LA 82601, they tend to occur in lower frequencies than at Kwahe'e period sites in the Tewa Basin, as most of the whiteware types from LA 82601 are tempered with some form of tuff. The frequency of whiteware types at this site at 16.7 percent is also higher than most Kwahe'e period sites, which average about 5 percent. This may indicate the local production of whiteware vessels at or near this site. Grayware types are reflected by a mixture of forms with corrugated types representing a slight majority. While most of the grayware pottery is tempered with a form of micaceous granite, some of which seems to be distinct from that found in grayware pottery produced in areas to the east, a low but significant frequency (23%) is tempered with anthill sand. This may reflect a gradual shift to locally available temper sources. Thus, while characteristic ceramics from this site are certainly within the range noted in Kwahe'e phase sites, some distinct characteristics may already reflect changes in technologies associated with the earliest Coalition period occupation.

Table 58.43. Distribution of ceramic tradition by ware (count/percent) at LA 82601.

Tradition	Gray	White	Total
Northern Rio Grande	295 (98.3)	49 (81.7)	344 (95.6)

Large tuff predominate with anthill sand	4 (1.3)		4 (1.1)
Total	**300 (100)**	**60 (100)**	**360 (100)**

Evidence of Coalition Period Production and Exchange Patterns

Trends relating to the production and exchange of Coalition period pottery largely conform to patterns noted during previous studies and seem to support the previously discussed models of tribalization. The majority of grayware and whiteware pottery was assigned to northern Rio Grande tradition types based on the presence of pastes and tempers characteristic of pottery known to have been produced for a long time on the Pajarito Plateau. The majority of whiteware pottery was assigned to Santa Fe Black-on-white based on design styles executed in organic paint, surface manipulations, and fine pastes with tuff temper characteristic of this type. Almost all the grayware pottery from Coalition period sites are tempered with similar anthill sand and exhibit pastes firing to yellow-red color.

The widespread distributions of organic-painted whitewares with "Santa Fe" designs with pastes and temper indicative of different areas of production have resulted in the proliferation of a number of similar types or varieties exhibiting decorations and manipulations similar to that described for Santa Fe Black-on-white (Habicht-Mauche 1993). An example of such variation is reflected in Warren's identification of 35 temper varieties for this type of pottery recovered at sites in the Cochiti Lake area (Snow 1976).

Recent studies have attempted to document local patterns in the distribution of ceramic paste and decorated styles of Santa Fe Black-on-white from sites on the Pajarito Plateau dating to different spans of the Coalition period (Kohler et al. 2004; Ruscavage-Barz 2002; Vint 1999). Compositional analysis of decorated pottery by Vint (1999) included Santa Fe Black-on-white types. Two techniques were used in the compositional analysis including inductively coupled plasma spectroscopy in order to determine paste composition and temper identifications using a binocular microscope. Variation in the chemical makeup of paste was used to evaluate the diversity of production score. Chemically similar ceramics were placed into groups that aid in identifying their area or origin or at least their differences. Santa Fe Black-on-white sherds were selected from 17 sites within Bandelier National Monument, which were grouped together by Early Coalition or Late Coalition period. Four distinct compositional groups were defined for Santa Fe Black-on-white sherds, with two groups indicating a point of origin in the Bandelier area. Bandelier Group 2 corresponds to moderate to abundant tuff with angular quartz inclusions. Group 1 contains lesser amounts of temper as well as samples with a higher frequency of quartz inclusions. Sites assigned to the Late Coalition period have more Santa Fe

Black-on-white with Group 2 temper than at Early Coalition period components, and may indicate increased technological variation (Vint 1999).

Ruscavage-Barz (2002) also examined variability in Santa Fe Black-on-white between earlier single roomblocks and later plaza pueblo sites dating to the Coalition period from Bandelier National Monument. Comparisons of design diversity values for ceramics from single roomblock and plaza pueblos were used to determine whether the range of design elements changed. Petrographic analysis was used to determine possible changes in patterns of production associated with Santa Fe Black-on-white. Temper analysis indicates a great deal of variability in Santa Fe Black-on-white ceramics. The temper variants local to the Pajarito Plateau include mixtures of fine sand and glassy pumice with occasional tuff. Most of the ceramics fall into one or two categories; more sand than glassy pumice or more glassy pumice than sand.

Petrographic analyses indicated a heterogeneous distribution of temper types as well possible shifts through time. This is indicated by a higher frequency of Santa Fe Black-on-white sherds with more sand at Early Coalition period assemblages, versus higher amounts of added pumice or tuff in Late Coalition period assemblages. Stylistic comparisons of pottery from the two site types also indicate no differences in the variety or manipulation design styles in the two groups. This indicates an increase in design diversity did not occur. The lack of differences in the range of stylistic diversity between single roomblock and plaza pueblos suggests design styles were not being used to differentiate plaza pueblos from other community settlements (Ruscavage-Barz 2002).

Coalition Period Production and Exchange at the C&T Project Sites

Ceramic distributions noted for assemblages from sites assigned to the Coalition period appear to support previously discussed models and observations. The majority of the whiteware sherds from almost all the Coalition period assemblages exhibit decorations executed in organic paint, surface manipulations, and pastes indicating they originated from Santa Fe Black-on-white vessels. The majority of grayware vessels from Coalition period sites exhibited smeared corrugated indentations and a relatively coarse temper described here as anthill sand (also see Chapter 59, this volume and Chapter 75, Volume 4).

Examinations of Santa Fe Black-on-white temper from different assemblages indicates some interesting differences in the sources employed in whiteware vessel production at different sites at sites located close to each other (Tables 58.45 through 58.50). Refiring analyses indicate that the whiteware sherds tend to be fired in a similar manner and are pink to yellow-red in color. These characteristics indicate the use of clays with some iron content. Visual characterizations of ceramic tempers were used to assign temper for the majority of Coalition period whiteware types to a fine tuff category. Sites in which this temper category dominated the whiteware ceramics include LA 99396 (Table 58.45), LA 86534 (Table 58.46), LA 12587 (Table 58.48), LA 4619 (Table 58.49), and LA 4618 (Table 58.50).

A notable exception to this observation was the dominance of visually distinct temper described as oblate shale and tuff at LA 135290. The majority (52%) of the whiteware sherds from LA 135290 contained oblate shale and tuff temper. Petrographic analyses indicate that sherds assigned to this category exhibited a distinct paste that was characterized by the additional presence of numerous rounded clay fragments. Very fine and sparse tuff fragments were also present. This temper was present in Coalition period whitewares at most other sites, but in very low frequencies. A relatively high frequency (43.4%) of pottery from this site was tempered with a fine tuff that is visually similar to that noted at other sites.

While the majority of whiteware sherds from other sites were tempered with fine tuff, the petrographic characterization of selected Santa Fe Black-on-white sherds indicate that several distinct local sources may have been employed in whiteware production by the different communities. Temper from Santa Fe Black-on-white sherds with some form of tuff temper may be characterized as an extremely variable group and suggests multiple production areas. Petrographic analyses indicate that pottery assigned to the fine tuff category could be placed into two distinct groups; one that was described as Tuff 1 temper (unmodified volcanic tuff) and the other as Tuff 2 temper (modified volcanic tuff). While mineral components in Tuff 1 temper (unmodified) and Tuff 2 temper (modified volcanic tuff) exhibit similarities to each other as well as to tempers common in grayware pottery described as anthill sand, the proportion of lithic grains and the general grain morphology is quite different.

Table 58.50. Distribution of ware by temper (count/percent) at LA 4618.

Temper	Gray	White	Red	Glaze	Historic Plain	Polychrome	Total
Indeterminate		1 (0.1)					1 (0.0)
Sand	1 (0.0)	2 (0.1)					3 (0.01)
Granite with mica	89 (1.1)						89 (0.9)
Granite without abundant mica			1 (14.3)				1 (0.0)
Sherd		8 (0.5)	4 (57.1)				12 (0.09)
Sherd and sand		5 (0.3)					5 (0.03)
Fine tuff or ash	64 (0.8)	1420 (88.8)	2 (28.6)		2 (100)		1488 (14.8)
Large vitric tuff fragments		2 (0.1)					2 (0.0)
Fine tuff and sand		30 (1.9)				4 (100)	34 (0.3)
Fine sandstone	1 (0.0)	1 (0.1)					2 (0.0)
Andesite or diorite and sherd		1 (0.1)					1 (0.0)
Andesite or diorite, sand and sherd		2 (0.1)					2 (0.0)
Latite Keres area				2 (100)			2 (0.0)
Tuff and phenocrysts (anthill sand)	8301 (98.2)	7 (0.4)					8308 (82.5)
Oblate shale and sand		3 (0.2)					3 (0.01)
Shale		13 (0.8					13 (0.1)
Mostly tuff with some phenocrysts		101 (6.3)					101 ((1.0)
Oblate shale and tuff		3 (0.2)					3 (0.01)
Total	**8456 (100)**	**1599 (100)**	**7 (100)**	**2 (100)**	**2 (100)**	**4 (100)**	**10,070 (100)**

Tuff 1 temper (unmodified volcanic tuff) is characterized by angular to very angular temper grains of low sphericity with a range of grain sizes from fine to very coarse sand. Vitric felsite is the predominant component, along with either quartz or sanidine. Tuff 2 temper (modified volcanic tuff) was defined as representing a mixture of volcanic tuff with some other tempering material, sufficiently distinguishable by either its composition or its morphology to be considered a purposeful addition. Main modifying components observed are anthill sand and incompletely wetted clay lumps. Morphologically, some Tuff 2 (modified volcanic tuff) tempers can be similar to anthill sand, although observed mixtures are variable in composition and morphological characteristics.

While LA 86534 is located in the Airport Tract near LA 135290, the majority of whiteware pottery was tempered with some form of fine tuff, and clay fragments were very rare. At LA 86534, four of the seven whiteware sherds subjected to petrographic analysis contained Tuff 2 (modified tuff) temper. The remaining sherds are tempered with Tuff 1 temper (unmodified volcanic tuff; n = 2) and anthill sand (n = 1). Seven of the nine whiteware sherds from LA 12587 have Tuff 2 (modified volcanic tuff) temper while one is tempered with anthill sand with clay lumps and another has Tuff 1 (unmodified volcanic tuff) temper. The primary differences in temper from Santa Fe Black-on-white sherds from LA 86534 and LA 12587 is a slightly higher frequency of sherds with numerous fine silt particles at LA 86534. A reexamination of a sample of Santa Fe Black-on-white sherds from the two sites indicates a slightly higher frequency of sherds with a silty paste at LA 86534. It is possible that the higher frequency of Tuff 1 (unmodified) temper noted at LA 86534 along with the distinct tempers noted at LA 135290 may reflect variations in clays from the Culebra Lake deposits that were being used during the Early and Middle Coalition period (Lakatos 1995).

Petrographic analysis indicates strong differences in the whiteware from LA 4618 (Wilson 2006). Six of the nine whiteware sherds (including Santa Fe and Wiyo Black-on-white) are tempered with Tuff 1 temper (unmodified volcanic tuff). Visual characteristics of temper in whitewares from LA 4618 indicate that the majority of sherds from this site were tempered with similar material. Biscuitware pottery is consistently tempered with Tuff 1 temper (unmodified volcanic tuff). Both compositionally and morphologically, the Tuff 1 (unmodified tuff) tempers in whiteware pottery from this site are generally similar to those of other sites studied. As a result, a shift to the use of crushed tuff temper, common during the Classic period, may have first occurred during the Late Coalition period. Three of the Santa Fe Black-on-white sherds from this site, however, are tempered with granitic sand. This temper type is considered to be non-local to the Pajarito Plateau and only occurs in a few grayware samples from sites also dating to the Classic period. This further suggests some shared characteristics in the use of specific tempers used by the inhabitants of LA 4618 and later Classic period sites. Later changes in whiteware pottery may reflect either the use of natural clay sources with higher amounts of tuff temper or the actual addition of fine tuff or ash to the clay.

Some of these differences were not readily detected during the binocular examination of temper, during which roughly equal amounts of tuff and tuff and sand were recorded. Most of the Santa Fe Black-on-white sherds are characterized by combinations of a variety of very small particles in varying proportions. These include small, rounded, white to tan silt grains, small angular white laminated ‘pumice’ particles, small linear black to glassy ‘ash,’ and larger rounded clear quartz phenocrysts. Examples of temper with numerous larger quartz fragments were assigned to the anthill sand or tuff with phenocrysts category. Examples with distinct sand grains were assigned to a tuff and sand category. Examples dominated by larger tuff grains were assigned to a larger vitric tuff category. The differences in combinations and frequencies of most particles, as examined through a binocular microscope, tended to be gradational; in most cases, it was not possible to differentiate temper. This resulted in the classification of most examples with very fine particles size as fine tuff.

Later changes, which are first reflected by pastes from LA 12587 and then more dramatically by those from LA 4618, may indicate a shift toward the use of self-tempered clay sources. These sources have higher amounts of tuff temper or the actual addition of fine tuff or ash to the clay and appear to correspond with observations from other studies. The shift from Santa Fe Black-on-white ceramics produced with local tempers to types with added temper is not only represented by transitions resulting in the production of biscuitwares on the Pajarito Plateau and Chama Valley, but is also reflected by the appearance of various other types with added tempers produced in various areas of the Rio Grande during the latter part of the Coalition period. Examples of such types include Pindi Black-on-white with large crushed pumice temper, Galisteo Black-on-white with sherd temper, and Poge Black-on-white with sand temper.

The majority of grayware ceramics from Coalition period sites are tempered with a similar material consisting of a very-coarse-grained angular sand of mixed sphericity. This material is characterized here as anthill sand and appears to have been consistently used in grayware vessels to provide a fairly coarse material suitable for utilitarian functions such as repeated exposure to heat during cooking. Comparisons with collected alluvial sands from two local drainages, Pueblo and Los Alamos canyons, and anthill sands allowed discrimination among the coarse sand tempers on the basis of morphological characteristics (see Chapter 59, this volume). Anthill sand dominates in grayware pottery from all the Coalition period sites examined here and can be readily distinguished from alluvial sand both in terms of morphology and composition. Anthill sand is characterized by angular to subangular sand of mixed sphericity with a bimodal grain size distribution. Composition in the study area is dominated by sanidine and quartz, but plagioclase feldspar is also present. Later grayware forms, which are associated with Classic period occupations, were occasionally tempered with granite.

All of the nine thin-sectioned grayware sherds from LA 135290 were tempered with anthill sand. There was one exception that contained sanidine and quartz as the dominant particles (see Chapter 59, this volume). Of the eight grayware sherds from LA 86534, five were tempered with anthill sand. All of these contained sanidine and quartz as the two most common particles. Three were tempered with Tuff 1 (unmodified tuff) temper. Under the petrographic microscope, the samples from LA 86534 appear to have a very homogeneous temper composition that is characterized primarily by sanidine and quartz, with lesser amounts of sanidine-bearing felsite and minor plagioclase. Samples from LA 135290, while also characterized primarily by sanidine and quartz, show much more varied secondary and minor temper components including sanidine felsite and minor plagioclase, tuff and vitric felsites, intermediate volcanics, and K-feldspar. Quantitatively, the proportion of plagioclase is lower and is more variable in the samples from LA 135290 relative to those samples from LA 86534. All 10 of the grayware sherds were tempered with anthill sand. This temper is generally similar in both composition and morphology to anthill sand tempers from the other sites.

While similar tempers were noted in Santa Fe Black-on-white ceramics occurring at sites throughout much of the Rio Grande region, it is likely most of the Santa Fe Black-on-white sherds were produced on the Pajarito Plateau. Styles and manipulations noted in these sherds are similar to those noted in Santa Fe Black-on-white ceramics from other areas of the Rio Grande, but are distinct from those noted in other regions of the Southwest.

The examination of pastes and manipulations associated with grayware pottery from the Coalition period may also provide clues concerning the production and exchange of utility forms during this period. Grayware ceramics from the C&T Project Coalition period sites tend to be fairly consistent in terms of pastes and surface characteristics. Vessel forms are almost exclusively represented by wide mouth jars with dark gray to black sooted exteriors. Exteriors surfaces on grayware types exhibit similar smeared corrugated treatments and interiors are completely unpolished with temper grains showing through the surface. Grayware ceramics consistently fire to similar red colors in a controlled oxidation atmosphere, which indicates the use of high-iron clays.

Grayware ceramics from all the C&T Project Coalition period sites examined consistently exhibit anthill sand temper. This temper is characterized visually by the presence of significant amounts of clear sand-like quartz phenocryst particles that are relatively large as compared to other particles and surrounded by tuff particles of various sizes. The basis for the separation of this temper from other "local" tuff categories was the presence of quartz phenocryst particles of large size. While variability was noted in the density and characteristics of these particles, they could not readily be separated into distinct categories. Almost all the indented corrugated and smeared corrugated sherds that contained anthill sand were subjected to petrographic analysis and contained mineralic temper. Comparisons with reference samples of anthill sand allowed for the recognition of this bimodal distribution as the result of a mixture between a very coarse mineral sand or the anthill sand component and the much finer sand contained in the clay. Petrographic analysis indicates possible differences in the anthill sand from the two Coalition period sites. Those from LA 86534, which is located in the Airport Tract, were characterized as almost exclusively of felsic volcanic origin either of a vitric or tuffaceous matrix. In contrast, most of the samples from LA 12587 in the White Rock Tract included plagioclase-rich, trachytic felsic, or indeterminate volcanic. This lithology appears to be absent within the Bandelier Tuff volcanic sequence that characterizes the Pajarito Plateau and likely corresponds to the more mafic composition of the Cerros del Rio volcanic field, which is located east of LANL. These attributes could indicate some specialization and short-distant exchange of this pottery.

Temper assigned to this category appears to have first been used during the Coalition period and reflects the common utilization of sorted tuff sources by potters on the Pajarito Plateau. The recognition of this temper as compared to micaceous granites and other materials utilized outside the Pajarito Plateau may provide the opportunity to examine broader patterns in production and exchange ties not possible through the visual examination of whiteware temper where tuff temper was used over a wide area.

During the Late Developmental period, when settlements in the northern Rio Grande region were mainly distributed along the drainages of the Rio Grande Valley (e.g., the Tewa and Santo Domingo basins), almost all grayware pottery was tempered with crushed micaceous granite common in this area (Wilson, n.d.). It is interesting to note that the majority of utilitywares from LA 82601, the only Late Developmental site examined during this study, are tempered with granite with mica although a significant number are also tempered with anthill sand (Table 58.51). As settlements became established at sites on the Pajarito Plateau and in other areas where micaceous granite sources were not readily available, material for potential temper may have been largely limited to local tuff or ash sources. The need for temper suitable for using in gray cooking jars was met through the use of material from sorted tuff deposits where larger quartz grains would have been present.

The majority of the grayware pottery from Coalition period sites in the Santo Domingo Basin is also tempered with anthill sand temper where it replaces the micaceous granite temper present in graywares produced during the Late Developmental period. Petrographic analyses conducted during the Peña Blanca Project indicate that grayware sherds tempered with anthill sand recovered from Coalition period sites from the Cochiti area were not locally produced but may represent pottery produced on the Pajarito Plateau. This may indicate the specialization and short-distant movement of grayware pottery somewhere on the Pajarito Plateau to the Cochiti area, and may reflect trends similar to those seen in the petrographic analyses of the C&T Project sites.

Micaceous granite temper that appears to be identical to that used during the Late Developmental period (Wilson, n.d.) continued to be used at settlements in the Tewa Basin during the Coalition period. At the Tesuque Valley Ruin, a Coalition period site near Tesuque Pueblo, almost all the grayware types were tempered with similar micaceous granite. These differences indicate very little exchange of utilitywares between the Tewa Basin and Pajarito Plateau sites. While grayware from Coalition period assemblages in the Santa Fe Valley are dominated by micaceous granite temper, about one-fifth of the graywares are tempered with anthill sand. It is possible these settlements were more closely linked to the Cochiti area and the Pajarito Plateau through routes along the Santa Fe River than those in the Tewa Basin.

Other distinct characteristics were noted in grayware pottery from the Coalition period C&T Project sites when compared to contemporary pottery produced in other regions of the Southwest. The most obvious trait is the dominance of smeared corrugated manipulations. Another distinct characteristic relates to the rarity of distinct rim fillets, which are present on the majority of contemporary grayware vessels produced in most Southwestern regions. Over 70 percent of the corrugated grayware pottery for which this attribute was recorded has no rim fillet. The interior of this grayware pottery is very smoothed, particularly when compared to contemporary micaceous grayware pottery from Coalition period sites in the Tewa Basin.

Table 58.51. Distribution of ware groups and ceramic traditions at Coalition period sites.

Ware	Tradition	4618	12587	61035	85864	86534	86607	99396	135290	Total

Histor-ic Poly-chrome	Historic Tewa	4 (0.0)								4 (0.0)
Total		**10,070 (100)**	**10,363 (100)**	**11 (100)**	**2 (100)**	**3925 (100)**	**9 (100)**	**85 (100)**	**4021 (100)**	**28,486 (100)**

The dominance of grayware sherds with anthill sand, red-yellow firing pastes, and similar surface characteristics indicates the utilization of very distinct resources and technologies characteristic of the Pajarito Plateau. The rarity of pottery tempered with micaceous granite that would have originated in the valleys to the west indicates the absence of exchange of grayware pottery between these areas and seems to indicate these areas were not closely linked in an exchange network involving the movement of grayware vessels. This trend contrasts with the dominance of anthill sand, which appears to have been locally unavailable in grayware vessels in Coalition period sites in the Cochiti area and a small significant frequency of grayware containing this temper in Coalition period sites in the Santa Fe Valley.

In summary, paste characteristics noted for both decorated whiteware and grayware pottery seem to reflect the utilization of tuff from formations or other sources on the Pajarito Plateau, with distinct variations selected for the different ware groups. Petrographic analyses indicate the possible utilization of distinct sources in the production of both whiteware and grayware pottery at different sites. However, these distinctions have thus far been difficult to distinguish through visual analysis, although future studies may try to extend distinctions made during petrographic analysis to visual distinctions. There is some evidence of spatial specialization of production and short-distant movement of grayware vessels. Evidence of local production also contrasts with the strong similarities in design styles of whiteware and grayware textures and support previous models indicating the local production of similarly constructed and decorated pottery over an extremely wide area of the Rio Grande region.

Almost all the pottery from Coalition period sites was assigned to pottery types of the northern Rio Grande region (Table 58.51). The use of extremely distinct paste technologies and decorative conventions by potters outside the northern Rio Grande region provide for a relatively easy identification of pottery produced in a number of different regions. Pottery assigned to the Rio Grande whiteware tradition includes single examples of Jemez Black-on-white and Gallina Black-on-white from areas to the west. Other nonlocal ceramic traditions reflected by types from Coalition period sites include Cibola Whiteware, Northern Jornada Mogollon (Chupadero) Whitewares, White Mountain Redware, San Juan Whiteware, and Mogollon Brownware types. The presence of this pottery indicates a pattern of very limited exchange with groups over a very wide area. However, this exchange network does not appear to have been concentrated in a particular area or even direction, but seems to reflect sporadic contacts or ties with groups scattered throughout the highlands of the Southwest.

Evidence of Classic Period Exchange and Production Patterns

Distributions associated with the small amount of pottery from Classic period components also seem to support patterns of economic specialization and regional integration discussed in models of tribalization (Habicht-Mauche 1993). The widespread exchange of specialized pottery forms produced in different areas of the Rio Grande region would have ultimately linked multiple pueblos into distinct "tribal" networks (Habicht-Mauche 1993; Vint 1999). In the northernmost areas of the Rio Grande region, which includes much of the Pajarito Plateau, Chama Valley, and Tewa Basin, the tradition of organic-painted whiteware forms reflected earlier in Santa Fe Black-on-white continued with the production of biscuitware types throughout the Classic period. In much of the southern part of this region where Santa Fe Black-on-white was also produced during the Coalition period, this earlier decorated black-on-white technology was replaced by a glazeware technology that first developed in areas to the west. Early in the Classic period, distinct forms of glazeware with distinct tempers were produced over a wide area. The north/south distributions of biscuitware versus glazeware types appear to roughly correspond with historical boundaries of Tewa- versus Keres-speaking Pueblo groups (Vint 1999). Both Keres and Tewa Pueblo groups claim the area between Frijoles and Ancho canyons, which is north of the Cochiti area and functions as the temporal dividing line between these groups (Mera 1935). Sourcing and petrographic studies conducted on Rio Grande glazeware pottery indicate the specialization and wide distribution of glazeware forms produced in specific areas where distinct temper resources were available and used (Shepard 1942, 1965; Warren 1969).

Most of the ceramics from Classic period sites are represented by types in the northern Rio Grande tradition, although glazeware types are represented in low frequencies. Characteristics of temper and clay noted for grayware and whiteware include some material sources similar to those noted for earlier Coalition period sites, but overall distributions are very different.

The majority of the grayware pottery from Classic period sites exhibited a combination of pastes and surface treatment. Most of the graywares from Classic period assemblages exhibited yellow-red firing pastes and smeared corrugated treatments similar to that noted in grayware types from the Coalition period sites. Some of the pottery from Classic period sites tempered with anthill sand also exhibited micaceous slips and treatments common in Sapawe utilityware.

Petrographic analysis of grayware pottery associated with the Classic period sites contained sherds tempered with anthill sand that indicate they were tempered with plagioclase trachytic felsic volcanic rock (Chapter 59, this volume). This temper is similar to that noted in Coalition period utilitywares and indicates the continual use of similar sources probably derived with the Bandelier tuff sequence. Grayware that have either granite with mica or Sapawe Igneous temper were distinguished from the local anthill sand temper by the presence of visible minerals, and they have mineralic tempers derived from a granitic or metagranitic temper source. Temper assigned to both categories was described during the petrographic analyses as crushed granitic rock with mica. In contrast to anthill sand, sources for micaceous granitic rock temper would not have been readily available to potters on the Pajarito Plateau. The similarity of temper and other characteristics of Sapawe Gray with pottery tempered with micaceous granitic rock from the nearby Tewa Basin indicate that this pottery may have originated in this area where the micaceous temper is locally available.

Distributions of grayware temper indicate a great deal of variation in temper type from Classic period sites (Tables 58.52 through 58.74). Sites where grayware sherds were examined are largely dominated (75% or more) by anthill sand temper and are represented at LA 21596B, LA 85404, LA 85606, LA 85861, LA 135291, LA 128804, LA 128805, and LA 135292; whereas those sites where the majority of grayware sherds were largely dominated by some form of micaceous granitic rock temper consist of LA 85867, LA 70025, LA 15116, LA 86605, and LA 127634. Sites in which relatively even mixtures of the two temper groups were represented in grayware sherds consist of LA 21596C, LA 127627, LA 85413, LA 86637, and LA 85408. At one other site (LA 85411), the most common temper category was large vitric tuff. This temper probably originated from local tuff sources, but appears to represent a distinct source distinguished from those used at other Classic period sites in the area. Distributions of temper classes appear to be variable through time and across spaces and a wide distribution of temper groups was noted within and between tracts as well as in different temporal spans within the Classic period.

Most of the decorated pottery from Classic period sites includes whiteware forms with similar paste and surface characteristics resulting in their assignment to biscuitware types or Sankawi Black-on-cream. This pottery consistently has a similar fine tuff temper and red firing paste. The dominance of these whiteware types in decorated assemblages and the presence of locally available resources indicate they were probably locally produced. Much of this pottery is well made and exhibits similar buff to tan surfaces, painted decorations, and rim profiles. It is likely these whiteware types represent specialized forms produced at or near their site of recovery, although similar pottery appears to have been widely exchanged into other areas of the Rio Grande region. Petrographic analysis of the biscuitwares indicates a homogenous group, particularly when compared to Coalition period whiteware pottery composed primarily of lithic volcanic tempers, which appear to be derived from vitric felsite (Chapter 59, this volume). The biscuitware types have tempers that are characterized by their uniform volcanic composition, angular to very angular morphology, low sphericity, and high frequency of vitric felsites as the predominant component. Biscuitware types appear to be consistently tempered with Tuff 1 temper (unmodified volcanic tuff), and a shift to the use of crushed tuff temper common during the Classic period may have first occurred during the late part of the Coalition period. Although distributions of temper in biscuitware types seem to suggest the utilization of fewer sources and thus greater specialization than represented in Santa Fe Black-on-white, the distribution of feldspar types in the biscuitware types displays some site variability that may suggest local production.

Almost none of the pottery associated with the Classic period was assigned to types other than those associated with the middle or northern Rio Grande tradition. The few grayware sherds assigned to the Cibola tradition on the basis of sand temper still could have been produced in the northern Rio Grande region. The strongest evidence of pottery produced in other areas of the Pajarito Plateau is represented by the presence of glazeware and micaceous utilityware types. As previously indicated, the glazeware types may represent specialized forms from several different production areas. Petrographic analyses indicate that the similarities in biscuitware temper from different sites contrast with the differences in earlier Santa Fe Black-on-white from the different sites examined during the present study. These differences indicate that the areas of production of biscuitware types may have been more limited and specialized than for earlier Santa Fe Black-on-white.

The presence of grayware forms with micaceous temper may reflect increasing interaction with other groups in the Tewa or Santo Domingo basins as well as other areas where this temper was more commonly used (e.g., see Chapter 76, Volume 4). The increase in exchange of micaceous grayware vessels may also represent the movement of increasingly specialized cooking forms. Such specialization may be reflected in the thinness of this pottery and the application of distinct micaceous slips on the exterior surface.

Glazeware types were consistently present in low frequencies at Classic period sites. About 3 to 8 percent of the pottery recovered from the Classic period sites are represented by glazewares. As previously indicated, this pottery was not produced at sites on the central Pajarito Plateau, but originated at communities to the south including areas of the southern Pajarito Plateau where glazeware types dominate decorated pottery (Goff 2005; Mera 1933; Shepard 1942, 1965; Vint 1999). Glazeware types were noted at 11 of the sites with larger assemblages resulting in components assigned to the Classic period. Temper types recorded for these glazeware sherds included various forms of fine tuff, basalt, and latite (Table 58.75). Glazeware sherds from three sites were tempered with fine tuff, those from eight sites were tempered with basalt, and those from four sites had latite temper. Despite the small sample of glazeware pottery noted, this variation in glazeware temper is consistent with observations noted for other sites on the Pajarito Plateau (Goff 2005). The distribution of these tempers indicates that the glazeware ceramics examined during this project could have been produced in a number of areas to the south including areas of the southern Pajarito Plateau, Galisteo Basin, and northern Santo Domingo Basin.

VESSEL USE

Pottery traits indicative of vessel use are reflected in ceramic ware group distinctions and vessel form categories. Distributions of attributes associated with these categories may indicate differences in the kind and range of activities for which ceramic vessels were used. Comparisons of functionally related traits at contemporaneous contexts may provide clues concerning the organization of activities and tasks in which pottery was used. Changes in distributions of such traits in assemblages assigned to different periods may provide insights concerning changes in the use of pottery in organization of various tasks that may reflect broader economic changes.

Functional Distributions at Coalition Period Components

Overall distributions of ware group and form categories are very similar at most Coalition period sites. For larger assemblages (over 100 sherds), grayware types from sites dating to all spans of the Coalition period make up just over 80 percent of the total pottery (Tables 58.14, 58.25, and 58.27). Grayware types from all of these sites are almost exclusively represented by wide mouth cooking jars. The majority of these jars exhibit coarse pastes, fairly wide rim diameters relative to size, dark-sooted exteriors, and smeared corrugated exteriors. The homogenous nature of this pottery appears to reflect pottery produced primarily for use in cooking. While the number of grayware jar rim sherds for which rim radius could be recorded was very small, a very wide range of sizes was indicated. The next most dominant form is represented by grayware forms, which could not be assigned to a particular category because of one or more missing surfaces. It is likely, however, that most of the sherds assigned to this category were derived from jars. An extremely low frequency of grayware pottery appears to have been derived from bowls. Other forms noted in extremely low frequencies in grayware pottery from Coalition period sites include jar body with lug handle, indeterminate coil or strap handle, miniature jar, miniature pinch pot, cloud blower, effigy, and appliqué.

Sherds assigned to whiteware types consisted of just over 15 percent of the pottery from these Coalition period sites. Whiteware pottery from Coalition period sites appears to represent a very homogenous group, resulting in the classification of most decorated pottery from Coalition period sites as Santa Fe Black-on-white. The majority of whiteware sherds from sites dating to this period are derived from bowls (Tables 58.76 through 58.82). These bowls tend to be slipped on the interior surface and unpolished on the exterior surface, exhibit fine tuff temper, and are fairly thin and well-fired. A wide range in vessel size is represented. The next most dominant category is represented by sherds that could not be assigned to a specific form because at least one surface was missing. Many of the sherds assigned to this category are assumed to have derived from bowls. Another whiteware category consists of jars that tend to make up about 5 percent of the whiteware sherds from Coalition period sites. Many of the jar forms are from pottery types associated with nonlocal traditions such as Chupadero Black-on-white. Other forms represented by extremely low frequencies of whiteware sherds include gourd dipper, bowl dipper, indeterminate coil or strap handle, and canteen rim.

Thus, the overwhelming majority of pottery recovered from Coalition period sites are represented by two fairly standardized functional groups and include smeared corrugated jars and whiteware bowls (also see Vierra 2000). While pottery assemblages associated with occupational sequences scattered over much of the northern Southwest are commonly dominated by similar grayware jar and whiteware bowl forms (Wilson and Blinman 1995b), the homogeneity of these forms is particularly notable at Coalition period sites in the northern Rio Grande; whereas, in Late Developmental site assemblages, grayware jar sherds exhibit a much higher range of exterior-textured treatments and whiteware pottery is represented by a wider range of forms including a higher frequency of jars (Wilson, n.d.).

It is likely that the patterns noted for Coalition period pottery in the northern Rio Grande reflect both widespread consensus concerning the appropriate way to produce and decorate utility- and whiteware vessels discussed earlier, as well as their intended use in very specific and similar ranges of tasks in most contexts. The dominance of smeared corrugated vessels, which consistently represent about 70 percent of the sherds at Coalition period sites, reflect the importance and the specialized nature of tasks relating to the cooking and storage of food. Whiteware vessels also appear to have been intended for use in distinct tasks associated with the serving and preparation of food. This may indicate that tasks relating to food preparation and serving were organized in similar and standardized fashions during the Coalition period in the northern Rio Grande.

Functional Distributions at Classic Period Components

Distributions of ceramic traits noted for Classic period components identified during the C&T Project analysis indicate a higher degree of variation in functionally related traits than noted in

Coalition period components (Tables 58.83 through 58.104). For example, a considerable amount of variability was noted in the frequency of ware groups, with some sites dominated by grayware and others by whiteware types. Sites in which the majority of pottery is represented by grayware sherds consist of LA 85404, LA 85861, LA 86606, LA 127635, LA 141505, LA 85414, LA 127625, LA 85413, LA 85867, LA 135291, LA 70025, LA 85411, LA 87430, LA 128804, LA 128805, and LA 135292. Distributions at sites dominated by grayware are also quite variable, with grayware at some of these sites representing just over 50 percent and over 85 percent at others. Ceramic assemblages from Classic period sites that were dominated by whiteware sherds consist of LA 21596B, LA 21566C, LA 86637, LA 15116, LA 85408, LA 86605, LA 110126, and LA 127634.

The variability in ware groups noted at assemblages assigned to the Classic period compared to trends noted for Coalition period assemblages may partly be a reflection of the small number of sherds in the Classic period assemblages. For example, all assemblages assigned to the Classic period consist of less than 500 sherds. In such assemblages, sherds from a single grayware or whiteware vessel can have a strong influence on the relative frequency of wares represented. Despite the influence of small sample size, it is still likely that the relatively high variation in ware group across sites indicates a real trend. This reflects a trend noted in other Classic period sites in the northern Rio Grande region and may indicate that a range of activities were being conducted at these sites.

The high variability in exterior surface finish of grayware types resulted in the identification of a wider range of grayware types. Classic period grayware pottery includes significant frequencies of forms with plain and smeared corrugated exteriors, as well as lower frequencies with micaceous slips, and a great deal of variation in the dominant form dominating at different sites. Grayware assemblages from some sites are dominated by plain exteriors and others by smeared corrugated exteriors. While smeared corrugated exterior treatments are still relatively common during this time period, there is an increase in obliteration resulting in more examples recorded with plain treatments. The combination of variation in surface and paste characteristics results in the dominance of different grayware types at different Classic period sites. Some are dominated by smeared corrugated forms similar to those dominating all Coalition period sites, while others are dominated by plain corrugated and Sapawe utilityware. This variation in types assigned to grayware vessels may also have functional implications. Another attribute that may have functional implications relates is the use of micaceous pastes or application of micaceous slips.

Another interesting contrast with Coalition period sites is the relatively high frequency of whiteware jars, which make up a small but significant frequency of the total whiteware sherds (Tables 58.77 through 58.81; Vierra 2000). This, along with the common occurrence of jars and other forms in the glazewares, seems to reflect a higher range of activities for which decorated wares were used during the Classic period. This may indicate a higher variation in activities for which different ware groups were used during the Classic period.

Other examples of historic ceramic types were identified at sites dominated by prehistoric types including LA 4618, LA 12587, and LA 85417 (Table 58.105). It is difficult to determine the specific time span represented by this pottery, although Tewa Polychrome, which was identified at LA 4618, dates to the 18th century.

Table 58.105. Distribution of Historic period ceramics (count/percent) at prehistoric sites.

Type	LA 4618	LA 12587	LA 85417

Ceramic Stylistic Change

Observations relating to the style and technology of pottery associated with various temporal periods indicate a long and gradual series of changes in the production of ceramic vessels produced in the northern Pajarito Plateau. The continual production of “whiteware” forms decorated in organic paint from the earliest part of the Coalition period to the Classic period and into the Historic period distinguishes the northern Pajarito Plateau pottery sequence from other regions to the south. In these more southerly regions, glazeware was produced during the Classic period and links it to those in the Tewa Basin and Chama Valley. The similarities provide further evidence that groups in the Pajarito Plateau are ancestral to the northern Tewa Pueblos that now occupy the Tewa Basin. In fact, some innovations and changes (e.g., the shift to biscuitware forms) may have been largely focused on the Pajarito Plateau. Thus, it is likely that changes documented in this area played a very important role in influencing pottery forms and styles that are still being produced by northern Tewa potters.

Characteristics associated with the earliest Santa Fe Black-on-white forms, including the general absence of forms other than bowls, the lack of polished or painted bowl exteriors, the dominance of tapered or painted rims, and the persistence of simple band organizations contrast with the characteristics associated with pottery produced from the Mesa Verde or northern San Juan region. In contrast, similarities in styles noted between Kwahe’e Black-on-white and Santa Fe Black-on-white suggest that populations may have migrated into the northern Pajarito Plateau from adjacent areas to the east (e.g., the Tewa Basin and Santa Fe Valley), although the Pueblo III styles occurring in Mesa Verde types also occur in Coalition period types in the northern Rio Grande region.

An examination of Santa Fe Black-on-white ceramics from sites dating to various parts of the Coalition period indicates a great deal of stylistic similarity across space and through time. Traits distinctive to Santa Fe Black-on-white include the absence of rim ticking or decoration, thin walls, and the lack of polish, slip, or painted decorations on the vessel exterior. Another distinctive characteristic of Santa Fe Black-on-white ceramics relative to other types of contemporaneous pottery from regions to the west is the total dominance of bowl forms and the almost complete absence of jars, kiva jars, and ladles.

Slight differences in the frequencies of pottery attributes recorded at LA 4618 indicate a greater average rim thickness and higher surface polish at components occupied during the Late Coalition period. Another change occurring during this time includes the shift to small, dense, Tuff 1 (unmodified) temper. Together these changes seem to mark the transition into Wiyo Black-on-white and early biscuitware types.

While the sample of rim sherds from Classic period sites was too small for stylistic analysis, attributes used to distinguish biscuitware types from earlier Coalition period types indicate the appearance of a new technology characterized by distinct pastes and temper, new firing regimes, thicker walls, and the use of wider lines organized into distinct overall designs such as Awanyu forms. Later biscuitware forms are represented by the presence of slipped, polished, and painted exterior surfaces, increased decoration, variable and flaring rim shapes, and increased jar forms.

Such changes continue during the Classic period where they are reflected by the distinct rims shapes associated with biscuitware and distinct pastes associated with Sankawi Black-on-cream.

One of the more interesting stylistic observations from this project was the occurrence of very low frequencies of Santa Fe Black-on-white from almost all the sites with Classic period components. At first such associations were assumed to reflect mixing from earlier components. A second look at evidence from this project and other areas seems to indicate that Santa Fe-like pottery continued to be made in low frequencies at much later dates than previously assumed. Recent analyses of the ceramics from the Civic Center in downtown Santa Fe indicate evidence of production of a late variety of Santa Fe Black-on-white that may be characterized as Pindi Black-on-white in contexts associated with early biscuitware and glazeware types. This type essentially represents a late variety of Santa Fe Black-on-white that may be distinguished from earlier varieties of this type by the presence of added vitric tuff temper and distinct paste and slip clays. In retrospect, it is likely that some of the Santa Fe Black-on-white ceramics identified from the Early Classic period C&T Project sites may actually represent Pindi Black-on-white or a related phenomenon associated with localized production of Santa Fe-like pottery after biscuitwares began to be produced on the Pajarito Plateau. Thus, it is not surprising that many of the Classic period sites included some Santa Fe Black-on-white.

CHAPTER 59
PETROGRAPHIC ANALYSIS OF POTTERY FOR THE CONVEYANCE AND TRANSFER PROJECT, LOS ALAMOS NATIONAL LABORATORY

Elizabeth J. Miksa

INTRODUCTION

Petrographic analysis of potsherds and corresponding resource samples (sands, clays, or crushed rock) has been used to develop provenance data for ceramics over the past 100 years or more. For the Pajarito Plateau Conveyance and Transfer (C&T) Project, pottery has been analyzed over all five project phases to add information about pottery provenance and technology.

Several pottery production and economy questions can be addressed using the sample set presented here. The first questions are very simple and direct in nature: what types of materials were used to make the pottery under study? Were they mixtures of clay and temper? If so, what types of tempering material were used? Is it possible to distinguish among primary rock temper, crushed rock temper, and various sources of sand? Once temper types—and thus broad sets of temper sources—are identified, can we see variations through place and time?

Previous yearly reports in this series have detailed the answers to some of these questions and hinted at patterns for others (Castro-Reino 2004, 2005; Castro-Reino and Lavayen 2002). In this chapter, I will examine primarily temporal, ware-based patterns that can be seen now that the full data set is available for comparison. Unfortunately, the petrographic sample was not selected as a strict representation of the overall ceramic set. It cannot be used to answer smaller scale questions such as geographic or contextual distribution of temper composition because the relative frequencies of the observed temper groups by ceramic type are not known.

THE PETROGRAPHIC SAMPLE

A total of 171 sherd, sand, and rock samples were submitted for thin-sectioning and subsequent petrographic analysis over the course of the project. The vast majority are sherd thin sections; only a few rock and sand comparative samples were collected (Table 59.1). Note that 175 sherds were actually submitted for analysis, but some were unsuitable for thin-sectioning (see Appendix Q, Table Q.1). In the end, 161 sherds, six rocks, and four sand samples were thin-sectioned. All of the sherds and sands were point counted, but the rocks were not. The sherds were drawn from 24 sites across the five tracts included in the C&T Project, as well as two previously excavated sites in two additional technical areas (LA 4618 and LA 4624 in Technical Area (TA) 54, Areas L and G, respectively). The sherds represent the full geographic range of the C&T Project sites (Figure 59.1).

Because of the nature of this data set, its primary use is in comparing the textural and compositional features of the sand-sized fraction by ware through time (see Appendix Q, Tables Q.1 and Q.2). Each year of analysis allowed various attributes to be explored.

[a]Rock samples were described petrographically but not point counted. An additional 16 rock samples were examined but not thin-sectioned.

The first year of petrographic analysis, 2002, occurred as fieldwork for the C&T Project was getting underway. To develop a sense of primary temper attributes, 18 sherds from LA 4624, a previously excavated site, were submitted for thin-sectioning (Tables 59.2 through 59.4). These sherds were evenly split among plain, corrugated, and Santa Fe wares and were examined primarily to establish temper type. Petrographic analysis was conducted by Sergio Castro-Reino and Carlos Lavayen. All of the sherds were found to have sand temper, though some differences in the angularity, roundness, and sorting of the sands were observed (Castro-Reino and Lavayen 2002). Diane Curewitz (personal communication) suggested that some of the differences might point to alluvial sources of sand versus those available from large anthills, and arrangements were made to test this hypothesis.

[a]Some sherds could not be thin-sectioned for size or other considerations, but this inventory preserves the complete original list of sherds sent for analysis.
[b]This column contains object-specific identifier information, in the format "Site-Accession code-Catalog number" or "Site-Provenience code-Object number."

The second group of samples, submitted in 2003 but analyzed in 2004, comprised 68 samples. The six rock samples were thin-sectioned to establish a baseline of rock composition and texture for comparison. Table Q.3 summarizes the rock analysis. Two alluvial sands and two anthill sands were submitted for both textural and compositional analysis (Table 59.5), and thin-section analysis was ultimately completed for 58 of the 60 sherds submitted (see Tables 59.2 through 59.4). LA 86534 from the Airport Tract; LA 12587, LA 86637, LA 127625, LA 128804, and LA 128805 from the White Rock Tract, and LA 21596B from TA-74 are represented in this sample. All of the wares (Biscuit, Corrugated, Plain, Santa Fe Black-on-white, and Sapawi'i) are represented, though plain and Sapawi'i sample numbers were too low for statistical comparisons. The previous year's analysis had suggested that temper type was likely to be sand, so the analysis of this group of sherds was focused on identifying and characterizing the different types of sand. Additionally, both primary and secondary tuff was identified as a temper type in the Santa Fe Black-on-white sherds and in the biscuitwares. Petrographic analysis was conducted by Sergio Castro-Reino. A detailed report of the findings of this phase of analysis was submitted in 2004. Background geology and archaeology and preliminary textural and compositional findings are presented in the report (Castro-Reino 2004).

Table 59.5. Inventory of thin-sectioned rock and sand samples.

Project Year	Sample	Sample type	Location	Sample notes/sampled unit	Type of analysis
2004	PAX37-0061	Tuff	State Road 502 road cut	Guaje Pumice, upper	Qualitative
2004	PAX37-0062	Tuff	Los Alamos Canyon	Cerro Toledo; Lower; OU 1106, Strat. 1-6	Qualitative
2004	PAX37-0063	Tuff	Los Alamos Canyon	Tsankawi Member (sample from pumice bed)	Qualitative
2004	PAX37-0064	Tuff	Los Alamos Canyon	Qbt 1g, lower	Qualitative
2004	PAX37-0065	Tuff	Los Alamos Canyon	Colonnade Tuff	Qualitative
2004	PAX37-0066	Tuff	Los Alamos Canyon	Qbt 2	Qualitative
2004	PAX37-0067	Anthill sand	LA 12587	Bandelier Tuff "Colonnade"	Point count/ qualitative
2004	PAX37-0068	Anthill sand	LA 86534	Bandelier Tuff "Unit 3"	Point count/ qualitative
2004	PAX37-0069	Alluvial sand	Pajarito Canyon	From a channel in Pajarito Canyon, between TA's 36 & 54	Point count/ qualitative
2004	PAX37-0070	Alluvial sand	Pueblo Canyon	From a trench across a channel in Pueblo Canyon	Point count/ qualitative

The third group of samples, submitted in 2004 and analyzed in 2005, comprised 47 sherds submitted for analysis. Of these, six were too small to attempt thin-sectioning, and one was destroyed in the process leaving a total of 40 thin-sectioned sherds (see Tables 59.2 through

59.4). These sherds comprise primarily a set of matched corrugated and Santa Fe Black-on-white sherds, one each from a series of contexts in LA 4618, LA 135290, and LA 99396. The goal of this phase of analysis was to explore compositional and textural variation in the anthill sand and tuff tempers. Petrographic analysis was conducted by Sergio Castro-Reino. Results from this analysis were included in the 2005 Society of American Archaeology presentation by Wilson and Castro-Reino (2005). A copy of this presentation was submitted as a report on the year's progress. The petrographic data strengthened patterns seen in the comprehensive 2004 data set and no additional conclusions were drawn.

The final two groups of samples, submitted in 2005 and 2006 for analysis in 2006 and 2007, comprise sherds from Rendija Tract sites. Thirty sherds from LA 15116, LA 70025, LA 85404, LA 86605, LA 87430, LA 127627, LA 127634, LA 127635, LA 135291, and LA 135292 were analyzed in 2006 by Sergio Castro-Reino. Fifteen sherds from LA 85408, LA 85411, LA 85413, LA 85417, and LA 86606 were analyzed in 2007 by Elizabeth Miksa. Primary analyzed wares were Sapawi'i Micaceous, corrugated, and biscuit, with only a handful of plain and Santa Fe Black-on-white examined. The primary goal of the final two years of petrographic analysis was to further explore composition of the temper in biscuitwares and Sapawi'i Micaceous sherds. The 2006 data were submitted as an interim tabular report. The 2007 data were incorporated into a paper presented at the C&T Project symposium at the 2007 Society for American Archaeology meetings but are presented here in their complete form for the first time.

METHODS

The petrographic analysis used standard qualitative and quantitative evaluation methods. Quantitative analysis of mineralogical composition was accomplished through petrographic modal analysis, or point counting, of all grains that were sand-sized or larger, that is greater than or equal to 0.0625 mm on the medial axis (Chayes 1956). Point counting involves imposing a virtual grid over the sample and counting the grain type found under each grid point. The grid size is based on the coarseness of the sample, with the goal of counting each grain only once. This goal is harder to achieve when the sample is poorly sorted (Chayes 1956).

A Gazzi-Dickinson method was used for the point counting, wherein all sand-sized mineral grains are counted as their specific mineral type, regardless of whether or not they occur in a rock fragment. For instance, a sand-sized quartz grain would be counted as "Quartz" whether it occurs as a free mineral or in a fragment of granite (Dickinson 1970). This method is particularly well-suited to archaeological materials, as it allows comparison of temper to source materials such as sand or rock, even if the relative maturity of the source is not the same as that of the temper (Miksa and Heidke 2001). The only "rock" types encountered using this method are fine-grained lithics in which the individual grain sizes are less than 0.0625 mm. This includes the volcanic rocks, which make up the bulk of the Pajarito Plateau.

The Gazzi-Dickinson point count method can be used with varying degrees of separation of rock types. For instance, one might count "fine-grained rocks," "metamorphic rocks," "sedimentary rocks," and "volcanic rocks," or even break these categories down into specific types of metamorphic, sedimentary, and volcanic rocks. The point count parameters, or groups of grain types selected for this analysis, were developed by researchers at Desert Archaeology, Inc. They follow Dickinson's method but separate the grains into groups that are generally easily recognized under both low- and high-power magnification (Lombard 1987; Miksa and Heidke 2001). This allows maximum use of the petrographic data by ceramicists who are attempting to identify temper characteristics while sorting sherds under low-power magnification. At present there are approximately 50 point count parameters, with the set of parameters used depending on the sample type and geographic area. Some parameters, such as "grog," are unique to sherds. Not all parameters are encountered in all sherds. In general, only 10 to 15 parameters may be encountered in any given sample. A full description of the point count parameters can be found in Table 59.6. At the end of the table are some "calculated parameters," or common parameter combinations used in the statistical analysis. The full set of point count data for the sherds is presented in Tables Q.4.1 through Q.4.4, while the full set of point count data for the sands is presented in Table Q.5; all of these tables can be found in Appendix Q. An attempt was made to count 400 sand-sized grains per sample, whenever possible.

Table 59.6. Point count parameters and calculated parameters used for quantitative petrographic analysis.

PARAMETER	DESCRIPTION
Mineralic Grains	
QTZ	All quartz types.
KSPAR	Alkali feldspars: yellow-stained potassium feldspars or unstained sodium feldspars, perthite, antiperthite.
SANID	Sanidine (alkali feldspar of volcanic origin). This feldspar was only counted separately for samples in the 2004, 2005, and 2006 analysis years. In other years, sanidine was included with potassium feldspar (KSPAR).
MICR	Microcline/anorthoclase: alkali feldspar with polysynthetic (cross-hatch) twinning, stained yellow or unstained.
PLAG	Plagioclase feldspar stained pink, commonly with albite twinning, occasional carlsbad twinning, alteration or sericitization affects less than 10 percent of the grain.
PLAGAL	Altered plagioclase: alteration affects 10 percent to 90 percent of the grain. Alteration products include sericite, clay minerals, carbonate, and epidote.
PLAGGN	Considerably altered plagioclase, with alteration affecting more than 90 percent of the grain.
MUSC	Muscovite mica.
BIOT	Biotite mica.
CHLOR	Undifferentiated chlorite group minerals.
PX	Undifferentiated members of the pyroxene group.
AMPH	Undifferentiated members of the amphibole group.
OLIV [a, b]	Undifferentiated members of the olivine group.
OPAQ	Undifferentiated opaque minerals such as magnetite/ilmenite, rutile, and iron oxides.
GAR [a, b]	Undifferentiated members of the garnet group.

PARAMETER	DESCRIPTION
EPID [b]	Undifferentiated members of the epidote group
SPHENE [b]	Sphene.
CACO [b]	Undifferentiated calcium carbonate minerals (not aggregates; see LSCA below)
Mineralic Grains Derived from Foliated Metamorphic Rocks	
SQTZ [a]	In schist-tempered sherds: All quartz derived from or contained within schist.
SPLAG [b]	In schist-tempered sherds: Plagioclase feldspar (sodic or calcic, altered or fresh) derived from or contained within schist.
SKSPAR [b]	In schist-tempered sherds: Alkali feldspar (sodic or potassic) derived from or contained within schist.
SMUSC [b]	Muscovite mica derived from or contained within schist.
SBIOT [a, b]	Biotite mica derived from or contained within schist.
SCHLOR [a, b]	Undifferentiated chlorite group minerals derived from or contained within schist.
SOPAQ [a, b]	Undifferentiated opaque minerals derived from or contained within schist.
Volcanic Lithic Fragments	
LVF	Felsic volcanic such as rhyolite: microgranular nonfelted mosaics of submicroscopic to microscopic quartz and feldspars, commonly with microphenocrysts of feldspar, quartz, or rarely ferromagnesian minerals. Groundmass is fine to glassy, always has well-developed potassium feldspar (yellow) stain, may have calcium plagioclase (pink) stain as well.
LVFB	Biotite-bearing felsic volcanic: microgranular nonfelted mosaics of submicroscopic quartz and feldspars, often with microphenocrysts of feldspar, quartz, always with phenocrysts of biotite. Groundmass is fine to glassy, always has well-developed potassium feldspar (yellow) stain.
LVI	Intermediate volcanic rock such as rhyodacite, dacite, latite, and andesite.
LVM [b]	Mafic volcanic: visible microlites or laths of feldspar crystals in random to parallel fabric, usually with glassy, devitrified, or otherwise altered dark groundmass. Often with phenocrysts of opaque oxides, occasional quartz, pyroxene, or olivine. Rarely yellow-stained, usually has well-developed pink stain, representing intermediate to basic lavas such as latite, andesite, quartz-andesite, basalt, or trachyte.
LVV	Glassy volcanics: vitrophyric grains showing relict shards, pumiceous fabric, welding, or perlitic structure, sometimes with microphenocrysts, representing pyroclastic or glassy volcanic rocks.

PARAMETER	DESCRIPTION
LVH	Hypabyssal volcanics (shallow igneous intrusive rocks): equigranular anhedral to subhedral feldspar-rich rocks with no glassy or devitrified groundmass, coarser-grained than LVF, most have yellow and pink stain.
	Sedimentary Lithic Fragments
LSS	Siltstones: granular aggregates of equant subangular to rounded silt-sized grains with or without interstitial cement. May be well to poorly sorted, with or without sand-sized grains. Composition varies from quartzose to lithic-arkosic with some mafic-rich varieties.
LSA [b]	Argillaceous: dark, semi-opaque, extremely fine-grained, without visible foliation, may have mass extinction, variable amounts of silt-sized inclusions, representing shales, slates, and mudstones.
LSCH [b]	Chert: microcrystalline aggregates of silica.
LSCA [b]	Carbonate: mosaics of very fine calcite crystals (micrite) with or without interstitial clay- to sand-sized grains. Most appear to be fragments of soil carbonate and are subround to very round. In sherds, this parameter can be broken down into three types: LSCA1 is lumps of carbonate from a soil or sand, LSCA2 is of uncertain origin, and LSCA3 is carbonate that has clearly developed in place within the fabric of the sherd, i.e., carbonate growing within pore spaces.
	Metamorphic Lithic Fragments
LMMF [b]	Microgranular quartz aggregate or foliated quartz aggregate: polygonal aggregates of newly grown strain-free quartz with sutured, planar, or curved grain boundaries.
LMA2 [b]	Metamorphic aggregate: quartz, feldspars, mica, and opaque oxides in aggregates with highly sutured grain boundaries but no planar-oriented fabric. Includes amphibolites, metasediments, and metavolcanics.
LMTTP [b]	Quartz-feldspar-mica tectonite (phyllite, schist, or gneiss): quartz, feldspars, mica, and opaque oxides with strong planar-oriented fabric. Often display mineral segregation with alternating quart-felsic and mica ribbons. Grains are often extremely sutured and/or elongated.
	Other Grains
UNKN	Grains that cannot be identified, grains that are indeterminate, and grains such as zircon and tourmaline that occur in extremely low percentages.
GROG [b]	Also called sherd temper: Dark, semiopaque angular to subround grains with discrete margins, including silt to sand size temper grains in a clay, iron oxide, and/or micaceous matrix. The grains differ in color and/or texture from the surrounding matrix of the "host" ceramic. This parameter is

PARAMETER	DESCRIPTION
	counted only in sherd samples.
CLAY LUMP [b]	Dark semiopaque round grains with discrete margins and a clay, iron oxide, and/or micaceous matrix. The grains have a color and texture similar to the paste in which they occur, but lack silt- or sand-sized fragments. This parameter is counted only in sherd samples.
Totals and Paste Parameters	
Total	The total number of point-counted sand-sized grains.
Paste	The total number of points counted in the silt- to clay-sized fraction of the paste. (Not counted in sand samples.)
Voids	The total number of points counted in open spaces within the paste. (Not counted in sand samples)
Grand Total	The sum of Total+Paste+Voids. In sand samples Total=Grand Total.
Calculated Parameters	
TQtz	QTZ + SQTZ
Tkspar	KSPAR + SKSPAR
TKsparSanid	Sum of Tkspar and sanidine = KSPAR+SKSPAR+SANID
K	Sum of all alkali feldspars = KSPAR+SKSPAR+ MICR+SANID
Tplag	Total plagioclase = PLAG + PLAGAL + PLAGGN+SPLAG
TplagMicr	Sum of Tplag and Micr = Tplag + Micr
F	Total feldspar = K+Tplag
TKsparSanid/F	Ratio of TKSPAR to the sum of all feldspars.
TplagMicr/F	Ratio of MICR to the sum of all feldspars.
Tbiot	BIOT + SBIOT
Tchlor	CHLOR + SCHLOR
Tmusc	MUSC + SMUSC
Topaq	OPAQ + SOPAQ
Pyr	PX + AMPH
Lvf2	LVF + LVFB
Lvm2	LVM + LVI
Tuff	Sum of Lvv (tuff) and related alkali feldspars = LVV + TKsparSanid. (Overall indicator for tuff and its component minerals.)
Plutonic	TplagMicr+Tbiot+Tchlor+Pyr+Topaq. (Overall indicator for the presence of granitic rocks and its component minerals.)
Generic temper composition	Total

[a]These parameters were not encountered in the sherd samples. [b]These parameters were not encountered in the reference sand samples.

The qualitative analysis was accomplished using visual estimation of the "temper" elements of the sherds. For the sand-sized fraction, grain size, roundness, shape, and sorting were estimated. In addition, the composition of the dominant grain type was indicated, as was the composition of up to three accessory grain types. This characterization helps identify the most easily seen grain types in the sample. One consequence of the Gazzi-Dickinson point count method is that the compositional data may not reflect what is most easily seen by eye. For instance both an arkosic sand temper and a crushed granite might have abundant quartz, plagioclase, and potassium feldspar, but the arkose might have plagioclase as the dominant grain type while the crushed granite would have "granite" as the visually dominant grain type. Table 59.7 provides definitions for the textural attributes recorded for the sherds, while Table Q.6 provides the full set of textural and qualitative data collected for each sherd.

Table 59.7. Description of qualitative attributes recorded for the sand-sized fraction.

<table>
<tr><td colspan="2">Textural Attributes</td></tr>
<tr><td>Sphericity</td><td>Are the grains most like a sphere or cube (high sphericity), a shoebox or football (moderate sphericity) or a rod or pancake (low sphericity)?</td></tr>
<tr><td>Angularity</td><td>Does the grain have sharp edges (angular) or are the edges somewhat removed (subangular to subround) or entirely removed (well-rounded)?</td></tr>
<tr><td>Sorting</td><td>Do grains occur in a wide variety of sizes with no dominant size (very poorly sorted), or is there a restricted set of grain sizes (moderately sorted to well sorted)? Are there two distinct modes of grain size (Bimodal)?</td></tr>
<tr><td>Grain size</td><td>Wentworth grain sizes are used to describe the sand-sized fraction
very fine sand (0.0625 - .125 mm)
fine sand (0.125 - 0.250 mm)
medium sand (0.250 - 0.5 mm)
coarse sand (0.5-1.0 mm)
very coarse sand (1.0 - 2.0 mm)
granule (>2.0 mm)</td></tr>
<tr><td colspan="2">Compositional Attributes</td></tr>
<tr><td>Sand fraction grain types</td><td>What are the most common grain types seen in the sand fraction? These may differ from the point count parameters, for instance, a temper counted as coarse-grained quartz, plagioclase, and potassium feldspar might have a dominant grain type of "Granite" or "Plagioclase" depending on whether the parent material is cohesive or disaggregated.</td></tr>
<tr><td>Dominant
Accessory 1
Accessory 2
Accessory 3</td><td>What is the dominant grain type in the coarse fraction?
What is the second most common grain type in the coarse fraction?
What is the third most common grain type in the coarse fraction?
What is the fourth most common grain type in the coarse fraction?</td></tr>
<tr><td>Dominant (grouped)</td><td>This column illustrates how grain types were lumped together for comparison. As an example, granite, granite-gneiss, muscovite granite, and meta-granite were combined together into "Granite or Granite-gneiss" for the purposes of this analysis.</td></tr>
</table>

During the textural analysis, temper type and generic temper group assessments were made. Temper type was not fully evaluated until the second year of analysis, when rock and sand samples and a full suite of ware samples were available for comparison. As used here, temper type refers strictly to the type of material used as temper in the sherds. Broad groups such as "sand," "crushed rock," or "grog" are separated at this level. The temper type distinction is meant to represent the broad class of materials collected to make a paste and should get at basic technological distinctions in pottery technology. Collecting a sand, selecting and crushing a rock, or curating old sherds to grind up later are activities that require quite different planning, procurement, and processing strategies. Table 59.8 presents the criteria developed for temper type analysis for the Pajarito Plateau sherds. It is drawn from work conducted at Desert Archaeology, Inc. (Heidke 1986; Lombard 1987; Miksa 2001a, b; Miksa and Heidke 2001) and from Castro-Reino's work on the 2003 analytical year sherds (Castro-Reino 2004). Note that Table 59.8 includes some "non-tempered" paste types. These are pastes that seem to be made from clays that include sand-sized grains and to which no additional sand-sized materials seem to have been added.

Table 59.8. Qualitative grain characteristics generalized by temper type.

Attribute	**Sand**	**Tuff**
Sphericity	Moderate-high	Low-moderate
Angularity	Subangular	Angular
Sorting	Variable; moderate-well or bimodal	V. Poor-moderate
Modal grain size	V. coarse	Medium
Occurrence of unaltered, cohesive rock fragments	Rare	Common-abundant
Occurrence of phenocrysts (crystals embedded in volcanic rock)	Rare	Common
Occurrence of monocrystalline quartz, feldspar (not in rock fragments)	Common-abundant	Rare
Ratio of minerals:rock	High	Low

By contrast, the generic temper groups are meant to represent similar groups of tempers. For instance, if a sand tempered is desired, then collecting sand, whether from an anthill or a stream, requires broadly similar behaviors. Collecting a particular non-tempered clay with just the right amount of sand-sized inclusions, however, requires a different set of actions. Table 59.9 presents the criteria developed for temper group assignments for the Pajarito Plateau sherds, primarily on the basis of Castro-Reino's work (2004) with modifications based on observations on the 2006 and 2007 materials.

Table 59.9. Generic temper group qualitative characteristics.

Temper Group	Description
Anthill sand	Moderate-high sphericity, subangular to subround, bimodally sorted mineralic sand. Can appear to have polished, dissolved, or rounded edges under high magnification. Mineral:Rock ratio high.
Anthill sand with clay lumps	Same characteristics as anthill sand with the addition of clay lumps in the paste. The clay lumps have low sphericity but are round, medium to coarse grain sizes. They lack the silt fraction apparent in the overall paste and are not tempered. It is not clear if the clay lumps are an additional temper or represent incompletely wetted paste.
Alluvial sand	Moderate sphericity, subangular, moderately to well-sorted mineralic sand. Can appear to have some broken edges or frosted faces under high magnification. Mineral:Rock ratio high.
Granitic sand	Low/moderate sphericity, subangular to subround, poorly sorted, coarse grain size. Granite or granite-gneiss fragments are large and conspicuous, paste is frequently micaceous.
Sedimentary sand	Much like alluvial sand, except that sedimentary rock fragments are present.
Tuff 1 (Unmodified tuff of Castro-Reino 2004)	Fine-grained tuff with small phenocrysts. Low sphericity, angular, moderately/poorly sorted, medium grain size over all. Often has delicate glassy bubbles or stirrup shapes preserved intact. Mineral:Rock ratio very low.
Tuff 2 (Modified tuff of Castro-Reino 2004)	Fine-grained tuff with small phenocrysts. Low sphericity, angular-subangular, moderately sorted, medium grain size over all. Often has broken bubbles or broken glassy fragments; fragments may be rounded. Mineral:Rock ratio elevated over Tuff 1.

RESULTS

The point count and qualitative data from all five years of analysis was combined and evaluated on the basis of composition and texture. For the most part, samples that had been assigned to a particular temper type or group stayed in their original group. Outliers were re-evaluated to see if their temper group should be changed for the final integrated analysis. Table 59.10 presents a summary and explanation of the 36 samples whose final temper assignment was altered.

Table 59.10. List of samples that were reassigned for the final temper groups, with discussion.

Sample	Ware	Tplag Micrpct	Lvpct	Claypct	Petrographer's original temper characterization	Final Temper Group	Comments
PAX33-001	Plain	11.2	1.3	0.0	Sand	Anthill	There was not enough data at the time of the first analysis to define temper groups.

PAX41-0204-2	Santa Fe	11.8	15.2	7.1	Granitic	Anthill	Lvpct is far more than three standard deviations above the mean for Granitic sand, while TplagMicrpct is three standard

Sample	Ware	Tplag Micrpct	Lvpct	Claypct	Petrographer's original temper characterization	Final Temper Group	Comments
							deviations below the mean for Granitic sand.
PAX41-0579-2	Santa Fe	16.5	6.5	11.0	Granitic	Anthill	Lvpct is three standard deviations above the mean for Granitic sand, while TplagMicrpct is two standard deviations below the mean for Granitic sand.
PAX41-0652-2	Santa Fe	4.9	47.9	2.1	Tuff 1	Tuff 2	Lvpct is more than three standard deviations below the mean for Tuff 1.
PAX41-1352-2	Santa Fe	1.6	66.4	23.7	Anthill	Tuff 1	Lvpct is far more than three standard deviations above the mean for Anthill sand. This sample also has claylumps, which suggest its paste is similar to the Anthill/clay group, but it clearly has added volcanic temper.
LANL4-0016	Biscuit	7.3	63.9	3.7	Tuff 1	Tuff 2	Lvpct is more than three standard deviations below the mean for Tuff 1.
LANL5-02	Biscuit	16.7	59.0	0.0	Tuff 1	Tuff 2	Lvpct is more than three standard deviations below the mean for Tuff 1.
LANL5-05	Biscuit	38.7	44.3	0.0	Tuff 1	Tuff Other	The volcanic tuff in this sample is considerably different than all other samples.
LANL5-07	Biscuit	16.9	57.8	0.0	Tuff 1	Tuff 2	Lvpct is more than three standard deviations below the mean for Tuff 1.

The sherds from the 2002 analytical year were originally assigned to the temper group "sand" because the criteria for distinguishing among sand types had not been established. Of the 18 sherds from the 2002 analytical year, 15 were assigned to anthill sand, two were assigned to granitic sand, and one, PAX33-11, was assigned to Tuff 2.

For the remaining 18 sherds, the compositional point count data were compared on the basis of means and standard deviations for the groups. If a sample exceeded two or more standard deviations from the mean it was evaluated for membership in the other temper groups. Table 59.10 provides values for the comparative parameters and the reassignment rationale for each sample. Table 59.11 provides the final temper type and temper group evaluation for each analyzed sherd sample, as well as the initial temper characterizations by the ceramicist and petrographer. Table 59.12 provides a cross-tabulation of these data, so that temper group changes by category can be easily reviewed. Note that there are only five major temper type changes, from sand to tuff or vice-versa, out of 161 sherds. These are noted in boldface type in the table. Some changes from Castro-Reino (2004) should also be noted. First, "unmodified" and "modified" volcanic tuff have been changed to the more neutral "Tuff 1" and "Tuff 2," respectively, and no samples have been assigned to alluvial sand. In the end, no particular signature could be identified for alluvial versus anthill sand. The two alluvial sand samples plot very close to the anthill samples on most measures.

Two of the final temper categories in Table 59.12 will not be addressed further. The two "Tuff other" samples have tuff compositions that are extremely different from the other samples in the Tuff 1 and Tuff 2 temper groups. Without comparative samples, it is impossible to evaluate these samples, so they will not be considered further. For the same reason, the single "sedimentary sand" sample will not be evaluated in the integrated analysis to follow. With these categories deleted, there are 158 sherds for the final integrated analysis.

COMPOSITIONAL CHARACTERISTICS OF THE FINAL TEMPER GROUPS

Since there are only four comparative sand samples available for this analysis, it seems unlikely that the entire compositional range of Pajarito Plateau alluvial and anthill sands has been captured and expressed. Given the final temper groups established using the combined point count data, it would be best to evaluate the compositional characteristics of each temper group, and evaluate the ware data by temper group.

Figures 59.2 through 59.4 illustrate the gross composition of the point counted sherds. Figure 59.2 shows that the Anthill and Granitic sands are enriched in quartz compared to the other groups. Tuff 2 has an intermediate amount of quartz, while Tuff 1 is quartz poor. The combined potassium feldspar plus sanidine (Ksanid) parameter measures the presence of monocrystalline alkalic feldspars derived from volcanic rocks. It is elevated in the Anthill sand samples and slightly elevated in the Tuff 2 and Anthill/Clay groups. The combined plagioclase feldspar and microcline parameter measures plagioclase derived from granitic rocks or arkose. It is elevated in Anthill sand, very high in Granitic sand, modestly elevated in Tuff 2, and low in Tuff 1 and Anthill/Clay. Total muscovite (Tmusc) and total biotite (Tbiot) are present only in Granitic sand samples. Chlorite, total opaque minerals, and pyroxene and amphibole (Pyr) are not particularly patterned by temper group. Figure 59.4 shows that felsic volcanic rock fragments (Lvf2) are elevated in Anthill Sand and Tuff 2, while Tuff fragments proper (Lvv) are elevated in Tuff 1 and Tuff 2, though they are also present in Anthill/Clay and Anthill sand. The Anthill/Clay samples have the only appreciable amount of clay lumps. Note that there is a single outlier sample of Tuff 1 that also bears clay lumps.

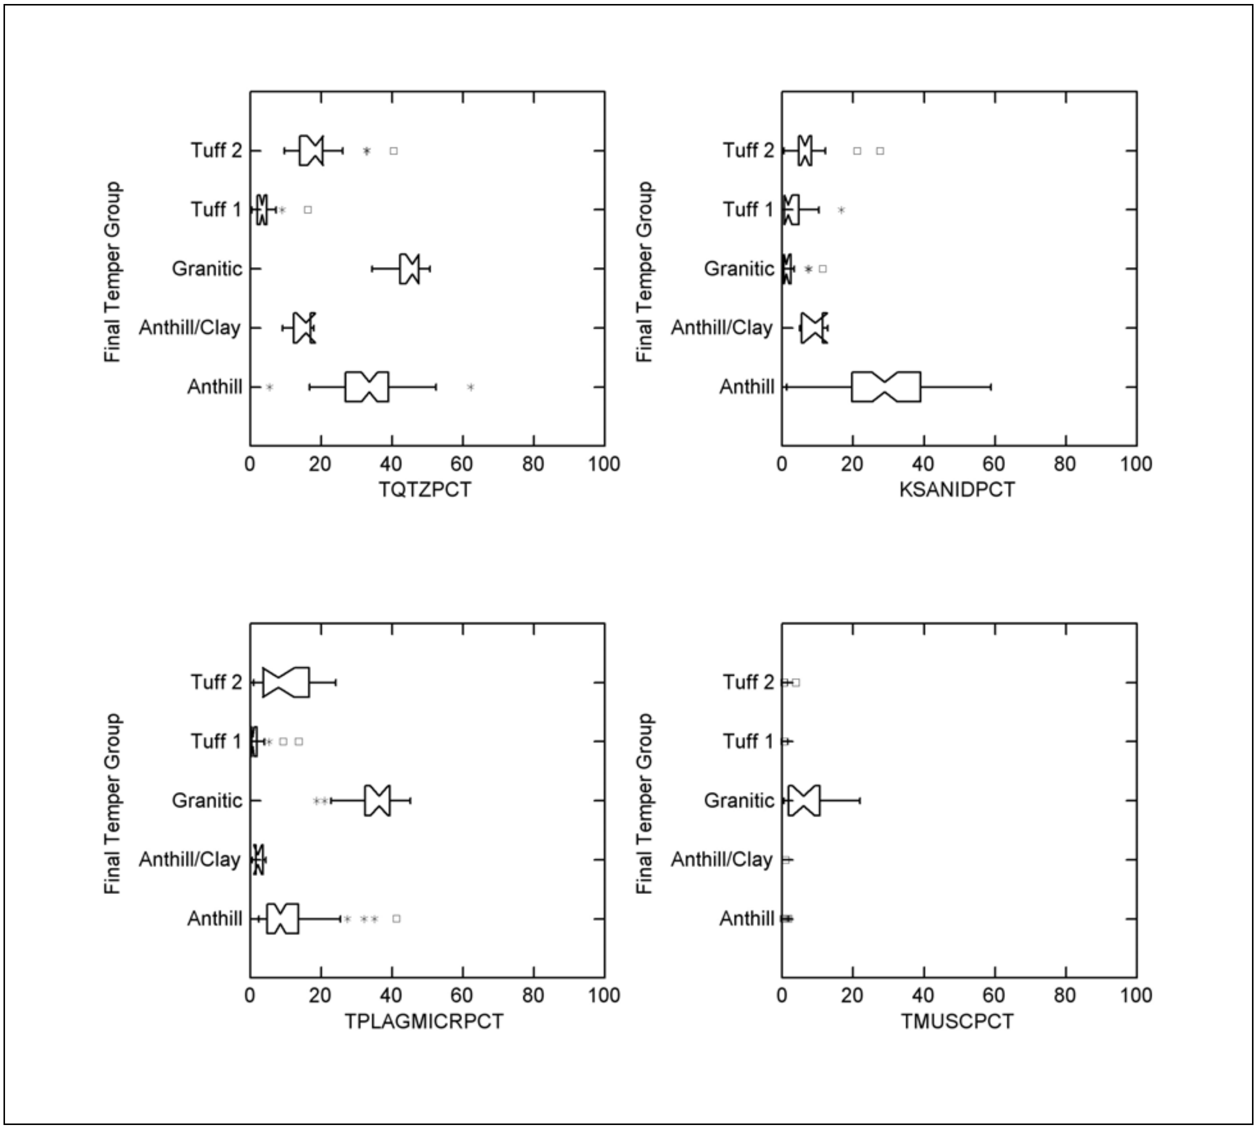

Figure 59.2. Box-and-whiskers plot of Tqtz percent, Tkspar+Sanid percent, Tplag+Micr percent, and Tmusc percent, for the sherds by final temper group.

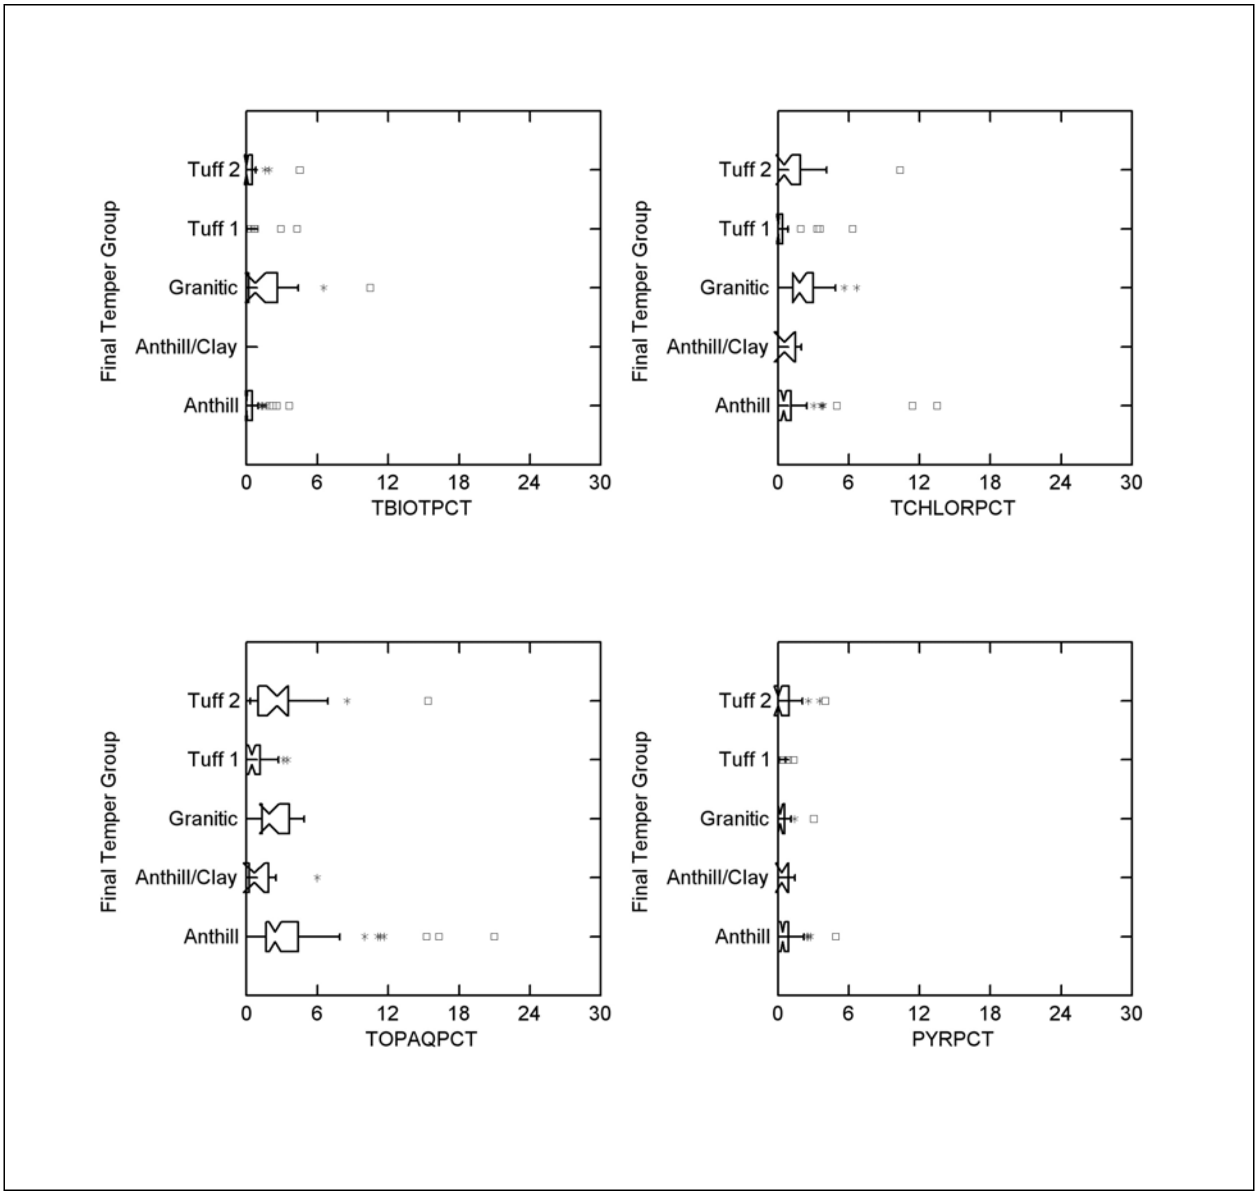

Figure 59.3. Box-and-whiskers plot of Lvf2 percent, Lvm2 percent, Lvv percent, and Claylump percent, for the sherds by final temper group.

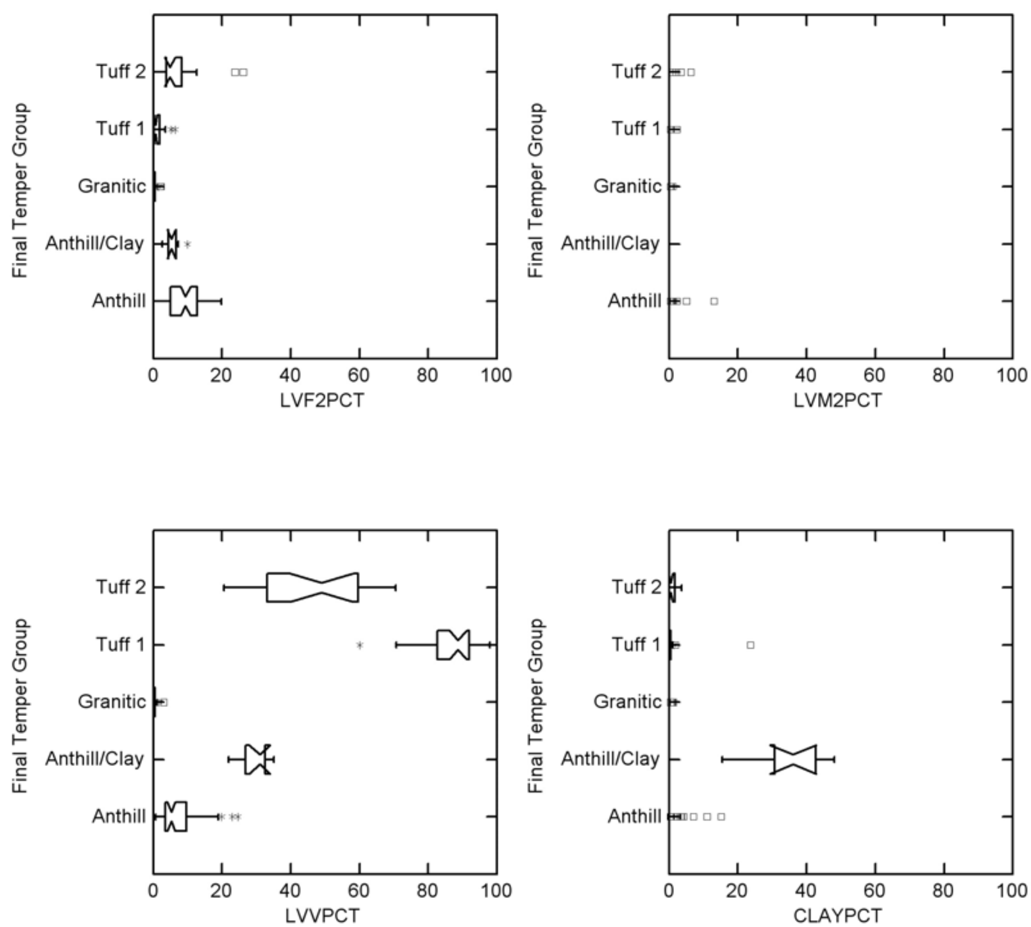

Figure 59.4. Box-and-whiskers plot of Tbiot percent, Tchlor percent, Topaq percent, and Pyr percent, for the sherds by final temper group.

Figure 59.5 combines the most distinctive of these basic compositional parameters into a ternary diagram, with the axes Tqtz, Tplag+Micr, and Kspar+Sanid+Lvv. Although these are not the standard axes for this diagram, this combination of variables combines those that are distinctive by temper group to provide a more clear picture of the compositional groups. Note that the Tuff 1 samples plot very close to the Kspar+Sanid+Lvv apex while the Granitic sands form a cohesive group opposite that apex. There is considerable overlap amongst the remaining groups in this view. Figure 59.6 takes these same data and submits them to a correspondence analysis. In this view we see that the Tuff 1 samples show a strong affinity to Lvv, while the Granitic sand samples plot with Tmusc, Tbiot, and Tplag. The Anthill temper samples are pulled by Lvf2 and sanidine, while the Anthill/Clay and Tuff 2 samples form an overlapping group at the center of the diagram. Alluvial sand samples fully within the Clay lumps could not be included, since they occur in only one subgroup in relatively low proportions compared to other parameters.

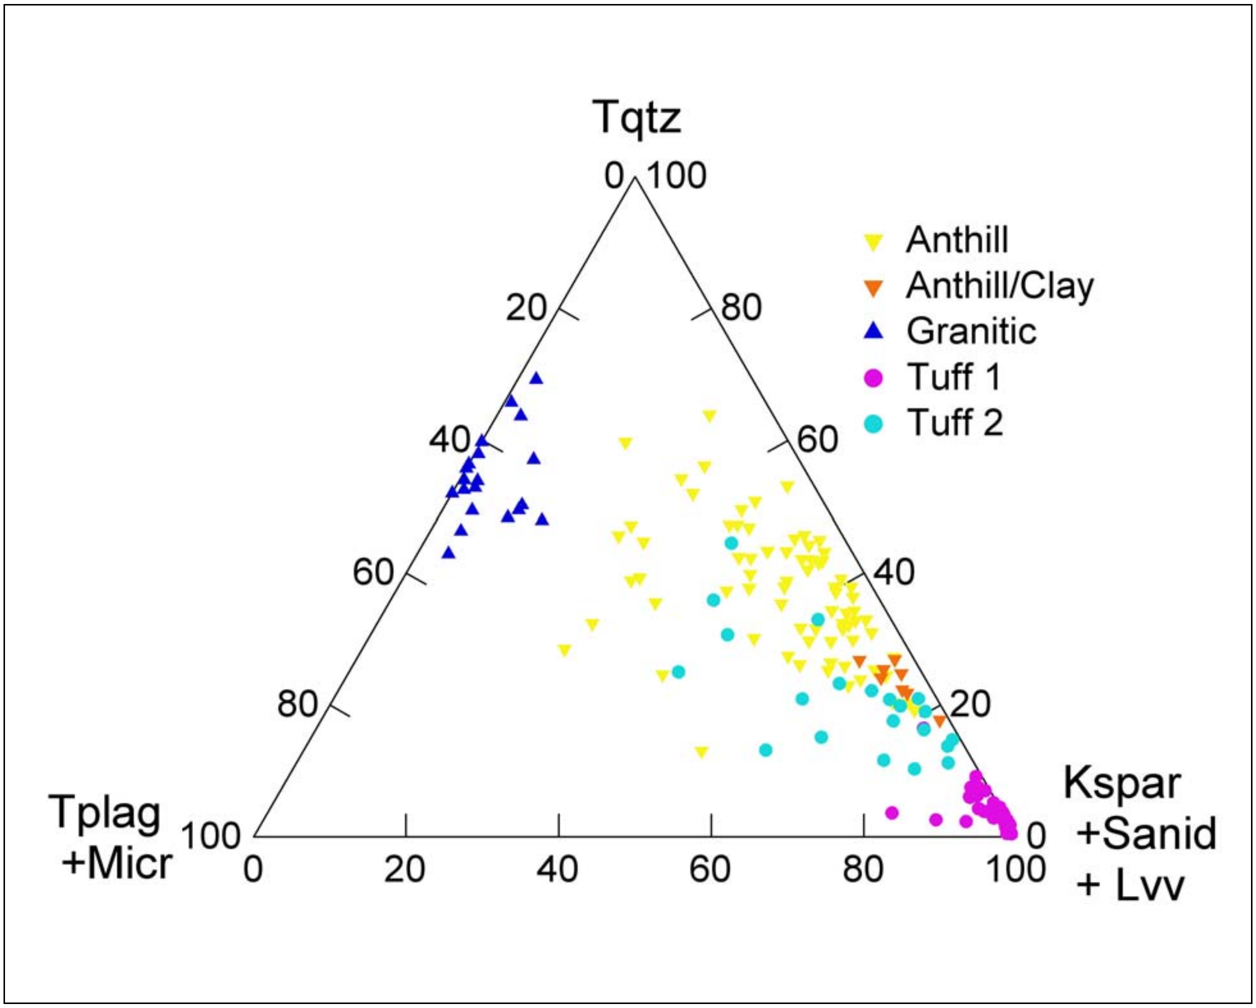

Figure 59.5. Ternary diagram of sherd samples by final temper group. Axes are Tqtz, Tplag+Micr, and Tkspar+Sanid+Lvv.

Having accepted the final temper group assignments as a useful measure of actual temper group, we can examine the textural attributes by temper group (Figure 59.7). Note the strong tendency to bimodal grain size moderate sphericity, and angular to subangular grains in the anthill and anthill/clay tempers. The split in sphericity characterization for the Tuff 1 tempers may be an artifact of having different analysts. These bar charts can be compared to the data for the four available sands samples (Table 59.13).

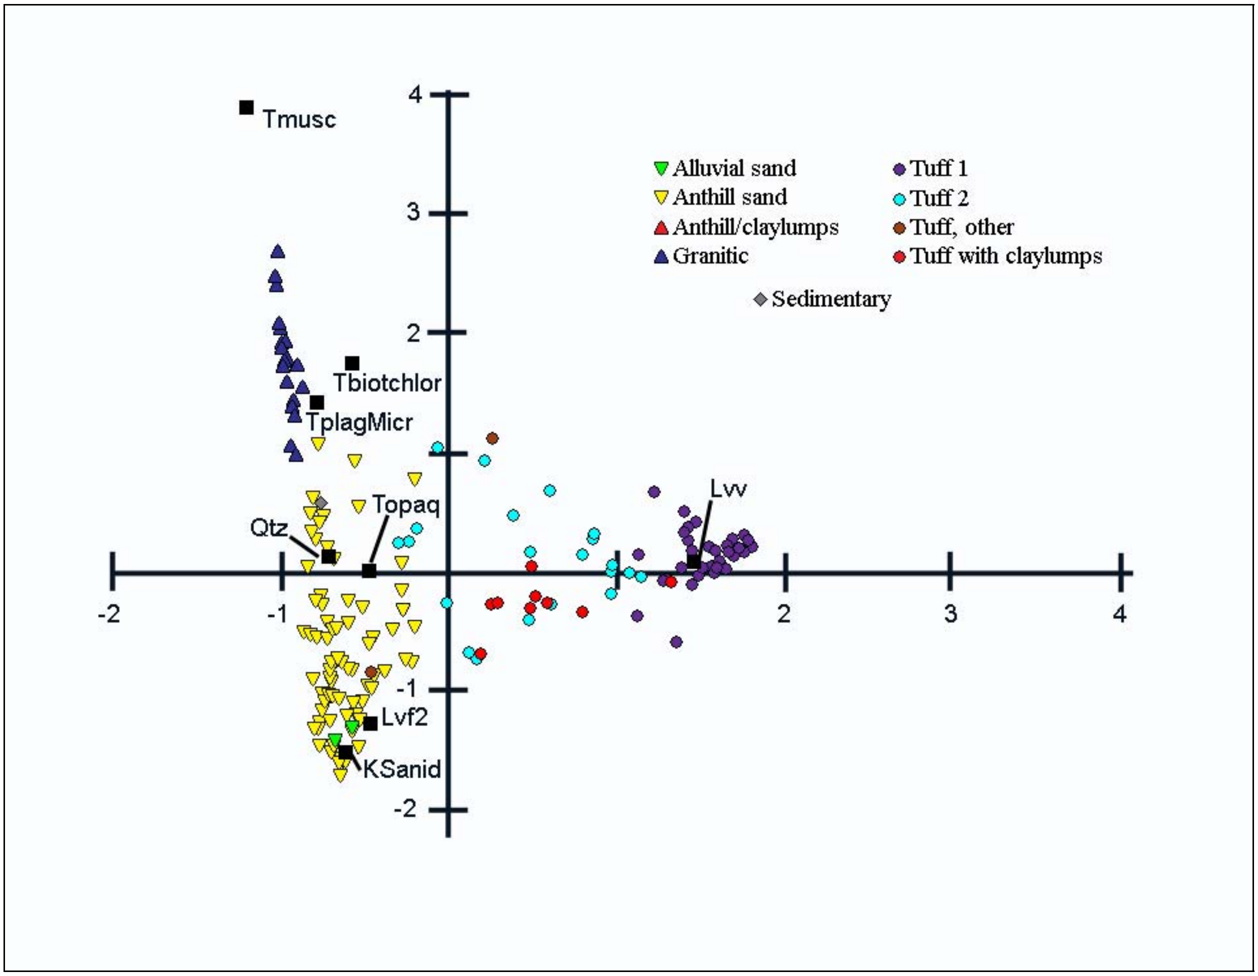

Figure 59.6. Scatter plot of the first two axes of the correspondence analysis of sand and sherd samples, plotted by final temper group.

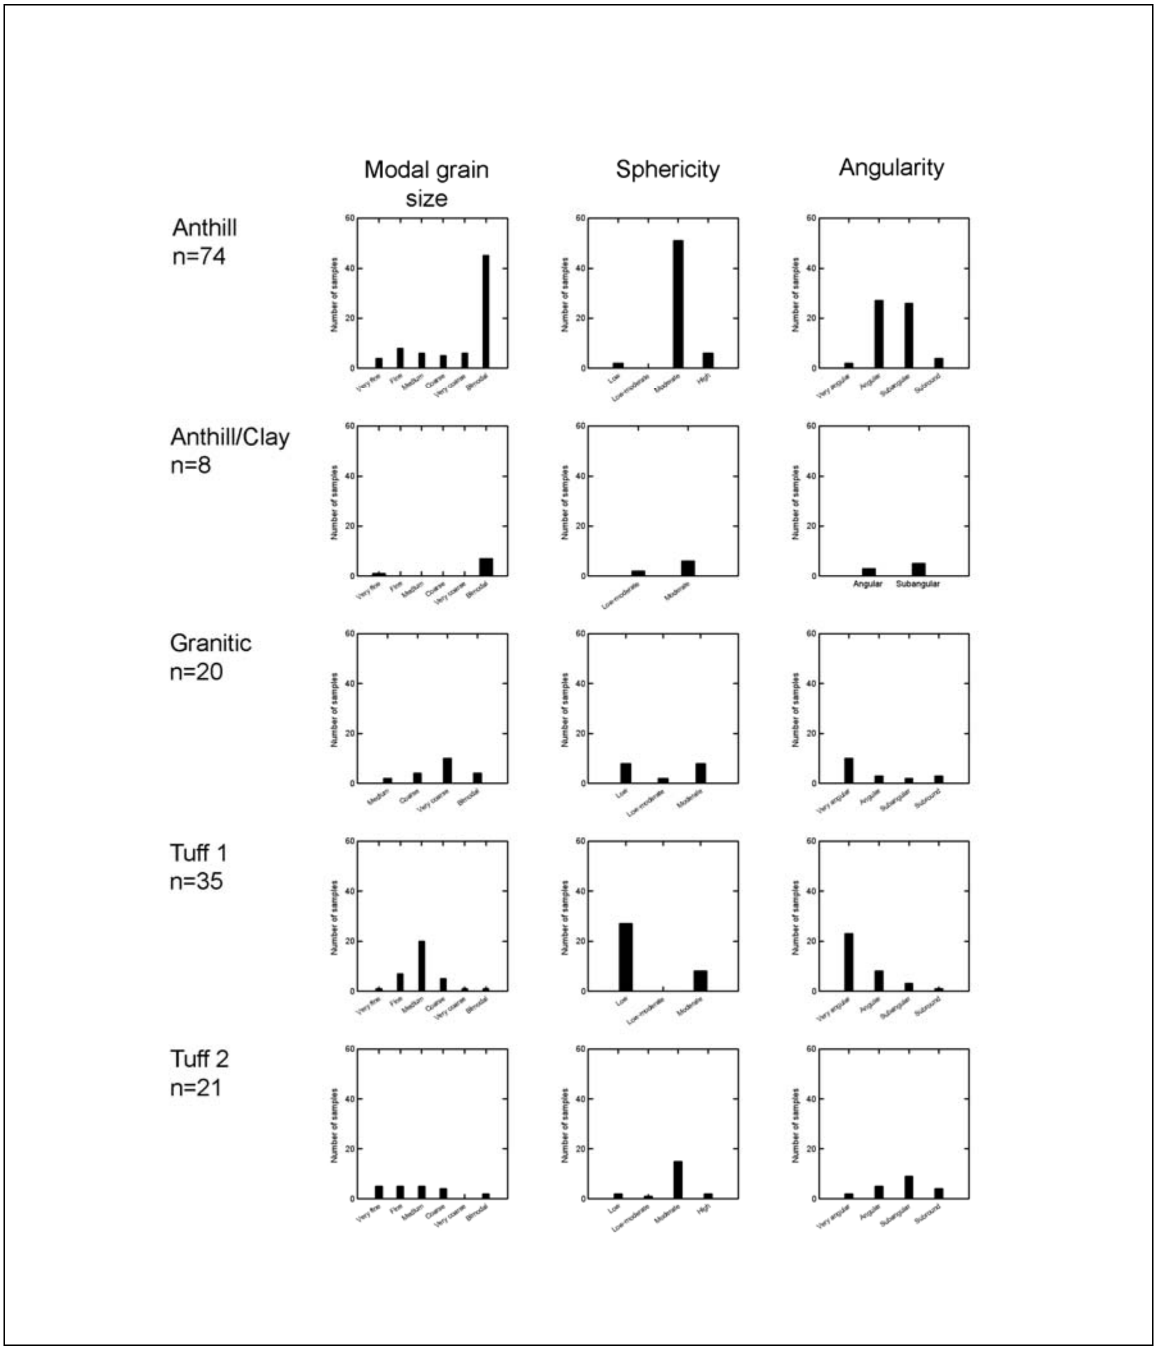

Figure 59.7. **Bar diagram of textural attributes of the sherd samples, plotted by final temper group for each attribute**.

Table 59.13. Qualitative attributes for sand samples: texture, morphology, and grain types.

		Texture and Grain Size Distributions				Sand Fraction Grain Types

PAX37-0070	Alluvial	Moderate	Angular	Moderate	V. coarse	Sanidine	Quartz	Vitric felsite	Interm. volc.

INTERPRETATION

By examining the sherds by temper group first, we are able to evaluate patterns by ceramic type much more easily. Castro-Reino (2004) concluded that the temper group was specific to ceramic type, though there were a number of samples outside of the suggested pattern. Table 59.14 cross-tabulates the temper group data by ware.

Table 59.14. Cross-tabulation of final temper group by ware.

	Ware					
Final temper group	**Plain**	**Corrugated**	**Santa Fe**	**Sapawi'i**	**Biscuit**	**Row Total**
Anthill	6	56	12	0	0	74
Anthill/Clay	0	0	8	0	0	8
Granitic	4	3	0	13	0	20
Total, sand tempers	*10*	*59*	*20*	*13*	*0*	*102*
Tuff 1	0	0	9	0	26	35
Tuff 2	0	0	16	0	5	21
Total, volcanic tempers	*0*	*0*	*25*	*0*	*31*	*56*
Column total	10	59	45	13	31	158

Castro-Reino (2004) applied a ratio of mineralic content to the analyzed pottery as one measure of composition. However, he evaluated the ratio in terms of ceramic type instead of temper group. For this reason, he had many outlying samples to explain, and the M/M+Lv parameter became difficult to use as a measure of group membership. By examining M/M+Lv by temper group, however, much of the within-group variation is lost, leaving a strongly patterned data set (Figure 59.8). Anthill and Granitic sands are strongly mineralic, Tuff 2 and Anthill/Clay tempers overlap in the middle, Tuff 1 temper is rich in volcanic rock fragments, sometimes to the near exclusion of single crystals of quartz and feldspar.

A breakdown of the ternary diagram by ware shows strong temper type by ware patterning (Figure 59.9). There are only a small number of plainware sherds, but none are tuff-rich. Similarly, only three of the corrugated sherds are granitic sand. The bulk of the corrugated sherds are tempered with anthill sand. None are tuff-rich. All of the Sapawi'i Micaceous sherds are tempered with granitic sand. Santa Fe Black-on-white shows the greatest variation, except that it is never tempered with granitic sand. All of the Biscuit sherds are tempered with either Tuff 1 or Tuff 2.

Evaluating the Compositional Patterns by Ware

The plainware sherds show considerable variation through time and space. There are a number of different plain ceramic types, and they are spread across the entire project area. Even so, they are tempered only with Anthill sand, Granitic sand, and a single "Tuff other" temper (Table 59.15). These sherds do not represent a cohesive enough group to evaluate further.

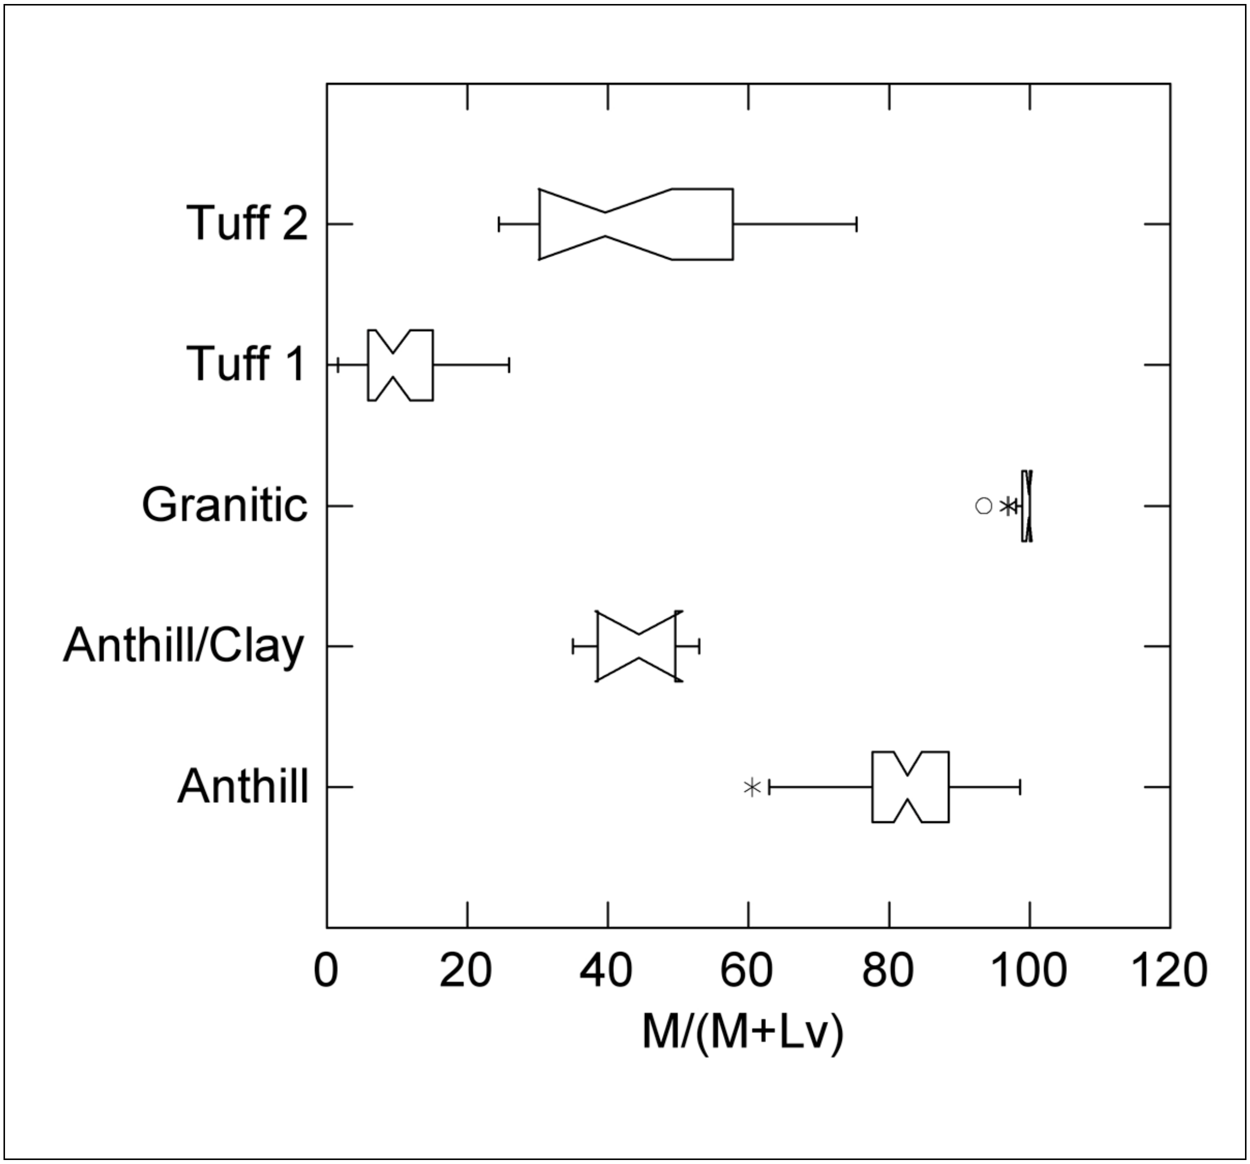

Figure 59.8. Box-and-whiskers plot of the mineral to lithic ratio M/M+Lv for the sherds by final temper group.

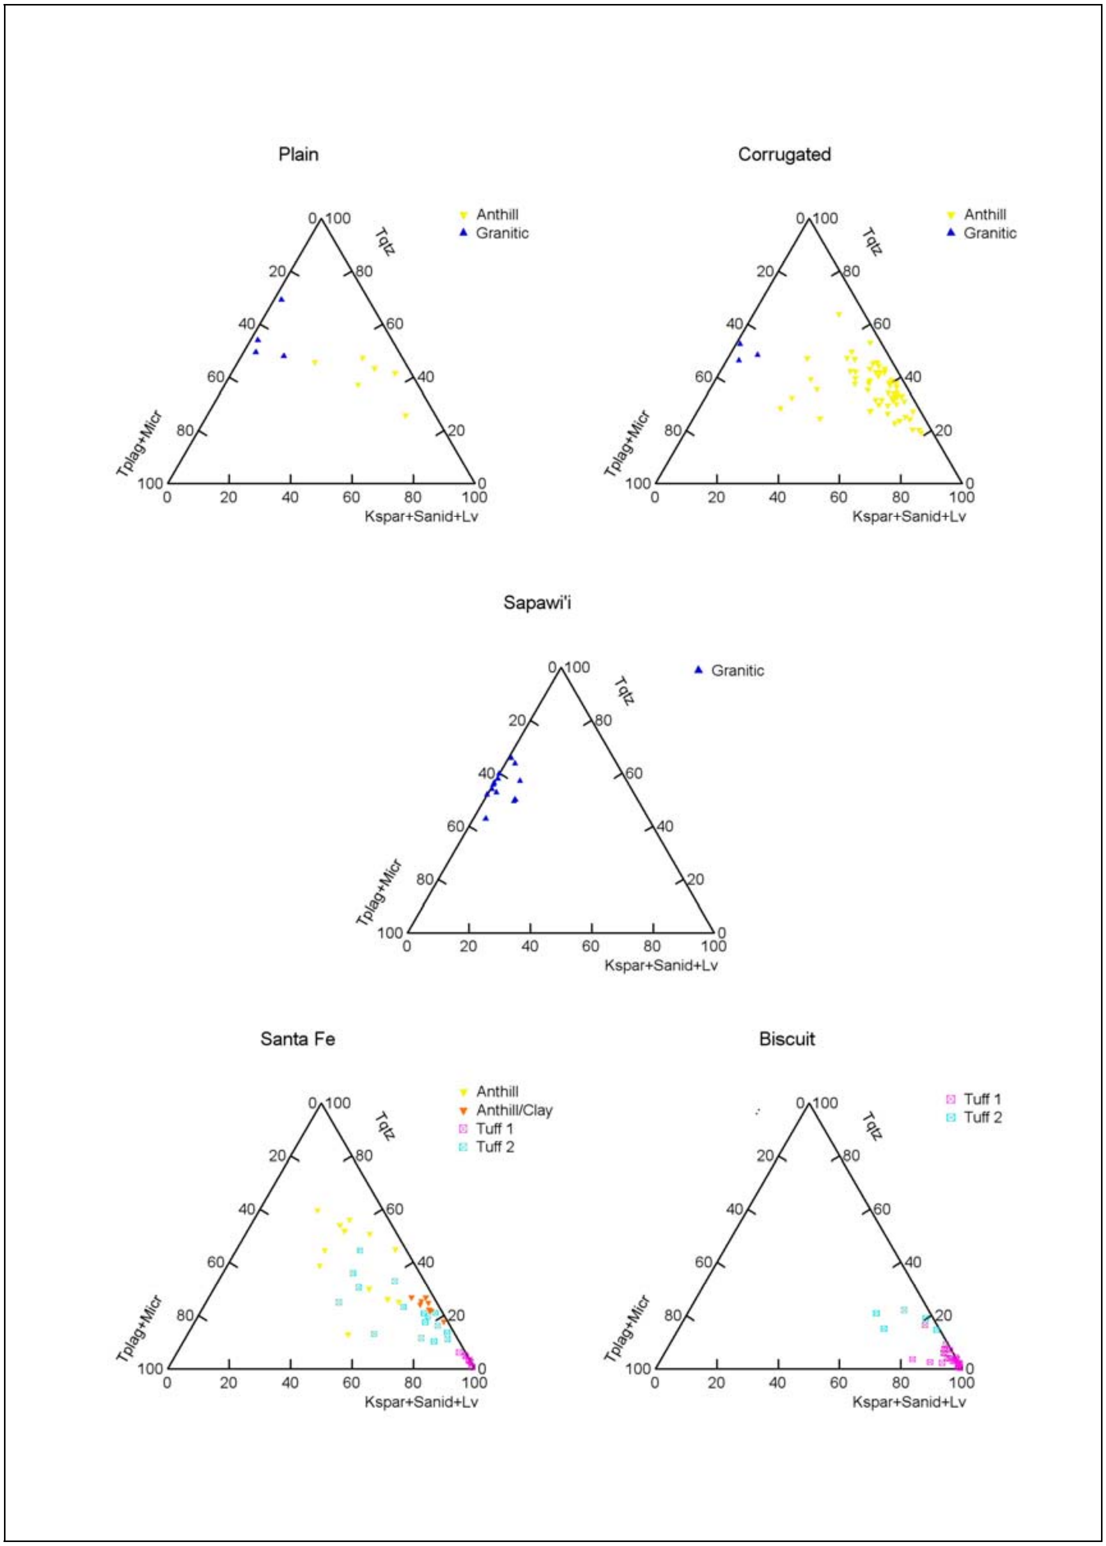

Figure 59.9. Ternary diagram of sherd samples by ware and final temper group. Axes are Tqtz, Tplag+Micr, and Tkspar+Sanid+Lvv.

[a]Note that this sherd is excluded from the summary diagrams, as noted in the text.

The corrugated sherds are all sand tempered, and the vast majority (56/59) are tempered with Anthill sand (Table 59.16). The granitic-sand-tempered corrugated sherds span the corrugated types found on the site, but two-thirds come from mixed contexts. These three sherds seem to be outliers on more than one level.

Table 59.16. Cross-tabulation of thin-sectioned corrugated sherds, showing period by ceramic type, subdivided by final temper group.

The Santa Fe Black-on-white sherds have a variety of tempers, however, they uniformly lack granitic sand. Examination of the Santa Fe Black-on-white sherds by time (Table 59.17, Figure 59.10), shows that there is a definite trend through time, with Anthill and Anthill/clay sherds occurring earlier, in general, while the Tuff tempers seem to reach a peak later in time.

Table 59.17. Cross tabulation of point counted Santa Fe Black-on-white sherds, showing period by final temper group.

The Biscuit sherds are tempered only with Tuff, though both Tuff 1 and Tuff 2 are represented. There does not seem to be any patterning by time or assigned type within the Biscuit group (Tables 59.19a and 59.19b), though there are very few identified Biscuit B sherds in the data set, and there is a large number of unassigned Biscuit sherds as well.

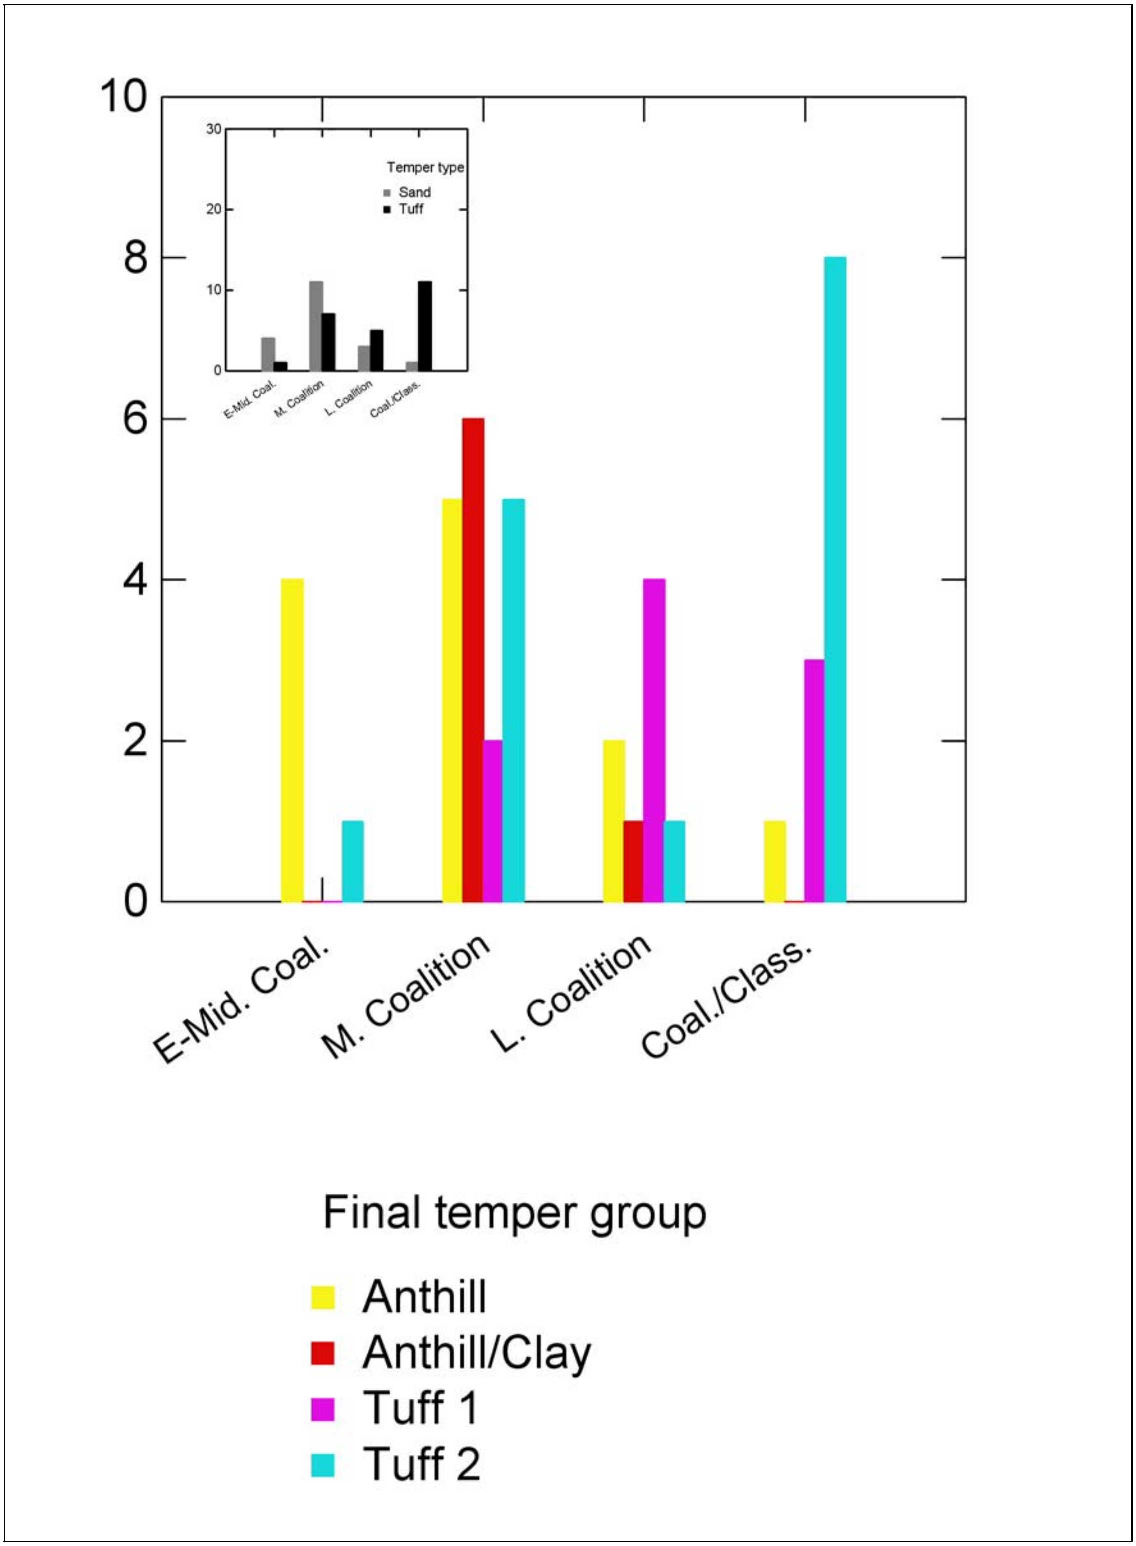

Figure 59.10. Bar diagram of final temper group for Santa Fe Black-on-white through time, where time is based on archaeological context of recovery. Inset bar diagram shows temper type, sand versus tuff, for the ware.

Provenance Interpretation

Returning to Table 59.9, the characteristics assigned to the temper groups, some provenance interpretation of the groups may be in order. Granitic sand is very distinctive both compositionally and texturally. It stands out from the other tempers very well and is seen in Plain, Corrugated, and Sapawi'i sherds, but never in the Santa Fe or biscuitwares. Because of its coarse grain size and distinctive granitic rock fragments, the Granitic temper must have been imported onto the Pajarito Plateau. As of this writing, there is no known source of this material on the plateau or within a reasonable distance. Thus the Sapawi'i Micaceous, some plain, and three point counted corrugated wares must have been brought into the C&T Project sites from elsewhere. The low compositional variation suggests a single source or set of closely related sources.

The Anthill and Anthill/clay temper groups are generally rich in mineral grains and show signs of transport (increased rounding and sphericity), however, they rarely lack at least some volcanic rock fragments, and the rock fragments and minerals in these samples are similar to those in the local bedrock (if in very different proportions). They are probably best interpreted as local to the Pajarito Plateau. Their wide compositional variation suggests collection of potting materials from a number of different sources and probably represents multiple manufacture locations around the study area.

The Tuff 1 and Tuff 2 tempers are closely related. Tuff 1 contains delicate glass spicules and other features that do not transport easily, if at all. Tuff 1 is interpreted as a clay source collected at or very near a primary deposit—possibly a clay deposit forming on tuff bedrock, or pooling at the base of a tuff bedrock. The grain sorting is more uniform and the grain size is finer. There is moderate to low compositional variation in this group, suggesting a high degree of control over the source, the production technology, or both. The potters could have removed coarse materials or they could have just chosen deposits that were finer grained/glassy, had fewer phenocrysts of quartz and feldspar, and were better sorted overall. Both Santa Fe Black-on-white and Biscuit ceramics were made with this source, and its use seems to be concentrated toward the later occupations, especially the Classic period. That is, the biscuitware potters were more selective, using a narrow range of materials.

Tuff 2 is much more variable in composition and texture and was commonly used for the production of Santa Fe Black-on-white than Tuff 1. It has a higher mineralic composition than Tuff 1, slightly better sorting, and lacks the really delicate features and finely controlled grain size of Tuff 1. For these reasons, Tuff 2 is interpreted as transported tuff. It could be pooling and providing a source for clay formation, or it could be added to volcanic clay. It seems to be collected from a number of locations. Overall, the potters producing Santa Fe Black-on-white used a wider range of materials, they were not as selective and primarily used the tempering material as occurred naturally.

CONCLUSIONS

The petrographic analysis of pottery from the Pajarito Plateau shows strong trends in resource selection by ware and over time. Corrugated pottery is tempered with sand with a wide variation in composition; thus it seems to have been made in a variety of places but with a "sand+clay" recipe that remains fairly uniform. Sapawi'i Micaceous pottery has a granitic temper that does not correspond to resources known from the Pajarito Plateau. It is also relatively uniform in composition, suggesting a particular trade source (or set of related sources) for this distinctive pottery. Santa Fe Black-on-white pottery changes through time, and exhibits a wide variety of textures and compositions. Earlier pots are more likely to be tempered with anthill sand with a low proportion of tuff and volcanics, but later Santa Fe Black-on-white sherds are rich in volcanics and seem to represent a slow switch to a volcanic tuff temper preference instead of sand. Biscuit pottery is uniformly tuff tempered, and seems to represent much more controlled selection of materials and possibly much better control of production technology.

CHAPTER 60
COPING WITH CHANGE: STONE TOOL TECHNOLOGY ON THE PAJARITO PLATEAU

Bradley J. Vierra and Michael J. Dilley

INTRODUCTION

The by-products of stone tool manufacturing are some of the most ubiquitous remains in the archaeological record. They represent a complicated process involving the acquisition of raw materials, tool production, tool use, and the subsequent discard of expended tools. Stone tools offer a direct link into how people coped with the uncertainties of living in a variety of natural and social ecological settings. The Land Conveyance and Transfer (C&T) Project provides a rare opportunity to study technological change over a roughly 7000 year time period on the central Pajarito Plateau.

The project research design presents a series of research questions that involves interpretations based on the analysis of the chipped and ground stone assemblages. The defined research contexts that include relevant lithic artifact data consist of chronometrics, land-use, community and site organization, subsistence, and technology, production, and exchange (Vierra 2002). The project lithic analysis has been designed to generate the information necessary to answering these research questions.

UNDERSTANDING STONE TOOL TECHNOLOGY

To answer these questions we must understand several key aspects of technological organization involving the stone tool manufacturing process. As previously noted, these components include tool design, the selection of raw materials, stone tool production, tool use and maintenance, and the eventual discard of worn out tools (Binford 1973, 1977, 1979; Hayden et al. 1996; Nelson 1991; Torrance 1989). How might these various aspects of tool organization affect the structure of the archaeological record and provide us with insights into the 7000 years of human occupation on the Pajarito Plateau?

When I refer to *technology*, I am referring to all the tools and facilities needed to help a person survive. This information is passed on to subsequent generations, with selection favoring those individuals who develop a technology that provides them with a competitive advantage over their neighbors. This competitive advantage enhances their ability to survive and reproduce at greater rates than their neighbors, eventually replacing technologies that may be less efficient at completing their tasks.

Significant changes in mobility and labor organization occurred during this 7000 year period. How people positioned themselves across the landscape changed radically from a foraging to agricultural-based society. This includes changes in *foraging strategies* (i.e., what foods people eat) and *foraging tactics* (i.e., how people procure these foods). There are two organizational components to foraging tactics and these are residential and logistical mobility. *Residential mobility* is when the whole group, including men, women, and children, move to a new residential location; whereas, *logistical mobility* is when a specialized task group moves out from the residential base for the purpose of conducting a specific activity. The former tactic involves the movement of food to people and the latter tactic moves people to food. Any hunter-gatherer group uses a mixture of these two foraging tactics as a means of reducing the spatial and temporal incongruities in the distribution of resources. This mixture is conditioned by several factors including the structure of the environment, a dependence on storage, and regional demographic factors. Nonetheless, as hunter-gatherers shift from an economy based on foraging to agriculture, there is a decrease in the use of residential mobility and subsequent increase in the use of logistical mobility. The types of tools needed for the completion of foraging versus task-group oriented activities can be quite different (Binford 1980; Bleed 1986; Keeley 1988; Kelly 1983, 1995; Kuhn 1989; Vierra 1995).

Material Selection

How people procured stone raw materials and whether they obtained them from local or nonlocal sources is important for understanding the organization of these past economic systems. Two important concepts need to be defined: procurement strategy and procurement tactic. *Procurement strategy* refers to the specific material types selected for tool production. This information is readily available in the archaeological record as the varying proportions of worked material types present. *Procurement tactic*, on the other hand, refers to the specific methods used to procure them (Vierra 1993a:141). Raw materials can be obtained in three ways. An *embedded* tactic involves the collection of raw material incidentally to subsistence-related movements (Binford 1977, 1979; Binford and Stone 1985). A *direct* tactic involves making a trip to the source location for the sole purpose of collecting raw materials (Binford 1979; Gould and Saggers 1985; Renfrew 1975:41). A distinction is made here between embedded and direct tactics, although these have often been subsumed as direct procurement tactics (e.g., Ericson 1984:6; McAnany 1988; Meltzer 1989). An *indirect* tactic involves obtaining items from an intermediary. This usually involves some form of trade or exchange relationship (Earle and Ericson 1977; Ericson and Earle 1982; Renfrew 1975, 1977; Santley et al. 1988).

Is has generally been argued that Southwestern hunter-gatherer groups procured lithic raw materials using an embedded procurement tactic (Shackley 1990:63, 1995; Vierra 1985, 1990, 1993b). In this case, tools are replaced with locally available materials during a group's annual rounds. The distribution of these materials may provide information on the procurement range or annual range traversed by hunter-gatherer groups. On the other hand, Meltzer (1989) suggests that exchange networks may have existed among prehistoric hunter-gatherer groups, but identifying the archaeological signature for this pattern is difficult.

Southwestern agriculturalists could have obtained lithic raw materials using an embedded, direct or indirect procurement tactic (Brown 1990; Cameron 1984, 2001; Findlow and Bolognese 1980, 1982a, 1982b; Harry 1989; Parry 1987; Vierra 1993a, 1997; Walsh 1997, 1998; Young and Harry 1989). A direct procurement tactic involves the bulk acquisition of raw materials, since these items are stored for future use. This might include nodules, prepared cores, or formal tools made of raw materials that are not locally available. Local materials are defined as any lithic material that is obtainable within a 10 km (6 mi) catchment radius of the site, and nonlocal materials are those from outside this catchment. This is the typical foraging radius covered during daily activities around a habitation site (Binford 1982).

This of course raises the question of how lithic raw materials were entering a site. That is, were they entering as unmodified nodules, prepared cores or formal tools, and what would the archaeological implications of these differing procurement tactics be? The reduction of nodules at a site would presumably produce a relatively greater proportion of primary and secondary cortical flakes with cortical platforms; the reduction of cores should produce relatively more secondary noncortical flakes with single-faceted platforms; and the reduction of formal tools should produce more tertiary retouch flakes with multi-faceted platforms (Vierra 1993a). It has been suggested that nodules, prepared cores, and formal tools may have been exchanged in some portions of the northern Southwest (Brown 1990, 1991; Cameron 1984; Harry 1989; Vierra 1993a, 1997). It has also been suggested that increases in material diversity during the Ceramic period may reflect growing exchange networks (Green 1985), and in some areas of the Southwest may be associated with periods of site aggregation (Harry 1989). Craft specialization could indicate the presence of formal trade networks. Archaeological evidence for stone tool craft specialists has been identified at the Salmon Ruins site in northwest New Mexico (Shelley 1983) and several Sinagua sites in the Anderson Mesa area of northern Arizona (Brown 1990; LePere 1981). In contrast, Cameron's (1984) study of Pueblo sites in Chaco Canyon did not identify any evidence of craft specialists.

Lithic Reduction

Stone tool design in North America is often characterized as a dichotomy of core reduction and bifacial tool production. That is, simple flake tools are generally associated with settled village communities, versus an emphasis on the production of bifacial tools by hunter-gatherers. In this case, *tools* are chipped or ground stone artifacts that exhibit evidence of retouch, grinding, and/or use-wear. Most rock types can be used for the production of simple flake tools since the sharp edge is used for a relatively short period of time and then discarded. However, higher quality materials that are easily worked by both percussion and pressure flaking techniques are required for the production of bifacial tools that are maintained over longer periods of time. Therefore, core reduction activities tend to be associated with the use of low quality materials like basalt that are available within the vicinity of the habitation site. In contrast, the production of bifacial tools is associated with the use of fine-grained materials like chalcedony and obsidian, which occur in restricted locations across the landscape and can end up in the archaeological record as a nonlocal rock type. Nonetheless, as was the case with residential versus logistical mobility, North American stone tool technologies include a mix of both core reduction and bifacial tool production as a means of coping with the uncertainties of food procurement and processing (Andrefsky 1994; Bamforth 1986; Goodyear 1979; Johnson and Morrow 1987; Kelly 1988; Nelson 1991; Odell 1996; Parry and Kelly 1987; Sullivan and Rozen 1985; Vierra 1990, 1993a).

The concept of residential mobility as a possible explanation for this technological variation often assumes that mobility limits the size and number of tools that a group can efficiently carry with them (Carr 1994; Ebert 1979; Kuhn 1994; Odell 1996; Shott 1986). For example, Parry and Kelly (1987) suggest that bifaces are portable tools that can also act as cores, something important for mobile groups with varying access to lithic materials; whereas, an expedient flake technology is sufficient for sedentary groups with access to locally available materials. In contrast, other studies of stone tool technology have emphasized the importance of time constraints, energetic efficiency, and risk reduction for explaining technological variation and long-term changes in technology (Jeske 1992; Nelson 1991; Torrance 1983, 1989; Vierra 1995). With the shift to agricultural-based economies, the conflicting demands of subsistence pursuits, labor, technology, and social activities need to be balanced in respect to energetic investment (Jeske 1992). This process has the *residual effect* on the stone tool technology, when increasing amounts of energy are diverted into other aspects of technology and labor organization. More specifically, there is a de-emphasis on the stone tool technology per se, and an increased emphasis on corporate labor group structure and that aspect of technology associated with agricultural intensification. This includes milling equipment, ceramics, storage facilities, architecture, and agricultural features. We need to remember that increasing "sedentism" actually reflects the increasing use of logistical mobility and changes in labor organization.

As Binford (1980:13) pointed out, technology does not consist solely of tools, but also labor. Indeed technological organization is a direct reflection of corporate labor group structure and economic organization. I have recently argued that differences between the chipped and ground stone assemblages at the early agricultural site of Cerro Juanaqueña would appear to reflect changes in the sexual division of labor. Spatial differences in the distribution of tool production, versus expedient flake and ground stone use may reflect the changing roles of men and women at these sites. That is, the increasing emphasis on core reduction and simple flake use at village sites probably represents the increasing importance of female activities and not simply "sedentism." (Vierra 2004, 2005b). This corresponded with Ogilvie's (2005) biological study of the structure of the femur. She observed that males residing at early Southwestern agricultural villages appeared to resemble their Archaic foraging counterparts. In contrast, the females from these early villages resembled women from later Ceramic period communities.

This raises the question of which lithic materials are being used to produce simple flake tools and formal tools, and how do these reduction trajectories differ from that exhibited by artifacts made of local and nonocal materials? The term r*eduction trajectory* refers to a stage-like sequence of stone tool manufacturing beginning with the preparation of a core and ending with the completion of a finished tool (e.g., Chapman 1982; Collins 1975; Inizan et al. 1999; Van Peer 1992). For example, this process might consist of a cobble-flake or a prepared core-flake-bifacial tool trajectory. Again, a distinction is made between reduction strategies and reduction tactics; *reduction strategy* refers to the specific tool being produced, such as a biface or flake, and *reduction tactic* refers to the manner in which the tool is produced, or the reduction trajectory (Vierra 2004). Although some raw material determinists propose that raw material availability conditions the reduction strategy (Bamforth 1986), this is not the case. It is the foraging strategy—what you eat—and the foraging tactic—how you get it—that conditions the reduction strategy. By contrast, it is the reduction tactic that is primarily affected by raw material availability. Nonetheless, a flint knapper produces a variety of by-products during the stone tool manufacturing process. It is these by-products that provide the intricate details of the specific techniques used to produce stone tools (Andrefsky 2001; Shott 1994; Whittaker 1994).

Bifacial technologies are hunting technologies, including projectile points and bifacial knives. One of the most important aspects of bifacial tools is that retouch can be used to extend tool use-life. This does, however, require the use of high quality materials that are easily worked by both percussion and pressure flaking techniques (Goodyear 1979, 1989; Kelly 1988; Kelly and Todd 1988). In general, higher quality (nonlocal) materials are used for the production of formal tools with longer use lives, versus lower quality materials (local) for the production of expedient flake tools (e.g., Bamforth 1986; Brown 1990).

Tool Use

Chipped stone use-wear studies in the American Southwest have been limited. Although the results of the high-power technique were promising, it involved training and access to specialized equipment. Therefore, most lithic analysts implement a low-power technique using a binocular scope with a 10x range that identifies the presence of obvious edge damage that could be attributed to use. In addition, edge angle measurements also provide an easy and quantifiable measure of possible tool function. This has been particularly informative concerning possible expedient flake use. For example, large flakes are often selected as hand held tools and edge angle distributions often mimic those represented by the retouched tool assemblage.

Traditional lithic analyses have tended to focus on the chipped stone component with less detailed work on the ground stone artifacts; however, recent studies have also begun to focus on ground stone implements as important sources for understanding past subsistence activities (J. Adams 1999, 2002). Although limited work has been done on ground stone artifact production (although see Fratt and Biancaniello 1993; B. Huckell 1986; VanPool and Leonard 2002), most analysts have emphasized tool function based on the artifact's form and presence of use-wear (e.g., see J. Adams 1988, 1989, 1999, 2002; Calamia 1991; Hard 1986, 1990; Lancaster 1984; Morris 1990). Adams' (2002) study separates ground stone implements into four major groups: grinding and pulverizing, abrading, smoothing and polishing, and percussion tools (i.e., hafted and nonhafted).

Manos and metates certainly form the primary basis for ground stone artifact analysis. They provide the technological means of milling various plant seeds into flour, which is something that Southwestern peoples have been doing for thousands of years. Researchers have recently begun to understand the data potential represented by this history, and have therefore used the information to help clarify the forager to farmer transition.

The one-hand cobble mano and millingstone or basin metates have been the hallmarks of the Archaic period and are associated with generalized grinding activities. In contrast, agriculturally dependent communities have required two-hand manos and specialized slab or trough metates for processing maize (e.g., Bartlett 1933; Haury 1950). Given their importance to pueblo life, milling bins containing multiple metates with varying textural grinding surfaces became the focus of daily activities. Hard (1986, 1990; Hard et al. 1996) has explored this relationship between ground stone tools and subsistence, arguing that mano length and the total area of the grinding surface on manos will increase as a function of a growing dependence on maize agriculture and corn processing (also see Mauldin 1993; Morris 1990).

Hard's study was designed to create a quantitative measure for identifying changes in subsistence economy. This was based on the regression analysis of ethnohistorically documented manos, from which he was able to demonstrate a significant linear relationship between increasing mano length and dependence on agriculture. For example, manos less than 11 cm in length presumably reflect an economy 0 to 15 percent dependent on agriculture, 11 to 15 cm of a 0 to 45 percent dependence, 15 to 20 cm of a 35 to 75 percent dependence. and greater than 20 cm of over 65 percent dependence. Figure 60.1 illustrates mano length data for a sample of sites in the San Juan Basin (Vierra 1993a). There is a step-like increase in mean mano length from the Archaic, to Basketmaker III to Pueblo I, with a leveling off during the Ancestral Pueblo time period. This is also reflected in the changing mano form over time; one-hand quartzite cobble manos with oval grinding surfaces, to one-hand sandstone manos with rectangular grinding surfaces, to two-hand manos with rectangular grinding surfaces. Macrobotanical studies in the northern Southwest appear to reveal a similar pattern of increasing dependence on agriculture (e.g., Hard et al. 1996; McBride 1994; Minnis 1989).

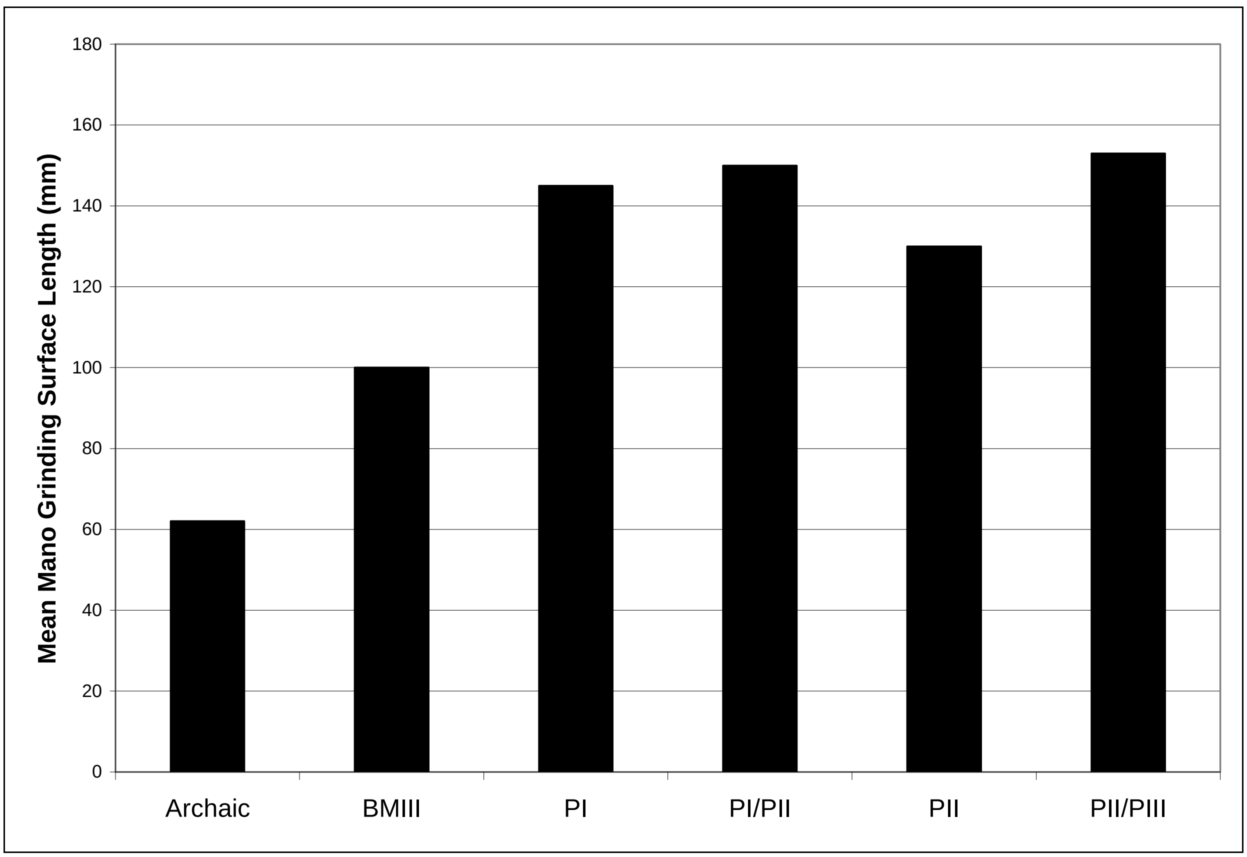

Figure 60.1. Mean mano grinding length for sites in the San Juan Basin.

Adams' (1999) critically reviewed the status quo of form equals function for ground stone analysts. She specifically questioned the assumptions of grinding surface size as an indirect measure of a group's dependence on agriculture, and suggests that variations in tool design may actually reflect differences in food processing strategies and not overall subsistence economy. For example, basin metates are equally well designed to process wet or oily seeds (e.g., wild or soaked maize kernels), while trough metates help to confine dry maize kernels while milling them into meal or flour. The confined space, with a larger mano, makes the trough metate more efficient at producing meal or flour than the basin or slab metate. By contrast, the basin metate would work well for processing soaked maize kernels for *masa*. Slab metates can also be efficient if they are placed within the confined space of a milling bin. At any rate, both Hard and Adams' studies are productive for understanding the complexities of ground stone tool use.

Other items associated with agricultural communities include axes, mauls, and hoes. A variety of axe forms have been documented from notched to full-grooved, with the amount of energy invested in tool manufacture correlated with tool use-life. However, Adams (2002:173) notes that some forms of axe-hafting technology may relate to regional cultural (i.e., stylistic) differences. In addition, axes may be either flaked or ground, and resharpening is conducted by either flake removal or by grinding the bit. The former technique is certainly less efficient in respect to extending tool use-life because it removes more material with each resharpening event. In the northern Rio Grande, fibrolite or sillimanite materials were used to produce ground stone axes (Montgomery 1977). Mauls are used for various heavy duty activities that range from building construction to warfare. They also exhibit a range in hafting techniques. Lastly, hoes vary greatly across the Southwest and include items called *tchamajillas*. Although *tchamajillas* are present on Ancestral Pueblo sites in the San Juan Basin, none have been identified in the northern Rio Grande Valley. On the other hand, notched cobbles that were presumably used as hoes are commonly found on agricultural features in the valley (Anschuetz 2001).

Hammerstones can also be used for a variety of activities. As a result, the evidence of use-wear should vary over time given changes in subsistence and residence patterns. For example, studies of Archaic hammerstones at Armijo Rockshelter near Albuquerque indicate that they were used for shaping and roughening the surfaces of metates and for processing plant and animal materials on metates. These activities created the extensive battering exhibited by many of the hammerstones (Dodd 1979). Cameron's (1984) Black Mesa study identified several temporal patterns in hammerstone use. This includes changes in raw material selection and use-location from Basketmaker II through the Ceramic periods. In the case of material selection, she identified changes from quartzite and siltstone dominated, to quartzite and silicified wood dominated, to silicified wood dominated. With respect to use-location, this involved changes from the primary use of edges and multiple surfaces, to convex and multiple surfaces to solely multiple surfaces. Lastly, although hammerstone size was generally constant, chopper size did decrease through time. Cameron notes that similar raw materials were selected for choppers and cores. Therefore, I suggest that these cores were being reused as choppers more frequently during the Ceramic period (e.g., see Vierra 1985). Indeed, with increasing length of occupation at Ceramic period sites we would expect to observe greater intensity of core reduction, artifact recycling, and multiple functions for cores, hammerstones, and choppers.

STONE TOOL STUDIES ON THE PAJARITO PLATEAU

Most current studies involving Southwestern stone tool technology focus on understanding the forager to farmer transition and the long-term effects of subsistence intensification on prehistoric society. The few systematic studies conducted of stone tool technology on the Pajarito Plateau have primarily focused on understanding the effects of Ancestral Pueblo site aggregation on stone tool procurement, production, and use. These are based on the studies conducted by Walsh (1997, 1998, 2000) and Head (1988, 1999).

Walsh specifically looks at the evidence for increasing site aggregation, resource competition, and territoriality from Coalition to Classic times. He suggests that there were significant changes in territoriality, and therefore, access to lithic raw material sources through time as a result of the site aggregation process. Assuming that lithic raw materials were incidentally collected during subsistence related activities and that the raw material sources are spatially distinct, then any shifts in land-use would therefore be reflected in the proportion of lithic materials represented in the archaeological record. Walsh's research focused on three primary lithic materials types: Pedernal chert, obsidian, and basalt. Walsh proposed that the Pajarito Plateau was open space that was used by the initial agricultural colonizing groups during the Early-Middle Coalition period, and that these people had few constraints on mobility and resource acquisition. This, however, changed during the Late Coalition period when increasing population densities restricted movement across the plateau due to marked territoriality. These limitations were subsequently relaxed during the Classic period when the occupants of the plaza pueblos controlled access to large resource areas or "buffer zones." Therefore, Walsh's predictions were: 1) lithic materials would reflect a simple distance-decay effect, with little conservation of materials during the Early-Middle Coalition period; 2) a decrease in lithic material diversity, the use of "alternative" materials, and increased conservation during the Late Coalition period; and 3) an increase in material diversity, a decrease in the use of alternative materials, and a decrease in efforts to conserve raw materials during the Classic period. His sample included five Early/Middle Coalition, eight Late Coalition, and a single Classic period (LA 170) site, and the results did provide some tentative support to his lithic procurement model. For example, in respect to material selection, he found that the Early/Middle Coalition period sites contained mostly chert and basalt, the Late Coalition period sites mostly chert, and the Classic period site of Tsirege mostly chert and obsidian. Lithic material diversity was generally greater during the Early/Middle Coalition and Classic periods, and lower during the Late Coalition period. The use of alternative materials (i.e., all other types) almost doubles during the Late Coalition period. Lastly, flake size was used as a proxy measure for raw material conservation. He found decreased mean flake weights for the three lithic types during the Late Coalition period and assumes this represents an attempt to maximize the use of these materials.

Head (1999) also focused her research on the effects of population growth and site aggregation on lithic procurement, manufacture and use activities; however, her study included both chipped and ground stone artifacts, and a broader range of research issues. These research issues involve studying the archaeological implications of reduced residential mobility, agricultural intensification, trade/exchange, and the delineation of social boundaries. Her database is different from Walsh's, as she had a much larger sample of sites from the southern Pajarito Plateau at Bandelier National Monument.

In respect to decreasing residential mobility Head refers to the common arguments following Parry and Kelly (1987). As previously discussed, this argument holds that biface technologies are associated with highly mobile groups and expedient flake technologies with sedentary (or residentially stable) groups. She therefore predicts an increasing emphasis on the production and use of informal tools, and a shift from the use of mostly chert/basalt to obsidian for tool production. Her analysis finds some preliminary support for these contentions, with an increase in both indicators during the Early to Middle Classic period.

Agricultural intensification is certainly an important factor affecting changes in labor and technology. Head predicted a decrease in hunting activities (i.e., projectile points) and an increase in the importance of milling activities. The latter would involve the increasing representation of two-hand manos, increases in mano grinding surface area, and increases in the presence of slab metates for milling flour. Her prediction for the decreasing presence of projectile points did not find support with the archaeological data. Indeed, it appears that the presence of projectile points decreases at habitation sites and increases at non-habitation sites. Head therefore suggests that maintenance of hunting gear was shifting to the non-habitation sites, which were acting as the focus for hunting activities. She also found basin, trough, and slab metates are present during all time periods; however, the presence of basin metates actually increased through time, trough metates decreased, and slab metates varied through time. That is, slab metates exhibit a saw-wave pattern with multiple peaks and valleys throughout the entire sequence, although she suggests that most of the peaks are associated with periods of marked aggregation. There is also no clear relation between one and two-hand manos through time, however, mean mano grinding surface area does exhibit a marked increase and leveling across the Late Coalition and Classic periods (140 to 148 sq cm).

Of course, the exchange of goods across the landscape in order to deter the effects of poor growing seasons is always seen as an important advantage to site aggregation (Hill et al. 1996; Kohler and Linse 1993; Powers and Orcutt 1999c). In this case, Head suggests a shift from the use of an embedded procurement tactics to the exchange of obsidian with increasing site aggregation. Indeed, the archaeological evidence indicates an increase in the presence of obsidian during the Early Classic period (with a decrease in basalt). She also documented a potential increase in the intensity of obsidian reduction with debitage/core ratios rising to about 6 to 9 also during the Early Classic period. Based on this evidence, and the presence of more cores and bifaces broken in manufacture, she suggests that bifaces were being produced for exchange (also see Root 1989:83).

Lastly, Head also addresses the issue of territoriality through the possible presence of the Keres/Tewa social boundary at Frijoles Canyon during the Early Classic period. She submitted a sample of 36 and 64 pieces of obsidian from the areas to the north and south of Frijoles Canyon, respectively. The results were that the north side of the canyon contained a mix of Cerro Toledo (58%) and Valle Grande (38%), with a little El Rechuelos (8.3%). Samples from the south side of the canyon were dominated by Cerro Toledo (99%) with very little Valle Grande (1%) and no El Rechuelos. The dominance of Cerro Toledo obsidian on the south side of the canyon can easily be explained by the location of the source within this area. But, Head felt that the Cerro Toledo source was actually closer to the north side sample than the Valle Grande source and was unclear why so much Valle Grande material was represented there. In actuality, both sources are about equally distant but the Valle Grande source is actually closer due to the presence of several canyons between the Tsankawi area and the Cerro Toledo source area near Rabbit Mountain and Obsidian Ridge. Nonetheless, Head concluded that there were no social barriers present that restricted access to these separate obsidian source areas.

ANALYTICAL METHODS

The lithic analysis methods were designed to collect information necessary to address the research issues as presented in Volume 4. The sampling methods, explicit artifact definitions, and more detailed information on the specific attributes recorded are presented in this section (also see Appendix R). In addition, data on the infield analysis and field collections of potential lithic raw material sources in the Rio Grande Valley and Pajarito Plateau are also presented in the following section. These field data were collected in order to document local raw material sources, raw material variation, and range in cobble size.

Sampling

One hundred percent of the collected lithic artifacts were submitted for analysis on most of the excavated sites. However, intra-site sampling was implemented on four sites with extremely large collections. These consist of the three Ancestral Pueblo roomblocks (LA 12587, LA 86534, and LA 135290) and a lithic scatter (LA 85859). On the other hand, the sampling strategy at LA 12587 (Area 8) was focused on the area of the scatter that represented the Late Archaic occupation and not the section that was a continuation of the surface scatter from the nearby pueblo roomblock.

The sampling strategy implemented for the Ancestral Pueblo roomblocks consists of selecting two or more 1 by 1 m grids within each room and analyzing all the artifacts from the stratigraphic column. In addition, all floor artifacts were analyzed and exterior activity areas and middens were also systematically sampled based on the overall aerial extent of the deposits. This was primarily done at LA 12587, which was the only site that contained a midden deposit. The result was that samples ranging from 16 to 18 percent for LA 12587 and LA 86534, and 35 percent for LA 135290 were selected for the lithic artifacts. Lastly, a sample of lithic artifacts was also selected from the Early Archaic lithic scatter at LA 85859. Lithic artifacts were only analyzed from a central section of the excavation, which provided the best example of the site stratigraphy. The result was that a 38 percent sample of the lithic artifacts from the site was studied.

ARTIFACT TYPE DEFINITIONS

Cores and Hammerstones

Cores (*n* = 84) are nodules that have faceted platforms from which specific kinds of flakes are removed. They are subdivided into unidirectional, bi-directional, multi-directional, bipolar, flake core, and undetermined fragment types (Figure 60.2). Flake cores were produced on large flakes, bipolar and undetermined types from flakes on nodules, and the remaining core types were produced directly from pebbles or cobbles. *Tested materials* (*n* = 5) are nodules with a single flake removed from an unprepared cortical platform at one or more isolated locations. They probably represent nodules that have been tested for material quality and were then rejected. *Cobble unifaces* (*n* = 5) have two or more flakes unifacially removed along a single edge margin, usually at one end of the pebble or cobble. Cobble unifaces probably represent unprepared cobble cores. *Cobble bifaces* (*n* = 1) have two or more flakes bifacially removed from a single edge at the end of a pebble or cobble. They presumably represent formal heavy-duty chopping tools (i.e., choppers), but might have also been used as a source for flakes. Cobble bifaces differ from bifacial cores in that bifacial cores are generally made of siliceous materials and have more than one continuous bifacially retouched edge perimeter. A *hammerstone* (*n* = 20) is a nodule that exhibits battering on an otherwise unmodified cortical portion of its surface. This battering usually occurs on the end or along the perimeter of the pebble or cobble. In contrast, *anvils* (*n* = 0) are artifacts that exhibit repeated battering in a specific isolated location, so that a small circular depression is created on a planar surface.

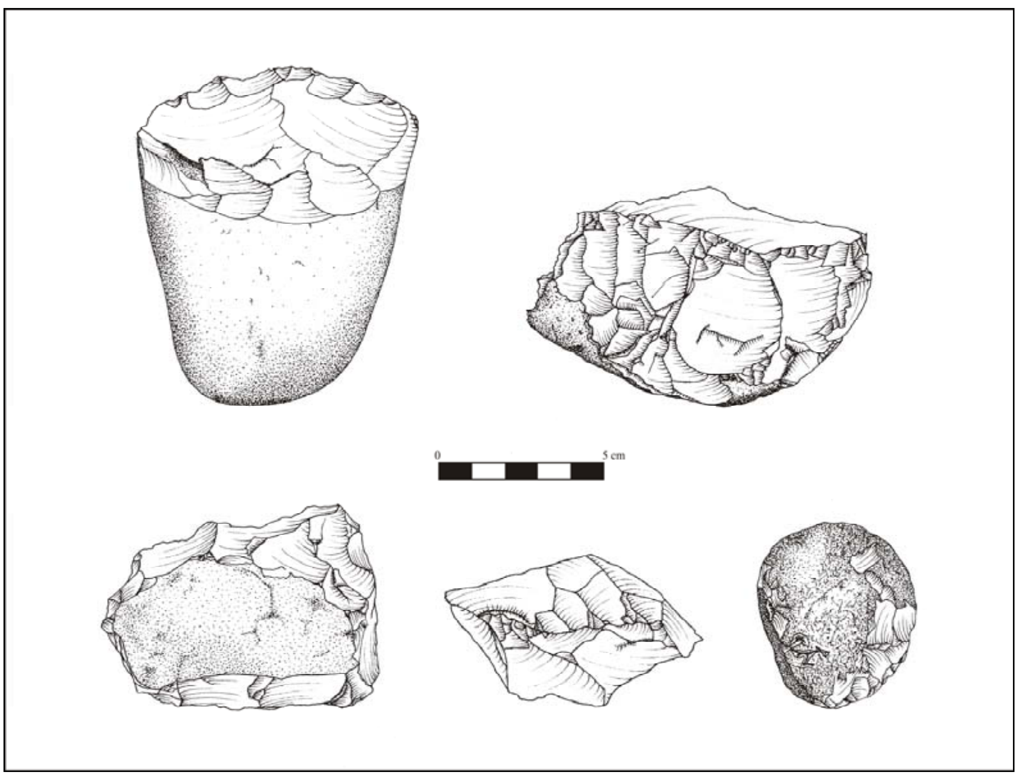

Figure 60.2. Cobble uniface and unidirectional (single face) core (upper). Unidirectional (multi face) core, bi-directional (bifacial) core, and hammerstone (bottom).

Debitage

Debitage consists of the by-products of core reduction and tool production. *Flakes* are pieces of material that have been detached from a core or tool by percussion or pressure, as opposed to *angular debris* (*n* = 990), which are pieces that are incidentally broken off during core reduction. These pieces of shatter lack definable flake characteristics, such as a platform, bulb of percussion, *eraillure*, ventral/dorsal surface, and proximal/distal ends. *Microdebitage* (*n* = 2556) are pieces of debitage with a maximum length equal to or less than 10 mm.

Core flakes (*n* = 4292) are flakes that have been detached from a core. A polythetic set (Clark 1968:36–37) of attributes for core flakes consists of a single or dihedral platform, a platform that is approximately as wide as the flake, a platform angle of greater than 75^{o}, cortex present on the dorsal surface, dorsal scars that may be absent, parallel, or perpendicular to the platform, a thickness of greater than about 5 mm, a pronounced bulb of percussion, and an *eraillure* scar. To be classified as a core flake, the flake must exhibit at least six of the eight defining attributes.

Bipolar flakes (*n* = 4) are flakes that have been detached from a core through the use of a bipolar reduction technique. That is, the core is set on an anvil and struck with the percussor (Crabtree 1972:42). The resultant flake differs from a core flake in that it may have two bulbs of percussion (positive or negative), *eraillures*, and/or scaling/crushing at one or both ends.

Core trimming flakes (*n* = 15) are pieces that have been struck at a 90^{o} angle to the major flaking axis of the core along the edge of the core platform and dorsal flaking surface. They are sometimes referred to as platform renewal or rejuvenation flakes, since they often remove the step fractures that can occur adjacent to the edge of the platform. However, they may also represent an attempt to change the orientation of the core, by preparing and reorienting a new flaking surface that is perpendicular to the previous major flaking axis. Core trimming flakes are similar to uniface rejuvenation flakes (Highley 1995:482), but are struck perpendicular and not parallel to the major flaking axis of the core or tool. *Core tablets* (*n* = 0) are also flakes that have been struck perpendicular to the major flaking axis of the core; however, they have been struck just below the platform to remove the whole striking platform from the core (Marks 1976:374).

Opposing core flakes (*n* = 2) have been detached from the bottom of the core by striking it at a 90^{o} angle to the major flaking axis. This then acts to create a platform from which flakes are removed in the opposite direction from previous removals. *Change-of-orientation flakes* (*n* = 1) are flakes removed from the opposite end of the major flaking axis of the core. Both flakes exhibit marked ventral curvature and multiple dorsal flake scars; however, these dorsal scars are perpendicular to the proximal-distal flake axis on the opposing core flake as opposed to radiating towards the proximal end (i.e., platform) of the change-of-orientation flake. These flakes are similar to overstruck flakes in that the distal end of the core is removed (e.g., Tixier 1963:43–44), but they do not originate from the major flaking axis platform.

Blades (*n* = 3) are specialized forms of flakes that are twice as long as they are wide, with parallel lateral sides and one or more parallel dorsal arrises (Bordes 1981:16). *Biface flakes* (*n* = 1995) are flakes that have been detached from a bifacially retouched artifact. A polythetic set of attributes for biface flakes consists of a multi-faceted platform, an isolated platform, a lipped platform, a platform angle less than 75°, a weak bulb of percussion, cortex absent on the dorsal surface, dorsal scars that are roughly parallel to each other and perpendicular to the platform, a thickness of less than 5 mm that is relatively even from proximal to distal ends, and a pronounced ventral curvature. A flake must exhibit at least six of the nine attributes to be classified as a biface flake. Biface flakes removed from retouched tools tend to exhibit a platform angle less than 50°, whereas, flakes removed from bifacial cores generally have platform angles from about 50 to 75°.

Overstruck flakes (*n* = 17) are flakes removed from the edge of a biface, but go over and beyond the face of the artifact detaching a portion of the opposite edge. These items are also referred to as *outrepassé* flakes (Tixier 1963:43–44). *Notching flakes* (*n* = 1) are flakes that exhibit a negative dorsal scar originating from the platform, a small indentation at the platform, a convex ventral profile, and a salient bulb of percussion (Titmus 1985:251–252).

Uniface flakes (*n* = 0) are flakes that have been detached from a unifacially retouched artifact (Jelinek 1966; Shafer 1970). A polythetic set of attributes for uniface flakes consists of a single-faceted platform, a platform angle of greater than 60^{o}, dorsal scars that are parallel to each other and perpendicular to the platform, a single distal scar on the dorsal surface of the flake (sometimes separated by an arris), and marked ventral curvature.

Burin spalls (*n* = 0) are pieces that have been struck from the edge of a flake, so the resulting scar (or facet) approaches a 90^{o} angle to the plane of the blank from which it was removed. *Pot lids* (*n* = 2) are Hertzian cones produced when siliceous rocks are subjected to heat. *Hammerstone flakes* (*n* = 9) are flakes with cortex on the platform and dorsal surface, with the platform being heavily battered. *Ground stone flakes* (*n* = 7) are flakes that have a ground facet(s) situated on their dorsal surface. *Undetermined flake fragments* (*n* = 701) are fragments for which flake type could not be determined.

Manuports (*n* = 7) are unmodified pieces of lithic raw material that have been transported from their source area to another location as a result of human behavior. This may include materials to be used in lithic reduction, ceramic production, or other miscellaneous functions.

Retouched Tools

Retouched tools are the result of the secondary percussion or pressure flaking of a piece in order to produce a specific tool shape (Figures 60.3 and 60.4). *Marginally retouched pieces* (*n* = 82) are pieces of debitage with retouch that extends over less than one-third of the surface of the artifact (Chapman and Schutt 1977:86). This is non-invasive retouch limited to the edge margin, but may be unidirectional or bidirectional. *Notches* (*n* = 3) are flakes with one or two contiguous notches along the edge of the piece, while *denticulates* (*n* = 1) are flakes with three or more contiguous notches along the edge of the piece (GEEM 1975). *Perforators and gravers* are flakes with retouched projections. Gravers (*n* = 1) exhibit a blunt end and perforators (*n* = 6) a pointed end. *Burins* (*n* = 0) are flakes that have had a portion of their edge removed (Crabtree 1972:48).

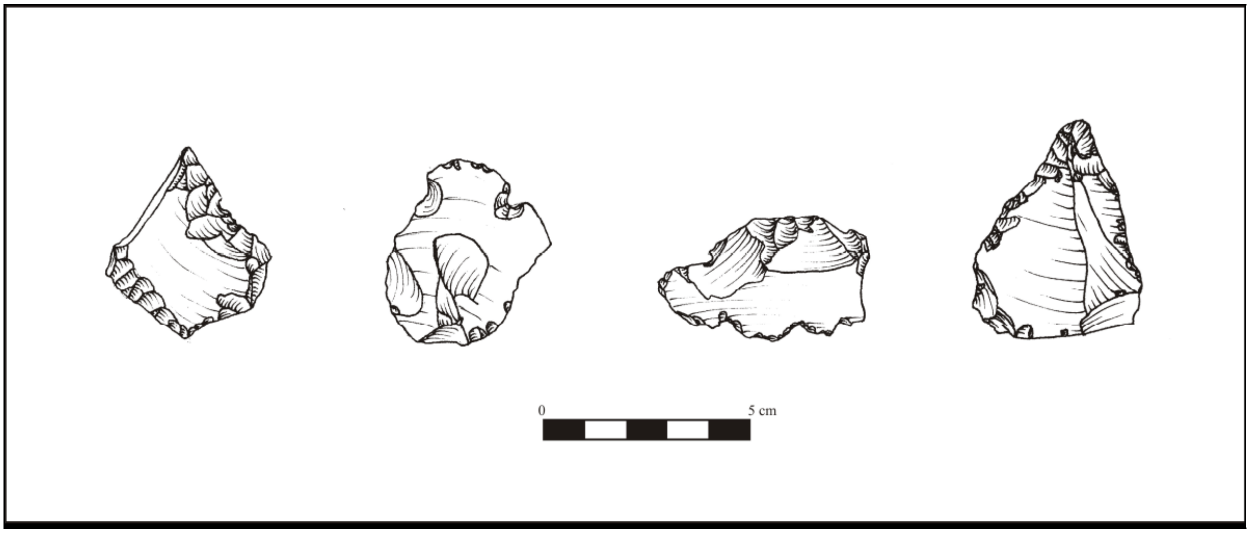

Figure 60.3. Informal tools; retouched piece, notch, denticulate, and perforator.

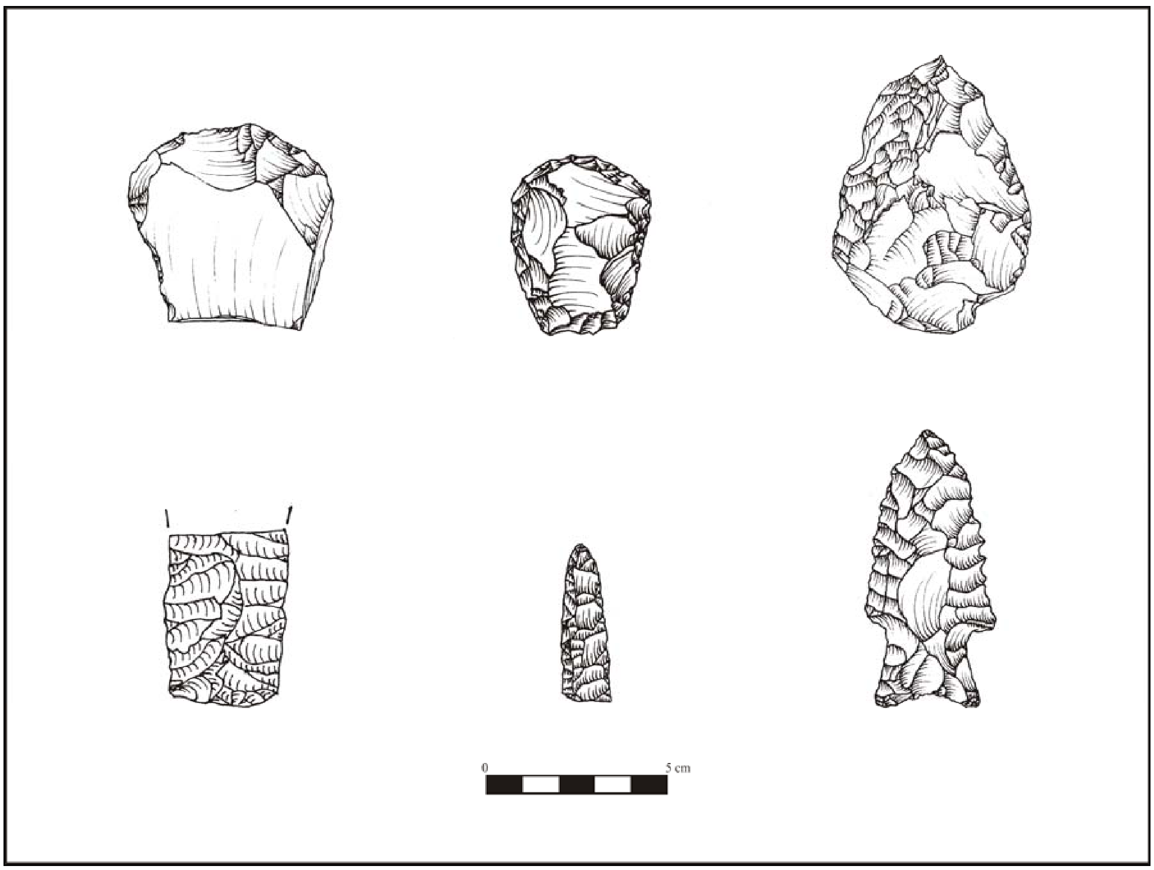

Figure 60.4. Uniface, scraper, and biface (upper). Biface, drill, and projectile point (lower).

Unifaces (*n* = 14) are artifacts that exhibit retouch scars over one-third or more of only one of their surfaces. This type of retouch can be defined as invasive. Unifaces exhibit initial edge retouch that lack a formal overall shape. In contrast, *scrapers* (*n* = 2) are specialized forms of unifaces that exhibit secondary edge retouch producing a formal shaped tool with an edge angle between 60 to 80°.

Bifaces (*n* = 45) are artifacts that exhibit retouch scars extending over one-third or more of both of their surfaces (Chapman and Schutt 1977:93). Generalized bifaces tend to be ovate or lanceolate in shape, with edge angles between about 30 to 50°. Drills and projectile points are specialized forms of bifaces. Drills (*n* = 7) are bifacially retouched flakes that are twice as long as they are wide, about as thick as they are wide and often exhibit a diamond-shaped cross-section. Projectile points (*n* = 27) are bifaces that exhibit hafting modifications that distinguish a stem from the blade. Composite tools (*n* = 5) are single artifacts that exhibit more than one tool type. These include retouched piece/perforator, perforator/notch, and denticulate/notch.

Ground Stone Tools

Ground stone tools are artifacts that exhibit ground and/or abraded surfaces. *Manos* are cobbles or slabs with at least one surface characterized by one or more smooth facets produced through grinding (Figure 60.5). They were handheld artifacts that were primarily used to crush and grind vegetal foodstuffs against a metate (Chapman and Schutt 1977:95; Christenson 1987:44). Polished surfaces on manos may indicate a function other than vegetal processing (e.g., hide processing [Adams 1988]). One-hand manos (*n* = 50) are less than 170 mm in length and two-hand manos (*n* = 26) have a length equal to or greater than 170 mm. *Undetermined manos* (*n* = 56) are fragments where the projected length of the artifact could not be determined.

Metates are characterized by at least one large grinding surface upon which vegetal foodstuffs may have been crushed and ground with a mano (Figure 60.6). They generally have a grinding surface greater than 450 cm^2 in size (Christenson 1987:47). *Millingstones* (*n* = 13) are informal unmodified slabs with flat grinding surfaces. Although the grinding surface may exhibit some pecking, the slab itself exhibits little in the way of formal shaping. *Basin metates* (*n* = 2) are slabs with concave basin-shaped grinding surfaces. These two metate types are usually associated with generalized seed processing and the use of a one-hand mano in a rotary motion, although millingstones can also be used with two-hand manos in a longitudinal grinding fashion. *Slab metates* (*n* = 6) are formal-shaped metates with large, flat prepared grinding surfaces.

Trough metates (*n* = 0) have a deep prepared trough as a grinding surface. The trough may be open at one or both ends. These two metate types are usually associated with more specialized corn milling and the use of two-hand manos in a longitudinal back and forth motion. If the type of metate could not be determined, it was classified as an undetermined metate fragment. *Grinding slabs* (*n* = 31) were, however, distinguished from millingstones by having a length less than 250 mm. These artifacts may have been used for a variety of purposes. Grinding slab fragments were separated from undetermined ground stone fragments by having a length greater than 100 mm. *Undetermined metate*s (*n* = 52) are fragments sufficiently large to determine that they represent portions of metates, but specific metate type could be determined.

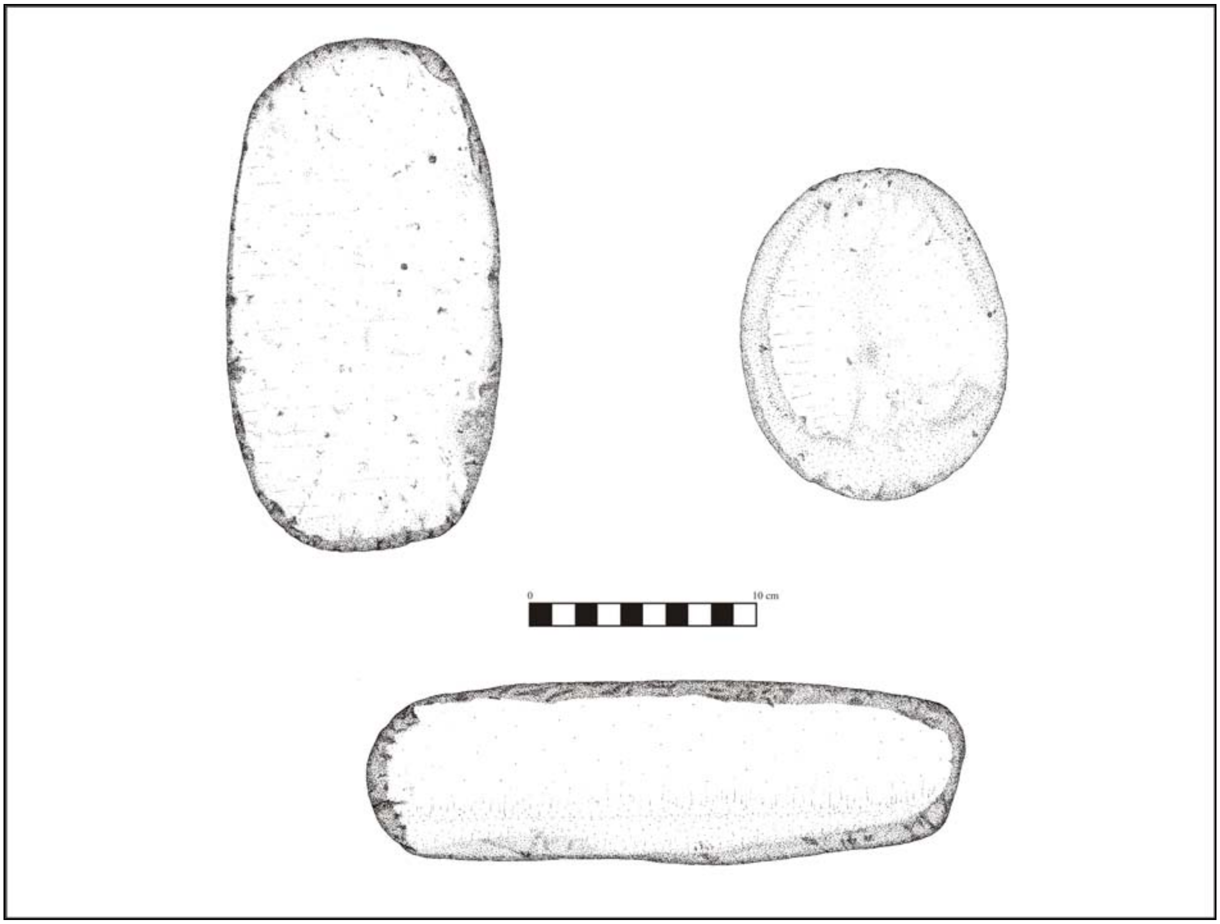

Figure 60.5. One- and two-hand manos.

Polishing stones (*n* = 15) are pebbles with finely ground and polished surfaces (Figure 60.7). These generally consist of small quartzite pebbles that could have been used to polish ceramic vessels. *Palettes* (*n* = 1) are tabular-shaped artifacts with finely ground and polished flat surfaces (Figure 60.7). *Mortars* (*n* = 0) are artifacts with large, deep, pecked, and ground concavities. *Pestles* (*n* = 1) are oblong artifacts with one or more ground ends. They presumably were used with the mortars to pulverize and grind various substances. *Abrading stones* (*n* = 13) are artifacts with localized but irregularly ground surfaces, with a distinction made between generalized abrading stones and *grooved abraders* (*n* = 2) (Figure 60.7). *Axes* (*n* = 6) exhibit a prepared bit (flaked or ground), whereas *mauls* (*n* = 2) exhibit battering on one or both butts (Figure 60.8). Either can be grooved for hafting (full or partial). In contrast, *hoes* (*n* = 6) exhibit an unprepared bit that often exhibits rounding and striations and hafting notches. *Vent plugs* (*tiponis*; *n* = 0) are pieces of the tuff that have been worked (ground) into cylindrical and conical shapes that are approximately 150 to 230 mm in length and 120 to 140 mm in width.

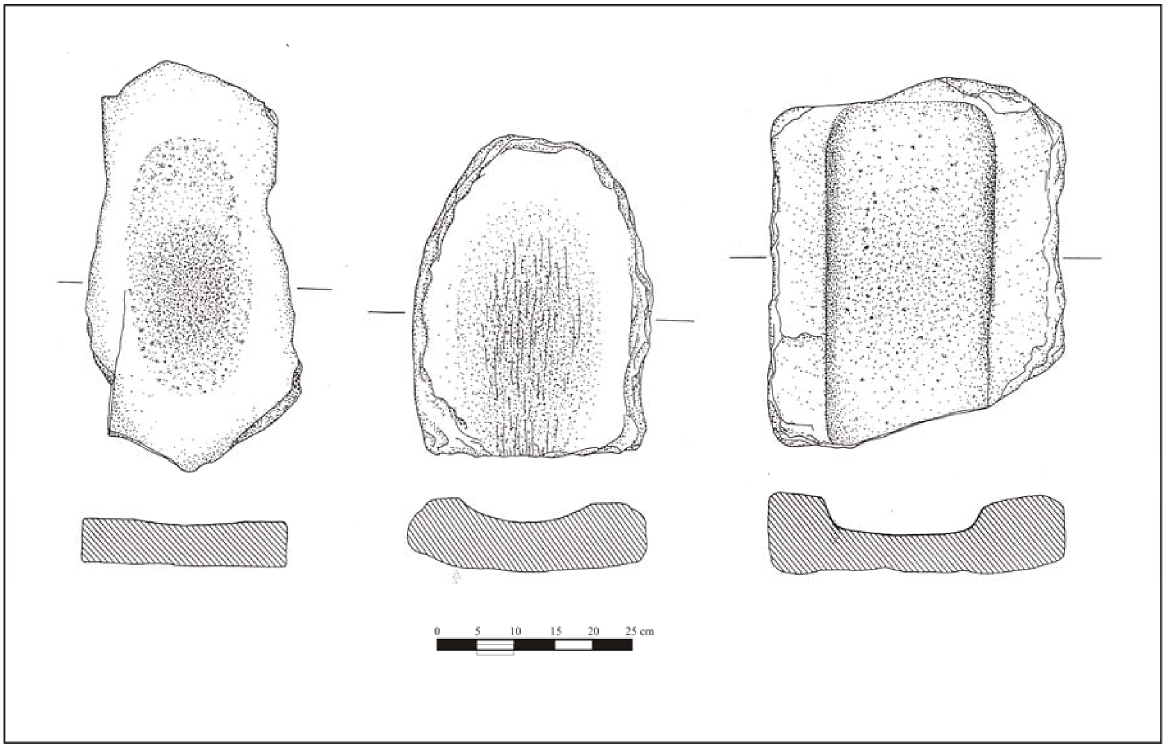

Figure 60.6. Milling stone, basin metate, and trough metate.

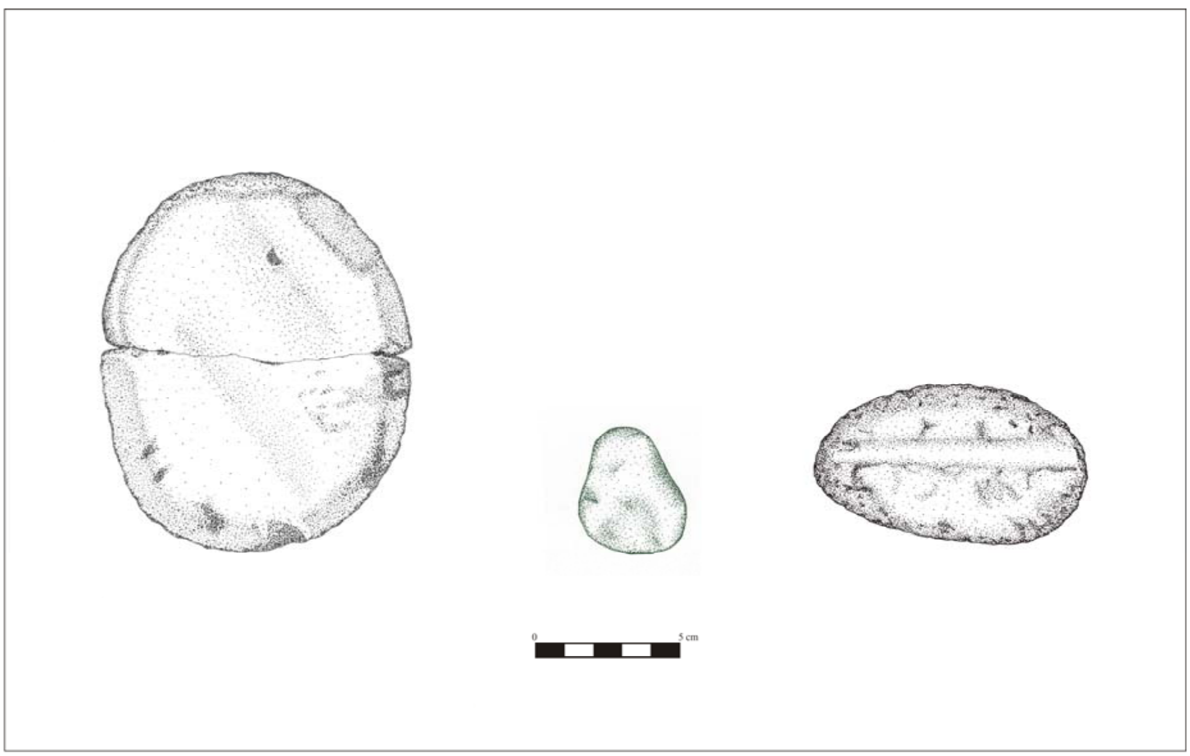

Figure 60.7. Palette, polishing stone, and grooved abrader.

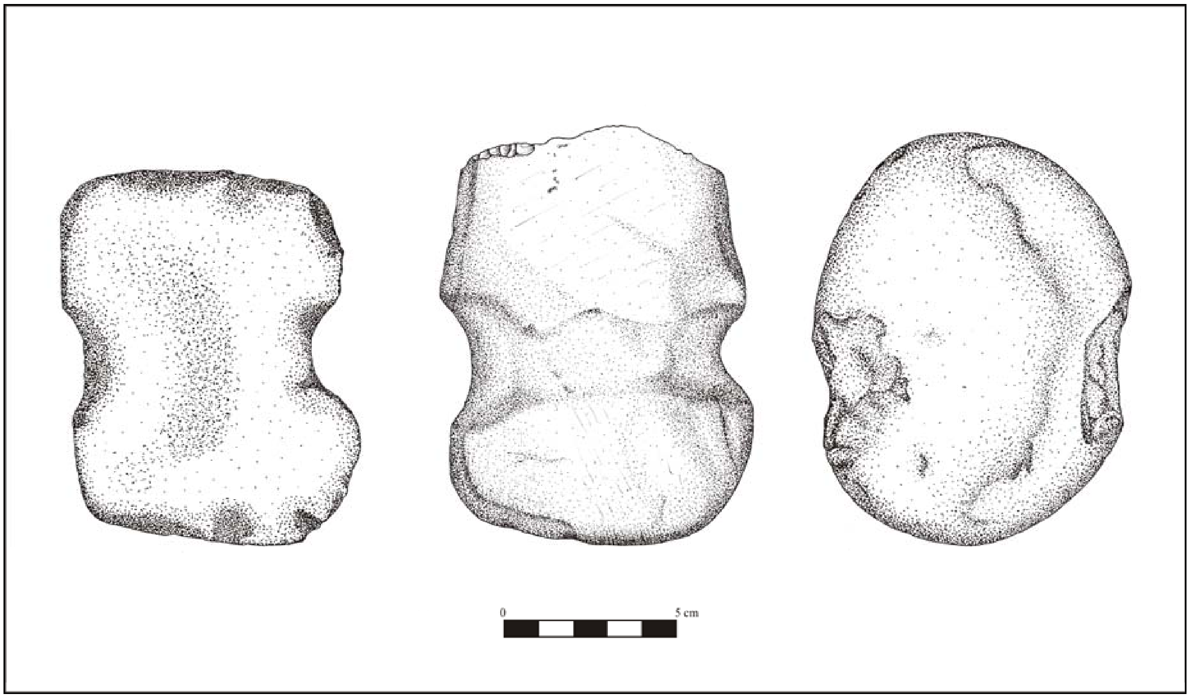

Figure 60.8. Maul, axe, and hoe.

Ornaments (*n* = 1) are beads, pendants, and other forms of jewelry. *Effigies* (*n* = 0) are anthropomorphic or zoomorphic figurines. *Stone ceramic lids* (*n* = 1) are thin circular-shaped artifacts whose perimeters have been bidirectionally retouched. These lids may have been used to cover storage or cooking vessels. *Shaped slabs* (*n* = 30) are large rectangular-shaped slabs (or fragments) that have been bidirectionally flaked along their perimeters. These artifacts were often used to cover ventilator shafts or door openings. A whet stone (*n* = 1) is a flat rectangular-shaped artifact that is finely ground. The *miscellaneous ground stone* (*n* = 15) category was used when the artifact could not be placed within any of the defined types, but was a recognizable artifact. In contrast, *undetermined ground stone* (*n* = 65) are unclassifiable ground stone fragments. These fragments often exhibit a single flat grinding surface.

Artifact Attributes

Cores and Core Tools

Material type and material grain were recorded for all the artifacts. Fine-grained materials are those that are glossy and translucent. Medium-grained materials exhibit a smooth surface, dull to glossy luster, and are aphanetic. Coarse-grained materials are grainy to the touch, dull in luster, and are porphyritic. Artifact condition was monitored as whole or fragmentary. Length for cores and cobble unifaces was measured in mm along the axis through the major flaking surface. Width was measured perpendicular to the length and thickness was measured as the remaining dimension. By contrast, the length of hammerstones was measured in mm along the longest axis, the width was measured perpendicular to length, and thickness was the smallest dimension of the artifact. Each artifact was weighed to the nearest tenth of a gram with an Ohaus digital scale. Weight was the only measurement recorded for core fragments.

Several core types were recorded based on platform orientation and core shape. As previously noted, these consist of single-directional, bi-directional, multidirectional, bipolar, flake cores, and core fragments. In addition, these core types were subdivided into specific subtypes. The single-directional cores as single-face, multi-face, prismatic, or pyramidal cores with flakes being removed from a single striking platform. Bi-directional cores are change-of-orientation, discoidal, bifacial, opposed same face, opposed different face, and 90° cores with flakes being removed from two separate striking platforms. In the case of the change-of-orientation cores, these flakes are removed from separate platforms at oblique angles to each other. Multi-directional cores are globular, opposed/90°, and opposed same/different face cores, with flakes being removed from three or more platforms. Bipolar cores exhibit battering, crushing, and/or negative or positive bulbs of percussion at one or both opposing ends. Flake cores are same-face and multi-face. Core fragments are broken cores.

Number of platforms, platform type, and platform preparation were recorded. Number of platforms was coded as zero for non-cores and core fragments. Bipolar cores were arbitrarily assigned a single platform. Platform type was cortical, single-faceted, multi-faceted, cortical/single-faceted, and undetermined/non-applicable (i.e., core fragments and non-cores). Platform preparation, either on the platform or along the platform edge, was recorded as none, abraded/crushed, ground, abraded/ground, and undetermined/non-applicable.

Cortex type was recorded as nodular, tabular, waterworn, quartz crystal, and undetermined. Nodule or tabular cortex is the natural weathered surface of a nodule or tabular-shaped rock. Waterworn cortex is the rolled surface created through water transport of a rock. The percentage of the cortical or unflaked surface was measured for whole artifacts as less than 25 percent, 26 percent to 50 percent, 51 percent to 75 percent, more than 75 percent, and undetermined fragments. The reason for discard was monitored for cores and cobble unifaces. This consisted of broken (material flaw), broken (culturally induced fracture), extensive hinging/stepping, exhausted, still useable, extensive battering, burned, undetermined, and non-applicable (i.e., hammerstones). The presence or absence of burning was recorded. This could be represented by the presence of discoloration, pot lids, and/or crackling.

The number of damaged loci was also recorded. This damage refers to possible use-wear and not to kind of platform preparation. Each damaged locus was given a sequential number for each artifact. The type of damage present was monitored as battering, rounding, scarring, and abrasion/ground. Battering is the pounding application of force to a specific locus when one object is struck against another. This action can produce conical impact rings (hertzian cones) on a natural surface, or bi-directional step fracturing and the deterioration of an edge margin. Rounding is the damage that results in the rounding of an edge margin and scarring from the removal of microflakes along an edge margin. Abrasion/ground is the presence of any abraded or ground surface on an artifact. Only damage that was obviously visible, or could be identified with a 10x hand lens, was recorded.

The location of the damage was recorded as an edge, convex surface, ridge, flat surface, flake scar ridge, or all over the artifact. An edge is the intersection of one or more negative flake scar facets, and edge damage is associated with the artifact being used as a chopper or pecking stone. A convex surface is a non-acute, natural convex surface of an object; damage in this location reflects use as a hammerstone. A ridge is an acute, naturally sharp surface; the damage on a ridge reflects use as an angular hammerstone. Flat is a naturally flat surface; damage on this surface reflects use as a hammerstone or anvil. Flake scar ridges (arrises) are the high points along the edge of negative flake scars; sometimes these areas are ground (e.g., on cobble unifaces) indicating that the tool may have been used as a plane or adze. Damage over the entire surface of an artifact presumably reflects a multi-functional use of the artifact (e.g., heavily battered hammerstone or pecking stone).

Debitage

Material type and material grain were recorded for each piece. The condition of the artifact was recorded as whole, proximal, mid-section, distal, lateral, or undetermined (e.g., flakes smaller than 10 mm). All pieces of angular debris were considered to be whole. Measurements were taken on all whole flakes. Length was defined as the distance along the proximal-distal axis of a flake (i.e., perpendicular to the platform) and was measured in mm using a sliding digital caliper. Weight was recorded for all debitage items to the nearest tenth of a gram.

The type of platform was recorded for all flakes as absent, cortical, single-faceted, dihedral, multi-faceted, crushed, collapsed, battered, and non-applicable (for angular debris and microdebitage). A cortical platform is unprepared and situated on cortex. A single-faceted platform consists of a single flake scar. A dihedral platform consists of two flake scars and a multi-faceted platform of three or more flake scars. A crushed platform is one in which the proximal end of the flake is covered with step fractures, indicative of crushing along the edge of the core platform. A collapsed platform is identified on whole flakes that lack a clear platform and any traces of crushing. A battered platform is a cortical platform that is covered with battering and impact marks, which may be indicative of a hammerstone spall. Platform preparation was monitored as none, abraded/crushed, ground, abraded/ground, retouched, retouched/abraded, retouched/ground, and undetermined/non-applicable. The latter category was used for flakes with collapsed, crushed, or battered platforms, as well as flake fragments, angular debris, and microdebitage.

Cortex type was recorded using the same attributes as for the cores. The placement of the cortex was recorded on whole flakes only. It was monitored as absent, on the platform only, on the dorsal surface only, on the platform and partially on the dorsal surface, orange rind (i.e., along the platform and lateral edge), on the platform, and/or totally covering the dorsal surface. The presence or absence of burning was recorded.

The presence or absence of edge damage was recorded as a possible indication of artifact use. A binocular scope at 10x or greater power was used, with possible damage being recorded if it was consistent along the edge margin (e.g., scarring, rounding, and polish). If present, the total number of modified edges was noted. The location with edge damage was recorded as end, lateral, projection, and dorsal (i.e., ground stone flake), and edge outline as straight, concave, convex, straight/concave, straight/convex, concave/convex, projection (i.e., graver or perforator), and flat (i.e., abraded/ground surface). Lastly, the edge angle of all the damaged edges was recorded to the nearest 5°. This measurement is equivalent to the "spine plane angle" (Tringham et al. 1974), which measures the intersection of the dorsal and ventral surfaces of the edge. If the angle varied along the edge, then a mean edge angle or the angle that characterized the majority of the edge was recorded. A "shurikan" edge-angle template was used for this analysis. It consists of a circular disk template with angles cut into its side at 5° increments from 20 to 90°. The edge to be measured is placed within a notch until the angle that fits most accurately is found.

Retouched Tools

Material type, material grain, condition, cortex type, cortex placement, and burning were recorded for retouched tools using the same attributes as those monitored for the debitage. Measurements were taken in mm for whole tools. Length was measured along the proximal-distal axis. Width was measured at a 90° angle to the proximal-distal axis. Thickness was the greatest measurement once the proximal-distal axis was rotated 90°. The proximal end is the same as that defined for flakes on informal retouched tools and the possible hafted end on formal tools (e.g., bifaces, projectile points, and scrapers). Weight was measured to the nearest tenth of a gram. Tool fragments were only weighed.

Biface shape and projectile (haft) type were recorded as ovoid, ovate, lanceolate, round, triangular, stemmed, contracting stemmed, corner-notched, side-notched, side-notched with basal notch, and non-applicable (i.e., not a biface).

The number of separate retouched edges was monitored on each tool. Each edge was given a sequential number. Only one edge was recorded on tools exhibiting a continuously retouched edge (e.g., bifaces, projectile points, drills, and scrapers). It is the marginally retouched pieces that most often exhibit separate retouched edges. Retouch type was recorded as unidirectional ventral (inverse), unidirectional dorsal (obverse), bi-directional (continuous on both faces), alternating (inverse and obverse retouch along the same edge), alternate (inverse and obverse retouch along opposite edges), beveled, alternate/beveled, burination, backed, and bi-directional/beveled.

Edge outline was recorded as straight, concave, convex, straight/concave, straight/convex, concave/convex (i.e., denticulate or double notch), projection (i.e., graver or perforator), flat (i.e., abraded or ground surface), and undetermined (i.e., fragments). Edge outline and edge angles were monitored, as was each edge of a retouched piece or along the blade of a biface and projectile point and the retouched edges on scrapers. Edge angles were measured the same as for utilized debitage.

A sketch was also made of each retouched tool and information on the presence and location for breakage type and the presence of hafting polish was noted. The bases of hafted tools were observed using a binocular scope at 10x or greater power in order to identify possible hafting wear (i.e., polish on arrises or tool surface). All of these data were used to infer possible manufacturing and use-related breakage patterns (see Callahan 1979; Crabtree 1972; Johnson 1979).

Ground Stone Tools

Material type and condition was monitored the same as for cores. Measurements were recorded in mm for all whole artifacts. Length was the greatest measurement along the longest axis of the artifact. Width is the greatest measurement perpendicular to the longest axis. Thickness is the greatest measurement on a 90° plane to the length and width. Weight was recorded in grams. Ground stone fragments were only weighed. It should be noted that the length measurement for some manos is actually perpendicular to the actual grinding motion. In addition to these measurements, the maximum length and width of the primary grinding surface was also recorded for manos and metates.

Use location was recorded as single unopposed surface, two opposed surfaces, perimeter (e.g., on abrading stones), edge (e.g., on axes), other (e.g., ornaments), undetermined, and non-applicable (e.g., stone lids). Tool cross-section was monitored for ground stone tools with single or double grinding surfaces as plano (flat), concave, convex, bi-plano, plano-convex, bi-convex, wedge-shaped (beveled), other (i.e., tools without grinding surfaces), and undetermined. Surface shape provides a general description of the primary grinding surface shape. It was recorded as roughly ovoid, rectangular, irregular, and other. Surface modification describes the nature of the modification to the primary worked surface. It was monitored as ground, pecked, ground/pecked, and polished.

The presence/absence of fingerholds on manos was recorded as absent, one side, two side, and non-applicable (i.e., non-manos). Non-ground stone use-wear was recorded as absent, battering (e.g., mauls or manos used as hammerstones), and flaked/rounded (e.g., axes). The presence or absence of burning (heating) was monitored (e.g., blackening or fire-cracked).

Lithic Raw Material Sources

Lithic raw materials are available from various locations across the Pajarito Plateau, Rio Grande Valley, and Jemez Mountains. Broxton et al. (Volume 1, Chapter 2) and Shackley (Volume 1, Chapter 10) have already discussed the bedrock geology and obsidian source studies for the east Jemez Mountains area. A variety of materials were available to the prehistoric Pajaritans for stone tool production. This ranges from obsidian, Pedernal chert, and basalt for chipped stone artifacts, to the use of tuff, dacite, quartzite, and vesicular basalt for ground stone artifacts.

The Cerros del Rio basalts and Bandelier Tuff formations are a source of local raw materials, as are the secondary drainages that cross-cut the plateau. An infield analysis was conducted of these secondary deposits to identify its lithology, including the range of lithic material types and cobble sizes that are represented. An exposure of gravels was identified in Rendija Canyon. A single 1- by 1-m sample grid was selected and all cobbles greater than 5 cm in diameter recorded. A total of 135 cobbles were identified; the results are presented in Table 60.1. Most of the cobbles are composed of dacite, with some rhyodacite, rhyolite and Bandelier tuff. The rhyolite is actually a gray coarse-grained material that would not be well suited for knapping. Information on the range of cobble size materials is presented in Table 60.2.

Table 60.1. Lithic materials recorded in the Rendija Canyon gravels.

Material	Frequency	Percent
Bandelier tuff	1	0.7
Dacite	107	79.3
Rhyodacite	18	13.3
Rhyolite	9	6.7
Total	**135**	**100.0**

Table 60.2. Cobble size recorded in the Rendija Canyon gravels (cm).

Material	*N*	Minimum	Maximum	Mean	Std Deviation
Bandelier tuff	1	10	--	--	--
Dacite	107	6	27	9.3	3.4
Rhyodacite	18				
Rhyolite	9				

The Totavi Lentil formation consists of late Pliocene axial gravels that are distributed along the Rio Grande Valley (Chapter 2, Volume 1; Walsh 1998; Warren 1977). An infield analysis was also conducted of this formation to identify its lithology, including the range of lithic material types and cobble sizes that are represented. An exposure of gravels was identified in White Rock Canyon below the community of White Rock. Four 1- by 1-m sample grids were selected and all cobbles greater than 5 cm in diameter recorded (Figure 60.9). A total of 102 cobbles were identified; the results are presented in Table 60.3. Most of the cobbles are composed of quartzite (61.1%), with a variety of other materials present. Other materials include Pedernal chert (chalcedony), a generalized chert (grays and tans), rhyolite, and sandstone, which are also present in the archaeological assemblages. Although smaller pieces of sandstone could be procured from exposures of the Totavi Lentil gravels, large tabular pieces would have been obtained from more distant formations in the Santa Fe or Abiquiu areas. Silicified wood was rarely observed in the surface gravels, but was not present within the sample. On the other hand, obsidian was not identified in the sample and could not be found in a surface reconnaissance of the gravel exposure or in a second exposure located nearby. Moore et al. (1998) report that they were also unable to identify any obsidian in the gravel outcrops near Totavi. However, Shackley (personal communication) has identified some El Rechuelos obsidian near Cochiti, and Church (2000) found a small number of nodules in his southern New Mexico gravel sample. Information on the range of cobble size materials for the Totavi Lentil gravels is presented in Table 60.4. Pedernal chert cobbles range in size from 7 to 17 cm in diameter; however, cobbles were observed as large as 20 cm in diameter. The chert cobbles are smaller, ranging from 6 to 10 cm in diameter with quartzite also ranging from 6 to 20 cm in diameter.

Table 60.3. Lithic materials recorded in the Totavi Lentil formation.

Material	Frequency	Percent
Basalt	17	8.4
Chert	6	3.0
Dacite	18	8.9
Gneiss	3	1.5
Granite	7	3.4
Metaconglomerate	7	3.4
Pedernal chert	7	3.4
Pegmatite	5	2.5
Quartzite	124	61.1
Rhyolite	2	1.0
Sandstone	7	3.4
Total	**203**	**100.0**

Sandstone	7	6	13	7.5	2.6

Three primary obsidian sources were commonly exploited by the prehistoric inhabitants of the Pajarito Plateau. The Cerro Toledo source is exposed at the heads of Frijoles, Alamo, and Capulin canyons, as well as the mesa tops in the area of Rabbit Mountain and Obsidian Ridge (Figure 60.10). In addition, small pebbles are present in secondary deposits associated with the Cerro Toledo interval that are scattered across the mesa top in Rendija Canyon.

Figure 60.9. Totavi Lentil gravel exposure in White Rock Canyon.

Figure 60.10. Close up of Cerro Toledo pebble source material.

The Valle Grande source is located at Cerro del Medio inside the Valles Caldera. This source provides some of the largest obsidian cobbles available in the region, ranging up to about 30 cm in diameter (see Figure 60.11). It appears that this source is restricted to the caldera, either at Cerro del Medio or interior drainages. Obsidian cobbles have not been observed in San Antonio Creek or Jemez River gravel deposits situated outside of the caldera (Shackley, personal communication). Although very small pebbles of this obsidian have been observed in pumice deposits located in Los Alamos, these pieces are too small for stone tool production. Lastly, El Rechuelos obsidian is present in the area around Polvadera Peak near Abiquiu (Figure 60.12).

As previously noted, no obsidian was observed in the Totavi Lentil; therefore, it is assumed that any artifacts made of El Rechuelos obsidian were primarily derived from exposures located further to the north in the Polvadera Peak or Abiquiu areas. Otherwise, a single artifact made of Bear Springs obsidian was also identified in an archaeological assemblage. This source is located in the southern Jemez Mountains.

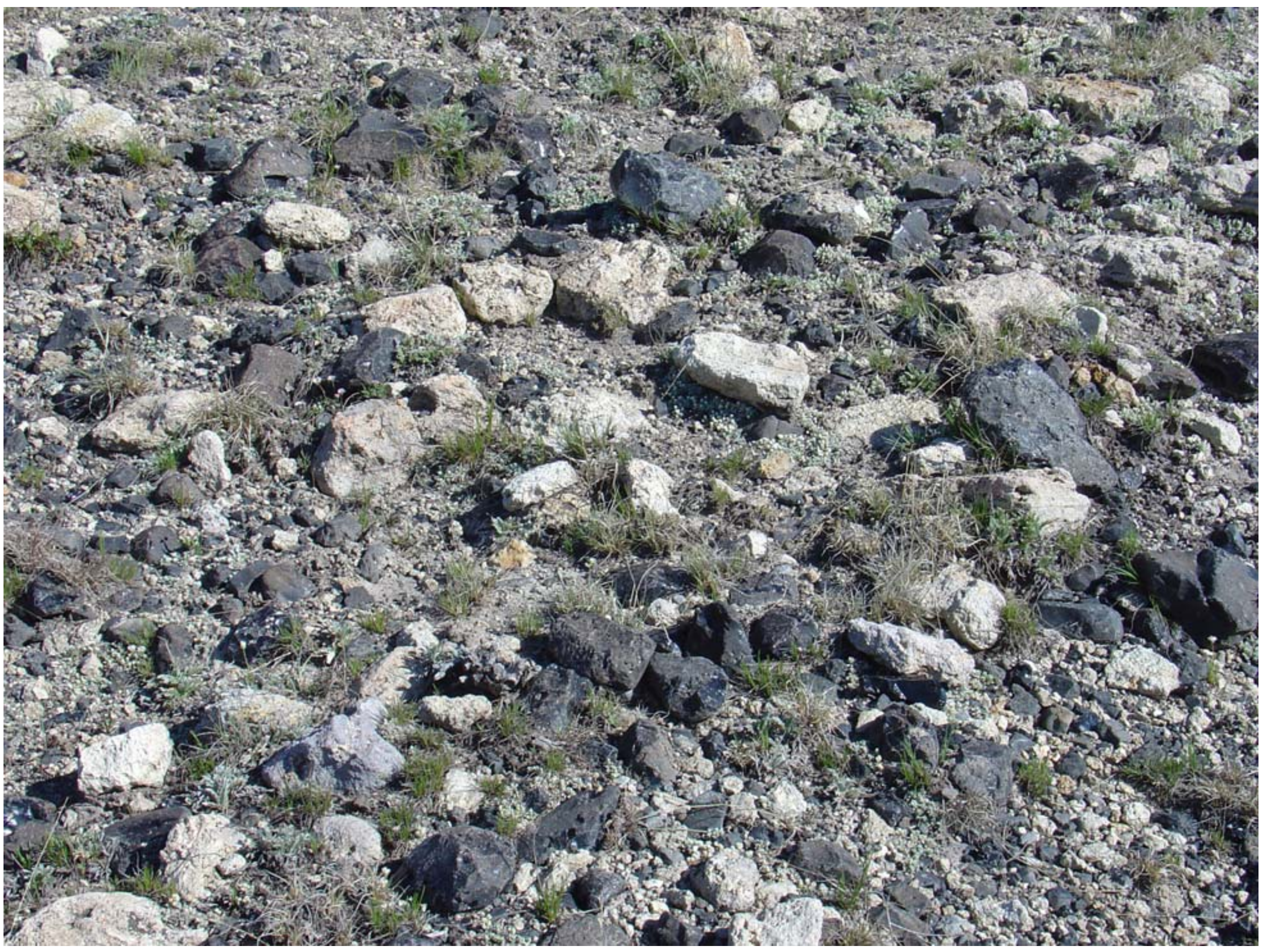

Figure 60.11. Valles Caldera obsidian cobble source material.

Basalt was a common material used for prehistoric stone tool production; however, it appears that some of the material referred to as fine-grained basalt is actually a fine-grained black dacite.

For example, this is the case for most of the Early Archaic artifacts that have been described in the northern Rio Grande. Three distinct fine-grained dacite sources have been identified through the fieldwork conducted by Vierra and Shackley (Chapter 10, Volume 1). A preliminary reconnaissance of a fine-grained dacite quarry was conducted by Dave Broxton, Rory Gauthier, and Brad Vierra in Bandelier National Monument. This outcrop comprises a roughly 2.5-m-thick horizontal zone of black dacite that forms the base of a thick Cerros del Rio lava flow exposed in a small butte near the Rio Grande at the mouth of Lummis Canyon. The fine-grained nature of the material is probably due to the rapid cooling of the deposit at the base of the flow (Figure 60.13). Maar deposits are exposed on the slope a few meters below the level of the quarry that appear to represent a mixing of flow material with alluvial deposits in the Rio Grande. In addition, two other distinctive dacite sources have been identified at San Antonio Mountain and Newman's Dome located about 115 km (70 miles) north of Los Alamos, and west of Taos and the Rio Grande (also see Newman and Nielson 1987).

Figure 60.12. El Rechuelos source area. Polvadera Peak is in the background and the obsidian-bearing domes are in the right foreground.

Lithic Artifacts

A total of 11,311 lithic artifacts were analyzed for the project. Table 60.5 presents the information on lithic artifact type by material type for the entire analyzed collection. A range of materials were used for core reduction and retouched tool and ground stone tool production. The cores are primarily made of chalcedony with less Pedernal chert, obsidian, basalt, and other materials. The debitage assemblage mostly consists of obsidian and chalcedony, with less Pedernal chert, basalt, and other materials, and a similar pattern for the retouched tools with chalcedony, obsidian, and less Pedernal chert, basalt, and other materials. In contrast, ground stone artifacts are primarily made of dacite, with less andesite, quartzite, tuff, basalt, vesicular basalt, sandstone, and other materials.

Figure 60.13. Dacite quarry in Bandelier National Monument.

X-Ray Fluorescence Analysis of Obsidian and Possible Dacite Artifacts

A total of 300 obsidian artifacts were submitted for X-ray fluorescence (XRF) analysis (Table 60.6). Five separate obsidian sources were identified: Cerro Toledo (Rabbit Mountain/Obsidian

Ridge area), Valle Grande (Cerro del Medio), El Rechuelos (Polvadera Peak area), Bear Springs, and an unknown source. The artifacts can be visually distinguished into six different types. A chi-square analysis of a contingency table of obsidian color by obsidian type (i.e., major sources) indicates that there are significant differences in this distribution (*chi-sq* = 329.7, *df* = 6, $p \leq 0.001$). Adjusted residuals were calculated to determine which of the cells were contributing to the significant chi-square value. Adjusted residuals greater than 1.96 or -1.96 are significant at the 0.05 level (Everett 1977:47). Valle Grande and El Rechuelos obsidian sources are significantly correlated with translucent (8.2) and black dusty (16.5) colors. In contrast, the Cerro Toledo source is characterized by a wider variety of color types, including black opaque (7.2) and other (2.7; green, brown and gray). A single piece of translucent Bear Spring obsidian and black opaque obsidian from an undetermined source were also identified.

A DESCRIPTION OF THE PROJECT LITHIC ASSEMBLAGE GROUPS

Eleven separate lithic assemblage groups were defined for the C&T Project excavation data. Together they span a 7000-year history of stone tool technology on the Pajarito Plateau. These data are summarized and contrasted in this section.

No Paleoindian sites were identified during the C&T Project survey; however, an isolated Late Paleoindian projectile point was found in the White Rock Y Tract at LA 61041 (Hoagland et al. 2000). The point is a lanceolate-shaped point with a concave base (Figure 60.14).

Figure 60.14. Late Paleoindian projectile point.

In contrast to the lack of Paleoindian materials, the Archaic occupation of the project area is represented by several sites. These consist of an Early Archaic lithic scatter (LA 85859), which is radiocarbon dated to circa 5000 BC, a Late Archaic lithic scatter (LA 12587, Area 8), and two sites (LA 99396 and LA 99397) that appear to be Archaic, but whose exact period of occupation is unclear. Based on the radiocarbon, obsidian hydration, and projectile point chronology data, these sites may have Middle and Late Archaic site components. In addition, several surface artifact scatters appear to contain Archaic components. These sites include LA 86533, LA 86637, and LA 139418.

There were no Early Coalition period sites excavated during the course of the C&T Project. However, LA 4624, an Early Coalition period roomblock, was partially excavated on Mesita del Buey near the White Rock Tract (Vierra et al. 2002). Two Middle Coalition period roomblocks (LA 86534 and LA 135290) were fully excavated during the C&T Project; both were located in the Airport Tract. A single Late Coalition period roomblock (LA 12587) was excavated in the White Rock Tract as part of the C&T Project. A second Late Coalition period roomblock (LA 4618) was excavated on Mesita del Buey in the early 1990s (Schmidt 2006).

The Classic period sites excavated as part of the C&T Project are restricted to fieldhouses that were excavated primarily in Rendija Canyon, with two in the Airport and White Rock tracts. These cover the entire occupation span of the Classic period, from the 14th through the 16th centuries. Five Late Coalition period fieldhouses were also excavated in these two tracts.

A late 18th or early 19th century Jicarilla Apache tipi ring site was excavated in Rendija Canyon (LA 85869). The site consists of two rock rings with an associated artifact scatter, which includes a lithic reduction locus situated near one of the tipi rings.

A single Homestead Era site (LA 85407) was excavated in Rendija Canyon. The Serna Homestead included a cabin, a horno, a corral, and a trash dump, as well as a prehistoric artifact scatter. The McDougall Homestead cabin was excavated in 2005 on Mesita del Buey (McGehee et al. 2006). A few chipped stone items were recovered, although they may not be associated with the homestead occupation.

These temporal lithic assemblage groups will be used to identify intra-group and inter-group variability, while making generalizations about assemblage composition and long-term changes in stone tool technology. Sample sizes vary, as do the nature of the site types represented. Nonetheless, they provide an excellent sample of changing land-use and technology on the Pajarito Plateau.

The following descriptions of the lithic groups are divided into three sections: material selection, lithic reduction, and tool use. The first section describes the variation in lithic raw materials and the possible sources of these materials. The lithic reduction section provides information on core reduction techniques, stages of reduction represented, and evidence of retouched tool production. The tool use section presents information on possible tool function, including presence/absence of use-wear and the variation among ground stone tools.

The Archaic Period

Early Archaic

A total of 2057 artifacts were analyzed from LA 85859, consisting of one core, 2046 pieces of debitage, 10 retouched tools, and one mano. This represents a 37 percent sample of the 5595 total lithic artifacts recovered during the site excavations. Three charcoal samples obtained from the lower contexts of the site provided calibrated intercepts ranging from 5300 to 4860 BC. However, no diagnostic projectile points were recovered from the Early Archaic context.

Late Archaic

A total of 485 artifacts were analyzed from LA 12587 (Area 8), consisting of one core, 465 pieces of debitage, three retouched tools, and 11 ground stone items. This represents a 22 percent sample of the 2196 total lithic artifacts recovered during the site excavations. Late Archaic components were also present in the surface scatters at LA 86533, LA 86637, and LA 139418, which contained projectile points (Figure 60.15).

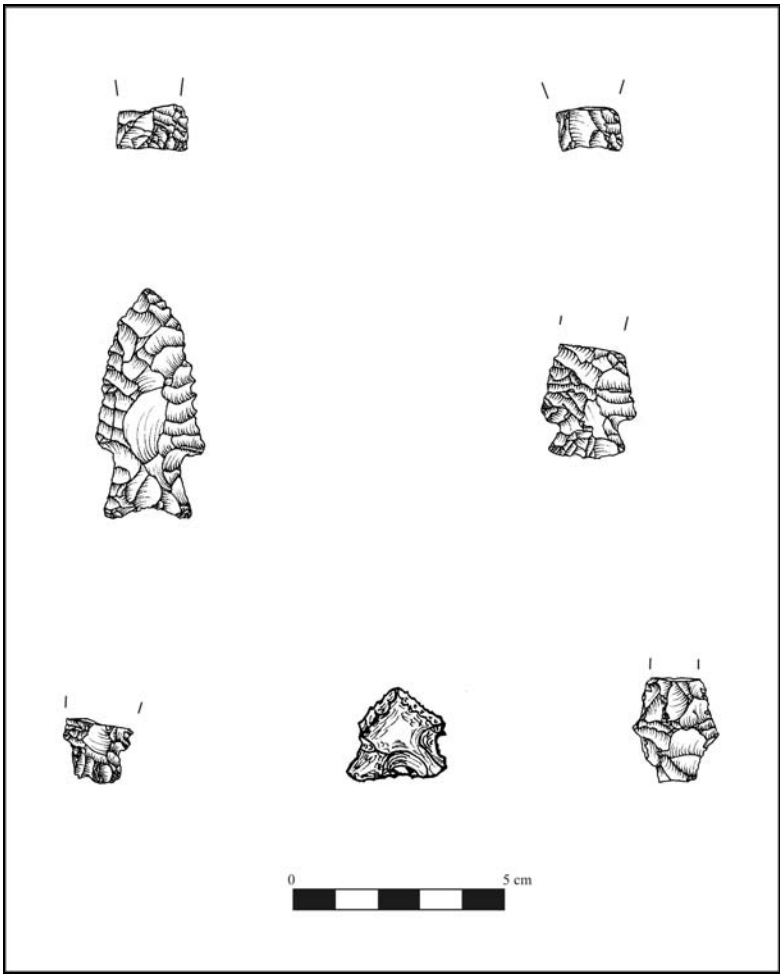

Figure 60.15. Archaic projectile points from the C&T Project.

Undetermined Archaic (Middle to Late?)

Two sites located in the Rendija Tract contain possible Middle to Late Archaic components. LA 99396 is a multi-component site that includes a surface Archaic lithic scatter with an ephemeral Coalition period structure. A total of 1252 lithic artifacts were analyzed from the Archaic component. No radiocarbon dates are available for this component, but obsidian hydration dates and several projectile point fragments indicate a possible Middle to Late Archaic occupation span. The assemblage recovered from LA 99397 was mostly removed from the upper 50 cm of excavation. Two charcoal samples yielded radiocarbon dates with calibrated intercepts of 380 and 160 BC from deposits containing the lithic artifacts. A total of 1090 artifacts were analyzed from this assemblage, including a possible Late Archaic point base (see Figure 60.15). In addition, obsidian hydration dates indicate possible Middle to Late Archaic period occupations.

Material Selection

A comparison of debitage assemblages indicate that all four of the sites are dominated by obsidian, with lesser amounts of chalcedony, Pedernal chert, igneous materials, and chert (Table 60.7). LA 85859 contains the most obsidian, followed by LA 12587 (Area 8) and LA 99396, and then LA 99397. The lower percentage for the latter site is due to the increased presence of chalcedony and Pedernal chert at the site.

Table 60.7. Archaic lithic debitage material types.

Site	Material Types (n/%)					
	Igneous	**Obsidian**	**Chalcedony**	**Pedernal**	**Chert**	**Total**
LA 85859	2	2036	6	2	0	2046
	0.1	99.5	0.3	0.1	0.0	
LA 12587 (Area 8)	3	438	16	6	1	464
	0.6	94.3	3.4	1.2	0.2	
LA 99396	4	1138	53	23	0	1218
	0.3	93.3	4.3	1.8	0.0	
LA 99397	1	845	166	55	1	1068
	0.1	79.1	15.5	5.1	0.1	
Total	**10**	**4457**	**241**	**86**	**2**	**4796**

Table 60.8 presents the results of the XRF analysis of 77 artifacts from the four Archaic sites and some noteworthy results were returned. All the obsidian samples at LA 85859 and LA 99397 were derived from the Valle Grande source. The Valle Grande source is situated about 17 km (11 mi) as the "crow flies" to the west of the sites. It appears that the occupants of the site geared up with obsidian from the caldera and then moved into the Rendija Canyon area. LA 99396 is also located in Rendija Canyon, but contains a mixture of Cerro Toledo, Valle Grande, and El Rechuelos obsidian. This site presumably reflects a north-south movement pattern with debitage from all three sources procured and deposited at the site. It is unclear if the Ceramic period component at this site is also contributing to the mixed pattern. Lastly, most of the obsidian at LA 12587 was derived from the Cerro Toledo source. The Cerro Toledo and Valle Grande sources are located about 15 km (10 mi) as the "crow flies" to the southwest and west of the site, respectively. The Late Archaic site occupants had presumably moved northeast out of the Cerro Toledo source area and into the White Rock Tract.

Table 60.8. Archaic obsidian source samples.

Site	Obsidian Source					
	Cerro Toledo	**Valle Grande**	**El Rechuelos**	**Bear Springs**	**Unknown**	**Total**
LA 85859	0	18	0	0	0	18

LA 99396	9	9	5	0	1	24
LA 99397	0	10	0	0	0	10
Total	**33**	**38**	**5**	**0**	**1**	**77**

Lithic Reduction

Very few cores were recovered from the Archaic sites. A single bifacial chalcedony core was recovered from both LA 85859 and LA 99397. The cores exhibited waterworn cortex, which indicates that they were obtained from the Totavi Lentil gravels. The site occupants presumably retrieved the cobbles during a visit to the valley. LA 12587 (Area 8) contained a single chalcedony core that was reduced using a bidirectional opposed-different-face technique. LA 99396 contained an obsidian pebble and large rhyolite cobble core. Both cores were reduced using a bidirectional, multi-face technique.

Table 60.9 presents the information on debitage type by site. All of the sites are dominated by microdebitage and biface flakes. Only LA 99397 contains more biface flakes than microdebitage; however, both debitage types presumably reflect the reduction of bifacial artifacts at these sites. This is best represented in Figure 60.16, which illustrates the distribution of biface edge angles for LA 85859 and LA 99397. This figure shows that bifacial cores and bifacial blanks were being produced at both sites and that finished projectile point or knives were also being made at LA 99397. The bifacial cores have platform angles ranging from 70 to 85°, the bifacial blanks from 55 to 65°, and projectile point/knives with edge angles ranging from 40 to 50°. LA 85867 probably represents a temporary campsite where bifacial tool blanks were being produced. By contrast, LA 99397 exhibits a wider range of core reduction and tool production/maintenance activities and therefore may represent a habitation site. Given this dichotomy, LA 12587 (Area 8) could represent a temporary campsite and LA 99396 a habitation site.

Table 60.9. Archaic debitage types.

Site	**Debitage Type (*n*/%)**							
	Debris	Core flake	Biface flake	*Outre-passé*	Micro-debitage	Und. Flake	Other	Total

Total	230	1159	1402	6	1560	433	7	4797

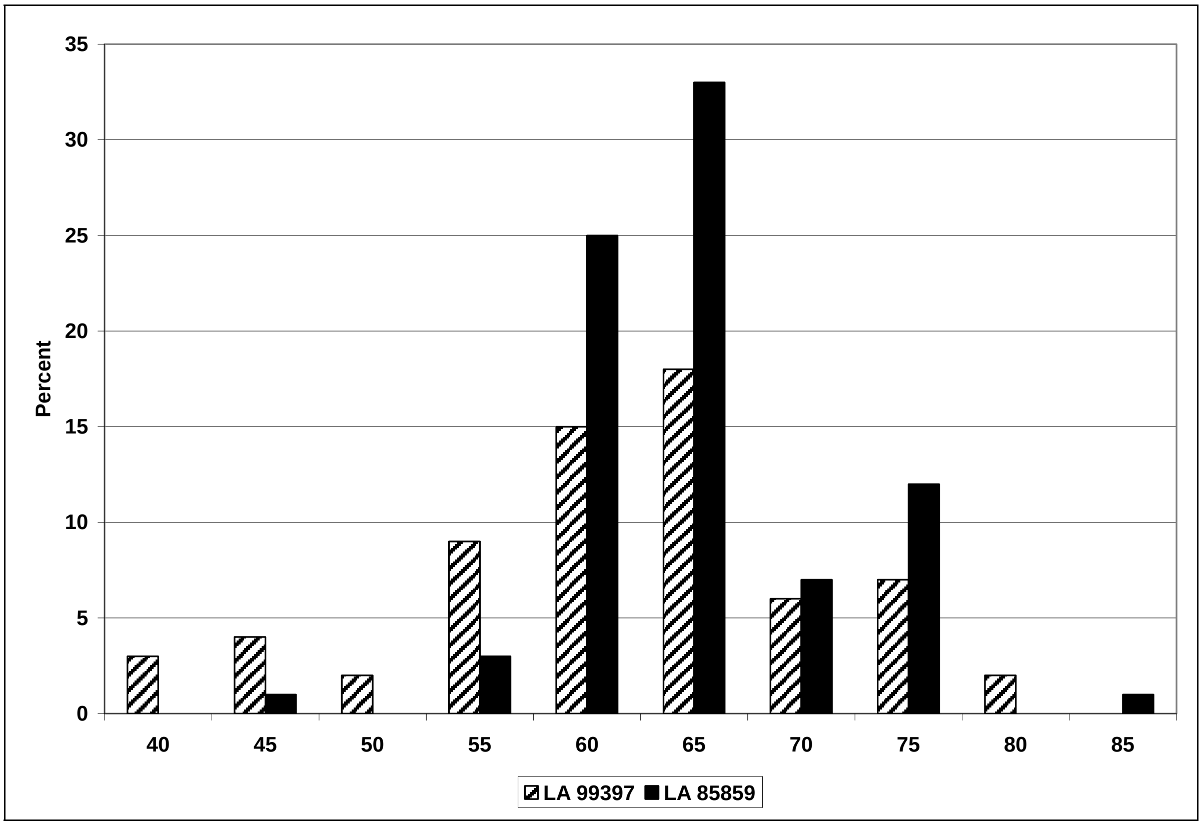

Figure 60.16. Biface flake platform angles from LA 85859 and LA 99397.

Given the importance of reducing obsidian raw materials for tool production, it should not be surprising that most of the flake platforms are crushed, with many collapsed and multi-faceted platforms (Table 60.10). Excluding LA 12587 (Area 8) due to its small sample size, 72.7 percent to 97.8 percent of the platforms exhibit preparation on the remaining three sites. Again, preparing the platform for flake removal would be important for the production of tools on obsidian.

Table 60.10. Archaic period platform types.

Site	Platform Types (*n*/%)						
	Cortical	Single	Dihedral	Multi	Collapsed	Crushed	Total
LA 85859	3 0.1	58 1.7	0 0.0	54 16.6	34 10.4	176 54.1	325
LA 12587 (Area 8)	0 0.0	15 45.4	1 3.0	4 12.1	3 9.0	10 30.3	33
LA 99396	9 5.4	7 4.2	0 0.0	31 18.7	24 14.5	94 56.9	165
LA 99397	9 4.3	38 18.5	4 1.9	26 12.6	38 18.5	90 43.9	205
Total	21	118	5	115	99	370	728

There are consistently few whole core or biface flakes in the Archaic assemblages (Tables 60.11 and 60.12). The majority of the core flakes are distal and midsection fragments, whereas most of the biface flakes are proximal fragments. The latter is in part due to the importance of platforms in classifying biface flakes. Indeed, many remnants of the biface manufacturing process end up classified as microdebitage or the distal fragments as undetermined flakes. Lastly, the core and biface flakes at LA 85859 are larger than those from LA 99396 and LA 99397 (Table 60.13). This presumably reflects the emphasis on the reduction of large bifacial cores and the production of bifacial blanks at LA 85859. By contrast, the LA 99396 and LA 99397 assemblages emphasize the full range of core reduction and tool production activities, including finished projectile points and knives.

Table 60.11. Archaic core flake condition.

Site	Core Flake Condition (*n*/%)						
	Whole	Proximal	Midsection	Distal	Lateral	Und.	Total

Total	72	135	328	591	12	34	1172

Figure 60.17 illustrates the distribution of retouched tool types by site. LA 12587 (Area 8) contains only four retouched tools and include bifaces and projectile points. On the other hand, the larger samples do exhibit some variability. LA 85859 solely contains retouched flakes and bifaces (n = 10). This presumably reflects the emphasis on the production of bifacial blanks at this campsite, with a few other subsistence related activities. By contrast, LA 99397 contains retouched flakes, bifaces, and projectile points (n = 18) and LA 99396 contains these tools plus a

composite tool (*n* = 23). As previously noted, these sites may represent habitation sites that include a variety of domestic activities.

Table 60.12. Archaic biface flake condition.

Site	Biface Flake Condition (*n*/%)

	Core Flake	Biface Flake	Angular Debris
LA 85859	24.2 (12.7)	25.9 (11.9)	0.5 (0.5)
LA 12587 (Area 8)	21.0	22.5 (16.2)	0.7 (0.6)
LA 99396	18.6 (5.6)	18.5 (6.8)	1.8 (3.9)
LA 99397	20.4 (8.2)	16.0 (6.9)	1.4 (1.8)

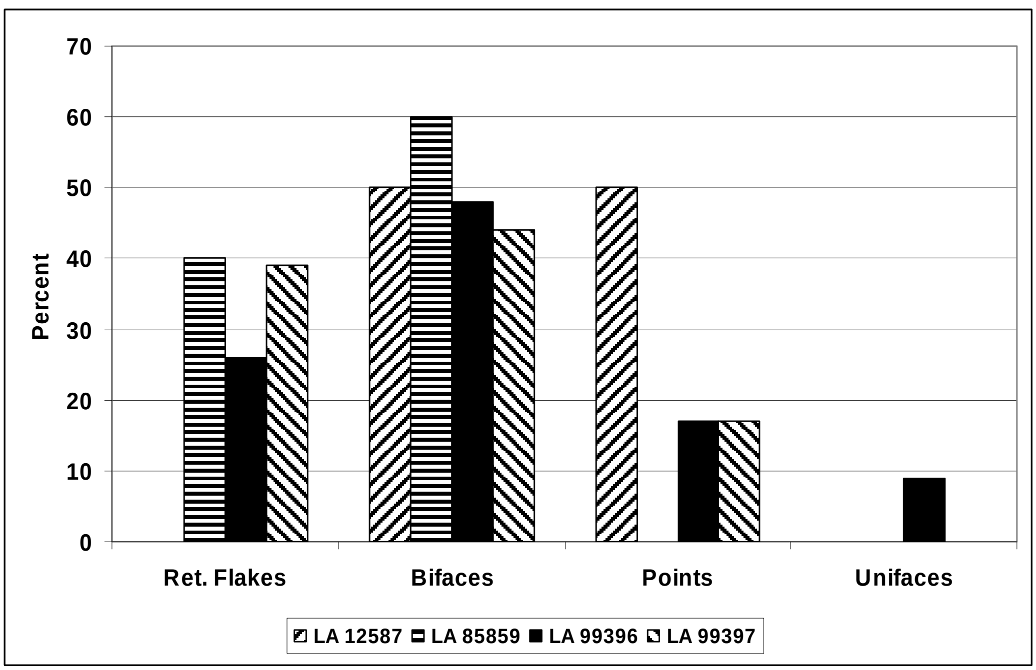

Figure 60.17. Archaic retouched tool types.

Tool Use

A very low frequency of edge damage, which could potentially be the result of use-wear, was present in all of the Archaic assemblages. Use-wear was identified as micro-scarring, rounding, and/or polish that was consistent along an edge margin and easily recognizable under 10x magnification. The paucity of use-wear is noteworthy, given the dominance of obsidian in these assemblages. The fragile nature of obsidian flakes should make them more susceptible to edge wear or post-occupational damage. Nonetheless, less than 1 percent of the individual flake assemblages exhibit obvious edge damage. The single exception is LA 12587 (Area 8) for which 4.2 percent of the flakes exhibit damage. The high percentage of damaged flakes at LA 12587 may be due to the site's location in a highly eroded and deflated area. Otherwise, a total of eight flakes (0.6%, *n* = 1159) were identified with possible use-wear in these assemblages, including six core flakes from LA 12587 and LA 99396 and two biface flakes from LA 85859. The latter reflects the importance of bifacial cores at the site, and their use for biface blank production and as sources for expedient flake tools (e.g., see Parry and Kelly 1987).

The distribution of ground stone items varies greatly between the Archaic sites. Two of these have very few ground stone artifacts, whereas the other two have numerous items. For example, there is only a single one-hand quartzite mano at LA 85859 and three millingstones at LA 99397. This contrasts with 11 ground stone artifacts at LA 12587 (Area 8) and nine ground stone artifacts at LA 99396. However, these latter two sites also contain Ceramic period components that could have contributed to their assemblages. This is certainly the case at LA 99396, which contains a two-hand mano. LA 99396 also has two one-hand manos, an undetermined mano fragment, two grinding slabs, two undetermined metate fragments, and a piece of undetermined ground stone. LA 12587 contains three undetermined mano fragments, an undetermined metate fragment, a polishing stone, an abrading stone, and five pieces of undetermined ground stone.

Early and Middle Coalition Period Roomblocks

Three Early and Middle Coalition period roomblocks have been excavated at LANL. LA 4624 is located on Mesita del Buey, which is located to the west of the White Rock Tract. LA 4624 consists of a 25-room pueblo that was partially excavated (Vierra et al. 2002). LA 86534 and LA 135290 are both nine-room pueblos that were fully excavated in the Airport Tract.

Material Selection

A comparison of debitage assemblages at these sites indicates that the sites are dominated by chalcedony, with lesser amounts of Pedernal chert, igneous rocks, and other materials (Table 60.14). The other materials mostly include chert and silicified wood. LA 86534 and LA 135290 contain similar material assemblages, with some minor differences. By contrast, LA 4624 contains relatively more igneous rock materials than the other two sites. There are geographical differences between the sites that may contribute to some of these differences.

Table 60.14. Early and Middle Coalition period roomblock lithic debitage material types.

Site	Material Types (n/%)						
	Igneous	Obsidian	Chalcedony	Pedernal	Quart-zite	Other	Total
LA 4624	50 28.4	18 10.2	79 44.8	25 14.2	0 0.0	4 2.2	176
LA 86534	26 5.4	45 9.4	267 55.8	104 21.7	28 5.8	19 1.6	488
LA 135290	40 8.1	28 5.7	303 61.7	117 23.8	2 0.4	6 0.1	496
Total	**116**	**91**	**649**	**246**	**30**	**29**	**1161**

Table 60.15 presents the results of the XRF analysis of 46 artifacts from the three Pueblo sites. There are some noteworthy differences. LA 4624 is dominated by Cerro Toledo obsidian. The Cerro Toledo (Rabbit Mountain/Obsidian Ridge) and Valle Grande (Cerro del Medio) source areas are located about 15 km (10 mi) as the "crow flies" to the southwest and west of the site. The El Rechuelos (Polvadera Peak) source area is located about 30 km (19 mi) to the northwest of the site. However, the Valle Grande source may be closer in actual walking distance, while the Cerro Toledo source area involves crossing Frijoles Canyon. Despite these differences, the obsidian from the Cerro Toledo source area was preferentially selected for at LA 4624. The Valle Grande (Cerro del Medio) and Cerro Toledo (Rabbit Mountain/Obsidian Ridge) source areas are located about 17 km (11 mi) as the "crow flies" to the west and southwest of LA 86534 and LA 135290. The Valle Grande source is actually closer in walking distance than the Cerro Toledo source from these two sites. Despite this, there is a mixture of Valle Grande and Cerro Toledo obsidian at LA 86534 and a predominance of Valle Grande obsidian at LA 135290. Two of the three artifacts made of El Rechuelos obsidian are retouched tools that could have been made while on trips to the source area.

Table 60.15. Early and Middle Coalition period roomblock obsidian source samples.

Site	Obsidian Source					
	Cerro Toledo	Valle Grande	El Rechuelos	Bear Springs	Unknown	Total
LA 4624	11 78.5	2 14.2	1 7.1	0 0.0	0 0.0	14
LA 86534	7 30.4	14 60.8	2 8.6	0 0.0	0 0.0	23
LA 135290	1 11.2	8 88.8	0 0.0	0 0.0	0 0.0	9
Total	**19**	**24**	**3**	**0**	**0**	**46**

Lithic Reduction

Sixteen cores were recovered from the sites, however, only seven of these were found at LA 4624 and LA 86534 and nine from LA 135290. Nonetheless, they were reduced using a single-directional (*n* = 4), bidirectional (*n* = 7), and bipolar (*n* = 1) reduction technique. In addition, a single cobble biface and a core fragment were also identified. These are platform cores that were made on chalcedony and Pedernal chert cobbles. The cobbles are broken to create a single platform core. The direction of flake removals increases as the core is reoriented with increasing reduction. In addition, at least one small piece of Pedernal chert was reduced with a bipolar technique. The cobble biface was made of basalt and exhibited battering along the edge perimeter; this item may not represent a core, but rather a heavy-duty chopping tool.

Table 60.16 presents the information on debitage type by site. All three sites are dominated by core reduction activities, including mostly core flakes, with some angular debris, microdebitage, and other types. LA 86534 does, however, contain relatively more microdebitage than the other two sites. The "other" debitage type includes hammerstone flakes, ground stone flakes, and notching flakes, which represent domestic and tool production activities.

Table 60.16. Early and Middle Coalition period roomblock debitage types.

Site	Debitage Type (*n*/%)						
	Debris	Core flake	Biface flake	Micro-debitage	Und. Flake	Other	Total
LA 4624	29 16.4	130 73.8	0 0.0	12 6.8	2 1.1	3 1.7	176
LA 86534	90 18.4	260 53.1	20 4.0	99 20.2	14 2.8	5 1.0	488
LA 135290	83 16.7	343 69.1	11 2.2	43 8.6	14 2.8	5 1.0	496
Total	**202**	**733**	**31**	**154**	**30**	**13**	**1163**

Given the emphasis on core reduction at these sites, it is not surprising that most of the platforms are single-faceted, with fewer that are cortical, collapsed, and crushed (Table 60.17). There is, however, a wide range of variability exhibited across the sites in relation to platform preparation. Only 3.3 percent of the platforms exhibit preparation at LA 135290, in contrast to 13.7 percent at LA 4624 and 20 percent at LA 86534.

Table 60.17. Early and Middle Coalition period roomblock platform types.

Site	Platform Types (*n*/%)						
	Cortical	**Single**	**Dihedral**	**Multi**	**Collapsed**	**Crushed**	**Total**
LA 4624	11 12.7	68 79.0	2 2.3	0 0.0	3 3.4	2 2.3	86
LA 86534	11 10.4	65 61.9	0 0.0	4 3.8	12 11.4	13 12.3	105
LA 135290	30	57	1	2	36	22	148

Site	Platform Types (*n*/%)						
	Cortical	Single	Dihedral	Multi	Collapsed	Crushed	Total
	20.2	38.5	0.6	1.3	24.3	14.8	
Total	**52**	**190**	**3**	**6**	**51**	**37**	**339**

There is also some variability exhibited between the sites in relation to flake condition. Most of the core flakes at LA 4624 are whole, whereas most of those recovered from LA 86534 and LA 135290 are distal fragments (Table 60.18). Despite differences in core flake attributes, the patterns are similar for biface flakes (Table 60.19). Core flake size is similar between the sites, but angular debris size does vary. Interestingly, biface flake size is unusually larger at LA 135290 (Table 60.20).

Table 60.18. Early and Middle Coalition period roomblock core flake condition.

Site	Core Flake Condition (*n*/%)

	Whole	Proximal	Midsection	Distal	Lateral	Und.	Total
LA 4624	0	0	0	0	0	0	0
LA 86534	6	3	2	8	1	0	20
LA 135290	3	3	1	4	0	0	11
Total	**9**	**6**	**3**	**12**	**1**	**0**	**31**

Table 60.20. Early and Middle Coalition period roomblock mean flake length (mm) and angular debris weight (g).

Site	Debitage Type (std)		
	Core Flake	Biface Flake	Angular Debris
LA 4624	22.5 (7.8)	0.0	3.0 (5.9)
LA 86534	21.8 (10.5)	15.4 (5.1)	2.8 (4.7)
LA 135290	23.8 (12.5)	30.0 (10.5)	3.9 (5.5)

Figure 60.18 illustrates the distribution of retouched tools between the sites. The assemblages contain retouched flakes, bifaces, projectile points, and unifaces. The retouched flake category includes retouched pieces, denticulates, perforators, and a perforator/notch. These retouched items can be separated into two groups: informal tools and formal tools. The former consist of

retouched flakes that are created with minimal energy investment and marginal retouch. The bifaces, projectile points, and unifaces are classified as formal tools since they involved a greater investment in production through shaping and facial retouch. The formal:informal tool ratio indicates that LA 4624 (2.5) and LA 86534 (1.5) contain relatively more formal tools, while LA 135290 (1.0) contains an equal number of informal and formal tools.

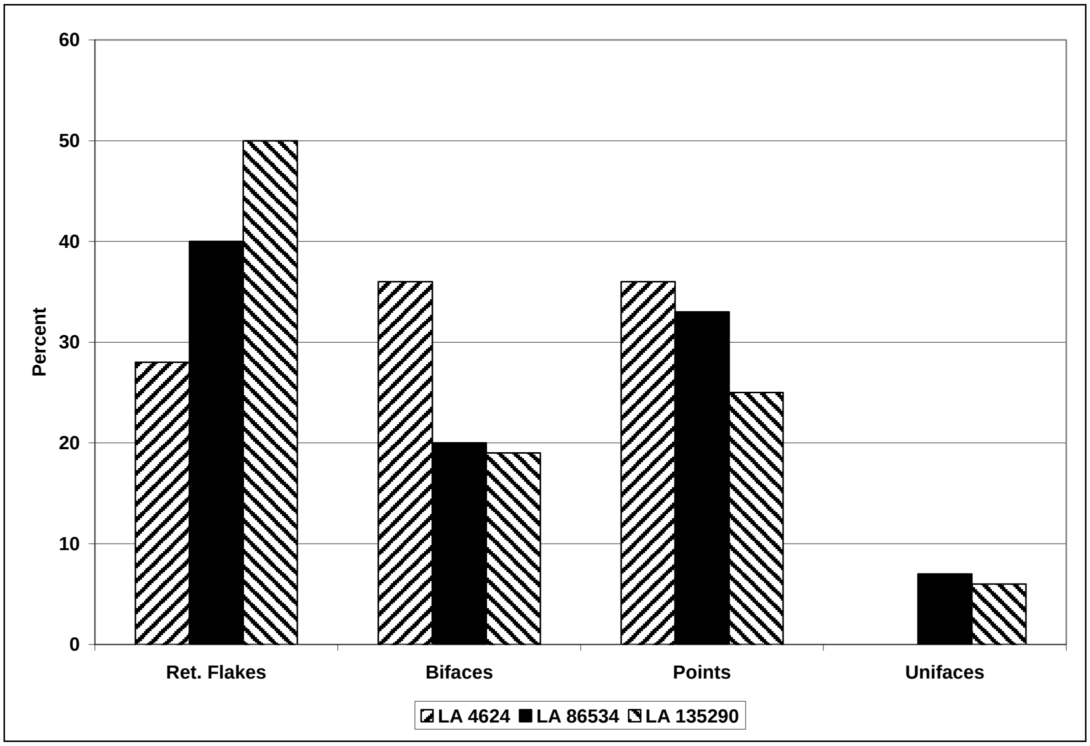

Figure 60.18. Early and Middle Coalition period roomblock retouched tool types.

There are slightly more, or relatively equal, amounts of formal and informal tools present at the sites. However, there does appear to be an inverse relationship between retouched flakes and bifaces and projectile points. Although each site contains a similar number of tools, LA 4624 has a much smaller overall sample size and therefore contains relatively more tools than the other two sites (e.g., bifaces and projectile points). Sample sizes range from 14 at LA 4624 to 15 at LA 86534 and 16 at LA 135290.

Tool Use

The percentage of flakes with damaged edges that could be attributed to use-wear ranges from 2.3 percent at LA 86534, to 3.8 percent at LA 135290, to 6.1 percent at LA 4624. The overall mean percent is 3.6 percent.

Figure 60.19 illustrates the distribution of ground stone tools between the sites. The assemblages contain a variety of ground stone tools including one- and two-hand manos, millingstones, slab metates, grinding slabs, polishing stones, abrading stones, and undetermined ground stone fragments. The most notable difference is the absence of one-hand manos from the LA 4624 assemblage and the absence of two-hand manos from the LA 86534 assemblage. The presence of formal slab metates at LA 4624 and LA 86534 corresponds to the presence of two-hand manos at the former site, but implies that two-hand manos were being used at the latter site (even if they were not present in the sample analyzed). By contrast, LA 135290 contained mostly undetermined metate fragments with some grinding slabs. The presence of two-hand manos indicates that slab metates were also used at this site, even though none were recovered.

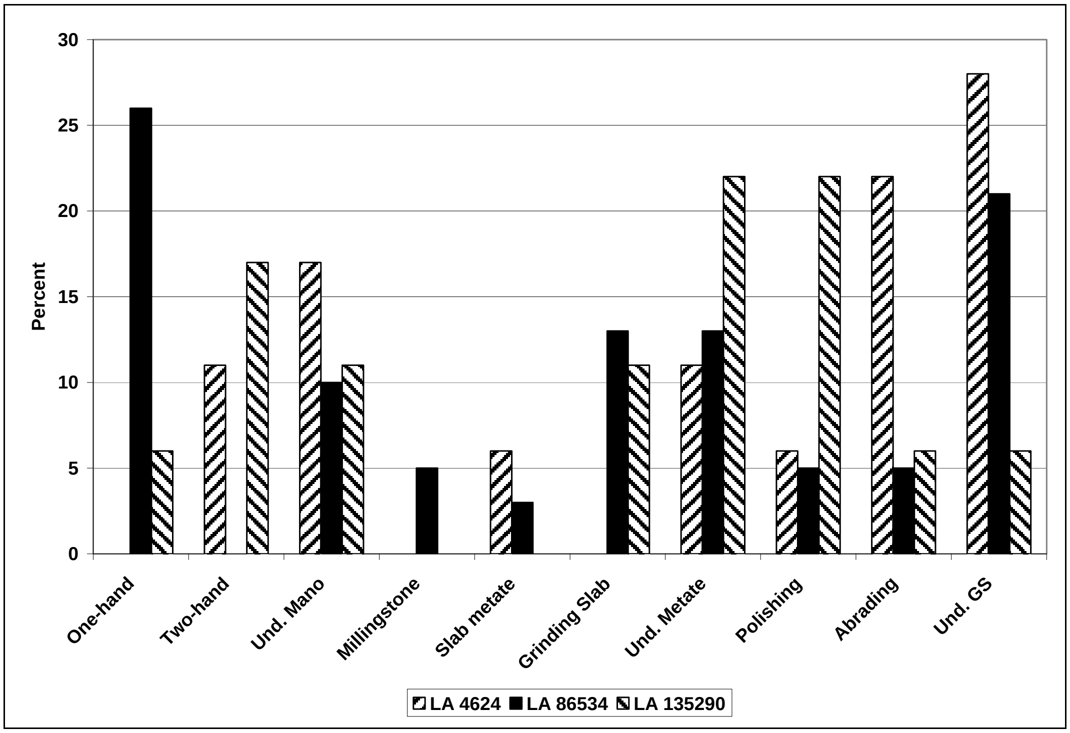

Figure 60.19. Early and Middle Coalition period roomblock ground stone tool types.

Besides the ground stone artifacts, a few other tools used for domestic activities, construction, and clearing fields were identified. These include a single flaked axe, two mauls, and nine hammerstones.

Late Coalition Period Roomblocks

Two Late Coalition period roomblocks have been excavated at Los Alamos National Laboratory. LA 4618 is located on Mesita del Buey, which is located west of the White Rock Tract near the town of White Rock. LA 4618 was completely excavated and contained 13 rooms including a subterranean circular kiva and an above-ground masonry kiva (Schmidt 2006). LA 12587 includes a seven-room pueblo that was fully excavated and a linear row of 13 rooms in which the construction was never completed. LA 12587 is located in the White Rock Tract and was excavated as part of the C&T Project.

Material Selection

A comparison of the debitage assemblages from LA 12587 and LA 4618 indicates that both are dominated by the use of chalcedony, with less obsidian, igneous rock, Pedernal chert, quartzite, and other materials (Table 60.21). The "other" materials include chert and silicified wood. LA 4618 contains relatively more debitage made of igneous rock and obsidian than LA 12587.

Table 60.21. Late Coalition period roomblock lithic debitage material types.

Site	Material Types (*n*/%)						
	Igneous	Obsidian	Chalcedony	Pedernal	Quart-zite	Other	Total
LA 4618	113 11.5	214 21.9	547 55.9	78 7.9	6 0.6	19 1.9	977
LA 12587	164 7.1	389 16.9	1505 65.5	150 6.5	34 1.4	54 2.3	2296
Total	**277**	**603**	**2052**	**228**	**40**	**73**	**3273**

Table 60.22 presents the results of the XRF analysis of 44 artifacts from LA 12587 and LA 4618. Even though the two sites are located near each other, they contain very different obsidian source profiles. LA 4618 primarily contains Valle Grande obsidian with some Cerro Toledo obsidian, while LA 12587 contains mostly Cerro Toledo obsidian, with some Valle Grande and El Rechuelos obsidian. Four of the five artifacts made from El Rechuelos obsidian are projectile points that could have been obtained while on trips to the source area. One possible explanation for the dominance of Cerro Toledo obsidian at LA 12587 is that the site occupants are collecting obsidian artifacts from the Late Archaic site located nearby (Area 8). The Late Archaic site is dominated by Cerro Toledo obsidian, although XRF source analyses failed to identify any El Rechuelos obsidian.

Table 60.22. Late Coalition period roomblock obsidian source samples.

Site	Obsidian Source					
	Cerro Toledo	Valle Grande	El Rechuelos	Bear Springs	Unknown	Total
LA 4618	2 18.1	7 63.6	0 0.0	0 0.0	2 18.1	11
LA 12587	22 66.6	6 18.2	5 15.2	0 0.0	0 0.0	33
Total	**24**	**13**	**5**	**0**	**2**	**44**

Lithic Reduction

Twenty-three cores were recovered from LA 12587 and LA 4618. Several different reduction techniques were used at the sites including single-directional (n = 9), bidirectional (n = 14), multi-directional (n = 7), and bipolar (n = 1). In addition, a flake core was also identified. The full range of core reduction techniques are represented, indicating that these cores were being fully reduced. Again, this primarily includes the reduction of chalcedony and Pedernal chert cobbles.

Table 60.23 presents the information on debitage type by site. Both sites are dominated by core reduction activities, including mostly core flakes, with some angular debris, microdebitage, and other types. The "other" debitage type includes hammerstone flakes, ground stone flakes, and notching flakes that represent domestic and tool production activities.

Table 60.23. Late Coalition period roomblock debitage types.

Site	Debitage Type (*n*/%)						
	Debris	Core flake	Biface flake	Micro-debitage	Und. Flake	Other	Total
LA 4618	121 12.3	642 65.7	39 3.9	111 11.3	50 5.1	13 1.3	977
LA 12587	294	1224	125	570	58	21	2296
Total	**415**	**1866**	**164**	**681**	**108**	**34**	**3273**

Given the emphasis on core reduction at these sites, it is not surprising that most of the platforms are single-faceted, with fewer that are cortical, collapsed, and crushed (Table 60.24). However, there is a wide difference in relation to platform preparation. Only 4.5 percent of the platforms at LA 4618 exhibit preparation, while 12.8 percent of the platforms at LA 12587 exhibit platforms.

Table 60.24. Late Coalition period roomblock platform types.

Site	Platform Types (*n*/%)						
	Cortical	**Single**	**Dihedral**	**Multi**	**Collapsed**	**Crushed**	**Total**
LA 4618	33 10.7	145 47.3	5 1.6	11 3.5	52 16.9	60 19.6	306
LA 12587	92 17.6	269 51.7	10 1.9	11 2.1	63 12.1	75 14.4	520
Total	**125**	**414**	**15**	**22**	**115**	**135**	**826**

There is also some variability exhibited between the sites in relation to flake condition. Most of the core flakes are distal fragments at both sites, although there are relatively more whole flakes at LA 4618 (Table 60.25). Otherwise, LA 4618 contains relatively more proximal/midsection fragments for biface flakes, while LA 12587 contains more distal fragments (Table 60.26). Lastly, core flake, biface flake, and angular debris sizes are similar between the two sites (Table 60.27).

Table 60.25. Late Coalition period roomblock core flake condition.

Site	Core Flake Condition (*n*/%)

LA 12587	12 9.6	37 29.6	28 22.4	48 38.4	0 0.0	0 0.0	125
Total	**17**	**50**	**41**	**56**	**0**	**0**	**164**

Table 60.27. Late Coalition period roomblock mean flake length (mm) and angular debris weight (g).

Site	Debitage Type (std)		
	Core Flake	Biface Flake	Angular Debris
LA 4618	22.6 (10.0)	20.8 (5.5)	2.2 (2.7)
LA 12587	21.0 (9.3)	18.5 (7.8)	2.4 (4.8)

Figure 60.20 illustrates the distribution of retouched tools between the two sites. In this case, the retouched flakes consist of retouched pieces, notches, denticulates, perforators, and gravers, whereas, the formal tools consist of biface, projectile points, unifaces, and drills. The formal:informal tool ratio for LA 4618 (0.7) and LA 12587 (1.0) indicate that there are somewhat more informal tools, or equal numbers of informal and formal tools on the sites.

Tool Use

The percentage of flakes with damaged edges that could be attributed to use-wear ranges from 1.2 percent at LA 12587 to 3.89 percent at LA 4618, and has an overall mean of 2.1 percent. Figure 60.21 graphically illustrates the distribution of ground stone tools between the sites. The assemblages contain a variety of ground stone tools including one- and two-hand manos, millingstones, slab metates, grinding slabs, polishing stones, abrading stones, and undetermined ground stone fragments. However, there are some notable differences between the two sites. LA 4618 contains relatively more one-hand manos, millingstones, and grinding slabs, while there are relatively more two-hand manos and slab metates at LA 12587.

Besides the ground stone artifacts, there are also a range of other tools used for domestic activities, construction, clearing, and tending fields. These include flaked axes (*n* = 3), mauls (*n* = 5), hoes (*n* = 7), and hammerstones (*n* = 5). In addition, 10 vent plugs were recovered from LA 4618, but none were recovered at LA 12587.

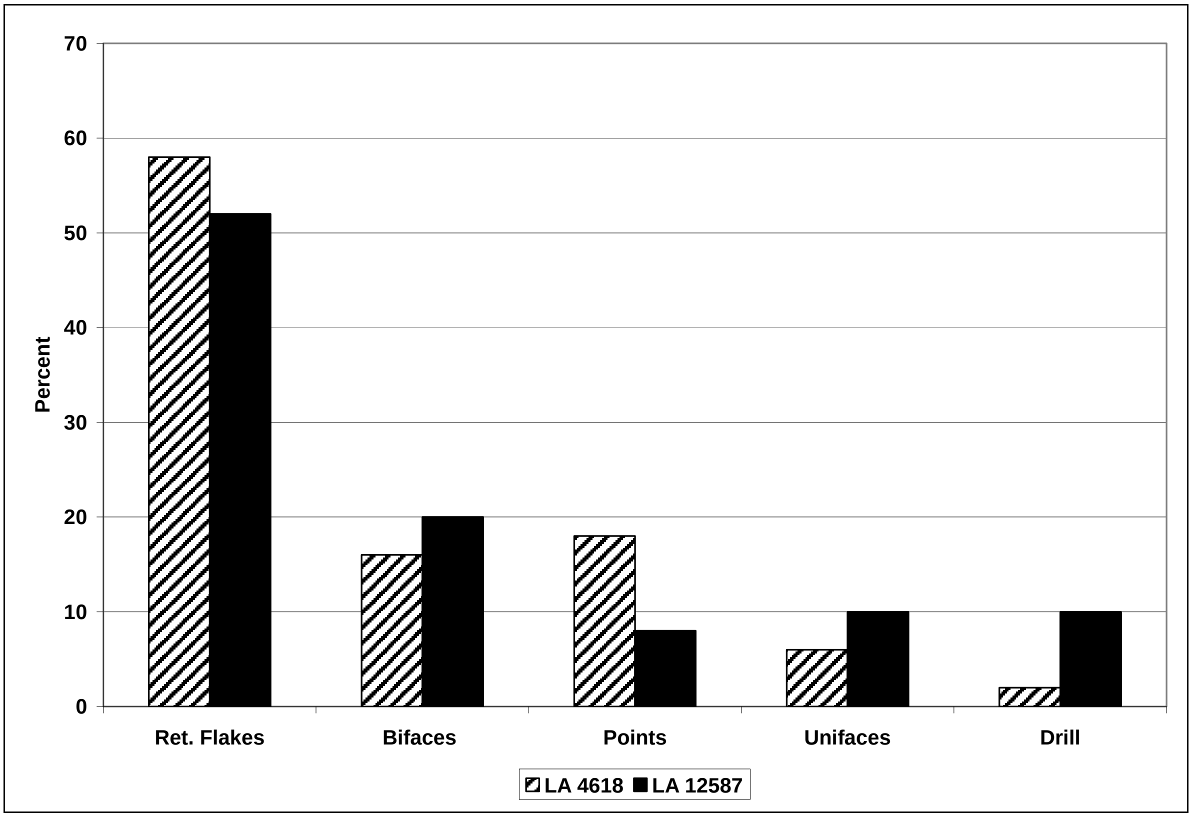

Figure 60.20. Late Coalition period roomblock retouched tool types.

Late Coalition Period Fieldhouses

Four Late Coalition period fieldhouses were excavated in Rendija Canyon. These consist of LA 85417, LA 85861, LA 86606, and LA 86607. All of these sites are one-room structures that represent two sets of sites located near each other. The first set is located in Cabra Canyon, whereas, the latter two sites are situated on the mesa top. No lithic artifacts were recovered from LA 86607.

Material Selection

The samples sizes are relatively small for two of the three sites, with chalcedony dominating the debitage assemblages and fewer pieces of Pedernal chert and obsidian (Table 60.28).

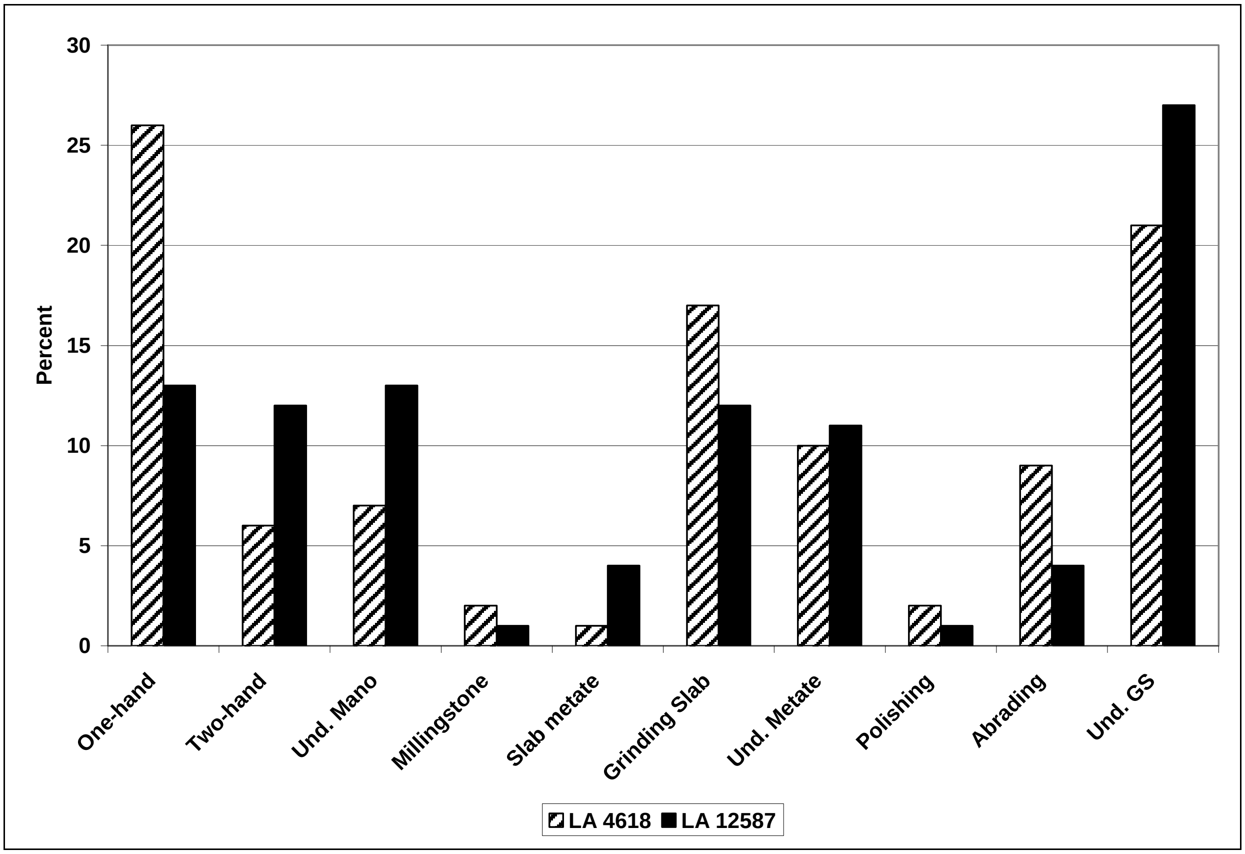

Figure 60.21. Late Coalition period roomblock ground stone tool types.

Table 60.28. Late Coalition period fieldhouse lithic debitage material types.

Site	Material Types (*n*/%)

Table 60.29 presents the results of the XRF analysis of 12 artifacts from two of the three fieldhouses. LA 85417 did not contain any obsidian artifacts. LA 85861 exhibits a larger sample size and contains mostly Cerro Toledo obsidian with some Valle Grande. A single item made of Cerro Toledo and one made of Bear Springs obsidian was identified at LA 86606. The Valle Grande (Cerro del Medio) and Cerro Toledo (Obsidian Ridge/Rabbit Mountain) source areas are located about 17 km (11 mi) and 19 km (12 mi) to the west and southwest, respectively. However, Cerro Toledo obsidian is also present on the nearby mesa top as small pebbles. These

pebbles compose part of the secondary deposits associated with the Cerro Toledo interval. The Bear Springs source area is situated 38 km (24 mi) to the southwest as the "crow flies." This artifact represents the only piece of Bear Springs obsidian identified on the entire project.

Total	**9**	**2**	**0**	**1**	**0**	**12**

Lithic Reduction

Four cores were recovered from the three sites. Two are made of Pedernal chert, one of chalcedony, and the other of obsidian. The chert and chalcedony cores were reduced using a single-directional, bidirectional/discoidal, and 90° techniques, whereas, the obsidian core was reduced using a bidirectional/bifacial technique.

Table 60.30 presents the information on debitage type by site. All three sites are dominated by core reduction activities, including mostly core flakes, with some angular debris, biface flakes, and other types.

Table 60.30. Late Coalition period fieldhouse debitage types.

Total	**17**	**69**	**16**	**2**	**4**	**1**	**109**

Given the emphasis on core reduction at these sites, it is again not surprising that the most of the platforms are single-faceted, with fewer that are cortical, collapsed, and crushed (Table 60.31). None of the platforms at LA 86606 or LA 85417 exhibit any obvious evidence of preparation; however, preparation was observed on four (11.7%) of the platforms at LA 85861.

All three sites exhibit a mix of whole and distal core flakes fragments, with a similar pattern for biface flakes at LA 85861 (Tables 60.32 and 60.33). Otherwise, there is some variation in core flake, biface flake, and angular debris sizes, but this is presumably due to the small samples sizes (Table 60.34).

Site	Debitage Type (std)		
	Core Flake	Biface Flake	Angular Debris
LA 86606	28.5 (7.5)	0.0	2.9 (2.3)

LA 85861 is the only site that contains retouched tools. These consist of five retouched pieces, three bifaces, and two unifaces.

Tool Use

A single flake from LA 86561 (2.1%) is the only piece of debitage that exhibits edge damage that can possibly be attributed to use.

Figure 60.22 illustrates the distribution of ground stone tools between the sites. The assemblages contain a limited number of ground stone tools including one- and two-hand manos, grinding slabs, undetermined metate fragments, and undetermined ground stone fragments. Most of these are from LA 85861. In addition to the ground stone artifacts, a grooved abrader and two hoes were recovered from LA 85861, and a flaked axe was recovered from LA 86606. The grooved abrader indicates that arrows were being produced at the site, whereas, the hoes were presumably used for maintaining agricultural fields. The axe may have been used for fieldhouse construction or possibly for clearing forested land for field plots. Five hammerstones were also recovered from the sites. Three of these were recovered from LA 85861.

Classic Period Fieldhouses

Two Classic period fieldhouses were excavated in the White Rock Tract (LA 127631 and LA 128805), one in the Airport Tract (LA 141505), and 16 in the Rendija Tract (LA 15116, LA 70025, LA 85403, LA 85404, LA 85408, LA 85411, LA 85413, LA 85414, LA 85867, LA 86605, LA 87430, LA 127627, LA 127634, LA 127635, LA 135291, and LA 135292).

Material Selection

The samples sizes vary among the sites, from a low of 14 to a high of 331 (Table 60.35). Nonetheless, most of the site assemblages are dominated by chalcedony, with less Pedernal chert, obsidian, and igneous rock materials. LA 128805 is the only notable difference to this pattern with 52.2 percent of the debitage assemblage consisting of obsidian. Otherwise, the igneous rocks primarily consist of basalt, with some andesite, rhyolite, and dacite, whereas, the other category includes chert and silicified wood.

Table 60.36 presents the results of the XRF analysis of 73 artifacts from the 19 fieldhouses. Most of this obsidian was identified as Cerro Toledo, with less from the Valle Grande and El Rechuelos sources. However, if we separate out the White Rock and the Rendija Canyon sites, we find that LA 128805 only has Cerro Toledo obsidian, LA 127631 has a mix of Cerro Toledo, Valle Grande, and El Rechuelos obsidian, and the Rendija Canyon sites contain mostly Cerro Toledo (55.3%), with less Valle Grande (33.9%) and El Rechuelos (10.7%). Cerro Toledo is locally available in Rendija Canyon, so it is not surprising that this obsidian and the nearby Valle Grande source were both being exploited. It is unclear how much, if any, of the Cerro Toledo obsidian identified in Rendija Canyon was actually procured from the Rabbit Mountain source area. On the other hand, all the Cerro Toledo obsidian identified at the White Rock sites was presumably obtained from the Rabbit Mountain source area. Although the Rendija Canyon source can not be excluded, the small pebble size limits the use of this material for small flakes and larger retouched tools.

Lithic Reduction

Four cores were recovered from the sites. Two are made of Pedernal chert, one of chalcedony, and the other of obsidian. The chert and chalcedony cores were reduced using a single-directional, bidirectional/discoidal, and 90° technique, whereas, the obsidian core was reduced using a bidirectional/bifacial technique.

Table 60.37 presents the information on debitage type by site. All the sites are dominated by core reduction activities, including mostly core flakes, with some angular debris, biface flakes, microdebitage, and other types. The other debitage types include core trimming flakes, change-of-orientation flakes, bipolar flakes, hammerstone flakes, and ground stone flakes. The most notable difference to this pattern is LA 128805, which contains relatively more biface flakes (20.5%) and microdebitage (21.1%) than the other sites. In addition, although no biface flakes were recorded at LA 85413, the presence of an *outrepassé* and uniface flake indicate that tool production activities were also occurring at this site.

Table 60.37. Classic period fieldhouse debitage types.

Given the emphasis on core reduction at these sites, it is again not surprising that the most of the platforms are single-faceted, with fewer that are cortical, collapsed, and crushed (Table 60.38). Very few site assemblages exhibit evidence of platform preparation. LA 85867, LA 85403, LA 127634, LA 127635, LA 135291, and LA 127631 contain one to three prepared platforms, with a total of nine. In contrast, 24 platforms exhibit evidence of preparation at LA 128805. This provides a total of 33 platforms, or about 10 percent of the single, dihedral, and multi-faceted platforms.

The sites exhibit a mix of mostly whole, proximal, and distal core flakes fragments, with mostly proximal, midsection, and distal portions of bifaces flakes (Tables 60.39 and 60.40). There is some variation in core flake and angular debris sizes, but this is presumably due in part to the small samples sizes (Table 60.41). Nonetheless, in looking at the six sites with the greatest number of debitage pieces, we find a range from 21 to 30 mm for mean core flake size and 3.5 to 7.5 g for mean angular debris weight suggesting that even these sites exhibit a wide range in flake and debris size.

The majority of the retouched tools recovered from the Classic period fieldhouses are retouched flakes (n = 25; 56.8%). There are fewer bifaces (n = 9) and projectile points (n = 7), with two unifaces and a drill.

Tool Use

Only nine flakes from seven sites exhibit edge damage that can possibly be attributed to use. This represents less than one percent of the total core flakes. Figure 60.23 illustrates the distribution of 77 ground stone tools recovered from the Classic period fieldhouses. The assemblages contain a range of items including one- and two-hand manos, undetermined mano fragments, millingstones, grinding slabs, undetermined metate fragments, and abrading and polishing stones. Two grooved abraders, two flaked axes, two hoes, and six hammerstones were also identified. The grooved abraders indicate that arrows were being produced at the site, whereas, the hoes were presumably used for maintaining agricultural fields and the axes for fieldhouse construction or possibly clearing forested land for field plots.

Classic Period Plaza Pueblos

No Classic period pueblo sites were excavated during the project; however, survey data are available from two Early Classic period sites located within the TA-72 Tract. These are the sites of Otowi (LA 169) and Little Otowi (LA 32), which are located in Pueblo Canyon. These data are compared with Coalition period roomblock sites that were surveyed during the original site recording project (Vierra 2002). Table 60.42 presents the information on debitage material type. Most of the artifacts are made of chalcedony/chert (including Pedernal); however, there is relatively more obsidian in the Classic period sample. Head's (1999:507) study at Bandelier National Monument indicated that obsidian began to dominate the site lithic assemblages during the Early Classic period. This corresponds with the data from Otowi and Little Otowi.

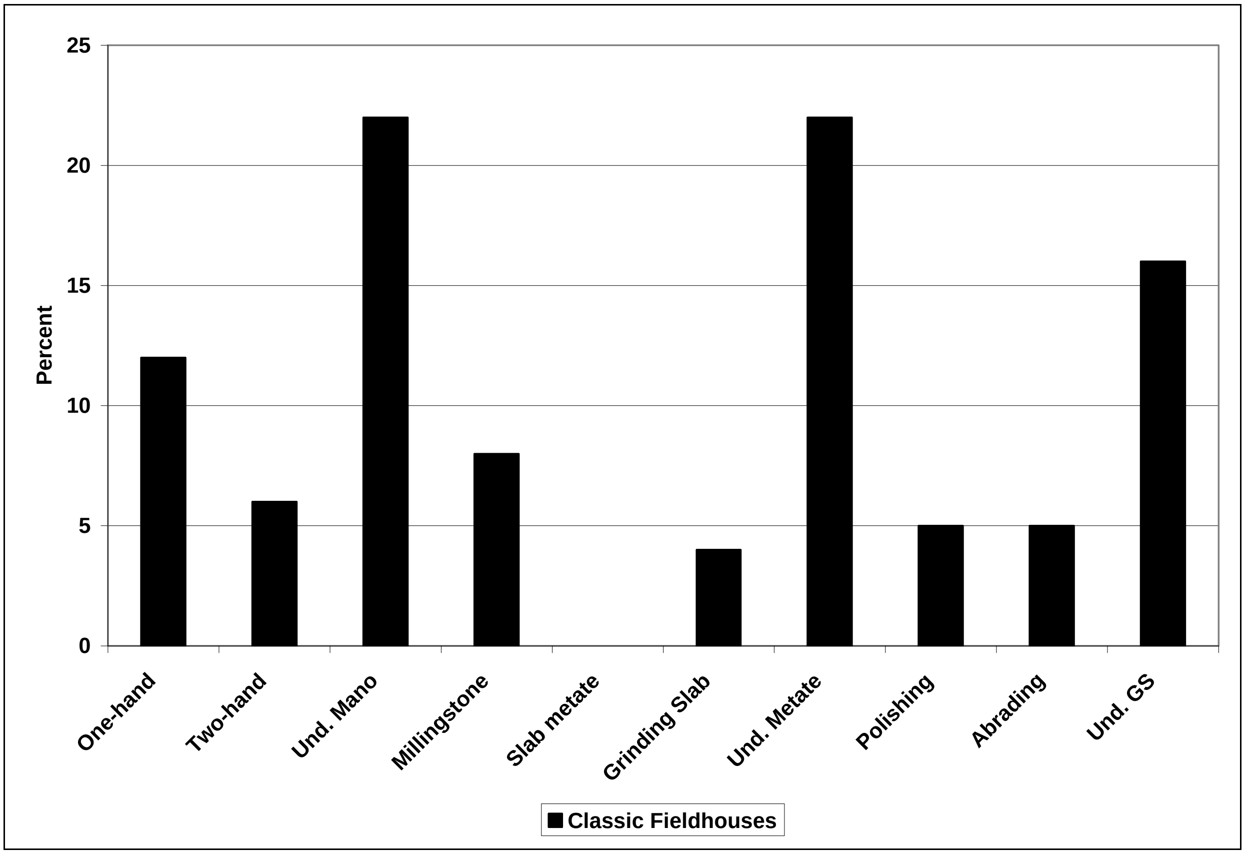

Figure 60.23. Classic period fieldhouse ground stone tool types.

Table 60.42. Coalition period roomblock and Classic period plaza pueblo lithic debitage material types.

Site	Material Types (n/%)			
	Igneous	Obsidian	Chalcedony/chert	Total

Classic Plaza Pueblo	28 4.3	80 12.4	537 83.2	645
Total	**168**	**134**	**1881**	**2183**

Head (1999:537) also submitted 10 pieces of obsidian debitage for XRF analysis from the Late Classic period site of Tsankawi. Tsankawi is situated roughly in between Otowi and Tsirege. Seven of the items analyzed were identified as Valle Grande obsidian (70%) and three were identified as Cerro Toledo obsidian. Twenty pieces of obsidian were submitted for analysis by the C&T Project from the Classic period plaza site of Tsirege. Tsirege is located on Mesita del Buey, which is located west of the White Rock Tract. Sixteen (80%) of the sampled items were identified as Cerro Toledo obsidian and four were identified as Valle Grande obsidian. Tsirege exhibits the opposite pattern as Tsankawi; however, the sample sizes are quite small. The sample of 20 artifacts from Tsirege was actually divided into two spatially distinct 10-item samples from the west and north of the site, respectively. Both samples contain the same frequency of Valle Grande and Cerro Toledo obsidian; the pattern exhibited at Tsankawi could not be replicated at Tsirege.

Table 60.43 presents the information on debitage type. Both Coalition period roomblocks and Early Classic period plaza pueblo sites are dominated by the by-products of core reduction activities, including core flakes and angular debris.

Jicarilla Apache Tipi Ring Site

LA 85869 is a turn-of-the-20th-century Jicarilla Apache tipi ring site located in Rendija Canyon. Two tipi rings were excavated and surface artifacts collected from a surrounding lithic and ceramic scatter. There appears to be a lithic reduction area located near one of the structures.

Information on debitage material types is presented in Table 60.44. The majority of the artifacts are made of obsidian. An analysis of 10 obsidian artifacts from the site indicates that nine of these are made from Valle Grande materials and only one from Cerro Toledo (Table 60.45). This is interesting given the fact that the surface gravels (Cerro Toledo interval) are present in the area of the site that contains small obsidian pebbles. Nonetheless, the site occupants presumably geared up with obsidian from the nearby caldera before camping in this location.

The majority of the debitage at the site represents the by-products of core reduction activities, including core flakes and angular debris (Table 60.46). Biface flakes do comprise 14 percent of the assemblage, however, and the presence of a single *outrepassé* flake indicates that bifaces were being manufactured at the site. In addition, a single bipolar flake was identified, indicating that the small local obsidian pebbles were also being reduced to produce flakes. Presumably the larger Valle Grande materials were being used for core reduction and biface production, while the local pebbles were used for simple flakes.

Given the emphasis on obsidian core reduction, it is again not surprising that the most of the platforms are single-faceted, with fewer that are cortical, collapsed, and crushed (Table 60.47). However, at least some of the collapsed platforms are on obsidian biface flakes. Five of the flake platforms exhibit evidence of preparation. Therefore, about 22 percent of the single and multi-faceted platforms exhibit preparation.

The core flake assemblage is dominated by distal fragments, with fewer other pieces, whereas, the biface flakes exhibit a mix of proximal, midsection, and distal fragments (Tables 60.48 and 60.49). The information on debitage size is provided in Table 60.50.

Only two retouched flakes, a proximal biface fragment, and an undetermined fragment of a projectile point that could represent a dart or lance point were analyzed. The biface was probably broken during the manufacturing process. Only a single flake exhibits evidence of damage that could possibly be attributed to use-wear. Otherwise, two one-hand cobble manos, an undetermined mano fragment that probably represents a one-hand mano, a millingstone, and a polishing stone were also recovered. The millingstone is a large fragment of dacite with a single flat ground surface, whereas, the polishing stone is a small dacite pebble that exhibits polish and grinding along a single surface. The manos and millingstone represent generalized milling activities.

A COMPARISON OF TEMPORAL LITHIC ASSEMBLAGE GROUPS

The previous sections provided detailed lithic information for each site and temporal period, and thereby illustrated the variability represented within each temporal period. In contrast, this section will attempt to make normative inter-group comparisons by lumping together the previously described data into the six defined temporal groups: Archaic, Early/Middle Coalition Roomblock, Late Coalition Roomblock, Late Coalition Fieldhouse, Classic Fieldhouse, and

Jicarilla Apache. Again, information on material selection, tool production, and tool use will be compared. These data can then be used to understand long-term changes in stone tool technology.

The following data will often be presented in two-way tables, with a chi-square analysis conducted of the contingency table. The null hypothesis of no difference between the variables is rejected if the probability (*p*) value is less than 0.05. If the chi-square test shows that there is a significant difference in the expected frequency of observations for the table at the 0.05 significance level, then adjusted residuals will be calculated to determine which of the cells is contributing to the significant chi-square value. Adjusted residuals greater than 1.96 or -1.96 are significant at the 0.05 level (Everett 1977:47; Haberman 1973; Reynolds 1984). The chi-square statistic, degrees of freedom (*df*), and *p*-values will be presented below for each contingency table.

Material Selection

Table 60.51 provides the information on lithic debitage material types by temporal group. It appears that the Archaic and Jicarilla Apache sites contain significantly more obsidian, while the Ancestral Pueblo sites contain relatively more igneous, chalcedony, Pedernal chert, and other materials. However, if we rerun the analysis including only the Ancestral Pueblo sites, we find that the Early/Middle Coalition period roomblocks contain significantly more Pedernal chert and "other" materials, the Late Coalition period roomblocks contain more chalcedony and obsidian, the Late Coalition period fieldhouses contain more Pedernal chert, and the Classic period fieldhouses contain more igneous, obsidian, and Pedernal chert (chi-square = 449.0; $df = 12$, $p \leq 0.001$).

This temporal pattern is contrary to the data and territoriality argument presented by Walsh. Although relatively more obsidian is present during the Classic period, there is also significantly more obsidian in the Late Coalition period roomblock assemblages. This seems more in keeping with Head, who suggested that obsidian became an important trade and exchange item; however, these exchange relationships may have already begun during the Late Coalition period.

Tables 60.52 and 60.53 provide information on the obsidian source studies by White Rock and Airport tracts versus the Rendija Tract. As can be seen, the Cerro Toledo source dominates the lower-elevation tracts and the Valle Grande source in the upper-elevation tract for the Archaic sites. In contrast, the Ancestral Pueblo sites in the White Rock and Airport tracts reveal a change from relatively more Valle Grande during the Early/Middle Coalition to more Cerro Toledo during the Late Coalition and Classic periods; however, Cerro Toledo obsidian was probably obtained from local surface gravels in Rendija Canyon and not from the Rabbit Mountain/Obsidian Ridge source area as at the White Rock and Airport tracts. Again, this pattern seems to indicate that an important shift in obsidian procurement, and possibly exchange, had already occurred during the Late Coalition period and continued into the later Classic period. Lastly, the Jicarilla site assemblage contains mostly Valle Grande obsidian, indicating that the site's occupants geared up with this material in the nearby caldera before arriving at the Rendija Canyon campsite.

Lithic Reduction

Information on core reduction technique and core type was collected during the analysis. The increasing intensity of core reduction is reflected when viewing decreases in core size from single to bidirectional to multi-directional core types, with small bipolar cores and core fragments being the smallest (Table 60.54). On the other hand, flake cores appear to be intermediate in size.

Table 60.54. Combined core type data for the C&T Project.

Core Type	N	Mean Weight (g)	Std.
Single-directional	31	176.2	157.8
Bidirectional	39	106.8	118.6
Multi-directional	14	97.2	86.9
Bipolar	2	32.2	26.2
Core fragment	5	35.3	17.9
Flake core	10	60.6	64.5

The few Archaic cores are bifacial cores from which biface blanks are produced for making dart points (Table 60.55). The Ancestral Pueblo site assemblages primarily contain platform cores, with a few bipolar and flake cores; however, the increasing intensity of core reduction is represented when comparing these sites through time. That is, Early/Middle Coalition period roomblock sites contain mostly single and bi-directional cores, with the increasing presence of multi-directional cores during the Late Coalition period. Although this would support Walsh's contention of increased raw material conservation during the Late Coalition period, it may also be due to increasing length of site occupation at these sites. On the other hand, the Classic period fieldhouses contain mostly single and bidirectional cores, but also have some multi-directional cores. In this case, the cores probably represent site furniture, with the early-stage cores having been brought recently to the site, while the later-stage (multi-directional) cores having been present at the site for a longer period of time.

Table 60.55. Core type by temporal period.

Period	Core type						
	Single	Bidirectional	Multi.	Bi-polar	Frag-ment	Flake	Total
Archaic	0	3 100.0	0	0	0	0	3
Early/Middle Coalition Roomblock	4 23.5	7 41.1	0 0.0	1 5.8	1 5.8	4 23.5	17
Late Coalition Roomblock	10 27.0	16 43.2	7 18.9	1 2.7	0 0.0	3 11.1	37
Late Coalition Fieldhouse	0	0	0	0	0	0	0
Classic Fieldhouse	11 37.9	9 31.0	4 13.7	0 0.0	1 3.4	4 13.7	29
Jicarilla Apache	0	0	0	0	0	0	0

The few Archaic cores were classified as exhausted and still useable when discarded (Table 60.56). Although the majority of the Early/Middle Coalition period roomblock cores were exhausted, this is not the case for Late Coalition period roomblock or Classic period fieldhouses. This is somewhat contrary to the core type data, where the latter two periods are characterized by the presence of relatively more multi-directional cores, which tend to be exhausted. It is also contrary to Walsh's argument that raw material conservation should be greatest at the Late Coalition period sites. This pattern continues with the Early/Middle Coalition period roomblocks exhibiting the only evidence of recycling cores as heavy duty tools (i.e., with edge damage); however, this might also be expected at the Late Coalition period roomblock sites with increased site occupation.

Table 60.56. Reason for discard by temporal period.

Period	Reason for Discard							
	Flaw	Cultural	Stepping	Exhausted	Useable	Dam-age	Und.	Total
Archaic	0 0.0	0 0.0	0 0.0	2 66.6	1 33.3	0 0.0	0 0.0	3
Early/Middle Coalition Roomblock	2 11.7	2 11.7	1 5.8	7 41.1	2 11.7	2 11.7	0 0.0	17
Late Coalition Roomblock	9 24.3	2 5.4	4 10.8	9 24.3	13 35.1	0 0.0	3 8.1	37
Late Coalition Fieldhouse	0	0	0	0	0	0	0	0
Classic Fieldhouse	8 27.5	3 10.3	2 6.8	5 17.2	11 37.9	0 0.0	4 13.7	29
Jicarilla Apache	0	0	0	0	0	0	0	0

Table 60.57 presents a contingency table of debitage type by temporal period. As is often the case, the Archaic assemblages emphasize bifacial core reduction and tool production, with significantly more biface flakes, microdebitage and undetermined flake fragments. In contrast, the Ancestral Pueblo and Jicarilla Apache sites emphasize core reduction activities, containing significantly more core flakes and angular debris. Nonetheless, the Jicarilla site assemblage is intermediate in percentage of biface flakes to the Archaic and Ancestral Pueblo sites.

Table 60.57. Debitage types.

Period	Debitage Type

Chi-square = 2642.1, $df = 25$, $p \leq 0.001$

The presence of relatively more biface flakes at fieldhouses relative to roomblocks may support Head's contention that more bifaces and projectile points were being produced at these field locations. This corresponds with the fact that grooved abraders were also recovered from both Late Coalition and Classic period fieldhouses. On the other hand, there are relatively more biface flakes at the Late Coalition period fieldhouses than at the Classic period fieldhouses as predicted by Head.

Information on the debitage reduction stages is provided in Table 60.58. This is based on the presence/absence of cortex and debitage type. These stages are defined somewhat differently than those used by some Southwestern researchers (e.g., Brown 1991; Parry 1987). Assuming that cobble raw materials are used, the outer cortex of the cobble is slowly removed during the reduction sequence so that primary reduction refers to core flakes with 100 percent dorsal cortex. Secondary cortical reduction consists of core flakes with a cortical platform and/or partial dorsal cortex and secondary noncortical reduction refers to core flakes with no cortex. These are removed during the later stages of core reduction. Lastly, tertiary reduction solely consists of retouch/resharpening flakes that are removed during the tool manufacturing/maintenance process (e.g., biface flakes). Only whole flakes are included in this tabulation. The reduction of nodules at the site would therefore produce a greater proportion of primary and secondary cortical flakes with cortical platforms; the reduction of prepared cores, relatively more secondary noncortical flakes, and single-faceted platforms; and the production of retouched tools more tertiary flakes and multi-faceted platforms. Low cortical:noncortical ratios reflect an emphasis on the latter stages for core reduction and/or tool production maintenance and high ratios on the earlier stages of core reduction.

The Archaic assemblage exhibits a low cortical:noncortical ratio of 0.20, which presumably reflects an emphasis on the reduction of bifacial cores and the production of bifacial tools. In contrast, the Ancestral Pueblo sites all reflect an emphasis on the latter stages of core reduction, with somewhat lower ratios at the fieldhouses (0.24 and 0.29), while there are higher ratios at the roomblocks (0.35 and 0.38). The small sample from the Jicarilla site reflects a roughly equal emphasis on the early and later stages of core reduction, with some biface production (0.55). There is little evidence of primary reduction in any of the assemblages, indicating that prepared cores (or large flakes) were primarily brought onto the sites for reduction.

Table 60.58. Debitage reduction stages.

Material	Primary	Secondary Cortical	Secondary Non-cortical	Tertiary	Cortical: Non-cortical ratio
Archaic	1	33	47	118	0.20
Early/Middle Coalition Roomblock	2	53	147	9	0.35
Late Coalition Roomblock	6	117	311	17	0.38
Late Coalition Fieldhouse	0	40	127	10	0.29
Classic Fieldhouse	0	29	112	8	0.24
Jicarilla Apache	0	6	8	3	0.55

Table 60.59 presents the information on platform type by temporal group. The Archaic period is characterized by more multi-faceted and crushed platforms. The former represents the reduction of bifacial cores and the production of bifaces and the latter platform preparation for reducing obsidian cores. In contrast, the Ancestral Pueblo roomblock sites contain relatively more cortical, single, and dihedral platforms, and Ancestral Pueblo fieldhouses contain more single faceted platforms. Both cobble and prepared cores were reduced at the roomblocks, while the platform or flake cores were being reduced at the fieldhouses. Nonetheless, both sites emphasize core reduction activities. Lastly, the Jicarilla Apache sample does not differ significantly from any other assemblage, however, the cortical platform frequency is close to being significant. All but one of these is obsidian, indicating that obsidian nodules were being reduced at the site; however, since none of these artifacts were submitted for XRF analysis, there is no way to determine which source they are derived from. They could represent cobbles that were brought from the nearby caldera, or the reduction of obsidian pebbles that were available in surface lag

gravels in the area of the site. Otherwise, the high percentage of collapsed and crushed platforms at this site also represents platform preparation for the reduction obsidian materials.

Table 60.59. Platform types.

Period	Platform Types						
	Cortical	**Single**	**Dihedral**	**Multi**	**Col-lapsed**	**Crushed**	**Total**
Archaic	21 2.9 -8.1	118 16.2 -16.4	5 0.7 -1.3	115 15.8 **12.9**	99 13.6 -1.2	370 50.8 **18.6**	728

Jicarilla Apache	12 17.9 1.9	22 32.8 -1.5	0 0.0 -0.9	1 1.5 -1.6	14 20.9 1.4	18 26.9 0.3	67

Chi-square = 668.3, *df* = 25, $p \leq 0.001$

Given the importance of obsidian biface production at the Archaic sites, it is not surprising that the flake assemblage is characterized by a high percentage of prepared platforms (82.7%). This contrasts with a much lower percentage for the roomblocks (19.0%, 19.2%) and Jicarilla Apache site (21.7%). The percentage for prepared platforms is even lower at the fieldhouses (13.7%, 10.9%). On the one hand, this would be expected in the case of simple expedient flake production; however, we might expect a higher percentage given the production of flake blanks to be used for tool production at these sites.

The majority of the assemblages contain relatively more distal core flake fragments (Tables 60.60 and 60.61). The Archaic and Jicarilla Apache sites contain significantly more midsection and distal flake fragments, while the Ancestral Pueblo sites contain significantly more whole flakes. The presence of more broken flakes at the Archaic and Jicarilla sites is presumably due to both biface production and the reduction of fragile materials like obsidian.

Chi-square = 68.5, *df* = 15, $p \leq 0.001$

Table 60.62 provides the information on mean flake length and angular debris weight. With the exception of the Late Coalition period fieldhouses, most core flakes have a mean length of about 20 to 22 mm. Late Coalition period fieldhouses tend to have larger core flakes, which presumably reflects their use as expedient flake tools. Again, with the exception of the Late Coalition period fieldhouses, the Ancestral Pueblo and Jicarilla assemblages have smaller biface flakes that range from 18 to 19 mm in length. These were presumably derived from smaller bifaces and arrow points. In contrast, the larger size of biface flakes from Archaic sites reflects the use of larger bifacial cores and biface blanks for dart point production. Angular debris is also smaller in size at the Archaic sites due to the soft hammer reduction of bifacial cores. The larger debris in the other assemblages are primarily the result of the hard hammer reduction of platform cores.

The Late Coalition period roomblocks do exhibit a somewhat smaller mean core flake and angular debris size. This could possibly support Walsh's argument of increased reduction intensity during this period; however, it seems more likely that this is primarily the result of increased length of site occupation, rather than a restricted access to raw materials.

Table 60.62. Mean flake length (mm) and angular debris weight (g).

Period	Debitage Type (std)		
	Core Flake	Biface Flake	Angular Debris
Archaic	22.0 (10.6)	24.3 (11.7)	1.3 (2.8)
Early/Middle Coalition Roomblock	22.5 (7.8)	---	3.0 (5.9)
Late Coalition Roomblock	21.7 (9.6)	19.2 (7.1)	2.3 (4.3)
Late Coalition Fieldhouse	22.0 (8.5)	27.2 (7.3)	4.1 (5.2)
Classic Fieldhouse	27.5 (11.4)	18.1 (6.1)	4.2 (7.2)
Jicarilla Apache	20.1 (3.1)	18.6 (3.1)	2.1 (2.4)

This emphasis on the production of bifaces at the Archaic sites is also represented in their relative frequency. As presented in Table 60.63, there are relatively more bifaces in the Archaic assemblages and more retouched flakes in the Ancestral Pueblo assemblages. The latter continues to reflect the importance of core reduction for simple flake use at these sites. However, the trend towards increasing expedient flake production increases through time with informal:formal tool ratios ranging from 0.45 (Archaic) to 0.67 (Early/Middle Coalition period roomblock) to 1.2 (Late Coalition period roomblock). This presumably corresponds with an increasing dependence on agriculture and residential site stability. These higher ratios are also present at the fieldhouses (1.0, 1.3), which reflect the importance of expedient flake use at these temporary sites as well.

Table 60.63. Retouched tool types.

Period	Retouched Tool Types (*n*/%)					
	Ret. Flakes	Bifaces	Points	Unifaces	Drills	Total
Archaic	17 30.9	27 49.0	9 16.3	2 3.6	0 0.0	55

Period	Retouched Tool Types (*n*/%)					
	Ret. Flakes	Bifaces	Points	Unifaces	Drills	Total
Early/Middle Coalition Roomblock	18 37.7	11 24.4	14 31.1	2 4.4	0 0.0	45
Late Coalition Roomblock	60 54.5	20 18.1	14 12.7	9 8.1	7 6.3	110
Late Coalition Fieldhouse	5 50.0	3 30.0	2 20.0	0 0.0	0 0.0	10
Classic Fieldhouse	25 56.8	9 20.4	7 15.9	2 4.5	1 2.2	44
Jicarilla Apache	2 50.0	1 25.0	1 25.0	0 0.0	0 0.0	4

Tool Use

Given the increasing importance of expedient flake use through time, we would expect this to be reflected in an increasing proportion of utilized debitage through time. There does appear to be an inverse relationship between the percent of flakes exhibiting edge damage and the frequency of retouched tools. Obvious edge damage, which could be attributed to use, was only identified on 0.8 percent of the Archaic debitage, 1.1 percent of the Early/Middle Coalition period roomblock debitage, and 2.3 percent of the Late Coalition period roomblock debitage. By contrast, 1.4 percent of the debitage at the Late Coalition period fieldhouses, 0.6 percent at the Classic period fieldhouses, and 0.5 percent of the debitage at the Jicarilla site exhibit edge damage.

Figure 60.24 presents a frequency polygon with utilized debitage edge angles (including multiple edges on same flake). Frequency data are used due to the small samples sizes. Most of the edge angles range from 30 to 70°. The larger Early/Middle Coalition period roomblock sample exhibits a peak at 55° and the Late Coalition period roomblock sample exhibits a bimodal distribution with peaks at 35 and 55°. The lower angles presumably reflect the importance of cutting activities, with the more obtuse angles being primarily used for scraping activities (e.g., Gould et al. 1971).

Information on the distribution of ground stone tools is provided in Figure 60.25. The histogram illustrates that Archaic sites are characterized by the presence of one-hand cobble manos, millingstones, and grinding slabs. The roomblock sites also contain mostly one-hand manos, but two-hand manos are represented as well. The percentage of two-hand manos actually increases slightly from the Early/Middle to the Late Coalition period, but is highest at the Late Coalition period fieldhouses. Slab metates are also present at the roomblock sites, and no trough metates were identified. The fieldhouses contain both one- and two-hand manos, with some grinding slabs and undetermined metate fragments. Lastly, one one-hand cobble mano and one slab metate were recovered from the Jicarilla site.

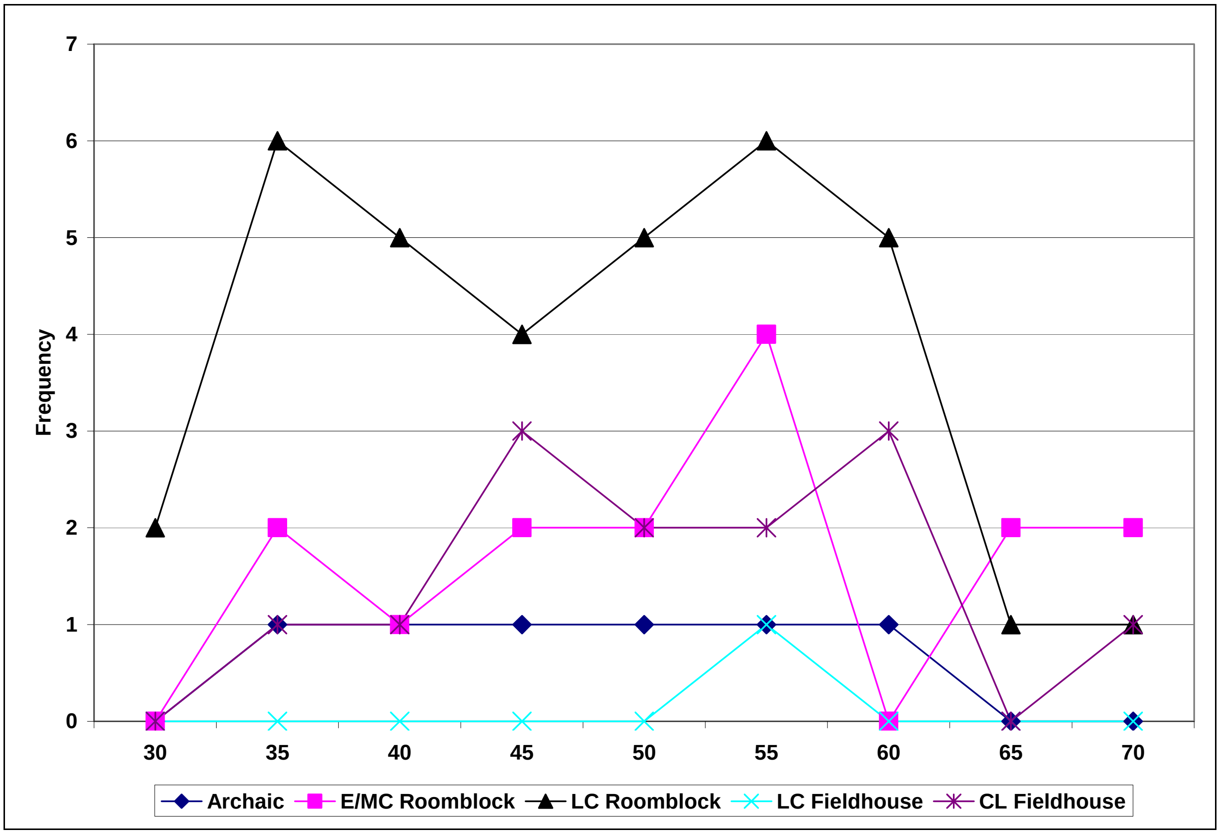

Figure 60.24. The distribution of edge angles for damaged flakes.

The sample sizes vary greatly for mean mano lengths. Samples are from the Archaic period (*n* = 3), the Early/Middle Coalition period roomblocks (*n* = 11), the Late Coalition period roomblocks (*n* = 38), the Late Coalition period fieldhouses (*n* = 3), and the Classic period fieldhouses (*n* = 13). These comparisons are also difficult given that two-hand manos tend to be discarded when broken and cannot therefore provide overall length measurements. Nonetheless, the information on mean mano length is presented in Figure 60.26. The histogram shows a similar pattern with smaller mean lengths for the Archaic period (mean = 118 mm, *std* = 16.0), the Early/Middle Coalition period (mean = 133 mm, std = 44.9), and the Late Coalition period roomblocks (mean = 120 mm, *std* = 48.2), and larger mean lengths for the Late Coalition period fieldhouses (mean = 176.6 mm, *std* = 52.5) and Classic period fieldhouses (mean = 151, *std* = 57.6). This trend emphasizes the general importance of smaller-size manos at the roomblock sites.

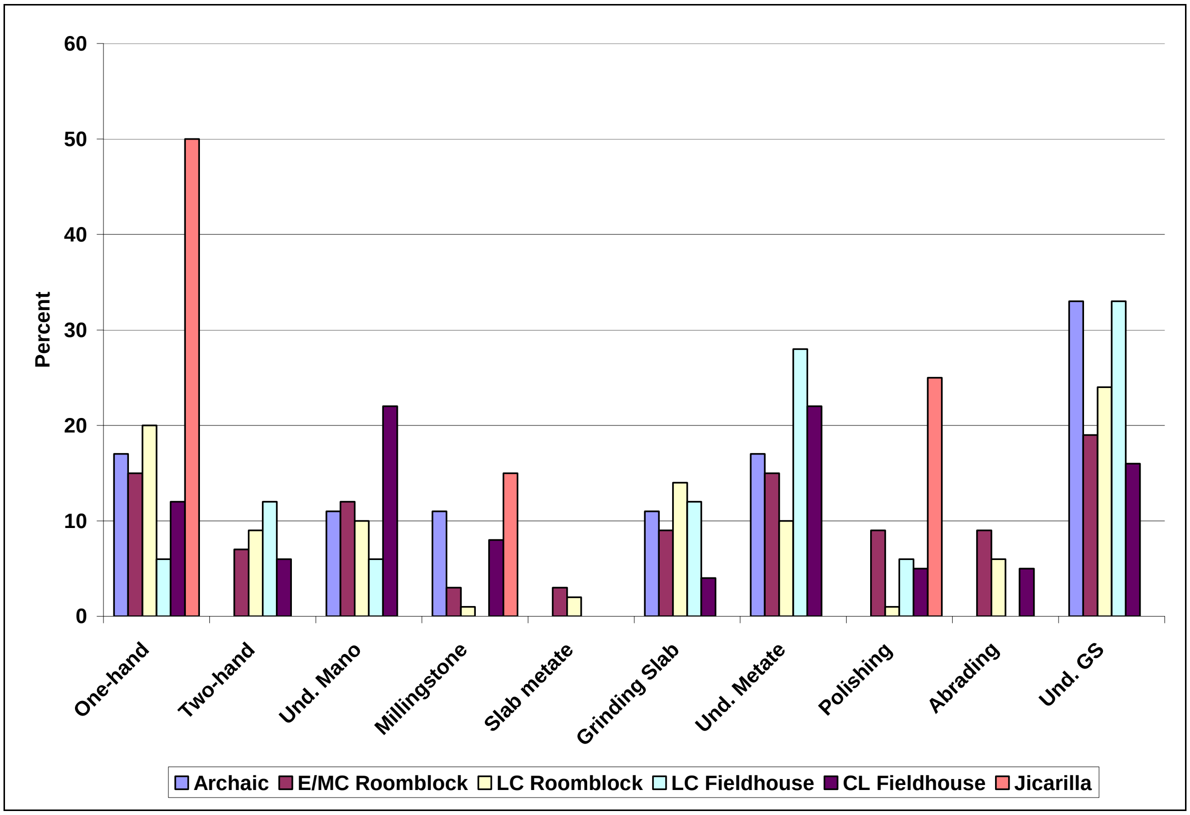

Figure 60.25. The distribution of ground stone artifact types.

Information on ground stone use-location and grinding surface shape is provided in Table 60.64. The Archaic manos tend to have ovoid-shaped grinding surfaces on cobble manos with one or more ground sides. The Early/Middle Coalition period roomblocks have slightly more one-sided manos, with mainly ovoid-shaped grinding surfaces. This pattern begins to change with the Late Coalition period roomblocks, which exhibit more two-sided manos, but still with mostly ovoid grinding surfaces. Not until the Classic period fieldhouses is there a shift to both more two-sided manos with the larger rectangular grinding surfaces. This includes the large "loaf-shaped" manos recovered at several of the fieldhouses. These data also correspond with the mano type and length data. Based on this information it appears that maize was being more intensively processed with large two-sided manos that exhibited rectangular grinding surfaces in the Classic period. Data from the Late Coalition period plaza pueblos would also help to clarify this long-term pattern.

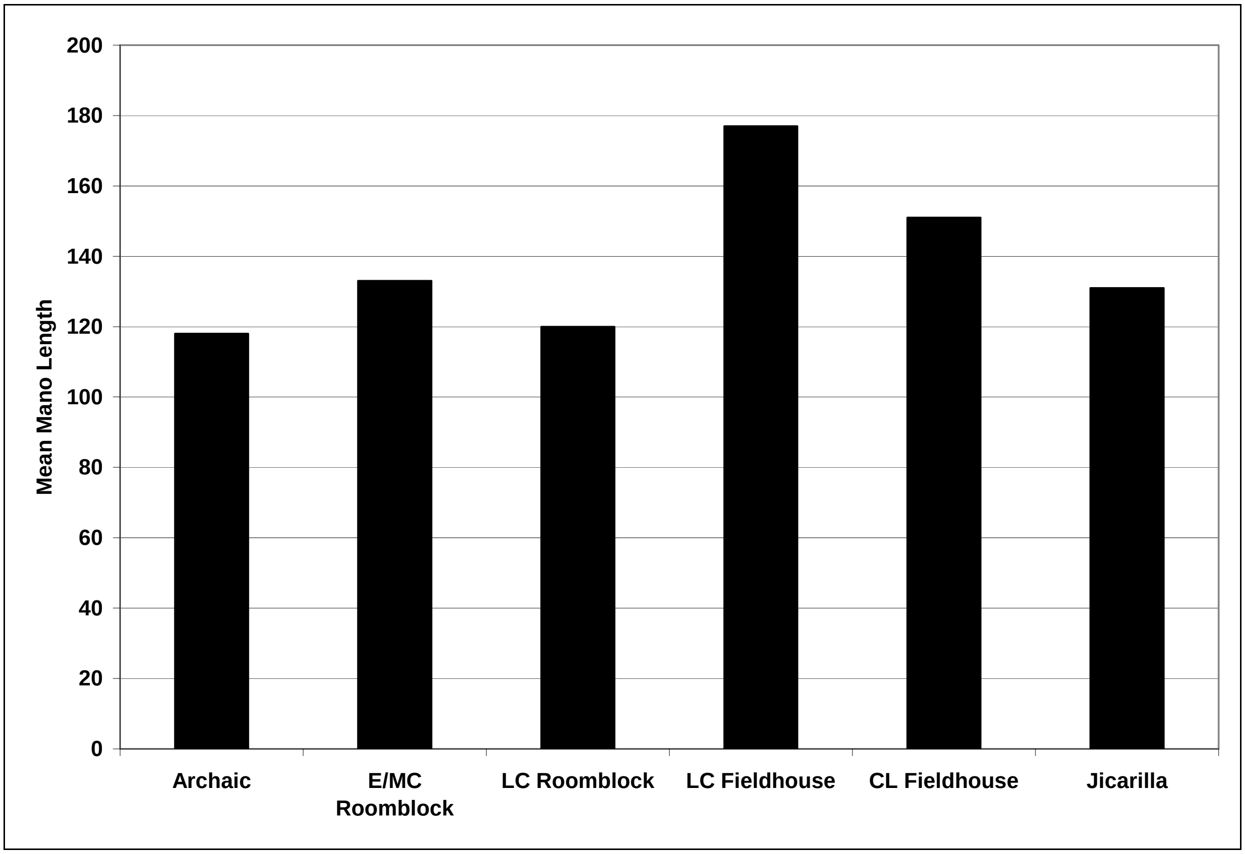

Figure 60.26. Mean mano length.

Table 60.64. Ground stone grinding surface location and shape.

Period	Use-location		Surface shape		
	1-side	2-sides	Ovoid	Rectangular	Und.
Archaic	2	2	3	0	1
Early/Middle Coalition Roomblock	8	5	10	3	1
Late Coalition Roomblock	27	31	39	9	10
Late Coalition Fieldhouse	2	3	2	3	0
Classic Fieldhouse	7	11	6	9	3
Jicarilla Apache	1	1	1	0	1

The sample sizes are again small for the hammerstones. Nonetheless, the available information on number of damaged loci and location of damage is presented in Table 60.65. Both roomblock assemblages are similar, ranging from one to three battered loci, with mostly angular ridges and battering "all over." In contrast, the Classic period fieldhouses exhibit one to two loci, with ridge and convex battered surfaces, but no "all over." The latter are typically used for roughening metate surfaces and processing materials on these surfaces, so the presence of these heavily battered items should be expected at the roomblock sites with longer occupation spans.

Table 60.65. Number of damaged loci and location of damage for hammerstones.

Period	No. Loci			Location of Damage		
	1	2	3	Ridge	Convex	All Over
Archaic	0	0	0	0	0	0
Early/Middle Coalition Roomblock	5 50.0	4 40.0	1 10.0	5 50.0	2 20.0	3 30.0
Late Coalition Roomblock	6 60.0	2 20.0	2 20.0	5 50.0	1 10.0	4 40.0
Late Coalition Fieldhouse	0	0	0	0	0	0
Classic Fieldhouse	2 66.6	1 33.3	0 0.0	3 50.0	3 50.0	0 0.0
Jicarilla Apache	0	0	0	0	0	0

Although no vent plugs (tiponis) were included in the systematic sample of the site lithic assemblages, several were in fact recovered during the site excavations. Since these items are distinctive to the Pajarito Plateau, a brief discussion of these items will be included. The artifacts are typically cylindrical or conical shaped being made of tuff (Figure 60.27). Steen (1982:48–51) suggests that that they may represent earth mother fetish stones. However, as he points out "none was found in a position in which it had been used or stored. Each was found in the rubble of the fallen walls (ibid:510)." This also appears to be the case with the vent plugs recovered from the recently excavated sites. Two were found at LA 86534 and both were situated in wall debris within and adjacent to Room 4. A single vent plug was also recovered from wall debris in Room 2 at LA 135290, with two vent plugs found in a similar context at LA 12587 within and adjacent to Room 9. Lastly, 10 vent plugs were recovered during the excavations at LA 4618. Most of these were found within Room 11 (a kiva), with a single item being situated in adjacent Room 1 (Schmidt 2006). Again, all of these artifacts appear to have been recovered from secondary wallfall deposits. The ones found at LA 12587, LA 86534, and LA 135290 are conical shaped, ranging from 180 to 230 mm in length and 120 to 140 mm in width. In contrast, the artifacts from LA 4618 are mostly cylindrical shaped (n = 6) with fewer conical shaped (n = 3) and a single disc shaped. They also range from about 150 to 200 mm in length. The function of the artifacts is undetermined, but their context indicates that they may have been incorporated into the wall architecture.

CONCLUSION

This chapter summarized approximately 7000 years of stone tool technology on the Pajarito Plateau. The Early Archaic inhabitants of the plateau appear to have periodically visited the Valles Caldera to collect obsidian raw materials. These materials were then used for the production of bifacial cores, which were subsequently reduced into biface blanks for dart points. The Middle to Late Archaic site assemblage also reflects an emphasis on the production of obsidian bifacial tools, but with a full range of by-products that could represent a habitation, rather than temporary campsite. Obsidian source studies indicate that the Rendija Canyon Middle to Late Archaic site contains Cerro Toledo, Valle Grande, and El Rechuelos obsidian that possibly reflects a north-south pattern of movement. In contrast, the Late Archaic site that is situated in the White Rock Tract may represent a temporary campsite with the occupants having recently visited the Cerro Toledo obsidian source area.

Figure 60.27. Cylindrical (left) and conical (right) shaped vent plugs (tiponis).

The Coalition period roomblocks reflect an emphasis on chalcedony core reduction activities. Obsidian source studies indicate a mix of Valle Grande and Cerro Toledo obsidian in the Early and Middle Coalition period roomblock assemblages and mostly Cerro Toledo in the Late Coalition period roomblock assemblages. Overall, the amount of obsidian increases through time, with relatively more present at the Classic period plaza pueblo site of Tsirege. This pattern could reflect the increasing importance of regional exchange networks during the Classic period. In contrast, obsidian pebbles were locally available in Rendija Canyon and were used by the inhabitants of the fieldhouses. The retouched tools in the Ceramic period assemblages are dominated by informal retouched flakes, with a larger relative proportion of utilized debitage. This reflects the importance of expedient flake tools in these later assemblages. The ground stone tools include one- and two-hand manos with slab metates and grinding slabs. Although there is a slight increase in the relative frequency of two-hand manos in the Late Coalition period assemblages, one-hand manos clearly dominate most of the ground stone assemblages.

The Jicarilla Apache lithic assemblage appears to be intermediate to Archaic and Ceramic period assemblages. It primarily contains obsidian that was derived from the nearby caldera like the Early Archaic site; however, it also contains significantly more core flakes and angular debris like the Ceramic period sites. Nonetheless, the proportion of biface flakes is intermediate to the Archaic and Ceramic period assemblages. Therefore, the use of high-quality obsidian was important to the site occupants for both core reduction and tool production/maintenance activities. The only ground stone recovered consisted of a one-hand mano, a millingstone, and a polishing stone.

CHAPTER 61
SOURCE PROVENANCE OF OBSIDIAN AND BASALT ARTIFACTS FROM THE LAND CONVEYANCE AND TRANSFER PROJECT DATA RECOVERY PROGRAM, LOS ALAMOS NATIONAL LABORATORY

M. Steven Shackley

INTRODUCTION

This study is focused on the source provenance of obsidian artifacts submitted by Los Alamos National Laboratory (LANL) from the Land Conveyance and Transfer Project Data Recovery Program between 2002 and 2005. All obsidian artifacts analyzed were produced from obsidian procured in the Jemez Mountains, Cerro Toledo Rhyolite, Valle Grande Rhyolite, and El Rechuelos. The dacite samples that could be assigned to source were procured from the Cerros del Rio dacite source on Bandelier National Monument or one of the two dacite sources in the Taos Plateau Volcanic Field.

ANALYSIS AND INSTRUMENTAL CONDITIONS

All archaeological samples are analyzed whole. The results presented here are quantitative in that they are derived from "filtered" intensity values ratioed to the appropriate X-ray continuum regions through a least squares fitting formula rather than plotting the proportions of the net intensities in a ternary system (McCarthy and Schamber 1981; Schamber 1977). Or more essentially, these data through the analysis of international rock standards, allow for inter-instrument comparison with a predictable degree of certainty (Hampel 1984).

The trace element analyses were performed in the Archaeological XRF Laboratory, Department of Earth and Planetary Sciences, University of California, Berkeley, using a Spectrace/ThermoNoran^{TM} *QuanX* energy dispersive X-ray fluorescence spectrometer. The spectrometer is equipped with an air-cooled Cu X-ray target with a 125-micron Be window, an X-ray generator that operates from 4 to 50 kV/0.02 to 2.0 mA at 0.02 increments, using an IBM PC based microprocessor and WinTraceTM reduction software. The X-ray tube is operated at 30 kV, 0.14 mA, using a 0.05-mm (medium) Pd primary beam filter in an air path at 200 seconds livetime to generate X-ray intensity Kα-line data for elements titanium (Ti), manganese (Mn), iron (as FeT), thorium (Th) using Lα line, rubidium (Rb), strontium (Sr), yttrium (Y), zirconium (Zr), and niobium (Nb). Trace element intensities were converted to concentration estimates by employing a least-squares calibration line established for each element from the analysis of international rock standards certified by the National Institute of Standards and Technology (NIST), the US Geological Survey (USGS), Canadian Centre for Mineral and Energy Technology, and the Centre de Recherches Pétrographiques et Géochimiques in France (Govindaraju 1994). Line fitting is linear (XML) for all elements but Fe where a derivative fitting is used to improve the fit for the high concentrations of iron and thus for all the other elements. Further details concerning the petrological choice of these elements in Southwest obsidian is available in Shackley (1988, 1990, 1992, 1995; also Mahood and Stimac 1991; and Hughes and Smith 1993). Specific standards used for the best fit regression calibration for elements Ti through Nb include G-2 (basalt), AGV-1 (andesite), GSP-1, SY-2 (syenite), BHVO-1 (hawaiite), STM-1 (syenite), QLO-1 (quartz latite), RGM-1 (obsidian), W-2 (diabase), BIR-1 (basalt), SDC-1 (mica schist), TLM-1 (tonalite), SCO-1 (shale), all USGS standards, BR-N (basalt) from the Centre de Recherches Pétrographiques et Géochimiques in France, and JR-1 and JR-2 (obsidian) from the Geological Survey of Japan (Govindaraju 1994). In addition to the reported values here, Ni, Cu, Zn, and Ga were measured, but these are rarely useful in discriminating glass sources and are not generally reported.

The data from the WinTrace software were translated directly into Excel for Windows software for manipulation and on into SPSS for Windows for statistical analyses. In order to evaluate these quantitative determinations, machine data were compared to measurements of known standards during each run. RGM-1 is analyzed during each sample run for obsidian artifacts to check machine calibration and is included in Table 10.1. Source assignment was made by comparison to regional source standards at Berkeley (see Shackley 1995, 2002, 2005a).

DISCUSSION

Obsidian Sample

While it is not surprising that the obsidian used to produce these tools and the resultant debitage is from the nearest sources in the Jemez Mountains, the proportion of these sources does deserve some discussion (see Tables 61.1 and 61.2; Figures 61.1 and 61.2). As noted in Chapter 10 (Volume 1), while all the major sources in the Jemez have eroded into the Rio Grande system, Valles Rhyolite (Cerro del Medio), a result of the last caldera collapse, has not eroded outside the caldera (see also Shackley 2005a). The Valles Rhyolite obsidian is the most common in the overall assemblage (56.25%) and was likely procured directly from Cerro del Medio or the erosional slopes into the caldera floor (Figure 61.1). El Rechuelos erodes from the small domes north and west of Polvadera Peak into the Rio Chama and has been found in secondary deposits as far south as the Cochiti Reservoir area in nodules up to about 49 mm in diameter. Cerro Toledo Rhyolite obsidian is available in various areas throughout the Pajarito Plateau as a result of the Rabbit Mountain ash flow eruptive event, including along the Rio Grande at Cerros del Rio (see Chapter 10, Volume 1; Shackley 2005a).

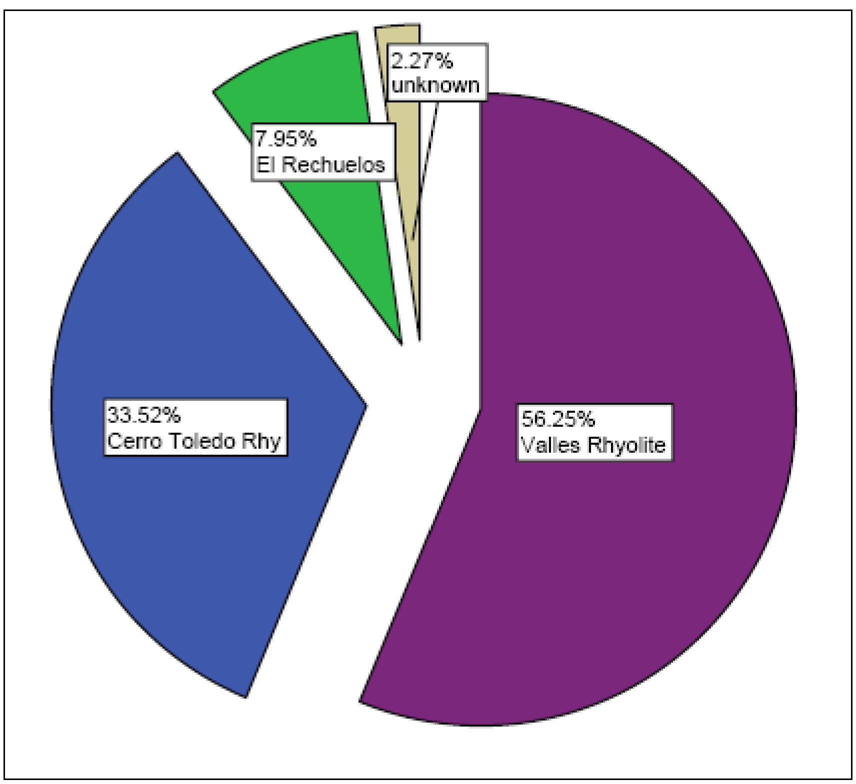

Figure 61.2. Distribution of obsidian source provenance from all sites.

Volcanic Rock Sample

Perhaps more interesting than the obsidian data from a source provenance standpoint, is the volcanic rock artifact sample (Table 61.3). While the artifacts produced from obsidian were produced from local sources, some of the other volcanic raw materials used to produce artifacts came from the Taos Plateau Volcanic Field, specifically San Antonio Mountain and the Newman Dome. It is possible that at least some of these artifacts were scavenged from Archaic period sites on the plateau, where artifacts produced from these sources are common, but it is not clear from this sample (see Shackley 2005b; Vierra et al. 2005). The "unknowns" in this assemblage are probably mafic or intermediate rocks found more locally, such as the mafic rocks in the Cerros de Rio Volcanic Field to the west.

CHAPTER 62
DIET AND SUBSISTENCE ON THE PAJARITO PLATEAU: EVIDENCE FROM FLOTATION AND VEGETAL SAMPLE ANALYSIS

Pamela J. McBride

INTRODUCTION

The Land Conveyance and Transfer (C&T) Project completed the excavation or testing of over 40 sites where flotation (489) and vegetal (324) samples were collected for analysis (Table 62.1). Situated primarily in two vegetative zones (piñon-juniper woodland and ponderosa pine forest), the C&T Project sites provide evidence for occupation of the Pajarito Plateau in the Archaic, Coalition, and Classic periods. Although 51 Archaic sites have been identified at Los Alamos National Laboratory (LANL) as a whole (Vierra and Foxx 2002), the Archaic signature on C&T Project land is sparse and consists of four lithic scatters and three lithic/ceramic scatters with Archaic components. The sites are in locations that seem to have been equally attractive to those who succeeded the hunter/gatherers; with the exception of the Early Archaic lithic scatter (LA 85859), artifact scatters are located downslope of Coalition cavate (LA 117883), one-room structure (LA 99396), or roomblock sites (LA 12587, Area 8) or Classic period fieldhouses (LA 99397 and LA 86637). Flotation and vegetal samples were not taken from LA 86533, a Late Archaic/Coalition lithic/ceramic scatter. Sites where hunters could make tools, gather wild plants, and track game that came to drink at washes or streams would offer future farmers a source of water for crops as well as an opportunity to hunt.

Samples from three roomblocks and four fieldhouses were analyzed from the Coalition period. Two of the roomblocks (LA 86534 and LA 135290) are on the Los Alamos Town Site Mesa at 2152 m (7050 ft) and 2164 m (7100 ft), respectively, while the third (LA 12587) is near the modern town of White Rock in piñon-juniper woodland about 600 feet lower in elevation. The roomblocks are associated with sandy loam soils (primarily Hackroy) that are usually good for agriculture (Nyhan et al. 1978). These deposits, however, are fairly thin at the tip of the Town Site Mesa where LA 86534 is located. The mesa tops were most suited for dryland farming, offering expanses of open and level areas for fields or grid gardens. Given above normal precipitation rates during the Coalition and Classic periods (AD 1024–1398; Allen 2004:48), farmers had less reason to move off the mesa tops to more well-watered locales. Most Coalition period fieldhouses are located near habitation sites in the piñon-juniper zone, but the four C&T Project fieldhouses from this period are in Rendija Canyon at elevations ranging from 2090 m (6860 ft) to 2145 m (7040 ft) in the piñon-juniper/ponderosa pine ecotone. Three of these fieldhouses date to the Late Coalition when the location of fieldhouses points to a broadening choice of soil types and landforms for farming. Garden plots were not only situated on mesa tops, but in canyon bottoms, near the base of mesas to take advantage of run-off, and in well-watered spots near springs or seeps. The transition to the Classic period is marked by increasing agricultural production coupled with aggregation (Hill et al. 1996; Kohler 1989; Powers and Orcutt 1999a; cited in Vierra 2002:6-44) and competition for land, presumably due to internal population growth or immigration. Burned rooms (at LA 12587 and Airport 2) and a fieldhouse burned to the ground (LA 85417) during this time period could be direct evidence of competition.

Table 62.1. List of C&T Project site numbers, tracts, number and type of samples analyzed, and period of occupation.

Site Type	LA Number	Tract	N/Type of Sample	Period of Occupation
Roomblock	12587	White Rock	125F, 109V	Late Coalition/Classic
Roomblock	86534	Airport	54F, 66V	Middle Coalition

Homestead	85407	Rendija	8F, 3V	Early 20th Century

F = flotation sample, V = vegetal sample.

With three exceptions, unmixed Classic sites consist entirely of fieldhouses located in Rendija Canyon at slightly higher elevations than the preceding Coalition period. A grid garden (LA 139418) on the Los Alamos Town Site Mesa is most likely contemporaneous with a nearby fieldhouse (LA 141505), as there was a correlation between soil profiles at the two sites (see Chapter 57, this volume). A Middle Classic lithic/ceramic scatter (LA 127625) is in a flat area just east of the mouth of Cañada del Buey and consists of redeposited material apparently originating from nearby slopes and mesa top sites (see Volume 2, Chapter 17). A Classic lithic/ceramic scatter (LA 61035) that was tested in the White Rock Tract is on the south side of the first bench adjacent to the Los Alamos Canyon drainage channel.

The Classic period is characterized by continuing population aggregation into large pueblos and intensification of maize agriculture. Within the confines of the C&T Project, the only Classic period habitation sites are Otowi (LA 169), the associated cavate complex (LA 127673) to the north, and a single roomblock at LA 12605. Otowi straddles the ridge between Bayo and Pueblo canyons over the best-watered and flat canyon bottomland in the area. The largest expanse of rock-lined garden plots is in this area (Masse and Vierra 2000) and spans several time periods. In general, fieldhouses in the Classic period tend to follow the pattern described above for those found during the C&T Project. That is, they are at slightly higher elevations than in preceding periods, which may be a factor of climactic conditions or simply that, with a peak in population, more diverse arable land was utilized. Three out of four of the most unfavorable periods for dryland farming occurred in the Classic period (AD 1440–1525, 1400–1440, and 1525–1600; Orcutt 1999: Figure 5.8, cited in Kohler 2004). In fact, the whole period from AD 1399–1790 was unusually dry (Allen 2004). Garden plots were not only increasingly located at higher elevations to take advantage of higher precipitation rates (about 19 inches of rain a year compared to lower elevations in the piñon-juniper zone near White Rock with approximately 13.5 inches a year [Foxx 2006:33]), but near springs or seeps. For instance, the gardens at LA 12701, associated with the Classic pueblo of Tsirege, were watered by a canal served by the Pajarito Springs (Steen 1977).

The Serna Homestead (LA 85407), located on a gently sloping bench immediately north of Rendija Canyon, was patented in 1922 by Andres Martinez and subsequently sold to José and Fidel Serna who farmed the land until the US government took possession of the property in 1942. The homestead, along with two turn of the century (circa 1890s) Jicarilla Apache tipi rings and a historic period check dam, comprise the historic sites excavated on C&T Project land. A few lithic/ceramic scatters have an historic trash element as well (LA 86637, LA 86528, LA 86531, and LA 61034).

Wild plant resources identified from throughout the C&T Project area include at least 11 weedy annuals, three grasses, and eight perennial genera (Table 62.2). Wood charcoal was primarily coniferous, but a diverse array of shrubs was present, as well as representatives from the riparian community (box elder, cottonwood/willow, and New Mexico locust). Specimens of the three most important domesticates (maize, beans, and possibly squash) were present in samples from LA 12587, LA 135290, and LA 127634, while maize and/or possible squash were identified at 20 of the remaining 45 sites. The hearth inside one of the Jicarilla Apache tipi rings (LA 85864) produced a possible wheat grain (very eroded), while evidence for other European cultivars (peach and possibly grape) was present at the early 20th century Serna Homestead (LA 85407).

Table 62.2. Charred plant taxa recovered from C&T Project flotation and macrobotanical samples.

Scientific Name	Common Name	Plant Part
Annuals		
Amaranthus	Pigweed	Seed
Chenopodiaceae	Goosefoot family	Seed
Chenopodium	Goosefoot	Seed
Chenopodium berlandieri	Pitseed goosefoot	Seed
Chenopodium/Amaranthus	Cheno-am	Seed
Cleome	Beeweed	Embryo, seed
Corispermum	Bugseed	Seed
Cycloloma	Winged pigweed	Seed
Helianthus	Sunflower	Achene
Kochia scoparia	Summer cypress	Seed
Lappula	Stickseed	Seed

Scientific Name	Common Name	Plant Part
Nicotiana	Tobacco	Seed
Portulaca	Purslane	Seed
Cultivars		
Phaseolus	Bean	Cotyledon
Prunus persica (uncharred)	Peach	Stone
Triticum	Wheat	Caryopsis
Vitis	Grape	Seed
Zea mays	Maize	Cob, cupule, cupule segment, embryo, glume, kernel, shank, stalk
Grasses		
Gramineae	Grass family	Caryopsis, culm
Achnatherum hymenoides	Ricegrass	Caryopsis
Sporobolus	Dropseed grass	Caryopsis
Other		
Compositae	Sunflower family	Achene
Croton	Doveweed	Seed
Cucurbita	Squash/coyote gourd	Rind
Cyperaceae	Sedge family	Seed
Labiatae	Mint family	Seed
Monocotyledonae	Monocot	Stem
Oenothera	Evening primrose	Seed
Physalis	Groundcherry	Seed
Plantago	Plantain	Seed
Polygonaceae	Knotweed family	Seed
Portulacaceae	Purslane family	Seed
Salvia	Sage	Seed
Indeterminate	Indeterminate	Embryo, seed, unknown plant part
Unknown #1	Unknown #1	Embryo, seed, stem, unknown plant part
Unknown #2	Unknown #2	Seed
Verbena	Vervain	Seed
Perennials		
Acer negundo	Box elder	Wood
Artemisia	Sagebrush	Wood
Atriplex canescens	Four-wing saltbush	Fruit, seed
Atriplex/Sarcobatus	Saltbush/greasewood	Wood
Cercocarpus	Mountain mahogany	Wood
Chrysothamnus	Rabbitbrush	Wood
Echinocereus	Hedgehog cactus	Seed
Foresteria	Desert olive	Wood
Gymnospermae	Unknown conifer	Wood
Juniperus	Juniper	Female cone, seed, twig, twigscale, wood

Scientific Name	Common Name	Plant Part
Lycium	Wolfberry	Wood
Mammillaria	Pincushion cactus	Seed
Pinus	Pine	Bark scale, cone scale, male cone, needle, seed, umbo, wood
Pinus edulis	Piñon	Needle, nutshell, twig, wood
Pinus ponderosa	Ponderosa pine	Fascicle, needle, wood
Platyopuntia	Prickly pear cactus	Embryo, seed
Populus/Salix	Cottonwood/willow	Wood
Pseudotsuga menziesii	Douglas fir	Needle, wood
Quercus	Oak	Wood
Rhus	Sumac	Wood
Robinia	New Mexico locust	Wood
Rosaceae	Rose family	Wood
Rumex	Dock	Seed
Unknown non-conifer	Unknown non-conifer	Wood
Yucca baccata	Banana yucca	Seed

The archaeobotanical assemblage reflects the gathering of grasses and perennials common in the juniper savanna and piñon-juniper woodland plant communities (Foxx and Tierney 1985). Tree and shrub species were procured from at least four of the five major vegetation cover types at LANL (juniper savanna, piñon-juniper woodland, ponderosa pine forest, mixed conifer forest, and spruce-fir forest; Foxx 2006:35). Riparian and wetland zones provided a source for cottonwood, willow, and plants in the sedge family. Coyote tobacco (*Nicotiana attenuata*) could have been found growing in sandy soils alongside streams and washes (Foxx and Tierney 1985). Annuals were collected from a variety of naturally and culturally disturbed areas.

Although evidence of deliberate setting of fires is lacking, fire could have been used by prehistoric peoples to enhance the density and vigor of certain species like sunflower and bugseed (Bohrer 1983, cited in Foxx 2006:61). Alternatively, people could simply have taken advantage of the results of natural fires in the region. Allen (2004) suggests that there were frequent surface fires during the Coalition and Classic period occupations of the Pajarito Plateau, either from lightning strikes or possibly human ignition. Wild onion, pigweed, goosefoot, and gooseberry are a few of the plants that benefit from the regenerative effects of fire (Foxx 2006:Table 3.9). Shrubs (such as oak) sprout almost immediately after fire, attracting browsing animals like deer and elk (Foxx 2001).

If the prehistoric occupants were managing certain resources with fire, it may be no accident that oak, mountain mahogany, and saltbush/greasewood were the most common non-conifer taxa in flotation and vegetal samples. Four-wing saltbush, although "not very tolerant of fire, may sprout to some degree if fire intensity is not too severe" (Ogle et al. 2005). Stand-replacing fires encourage oak (Dick-Peddie 1993: 69); it is one of the many early succession shrubs and trees that sprout after a fire (Foxx 2006:63). *Quercus gambelii* is a fire-adapted species with a well-developed root system that allows it to draw moisture from a large volume of soil resulting in rapid resprouting after fire (Simonin 2000). After fire, mountain mahogany will recolonize a site through root crown or rhizome sprouts (Cronquist et al. 1997).

Today, the average annual precipitation at both the Airport Tract and the White Rock Tract is 12 to 14 inches (Foxx 2003:35) while that in Rendija Canyon is about 19 to 20 inches. Based on historic data, the growing season ranges from 133 to 246 days (Bowen 1990). The amount of rainfall in an average year, soil conditions, and growing season length would have been sufficient to produce successful crops of several native Southwest maize varieties (Muenchrath and Salvador 1995). These include chapolote (flowers in about 50 days after planting; LAMP 1991:691–692), Cochiti (matures in 90 days; Native Seeds/SEARCH 1992), and Hopi flour corn (matures in about 75 days after sowing; Seeds of Change 1990). Using a variety of agricultural techniques and maize varieties with short maturation periods could have resulted in fairly successful crop yields from dryland farming in the Los Alamos and White Rock areas.

The method followed and results obtained from archaeobotanical analysis of flotation and vegetal samples are presented in this chapter. The goals of this report are to 1) describe plant taxa exploited by prehistoric populations, 2) compare resource use patterns with other archaeobotanical analysis results from sites in the region, and 3) address research questions such as season of occupation, diet, and subsistence practices.

METHODS

Archaeobotanical analysis of material from the project involved vegetal sample analysis, flotation processing, full sort analysis, and quantification as described below. Identification was aided by the use of a modern comparative collection and comparison to photographs in seed identification manuals (Delroit 1970; Martin and Barkley 1961). Scientific nomenclature and common names followed those presented in Martin and Hutchins (1980). Identifications were made to different taxonomic levels: families (e.g., Gymnospermae), genus (e.g., *Chenopodium*), species (e.g., *Pinus edulis*), and non-Linnaean categories (e.g., cheno-am). The cheno-am category refers to seeds that could be either in the genus *Chenopodium* or *Amaranthus*. This category is used when the condition of a seed prohibits a more specific identification.

Table 62.2 lists the Latin and common name, plant part, and plant category (e.g., annuals, perennials) of all charred plants recovered from the project. For ease of reporting, taxa in all other tables are recorded using the common name only. Plant remains designated as “unknown” indicate remains that might be identified later using a more extensive comparative collection. “Indeterminate” plant remains are unidentifiable due to erosion or fragmentation.

Vegetal Sample Analysis

Macrobotanical field samples are fortuitous plant specimens collected as they are encountered in the field either during excavation or the screening of fill and are not associated with an exact provenience. In spite of this, vegetal specimens can offer further insight into the diet and subsistence of prehistoric populations. Vegetal specimens are identified, counted and weighed, and placed in protective containers such as film canisters or polypropylene vials, depending on specimen size. The taxon, plant part, confidence of the identification, condition, count, and weight of the specimen were recorded along with any observations that may be important in the interpretation of the material.

Flotation Samples: Flotation Processing

LANL uses a standard decant flotation system as described by Hammett and McBride (1993). The 489 flotation samples ranged in volume from 0.2 to 6.7 liters. Each flotation sample was poured into a bucket of water, agitated gently until the botanical material floated to the surface, and then decanted onto a clean piece of chiffon material. The squares of fabric were laid flat on coarse mesh screen trays until the recovered material had dried. The residue at the bottom of the bucket (called the heavy fraction) was rinsed to eliminate soil matrix, dried, and examined to recover lithic and bone material.

Full Sort Analysis

The floated material was passed through a series of graduated screens (US Standard Sieves with 4-mm, 2-mm, 1-mm, and 0.5-mm mesh sizes). The material from each screen size was then examined using a binocular microscope at a magnification of 7x to 45x. Charred reproductive plant parts like seeds and fruits were identified and counted. Charred non-reproductive plant parts (bark, needles, etc.) and uncharred plant parts were also identified and quantified as an estimate of abundance/liter.

If more than 20 pieces of wood charcoal were present in a sample, then 20 pieces (selected randomly from the 4-mm and 2-mm screens) were identified, separated by taxon, counted, and weighed. Then the remainder of each fraction was scanned to identify any taxa that might have been missed. Otherwise, all identifiable wood charcoal from a sample was analyzed.

Several problems that arise consistently during wood identification in the southwest are addressed by placing specimens in more general categories. The identification of unknown conifer is used when a specimen is too fragmentary or the presence of root holes precludes differentiation between juniper and other conifers such as piñon or fir. Pine is designated when resin ducts are present, but the fragmentary nature of a specimen prevents identification to species. Several species of shrubs that are in the Chenopodiaceae (goosefoot) family have morphological characteristics that are essentially identical (four-wing saltbush, greasewood, winterfat, etc.). For this reason, identification to species is not possible and specimens are placed in the combined saltbush/greasewood taxon. Finally, small-diameter twigs of cottonwood and willow are nearly impossible to distinguish, so specimens are designated as *Populus/Salix*.

All wood and reproductive plant parts that were counted and identified from each sample were placed in polypropylene capsules or plastic bags and labeled for future reference. An example of each uncharred or non-reproductive charred plant part encountered during analysis was also separated and placed in a polypropylene capsule or plastic bag. Non-cultural remains such as roots and insect parts observed during flotation analysis were also recorded. These observations are reported along with sample volumes (before flotation) and sample weights (after flotation) in Appendix S.

QUANTIFICATION

Three forms of quantification were used during flotation analysis: abundance, ubiquity, and minimal number of individuals (MNI). Each of these is described below.

Abundance

To determine the estimated abundance of charred non-reproductive plant parts and uncharred taxa present in a sample, an estimate of the number of these materials per liter of soil is recorded. This allows for an approximate quantification of non-reproductive plant parts and an estimation of the degree of contamination.

Ubiquity

Many factors can affect the number and type of taxa recovered from flotation samples including differential preservation of plant remains, plant processing techniques, and archaeological sampling strategies. Seeds and nuts with hard testa will preserve, while tubers and leafy greens rarely, if ever, preserve. Plants that were parched during processing are more likely to preserve due to "kitchen accidents" than those that do not require this step during food preparation. A 5-liter flotation sample has a greater probability of yielding a diverse number of plant taxa than a 1-liter sample.

When the first two factors are considered, it can be difficult or impossible to determine the exact composition of the prehistoric diet or the degree of dependence on one plant as compared to another. The latter problem of differential sample size can be resolved by standardizing flotation sample volumes or by applying statistical analyses to determine the effects of sample size on archaeobotanical analysis results. Ubiquity is a quantification method used by archaeobotanists to identify possible trends or patterns that can lead to the identification of plant processing or storage loci or changes in plant exploitation through time.

To determine which plant remains were most common in samples, ubiquity tables were created for non-wood plant taxa recovered from the project. Ubiquity tallies the presence or absence of a taxon in each sample. The number of remains of a particular taxon found in a sample is not reported in this method of quantification. Presence is recorded for one specimen of a taxon or 200. Therefore, ubiquity measures the frequency of occurrence of taxa as opposed to absolute counts that measure abundance. The flotation analysis results are reported in ubiquity tables as a count (the number of samples in which the taxon is present) and percent presence (the number of samples in which the taxon is present expressed as a percentage of the total number of samples) as Popper (1988) describes. For example, if goosefoot occurs in two samples out of ten the count would be two and the percent presence would be 20 percent.

Absolute Counts and MNI

Absolute counts measure the absolute abundance of taxa in a sample and become especially useful in situations where the absolute abundance of taxa changes over time, but the frequency of those taxa does not. During full-sort analysis, absolute counts and MNI were recorded for charred seeds, other reproductive plant parts, and unknown plant parts. Absolute counts and MNI were recorded for charred and uncharred reproductive plant parts during vegetal sample analysis. The absolute count includes fragments and whole reproductive plant parts. The MNI count was used effectively by Hammett and McBride (1993) on the Transwestern Pipeline Project. This is a quantification measure borrowed from faunal analysts and osteologists, which allows the archaeobotanist to clearly distinguish between the presence of whole or fragmented remains when reporting results. In tables, there are two numbers for reproductive or unknown plant parts. The first number is the total number including fragments encountered in a sample, while the number in parentheses represents the MNI value. An MNI value of 1 was given to a seed or fruit if more than one half of that reproductive unit was present.

MAIZE AND BEAN MEASUREMENTS

Maize specimens were measured using digital calipers, following parameters detailed in Bird (1994) and Toll and Huckell (1996). To be considered measurable, cob fragments needed to possess a full circumference, and kernels needed to be complete in all of the three possible dimensions (length, width, and thickness). Kernel measurements are reported in Appendix V. Two carbonized bean cotyledons and one whole bean were measured as to length, width, and thickness with digital calipers, to the nearest 0.1 mm.

RESULTS OF FLOTATION AND VEGETAL ANALYSIS

The following sections describe the results of analysis of charred and uncharred plant remains, as well as wood, from flotation and vegetal samples. In addition to taxon, plant part, and quantity, the confidence of the identification (positive, fairly certain, resembles taxon) and condition of the plant part (charred, partially charred, or uncharred) were recorded by field specimen (FS) number (Appendices T and U). Vegetal sample analysis results are also itemized by FS number in Appendices T and U. Flotation plant remains in tables are seeds unless otherwise indicated and cultural plant material is charred or partially charred and non-cultural material is uncharred.

Uncharred Plant Remains from Flotation Samples

Archaeobotanists have struggled with the interpretation of uncharred seeds recovered from subsurface samples. The uncertainty as to whether uncharred seeds were deposited because of cultural activity, from rodent and insect activity, or from seed rain precludes their clear interpretation. Minnis (1981) discussed problems inherent in interpreting uncharred seeds recovered from open-air sites. He tested a modern facsimile of an archaeological site to compare the presence of taxa known to have been used (called "economic taxa") to the number of contaminants. Three economic taxa were recovered, as well as 16 taxa that had been deposited by non-human processes such as seed rain or rodent movement. Because of these kinds of questions about the origins of uncharred seeds found in open-air sites, this report will focus on charred plant remains. Therefore, when present, uncharred remains were recorded during full sort analyses, but were considered intrusive and not associated with the prehistoric use of the site.

The most common plant remains of the 46 or so uncharred taxa (Table 62.3) observed in flotation samples were goosefoot, juniper, purslane, and spurge seeds along with juniper twigs piñon nutshell, and piñon needles. Goosefoot, spurge, and purslane are weedy taxa that are part of a wide variety of plants that are defined as agrestals and/or ruderals. Agrestals are plants that are adapted to agricultural pursuits and are often associated with a particular crop. Ruderals are plants that occur in areas of irregular or inadvertent disturbance such as roadsides (Stuckey and Barkley 2000). Although goosefoot and pigweed are frequently found in association with maize, these taxa are also found in virtually any disturbance situation. Conifer duff like juniper twigs and pine needles are part of the background vegetation, unavoidably included in flotation samples. Cactus seeds, sunflower seeds, and groundcherry seeds may have been introduced into site deposits as part of rodent meals. The high number of unburned intrusive taxa in project samples is not surprising in an environment where there are thick layers of detritus and rodents thrive.

Charred Plant Remains from Flotation Samples

Maize cupules had the highest percent presence of all charred plant remains recovered from project samples, followed by maize kernels and goosefoot seeds (Table 62.4). Beans and possible squash, along with one instance of wheat were other cultivars that were identified. In addition to goosefoot, annual taxa included bugseed, pigweed, pitseed goosefoot, purslane, sunflower, and tobacco. Identified grass genera were limited to dropseed and ricegrass and perennials consisted of banana yucca, dock, four-wing saltbush, hedgehog cactus, juniper, pincushion cactus, piñon, ponderosa pine, and prickly pear cactus.

*Count: Number of samples with common name/plant part present. **%: Number of samples with common name/plant part divided by total number of flotation samples with charred remains (376) × 100.

Despite the diversity of the archaeobotanical assemblage (at least 37 taxa), the majority of taxa occurred in less than 10 percent of samples. Most of these plants have documented economic uses, but their low frequency presents interpretation problems. Whether the plant parts are included in the archaeobotanical record unintentionally (deposited by wind, on clothing, or by rodents) or as part of the firewood debris (four-wing saltbush fruit still adhering to branches), or are kitchen accidents from processing plants for food or medicine is impossible to determine.

Beans rarely show up in open-air site contexts except when rare conditions (usually a smothering burn) allow for bean preservation. Durable corncobs preserve much more consistently than beans especially since cobs were used as fuel. Cob fragments and cupules show up in a greater number of contexts because of their ubiquitous association with fire pit debris. Beans have a thin, fragile seed coat that breaks easily, leaving the endosperm exposed to environmental factors that cause deterioration (Gasser and Adams 1981). Other seeds with tougher seed coats have a distinct preservation advantage. At Walpi, Gasser and Adams (1981) recovered 509 beans compared to 24,746 watermelon seeds.

Possible squash rind was scarce and was present in only four samples from LA 12587, two from LA 86534 and LA 135290, and one from LA 127631, LA 127634, and LA 127635. Like beans, squash parts seem to have taphonomic problems that inhibit their reliable recovery. Most archaeological cucurbit rind found in significant quantities comes from well- preserved dry sites, with very few specimens showing signs of charring. C*ucurbita* rind recovered from this project follows the pattern at the majority of open-air sites: carbonized rind fragments were miniscule, few in number, and measured less than 1 mm in thickness. As cited by King (1985:91), the average rind thickness of coyote gourd is 0.7 mm, with a maximum thickness of 2.0 mm. King also states that the measurements of wild gourd and domestic squash overlap. The measurements of rind fragments recovered in flotation samples from the current project fall within this overlap and a differentiation between wild gourd (*Cucurbita foetidissima*) and domesticated squash such as *Cucurbita pepo* cannot be made. Therefore, *Cucurbita* sp. rind has been placed in a combined category of squash/coyote gourd.

Grasses may have been used in a limited way because the domesticated grass, maize, replaced the small-seeded dropseed and ricegrass that is larger, but far from comparable in size to maize.

LA 12587 was the only site where ricegrass was recovered, while dropseed grass showed up in 13 samples from LA 12587, one sample from LA 85407, and six samples from LA 135290.

The majority of perennial plant remains probably became part of the archaeobotanical record as a direct result of firewood use. Needles, twigs, bark, and cones could have been used as tinder or were burned along with branches. The presence of cactus seeds indicates processing of the fruits. Ethnographically, the fruits of prickly pear and hedgehog cactus were eaten raw, boiled, or dried (Castetter 1935:26, 35–36). The fall-ripening piñon nut crop is a valuable wild food resource, especially given its nearby availability. The nuts are distinguished by a particularly high energy value (635 calories per 100 grams, higher than most other plant and animal foods used prehistorically, including corn; Ford 1968:158,160). However, piñon nut remains are rarely abundant at open-air sites except at the occasional catastrophically burned site where cachepots are preserved with their contents. Piñon may not be showing up in flotation samples because the whole nut including the shell was consumed and therefore evidence would only be present in coprolites. Though piñon nutshell appears to be highly lignified, it is rarely preserved in open sites unless it is carbonized. Infrequent archaeological recovery may occur only if nutshell was spit out into the fire or a kitchen accident happened during roasting of the nuts.

In Minnis's study (1989) and overview of coprolite analyses in the Four Corners region, piñon showed up consistently in Basketmaker III samples, but was uncommon in Pueblo III samples. This suggested either a decrease in protein consumption or deforestation of woodlands to clear land for fields during Pueblo III times. It would be interesting to know how the occupation of sites included in the study corresponds to periods of drought and to calculate the effects of the erratic nature of piñon crops (the interval between optimal mast abundance is 4 to 7 years and is dependent on ample spring rains; Ford 1968).

Wood charcoal from the project was predominately coniferous; unknown conifer and ponderosa pine were the most common taxa recovered (Table 62.5). Significant quantities of juniper, pine, and piñon were also identified. Douglas fir, a tree that grows at elevations of 1981 m (6500 ft) to nearly tree line (Foxx and Tierney 1985:99) on canyon sides, canyon bottoms, and in mixed conifer forest, was identified at LA 12587, LA 86534, LA 135290, and LA 141505. Riparian species are represented by cottonwood/willow and New Mexico locust. The most common non-conifers were oak and saltbush/greasewood. Other shrubby taxa that were present included desert olive, mountain mahogany, rabbitbrush, rose family, sagebrush, and sumac.

The wood charcoal assemblage from vegetal samples is similar to that from flotation except that the percent presence of juniper, ponderosa pine, and cottonwood/willow is much greater in vegetal samples (Table 62.6). Large diameter ponderosa pine trunks or cottonwood branches were often the preferred material used for roof beams or latillas (e.g., Chaco Canyon: Windes and Ford 1996). It could be that larger specimens collected as vegetal samples in the field were from construction material. The percent presence of other wood taxa that occur in both sample types are equal or nearly so, lending support to this argument. In addition, two vegetal samples from LA 12587, one a beam fragment and the other labeled as a possible dendro sample were both juniper, and a partially charred beam fragment from LA 135290 was identified as ponderosa pine. Box elder, a species that prefers moist conditions, and wolfberry were two shrubby taxa present that were not identified in flotation samples.

White Rock Tract

LA 12587 (Late Coalition Period Roomblocks and Classic Period Fieldhouse)

The Coalition period at LA 12587 is characterized by the predominance of maize, with a few instances of possible squash and beans to round out the traditional triad of domesticated plants (Table 62.7). Annual seeds were the next most common plant remains, easily procured in cultivated fields and other disturbed areas. Annual taxa included bugseed, goosefoot (the most common annual taxon, found in 24% of samples), pigweed, and purslane. Pitseed goosefoot, sunflower, and tobacco were less common annual taxa, found in less than 5 percent of samples. Perennial taxa were primarily those associated with firewood use like conifer needles, bark, and twigs, but cactus seeds and piñon nutshell indicate cactus fruits and piñon nuts were gathered and eaten. Four-wing saltbush fruits could be firewood debris or evidence for their use as food or for their salty flavor. Grass taxa diversity and abundance is low with grass family and dropseed grass occurring in less than 4 percent of samples and ricegrass occurring in 12 percent of samples.

Wood from flotation samples is dominated by juniper and unknown conifer (Table 62.8). Other conifers included Douglas fir, piñon, and ponderosa pine. Although non-conifers were diverse, saltbush/greasewood was the only one that was present in significant quantities. Desert olive, cottonwood/willow, mountain mahogany, oak, rabbitbrush, rose family, sagebrush, and sumac complete the list of non-conifer taxa identified at the site. There were no remarkable differences in wood taxa from back rooms versus front rooms and wood from both thermal and non-thermal contexts was primarily juniper and unknown conifer.

Vegetal Samples. Ubiquity of wood from LA 12587 vegetal samples is close to that of flotation charcoal with the exception of ponderosa and cottonwood/willow (Table 62.9). In flotation samples, ubiquity of cottonwood/willow was 18 percent and that of ponderosa 23 percent. In vegetal samples the percent presence of cottonwood/willow (43%) and ponderosa pine (46%) is double that found in flotation samples. This appears to be an example of a bias toward larger diameter specimens when collecting vegetal samples in the field. Box elder, New Mexico locust, and wolfberry wood were identified in vegetal samples, taxa that were absent from flotation samples. Two beam fragments from Room 2 were identified as juniper; a ceremonial bundle was apparently secured to one of these (see Chapter 14, Volume 2).

Six percent (330) of the incredibly large number of whole kernels (*n* = 5264) recovered in flotation and vegetal samples was measured (Appendix V). The average height of the sub-sampled kernels was 7.3 mm, average width was 6.6 mm, and average thickness was 4.0 mm

(Figure 62.1). Kernels from two sites also on Mesita del Buey (four from LA 4624, an Early Coalition pueblo, and nine from LA 4618, another Late Coalition site) and 122 kernels from LA 135290, a Middle Coalition roomblock on the Los Alamos Town Site Mesa will be compared with those from LA 12587 later in the discussion section.

Figure 62.1. Example of measured *Zea mays* kernels from LA 12587.

The average row number of 20 maize cobs from LA 12587 was 10 and rows were straight in appearance (Table 62.10; Figure 62.2). The average rachis segment length was 3.4 mm, average cob diameter was 10.3 mm, and average cupule width was 5.2 mm. Environmental stress such as high temperatures and water or nutrient deficiencies during various early developmental stages of a maize plant can lead to ears that are partially or completely barren (Muenchrath and Salvador 1995:316). Only one cob with an undeveloped row may have been a product of this kind of environmental stress. Five cobs from LA 86534, 17 from LA 135290, and 20 from LA 4618 will also be compared to cobs from LA 12587 in the discussion section later.

Table 62.10. *Zea mays* cob morphometrics (in mm) from LA 12587.

Two rows of cob have kernels. T = tip, U = undeveloped row present.

Other charred non-wood plant parts were limited to pine bark scales and cone umbos. These are probably part of the record as a result of firewood use. An uncharred grape seed was recovered in FS 1029 from Room 1 (Stratum 1) that is described as a loose surface deposit with some artifacts and vegetal material. The context and the uncharred state of the seed suggest it is non-cultural or modern in origin.

Roomblock 1

The majority of samples were collected from Roomblock 1 (Rooms 1 to 9; only 15% were from Roomblock 3) and focused on the hearths in the front Rooms 2, 4/5, and 7. Rooms 4/5 and 7 may have been primarily used for food preparation, while Room 2 served as a location for both food preparation and storage. Fused masses of kernels that were found in Room 2 indicate that stacks of cobs were stored on the floor or on top of the roof. Most of the cobs holding the kernels were burned to ash, leaving kernels still fused in alignment (Figure 62.3). Several thousand loose kernels were also recovered in Room 2, primarily from post-occupational fill and rooffall (1563 kernel fragments, 2771 whole), but also from floor, fill above the floor, and hearth contexts.

Figure 62.2. Example of measured *Zea mays* cobs from LA 12587.

Figure 62.3. Fused *Zea mays* kernel masses from Roomblock 1 at LA 12587.

There were two hearths in Room 2; Feature 4 was a plastered, collared hearth associated with the Late Coalition occupation of the site and Feature 20 was the oldest feature at the site, with an archaeomagnetic date placing it in the early part of the Late Coalition (AD 1200). Maize is the most common taxon in both hearths; weedy annual seeds and dropseed grass were recovered from both features. Possible squash/coyote gourd rind was identified in the older hearth, while groundcherry, mint family, and hedgehog seeds were restricted to Feature 4. This indicates that the diets of earlier and later site occupants were probably not considerably different, especially when sample bias is taken into account (four samples were analyzed from Feature 20 versus 10 from Feature 4). Given that rodent burrowing was fairly extensive throughout Feature 20, the likelihood that some or all of the remains from the feature are associated with activities that took place after the abandonment of the hearth cannot be ruled out. A possible extramural storage cist constructed on the east wall of Room 2 contained annual seeds, maize, and piñon needles along with at least five wood taxa, indicating a trashy fill signature, and thus obfuscating any clues about the contents of the cist.

The recovery of three of four tobacco seeds from the site in the lower and general hearth fill of Room 7, along with the presence of a deflector and ash box that do not occur in other rooms, indicates the room might have had a ceremonial function. A bean cotyledon and three cotyledon fragments were also recovered from the Room 7 hearth. In Hopi tradition, beans also have ritual significance. Beans (usually tepary) were the first salted dish a priest could eat after a fast (Whiting 1966:40). Perhaps the inhabitants of LA 12587 used beans for a similar purpose. A fourth tobacco seed was found in the Room 4/5 hearth, suggesting ritual activities were not restricted to Room 7.

Diversity of taxa from the back rooms (1, 6, and 8) is very low and evidence of their use as storage rooms is not apparent in the macrobotanical assemblage. Taxonomic diversity was also low in Room 9, the largest of the back rooms. The back rooms could have been cleaned out before abandonment or the macrobotanical assemblage may be biased by sample size differences, as 15 flotation samples were analyzed from back rooms compared to 76 from front rooms. The heavy focus on front room sampling is a function of the paucity of features in backrooms, extensive rodent disturbance, and a lack of the concentrated deposits of plant material (i.e., piles of maize) found in the front rooms.

Room 3. Flotation and vegetal samples were taken from post-occupational fill and wallfall from the Classic period fieldhouse (Room 3) superimposed over Roomblock 1. Charred plant material consisted of maize embryo and kernel fragments, as well as cupules, and piñon needles. Cottonwood/willow, juniper, mountain mahogany, oak, piñon, ponderosa, sagebrush, saltbush/greasewood, unknown conifer, unknown non-conifer, and wolfberry wood were also identified. Piñon needles may be part of firewood debris and maize parts probably represent a combination of cooking accidents and the use of cobs for fuel. However, whether these reflect refuse from the Classic period occupation or Coalition period room fill incorporated into the fieldhouse during its construction or as post-abandonment fill is impossible to determine.

Roomblock 3

Roomblock 3 was only partially excavated and in most cases only a basal course of masonry existed to define room outlines. A lack of wallfall in many of the 13 rooms indicates that construction of rooms may never have been completed. Carbonized plant material consisted of cheno-am, goosefoot, groundcherry, and grass seeds, grass stems, maize cupules and kernels, conifer cone scales, twigs, and needles, four coniferous woods, and nine non-conifers. Uncharred plant material was abundant and included Russian olive seeds, an obvious intrusive species. Occupants of this roomblock utilized disturbance-loving plants and grasses, grew maize, and collected local wood species for fuel and construction material.

Extramural Features. Flotation samples from a midden to the east of Roomblock 1 contained annual seeds, maize cupules, cupule segments, and kernels, groundcherry seeds, piñon nutshell and needles, along with juniper, piñon, sagebrush, saltbush/greasewood, and unknown conifer wood. The fill around Burial 2 that was found in the midden contained similar plant material, indicating that although the individual was placed in a natural niche in the bedrock and may have been covered with a tuff slab (see Chapter 14, Volume 2), plant material from the sample derives from midden deposits.

Maize and juniper, piñon, and saltbush/greasewood wood were recovered from an ashy area east and southeast of Roomblock 1 (Feature 3). This feature may be a deflated hearth, representing an extramural area where maize may have been prepared. Another ash/charcoal stain (Feature 21) in an extension of the middle wall of Roomblock 1 with an associated floor surface produced maize, possible squash, and purslane seeds along with juniper, pine, and oak wood and could represent cooking accidents from additional extramural activities.

Because of its proximity in time and space to LA 12587, data from LA 4618 provide good comparative material. LA 4618 is a 13-room masonry pueblo that included two kivas (Schmidt 2006). The number of taxa recovered from the two sites is nearly equal (21 from LA 4618 and 19 from LA 12587). Taxonomic diversity is low in back rooms at both sites, with front rooms (and the kivas at LA 4618) exhibiting much greater taxonomic richness. Cheno-ams, pigweed, purslane, and goosefoot were the most commonly encountered weedy annuals at both sites. Pigweed and purslane, however, occur at LA 4618 in more than double the number of samples in which they were found at LA 12587. Maize cupules were by far the most frequently recovered plant parts, present in 95 percent of samples with carbonized plant remains at LA 12587 and 100 percent of samples at LA 4618. There is a significant disparity in maize kernel presence (52% at LA 12587 versus 23% at LA 4618). The few intact kernel specimens from LA 4618 are unusual in that they are extremely diminutive and would ordinarily be the size of kernels near the tip of cobs. Only one kernel was of "normal" size. Beans and possible squash rind round out the cultivars recovered at the two sites.

Carbonized tobacco was found at both sites, although clear evidence for its ritual use was restricted to LA 4618. Along with charred specimens, uncharred tobacco seeds were also present in kivas at LA 4618 together with pipes containing daub. One of the components of the daub was Solanaceae pollen (the same family as tobacco; S. Smith 2006a), leaving little doubt that tobacco was used ceremonially.

Aside from firewood debris, evidence of perennial use consisted of very low percentages of piñon nutshell, hedgehog cactus and prickly pear cactus seeds, and banana yucca seeds (only at LA 4618). Dropseed grass and grass family seeds were identified in less than 20 percent of samples at each site while ricegrass was recovered from an even smaller percentage of samples at LA 12587.

The wood assemblages from LA 4618 and LA 12587 display a marked difference in occurrences of juniper and ponderosa pine. Juniper occurs in 85 percent of vegetal and flotation samples at LA 12587 and in only 27 percent of samples at LA 4618. Ponderosa is reversed, recovered in only 34 percent of samples from LA 12587 versus 97 percent of samples from LA 4618. This could indicate some deforestation of lower-elevation conifers in the Late Coalition and a focus on procuring higher-elevation taxa for roofing material (for more details see the Coalition period wood charcoal discussion).

The occupants of LA 12587 were obviously successful farmers as evidenced by the large number of cobs and kernels stored in front rooms or on the roof of Roomblock 1 that were destroyed in a fire as opposed to the lack of evidence for maize storage at LA 4618. A similar dichotomy was found between two Middle Coalition sites where very few kernels were found at one site (LA 86534), versus several masses of kernels and 99 loose kernels that were recovered at a neighboring site (LA 135290). Whether this suggests sharing of resources or competition that resulted in arson (at least at LA 12587) is difficult to say. Annual plants formed a high percentage of the wild resources used by site occupants, while perennials and grasses may have comprised a much smaller part of the diet. Trees and shrubs of the surrounding piñon-juniper woodland were utilized for fuel and construction along with ponderosa pine found in canyons or elevations above 2134 m (7000 ft), Douglas fir from the mixed conifer zone, and several species from the riparian community.

LA 12587 (Area 8, Late Archaic Lithic Scatter)

Goosefoot and pitseed goosefoot seeds comprised the only carbonized floral remains from test pits in Area 8 (Table 62.11). Non-cultural material was primarily conifer duff along with goosefoot, spurge, and prickly pear cactus seeds. Fragments of juniper and unknown conifer charcoal were recovered in flotation samples. Vegetal samples from Test Pits 1 and 3 yielded five specimens of piñon wood. Soils adjacent to the lithic scatter were tested and found to be weakly developed and that the surface is actively eroding "with minimal potential for preserving an intact archaeological record" (Chapter 15, Volume 2). If the plant remains identified from Area 8 do in fact represent remains from the Archaic component and not material washed in from the Coalition midden just to the north, the most that can be said is that weedy annual seeds may have been used for food and locally available conifers for fuel.

LA 86637 (Late Archaic, Coalition, and Early Classic Period Lithic and Ceramic Scatter)

One unidentifiable plant part fragment was the sole cultural plant remain recovered from LA 86637 (Table 62.12). The balance of the floral assemblage was unburned conifer duff including twigs, needles, cones, and bark. The site consists of artifacts from the Late Archaic, Coalition, and Classic periods in secondary deposits, much of which has washed down from a Classic period fieldhouse upslope from the scatter (see Chapter 16, Volume 2). The possibility of any carbonized material being related to activities here is remote at best.

LA 127625 (Middle Coalition Lithic and Ceramic Scatter)

A single charred goosefoot seed was recovered from Test Pit 1 (Table 62.13) and a fragment of unknown conifer charcoal from Test Pit 2. Other floral material consisted of unburned goosefoot, purslane, and spurge seeds and conifer duff. The presence of unburned plant material is not surprising considering that samples were taken from Stratum 1 that was a thin layer of silty sand along with a lot of duff and other detritus. The recovery of the charred floral material is somewhat unexpected and problematical. With no thermal feature present, it is likely that it was deposited in "runoff episodes from nearby slopes and mesa top sites" (see Chapter 17, Volume 2), as it was determined the cultural material recovered at the site was not in its original context.

LA 127631 (Early Classic Period Fieldhouse)

One sample (from room fill) of the nine flotation samples from LA 127631 yielded cultural plant remains. These consisted of maize cupules, a maize embryo fragment, and possible squash/coyote gourd rind (Table 62.14). Non-cultural plant remains consisted of conifer duff, cactus seeds, weedy annual seeds, grass, a raspberry or thimbleberry seed, a possible sumac seed, and a Russian olive seed. The uncharred seeds from perennial plants are all from fruits and may represent the remains of a meal consumed by a rodent or bird.

Nine pieces of juniper and two of unknown conifer charcoal were also recovered in flotation samples (Table 62.15). Vegetal samples yielded a fragment of unburned, unknown wood and small pieces of juniper, pine, possible rabbitbrush, and saltbush/greasewood charcoal (Table 62.16). The carbonized maize and possible squash rind suggest the occupants may have been enjoying the fruits of their labor, while wood charcoal demonstrates use of local conifers and shrubs for fuel.

LA 128803 (Classic Period Grid Garden)

Situated at the mouth of Cañada del Buey, farmers who used these grid gardens were taking advantage of run-off from the uplands and the rock borders of the gardens served to capture nutrient-rich sediment. Carbonized corn cupules and goosefoot and cheno-am seeds were identified from three of 10 samples collected from within the grid garden borders (Table 62.17). A corn cupule fragment was also recovered from Stratum 3 of the test pit that was to the south of the grid gardens (FS 14).

Nearby thermal features were not recorded so it is curious how charred plant remains came to be deposited. Cushing (1974) describes in detail the process of creating a run-off field at the mouth of an arroyo at Zuni. The first year the farmer piles soil up to make an outline of the field boundary and marks the corners with columnar stones. Vegetation is cut away and placed in the center of the field where it is burned. A brush fence is also constructed and strategically placed to catch eolian sediment that results in a fine loam deposit over the field.

Brandt (1995) states that burning brush and the collection of nutrient-laden sediment are the only references to fertilizing fields found in the ethnographic literature. Along with the collection of sediment behind garden borders, it is possible that shelled corncobs and brush were burned to clear or fertilize grid gardens in a similar manner described by Cushing (1974).

LA 128804 (Historic Period Check Dam)

Non-cultural debris in flotation samples from upslope and downslope of the check dam included spurge seeds, juniper twigs, and piñon needles (Table 62.19). Cultural plant remains were absent from samples, which is not remarkable considering the context and that the dam has been partially breached by an incised channel.

Flotation wood charcoal included pine, piñon, and saltbush/greasewood (Table 62.21). Vegetal samples from room fill yielded a maize kernel and kernel fragments and cupules (Table 62.22). Piñon was the most common wood by weight in vegetal samples, followed by ponderosa and cf. rabbitbrush. Two fragments of cf. wolfberry were also identified, along with several pieces of oak, pine, unknown conifer, saltbush/greasewood, and unknown non-conifer.

Since maize was the only identifiable non-wood plant recovered, it might be safe to say that tending maize fields was the primary focus of fieldhouse occupants. Despite the absence of a formal thermal feature, the presence of maize and wood charcoal indicates maize was processed inside the structure and that a variety of locally available conifers and shrubs were used for fuel or construction material.

Airport Tract

LA 86534 (Middle Coalition Period Roomblock)

Maize cupules were the most frequently recovered plant remains at LA 86534, followed by goosefoot seeds (Table 62.23). The only other plant parts that occurred with a percent presence over 20 percent were pine bark scales, piñon and ponderosa needles, and purslane seeds. Maize kernels were present in 15 percent of the samples, yet the percent presence of maize cupules was 94 percent. Kernel absolute counts were extremely low, totaling only 15 in flotation and vegetal samples, with a mere three intact specimens. Several possible explanations come to mind: 1) maize was grown at or near the site, but shelled corn was taken elsewhere for consumption or storage, 2) unlike at LA 135290 where maize was probably stored either on the roof or in back rooms, maize was stored in a room or pits that were covered by the construction of New Mexico Highway 502, or 3) rooms were cleaned out before abandonment. Differential preservation is probably not a factor because preservation seems to be fairly good at LA 86534 with 14 taxa present and more occurrences of the elusive piñon nutshell than at LA 135290. Possible squash (rind was recovered in the kiva hearth and on the floor of Room 4) was the only other cultivar identified at the site.

Aside from piñon nutshell, perennial floral material possibly unrelated to fuel use was restricted to four-wing saltbush fruit. Juniper twigs and cones and pine bark, needles, and twigs are probably firewood debris. Grass family stems and seeds, found in the Room 1 and Room 9 (kiva) hearths, were the sole representatives from this plant category.

Ponderosa pine was the most common wood taxon identified in flotation samples (Table 62.24). Oak and mountain mahogany occur in nearly the same frequency as juniper. Cottonwood/willow, present in 23 percent of flotation samples at nearby LA 135290, is absent from the flotation wood assemblage at LA 86534. Another riparian type, New Mexico locust (found in river bottoms, along streams, and in canyons at 1371 to 2743 m [4500 to 9000 ft; Carter 1997:440]), was present, but only in two samples. Mountain mahogany was found at LA 86534 in slightly more than double the number of samples from LA 135290.

*Count: Number of samples with wood taxon present. **%: Number of samples with wood taxon present divided by total number of flotation samples with wood charcoal (53) × 100.

Vegetal Samples. The greatest difference between flotation and vegetal sample wood taxa from LA 86534 is the ubiquity of juniper, present in 51 percent of vegetal samples versus 26 percent of flotation samples (Table 62.25). Like the wood assemblage from flotation samples, ponderosa pine and unknown conifer were the most common taxa present. Box elder, cottonwood/willow, Douglas fir, and wolfberry were identified wood taxa that were not present in flotation samples. Any differences in flotation and vegetal sample wood taxa may be a function of context. The majority of vegetal samples with wood were from post-occupational fill and rooffall, while flotation samples were primarily from thermal features.

*Count: Number of samples with common name/wood present. **%: Number of samples with common name/wood divided by total number of vegetal samples with wood charcoal (61) × 100.

Maize cupule segments and cupules were plant remains most frequently encountered in vegetal samples from LA 86534 (Table 62.26). The percent presence of kernels is only 11 percent at LA 86534 as opposed to 72 percent in vegetal samples from LA 135290. Measurements of five cobs from LA 86534 (Table 62.27), one 12-rowed and four 10-rowed, suggest they are considerably less robust than those from LA 135290, but with such a small sample, it is impossible to know if the cobs from LA 86534 are representative or not (Figure 62.4).

The only other carbonized non-wood plant parts were pine cone umbos, most likely firewood debris. An uncharred cholla bud was recovered from Feature 1 in Room 5, Stratum 1. This Stratum is described as loose post-occupational fill with areas of high organic content from juniper and piñon duff and the room as a whole was highly disturbed by bioturbation (see Chapter 24, Volume 2), so the bud most likely represents modern surface debris.

Rooms. Front and back rooms were distinguished by low densities of plant remains as well as low taxonomic diversity. Maize cupules, annual seeds, and conifer needles were recovered from both sets of rooms. Despite the disparity in the number of samples analyzed (8 from back rooms versus 20 from front rooms), differences in assemblages between front and back rooms were not remarkable. A four-wing saltbush fruit fragment and squash/coyote gourd rind were recovered from the back rooms, while evening primrose and grass seeds, piñon nutshell, and a wider variety of conifer detritus were recovered in front rooms. This is logical, as hearths were exclusive to front rooms where food preparation took place and a greater percentage of fuelwood debris would be expected. Rather than questioning the interpretation of back rooms as storage spaces, the paucity of plant material from back rooms could indicate they were cleared out before abandonment. Juniper, piñon, ponderosa, mountain mahogany, and saltbush/greasewood wood occurred in both front and back rooms; oak and New Mexico locust were found only in front rooms and rose family wood was identified only in back rooms. Flotation wood from thermal features and non-thermal contexts was undifferentiated. Ponderosa was by far the most common taxon identified.

Front Room Hearths and Room 6 Features

Plant remains were quite different from primary- and secondary-use deposits of the hearth in Room 1. Ponderosa pine and unknown conifer charcoal were identified in both deposits, but the similarity ends there. Annual and grass family seeds were identified in the primary-use deposits together with juniper wood, while maize parts and ponderosa pine needles were present in secondary-use deposits along with mountain mahogany, saltbush/greasewood, piñon, and pine wood. The hearth fill (Feature 2) of Room 2 produced goosefoot seeds, maize parts, and piñon nutshell. The pine cone scales that were also identified in the hearth could be evidence for home-based processing of nuts for storage or consumption. Ethnographic accounts of piñon processing refer to nuts "gathered in the cone," with the cone later "burned off the nuts near where gathered or after the return home" (Reagan 1928:146–147; see also Murphey 1959:23). Other accounts note how roasting the nuts benefits both flavor and preservation (Castetter 1935:42; Robbins et al. 1916:41; M. Stevenson 1993:36; Swank 1932:61). Tobacco was also identified in Feature 2 fill, but because it was uncharred it may merely indicate that tobacco grew near the site and the seeds were deposited by insects or other vectors. However, uncharred tobacco seeds were identified from back rooms as well (the milling bin in Room 6 and the floor of Room 4), suggesting tobacco plants could have been stored in back rooms and may be the source of the seeds in Room 2. The milling bin in Room 6 also contained maize cupules and juniper, ponderosa pine, saltbush/greasewood, and unknown conifer wood. The lined pit in Room 6 yielded four-wing saltbush fruit, piñon needles, maize cupules, and four wood taxa. The array of taxa from both features suggests mixed fill and that the contents cannot be directly related to the use of features.

Room 9 (Kiva)

The kiva, in contrast to the roomblock, yielded a higher diversity of taxa (11) and several taxa were only found in kiva contexts including groundcherry, mint family, sunflower family, and most significantly, tobacco. The majority of maize kernels were recovered in the kiva hearth and ash pit, including two of the three measurable specimens from the site. Along with tobacco, several members of the sunflower family were used ceremonially by the Zuni (M. Stevenson 1993). Interpretation of room function often separates food preparation activities from ritual practices. Cushing (1974) describes songs and dances that accompany corn grinding; in other words, food preparation was a sacred endeavor and perhaps not necessarily conducted strictly in habitation rooms. Maize was also part of ceremonies like one described by Stevenson (1993:65–66) at Zuni where maize ears with kernels of a variety of colors were placed around a medicine bowl on an altar, representing the four cardinal directions and above and below. The kiva was most likely a center for processing plants as well as ceremonial activities. Wood taxa, with the exception of New Mexico locust, were the same as those identified in front rooms.

Of the two sites excavated on the Los Alamos Town Site Mesa dating to the Middle Coalition period (LA 86534 and LA 135290), only LA 86534 appears to have had a formal underground ceremonial room. Perhaps this served as a center for ritual activities for both habitations, and agricultural products and subsistence activities were shared. Primary storage facilities could have been located at LA 135290, offering a possible explanation for the scarcity of maize kernels at LA 86534. Evidence for exploitation of at least three annual, two perennial, and two cultivated taxa was present. A variety of high- and lower-elevation conifers, riparian trees, and local shrubby species were used for firewood and construction material.

LA 135290 (Middle Coalition Period Roomblock)

Evidence for the triad of maize, beans, and squash was present in flotation samples. As at LA 86534, maize cupules were the most common plant remains recovered, followed by goosefoot and cheno-am seeds (Table 62.28). Maize kernels, on the other hand, were present in a much higher percentage of samples (41%) than at LA 86534.

Table 62.28. Ubiquity of flotation sample carbonized plant remains from LA 135290.

*Count: Number of samples with common name/plant part present. **%: Number of samples with common name/plant part divided by total number of flotation samples with charred remains (75) × 100.

Maize cupules were found everywhere except floor matrix and Floor 2 contexts and although present in every room, they were the most common in Rooms 1 and 2. Kernels were also encountered most often in Room 2. Beans were found on the floor of Room 1, in Room 2 rooffall, and in the fill of Features 4 and 11 in Room 2. Possible squash rind occurred on the floor surface of the doorway between Rooms 4 and 5. Squash pollen identified on the floor of Room 1 confirms the identity of the rind also encountered from this context as squash.

Grasses had a low percent presence; dropseed grass occurred in 11 percent and grass family seeds in 5 percent of flotation samples. The only perennial genera with a percent presence above 10 are those that are most likely an artifact of fuelwood use like piñon and ponderosa pine needles. Piñon nutshell in particular is extremely scarce, limited to one sample only.

Ponderosa pine was the most common wood taxon encountered in flotation samples (Table 62.29), found in 12 percent more flotation samples than at the neighboring site LA 86534. Piñon and unknown conifer were the next most prevalent taxa. Riparian resources were represented by cottonwood/willow. A few of the same shrubby species found at LA 86534 were identified at LA 135290 and included mountain mahogany, oak, and saltbush/greasewood. Douglas fir, recovered in a single sample, is generally from slightly higher elevations or canyon slopes and could have been brought from Pueblo Canyon or DP Canyon.

*Count: Number of samples with common name/plant part present. **%: Number of samples with common name/plant part divided by total number of flotation samples with charred remains (71) × 100.

Vegetal Samples. Maize kernels had the highest percent presence of non-wood plant remains in vegetal samples (Table 62.30). Although maize kernels were found in every room except 8 and 9A, the majority of kernels were from the fill of Rooms 1 and 6. Three kernel masses were also found in the room fill from Room 6 (Figure 62.5). The kernels could be part of rooffall debris that is indistinguishable from the general room fill. Although excavators in many cases could distinguish between upper and lower room fill layers (lower sections contained more charcoal, botanical remains, artifacts and roof casts; see Chapter 25, Volume 2), these were not always discernable.

Maize cobs (17) from Rooms 1, 2, 3, and 5 were measured and had an average cob diameter of 11.9 mm and an average cupule width of 5.6 mm (Table 62.31; Figure 62.6). The average row number was 11.4. Comparison with cobs from LA 12587 and LA 86534 will follow in the discussion section.

** a few kernels present. F flattened, IR irregular, ST straight.

Beans were fairly widespread and were found in Rooms 1, 5, 6, 7, and 9A, primarily in room fill. Two beans were measurable from the site: one whole bean from a vegetal sample (FS 1201) that was 11.6 mm in height, 6.5 mm in width, and 4.9 mm thick and a single cotyledon from flotation sample FS 2353 that had a height of 10.8 mm, a width of 6.2 mm, and a thickness of 2.6 mm (Figure 62.7). Height and width measurements fall around the middle of the range given by Kaplan (1956: Table III) for *Phaseolus vulgaris,* or common bean. These also fit in the range of dimensions given for tepary beans, but the shape of the two species is quite different.

A possible beeweed stem (in vegetal sample from Room 1 lower fill, FS 1450) and embryo (in a flotation sample from Room 2 possible rooffall, FS 1897) mark the only archaeobotanical evidence for the potential use of this resource for the site.

As in flotation samples, ponderosa pine was the most common wood taxon in vegetal samples (Table 62.32). A partially burned roof beam fragment compared favorably to ponderosa pine. Cottonwood/willow, pine, and piñon occur in nearly equal percentages of samples (40% to 45%), while juniper was found in 29 percent of samples. Douglas fir is slightly more abundant than in flotation samples, present in 5 of the 55 samples containing charcoal. The same shrubby species encountered in flotation samples (mountain mahogany, saltbush/greasewood, and oak) were identified in vegetal samples.

Table 62.32. Ubiquity of vegetal sample wood charcoal from LA 135290.

Figure 62.7. *Phaseolus* (common bean) specimen from LA 135290.

Back Rooms. Thirteen taxa were recovered from back rooms at LA 135290 including pincushion cactus and evening primrose, two taxa that were not found in front rooms. Cheno-am seeds were the most common plant materials recovered, followed by goosefoot seeds and maize cupules. Room 6 was the only back room where notable quantities of plant material were recovered and may indicate storage of corn either on the roof or on the floor. Three masses of kernels and 99 loose kernels were recovered from rooffall and room fill. Ponderosa pine was present in all but four of the 16 flotation samples with wood charcoal and was by far the most frequently encountered taxon, both in rooffall vegetal samples and all other samples.

Front Rooms. Fifty-five flotation samples were analyzed from front rooms, slightly more than three times the number analyzed from back rooms (17). Analysis documented the presence of 16 taxa. Beans, dropseed grass, piñon, plantain, tobacco, and winged pigweed were taxa recovered from front rooms that were not identified in back rooms. Maize cupules and kernels and goosefoot and cheno-am seeds were the predominant plant parts in samples. Features were present in Rooms 1, 2, and 8. Plant remains from two adobe-lined pits in Room 1 were restricted to maize cupules. The complex of features composed of a collared hearth (Feature 1) and three adobe-lined pits (Features 3, 4, and 6) in Room 2 all contained similar taxa including weedy annuals, mint family, and maize. The hearth that was attached to Pit 3 was the last floor feature in Room 2 to be constructed and displays no signs of burning. Consequently, it may never have been used as a thermal feature. The similarity of plant remains from the complex of features indicates the contents represent room fill, confirming the excavator's observation that the fill of these pits was quite similar to the Stratum 4 sediments surrounding them.

Two superimposed hearths were located just southeast of Feature 1 in Room 2. Feature 16 may have been cleaned out before the construction of the upper hearth (Feature 11); there was a layer of sandy fill between it and Floor 1. Feature 16 was also partially destroyed when the upper hearth was built. These two factors probably account for the paucity of floral material recovered that was limited to goosefoot seeds and maize cupules. The fill of Feature 11 was described as quite distinct from that encountered in the other pit features. The sides of the pit were burned and the fill was very ashy with lots of adobe and charcoal mixed with the clay loam soil (see Chapter 25, Volume 2). Feature 11 was also capped with an ash lens. Plant remains from the upper and lower fill did not differ greatly. Tobacco was the most intriguing taxon found in both the upper and lower fill, indicating sequestered use of this important ceremonial plant. Annual seeds, grass family seeds, and maize cob parts and kernels were repetitive of taxa found elsewhere in the room. Beans, dropseed grass, and mint family were recovered only from upper fill while winged pigweed was recovered exclusively from lower fill.

Patches of burned sediment or adobe and charcoal on the floor of Rooms 2 and 3 were presumed to be rooffall material. However, plant remains were not significantly different from those found in Features 1 and 4 or the upper fill of Feature 11, suggesting that distinguishing rooffall from room or feature fill is not possible. The number of features located in Room 2 was the highest, more being added as time progressed. The bulk of the maize remains from the site (135 whole kernels and 12 of 17 cobs) were recovered from Rooms 1 and 2. Taxonomic diversity was also high (n = 14) in Room 2 compared to other rooms with the exception of Room 5, which yielded 12 taxa. Not only were tobacco seeds found solely in Room 2 contexts, but plantain, beeweed, piñon nutshell, and winged pigweed were also found exclusively in Room 2. Of these, like tobacco, beeweed and winged pigweed have ritual associations. Beeweed pigment made from boiling down large quantities of the plant and allowing it to thicken (Robbins et al. 1916:59) was used to paint pottery or ritual items (Adams et al. 2002) and the stems (found in Room 1) were used by the Hopi to make prayer sticks (Voth 1901:78). Winged pigweed medicine is associated with the grandmother of the Gods of War in Zuni stories. She gave it to them, instructing them that when they were near the enemy they should chew the blossoms of the plant and spit the masses into their hands and rub them together. This resulted in a yellow light that spread over the world, obscuring their enemy's ability to aim their arrows surely (M. Stevenson 1993:50). These factors indicate that Room 1 and especially Room 2 were probably the center of food preparation activities and Room 2 was also the focus of ritual activity.

Despite the collection of nine samples from the hearth (Feature 9) in Room 8, taxonomic diversity was low; cheno-am, goosefoot, and purslane seeds were identified together with maize cupules, glumes, and kernels. Rooms 9A and 9B had extremely low densities of plant material and taxonomic diversity; cheno-ams, goosefoot, mint family, and purslane seeds were recovered along with maize cupules. The east wall of room 9A was never a standing wall and it is unclear whether any of the walls of Room 9B were ever completed, thus any plant-related activities that took place in the rooms may have been chiefly obliterated from exposure to the elements.

Wood from hearths and non-thermal features in front rooms was predominately ponderosa pine, piñon, and juniper. Cottonwood/willow, often associated with roofing material, was actually more common in hearth samples than from non-thermal contexts. Ponderosa pine, oak, and unknown conifer were the most frequently identified woods in flotation and vegetal rooffall samples from front rooms. Corn, beans, and squash were probably grown nearby and weedy annuals that either volunteered in agricultural fields or thrived in the disturbed ground around the site were harvested for their seeds and edible greens. At least two grass taxa, beeweed, pincushion cactus, knotweed family, evening primrose, and piñon could have been used for food, dye, or medicine. The recovery of tobacco suggests this plant was part of the ceremonial life of the people who inhabited LA 135290 during the Coalition period. Wood for construction and fuel was harvested from local sources.

LA 139418 (Classic Period Grid Garden)

Flotation samples from two of the three garden grids at LA 139418 produced unburned non-cultural plant remains, all representative of herbaceous plants or trees growing in the immediate vicinity of the site today, including goosefoot seeds and conifer duff (Table 62.33). A fragment of pine and another of unknown conifer charcoal were recovered from the rock concentration in the northwest corner of Grid 3. Vegetal sample charcoal was primarily pine (75% by weight), and cf. piñon, cf. ponderosa pine, unknown conifer, and saltbush/greasewood were also present (Table 62.34). The presence of charcoal in the grid garden could be a product of burning brush to clear or fertilize the fields as described in the discussion of grid gardens at LA 128803 in Chapter 19 (Volume 2). On the other hand, it could also represent natural slope wash into the grids. A radiocarbon sample consisting of several fragments of piñon pine charcoal from Stratum 2 within Grid 1 yielded an intercept date of AD 690, much earlier than the ceramics and geomorphologic context indicate. The charcoal was most likely surface material washed into the grid at its open northern end (see Chapter 23, Volume 2).

LA 141505 (Classic Period Fieldhouse)

A possible corn cupule fragment from the northwestern corner of the Room 2 floor was the only cultural plant part recovered from flotation samples besides wood charcoal (Table 62.35). Modern intrusive material comprised the balance of the flotation plant record: uncarbonized weedy annual seeds, juniper twigs, pine umbos, and piñon needles.

A sample from the fill of a rodent hole was taken as a control sample and, indeed, this sample was quite different from others, resembling a cache of rodent edibles that included large numbers of unburned juniper seeds and twigs, pine umbos, piñon seeds, and prickly pear cactus seeds (absent in all other samples; Table 62.37). Vegetal sample wood was similar to flotation with possible Douglas fir, mountain mahogany, and unknown conifer identified in the fill and floor of Room 1.

The possible cupule fragment on the Room 2 floor could indicate corn was processed or burned for fuel in the room. Pine and mountain mahogany are readily available today at LA 141505, but Douglas fir may have come from Pueblo Canyon to the north or DP Canyon to the south. It is also possible that while the site was occupied Douglas fir grew closer, as this species has a range of 1981 m (6500 ft) to nearly tree line and the site is at an elevation of 2164 m (7100 ft).

Rendija Tract

LA 15116 (Classic Period Fieldhouse)

The majority of plant remains from this one-room fieldhouse associated with the Late Classic period consisted of burned and unburned conifer needles (Table 62.38). Aside from the piñon and ponderosa pine needles, cultural material was limited to single occurrences of burned seeds that compare favorably to dock along with grass family seeds and unidentifiable plant parts. The conifer needles are probably part of conifer fuel wood residue. Although young dock leaves can be eaten like spinach (H. Harrington 1967:90), basing use of the plant on the recovery of a single seed is dubious. Unburned seeds of this taxon were recovered from all three samples as well, making it even more difficult to say with any certainty that the seed represents economic use.

Ponderosa pine dominated the wood assemblage, but oak, piñon, sagebrush, and unknown conifer were also present (Table 62.39). The most that can be said about subsistence at LA 15116 is that local wood resources were used for fuel or construction.

LA 70025 (Early-Middle Classic Period Fieldhouse)

LA 70025, which was located on a ridge near the mouth of Cabra Canyon, yielded very little in the way of non-wood cultural plant remains (Table 62.40). Charred grass stems from inside a pot base were the only possible materials associated with the occupation of the site. Unburned grass stems, sunflower seeds, and ponderosa pine needles were recovered as well, but have no cultural affiliation.

LA 85403 (Classic Period Fieldhouse)

Maize cupules, a possible goosefoot seed fragment, a purslane seed, pine bark, and an unidentifiable plant part comprised the cultural plant material recovered from this one-room masonry fieldhouse (Table 62.42). Maize could have been grown near the fieldhouse that was located on a relatively flat, open area along the south side of Rendija Canyon. Pine bark is most likely part of the firewood residue. The goosefoot seed fragment and purslane seed may indicate use of these weedy annual plants that proliferate in agricultural fields. Local woods were used as fuel and included oak, ponderosa pine, and unknown conifer (Table 62.43).

LA 85404 (Early-Middle Classic Period Fieldhouse)

Charred goosefoot and groundcherry seeds found on the floor of the structure, and two corn cupule fragments from the northwest corner, were the only cultural plant remains aside from conifer duff that were recovered at LA 85404 (Table 62.44). A possible pine seed and ponderosa pine needles comprised the unburned, probably non-cultural material from flotation samples. Uncharred tobacco seeds were recovered from both burned floor samples. These could be residue from plants brought into the structure for ceremonial use, although because the seeds are unburned the verdict is uncertain. Goosefoot seeds could have been ground into meal, groundcherry fruits may have been boiled or eaten raw, and corncobs were probably used for fuel along with piñon, ponderosa pine, oak, sagebrush, and possible Douglas fir wood (Table 62.45).

LA 85859 (Early Archaic Lithic Scatter)

The majority of flotation and vegetal samples were from the center of the main activity area (90N/190E) from strata that yielded the highest number of lithic artifacts. One of these samples produced a goosefoot seed fragment. The remaining assemblage consisted of burned and unburned conifer duff including pine cone fragments, piñon and ponderosa needles, and juniper twigs (Table 62.46). Samples from that part of the site along the upper western margin (FS 353) and from the northeastern portion of the site (FS 310) also contained unburned weed seeds of goosefoot, spurge, bean family, composite family, and the knotweed family.

Wood charcoal at LA 85859 was entirely coniferous and piñon was the only taxon identified as charcoal was very fragmented and sparse (Tables 62.47 and 62.48). Unknown conifer and undifferentiated pine were also part of the record. The archaeobotanical remains from LA 85859 could be remnants of vegetation that burned during the Cerro Grande fire, especially those from Strata 1 and 2. Strata 4 and 5 displayed frequent rodent burrows indicating floral material from the fire could have been deposited by bioturbation.

LA 85864 (Jicarilla Apache Rock Ring)

The sample from the base of the informal central hearth in the tipi ring produced charred conifer duff (juniper twigs, pine needles and bark) along with an unusual find: a badly eroded possible wheat caryopsis (or seed). The caryopsis appeared to have two attributes characteristic of wheat: a crease running longitudinally for the length of the grain and the germ. The distal end of the seed was the most eroded and the general condition of the seed led to a tentative identification. As wheat had been around a long time before the occupation of LA 85864, it would not be unusual for it to have been part of the Jicarilla Apache diet. The Mescalero Apache would obtain wheat from raids in Mexico or from early settlers; wheat was planted in sandy loam, harvested by beating it with a stick, and subsequently used to make bread (Castetter and Opler 1936). Aside from wood, the remainder of the archaeobotanical assemblage consisted of unburned goosefoot seeds and burned and unburned conifer duff (Table 62.49).

+ 1-10/liter

Flotation and vegetal sample wood charcoal was primarily piñon, present in 84 percent and 89 percent, respectively, by weight (Tables 62.50 and 62.51). Juniper, pine, cf. ponderosa pine, and unknown conifer were also recovered. The occupants of LA 85864 were probably incorporating the Old World grain wheat into their diet and burning local conifers for fuel.

LA 85869 (Jicarilla Apache Rock Rings)

Two Jicarilla Apache tipi rings and a ring of cobbles were sampled for floral material at LA 85869. A charcoal concentration in the center of the Feature 4 tipi ring was the only context where carbonized plant material that was not associated with firewood use was recovered, represented by a single goosefoot seed (Table 62.52). The balance of the recognizable plant remains consisted of charred and uncharred conifer duff. Aside from conifer twigs, needles, and cone parts, non-cultural plant material included weedy annual, dock, sweet clover, and hedgehog cactus seeds, as well as unknown dicot and oak leaves. Rodent activity was especially evident in the vegetal sample from Stratum 1, level 1 of the Feature 4 tipi ring, where sample taxa and rodent feces suggested the remains of a rodent nest (unburned juniper twigs and seeds, pine cone parts, and piñon needles). Rodent feces were also present in FS 297 from the Feature 6 cobble ring.

Wood from flotation and vegetal samples was entirely coniferous, with the most significant amount of charcoal (piñon 1.4 g and unknown conifer 0.1 g) occurring in the Feature 8 charcoal concentration (Tables 62.53 and 62.54). The site occupants were using locally available wood for fuel and kindling and possibly processing goosefoot seeds as food. However, it is unknown if the goosefoot seed represents accidental charring from food processing or of a wind blown seed.

LA 86605 (Classic Period Fieldhouse)

Corn cupules, a grass seed fragment, and ponderosa pine needles were recovered from the two samples analyzed from under a tuff block on the fieldhouse floor and post-occupational fill (Table 62.55). With the exception of four fragments of ponderosa pine charcoal (Table 62.56), the sample from the lower living surface contained only unburned plant material. In comparison, the wood assemblage from post-occupational fill was quite diverse, including piñon, ponderosa pine, cottonwood/willow, mountain mahogany, and sagebrush.

LA 87430 (Classic Period Fieldhouse)

Burned pine needles were the most common plant materials recovered from this Classic period fieldhouse, followed by corn parts (Table 62.57). Besides corn, samples from the hearth yielded charred goosefoot, purslane, and beeweed seeds. A seed that compares favorably to beeweed was also identified from the charcoal concentration in Room 1. Young beeweed plants were used as greens, eaten much like spinach. The seeds were also dried, ground, and mixed with cornmeal. The leaves of older plants were cooked down until they formed a paste, sun-dried, and made into cakes that could later be eaten with cornmeal mush or fried with fat. Another, more unusual and important use of the reconstituted cakes was as a black pigment for decorating pottery and baskets (Dunmire and Tierney 1995:182–184).

Piñon and ponderosa pine dominated the wood assemblage, while mountain mahogany was the most common non-conifer with small amounts of sagebrush and oak also occurring (Table 62.58). Corn, grown in nearby fields, was probably cooked on the hearth, possibly along with goosefoot, purslane, and beeweed. Locally available woods were used as fuel.

LA 99396 (Archaic Period Lithic Scatter/Coalition Period Fieldhouse)

Evidence from the use of the one-room structure, an extramural hearth, and the central hearth of the structure consisted of pine bark, piñon and ponderosa pine needles, an unidentifiable plant part, and one purslane seed (Table 62.59). Non-cultural plant material included weedy annual and dropseed grass seeds and juniper duff. The charred bark and needles are probably artifacts of firewood use. Piñon dominated the wood assemblage (present in 70% of samples by weight; Table 62.60). Small amounts of juniper, unknown conifer, and unknown non-conifer were also present. The post fragment from the structure was most likely piñon (Table 62.61). Economic activity at the site is reflected in the use of locally available wood taxa for fuel and building materials and the possible use of purslane for food although one charred seed could have been burned in the exterior hearth after being deposited there by vectors other than humans. Samples were not taken from the Archaic component.

LA 99397 (Late Archaic? Lithic Scatter)

Very little wood charcoal or other charred macrobotanical remains were found at LA 99397 and none of the remains could be linked to cultural activities. The entire assemblage at LA 99397 appears to be in a reworked context, either through bioturbation or erosional activities. Although the central portion of the site was unburned, the northern and northwestern periphery of the site was badly burned by the Cerro Grande fire. Charred plant remains were limited to ponderosa pine needles, most likely part of the ponderosa tree that burned at the 100N/106.20E grid locus (Table 62.62). Hedgehog cactus, goosefoot, composite family, groundcherry, and purslane family seeds along with grass leaves and rhizomes, and juniper and pine duff comprised the unburned material. One flotation sample yielded two fragments of piñon wood and vegetal samples produced largely ponderosa pine (FS 282 was from the stump of the ponderosa tree) and piñon (found in 38% of samples) and small amounts of unknown conifer (Table 62.63).

Coniferous woods dominated the wood assemblage; two fragments of oak identified in occupational fill were the only representatives of non-conifer wood (Table 62.65). Ponderosa and pine were the most abundant wood taxa, but may not be cultural in origin as the site area was heavily burned in the Cerro Grande fire. A single fragment of juniper was recovered from under the stone in the northwest corner of the structure. Corncobs and possibly local woods were used for fuel and site occupants may have consumed goosefoot (but considering only a fragment was recovered and the condition of the site, this is equivocal at best).

LA 127633 (Ancestral Pueblo Fieldhouse)

Contexts associated with a rectangular feature (possible storage bin or cist?) produced carbonized goosefoot seeds, ponderosa pine needles, and unidentifiable plant parts (Table 62.66). The site was extremely compromised, the southern and eastern sides of the site having eroded downslope. Wood taxa were limited to ponderosa pine and unknown conifer (Table 62.67). Considering the poor condition of the site, the charred plant remains are most likely non-cultural.

LA 127634 (Classic Period Fieldhouse)

Aside from charred conifer duff, beeweed and corn were the most common taxa identified in flotation samples (Table 62.68). Banana yucca, beans, and tobacco seeds were found in samples from the hearth, while bugseed and possible squash rind were present in floor contexts near the hearth. This is quite a remarkable floral assemblage from a one-room fieldhouse. Carbonized tobacco indicates ritual activities may have taken place here that may have included using beeweed pigment to paint pottery or ritual items (Adams et al. 2002). Beeweed was of course also used extensively as a potherb and the seeds were ground into a meal for flour or gruel (see V. Jones 1931 or Lange 1968a) and its presence may have more to do with food preparation rather than pigment manufacture.

+ 1-10/liter, c cupule, cf. compares favorably, cot cotyledon, e embryo, k kernel, pc partially charred, pp plant part

The wood assemblage was composed of ponderosa pine, piñon, cottonwood/willow, mountain mahogany, oak, and sagebrush (Table 62.69). Site occupants probably used corncobs for fuel and the presence of kernels and embryos points to processing of maize. Compared to other fieldhouses on C&T Project land, LA 127634 and LA 127635 yielded the greatest number of wild and domesticated taxa including ritual plants, indicating that perhaps these sites were in use over a longer period of time.

LA 127635 (Classic Period Fieldhouse)

Floral remains from this fieldhouse resemble those from the neighboring fieldhouse, LA 127634, to the east. Beeweed and maize were the most common taxa from both fieldhouses. While tobacco was found in hearths at both sites, only one sample out of 14 at LA 127634 yielded tobacco, whereas tobacco was present in 56 percent of samples from LA 127635. Beans were present at LA 127634 and not at LA 127635. Aside from conifer needles and bark, evidence for perennial plant use was represented by a hedgehog cactus seed fragment from the upper fill of the hearth, while at LA 127634, a banana yucca seed in the hearth was the only non-conifer perennial plant part recovered. Possible squash rind was identified from both structures.

LA 127635 floor scrape and floor samples (FS 116 and FS 141) yielded very similar taxa to those encountered in post-occupational fill samples (FS 45 and FS 53) including corn cupules and charred conifer duff (Table 62.70). The exception was possible squash rind identified in the general fill sample. Only unburned material was recovered from under the patterned rock concentration (Feature 1). Lower and upper fill of the hearth (Feature 2) yielded cheno-ams, tobacco, beeweed, maize, and conifer duff; bugseed and hedgehog cactus seeds were restricted to the upper fill. One sample from the upper fill of the hearth consisted almost entirely of kernel fragments. In general, much higher concentrations of maize kernels were present at LA 127635 than at LA 127634. The sample taken from under the concentration of tuff rocks adjacent to the south wall of the structure (Feature 1) contained only unburned plant material. It has been suggested that this rock concentration may represent the deliberate walling up of the entrance to the structure (see Chapter 52, Volume 2). Two ceramic sherds and two chipped stone artifacts were found in the fill under Feature 1 and it was determined that this was post-occupational fill. However, if this were the case, the sample would be more likely to contain similar remains to those found in FS 45 that included conifer needles, bark, and charcoal.

Wood charcoal from the floor scrape was very different from the floor sample; ponderosa pine was the only wood type identified in the floor scrape sample, while pine, piñon, and mountain mahogany were identified in the floor sample (Table 62.71). Charcoal from the two general fill samples was also very different. Fill above the living surface produced only coniferous woods, while the majority of charcoal from the general fill sample was mountain mahogany with a small amount of unknown conifer. The Feature 2 wood assemblage was much more diverse than other contexts, yielding coniferous (including juniper) as well as cottonwood/willow, mountain mahogany, oak, and sagebrush.

Feature 2 was the best-preserved hearth that was excavated in Rendija Canyon (Lockard, personal communication), and the preservation of plant material certainly confirms this observation. Plant remains indicate occupants of LA 127635 were utilizing several annual species (including ritual use of tobacco), hedgehog cactus, maize, and possibly squash and wood species from the riparian, mountain foothills, and ponderosa pine forest zones.

LA 135291 (Classic Period Fieldhouse)

Maize cupules from the ash concentration found outside the structure just to the east were the only plant remains hinting at the agricultural activities that took place near the fieldhouse (Table 62.72). Juniper twigs and ponderosa pine and piñon needles could be related to fuelwood use or represent residue from the Cerro Grande fire. Unburned juniper twigs, ponderosa pine needles, hedgehog cactus seeds, and weedy annual seeds most likely represent modern intrusives, transported into the site by wind or rodents.

+ 1-10/liter

Wood charcoal from inside the structure consisted of pine, ponderosa pine, and unknown conifer (Table 62.73). The wood may also be the result of the Cerro Grande fire. The site is located in a ponderosa pine forest that was severely burned during the fire and two burned juniper trees were found directly inside the feature. In contrast, the wood assemblage from the possible discard pile outside the structure was quite different in composition, including possible Douglas fir, mountain mahogany, and oak. The presence of maize in this feature along with this unique wood assemblage suggests a discrete dumping episode that may be the only intact evidence at the site of fuel use.

LA 135292 (Classic Period Fieldhouse)

Another Classic period fieldhouse, LA 135292, was also severely affected by the Cerro Grande fire and all but the southwest corner of the room was destroyed by modern machinery. The sample from room fill contained a charred cheno-am seed, ponderosa pine needles, and a possible cupule fragment (Table 62.74). Unidentifiable plant parts were recovered from the area of burned earth that may represent what remains of the living surface. Modern uncharred grass, annual, and groundcherry seeds were all that was recovered from the sample just inside the room's west wall.

The wood assemblage was much more diverse than that present at LA 135291, including juniper, ponderosa pine, and mountain mahogany (Table 62.75). Possible Douglas fir and oak were identified in the sample from the burned earth, wood taxa that were absent from general fill samples. Excavators noted that burned wood resulting from the Cerro Grande fire could not be distinguished from possible prehistoric charcoal (Lockard, Chapter 54). Therefore, the cultural origin of wood from flotation samples is doubtful.

LA 85407 (Serna Homestead).

The contents of samples from post-occupational fill in the log cabin, a test pit in the corral, and an area of burned soil and charcoal in the shed produced a similar assemblage of burned conifer duff, native annual seeds, grass seeds, grass stems, and other disturbance-loving plants like groundcherry and vervain (Table 62.76). Burned sedge family seeds from the cabin and the shed together with unburned bulrush seeds from the corral attest to the proximity of the homestead to the creek just below in Rendija Canyon. Burned seeds that resembled summer cypress were recovered from the corral. Summer cypress is a weed introduced from Eurasia that is widespread in New Mexico and flourishes in waste places and open fields. The corral and some of the cabin burned during the Cerro Grande fire. Because of this and the similarity of the wild plant assemblages, the majority of wild floral remains probably represent weeds burned in the conflagration rather than debris from food preparation or animal feed.

Evidence for domesticates was restricted to the inside of the cabin and included maize cupules and one burned and one unburned grape seed. Interviews with Annie Lujan, the daughter of José María Serna, owner of the homestead, reported that crops grown included pinto beans, corn, wheat, pumpkins, and other "soft vegetables" (see Chapter 32, Volume 2). There is no mention of grapes or vineyards, but two peach pit fragments were identified in the vegetal sample from Room 1 post-occupational fill and Ms. Lujan did not mention that they grew peaches at the homestead either. Measurements of the whole burned seed indicate the specimen is from canyon grape (*Vitis arizonica*), although charring does diminish seed size, making it difficult to determine with certainty. Wild grapes grow on canyon walls, in canyon bottoms, and piñon/juniper woodland (Foxx et al. 1998:40). While there are no gnaw marks on the specimens, the possibility that rodents deposited them (especially the unburned fragment) cannot be ruled out. The grape seeds and peach pits could also be remnants of fruit "brought up from the Pojoaque-Española Valley orchards and vineyards" (Foxx and Tierney 1999:22) or orchards were present on the homestead, but were either not mentioned by Ms. Lujan or by Lockard (Chapter 32, Volume 2).

A broken bean cotyledon from the same context and a piece of ponderosa pine wood were also identified in vegetal samples (Table 62.77). Interviews with residents or descendants of residents of the area document beans as the primary cash crop that was grown on the Pajarito Plateau (Tierney 1999c:15–23). With only one fragment recovered, it seems difficult to fathom the huge volume of beans grown on the Pajarito Plateau by homesteaders. One informant said that in 1915, he harvested about 2100 pounds of beans (Tierney and Foxx 1999:10) and this was not unusual before the drought of the late 1930s. The paucity of physical evidence is related to the fragility of beans and threshing and preparation methods. Beans may be removed from the pods elsewhere than the house interior and preparation does not usually involve parching or frying. Beans have no protective seed coat, as the pod acts as a container before harvest, leaving them vulnerable to consumption by animals or insects.

Wood			
Ponderosa pine		1/<0.1 g	

Wood charcoal from the majority of contexts at LA 85407 is overwhelmingly ponderosa pine (Table 62.78). Exceptions are the samples from inside the horno and the burned soil/charcoal concentration in the shed. Fuel used for cooking seems to have been primarily juniper, although piñon and ponderosa were also present. Wood from the shed context is a mixture of juniper, piñon, and ponderosa, but here ponderosa was the most common wood identified. This could reflect the use of ponderosa for construction and juniper for fuel in the horno.

The Serna family grew corn and beans among other crops documented in interviews and the Homestead Entry Survey. The family traveled to the homestead three times a year by wagon and stayed for about two weeks during each visit. The burned beeweed, goosefoot, pigweed, and groundcherry seeds could be evidence that the family ate the fruits of groundcherry and encouraged and collected annual greens from the fields, a practice documented in several interviews of Spanish residents of the region (Tierney 1999c:15–23). However, these plants all thrive in disturbed ground and are part of the early successional stage after site abandonment (Foxx 1999) and are more likely to represent weeds that burned in the Cerro Grande fire. Although some of the wood charcoal may also derive from the fire, excavators noted that the cabin fill was extremely rich in charcoal and that most if not all of the charcoal probably derived from the beams and boards that formed the cabin's walls and floor (Chapter 32, Volume 2). Charcoal from the horno indicates juniper was a primary fuel resource and wood from the cabin suggests ponderosa was used for construction.

LA 85408 (Classic Period Fieldhouse)

Possible piñon nutshell was the only cultural plant material not directly related with firewood use that was found in the fieldhouse (Table 62.79). A total of five pieces of unknown conifer wood, four from the middle fill of the pit and one from post-occupational fill were also recovered. Modern debris included unburned goosefoot, prickly pear, and sedge seeds, grass florets, piñon nutshell, and conifer twigs and needles.

LA 85411 (Classic Period Fieldhouse)

Tobacco was found in the small pit hearth (Feature 2) in Room 2 along with pigweed and purslane seeds (in upper and middle fill) and the ever present conifer needles and cone fragments (Table 62.80). Unlike the hearth in Room 2, it was only the lower fill of the Feature 1 hearth in Room 1 that yielded floral remains unrelated to wood use (maize and one goosefoot seed). Ponderosa pine and mountain mahogany were the two most frequently encountered wood taxa (Table 62.81). Unknown conifer, pine, and oak were also present. A single vegetal sample from post-occupational fill just outside Room 1 contained a pine umbo and six pieces of ponderosa pine weighing a tenth of a gram.

LA 85413 (Classic Period Fieldhouse)

Cultural plant remains consisted of one goosefoot seed and one possible maize cupule fragment (Table 62.82). Charred and partially charred plant part fragments could not be identified and conifer needles are probably a product of firewood use. Wood charcoal was primarily mountain mahogany and unidentified pine with piñon, ponderosa pine, oak, and unknown conifer occurring in smaller numbers (Table 62.83).

LA 85414 (Classic Period Fieldhouse)

Piñon needles were the only non-wood plant materials recovered from the fieldhouse and most likely relate to fuelwood use (Table 62.84). Wood charcoal was limited to five pieces of pine recovered from the southeast corner of the living surface.

LA 85417 (Late Coalition Period Fieldhouse)

Cheno-am seeds were identified in the south half of the ash pit fill and in the ash/charcoal deposit on the floor of the structure (Table 62.85). Piñon seeds (immature, so identification is tentative), a juniper cone fragment, and unidentifiable plant parts were also recovered in the south half of the ash pit. Non-cultural material included annual seeds, cactus seeds, and conifer needles. Wood charcoal was entirely coniferous, with ponderosa pine and unknown conifer the most common taxa, followed by pine and juniper (Table 62.86).

LA 85861 (Late Coalition Period Fieldhouse)

In comparison with the three other fieldhouses from this time period, LA 85861 stands out with greater taxonomic diversity, including the recovery of beeweed seeds from the hearth, reminiscent of LA 127634 and LA 127635, two Classic period fieldhouses where beeweed was a significant element in the floral assemblages. A cheno-am seed fragment, a mint family seed, an unidentifiable plant part fragment, piñon needles, and two maize cupules comprise the balance of the cultural plant material recovered (Table 62.87). Unburned piñon needles were the only modern plant parts present. Small quantities of pine, piñon, ponderosa pine, and unknown conifer charcoal were also identified (Table 62.88).

LA 85867 (Classic Period Fieldhouse)

Two samples from the living surface of this one-room fieldhouse yielded charred ponderosa pine needles and uncharred hedgehog cactus seeds. Fourteen pieces of ponderosa pine and 12 pieces of unknown conifer, weighing 0.5 g round out the cultural plant material recovered.

LA 86606 (Coalition Period Fieldhouse and Classic Period Extramural Feature)

Carbonized purslane seeds, grass stems, conifer duff, and unidentifiable plant parts were found on a well-preserved patch of the living surface in the southwest corner of the fieldhouse (Table 62.89). An unidentifiable plant part and ponderosa pine needles were recovered from the fill between three rocks that may have been the remnants of a Classic period exterior hearth or pot rest next to a hearth. Ashy sediment found south of the three rocks yielded ponderosa pine needles. Ponderosa pine was the only wood taxon identified from the structure living surface, possibly indicating the identity of a ceiling or wall element. Mountain mahogany was the dominant wood taxon in the ashy sediment and the possible hearth (Table 62.90). Logically, the ashy sediment (possible dump from the hearth) was the most diverse, containing ponderosa pine, piñon, mountain mahogany, and oak.

LA 86607 (Coalition Period Fieldhouse)

One fragment of ponderosa pine charcoal weighing less than a tenth of a gram was the sole floral material from post-occupational fill in the structure. The paucity of remains is not surprising considering the impact of trail building (Pajarito Trail #286 passes through the site); some of the rocks that were originally part of the structure walls were probably used to construct the trail and rock alignments that cross the trail, built to control erosion.

TA-74 Testing

LA 21596B and LA 21596C (Coalition/Classic Period Grid Gardens)

The grid gardens are located at the base of a colluvial slope adjoining floodplains or fluvial terraces in the bottom of Pueblo Canyon (see Chapter 55, Volume 2). Non-cultural unburned conifer twigs, cone parts, and needles formed the primary constituents of the plant assemblage from the two grid gardens. One maize cupule fragment was recovered from LA 21596C and five from LA 21596B. Fragments of piñon nutshell were also recovered from LA 21596C. Small fragments of unknown conifer wood were found in both grid gardens.

The same process described in the discussion of LA 128803 whereby debris is burned to fertilize or clear gardens may have taken place at these two, leaving charred evidence of the procedure. Another possibility is that these remains represent trash washed downslope from Otowi Pueblo, a Classic period large multi-room habitation site, located on the second bench upslope from the gardens. "There is a continuous scatter of artifacts down from Otowi including approximately 200 to 300 items on the first bench near the site" (Chapter 55, Volume 2). This pattern along with 273 artifacts (mostly ceramics) recorded near LA 21596A, 44 at LA 21596B, and 91 more at LA 21596C, suggest the latter possibility is more likely.

LA 86528 (Classic/Historic Period Rockshelter)

A partially charred juniper seed and unknown bark were the sole possibly cultural plant materials recovered from Test Pit 1. Test Pit 1 was excavated to sample a charcoal stain at the edge of the overhang of the rockshelter. The stain may represent a pit excavated into the Pleistocene soil horizon or the remains of a natural fire and the shelter itself may never have been occupied. The recovery of maize pollen from the same context suggests the former.

LA 86531 (Coalition/Historic Period Lithic and Ceramic Scatter)

This is an eroded site on a Pleistocene terrace about 30 m above the floor of Pueblo Canyon. Level 1 of the test pit yielded two maize cupule fragments, five possible kernel fragments, pine bark, and ponderosa pine needles. Cultigens were not recovered from Level 2 of the test pit. Piñon, juniper, ponderosa, mountain mahogany, and oak charcoal were also identified. Site occupants could have been farming on the bottomlands of the canyon. They were certainly using locally available shrubs and conifers for fuel.

LA 110126 (Classic Period Fieldhouse)

Slightly downslope from where the structure was located, samples from a shovel test yielded carbonized pine bark, grass stems, and one fragment each of unknown conifer, mountain mahogany, and unknown non-conifer charcoal. Macrobotanical wood sample taxa included the same three found in flotation samples with the addition of wood that compared favorably to rabbitbrush. The paucity of plant material is not surprising considering that the only recognizable remnant of the site was an alignment of four tuff rocks.

LA 110130 (Classic Period Fieldhouse)

LA 110130 is situated on a terrace above the floodplain of Pueblo Canyon. A burned amaranth seed was recovered from Stratum 2 in Test Unit 1 from inside the structure. A cupule and a cupule segment were identified from a charcoal stain encountered in Test Unit 2, excavated into a rubble pile in the southeastern portion of the structure. Wood charcoal consisted of 17 pieces of sagebrush identified in the charcoal stain and one fragment of oak from Test Unit 1. Farmers at LA 110130 could have cultivated crops in the floodplain of Pueblo Canyon and collected seeds of annual plants like amaranth that thrive in the disturbed ground of agricultural fields.

LA 117883 (Archaic Lithic Scatter)

Macrobotanical wood charcoal was collected from two test pits and included piñon, oak, and unknown conifer. The Pueblo Canyon drainage flows around the site that is situated on a sandbar. Charcoal could have been washed in or deposited downslope from a large Coalition cavate site above.

LA 61034 (Classic-Historic Period Lithic/Ceramic Scatter)

A single fragment of unknown conifer wood was the sole charred plant part from the flotation sample. Macrobotanical wood charcoal consisted of three pieces of pine and one of oak.

LA 61035 (Classic Period Lithic/Ceramic Scatter)

A fragment of an unknown plant part was recovered from the flotation sample along with a piece of pine wood and another of unknown conifer. The six macrobotanical samples were more productive, yielding juniper, piñon, and unknown conifer charcoal for a count of 23 and a total weight of 2.1 g.

DISCUSSION: THE C&T PROJECT PREHISTORIC DATA IN A REGIONAL PERSPECTIVE

Plant Remains from Flotation

Coalition Period

Carbonized plant remains from LA 12587, LA 86534, and LA 135290 are compared with other Coalition period sites on the Pajarito Plateau in Table 62.91. Data from LA 4624, a 25-room pueblo, come from three of the 10 rooms excavated in 1993 by LANL. LA 60372 (Burnt Mesa Pueblo) is a multi-room pueblo with a plaza. Area 2 of the site was occupied during the Early Coalition. Samples were analyzed from rooffall, an ash pit, extramural contexts, and hearths in Rooms 2 and 8. LA 29746, LA 21432, and LA 21422 were all part of the University of California's Pajarito Archaeological Research Project (PARP) and samples were taken from excavations in middens associated with the three pueblos. With the exception of LA 21422 and LA 21432, the number of flotation samples analyzed from the current project far outstrip the number from any of the other projects, so comparison largely emphasizes how much richer our picture of subsistence can be when an extensive database is available.

Maize fragments and goosefoot, pigweed, and purslane seeds are widespread in the sites compared in Table 62.91, emphasizing the important dietary role played by these key species during the Coalition period. Annuals like pigweed, goosefoot, and purslane that readily volunteer in agricultural fields were likely encouraged (Medsger 1939). Bye (1981) has documented the encouragement and harvest of goosefoot, pigweed, mustard, and purslane in the modern cultivated fields of the Tarahumara of northern Mexico. The leaves provide a welcome source of greens early in the growing season and, later, the seeds can be collected, parched, and added to corn meal to make bread, cakes, mush, or gruel (Harrington 1967). Other domesticates recovered in flotation samples include possible squash rind at four out of six sites and beans at three sites. In addition to the sites compared in Table 62.91, Matthews (1989) analyzed two flotation samples from Casa del Rito (LA 3852, an Early Coalition site) and found a small fragment of *Cucurbita* rind and three maize cupules, while eight cob fragments were also identified in vegetal samples. Kohler and Root (2004:148), however, consider it likely that the squash rind and some of the maize remains may postdate the habitation of the site.

The diversity and abundance of grasses is low. Unidentified grasses occur at five out of six sites and perhaps when archaeobotanists become more adept at identifying this class of plants to genus or species, diversity of assemblages will expand. Groundcherry, evening primrose, and mint family seeds were recovered from the current project. After Spanish contact, the mashed fruits of groundcherry were used by the Zuni in a salsa along with onions, chile, and coriander. The Rio Grande pueblos ate the fruit either boiled or fresh (Castetter 1935:39–40). Members of the mint family like horsemint (*Monarda menthaefolia*) and mint (*Mentha canadensis*) were used as seasonings (Castetter 1935:33–34). The leaves, roots, and shoots of evening primrose are edible and the Navajo use many species for medicine. The Hopi also smoked *Oenothera albicaulis* as a tobacco (Dunmire and Tierney 1997:240–241).

+ present; * charred pine cone scales and conifer needles also present; [1]McBride and Smith 2002; [2]Matthews 1989; [3]Trierweiler 1990; [4]McBride 2006

Cacti comprise a large proportion of the perennial plants utilized on the Pajarito Plateau. Cactus fruits were among the very few sweets available to pre-contact southwesterners and may have been sought after not only for the taste, but as a source of protein, vitamin C, potassium, and calcium (Dunmire and Tierney 1997:234). Piñon was the most frequently encountered perennial taxon at sites in Los Alamos, but was absent from sites in Bandelier National Monument. Banana yucca, sage, and globemallow had singular appearances in the record. Banana yucca is listed as not common on the Pajarito Plateau by Foxx and Tierney (1985:89), which explains the paucity of evidence for its' use. However, one species of sage (*Salvia reflexa*) is locally common in disturbed soils of the area. The most common use of sage is to soak the whole unprocessed seeds in water to make a refreshing, mucilaginous drink (Kirk 1970:85; Russell 1908:77) and may be the reason for the scanty appearance of this taxon in the record. One species of globemallow (*Sphaeralcea fendleri*) is listed as widespread in New Mexico at elevations from 1646 to 2438 m (5400 to 8000 ft) (Martin and Hutchins1980:1262) so it is hard to explain why this perennial resource is not more widely represented in archaeobotanical assemblages from the Pajarito Plateau. Juniper cones and seeds and four-wing saltbush fruits may be residue from firewood use or could have been used as seasoning or emergency foods.

Four Coalition fieldhouses from the C&T Project were not included for comparison, but warrant some discussion. The meager non-wood cultural plant material from three of the fieldhouses consisted of burned cheno-am and purslane seeds, grass stems, and immature piñon seeds (from LA 85417). Although lacking the diversity of taxa from Classic period fieldhouses, the assemblage from the fourth fieldhouse (LA 85861) resembles those of several Classic period fieldhouses in that beeweed seeds were recovered in two samples from the hearth. This may indicate that in the Classic period, fieldhouses were occupied for a longer part of the growing season, or that differential preservation is a factor.

Classic Period

The 21 C&T Project Classic fieldhouses produced a much more diverse array of cultural plant remains than those of the previous period and many more taxa than the multi-room Classic period pueblos compared in Table 62.92. In particular, LA 87430, LA 87411, LA 127634, and LA 127635 were remarkable in that tobacco was recovered along with the only beeweed, bugseed, beans, squash, and banana yucca seeds (from LA 127634) from Classic period sites. Compared to plant assemblages from the Classic period pueblos in Bandelier, LA 5173 is the only one that comes close. This is probably due to vast sample size differences since the pueblos presumably represent much longer occupational sequences.

Shohakka is a horseshoe-shaped pueblo with three kivas in the central plaza and a midden to the south. Samples were taken from the use surface of Room 1, room fill, wall/rooffall, and hearth fill in Room 2, the center of Kiva 3 and wall/rooffall from the kiva, and from a trench in the midden area. Tyuonyi Annex was a pueblo of about 50 ground floor rooms with second-story rooms in some parts of the roomblock. Samples were collected from four levels of secondarily deposited cultural fill in a test unit and post-occupational fill of two rooms. Finally, LA 5137 is another PARP site where midden samples were collected and analyzed.

Like Coalition period assemblages, maize, goosefoot, pigweed, and purslane are still the most commonly encountered taxa from Classic period contexts. Grass diversity is also low at this time and the perennial assemblage is quite similar to the previous period, with more species of cacti than any other plant group. Possible dock seeds that were recovered at one of the Rendija fieldhouses (LA 15116) represent the only taxon found exclusively in the Classic period. Dock seeds were ground into a meal, while the young leaves were cooked as a potherb. The seeds were also used as a substitute for tobacco or in combination with it (Harrington 1967:92). In contrast to the preceding period, where beans and squash were found at more than 40 percent of sites, in the Classic period only fieldhouses produced all three cultivars. The large variety of annual taxa present at the majority of sites in the Coalition period was restricted to Classic period fieldhouses as well.

Summary of Plant Remains from Flotation over Time

The percentages of plant classes remain fairly stable throughout the occupational sequence of the Pajarito Plateau (Figure 62.8). Early Coalition period sites include LA 4624 and LA 60372 (Area 2), Middle Coalition period sites include LA 86534 and LA 135290, Late Coalition period sites include LA 12587, LA 4618, LA 85417, and LA 85861, and Classic period sites include LA 3840, LA 6550, LA 15116, LA 85403, LA 85404, LA 85411, LA 85413, LA 87430, LA 110130, LA 127627, LA 127631, LA 127634, LA 127635, LA 128805, LA 135291, LA 135292, and LA 141505.

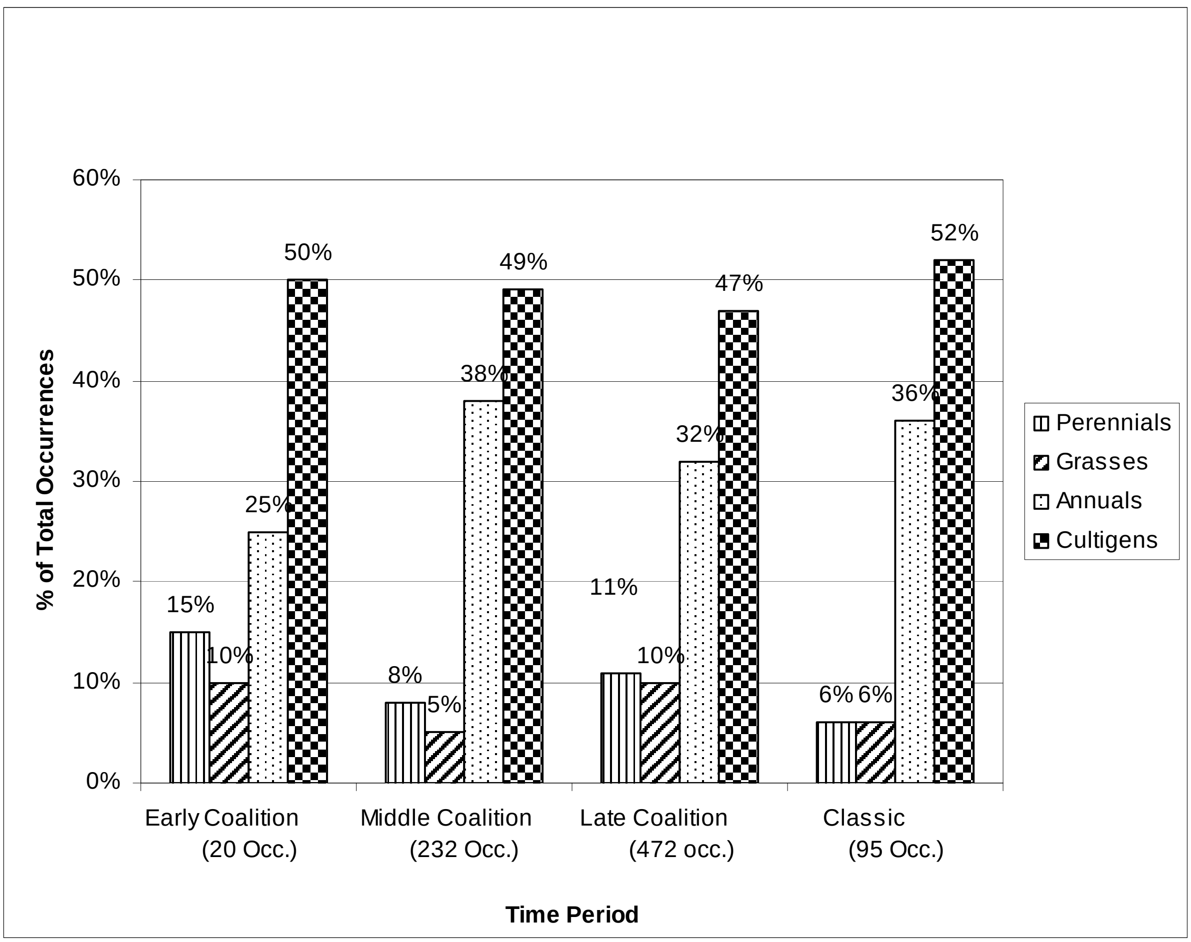

Figure 62.8. Comparison of plant classes from sites on the Pajarito Plateau.

Originally Figure 62.8 included data from two Bandelier sites dating to the transitional Coalition/Classic period together with all the sites used in comparison tables, but for reasons described below, the PARP data have been eliminated. Midden material from LA 174 (Trierweiler 1990) was the primary source of data for the Coalition/Classic period (of the 154 total occurrences, 144 were recorded for LA 174). There is something very different about this site where perennials, annuals, and cultigens were identified in a nearly equal number of samples. Trierweiler (1990) identified piñon nutshell in all but six of the 48 samples analyzed. This is in marked contrast to the current project where piñon was identified in only 14 samples out of 489. Matthews (1898, 1993) found no burned piñon nut remains from the Coalition and Classic period samples that she analyzed for the Bandelier Archaeological Project. Chokecherry seeds had never been identified before in Pajarito Plateau assemblages and Trierweiler recovered the seeds at three of the five sites he analyzed. Furthermore, *Opuntia* seeds were also identified at three of the five sites, whereas only two of the C&T Project samples contained evidence of prickly pear cactus seeds. These differences beg the question of whether midden samples provide evidence strictly of food preparation or whether they contain debris from activities more encompassing in nature and, thus, presenting a comparability issue.

Without the data from LA 174 there was insufficient data, precluding the inclusion of the Coalition/Classic period in Figure 62.8. The percentage of annuals compared to cultigens is closest in the Middle Coalition. This may indicate agricultural intensification during this period with an increase in the annual plants that abound in the disturbed ground of cultivated fields. If weedy annuals were encouraged in or near agricultural fields as suggested by Matthews (1985) and Bye (1981), then with a spike in cultivation, one could expect a concomitant spike in annuals. Multi-cropping is also implied whereby farmers would harvest annual greens early in the season and the small, nutritious seeds later in the summer along with green corn, and then finally the mature domesticated crops. After the initial increase in annuals in the Middle Coalition, ubiquity remains fairly steady for the duration of the occupation. Maize ubiquity also remains steady, with only slight dips in the Middle and Late Coalition period, to its highest percentage in the Classic period. It should be noted that any interpretation including the comparatively tiny database of the Early Coalition is tentative at best.

Wood Charcoal

Coalition Period

Wood assemblages from Coalition period sites are primarily coniferous, dominated by juniper, piñon, or ponderosa pine, depending perhaps to some extent on which resource was most expedient (Table 62.93). Ubiquity of juniper, ponderosa, and piñon is nearly equal during the earlier occupations of LA 4624 and LA 60372. The same is true of juniper and piñon at LA 3852; the lower percentage of ponderosa may reflect less use as a direct effect of distance from the resource. LA 3852 and LA 12587 are close in elevation and with the exception of piñon, very similar in the number of samples in which coniferous taxa occur. The percentage of undifferentiated pine from LA 12587 doubles the percentage from LA 3852. Some of the wood identified as pine could be piñon, thereby accounting for at least some of the difference in ubiquity. Saltbush/greasewood is much more abundant at LA 12587 and the diversity of taxa is also much greater, possibly indicating that a wider catchment area was exploited in the Late Coalition period as preferred wood resources were depleted or that wood procurement changed with new social and religious practices.

The case of LA 4618 reveals some important issues of context. Viewed alongside LA 12587 (also on Mesita del Buey and at a similar elevation), we see wood assemblages with wildly different occurrences of juniper and ponderosa (Table 62.93). Given general similarity in environmental and cultural factors, we look instead at sample context (Table 62.94). Sites (like LA 4618) with a preponderance of samples from rooffall and features display an increase through time in the use of high-elevation conifers like Douglas fir and ponderosa. At sites (like LA 12587) where post-occupational fill or room fill were heavily sampled, wood is more likely to reflect a mixture of redeposited construction and fuelwood debris. These remains seem to reflect wood resources collected close at hand. The former pattern may indicate some deforestation of lower-elevation conifers in the Late Coalition period and a focus on procuring higher-elevation taxa for roofing material.

Classic Period

Wood taxa recovered from Classic period pueblos at Bandelier are compared to the wood assemblage from C&T Project Classic fieldhouses in Table 62.95. Juniper, piñon, and ponderosa are the most common conifer wood taxa recovered at the two pueblos and the Cavate M77. LA 3840 also has relatively high percentages of cottonwood/willow, mountain mahogany, and oak, although the percent presence of oak is similar at all three sites. The high percentage of riparian taxa at LA 3840 compared to all other sites may be explained by the site's location in a canyon bottom near Capulin Creek, which is a perennial stream. This was also the only site where *Phragmites* (common reedgrass) was recovered. Common reedgrass grows in wet ground at 1067 to 1828 m (3500 to 6000 ft) (Martin and Hutchins 1980:177). Clearly, inhabitants were exploiting species that were close at hand, a pattern that is reflected in other areas such as LA 4624 on the Pajarito Plateau (McBride and Smith 2002), at Bandelier (Matthews 1989 and 1990), on the Colorado Plateau along the lower Chaco River (M. Toll 1983), and in Santa Fe (McBride and Toll 2001).

F flotation, V vegetal. *Includes LA 15116, LA 70025, LA 85403, LA 85404, LA 85408, LA 85411, LA 85413, LA 85414, LA 85867, LA 86605, LA 87430, LA 110126, LA 110130, LA 127627, LA 127631, LA 127634, LA 127635, LA 128805, LA 135291, LA 135292, and LA 141505. [1]Matthews 1993; [2]Matthews 1989

The fieldhouse wood assemblage is dominated by ponderosa pine, but the nearly equal percentage of unknown conifer may include specimens of unidentifiable juniper or piñon. Mountain mahogany and oak are the most common non-conifers. The majority of the fieldhouse wood charcoal was from room fill, floor, and hearth samples. Samples from LA 3840 were collected primarily from room fill and rooffall/wallfall. The cavate samples came from post-occupational fill and storage features, while LA 60550 charcoal was from secondarily deposited cultural fill and post-occupational fill. The fieldhouse wood assemblage may be more representative of fuelwood use, and charcoal from LA 3840 may be remnants of construction wood. The wood from the cavate and LA 60550 is probably a mixture of fuel and construction wood.

Summary of Wood Charcoal over Time

Figure 62.9 illustrates the distribution of hardwoods, shrubs, and conifers through time on the Pajarito Plateau.

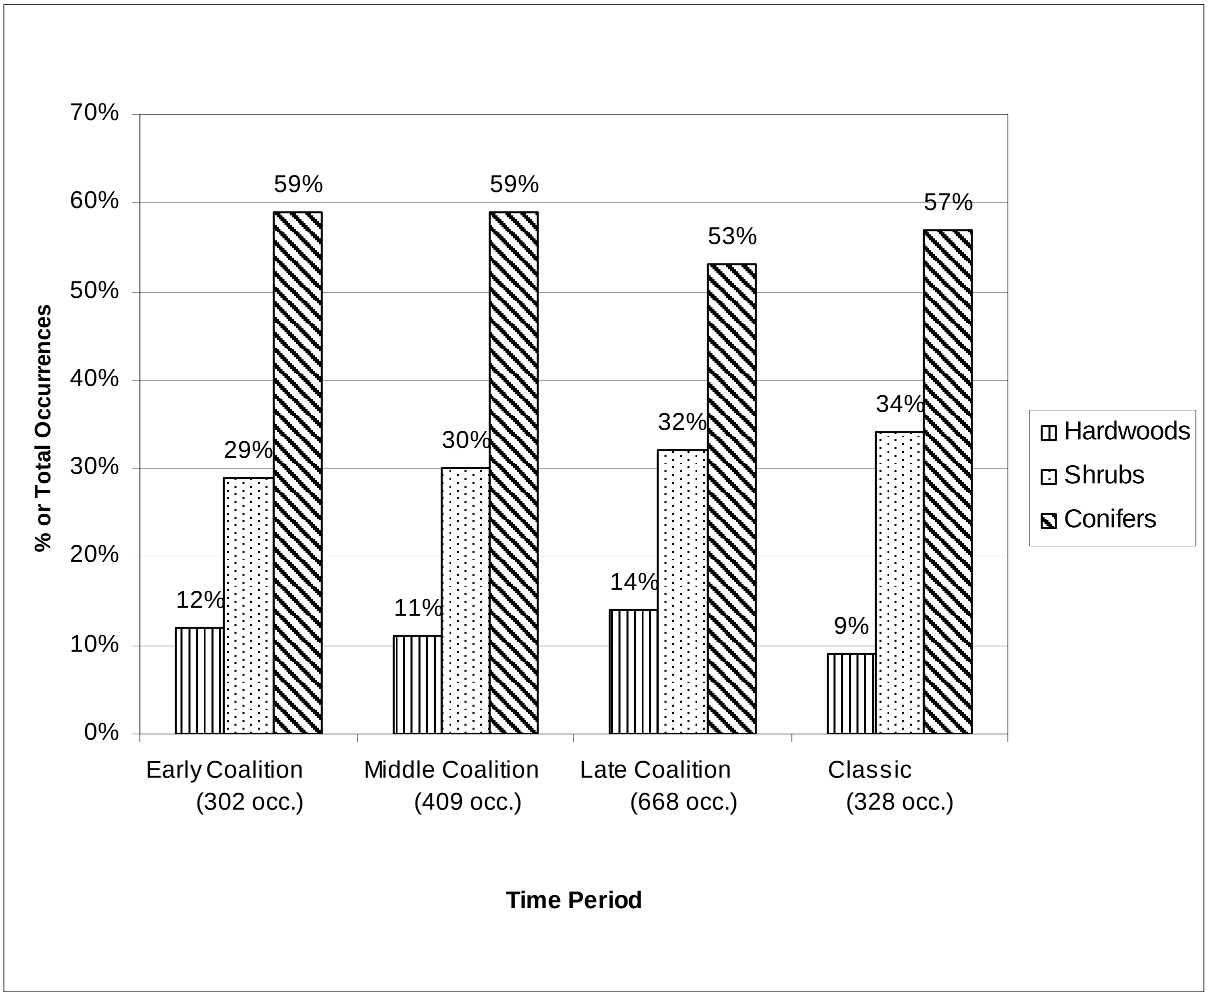

Figure 62.9. Comparison of wood classes from sites on the Pajarito Plateau.

This type of distribution study is simply an attempt to detect any broad patterning in wood class use through time and does not take site location into account. The total occurrence of each wood class was divided by the total number of occurrences of all classes for each time period. The percentages of wood classes do not change significantly through time, indicating a consistent emphasis on conifers for all occupations on the plateau. A similar pattern of fuelwood use for the Coalition and Classic periods is demonstrated in the distribution of wood classes found in hearths (Figure 62.10).

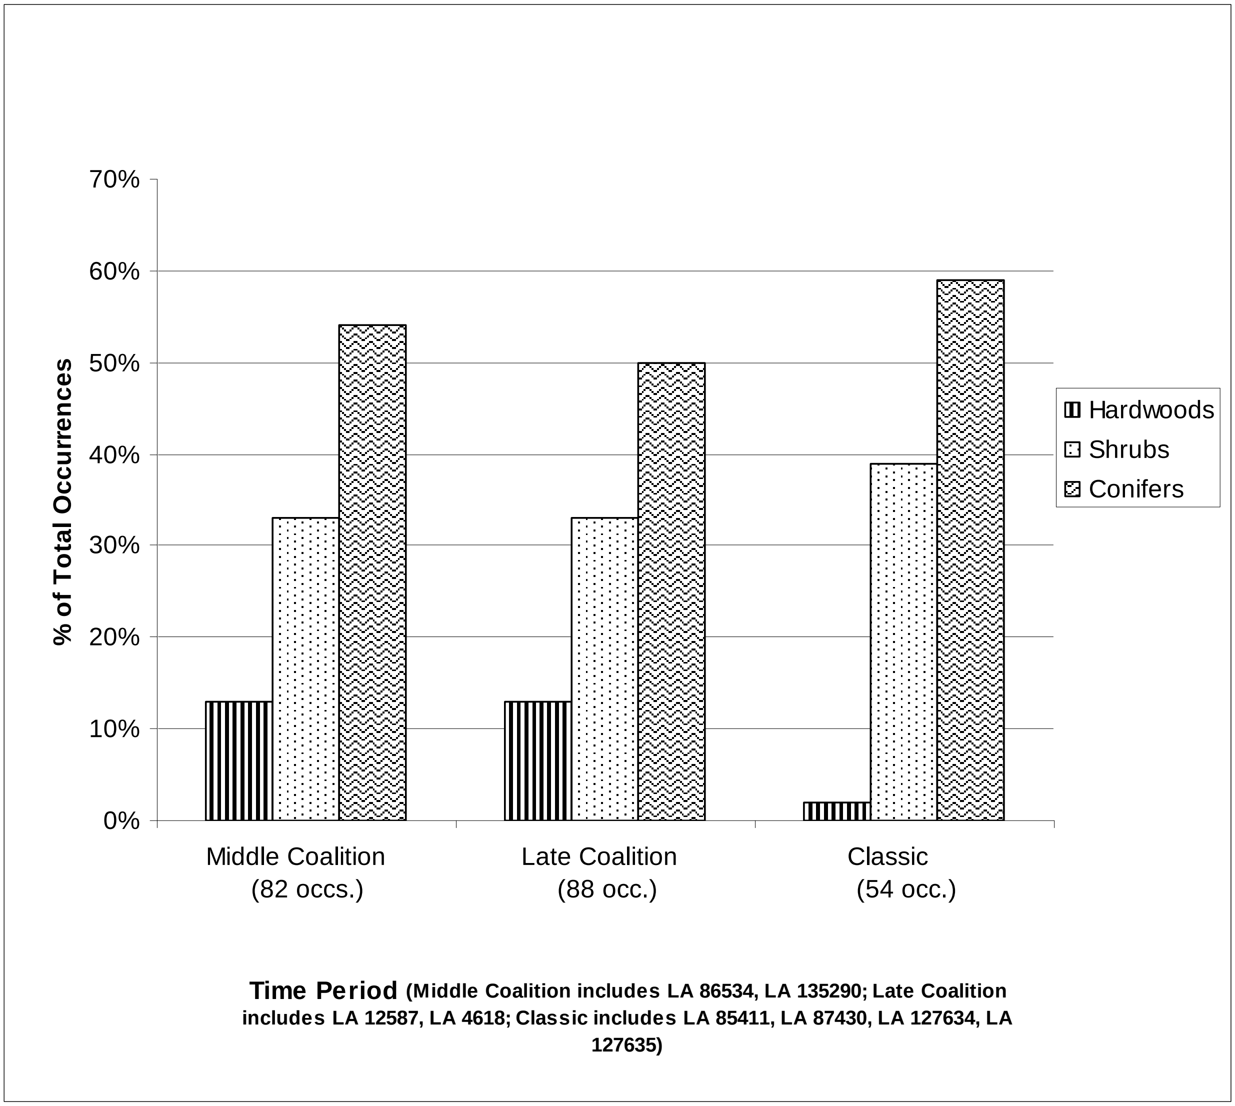

Figure 62.10. Comparison of wood classes from hearths at Coalition and Classic sites.

At LA 86534, LA 135290, and LA 4618, the presence of conifer needles, bark, and low levels of cone scales throughout the occupation suggests access to either living or recently dead pine wood with attached branches. Presence of these same conifer parts is extremely low at LA 12587, perhaps indicating less access to pine and may explain in part the heavier reliance on saltbush/greasewood. Juniper twigs do not occur at any of the sites with frequencies above 4 percent, suggesting that branches may have been removed before use for construction or fuel. There may have been some deforestation, especially of the mesa tops, resulting in an environment advantageous for herbaceous vegetation over trees of the piñon-juniper woodlands and ponderosa pine forests of the lower elevations as Allen (2004:66) suggests. However, widespread depletion of conifer woods through time is not apparent in the archaeobotanical assemblage, although there is some evidence that lower-elevation conifers (juniper in particular) may have been depleted and higher-elevation woods became the primary resource for construction material in the Late Coalition. People of the Pajarito Plateau may have avoided cutting piñon trees for the reasons given below.

Although deforestation by prehistoric inhabitants has been suggested in several areas of the southwest such as Chaco Canyon (Betancourt and Van Devender 1981; Betancourt et al. 1983; Samuels and Betancourt 1982), Mesa Verde (Wyckoff 1977), and the Dolores area (Kohler and Matthews 1988), others (Windes and Ford 1996) have suggested otherwise. Windes and Ford found evidence for the practice of silviculture until late in the occupation of Chaco Canyon. Chacoans preserved nearby stands of piñon for nut collecting until the trees were beyond the prime productivity age (between 75 and 100 years of age Evans 1988:11; cited in Windes and Ford 1996:306). Deforestation of piñon in particular is counter to traditional harvesting practices documented by Ford (1968) at San Juan Pueblo where piñon is important both dietetically and for fuelwood. Piñon is their preferred firewood, so they gather any dead limbs from trees and by doing so maintain the health of the tree. Ford cites F. Phillips (1909:220) as asserting that if dead limbs are removed within two years after dying, the tree will be more productive and remain healthy. By collecting dead limbs and not cutting down trees for firewood, they preserve stands of piñon for nut collection and as a future source of dead limbs for fuel. With increasing importance of wild turkeys for either feathers or food (see Chapter 64, this volume), it would have been to the advantage of Pajaritans to preserve piñon trees for their nuts since "piñon nut crops are the turkey's 'corn' of the southwestern forest" (American Ornithologists' Union 1957).

Maize

Kernels

Six percent of the kernels recovered from LA 12587 were measured and the average height, width, and thickness are compared with kernels from LA 4624, LA 135290, and from the Airport 2 site in Table 62.96.

Table 62.96. Comparison of average *Zea mays* kernel measurements (in mm) from Los Alamos area sites.

Site	Number of specimens	Height	Width	Thickness
LA 12587	330	7.3	6.6	4.0
LA 4624	4	8.5	8.4	4.9
LA 135290	122	7.6	7.2	4.4
Airport 2	50	7.4	6.6	4.1
LA 4618	9	3.9	3.5	2.6

For a complete list of all kernel measurements see Appendix V. The kernels from Airport 2 were recovered by Frederick Worman in 1951 (Steen 1977) from Room 3 of the nine-room pueblo. At first glance, the kernels from LA 4624 seem like they are far more robust than those from the other three sites, but herein lies the danger in comparing such disparate data. It is impossible to know whether the four kernels from LA 4624 are representative of the entire population or not. In fact there are kernels from the other three sites that have similar measurements to the four kernels from LA 4624, but they are not a representative sample of the whole. As discussed earlier, morphometrics of the small sample of kernels from LA 4618, a Late Coalition site on Mesita del Buey, are half the size or less than those from other sites compared in Table 62.97 (see McBride 2006). Kernels were from either one of two kivas (Rooms 10 and 11) or from Room 13, a front room that had comparatively high taxonomic richness considering its poor condition. Why such diminutive kernels comprised the majority of the assemblage from the site is unknown.

The average width of kernels from LA 12587 and Airport 2 are identical, and average height and thickness are nearly so, suggesting a similar source of maize and preparation technique. King (1987) discusses the relationship between processing techniques and kernel distortion. From experimental replication, she found that kernels that had been boiled or treated with alkali before carbonization displayed a greater change in size, but less distortion than unprocessed kernels. Boiled or treated kernels do not pop or split and extrude their contents and were the only specimens from her study that did not become so misshapen that they were immeasurable. King goes on to say further that the increase in width and height, together with a usually missing embryo results in a crescentic shape, resembling many of the archaeological kernels examined from eastern North America. Goette et al. (1994) found that archaeological kernels most closely matched kernels that were experimentally boiled with wood ash and then charred. These kernels lacked a pericarp, the point of attachment was frequently missing, and embryos were occasionally missing.

Experiments by Steen (1982:44) suggest additional processing techniques. He tested white material on two-hand manos from two other sites on Mesita del Buey (LA 4627 and LA 4629) as well as deposits on six sherds from the base of a large corrugated jar found at LA 4716 on Mesita de los Alamos (all apparently Coalition period roomblocks). Raymond N. Rogers of the Laboratory staff determined the material was anhydrous lime. Steen concludes that the lime was added to corn and boiled to produce hominy.

Moderate kernel swelling was noted in 25 percent of the kernels from LA 12587 and loss of embryos in 37 percent. Thirty-six percent of the kernels were swollen at the Airport 2 site and loss of embryos occurred in only 10 percent of the specimens. Gross swelling was rarely observed at LA 12587, but kernels from the Airport site were very distorted and endosperm was often extruded, indicating the kernels were unprocessed and burned at a very high temperature and/or the moisture content of the kernels was fairly high (King 1987:145). The kernels from LA 135290 are slightly thicker and wider than those from LA 12587 and the Airport site and may have been treated with lime or had a higher moisture content when burned, causing slightly more swelling and loss of embryos (King 1987; Stewart and Robertson 1971). Thirty percent of the kernels were swollen and 47 percent lacked embryos. The condition of the kernels from LA 135290 suggests boiling and/or treatment with alkali. This type of treatment (supported somewhat by the indirect evidence found by Steen) could have been part of processing before storage and carbonization.

Several masses of kernels were present in collections from both LA 12587 and the Airport 2 site and the regular arrangement of the kernels of many masses indicates maize was stored on the cob and stacked in very orderly rows, multiple layers high. The cob rachis was burned away and ears were probably husked before storage (kernels were fused "head to head," with no husk remnants between and no space where a husk might have been). Several questions come to mind: 1) what burn conditions (temperature, oxygen content) would produce this condition? (intact kernels, fused ear-to-ear, but rachis consumed), and 2) what combination of desiccation and burn conditions would create this kind of maize specimen? These questions might be answered by conducting experimental burns of kernels at measured temperatures. Groups of kernels could be burned at varying intervals after harvest (i.e., one month, three months, etc.).

Finally, a disparity in the ratio of burned kernels to cupules could suggest a shift in maize processing (Adams and Bowyer 2002). A shift from parching or roasting to boiling might decrease opportunities for accidental kernel charring, and therefore the ratio of kernels to cupules would decrease. Looking at these ratios for Middle and Late Coalition C&T Project sites reveals an extremely low kernel to cupule ratio at LA 86534 and LA 4618 both in all proveniences and in thermal features (Table 62.97). This could indicate a greater proportion of kernels were boiled at the two sites, kernels were stored in features that were not discovered or sampled during excavation, or rooms were cleared out before abandonment. Another possibility is that we're seeing functional differences between sites with kivas and those without. Those with kivas could have been the focus of ceremonial activities while activities at those without formal ceremonial structures could have focused on agricultural pursuits.

Table 62.97. Percent presence of kernels and cupules from C&T Project Coalition period sites.

Site	All Contexts		Thermal Features	
	Kernels	Cupules	Kernels	Cupules
LA 86534	15%	94%	8%	19%
LA 135290	41%	81%	12%	19%
LA 12587	52%	95%	23%	35%
LA 4618	14%	100%	7%	9%

Cobs

Comparison of average cob diameter, cupule width, and row number from LA 86534, LA 135290, LA 12587, and LA 4618 (Table 62.98) indicates the cobs from LA 135290 are slightly more robust, with wider cupules, more rows, and larger diameters. Fourteen-rowed cobs, present at LA 135290 and LA 4618, are absent from the other two cob assemblages. However, the percentages of 12-row cobs are nearly equal in LA 12587 and LA 135290 cob assemblages (45% and 47%, respectively) and the distribution of 12- and 14-row cobs are equal in LA 4618 and LA 135290 assemblages. The lack of 14-rowed cobs at LA 12587 and LA 86534 may be a factor of sampling vagaries. Until larger sample sizes from equally well-dated sites can be obtained, it cannot be determined with any degree of certainty if the differences noted here can be attributed to natural variation within a population or if different maize varieties were grown on the Pajarito Plateau. Nickerson (1953:99) states that: "Within any race, many cobs possess characters the measurements of which lie well within the range of variation of the same measurements from several other races." In other words, the prospect of classifying races of maize in the archaeological record is dim.

Table 62.98. C&T Project comparison of average *Zea mays* cob measurements.

Site	No. of Cobs	Cob Diameter (in mm)	Cupule Width (in mm)	Row #	Distribution of Row #			
					8	10	12	14 +
LA 86534	5	9.5	4.8	10.4		4	1	-
LA 135290	17	11.9	5.6	11.4	2	4	8	3
LA 12587	20	10.3	5.2	10.0	6	5	9	-
LA 4618	20	9.8	4.9	11.1	3	6	8	3
Classic cobs	19	19.0	8.4	11.8	2	1	14	2

Numerous cobs have been collected during surveys that have been conducted over the years at LANL and four were directly dated for this project. The four unburned cobs dated to the Middle Classic period. One cob from Room 11 at LA 4628 dated to AD 1500, one that was an isolated occurrence in the TA-74 Tract dated to AD 1440, while the remaining two (one from Camp Hamilton Trail also in the TA-74 Tract and the other from the TA-39 Tract) dated to AD 1480. It is assumed that other cobs from LA 4628 and Camp Hamilton Trail date to the same general period and have been included in Table 62.99 (see Figures 62.11, 62.12, and 62.13). Because these cobs are all unburned, it is not possible to compare actual measurements with those of the C&T Project cobs. However, it is interesting to note that the distribution of row numbers as well as average row numbers for the LA 135290 (a Middle Coalition site) and the Classic period cobs are similar. The bulk of the cobs are 12-rowed, 14-rowed cobs and above are present, and there is a low number of 10- and 8-rowed cobs.

Table 62.99. LA 4628, Isolated Occurrence (IO) 6, TA-39, and Camp Hamilton Trail *Zea mays* cob morphometrics (in mm).

Agriculture on the Pajarito Plateau

Puebloan farmers manipulated the land and water sources to increase their chances of success. Dryland farming techniques included several methods of water harvesting, diversion, or increasing water retention of the soil. Water could be managed by building check dams across minor drainage channels such as those described by Steen (1982:43) to control erosion, slow run-off waters, and trap their alluvial deposits. This strategy replenished soils and spread water across fields slightly downslope. Grid gardens such as those documented in Bayo Canyon near Otowi (LA 21592), in White Rock Canyon (LA 12701), and at LA 139418 and LA 128803 have also been found in the Chama Valley, the Pot Creek area of Taos, and the Galisteo Basin. Grid gardens had partially or fully enclosing borders of cobbles that served to “catch and retain soil, block erosion from above or within the field, slow water movement across the planting bed, and conserve snow melt and water derived from direct rainfall” (Lang 1995:52). According to Lightfoot (1990:52–53), the use of cobble borders would by increasing surface roughness, create a more turbulent airflow over the plots and decrease daytime temperature of the soil. The decrease in the maximum daytime soil temperature would decrease moisture loss to evaporation.

Agricultural pursuits on the Pajarito Plateau change through time from a focus on farming mesa tops near habitations to more varied locations associated with fieldhouses at some distance from the aggregated pueblos of the Classic period. Complexes of cobble-bordered gardens such as those in the area of Otowi Pueblo attest to the use of water-conserving techniques. The placement of Classic period agricultural features on top of collapsed Coalition roomblocks (as at LA 12587 and in Bandelier, Gauthier and Herhahn 2005) affirms the ingenuity of Classic period farmers in their search for fertile agricultural land. Possible Classic period irrigation ditches were present at the White Rock Canyon site of LA 12701. One of these ditches was partially excavated and revealed the feature to be 2 m wide and about 40 cm deep, and lined with basalt slabs (Steen 1977:34). Irrigation canals or ditches have been documented in west-central New Mexico (Neely 1995), Pot Creek (J. Moore 1995), Zuni (Zuni Cultural Resource Enterprise 2000), and the Galisteo Basin (Lang 1995).

The question arises: were Classic period farmers maximizing efficiency and reducing risk by having multiple small fields in a range of topographical situations or were they specializing in the production of certain crops like tobacco for trade as proposed by Kohler (2004:263)? The presence of charred tobacco seeds at three of the C&T Project Classic period fieldhouses provides intriguing evidence that could support Kohler’s argument. On the other hand, their presence could signify the growing importance of tobacco as part of the ritual life of Pajaritans, such that its use was not restricted to ceremonial or circumscribed events.

Seasonality

Inferences concerning seasonality should be made using a combination of data from faunal, pollen, macrobotanical, and archaeological analysis results. Indeed, Brandt (1992) states:

> Inferring seasonality of site occupation based solely on the presence of plant remains is difficult for several reasons. First, certain plants do not follow calendric cycles. Second, climate may affect the production of seed and fruit by influencing abundance; flowering and fruiting can be delayed or stimulated. Finally, seeds and nuts may be stored through several seasons.

This chapter incorporates data from vegetal and flotation sample analysis only. For a discussion integrating these and data mentioned above please see Chapters 63 and 64 (this volume).

The wild plant assemblage from the project consists of taxa with seeds, leaves, or fruits that could have been gathered during the spring and fall, although the short list of taxa that set seed in spring were either absent or very scarce in the floral assemblage. Mustard, one of the earliest herbaceous plants to bloom and ripen, was not present and Indian ricegrass, another early arrival, was identified in less than one percent of samples. While the young leaves of tansy mustard and goosefoot can be collected in early April and those of beeweed in early summer, such fragile plant parts do not preserve in open-air sites. We are left with a wild plant assemblage that consists of plants with seeds or fruits that could only have been gathered during late summer and into the fall (Knight 1982). The seeds of goosefoot, pigweed, and purslane mature in mid to late summer, while cactus fruit, yucca fruit, and piñon nuts can be collected as late as October or November. A continuum of plant utilization from late spring through the fall can be inferred from the archaeobotanical assemblage. It is reasonable to assume that the larger habitation sites were occupied most or all of the year and fieldhouses were inhabited at least from spring, before the sowing of maize through harvest time.

THE C&T PROJECT HISTORIC DATA IN A REGIONAL PERSPECTIVE

LA 85407 (Serna Homestead), patented in 1922, was one of many homesteading ventures on the Pajarito Plateau that began in 1893 and ended when land was confiscated for the creation of LANL in 1942. Seasonal land use was frequently practiced by families who grazed livestock or farmed homesteads in the late spring through the fall, and then moved down to homes in the Pojoaque-Española Valley for the winter months. The previously investigated Romero Cabin and the adjacent McDougall and Roybal homesteads on Pajarito Mesa offer archaeological data from similar seasonal habitations (McGehee et al. 2006). Copious numbers of charred or uncharred weedy annuals like pigweed, goosefoot, beeweed, and purslane were present along with other seeds (e.g., doveweed and stickseed) that “colonize or invade waste areas and especially old fields on the plateau” (Tierney 1999a:49). Summer cypress, a weedy introduction from Eurasia that flourishes in waste places and open fields, was recovered at both the Serna and McDougall/Roybal Homesteads. Foxx and Tierney (1999) recorded all these plants growing in the Romero Cabin complex and an adjacent control plot. Remains of these prolific seed producers from all three sites are interpreted here to be natural seed rain or the result of burns (lightning strikes or field clearing). Therefore, the only plant material compared in Table 62.100 is that of cultigens and wild fruits. The Romero Cabin was more extensively sampled than the other two homesteads, particularly the McDougall/Roybal homestead where the house had burned down, leaving only a cistern and a root cellar for excavators to sample.

Table 62.100. Comparison of plant material from historic homesteads on the Pajarito Plateau.

Site	Serna Homestead	Romero Cabin	McDougall/Roybal Homestead
Cultigens			
Apricot		13 u	
Bean	1(0)

Summary of Historic Plant Remains on the Pajarito Plateau

Peaches were found at all three homestead sites (Table 62.100). At the Romero Cabin, Tierney (1999b) determined that two types of peaches were represented and were about half the size of commercial varieties, but resembled those of surviving heirloom varieties grown in the Rio Grande Valley that are hardy in New Mexico winters. These peaches are likely of local origin, either from trees grown on the homesteads or brought up from the Pojoaque-Española Valley. There is no mention in written records of vineyards at either of the two homesteads where grapes were found, neither are they listed in interviews with residents and descendants of residents (Tierney 1999c) as fruits that were grown on the plateau. The seed from LA 85407 measures 4.2 mm in length, 2.7 mm wide, and 2.2 mm thick. The uncharred specimen from the McDougall Roybal homestead is 4.0 mm long, 3.4 mm wide, and 2.4 mm thick. Measurements of a domestic variety (uncharred) were 2.0 to 2.2 mm longer, 0.9 to 1.6 mm wider, and 0.4 to 0.6 mm thicker. Charring could account for much of the differences between the seed from LA 85407 and the modern specimens, but the seed from the McDougall/Roybal homestead is most likely from the wild canyon grape (*Vitis arizonica*). Beans, referred to by past residents as the primary cash crop grown on the plateau, were only found at the Serna Homestead. Low recovery of bean remains is related to the fragility of beans and threshing and preparation methods. Beans may be removed from the pods outside the house and preparation does not usually involve parching or frying. The thin, brittle seed coat of beans leaves them vulnerable to consumption by animals or insects.

Apricots, maize, zucchini squash, pumpkins, and cherries were listed among the crops grown on the plateau and were in evidence in the Romero Cabin samples. Plum pits identified at the Romero Cabin included those of the domesticated plum (a tree was found still living near the cistern on the homestead), a native wild plum, and a flowering plum. Squash seeds were from pumpkin, summer, or winter squash varieties. Although watermelon is not mentioned in interviews with settlers of European descent, San Ildefonso Indians told J. P. Harrington that watermelons were once grown in Sandia Canyon (aptly named by the Spanish; cited in Tierney 1999b). By all accounts, it appears that homesteaders on the Pajarito Plateau were successfully growing a variety of fruits and vegetables, especially beans, which were shipped out by the train load (Chambers 1974: cited in Foxx and Tierney 1999).

Wood from the McDougall/Roybal and Serna Homesteads was analyzed and ponderosa, recovered in every flotation and vegetal sample with charcoal present, was most likely the preferred construction material. The sawmill in the little town of Buckman, New Mexico, was probably where trees from the Pajarito Plateau were cut into boards and subsequently brought back to the plateau where they were used in floors, while the unmilled beams were used for the infrastructure. Small amounts of juniper, piñon, and oak were recovered and may have been used for firewood or smaller construction elements.

At LA 85864, another historic site not listed in Table 62.100, a seed that closely resembled a wheat grain was recovered, possibly documenting the use of this European domesticate by Jicarilla Apache at the turn of the century.

SUMMARY AND CONCLUSIONS

Maize agriculture appears to have been the backbone of the prehistoric subsistence regime on the Pajarito Plateau. Much lower ubiquities of beans and possible squash are probably more factors of preservation biases than a measure of their importance in the diet. Maize cobs from Coalition period roomblocks were predominately 12-rowed, with the exception of the five cobs from LA 86534, where 10-rowed cobs were most common. The majority of cobs collected from Classic period sites during survey at LANL were also 12-rowed, indicating a continuing trend toward selection of 12-rowed varieties adapted to high-elevation growing conditions.

Weedy annual taxa were the most commonly encountered category of wild plant remains and included beeweed, bugseed, goosefoot, pigweed, purslane, sunflower, tobacco, and winged pigweed. Grasses and perennial taxa were less diverse than annuals; two grass taxa (dropseed grass and ricegrass) were identified and six perennials (banana yucca, dock, hedgehog cactus, globemallow, pincushion cactus, piñon, and prickly pear cactus) that were not related to fuel use.

The wood assemblage is predominately coniferous with juniper, piñon, and ponderosa pine most common in flotation and vegetal samples. Saltbush/greasewood, mountain mahogany, and oak were non-conifer woods most often identified in flotation and vegetal samples. There is some evidence that access to piñon and ponderosa at LA 12587 was limited and may have caused a heavy reliance on juniper and shrubs like saltbush and sagebrush.

Comparison to other sites in the Pajarito Plateau region suggests a similar subsistence regime of maize agriculture, with beans and squash in evidence from all time periods except the Early Coalition when squash is absent from the record. Annual plant use is focused on goosefoot, pigweed, and purslane that readily volunteer in agricultural fields. Tobacco is found at sites dating from the Middle Coalition through the Classic period, found at roomblocks as well as Classic period fieldhouses, suggesting a continuum of ritual activity. The comparatively scarce occurrence of perennial and grass taxa at C&T Project sites is mirrored in the assemblages from other sites on the Pajarito Plateau. Wood procurement is focused on conifers, with very light use of the riparian corridor throughout the occupation. Although historic accounts of homesteading on the Pajarito Plateau in the early 20th century focus on beans as the primary cash crop, little evidence of bean farming has survived. Watermelon seeds and the stony pits of fruits such as peaches and plums preserved well and of course maize, the enduring mainstay of the southwest, was present and accounted for.

CHAPTER 63
POLLENS' EYE VIEW OF ARCHAEOLOGY ON THE PAJARITO PLATEAU

Susan J. Smith

INTRODUCTION

The pollen research component for the Los Alamos National Laboratory (LANL) Land Conveyance and Transfer (C&T) Project is an ambitious investigation of 478 archaeological samples from 38 sites dating primarily to the Coalition through Classic periods, complemented by two supporting studies of natural pollen representation from 39 surface and subsurface samples (Table 63.1). Another 117 pollen samples from 11 archaeological sites on Los Alamos lands have also been documented (see Previous Research section below).

Table 63.1. Number of C&T Project pollen samples analyzed by land tract and for special studies.

Tracts	Sites or Stations (Geology and Modern Pollen)	Number of Samples
White Rock	6	159
Airport	4	154
Otowi North	1	11
Rendija	27	154
Archaeological Component Totals	**38**	**478**
Modern pollen study (Smith 2007a)	20	20
Geology soil pits study[a]	5	19
Special Studies totals	**25**	**39**

[a]An additional 23 geology samples collected during site excavations are included under the archaeological component (see Table 63.2).

The majority of sites were 100 percent excavated and intensively sampled during the C&T Project data recovery phase. There are three major site types represented: pueblo roomblocks, fieldhouses, and gardens. Suites of samples from all of the major contexts at each site were analyzed (Table 63.2). The numbers of pollen samples and distribution in structure floors and fill at each site comprise a remarkably complete statistical population of the archaeopollen spectra on the Pajarito Plateau. This data set allows more detailed analyses than is usually possible when only portions of sites are excavated or token numbers of samples analyzed.

The project and the pollen results are organized by the three land tracts: White Rock, Airport, and Rendija. Almost half of the C&T pollen samples come from three pueblos (Table 63.2)—a Late Coalition period site in the White Rock Tract (LA 12587) and two Middle Coalition roomblocks in the Airport Tract (LA 86534 and LA 135290). The next largest group of samples is from fieldhouses and the majority of those are in the Rendija Tract and date primarily to the Classic period. Fifty-eight samples were also collected from gardens at four of the sites.

Table 63.2. Number of C&T Project pollen samples by sites and contexts.

*Three garden samples at LA 12587 are rock piles.

The C&T Project archaeological pollen investigation was guided by the following four research questions:

1. *What subsistence resources are visible in the pollen spectra at individual sites?* This research theme was explored by comparing and contrasting samples from primary cultural contexts, such as floors and hearths, to post-occupation fill and wallfall samples. Maize pollen is almost ubiquitous at every pre-Columbian habitation site investigated, testifying to the fact that farming was the mainstay of the pueblo economy. Correlations between the abundance of maize and other cultigens with wild, native resources and comparisons between archaeological and modern surface control samples are another tool used here to unravel the native cultural resources from the environmental background pollen.

2. *Is there any information that might reflect the seasons sites were occupied or the duration of occupation?* The pueblos and fieldhouses excavated for the C&T Project were obviously occupied for different purposes. Comparisons of these two site types offer an ideal test of this research theme.

3. *Can different contexts be defined by discrete pollen signatures? Can storage rooms be differentiated from habitation rooms in the roomblocks?* The roomblocks provide a rich database of multiple samples carefully collected from almost every room and feature. This extensive data set makes it possible to investigate the distribution and abundance of economic pollen taxa by context.

4. *Are there any chronological trends or patterns in the economic pollen signatures?* The C&T Project data are particularly suited to critically examine the question of chronological changes between the Coalition and Classic periods. Most of the habitation and fieldhouse sites are single component, or with limited reuse, except for the pueblos at LA 12587. There are a few Late Archaic scatters represented in the pollen data, but the exposed environmental setting of these camps and limited activity sites combined with the age of the sites produced only ambiguous results.

PREVIOUS RESEARCH

There is an atypical wealth of environmental information concerning ecosystems, fire history, and botany on the Pajarito Plateau due to well-funded LANL programs and academic and National Park Service research conducted at Bandelier National Monument, the Valles Caldera, and the Jemez Mountains (Table 63.3). Although the history and consequences of environmental change in the Jemez Mountains are not the topic of this chapter, it is pertinent and important to acknowledge that the modern landscape is significantly changed from pre-Columbian times. Vorsila Bohrer has recognized profound historic changes in modern landscapes and the implications to archaeobotanical studies, stating that “our botanical understanding of the land could be historically nearsighted” (Bohrer 1978:11).

Within the past 200 years, the Jemez Mountains have experienced complex and at times intensive land uses (e.g., grazing, logging, and water control) that in combination with climatic cycles have initiated a cascade of environmental responses (Nabhan et al. 2004). Forest and woodland tree densities on the Pajarito Plateau have increased approximately tenfold since the pre-AD 1900s, reducing the cover and diversity of understory herbs and shrubs and increasing the incidence of catastrophic wildfire (Allen et al. 1998; Swetnam et al. 1999). The area of montane grasslands shrank by greater than 50 percent within the relatively short span of 46 years (AD 1935–1981) due to tree invasions (Allen 1998), and exotic, introduced plant species are displacing native plants at an alarming rate, especially in the increasingly limited riparian habitats. Foxx (2006:Appendix B) has documented 74 non-native plant species on the Pajarito Plateau and in the Jemez Mountains. The pre-Columbian landscapes on the Pajarito Plateau were undoubtedly richer in native plant and wildlife species with more open forests and extensive grasslands compared to modern ecosystems.

In contrast to the ecological disciplines, there has been only minimal archaeobotanical investigation on the Pajarito Plateau and in the upper Rio Grande Valley—a surprising gap given the number of spectacular ruins and archaeological research in the region. Most of the inquiry into past plant use has focused on macrobotanical materials. Pollen studies were extremely rare until the late 1990s (Table 63.4).

M. Toll (1992) has reviewed the scant botanical information from regional sites dating from Late Coalition to Spanish contact. She concluded that by the late AD 1500s, pueblos were dependent on maize agriculture with use of beans and squash and a variety of wild foods, particularly weedy cheno-am annuals, such as goosefoot and pigweed. Toll (1992:51) reported that cotton macro remains are conspicuously absent from any site of strictly Puebloan association in the Rio Grande Valley; this situation has changed with the cotton pollen reported here from Coalition and Classic sites on the Pajarito Plateau and from fields along the Rio Grande near San Ildefonso.

Pollen Study	Reference	Number of Pollen Samples	Results
Bandelier National Monument			
LA 60372 Burnt Mesa Pueblo, profile through kiva fill	Huber and Kohler 1993	15	30 samples were processed, but half were evaluated sterile; interpreted economic taxa include maize, squash, beeweed, grasses, cattail, parsley family, sunflower family, mustard, and fern spores; high conifer-low cheno-am in modern surface and low conifer-high cheno-am in fill interpreted as deforestation signal.
Six sites in and near Alamo Canyon	Fish 1982	25	Cheno-am signature in fill and floors and contrasting high conifer pollen in modern samples interpreted as evidence of cultural activities; economic taxa include maize, beeweed, *Opuntia*, and lily family.
Five sites in and near Capulin Canyon including Shohakka pueblo (LA 3840), Classic 90-room plaza pueblo; one site above Frijoles Canyon	Smith 1998a	50	Economic types: maize, squash, cholla, prickly pear, beeweed, purslane, nightshade family, parsley family, grasses, *Helianthus* type (sunflower), sedge, cattail, and possible reed grass (*Phragmites*) and dove weed (*Croton*).
Pajarito Plateau			
Modern analog pollen study, elevational transect of the Pajarito Plateau	Smith 2007a	20	Modern pollen spectra generally track local vegetation; disturbance areas characterized by weedy pollen types; riparian locales also register in soil samples with riparian pollen types.
Geology soil pits pollen study	Smith (unpublished data)	19	Strong preservation gradient destroys most conifer pollen below ca. 5 cm.
Mesita del Buey possible field areas	Bohrer 1982	14	Field pollen samples scanned for cultigens; maize, prickly pear, and cattail documented.
LA 4624, Mesita del Buey, roomblock	McBride and Smith 2002	3	Economic types: maize, cholla, prickly pear.

Pollen Study	Reference	Number of Pollen Samples	Results
LA 4618, Mesita del Buey, roomblock with two kivas	Smith 2006a	57	Economic types: cotton, squash, maize, cholla, prickly pear, beeweed, grass, sunflower family, sagebrush, evening primrose, nightshade family (includes tobacco), mustard family, a type referred to as marshelder, purslane, an unknown referred to as small sage, and another unknown probable four o'clock family.
LA 4619, Mesita del Buey, roomblock (samples from outside the pueblo)	Smith 2007b	10	LA 4619 adjacent to LA 4618; 4 soil pits dug into the sediment apron on the northeastern side of LA 4619; maize pollen recovered from 3 samples.
LA 131237, McDougall Homestead	Smith 2006b	9	No cultigens; enriched subsurface cheno-am related to ground disturbance.
LA 21596 Otowi (South) grid gardens, (13 samples); LA 61034, LA 61035, LA 86531 - three artifact scatters and LA 21150, LA 110130, LA 86528 - three small sites	Smith 2007c	24	Economic types: maize and squash in the grid gardens; maize at LA 86528 and LA 86531; grass at LA 61034 and LA 61035.

One of the landmark archaeobotanical sites in the Southwest is Jemez Cave on the west side of the Jemez Mountains and north of Jemez Springs (Alexander 1935; Ford 1975). The record encompasses a long period of human use; corn kernels recovered from the cave were recently dated to 1380–1100 BC (Vierra and Ford 2006:503). Excavations documented an array of worked stone, wood, and fiber artifacts. Sandals made from yucca and Indian hemp (*Apocynum* sp.), a variety of cords, some made from cotton, a cotton head band, two feather cloaks, and worked skins were part of the Jemez Cave assemblage, and maize and squash remains were common.

In a study of two AD 1700s medicine baskets found in a dry shelter in the Galisteo Basin, New Mexico, M. Toll and McBride (1996) documented a suite of 14 root types that included osha (*Ligusticum porteri*), iris (cf. *Iris missouriensis*.), dock (*Rumex* sp.), and possibly datura (*Datura* sp.) and gayfeather (*Liatris punctata*). Other materials in the baskets were stems and leaves of grasses and silvery scurfpea (*Psoralea argophylla*), a corn husk container, ties made from corn leaves and yucca strips, and bark pieces of corkbark fir (*Abies lasiocarpa* var. *arizonica*), ponderosa pine (*Pinus ponderosa*), and Douglas fir (*Pseudotsuga menziesii*). These assemblages preserve a remarkable perspective on a traditional tool kit of medicinal plants that are practically invisible in the archaeological record, since root resources rapidly degrade and pollen is typically not retained on these parts. The medicine baskets are also important because they date to the period when native pueblo medicinal and subsistence practices were being transformed by Spanish colonial rule.

The standard for New Mexico archaeopalynology since 1986 has been Vorsila Bohrer's study at Arroyo Hondo, near Santa Fe (Bohrer 1986). Arroyo Hondo is located several miles south of the main plaza of Santa Fe on the western margin of the foothills of the Sangre de Cristo Mountains. The pollen results from 42 pollen samples from Arroyo Hondo, the majority from a plaza, were interpreted to record evidence of agriculture (squash and corn pollen) and use of several native plants, such as buckwheat (*Eriogonum*), beeweed (*Cleome*), sunflower (*Helianthus*), cacti, cholla (*Opuntia*), prickly pear (*Opuntia*), cattail (*Typha*), and cheno-am. One pollen grain of datura (*Datura* sp.) was also recovered in a sample from a basin, which Bohrer (1986:204) suggested could be related to medicinal practices. One of the innovative approaches used by Bohrer (1986) was to test cultural pollen samples against subsurface soil samples taken from non-cultural strata.

The first pollen study in the Los Alamos region was in 1982 (Bohrer 1982). Fourteen pollen samples from possible field areas on Mesita del Buey were analyzed and maize, prickly pear, and cattail pollen identified. Bohrer (1982) evaluated the cattail pollen as natural from local sources or possibly evidence that there was a nearby prehistoric reservoir. At Bandelier National Monument, Fish (1982) conducted one of the first detailed pollen studies, which included 25 pollen samples from six sites.

The first systematic archaeological investigations were completed in the early 1980s for the Cochiti Lake flood pool in Bandelier National Monument (Hubbell and Traylor 1982) followed by the Bandelier Archaeological Project in the early 1990s (Kohler 1990; Kohler and Root 1992b). Matthews (1990, 1992) analyzed macrobotanical samples for the Bandelier Archaeological Project, and there was one limited pollen study—analysis of a profile of samples from 2.7 m of sediment filling a kiva (Room 1, Area 1) at Burnt Mesa Pueblo (Huber and Kohler 1993). Huber and Kohler (1993) reported only on 15 samples out of 30 processed; half of the pollen samples were rejected based on scan evaluations that there was insufficient pollen for statistical counts. The 15 productive samples produced a pattern typical of southwestern archaeological sites. High conifer pollen in the top surface samples is replaced by progressively higher representation of weed taxa (cheno-am and sunflower family) down through various levels of fill. Huber and Kohler (1993) interpreted the Burnt Mesa results as representing deforestation during the early stages of site occupation. This pattern is discussed in more detail using the C&T Project results presented here and is shown to be first a natural phenomenon in natural stratigraphic profiles and second a probable expression of weeds and camp followers growing on the disturbed ground around sites.

The numbers and level of detail of archaeobotany studies on the Pajarito Plateau have dramatically increased with the advent of the C&T Project and peripheral studies (see Table 63.4). One hundred and three pollen samples have been analyzed from 10 sites and another 39 samples have been completed for analog studies, all within the past five years.

The recent research on the Pajarito Plateau documents a strong agricultural tradition. Maize and squash were cultivated throughout the region, and although invisible through pollen analysis, macrobotanical studies show that beans were also part of the farming economy (Chapter 62, this volume). Cotton is another crop resolved by recent pollen studies and in the C&T Project results. Cotton may have been grown only at the larger pueblos, probably with some form of irrigation or at least pot watering. Prickly pear, cholla, and lily family are consistently recorded at sites (Table 63.4) and were undoubtedly important subsistence resources. Beeweed is another common economic plant resolved by the pollen studies.

Larger sites that were occupied longer are characterized by more diverse assemblages; LA 4618 on Mesita del Buey is one such site. LA 4618 was a Late Coalition nine-room pueblo with two kivas. The roomblock may have been hastily abandoned, as tools and artifacts still in usable condition were recovered, but there is evidence of burning in the rooms and kivas (Schmidt 2006b). The pollen record from LA 4618 is one of the best in the region because of the rich assemblages.

Summary of Pajarito Plateau Pollen Analog Studies

Two pollen analog studies were completed for the C&T Project: a study of 20 modern pollen stations (Smith 2007a) and a study of geology soil pit profiles. The results of these studies are reported in Volume 1, but a brief summary is included here because the characterization of natural pollen representation from the local landscape is an important component for the C&T Project archaeopalynology, providing critical baseline data.

The LANL modern pollen analog was constructed from the 20 stations located along an elevational transect from the piñon and juniper woodland to above the spruce fir forest (Smith 2007a). The natural pollen spectra is sensitive to the elevation and vegetation gradient and to finer-scale compositions that reflect local site histories. Piñon and juniper woodland, ponderosa pine, and high-elevation mixed conifer forests are differentiated by changing percentages of fir, pine, and juniper pollen. Cheno-am, sunflower family, and sagebrush characterize disturbed areas, such as historic fields. Cheno-am, sunflower family, and grass pollen also distinguished two meadows that were sampled. Riparian sites are scarce, but the only station where cattail was growing yielded the only cattail pollen recovered in the modern study. Other indicator pollen types are Douglas fir and limber pine (*Pinus flexilis*) from mixed conifer forests, maple and birch from mesic sites, willow from riparian environments, and sagebrush, thistle, and cf. sunflower (*Helianthus* type) from disturbed sites.

The geology pollen study consisted of analysis of 42 pollen samples collected from soil pits that were excavated as part of the C&T Project geology and geomorphology investigations (Drakos and Reneau 2003, 2004). The pollen samples were collected primarily in vertical columns from soil pit walls in order to reconstruct, if possible, any paleoenvironmental history that might complement the geomorphology research and other regional pollen studies (see Chapter 5, Volume 1).

Only 25 of the 42 geology samples contained adequate pollen to describe statistically significant pollen populations. The problem is preservation, which is evident down-profile by increasing frequencies of pollen too degraded to identify and corresponding diminishing pollen density, as estimated by pollen concentrations. Four consistent patterns were evident in the soil pit results:

1. The abundance of pollen decreases dramatically from A to B soil horizons and continues dropping with depth below surface. After approximately 10 to 20 cm depth below ground surface, pollen density is thinned by 70 percent to 90 percent of the surface concentration.

2. The decrease in pollen concentrations with depth is explained by a significant increase in the frequencies of pollen too degraded to identify.

3. The preservation gradient is also a function of differential loss of more conifer pollen than other types; 10 percent to 65 percent of the conifer pollen in surface samples is lost below A horizon levels.

4. Trends in cheno-am pollen are more variable, but generally cheno-am percentages increase with depth in soil profiles, from less than 1 percent in A horizon and surface samples to 42 percent in B horizon and deeper levels.

LIMITATIONS OF POLLEN DATA

Not every pollen type recovered in an archaeological sample is significant or related to past cultural activities. Very little is known about how pollen is moved and deposited during the various steps involved in producing and consuming food, but recent empirical data show that each plant species registers differentially in the archaeological pollen record (Geib and Smith 2007). And there is a significant component of “other” pollen types always present that hitchhike along on harvested plant materials. These other taxa represent the atmospheric pollen rain and local vegetation where plants were harvested and these can be more abundant in pollen samples than the harvested taxon (Geib and Smith 2007).

Another ecological characteristic important to understanding how pollen works in archaeological sites is that pollen signifies flowers, and with some notable exceptions (e.g., use of corn pollen), most of the plant products harvested for subsistence were well past the flowering stage. Pollen analysis is biased toward plants that leave a strong pollen record. Thus, while some plants will be missed entirely, such as root crops, others are easily detected through the pollen lens. Cholla is an example of a resource that is visible to pollen studies, because flower buds full of pollen were often the harvested resource.

The probability of recovering certain pollen taxa is also greatly influenced by pollination ecology. Most plant species can be divided into two categories—wind pollinated and insect pollinated. Wind-pollinated plants such as pine (*Pinus*), sagebrush (*Artemisia*), and grass (Poaceae) produce abundant pollen, but the insect-pollinated plants, such as herbs, forbs, and berries, produce small amounts of pollen designed to hitchhike short distances on insects or remain within the parent flower. A single pine tree may produce more than a billion wind-transported pollen grains, whereas *Plantago* (plantain) may produce fewer than 100 pollen grains (Fægri and Iversen 1989:12). Abundance of an insect-pollinated plant in archaeological contexts is thus indicative of cultural use, but can also result from other vectors, such as insects.

Identifying trends in archaeological pollen data is often a subjective and sometimes intuitive process. A theoretical model describing the pollen characteristics from the different types of archaeological contexts is summarized in Table 63.5. Unlike paleoenvironmental records from stable collecting basins such as lakes and bogs (Prentice 1985), the pollen record from archaeological sites cannot be analyzed as a steady-state phenomenon. Spikes in pollen abundance in archaeological features may reflect human activities (e.g., construction, firewood gathering, and food processing) or physical, biological, and chemical processes in site soils (e.g., bioturbation and sheetwash). As with macrobotanical analyses, archaeological pollen records contain a history of accidents, events, or unusual preservation situations. Past cultural activities can be inferred from archaeological pollen records when pollen is represented over what would be expected from natural background pollen rain, mediated by an understanding of how natural soil processes work. Another class of evidence is the repeated associations of pollen types by context (Bohrer 1981). Both avenues of inquiry are used here to identify plant resources resulting from human activities.

Table 63.5. Theoretical model of pollen taphonomy in archaeological sites.

Context	Pollen Source Areas	Time Involved	Typical Pollen Spectra and Characteristics
Floors	Natural – from natural atmospheric pollen rain and insects and wildlife coming into structure (dead and alive). Cultural – deliberate import of plant materials adds pollen from the harvested plant plus hitchhiking pollen from plants surrounding the harvested resource. This extraneous component comes in on crop materials, as well as people, tools, and fire wood. Interior pollen rain from roof thatch materials is another cultural source area.	Duration of occupation	Spiky values but tend towards lower pollen concentrations; cheno-am and other weedy taxa usually dominant; highest expression of subsistence pollen types.

Context	Pollen Source Areas	Time Involved	Typical Pollen Spectra and Characteristics
Fill	Natural – sheetwash primary source, runoff is funneled into depressions of houses, pits, and other structures. Aeolian deposition also may rework sediments. Cultural – wallfall, rooffall, trash from post-occupation use of structure depressions, and reworked trash material from site footprint.	No data. Relatively rapid, less than 50 (?) years; episodic depositional events.	Low to high pollen concentrations; cheno-am and other weedy taxa usually dominant.
Modern surface controls	Natural – there is an issue of *no modern analog comparable to prehistoric natural landscapes*; modern woodlands and forests are unnaturally dense with less understory due to historic fire suppression and over-grazing.	No data. Estimate 10 to 100 (?) years; relatively consistent accumulation rates.	In woodlands and forests, high pollen concentrations, high percentages of conifer pollen, low percentages of weedy taxa and degraded pollen.

METHODS

Two types of pollen samples were processed and analyzed—pollen washes of artifacts and bulk sediment samples.

Pollen Extraction of Sediment Samples
