## Department of Energy

Washington, DC 20585

November 28, 2000

Dear Interested Party:

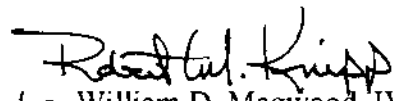

The *Final Programmatic Environmental Impact Statement for Accomplishing Expanded Civilian Nuclear Energy Research and Development and Isotope Production Missions in the United States, Including the Role of the Fast Flux Test Facility [NI PEIS]* (DOE/EIS-0310) has now been completed. This document has been prepared in accordance with the National Environmental Policy Act and reflects consideration of comments received on the draft NI PEIS released in July 2000.

The Department of Energy (DOE) is responsible for undertaking research and development activities related to development of nuclear power for civilian use, meeting the nuclear material needs of other Federal agencies, and ensuring the availability of isotopes for medical, industrial, and research applications. The NI PEIS presents an evaluation of the potential environmental impacts associated with the proposed expansion of the nuclear irradiation capabilities for accomplishing civilian nuclear energy research and development activities, accommodating the projected growth in demand for medical and industrial isotopes, and production of plutonium-238 to support future National Aeronautics and Space Administration space exploration missions. In addition to the "No Action" alternative, DOE evaluated other alternatives that include using operating facilities within the DOE complex, building a new research reactor, building one or two accelerators, and restarting the Fast Flux Test Facility (FFTF) that is currently in standby status. In addition, the NI PEIS includes an alternative to permanently deactivate FFTF.

After careful consideration of public comments, environmental impacts, and programmatic objectives, DOE's preferred alternative is to use its existing nuclear facility infrastructure to the extent possible to pursue the missions outlined in the PEIS, i.e., Alternative 2, Option 7. DOE would reestablish domestic production of plutonium-238, as needed, using the Advanced Test Reactor in Idaho and the High Flux Isotope Reactor in Tennessee and would process irradiated plutonium-238 targets at the Radiochemical Engineering Development Center in Tennessee. DOE would permanently deactivate FFTF under the "Preferred Alternative." Lack of clear commitments from likely users discouraged the Department from planning to build new facilities or to restart the FFTF. Further details on the Preferred Alternative can be found in the summary and in section 2.8 of volume 1 of this NI PEIS.

We appreciate your continued participation in this decision-making process.

Sincerely,

  
for William D. Magwood, IV, Director  
Office of Nuclear Energy, Science  
and Technology

**Abstract:** Under the authority of the Atomic Energy Act of 1954, as amended, the DOE is responsible for ensuring the availability of isotopes for medical, industrial and research applications, meeting the nuclear material needs of other Federal agencies, and undertaking research and development activities related to development of nuclear power for civilian use. To meet these responsibilities, DOE maintains nuclear infrastructure capabilities that support various missions. Current estimates for the future needs of medical and industrial isotopes, plutonium-238, and research requirements indicate that the current infrastructure may soon be insufficient to meet the projected demands. DOE proposes to enhance these capabilities to provide for: (1) production of isotopes for medical and industrial uses, (2) production of plutonium-238 for use in advanced radioisotope power systems for future National Aeronautics and Space Administration (NASA) space exploration missions, and (3) the Nation's nuclear research and development needs for civilian application.

This NI PEIS evaluates the environmental impacts of a No Action Alternative (maintaining status quo), four alternative strategies to accomplish this mission, and an alternative to permanently deactivate the Fast Flux Test Facility (FFTF), with no new missions. Alternatives 2, 3, and 4 also include permanent deactivation of FFTF. The alternatives are:

- No Action
1. Restart FFTF at Hanford, Washington
  2. Use only existing operational facilities
  3. Construct one or two new accelerators
  4. Construct a new research reactor
  5. Permanently deactivate FFTF (with no new missions)

The Preferred Alternative is Alternative 2, Option 7, Use Only Existing Operational Facilities. DOE would reestablish domestic production of plutonium-238, as needed, using the Advanced Test Reactor in Idaho and the High Flux Isotope Reactor in Tennessee, and would process irradiated plutonium-238 targets at the Radiochemical Engineering Development Center in Tennessee. DOE would permanently deactivate FFTF under the Preferred Alternative.

**Public Comments:** The Draft NI PEIS was issued for public review and comment on July 21, 2000. The comment period ended on September 18, 2000, although late comments were considered to the extent practicable. Public hearings were held to obtain comments on the Draft NI PEIS in Oak Ridge, Tennessee; Idaho Falls, Idaho; Hood River and Portland, Oregon; Seattle and Richland, Washington; and Arlington, Virginia. All comments were considered by DOE in preparing the Final NI PEIS, which also incorporates any new information received since issuance of the Draft NI PEIS. In response to comments on the Draft NI PEIS and as a result of information that was unavailable at the time of the issuance of the Draft PEIS, the Final PEIS contains revisions and new information, indicated by a sidebar in the margin. Volume 3 contains the comments received during the public review period for the Draft NI PEIS and DOE's responses to these comments. DOE will use the analyses presented in the Final NI PEIS as well as other information, including public input, costs, nonproliferation impacts, schedules, technical assurance, and other policy and programmatic objectives, in preparing the Record of Decision for accomplishing expanded civilian nuclear energy research and development and isotope production missions in the United States, including the role of FFTF. DOE will issue the Record of Decision no sooner than 30 days after the U.S. Environmental Protection Agency publishes a notice of availability of the Final NI PEIS in the Federal Register.

## Summary

### S.1 PURPOSE AND NEED FOR AGENCY ACTION

Under the authority of the Atomic Energy Act of 1954, as amended, the U.S. Department of Energy (DOE) is responsible for ensuring the availability of isotopes for medical, industrial and research applications, meeting the nuclear material needs of other Federal agencies, and undertaking research and development activities related to development of nuclear power for civilian use.

To meet these responsibilities, DOE maintains nuclear infrastructure capabilities that support various missions in areas such as nuclear materials production and testing, research, and development activities related to civilian applications of nuclear power. These infrastructure capabilities include research and test facilities such as research reactors and accelerators used for steady-state neutron irradiation of materials to produce radionuclides, as well as shielded “hot cell” and glovebox facilities used to prepare materials for testing and/or to handle postirradiation materials. An additional component of this infrastructure is the highly trained workforce that specializes in performing complex tasks that have been learned and mastered over the life of these facilities.

Over the years, DOE’s nuclear facility infrastructure has diminished because of the shutdown of facilities, recent examples being the High Flux Beam Reactor at Brookhaven National Laboratory (BNL), New York, and the Cyclotron Facility at Oak Ridge National Laboratory (ORNL), Tennessee. This, in turn, has hampered DOE’s ability to satisfy increasing demands in various mission areas. To continue to maintain sufficient irradiation facilities to meet its obligations under the Atomic Energy Act, DOE has assessed the need for expansion of its existing nuclear infrastructure in light of its commitments to ongoing programs, its commitments to other agencies for nuclear materials support, and its role in supporting civilian nuclear energy research and development programs to maintain the viability of civilian nuclear power as one of the major energy sources available to the United States.

The Nuclear Energy Research Advisory Committee (NERAC) was established in 1998 by DOE in accordance with the Federal Advisory Committee Act to provide independent, expert advice on complex science and technical issues that arise in the planning, management, and implementation of DOE’s civilian nuclear energy research programs. The chairman of NERAC has informed the Secretary of Energy that:

- “There is an urgent sense that the nation must rapidly restore an adequate investment in basic and applied research in nuclear energy if it is to sustain a viable United States capability in the 21<sup>st</sup> Century.”
- “[T]he most important role for DOE [Office of Nuclear Energy, Science and Technology] in the nuclear energy area at the present time is to ensure that the education system and its facility infrastructure are in good shape.”
- “Of particular need over the longer term are dependable sources of research isotopes and reactor facilities providing high volume flux irradiation for nuclear fuels and materials testing” (Duderstadt 2000).

Under the guidance of NERAC, DOE has completed an internal assessment of its existing nuclear facility infrastructure capabilities. This *Nuclear Science and Technology Infrastructure Roadmap* evaluates the existing DOE infrastructure, and identifies gaps in that infrastructure for meeting projected demands (DOE 2000a). The basic finding of this assessment also concluded that the capabilities of currently operating

DOE facilities will not meet projected U.S. needs for nuclear materials production and testing, research, and development.

Consistent with these findings, DOE recognizes that adequate nuclear research reactor, accelerator, and associated support facilities must be available to implement and maintain a successful nuclear energy program. As demand continues to increase for steady-state neutron sources needed for isotope production and civilian nuclear energy research and development, DOE's nuclear infrastructure capabilities to support this demand have not improved. To continue meeting its responsibilities under the Atomic Energy Act and to satisfy projected increases in the future demand for isotope products and irradiation services, DOE proposes to enhance its existing nuclear facility infrastructure to provide for: (1) production of isotopes for medical, research, and industrial uses, (2) production of plutonium-238 for use in advanced radioisotope power systems for future National Aeronautics and Space Administration (NASA) space exploration missions, and (3) support of the Nation's civilian nuclear energy research and development needs.

To evaluate the potential environmental impacts associated with this proposed enhancement, DOE has prepared the *Programmatic Environmental Impact Statement for Accomplishing Expanded Civilian Nuclear Energy Research and Development and Isotope Production Missions in the United States, Including the Role of the Fast Flux Test Facility (Nuclear Infrastructure Programmatic Environmental Impact Statement [NI PEIS])*. The NI PEIS evaluates impacts from new facility construction, modification, startup, and 35 years of operation, followed by decommissioning when applicable. For analysis purposes, a 35-year operating period was established based on the projected availability of existing DOE irradiation facilities to potentially support these missions. This timeframe also accommodates current projections that indicate the demand for radioisotopes and civilian nuclear energy research and development will extend for at least the next 20 years (Wagner et al. 1998; NERAC 2000a; DOE 2000a).

### **Medical and Industrial Isotope Production**

Over the past few decades, isotopes have become vital tools for use in medicine, industry, and scientific research. Isotopes, including both radioisotopes and stable isotopes, play a particularly important role in medical diagnosis, treatment, and research. Currently, more than 12 million nuclear medicine procedures are performed each year in the United States, and approximately one-third of all patients admitted to U.S. hospitals undergo at least one medical procedure that employs the use of medical isotopes (NERAC 2000a). Many medical isotopes are produced in the United States by DOE in nuclear reactors and particle accelerators. In limited cases, some medical isotopes can also be produced by extracting them from existing radioactive materials, such as thorium-229 obtained from DOE's existing stockpile of uranium-233. Radioisotopes are used for both diagnosis and therapy. Diagnostic radioisotopes are used for imaging internal organs. Unlike conventional radiology, imaging with radioisotopes reveals organ function and structure, which provides additional data for a more accurate diagnosis, and assists in the early detection of abnormalities. In ongoing clinical testing, therapeutic isotopes have proven effective in treating cancer and other illnesses by cell-directed localized radiation therapy (i.e., deploying antibodies or carriers of radioactive isotopes to seek and destroy invasive cancer cells). This directed therapy can minimize adverse side effects (e.g., healthy tissue damage, nausea, hair loss), making it an effective, attractive alternative to traditional chemotherapy or radiation treatments.

For nearly 50 years, DOE has actively promoted the use of radioisotopes to improve the health and well-being of U.S. citizens. DOE's use of its unique technologies and capabilities to develop isotopes for civilian purposes has enabled the widespread application of medical and industrial isotopes seen today. DOE must provide an adequate supply of isotopes to keep pace with the growing and changing needs of the research community if it is to continue to serve this key role.

An Expert Panel convened by DOE in 1998 reviewed several industry projections for growth in demand for medical isotopes. The Expert Panel concluded that the growth rate in medical isotope use will be significant over the next 20 years (Wagner et al. 1998). Specifically, the Expert Panel estimated that the expected growth rate of medical isotope use during the next 20 years will range from 7 to 14 percent per year for therapeutic applications, and from 7 to 16 percent per year for diagnostic applications. The panel noted that these growth rates are attainable only if basic research in nuclear medicine is supported and modern, reliable isotope production facilities are available. In the period since the initial estimates were made, the actual growth of medical isotope use has tracked at levels consistent with the Expert Panel findings. DOE and NERAC have agreed with the following findings and recommendations provided by the Expert Panel.

- Several isotopes have proven their clinical efficacy, but supply and cost concerns could dramatically affect the use of these isotopes in the practice of nuclear medicine.
- Although commercial and research applications for certain isotopes have been developed or are being developed, their limited availability and high prices are inhibiting their use in clinical applications.
- Research isotopes that have shown promise as diagnostic and therapeutic materials are not being explored because of their lack of availability or high price.
- At present, there is no domestic production facility to guarantee the continued supply of many of these isotopes.
- To meet current and future needs of the biomedical sciences community, the Expert Panel recommended:

“. . . the United States develop a capability to produce large quantities of radionuclides [radioisotopes] to maintain existing technologies and to stimulate future growth in the biomedical sciences. The successful implementation of such a program would help insure our position as an international leader in the biomedical sciences well into the twenty-first century. The panel recommends that the U.S. Government build this capability around a reactor, an accelerator, or a combination of both technologies as long as isotopes for clinical and research applications can be supplied reliably, with diversity in adequate quantity and quality” (Wagner et al. 1998).

In its recent report from the Subcommittee for Isotope Research and Production Planning, NERAC further identified that:

“It is now widely conceded that limited availability of specific radionuclides is a constraint on the progress of research. The problem is especially apparent in a number of medical research programs that have been terminated, deferred, or seriously delayed by a lack of isotope availability . . . The lack of radionuclides significantly inhibits progress in evaluating a host of promising diagnostic and therapeutic drugs in patients with debilitating and fatal diseases, examining fundamental basic science questions, studying human behavior and normal growth and development, and exploring the aging process and the products of transgene expression . . . the DOE long-term goal to have a reliable isotope supply system in place that would enable scientists to bring their creative ideas into practical use safely, quickly and efficiently is appropriate, be it basic science research, clinical medicine, or industrial endeavors. The discovery and dissemination of new knowledge should continue to be a core mission, and basic science and the application of basic science to clinical research discoveries

to improve the diagnosis and treatment outcomes should be a crucial component of that mission. [DOE], in providing a federal system for the reliable supply of stable and radioactive isotopes for research, will be an important aspect of fulfilling the federal responsibility to support biomedical research” (NERAC 2000a).

Current domestic and global producers of radioisotopes include governments that operate reactors and accelerators at national laboratories or institutes, and private sector companies that own and operate accelerators. There are also many partnership arrangements where companies lease irradiation space in government reactors or operate processing facilities in coordination with the government. A few universities also produce radioisotopes, but their ability to provide reliable and diverse supplies is generally limited by the small-scale capabilities or operating schedules of their facilities.

DOE’s production and sale of radioisotopes fall into two categories: “commercial” and “research”. Commercial radioisotopes are those that are produced in large, bulk quantities and sold to pharmaceutical companies or distributors, or to equipment or sealed source manufacturers. DOE only produces commercial isotopes when there is no U.S. private sector capability or when foreign sources do not have the capacity to meet U.S. needs reliably.

In contrast, research radioisotopes are typically produced and sold in small quantities in response to specialty orders from researchers preparing experiments in the field of medicine, with small quantities of these radioisotopes also purchased by industrial researchers. Because small-quantity production of research isotopes is not financially attractive to private-sector producers, it is generally not undertaken. DOE attempts to provide all research radioisotopes that are requested, subject to production capability, inventory, and financial constraints. As successful application of a specific research isotope is established, the production and sales of that radioisotope may shift from research to commercial status. In recent years, over 95 percent of DOE’s sales of radioisotopes by dollar volume were commercial, and 5 percent were for research.

DOE produces radioisotopes using the High Flux Isotope Reactor (HFIR) at ORNL, the Advanced Test Reactor (ATR) at Idaho National Engineering and Environmental Laboratory (INEEL), and the Annular Core Research Reactor at Sandia National Laboratories. DOE also produces radioisotopes using accelerators, namely the Isotope Production Facility (IPF) at Los Alamos National Laboratory (LANL) and the Brookhaven LINAC (Linear Accelerator) Isotope Producer (BLIP) at BNL. At each of these DOE sites, the radioisotope production mission shares the reactor or accelerator with other basic energy sciences or defense missions that are generally much larger and exercise considerable influence on facility schedules and priorities. As such, radioisotope production is often relegated to fulfilling a secondary mission that is dependant on the operating constraints of these larger, primary missions. Currently, approximately 50 percent of DOE’s isotope production capability is being utilized. Assuming a midpoint growth curve for future isotope demand and ensuring a diversity and redundancy of isotope supply, DOE estimates that its isotope production facilities would be fully used within a 5- to 10-year timeframe if no enhancements to the existing nuclear facility infrastructure are implemented. This projection is made in the context of a worldwide market for radioisotopes. Although DOE’s market share is a small fraction of the overall total, it is very significant for some radioisotopes and particularly important for a large number of radioisotopes that are used in relatively small quantities for research. These isotopes, which are used almost exclusively by researchers at universities and hospitals, are not purchased in quantities that would attract private industry to take over their production. However, DOE may need to significantly increase the production levels of these radioisotopes as world demand changes and promising research developments in their medical use are brought to commercialization.

Recent analyses indicate that the greatest challenge to meeting projected isotope market requirements over the next 20 years will be in the area of therapeutic medical isotopes, several of which are currently unavailable or are available only in limited quantities (Battelle 1999). For the purpose of analysis in the NI PEIS, a

representative set of isotopes was selected on the basis of the recommendations of the Expert Panel, medical market forecasts (Frost & Sullivan 1997), reviews of medical literature, and more than 100 types of ongoing clinical trials that use radioisotopes for the treatment of cancer and other diseases. Currently, these medical applications primarily involve the diagnosis and treatment of three major classes of disease—cancer, vascular disease, and arthritis. Although these isotopes are a representative sample of possible isotopes that could be produced, DOE expects that the actual isotopes produced as a result of the proposed action would vary from year to year in response to the focus of clinical research and the specific market needs occurring at that time.

The United States currently purchases approximately 90 percent of its medical isotopes from foreign producers, most notably Canada. However, Canada only supplies a limited number of economically attractive commercial isotopes (primarily molybdenum-99), and it does not supply research isotopes or the diverse array of medical and industrial isotopes considered in the NI PEIS. As such, reliance on Canadian sources of isotopes to satisfy projected U.S. isotope needs would not meet DOE's mission requirements.

Industrial isotope applications fall into three broad categories: nucleonic instrumentation, irradiation and radiation processing, and technologies that use radioactive tracers. Examples of nucleonic instrumentation include gauges for measuring physical parameters, e.g., detection systems for pollutants, explosives, drugs, ores, petroleum, and natural gases; nondestructive testing by gamma radiography; and smoke detectors. Irradiation and radiation processing technologies include radiation sterilization of food and medical products and the curing of plastics. Radioactive tracer applications include studies of chemical synthesis reactions; mass transfer monitoring in industrial plants; analysis of the transport and uptake of nutrients, fertilizers, herbicides, and waste materials in plants, soils, and groundwater; and laboratory-based studies of the properties of materials.

In proposing to expand its radioisotope production capability, DOE intends to continue to complement the commercial availability of these radioisotopes. Consistent with current isotope production activities, DOE will continue to make its facilities available to the private sector to support production and sales of isotopes.

### **Plutonium-238 Production for Space Missions**

As part of its charter under the Atomic Energy Act, DOE and its predecessor agencies have been developing and supplying radioisotope power systems to NASA for space exploration for more than 30 years. These radioisotope power systems include radioisotope thermoelectric generators used to power electrical components and radioisotope heater units used to keep spacecraft instruments warm. Previous NASA space missions that have used radioisotope power systems include the Apollo lunar scientific packages and the Pioneer, Viking, Voyager, Galileo, and Ulysses deep space probes. More recent missions include the Mars Pathfinder mission launched in 1996 and the Cassini mission launched in 1997. These radioisotope power systems have repeatedly demonstrated their performance, safety, and reliability in various NASA space missions. Without these power systems, these types of space exploration missions could not have been performed by NASA.

The radioisotope used in these power systems is plutonium-238. Through a Memorandum of Understanding with NASA, DOE provides these radioisotope power systems, and the plutonium-238 that fuels them, for space missions that require or would be enhanced by their use (DOE and NASA 1991). In addition, under the National Space Policy issued by the Office of Science and Technology Policy in September 1996, and consistent with DOE's charter under the Atomic Energy Act, DOE is responsible for maintaining the capability to provide the plutonium-238 needed to support these missions. The Intersector Guidelines section of the National Space Policy states that, "The Department of Energy will maintain the necessary capability to support space missions which may require the use of space nuclear power systems" (The White House 1996). Although research to identify other potential fuel sources to support these space exploration missions has been conducted, no viable alternative to using plutonium-238 has been established.

Historically, the reactors and chemical processing facilities at DOE's Savannah River Site (SRS) were used to produce plutonium-238; however, downsizing of the DOE nuclear weapons complex resulted in the shutdown of the last remaining SRS operating reactor, K-Reactor, in early 1996. Also, in 1992 then-Secretary of Energy Watkins issued a decision to phase out operations at the two chemical processing facilities (F-Canyon and H-Canyon) at SRS. In accordance with that decision, the separation facilities are planned to be shut down following completion of their current missions to stabilize and prepare for the disposition of Cold War legacy nuclear materials and certain spent nuclear fuel, and a determination that a new nonchemical processing technology is capable of preparing aluminum-based research reactor spent nuclear fuel for ultimate disposition.

In order to obtain a source of plutonium-238 to support NASA space missions, DOE signed a 5-year contract in 1992 to purchase plutonium-238 from Russia, authorizing the United States to purchase up to 40 kilograms (88.2 pounds) of plutonium-238, with the total available for purchase in any one year limited to 10 kilograms (22 pounds).<sup>1</sup> Under this contract, DOE purchased approximately 9 kilograms (19.8 pounds) of plutonium-238<sup>2</sup>. This material constitutes the only available U.S. inventory that has been reserved for space missions, an amount that is expected to be depleted by approximately 2005. DOE's practice of purchasing on an as-needed basis has avoided the costs from processing the plutonium-238 to remove the decay products that would result from storing it for an extended period of time. In 1997, DOE extended the contract for another 5 years; therefore, it is set to expire in 2002. Any purchases beyond 2002 would likely require the negotiation of a new contract and may require additional NEPA review. The long-term viability of pursuing additional contract extensions or entering into a new contract is unclear.

The political and economic climate in Russia creates uncertainties that could affect its reliability as a source of plutonium-238 to satisfy future NASA space mission requirements. Reestablishing a domestic plutonium-238 production capability would ensure that the United States has a long-term, reliable supply of this material. In doing so, the United States would have greater control over the available supply, plans for satisfying future demand, and the nuclear safety and nonproliferation implications of the material. As such, DOE's preference is to reestablish a domestic plutonium-238 production capability rather than to rely on Russia as the sole long-term supplier. A plutonium-238 production rate of 2 to 5 kilograms (4.4 to 11 pounds) per year is expected to be sufficient to meet NASA's estimated long-term requirements.

DOE is planning to provide radioisotope heater units for several NASA Mars Exploration missions over the next 10 years. Each heater unit would require approximately 2 grams (0.07 ounce) of plutonium-238. The number of heater units varies depending on the spacecraft. Each of the two Mars missions in 2003 is projected to require up to 11 heater units. In May 2000, NASA provided preliminary guidance to DOE to also plan for the potential use of radioisotope power systems for the Pluto/Kuiper Express mission scheduled for launch in 2004, the Europa Orbiter mission scheduled for launch in 2006, and the Solar Probe mission scheduled for launch in 2007 (NASA 2000a). The amount of plutonium-238 needed for these missions was approximately 7.4 kilograms (16.3 pounds) for the Pluto/Kuiper Express mission, which would use an existing spare radioisotope thermoelectric generator, and approximately 3 kilograms (6.6 pounds) each for the Europa Orbiter and Solar Probe missions, which would use the Stirling radioisotope power system (SRPS). With NASA's current emphasis on smaller and less expensive spacecraft, the SRPS is being developed as a new, more efficient and lighter weight power system requiring one-third less plutonium-238 as its fuel source. However,

---

<sup>1</sup> The NI PEIS presents the weight of plutonium-238 in terms of kilograms of isotope. In contrast, NASA documentation expresses this weight in terms of plutonium oxide. The equivalent plutonium oxide weight can be approximated by multiplying the isotope kilogram weight by 1.134.

<sup>2</sup> The environmental impacts of purchasing plutonium-238 from Russia are evaluated and documented in the *Environmental Assessment of the Import of Russian Plutonium-238* (DOE 1993), prepared by DOE's Office of Nuclear Energy.

the technology is developmental, and NASA has requested that the plutonium-238 needed for a large radioisotope thermoelectric generator be maintained as backup.

A plutonium-238 production goal of 2 to 5 kilograms (4.4 to 11 pounds) per year could produce sufficient quantities of plutonium-238 to theoretically yield a SRPS every 8 months if production were maintained at the high end of the range. However, DOE chose the 5-kilogram (11-pound) per year production rate as an upper bound due to uncertainties in the SRPS technology development requirements for backup units, and variability in the amount of plutonium-238 that may be needed for each of the units to meet NASA's power requirements.

In updated mission planning guidance provided in September 2000, NASA indicated that for programmatic and technical reasons, implementation of the Pluto/Kuiper Express mission as currently conceived was being deferred, and that the SRPS generators were candidate power systems for the Europa Orbiter and Solar Probe missions (NASA 2000b, 2000c). NASA also requested that the spare radioisotope thermoelectric generator and assembling and fueling a spare thermoelectric converter be maintained as backups for the Europa Orbiter mission in the event the SRPS technology was not ready in time. If NASA chooses to use the SRPS to support the Europa Orbiter and Solar Probe missions, there would be no change in NASA's requirements regarding the plutonium-238 needed for these two missions (i.e., approximately 3 kilograms [6.6 pounds] each, as described above), although the remaining quantity of plutonium-238 would not be sufficient to support additional deep space or long-lived exploration missions. Should NASA decide to use the backup radioisotope thermoelectric generators rather than the SRPS to support the Europa Orbiter mission, approximately 8 kilograms (17.6 pounds) of plutonium-238 would be needed, which would effectively expend all of DOE's available plutonium-238 inventory prior to supporting the Solar Probe mission. While this latest NASA guidance modifies the specific radioisotope power systems and missions for which DOE needs to plan, it does not fundamentally change NASA's overall potential plutonium-238 requirements, or the expectation that the available U.S. inventory of this material would effectively be depleted by approximately 2005.<sup>3</sup>

Although future space mission schedules over a long-term planning horizon of 10 to 35 years cannot be specified at this time, DOE anticipates that NASA space exploration missions conducted during this period will continue to require plutonium-238-fueled power systems. For example, NASA announced in a recent press conference (October 26, 2000) that mission launches in 2014 and 2016 for the long-term exploration of Mars would involve long-life rover vehicles. Radioisotope power systems would be required to provide the long-life capability.

Therefore, DOE proposes to reestablish a domestic capability for producing and processing this material. Because the SRS facilities previously used for plutonium-238 production are no longer available, DOE needs to evaluate other DOE irradiation and chemical processing facilities, as well as potential commercial light water reactors (CLWR), for this mission. Unless an assured domestic supply of plutonium-238 is established, DOE's ability to provide radioisotope power systems to support future NASA space exploration missions may be lost.

### **Civilian Nuclear Energy Research and Development**

Nuclear energy is an important contributor in reducing greenhouse gas emissions in the United States, Asia, and Europe. Globally, nuclear energy produces 17 percent of the world's electricity. In the United States, nuclear energy generated 20 percent of all electricity consumed in 1999. In view of energy and environmental contributions, there is a renewed interest in nuclear power to meet an equivalent portion of the Nation's future expanding energy requirements.

---

<sup>3</sup> Applicable NASA mission planning correspondence is presented in Appendix R, Volume 2 of the NI PEIS.

In January 1997, President Clinton tasked his Committee of Advisors on Science and Technology (PCAST) to evaluate the current national energy research and development portfolio and to provide a strategy that ensures the United States has a program to address the Nation's energy and environmental needs for the next century. In its November 1997 report responding to this request, the PCAST Energy Research and Development Panel determined that restoring a viable nuclear energy option to help meet our future energy needs is important and that a properly focused research and development effort to address the potential long-term barriers to expanded use of nuclear power (e.g., nuclear waste, proliferation, safety, and economics) was appropriate. The PCAST panel further recommended that DOE reinvigorate its nuclear energy research and development activities to address these potential barriers.

Clean, safe, reliable nuclear power has a role today and in the future for our national energy security. Recognizing this need, two significant new nuclear energy research and development programs have been initiated: the Nuclear Energy Research Initiative (NERI) and Nuclear Energy Plant Optimization (NEPO). The NERI program, initiated in fiscal year 1999, sponsors new and innovative scientific and engineering research and development to address the potential long-term barriers identified by the PCAST Panel affecting the future use of nuclear energy. The NEPO program, a cost-shared program with industry, initiated in fiscal year 2000, sponsors applied research and development to ensure that current nuclear plants can continue to deliver adequate and affordable energy supplies up to and beyond their initial 40-year license period by resolving open issues related to plant aging, and by applying new technologies to improve plant reliability, availability, and productivity.

The NERAC Subcommittee on Long-Term Planning for Nuclear Energy Research has set forth a recommended 20-year research and development plan to guide DOE's nuclear energy programs in areas of materials research, nuclear fuel, and reactor technology development (NERAC 2000b). This plan stresses the need for DOE facilities to sustain the nuclear energy research mission in the years ahead. Such civilian nuclear energy research and development initiatives requiring an enhanced DOE nuclear facility infrastructure fall into three basic categories: materials research, nuclear fuel research, and advanced reactor development.

**Materials Research.** The high radiation fields, high temperatures, and corrosive environments in nuclear reactors (terrestrial or space) and other complex nuclear systems (e.g., accelerator transmutation of waste [ATW] systems) can accelerate the degradation of pressure vessels and structural material, component materials, material interfaces and joints between materials (e.g., welds). Radiation effects in materials can cause a loss of mechanical integrity (fracture toughness and ductility) by embrittlement, dimensional changes (creep and swelling), and fatigue and cracking (irradiation-assisted stress corrosion cracking). Acquiring a fundamental understanding of radiation effects in current and future reactor materials (engineered steel alloys, ceramics, composites, and refractory metals), as well as the experimental validation of analytical models and computational methods, would require material irradiation testing over a range of neutron energies (thermal and fast flux) and doses. Material testing under simulated reactor conditions would be required to ensure the compatibility of advanced materials with the various moderators/coolants of future reactor concepts. In addition, the thermophysical properties and behaviors of liquid metal coolants being considered for advanced reactor (terrestrial or space) and ATW systems require further irradiation testing. One key area of materials research that is important to plant safety and the license renewal of existing nuclear power plants is the accelerated aging of materials to simulate radiation effects over a plant lifetime. Researchers from the United States and many foreign countries use DOE's high flux research reactors for materials testing and experimentation. These facilities have the capability to maintain a high density of neutrons in a given test volume for materials testing; shorten the time needed for such testing; tailor the neutron flux to simulate the different reactor types and conditions; and instrument the core for close monitoring of the test conditions.

**Nuclear Fuel Research.** Increasing demands are being placed on nuclear fuel and cladding material performance as the fuel burnup limits are extended in existing light water reactors to maximize plant

performance and economic benefits. New fuel types and forms are being investigated that offer potential benefits such as enhanced proliferation resistance (uranium-thorium fuel), higher burnup, and improved waste forms for the new reactor concepts being researched and developed by DOE. In addition, plutonium-uranium mixed oxide fuels are being developed for the disposition of surplus weapons material, and high temperature, long-life fuels may be required for space reactors. Each of the various fuel and cladding types, forms, and material compositions would require research and irradiation testing under prototypical reactor conditions to fully understand fuel performance, cladding performance, cladding/fuel interaction, and cladding/coolant material compatibility. Fuel research includes a variety of thermal and fast spectrum power reactor fuel forms (ceramic, metal, hybrids such as cermet) and various fuel types (oxides, nitrides, carbides, and metallics). Irradiation experiments to characterize fuel performance would require the capability to test fuel pellets, pins, and fuel assemblies under steady-state and transient conditions in the higher temperature environments expected in future reactor designs. Reactor physics and criticality safety data for benchmarking computational codes and analytical methods used in fuel design and performance analysis would also be required.

**Advanced Reactor Development.** Certification and licensing of advanced reactor and complex nuclear systems will require the demonstration and validation of reactor and safety system thermal and fluid dynamic properties under steady-state and transient conditions. Typically, nonnuclear test loops are used to perform this research. However, because of the unique nature of some proposed advanced reactor concepts, test loop operation under prototypical temperature and neutron flux conditions would be necessary to adequately test and demonstrate coolant/moderator physics and thermal properties, heat transfer, fluid flow, and fuel-moderator performance.

## S.2 SCOPE OF THE NI PEIS

### Public Scoping Process

On October 5, 1998, DOE published in the Federal Register (63 FR 53398) a Notice of Intent to prepare an environmental impact statement (EIS) on the proposed production of plutonium-238 for use in advanced radioisotope power systems for future space missions. With that announcement, DOE began preparing the *Environmental Impact Statement for the Proposed Production of Plutonium-238 for Use in Advanced Radioisotope Power Systems for Future Space Missions (Plutonium-238 Production EIS)*. The scope of the *Plutonium-238 Production EIS* was established through a public scoping process conducted from November 4, 1998 through January 4, 1999. As part of the scoping process for that draft, DOE announced that the Fast Flux Test Facility (FFTF) would not be considered a reasonable alternative for the plutonium-238 production mission unless restart of the facility was proposed for other reasons.

Since then, the Secretary of Energy announced on August 18, 1999, that DOE would prepare the NI PEIS. Because plutonium-238 production would be among the missions considered in the NI PEIS, the scope of the *Plutonium-238 Production EIS* in its entirety was incorporated within the scope of the NI PEIS, and preparation of the *Plutonium-238 Production EIS* as a separate National Environmental Policy Act (NEPA) review was terminated.

On September 15, 1999, DOE published in the Federal Register a Notice of Intent to prepare the NI PEIS (64 FR 50064). In this Notice of Intent, DOE invited the public to comment on the proposed actions during the 45-day NI PEIS scoping period that ended October 31, 1999. During this period, DOE held public scoping meetings at seven locations: Oak Ridge, Tennessee; Idaho Falls, Idaho; Richland and Seattle, Washington; Hood River and Portland, Oregon; and Washington, D.C. The written and oral comments received at these meetings and the additional comments received via U.S. mail, electronic mail, and toll-free faxes and telephone calls during the public scoping period were reviewed and considered by DOE in preparing

the NI PEIS. Similarly, DOE reviewed and considered all comments and input originally received from the public during the *Plutonium-238 Production EIS* scoping period in the preparation of the NI PEIS.

For the *Plutonium-238 Production EIS*, approximately 750 scoping comments were received by DOE. At the scoping meetings on the *Plutonium-238 Production EIS*, the following general issues and concerns were raised:

- Additional irradiation service alternatives, such as CLWRs and accelerators
- Additional storage, target fabrication, and target processing alternatives, such as Argonne National Laboratory's Hot Fuels Examination Facility and the SRS H-Canyon and HB-Line
- Generation of additional waste
- Costs of implementing the various alternatives

In general, the people who attended the meetings in Idaho and Tennessee were supportive of DOE's proposed plans to produce plutonium-238 domestically for future space missions. However, in Richland, Washington, the meeting was attended by several stakeholder and environmental groups who voiced considerable opposition to DOE's consideration of FFTF for plutonium-238 production.

At the meeting in Richland, Washington, the main concern was that DOE should not consider restarting FFTF, that DOE has worked hard over the years to change the Hanford Site's (Hanford) mission from "production" to "cleanup," and that DOE should continue to honor its commitment to cleanup. There were concerns about the generation of additional waste at the site and the operational safety of FFTF. There was strong opposition to restart of FFTF for any mission.

For the NI PEIS, approximately 7,000 scoping comments were received by DOE. At the scoping meetings on the NI PEIS, the most prevalent concerns were:

- Status of and commitment to cleanup at Hanford and the impact of FFTF restart on the existing waste cleanup at Hanford
- Lack of justification for the identified missions
- Costs of implementing the various alternatives
- Need for an additional alternative calling for the permanent deactivation of FFTF coupled with the No Action alternative elements, that is, no plutonium-238 production and no additional research and development or medical isotope production beyond existing operating levels

The number of people who commented at the scoping meetings conducted in Oak Ridge, Tennessee; Idaho Falls, Idaho; and Washington, D.C., was smaller in comparison to the meetings held in the Pacific Northwest. At the scoping meeting in Oak Ridge, Tennessee, a commentor was concerned with the relationship of the NI PEIS to other DOE programs and the relative merits of accelerator and reactor performance. The commentor stated that the NI PEIS should include an explanation of mixed oxide fuel disposition. In addition, the commentor supported medical isotope production in Oak Ridge because it is near a transportation hub and some medical isotopes are short-lived; therefore, transportation is key.

At the scoping meeting in Idaho Falls, Idaho, most commentors supported siting the new missions at INEEL. The commentors also stated that the socioeconomic impacts of the alternatives need to be considered in the NI PEIS. A commentor stated that decisions in regard to medical isotope production should be based on the needs of the Nation as a whole and not on perceived commercial needs. The commentor also stated that incremental DOE and commercial investments in ATR would be sufficient to enhance reactor radioisotope production needs and meet the requirements of the nuclear medicine industry.

At the scoping meetings held in the states of Washington and Oregon, many of the comments concerned using FFTF to accomplish the proposed action. Many who attended the meetings in Seattle, Washington; Portland, Oregon; and Hood River, Oregon, were strongly opposed to restart of FFTF. Many commentors stated that the Hanford cleanup mission would be jeopardized, especially when DOE has not met the Hanford cleanup milestones. Many of the comments received at the Richland, Washington, meeting supported restarting FFTF, stated that restart would not hamper Hanford's cleanup mission, and further stated that operation of FFTF could help save the lives of many people by producing isotopes to be used in new ways to treat cancer, heart disease, and other illnesses. Commentors were also concerned about the potential generation of radioactive and hazardous wastes as a result of the proposed action, as well as DOE's commitment to ongoing cleanup programs, particularly at Hanford.

At the scoping meeting in Washington, D.C., the commentors supported the need for medical isotope production. Several commentors were against the restart of FFTF and others stated that DOE needs to consider partnerships with private industry to generate necessary funds for restart. Some commentors thought a cost study should be prepared and include avoided future health care costs and cost savings to the national Medicare and Medicaid programs that could be realized by using nuclear isotopes in medical applications. Proliferation concerns were also raised as some commentors stated that: (1) the United States would be sending the wrong message by restarting FFTF; (2) a change in the U.S. nonproliferation policy will be required to import German mixed oxide fuel; and (3) the use of highly enriched uranium is contrary to existing U.S. nonproliferation policy. Other concerns included waste generation, Hanford cleanup, and safety at FFTF.

Comments received during the scoping periods were systematically reviewed by DOE. As a means of summarizing the issues raised during scoping, those comments with similar or related topics were grouped into categories to identify specific issues of public concern. After these issues were identified, they were further evaluated to determine whether they fell within or outside the proposed scope of the NI PEIS. In several instances, the original scope was expanded to accommodate additional issues resulting from the public scoping process.

Comments received that contributed to expansion of the scope concerned the following general areas:

- Deactivate FFTF: Alternative 5, Permanently Deactivate FFTF with no new missions at existing facilities, has been added to the scope of the NI PEIS.
- Cleanup at Hanford: Although not within the scope of the NI PEIS, information is included about the cleanup mission at Hanford and land-use planning efforts.
- Environmental contamination at Hanford: Information is included about the groundwater quality at the Hanford Site.
- Nonproliferation issues: The import of German SNR-300 fuel is addressed, and a separate *Nuclear Infrastructure Nonproliferation Impact Assessment for Accomplishing Expanded Civilian Nuclear Energy Research and Development and Isotope Production Missions in the United States, Including*

*the Role of the Fast Flux Test Facility (NI Nonproliferation Impact Assessment)* report was prepared and distributed to the public in September 2000.

- Transition of FFTF stewardship after it is deactivated: The appropriate transition information is included.
- Restart of FFTF and budget constraints: DOE has made a commitment that implementation of the Record of Decision will not divert or reprogram budgeted funds designated for Hanford cleanup.
- Tri-Party Agreement at Hanford: Information about the Tri-Party Agreement and its relationship to the NI PEIS is included.

The public comments and materials submitted during the public scoping periods for both the *Plutonium-238 Production EIS* and the NI PEIS were logged and placed in the Administrative Record for the NI PEIS. Appendix N of the NI PEIS summarizes the comments received during both public scoping periods.

### **Issues Raised During the Public Comment Period on the Draft NI PEIS**

DOE published the Draft NI PEIS in July 2000. In accordance with Council on Environmental Quality (CEQ) and DOE NEPA regulations, DOE announced the availability of the Draft NI PEIS in the Federal Register (65 FR 46443) and invited interested parties to provide comments on the Draft NI PEIS analysis and results. The Draft NI PEIS or Summary was distributed to approximately 6,000 individuals.

NEPA regulations mandate a minimum 45-day comment period after the U.S. Environmental Protection Agency's (EPA) Notice of Availability of a draft EIS to provide an opportunity for the public to comment on the EIS analysis and results. The original 45-day comment period on the Draft NI PEIS began on July 28, 2000. To provide interested parties with additional time to comment, the deadline for transmittal of comments was changed from September 11, 2000 (as stated in the transmittal letter of the Draft PEIS and the Summary) to September 18, 2000. During the 52-day comment period, DOE held seven hearings to discuss the proposed action and to receive oral and written comments on the Draft NI PEIS. These hearings were held at Oak Ridge, Tennessee; Idaho Falls, Idaho; Hood River, Oregon; Portland, Oregon; Seattle, Washington; Richland, Washington; and Arlington, Virginia. In addition, the public was encouraged to submit comments via U.S. mail, e-mail, a toll-free phone line, and a toll-free fax line. During the public comment period, DOE received approximately 3,400 submittals containing over 6,200 comments. DOE has responded to all comments received during the public comment period. These comments are presented in Volume 3 of the Final NI PEIS. DOE considered comments received after the close of the public comment period to the extent practicable.

The public comments received on the Draft NI PEIS addressed a wide range of issues. The following discusses the major issues raised, and DOE's responses to these issues. Changes made in response to comments received on the Draft NI PEIS are described in the next section.

Major issues raised addressed purpose and need for the proposed action; impact of FFTF on Hanford cleanup; waste management and spent nuclear fuel; cost of the various alternatives; nuclear nonproliferation policy; public involvement; and environmental impacts. Aside from comments on the proposed action and its environmental impacts, many commentors expressed support for or opposition to FFTF restart, the major point of public controversy associated with the NI PEIS.

**Purpose and Need for the Proposed Action.** Many commentors expressed the opinion that DOE failed to demonstrate a compelling argument for the projected need for medical isotopes, and that such medical isotopes

could be produced or purchased elsewhere, particularly in Canada. In contrast, a large number of commentors expressed support for expanded isotope production by sharing personal stories of how medical isotopes had either saved a relative or friend, or could have saved them had isotopes been available. As presented in Section 1.2.1 of Volume 1 of the NI PEIS, DOE sought independent analysis of trends in the use of medical isotopes, and established two advisory bodies, the Expert Panel and the NERAC. DOE has adopted these growth projections as a planning tool for evaluating the potential capability of the existing nuclear facility infrastructure to meet programmatic requirements. In the period since the initial estimates were made, the actual growth of medical isotope use has tracked at levels consistent with the Expert Panel findings. While Canada currently provides a large amount of the medical radioisotopes used in the United States, it only supplies a limited number of economically attractive commercial isotopes (primarily molybdenum-99), and it does not supply research isotopes or the diverse array of medical and industrial isotopes considered in the NI PEIS.

A number of commentors also questioned the suitability of using FFTF for producing research isotopes in light of findings presented in the NERAC Subcommittee for Isotope Research and Production Planning Report (NERAC 2000a). While it would not be cost effective to restart FFTF for the singular purpose of producing small quantities of various research isotopes, sustained operation of FFTF for the production of larger quantities of both research and commercial isotopes would be viable if FFTF were operated in concert with producing plutonium-238 and conducting nuclear energy research and development for civilian applications. In recognition of these constraints on its operational feasibility, the NI PEIS only evaluates the use of FFTF for isotope production when coupled with these other missions.

Commentors also questioned the need for the United States to reestablish domestic production of plutonium-238. In particular, commentors pointed to the availability of plutonium-238 that could be purchased from Russia, and recent guidance from NASA stating that DOE no longer needed to support certain radioisotope power systems. As discussed in Section 1.2.2 of Volume 1, DOE could purchase plutonium-238 from Russia. However, for supply reliability reasons and concern of nuclear nonproliferation, DOE's preference is to establish a domestic plutonium-238 production capability. Current NASA guidance to DOE is also discussed in Section 1.2.2. The May 22, 2000, correspondence from NASA identifies that it no longer has a planned requirement for Small Radioisotope Thermoelectric Generator (SRTG) power systems (NASA 2000a). This does not mean that NASA no longer requires DOE to provide the necessary plutonium-238 to support deep space missions. Rather, SRTG development efforts were stopped in order to permit reprogramming of funds to support development of a new radioisotope power system based on an SRPS technology. This new radioisotope power system, referred to in the subject correspondence, requires one-third less plutonium as its fuel source. Because the SRPS technology is developmental, NASA has requested in a September 22, 2000, letter to DOE that the plutonium-238 needed for a large radioisotope thermoelectric generator be maintained as a backup (NASA 2000b).

**Impact of FFTF Restart on Hanford Cleanup.** A number of commentors expressed concern that DOE's primary mission at Hanford needs to be cleanup, including compliance with the Tri-Party Agreement. Although beyond the scope of the NI PEIS, ongoing Hanford cleanup activities are high priority to DOE. Hanford environmental restoration activities are conducted in accordance with the Tri-Party (i.e., DOE's Richland Operations Office, EPA, and the State of Washington Department of Ecology) Agreement. This agreement specifies milestones and schedules for restoration of all parts of Hanford. FFTF milestones in the Tri-Party Agreement were placed in abeyance (suspension) by agreement of the three parties until a decision is made on the future of FFTF. Public meetings were held on this formal milestone change. DOE is fully committed to honoring this agreement.

A number of commentors also expressed concern that funding for Hanford cleanup would be diverted for FFTF restart and hamper the progress of cleanup activities. The U.S. Congress funds Hanford cleanup through

the Office of the Assistant Secretary for Environmental Management. Congress also funds FFTF through the Office of Nuclear Energy, Science and Technology (NE). The nuclear infrastructure missions described in Section 1.2 of Volume 1 would also be funded through NE, which has no funding connection to Hanford cleanup activities. As stated in Section N.3.2 of Volume 2, implementation of the nuclear infrastructure alternatives would not divert or reprogram budgeted funds designated for Hanford cleanup, regardless of the alternative(s) selected.

**Waste Management and Spent Nuclear Fuel.** A number of commentors expressed concern over the generation and disposition of waste resulting from the proposed action. In particular, commentors pointed to past DOE waste management practices and questioned whether wastes resulting from proposed NI PEIS activities would be properly managed. The NI PEIS addresses wastes produced for each alternative, as well as cumulative impacts related to waste production. Waste minimization programs at each of the alternative sites are also addressed. These programs would be implemented for the alternative selected in the Record of Decision. The waste generated from any of the alternatives considered in the NI PEIS would be managed (i.e., treated, stored, and disposed of) in a safe and environmentally protective manner and in compliance with all applicable Federal and state laws and regulations and applicable DOE orders.

A number of commentors expressed specific concern over the generation and disposition of waste resulting from FFTF restart and operation, and how this would impact Hanford's existing waste management infrastructure. Management of wastes that would be generated under implementation of Alternative 1 (Restart FFTF) is discussed in Section 4.3 of Volume 1 (e.g., see Section 4.3.1.1.13). Section 4.3.1.1.13 of the NI PEIS was revised to clarify that the Hanford waste management infrastructure is analyzed in the PEIS for the management of waste resulting from FFTF restart and operation. This analysis is consistent with policy and DOE Order 435.1, *Radioactive Waste Management*, that DOE radioactive waste shall be treated, stored, and in the case of low-level waste, disposed of at the site where the waste is generated, if practical, or at another DOE facility. However, if DOE determines that use of the Hanford waste management infrastructure or other DOE sites is not practical or cost effective, DOE may issue an exemption under DOE Order 435.1 for the use of non-DOE facilities (i.e., commercial facilities) to store, treat, and dispose of such waste generated from the restart and operation of FFTF. In addition, Sections 4.3.3.1.13 and 4.4.3.1.13 also address the potential impacts associated with the waste generated from the target fabrication and processing in the Fuels and Materials Examination Facility (FMEF) and how this waste would be managed at the site.

A number of commentors also raised concern that processing of irradiated targets for production of plutonium-238 would generate high-level radioactive waste. DOE Manual 435.1, *Radioactive Waste Management*, defines high-level radioactive waste as "the highly radioactive waste material resulting from the reprocessing of spent nuclear fuel, including liquid waste produced directly in reprocessing and any solid material derived from such liquid waste that contains fission products in sufficient concentrations; and other highly radioactive material that is determined, consistent with existing law, to require permanent isolation." DOE has prepared an implementation guide to M 435.1 to assist in implementing the requirements contained in that manual. For this particular "requirement," the definition of high-level radioactive waste, the guide is intended to facilitate the classification of indefinite waste as to whether or not it is high-level radioactive waste. It is recognized that the definition of high-level radioactive waste is not precise and is essentially a source-based definition that also alludes to concentrations of a given waste stream. Page II-8 of the guide notes that "For the purpose of managing high-level waste under DOE M 435.1 [sic], spent nuclear fuel includes spent driver elements and/or irradiated target elements that contain transuranium elements." This statement was included in the guide because the concentrations of long-lived isotopes are likely to be somewhat high during reprocessing and it also meets the source-based definition. As a result of reviewing this guide and to address the comments raised, DOE is considering whether the waste from processing of irradiated neptunium-237 targets should be classified as high-level radioactive waste and not transuranic waste. As a result, the Waste Management sections (i.e., Sections 4.3.1.1.13, 4.3.2.1.13, 4.3.3.1.13, and 4.4.3.1.13) of the

NI PEIS have been revised to reflect this different classification from what was assumed in the Draft NI PEIS. As discussed in these revised sections, irrespective of how the waste is classified (i.e., transuranic or high-level radioactive waste), the composition and characteristics are the same and the waste management (i.e., treatment and onsite storage) for the NI PEIS would be the same. In addition, even if the waste is managed as high-level radioactive waste it would have no impact on the existing high-level radioactive waste management infrastructure (e.g., high-level waste storage tanks) because the high-activity waste from processing of the targets would be initially stored and vitrified within the processing facility (i.e., FMEF, the Radiochemical Engineering Development Center (REDC) or the Fluorinel Dissolution Process Facility [FDPF]).

Commentors also expressed concern over the potential impacts of spent nuclear fuel generation from FFTF restart and operation, particularly regarding human health risk. The NI PEIS estimates that about 16 metric tons of heavy metal spent nuclear fuel would be generated over 35 years of operation of FFTF. Hanford is currently managing about 2,000 metric tons of heavy metal spent nuclear fuel. The radiation risk to a maximally exposed individual from normal operational activities during management of the current stored spent nuclear fuel over 35 years is  $1.4 \times 10^{-8}$  latent cancer fatality. The risk to the maximally exposed individual that would be associated with the new nuclear infrastructure operations to restart FFTF and operate FMEF or the Radiochemical Processing Laboratory is  $9.5 \times 10^{-8}$  latent cancer fatality. Furthermore, only a small fraction of this risk would be attributable to management of the additional spent nuclear fuel at FFTF. The annual dose to the maximally exposed individual from all current and reasonably foreseeable activities at Hanford is less than 0.2 millirem. The dose is well within the DOE dose limits given in DOE Order 5400.5, *Radiation Protection of the Public and the Environment*. As discussed in that order, the dose limit from airborne emissions is 10 millirem per year, as required by EPA regulations under the Clean Air Act; the dose limit from drinking water is 4 millirem per year, consistent with the EPA drinking water criteria under the Safe Drinking Water Act; and the dose limit from all pathways combined is 100 millirem per year. The risk to the population from all activities at Hanford would be 0.21 latent cancer fatality over 35 years. DOE has committed to remove the spent nuclear fuel at Hanford for ultimate disposition in a geologic repository.

**Cost of the Various Alternatives.** Commentors expressed opinions about the costs related to the stated missions. Commentors stated that a cost-benefit analysis was necessary to show the value of production of medical isotopes balanced against facility costs, in particular, the restart of FFTF, and noted that perhaps facilities would be able to pay for themselves. There were concerns that FFTF restart would take funds away from the cleanup of Hanford. Commentors noted that the decommissioning costs were not included for the restart FFTF option in the *Cost Report for Alternatives Presented in the Draft Programmatic Environmental Impact Statement for Accomplishing Expanded Civilian Nuclear Energy Research and Development and Isotope Production Missions in the United States, Including the Role of the Fast Flux Test Facility (NI Cost Report)*. Several commentors remarked that the expense of plutonium-238 production cannot be justified when DOE needs to clean up existing problems at its sites.

Although the costs of proposed actions are not required by NEPA and CEQ regulations to be included in a PEIS, DOE prepared a separate *NI Cost Report*. This report would provide additional pertinent information to the Secretary of Energy so that he may make an informed decision with respect to the alternatives presented in the Final NI PEIS. Pursuant to CEQ regulations (40 CFR Section 1505.1(e)), such documents comparing alternatives should be made available to the public prior to any decision being made. DOE mailed this document to more than 730 interested parties on August 24, 2000. This report was made available immediately upon release on the NE web site (<http://www.nuclear.gov>) and in the public reading rooms. DOE has also provided the summary of the *NI Cost Report* in Appendix P, of the Final NI PEIS.

**Nuclear Nonproliferation Policy.** Commentors expressed opinions about the nuclear nonproliferation implications of the proposed action. Commentors were concerned about keeping plutonium-238 out of the hands of third parties, and it was suggested that the purchase of plutonium-238 from Russia would stop

proliferation of the material and the United States would know the disposition of the quantity purchased. Several commentors raised concerns about specific facilities described in the NI PEIS, including FDPF and FFTF. The use of highly enriched uranium fuel in FFTF was questioned related to possible violation of U.S. nuclear nonproliferation policy. Conversely, the shutdown of FFTF that occurred previously was characterized as being done to discourage proliferation of nuclear weapons worldwide, but had instead weakened the U.S. position as a world leader in nuclear technology. There were comments about the timeliness of release of the *NI Nonproliferation Impact Assessment*, that no nonproliferation information was included in the Draft NI PEIS, and that nuclear nonproliferation policy should be considered by DOE in selection of its preferred alternative.

The plutonium being considered for production in the NI PEIS is plutonium-238, which is not the same isotope of plutonium that is used in nuclear weapons. The production of plutonium-238 does not present a nonproliferation concern. DOE developed the separate *NI Nonproliferation Impact Assessment*, published in September 2000, that analyzed the nonproliferation impacts of the actions considered in the NI PEIS and found that there are no U.S. nonproliferation policies, laws, regulations, or international agreements that preclude the use of any of the facilities in the manner described in the Draft NI PEIS. Although this policy analysis is not required under NEPA, it is an essential element in the decision-making process for the DOE nuclear infrastructure. A summary of the *NI Nonproliferation Impact Assessment* is included in Appendix Q of the Final NI PEIS. It is also available on the DOE NE web site (<http://www.nuclear.gov>).

**Public Involvement.** Commentors expressed opinions about the length of the comment period on the Draft NI PEIS, and said they wanted additional time to obtain and review relevant documents, including the *NI Cost Report* and *NI Nonproliferation Impact Assessment*. The deadline for transmittal of comments was changed from September 11, 2000 (as stated in the transmittal letter of the Draft PEIS and the Summary) to September 18, 2000. While the official comment period ended on September 18, 2000, DOE addressed late comments to the extent practicable and considered all comments received through October 31, 2000, in preparing the Final NI PEIS. Comments that were received through September 25, 2000, along with corresponding responses, have been included in Chapter 2 of the comment response volume (Volume 3). Direct responses are not included to comments that were received after September 25, 2000. However, all of these comments were considered and are characterized by other comments received during the comment period (for which a response has been provided).

Many commentors expressed the opinion that public input is intended for “show only,” and that DOE has already made its decisions. Commentors also stated that they had given the same comments over and over again and that DOE representatives were not listening. DOE policy encourages effective public participation in its decision-making process. In compliance with NEPA and CEQ regulations, DOE provided opportunity to the public to comment on the scope of the NI PEIS and the environmental impact analysis of DOE's proposed alternatives. DOE gave equal consideration to all comments. In preparing the Final NI PEIS, DOE carefully considered all comments received from the public.

Some commentors expressed opinions about the conduct of the hearings, both positive and negative. The public hearing format was designed to be fair. The public hearing format used was based on stakeholder input and was presented in the Notice of Availability (65 FR 46443 et seq.) for the Draft NI PEIS. This format was intended to encourage public participation, regardless of the motivation for attending the hearing. It provided an opportunity for the participants to meet, exchange information, and share concerns with DOE personnel available throughout the course of each hearing to answer questions. The meetings were facilitated by an independent moderator to ensure that all persons wishing to speak had an opportunity to do so. Persons wishing to comment were selected at random from the audiences rather than according to the order in which they registered. This was accomplished by a random number drawing. In addition to the comment recorder stationed at the main hearing, a second recorder was available in an adjacent room to receive comments

without the need to await selection at the main proceeding. The hearing format promoted open and equal representation by all individuals and groups.

**Environmental Impacts.** A number of commentors questioned the results of the environmental impact analysis and cumulative impacts, specifically at Hanford. Many of these comments focused on concerns that the proposed action would result in negative impacts to the health of individuals residing in the Hanford region. The NI PEIS analyzes the impacts of the various alternatives, and the environmental impacts associated with all proposed nuclear infrastructure activities are addressed in detail in Chapter 4 of Volume 1. Specifically, the environmental impacts associated with operation of the Hanford facilities during normal operations and from postulated accidents are presented in Section 4.3. These assessments were made using well-established and accepted analytical methods, as described in Appendixes G through L in Volume 2. The analytical methodology is conservative by nature; the actual impacts to the environment would be expected to be less than calculated. All impacts have been shown to be small. No fatalities among workers or the general public would be expected over the 35-year operational period. The impacts to the biosphere (air, water, and land) were also evaluated and determined to be small.

Some commentors raised specific concern over potential contamination of the Columbia River resulting from the restart of FFTF. However, FFTF is approximately 4.5 miles from the Columbia River. There are no discharges to the river from FFTF and no radioactive or hazardous discharges to groundwater. As indicated in analyses presented in Chapter 4 of Volume 1 (e.g., Sections 4.3.1.1.4, 4.3.3.1.4, 4.4.3.1.4, 4.5.3.2.4, and 4.6.3.2.4), there would be no discernible impacts to groundwater or surface water quality at Hanford from operation of Hanford facilities that would support the nuclear infrastructure missions described in Section S.1.

A number of commentors also expressed concern that DOE would expose individuals in the Pacific Northwest to risks associated with the importing weapons-grade plutonium. None of the proposed alternatives involve the shipment of any weapons-grade plutonium to any port in the United States. Alternative 1 does postulate that DOE might decide at some point to import mixed oxide fuel from Europe to fuel FFTF. At this time, however, DOE has not proposed to import this fuel through any specific port. If DOE ultimately decides to import fuel from Europe, it would perform a separate NEPA analysis to select a port. This review would address all relevant potential impacts of overseas and inland water transportation, shipboard fires, package handling, land transportation, as well as safeguards and security associated with the import of SNR-300 mixed oxide fuel through a variety of specific candidate ports on the west and east coasts. It would take into account all public comments, including local resolutions, concerning the desirability of bringing mixed oxide fuel into the proposed alternative ports.

In the event that DOE decides to enhance its nuclear infrastructure, it would not expose any population to high, unacceptable risks under any alternative. Any transportation activities that would be conducted by DOE would comply with U.S. Nuclear Regulatory Commission (NRC) and U.S. Department of Transportation regulations. Associated transatlantic shipments would comply with International Atomic Energy Agency requirements. In Section J.6.2 of Volume 2, DOE reviewed the potential maximum impacts from the marine transportation of mixed oxide fuel from Europe to a representative military port (Charleston, South Carolina), and overland transportation to Hanford. Also in that section, the results of a bounding analysis show that the maximum potential radiological risks to the surrounding public from mixed oxide fuel shipments would be extremely small (e.g., less than 1 chance in a trillion for a latent cancer fatality per shipment from severe accidents at docks and in channels and less than 1 chance in 50 billion for a latent cancer fatality per shipment from overland highway accidents).

## **Changes from the Draft NI PEIS**

In response to comments on the Draft NI PEIS and as a result of information that was unavailable at the time of its issuance, the Final NI PEIS contains revisions and new information. These revisions and new information are indicated by sidebars. A brief discussion of the most important changes included in the Final NI PEIS is provided in the following paragraphs.

**Chapter 1. Purpose and Need for Agency Action:** As a result of public comments, additional discussion was incorporated to address DOE's production of medical, research, and industrial isotopes relative to global isotope production and availability. In addition, the discussion of the need for plutonium-238 production for space missions was expanded and updated to reflect the most recent planning guidance provided by NASA to DOE.

**Issues Raised During the Public Comment Period on the Draft NI PEIS:** Section 1.5, Issues Raised During the Public Comment Period on the Draft NI PEIS, was added to the Final NI PEIS.

**Related NEPA Reviews:** The Final NI PEIS was revised to add descriptions of the *Final Environmental Impact Statement, Management of Spent Nuclear Fuel from the K Basins at the Hanford Site, Richland, Washington* (DOE/EIS-0245F), and the *Environmental Assessment, Management of Hanford Site Non-Defense Production Reactor Spent Nuclear Fuel* (DOE/EA-1185). The impacts of these NEPA actions were factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action. The Final NI PEIS was also revised to reflect recent Records of Decision that have been issued for the *Final Environmental Impact Statement on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel* (DOE/EIS-0218F), the *Final Environmental Impact Statement for Treating Transuranic (TRU)/Alpha Low-Level Waste at the Oak Ridge National Laboratory Oak Ridge, Tennessee* (DOE/EIS-0305), and the *Final Environmental Impact Statement for the Treatment and Management of Sodium-Bonded Spent Nuclear Fuel* (DOE/EIS-0306).

**Changes from the Draft NI PEIS:** Section 1.8, Changes from the Draft NI PEIS, was added to the Final NI PEIS.

**Chapter 2. Transportation Requirements:** Additional U.S. ports were named as candidates for receiving mixed oxide fuel from Europe.

**Alternatives Considered and Dismissed:** Information was provided to explain why the IPF at LANL, the BLIP and the Alternating Gradient Synchrotron (AGS) accelerator complex at BNL, and CLWRs were not considered reasonable alternatives for the production of medical isotopes. Information was also provided to explain why increasing the power levels at ATR and/or HFIR or installing rapid radioisotope retrieval systems would be insufficient to meet the long-term growth projection needs and therefore dismissed as reasonable alternatives.

**Preferred Alternative:** The discussion of DOE's preferred alternative for accomplishing the proposed action, that is, Alternative 2, Use Only Existing Operational Facilities, Option 7, is included in the Final NI PEIS.

**Summary of Environmental Impacts:** Section 2.7 of the NI PEIS was revised in response to comments that it was difficult to compare environmental impacts among alternatives. Although estimates of the environmental impacts that would result from implementation of the alternatives are the same as those in the Draft NI PEIS, the tables and accompanying text were reformatted for ease in comparing environmental impacts among alternatives and among options within alternatives. Section 2.7 was also revised to focus on incremental impacts that would result from implementation of the alternatives. Baseline environmental

impacts were removed from the comparisons among alternatives and options. This information is now presented in Chapter 3.

**Chapter 3. *Affected Environment:*** Additional information was provided on the environmental baseline at each site, including graphics to more clearly illustrate existing surface water and groundwater conditions.

Estimates of existing impacts for current HFIR/REDC operations were added to Sections 3.2.3.2 (Air Quality), 3.2.9.1.2 (Radiation Exposure and Risk), and 3.2.11.1 (Waste Inventories and Activities). Similarly, estimates for current ATR operations were added to Sections 3.3.3.2 (Air Quality), 3.3.9.1.2 (Radiation Exposure and Risk), and 3.3.11.1 (Waste Inventories and Activities). Information was also provided on the impacts of the range fires affecting Hanford and INEEL during the summer of 2000. In addition, site data were updated to reflect recent measurements and analyses. Estimates of existing impacts of maintaining FFTF in standby were added to Section 3.4.3.1 (Air Quality).

In response to public comments on the Draft NI PEIS, additional information on health studies conducted in the Hanford area was also incorporated.

**Chapter 4. *Air Quality:*** Stack parameters used for the air quality modeling were added. In response to public comment, estimates of the ambient air quality concentrations from FFTF sources were added to the deactivation section.

***Water Resources:*** New water use and sanitary wastewater generation increments for REDC and FDPF were added to reflect the revised additional workforce required at these facilities and to be consistent with FMEF. Water use and waste water generation rates for the New Accelerator(s) and New Research Reactor alternatives were also revised. These changes were also incorporated into the waste management analyses.

***Ecological and Cultural and Palentological Resources:*** These sections were updated to reflect consultations concerning threatened and endangered species and cultural resources conducted with appropriate Federal and state agencies. Consultations were also conducted with interested Native American tribes. No major issues were raised as a result of these consultations.

***Socioeconomics:*** Section 4.5.1.1.8 was revised to reflect changes in the number of workers associated with FFTF operations and deactivation. The associated impacts on community services were also incorporated. In addition, the number of workers at the Oak Ridge Reservation was revised to reflect the entire site workforce rather than just the number of workers at ORNL.

***Normal Operations:*** Based on more recent site data on occupational radiation exposure for workers at REDC, all worker health impacts for target processing at REDC, FMEF, and FDPF and for neptunium target storage at REDC, Chemical Processing Plant 651 (CPP-651), and FMEF were updated. Also, low-energy accelerator source terms were modified to properly reflect normal operational emissions resulting in modifications to the population health impacts for all options of Alternative 3.

***Facility Accidents:*** The high-energy accelerator analysis was redone to incorporate a more accurate revised source term, and the risks for currently operating reactors were added to the tables. An additional analysis addressing industrial accidents was also performed and incorporated into Chapter 4.

***Transportation:*** The neptunium inventory was revised to use the recently declassified actual inventory. The number of actual shipments from SRS to the processing facilities and the transportation risk estimates were modified accordingly.

**Waste Management:** The analysis for the Draft NI PEIS assumed that the waste generated from the processing of irradiated neptunium-237 targets is transuranic waste. However, as a result of comments received during the public comment period, DOE is considering whether the waste from processing of irradiated neptunium-237 targets should be classified as high-level radioactive waste and not transuranic waste. The Waste Management sections (i.e., Sections 4.3.1.1.13, 4.3.2.1.13, 4.3.3.1.13, and 4.4.3.1.13) were revised to reflect this different classification from what was assumed in the Draft NI PEIS.

**Spent Nuclear Fuel Management:** The sections were revised to quantify the generation of spent fuel from 35 years of operation and to state that dry spent nuclear fuel storage at the FFTF site is similar to NRC-approved methods currently being used for interim storage of commercial spent nuclear fuel. In addition, based on public comments, a K Basins spent fuel storage reference document was added.

**Cumulative Impacts:** Cumulative impact tables in Section 4.8 were revised to present the contributions from each of the various site actions anticipated during the course of the operational period evaluated in the NI PEIS. Air quality tables were also revised to incorporate the revised baseline from Chapter 3. In addition, waste management tables were revised to include the site's treatment, storage, and disposal capacities for easier comparison of the waste generations, by waste type, to the waste management capacities at the sites.

**Chapter 5.** In response to public comments, a list of organizations that DOE contacted during the consultation process was added.

**Volume 2.** Summaries of the *NI Cost Report* and *NI Nonproliferation Impact Assessment* were added as Appendixes P and Q, respectively. NASA mission guidance correspondence was added as Appendix R.

**Volume 3.** Volume 3 of the NI PEIS was added to present the comments received during the public review period for the Draft NI PEIS and DOE's responses to these comments.

### S.3 ALTERNATIVES EVALUATED IN THE NI PEIS

The NI PEIS analyzes the potential environmental impacts of using various irradiation and processing facilities to meet the following projected DOE irradiation service mission needs for 35 years: (1) production of medical and industrial isotopes, (2) production of up to 5 kilograms (11 pounds) per year of plutonium-238 for use in advanced radioisotope power systems for future NASA space missions, and (3) support for U.S. civilian nuclear energy research and development activities. The proposed irradiation facilities include facilities that are currently operating, those that could be brought on line, or those that could be constructed and operated to meet DOE's nuclear infrastructure mission requirements. A No Action Alternative and five programmatic alternatives are listed below.

- No Action Alternative
- Alternative 1—Restart FFTF
- Alternative 2—Use Only Existing Operational Facilities
- Alternative 3—Construct New Accelerator(s)
- Alternative 4—Construct New Research Reactor
- Alternative 5—Permanently Deactivate FFTF (with No New Missions)

It is possible during the Record of Decision process that a combination of the alternatives could be selected, for example, a low-energy power accelerator in combination with the existing reactors to optimize research isotope production, or in combination with FFTF to optimize research and therapeutic isotope production.

The alternatives, their associated facility options, and their relative capabilities are described in detail in Chapter 2 of the NI PEIS. As presented in **Table S-1**, the NI PEIS evaluates 26 specific technology/siting options associated with the alternatives identified above. DOE's Preferred Alternative for accomplishing expanded civilian nuclear energy research and development and isotope production missions in the United States is Alternative 2, Use Only Existing Operational Facilities, Option 7. Under this alternative and option, DOE would reestablish domestic production of plutonium-238, as needed, using irradiation capabilities at both ATR at INEEL and HFIR at ORNL. REDC at ORNL would be used to store neptunium-237 and to fabricate and process the targets irradiated at ATR and HFIR. The production of medical and industrial isotopes and support of civilian nuclear energy research and development would continue and increase to the extent possible under current reactor operating levels. FFTF at Hanford would be permanently deactivated. The preferred alternative is discussed in more detail at the end of this section.

**No Action Alternative.** Under the No Action Alternative (maintain status quo), FFTF would be maintained in standby status for all or a portion of the 35-year evaluation period for operations covered in the NI PEIS. For purposes of analysis in the NI PEIS, the maximum of 35 years was assumed. Ongoing operations at existing facilities, as described in Chapter 3 of the NI PEIS, would continue under this alternative. DOE would not establish a domestic plutonium-238 production capability, but could, instead, continue to purchase Russian plutonium-238 to meet the needs of future U.S. space missions. For the purposes of analysis in the NI PEIS, DOE assumed that it would continue to purchase plutonium-238 to meet the space mission needs for the 35-year evaluation period, and has included in the NI PEIS the transportation impacts of purchasing up to 175 kilograms (385.8 pounds) from Russia. However, DOE recognizes that any purchase beyond what is currently available to the United States through the existing contract will require additional NEPA review. DOE would continue its medical and industrial isotope production and civilian nuclear energy research and development activities at the current operating levels of existing facilities. A consequence of a No Action decision would be the need to determine the future of the neptunium-237 stored at SRS. Therefore, the impacts of possible future transportation and storage of neptunium-237 are evaluated as part of the No Action Alternative.

Four options are analyzed under the No Action Alternative. If DOE decides not to establish a domestic plutonium-238 production capability in the future, the neptunium-237 would have no programmatic value and Option 1 would be selected. Under this option, DOE would follow its current stabilization strategy for the neptunium-237, currently in solution form at SRS. If, however, DOE decides to maintain the neptunium-237 inventory for future plutonium-238 production, the neptunium-237 oxide would be transported from SRS to one of three candidate DOE sites for up to 35 years of storage for possible future use: Option 2, REDC at ORNL; Option 3, Building CPP-651 at INEEL; or Option 4, FMEF at Hanford.

**Alternative 1—Restart FFTF.** Under Alternative 1, FFTF at Hanford would be restarted and operated at a nominal 100 megawatts for the 35-year evaluation period. FFTF would be used to irradiate targets for medical and industrial isotope production, plutonium-238 production, and research and development irradiation requirements. Ongoing operations at existing facilities as described in Chapter 3 of the NI PEIS would continue.

Targets for medical and industrial isotope production would be fabricated in one or more facilities at Hanford. Target material would typically be acquired from ORNL, where enrichment processes are conducted to produce high purity target material suitable for production of medical isotopes, and stored at Hanford. The targets would be irradiated at FFTF and then returned to the fabrication facility for postirradiation processing. From there, the isotope products would be sent directly to commercial pharmaceutical distributors.

**Table S-1 NI PEIS Alternatives and Options**

	Option Number	Irradiation Facility	Plutonium-238 Production Mission		Medical and Industrial Isotope Production and Civilian Nuclear Energy Research and Development Mission	
			Storage Facility	Target Fabrication and Processing Facility	Storage Facility	Target Fabrication and Processing Facility
<b>No Action Alternative</b>	1	–	–	–	–	–
	2	–	REDC	–	–	–
	3	–	CPP-651	–	–	–
	4	–	FMEF	–	–	–
<b>Alternative 1: Restart FFTF</b>	1	FFTF <sup>a</sup>	REDC	REDC	RPL/306-E	RPL/306-E
	2	FFTF <sup>a</sup>	FDPF/CPP-651	FDPF	RPL/306-E	RPL/306-E
	3	FFTF <sup>a</sup>	FMEF	FMEF	FMEF	FMEF
	4	FFTF <sup>b</sup>	REDC	REDC	RPL/306-E	RPL/306-E
	5	FFTF <sup>b</sup>	FDPF/CPP-651	FDPF	RPL/306-E	RPL/306-E
	6	FFTF <sup>b</sup>	FMEF	FMEF	FMEF	FMEF
<b>Alternative 2: Use Only Existing Operational Facilities</b>	1	ATR	REDC	REDC	–	–
	2	ATR	FDPF/CPP-651	FDPF	–	–
	3	ATR	FMEF	FMEF	–	–
	4	CLWR	REDC	REDC	–	–
	5	CLWR	FDPF/CPP-651	FDPF	–	–
	6	CLWR	FMEF	FMEF	–	–
	7	HFIR and ATR	REDC	REDC	–	–
	8	HFIR and ATR	FDPF/CPP-651	FDPF	–	–
	9	HFIR and ATR	FMEF	FMEF	–	–
<b>Alternative 3: Construct New Accelerator(s)</b>	1	New	REDC	REDC	New <sup>c</sup>	New <sup>c</sup>
	2	New	FDPF/CPP-651	FDPF	New <sup>c</sup>	New <sup>c</sup>
	3	New	FMEF	FMEF	New <sup>c</sup>	New <sup>c</sup>
<b>Alternative 4: Construct New Research Reactor</b>	1	New	REDC	REDC	New <sup>c</sup>	New <sup>c</sup>
	2	New	FDPF/CPP-651	FDPF	New <sup>c</sup>	New <sup>c</sup>
	3	New	FMEF	FMEF	New <sup>c</sup>	New <sup>c</sup>
<b>Alternative 5: Permanently Deactivate FFTF (with No New Missions)</b>	–	–	–	–	–	–

a. Hanford FFTF would operate with mixed oxide fuel for 21 years and highly enriched uranium fuel for 14 years.

b. Hanford FFTF would operate with mixed oxide fuel for 6 years and highly enriched fuel for 29 years.

c. The new facility would not be required if a DOE site with available support capability and infrastructure is selected.

**Key:** ATR, Advanced Test Reactor at INEEL; CLWR, commercial light water reactor; CPP-651, INEEL Building CPP-651 Storage Vault; FDPF, Fluorinel Dissolution Process Facility at INEEL; FFTF, Fast Flux Test Facility at Hanford; FMEF, Fuels and Materials Examination Facility at Hanford; HFIR, High Flux Isotope Reactor at ORNL; REDC, Radiochemical Engineering Development Center at ORNL; RPL/306-E, Radiochemical Processing Laboratory and Building 306-E at Hanford.

Targets for plutonium-238 production would be fabricated in one of three candidate facilities at ORNL, Hanford, or INEEL. The material needed for target fabrication (neptunium-237) would be transported from SRS to the fabrication facilities, where it would be stored until fabrication. The nonirradiated targets would be transported to and irradiated at FFTF and transported back to the fabricating facilities for postirradiation processing. The separated plutonium-238 would be transported to LANL for fabrication into heat sources for radioisotope power systems and heating units.

Under Alternative 1, raw materials, nonirradiated targets, irradiated targets, and processed materials would be transported between the locations selected for raw target material acquisition, material storage, target fabrication, target irradiation, and postirradiation processing and the final destination for the medical and industrial isotopes and the plutonium-238 product or various research and development test sites.

The six options under this alternative are associated with the type of nuclear fuel to be used for FFTF operations and the specific facilities to be used for target fabrication and processing. The first three options (Options 1 through 3) would involve operating FFTF with a mixed oxide fuel core for the first 21 years and a highly enriched uranium fuel core for the remaining 14 years. The last three options (Options 4 through 6) would involve operating FFTF with a mixed oxide fuel core for the first 6 years and a highly enriched uranium fuel core for the remaining 29 years. FFTF can provide similar irradiation services with either a mixed oxide core or a highly enriched uranium core. Potential impacts from the deactivation of FFTF at the end of its operating life are not explicitly covered under this alternative, but are addressed under Alternative 5.

The U.S. nonproliferation policy (U.S. House of Representatives 1992 and the White House 1993) strongly discourages the use of highly enriched uranium fuel in civilian research and test reactors. The Reduced Enrichment for Research and Test Reactors Program implements this policy by developing technical means to reduce and eventually eliminate the use of highly enriched uranium in research and test reactors throughout the world and in the United States, without decreasing their safety or significantly affecting their performance and operating costs.

To be in compliance with these policy directives, the most appropriate fuel supply for FFTF in the out years (beyond current Hanford mixed oxide and possible SNR-300 mixed oxide supplies) must be determined by a technical study with the preferred fuel source being low-enriched uranium. Highly enriched uranium fuel should only be considered if low-enriched uranium is not technically feasible, or if there are significant impacts on safety, performance, or cost associated with using fuels other than highly enriched uranium.

In the event that a decision is made to restart the reactor, and to support these policy directives, DOE's Office of Nonproliferation and National Security would undertake a study to consider the technical feasibility of low-enriched uranium fuel (under the Reduced Enrichment for Research on Test Reactors Program) for FFTF. If low-enriched uranium fuel is found infeasible, DOE would subsequently procure highly enriched uranium fuel in a manner consistent with U.S. nonproliferation policy. This study would be conducted, decisions implemented, and fuel made available during the time period between a Record of Decision indicating an FFTF restart and prior to the end of available Hanford mixed oxide and possible SNR-300 mixed oxide fuel supplies.

For the purposes of presenting a bounding analysis in the NI PEIS, DOE has analyzed the impacts of using highly enriched uranium fuel in FFTF after the available mixed oxide fuel supplies have been expended. These impacts would bound those of using a low-enriched uranium fuel form.

**Alternative 2—Use Only Existing Operational Facilities.** Under Alternative 2, DOE would use existing operating DOE reactors or U.S. commercial nuclear power plants to produce plutonium-238 for future space

missions. The production of medical and industrial isotopes and support of civilian nuclear energy research and development in DOE reactors and accelerators would continue at the No Action Alternative level.

The currently operating DOE reactors, HFIR and ATR, cannot fully meet the projected long-term need for medical isotope production and civilian nuclear energy research and development, with or without the plutonium-238 production mission. Depending on the combination of facilities used in Alternative 2, HFIR and ATR could continue their current support of the medical and industrial isotope and research and development missions, including some near-term growth, while accommodating the production of plutonium-238. Under other scenarios, some of the near-term growth in medical and industrial isotope production and civilian nuclear energy research and development possible in these reactors could be limited by the addition of the plutonium-238 production. In any case, non-DOE use of these facilities would be affected by the addition of the plutonium-238 mission. If a commercial reactor were used for plutonium-238 production, the DOE facilities would be unaffected and would continue operating as discussed under the No Action Alternative.

Another component of Alternative 2 is permanent deactivation of FFTF. Permanent deactivation of FFTF (Alternative 5) would occur in conjunction with any of the options under Alternative 2, 3, or 4. Ongoing operations at existing facilities as described in Chapter 3 of the NI PEIS would continue under Alternative 2.

Targets for plutonium-238 production would be fabricated in one of three facilities at ORNL, INEEL, or Hanford. The material needed for target fabrication (neptunium-237) would be processed and transported from SRS to the fabrication facilities where it would be stored until fabrication. The targets would be irradiated at existing reactor facilities (HFIR, ATR, CLWR, as described in Section S.4) and would be transported back to the fabricating facilities for postirradiation processing.

Under Alternative 2, nonirradiated targets, irradiated targets, and processed materials would be transported between the locations selected for storage, target fabrication, target irradiation, and postirradiation processing. In addition, the plutonium-238 product would be transported to LANL.

Nine options are proposed under this alternative. Options 1 through 3 involve the irradiation of targets in ATR at INEEL. Options 4 through 6 involve the irradiation of targets in a generic CLWR. Options 7 through 9 involve the irradiation of targets in both INEEL's ATR and ORNL's HFIR.

**Alternative 3—Construct New Accelerator(s).** Under Alternative 3, one or two new accelerators would be used for target irradiation for the evaluation period of 35 years. The new accelerator(s), which would be constructed at an existing DOE site(s), would be used to irradiate all of the targets (i.e., for production of plutonium-238, isotopes for medical and industrial uses, and materials testing for research and development). Ongoing operations at existing facilities as described in Chapter 3 of the NI PEIS would continue.

The targets for plutonium-238 production would be fabricated in one of the three alternative facilities at ORNL, INEEL, or Hanford. The material needed for the target fabrication (neptunium-237) would be transported from SRS to the fabrication facilities, where it would be stored until fabrication. The targets would be irradiated at a new high-energy accelerator facility and transported back to the target fabricating facilities for postirradiation processing.

Targets for medical and industrial isotope production would be fabricated in a new support facility located at the same site as the low-energy accelerator. Target materials would be stored on site until fabrication. The targets would be irradiated in the low-energy accelerator and returned to the new support facility for postirradiation processing. Site selection for Alternative 3 is not evaluated as part of the NI PEIS. Because Alternative 3 is evaluated at a generic DOE site, no credit was taken for any support infrastructure existing at

the site, and it was postulated that a new support facility would be required to support operation of the low-energy accelerator and its missions and the high-energy accelerator civilian nuclear energy research and development missions if both accelerators were located on the same site. While this approach bounds the environmental impact assessment for the implementation of Alternative 3, it overstates the impacts because the NI PEIS integrates the impacts associated with constructing new support facilities and infrastructure that may be available at the existing DOE site. In the event that Alternative 3 or the low-energy accelerator alone is selected by the Record of Decision for subsequent consideration, follow-on NEPA reviews would evaluate potential locations for either both accelerators or one of the accelerators. It is unlikely that DOE would consider locating the new low-energy or high-energy accelerator on a DOE site that does not have existing infrastructure capable of supporting all or most of the mission requirements.

Under Alternative 3, nonirradiated targets, irradiated targets, and processed materials would be transported between the locations selected for storage, target fabrication, target irradiation, postirradiation processing, and the final destination of the plutonium-238. Alternative 3 also would include decontamination and decommissioning of the accelerator(s) and the processing facility when the missions are over, as well as deactivation of FFTF at Hanford.

**Alternative 4—Construct New Research Reactor.** Under Alternative 4, a new research reactor would be used for target irradiation for the evaluation period of 35 years. The new research reactor, to be constructed at an existing DOE site, would be used to irradiate all targets (i.e., for the production of plutonium-238, isotopes for medical and industrial uses, and materials testing for civilian nuclear energy research and development). Ongoing operations at existing facilities as described in Chapter 3 of the NI PEIS would continue.

The targets for plutonium-238 production would be fabricated in one of the three facilities at ORNL, INEEL, or Hanford. The material needed for the target fabrication (neptunium-237) would be transported from SRS to the fabrication facilities where it would be stored until fabrication. The targets would be irradiated at the new research reactor facility and transported back to the target fabrication facilities for postirradiation processing.

Targets for medical and industrial isotope production would be fabricated in a new support facility located at the same site as the new research reactor. Target materials would be stored on site until fabrication. The targets would be irradiated in the new research reactor and returned to the new support facility for postirradiation processing.

Alternative 4 site selection is not evaluated as part of the NI PEIS. Because Alternative 4 is evaluated at a generic DOE site, no credit was taken for any existing support infrastructure at the site and it was postulated that a new support facility would be required to support operation of the new research reactor and its missions. While this approach bounds the environmental impact assessment for the implementation of Alternative 4, it overstates the impacts because the NI PEIS integrates the impacts associated with constructing new support facilities and infrastructure that may be available at the existing DOE site. In the event that Alternative 4 is selected by the Record of Decision for subsequent consideration, follow-up NEPA reviews would evaluate potential locations for the new research reactor. It is unlikely that DOE would consider locating the new research reactor on a DOE site that does not have existing infrastructure capable of supporting all or most of the proposed medical and industrial isotope production and civilian nuclear energy research and development mission requirements.

Under Alternative 4, nonirradiated targets, irradiated targets, and processed materials would be transported between the locations selected for storage, target fabrication, target irradiation, postirradiation processing, and the final destination of the plutonium-238. Alternative 4 also would include the decontamination and

decommissioning of both the research reactor and the support facility when the missions are over, as well as deactivation of FFTF at Hanford.

**Alternative 5—Permanently Deactivate FFTF (with No New Missions).** Under Alternative 5, DOE would permanently deactivate FFTF, with no new missions. Medical and industrial isotope production and civilian nuclear energy research and development missions, at the existing facilities described in Chapter 3, would continue. DOE's nuclear facilities infrastructure would not be enhanced.

### **Selection of Alternatives**

In the NI PEIS Record of Decision, DOE can select any alternative or combination of alternatives or elements of alternatives. For example, DOE could select Alternative 2 in combination with the new low-energy accelerator element of Alternative 3. This combination of alternative elements would provide for the requirements of the plutonium-238 production, enhanced civilian nuclear energy research and development capability, and enhanced medical and industrial isotope production capability.

### **Alternatives Considered and Dismissed**

In developing a range of reasonable alternatives, DOE examined the capabilities and available capacities of the existing and planned nuclear research facilities (accelerators, reactors, and processing [hot] cells) that potentially could be used to support one or all of the proposed isotope production and research missions (DOE 2000a). The following facilities were initially considered, but were subsequently dismissed as reasonable alternatives for meeting DOE's nuclear infrastructure mission requirements.

**Irradiation Facilities Dismissed.** DOE evaluated the irradiation capabilities of existing government, university, and commercial irradiation facilities to determine whether they could significantly support the proposed expanded nuclear infrastructure missions. **Table S-2** presents irradiation facilities that were initially considered but dismissed from further evaluation because they lacked technical capability or available capacity. Reasons for lacking technical capability include that the facility has been permanently shut down, it does not possess the capability to produce steady-state neutrons, or that it could not maintain sufficient power levels to adequately support steady-state neutron production. Facilities were similarly dismissed if existing capacity was fully dedicated to existing missions, or if use of existing capacity to support the NI PEIS proposed action would impact existing missions. Although a number of facilities shown in Table S-2 have some available capacity, their combined available capacity is a very small percentage of the capacity needed to support the missions evaluated in the NI PEIS.

Two of these facilities, IPF at the Los Alamos Neutron Science Center (LANSCE) and BLIP at BNL, were identified in the NI PEIS Notice of Intent as existing facilities that could potentially support the proposed nuclear infrastructure missions. IPF produces radioisotopes using LANSCE's half-mile accelerator that delivers medium-energy protons. IPF's three major products include germanium-68, strontium-82, and sodium-22. As a result of changing DOE missions, the production of radioisotopes at target area "A" of the LANSCE has been rendered inoperable. DOE is currently in the process of upgrading the LANSCE facility with a new 100-million-electron-volt IPF. The facility is scheduled for completion in 2001. After completion of the LANSCE upgrade, the existing capability at these two facilities will be twice the current need for accelerator-generated medical isotopes. Thus, no new accelerator capacity is needed in the short term. Should isotope demand grow consistent with the Expert Panel Report, there will be a need for expanded isotope production capacity for those isotopes generated by IPF and BLIP. IPF and BLIP were dismissed as a reasonable alternative for the production of medical isotopes because they cannot meet the projected future demand for accelerator-produced isotopes.

**Key:** LINAC, linear accelerator; ATLAS, Argonne Tandem - LINAC Accelerator System.

**Source:** DOE 2000a.

The AGS accelerator complex at BNL was evaluated for meeting the mission requirements of medical and industrial isotope production, plutonium-238 production, and civilian nuclear energy research and development. AGS presently accelerates up to  $7 \times 10^{13}$  protons to 24 gigavolts (1,000 million electron volts) with a cycle time of approximately 2.5 seconds. This corresponds to a beam power of approximately 100 kilowatts. The complex was dismissed as a reasonable alternative because the potential neutron flux generated by the facility in the required configuration (i.e., with a spallation target) would not be adequate to meet the mission goals and, in addition, operating the complex in the required configuration would not be compatible with the present primary mission of the facility (Kovar 2000).

Two existing operating DOE facilities, ATR and HFIR, were evaluated as components of Alternative 2, Use Only Existing Operational Facilities. These two facilities currently provide isotope production capability, and were examined for their ability to meet the isotope production and civilian nuclear energy research and development requirements of the proposed expanded missions. In addition, DOE considered whether production from ATR and HFIR could be enhanced by increasing power levels at the reactors or through other modifications to the facilities, which included the installation of rapid radioisotope retrieval systems for the production of isotopes with a short half-life. In general, the installation of rapid radioisotope retrieval systems in reactors does not increase the ability of reactors to produce larger quantities of isotopes, it enable the reactors to produce a broader spectrum of isotopes. While some growth is possible in isotope production at ATR and HFIR, such growth would be insufficient to meet the long-term growth projections. Further growth could only be enabled by increasing reactor power levels. At ATR, increases in power levels are possible to the extent that priority DOE Office of Naval Reactor missions are not impacted. Raising ATR power would only delay the point in time at which capacity is reached. The power level at HFIR is already at 100 percent of its current Authorization Basis (85 megawatts), and modification of this Authorization Basis would be required to increase to full-design power (100 megawatts). Increasing the power levels at ATR and/or HFIR will enhance the isotope production capability of these reactors. However, the enhancement in production capability would not be adequate to meet the future demand for isotope production; it would only delay the point in time at

which the United States' reactor isotope production capacity is reached. Therefore, increasing the power levels at ATR and/or HFIR was dismissed as a reasonable alternative for meeting the requirements of the DOE missions.

Modification of CLWRs to enable online insertion and retrieval of targets for the medical and industrial isotope production missions was evaluated and dismissed as a reasonable alternative. This decision was made because the required facility modifications would be significant and would include penetrations into the reactor vessel and, potentially, the containment vessel. Additional facility modifications would be required to enable loading of the targets into a shielded cask for transport to a processing facility. Performing these facility modifications would require an extended refueling outage (with a resulting loss of power generation revenue to the CLWR owner) and could potentially extend subsequent maintenance or refueling outages to inspect, test and maintain the insertion and retrieval system, reactor vessel penetrations, and potential containment vessel penetrations. CLWRs were considered for the production of medical isotopes with moderate and long half-lives by irradiating targets in the CLWR vessel but outside the reactor core region (i.e., outside of the fuel assembly region). Only one isotope, strontium-89, was considered a potential candidate for production in the CLWR outside of the reactor core region. Strontium-89 has a half-life of 50.5 days. Irradiated targets containing strontium-89 could only be harvested from a CLWR every 18 to 24 months during a scheduled reactor refueling outage. Approximately 10 CLWRs, with refueling outages scheduled every 2 to 3 months, would be required to support a program to ensure a continuous and reliable supply of strontium-89. Due to the CLWR's ability to irradiate targets for only a very limited array of medical isotopes (only one isotope in current demand was identified), it was not considered a reasonable alternative for expanding the U.S. infrastructure to provide an overall enhancement of the medical isotope production mission. CLWRs were also considered for the DOE civilian nuclear energy research and development missions. CLWRs will continue to support the commercial industry research and development activities by providing a test bed for industry sponsored lead test assemblies and other related research. CLWRs cannot meet most of the requirements for supporting the DOE civilian nuclear energy research and development missions and were therefore dismissed as a reasonable alternative for supporting these missions.

Canadian Deuterium Uranium (CANDU) reactors, operating in Canada, were considered for supplying irradiation services for the plutonium-238 production mission. (Note: Canada is currently the major supplier of medical radioisotopes used in the United States.) Since use of the CANDU reactors does not meet the programmatic issue being addressed in the NI PEIS, that is the enhancement of the United States infrastructure to support the proposed missions, the CANDU reactors were considered and dismissed as a reasonable alternative. However, the environmental impacts associated with transporting the nonirradiated and irradiated neptunium-237 targets between the CANDU reactors and the target fabrication and processing facilities in the United States are bounded by the evaluations presented in the NI PEIS for the commercial light water reactor options of Alternative 2, Use Only Existing Operational Facilities.

Some facilities listed in Table S-2 that do not have the capacity to support the proposed action without impacting existing missions do have some existing medical or industrial isotope production or civilian nuclear energy research and development missions. These facilities will continue to support their existing missions at current levels.

**Processing Facilities Dismissed.** Numerous existing U.S. processing hot cell facilities possess the capabilities and capacity to support the proposed missions. Given this general availability, only existing processing facilities that are colocated at DOE's candidate irradiation facility sites (i.e., ORNL, INEEL, and Hanford) were evaluated in the NI PEIS. Although multiple processing facilities exist at each of these sites, only the most suitable facilities in terms of capability, capacity, and availability were given further consideration. The processing facilities that were dismissed from consideration are listed in **Table S-3**.

**Table S-3 Processing Facilities Considered and Dismissed from Further Evaluation**

Location	Facility
Argonne National Laboratory	Irradiated Materials Facility
	Alpha-Gamma Hot Cell Facility
	Building 205

	Californium processing facility

Source: DOE 2000a.

Based on comments on the scope of the *Plutonium-238 Production EIS*, the H-Canyon and HB-Line facilities at SRS that previously performed the processing for the plutonium-238 production mission were reconsidered as potential processing facilities for the proposed plutonium-238 production mission even though the facilities are not colocated with a proposed irradiation facility. After reviewing the plutonium-238 production target fabrication and processing requirements, the capabilities and capacities of the facilities, and the modifications and resources required to support the plutonium-238 production mission, use of the H-Canyon and HB-Line facilities was dismissed as a reasonable alternative because:

1. DOE plans to shut down these facilities following completion of their current missions to stabilize and prepare for disposition of Cold War legacy nuclear materials and certain spent nuclear fuel, and a determination that a new nonchemical processing technology is capable of preparing aluminum-clad research reactor spent nuclear fuel for ultimate disposition.
2. The cost to extend the operating lives of these facilities to support plutonium-238 production for the proposed 35-year evaluation period would be approximately one order of magnitude higher than the costs associated with the processing facilities evaluated in the NI PEIS.

A commentator also proposed using the H-Canyon and HB-Line for a short campaign to produce all of the required plutonium-238. Based on prior production rates, it would take approximately 7 years to produce 175 kilograms (385 pounds) of plutonium-238, the total plutonium-238 production goal. The target fabrication and irradiation requirements to support this processing campaign to produce 25 kilograms (55 pounds) per year of plutonium-238 would be significant but feasible. The irradiation requirements could be supported by operating five CLWRs or operating FFTF at the 400-megawatt power level. However, a concern about the short campaign option is that the plutonium-238 would be stored a long time before use and because of natural decay may not meet the specification requirements when finally needed. This alternative was dismissed because of the uncertainty that, over time, the plutonium-238 produced may not meet the required specification for NASA missions.

### **Preferred Alternative**

CEQ regulations require an agency to identify its preferred alternative(s) in the final programmatic environmental impact statement (40 CFR 1502.14(e)). The preferred alternative is the alternative that the agency believes would fulfill its statutory mission, giving consideration to environmental, economic, technical, and other factors. Consequently, to identify a preferred alternative, DOE has developed information on potential environmental impacts, costs, policy issues, technical risks, and schedule risks for the alternatives under consideration. The NI PEIS provides information on the environmental impacts. Cost, nonproliferation policy, and various technical reports have also been prepared and are available in the appropriate DOE Reading Rooms for public review.

Based on the analysis discussed above, DOE's Preferred Alternative is to apply its existing infrastructure to the extent possible to pursue the missions outlined in the NI PEIS, that is, Alternative 2, Option 7. Under this approach, DOE proposes to consider opportunities to enhance its existing facilities to maximize the agency's ability to address future mission needs.

The Preferred Alternative also addresses the future of FFTF. While DOE recognizes that this facility has unique capabilities, the Department did not receive the commitments from the private sector or other governments that would clearly justify the restart of the facility. Lacking such commitment, DOE would permanently deactivate FFTF under the Preferred Alternative.

Finally, under the Preferred Alternative, DOE proposes to reestablish domestic production of plutonium-238, as needed, to support U.S. space exploration. ATR in Idaho and HFIR in Tennessee would be used, as appropriate, to irradiate targets for this purpose without interfering with either reactor's primary mission. The Preferred Alternative includes processing the irradiated plutonium-238 targets at REDC at ORNL.

In view of the lack of commitments that would justify the restart of FFTF or the construction of new facilities as proposed under Alternatives 3 and 4, DOE anticipates that its current infrastructure will serve the needs of the research and isotope communities for the next several years. In particular, DOE will consider opportunities to enhance its effort to provide medical and research isotopes. If significantly larger amounts of isotopes are required in the future, DOE would rely on the private sector to fulfill these needs.

As a potential option for the longer-term future, DOE proposes to work over the next 2 years to establish a conceptual design for an Advanced Accelerator Applications (AAA) facility. Such a facility, which would be used to evaluate spent fuel transmutation, conduct various nuclear research missions, and ensure a viable backup technology for the production of tritium for national security purposes, was proposed and initial work funded in the fiscal year 2001 Energy and Water Appropriation. If DOE proposes specific enhancements of existing facilities or development of the AAA facility, further NEPA review would be conducted.

## **S.4 OVERVIEW OF NUCLEAR INFRASTRUCTURE FACILITIES AND TRANSPORTATION**

The following is a brief description of the facilities involved in target fabrication and postirradiation processing and target irradiation. Detailed descriptions of these facilities and the processes associated with them are provided in Appendixes A through F of the NI PEIS. Also provided is a summary of the transportation required by each alternative.

### **Target Fabrication and Postirradiation Processing Facilities**

**Radiochemical Engineering Development Center.** REDC at ORNL is a companion facility to the HFIR. REDC's two buildings house heavily shielded hot cells and analytical laboratories that are used for remote fabrication of rods and targets (for irradiation in HFIR) and processing of irradiated rods and targets for the separation and purification of transuranic elements, process development, and product purification and packaging. ORNL's REDC Building 7930 is proposed for the storage of neptunium-237 in one option of the No Action Alternative. It also is proposed for the storage of neptunium-237, fabrication of neptunium-237 targets, and processing of irradiated neptunium-237 targets for two irradiation options in Alternative 1 (Restart FFTF), three irradiation options in Alternative 2 (Use Only Existing Operational Facilities), and for one irradiation option in Alternative 3 (Construct New Accelerator[s]) and Alternative 4 (Construct New Research Reactor). REDC's current radiochemical missions would not be impacted by the addition of the proposed storage of neptunium-237, fabrication of neptunium-237 targets, and the processing of irradiated neptunium-237 targets activities. REDC would have no role in support of Alternative 5 (Permanently Deactivate FFTF [with No New Missions]). **Figure S-1** presents a map of the Oak Ridge Reservation (ORR) that depicts the location of REDC.

REDC Building 7930 is divided into four major areas: (1) a cell complex with seven cells, six shielded and one unshielded; (2) maintenance and service areas surrounding the cell complex; (3) an operating control area; and (4) an office area adjacent to, but isolated from, the operating areas. Utility services, ventilation systems, crane and manipulator systems, and liquid-waste systems also are included. The proposed plutonium-238 processing and storage activities would require equipment installation in three main areas of the second floor of REDC Building 7930. The REDC hot cell facilities that would be used for the proposed action have never been used. The activities required for target fabrication would take place in shielded gloveboxes. (Appendix A of the NI PEIS provides a description of the target fabrication process.) The mechanical operations involved in the final target fabrication may present lesser hazards that permit them to be carried out in open boxes. Cell E would contain processing equipment to purify the separated plutonium-238 product, prepare the plutonium oxide, and transfer the oxide into shipping containers. Cell E would also contain vertical storage wells for dry storage of neptunium and other actinides.

Cell D activities would include receipt of irradiated targets, as well as target dissolution, chemical separation of neptunium and plutonium from fission products, and partitioning and purification of neptunium. Cell D also contains process equipment to remove transuranic elements from the aqueous waste streams and vitrifying waste.

**Fluorinel Dissolution Process Facility.** FDPF is in the Idaho Nuclear Technology and Engineering Center (INTEC), which is located northeast of the Central Facilities Area at INEEL and approximately 3.2 kilometers (2 miles) southeast of ATR. **Figure S-2** presents a map of the INEEL site that depicts the location of FDPF. FDPF is proposed for fabrication of neptunium-237 targets, and processing of irradiated neptunium-237 targets for two irradiation options in Alternative 1 (Restart FFTF), three irradiation options in Alternative 2 (Use Only Existing Operational Facilities), and one irradiation option in Alternative 3 (Construct New Accelerator[s]) and Alternative 4 (Construct New Research Reactor).

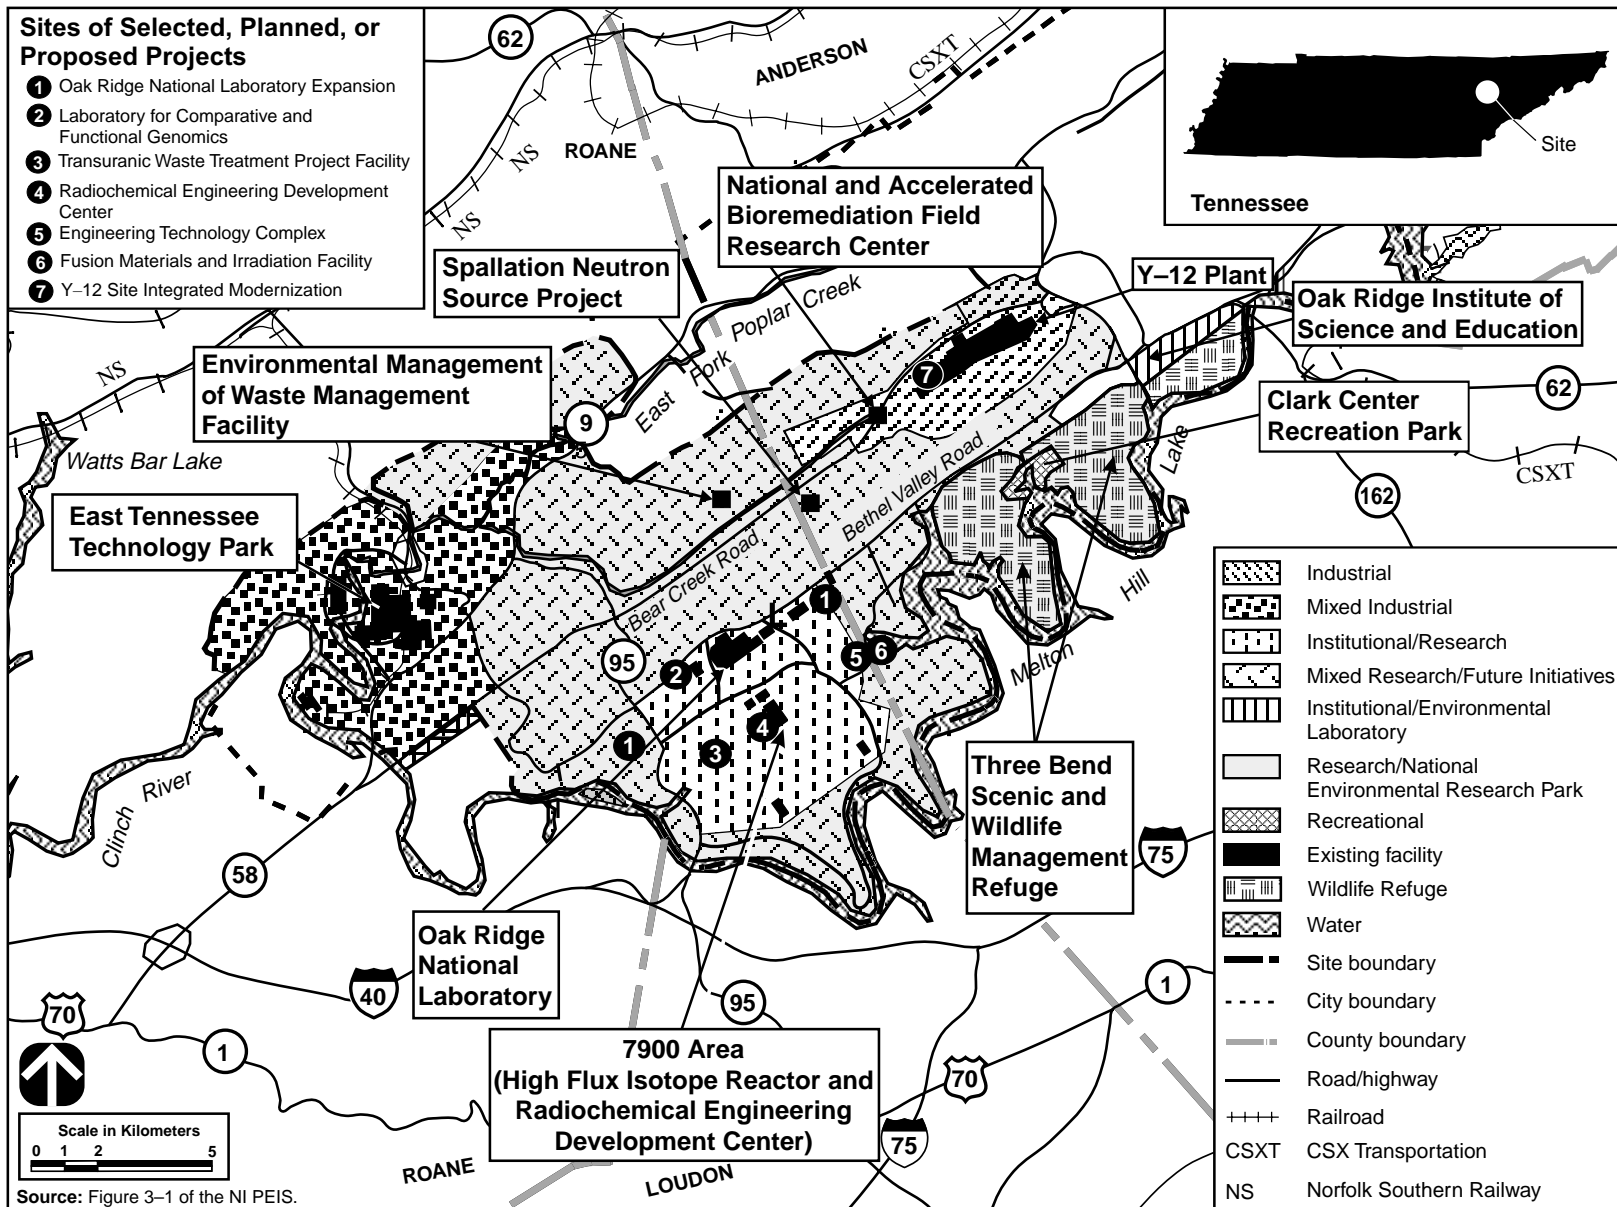

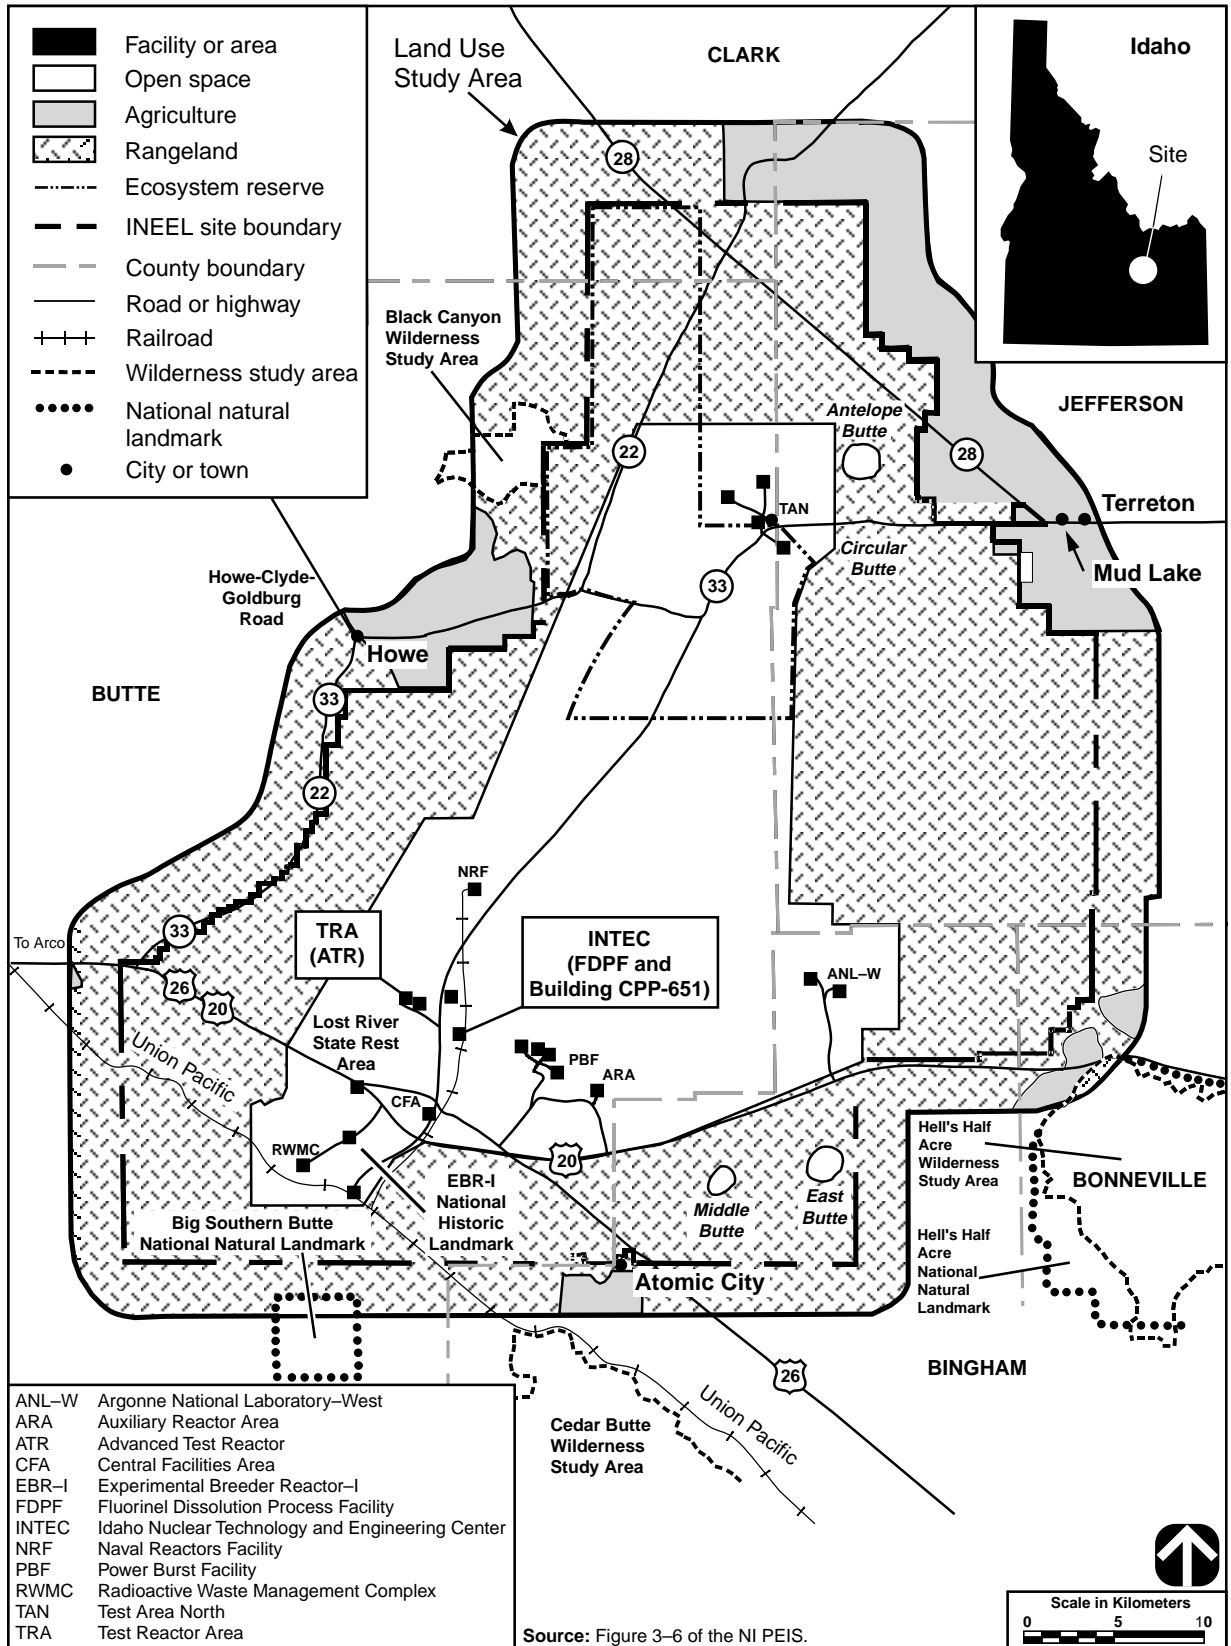

Figure S-1 Generalized Land Use at Oak Ridge Reservation and Vicinity

**Figure S-2 Generalized Land Use at Idaho National Engineering and Environmental Laboratory and Vicinity**

FDPF has no current mission. Historically, INTEC reprocessed spent nuclear fuel from U.S. Government reactors to recover reusable highly enriched uranium. After DOE announced in April 1992 that it would no longer reprocess spent fuel, reprocessing operations at INTEC ended. Two buildings at INTEC are candidate storage and processing sites for plutonium-238 production: Building CPP-651, the Unirradiated Fuel Storage Facility, and Building CPP-666, FDPF.

Building CPP-651 was originally designed for the storage of special nuclear materials to support Defense Programs and is flexible in terms of the size and shape of special nuclear materials that it can receive and store. The 100 storage positions in the vault use the existing structural barriers of Building CPP-651 (earth and concrete) and provide supplemental security protection via their in-ground concrete storage silo design. Each storage position houses a rack that holds seven highly enriched uranium product cans. Racks are raised and lowered in their storage positions via an overhead 1-ton hoist.

Building CPP-666 is divided into two parts, the Fuel Storage Facility and FDPF. The Fuel Storage Facility consists of receiving and unloading areas, a fuel unloading pool, and six storage pools for storing nuclear fuel. FDPF was designed and built to process Navy fuel via three dissolver trains. When fuel reprocessing was discontinued, uranium and hazardous materials were flushed from FDPF, and the facility is currently under consideration for new missions. FDPF consists of a large hot cell and supporting areas with a total area of approximately 3,700 square meters (40,000 square feet). The facility is divided into five levels identified by their elevation relative to ground level.

The chemical separation would take place in the FDPF cell using small centrifugal contactors installed for that purpose. Storage of neptunium-237 would be performed in Building CPP-651, which is located within 100 meters (328 feet) of FDPF. There are 100 in-ground concrete-shielded storage well positions in this vault. Each storage well contains a rack that can be modified to house cans of neptunium-237.

**Fuels and Materials Examination Facility.** Use of Hanford's FMEF is proposed for storage of neptunium-237 in one option of the No Action Alternative. It is also proposed for storage of neptunium-237, fabrication of neptunium-237 targets, and processing of irradiated neptunium-237 targets for two irradiation options in Alternative 1 (Restart FFTF), three irradiation options in Alternative 2 (Use Only Existing Operational Facilities), and for one irradiation option in Alternative 3 (Construct New Accelerator[s]) and Alternative 4 (Construct New Research Reactor). In addition to the support of the plutonium-238 production mission activities in Alternative 1, FMEF would also support medical and industrial production mission and civilian nuclear energy research and development mission activities at the Hanford Site. FMEF would have no role in supporting Alternative 5 (Permanently Deactivate FFTF [with No New Missions]). FMEF is adjacent to the west of FFTF in the 400 Area of Hanford. **Figure S-3** presents a map of Hanford that depicts the location of FMEF. FMEF was built during the late 1970s and early 1980s as a major addition to the breeder reactor technology development program at Hanford. Although it has never been used, the facility was constructed to perform fuel fabrication and development and postirradiation examination of breeder reactor fuels.

FMEF is currently being maintained in a condition suitable for a future mission. In 1998, FMEF was placed into a partial layup condition in order to reduce the cost of maintaining the facility. Many systems were shut down and most hazardous materials were removed from the building. However, FMEF is considered clean and uncontaminated because no nuclear materials have been introduced. Some critical systems remain in operation, e.g., the fire detection and protection systems. In order to avoid freezing of the fire protection water systems, limited heating and ventilation remains available. For example, the heating, ventilating, and air conditioning system has been modified to simplify its operation by clocking automatic dampers in appropriate configurations. Also, although the chillers have been laid up, including removal of the refrigerant, the chilled water system (containing an ethylene glycol-water mixture) remains available to help distribute heat within

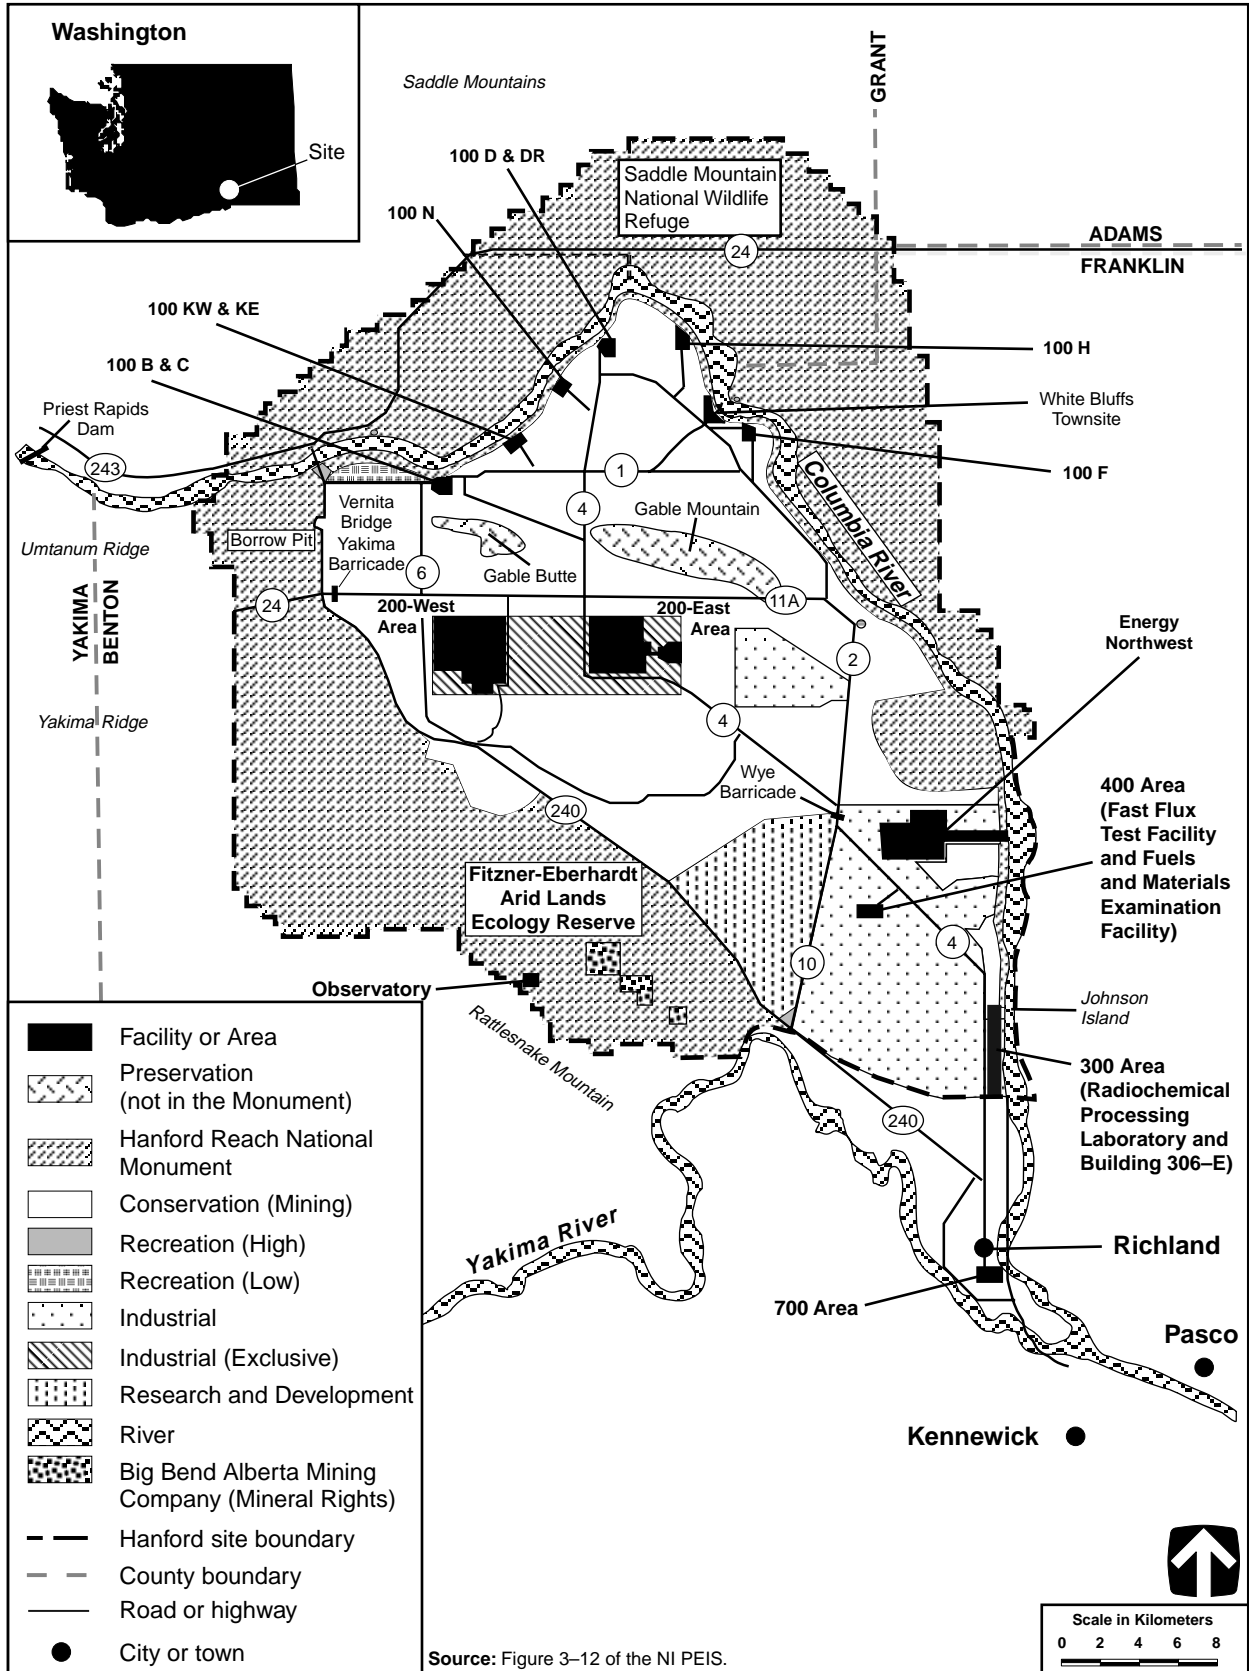

Figure S-3 Generalized Land Use at the Hanford Site and Vicinity

the building. Electrical power and lighting remain available, and the freight elevator remains in service to support routine facility walkdowns and any required maintenance. FFTF staff conducts surveillance and maintenance of FMEF.

FMEF consists of a 30-meter (98-foot) high Process Building, which has an attached Mechanical Equipment Wing on the west side and an Entry Wing on the south (front) side. The Mechanical Equipment Wing houses utility and support equipment, including water treatment equipment, air compressors, and a portion of the air conditioning equipment. The Entry Wing contains space for reactor fuel assembly (recently used as a training facility in support of Hanford's cleanup mission), lunchroom and change rooms, and heating and air conditioning equipment associated with the Entry Wing. Office space and administrative support areas are also housed on the second floor of the Entry Wing.

The Process Building is approximately 53.3 meters (175 feet) wide by 82.3 meters (270 feet) long, and extends from around 10.7 meters (35 feet) below grade to 30 meters (98 feet) above grade. Total potential operating space is approximately 17,470 square meters (188,000 square feet). The Process Building contains several large interconnected hot cells and many smaller connected hot cells. Major cranes are available, but some cranes, windows, and manipulators were not installed because construction of FMEF was halted prior to completing work on the hot cell complex. Nevertheless, the building is divided into six operating floors or levels, which are identified by their elevation relative to ground level and their primary function. The use of FMEF for neptunium-237 target material storage, target fabrication, and postirradiation processing would require the construction of a new 76-meter (250-foot) stack. The neptunium dioxide containers will be stored in specially designed storage vaults to provide secure, safe storage for the materials.

**Hanford 300 Area Facilities (Radiochemical Processing Laboratory/Building 306-E).** Two Hanford 300 Area facilities are proposed to support medical and industrial isotope target fabrication and postirradiation: RPL and the Development Fabrication Test Laboratory (Building 306-E). The facilities support the four irradiation options in Alternative 1 (Restart FFTF) that are not supported by FMEF. RPL/306-E would be used to support medical and industrial isotope production and civilian nuclear energy research and development activities. These activities would not impact current missions at the facilities. RPL/306-E have no role in support of the No Action Alternative, Alternative 2 (Use Only Existing Operational Facilities), Alternative 3 (Construct New Accelerator[s]), Alternative 4 (Construct New Research Reactor), and Alternative 5 (Permanently Deactivate FFTF [with No New Missions]). Figure S-3 presents a map of Hanford that depicts the location of RPL/306-E.

**Radiochemical Processing Laboratory:** The research and development activities of the Radiochemical Processing Group are conducted at RPL in the 300 Area of Hanford. RPL consists of a central area that contains general purpose laboratories designed for low-level radioactive work, a front wing that contains office space and shops, and two annexes that provide shielded enclosures with remote manipulators for high-level radiochemical work. The facility also contains laboratories and specialized facilities designed for work with nonradioactive materials, microgram-to-kilogram quantities of fissionable materials, and up-to-megacurie quantities of radionuclides. RPL would be the primary site for fabricating the radioactive targets (i.e., targets containing radium-226 or recycled materials from previous irradiations).

Total space within RPL is 13,350 square meters (143,700 square feet), of which 4,140 square meters (44,500 square feet) are occupied by general chemistry laboratories. A recent space utilization survey of RPL indicated that 646 square meters (6,950 square feet), representing 15.6 percent of the laboratory area, are presently unoccupied. All of the occupied and nearly all of the unoccupied laboratories are functional and are fully equipped with standard utilities. Several of the laboratories, especially those used for radioanalytical work, have been renovated during the past few years. Upgrading and modernization of the equipment within the chemistry laboratories has been given a high priority during the past 2 years. During the space utilization

survey at RPL, an assessment was made of the number of fume hoods and shielded gloveboxes (including several small hot cells) that are available in the chemistry laboratories for additional programmatic work. Of the 79 functional fume hoods and 23 shielded gloveboxes, 50 fume hoods and 15 gloveboxes are available for additional work.

A special feature of RPL is the existence of two heavily shielded hot cell facilities located in annexes on the east and west sides of the building. These shielded facilities are the High-Level Radiochemistry Facility and the Shielded Analytical Laboratory. These two hot cell complexes are heavily used because they provide capabilities for conducting bench-scale to pilot-scale work with a wide variety of highly radioactive materials. Their capabilities include those required to conduct radiochemical separation and purification procedures, irradiated fuel or target sectioning and processing, metallography, physical properties testing of activated metals, thermal processing (including waste vitrification), and radioanalytical and preparatory chemistry operations.

The High-Level Radiochemistry Facility contains three large, interconnected hot cells designated as A-Cell, B-Cell, and C-Cell. Each of the three cells is 4.6 meters (15 feet) high and 2.1 meters (7.0 feet) deep. The A-Cell is 4.6 meters (15 feet) wide, and the B-Cell and C-Cell are each 1.8 meters (6.0 feet) wide. In-cell operations are performed using medium-duty electromechanical manipulators, and operators view their work through leaded-glass, oil-filled windows. Closed-circuit television cameras and videocassette recorders have been installed for detailed inspection work within the hot cells. The A-Cell and C-Cell also have overhead bridges that contain hoists with a 2,200-kilogram (4,840-pound) capacity. The hot cells are fully equipped with utilities and have shielded service penetrations at the front wall to allow insertion of special instruments. Each hot cell contains several process vessels located below the work deck that range in capacity from 4.0 to 320 liters (1.1 to 84.5 gallons). A large shielded door and a shielded double-door transfer port located in the rear wall of the cell provide access to each hot cell in the High-Level Radiochemistry Facility. Cask payloads weighing up to 2,200 kilograms (4,840 pounds) can be transferred into and out of the hot cells using a bridge crane located in the canyon behind the cells.

The Shielded Analytical Laboratory contains six interconnecting hot cells, each of which is 1.7 meters (5.5 feet) wide, 1.7 meters (5.5 feet) deep, and 2.9 meters (9.5 feet) high. Each hot cell is equipped with a pair of medium-duty manipulators. Turntables built into the rear walls of the hot cells provide rapid transfers of radioactive samples into and out of the cells. The Shielded Analytical Laboratory hot cells are equipped to perform a wide variety of analytical chemistry operations with highly radioactive samples.

**Building 306-E:** Building 306-E was constructed in 1956 as part of the nuclear material production program at Hanford, and was used to develop the co-extrusion process for N-Reactor fuel. Major upgrades and renovations were completed in the late 1960s and early 1970s to support the civilian reactor development program (Liquid Metal Reactor Program-FFTF). The building has 4,273 square meters (46,000 square feet) of floor space, with a 36.5-meter by 61-meter by 6.4-meter high (120-foot- by 200-foot- by 21-foot-high) bay containing three 10-ton, one 5-ton, and one 1.5-ton cranes. The facility has electron beam laser welding, certified nondestructive testing, a 3.7-meter by 3.7-meter (12-foot by 12-foot) vertical assembly and test station with 24.4-meter (80-foot) hook height, a machine shop, and an instrument development laboratory.

The building is serviced by three 1,416-cubic-meter-per-minute (50,000-cubic-foot-per-minute) supply units complete with filters, steam coils and spray chambers. Two of the units have refrigeration coils for summer time cooling. Two ceiling mounted 1,012-cubic-meter-per-minute (35,750-cubic-foot-per-minute) recirculation fans with freon compressors provide additional cooling and air movement. Fume hoods have individual exhaust fans. Chemical and acid tanks exhaust through two 340-cubic-meter-per-minute (12,000-cubic-foot-per-minute) fume scrubbers to a 12.2-meter-high 7.6-centimeter diameter (40-foot-high 3-inch diameter) stainless steel exhaust stack. Equipment exhaust collects through a grid that leads to two 566-cubic-meter-per-

minute (20,000-cubic-feet-per-minute) exhaust fans. Plastic hoods and duct work are provided for highly corrosive service. Major equipment includes three industrial x-ray machines, a 6-kilowatt Hamilton Standard electron beam welder, five open face hoods, two inert gas welding chambers and one electrolytic cutoff saw.

Utilities include hot and cold water, deionized water, propane, helium, compressed air, argon, steam, and sanitary and process sewers as well as a special acid drain and neutralizing tank. Normal power is provided by a 1500-kilovolt-ampere transformer with 15-kilovolt-ampere backup power from an adjoining building, and a 30-kilovolt-ampere emergency transformer. The building is protected by redundant emergency alarm systems, fire gongs, and an evacuation siren.

**New Support Facility.** A new generic support facility would have the mission of preparing medical and industrial isotope targets for irradiation, processing exposed targets, and housing the materials research and development activities in association with Alternatives 3 and 4. Siting of the generic support facility for medical and industrial isotope production would require that the facility be located in the same general vicinity (0.2 to 20 kilometers [0.07 to 12.4 miles]) as the new irradiation facility (accelerator or reactor). Colocation with the irradiation facility would be needed to process some irradiated target materials promptly after removal from the reactor/accelerator. Colocation would also minimize transportation time, which is desirable because some isotopes have short half-lives. Although the facility could be located within the irradiation facility security protection area, the lack of a defense mission and the lack of a fissile material presence in the generic support facility indicates that a high level of physical protection would not be warranted.

The generic support facility mission would be accommodated by a one-story, 3,345-square-meter (36,000-square-foot) above-grade building with a 1,490-square-meter (16,000-square-foot) basement area under a portion of the footprint. The facility is designed around a center area containing the highest-risk activities and the material inventories requiring the highest level of engineered controls. Irradiated materials in casks or other shielded transport containers would enter a loading dock with a straight-line access to the primary facility hot cell. The hot sample entry area would be a high bay area with a high floor loading area between the loading dock and the hot cell access port. This configuration would allow transport cask access to the hot cell. In addition, an overhead hoist would be available to facilitate handling of materials and devices in the proximity of the hot cell.

The hot cell would accept high-radiation-level samples or those difficult to shield or manipulate (e.g., reactor core components containing samples). The hot cell would have access to a conveyor that can remotely transport samples to the hot process laboratories. In addition, samples from the hot cell could be transferred to the hot research and development laboratory gloveboxes for detailed analysis and testing. Hot cell manipulators would be located on both the operating gallery and the research and development sides of the hot cell. Adjacent to that would be the central receiving station for all other radioactive and short-exposure samples not in the reactor core components. This area, while not a hot cell, would provide personnel protection (i.e., shielding and controlled ventilation) for preliminary sample preparation and examination. It would also provide interim irradiated sample storage prior to delivery to the designated processing laboratory. When needed, samples would be transported remotely to the processing laboratories by the conveyor system.

Samples requiring a lesser degree of control would be distributed for processing throughout the remaining process laboratory wing. After processing, the radiopharmaceuticals would be either stored or packaged and shipped immediately to offsite vendors. Radioactive waste would be packaged and stored for eventual disposal. Those materials containing short-lived isotopes would be delivered to a decay/holding room so that, given appropriate decay time, they could be disposed of without a radioactive component. The process and research and development areas would be considered radiologically controlled areas, but no routinely occupied areas would require control as contaminated radiological areas. Radioactive contamination would be controlled at the hood or glovebox face. Due to this configuration, protective clothing and change rooms

would be needed only for occasional maintenance activities when temporary radiological areas are established. Cold sample (nonradioactive) preparation would be accomplished in a set of three large laboratories where radiological conditions are not anticipated. Completed samples would be stored in an adjacent room along with raw sample materials (nonradioactive). Radioactive sample preparation and irradiated material recycling activities would be conducted in one of the laboratories adjacent to the conveyor. Irradiated research and development samples introduced into the hot cell could be processed or examined using manipulators within the hot cell. Samples could also enter the research and development suite of lab rooms through the hot cell port into a hot cell or glovebox. From there, they could be moved to additional research and development laboratory rooms within a controlled environment for detailed analysis and testing.

### **Target Irradiation Facilities**

**Fast Flux Test Facility.** FFTF is proposed to support the three proposed missions: (1) plutonium-238 production, (2) medical and commercial isotope production, and (3) civilian nuclear energy research and development.

FFTF is a 400-megawatt thermal, liquid-cooled (sodium) nuclear test reactor that is owned by DOE and is at the Hanford Site in southeastern Washington State near Richland, Washington. Figure S-3 presents a map of Hanford that depicts the location of FFTF. Following extensive testing, FFTF was started in April 1982. During its operation, FFTF successfully tested advanced nuclear fuels, materials, components, operating protocols, and reactor safety designs. FFTF also produced a wide variety of medical isotopes and made tritium for the U.S. fusion research program.

FFTF was originally designed and operated as a science test bed for U.S. liquid metal fast reactor programs. These programs, which were canceled in 1993, were key elements both in closed fuel cycle and actinide waste disposition technology development. In December 1993, DOE decided not to operate FFTF due to a lack of economically viable missions at that time. In accordance with NEPA, DOE published an environmental assessment (EA) and Finding of No Significant Impact (FONSI) for the shutdown and deactivation of FFTF in May 1995 (DOE 1995a). The EA contained an evaluation of the environmental impacts associated with the actions necessary to place FFTF in a radiologically and industrially safe shutdown condition suitable for long-term surveillance and maintenance before final decontamination and decommissioning.

The FFTF complex includes the reactor, as well as equipment and structures for heat removal, containment, reactor safety and shutdown systems core component handling and examination, fuel off-loading and storage, utilities, and other essential services. There are 100 systems supporting various functions of FFTF during operations. The central structure of FFTF is the reactor containment building, an all-welded cylindrical steel structure 41 meters (135 feet) in diameter and 57 meters (187 feet) high. The reactor is located below grade in a shielded cell in the center of the containment structure. Heat is removed from the reactor by circulating liquid sodium under low pressure through three separate closed primary piping loops, which include pumps, piping, and intermediate heat exchangers. These loops are located within inerted cells (cells filled with inert gases) within the containment structure. Three secondary sodium loops transport reactor heat from the intermediate heat exchangers to the air-cooled tubes of the dump heat exchangers. From there, the heat dissipates into the atmosphere through the forced draft dump heat exchanger. [Commercial nuclear power reactors use reactor heat to create steam, which turns a turbine to produce electricity. FFTF, however, does not generate electricity.]

FFTF has demonstrated its capability to function as a nuclear science and irradiation services user facility. It has five distinct features: size, flux, test evaluation and irradiation capabilities, fuel type, and coolant type. In combination, these features provide a multipurpose facility suitable for medical and industrial isotopes production, plutonium-238 production, and civilian nuclear energy research and development purposes.

Although FFTF was used primarily to evaluate reactor fuels and different fuel assembly materials during its 10 years of operation, the reactor facility has also supported large and varied test programs for industry, nuclear energy (domestic and international), medical isotope applications and research, space nuclear power, and fusion research programs.

FFTF is currently defueled and is being maintained in a standby condition. Seventy-seven of the 100 systems are operational; the other 23 are in a recoverable standby state. System integrity and configuration control are being maintained. The Main Heat Transport System is being operated at approximately 200 °C (400 °F) to keep the sodium coolant in the reactor liquefied and circulating. If a decision were made to restart FFTF, several equipment upgrades are planned to return systems to operation, improve reliability, conform to current standards, improve efficiency, and minimize waste. Most of the required modifications would consist of either mechanical equipment upgrades or replacement of outdated control and computer systems.

The NI PEIS postulates that FFTF would operate at a nominal power level of 100 megawatts, one quarter of the reactor design power level, to meet the irradiation requirements of the proposed missions. Periodic increases in power level between 100 and 400 megawatts may be required to support civilian nuclear energy research and development activities. Operating FFTF at a nominal 100-megawatt power level extends the reactor life and significantly reduces the generation rate of spent fuel. FFTF is currently designed to operate using mixed oxide fuel, however, it can also be operated using highly enriched uranium fuel.

There are eight locations available in the FFTF reactor core that are termed Open Test Assembly positions. These positions are located under spool pieces in the reactor head and allow the installation of 38-foot-long assemblies that extend from the reactor head down to the reactor core. Within the 82 active core locations, there are up to 20 or more additional locations that could contain a standard length (3.6-meter or 12-foot) test assembly. In addition to the test locations within the active fueled region of the core, there are 108 locations available in the surrounding reflector region where other tests could be inserted.

The FFTF core would be modified to include an array of target assemblies and rapid radioisotope retrieval systems capable of producing a number of long- and short-lived isotopes for medical and industrial applications and plutonium-238 for space power applications. In addition, reactor space would be provided for research and development test articles.

Fifteen plutonium-238 production targets would be included in the reflector region with an annual production rate of 5 kilograms. The residence time for these targets would be three 100-day cycles with five assemblies being harvested at the end of each cycle.

Long-Term Irradiation Vehicles would be used to irradiate targets to produce long-lived isotopes, installed in the reactor during normal refueling operations, and handled using standard FFTF handling equipment. The Long-Term Irradiation Vehicle would consist of a bundle of target pins installed inside a nozzle, duct, and handling socket assembly similar in appearance to an FFTF 3.6-meter (12-foot) long fuel assembly. Rapid radioisotope retrieval systems would be installed in selected Open Test Assembly positions for the production of short-lived isotopes. There would be a maximum of eight systems in the core.

**Advanced Test Reactor.** ATR is a light-water-cooled and moderated reactor with a design thermal power of 250 megawatts that is owned by DOE and is in the Test Reactor Area in the southwest portion of INEEL. Figure S-2 presents a map of INEEL that depicts ATR's location. ATR would continue to operate and meet its current mission requirements including naval reactor research and development, medical and industrial isotope production, and civilian nuclear energy research and development activities, at its current operating levels under the No Action Alternative, Alternative 1 (Restart FFTF), Alternative 3 (Construct New Accelerator[s]), Alternative 4 (Construct New Research Reactor), Alternative 5 (Permanently Deactivate FFTF

[with No New Missions]), and Alternative 2 (Use Only Existing Operational Facilities) when it is not providing irradiation services in support of the plutonium-238 production mission. When ATR is supporting the plutonium-238 production mission, it would fully support its primary mission, naval reactor research and development; however, it would support the medical and industrial isotope production and civilian nuclear energy research and development activities to the extent possible within its current reactor operating levels. Consideration must be given to the need to maintain appropriate levels of neutron flux to support ATR's primary mission. Neutron flux levels can be impacted by the placement of targets, such as neptunium-237 targets for production of plutonium-238, in the reactor core. The production planning assumption for ATR is from 3 kilograms (6.6 pounds) of plutonium-238 per year (if used in conjunction with HFIR) to 5 kilograms (11 pounds) of plutonium-238 per year (if ATR were used alone). Thus, ATR alone could meet the program goal of up to 5 kilograms (11 pounds) per year and could be used in combination with any one of the three processing facilities for the plutonium-238 production mission.

Special features of ATR include high neutron flux levels (ranging from  $1 \times 10^{15}$  neutrons per square centimeter per second in the flux traps to  $1 \times 10^{13}$  neutrons per square centimeter per second in the outer reflector positions) and the ability to vary power to fit different experiment needs in different test positions. The primary user of ATR is the U.S. Naval Nuclear Propulsion Program. A variety of other users include foreign and domestic government programs, a commercial isotope production company, industrial customers, and research and development interests. A number of support facilities are important to the operation of ATR. Among these are the Advanced Test Reactor Critical Facility, which is used to baseline experiment impacts to ATR flux profile, and the Nuclear Materials Inspection and Storage facility, which is used to receive, store and inspect reactor fuel prior to its placement in ATR.

The reactor, its primary coolant system, control room, and much of its auxiliary and experimental support equipment are in Test Reactor Area Building 670. ATR began operation in 1967 and is expected to continue operating for several decades. The reactor vessel is entirely stainless steel and the core internals are replaced every 7 to 9 years. Buildings and structures in other parts of the Test Reactor Area provide additional support functions.

ATR is currently operating at approximately 140 megawatts or less. ATR operates with highly enriched uranium fuel. Typical operating cycles are 42 days or 49 days at power followed by a 7-day outage for refueling and changeout of experiments and isotope production targets. The core is 1.2 meters (4 feet) high and is surrounded by a 1.3-meter-diameter (4.25-foot-diameter) beryllium reflector. Beryllium is an excellent neutron reflector and is used to enhance the neutron flux essential to a test reactor. ATR has nine flux traps in its core and achieves a close integration of flux traps and fuel by means of a serpentine fuel arrangement. When viewed from above, the ATR fuel region resembles a four-leaf clover. The four flux traps positioned within the four lobes of the reactor core are almost entirely surrounded by fuel, as is the center position. Four other flux trap positions between the lobes of the core have fuel on three sides. The ATR's unique control device design permits large power shifts among the nine flux traps. Testing can be performed in test loops installed in some flux traps with individual flow and temperature control or in reflector irradiation positions with primary fluid as coolant. The curved fuel arrangement brings the fuel closer on all sides of the test loops than is possible in a rectangular grid.

Of the nine flux traps, five are configured with pressurized-water loops that allow for individual temperature, pressure, flow, and chemistry controls. The five test loops are used by the Naval Reactors program. Of the remaining four flux traps, one is dedicated to the Naval Reactors program, one is used for isotope production, one is used for low-specific-activity cobalt production, and the fourth has recently had the Irradiation Test Vehicle installed. The Irradiation Test Vehicle can be described as three small pressurized-gas test loops. The use of one of these three test loops was recently purchased by a British corporation; negotiations for use of the other two are currently under way.

In addition to the primary flux trap irradiation positions, there are some 70 irradiation positions in the beryllium reflector (and aluminum support structure) that are available for experiment irradiation and isotope production. These position diameters range from 1.6 centimeters (0.625 inch) to 12.7 centimeters (5.0 inches) with thermal neutron flux levels ranging from  $1 \times 10^{15}$  neutrons per square centimeter per second to  $1 \times 10^{13}$  neutrons per square centimeter per second.

INEEL has privatized the production of medical and industrial isotopes through contracting with a commercial entity, which specializes in producing isotope targets for irradiation in ATR and processing and distributing commercial-grade isotopes to its customers. Prior to commercialization, INEEL's isotope production operations were limited in types and quantities. Since the start of commercial activities, production has expanded. Incremental investments have been identified for ATR that would make it a more versatile and capable reactor for isotope production. Commercial companies are in the discussion phase of investing in ATR to install an isotope shuttle (or rabbit) system for the production of short-lived radioisotopes. Many of these short-lived radioisotopes are expected to be in growing demand for various cancer therapies.

**High Flux Isotope Reactor.** HFIR is a beryllium-reflected, light-water-moderated and -cooled reactor operating at a thermal power level of 85 megawatts. HFIR is owned by DOE and is in the 7900 Area in the southern portion of ORR. Figure S-1 presents a map of ORR that depicts the location of HFIR.

HFIR would continue to be operated to meet the primary mission of neutron science based research for DOE's Office of Science. In addition, medical and industrial isotope production and civilian nuclear energy research and development activities would be performed on a not-to-interfere basis at the current operating level in the No Action Alternative, Alternative 1 (Restart FFTF), Alternative 3 (Construct New Accelerator[s]), Alternative 4 (Construct New Research Reactor), Alternative 5 (Permanently Deactivate FFTF [with No New Missions]), and Alternative 2 (Use Only Existing Operational Facilities). When HFIR is supporting the plutonium-238 production mission, it would fully support its primary mission, but would support the medical and industrial isotope production and civilian nuclear energy research and development activities to the extent possible within the current reactor operating levels. Consideration must be given to the need to maintain appropriate levels of neutron flux to support HFIR's primary mission. Neutron flux levels can be impacted by the placement of targets, such as neptunium-237 targets for the production of plutonium-238, in the reactor core. Under the planning assumptions for plutonium-238 production, HFIR could only produce from 1 to 2 kilograms (2.2 to 4.4 pounds) per year without impacting ongoing missions. As the program goal is to achieve a production rate of 5 kilograms (11 pounds) per year, production at HFIR would need to be augmented by the use of ATR to meet this goal. HFIR and ATR together could meet the program goal of up to 5 kilograms (11 pounds) per year, and could be used in combination with any one of the three processing facilities for the plutonium-238 production mission.

HFIR was originally designed as both an isotope production and a research reactor with a thermal flux of 3 to  $5 \times 10^{15}$  neutrons per square centimeter per second and a full power level of 100 megawatts-thermal ( $3.4 \times 10^8$  British thermal units per hour). It is currently operating at a maximum authorized power level of 85 megawatts-thermal ( $2.9 \times 10^8$  British thermal units per hour) to extend the useful life of the reactor. Many experiment-irradiation facilities were provided for in the original design and several others have been added. The primary mission of HFIR is neutron science research. Isotope production is done on a not-to-interfere basis.

HFIR transfers its primary coolant heat load to secondary coolant through heat exchangers for dissipation to the atmosphere by an induced-draft cooling tower. The reactor uses highly enriched uranium and aluminum-clad plate fuel. The reactor vessel itself is immersed in a pool in a poured-concrete reactor building that also houses the primary coolant pumps and heat exchangers, a spent fuel pool, and experiment areas. The control and water wing of the reactor building contains the reactor control room; relay and amplifier areas; heating and

ventilating equipment; pool and fire alarm equipment; instrumentation systems; and office and support rooms. A separate electrical building adjacent to the reactor building contains switchgear, diesel generators, and associated transformers that connect the facility to offsite power. The reactor building is essentially airtight and provides dynamic confinement. A special hot exhaust system exhausts air from potentially contaminated areas of the building through filters (two high-efficiency particulate air and two charcoal filters) before being released to the atmosphere through a 76-meter (250-foot) stack. The stack serves as the exhaust point for both HFIR and REDC at ORNL.

After the reactor completed 17.2 full-power years of its 20 full-power year design life in November 1986, several measures were taken to extend the useful life of the reactor, including reducing the 100 megawatts-thermal ( $3.4 \times 10^8$  British thermal units per hour) rated power level to 85 megawatts-thermal ( $2.9 \times 10^8$  British thermal units per hour); adjusting the primary coolant temperature and pressure; conducting periodic hydrostatic tests; establishing an irradiation embrittlement surveillance program; and installing an emergency depressurization system. Subsequent life extension programs can enable HFIR to provide support during the total 35-year evaluation period for operations.

Experiment-irradiation facilities available include (1) the hydraulic tube facility, located in the very high flux region of the flux trap, which allows for insertion and removal of irradiation samples while the reactor is operating; (2) 30 target positions in the flux trap, which normally contain transuranium production rods but which can be used for the irradiation of other experiments (two are instrumented target positions provided by a recent modification); (3) six peripheral target positions located at the outer edge of the flux trap; (4) numerous vertical irradiation facilities of various sizes located throughout the beryllium reflector; (5) two pneumatic tube facilities in the beryllium reflector, which allow for insertion and removal of irradiation samples while the reactor is operating for activation analysis; (6) four horizontal beam tubes, which originate in the beryllium reflector; and (7) four slant access facilities, called "engineering facilities," located adjacent to the outer edge of the beryllium reflector. In addition, spent fuel assemblies are used for gamma irradiation in the gamma irradiation facility in the reactor pool.

The reactor core assembly is contained in a 2.44-meter (8-foot) diameter pressure vessel located in a pool of water. The top of the pressure vessel is 5.18 meters (17 feet) below the pool surface, and the reactor horizontal midplane is 8.38 meters (27.5 feet) below the pool surface. The control plate drive mechanisms are located in a subpile room beneath the pressure vessel. These features provide the necessary shielding for working above the reactor core and greatly facilitate access to the pressure vessel, core, and reflector regions.

The neutron flux within HFIR is primarily a thermal neutron flux ranging from approximately  $2 \times 10^{15}$  neutrons per square centimeter per second in the flux trap to approximately  $4 \times 10^{14}$  neutrons per square centimeter per second in the outer regions of the beryllium reflector. Specially designed neutron beam tubes provide access to neutrons that supply intense neutron beams to various specialized instruments used for neutron scattering research.

ORNL produces a variety of medical isotopes using the HFIR for irradiation and various hot cell and glovebox facilities for target fabrication and final product purification. The nine hydraulic tube positions in the central high flux region permit the insertion and removal of targets at any time during the operating cycle (22 to 24 days) and have traditionally represented a major site for the production of medical radioisotopes. In addition to providing radioisotopes for extramural research and development and commercial applications by distribution through the DOE Isotope Production and Distribution Program, there are medical radioisotope research and development programs at ORNL that depend on the availability of HFIR-produced radioisotopes.

**Commercial Light Water Reactor.** A CLWR would continue to operate and meet its primary mission requirement, providing steam for the generation of electrical power in the No Action Alternative, Alternative 1

(Restart FFTF), Alternative 3 (Construct New Accelerator[s]), Alternative 4 (Construct New Research Reactor), Alternative 5 (Permanently Deactivate FFTF [with No New Missions]), and Alternative 2 (Use Only Existing Operational Facilities) when it is not providing irradiation services in support of the plutonium-238 production mission. When the CLWR is supporting the plutonium-238 production mission, it would still fully support its primary mission. The production planning assumption for the generic CLWR is 5 kilograms (11 pounds) per year of plutonium-238 or 7.5 kilograms (16.5 pounds) per 18-month operating cycle. Thus, the CLWR alone could meet the program goal of up to 5 kilograms (11 pounds) per year and could be used in combination with any one of the three processing facilities for the plutonium-238 production mission. The use of a CLWR for the medical and industrial isotope production mission and the DOE civilian nuclear energy research and development mission were not considered practical.

A typical pressurized water reactor core consists of 170 to 200 fuel assemblies arranged in the reactor vessel in an approximately cylindrical pattern. Most pressurized water reactors operating in the United States are licensed to operate at thermal power levels of 2,500 to 3,500 megawatts ( $8.5 \times 10^9$  to  $1.2 \times 10^{10}$  British thermal units per hour) for net station electrical outputs of 800 to 1,200 megawatts electric ( $2.7 \times 10^9$  to  $4.1 \times 10^9$  British thermal units per hour).

The nuclear steam supply system powered by the pressurized water reactor is generally arranged as two heat transport loops, each with two primary coolant circulating pumps and one steam generator in which the primary coolant dissipates heat generated in the reactor core to the secondary fluid in the steam generator. In addition to serving as a heat transport medium, the primary coolant also serves as a neutron moderator and reflector and as a solvent for the soluble boron used in chemical reactivity control. All nuclear steam supply system components are designed to withstand the effects of earthquakes and loss-of-coolant accidents.

The containment for a pressurized-water reactor plant consists of two structures: (1) a steel containment vessel and (2) a reinforced-concrete shield building. The containment, including all of its penetrations, is a low-leakage steel structure designed to withstand a postulated loss-of-coolant accident and to confine a postulated release of radioactive material. It houses the reactor pressure vessel, reactor coolant piping, pressurizer, pressurizer quench tank and coolers, reactor primary coolant pumps, steam generators, core flooding tanks, and letdown coolers. Safety systems directly associated with this vessel include the containment spray system, the containment air cooling system, and the containment isolation system. An annular space is provided between the wall of the containment vessel and the shield building. Overhead clearance from the dome of the shield building is also provided.

The shield building itself is a concrete structure surrounding the containment that is designed to provide biological shielding during both normal operations and hypothetical accident conditions. The shield building enables the collection and filtration of fission product leakage from the containment following a hypothetical accident by means of its emergency ventilation system. In addition, the shield building provides environmental protection for the containment from adverse atmospheric conditions and external missiles (e.g., tornado debris).

All fuel assemblies are identical in mechanical construction and are interchangeable in any core location. The basic fuel assembly is normally composed of 208 fuel rods, 16 control rod guide tubes, and one centrally located position for instrumentation, all within a  $15 \times 15$  position square array. The fuel assembly is approximately  $20.3 \times 20.3$  centimeters ( $8 \times 8$  inches) in cross section and has an overall length of 419 centimeters (165 inches).

The neptunium-237 targets can be placed in numerous locations within the reactor core region (i.e., fuel assembly region) and outside the reactor core region to be irradiated for the production of plutonium-238. Three potential target arrangements were considered for evaluation in the NI PEIS: (1) all targets located in the center fuel assembly position in the reactor core, (2) all targets distributed within locations in the reactor

core, and (3) all targets distributed outside the reactor core region. The center fuel assembly position was selected for evaluation in the NI PEIS because it was assumed that this would be the worst-case location during postulated beyond-design-basis accident conditions. This assumption conservatively postulated that during a beyond-design-basis core disruptive accident, temperatures in the center fuel assembly position would reach levels that would fail the cladding on all of the neptunium-237 targets located in that position, resulting in worst-case releases.

The substitution of target rods for fuel rod positions in the center fuel assembly would only minimally impact reactor operations. The fuel rods located in the center fuel assembly position would normally not be fresh fuel (i.e., fuel inserted within the first 18-month operating cycle in the reactor); instead, they would be in their second or third operating cycle. The normal power distribution within the core and reactor coolant flow and its distribution within the core would remain within existing technical specification limits.

**New Accelerator(s).** One or two new accelerators would be constructed and operated in Alternative 3 (Construct New Accelerator[s]). Preconceptual designs have been developed for a low-energy accelerator and a high-energy accelerator for evaluation in the NI PEIS. The low-energy accelerator would support the medical and industrial isotope production missions and the civilian nuclear energy research and development mission. This could effectively be accomplished with accelerator energies in the range of 30 to 70 million electron volts. The high-energy accelerator design would support the plutonium-238 production mission and the civilian nuclear energy research and development mission. An accelerator with an energy level of 1,000 million electron volts is required to support the plutonium-238 and civilian nuclear energy research and development missions.

The preconceptual design of the high-energy accelerator presented in Appendix F of the NI PEIS focused on supporting the plutonium-238 production mission. Although not analyzed in the NI PEIS, the design of the high-energy accelerator could be refined and expanded to perform additional missions such as the production of a select set of medical and industrial radioisotopes. In addition, DOE is aware of longer-term concepts that would apply high-energy accelerators to produce “tuneable” neutrons in a subcritical assembly. Such a facility could be used to address some of the missions more familiar to reactor facilities and may hold considerable promise for future science and technology research. A facility of this nature could provide unique capabilities in areas such as the testing of many different nuclear system coolant, fuel, and materials interactions.

The accelerator(s) would be constructed and operated at one or two existing DOE sites. The low-energy accelerator would be located on the same DOE site as the new support facility or at a DOE site with an existing support facility. The high-energy accelerator could be located at a different DOE site. Alternative 3 site selection is not evaluated as part of the NI PEIS.

Because Alternative 3 is evaluated at a generic DOE site, no credit was taken for any existing support infrastructure at the site(s), and it was postulated that a new support facility would be required to support operation of the low-energy accelerator and its missions and the high-energy accelerator civilian nuclear energy research and development missions if both accelerators are located on the same site. While this approach bounds the environmental impact assessment for the implementation of Alternative 3, it overstates the impacts because the NI PEIS integrates the impacts associated with constructing new support facilities and infrastructure that may be available at the existing DOE site(s). In the event that Alternative 3 or the low-energy accelerator alone is selected in the Record of Decision for subsequent consideration, follow-on NEPA reviews would evaluate potential locations for either both or one of the accelerators. It is unlikely that DOE would consider locating the new low-energy or high-energy accelerator on a DOE site that does not have an existing infrastructure capable of supporting all or most of the mission requirements. To determine the environmental impacts if Alternative 3 is implemented at a site with adequate support infrastructure, the environmental impacts for the construction of the support facility could be subtracted from the environmental

impacts of Alternative 3 as presented in the NI PEIS. Section 4.5 of the NI PEIS presents the environmental impacts from construction and operation of the new support facility separately.

**Low-Energy Accelerator:** Three low-energy accelerator options would be available for the production of medical and industrial isotopes and to support nuclear energy research and development: (1) a high-current proton linear accelerator, (2) a multiparticle cyclotron, or (3) a proton-only cyclotron. The proton-only cyclotron would have distinct technical advantages over the other two options and is described further in the section that follows.

The proton-only cyclotron can be either a positive proton or negative ion type and is referred to as a proton cyclotron  $H^+$  or proton cyclotron  $H^-$ . The alternative of a positive proton cyclotron would offer lower vacuum requirements and, with the latest technology, high-extraction efficiency can be achieved. But obtaining variable energy output would be complicated; extraction can be into only a single port and splitting the beam would require a complicated septum magnet. In comparison, the negative ion cyclotron would offer a continuous beam with high-current capacity using very simple high-efficiency extraction, a simple method to vary the particle energy, and the possibility of simultaneous irradiation of two different target arrays at different energies. The high-extraction efficiency would be achieved simply by passing the negatively charged beam through a thin foil that strips the electrons from the ion, creating a positive proton. The proton would be directly ejected from the machine by the existing magnetic field with high efficiency (greater than 98 percent). This feature would be important to minimize the activation of the cyclotron structure and thus reduce radiation exposure to the operational staff.

A high-beam current would be advantageous because more products could be prepared in a shorter time. In addition, a much higher specific-activity radioisotope could be prepared at the higher-beam current of the cyclotron. Specific activity is often a critical parameter in many nuclear medicine applications, including research and clinical use. The cyclotron can also continuously tune the beam energy, which would be an advantage for research. The ability to tune the energy with precision can also help achieve high-purity isotope production by avoiding energies where impurity isotopes would be readily co-produced. These are important advantages for flexibility in research isotope production and are within the capabilities of commercially proven technology.

A new building, with a 43-meter (140-foot) by 43-meter (140-foot) footprint, would be constructed to house the cyclotron and the four beam lines. The walls of the facility would be 4.6 meters (15 feet) thick behind the target stations to minimize the neutron flux outside the building. The walls surrounding the cyclotron itself would be 3 meters (10 feet) thick. The mazes throughout the building in general would have walls 1.5 meters (5 feet) thick, so that the total thickness surrounding the cyclotron area would be 3 meters (10 feet). The beam would be diverted to the four target stations by switching magnets located in the cyclotron vault. The beam would be directed through focusing and steering magnets to the target. In the isotope production beam line (northwest cave), the targets would be installed and removed vertically from a hot cell, which would be located on the second floor directly above the target station. The power supplies for the magnets would be housed with the power supplies for the cyclotron. The mechanical equipment for cooling water would be housed in a shielded mechanical room adjacent to the cyclotron vault. Recirculating water for cooling of the targets and systems that could contain potentially radioactive material would be separated to prevent cross-contamination. These systems would be contained in mechanical equipment rooms near the respective target station. Piping would be contained in waterproof trenches with leak detection.

**High-Energy Accelerator:** In accelerator production of plutonium-238, an energetic beam of protons generated by a linear accelerator would be transported to a heavy metal target where spallation neutrons would be produced and moderated in a surrounding blanket. The blanket containing neptunium-237 would capture the slowed neutrons to produce plutonium-238 through the same nuclear sequence that occurs in a reactor. The

accelerator would be housed in a concrete tunnel, buried below ground to provide radiation shielding for operating personnel. A building housing radio frequency power systems and other equipment used to drive, monitor, and control the accelerator would be located above ground close to the accelerator tunnel. The target/blanket assembly would be housed inside a steel and concrete shield located within a multistory building that would contain appropriate service equipment. At the target, the small-diameter proton beam transported magnetically from the accelerator would be converted to a much larger cross section by a beam expander to reduce the power density to acceptable levels for the target cooling systems.

A source of neutrons produced by an accelerator can be used to produce plutonium-238 from neptunium-237 feedstock through the capture and decay nuclear processes. A 1,000-million-electron-volt proton beam produced by a radio frequency linear accelerator would bombard a heavy metal (uranium-238) target, with each proton producing about 40 neutrons.

A very preliminary target/blanket design has been developed for scoping purposes, based on the architecture employed in the accelerator production of tritium target/blanket design. It would use uranium-238 (cooled by heavy water [D<sub>2</sub>O]) as the neutron-production target. The target would be surrounded by a blanket of neptunium-237 in a dilute mixture of aluminum and water coolant. Enclosing the blanket would be a beryllium reflector.

To meet the plutonium-238 production goal of 5 kilograms (11 pounds) per year, the high-energy accelerator facility would conduct three 4-month production campaigns. Each campaign would be divided into 100 days of production and 21 days for recycling the production blanket. A 90 percent plant availability during the scheduled operating periods is assumed. Based on operating experience at the Los Alamos Neutron Science Center Linear Accelerator, the 90 percent plant availability should be achievable.

The preconceptual design of the high-energy accelerator presented in Appendix F of the NI PEIS focused on supporting the plutonium-238 production mission. While not evaluated in the NI PEIS, the design of the high-energy accelerator could be refined and expanded to perform additional missions such as the production of a select set of medical and industrial radioisotopes. In addition, DOE is aware of longer-term concepts that would apply high-energy accelerators to produce “tuneable” neutrons in a subcritical assembly. Such a facility could be used to address some of the missions more familiar to reactor facilities and may hold considerable promise for future science and technology research. A facility of this nature could provide unique capabilities in areas such as the testing of many different nuclear system coolant, fuel, and materials interactions. The accelerator designs for Alternative 3 were developed to a level of detail that was adequate to assess the environmental impacts associated with the construction and operation of the proposed facilities and the technical feasibility of meeting the mission objectives. In the event that the NI PEIS Record of Decision selects Alternative 3, DOE would prepare conceptual, preliminary, and detailed designs and optimize the facility designs to accomplish the stated missions. Additional NEPA review would be required for site selection and to evaluate the environmental impacts of integrating the more refined accelerator designs with the existing site infrastructure(s).

**New Research Reactor.** A new research reactor would be constructed and operated in Alternative 4 (Construct New Research Reactor). A preconceptual design for a new research reactor was developed to meet the following DOE missions: (1) producing medical and industrial isotopes, (2) producing plutonium-238 (annual production of up to 5 kilograms [11 pounds]), and (3) supporting nuclear energy research and development. In accordance with U.S. nuclear nonproliferation policy, a design limitation of this new research reactor is that it can only use low-enriched uranium with an enrichment of less than 20 percent uranium-235. This preconceptual design includes the basic elements of the research reactor facility, which are sufficient to support the NI PEIS, but does not include the design details (e.g., system and layout drawings, bill of materials, electrical and piping routing) commensurate with a complete preliminary reactor design.

The reactor design was developed to a level of detail that was adequate to assess the environmental impacts associated with the construction and operation of the proposed facilities and the technical feasibility of meeting the mission objectives. The design of the new research reactor is based on current research reactor designs that have been approved by both the NRC and the International Atomic Energy Agency, as well as nuclear regulatory authorities of many nations. Reactor core physics calculations were performed to evaluate three different nuclear fuel designs. Based on this analysis, the desired mission for this reactor, current nuclear fuel manufacturing capabilities, and safety considerations; a training, research, isotope General Atomics (TRIGA) production reactor fuel design was selected for the new research reactor. The principal distinguishing features of the TRIGA fuel are its proven safety performance during power pulsing and its demonstrated long-term irradiation integrity.

To concurrently produce medical and industrial isotopes along with the required quantity of plutonium-238 production goal of 5 kilograms (11 pounds) per year and provide irradiation services for civilian nuclear energy research and development, it was determined that a reactor core power of 50 megawatts-thermal would be necessary. Higher power levels and alternative target designs capable of meeting production requirements were also considered in the new research reactor design analysis but were not analyzed in the NI PEIS. For example, although not analyzed in the NI PEIS, operating at 100 megawatts-thermal could reduce the amount of neptunium-237 required to meet plutonium-238 production requirements. At the 50-megawatts-thermal power level, the core would require an active cooling system with forced coolant flow to maintain the fuel below its material thermal limits. The new research reactor cooling system would use a tank within a pool that is connected to primary coolant circulating pumps, heat exchangers, and an ultimate heat sink consisting of two cooling towers. The pool would be housed in a reactor building that would also enclose the pumps, heat exchangers, secondary systems, and spent nuclear fuel storage pool. The spent nuclear fuel storage pool, sized to store the reactor core's discharged spent nuclear fuel for its entire 35-year production period, could be hydraulically connected to the reactor core pool for refueling and emergency reflooding. The ultimate heat sink cooling towers, air exhaust stack, and emergency diesel generators would be located outside the reactor building.

The fuel for the new research reactor would be based on an extension of current licensed low-enriched uranium TRIGA fuel designs for 10- to 16-megawatts-thermal reactors. The new research reactor fuel design would be identical to current low-enriched uranium TRIGA fuel for higher power cores, except the new reactor fuel would have a larger assembly configuration array (i.e., 8 by 8 versus 4 by 4) and a longer active fuel length (153.7 centimeters [60.5 inches] versus 55.88 centimeters [22.0 inches]). The larger array and length were selected to meet the plutonium-238 production requirements and to maintain high safety factors with respect to fuel thermal performance.

Along with the fuel rods, the core would contain a number of medical and industrial isotope and plutonium-238 production target rods. These rods would occupy positions in a fuel assembly where a fuel rod would otherwise exist. Each of these positions would have an Incoloy-800 alloy guide tube with the same dimensions as the fuel rod cladding. The target rods would be inserted into these guide tubes for their design irradiation time period. In addition, some fuel rod positions in core fuel assemblies would be replaced with similar guide tubes to accommodate Incoloy-800-clad boron carbide control rods. Boron carbide is a widely used, proven, and accepted neutron absorber for control rods. The new research reactor core design would consist of 68 fuel assemblies, each of which would be enclosed in a square aluminum shroud for structural support and coolant flow control. The core would include eight rabbit tubes for short irradiation time production of medical or industrial isotopes and civilian nuclear energy research and development. These rabbit tubes would be located outside the fuel region of the core, but still within an area with a relatively high neutron flux.

The new research reactor would be constructed and operated at an existing DOE site. Since the potential site has not been selected, it is evaluated in the NI PEIS as a generic DOE site. Because Alternative 4 was evaluated at a generic DOE site, no credit was taken for any existing support infrastructure at the site, and it was postulated that a new support facility would be required to support operation of the new research reactor and its medical isotope production and civilian nuclear energy research and development missions. While this approach bounds the environmental impact assessment for the implementation of Alternative 4, it overstates the impacts because the NI PEIS integrates the impacts associated with constructing new support facilities and infrastructure that may be available at the existing DOE site. In the event that Alternative 4 were selected in the Record of Decision for subsequent consideration, follow-on NEPA reviews would evaluate potential site locations. It is unlikely that DOE would consider locating the new research reactor on a DOE site that does not have an existing infrastructure capable of supporting all or most of the mission requirements. To determine the environmental impacts if Alternative 4 were implemented at a site with adequate support infrastructure, the environmental impacts for the construction of the support facility could be subtracted from the environmental impacts of Alternative 4 as presented in the NI PEIS. Section 4.6 of the NI PEIS presents the environmental impacts from construction and operation of the new support facility separately.

### **Transportation**

For all alternatives, overland shipments of nuclear materials are assumed to use trucks, either commercial vehicles or DOE safe secure trailers. Transatlantic shipments of mixed oxide fuel would use purpose-built ships and certain isotopes would be shipped in aircraft. The types of packaging used to transport materials is discussed in Appendix J of the NI PEIS.

Plutonium-238 purchased from Russia under all options of the No Action Alternative would be transported from St. Petersburg to a U.S. port of entry, and from there to LANL where it would be prepared for use in radioisotope power systems and heating units. The impacts of the transportation of a total of 40 kilograms (88.2 pounds) of plutonium-238 are estimated in the *Environmental Assessment of the Import of Russian Plutonium-238* (DOE 1993) and are summarized in Section 4.2 of the NI PEIS. The impacts associated with transporting 175 kilograms (385 pounds) (5 kilograms per year for the 35-year evaluation period) of plutonium-238 have been determined by extrapolation and are included in the same section. Under Options 2 through 4 of the No Action Alternative, neptunium-237 would be shipped from SRS to the designated storage facilities at ORNL, INEEL, or Hanford for long-term storage. Under Alternatives 1 through 4, the neptunium-237 would be shipped to the same facilities for storage and subsequent processing for fabrication of targets for plutonium-238 production. Under all alternatives, medical isotopes would continue to be shipped to commercial vendors via truck and air from DOE locations throughout the country.

Under Alternative 1, targets for plutonium-238 production would be fabricated in one of three alternative facilities at ORNL, INEEL, or Hanford. The targets would be irradiated at FFTF using mixed oxide fuel currently stored at Hanford or shipped from Europe and/or highly enriched uranium fuel from a commercial fuel fabricator in the United States. The irradiated targets would be transported back to the fabricating facilities for postirradiation processing. The separated plutonium-238 would be transported to LANL for fabrication into heat sources for radioisotope power systems. Targets for medical and industrial isotope production would be fabricated in one or more facilities at Hanford. Target materials would be shipped to Hanford from other offsite facilities. The targets would be irradiated in FFTF and returned to the fabrication facilities for postirradiation processing. Medical and commercial isotopes would then be shipped to commercial vendors via truck and air.

Under Alternative 2, targets for plutonium-238 production would be fabricated in one of three facilities at ORNL, INEEL, or Hanford. The targets would be irradiated at ATR, HFIR, or a CLWR and transported back to the fabricating facilities for postirradiation processing. The separated plutonium-238 would then be shipped

to LANL following postirradiation processing. Medical isotopes would continue to be shipped to commercial vendors via truck and air from DOE locations throughout the country.

Under Alternative 3, the targets for plutonium-238 production would be fabricated in one of three facilities at ORNL, INEEL, or Hanford. The targets would be irradiated at the new high-energy accelerator and transported back to the fabricating facilities for postirradiation processing. The separated plutonium-238 would then be shipped to LANL following postirradiation processing. Targets for medical and industrial isotope production would be fabricated in a new facility at the generic DOE site. Target materials would be shipped to the new facility from offsite. The targets would be transported to the on site low-energy accelerator for irradiation and returned to the fabrication facilities for postirradiation processing. Products would then be shipped to commercial vendors via truck and air transport.

Under Alternative 4, the targets for plutonium-238 production would be fabricated in one of three facilities at ORNL, INEEL, or Hanford. The targets would be irradiated at the new reactor and transported back to the fabricating facilities for postirradiation processing. The separated plutonium-238 would then be shipped to LANL following postirradiation processing. Targets for medical and industrial isotope production would be fabricated in a new facility at the generic DOE site. Target materials would be shipped to the new facility from offsite. The targets would be transported to the new on site research reactor for irradiation and returned to the fabrication facilities for postirradiation processing. Products would then be shipped to commercial vendors via truck and air transport.

No transportation is analyzed for Alternative 5, the deactivation of FFTF, with no new missions. Medical isotopes would continue to be shipped to commercial vendors via truck and air from DOE locations throughout the country.

For alternatives that include fabrication and irradiation of targets at one site, intrasite transportation between facilities is analyzed. The shipment of fuel to the irradiation facilities is also analyzed. For Alternative 4, this includes the shipment of low-enriched uranium fuel to the new reactor. For alternatives involving irradiation at FFTF, this includes the shipment of mixed oxide fuel from Europe and/or highly enriched uranium fuels from a commercial fuel fabricator in the United States. At this time, however, DOE has not proposed to import the European fuel through any specific port. DOE did, however, review the potential maximum impacts from the marine transportation of mixed oxide fuel from Europe to a representative military port (i.e., Charleston, South Carolina). If DOE ultimately decides to import fuel from Europe, it would perform a separate NEPA analysis to select a port.

## **S.5 APPROACH TO ENVIRONMENTAL IMPACT ANALYSIS**

The environmental impact analysis addresses the full range of natural and human resource areas pertinent to the sites considered for the nuclear infrastructure alternatives. Impacts are assessed for land resources, noise, air quality, water resources, geology and soils, ecological resources, cultural and paleontological resources, socioeconomics, waste management, and cumulative impacts. A region of influence for each resource area is identified and analyzed for each candidate site.

Baseline conditions at the three DOE sites (ORR, INEEL, and Hanford) assessed in the NI PEIS, as well as an existing CLWR, include present and reasonably foreseeable future actions at each site. Option 1 of the No Action Alternative was used as the basis for the comparison of impacts that would occur under implementation of the other options and alternatives.

Impacts within each resource area were analyzed consistently; that is, the impact values were estimated using a consistent set of input variables and computations. Moreover, calculations in all areas used accepted

protocols and up-to-date models. The following is a brief summary of the affected resources and their impact assessment methodologies.

### **Land Use**

Land use includes the land on and adjacent to each site, the physical features that influence current or proposed uses, pertinent land use plans and regulations, and land ownership and availability. The region of influence for land use varies due to the extent of land ownership, adjacent land use patterns and trends, and other geographic or safety considerations. The amount of land disturbed and conformity with existing land use were considered in order to evaluate impacts. Conformity with existing land use was evaluated for each alternative. Land disturbance was considered only for those alternatives involving new construction. However, because the location of one or two new accelerators or a research reactor and support facility is unknown, the acreage required is only an approximation. In order to determine the range of potential effects from new facilities, the analysis considered potential impacts from construction and operation at both a disturbed and undisturbed location at a generic DOE site.

### **Visual Resources**

Visual resources are the natural and human-created features that give a particular landscape its character and aesthetic quality. Landscape character is determined by the visual elements of form, line, color, and texture. The region of influence for visual resources includes the geographic area from which the proposed facilities may be seen. Impacts to visual resources were determined by evaluating whether or not the Bureau of Land Management Visual Resource Management classification of the site would change as a result of the proposed action. For those alternatives involving existing facilities at known DOE sites, alterations to visual features were readily evaluated and the impact on the current Visual Resource Management classification determined. For those alternatives involving construction and operation of one or two new accelerators or a research reactor at a generic DOE site, the visual characteristics of the site are unknown. Thus, to determine the range of potential visual effects, the analysis considered potential impacts from construction and operation at both a disturbed and an undisturbed location at the generic site. Impacts associated with the use of an existing CLWR are also described in a general manner because its location is not known.

### **Noise**

Sound results from the compression and expansion of air or some other medium when an impulse is transmitted through it. Sound requires a source of energy and a medium for transmitting the sound wave. Propagation of sound is affected by various factors, including meteorology, topography, and barriers. Noise is undesirable sound that interferes or interacts negatively with the human or natural environment. The region of influence for each site includes the site and surrounding area, including transportation corridors, where proposed activities might increase noise levels. Impacts from facility modification and operation were assessed according to the types of noise sources and the locations of the proposed facilities relative to the site boundary. Potential noise impacts from traffic were based on the likely increase in traffic volume. Possible impacts to wildlife were evaluated based on the possibility of sudden loud noises occurring during facility modification and operation. Acoustic impacts from facility construction and operation at generic sites were assessed according to the types of new noise sources and characteristics identified for a generic site. The change in traffic noise levels at a generic site could not be assessed without site-specific data.

### **Air Quality**

Air pollution refers to the introduction, directly or indirectly, of any substance into the air that could result in harmful effects of such nature as to endanger human health and harm living resources and ecosystems, as well

as material property, and impair or interfere with the comfortable enjoyment of life and other legitimate uses of the environment. For the purpose of the NI PEIS, only outdoor air pollutants were addressed, which may be in the form of solid particles, liquid droplets, gases, or a combination of these forms. Air pollutants are transported, dispersed, or concentrated by meteorological and topographical conditions. Potential air quality impacts of pollutant emissions from facility modification and normal operations were evaluated for those alternatives associated with FFTF restart and the use of existing facilities. This assessment included a comparison of pollutant concentrations from each alternative with applicable Federal and state ambient air quality standards. If both Federal and state standards exist for a given pollutant and averaging period, compliance was evaluated using the more stringent standard. Air quality impacts associated with a CLWR were addressed as a contribution from the facility operation. Air quality impacts from one or two new accelerators or a new research reactor were discussed for construction and operation at a generic DOE site. Emissions of potential stratospheric ozone-depleting compounds were not evaluated, as no emissions of these pollutants were identified in conceptual engineering design reports.

### **Water Resources**

Water resources are the surface and subsurface waters that are suitable for human consumption, aquatic or wildlife propagation, agricultural purposes, irrigation, or industrial and commercial purposes. The region of influence used for water resources encompasses those surface water and groundwater systems that could be impacted by water withdrawals, effluent discharges, and/or spills or stormwater runoff associated with construction and operation of the proposed facilities. Water use analysis involved the review of engineering estimates of expected water use and effluent discharges associated with each alternative, and the impacts on local water availability and quality, including surface water and groundwater. Impacts on water use were assessed by determining changes in the volume of current water usage and effluent discharges as a result of the proposed activities. Water quality analysis consisted of determining how effluent discharges to surface water, as well as discharges reaching groundwater, from the proposed facilities would affect current water quality. A comparison of the projected water quality with relevant regulatory standards was made. Separate analyses were conducted for surface water and groundwater impacts.

### **Geology and Soils**

Geologic resources include consolidated and unconsolidated earth materials, including mineral assets such as ore and aggregate materials, and fossil fuels such as coal, oil, and natural gas. Geologic conditions include hazards such as earthquakes, faults, volcanoes, landslides, and land subsidence. Soil resources include the loose surface materials of the earth in which plants grow, usually consisting of mineral particles from disintegrating rock, organic matter, and soluble salts. Prime farmland includes cropland, pasture land, rangeland, and forest land. The region of influence for geology and soils includes all areas subject to disturbance by construction and operation of the proposed facilities, as applicable, and those areas beneath existing or proposed new facilities that would remain inaccessible for the life of the facilities. The geology and soils impact analysis considered the risks to the existing and proposed new facilities of large-scale geologic hazards such as faulting and earthquakes, lava extrusions and other volcanic activity, landslides, and sinkholes, (i.e., conditions that tend to affect broad expanses of land). As the exact nature of the generic DOE or CLWR sites is not known, bounding assumptions were made regarding the range of potential geologic and soils conditions that could be present, coupled with the use of highly conservative estimates of expected impacts. If a DOE or CLWR site were selected, subsequent NEPA assessment would be required.

### **Ecological Resources**

Ecological resources include terrestrial and aquatic resources (plants and animals), wetlands, and threatened and endangered species. Terrestrial resources are defined as those plant and animal species and communities

that are most closely associated with the land; for aquatic resources, a water environment. Wetlands generally include swamps, marshes, bogs, and similar areas. Endangered species are defined as those species in danger of extinction throughout all or a large portion of their range. Threatened species are defined as those species likely to become endangered within the foreseeable future. Critical habitat is defined as specific areas that contain physical and biological features essential to the conservation of species and that may require special management consideration or protection. The region of influence used for the ecological resource analysis encompassed the area potentially disturbed by construction and operation of the proposed facilities. Impacts to ecological resources may occur as a result of land disturbance, water use, air and water emissions, human activity, and noise associated with project implementation. For alternatives involving construction and operation of one or two new accelerators or a research reactor at a generic DOE site, the analysis generally considered impacts at both a disturbed and an undisturbed location at a generic DOE site. Impacts to terrestrial and aquatic ecosystems and wetlands from water use and air and water emissions were evaluated based on the results of the analysis conducted for air quality and water resources.

### **Cultural and Paleontological Resources**

Potential impacts were assessed separately for each of the three general categories of cultural resources: prehistoric, historic, and Native American. Prehistoric resources are physical remains of human activities that predate written records. Historic resources consist of physical remains that postdate the emergence of written records; in the United States, they are architectural structures or districts, archaeological objects, and archaeological features dating from 1492 and later. Native American resources are sites, areas, and materials important to Native Americans for religious or heritage reasons. Paleontological resources are the physical remains, impressions, or traces of plants or animals from a former geological age. The region of influence for the cultural and paleontological resource analysis encompassed the area potentially disturbed by construction and operation of the proposed facilities. The analysis of impacts to cultural and paleontological resources addressed potential direct and indirect impacts at each site. Potential indirect impacts include those associated with reduced access to a resource site, as well as impacts associated with increased traffic and visitation to sensitive areas. Direct impacts include those resulting from groundbreaking activities associated with new construction. Because the specific location is unknown, impacts from new construction of one or two new accelerators or a research reactor, as well as operation of an existing CLWR, were addressed in a general manner. In order to determine the range of potential impacts, the analysis for new construction considered potential effects at both a disturbed and an undisturbed location at a generic DOE site.

### **Socioeconomics**

Socioeconomic impacts are defined in terms of changes to the demographic and economic characteristics of a region. The socioeconomic environment is made up of two geographic regions, the regional economic area and region of influence. Regional economic areas are made up of regional economies and include descriptions of industrial and service sector characteristics and their linkages to the communities within a region. For each regional economic area, data were compiled on the current socioeconomic conditions, including unemployment rates, economic industrial and service sector activities, and the civilian labor force. The workforce requirements of each alternative were determined in order to measure their possible effect on these socioeconomic conditions. Similarly, potential demographic impacts were assessed for the region of influence. The region of influence could represent a smaller geographic area. For each region of influence, census statistics were compiled on population, housing demand, and community services. U.S. Census Bureau population forecasts for the regions of influence were combined with overall projected workforce requirements for each of the alternatives being considered at each of the sites to determine the extent of impacts on housing demand and levels of community services. For those alternatives involving construction and operation of one or two new accelerators or a research reactor at a generic DOE site, the socioeconomic characteristics of the site are unknown. Specific impacts cannot be measured until candidate sites are identified and therefore,

impacts were addressed in a general manner. Impacts associated with the use of an existing CLWR were also addressed in a general manner as the location is unknown.

### **Public and Occupational Health and Safety—Normal Operations**

An individual may be exposed to ionizing radiation externally (from a radioactive source outside the body) or internally (from ingesting or inhaling radioactive material). For the analyses conducted in the NI PEIS, exposure to a radioactive source as a result of releases to air and water pathways has been considered. The dose from internal exposure was calculated over 50 years following the initial exposure. The three types of doses calculated are external dose, internal dose, and combined external and internal dose. The external dose can result from several different pathways (exposure to a radioactive source in the air, water, or ground), all having in common the fact that the radiation causing the exposure is external to the body. The appropriate measure of dose is called the effective dose equivalent. The internal dose results from a radiation source entering the human body through either ingestion of contaminated food or inhalation of contaminated air. The unit of measure for internal dose is the committed effective dose equivalent. The units used for combined external and internal dose are the rem and millirem (1/1000 of 1 rem). The corresponding unit for the collective dose to a population (the sum of the doses to members of the population, or the product of the number of exposed individuals and their average dose) is the person-rem.

The potential impacts of exposure to hazardous chemicals released to the atmosphere were also evaluated for routine operations associated with the alternatives analyzed in the NI PEIS. The receptors considered in these evaluations are the public. Impacts of exposures to hazardous chemicals for workers directly involved in the treatment process were not quantitatively evaluated because workers use personal protective equipment and engineering process controls that limit their exposure to levels within applicable limits. The health effect endpoints evaluated in this analysis include excess incidences of latent cancers for carcinogenic chemicals, and a spectrum of chemical-specific noncancer health effects expressed in terms of a hazard index. This index is a measure of the likelihood of noncancer health effects, such as headache, membrane irritation, neurotoxicity, immunotoxicity, liver toxicity, kidney toxicity, developmental toxicity, reproductive toxicity, and genetic toxicity for noncarcinogens.

### **Public and Occupational Health and Safety—Facility Accidents**

The accidents considered in the NI PEIS for both the irradiation facilities and the processing facilities are based on a spectrum of accidents ranging from high-probability low-consequence events to extremely unlikely higher consequence events. All the facilities have been treated comparably with regard to accident evaluation, while incorporating facility-specific differences in design and mitigation features.

For each evaluated accident, radiological dose consequences are provided for the maximally exposed individual. The maximally exposed individual is typically defined as a hypothetical individual who resides at the nearest site boundary in the direction that would result in the highest dose, assuming an accident occurs. Since major highways pass through some of the sites and these are well traveled, the NI PEIS also included an evaluation of individuals assumed to be located on a highway within the site. Accident doses to individuals at the nearest site boundary and on highways within the site were evaluated and the hypothetical individual receiving the highest dose was designated as the maximally exposed individual. For the hazardous chemical accident analysis, consequences are determined by comparing estimated airborne chemical concentrations to emergency response guidelines. Hazardous chemical impact information is presented for both individuals.

While it is possible that an individual member of the public could be closer to a facility than either the site boundary or the nearest onsite highway, such individuals would be present only occasionally and for brief periods (a few hours or more). Therefore, the annual probability that an individual would be close to a facility

is relatively low, and the associated risk to that individual would be bounded by the maximally exposed individual at the site boundary or nearest onsite highway.

In addition to the maximally exposed individual, accident consequence information is also provided for a noninvolved worker. For the NI PEIS accident analysis, the noninvolved worker is a hypothetical individual located 640 meters (0.4 miles) from the affected facility. The noninvolved worker impacts are provided for each facility except the CLWR. CLWR accidents selected for analysis in the NI PEIS are severe accidents that are intended to envelop the accident risk. Due to the nature and timing of these accidents, there is sufficient time prior to a radioactive release to initiate site emergency procedures. The NI PEIS accident analysis assumes that noninvolved workers, trained in emergency procedures, would have sufficient time to evacuate without suffering any consequences.

Radiological accident impacts are also provided for the offsite population within an 80 kilometer (50 mile) radius of each facility. Additional accident analyses include the evaluation of involved worker impacts and industrial accidents. Because of the large uncertainties associated with involved worker impacts, the consequences are presented qualitatively.

### **Public and Occupational Health and Safety—Transportation**

The transportation of any commodity involves a risk to both transportation crew members and members of the public. This risk results directly from transportation-related accidents and indirectly from the increased levels of pollution from vehicle emissions, regardless of the cargo. The transportation of certain materials, such as hazardous or radioactive substances, can pose an additional risk due to the unique nature of the material itself. To permit a complete appraisal of the environmental impacts of the proposed action and alternatives, the human health risks associated with the overland transportation of neptunium- and plutonium-bearing material are analyzed in the NI PEIS. For each alternative, radiological risks (i.e., those risks that result from the radioactive nature of the neptunium and plutonium) are assessed for both incident-free (i.e., normal) and accident transportation conditions. The radiological risk associated with incident-free transportation conditions would result from the potential exposure of people to external radiation in the vicinity of a loaded shipment. The radiological risk from transportation accidents would come from the potential release and dispersal of radioactive material into the environment during an accident and the subsequent exposure of people. All radiological impacts are calculated in terms of committed dose and associated health effects in the exposed populations.

In addition to the radiological risks posed by overland transportation activities, vehicle-related risks are also assessed for nonradiological causes (i.e., causes related to the transport vehicles and not the radioactive cargo) for the same transportation routes. The nonradiological transportation risks, which would be incurred for similar shipments of any commodity, are assessed for both incident-free and accident conditions. The nonradiological risks during incident-free transportation conditions would be caused by potential exposure to increased vehicle exhaust emissions. The nonradiological accident risk refers to the potential occurrence of transportation accidents that directly result in fatalities unrelated to the shipment of cargo. National transportation fatality rates are used in the assessment. Nonradiological risks are presented in terms of estimated fatalities.

### **Environmental Justice**

The NI PEIS provides an assessment of the potential for disproportionately high and adverse human health or environmental effects on minority and low-income populations from the implementation of each alternative. Adverse health effects are measured in risks and rates that could result in latent cancer fatalities, as well as other fatal or nonfatal adverse impacts to human health. Disproportionately high and adverse human health

effects occur when the risk or rate of exposure to an environmental hazard for a minority population or low-income population is significant and exceeds the risk or exposure rate for the general population or, where available, for another appropriate comparison group. A disproportionately high and adverse environmental impact refers to an impact (or risk of an impact) in a low-income or minority community that is significant and exceeds the adverse environmental impact on the larger community. In assessing cultural and aesthetic environmental impacts, impacts that uniquely affect geographically dislocated or dispersed or minority low-income populations are considered. Potentially affected areas examined in the NI PEIS include areas defined by an 80-kilometer (50-mile) radius centered on candidate facilities for plutonium-238 production, radioisotope production, or processing activities located at INEEL, ORR, and Hanford. Potentially affected areas used in the analysis of environmental justice are the same as those used in the analysis of radiological health effects. Potentially affected areas for the other resource areas are included in the potentially affected areas used for the analysis of radiological health effects.

### **Waste Management**

The construction and operation of the proposed facilities, as well as the permanent deactivation of FFTF and decontamination and decommissioning of one or two accelerators, research reactor, and support facility, would generate several types of waste, depending on the alternative. Such waste may include high-level radioactive waste, transuranic waste, low-level radioactive waste, mixed low-level radioactive waste, hazardous waste and nonhazardous waste. The alternatives could have an impact on existing site facilities devoted to the treatment, storage, and disposal of these categories of waste. Impacts were assessed by comparing the projected waste stream volumes generated from the proposed activities at each site with that site's waste management capacities and generation rates. Only the impacts relative to the capacities of waste management facilities were considered; other environmental impacts of waste management facility operations (e.g., human health effects) are evaluated in other sections of the NI PEIS, or in other facility-specific or sitewide NEPA documents. Projected waste generation rates for the proposed activities were compared with site processing rates and capacities of those treatment, storage, and disposal facilities likely to be involved in managing the additional waste. Projected waste stream volumes could not be compared to site waste management capacities and generation rates for the alternatives involving the use of a generic DOE site or a CLWR site because a specific location was not identified.

### **Cumulative Impacts**

Cumulative impacts can result from individually minor but collectively significant actions taking place over a period of time. The cumulative impact analysis for the NI PEIS involved combining the impacts of the alternatives (including No Action) with the impacts of other present and reasonably foreseeable activities in the regions of influence. The regions of influence for different resources can vary widely in extent. In general, cumulative impacts were calculated by adding the values for the baseline affected environment (i.e., conditions attributable to present actions by DOE and other public and private entities), the proposed action (or no action), and other future actions. This cumulative value was then weighed against the appropriate impact indicators (e.g., standards) to determine the potential for impact. For this cumulative impact assessment, it was conservatively assumed that all facilities would operate concurrently at the DOE sites. Decontamination and decommissioning of the proposed facilities was not addressed in the cumulative impact estimates. Given the uncertainty regarding the timing of decontamination and decommissioning, any impact estimate at this time would be highly speculative. A detailed evaluation of decontamination and decommissioning will be provided in follow-on NEPA documentation closer to the actual time of those actions.

## **S.6 SUMMARY OF ENVIRONMENTAL IMPACTS AND MISSION EFFECTIVENESS**

The following section summarizes the environmental impacts associated with the alternatives and options and compares the impacts among the alternatives described in Chapter 4 of the NI PEIS. Chapter 4 shows construction impacts that would result from implementation of Alternatives 3 and 4, as well as operational impacts for all of the alternatives.

As discussed in Section S.2, tables and text in this section have been revised in response to comments about the difficulty of comparing environmental impacts among the alternatives in the Draft NI PEIS. Tables and figures in this section now focus on estimated environmental impacts that would result from implementation of the alternatives. Baseline environmental data for the sites and for the candidate facilities are now given in Chapter 3 of the NI PEIS. In the NI PEIS, Option 1 of the No Action Alternative is used as a basis for the comparison of impacts at candidate sites.

Numerical values are assigned to environmental impacts that include radiological and nonradiological risks to the public and workers at the candidate sites and along representative transportation routes, potential quantities of waste generated, and potential quantities of spent nuclear fuel generated. These numerical values reflect the degree to which the proposed activities would increase the environmental impacts of current activities and operations at the candidate sites. It should be noted that most of the options being considered under the various alternatives involve the use of more than one site, so the numerical values presented are the sums of the values for all of the relevant sites or transportation routes. There are two exceptions—the health risks to the maximally exposed individual and the noninvolved worker. For these two exceptions, the numerical value presented is the maximum value among all relevant sites.

### **Radiological and Hazardous Chemical Impacts**

**Radiological Impacts.** Table S-4 summarizes radiological and hazardous chemical risks that could occur under implementation of the alternatives from operations at fabrication, processing, and irradiation facilities. Radiological risks to the maximally exposed individual are listed in columns 2 and 5 for normal operations and accidents, respectively. Similarly, columns 3 and 6 display radiological risks to the public for normal operations and accidents, and columns 4 and 7 show radiological risks to workers at candidate irradiation facilities and processing and fabrication facilities. As indicated in the table, Option 1 of the No Action Alternative is the basis for comparing impacts that would result from implementation of the other alternatives and options. Impact values for Option 1 of the No Action Alternative are set to zero and provide a reference point for comparing impacts that would result from implementation of the other alternatives and options. Negative values in the table indicate a decrease in risk with respect to Option 1 of the No Action Alternative.

The risk values presented are the sum of individual risk values from operational activities in the fabrication, processing, and irradiation facilities used under each alternative and option. For Alternatives 2 through 4, where FFTF would be permanently deactivated, the values presented also include the reduction in risk from FFTF deactivation, where applicable. For example, the radiological risk to the population from normal operations for Option 3 of Alternative 2 (i.e., irradiation at ATR, fabrication and processing at FMEF, and deactivation of FFTF) is given as  $-4.7 \times 10^{-4}$  latent cancer fatality. This value was calculated by adding the population risks from fabrication and processing at FMEF and irradiation at ATR,  $7.7 \times 10^{-7}$  latent cancer fatality, and Alternative 5 (Permanently Deactivate FFTF [with No New Missions]),  $-4.7 \times 10^{-4}$  latent cancer fatality. The latter risk is the sum of the population risk associated with the activities during permanent deactivation of FFTF,  $1.8 \times 10^{-5}$  latent cancer fatality, and that resulting from not keeping FFTF in standby for 35 years,  $-4.9 \times 10^{-4}$  latent cancer fatality (the negative value reflects the reduction in risk). The radiological risks for accident conditions are the sum of accident risks evaluated for each option. For each accident, the

**Table S-4 Comparison Among Alternatives: Impacts on Occupational and Public Health and Safety from Baseline Conditions**

Options <sup>a</sup>	Radiological Risks from Normal Operations over 35 Years			Radiological Risks <sup>b</sup> from Accidents over 35 Years			Hazardous Chemical Risks from Normal Operations over 35 Years

a. For detailed descriptions of the options under each alternative, see Section 2.5 of the NI PEIS.

b. Accident risks include accident likelihood over 35 years and the consequences.

c. Probability that an individual would develop cancer from exposure to hazardous (carcinogenic) chemicals.

d. A measure of hazard from exposure to multiple toxic (noncarcinogenic) chemicals. If this value is less than 1, the exposure is unlikely to produce an adverse toxic effect.

e. Baseline conditions for the comparison of impacts is Option 1 of the No Action Alternative.

f. These alternatives include FFTF deactivation impacts. The deactivation would lead to negative impacts (reduced risk); see Alternative 5.

g. The reduction in impacts from deactivating FFTF would affect the impacts to the population and workforce for Alternatives 2 through 4 and to the maximally exposed individual only for those options within Alternatives 2 through 4 that use FMEF.

**Note:** Refer to the text for a discussion on how the risk values in this table have been generated.

**Key:** LCF, latent cancer fatalities.

risk value is the product of the accident consequences and its occurrence likelihood over 35 years of operation. Chapter 4, Appendix H, and Appendix I of the NI PEIS provide the details on public and occupational risk calculations.

A comparison of radiological risks estimated to result from normal operations over 35 years (columns 2 and 3 of Table S-4) shows that implementation of the alternatives would result in a small risk of a latent cancer fatality among the general public. Radiological accident risks to the public over 35 years (columns 5 and 6 of Table S-4) are estimated to be less than one latent cancer fatality. **Figure S-4** shows estimated latent cancer fatalities among the population at risk from potential accidents at candidate sites. Each bar in Figure S-4 represents the estimated latent cancer fatalities for a given option.

For example, there are six bars shown above the alternative labeled “Restart FFTF.” The first of the six bars represents the estimated latent cancer fatalities for implementation of Option 1, the second bar represents the estimated latent cancer fatalities for implementation of Option 2, etc. Storage containers for neptunium-237 targets would not be expected to rupture under the most severe accident evaluated in the NI PEIS. Therefore, no latent cancer fatalities would be expected under implementation of the No Action Alternative. Deactivation of FFTF (with no new missions) would result in a small reduction in radiological accident risks in comparison with the No Action Alternative. Differences in the radiological accident risks among alternatives and among options within a given alternative are driven by accident risks at the target fabrication and processing facilities. This point is illustrated in **Figure S-5**.

Figure S-5 shows risks to the public that would result from radiological accidents at candidate fabrication and processing facilities and candidate irradiation facilities. Latent cancer fatalities estimated for candidate fabrication and processing facilities are shown to the left of the dividing line in Figure S-5, and the estimated latent cancer fatalities for candidate irradiation facilities appear on the right side of the dividing line. The estimated latent cancer fatalities for FMEF under Options 3 and 6 of Alternative 1 are labeled “FMEF (Hanford).” Under Options 3 and 6 of Alternative 1, FMEF would serve as the fabrication and processing facility for all targets. If FMEF were selected to fabricate and process neptunium-237 targets only, the radiological risk to the public would be reduced by approximately a factor of two, as shown by the bar labeled “FMEF (Hanford, neptunium-237 targets only)” in Figure S-5. Among the candidate fabrication and processing facilities, accident risks to the public range from a low of 0.029 latent cancer fatality at FDPF (INEEL) to 0.377 latent cancer fatality at RPL (Hanford). Although all of the accident risks shown in Figure S-5 are less than one latent cancer fatality, risks to the public that would be expected from radiological accidents at candidate fabrication and processing facilities are relatively large in comparison to those for candidate irradiation facilities.

Prevailing weather conditions, the geographical distribution of the population at risk, and the type of target(s) processed (neptunium-237 only, other isotopes only, or both) all contribute to variations in the radiological risk to the public. Calculations of accident consequences and risks include populations residing within 80 kilometers (50 miles) of the accident site, although the consequences and risks decrease noticeably with increasing distance from the accident site. As shown in **Figure S-6**, RPL (Hanford) and REDC (ORR) have the largest populations residing within 16 kilometers (10 miles) of candidate sites, while FDPF (INEEL) has the smallest. Because the total population residing within 16 kilometers (10 miles) of FDPF is relatively small, the curve representing populations residing near FDPF is nearly coincident with the horizontal axis in Figure S-6. Comparing Figures S-5 and S-6, it is clear that accident risks due to fabrication and processing activities are driven by both the type of processing activities and the total population residing near the facilities. In turn, variations in accident risks among the alternatives, as well as variations among options within an alternative, are driven by the selection of fabrication and processing facilities. The choice for irradiation facility would have little effect on radiological accident risks to the public.

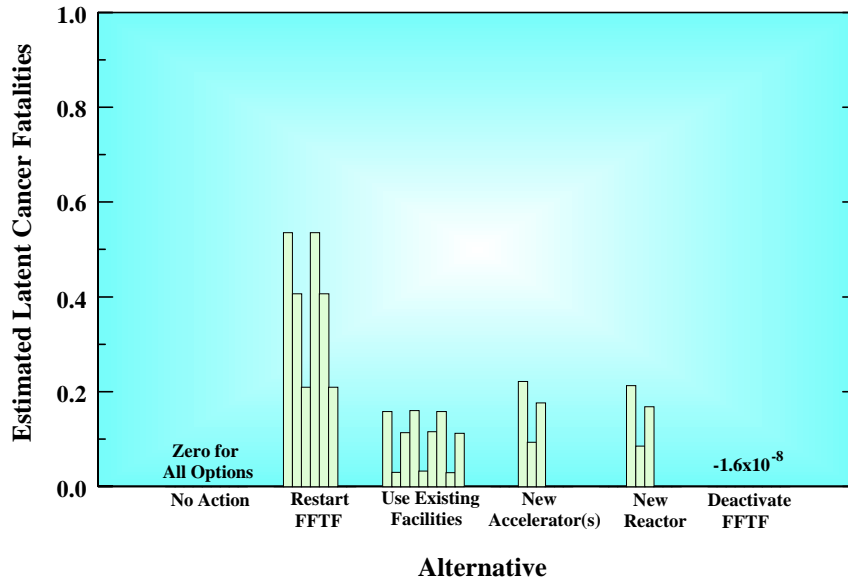

Figure S-4 Public Risks Due to Radiological Accidents at Candidate Sites (35 Years)

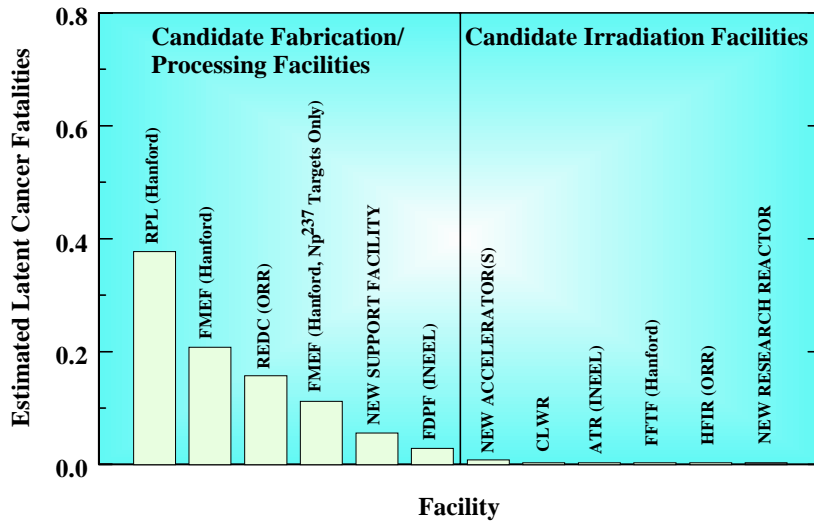

Figure S-5 Public Risks Due to Radiological Accidents at Candidate Facilities (35 Years)

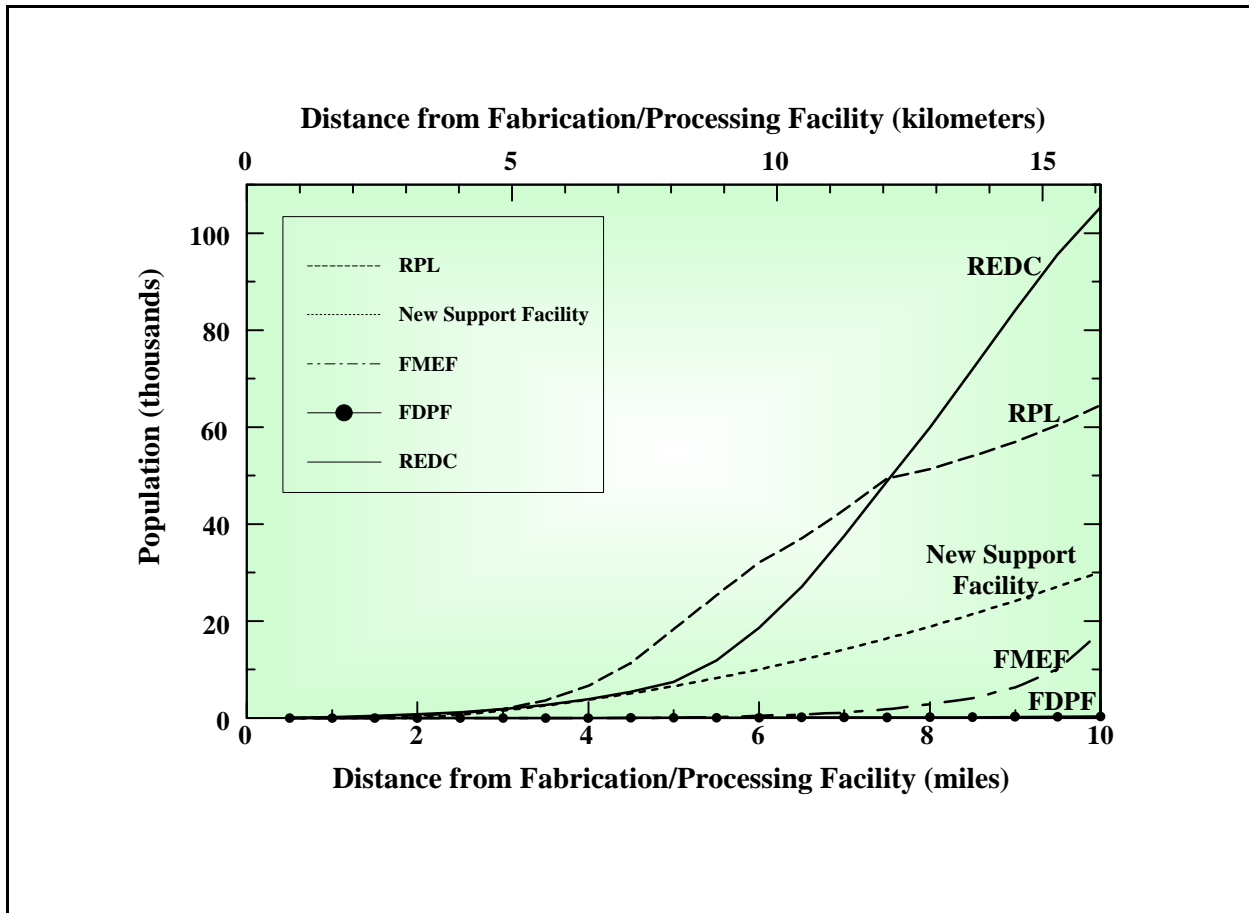

Figure S-6 Population Residing Within 16 Kilometers (10 Miles) of Candidate Fabrication and Processing Facilities

**Hazardous Chemical Impacts.** Columns 8 and 9 of Table S-4 display cancer risks and hazard indexes that could result from airborne emissions of hazardous chemicals from candidate processing facilities. Cancer risk factors listed in column 8 of Table S-4 are estimates of an upper-bound lifetime probability of an individual developing cancer due to exposure to carcinogenic chemicals. For all alternatives and options, the maximum cancer risk factor is  $2.6 \times 10^{-7}$  (or a likelihood of approximately 1 in 3,800,000) or less. Different carcinogens can cause or promote different forms of cancer. In general, cancer risk factors for different carcinogens are not additive because there are potential synergistic or antagonistic chemical interactions in multiple-substance exposures (EPA 1989). Therefore, column 8 of the table lists the maximum cancer risk factor for each alternative. Hazard indexes listed in column 9 of Table S-4 estimate the potential for adverse toxic (noncancerous) health effects due to exposure to hazardous chemicals. If the hazard index is less than one, adverse (noncancerous) health effects would not be expected. For all of the alternatives and options, hazard indexes are 0.0064 or less. The results (presented in columns 8 and 9 of Table S-4) indicate that no adverse toxic health or cancer effects would be expected from exposure to hazardous chemicals released under the implementation of any of the alternatives.

### Generation and Disposition of Waste and Spent Nuclear Fuel

Table S-5 summarizes the estimated amount of waste and spent nuclear fuel that would be generated under implementation of the nuclear infrastructure alternatives. Waste that would result from implementation of the alternatives would be relatively small in comparison to current waste generation at the candidate sites. Current

waste management practices at the candidate sites would be sufficient to manage waste that would result from the nuclear infrastructure alternatives.

**Table S-5 Comparison of Waste and Spent Nuclear Fuel Generation Among Alternatives**

<b>Alternative 5: Permanently Deactivate FFTF (with No New Missions)</b>						
	0.0	0.0	(b)	2,500 <sup>d</sup>	0.0	0

a. For detailed descriptions of the options under each alternative, see Section 2.5 of the NI PEIS.

b. The deactivation of FFTF would result in the removal of approximately 980,000 liters (260,000 gallons) of sodium. This sodium would be evaluated for alternate uses and is therefore not included in mixed low-level radioactive waste for Alternatives 2 through 5.

c. 2,500 cubic meters of these materials would be evaluated for radioactive contamination and would be reused or recycled if possible.

d. These materials would be evaluated for radioactive contamination and would be reused or recycled if possible.

**Key:** NA, not applicable.

**Transuranic Waste/High-Level Radioactive Waste.** The analysis for the Draft NI PEIS assumed that the waste generated from the processing of irradiated neptunium-237 targets is transuranic waste. However, as a result of comments received during the public comment period, DOE is considering whether the waste from processing of irradiated neptunium-237 targets should be classified as high-level radioactive waste. Irrespective of how the waste is classified (i.e., transuranic or high-level radioactive), the waste composition and characteristics are the same, and the waste management (i.e., treatment and onsite storage) as described in the NI PEIS would be the same. In addition, either waste type would require disposal in a suitable repository. As shown in column 2 of Table S-5, between 240 and 380 cubic meters (314 and 497 cubic yards) of transuranic waste or high-level radioactive waste would result from implementation of Alternatives 1 through 4. This waste would result from processing irradiated neptunium-237 targets to harvest plutonium-238. Approximately 380 cubic meters (497 cubic yards) of this waste per year for 35 years would be generated for all options under Alternatives 1 through 4, except those for which target fabrication and processing would be conducted at FDPF at INEEL. If FDPF were selected for neptunium target fabrication and processing, then approximately 240 cubic meters (314 cubic yards) of waste would be generated during the program.

**Low-Level and Mixed Low-Level Waste.** Columns 3 and 4 of Table S-5 summarize the total low-level radioactive waste and mixed low-level radioactive waste generation that would be expected from implementation of the alternatives. Low-level radioactive waste would be generated at the irradiation facilities and at the fabrication and processing facilities. As shown, the low-level radioactive waste generation that would result under Alternative 2 would be less than half of that for Alternatives 1, 3, and 4, and mixed low-level radioactive waste generation would be almost half. This is because under Alternative 2 currently operational facilities would be used for target irradiation and these facilities would generate little additional low-level and mixed low-level radioactive waste. Also under Alternative 2, no waste generation would result from production of additional medical and industrial isotopes.

DOE's approach for managing low-level and mixed low-level radioactive waste is provided in the Record of Decision for its Waste Management Program (65 FR 10061). The Record of Decision states that for the management of low-level radioactive waste, minimal treatment will be performed at all sites, and disposal will continue to the extent practicable, on site at INEEL, LANL, ORR, and SRS. In addition, Hanford and the Nevada Test Site will be available to all DOE sites for low-level radioactive waste disposal. The Record of Decision does not preclude the use of commercially licensed low-level radioactive waste disposal facilities. Low-level radioactive waste generated at Hanford would be disposed of on site. However, if DOE determines that use of the Hanford waste management infrastructure or other DOE sites is not practical or cost effective, DOE may issue an exemption under DOE Order 435.1 for the use of non-DOE facilities (i.e., commercial facilities) to store, treat, and dispose of such waste generated from the restart and operation of FFTF.

Solid low-level radioactive waste generated at ORR eventually would have to be disposed of off site due to lack of low-level waste disposal capacity at ORR. Low-level radioactive waste generated at INEEL would be disposed of on site. At some future time, low-level radioactive waste would be disposed of off site.

In compliance with the Waste Management Program Record of Decision, DOE's mixed low-level radioactive waste will be treated at: Hanford, INEEL, ORR, and SRS, and disposed of at Hanford and the Nevada Test Site. Existing candidate sites analyzed in the NI PEIS all have treatment facilities for mixed low-level radioactive waste. Solid mixed low-level radioactive waste generated at ORR and INEEL would have to eventually be disposed of off site due to lack of onsite mixed low-level radioactive waste disposal capacity.

**Hazardous Waste.** Hazardous waste that would result from implementation of the nuclear infrastructure alternatives is shown in column 5 of Table S-5. The amount of hazardous waste generated under the alternatives is relatively small in comparison to hazardous waste currently generated at the candidate sites. Estimated amounts of hazardous waste that would be generated under Alternatives 2 through 4 include the hazardous waste that would be generated under Alternative 5 (Permanently Deactivate FFTF [with No New Missions]).

Based on the Record of Decision for hazardous waste issued on August 5, 1998 (63 FR 41810), nonwastewater hazardous waste would be treated and disposed of at offsite commercial facilities. Hazardous waste generated under the nuclear infrastructure alternatives would be stored in onsite facilities permitted under the Resource Conservation and Recovery Act or generator accumulation areas prior to shipment to a commercial facility permitted to manage hazardous waste.

**Nonhazardous Waste.** Nonhazardous waste that would be expected from implementation of the nuclear infrastructure alternatives is listed in column 6 of Table S-5. Nonhazardous waste that would be expected under implementation of Alternative 3 (Construct New Accelerator[s]) is at least a factor of six larger than the nonhazardous waste estimated for the other alternatives. Nonhazardous waste that would be produced under Alternative 3 would be driven by sanitary waste and process wastewater resulting from construction and operation of accelerators and the new support facility.

Nonhazardous solid waste that would be generated at ORR and INEEL would represent less than 0.5 percent of the generating site's onsite nonhazardous waste disposal capacity. Nonhazardous solid waste that would be generated at Hanford under the nuclear infrastructure alternatives would be recycled or sent off site for disposal as industrial waste. Nonhazardous process wastewater at the candidate sites would represent a small fraction of the generating sites capacity and would be treated on site. Sanitary wastewater would be treated on site as necessary prior to offsite disposition.

**Spent Nuclear Fuel.** Changes in the generation of spent nuclear fuel would occur only under implementation of Alternatives 1 (Restart FFTF) and 4 (Construct New Research Reactor). Spent nuclear fuel that would be generated under Alternative 1 would be less than 1 percent (by weight) of the current spent nuclear fuel inventory at Hanford. Spent nuclear fuel that would be generated at Hanford under implementation of Alternative 1 would be placed in facility storage vessels and onsite dry storage pending ultimate disposal in a geologic repository. Spent nuclear fuel generated under Alternative 4 would be stored on site in wet storage pending ultimate disposal in a geologic repository.

## Water Use

**Construction.** For construction of new facilities under Alternatives 3 (Construct New Accelerator[s]) and 4 (Construct New Research Reactor), water is expected to be required for such uses as mixing concrete, dust control, washing activities, and potable and sanitary needs. Water use for facility construction is estimated at 22.7 million liters (6 million gallons) for the high-energy accelerator, 14 million liters (3.7 million gallons) for the low-energy accelerator, 11.7 million liters (3.1 million gallons) for the new research reactor, and 14.6 million liters (3.85 million gallons) for the new support facility on an annualized (construction-year) basis.

**Operations.** Figure S-7 shows the annual water use that would be expected to occur under the nuclear infrastructure alternatives. Under the No Action Alternative, FFTF would remain in standby and DOE's nuclear infrastructure would not be enhanced. In standby condition, the FFTF uses approximately 197 million liters (52 million gallons) of groundwater per year. In Figure S-7, the No Action Alternative is used as a basis for comparison of water use among the alternatives. Therefore, water use for the No Action Alternative is shown as zero. The water use shown in Figure S-7 for Alternative 1 (Restart FFTF) is the additional

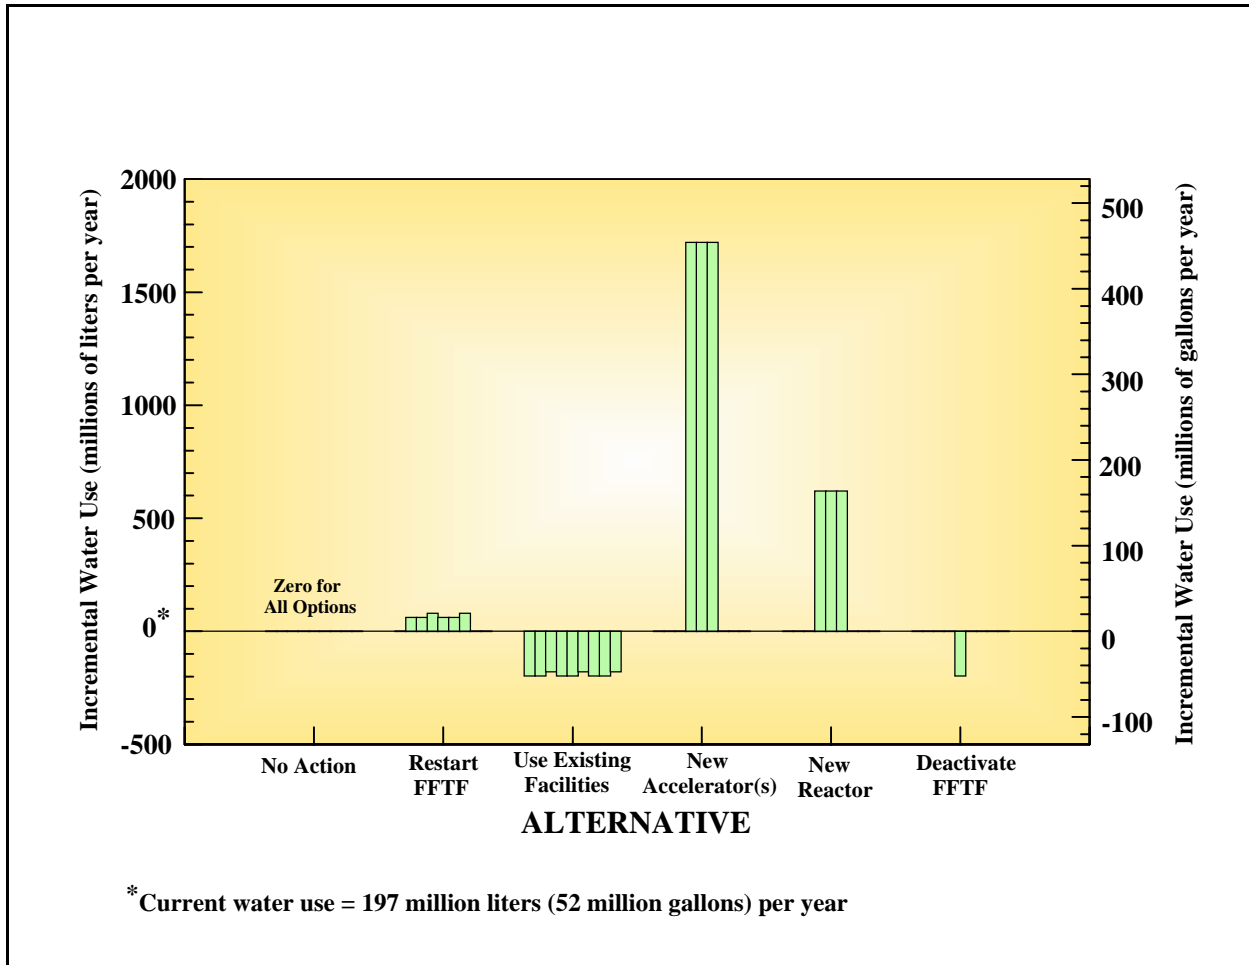

Figure S-7 Annual Water Use Under the Nuclear Infrastructure Alternatives

groundwater use that would result from operation of the FFTF. Under Alternatives 2 through 5, FFTF would be deactivated, thus saving approximately 197 million liters (52 million gallons) per year in groundwater required for maintaining FFTF in standby. As a result, the water use is negative for Alternatives 2 (Use Only Existing Operational Facilities) and 5 (Permanently Deactivate FFTF [with No New Missions]). The negative increment in water use would be more than offset by the increase in water use estimated for Alternatives 3 (Construct New Accelerator[s]) and 4 (Construct New Research Reactor).

### Air Quality

**Construction.** Under Alternatives 3 (Construct New Accelerator[s]) and 4 (Construct New Research Reactor), new irradiation and support facilities would be constructed to support DOE's nuclear missions. Facility construction would not be required under the other alternatives. Since no specific site has yet been selected for the new accelerator[s] or the new research reactor, Federal standards are used to evaluate estimated concentrations of air pollutants. The effects of constructing the new high-energy accelerator were used to characterize air quality impacts under Alternative 3 (Construct New Accelerator[s]). Construction impacts of the low-energy accelerator and support facilities would add relatively small concentrations of air pollutants. If Alternative 3 and/or Alternative 4 were selected for implementation, site-specific environmental documentation would be prepared prior to site selection.

Construction of the new irradiation and support facilities would not be expected to exceed Federal standards and guidelines for ambient air quality. However, in comparison with air pollutant concentrations expected from facility operations, concentrations of air pollutants that would be expected during construction are relatively large. If the new facilities were constructed in an area with existing high background concentrations, construction activities could produce enough air pollutant emissions to exceed ambient air quality standards.

**Operations—No Action Alternative.** Under the No Action Alternative, FFTF would remain in standby and DOE's nuclear infrastructure would not be enhanced to meet the nuclear infrastructure missions. Air quality effects that would be expected from transportation of neptunium-237 oxide to REDC (Option 2), FDPF (Option 3), or FMEF (Option 4) are summarized in transportation discussion later in this section.

**Operations—Alternatives 1 through 5. Oak Ridge Reservation:** Under Alternatives 1 (Options 1 and 4), 2 (Options 1, 4, and 7), 3 (Option 1), and 4 (Option 1), air quality impacts at ORR would result from the production of plutonium-238 at REDC. All of the expected concentrations are small in comparison with the most stringent ambient air quality standards. Operation of REDC in support of plutonium-238 production would not be expected to significantly affect air quality or to result in air pollutant concentrations in excess of ambient air quality standards. No air quality impacts would result from operation of HFIR under Alternative 2 (Use Only Existing Operational Facilities).

**Idaho National Engineering and Environmental Laboratory:** Under Alternatives 1 (Options 2 and 5), 2 (Options 2, 5, and 8), 3 (Option 2) and 4 (Option 2), air quality impacts at INEEL would result from the production of plutonium-238 at FDPF. All of the expected concentrations are small in comparison with the most stringent ambient air quality standards. Operation of FDPF in support of plutonium-238 production would not be expected to significantly affect air quality or to result in air pollutant concentrations in excess of ambient air quality standards. No air quality impacts would result from operation of ATR under Alternative 2 (Use Only Existing Operational Facilities).

**Hanford Site:** If Alternative 1 were selected for implementation, impacts on air quality at Hanford would result from operation of FFTF (all options), RPL (Options 1, 2, 4, and 5), and FMEF (Options 3 and 6). FMEF could also be used for production of plutonium-238 under Alternatives 2 (Options 3, 6, and 9), 3 (Option 3), and 4 (Option 3). FFTF would be deactivated under Alternatives 2 through 5. Deactivation would, in turn, result in the shutdown of diesel-driven fire pumps, oil-fired preheaters, and a gas turbine that currently support FFTF's standby condition. If any of Alternatives 2 through 5 were selected for implementation, emissions from this supporting equipment would cease, thereby improving the air quality near FFTF. Emissions of air pollutants from FMEF are relatively small in comparison to those associated with FFTF supporting equipment.

Air quality concentrations for FFTF and FMEF were calculated with the SCREEN3 model developed by EPA. The model is intended to provide conservative estimates of the concentrations of air pollutants emitted from point or extended sources. Concentrations shown under Alternatives 2 through 5 were obtained by summing estimated emissions from the diesel-driven oil pumps, the oil-fired preheaters, and the gas turbine. Because these sources operate intermittently and do not necessarily operate at the same time, estimates of the concentrations of air pollutants are conservative because they were obtained under the assumption that all supporting equipment for FFTF would operate simultaneously, which is considered a worst-case scenario.

**Generic Site for the New Accelerator(s):** Under Alternative 3 (all options), air quality impacts at the site for the new accelerator(s) would result from the operation of emergency diesel generators for the high-energy accelerator and any support facilities. The low-energy accelerator would not require emergency diesel power, and it was assumed in the analysis that air quality effects of the low-energy accelerator could be ignored. Air quality impacts of the support facilities would be assessed if Alternative 3 (Construct New Accelerator[s]) were selected for implementation. In comparison with the air quality concentrations that would be expected during

construction, air quality impacts resulting from operation of the diesel generators would be relatively small. All of the expected concentrations resulting from operation of emergency generators would be small in comparison with the most stringent ambient air quality standards, and would not be expected to result in air pollutant concentrations in excess of ambient air quality standards. If the new accelerator(s) were located in an area that has high background pollutant concentrations, diesel emissions could result in pollutant concentrations in excess of the ambient standards. If Alternative 3 were selected for implementation, site-specific environmental documentation would be prepared prior to site selection.

**Generic Site for the New Research Reactor:** Under Alternative 4 (all options), air quality impacts at the site for the new research reactor would result from the operation of emergency diesel generators for the reactor. In comparison with the air quality concentrations that would be expected during construction, air quality impacts resulting from operation of the diesel generator would be relatively small. All of the expected concentrations resulting from operation of the emergency generator would be small in comparison with the most stringent ambient air quality standards and would not be expected to result in air pollutant concentrations in excess of ambient air quality standards. If the new research reactor were located in an area that has high background pollutant concentrations, diesel emissions could result in pollutant concentrations in excess of the ambient standards. If Alternative 4 were selected for implementation, site-specific environmental documentation would be prepared prior to site selection.

### Socioeconomics

Implementation of the nuclear infrastructure alternatives would have no significant impact on regional economic areas or community services at Hanford, INEEL, and ORR. Socioeconomic impacts at the generic sites could not be evaluated in detail because areas potentially affected under Alternatives 3 and 4 could vary widely in demographic and economic composition. If Alternative 3 or 4 were selected for implementation, site-specific environmental analysis would be conducted prior to site selection. **Table S-6** shows the number of direct jobs that would be generated under implementation of the nuclear infrastructure alternatives. Deactivation of the FFTF under Alternatives 2 through 5 would result in the loss of 242 jobs that are required to keep the facility in standby condition. That loss would be offset under alternatives and options for which the FMEF would support the production of plutonium-238 (62 direct jobs).

### Transportation Impacts

The transportation impacts for Option 1 of the No Action Alternative are those resulting from transporting 175 kilograms (385 pounds) (5 kilograms [11 pounds] per year for the 35-year evaluation period) of plutonium-238 from Russia to LANL. The impacts were obtained by extrapolating the impact analysis presented in the *Environmental Assessment of the Import of Russian Plutonium-238* (DOE 1993) for the purchase of 40 kilograms (88.2 pounds) of plutonium-238. The impacts presented for the other options of the No Action Alternative include those of Option 1 plus the impact from transporting neptunium oxide from SRS to the selected facilities at ORNL, INEEL, and Hanford. Because the assumptions and data used to assess the transportation impacts in the above environmental assessment are different from those used in this NI PEIS, incremental transportation impacts compared to the baseline condition (Option 1 of the No Action Alternative) can only be presented for the options under the No Action Alternative. Therefore, the transportation impacts presented in this section are not compared to the baseline condition.

**Table S-6 Comparisons Among Alternatives: Change in Direct Jobs Under the Nuclear Infrastructure Alternatives**

Options <sup>a</sup>	Oak Ridge Reservation	Idaho National Engineering and Environmental Laboratory	Hanford Site	Generic Accelerator(s) Site(Construction/Operation)	Generic Research Reactor Site(Construction/Operation)

a. For detailed descriptions of the options under each alternative, see Section 2.5 of the NI PEIS.

Radiological and nonradiological transportation impacts over the 35-year program duration are summarized in **Table S-7**. Risks to the public and workers due to incident-free transportation are shown in columns 3 through 5 of the table. Columns 6 and 7 summarize radiological and nonradiological risks to the public that could result from transportation accidents. Chapter 4 and Appendix J of the NI PEIS discuss transportation impacts in more detail.

**Radiological Transportation Risks.** **Figure S-8** illustrates the data listed in column 6 of Table S-7. The results indicate a large risk to the public due to transportation accidents that could occur over 35 years under implementation of Alternatives 1 (Restart of FFTF), 3 (Construct New Accelerator[s]), and 4 (Construct New Research Reactor) as compared to those from implementation of Alternative 2 (Use Only Existing Operational Facilities). This large difference is due to the more than 8,000 medical isotope shipments by air transport considered under Alternatives 1, 3, and 4, and not under Alternative 2. Nearly all of the radiological and traffic accident risk are due to those involving medical and industrial isotope shipments. No enhancement of medical and industrial isotope production is considered under Alternative 2.

Implementation of Alternative 5 (Permanently Deactivate FFTF [with No New Mission]) would not result in any new transportation activities.

**Table S-7 Comparison Among Alternatives: Impacts of Transportation on Occupational and Public Health and Safety**

a. For detailed descriptions of the options under each alternative, see Section 2.5 of the NI PEIS.

b. No radiological spill.

c. No new transportation activities would occur under Alternative 5.

**Key:** LCF, latent cancer fatalities.

**Figure S-8 Public Risks Due to Radiological Transportation Accidents (35 Years)**

**Figure S-9** shows the radiological risks to the public that could result from incident-free transportation over 35 years (column 3 of Table S-7). For all of the alternatives and options, incident-free radiological transportation risks are approximately 0.2 latent cancer fatality over 35 years. As shown in column 4 of Table S-7, radiological risks to workers due to incident-free transportation are less than approximately 0.012 latent cancer fatality for all alternatives and options.

**Nonradiological Transportation Risks.** Column 7 of Table S-7 shows the risks of traffic fatalities that would be expected to result from vehicular collisions in which there is no radiological spill. Under all alternatives and options, the expected number of traffic fatalities would be less than approximately 0.2. Data listed in column 5 of the same table indicates that less than approximately 0.03 fatality would be expected from vehicular exhaust emissions. Fatalities that would be expected to result from both vehicular collisions and exhaust emissions are closely correlated with the estimated highway mileage that would be traveled under implementation of the alternatives (see column 2 of Table S-7 and **Figure S-10**). Traffic accident rates depend on the type of carrier. Both commercial trucks and DOE's safe, secure trailer/SafeGuards Transports (SST/SGTSs) would be used for the highway transport of isotopes. Accident rates for the safe, secure trailer system are less than those for commercial trucks by at least a factor of five. As a result, expected collision fatalities for any option would increase the total distance traveled, but the impacts would also depend on relative amounts of transportation by commercial truck and the SST/SGTs.

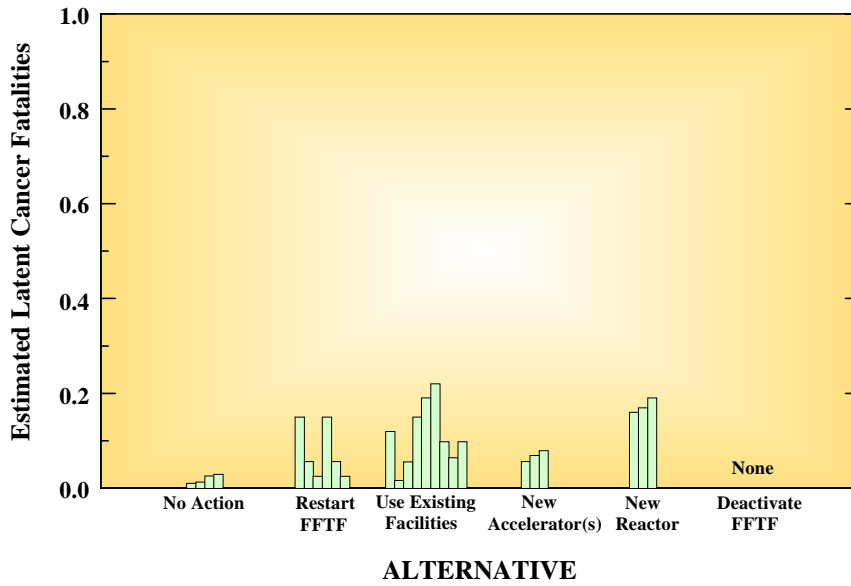

Figure S-9 Radiological Risks to the Public Due to Incident-Free Transportation (35 Years)

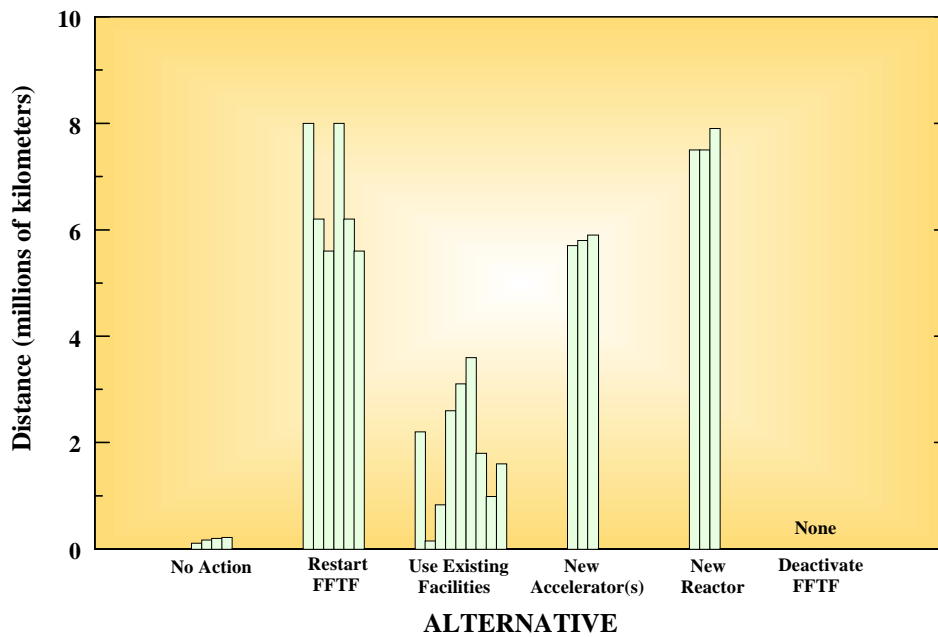

Figure S-10 Highway Distances That Would Be Traveled Under the Alternatives (35 Years)

## Resource Areas Discussed in Less Detail

Implementation of the nuclear infrastructure alternatives at existing candidate sites would be expected to have little effect on land use, visual resources, noise, water quality, geology and soils, ecology, cultural resources, and environmental justice. Implementation of the alternatives at one or more generic sites could potentially result in significant impacts in one or more of these resource areas. However, these impacts are site-specific and could not be evaluated in detail in this programmatic document. If Alternative 2 (Options 4, 5, and 6), 3, or 4 were selected for implementation, site-specific environmental documentation would be prepared prior to site selection.

**Land Use.** Implementation of the nuclear infrastructure alternatives at existing operational candidate sites at Hanford, INEEL, and ORR would be consistent with ongoing activities and current land use at these sites. Irradiation of neptunium targets at an existing CLWR would also be consistent with the land use at the reactor site. If Alternative 3 or 4 were selected for implementation, a site-specific evaluation of land use would be conducted prior to site selection. Deactivation of the FFTF under Alternatives 2 through 5 would have no effect on ongoing land use in the 400 Area of Hanford.

**Visual Resources.** Existing sites that are candidates for implementation of the nuclear infrastructure alternatives are rated Class IV under the U.S. Bureau of Land Management classification guidelines for visual resources (DOI 1986). Selection of one or more of the existing candidate sites for implementation would not affect their visual resource classification as areas in which industrial development dominates the landscape. Use of a CLWR for irradiation of neptunium targets would not alter the appearance of the reactor or the surrounding landscape. Implementation of Alternative 3 (Construct New Accelerator[s]) or 4 (Construct New Research Reactor) could result in reclassification under U.S. Bureau of Land Management guidelines. If Alternative 3 or 4 were selected for implementation, a site-specific evaluation of visual resources would be conducted prior to site selection. Deactivation of FFTF under Alternatives 2 through 5 would not significantly alter the overall landscape in the 400 Area of Hanford.

**Noise.** Noise associated with target fabrication and processing and irradiation at existing candidate sites would be similar to currently existing onsite noise and would not be audible beyond site boundaries. These activities would not produce sudden, loud noises that would startle wildlife. Noise levels that would be generated at a CLWR under Alternative 2 (options 4, 5, and 6) would be the same as those currently existing at the reactor site. Implementation of Alternative 3 (Construct New Accelerator[s]) or 4 (Construct New Research Reactor) would result in construction activities that could disturb nearby residents or wildlife. If Alternative 3 or 4 were selected for implementation, a site-specific NEPA review would be prepared, and an evaluation of potential noise impacts would be conducted prior to site selection. Deactivation of FFTF under Alternative 5 would not significantly alter the noise levels in the 400 Area of Hanford.

**Water Quality.** Under Alternative 1 (Restart FFTF), there would be no liquid radiological effluent pathways to the environment from FFTF. Process wastewater from cooling tower blow-down would be ultimately discharged to the 400 Area Pond (i.e., the 4608 B/C percolation ponds). No impact on the quality of ground or surface water would be expected. Irradiation of neptunium targets at existing reactors and a generic CLWR would have no measurable effect on the quantity or quality of discharged effluents. Use of existing facilities for target fabrication and processing would not result in direct effluent discharge to the environment, and additional wastewater generation would be relatively small in comparison to existing wastewater treatment volumes at the sites. If Alternative 3 (Construct New Accelerator[s]) or 4 (Construct New Research Reactor) were selected for implementation, construction and operation of new facilities would not be anticipated to significantly impact water quality. While the water quality impacts are expected to be small, a site-specific environmental evaluation of potential water quality impacts and mitigation measures would be conducted prior to site selection. Sodium removal during deactivation of FFTF under Alternatives 2 through 5 would result

in approximately 7,600 liters (2,000 gallons) of wastewater that would be disposed of in existing wastewater treatment facilities at Hanford. Deactivation of FFTF would not be expected to impact water quality.

**Geology and Soils.** Except for Alternatives 3 (Construct New Accelerator[s]) and 4 (Construct New Research Reactor), activities conducted under the nuclear infrastructure alternatives would not require construction of new facilities. No soil would be disturbed, and there would be no impacts on the geology of potentially affected sites. Construction of new accelerators and support facilities under Alternative 3 would be expected to disturb up to approximately 27 hectares (66 acres) of soil. If Alternative 4 were selected for implementation, construction of the new reactor and support facility would be expected to disturb approximately 4 hectares (10 acres) of soil. If Alternative 3 or 4 were selected for implementation, a site-specific environmental evaluation would be conducted prior to site selection. Deactivation of FFTF under Alternatives 2 through 5 would take place on previously disturbed land. Impacts of deactivation on geology and soils would be negligible.

**Ecology.** Activities that would be conducted under the nuclear infrastructure alternatives at candidate existing facilities and the generic CLWR would not involve construction of new facilities or significant changes in traffic, noise, air quality, or water quality. In addition, irradiation and processing activities would take place in established industrial areas. Impacts on terrestrial resources and wetlands would be negligible. Consultations concerning threatened and endangered species were conducted with appropriate Federal and state agencies. No major issues were raised as a result of these consultations. (Chapter 4 of the NI PEIS provides detailed discussions of the results of these consultations.)

Under Alternatives 3 (Construct New Accelerator[s]) and 4 (Construct New Research Reactor), construction of new facilities at a yet-to-be-determined site could potentially have a significant effect on wildlife and wetlands. If Alternative 3 or 4 were selected for implementation, site-specific ecological evaluations would be conducted prior to site selection. The evaluation would include consultation with the U.S. Fish and Wildlife Service and appropriate state authorities concerning threatened and endangered species. Deactivation of FFTF under Alternatives 2 through 5 would take place on previously disturbed land in the 400 Area. No threatened or endangered species are known to reside in the 400 Area, and noise impacts on local wildlife would be temporary.

**Cultural Resources.** Existing candidate facilities that would host activities under the nuclear infrastructure alternatives are located within areas that contain National Historic Landmarks or structures that are eligible for nomination to the National Register of Historic Places. Several candidate facilities are eligible for nomination to the National Register, including the Reactor Containment Building and the Control Building for FFTF at Hanford, RPL at Hanford, and ATR at INEEL. Selection of these facilities to support the nuclear infrastructure missions would not alter their eligibility.

Under the nuclear infrastructure alternatives, activities at candidate existing sites and the generic CLWR would be conducted within existing facilities. Use of the FMEF at Hanford for target fabrication and processing would require construction of a 76-meter-high (250-foot-high) stack on previously disturbed land. Similarly, construction of a support facility for deactivation of the FFTF would take place on previously disturbed land in the 400 Area. Thus, except for Alternatives 3 (Construct New Accelerator[s]) and 4 (Construct New Research Reactor), no disturbance of archeological resources would be expected under the nuclear infrastructure alternatives. Consultations with the State Historic Preservation Offices and potentially affected Native American tribes have been conducted for the candidate existing sites. No major issues were raised as a result of these consultations. (Chapter 4 of the NI PEIS provides detailed discussion of the results of these consultation.)

Implementation of Alternative 3 or 4 would require construction on potentially undisturbed lands. If Alternative 3 or 4 were selected for implementation, a site-specific NEPA review would be prepared, and an environmental evaluation of cultural resources would be conducted prior to site selection. The evaluation would include consultation with State Historic Preservation Offices and potentially affected Native American tribes.

**Environmental Justice.** The objective of the environmental justice analysis was to determine whether or not implementation of the nuclear infrastructure alternatives would result in significant environmental impacts that disproportionately affect low-income or minority populations. Normal operations at the candidate sites and incident-free transportation pose no significant radiological risks to the public or to maximally exposed offsite individuals among the public.

Portions of the Fort Hall Indian Reservation and the Yakama Indian Reservation lie within potentially affected areas surrounding INEEL and Hanford, respectively. As discussed in Appendixes H and I of the NI PEIS, calculations of radiological risks considered human exposures due to inhalation and ingestion of radioactive materials. Ingestion of contaminated fish, vegetation, and/or wildlife is an environmental justice consideration due to potential patterns of subsistence consumption for minority or low-income populations. Radiological health models used in the environmental evaluation assumed accidents at the irradiation facilities or the fabrication and processing facilities would contaminate all of the food produced in the area, and that all of the contaminated food would be consumed by persons residing in the potentially affected area. The expected risk that would result from ingestion of radiologically contaminated food for persons residing near Hanford would be approximately 0.004 latent cancer fatality and essentially zero for persons residing near the INEEL or ORR. Thus, no credible pattern of food consumption would be expected to result in a significant health risk to low-income or minority populations residing within potentially affected areas surrounding the existing candidate sites. Implementation of the alternatives would not be expected to result in significant environmental impacts in any of the environmental resource areas. Thus, no disproportionately high and adverse impacts on minority and low-income populations would be expected to result from implementation of the alternatives.

Accidents at candidate fabrication and processing facilities and during transportation of radioisotopes by aircraft were found to pose the largest risks to the public. Under conservative assumptions described in Appendix I of the NI PEIS, no latent cancer fatalities due to accidents would be expected at the existing sites. Accidents during air transport of radioisotopes could occur anywhere along the flight path and would not place any identifiable group within the general population at disproportionate risk.

The density and distribution of total, low-income, and minority populations varies from site to site, so that evaluations of environmental justice are necessarily site-specific. If Alternatives 3 (Construct New Accelerator[s]) or 4 (Construct New Research Reactor) were selected for implementation, a site-specific NEPA review would be prepared, and an evaluation of environmental justice would be conducted prior to site selection. The evaluation would include patterns of food consumption that could result in disproportionately high and adverse effects on low-income or minority populations at risk.

### **Industrial Safety**

Estimates of potential industrial impacts to workers during construction, irradiation, fabrication and processing were evaluated based on DOE and Bureau of Labor Statistics data. Impacts are classified into two groups: total recordable cases and fatalities. A recordable case includes work-related death, illness, or injury which resulted in loss of consciousness, restriction of work or motion, transfer to another job, or required medical treatment beyond first aid. The industrial safety evaluation is discussed in more detail in Section I.3 of the NI PEIS.

The average occupational total recordable cases and fatality rates for construction and operation activities are presented in **Table S–8**.

**Table S–8 Average Occupational Total Recordable Cases and Fatality Rates (per worker-year)**

Labor Category	Total Recordable Cases	Fatalities
Construction	0.053	$1.3 \times 10^{-4}$
Operation	0.033	$1.3 \times 10^{-5}$

The expected impacts (both annual and for the duration of the activity) to workers at each facility for construction and operation are presented in **Table S–9**.

**Table S–9 Industrial Safety Impacts from Construction and Operation**

Facility	Estimated Number of Workers	Construction or Operation Duration (years)	Expected Annual Total Recordable Cases	Expected Activity Duration Total Recordable Cases	Annual Fatalities	Activity Duration Fatalities
<b>Construction</b>						
Low-energy accelerator	75	3	4.0	12	0.010	0.030
High-energy accelerator	410	5	22	110	0.057	0.285
New research reactor	160	7	8.5	59.5	0.022	0.154
<b>Operation</b>						
ATR <sup>a</sup>	0	35	–	–	–	–
HFIR <sup>a</sup>	0	35	–	–	–	–
CLWR <sup>a</sup>	0	35	–	–	–	–
FFTF	242	35	8.0	280	0.0031	0.109
Low-energy accelerator	13	35	0.4	14	$1.7 \times 10^{-4}$	0.00595
High-energy accelerator	225	35	7.4	259	0.0029	0.102
New research reactor	120	35	4.0	140	0.0016	0.056
REDC	116	35	3.8	133	0.0015	0.0525
FDPF	75	35	2.5	87.5	$9.8 \times 10^{-4}$	0.0343
FMEF	105	35	3.5	123	0.0014	0.049
RPL/306–E	30	35	1.0	35	$3.9 \times 10^{-4}$	0.0137
New support facility	100	35	3.3	116	0.0013	0.0455

a. No additional workers would be required for the proposed activities evaluated in the NI PEIS.

No fatalities would be expected from either construction or operation of any facility.

### Comparison of Mission Effectiveness Among Alternatives

This section compares the effectiveness of Alternatives 1, 2, 3, and 4 in supporting the three missions evaluated in the NI PEIS:

- Medical and industrial isotope production
- Plutonium-238 production to support NASA space missions
- Nuclear energy research and development for civilian applications

**Table S–10** lists the medical isotopes that were included in the Expert Panel’s forecast of future demands (Wagner et al. 1998), and identifies their means of production using accelerators, reactors, or separation from

existing stockpiles of radioisotopes. Consistent with the panel's report, the list of isotopes is presented in three categories: proven medical isotopes currently used in clinical applications, those under development for clinical applications, and radioisotopes that have shown promise during medical research. Some are most suited for production in an accelerator, some in a nuclear reactor, and some are harvested by chemical separation from existing stockpiles of long-lived radioactive isotopes. Those isotopes that can be harvested from existing stockpiles of radioactive isotopes require only hot cells for the extraction process; neither accelerators or nuclear reactors are necessary for their production.

**Table S-10 Medical Isotopes and Their Means of Production**

Isotope <sup>a</sup>	Accelerator-Produced	Reactor-Produced	Separation from Existing Stockpiles of Radioactive Isotopes
<b>Proven Isotopes Currently Used in Clinical Applications That Face Supply and Cost Concerns</b>			
Yttrium-90	(b)	●	
Molybdenum-99 <sup>c</sup>	(b)	●	
Indium-111	●		
Iodine-123	●		
Rhenium-186	(b)	●	
<b>Developmental Isotopes for Clinical Applications That Face Availability and Cost Concerns</b>			
Fluorine-18	●		
Phosphorus-32	(b)	●	
Krypton-81m	●		
Strontium-89	(b)	●	
Palladium-103	(b)	●	
Tin-117m	(b)	●	
Xenon-127	(b)	●	
Iodine-125	(b)	●	
Iodine-131	(b)	●	
Samarium-153	(b)	●	
<b>Promising Research Isotopes That Are Not Being Explored Due to Lack of Availability or Cost</b>			
Scandium-47	(b)	●	
Zinc-62	●		
Copper-64	●	●	
Copper-67	●	●	
Germanium-68	●		
Gadolinium-153	(b)	●	
Holmium-166	●	●	
Lutetium-177	(b)	●	
Rhenium-188	(b)	●	
Astatine-211	α		
Bismuth-212		●	● <sup>d</sup>
Bismuth-213	(b)	●	● <sup>e</sup>
Radium-223	(b)	●	● <sup>f</sup>

a. Wagner et al. 1998.

b. These isotopes are produced by neutron capture and could be produced in a high-energy accelerator. However, this capability has not been included in the design, analysis, or cost estimates of Alternative 3.

c. Sufficient supplies of this isotope are available from Canadian suppliers.

d. Bismuth-212 is a progeny of thorium-232.

e. Bismuth-213 is a progeny of uranium-233.

f. Radium-223 is a progeny of protactinium-231.

**Key:** α, efficient means of production with an alpha particle accelerator; ●, efficient means of production.

No single production method would satisfy all of the Expert Panel’s projected requirements for medical isotopes. Isotopes produced by neutron capture are typically provided by a reactor, but could be produced by a high-energy accelerator with a spallation neutron source. Accelerator production of these isotopes would be relatively inefficient, and might not be practical to provide the large quantities needed to meet clinical demands. The proposed high-energy accelerator described in the NI PEIS could be modified to provide such capability, but this would add to the design, construction, and operating complexity, would require an increase in particle energy greater than 1 gigaelectron volts, and would increase the capital and operating costs.

Bismuth and radium isotopes, which were identified as promising medical isotopes by the Expert Panel, are currently harvested from existing stockpiles of long-lived radioisotopes and can also be readily produced in a reactor.

**Alternative 1—Restart FFTF.** FFTF would produce high-energy neutrons and a large flux level ( $10^{15}$  neutrons per square centimeter per second) that can be tailored to nearly any desired energy level. FFTF would provide the greatest flexibility for both isotope production and nuclear-based research and development among the baseline configurations for all of the proposed alternatives. Due to its large core size, flux spectrum, demonstrated testing capability, and rated power level, it would be able to concurrently support the projected plutonium-238 needs, production of medical and industrial isotopes, and civilian nuclear energy research and development related to a broad range of materials, advanced reactors, advanced fuels, and waste transmutation.

**Alternative 2—Use Only Existing Operational Facilities.** Due to current mission commitments at the existing DOE facilities, a large portion of the reactor irradiation space is committed to existing users. The existing reactors are able to provide for the current plutonium-238 needs. However, fulfilling this requirement with these facilities would use most, if not all, excess capacity, and may require some non-Federal missions to be terminated. The ability to expand medical and industrial isotope production would require some current missions to be postponed or terminated. If the CLWR were used for plutonium-238 production, then the existing facilities would gain additional margin for medical and industrial isotope production and limited civilian nuclear energy research and development activities. These facilities have primary missions with sponsors who reserve the right to dictate to what degree and the times the facility could be used.

**Alternative 3—Construct New Accelerator(s).** Two accelerators, a low-energy accelerator and a high-energy accelerator, are proposed for Alternative 3. The low-energy accelerator would serve as a dedicated isotope production facility. Due to the nature of this type of accelerator, it could only produce a limited number of the representative isotopes discussed in Section S.1, it has no ability to satisfy the plutonium-238 needs, and a limited ability to support the proposed nuclear-based research and development needs. The preconceptual design of the high-energy accelerator focused on supporting the plutonium-238 production mission. The design of the high-energy accelerator could be refined and expanded to perform additional missions such as the production of a select set of medical and industrial radioisotopes. In addition, DOE is aware of longer-term concepts that would apply high-energy accelerators to produce “tuneable” neutrons in a subcritical assembly. Such a facility could be used to address some of the missions more familiar to reactor facilities and may hold considerable promise for future science and technology research. A facility of this nature could provide unique capabilities in areas such as the testing of many different nuclear system coolant, fuel, and material interactions. The changes required to add additional capability to the high-energy accelerator could be provided, but they would increase the size of the facility, add complexity to the facility design and operation, increase the cost of construction and operation, and potentially require more time for design and construction.

**Alternative 4—Construct New Research Reactor.** The proposed new research reactor would provide ample neutrons for the production of plutonium-238 and for many of the representative isotopes. The thermal flux would limit the new research reactor's ability to produce a number of isotopes requiring fast or high-energy neutrons. Its lower flux levels ( $10^{13}$  neutrons per square centimeter per second) and predominantly thermal flux would limit its ability to support many of the projected nuclear-based research and development needs.

## S.7 CUMULATIVE IMPACTS

The projected environmental impacts of (1) constructing (as necessary) and operating the proposed facilities to store, fabricate, irradiate, and process the various targets addressed in the NI PEIS for 35 years and (2) deactivating FFTF were added to the environmental impacts of other present and reasonably foreseeable future actions at or near the identified sites to obtain cumulative site impacts under normal conditions. The other present and reasonably foreseeable future actions at or near the candidate sites are included in the baseline impacts presented in Chapter 3 of the NI PEIS. Cumulative transportation impacts were determined by analyzing the impacts along the various routes used to transport the materials associated with nuclear infrastructure activities over the 35-year period.

In this section, cumulative site impacts are presented only for those “resources” at a site that may reasonably be expected to be affected by the storage, fabrication, irradiation, and processing of the various targets. These include site employment, electrical consumption, water usage, air quality, waste management, and public and occupational health and safety. This section also includes the cumulative impacts associated with intersite transportation.

Impacts of the following are considered in the cumulative site impact assessment:

- Current (baseline) activities at or in the vicinity of the candidate sites
- Other onsite and offsite activities that are reasonably foreseeable and documented
- Construction (as necessary), operation, and deactivation (as necessary) of the proposed nuclear infrastructure facilities to fabricate, irradiate, and process targets

Details of activities that may be implemented in the foreseeable future at any of the nuclear infrastructure candidate sites and evaluated in the cumulative impact assessment are given in the following documents:

- *Surplus Plutonium Disposition Final Environmental Impact Statement* (DOE 1999a) (Record of Decision issued)
- *Storage and Disposition of Weapons-Usable Fissile Materials Final Programmatic Environmental Impact Statement* (DOE 1996a) (Record of Decision issued)
- *Disposition of Surplus Highly Enriched Uranium Final Environmental Impact Statement* (DOE 1996b) (Record of Decision issued)
- *Final Programmatic Environmental Impact Statement for Tritium Supply and Recycling* (DOE 1995b) (Record of Decision issued)
- *Final Waste Management Programmatic Environmental Impact Statement for Managing Treatment, Storage, and Disposal of Radioactive and Hazardous Waste* (DOE 1997a) (Records of Decision issued for the various waste types)

- *Department of Energy Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs Final Environmental Impact Statement* (DOE 1995c) (Record of Decision issued)
- *Final Environmental Impact Statement on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel* (DOE 1996c) (Record of Decision issued)
- *Final Programmatic Environmental Impact Statement for Stockpile Stewardship and Management* (DOE 1996d) (Record of Decision issued)
- *Advanced Mixed Waste Treatment Project Final Environmental Impact Statement* (DOE 1999b) (Record of Decision issued)
- *Final Environmental Impact Statement for Management of Spent Nuclear Fuel from the K-Basins at the Hanford Site, Richland, Washington,* (DOE 1996e) (Record of Decision issued)
- *Final Environmental Impact Statement for the Tank Waste Remediation System, Hanford Site, Richland, Washington* (DOE 1996f) (Record of Decision issued)
- *Hanford Reach of the Columbia River Comprehensive River Conservation Study and Environmental Impact Statement, Final* (NPS 1994) (Record of Decision issued)
- *Final Hanford Comprehensive Land-Use Plan Environmental Impact Statement* (DOE 1999c) (Record of Decision issued)
- *Final Environmental Impact Statement for the Treatment and Management of Sodium-Bonded Spent Nuclear Fuel* (DOE 2000b) (Record of Decision issued)
- *Final Environmental Impact Statement, Construction and Operation of the Spallation Neutron Source* (DOE 1999d) (Record of Decision issued)
- *Final Programmatic Environmental Impact Statement for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride* (DOE 1999e) (Record of Decision issued)
- *Idaho High-Level Waste and Facilities Disposition Draft Environmental Impact Statement* (DOE 1999f)
- *Final Environmental Impact Statement for Treating Transuranic (TRU)/Alpha Low-Level Waste at the Oak Ridge National Laboratory, Oak Ridge, Tennessee* (DOE 2000c) (Record of Decision issued)
- *Environmental Assessment Melton Valley Storage Tanks Capacity Increase Project - Oak Ridge National Laboratory, Oak Ridge, Tennessee* (DOE 1995d) (FONSI issued)
- *Environmental Assessment for Management of Spent Nuclear Fuel on the Oak Ridge Reservation, Oak Ridge, Tennessee* (DOE 1996g) (FONSI issued)
- *Environmental Assessment - Management of Hanford Site Non-Defense Production Reactor Spent Nuclear Fuel, Hanford Site, Richland, Washington* (DOE 1997b) (FONSI issued)

- *Environmental Assessment for Transportation of Low-Level Radioactive Waste from the Oak Ridge Reservation to Off-Site Treatment or Disposal Facilities* (DOE 2000d)
- *Environmental Assessment for Transportation of Low-Level Radioactive Mixed Waste from the Oak Ridge Reservation to Off-Site Treatment or Disposal Facilities* (DOE 2000e) (Draft issued)
- *Environmental Assessment for Selection and Operation of the Proposed Field Research Centers for the Natural and Accelerated Bioremediation Research (NABIR) Program* (DOE 2000f) (FONSI issued)

The related programs included in the cumulative impact assessment for the potentially affected candidate sites are identified in **Table S–11**.

**Table S–11 Other Present and Reasonably Foreseeable Actions Considered in the Cumulative Impact Assessment**

Activities	ORR	INEEL	Hanford
Disposition of Surplus Plutonium	X

**Source:** Table 4–162 of the NI PEIS.

In the tables that are included in the following sections, all relevant activities at each site are identified to the extent possible. They include existing and reasonably foreseeable activities, and those associated with nuclear infrastructure operations. The impacts associated with the latter are specifically shown as “New Nuclear Infrastructure Operations.” They include the impacts from construction (as necessary), operation, and deactivation (as necessary) of the proposed target fabrication, irradiation, and processing facilities assessed in the NI PEIS.

A bounding option was analyzed for each site. The bounding option is the option that would involve the greatest amounts of operational activities and associated environmental impacts at the candidate site. For example, the bounding option for ORR is Option 7 of Alternative 2, under which both HFIR and REDC operations would be involved in plutonium-238 production.

In addition to reasonably foreseeable site activities, other activities within the regions of the candidate sites were considered in the cumulative impact analysis for the selected resources. However, because of the distances between the candidate sites and these other existing and planned facilities, there is little opportunity for interactions among them.

### Cumulative Impacts at ORR

For ORR, the bounding option for the NI PEIS is Option 7 of Alternative 2. This option calls for the operation of HFIR to irradiate neptunium-237 targets and operation of REDC to fabricate and process these targets and other neptunium-237 targets irradiated in ATR. The impacts associated with HFIR and REDC operations for other missions are included under “existing site activities.”

**Resource Requirements.** Cumulative impacts on resource requirements at ORR are presented in **Table S–12**. ORR would remain within its site capacity for all major resources. If Option 7 of Alternative 2 were implemented, the proposed nuclear infrastructure facilities would require essentially no change in the site’s use of electricity or water. Cumulatively, ORR would use approximately 10 percent of its electrical capacity and 37 percent of its water capacity. Site employment would increase by approximately 41 workers.

**Table S–12 Maximum Cumulative Resource Use and Impacts at ORR**

Activities	Site Employment	Electrical Consumption (megawatt-hours per year)	Water Usage (million liters per year)
<b>Existing site activities<sup>a</sup></b>	14,215	726,000	14,210
Storage and Disposition PEIS	Included above	7,260	0.24
Waste Management PEIS	1,259	84,160	394
Spallation Neutron Source	744	543,120	1,592
Treatment and Shipment of Transuranic Waste	17	3,000	3.8
<b>New nuclear infrastructure operations<sup>b</sup></b>	41 <sup>c</sup>	Negligible <sup>d</sup>	2.86
<b>Total</b>	16,276	~1,363,540	16,203
<b>Total site capacity</b>	NA	13,880,000	44,348

a. Reflects current sitewide activities that are anticipated to continue during all or part of the 35-year period evaluated for proposed nuclear infrastructure operations.

b. Nuclear infrastructure activities from Alternative 2, Option 7.

c. Some, or all, of these worker requirements may be filled by the reassignment of the existing site workforce.

d. Additional electricity consumption associated with this option would be negligible compared to that associated with existing facility activities.

**Note:** To convert from liters per year to gallons per year, multiply by 0.264; to convert from megawatt-hours to British thermal units, multiply by  $3.42 \times 10^6$ ; ~ means “approximately” and indicates that new nuclear infrastructure operations would contribute only minimally.

**Key:** NA, not applicable.

**Source:** Table 4–163 of the NI PEIS.

**Air Quality.** Cumulative impacts on air quality at ORR are presented in **Table S–13**. ORR is currently in compliance with all Federal and state ambient air quality standards, and would continue to be in compliance even if the cumulative effects of all activities are included. As shown in the table, the contributions of nuclear infrastructure operations to overall site concentrations would be very small.

**Table S–13 Maximum Cumulative Air Pollutant Concentrations at ORR for Comparison with Ambient Air Quality Standards**

Parameter	Carbon Monoxide		Nitrogen Dioxide	PM <sub>10</sub>		Sulfur Dioxide		
	8 hours	1 hour	Annual	Annual	24 hours	Annual	24 hours	3 hours
<b>Activities</b>								
Existing site activities <sup>a</sup> (micrograms per cubic meter)	7.75	26.5	0.98	1.6	12.6	4.76	33.4	106.4
HEU disposition <sup>b</sup> (micrograms per cubic meter)	11.5	53	1.33	0.03	0.37	2.46	29.3	161
Waste management program (micrograms per cubic meter)	0	0	0	3	9	2.4	11	39
Spallation Neutron Source (micrograms per cubic meter)	69	99	16	1.9	23	0.1	1	2.4
New nuclear infrastructure operations <sup>c</sup> (micrograms per cubic meter)	0	0	1.99×10 <sup>-4</sup>	0	0	0.04	0.31	0.7
Total concentration (micrograms per cubic meter)	88.3	179	18.3	6.53	45	9.76	75	310
<b>Standard</b>								
Most stringent standard <sup>d</sup> (micrograms per cubic meter)	10,000	40,000	100	50	150	80	365	1,300

- a. Environmental impacts associated with existing site activities (based on 1998 emissions from the *Oak Ridge Reservation Annual Site Environmental Report 1998*) that are anticipated to continue during part or all of the 35-year period evaluated for nuclear infrastructure operations. The values in this row reflect a curtailment of stockpile stewardship management activities during this time period.
- b. Highly enriched uranium disposition activities.
- c. Nuclear infrastructure activities from Alternative 2, Option 7.
- d. The more stringent of the Federal and state standards is presented if both exist for the averaging period.

**Source:** Table 4–164 of the NI PEIS.

**Public and Occupational Health and Safety—Normal Operations.** Cumulative impacts in terms of radiation exposure to the public and workers at ORR are presented in **Table S–14**. There would be no increase expected in the number of latent cancer fatalities in the population from ORR site operations if nuclear infrastructure operations were to occur at HFIR and REDC. The dose limits for individual members of the public are given in DOE Order 5400.5. As discussed in that Order, the dose limit from airborne emissions is 10 millirem per year, as required by the Clean Air Act; the dose limit from drinking water is 4 millirem per year, as required by the Safe Drinking Water Act; and the dose limit from all pathways combined is 100 millirem per year. Therefore, as is evident in Table S–14, the dose to the maximally exposed individual would be expected to remain well within the regulatory limits. Onsite workers would be expected to see an increase of approximately 0.17 latent cancer fatality due to radiation from nuclear infrastructure operations over the 35-year operational period.

**Table S-14 Maximum Cumulative Radiation Impacts at ORR**

Impact	Maximally Exposed Individual		Population Dose Within 80 Kilometers (50 Miles) (Year 2020)		Total Site Workforce	
	Annual Dose (millirem per year)	Risk of a Latent Cancer Fatality <sup>a</sup>	Dose (person-rem)	Number of Latent Cancer Fatalities <sup>a</sup>	Dose (person-rem per year)	Number of Latent Cancer Fatalities <sup>a</sup>
Existing site activities <sup>b</sup>	4.4	$7.7 \times 10^{-5}$	60.3	1.1	103	1.4
HEU disposition	0.039	$6.8 \times 10^{-7}$	0.16	0.0028	11	0.16
Stockpile stewardship and management	0.2	$3.5 \times 10^{-6}$	0.6	0.011	-1.8	-0.025
Waste management	0.35	$6.1 \times 10^{-6}$	1.2	0.021	0.45	0.0063
New nuclear infrastructure operations at ORR <sup>c</sup>	$1.9 \times 10^{-6}$	$3.3 \times 10^{-11}$	$8.8 \times 10^{-5}$	$1.5 \times 10^{-6}$	12	0.168
Total	5.0 <sup>d</sup>	$8.7 \times 10^{-5(d)}$	62	1.1	125	1.7

- These values are calculated based on a 35-year exposure period.
- Environmental impacts associated with present activities at ORR that are anticipated to continue during all or part of the 35-year period evaluated for proposed nuclear infrastructure operations.
- Impacts are bounded by Option 7 of Alternative 2.
- The same individual would not be expected to be the maximally exposed individual for all activities at ORR. The location of the maximally exposed individual depends upon where on the site an activity is performed. However, to provide an upper bound of the cumulative impacts to the maximally exposed individual, the impacts from each activity have been summed.

Source: Table 4-165 of the NI PEIS.

**Waste Management.** Cumulative amounts of wastes generated at ORR are presented in **Table S-15**. It is unlikely that there would be major impacts on waste management at ORR because sufficient capacity would exist to manage the site wastes. As discussed in Section 4.3.1.1.13 of the NI PEIS, irrespective of how the waste from processing irradiated neptunium-237 targets is classified (i.e., transuranic or high-level radioactive), the waste composition and characteristics are the same, and the management (i.e., treatment and onsite storage), as described in the NI PEIS, would be the same. In addition, either waste type would require disposal in a suitable repository. None of the options assessed in the NI PEIS would generate more than a small amount of additional waste at ORR.

### Cumulative Impacts at INEEL

For INEEL, the bounding option for the NI PEIS is Option 2 of Alternative 2. This option calls for the operation of ATR to irradiate neptunium-237 targets and operation of FDPF to fabricate and process these targets. The impacts associated with ATR and FDPF operations for other missions are included under “existing site activities.”

**Resource Requirements.** Cumulative impacts on resource requirements at INEEL are presented in **Table S-16**. INEEL would remain within its site capacity for all major resources. If Option 2 of Alternative 2 were implemented, the proposed nuclear infrastructure facilities would require essentially no change in the site’s use of electricity or water. Cumulatively, INEEL would use 80 percent of its electrical capacity and 13 percent of its water capacity. Site employment would increase by approximately 24 workers.

**Table S–15 Cumulative Impacts on Waste Management Activities at ORR Over the 35-Year Period (cubic meters)**

Waste Type	Existing Site Activities	Treatment and Shipment of Transuranic Waste <sup>a</sup>	Surplus Plutonium Disposition <sup>b</sup>	Spallation Neutron Source <sup>c</sup>	New Nuclear Infrastructure Operations <sup>d</sup>	Total	Site Capacity <sup>e</sup>		
							Treatment (cubic meters/year)	Storage	Disposal
Transuranic (High-level radioactive) <sup>f</sup>	766 (0)	607 (0)	11 (0)	0 (0)	385 (385)	1,769 (385)	4,050/ 5 years (0)	2,845 (0)	NA (NA)

a. Data from the *Final Environmental Impact Statement for Treating Transuranic (TRU)/Alpha Low-Level Waste at the Oak Ridge National Laboratory Low-Temperature Drying* Alternative was selected in the Record of Decision (65 FR 48683).

b. Data from the *Surplus Plutonium Disposition Final EIS* (DOE 1999a:4-394) postirradiation examination (2006 through 2009) and selected in Record of Decision (65 FR 1608).

c. Data from the *Spallation Neutron Source Final EIS*.

d. Option 7 of Alternative 2. This alternative would generate the most waste for all waste types.

e. Total 35-year and annual capacity derived from Table 3–13 of the NI PEIS.

f. Volumes in parentheses represent high-level radioactive waste. Section 4.3.1.1.13 of the NI PEIS provides a discussion on classification of waste from processing irradiated neptunium-237 targets.

g. Assumes for hazardous waste that 353 kilograms equal 1 cubic meter (22.0 pounds equal 1 cubic foot).

**Note:** To convert from cubic meters to cubic yards, multiply by 1.308; < means “less than”; ~ means “approximately;” NA, not applicable (i.e., the majority of the waste is not routinely treated, stored, or disposed of on site).

**Source:** Table 4–166 of the NI PEIS.

**Table S–16 Maximum Cumulative Resource Use and Impacts at INEEL**

Activities	Site Employment	Electrical Consumption (megawatt-hours per year)	Water Usage (million liters per year)
<b>Existing site activities<sup>a</sup></b>	7,993	232,500	4,830
SNF Management and INEL Environmental Restoration and Waste Management	–	2,200	2
Foreign Research Reactor SNF Management	–	1,000	2
Waste Management PEIS	–	13,980	194
Advanced Mixed Waste Treatment Project	–	33,000	16
High-Level Waste and Facilities Disposition	–	33,000	351
<b>New nuclear infrastructure operations<sup>b</sup></b>	24 <sup>c</sup>	Negligible <sup>d</sup>	1.68
<b>Total</b>	8,017	~315,680	5,397
<b>Total site capacity</b>	NA	394,200	43,000

a. Reflects current sitewide activities (except that “Site Employment” value also reflects projected employment from other activities) that are anticipated to continue during all or part of the 35-year period evaluated for proposed nuclear infrastructure operations.

b. Nuclear infrastructure activities from Alternative 2, Option 2.

c. Some, or all, of those worker requirements may be filled by the reassignment of the existing workforce.

d. Additional electricity consumption associated with this option would be negligible compared to that associated with existing facility activities.

**Note:** To convert from liters per year to gallons per year, multiply by 0.264; to convert from megawatt-hours to British thermal units, multiply by  $3.42 \times 10^6$ ; ~ means “approximately;” and indicates that new nuclear infrastructure operations would contribute only minimally.

**Key:** NA, not applicable; SNF, spent nuclear fuel.

**Source:** Table 4–167 of the NI PEIS.

**Air Quality.** Cumulative impacts on air quality at INEEL are presented in **Table S–17**. INEEL is currently in compliance with all Federal and state ambient air quality standards, and would continue to remain in compliance, even with consideration of the cumulative effects of all activities. The contributions of nuclear infrastructure operations to overall site concentrations are expected to be very small.

**Table S–17 Maximum Cumulative Air Pollutant Concentrations at INEEL for Comparison with Ambient Air Quality Standards**

Parameter	Carbon Monoxide		Nitrogen Dioxide	PM <sub>10</sub>		Sulfur Dioxide		
	8 hours	1 hour	Annual	Annual	24 hours	Annual	24 hours	3 hours
<b>Averaging Period</b>	8 hours	1 hour	Annual	Annual	24 hours	Annual	24 hours	3 hours
<b>Activities</b>								
Existing site activities <sup>a</sup> (micrograms per cubic meter)	78	206	0.46	0.49	12	0.14	5.3	24
ANL–W contribution <sup>b</sup> (micrograms per cubic meter)	41	59	13	0.14	1.1	3.3	27	60
Advanced Mixed Waste Treatment Project <sup>c</sup> (micrograms per cubic meter)	0.85	115	0.34	0.006	4.6	0.012	4.5	25
HLW & facilities disposition <sup>d</sup> (micrograms per cubic meter)	4.2	10	0.19	0.02	0.28	0.57	8.9	42
New nuclear infrastructure operations <sup>e</sup> (micrograms per cubic meter)	0	0	3.66×10 <sup>-4</sup>	0	0	0.024	0.19	0.43
Total concentration (micrograms per cubic meter)	124	390	14	0.656	18	4.05	45.9	151
<b>Standard</b>								
Most stringent standard <sup>f</sup> (micrograms per cubic meter)	10,000	40,000	100	50	150	80	365	1,300

- Environmental impacts associated with existing site activities (excluding activities at ANL–W) as shown in the *Idaho High-Level Waste and Facilities Disposition Draft EIS*, and in the *Final EIS for the Treatment and Management of Sodium-Bonded Spent Nuclear Fuel*. The activities whose concentrations are given in this row are anticipated to continue during part or all of the 35-year period evaluated for proposed nuclear infrastructure operations.
- The contribution from existing ANL–W sources as shown in the *Final EIS for the Treatment and Management of Sodium-Bonded Spent Nuclear Fuel*.
- Advanced Mixed Waste Treatment Project EIS* activities—proposed action with microencapsulation or vitrification.
- High-level waste and facilities disposition site boundary contribution for planning basis option.
- Nuclear infrastructure activities from Alternative 2, Option 2.
- The more stringent of the Federal and state standards is presented if both exist for the averaging period.

**Key:** ANL–W, Argonne National Laboratory–West; HLW, high-level radioactive waste.

**Source:** Table 4–168 of the NI PEIS.

**Public and Occupational Health and Safety—Normal Operations.** Cumulative impacts in terms of radiation exposure to the public and workers at INEEL are presented in **Table S–18**. There would be no increase expected in the number of latent cancer fatalities in the population from INEEL site operations if nuclear infrastructure operations were to occur at ATR and FDPF. The dose limits for individual members of the public are given in DOE Order 5400.5. As discussed in that Order, the dose limit from airborne emissions is 10 millirem per year, as required by the Clean Air Act; the dose limit from drinking water is 4 millirem per year, as required by the Safe Drinking Water Act; and the dose limit from all pathways combined is 100 millirem per year. Therefore, as is evident in Table S–18, the dose to the maximally exposed individual would be expected to remain well within the regulatory limits. Onsite workers would be expected to see an increase of approximately 0.17 latent cancer fatality due to radiation from nuclear infrastructure operations over the 35-year operational period.

**Table S–18 Maximum Cumulative Radiation Impacts at INEEL**

Impact	Maximally Exposed Individual		Population Dose Within 80 Kilometers (50 Miles) (Year 2020)		Total Site Workforce	
	Annual Dose (millirem per year)	Risk of a Latent Cancer Fatality <sup>a</sup>	Dose (person-rem)	Number of Latent Cancer Fatalities <sup>a</sup>	Dose (person-rem per year)	Number of Latent Cancer Fatalities <sup>a</sup>
Existing site activities <sup>b</sup>	0.008	$1.7 \times 10^{-7}$	0.075	0.0013	64.9	0.91
Storage and disposition	$1.6 \times 10^{-6}$	$2.8 \times 10^{-11}$	$1.8 \times 10^{-5}$	$3.2 \times 10^{-7}$	25	0.35
Foreign research reactor spent nuclear fuel	$5.6 \times 10^{-4}$	$9.8 \times 10^{-9}$	0.0045	$7.9 \times 10^{-5}$	33	0.46
Spent nuclear fuel	0.008	$1.4 \times 10^{-7}$	0.19	0.0033	5.4	0.076
Advanced Mixed Waste Treatment Project	0.022	$3.9 \times 10^{-7}$	0.009	$1.6 \times 10^{-4}$	4.1	0.057
High-level waste and facilities disposition	0.002	$3.5 \times 10^{-8}$	0.10	0.0018	59	0.83
Sodium-bonded spent nuclear fuel	0.002	$3.5 \times 10^{-8}$	0.012	$2.1 \times 10^{-4}$	22	0.31
New nuclear infrastructure operations at ATR and FDPF <sup>c</sup>	$2.6 \times 10^{-7}$	$4.6 \times 10^{-12}$	$3.9 \times 10^{-6}$	$6.8 \times 10^{-8}$	12	0.17
Total	0.043 <sup>d</sup>	$7.4 \times 10^{-7(d)}$	0.39	0.0068	225.4	3.16

a. These values are calculated based on a 35-year exposure period.

b. Environmental impacts associated with present activities at INEEL that are anticipated to continue during all or part of the 35-year period evaluated for proposed nuclear infrastructure operations.

c. Impacts are bounded by Option 2 of Alternative 2.

d. The same individual would not be expected to be the maximally exposed individual for all activities at INEEL. The location of the maximally exposed individual depends upon where on the site an activity is performed. However, to provide an upper bound of the cumulative impacts to the maximally exposed individual, the impacts from each activity have been summed.

**Source:** Table 4–169 of the NI PEIS.

**Waste Management.** Cumulative amounts of wastes generated at INEEL are presented in **Table S–19**. It is unlikely that there would be major impacts on waste management at INEEL because sufficient capacity would exist to manage the site wastes. As discussed in Section 4.3.2.1.13, irrespective of how the waste from processing of irradiated neptunium-237 targets is classified (i.e., transuranic or high-level radioactive), the waste composition and characteristics are the same, and the management (i.e., treatment and onsite storage), as discussed in the NI PEIS, would be the same. In addition, either waste type would require disposal in a suitable repository. None of the alternatives assessed in the NI PEIS would generate more than a small amount of additional waste at INEEL.

**Table S–19 Cumulative Impacts on Waste Management Activities at INEEL Over the 35-Year Period (cubic meters)**

Waste Type	Existing Site Activities	Idaho HLW and Facility Disposition EIS <sup>a</sup>	Treatment and Management of Sodium-Bonded SNF <sup>b</sup>	New Nuclear Infrastructure Operations <sup>c</sup>	Total	Site Capacity <sup>d</sup>		
						Treatment (cubic meters/ year)	Storage	Disposal (cubic meters/ year)
Transuranic (High-level radioactive) <sup>e</sup>	65,000 <sup>f</sup> (0)	110 (0)	14 (0)	245 (245)	65,369 (245)	57,794 (6,434)	190,319 (19,483)	NA (NA)
Low-level radioactive	135,600	15,325	862	<2,320	~154,107	42,363	177,493	69,530
Mixed low-level radioactive	3,767	12,837	40	<175	~16,819	157,092	187,761	NA
Hazardous	1,180	2,457	0	227,500 kilograms (644 cubic meters) <sup>g</sup>	4,281	NA	9,619	NA
Nonhazardous	124,905	145,262	4,960	64,015	339,142	3,200,000	NA	3,062,000

- a. Data from the *Idaho HLW and Facility Disposition EIS*, Separations Alternative. Maximum quantities for any alternative.
- b. Data from the *Treatment and Management of Sodium-Bonded Spent Nuclear Fuel EIS*, Alternative 1, electrometallurgically treat blanket and driver fuel at ANL–W; 12 years of operation and selected in the Record of Decision (65 FR 56565).
- c. Option 2 of Alternative 2 would generate the most waste for all waste types.
- d. Total 35-year and annual capacity derived from Table 3–27 of the NI PEIS.
- e. Volumes in parentheses represent high-level radioactive waste. Section 4.3.2.1.13 of the NI PEIS provides a discussion on classification of waste from processing irradiated neptunium-237 targets.
- f. This 65,000 cubic meters is in storage at the Radioactive Waste Management Complex.
- g. Assumes for hazardous waste that 353 kilograms equals 1 cubic meter (22.0 pounds equals 1 cubic foot).

**Note:** To convert from cubic meters to cubic yards, multiply by 1.308; HLW means high-level radioactive waste; SNF means spent nuclear fuel; < means “less than”; ~ means “approximately;” NA, not applicable (i.e., the majority of the waste is not routinely treated, stored, or disposed of on site).

**Source:** Table 4–170 of the NI PEIS.

### Cumulative Impacts at Hanford

For Hanford, the bounding option for the NI PEIS depends on the parameter assessed. For example, under Public and Occupational Health and Safety, the highest radiological doses and associated latent cancer fatalities to the public would be associated with Option 1 of Alternative 1, whereas the highest doses and latent cancer fatalities to workers would be associated with Option 3 of this same alternative. Processing of targets in RPL versus processing in FMEF accounts for there being different bounding options. For each of the parameters addressed in this section, a footnote is included in each of the cumulative impact tables, as necessary, to indicate the bounding alternative/option.

**Resource Requirements.** Cumulative impacts on resource requirements at Hanford are presented in **Table S–20**. Hanford would remain within its site capacity for all major resources. If any of the options under Alternative 1 were implemented, the proposed nuclear infrastructure facilities would require a small increase in the site’s use of electricity and water. For the bounding options identified in Table S–20, this would reflect an increase of about 2 and 1 percent, respectively, over current baseline utilization for these resources. There would be no additional land disturbance or development. Cumulatively, Hanford would use approximately, 23 percent of its electrical capacity and 38 percent of its water capacity. Site employment would increase by approximately 130 workers.

**Air Quality.** Cumulative impacts on air quality at Hanford are presented in **Table S–21**. Hanford is currently in compliance with all Federal and state ambient air quality standards, and would continue to be in compliance even with consideration of the cumulative effects of all activities. The nuclear infrastructure contributions to overall site concentrations are expected to be very small.

**Table S–20 Maximum Cumulative Resource Use and Impacts at Hanford**

Activities	Site Employment	Electrical Consumption (megawatt-hours per year)	Water Usage (million liters per year)
<b>Existing site activities<sup>a</sup></b>	16,005	323,128	2,754 <sup>b</sup>
Tank waste remediation system	–	170,000	200
Waste Management PEIS	–	13,920	133
<b>New nuclear infrastructure operations<sup>c</sup></b>	130 <sup>d</sup>	55,000	80
<b>Total</b>	16,135	562,048	3,167
<b>Total site capacity</b>	NA	2,484,336	8,263 <sup>b</sup>

- a. Reflects current sitewide activities. The “Site Employment” value also reflects projected employment from other activities that are anticipated to continue during all or part of the 35-year period evaluated for proposed nuclear infrastructure operations.
- b. Reflects domestic/potable water only and not raw water usage or availability.
- c. Electrical consumption and water usage are bounded by Option 3 or 6 of Alternative 1, with the values reflecting the increase over standby operations from restart of FFTF and associated support activities in FMEF.
- d. Some, or all, of these worker requirements may be filled by the reassignment of the existing site workforce.

**Note:** To convert from liters per year to gallons per year, multiply by 0.264; to convert from megawatt-hours to British thermal units, multiply by  $3.42 \times 10^6$ .

**Key:** NA, not applicable.

**Source:** Table 4–171 of the NI PEIS.

**Table S–21 Maximum Cumulative Air Pollutant Concentrations at Hanford for Comparison with Ambient Air Quality Standards**

Parameter	Carbon Monoxide		Nitrogen Dioxide	PM <sub>10</sub>		Sulfur Dioxide			
	8 hours	1 hour	Annual	Annual	24 hours	Annual	24 hours	3 hours	1 hour
<b>Activities</b>									
Existing site activities <sup>a</sup> (micrograms per cubic meter)	27.3	63.3	0.666	0.0182	1.01	0.175	30.17	69.4	79.4
Tank waste remediation <sup>b</sup> (micrograms per cubic meter)	34	48	0.12	0.0079	0.75	0.020	1.6	3.6	4
Spent nuclear fuel management <sup>c</sup> (micrograms per cubic meter)	0	0	0.1	0	0	0	0	0	0
New nuclear infrastructure FFTF operations <sup>d</sup> (micrograms per cubic meter)	52.1	74.4	0.0118	$8.39 \times 10^{-4}$	9.84	0.00785	9.11	20.5	22.8
New nuclear infrastructure FMEF operations <sup>d</sup> (micrograms per cubic meter)	0	0	$4.43 \times 10^{-5}$	0	0	0.0087	0.069	0.16	0.17
Total concentration (micrograms per cubic meter)	113.4	185.7	0.90	0.027	11.6	0.212	40.9	93.7	106
<b>Standard</b>									
Most stringent standard <sup>e</sup> (micrograms per cubic meter)	10,000	40,000	100	50	150	50	260	1,300	660

- a. Environmental impacts associated with existing activities. These activities are anticipated to continue during part or all of the 35-year period evaluated for proposed nuclear infrastructure operations.
- b. *Hanford Tank Waste Remediation EIS* activities, vitrification facilities, Phased Implementation – Phase II Operation.
- c. *Spent Nuclear Fuel Management* – regionalization alternative.
- d. Nuclear infrastructure contributions are bounded by Alternative 1, Option 3. Periodic testing of emergency diesel generators would result in higher values for certain pollutants and time periods.
- e. The more stringent of the Federal and State standards is presented if both exist for the averaging period.

**Note:** The contribution from activities in the *Final Waste Management Programmatic EIS* are small and are not shown.

**Source:** Table 4–172 of the NI PEIS.

**Public and Occupational Health and Safety—Normal Operations.** Cumulative impacts in terms of radiation exposure to the public and workers at Hanford are presented in **Table S–22**. There would be no increase expected in the number of latent cancer fatalities in the population from Hanford site operations if nuclear infrastructure operations were to occur at FMEF. The dose limits for individual members of the public are given in DOE Order 5400.5. As discussed in that order, the dose limit from airborne emissions is 10 millirem per year, as required by the Clean Air Act; the dose limit from drinking water is 4 millirem per year, as required by the Safe Drinking Water Act; and the dose limit from all pathways combined is 100 millirem per year. Therefore, as is evident in Table S–22, the dose to the maximally exposed individual would be expected to remain well within the regulatory limits. Onsite workers would be expected to see an increase of approximately 0.26 latent cancer fatality due to radiation from nuclear infrastructure operations over the 35-year operational period.

**Table S–22 Maximum Cumulative Radiation Impacts at Hanford**

Impact	Maximally Exposed Individual		Population Dose Within 80 Kilometers (50 Miles) (Year 2020)		Total Site Workforce	
	Annual Dose (millirem per year)	Risk of a Latent Cancer Fatality <sup>a</sup>	Dose (person-rem)	Number of Latent Cancer Fatalities <sup>a</sup>	Dose (person-rem per year)	Number of Latent Cancer Fatalities <sup>a</sup>
Existing site activities <sup>b</sup>	0.02	$3.5 \times 10^{-7}$	0.6	0.011	181	2.5
Waste management	0.0057	$2.9 \times 10^{-9}$	0.28	0.0014	1,300	5.2
Tank remediation	(c)	$2.4 \times 10^{-6}$	(c)	0.19	(c)	3.27
Spent nuclear fuel management	(c)	$1.4 \times 10^{-8}$	(c)	$8.0 \times 10^{-4}$	(c)	0.057
Burial of low-level waste	0	0	0	0	1,018	0.41
Plutonium Finishing Plant stabilization	0.13	$3.9 \times 10^{-7}$	2.3	0.007	157	0.38
New nuclear infrastructure operations at FFTF and FMEF or RPL <sup>d</sup>	0.0054	$9.5 \times 10^{-8}$	0.25	0.0044	18	0.26
Total	(e)	$3.3 \times 10^{-6(f)}$	(e)	0.21	(e)	12

- These values are calculated based on a 35-year exposure period except for waste management (project duration for waste transfer of 10 years) and Plutonium Finishing Plant stabilization (a 6-year project).
- Environmental impacts associated with present activities at Hanford (including activities at other non-DOE facilities at or near Hanford) that are anticipated to continue during all or part of the 35-year period evaluated for proposed nuclear infrastructure operations.
- Source document provides project total; annual values are not constant.
- Impacts on the public are bounded by Option 1 of Alternative 1; impacts on workers are bounded by Option 3 of Alternative 1.
- Some source documents did not provide dose values, only expected latent cancer fatalities. Therefore, no total dose estimates have been developed.
- The same individual would not be expected to be the maximally exposed individual for all activities at Hanford. The location of the maximally exposed individual depends upon where an activity is performed on the site. However, to provide an upper bound cumulative impact for the maximally exposed individual, the impacts from each activity have been summed.

**Source:** Table 4–173 of the NI PEIS.

**Waste Management.** Cumulative amounts of wastes generated at Hanford are presented in **Table S–23**. It is unlikely that there would be major impacts on waste management at Hanford because sufficient capacity would exist to manage the site wastes. As discussed in Sections 4.3.3.1.13 and 4.4.3.1.13 of the NI PEIS, irrespective of how the waste from processing of irradiated neptunium-237 targets is classified (i.e., transuranic or high-level radioactive), the waste composition and characteristics are the same, and the management

(i.e., treatment and onsite storage), as described in the NI PEIS, would be the same. In addition, either waste type would require disposal in a suitable repository. None of the alternatives assessed in the NI PEIS would generate more than a relatively small amount of additional waste at Hanford.

**Table S–23 Cumulative Impacts on Waste Management Activities at Hanford Over the 35-Year Period (cubic meters)**

Waste Type	Existing Site Activities	New Nuclear Infrastructure Operations	Total	Site Capacity <sup>a</sup>		
				Treatment (cubic meters/year)	Storage	Disposal
Transuranic (High-level radioactive) <sup>b</sup>	9,880 (0)	385 <sup>c</sup> (385)	10,265 (385)	98,520 (50,000)	17,216 (146,000)	NA (NA)
Low-level radioactive	95,666	5,015 <sup>c</sup>	100,681	398,112	99,910	1,970,000
Mixed low-level radioactive	46,207	315 <sup>c</sup>	46,522	413,211	100,483	14,200
Hazardous	19,600	3,100 <sup>d</sup>	22,700	NA	NA	NA
Nonhazardous						
Liquid	7,000,000	1,494,500 <sup>c</sup>	8,494,500	120,000	NA	4,807,720
Solid	1,505,000	10,500 <sup>c</sup>	1,515,500	NA	NA	NA

a. Total 35-year and annual capacity derived from Table 3–36 of the NI PEIS.

b. Volumes in parentheses represent high-level radioactive waste. Sections 4.3.3.1.13 and 4.4.3.1.13 of the NI PEIS provide a discussion on classification of waste from processing irradiated neptunium-237 targets.

c. The bounding alternative for this waste type is Alternative 1, Option 3 or 6.

d. The bounding alternative for this waste type is Alternative 2, Option 3, 6 or 9; Alternative 3, Option 3; or Alternative 4, Option 3; which all include the deactivation of FFTF and neptunium-237 target fabrication and processing at FMEF. The inventory of bulk metallic sodium is not included because alternative sponsors and/or users will be found for its disposition.

**Note:** To convert from cubic meters to cubic yards, multiply by 1.308; < means “less than”; ~ means “approximately”; NA, not applicable.

**Source:** Table 4–174 of the NI PEIS.

**Spent Nuclear Fuel Management.** The operation of FFTF for the proposed mission at 100 megawatts for 35 years under Alternative 1 would produce a total of about 16 metric tons of heavy metal (35,200 pounds) of spent nuclear fuel. The existing spent nuclear fuel at Hanford is about 2,133 metric tons of heavy metal (4,700,000 pounds) (DOE 1995c). The management of the existing spent nuclear fuel at Hanford results in a dose of less than 0.1 millirem per year to the maximally exposed member of the public. This dose is well within the DOE dose limits cited in DOE Order 5400.5. DOE has committed to remove the spent nuclear fuel at Hanford for ultimate disposition in a geologic repository. The restart of FFTF under Alternative 1 would generate 16 metric tons of heavy metal of spent nuclear fuel, which is less than 1 weight-percent of the total spent nuclear fuel inventory presently at Hanford. Only a small fraction of the dose shown for nuclear infrastructure operations would be attributable to the management of this spent nuclear fuel at FFTF. The doses at Hanford, including those associated with spent nuclear fuel management, would remain within the DOE dose limits.

### Cumulative Impacts at the Generic CLWR Site

No incremental environmental impacts at the generic site would be expected with the normal operation of a CLWR to irradiate targets. Therefore, the cumulative impacts at the generic CLWR site would not be affected by any action assessed in the NI PEIS, and are not addressed further.

### **Cumulative Impacts at the New Accelerator(s) Generic DOE Site**

Cumulative impacts cannot be presented for a generic site. If Alternative 3 were selected for implementation, a subsequent site-specific analysis would be conducted for the DOE site chosen for the combination of new accelerator(s) and support facility or research reactor only, and appropriate NEPA documentation would be prepared to address the cumulative impacts for that site.

### **Cumulative Impacts at the New Research Reactor Generic DOE Site**

Cumulative impacts cannot be presented for a generic site. If Alternative 4 were selected for implementation, a subsequent site-specific analysis would be conducted for the DOE site chosen for the new research reactor and support facility or research reactor only, and appropriate NEPA documentation would be prepared to address the cumulative impacts for that site.

### **Cumulative Impacts of Transportation**

Because likely transportation routes cross many states, cumulative impacts are compared on a national basis. Under all alternatives assessed in the NI PEIS, occupational radiation exposure to transportation workers and exposure to the public are estimated to each represent less than 0.05 percent of the cumulative exposures from nationwide transportation over the 35-year period of nuclear infrastructure activities. No additional traffic fatality is expected; the increase in traffic fatalities would be less than 0.0001 percent per year.

# Appendix A

## Neptunium-237 Target Fabrication and Processing Operations for Plutonium-238 Production

This appendix includes a description of the Oak Ridge National Laboratory (ORNL) Radiochemical Engineering Development Center (REDC), the Idaho National Engineering and Environmental Laboratory (INEEL) Fluorine Dissolution Process Facility (FDPF), the Hanford Site (Hanford) Fuels and Materials Examination Facility (FMEF), and the proposed processing facilities and technologies that would be used to store neptunium-237, fabricate neptunium-237 targets, process irradiated targets for plutonium-238 production, recycle neptunium-237, and ship plutonium-238 oxide to Los Alamos National Laboratory (LANL). The material presented in this appendix is based primarily on *Preconceptual Design Planning for Chemical Processing to Support Pu-238 Production* (Wham et al. 1998), except where noted.

### A.1 RADIOCHEMICAL ENGINEERING DEVELOPMENT CENTER

#### A.1.1 Facility Description

REDC is part of the Melton Valley 7900 Complex at ORNL. The High Flux Isotope Reactor (HFIR) is also part of the Melton Valley 7900 Complex. The REDC Complex includes a hot cell facility, Building 7930, which is specifically designed to address the problems associated with the containment of actinide element isotopes and their daughter isotopes. This facility was also designed to protect workers from high dose rates of penetrating radiation, including fast neutrons from spontaneous fission that require thick shielding and the capability for remote operation using manipulators. Building 7930, the proposed site for the plutonium-238 production project, has been used for a variety of transuranium actinide element projects, most notably the processing of californium-252, curium-244, and curium-248 for use as high-intensity neutron sources and research radioisotopes. The current californium-252 operations in Building 7930 would continue and coexist with the plutonium-238 production project.

Building 7930 is a three-story structure with a partial basement, constructed of structural steel, reinforced concrete, and masonry. Perimeter walls are reinforced concrete block. Floors are reinforced concrete slabs that are either poured on compacted aggregate or are supported by structural steel. The roof, replaced in the summer of 1997, is metal decking covered with built-up roofing. The building has a gross floor area of 3,062 square meters (32,950 square feet), exclusive of hot cells. The cell complex adds 286 square meters (3,080 square feet). The total enclosed volume is 18,295 cubic meters (646,000 cubic feet). The building is divided into four major areas: (1) the hot cell complex, consisting of six shielded cells and one unshielded cell; (2) maintenance and service areas; (3) an operating control area; and (4) an office area. Also included are utility services, ventilation systems, crane and manipulator systems, and liquid waste systems. The first and second floor plans of Building 7930 are shown in **Figures A-1** and **A-2**, respectively.

Cells D and E and space on both the second and third floors would be used for the plutonium-238 project. Cells D and E are both clean and empty and could be used for this work with minimal modifications. Cell D activities would include receipt of irradiated targets, target dissolution, chemical separation of neptunium and plutonium from fission products, partitioning and purification of the neptunium, and transuranic waste processing. Cell E would contain processing equipment to purify the plutonium-238, prepare plutonium oxide, and transfer the oxide into shipping containers. Cell E also would provide temporary storage of the neptunium oxide from the Savannah River Site (SRS). Cell F is also a possible interim location for storing neptunium. Neptunium-237 target fabrication would be completed on the second floor outside the cell, but inside a glovebox.

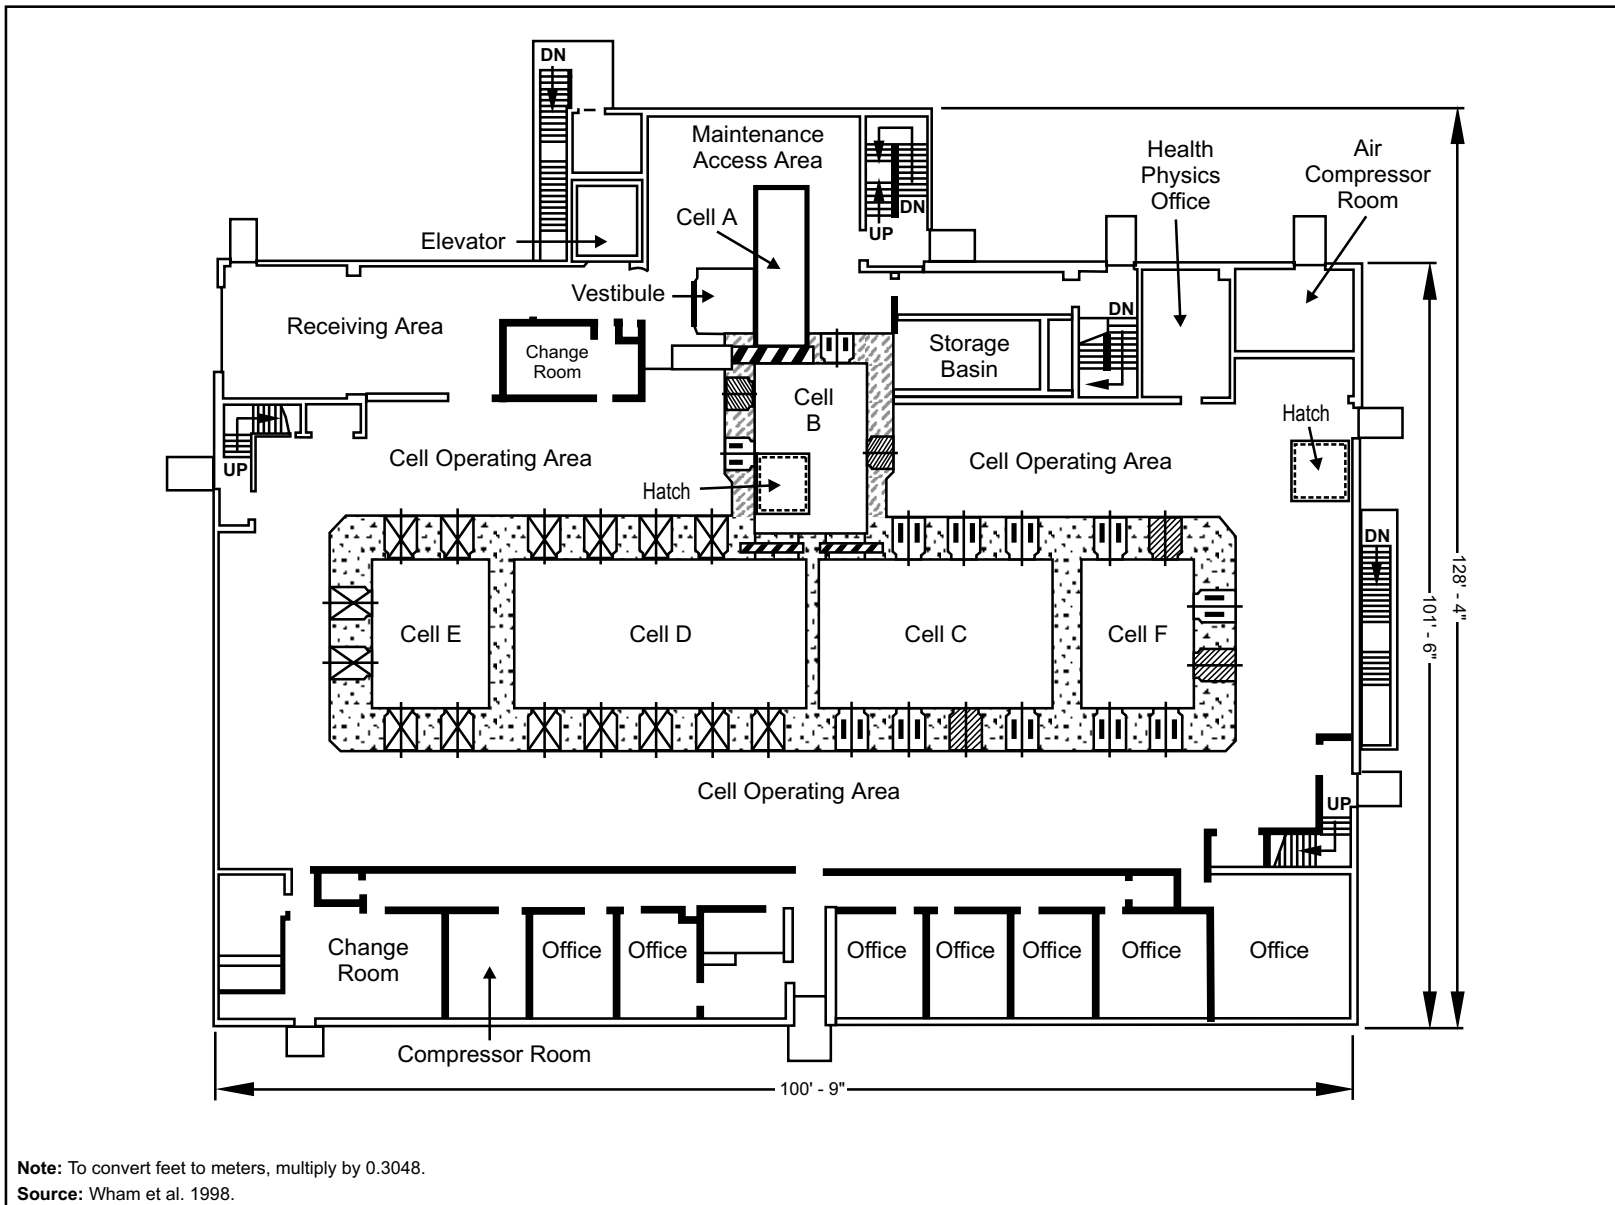

Figure A-1 First Floor Plan for Building 7930

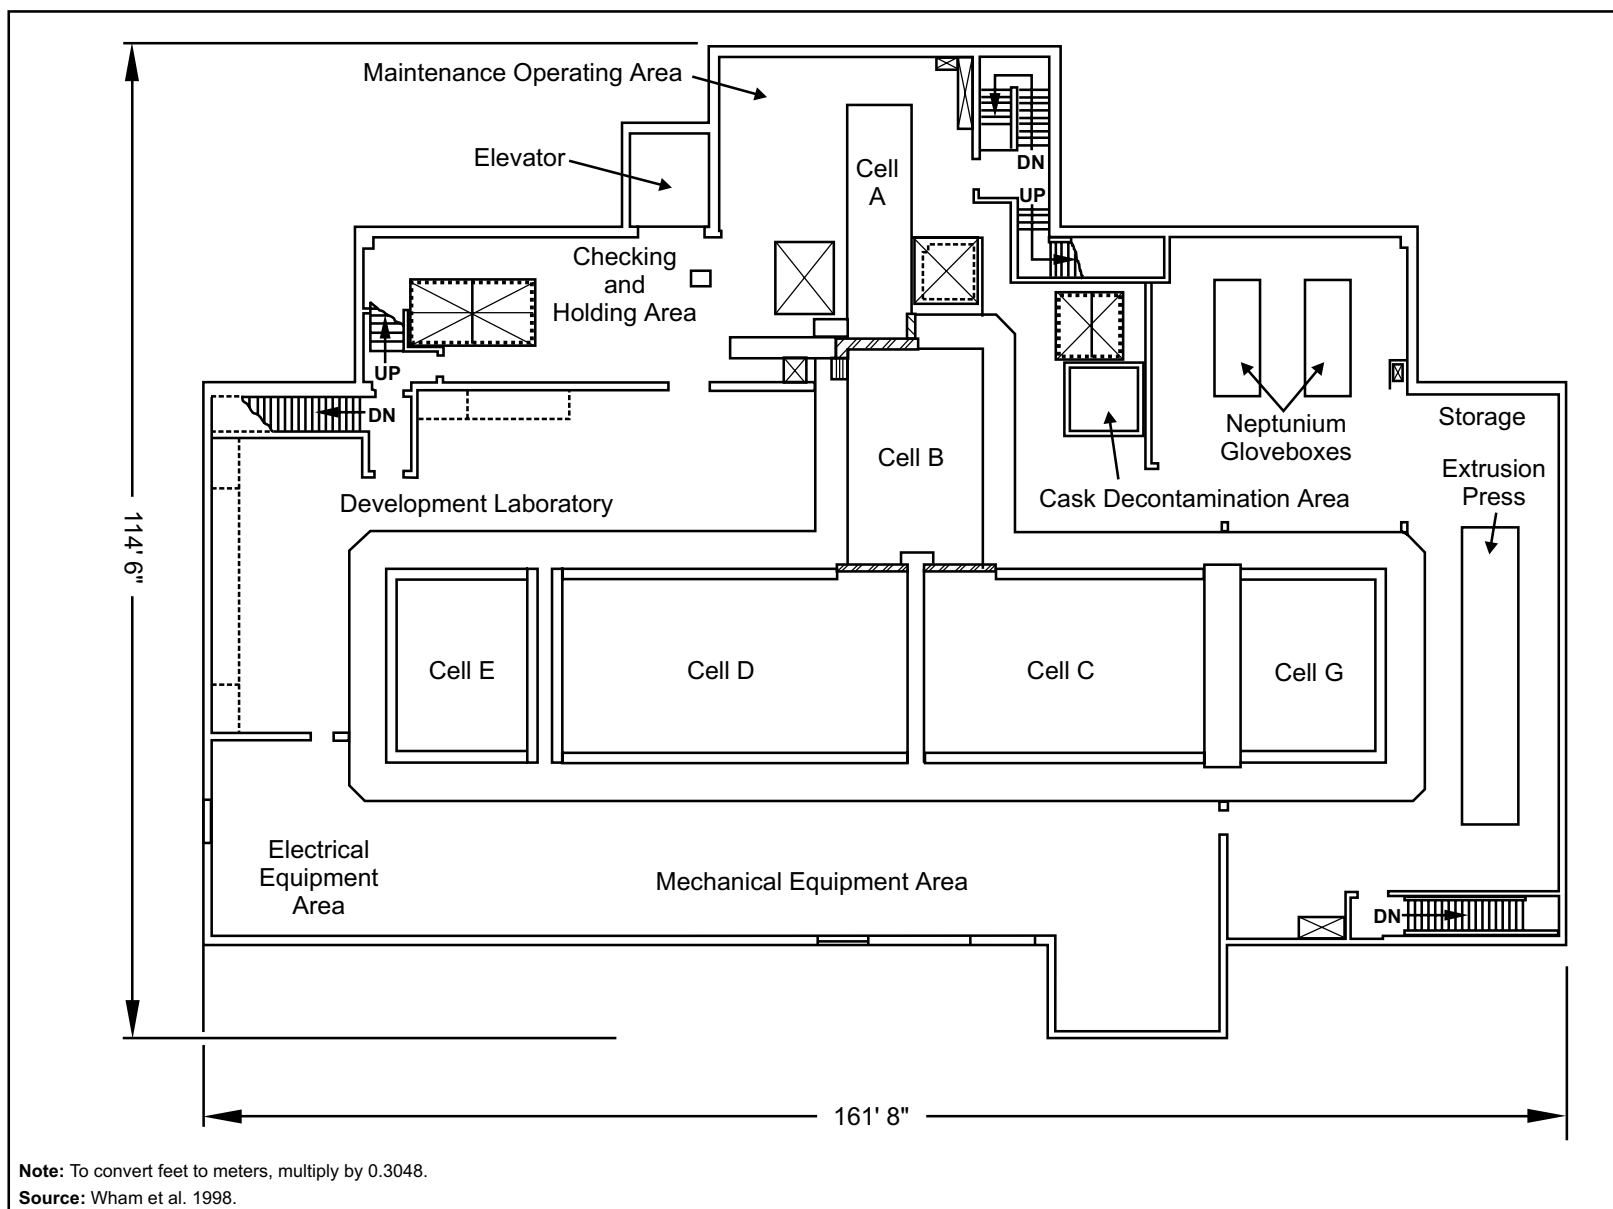

Figure A-2 Second Floor Plan for Building 7930

Cells D and E are adjacent and separated by a 1.2-meter-thick (4-foot-thick) shielding wall. The exterior walls are reinforced concrete 1.7 meters (5.5 feet) thick to a height of 3.4 meters (11 feet) above the first floor, and 1.4 meters (4.5 feet) thick from there to the roof, which is 1.5 meters (5 feet) thick. The cell floors are lined with Type 304L stainless steel, as are the walls and ceiling of Cell D. Currently, only the lower 0.3 meters (12 inches) of the Cell E walls are lined with stainless steel; above that, the walls are concrete with a 0.051-centimeter-thick (0.020-inch-thick) modified phenolic protective coating. For the plutonium-238 project, the walls in Cell E must be completely lined with stainless steel to improve containment and facilitate decontamination.

The lower section of each cell has operating modules, each with a large penetration for a viewing window and a pair of sleeves through which manipulators can be installed. Each cell is also equipped with transfer hatches and ports in the roof through which tools and equipment can be inserted.

Within a cell, operations would take place primarily with equipment contained in a workstation. A workstation is a stainless steel pan with short walls, and is open to the surrounding cell. The workstation has dimensions such that the manipulators can reach all equipment, and the entire area is viewable to the operators through the viewing window. A servomanipulator would be used to transfer materials between workstations. Transfer of items within workstations would be accomplished using the manipulators at each workstation.

Cell D has interior dimensions of 6.1 meters (20 feet) wide, 12.5 meters (41 feet) long, and 7.3 meters (24 feet) high. Currently, five chemical processing workstations and one analytical chemistry workstation are planned for Cell D. One window location would be used for transfer lines to bring in process solutions.

Cell E has interior dimensions of 6.1 meters (20 feet) wide, 4.9 meters (16 feet) long, and 9.1 meters (30 feet) high. A storage facility would be added, and three window locations would be used for chemical processing workstations. One of the workstations would be an enclosed stainless steel box. This workstation would be used for handling plutonium-238 oxide as a powder. Use of an enclosed area in this manner would minimize migration of plutonium-238 oxide powder and contamination.

All cells would be ventilated by air drawn from the occupied areas of the building through high-efficiency particulate air filters, and then through the cells on a once-through basis. The air leaving the cells would be filtered at the point of exit by high-capacity roughing filters, and then by two banks of high-efficiency particulate air filters in succession before being released to the atmosphere from Stack 7911.

Currently, Cells D and E have heat detectors, but are not equipped with fire suppression systems.

Target fabrication would be carried out on the second floor of Building 7930. The area is currently used as a maintenance shop and storage area. The walls between the maintenance shop and storage area would be removed to allow room for gloveboxes. The gloveboxes would be used to convert aqueous neptunium solutions into a form suitable for target fabrication. The storage area would be moved to another location within REDC and would be used for target fabrication equipment.

### **A.1.2 Neptunium-237 Storage**

The neptunium-237 from SRS would arrive as neptunium dioxide, the most stable of the neptunium oxides. Upon arrival at REDC, the neptunium oxide would be removed from the shipping container(s). The product canister containing the neptunium oxide would remain in the containment vessel for storage in a designated shielded storage area until initiation of the purification process to remove protactinium-233.

After the neptunium-237 is processed into targets, the targets would be placed in shielded containers. The product canisters would be placed into containment vessels, and loaded directly into shipping containers for transport to the irradiation facility.

### A.1.3 Neptunium-237 Target Fabrication Process Description

The fabrication of neptunium-237 targets for plutonium-238 production would require dissolving the neptunium oxide (if necessary), purification of neptunium to remove radioactive decay products, conversion of the neptunium to an oxide, and fabrication of neptunium oxide into targets for irradiation. The neptunium-237 to be used in the targets would come from two sources: (1) neptunium that had been separated previously during spent nuclear fuel processing at SRS, converted to an oxide, and then shipped to ORNL for storage (Section A.1.2); and (2) neptunium that would be recovered from irradiated neptunium-237 targets and recycled for use in new targets (Section A.1.4).

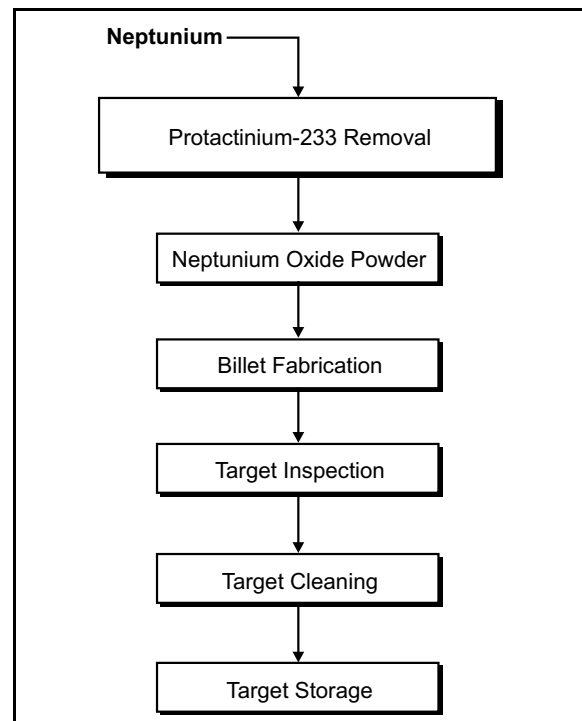

Initially, all of the neptunium-237 required for target fabrication would come from the neptunium oxide in storage. After postirradiation processing begins, most of the neptunium requirements would be met by using recycled neptunium, and only a small quantity of the stored neptunium would be needed to replace the neptunium transformed to plutonium-238 during irradiation.

All target fabrication activities at ORNL would be conducted in REDC Building 7930. The first stage of the target fabrication process would involve neptunium purification to remove protactinium-233 (a product of neptunium-237 alpha decay) and would be conducted in shielded facilities to minimize radiation exposure. Oxidation of the purified neptunium, mixing neptunium oxide with a suitable diluent, and preparing a billet for extrusion for Advanced Test Reactor (ATR) or HFIR targets, or preparing wafers or pellets for Fast Flux Test Facility (FFTF) targets, would be conducted in shielded gloveboxes on the second floor of Building 7930. The mechanical operations involved in the final target fabrication would be conducted in open boxes located in the target fabrication room.

The fabrication process for neptunium-237 targets is shown in **Figure A-3**. The neptunium would be brought from storage or recycling in preparation for purification. The neptunium would be dissolved (if necessary), treated to remove protactinium-233, and converted to an oxide. The oxide then would be transferred to the target fabrication line, where it would be formed into neptunium-237 targets.

#### A.1.3.1 Neptunium-237 Purification

Neptunium-237 is a radioactive isotope that decays to protactinium-233 through loss of an alpha particle. The protactinium reaches 90 percent of the equilibrium activity in approximately 10 weeks. Protactinium-233 has a short half-life (27 days) and decays to uranium-233, releasing gamma rays. The decay of this protactinium ingrowth would contribute significantly to the radiation doses to workers in the target fabrication

**Figure A-3 Steps Required for Target Fabrication**

line. Removal of the protactinium prior to oxide conversion and target fabrication would result in less radiation exposure for personnel involved in the target fabrication activities.

Neptunium oxide would be removed from its storage location in Cell E and transferred to dissolution equipment, which also would be located in Cell E. This dissolution may also take place in Cell D. The equipment would be sized to dissolve kilogram-size batches of neptunium-237. The neptunium would be dissolved in nitric acid and the solution would be passed through a column of silica gel, which would adsorb the protactinium. The purified neptunium-bearing solution, obtained in the third solvent extraction step during processing of irradiated neptunium-237 targets, would become the primary source of neptunium-237 for targets, once irradiated target processing began (Section A.1.4). Additional neptunium needed to supplement this source would come from the neptunium oxide stored in Cell E. The protactinium adsorbed in the silica gel then would be converted to a solid waste form. Because of the relatively short half-life of the protactinium-233, and its decay to uranium-233 (a relatively stable isotope), the radioactivity from this waste would be small after about 1 year of storage. The purified neptunium-237 solution would then be transferred to the target fabrication glovebox line for conversion of the neptunium to oxide.

### **A.1.3.2 Neptunium Oxide Production**

The desired form of neptunium oxide for target fabrication is currently assumed to be oxide microspheres. The neptunium-237 solution would be passed through a cation-exchange column containing a resin, such as Dowex 50W-X8, of selected particle-size range (typically 60 to 80 microns [0.000024 to 0.000031 inches]). The loaded resin would be washed with dilute acid and dried with an air stream pulled through the column via a vacuum.

To convert the resin to oxide, a multistep heating cycle with ramp and hold times using both air and 4 percent hydrogen/argon streams would be employed. The preferred method would use heated air to burn the resin and to form the neptunium oxide microspheres. A typical cycle would be as follows: initially heat the resin with air (7 to 10 millimeters [0.28 to 0.39 inches] per second superficial velocity) at 150 °C (300 °F) for 1 hour; ramp to 450 °C (840 °F) at 5 °C (9 °F) per minute and hold for 1 hour with air; ramp to 800 °C (1,470 °F) at 10 °C (18 °F) per minute and hold for 4 hours with air (most of the carbon should be removed in this step); and switch to 4 percent hydrogen/argon and continue at 800 °C (1,470 °F) for a final 4-hour period to complete conversion to the oxide. The oxide then would be cooled for handling, transferred to a crucible, and sintered at 1,200 °C (2,190 °F) in air for 10 hours to complete the oxidation. This material would be weighed and characterized (tap density, radiochemical analysis, and particle size) to determine the blends for fabrication into pellets.

An alternative procedure for producing neptunium oxide would be precipitation of neptunium oxalate, followed by filtration and calcination to form neptunium oxide. The neptunium-bearing solution would be mixed with a solution containing oxalic acid. After mixing for at least 30 minutes, the supernatant would be decanted and filtered into a holding tank. The neptunium oxalate would be drained into a filter boat. The tank would be washed with 0.1 molar (*M*) oxalic acid and drained through the filter. The oxalate would dry on the filter and then be transferred to a platinum-lined furnace can. The filtrate would be sampled and sent to liquid waste treatment. The furnace can containing the neptunium oxalate would be placed into a calciner and heated to approximately 400 °C (750 °F) for 1 hour to decompose the neptunium oxalate to neptunium oxide and carbon dioxide.

### A.1.3.3 Neptunium-237 Target Fabrication

Fabrication of the targets would take place in dedicated gloveboxes in Building 7930. The target for the ATR and HFIR reactors consists of the neptunium oxide blended with an inert filler such as aluminum powder, pressed into a target core, and clad with aluminum. This type of target has been used historically in nearly all of the U.S. Department of Energy (DOE) water-cooled and -moderated production and research reactors used to produce isotopes, including plutonium-238. Three different fabrication techniques could be employed in making these types of targets for ATR and HFIR:

- Blending the neptunium oxide and aluminum powders, pressing the mixture into individual pellets, loading the pellets into aluminum target tubes, and seal welding and hydrostatic compression of the tubes
- Blending the neptunium oxide and aluminum powders, pressing the mixture into compacts, roll milling the compacts between aluminum-clad material, and seal welding the aluminum-clad neptunium dioxide and aluminum plates
- Blending the neptunium oxide and aluminum powders; pressing the mixture into billets; assembling the billets into welded, evacuated containers; and coextruding the neptunium oxide and aluminum mixture with the aluminum container to produce target tubes

Another fabrication technique that may be considered is mixing the neptunium oxide with a high-temperature diluent (other than aluminum), pressing the mixture into pellets or tubes, and sealing it into Zircaloy tubing. Targets with Zircaloy or stainless steel cladding would be used in targets for the commercial light water reactor (CLWR) or a high-energy accelerator due to higher operating temperatures. This fabrication technique would use similar gloveboxes for target fabrication and quality assurance tests of the targets. The proposed target for the FFTF reactor would consist of alternating wafers or pellets of neptunium oxide and yttrium hydride (moderator) sealed in stainless or ferritic alloy steel tubing to make target pins. These pins, up to 2.5 centimeters (1 inch) in diameter by 2.4 meters (8 feet) long, would subsequently be inserted into an inlet nozzle, duct, and handling socket assembly for handling and insertion in the FFTF reactor. Fabrication and assembly operations would be done in shielded gloveboxes to minimize personnel radiation exposure. The completed targets then would be stored in Building 7930 until shipment to a reactor for irradiation.

### A.1.4 Postirradiation Target Processing Description

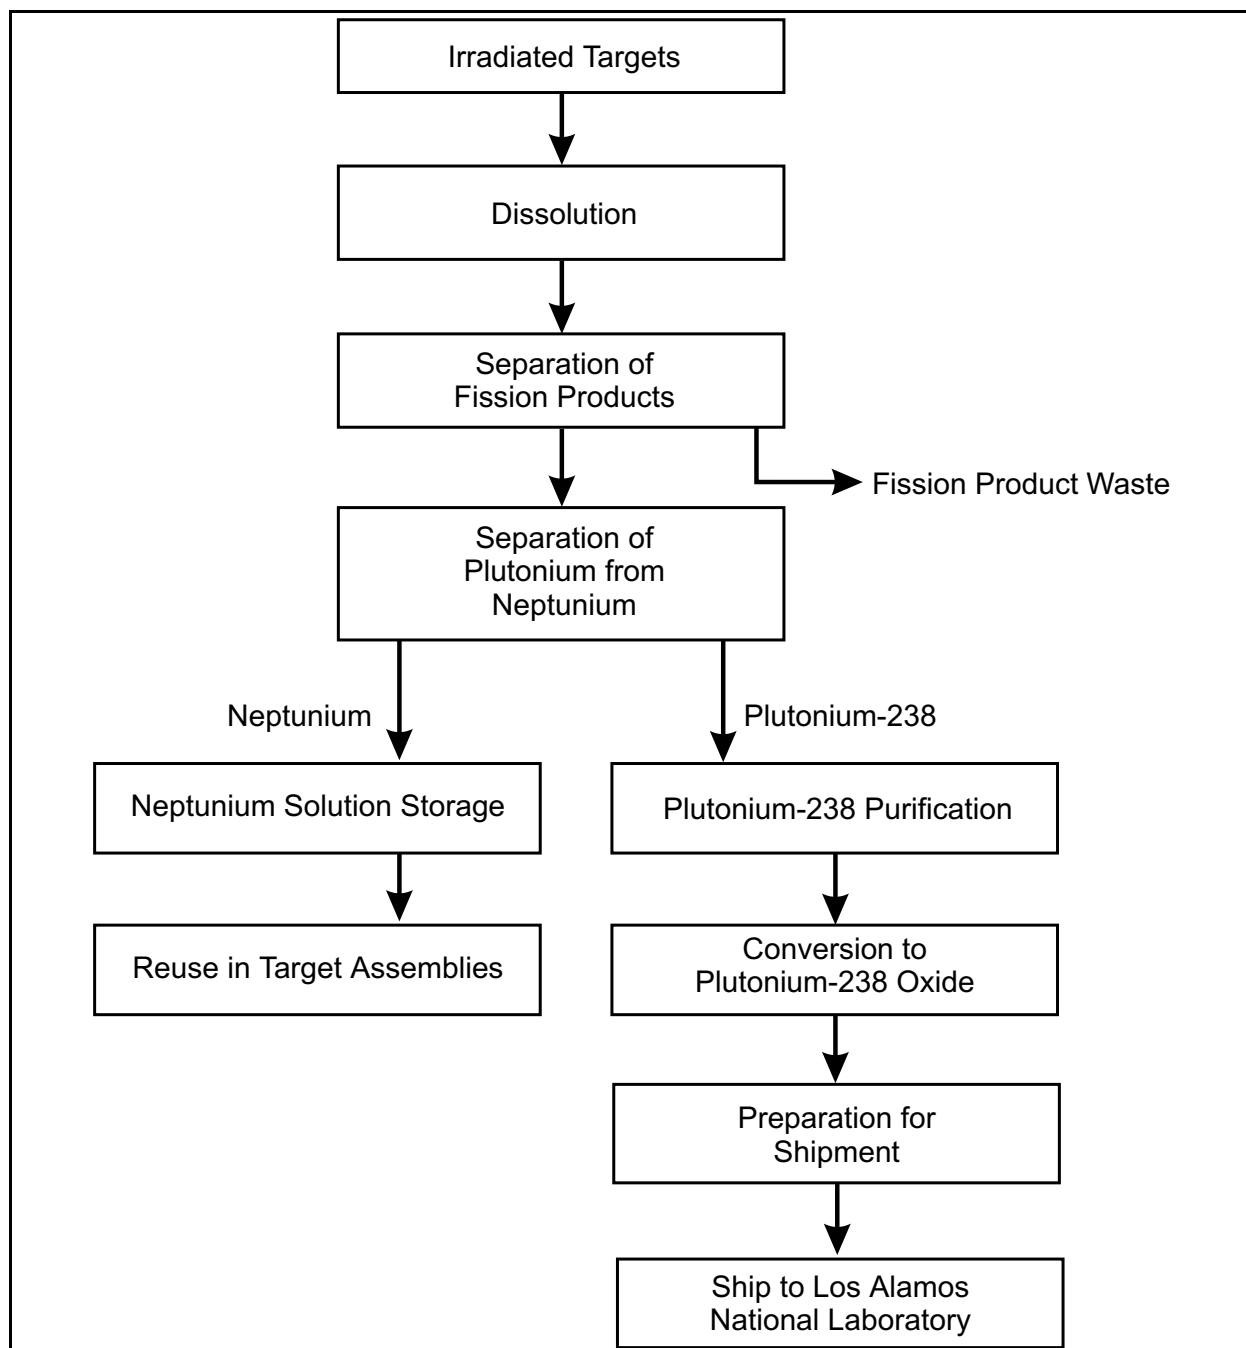

Postirradiation processing of neptunium-237 targets at ORNL would involve dissolution; separation of the actinides from the fission products; separation of neptunium from plutonium; a third solvent extraction process to purify the remaining neptunium; purification of plutonium; precipitation of plutonium oxalate; calcination of plutonium oxalate to plutonium oxide; and exchange of oxygen-17 and -18 by oxygen-16 in the plutonium oxide. The dissolution and purification processes would be conducted in Cell D of Building 7930, and the plutonium purification, plutonium oxide preparation, oxygen exchange reaction, and transfer of the plutonium oxide to shipping containers would be conducted in Cell E of Building 7930.

The postirradiation target processing steps are shown in **Figure A-4**. The irradiated targets would be cooled at the irradiation site for at least 120 days to allow time for decay of short-lived fission products.

#### A.1.4.1 Target Dissolution

Irradiated targets from ATR or HFIR would be brought to Building 7930 in a Type B shipping cask with sufficient shielding to meet U.S. Department of Transportation (DOT) requirements and transferred to Cell D,

**Figure A-4 Irradiated Neptunium-237 Target Processing**

where postirradiation processing of the targets would be conducted. Dissolution of the aluminum-clad irradiated targets from HFIR or ATR would be accomplished using a two-step process. In the first step, the irradiated targets would be submerged in a 2.25 M sodium nitrate solution and heated to 90 to 95 °C (194 to 203 °F). A 10 M sodium hydroxide solution then would be added at a controlled rate to sustain the dissolution reaction. The aluminum-bearing caustic solution would be pumped through parallel sintered stainless steel filters and discarded as low-level waste. The filter then would be backflushed to the dissolver tank, where the remaining solids would be digested in a solution consisting of 8 M nitric acid and 0.02 M sodium fluoride. This solution would dissolve the actinides and most of the remaining fission products. This solution would

be filtered to remove any remaining solids (primarily silica fission products) and produce an acid product for solvent extraction.

Stainless steel- or Zircaloy-clad targets irradiated in the CLWR or in FFTF would be cut into small pieces and leached with nitric acid or other suitable solution to dissolve the neptunium, plutonium, and fission products away from the insoluble cladding. The solution would be filtered and the undissolved cladding would be discarded as low-level waste.

#### **A.1.4.2 Plutonium Separation and Neptunium Recycling**

The solution containing neptunium and plutonium would be processed in a series of three solvent extraction steps. In the first step, the neptunium and plutonium would be separated from fission products by extraction into an organic phase consisting of tributyl phosphate dissolved in normal paraffin hydrocarbon. Fission products and other contaminants would remain in the aqueous phase. After separation of the aqueous and organic phases, neptunium and plutonium would be stripped from the organic phase into another aqueous phase using a solution of 0.1 *M* nitric acid containing 0.1 *M* hydroxylamine nitrate as a reducing agent. Reduction would convert neptunium into the +4 oxidation state and plutonium into the +3 oxidation state. This solution then would flow to the second solvent extraction stage.

In the second solvent extraction step, neptunium (which would be in the +4 oxidation state) would be selectively extracted back into an organic phase consisting of 30 percent tributyl phosphate in normal paraffin hydrocarbon, while plutonium (which would be in the +3 oxidation state) would remain in the aqueous phase. Control of the oxidation states would be accomplished by the presence of hydroxylamine nitrate in the feed solution and the use of an aqueous hydroxylamine nitrate scrub stream to maintain the proper oxidation states within the solvent extraction contactor. Neptunium then would be stripped from the organic phase using a solution of 0.1 *M* hydroxylamine nitrate and 0.2 *M* nitric acid. The acidity of the neptunium-bearing solution would be adjusted to 2 *M* nitric acid and would be routed to a third solvent extraction step, where the solution would be further purified. The plutonium-bearing stream would be transferred to Cell E, where it would be further purified, if necessary, and converted to an oxide.

In the third solvent extraction step, any plutonium remaining in the neptunium-bearing solution would be separated from the neptunium. The neptunium-bearing solution from the second solvent extraction step would be mixed with a solution of 30 percent tributyl phosphate in normal paraffin hydrocarbon and a solution of 0.1 *M* nitric acid and 0.1 *M* ferrous sulfamate. The ferrous sulfamate would act as a reductant to ensure that the plutonium would remain in the +3 oxidation state and in the aqueous phase. The neptunium would be extracted into the organic phase. After separation of the aqueous and organic phases, neptunium would be stripped from the organic phase using a solution of 0.2 *M* nitric acid and 0.1 *M* hydroxylamine nitrate. The purified neptunium-bearing solution then would be stored in a tank below Cell D until needed for conversion to an oxide for fabrication into targets, as described in Section A.1.3.

#### **A.1.4.3 Plutonium Purification and Preparation of Plutonium Oxide**

Although the necessity for further plutonium purification from the second solvent extraction has not yet been fully determined, provisions would be made to purify the plutonium-bearing solution using an anion exchange process. This process has been used previously at REDC to purify plutonium products in preparation for precipitation and calcination to an oxide product. If the plutonium product solution from the second-cycle solvent extraction process meets the desired specifications, no anion exchange processing would be needed and the solution would be sent directly to the oxalate precipitation process. If purification were required, the feed solution would be adjusted to a high acid concentration (approximately 8 *M* nitric acid) and the oxidation states of the actinides would be adjusted to form the metal nitrate complex that loads on the anion exchange

resin. The oxidation state of the metals would be adjusted using a reductant such as ferrous sulfate or ferrous sulfamate. After loading the plutonium onto the resin, the resin would be washed with an acid solution to remove impurities, and the plutonium would be selectively stripped with a dilute acid solution or a dilute acid solution containing reductants (hydroxylamine nitrate, nitrous acid, or hydrazine) to reduce the oxidation state of the loaded complex and strip it from the anion resin column.

The plutonium product from the second-cycle solvent extraction process or the anion exchange process would be adjusted to give a final solution of 1 *M* nitric acid with plutonium in the +4 oxidation state. Ascorbic acid would be used as the reductant to adjust the plutonium oxidation state because it would not add any extraneous ions to the final product upon conversion to the oxide. Two additions of 1 *M* oxalic acid would be made to the plutonium solution to quantitatively precipitate plutonium oxalate. The solution would be filtered and the plutonium oxalate collected on a sintered platinum/Inconel filter for calcination to the oxide. The precipitated plutonium oxalate and filter then would be transferred to a furnace and calcined in air at 735 °C (1,355 °F) for 2 hours to produce plutonium oxide.

The alpha-neutron reaction, which occurs when alpha particles emitted from plutonium-238 interact with atoms of naturally occurring oxygen, results in a high neutron emission rate from plutonium oxide, and may cause a high neutron exposure to workers. To reduce this exposure, an oxygen exchange process would be used to replace the higher cross-section oxygen isotopes (oxygen-17 and oxygen-18) with oxygen-16, which has a very small cross section for the alpha-neutron reaction. To accomplish this exchange, a stream of oxygen-16 enriched gas would be passed through the plutonium oxide product from the calcination step, above, at a temperature of approximately 800 °C (1,470 °F) for approximately 4 hours. The progress of the exchange reaction would be constantly monitored with a neutron detector located adjacent to the plutonium oxide. After completion of the exchange reaction, the plutonium oxide would be cooled in an inert atmosphere and immediately transferred to a container (e.g., EP-60) for final packaging (see Section J.3.3.3 for a further discussion of this packaging system).

#### **A.1.5 Plutonium-238 Storage Description**

A container (e.g., EP-60) containing plutonium-238 would be placed into a primary containment vessel (e.g., EP-61), which then would be placed into a secondary containment vessel (e.g., EP-62) and stored until shipment to LANL. The secondary containment vessel then would be loaded into a shipping package (e.g., 5320B). DOE anticipates about four shipments per year to LANL, as described in Appendix J.

### **A.2 FLUORINEL DISSOLUTION PROCESS FACILITY**

#### **A.2.1 Facility Description**

The Idaho Nuclear Technology and Engineering Center (INTEC) is located northeast of the Central Facilities Area at INEEL and approximately 3.2 kilometers (2 miles) southeast of ATR. Two buildings at INTEC are proposed storage and processing sites for plutonium-238 production: Building CPP-651, the Unirradiated Fuel Storage Facility, and Building CPP-666, FDPF and Fuel Storage Facility.

Building CPP-651 was originally designed for the storage of special nuclear materials to support Defense Programs and is quite flexible in terms of the size and shape of special nuclear materials that it can receive and store. The 100 storage positions in the vault use the existing structural barriers of Building CPP-651 (earth and concrete) and provide supplemental security protection via their in-ground concrete storage silo design. Each storage position houses a rack that holds seven highly enriched uranium product cans. Racks are raised and lowered in their storage positions via an overhead 1-ton hoist.

Building CPP-666 is divided into two parts, the Fuel Storage Facility and FDPF. The Fuel Storage Facility consists of receiving and unloading areas, a fuel unloading pool, and six storage pools for storing nuclear fuel.

FDPF was designed and built to process Navy fuel via three dissolver trains. When fuel reprocessing was discontinued, uranium and hazardous materials were flushed from FDPF, and the facility is currently under consideration for new missions. FDPF consists of a large hot cell and supporting areas with a total area of approximately 3,700 square meters (40,000 square feet). The facility is divided into five levels identified by their elevation relative to ground level (Hochhalter 1982). A floor plan of the +28-foot level, the proposed location for the neptunium glovebox train and the target fabrication glovebox, is shown in **Figure A-5**.

The FDPF cell is approximately 6 meters (20 feet) wide, 30 meters (100 feet) long, and 15 meters (50 feet) deep (Sire et al. 1992) with 1.8-meter-thick (6-foot-thick) concrete walls. A plan view of the FDPF cell is shown in **Figure A-6**. The cell includes manipulators, three dissolvers, off-gas cleanup systems, complexing vessels, process makeup vessels, pumps, valves, piping, and instrumentation (Hochhalter 1982). The interim storage rack area located in the south end of the cell could be used to store irradiated targets. A new 12.5-liter (3.3-gallon) or 200-liter (53-gallon) dissolution vessel would need to be installed. This dissolution vessel would be located in proximity to the existing Train One dissolver to facilitate the use of the existing dissolver off-gas system (Kirkham 1999).

## **A.2.2 Neptunium Storage**

Neptunium-237 oxide would be shipped from SRS to INEEL in double-sealed containers loaded in Type B packages. At INEEL, it would be stored in the Building CPP-651 vault. There are 100 in-ground concrete-shielded storage positions (each approximately 25 centimeters [10 inches] in diameter by 2.4 meters [8 feet] in length) in this vault. Each storage position houses a rack that holds seven highly enriched uranium product cans, with each can containing about 8 to 10 kilograms (18 to 22 pounds) of highly enriched uranium (the total mass of the rack and cans is about 148 kilograms [325 pounds]). The design-basis radiation level for these cans is about 800 millirem per hour at contact. The rack that fits into the storage position can be redesigned for neptunium oxide containers if its existing dimensions are not adequate. Alternatively, neptunium-237 oxide may be stored in the processing hot cell (Cook and Hill 1999).

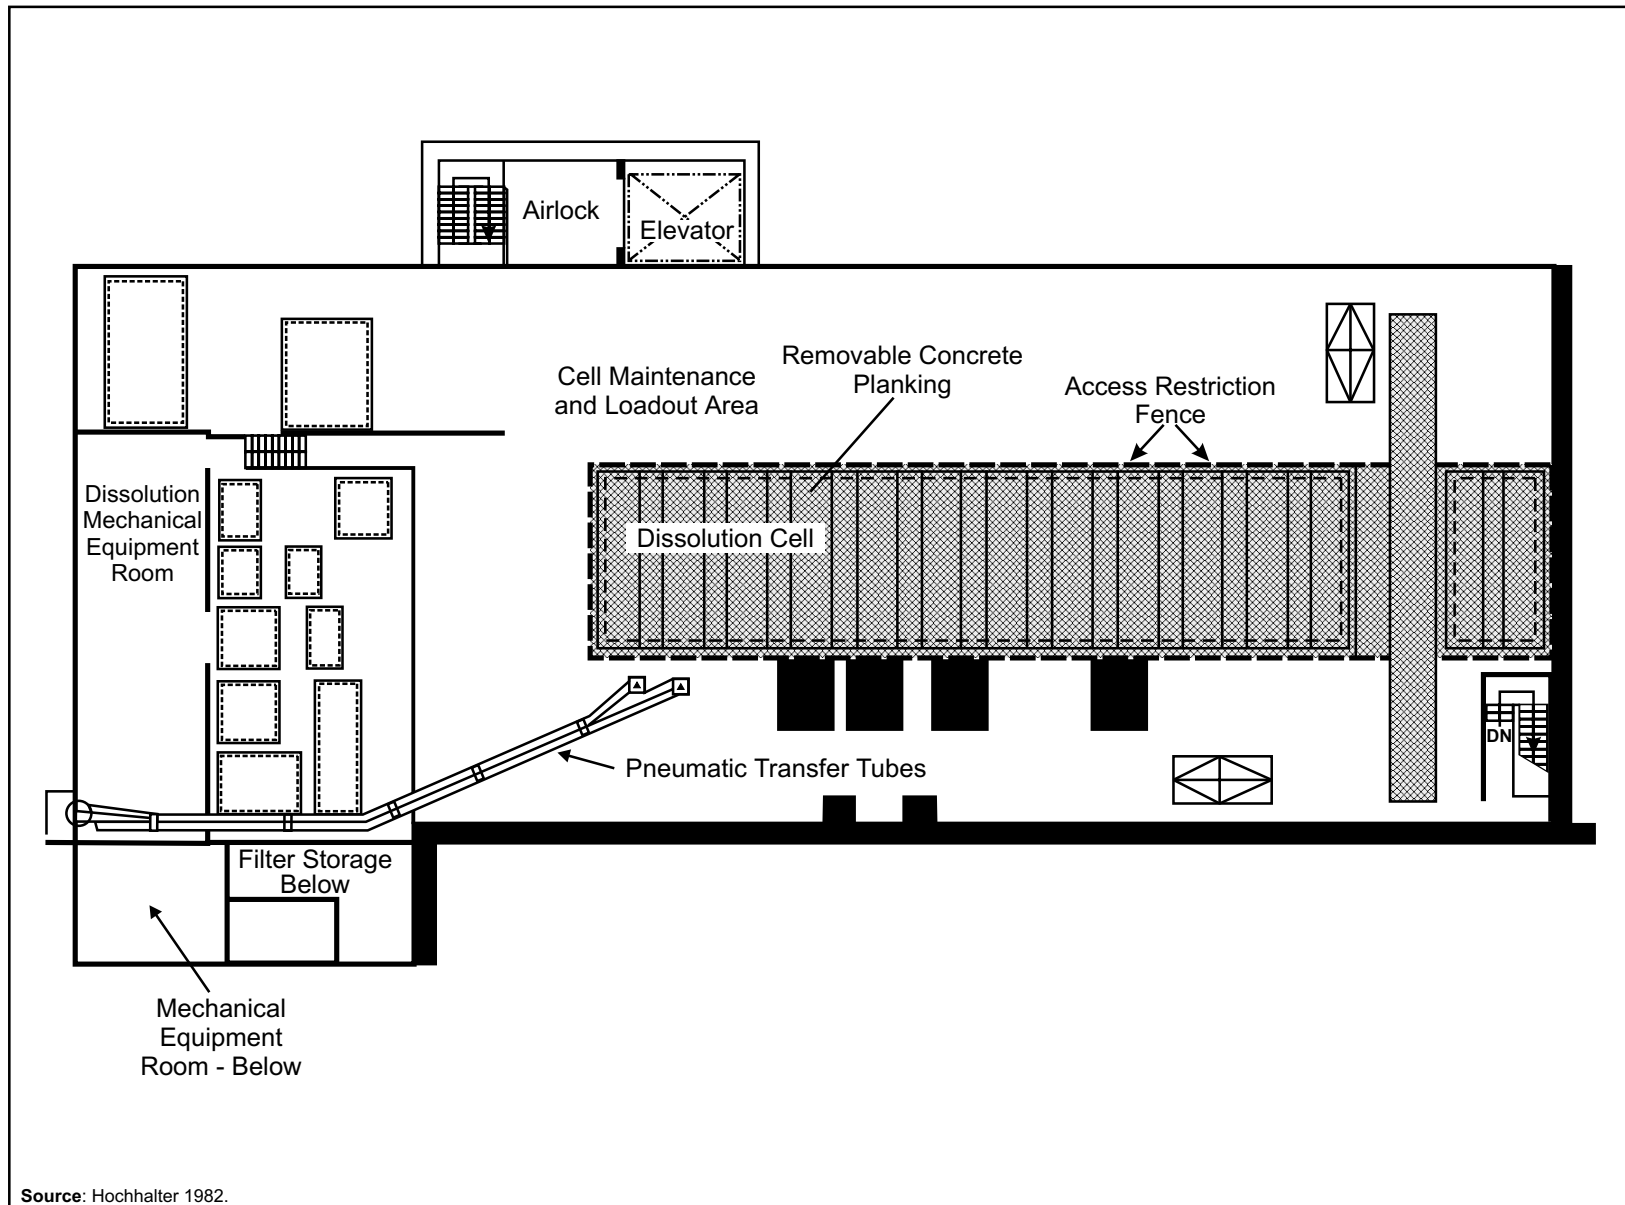

## **A.2.3 Neptunium-237 Target Fabrication Process Description**

The neptunium-237 target fabrication process used at INEEL would be similar to that described in Section A.1.3 for target fabrication in REDC at ORNL and in more detail in *Preconceptual Design Planning for Chemical Processing to Support Pu-238 Production* (Wham et al. 1998). In addition to the target design considered in that document, INEEL could produce targets suitable for a commercial reactor or for an accelerator. The latter target is significantly longer than those considered by ORNL. The target fabrication process would include neptunium-237 purification, neptunium oxide production, and target fabrication.

### **A.2.3.1 Neptunium-237 Purification**

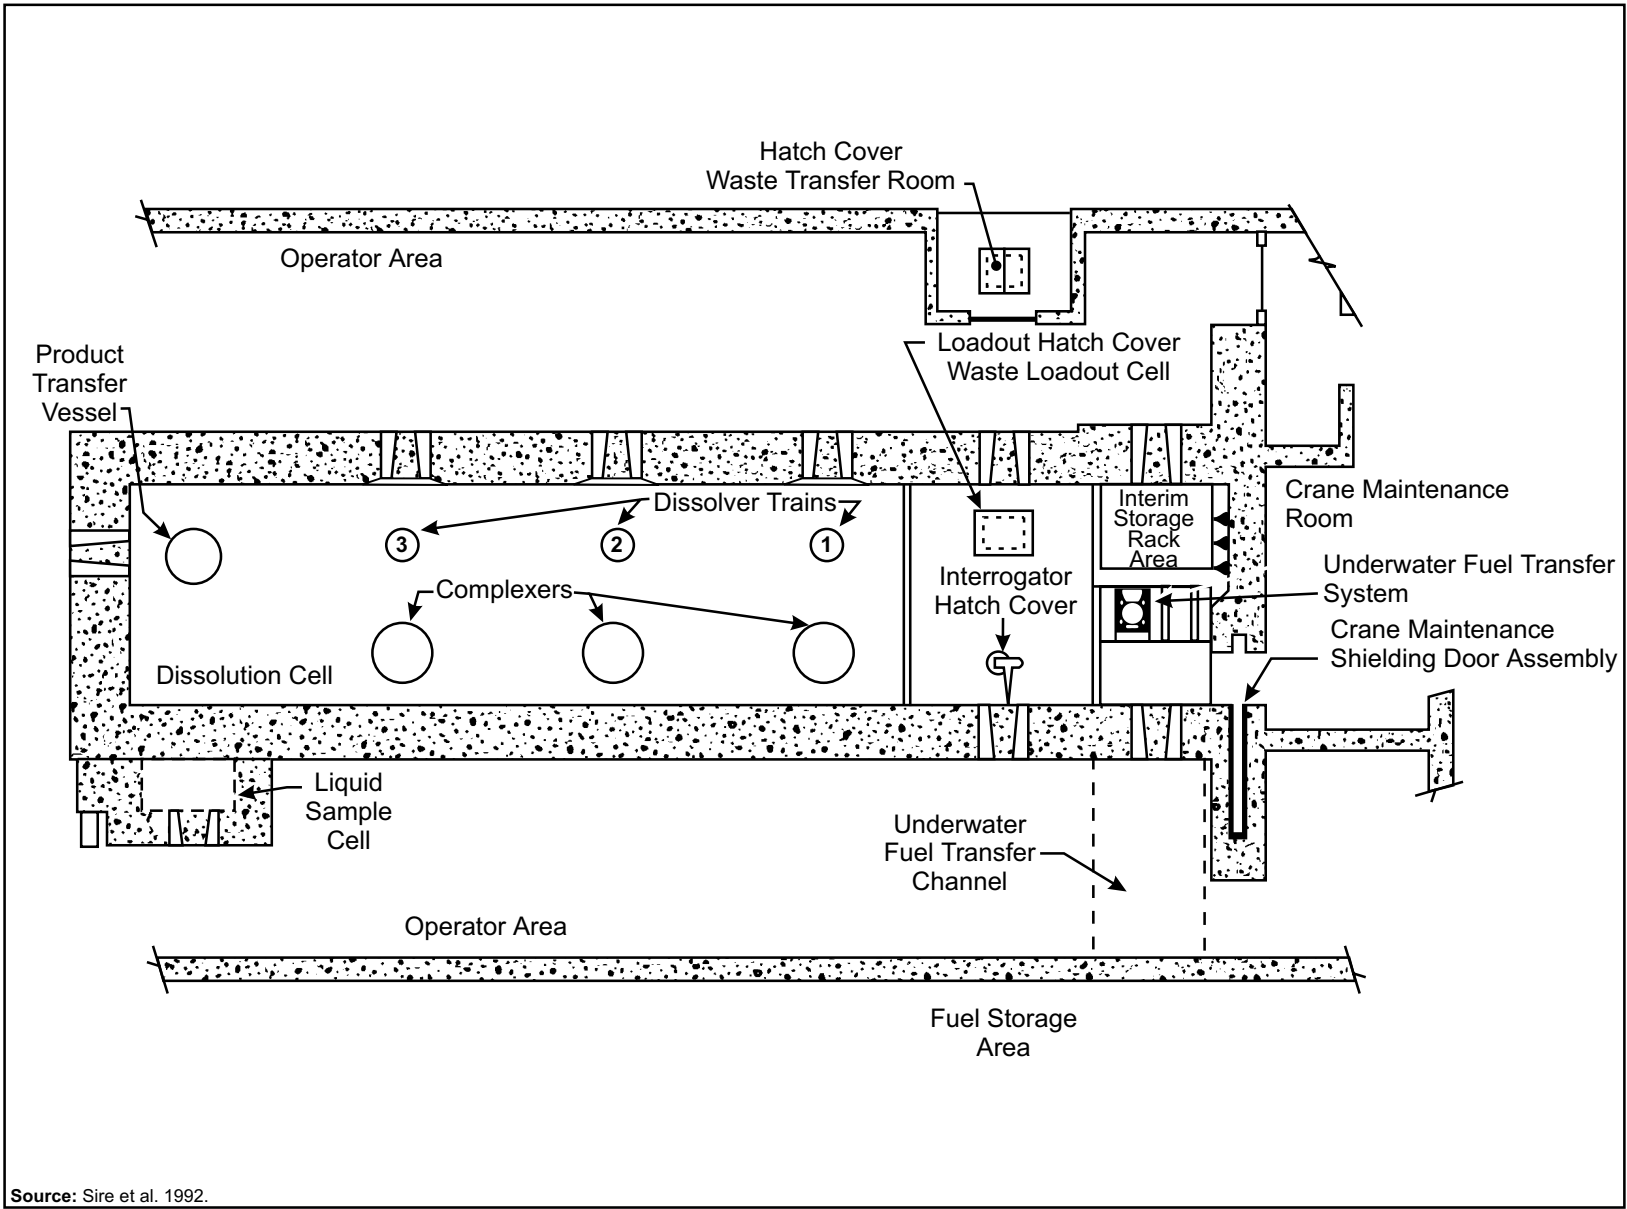

Neptunium-237 oxide retrieved from storage would be purified by dissolving the material in nitric acid and passing the neptunium nitrate solution through a silica gel bed. During this process, the protactinium would adsorb onto the silica gel, leaving a protactinium-233-free neptunium nitrate solution. This process would either be conducted in the hot cell near the third-cycle solvent extraction equipment or within the neptunium processing glovebox train at the +28-foot level.

Neptunium nitrate recovered from postirradiation processing should not be contaminated by protactinium-233, as this isotope should have been removed in the solvent extraction process. However, if neptunium-237 target

Source: Hochhalter 1982.

Figure A-5 Fluorinel Dissolution Process Facility +28-Foot Level

Source: Sire et al. 1992.

Figure A-6 Plan View of the Fluorinel Dissolution Process Facility Cell

fabrication were delayed, the ingrowth of protactinium-233 would require that the solution be passed through a silica gel bed to remove the protactinium prior to formation of neptunium oxide (Kirkham 1999).

### **A.2.3.2 Neptunium Oxide Production**

Neptunium oxide production would be accomplished using the same process described for ORNL (Section A.1.3.2 and Wham et al. 1998). Conversion of the purified neptunium nitrate solution would be accomplished by adsorption of the neptunium on a cation resin bed in a glovebox train located on the cell maintenance level (+28-foot level). Solutions from the hot cell would be pumped from in-cell storage through a K-plug installed in an existing penetration. The routing would be through doubly contained lines run through the +17- and +28-foot levels from the operating level (0-foot level). (Note: The glovebox train may be located on any level on either side of the cell. The +28-foot level has ample area available for the glovebox train; however, it may be desirable to locate the glovebox train elsewhere because of better shielding and protection to the outside environment.) The resin then would be calcined to create microspheres of neptunium dioxide powder of the required morphology. All waste solutions from this process would be transferred to the cell waste collection system. The off-gas from the glovebox train would be filtered with a high-efficiency particulate air filtering system and tied into the existing cell off-gas system (Kirkham 1999).

### **A.2.3.3 Neptunium-237 Target Fabrication**

Neptunium-237 target fabrication would be accomplished using the same target fabrication and assembly methods described for ORNL (Section A.1.3.3 and Wham et al. 1998). The proposed target design for ATR or HFIR consists of neptunium dioxide blended with aluminum powder, pressed into a target core, and clad with aluminum. The target used for ATR would be similar in appearance, but longer than the target that would be used for HFIR. (The ATR target length would be sized for the 1.2-meter [4-foot] active core length of ATR rather than the 51-centimeter [20-inch] active length of HFIR.) Target fabrication would be performed in an area adjacent to the neptunium glovebox train on the +28-foot level. The target fabrication operations would be performed in a shielded glovebox to provide adequate personnel protection from the varying dose rate. The target pins would be transferred to a shielded glovebox where they would be assembled into a target assembly. When completed and accepted, a target assembly would be removed from the glovebox, undergo required nondestructive assay analysis and verification, and be moved by elevator to the ground level and then by vehicle to the use location or to storage in the security area (CPP-651) (Kirkham 1999).

## **A.2.4 Postirradiation Processing Description**

Postirradiation processing of neptunium-237 targets would use a similar process to the one described for ORNL in Section A.1.4 and in more detail in the preconceptual design study (Wham et al. 1998). An exception to this process is that aluminum-clad target dissolution would use a one-step dissolution using a nitric acid-fluoroboric acid solution instead of the two-step process that would be used by ORNL. There is adequate shielded cell floor space in FDPF to do the recovery operation.

### **A.2.4.1 Target Dissolution**

Irradiated targets would be unloaded in the Fuel Storage Facility pool from the transfer cask. (This could be one of several approved existing casks used to transfer spent nuclear fuel.) The target container would be loaded under water into the transfer cart and moved up the incline channel into the FDPF cell. The targets may be placed in interim storage in the existing fuel storage ports in the cell or loaded directly into the dissolver. The dissolution would take place in a new 12.5-liter (3.3-gallon) vessel with an overflow into an existing dissolver vessel for continuous dissolution. Alternatively, a new vessel with about a 200-liter (53-gallon) capacity could be used for a batch process. This equipment would be located near the existing Train One

dissolver. Each aluminum-clad target from ATR or HFIR would be dissolved in 120 liters (31.7 gallons) of 7.5 M nitric acid and 0.15 M fluoroboric acid at 100 °C (212 °F). This dissolution results in the neptunium and plutonium being highly complexed with fluoride. Therefore, to perform a solvent extraction separation, the fluoride would have to be complexed to free the actinide ions. This could be accomplished by adding zirconium (IV) nitrate (Cook and Hill 1999).

At ORNL and Hanford, targets with a stainless steel or Zircaloy cladding (e.g., CLWR, FFTF, or high-energy accelerator targets) would be cut into pieces and leached with nitric acid or another suitable solution to dissolve the neptunium, plutonium, and fission products away from the insoluble cladding. The solution would be filtered and the undissolved cladding would be discarded as waste. At INEEL, the stainless steel- or Zircaloy-clad targets would be dissolved in a one-step process using a suitable solution.

#### **A.2.4.2 Plutonium Separation and Neptunium Recycling**

The process solution would be transferred by a positive displacement pump to the solvent extraction system, which would use centrifugal contactors. The solvent extraction system would be located at the south end of the cell near manipulators. Crucial components would be skid-mounted and within reach of manipulators. Because of the small flow rates needed, reagents would be fed into the separation system from small feed vessels located on the +28-foot level or in the operating corridor. Chemical makeup would take place in the existing makeup area with transfers to these smaller vessels. The acidic target solution would be treated with tributyl phosphate dissolved in normal paraffin hydrocarbon in three trains of centrifugal contactors and the plutonium and neptunium would be extracted into the tributyl phosphate/normal paraffin hydrocarbon phase.

Four separate transfer lines connect the FDPF hot cell with Building CPP-601, where the waste can be transferred to Building CPP-604. Building CPP-604 houses the Process Waste Evaporator, which would be used to evaporate the liquid waste for subsequent disposal. Aqueous waste streams would be collected in one of the existing complexer vessels, transferred to the existing product transfer vessel, and bled off to the Process Equipment Waste Evaporator system. An intercycle evaporator might be necessary to concentrate the first cycle strip before the second cycle. It would be located in the cell area south of and near the Train One dissolver or complexer vessel and suspended below the grating at the 0-foot level. The condensate would be routed to waste collection, with the concentrated solution going to the second solvent extraction cycle to separate neptunium and plutonium from each other. This extraction cycle also would use centrifugal contactors. The partitioned neptunium would go to the third solvent extraction cycle where it would be purified of any remaining fission products and stored for conversion to neptunium oxide (Section A.2.3). The plutonium-bearing solution would be purified by ion exchange and stored in the cell for subsequent processing to plutonium oxide.

#### **A.2.4.3 Preparation of Plutonium Oxide**

The conversion of plutonium nitrate solution to plutonium oxide would be accomplished in the same manner identified in the ORNL preconceptual design study for plutonium-238 production support operations (Wham et al. 1998). Plutonium oxide conversion would occur in shielded gloveboxes on the +28-foot level. The plutonium nitrate solution would be treated to adjust the plutonium oxidation state and then precipitated as an oxalate. The plutonium oxalate would be washed with dilute acid and calcined at the required temperature. The required oxygen-16 exchange would be done as part of the calcination step. The oxide would be packaged in a manner to assure maintenance of the desired degree of oxygen-16 exchange. The packaged material would undergo nondestructive assay analysis for accountability control and placed into storage pending packaging for shipment.

### **A.2.5 Plutonium-238 Storage Description**

Plutonium-238 oxide would be transferred to the security area in Building CPP-651 for storage prior to shipment to LANL. Storage quantities would be expected to be small, as shipments would be made on a regular basis.

## **A.3 FUELS AND MATERIALS EXAMINATION FACILITY**

### **A.3.1 Facility Description**

FMEF is located in the 400 Area on Hanford adjacent to the FFTF. Constructed in the late 1970s and early 1980s to perform fuel fabrication and development, and postirradiation examination of breeder reactor fuels, FMEF is being maintained in a condition suitable for a future mission. The building is clean and uncontaminated, as no nuclear materials have been introduced. FMEF has been well maintained for potential future missions (Hoyt et al. 1999).

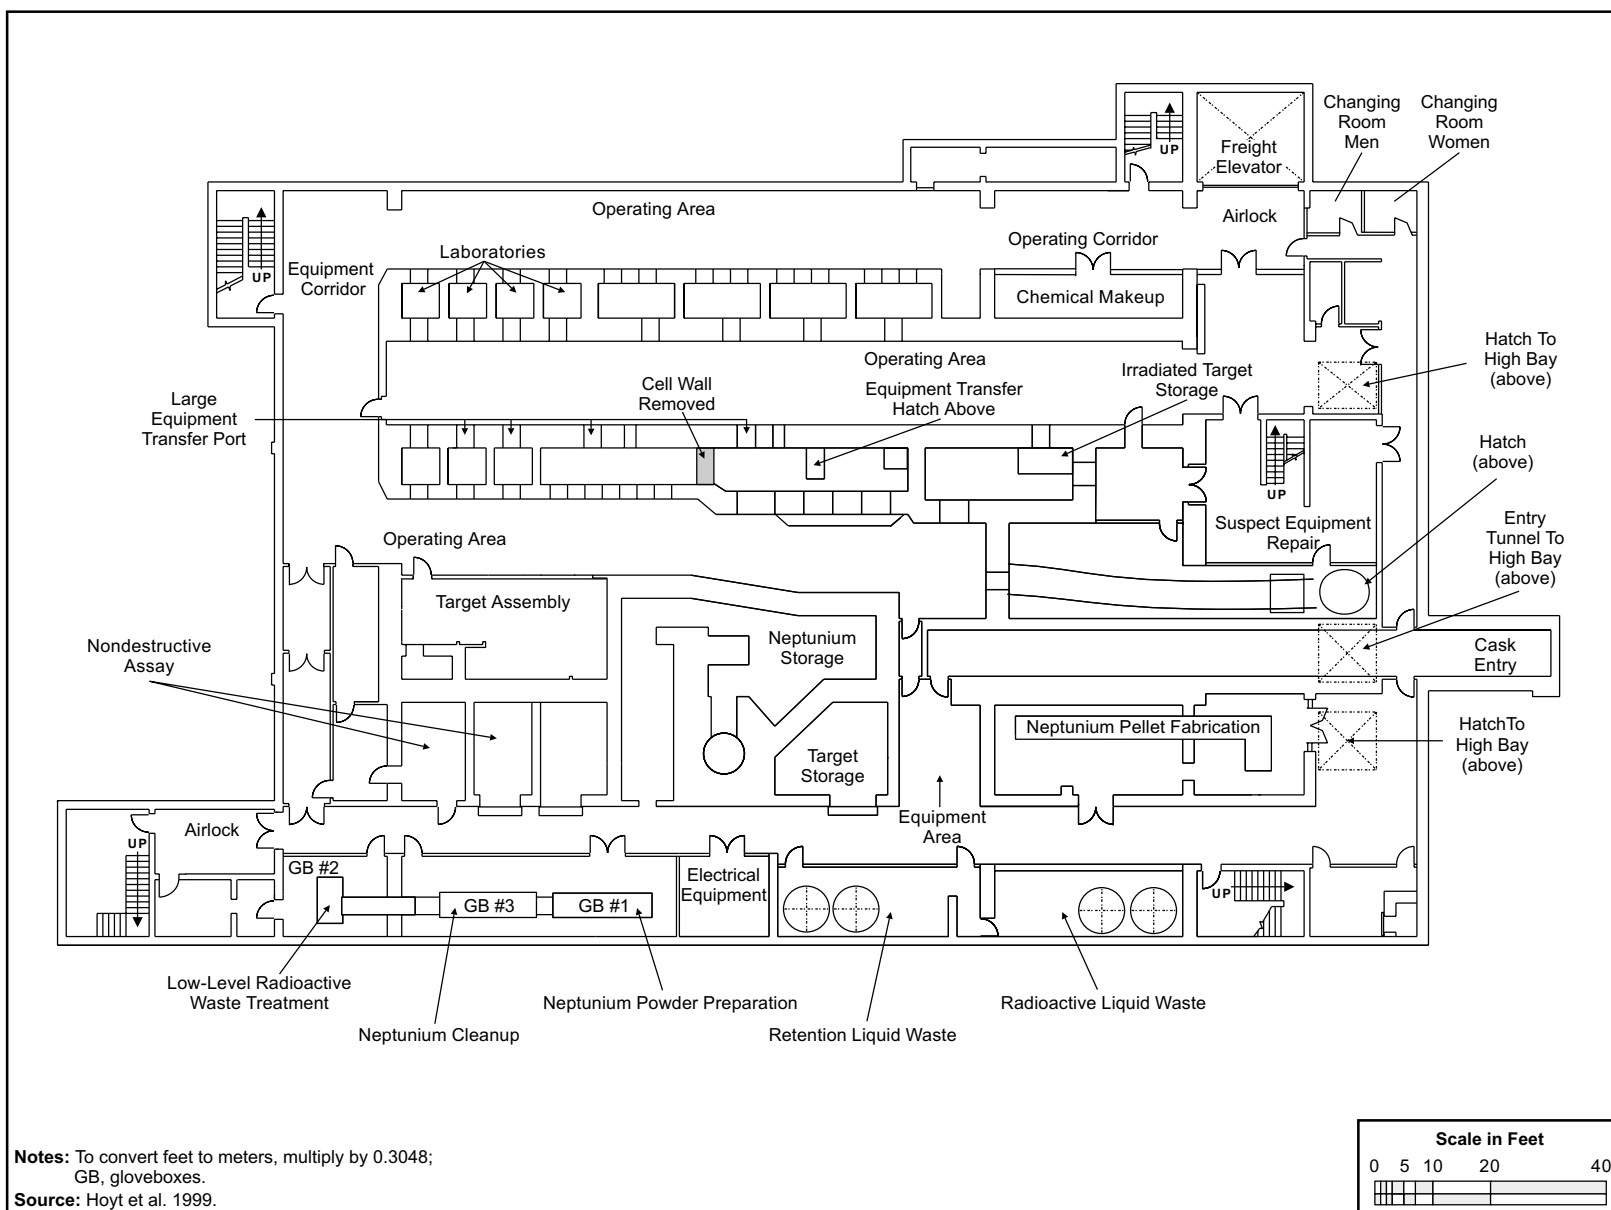

FMEF consists of the Process Building with an attached Mechanical Equipment Wing on the west side and an Entry Wing across the south side of the building. The Mechanical Equipment Wing houses facility utility and support equipment. The Entry Wing provides space for reactor fuel assembly, a lunchroom, change rooms, a security station, office space, and administrative support areas (DOE 1995).

The Process Building is 53.3 meters (175 feet) wide by 82.3 meters (270 feet) long and extends from 10.7 meters (35 feet) below grade to 29.7 meters (98 feet) above grade. The total operating space is approximately 17,400 square meters (188,000 square feet). The building is divided into six operating floors, or levels, which are identified by their elevation relative to ground level (DOE 1995). The Process Building contains several large interconnected hot cells and many smaller connected hot cells. However, most cranes, windows, and manipulators were not installed because construction was halted prior to completing work on the hot cell complex (Hoyt et al. 1999).

FMEF has the physical attributes required to process, handle, and store large quantities of special nuclear material. It is a massive, reinforced-concrete, hardened structure with safety-related equipment and systems, designed as a seismic Category 1 to withstand the Hanford design-basis earthquake, tornado, high-wind, and volcanic ashfall events. FMEF was also designed to meet the physical safeguards and security requirements for processing and storing Category 1 quantities of special nuclear material (Hoyt et al. 1999).

Ample space exists in FMEF for plutonium-238 production support, and numerous facility configurations are possible. In the absence of a detailed engineering study, it was decided that the process support would be located at the -35-foot level using the process support cells to house the irradiated target processing. This configuration also would contain this project, with its relatively modest requirements, to as few levels as possible. Alternative facility configurations can be found in the *Summary of Strategy for Implementing Plutonium-238 Production Support Activities in FMEF* (Hoyt et al. 1999). A floor plan of the -35-foot level is shown in **Figure A-7**.

The shipping and receiving bay located on the 0-foot level would be used to support the shipment and receipt of safe, secure trailer/SafeGuards Transports and irradiated target cask transporters. Additional facilities on the 0-foot level would be used to transfer irradiated targets into the storage area, decontaminate, and prepare equipment for maintenance, and package remote-handled solid waste for disposal. On the -17-foot level, the entry tunnel transporter would be used, as well as existing facility systems, as needed (Hoyt et al. 1999).

**Figure A-7 Layout of the Fuels and Materials Examination Facility**

The -35-foot level would house most of the processing and storage functions for plutonium-238 production. Neptunium-237 storage, target fabrication, and assembly would be located in rooms on the south side of the -35-foot level and include Rooms 112, 114, 124, and 128 (Hoyt et al. 1999).

The south bank of process support cells would be dedicated to target processing. Located on the -35-foot level, the 14 process support cells are arranged in two parallel rows along a horizontal transfer corridor. The process support cell complex is approximately 12.1 meters (40 feet) wide by 30.2 meters (99 feet) long. With the exception of Cell 146, each of the process support cells is 4.3 meters (14 feet) high and lined with stainless steel. Cell 146 extends to the 0-foot level and would be lined with stainless steel for the proposed project. The process support cell area is heavily shielded with either 122 centimeters (48 inches) or 81 centimeters (32 inches) of high-density concrete. Work in the cells would be performed using remotely operated equipment (DOE 1997).

Irradiated neptunium targets would be lowered through a hatch into Cell 147 and stored awaiting processing. Target processing would begin in Cell 146 and proceed through to plutonium-238 oxide conversion, storage, and loadout in Cell 142. The main target processing activities would occur in Cell 146. Existing wastewater collection systems would be used, and hot repair facilities also would be available on this level (Hoyt et al. 1999).

### **A.3.2 Neptunium Storage**

Neptunium-237 oxide would be shipped from SRS to Hanford in double-sealed containers loaded in Type B packages. At Hanford, it would be stored in a vertical tube rack located in Room 114 on the -35-foot level of FMEF. This room was designed earlier to contain the TRIGA (training, research, isotopes General Atomics) reactor spent nuclear fuel and would provide excellent shielding capabilities. The room would be modified to provide storage racks to hold the 3013 containers. Individual 3013 container transfers would be accomplished remotely with an overhead crane to minimize personnel exposure.

### **A.3.3 Neptunium-237 Target Fabrication Process Description**

The neptunium-237 target fabrication process used at Hanford would be similar to that described in Section A.1.3 for target fabrication in REDC at ORNL and in more detail in *Preconceptual Design Planning for Chemical Processing to Support Pu-238 Production* (Wham et al. 1998). In addition to the target designs considered in that document, Hanford could produce targets suitable for FFTF, a commercial reactor, or an accelerator. The latter target is significantly longer than those considered by ORNL. The target fabrication process would include neptunium-237 purification, neptunium oxide production, and target fabrication.

#### **A.3.3.1 Neptunium-237 Purification**

Neptunium-237 oxide retrieved from storage would be purified by dissolving the material in nitric acid and passing the neptunium-nitrate solution through a silica gel bed. During this process, the protactinium would adsorb onto the silica gel, leaving a neptunium nitrate solution that is free of protactinium-233.

For neptunium nitrate recovered from postirradiation processing, the protactinium-233 should have been removed in the solvent extraction process. However, if any additional purification were required, this would be achieved either through an anion exchange or an oxalate precipitation process. If oxalate precipitation were to be used, the neptunium oxalate precipitate would be washed to remove entrained liquor, and redissolved in nitric acid (Kirkham 1999).

### **A.3.3.2 Neptunium Oxide Production**

Conversion of the purified neptunium nitrate solution would be accomplished by adsorption of the neptunium on a cation resin bed. The resin then would be calcined to create microspheres of neptunium dioxide powder of the required morphology.

### **A.3.3.3 Neptunium-237 Target Fabrication**

Neptunium-237 target fabrication would be accomplished using the same target fabrication and assembly methods described for ORNL (Section A.1.3.3 and Wham et al. 1998). Target fabrication would be performed in FMEF Room 124, which would be modified by removing a wall in the area to create sufficient unencumbered floor space. The target fabrication operations would be performed in a shielded glovebox to provide adequate personnel protection from the varying dose rate. The target pins would be transferred to a shielded glovebox in Room 128, where they would be assembled into a target assembly. When completed and accepted, a target assembly would be removed from the glovebox, undergo required nondestructive assay analysis and verification, and be packaged for interim storage in Room 112 on the -35-foot level pending shipment to the reactor site. Fuel storage tubes located in the Fuel Assembly Area also could be used. Final selection would depend on protection requirements and the optimized building configuration (Kirkham 1999).

### **A.3.4 Postirradiation Processing Description**

Postirradiation processing of neptunium-237 targets would use the same process described for ORNL in Section A.1.4 and in more detail in the preconceptual design study (Wham et al. 1998). There is adequate shielded cell floor space on the -35-foot level in FMEF to do the recovery operation. The cells would have either 122 centimeters (48 inches) or 81 centimeters (32 inches) of high-density concrete as shielding walls.

#### **A.3.4.1 Target Dissolution**

The targets would be transferred from their storage position in Cell 147 to the dissolving cell, Cell 146. There the extraneous hardware would be removed and the target pins would be sheared into small segments and placed into a dissolver vessel located near the shear in Cell 146. Segments from targets irradiated in HFIR or ATR would be agitated in a caustic solution to dissolve the aluminum cladding and aluminum target diluent. After removal of the caustic aluminum waste solution, the neptunium target would be treated with nitric acid to dissolve the neptunium, plutonium, and fission products.

Stainless steel- or Zircaloy-clad targets irradiated in the CLWR, FFTF, or the high-energy accelerator would be cut into small pieces and leached with nitric acid or other suitable solution to dissolve the neptunium, plutonium, and fission products away from the insoluble cladding. The solution would be filtered and the undissolved cladding would be discarded as waste.

#### **A.3.4.2 Plutonium Separation and Neptunium Recycling**

The acidic target solution would be treated with tributyl phosphate dissolved in normal paraffin hydrocarbon in a mixer-settler vessel and the plutonium and neptunium would be extracted into the tributyl phosphate/normal paraffin hydrocarbon phase. The aqueous phase containing the mixed fission products would be treated again to remove trace quantities of neptunium and plutonium. Waste-handling equipment would be used to minimize the activity in low-level radioactive liquid waste and to stabilize solid waste into an acceptable waste form. This equipment would be included in the hot cells used for the chemical processing of irradiated targets for plutonium-238 production. The neptunium and plutonium would be extracted from the tributyl phosphate/normal paraffin hydrocarbon solution as an aqueous nitrate solution. The neptunium

and plutonium next would be separated from each other by additional solvent extraction and stored in their respective storage tanks pending further purification and conversion to oxides.

Alternatively, an anion exchange process may be added to the existing FMEF for separating fission products and purifying neptunium-237 and plutonium-238 from irradiated targets using a series of ion exchange columns.

#### **A.3.4.3 Preparation of Plutonium Oxide**

The conversion of plutonium nitrate solution to plutonium oxide would be accomplished in the same manner identified in the ORNL preconceptual design study for plutonium-238 production support operations (Wham et al. 1998). Plutonium oxide conversion would occur in Cell 144. The plutonium nitrate solution would be treated to adjust the plutonium oxidation state and then precipitated as an oxalate. The plutonium oxalate would be washed with dilute acid to remove entrained liquor, transferred to a boat and calcined at the required temperature. The required oxygen-16 exchange would be done as part of the calcination step. The oxide would be packaged in a manner to assure maintenance of the desired degree of oxygen-16 exchange. The packaged material would undergo nondestructive assay analysis for accountability control and then be placed into storage pending packaging for shipment.

#### **A.3.5 Plutonium-238 Storage Description**

Plutonium-238 oxide would be stored in racks in Cell 143 on the -35-foot level. Storage quantities would be expected to be small, since shipments would be made to LANL on a regular basis. Alternatively, the special nuclear material storage vault located in Rooms 428 and 429 on the 21-foot level could be used. In addition, any of several hardened rooms within FMEF could be modified to be vault-type rooms for storage of plutonium-238 oxide packaged in shipping containers awaiting shipment.

## Department of Energy

Washington, DC 20585

November 28, 2000

Dear Interested Party:

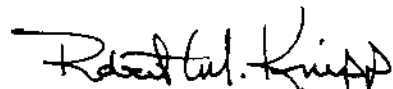

The *Final Programmatic Environmental Impact Statement for Accomplishing Expanded Civilian Nuclear Energy Research and Development and Isotope Production Missions in the United States, Including the Role of the Fast Flux Test Facility [NI PEIS]* (DOE/EIS-0310) has now been completed. This document has been prepared in accordance with the National Environmental Policy Act and reflects consideration of comments received on the draft NI PEIS released in July 2000.

The Department of Energy (DOE) is responsible for undertaking research and development activities related to development of nuclear power for civilian use, meeting the nuclear material needs of other Federal agencies, and ensuring the availability of isotopes for medical, industrial, and research applications. The NI PEIS presents an evaluation of the potential environmental impacts associated with the proposed expansion of the nuclear irradiation capabilities for accomplishing civilian nuclear energy research and development activities, accommodating the projected growth in demand for medical and industrial isotopes, and production of plutonium-238 to support future National Aeronautics and Space Administration space exploration missions. In addition to the "No Action" alternative, DOE evaluated other alternatives that include using operating facilities within the DOE complex, building a new research reactor, building one or two accelerators, and restarting the Fast Flux Test Facility (FFTF) that is currently in standby status. In addition, the NI PEIS includes an alternative to permanently deactivate FFTF.

After careful consideration of public comments, environmental impacts, and programmatic objectives, DOE's preferred alternative is to use its existing nuclear facility infrastructure to the extent possible to pursue the missions outlined in the PEIS, i.e., Alternative 2, Option 7. DOE would reestablish domestic production of plutonium-238, as needed, using the Advanced Test Reactor in Idaho and the High Flux Isotope Reactor in Tennessee and would process irradiated plutonium-238 targets at the Radiochemical Engineering Development Center in Tennessee. DOE would permanently deactivate FFTF under the "Preferred Alternative." Lack of clear commitments from likely users discouraged the Department from planning to build new facilities or to restart the FFTF. Further details on the Preferred Alternative can be found in the summary and in section 2.8 of volume 1 of this NI PEIS.

We appreciate your continued participation in this decision-making process.

Sincerely,

  
for William D. Magwood, IV, Director  
Office of Nuclear Energy, Science  
and Technology

**Abstract:** Under the authority of the Atomic Energy Act of 1954, as amended, the DOE is responsible for ensuring the availability of isotopes for medical, industrial and research applications, meeting the nuclear material needs of other Federal agencies, and undertaking research and development activities related to development of nuclear power for civilian use. To meet these responsibilities, DOE maintains nuclear infrastructure capabilities that support various missions. Current estimates for the future needs of medical and industrial isotopes, plutonium-238, and research requirements indicate that the current infrastructure may soon be insufficient to meet the projected demands. DOE proposes to enhance these capabilities to provide for: (1) production of isotopes for medical and industrial uses, (2) production of plutonium-238 for use in advanced radioisotope power systems for future National Aeronautics and Space Administration (NASA) space exploration missions, and (3) the Nation's nuclear research and development needs for civilian application.

This NI PEIS evaluates the environmental impacts of a No Action Alternative (maintaining status quo), four alternative strategies to accomplish this mission, and an alternative to permanently deactivate the Fast Flux Test Facility (FFTF), with no new missions. Alternatives 2, 3, and 4 also include permanent deactivation of FFTF. The alternatives are:

- No Action
- 1. Restart FFTF at Hanford, Washington
- 2. Use only existing operational facilities
- 3. Construct one or two new accelerators
- 4. Construct a new research reactor
- 5. Permanently deactivate FFTF (with no new missions)

The Preferred Alternative is Alternative 2, Option 7, Use Only Existing Operational Facilities. DOE would reestablish domestic production of plutonium-238, as needed, using the Advanced Test Reactor in Idaho and the High Flux Isotope Reactor in Tennessee, and would process irradiated plutonium-238 targets at the Radiochemical Engineering Development Center in Tennessee. DOE would permanently deactivate FFTF under the Preferred Alternative.

**Public Comments:** The Draft NI PEIS was issued for public review and comment on July 21, 2000. The comment period ended on September 18, 2000, although late comments were considered to the extent practicable. Public hearings were held to obtain comments on the Draft NI PEIS in Oak Ridge, Tennessee; Idaho Falls, Idaho; Hood River and Portland, Oregon; Seattle and Richland, Washington; and Arlington, Virginia. All comments were considered by DOE in preparing the Final NI PEIS, which also incorporates any new information received since issuance of the Draft NI PEIS. In response to comments on the Draft NI PEIS and as a result of information that was unavailable at the time of the issuance of the Draft PEIS, the Final PEIS contains revisions and new information, indicated by a sidebar in the margin. Volume 3 contains the comments received during the public review period for the Draft NI PEIS and DOE's responses to these comments. DOE will use the analyses presented in the Final NI PEIS as well as other information, including public input, costs, nonproliferation impacts, schedules, technical assurance, and other policy and programmatic objectives, in preparing the Record of Decision for accomplishing expanded civilian nuclear energy research and development and isotope production missions in the United States, including the role of FFTF. DOE will issue the Record of Decision no sooner than 30 days after the U.S. Environmental Protection Agency publishes a notice of availability of the Final NI PEIS in the Federal Register.

## Chapter 4

<b>Environmental Consequences</b>	4-1	
4.1	Introduction	4-1
4.2	No Action Alternative	4-3
4.2.1	No Action Alternative—Option 1	4-3
4.2.1.1	Importation of Plutonium-238 from Russia	4-3
4.2.1.2	Maintenance of FFTF in Standby	4-4
4.2.1.2.1	Land Resources	4-5
4.2.1.2.2	Noise	4-5
4.2.1.2.3	Air Quality	4-5
4.2.1.2.4	Water Resources	4-5
4.2.1.2.5	Geology and Soils	4-6
4.2.1.2.6	Ecological Resources	4-6
4.2.1.2.7	Cultural and Paleontological Resources	4-7
4.2.1.2.8	Socioeconomics	4-7
4.2.1.2.9	Public and Occupational Health and Safety—Normal Standby Activities	4-7
4.2.1.2.10	Public and Occupational Health and Safety—Standby Accidents	4-9
4.2.1.2.11	Public and Occupational Health and Safety—Transportation	4-10
4.2.1.2.12	Environmental Justice	4-10

	4.2.1.2.13	Waste Management	4-11
	4.2.1.2.14	Spent Nuclear Fuel Management	4-13
4.2.2		No Action Alternative—Option 2	4-13
	4.2.2.1	Importation of Plutonium-238 from Russia	4-13
	4.2.2.2	Transportation and Storage	4-13
	4.2.2.2.1	Land Resources	4-14
	4.2.2.2.2	Noise	4-14
	4.2.2.2.3	Air Quality	4-14
	4.2.2.2.4	Water Resources	4-14
	4.2.2.2.5	Geology and Soils	4-14
	4.2.2.2.6	Ecological Resources	4-15
	4.2.2.2.7	Cultural and Paleontological Resources	4-15
	4.2.2.2.8	Socioeconomics	4-15
	4.2.2.2.9	Public and Occupational Health and Safety—Normal Operations	4-15
	4.2.2.2.10	Public and Occupational Health and Safety—Facility Accidents	4-17
	4.2.2.2.11	Public and Occupational Health and Safety—Transportation	4-17
	4.2.2.2.12	Environmental Justice	4-18
	4.2.2.2.13	Waste Management	4-19
	4.2.2.3	Maintenance of FFTF in Standby	4-19
4.2.3		No Action Alternative—Option 3	4-19
	4.2.3.1	Importation of Plutonium-238 from Russia	4-19
	4.2.3.2	Transportation and Storage	4-19
	4.2.3.2.1	Land Resources	4-20
	4.2.3.2.2	Noise	4-20
	4.2.3.2.3	Air Quality	4-20
	4.2.3.2.4	Water Resources	4-20
	4.2.3.2.5	Geology and Soils	4-20
	4.2.3.2.6	Ecological Resources	4-21
	4.2.3.2.7	Cultural and Paleontological Resources	4-21
	4.2.3.2.8	Socioeconomics	4-21
	4.2.3.2.9	Public and Occupational Health and Safety—Normal Operations	4-22
	4.2.3.2.10	Public and Occupational Health and Safety—Facility Accidents	4-23
	4.2.3.2.11	Public and Occupational Health and Safety—Transportation	4-23
	4.2.3.2.12	Environmental Justice	4-24
	4.2.3.2.13	Waste Management	4-24
	4.2.3.3	Maintenance of FFTF in Standby	4-25
4.2.4		No Action Alternative—Option 4	4-25
	4.2.4.1	Importation of Plutonium-238 from Russia	4-25
	4.2.4.2	Transportation and Storage	4-25
	4.2.4.2.1	Land Resources	4-25
	4.2.4.2.2	Noise	4-25
	4.2.4.2.3	Air Quality	4-26
	4.2.4.2.4	Water Resources	4-26
	4.2.4.2.5	Geology and Soils	4-26
	4.2.4.2.6	Ecological Resources	4-26
	4.2.4.2.7	Cultural and Paleontological Resources	4-27

	4.2.4.2.8	Socioeconomics	4-27
	4.2.4.2.9	Public and Occupational Health and Safety—Normal Operations	4-27
	4.2.4.2.10	Public and Occupational Health and Safety—Facility Accidents	4-29
	4.2.4.2.11	Public and Occupational Health and Safety—Transportation	4-29
	4.2.4.2.12	Environmental Justice	4-29
	4.2.4.2.13	Waste Management	4-30
	4.2.4.3	Maintenance of FFTF in Standby	4-30
4.3	Alternative 1—Restart FFTF		4-31
	4.3.1	Alternative 1 (Restart FFTF)—Option 1	4-32
	4.3.1.1	Operations and Transportation	4-33
	4.3.1.1.1	Land Resources	4-33
	4.3.1.1.2	Noise	4-34
	4.3.1.1.3	Air Quality	4-34
	4.3.1.1.4	Water Resources	4-36
	4.3.1.1.5	Geology and Soils	4-38
	4.3.1.1.6	Ecological Resources	4-38
	4.3.1.1.7	Cultural and Paleontological Resources	4-39
	4.3.1.1.8	Socioeconomics	4-40
	4.3.1.1.9	Public and Occupational Health and Safety—Normal Operations	4-41
	4.3.1.1.10	Public and Occupational Health and Safety—Facility Accidents	4-44
	4.3.1.1.11	Public and Occupational Health and Safety—Transportation	4-48
	4.3.1.1.12	Environmental Justice	4-49
	4.3.1.1.13	Waste Management	4-50
	4.3.1.1.14	Spent Nuclear Fuel Management	4-55
	4.3.2	Alternative 1 (Restart FFTF)—Option 2	4-57
	4.3.2.1	Operations and Transportation	4-57
	4.3.2.1.1	Land Resources	4-58
	4.3.2.1.2	Noise	4-58
	4.3.2.1.3	Air Quality	4-59
	4.3.2.1.4	Water Resources	4-60
	4.3.2.1.5	Geology and Soils	4-60
	4.3.2.1.6	Ecological Resources	4-61
	4.3.2.1.7	Cultural and Paleontological Resources	4-61
	4.3.2.1.8	Socioeconomics	4-62
	4.3.2.1.9	Public and Occupational Health and Safety—Normal Operations	4-62
	4.3.2.1.10	Public and Occupational Health and Safety—Facility Accidents	4-64
	4.3.2.1.11	Public and Occupational Health and Safety—Transportation	4-69
	4.3.2.1.12	Environmental Justice	4-70
	4.3.2.1.13	Waste Management	4-71
	4.3.2.1.14	Spent Nuclear Fuel Management	4-74
	4.3.3	Alternative 1 (Restart FFTF)—Option 3	4-74
	4.3.3.1	Operations and Transportation	4-74
	4.3.3.1.1	Land Resources	4-75
	4.3.3.1.2	Noise	4-75

	4.3.3.1.3	Air Quality . . . . .	4-75
	4.3.3.1.4	Water Resources . . . . .	4-76
	4.3.3.1.5	Geology and Soils . . . . .	4-77
	4.3.3.1.6	Ecological Resources . . . . .	4-78
	4.3.3.1.7	Cultural and Paleontological Resources . . . . .	4-78
	4.3.3.1.8	Socioeconomics . . . . .	4-78
	4.3.3.1.9	Public and Occupational Health and Safety—Normal Operations . . . . .	4-79
	4.3.3.1.10	Public and Occupational Health and Safety—Facility Accidents . . . . .	4-81
	4.3.3.1.11	Public and Occupational Health and Safety—Transportation . . . . .	4-85
	4.3.3.1.12	Environmental Justice . . . . .	4-86
	4.3.3.1.13	Waste Management . . . . .	4-87
	4.3.3.1.14	Spent Nuclear Fuel Management . . . . .	4-90
4.3.4	Alternative 1 (Restart FFTF)—Option 4 . . . . .		4-90
	4.3.4.1	Operations and Transportation . . . . .	4-90
	4.3.4.1.1	Land Resources . . . . .	4-90
	4.3.4.1.2	Noise . . . . .	4-91
	4.3.4.1.3	Air Quality . . . . .	4-91
	4.3.4.1.4	Water Resources . . . . .	4-91
	4.3.4.1.5	Geology and Soils . . . . .	4-91
	4.3.4.1.6	Ecological Resources . . . . .	4-92
	4.3.4.1.7	Cultural and Paleontological Resources . . . . .	4-92
	4.3.4.1.8	Socioeconomics . . . . .	4-92
	4.3.4.1.9	Public and Occupational Health and Safety—Normal Operations . . . . .	4-92
	4.3.4.1.10	Public and Occupational Health and Safety—Facility Accidents . . . . .	4-92
	4.3.4.1.11	Public and Occupational Health and Safety—Transportation . . . . .	4-93
	4.3.4.1.12	Environmental Justice . . . . .	4-96
	4.3.4.1.13	Waste Management . . . . .	4-96
	4.3.4.1.14	Spent Nuclear Fuel Management . . . . .	4-97
4.3.5	Alternative 1 (Restart FFTF)—Option 5 . . . . .		4-97
	4.3.5.1	Operations and Transportation . . . . .	4-97
	4.3.5.1.1	Land Resources . . . . .	4-97
	4.3.5.1.2	Noise . . . . .	4-98
	4.3.5.1.3	Air Quality . . . . .	4-98
	4.3.5.1.4	Water Resources . . . . .	4-98
	4.3.5.1.5	Geology and Soils . . . . .	4-98
	4.3.5.1.6	Ecological Resources . . . . .	4-98
	4.3.5.1.7	Cultural and Paleontological Resources . . . . .	4-99
	4.3.5.1.8	Socioeconomics . . . . .	4-99
	4.3.5.1.9	Public and Occupational Health and Safety—Normal Operations . . . . .	4-99
	4.3.5.1.10	Public and Occupational Health and Safety—Facility Accidents . . . . .	4-99
	4.3.5.1.11	Public and Occupational Health and Safety—Transportation . . . . .	4-102
	4.3.5.1.12	Environmental Justice . . . . .	4-103
	4.3.5.1.13	Waste Management . . . . .	4-103
	4.3.5.1.14	Spent Nuclear Fuel Management . . . . .	4-103

4.3.6	Alternative 1 (Restart FFTF)—Option 6	4-103
4.3.6.1	Operations and Transportation	4-104
4.3.6.1.1	Land Resources	4-104
4.3.6.1.2	Noise	4-104
4.3.6.1.3	Air Quality	4-104
4.3.6.1.4	Water Resources	4-104
4.3.6.1.5	Geology and Soils	4-104
4.3.6.1.6	Ecological Resources	4-105
4.3.6.1.7	Cultural and Paleontological Resources	4-105
4.3.6.1.8	Socioeconomics	4-105
4.3.6.1.9	Public and Occupational Health and Safety—Normal Operations	4-105
4.3.6.1.10	Public and Occupational Health and Safety—Facility Accidents	4-105
4.3.6.1.11	Public and Occupational Health and Safety—Transportation	4-108
4.3.6.1.12	Environmental Justice	4-108
4.3.6.1.13	Waste Management	4-109
4.3.6.1.14	Spent Nuclear Fuel Management	4-109
4.4	Alternative 2—Use Only Existing Operational Facilities	4-110
4.4.1	Alternative 2 (Use Only Existing Operational Facilities)—Option 1	4-111
4.4.1.1	Operations and Transportation	4-112
4.4.1.1.1	Land Resources	4-112
4.4.1.1.2	Noise	4-112
4.4.1.1.3	Air Quality	4-113
4.4.1.1.4	Water Resources	4-113
4.4.1.1.5	Geology and Soils	4-114
4.4.1.1.6	Ecological Resources	4-114
4.4.1.1.7	Cultural and Paleontological Resources	4-115
4.4.1.1.8	Socioeconomics	4-115
4.4.1.1.9	Public and Occupational Health and Safety—Normal Operations	4-115
4.4.1.1.10	Public and Occupational Health and Safety—Facility Accidents	4-118
4.4.1.1.11	Public and Occupational Health and Safety—Transportation	4-121
4.4.1.1.12	Environmental Justice	4-121
4.4.1.1.13	Waste Management	4-122
4.4.1.1.14	Spent Nuclear Fuel Management	4-122
4.4.1.2	Permanent Deactivation of FFTF	4-122
4.4.1.2.1	Land Resources	4-123
4.4.1.2.2	Noise	4-123
4.4.1.2.3	Air Quality	4-123
4.4.1.2.4	Water Resources	4-123
4.4.1.2.5	Geology and Soils	4-124
4.4.1.2.6	Ecological Resources	4-124
4.4.1.2.7	Cultural and Paleontological Resources	4-124
4.4.1.2.8	Socioeconomics	4-125
4.4.1.2.9	Public and Occupational Health and Safety—Normal Deactivation Activities	4-125

	4.4.1.2.10	Public and Occupational Health and Safety—Deactivation Accidents . . . . .	4-126
	4.4.1.2.11	Public and Occupational Health and Safety—Transportation . . . . .	4-128
	4.4.1.2.12	Environmental Justice . . . . .	4-128
	4.4.1.2.13	Waste Management . . . . .	4-128
	4.4.1.2.14	Spent Nuclear Fuel Management . . . . .	4-128
4.4.2	Alternative 2 (Use Only Existing Operational Facilities)—Option 2 . . . . .		4-129
4.4.2.1	Operations and Transportation . . . . .		4-129
	4.4.2.1.1	Land Resources . . . . .	4-129
	4.4.2.1.2	Noise . . . . .	4-129
	4.4.2.1.3	Air Quality . . . . .	4-130
	4.4.2.1.4	Water Resources . . . . .	4-131
	4.4.2.1.5	Geology and Soils . . . . .	4-131
	4.4.2.1.6	Ecological Resources . . . . .	4-131
	4.4.2.1.7	Cultural and Paleontological Resources . . . . .	4-132
	4.4.2.1.8	Socioeconomics . . . . .	4-132
	4.4.2.1.9	Public and Occupational Health and Safety—Normal Operations . . . . .	4-132
	4.4.2.1.10	Public and Occupational Health and Safety—Facility Accidents . . . . .	4-134
	4.4.2.1.11	Public and Occupational Health and Safety—Transportation . . . . .	4-138
	4.4.2.1.12	Environmental Justice . . . . .	4-139
	4.4.2.1.13	Waste Management . . . . .	4-139
	4.4.2.1.14	Spent Nuclear Fuel Management . . . . .	4-139
	4.4.2.2	Permanent Deactivation of FFTF . . . . .	4-140
4.4.3	Alternative 2 (Use Only Existing Operational Facilities)—Option 3 . . . . .		4-140
4.4.3.1	Operations and Transportation . . . . .		4-140
	4.4.3.1.1	Land Resources . . . . .	4-140
	4.4.3.1.2	Noise . . . . .	4-140
	4.4.3.1.3	Air Quality . . . . .	4-141
	4.4.3.1.4	Water Resources . . . . .	4-142
	4.4.3.1.5	Geology and Soils . . . . .	4-142
	4.4.3.1.6	Ecological Resources . . . . .	4-143
	4.4.3.1.7	Cultural and Paleontological Resources . . . . .	4-143
	4.4.3.1.8	Socioeconomics . . . . .	4-144
	4.4.3.1.9	Public and Occupational Health and Safety—Normal Operations . . . . .	4-144
	4.4.3.1.10	Public and Occupational Health and Safety—Facility Accidents . . . . .	4-147
	4.4.3.1.11	Public and Occupational Health and Safety—Transportation . . . . .	4-151

	4.6.2.2.12	Environmental Justice	4-298
	4.6.2.2.13	Waste Management	4-298
	4.6.2.2.14	Spent Nuclear Fuel Management	4-298
	4.6.2.3	Decontamination and Decommissioning of the Research Reactor and Support Facility	4-298
	4.6.2.4	Permanent Deactivation of FFTF	4-299
4.6.3		Alternative 4 (Construct New Research Reactor)—Option 3	4-299
	4.6.3.1	Construction of the New Research Reactor and Support Facility	4-299
	4.6.3.2	Operations and Transportation	4-299
	4.6.3.2.1	Land Resources	4-299
	4.6.3.2.2	Noise	4-300
	4.6.3.2.3	Air Quality	4-300
	4.6.3.2.4	Water Resources	4-300
	4.6.3.2.5	Geology and Soils	4-301
	4.6.3.2.6	Ecological Resources	4-301
	4.6.3.2.7	Cultural and Paleontological Resources	4-301
	4.6.3.2.8	Socioeconomics	4-302

	4.6.3.2.9	Public and Occupational Health and Safety—Normal Operations	4–302
	4.6.3.2.10	Public and Occupational Health and Safety—Facility Accidents	4–304
	4.6.3.2.11	Public and Occupational Health and Safety—Transportation	4–306
	4.6.3.2.12	Environmental Justice	4–307
	4.6.3.2.13	Waste Management	4–308
	4.6.3.2.14	Spent Nuclear Fuel Management	4–308
	4.6.3.3	Decontamination and Decommissioning of the Research Reactor and Support Facility	4–308
	4.6.3.4	Permanent Deactivation of FFTF	4–308
4.7		Alternative 5—Permanently Deactivate FFTF (with No New Missions)	4–309
4.8		Cumulative Impacts	4–310
	4.8.1	Cumulative Impacts at ORR	4–313
	4.8.1.1	Resource Requirements	4–313
	4.8.1.2	Air Quality	4–314
	4.8.1.3	Public and Occupational Health and Safety—Normal Operations	4–314
	4.8.1.4	Waste Management	4–315
	4.8.2	Cumulative Impacts at INEEL	4–315
	4.8.2.1	Resource Requirements	4–316
	4.8.2.2	Air Quality	4–317
	4.8.2.3	Public and Occupational Health and Safety—Normal Operations	4–318
	4.8.2.4	Waste Management	4–319
	4.8.3	Cumulative Impacts at Hanford	4–320
	4.8.3.1	Resource Requirements	4–320
	4.8.3.2	Air Quality	4–321
	4.8.3.3	Public and Occupational Health and Safety—Normal Operations	4–321
	4.8.3.4	Waste Management	4–323
	4.8.3.5	Spent Nuclear Fuel Management	4–324
	4.8.4	Cumulative Impacts at the Generic CLWR Site	4–325
	4.8.5	Cumulative Impacts at the New Accelerator(s) Generic DOE Site	4–325
	4.8.6	Cumulative Impacts at the New Research Reactor Generic DOE Site	4–325
	4.8.7	Cumulative Impacts of Transportation	4–325
4.9		Mitigation Measures	4–326
4.10		Unavoidable Adverse Environmental Impacts	4–327
4.11		Relationship Between Short-Term Use of the Environment and Long-Term Productivity	4–328
4.12		Irreversible and Irrecoverable Commitments of Resources	4–329
4.13		Industrial Safety	4–330
4.14		References	4–331

## Chapter 5

		<b>Applicable Laws, Regulations, and Other Requirements</b>	5–1
5.1		Environmental, Safety, and Health Laws, Regulations, Executive Orders, and U.S. Department of Energy Orders	5–1
	5.1.1	Federal Environmental, Safety, and Health Laws and Regulations	5–2
	5.1.2	Environmental, Safety, and Health Executive Orders	5–12
	5.1.3	DOE Environmental, Safety, and Health Regulations and Orders	5–14
	5.1.4	State Environmental Laws, Regulations, and Agreements	5–16

5.2	Radioactive Material Packaging and Transportation Regulations .....	5-18
5.3	Emergency Management and Response Laws, Regulations, and Executive Orders .....	5-19
5.3.1	Emergency Management and Response Federal Laws .....	5-19
5.3.2	Emergency Management and Response Federal Regulations .....	5-20
5.3.3	Emergency Response and Management Executive Orders .....	5-20
5.4	Consultations with Federal, State, and Local Agencies and Federally Recognized Native American Groups .....	5-21
 <b>Chapter 6</b>		
	<b>List of Preparers</b> .....	6-1
 <b>Chapter 7</b>		
	<b>Distribution List</b> .....	7-1
 <b>Chapter 8</b>		
	<b>Glossary</b> .....	8-1
 <b>Chapter 9</b>		
	<b>Index</b> .....	9-1

## List of Figures

### Volume 1

Figure 2–1	Chemical Processing Flowsheet for Irradiated Neptunium-237 Target Processing . . . . .	2–8
Figure 2–2	Fast Flux Test Facility . . . . .	2–9
Figure 2–3	FFTF Complex . . . . .	2–11
Figure 2–4	Cutaway of the Reactor Containment Building . . . . .	2–12
Figure 2–5	Vertical Cross Section of the ATR Vessel . . . . .	2–17
Figure 2–6	Plan View (Cross Section) of ATR . . . . .	2–18
Figure 2–7	Typical Transuranic Isotope Production Target . . . . .	2–20
Figure 2–8	Plan View (Cross Section) of HFIR . . . . .	2–23
Figure 2–9	Plan View (Cross Section) of a Generic CLWR . . . . .	2–25
Figure 2–10	CLWR Fuel Assembly . . . . .	2–26

## List of Tables

### Volume 1

Table 1–1	Representative Radioisotopes . . . . .	1–6
Table 2–1	NI PEIS Alternatives and Options . . . . .	2–3
Table 2–2	Examples of HFIR-Produced Radioisotopes of Current Interest for Therapy . . . . .	2–23
Table 2–3	Alternatives and Options Matrix . . . . .	2–58
Table 2–4	Irradiation Facilities Considered but Dismissed from Further Evaluation . . . . .	2–67
Table 2–5	Processing Facilities Considered but Dismissed from Further Evaluation . . . . .	2–70
Table 2–6	Comparison Among Alternatives: Impacts on Occupational and Public Health and Safety from Baseline Conditions . . . . .	2–72
Table 2–7	Comparison of Waste and Spent Nuclear Fuel Generation Among Alternatives . . . . .	2–78
Table 2–8	Air Pollutant Concentrations Resulting from Construction of a High-Energy Accelerator Under All Options of Alternative 3 . . . . .	2–81
Table 2–9	Air Pollutant Concentrations Resulting from Construction of a New Research Reactor Under All Options of Alternative 4 . . . . .	2–82
Table 2–10	Air Pollutant Concentrations Expected from Operation of the Radiochemical Engineering Development Center Under Alternatives 1 Through 4 . . . . .	2–83
Table 2–11	Air Pollutant Concentrations Expected from Operation of the Fluorinel Dissolution Process Facility Under Alternatives 1 Through 4 . . . . .	2–83
Table 2–12	Comparison Among Alternatives: Impacts on Criteria Air Pollutants at the Hanford Site . . . . .	2–84
Table 2–13	Air Pollutant Concentrations Expected from Operation of the Emergency Diesel Generators for the High-Energy Accelerator . . . . .	2–85
Table 2–14	Air Pollutant Concentrations Expected from Operation of the Emergency Diesel Generator for the New Research Reactor . . . . .	2–86
Table 2–15	Comparisons Among Alternatives: Change in Direct Jobs Under the Nuclear Infrastructure Alternatives . . . . .	2–87
Table 2–16	Comparison Among Alternatives: Impacts of Transportation on Occupational and Public Health and Safety . . . . .	2–88
Table 2–17	Average Occupational Total Recordable Cases and Fatality Rates . . . . .	2–94
Table 2–18	Industrial Safety Impacts from Construction and Operation . . . . .	2–94
Table 2–19	Medical Isotopes and Their Means of Production . . . . .	2–101

Table 3–1	General Regions of Influence for the Affected Environment . . . . .	3–2
Table 3–2	Comparison of Modeled Ambient Air Concentrations from Oak Ridge Reservation Sources with Most Stringent Applicable Standards or Guidelines, 1998 . . . . .	3–8
Table 3–3	Comparison of Modeled Ambient Air Concentrations from Sources at HFIR and REDC with Most Stringent Applicable Standards or Guidelines . . . . .	3–10
Table 3–4	The Modified Mercalli Intensity Scale of 1931, with Approximate Correlations to Richter Scale and Maximum Ground Acceleration . . . . .	3–19
Table 3–5	Distribution of Employees by Place of Residence in the ORR Region of Influence, 1998 . . . . .	3–27
Table 3–6	Sources of Radiation Exposure to Individuals in the ORR Vicinity Unrelated to ORR Operations . . . . .	3–29
Table 3–7	Radiation Doses to the Public from ORR Normal Operations in 1998 . . . . .	3–29
Table 3–8	Radiation Doses to Workers from ORR Normal Operations in 1998 . . . . .	3–30
Table 3–9	Radiation Doses to the Public from Normal Operations at HFIR and REDC in 1999 . . . . .	3–31
Table 3–10	Radiation Doses to Workers from HFIR and REDC Normal Operations . . . . .	3–31
Table 3–11	Waste Generation Rates and Inventories at ORR and ORNL . . . . .	3–35
Table 3–12	Waste Generation Rates at HFIR and REDC . . . . .	3–35
Table 3–13	Waste Management Capabilities at ORR . . . . .	3–36
Table 3–14	Waste Management PEIS Records of Decision Affecting ORR . . . . .	3–42
Table 3–15	Comparison of Modeled Ambient Air Concentrations from INEEL Sources with Most Stringent Applicable Standards or Guidelines . . . . .	3–49
Table 3–16	Prevention of Significant Deterioration Increment Consumption at Craters of the Moon Wilderness (Class I) Area by Existing (1996) and Projected Sources Subject to Prevention of Significant Deterioration Regulation . . . . .	3–50
Table 3–17	Prevention of Significant Deterioration Increment Consumption at Class II Areas by Existing (1996) and Projected Sources Subject to Prevention of Significant Deterioration Regulation at INEEL . . . . .	3–50
Table 3–18	Comparison of Modeled Ambient Air Concentrations from ATR Sources with Most Stringent Applicable Standards or Guidelines . . . . .	3–51
Table 3–19	Distribution of Employees by Place of Residence in the INEEL Region of Influence, 1997 . . . . .	3–72
Table 3–20	Sources of Radiation Exposure to Individuals in the INEEL Vicinity Unrelated to INEEL Operations . . . . .	3–75
Table 3–21	Radiation Doses to the Public from INEEL Normal Operations in 1998 . . . . .	3–75
Table 3–22	Radiation Doses to Workers from INEEL Normal Operations in 1998 . . . . .	3–76
Table 3–23	Radiation Doses to the Public from Normal Operations at ATR and ATR Critical Facility in 1999 . . . . .	3–77

	Table 3–24	Radiation Doses to Workers from the Test Reactor Area and ATR Normal Operations in 1998 . . . . .	3–77

## List of Acronyms

AAA	Advanced Accelerator Applications
ALARA	as low as is reasonably achievable
ALOHA	Area Locations of Hazardous Atmospheres
ATR	Advanced Test Reactor
ATW	Accelerator Transmutation of Waste
BEIR	Biological Effects of Ionizing Radiation
BLIP	Brookhaven LINAC Isotope Producer
CEQ	Council on Environmental Quality
CERCLA	Comprehensive Environmental Response, Compensation, and Liability Act
CFR	Code of Federal Regulations
CLWR	commercial light water reactor
CPP-651	Chemical Processing Plant 651 (Building CPP-651)
dBA	decibels A-weighted
DOD	U.S. Department of Defense
DOE	U.S. Department of Energy
DOT	U.S. Department of Transportation
EIS	environmental impact statement
EPA	U.S. Environmental Protection Agency
FDPF	Fluorinel Dissolution Process Facility
FFTF	Fast Flux Test Facility
FMEF	Fuels and Materials Examination Facility
FONSI	Finding of No Significant Impact
FPF	Fuel Processing Facility
FR	Federal Register
g	gravitational acceleration
Hanford	Hanford Site
HB	horizontal beam
HEPA	high-efficiency particulate air (filter)
HFIR	High Flux Isotope Reactor
HVAC	heating, ventilating, and air conditioning
I <sup>4</sup>	International Isotopes Idaho, Inc.
IAEA	International Atomic Energy Agency
IEM	Interim Examination and Maintenance Cell
INEEL	Idaho National Engineering and Environmental Laboratory
INTEC	Idaho Nuclear Technology and Engineering Center
IPF	Isotope Production Facility
ISC3	Industrial Source Complex
ISCST3	Industrial Source Complex (short-term model)
LANL	Los Alamos National Laboratory
LANSCE	Los Alamos Neutron Science Center
LCF	latent cancer fatality
LINAC	linear accelerator
MASF	Maintenance and Storage Facility
NAAQS	National Ambient Air Quality Standards
NASA	National Aeronautics and Space Administration
NEPA	National Environmental Policy Act
NEPO	Nuclear Energy Plant Optimization

NERAC	Nuclear Energy Research Advisory Committee
NERI	Nuclear Energy Research Initiative
NESHAPs	National Emissions Standards for Hazardous Air Pollutants
NI PEIS	<i>Final Programmatic Environmental Impact Statement for Accomplishing Expanded Civilian Nuclear Energy Research and Development and Isotope Production Missions in the United States, Including the Role of the Fast Flux Test Facility</i>
NPDES	National Pollutant Discharge Elimination System
NRC	U.S. Nuclear Regulatory Commission
ORNL	Oak Ridge National Laboratory
ORR	Oak Ridge Reservation
OSHA	Occupational Safety and Health Administration
PCAST	President's Committee of Advisors on Science and Technology
PEIS	programmatic environmental impact statement
P.L.	Public Law
PM <sub>2.5</sub>	particulate matter with an aerodynamic diameter less than or equal 2.5 microns
PM <sub>10</sub>	particulate matter with an aerodynamic diameter less than or equal to 10 microns
PNNL	Pacific Northwest National Laboratory
RCRA	Resource Conservation and Recovery Act
REDC	Radiochemical Engineering Development Center
RPL	Radiochemical Processing Laboratory
SNL	Sandia National Laboratories
SRPS	Stirling radioisotope power systems
SRS	Savannah River Site
SRTG	Small Radioisotope Thermoelectric Generator
SST/SGT	safe, secure trailer/SafeGuards Transport
TEDF	Treated Effluent Disposal Facility
TRIGA	training, research, isotopes General Atomics (reactor)
UZrH	uranium-zirconium-hydride
U.S.C.	United States Code
USGS	U.S. Geological Survey
WAG	waste area grouping
WIPP	Waste Isolation Pilot Plant
Y-12	Y-12 Plant

# Chapter 1

## Introduction

This *Final Programmatic Environmental Impact Statement for Accomplishing Expanded Civilian Nuclear Energy Research and Development and Isotope Production Missions in the United States, Including the Role of the Fast Flux Test Facility* identifies reasonable alternatives and potential impacts associated with the proposed action to enhance the U.S. Department of Energy's existing nuclear facility infrastructure for: (1) the production of isotopes for medical, research, and industrial uses, (2) the production of plutonium-238 for use in advanced radioisotope power systems for future space missions, and (3) supporting the Nation's civilian nuclear energy research and development needs.

### 1.1 BACKGROUND

Under the authority of the Atomic Energy Act of 1954, as amended, the U.S. Department of Energy (DOE) is responsible for ensuring the availability of isotopes for medical, industrial, and research applications; meeting the nuclear material needs of other Federal agencies; and undertaking research and development activities related to development of nuclear power for civilian use.

To meet these responsibilities, DOE maintains nuclear infrastructure capabilities that support various missions in areas such as nuclear materials production and testing, and research and development activities related to civilian applications of nuclear power. These infrastructure capabilities include research and test facilities such as research reactors and accelerators used for steady-state neutron irradiation of materials to produce radionuclides, as well as shielded "hot cell" and glovebox facilities used to prepare materials for testing and/or to handle postirradiation materials. An additional component of this infrastructure is the highly trained workforce that specializes in performing complex tasks that have been learned and mastered over the life of these facilities.

Over the years, DOE's nuclear facility infrastructure has diminished because of the shutdown of facilities; recent examples are the High Flux Beam Reactor at Brookhaven National Laboratory, New York, and the Cyclotron Facility at Oak Ridge National Laboratory (ORNL), Tennessee. This, in turn, has hampered DOE's ability to satisfy increasing demands in various mission areas. To continue to maintain sufficient irradiation facilities to meet its obligations under the Atomic Energy Act, DOE has assessed the need for expansion of its existing nuclear infrastructure in light of its commitments to ongoing programs, its commitments to other agencies for nuclear materials support, and its role in supporting civilian nuclear energy research and development programs to maintain the viability of civilian nuclear power as one of the major energy sources available to the United States.

### 1.2 PURPOSE AND NEED FOR AGENCY ACTION

The Nuclear Energy Research Advisory Committee (NERAC) was established in 1998 by DOE in accordance with the Federal Advisory Committee Act to provide independent, expert advice on complex science and technical issues that arise in the planning, management, and implementation of DOE's civilian nuclear energy research programs. The chairman of NERAC has informed the Secretary of Energy that:

- "There is an urgent sense that the nation must rapidly restore an adequate investment in basic and applied research in nuclear energy if it is to sustain a viable United States capability in the 21<sup>st</sup> Century."
- "[T]he most important role for DOE [Office of Nuclear Energy, Science and Technology] in the nuclear energy area at the present time is to ensure that the education system and its facility infrastructure are in good shape."

- “Of particular need over the longer term are dependable sources of research isotopes and reactor facilities providing high volume flux irradiation for nuclear fuels and materials testing” (Duderstadt 2000).

Under the guidance of NERAC, DOE has completed an internal assessment of its existing nuclear facility infrastructure capabilities. This *Nuclear Science and Technology Infrastructure Roadmap* evaluates the existing DOE infrastructure and identifies gaps for meeting projected demands (DOE 2000a). The basic finding of this assessment also concluded that the capabilities of currently operating DOE facilities will not meet projected U.S. needs for nuclear materials production and testing or research and development.

Consistent with these findings, DOE recognizes that adequate nuclear research reactor, accelerator, and associated support facilities must be available to implement and maintain a successful nuclear energy program. As demand continues to increase for steady-state neutron sources needed for isotope production and civilian nuclear energy research and development, DOE’s nuclear infrastructure capabilities to support this demand have not improved. To continue meeting its responsibilities under the Atomic Energy Act and to satisfy projected increases in the future demand for isotope products and irradiation services, DOE proposes to enhance its existing nuclear facility infrastructure to provide for: (1) production of isotopes for medical, research, and industrial uses, (2) production of plutonium-238 for use in advanced radioactive isotope (radioisotope) power systems for future National Aeronautics and Space Administration (NASA) space exploration missions, and (3) support of the Nation’s civilian nuclear energy research and development needs.

To evaluate the potential environmental impacts associated with this proposed enhancement, DOE has prepared this *Programmatic Environmental Impact Statement for Accomplishing Expanded Civilian Nuclear Energy Research and Development and Isotope Production Missions in the United States, Including the Role of the Fast Flux Test Facility (Nuclear Infrastructure Programmatic Environmental Impact Statement [NI PEIS])*. This NI PEIS evaluates impacts from new facility construction, modification, startup, and 35 years of operation, followed by decommissioning when applicable. For analysis purposes, a 35-year operating period was established based on the projected availability of existing DOE irradiation facilities to potentially support these missions. This timeframe also accommodates current projections that indicate the demand for radioisotopes and civilian nuclear energy research and development requiring these enhancements will extend for at least the next 20 years (Wagner et al. 1998; NERAC 2000a; DOE 2000a).

### **1.2.1 Medical and Industrial Isotope Production**

Over the past few decades, isotopes have become vital tools for use in medicine, industry, and scientific research. Isotopes, including both radioisotopes and stable isotopes, play a particularly important role in medical diagnosis, treatment, and research. Currently, more than 12 million nuclear medicine procedures are performed each year in the United States, and approximately one-third of all patients admitted to U.S. hospitals undergo at least one medical procedure that employs the use of medical isotopes (NERAC 2000a). Many medical isotopes are produced in the United States by DOE in nuclear reactors and particle accelerators. In limited cases, some medical isotopes can also be produced by extracting them from existing radioactive materials, such as thorium-229 obtained from DOE’s existing stockpile of uranium-233. Radioisotopes are used for both diagnosis and therapy. Diagnostic radioisotopes are used for imaging internal organs. Unlike conventional radiology, imaging with radioisotopes reveals organ function and structure, which provides additional data for a more accurate diagnosis, and assists in the early detection of abnormalities. In ongoing clinical testing, therapeutic isotopes have proven effective in treating cancer and other illnesses by cell-directed localized radiation therapy (i.e., deploying antibodies or carriers of radioisotopes to seek and destroy invasive cancer cells). This directed therapy can minimize adverse side effects (e.g., healthy tissue damage, nausea, hair loss), making it an effective, attractive alternative to traditional chemotherapy or radiation treatments.

For nearly 50 years, DOE has actively promoted the use of radioisotopes to improve the health and well-being of U.S. citizens. DOE's use of its unique technologies and capabilities to develop isotopes for civilian purposes has enabled the widespread application of medical and industrial isotopes seen today. DOE must provide an adequate supply of isotopes to keep pace with the growing and changing needs of the research community if it is to continue to serve this key role.

An Expert Panel convened by DOE in 1998 reviewed several industry projections for growth in demand for medical isotopes. The Expert Panel concluded that the growth rate in medical isotope use will be significant over the next 20 years (Wagner et al. 1998). Specifically, the panel estimated that the expected growth rate of medical isotope use during the next 20 years would range from 7 to 14 percent per year for therapeutic applications and from 7 to 16 percent per year for diagnostic applications. The panel noted that these growth rates are attainable only if basic research in nuclear medicine is supported and if modern, reliable isotope production facilities are available. In the period since the initial estimates were made, the actual growth of medical isotope use has tracked at levels consistent with the Expert Panel findings. DOE and NERAC have agreed with the following findings and recommendations provided by the Expert Panel:

- Several isotopes have proven their clinical efficacy, but supply and cost concerns could dramatically affect the use of these isotopes in the practice of nuclear medicine.
- Although commercial and research applications for certain isotopes have been or are being developed, their limited availability and high prices are inhibiting their use in clinical applications.
- Research isotopes that have shown promise as diagnostic and therapeutic materials are not being explored because of their lack of availability or high price.
- At present, there is no domestic production facility to guarantee the continued supply of many of these isotopes.
- To meet current and future needs of the biomedical sciences community, the Expert Panel recommended:

“ . . . the United States develop a capability to produce large quantities of radionuclides [radioisotopes] to maintain existing technologies and to stimulate future growth in the biomedical sciences. The successful implementation of such a program would help insure our position as an international leader in the biomedical sciences well into the twenty-first century. The panel recommends that the U.S. Government build this capability around a reactor, an accelerator, or a combination of both technologies as long as isotopes for clinical and research applications can be supplied reliably, with diversity in adequate quantity and quality” (Wagner et al. 1998).

In its recent report from the Subcommittee for Isotope Research and Production Planning, NERAC further identified that:

“It is now widely conceded that limited availability of specific radionuclides is a constraint on the progress of research. The problem is especially apparent in a number of medical research programs that have been terminated, deferred, or seriously delayed by a lack of isotope availability . . . The lack of radionuclides significantly inhibits progress in evaluating a host of promising diagnostic and therapeutic drugs in patients with debilitating and fatal diseases, examining

fundamental basic science questions, studying human behavior and normal growth and development, and exploring the aging process and the products of transgene expression . . . the DOE long-term goal to have a reliable isotope supply system in place that would enable scientists to bring their creative ideas into practical use safely, quickly and efficiently is appropriate, be it basic science research, clinical medicine, or industrial endeavors. The discovery and dissemination of new knowledge should continue to be a core mission, and basic science and the application of basic science to clinical research discoveries to improve the diagnosis and treatment outcomes should be a crucial component of that mission. [DOE], in providing a federal system for the reliable supply of stable and radioactive isotopes for research, will be an important aspect of fulfilling the federal responsibility to support biomedical research” (NERAC 2000a).

Current domestic and global producers of radioisotopes include governments that operate reactors and accelerators at national laboratories or institutes, and private sector companies that own and operate accelerators. There are also many partnership arrangements where companies lease irradiation space in government reactors or operate processing facilities in coordination with the government. A few universities also produce radioisotopes, but their ability to provide reliable and diverse supplies is generally limited by the small-scale capabilities or operating schedules of their facilities.

DOE’s production and sale of radioisotopes fall into two categories: “commercial” and “research.” Commercial radioisotopes are those that are produced in large, bulk quantities and sold to pharmaceutical companies or distributors, or to equipment or sealed source manufacturers. DOE only produces commercial isotopes when there is no U.S. private sector capability or when foreign sources do not have the capacity to meet U.S. needs reliably.

In contrast, research radioisotopes are typically produced and sold in small quantities in response to specialty orders from researchers preparing experiments in the field of medicine, with small quantities of these radioisotopes also purchased by industrial researchers. Because small-quantity production of research isotopes is not financially attractive to private sector producers, it is generally not undertaken. DOE attempts to provide all research radioisotopes that are requested, subject to production capability, inventory, and financial constraints. As successful application of a specific research isotope is established, the production and sales of that radioisotope may shift from research to commercial status. In recent years, over 95 percent of DOE’s sales of radioisotopes by dollar volume were commercial, and 5 percent were for research.

DOE produces radioisotopes using the High Flux Isotope Reactor (HFIR) at ORNL, the Advanced Test Reactor (ATR) at Idaho National Engineering and Environmental Laboratory (INEEL), and the Annular Core Research Reactor at Sandia National Laboratories (SNL). DOE also produces radioisotopes using accelerators, namely the Isotope Production Facility at Los Alamos National Laboratory (LANL) and the Brookhaven LINAC (Linear Accelerator) Isotope Producer at Brookhaven National Laboratory. At each of these DOE sites, the radioisotope production mission shares the reactor or accelerator with other basic energy sciences or defense missions that are generally much larger and exercise considerable influence on facility schedules and priorities. As such, radioisotope production is often relegated to fulfilling a secondary mission that is dependant on the operating constraints of these larger, primary missions. Currently, approximately 50 percent of DOE’s isotope production capability is being used. Assuming a midpoint growth curve for future isotope demand and a diversity and redundancy of isotope supply, DOE estimates that its isotope production facilities would be fully used within a 5- to 10-year timeframe if no enhancements to the existing nuclear facility infrastructure are implemented. This projection was made in the context of a worldwide market for radioisotopes. Although DOE’s market share is a small fraction of the overall total, it is very significant for some radioisotopes and particularly important for a large number of radioisotopes that are used in relatively

small quantities for research. These isotopes, which are used almost exclusively by researchers at universities and hospitals, are not purchased in quantities that would attract private industry to take over their production. However, DOE may need to significantly increase the production levels of these radioisotopes as world demand changes and promising research developments in their medical use are brought to commercialization.

Recent analyses indicate that the greatest challenge to meeting projected isotope market requirements over the next 20 years will be in the area of therapeutic medical isotopes, several of which are currently unavailable or are available only in limited quantities (Battelle 1999). For the purpose of analysis in this NI PEIS, a representative set of isotopes was selected on the basis of the recommendations of the Expert Panel, medical market forecasts (Frost & Sullivan 1997), reviews of medical literature, and more than 100 types of ongoing clinical trials that use radioisotopes for the treatment of cancer and other diseases. These isotopes are listed in **Table 1–1**, along with a brief description of their medical and, in some cases, industrial applications. Currently, these medical applications primarily involve the diagnosis and treatment of three major classes of disease—cancer, vascular disease, and arthritis. Although these isotopes are a representative sample of possible isotopes which could be produced, DOE expects that the actual isotopes produced as a result of the proposed action would vary from year to year in response to the focus of clinical research and the specific market needs occurring at that time.

The United States currently purchases approximately 90 percent of its medical isotopes from foreign producers, most notably Canada. However, Canada only supplies a limited number of economically attractive commercial isotopes (primarily molybdenum-99), and it does not supply research isotopes or the diverse array of medical and industrial isotopes considered in this NI PEIS. As such, reliance on Canadian sources of isotopes to satisfy projected U.S. isotope needs would not meet DOE’s mission requirements.

Industrial isotope applications fall into three broad categories: nucleonic instrumentation, irradiation and radiation processing, and technologies that use radioactive tracers. Examples of nucleonic instrumentation include gauges for measuring physical parameters (e.g., detection systems for pollutants, explosives, drugs, ores, petroleum, and natural gases; nondestructive testing by gamma radiography; and smoke detectors). Irradiation and radiation processing technologies include radiation sterilization of food and medical products and the curing of plastics. Radioactive tracer applications include studies of chemical synthesis reactions; mass transfer monitoring in industrial plants; analysis of the transport and uptake of nutrients, fertilizers, herbicides, and waste materials in plants, soils, and groundwater; and laboratory-based studies of the properties of materials.

In proposing to expand its radioisotope production capability, DOE intends to continue to complement the commercial availability of these radioisotopes. Consistent with current isotope production activities, DOE will continue to make its facilities available to the private sector to support the production and sale of isotopes.

### **1.2.2 Plutonium-238 Production for Space Missions**

As part of its charter under the Atomic Energy Act, DOE and its predecessor agencies have been developing and supplying radioisotope power systems to NASA for space exploration for more than 30 years. These radioisotope power systems include radioisotope thermoelectric generators used to power electrical components and radioisotope heater units used to keep spacecraft instruments warm. Previous NASA space missions that have used radioisotope power systems include the Apollo lunar scientific packages and the Pioneer, Viking, Voyager, Galileo, and Ulysses deep space probes. More recent missions include the Mars Pathfinder mission launched in 1996 and the Cassini mission launched in 1997. These radioisotope power systems have repeatedly demonstrated their performance, safety, and reliability in various NASA space missions. Without these power systems, these types of space exploration missions could not have been performed by NASA.

**Table 1–1 Representative Radioisotopes**

<b>Radioisotope</b>	<b>Applications</b>
Actinium-227	Parent of radium-223 (monoclonal antibody attachment used for cancer treatment by radioimmunotherapy)
Astatine-211	Alpha-emitting radioisotope being studied for a variety of radioimmunotherapy applications
Gold-198	Ovarian, prostate, and brain cancer; intracavity therapy
Cadmium-109	Cancer detection; pediatric imaging; industrial detection systems for pollutants, explosives, drugs, ores, petroleum, and natural gas
Copper-64	Diagnostic imaging, dosimetry studies, cerebral and myocardial blood flow, colorectal cancer therapy
Copper-67	Cancer treatment/diagnostics, cancer treatment by radioimmunotherapy, planar imaging, diagnostic imaging
Fluorine-18	Cancer detection/diagnostics
Gadolinium-153	Osteoporosis detection, diagnostic imaging
Germanium-68	Diagnostic imaging calibration, potential antibody labeling
Holmium-166	Treatment of rheumatoid arthritis, radiolabeling, and monoclonal antibody techniques
Indium-111	Cancer treatment/diagnostics
Iodine-123	Alzheimer's Disease and Schizophrenia diagnostic, breast cancer imaging, cardiac imaging, radioimmunotherapy of Parkinson's Disease
Iodine-125	Osteoporosis detection, diagnostic imaging, tracer drugs, monoclonal antibodies, brain cancer treatment (iodine-131 replacement), radiolabeling, tumor imaging, mapping of receptors in the brain, interstitial radiation therapy, brachytherapy for treatment of prostate cancer, determination of glomerular filtration rate, determination of plasma volume, detection of deep vein thrombosis of the legs
Iodine-131	Lymphoid tissue tumor/hyperthyroidism treatment; antibody labeling; brain biochemistry in mental illness; diagnosis of thyroid disorders by gamma camera imaging or counting; radioimmunotherapy; imaging; cellular dosimetry; adrenal medulla scintigraphy; treatment of Grave's disease, goiters, prostate cancer, hepatocellular carcinoma, neuroblastoma and malignant pheochromocytoma, thyroid carcinoma, and melanoma; locating metastatic lesions; internal (systemic) radiation therapy; study of kidney functions; construction of renogram; adrenal cortex imaging; investigations of hepatobiliary function; determination of plasma volume
Iridium-192	Brachytherapy, brain and spinal cord tumor treatment, heart disease treatment (restenosis therapy), seed implants for breast and prostate tumors, industrial nondestructive testing by gamma radiography
Krypton-81m	Cardiac imaging
Lutetium-177	Heart disease treatment (restenosis therapy), cancer treatment by radioimmunotherapy
Molybdenum-99	Parent for technetium-99m generator used for brain, liver, lungs, heart imaging
Osmium-194	Monoclonal antibody attachment used for cancer treatment by radioimmunotherapy
Phosphorus-32	Polycythemia rubra vera (blood cell disease) and leukemia treatment, bone disease diagnosis/treatment, diagnostic imaging of tumors, pancreatic and liver cancer treatment, radiolabeling, labeling nucleic acids for in vitro research, diagnosis of superficial tumors, heart disease treatment (restenosis therapy), intracavity therapy
Phosphorus-33	Leukemia treatment, bone disease diagnosis/treatment, diagnostic imaging of tumors, radiolabeling, heart disease treatment (restenosis therapy)
Palladium-103	Prostate cancer treatment
Platinum-195m	Noninvasive monitoring of drug biodistribution and metabolism, studies with intra-arterial platinum-195m-cisplatin
Rhenium-186	Cancer treatment/diagnostics, monoclonal antibodies, bone cancer pain relief, treatment of rheumatoid arthritis, treatment of prostate cancer
Scandium-47	Bone cancer pain relief, cancer treatment by radioimmunotherapy
Selenium-75	Radiotracer used in brain studies, imaging of adrenal cortex by gamma-scintigraphy, lateral locations of steroid secreting tumors, pancreatic scanning, detection of hyperactive parathyroid glands, measuring the rate of bile acid loss from the endogenous pool
Samarium-145	Treatment of ocular cancer
Samarium-153	Cancer treatment/diagnostics, bone cancer pain relief, treatment of leukemia
Strontium-85	Detection of bone lesions, brain scans
Strontium-89	Bone cancer pain relief, treatment of prostate cancer, treatment of multiple myeloma, osteoblastic therapy, potential agent for treatment of bone metastases from prostate and breast cancer
Thorium-228	Cancer treatment by radioimmunotherapy, monoclonal antibodies, parent of bismuth-212
Thorium-229	Grandparent of bismuth-213 (alpha-emitter used in cancer treatment by radioimmunotherapy), parent of actinium-225, daughter of uranium-233

**Table 1–1 Representative Radioisotopes (Continued)**

Radioisotope	Applications
Tin-117m	Bone cancer pain relief
Tungsten-188	Cancer treatment by radioimmunotherapy, parent for rhenium-188 generator
Xenon-127	Neuroimaging for brain disorders, research on variety of neuropsychiatric disorders (especially schizophrenia and dementia), higher resolution diagnostic studies with lower patient dose, lung imaging evaluation of pulmonary ventilation, indicator for measurement of local cerebral blood flow
Yttrium-91	Cancer treatment by radioimmunotherapy, cellular dosimetry
Zinc-62	Parent for copper-64 generator used for diagnostic imaging

Source: Battelle 1999.

The radioisotope used in these power systems is plutonium-238. Through a Memorandum of Understanding with NASA, DOE provides these radioisotope power systems, and the plutonium-238 that fuels them, for space missions that require or would be enhanced by their use (DOE and NASA 1991). In addition, under the National Space Policy issued by the Office of Science and Technology Policy in September 1996, and consistent with DOE's charter under the Atomic Energy Act, DOE is responsible for maintaining the capability to provide the plutonium-238 needed to support these missions. The Intersector Guidelines section of the National Space Policy states that, "The Department of Energy will maintain the necessary capability to support space missions which may require the use of space nuclear power systems" (The White House 1996). Although research to identify other potential fuel sources to support these space exploration missions has been conducted, no viable alternative to using plutonium-238 has been established.

Historically, the reactors and chemical processing facilities at DOE's Savannah River Site (SRS) were used to produce plutonium-238; however, downsizing of the DOE nuclear weapons complex resulted in the shutdown of the last remaining SRS operating reactor, K-Reactor, in early 1996. Also, in 1992 then-Secretary of Energy Watkins issued a decision to phase out operations at the two chemical processing facilities (F-Canyon and H-Canyon) at SRS. In accordance with that decision, the separation facilities are planned to be shut down following completion of their current missions to stabilize and prepare for the disposition of Cold War legacy nuclear materials and certain spent nuclear fuel, and a determination that a new nonchemical processing technology is capable of preparing aluminum-based research reactor spent nuclear fuel for ultimate disposition.

In order to obtain a source of plutonium-238 to support NASA space missions, DOE signed a 5-year contract in 1992 to purchase plutonium-238 from Russia, authorizing the United States to purchase up to 40 kilograms (88.2 pounds) of plutonium-238, with the total available for purchase in any one year limited to 10 kilograms (22 pounds).<sup>1</sup> Under this contract, DOE purchased approximately 9 kilograms (19.8 pounds) of plutonium-238.<sup>2</sup> This material constitutes the only available U.S. inventory that has been reserved for space missions, an amount that is expected to be depleted by approximately 2005. DOE's practice of purchasing on an as-needed basis has avoided the costs from processing the plutonium-238 to remove the decay products that would result from storing it for an extended period of time. In 1997, DOE extended the contract for another 5 years; therefore, it is set to expire in 2002. Any purchases beyond 2002 would likely require the negotiation of a new contract and may require additional National Environmental Policy Act (NEPA) review. The long-term viability of pursuing additional contract extensions or entering into a new contract is unclear.

<sup>1</sup> The NI PEIS presents the weight of plutonium-238 in terms of kilograms of isotope. In contrast, NASA documentation expresses this weight in terms of plutonium oxide. The equivalent plutonium oxide weight can be approximated by multiplying the isotope kilogram weight by 1.134.

<sup>2</sup> The environmental impacts of purchasing plutonium-238 from Russia are evaluated and documented in the *Environmental Assessment of the Import of Russian Plutonium-238* (DOE 1993), prepared by DOE's Office of Nuclear Energy.

The political and economic climate in Russia creates uncertainties that could affect its reliability as a source of plutonium-238 to satisfy future NASA space mission requirements. Reestablishing a domestic plutonium-238 production capability would ensure that the United States has a long-term, reliable supply of this material. In doing so, the United States would have greater control over the available supply, plans for satisfying future demand, and the nuclear safety and nonproliferation implications of the material. As such, DOE's preference is to reestablish a domestic plutonium-238 production capability rather than to rely on Russia as the sole long-term supplier. A plutonium-238 production rate of 2 to 5 kilograms (4.4 to 11 pounds) per year is expected to be sufficient to meet NASA's estimated long-term requirements.

DOE is planning to provide radioisotope heater units for several NASA Mars Exploration missions over the next 10 years. Each heater unit would require approximately 2 grams (0.07 ounce) of plutonium-238. The number of heater units varies depending on the spacecraft. Each of the two Mars missions in 2003 is projected to require up to 11 heater units. In May 2000, NASA provided preliminary guidance to DOE to also plan for the potential use of radioisotope power systems for the Pluto/Kuiper Express mission scheduled for launch in 2004, the Europa Orbiter mission scheduled for launch in 2006, and the Solar Probe mission scheduled for launch in 2007 (NASA 2000a). The amount of plutonium-238 needed for these missions was approximately 7.4 kilograms (16.3 pounds) for the Pluto/Kuiper Express mission, which would use an existing spare radioisotope thermoelectric generator, and approximately 3 kilograms (6.6 pounds) each for the Europa Orbiter and Solar Probe missions, which would use the Stirling radioisotope power system (SRPS). With NASA's current emphasis on smaller and less expensive spacecraft, the SRPS is being developed as a new, more efficient and lighter weight power system requiring one-third less plutonium-238 as its fuel source. However, the SRPS technology is developmental, and NASA has requested that the plutonium-238 needed for a large radioisotope thermoelectric generator be maintained as backup.

A plutonium-238 production goal of 2 to 5 kilograms (4.4 to 11 pounds) per year could produce sufficient quantities of plutonium-238 to theoretically yield an SRPS every 8 months if production were maintained at the high end of the range. However, DOE chose the 5-kilogram (11-pound) per year production rate as an upper bound due to uncertainties in the SRPS technology development requirements for backup units, and variability in the amount of plutonium-238 that may be needed for each of the units to meet NASA's power requirements.

In updated mission planning guidance provided in September 2000, NASA indicated that for programmatic and technical reasons, implementation of the Pluto/Kuiper Express mission as currently conceived was being deferred, and that the SRPS generators were candidate power systems for the Europa Orbiter and Solar Probe missions (NASA 2000b, 2000c). NASA also requested that the spare radioisotope thermoelectric generator and assembling and fueling a spare thermoelectric converter be maintained as backups for the Europa Orbiter mission in the event the SRPS technology was not ready in time. If NASA chooses to use the SRPS to support the Europa Orbiter and Solar Probe missions, there would be no change in NASA's requirements regarding the plutonium-238 needed for these two missions (i.e., approximately 3 kilograms [6.6 pounds] each, as described above), although the remaining quantity of plutonium-238 would not be sufficient to support additional deep space or long-lived exploration missions. Should NASA decide to use the backup radioisotope thermoelectric generators rather than the SRPS to support the Europa Orbiter mission, approximately 8 kilograms (17.6 pounds) of plutonium-238 would be needed, which would effectively expend all of DOE's available plutonium-238 inventory prior to supporting the Solar Probe mission. While this latest NASA guidance modifies the specific radioisotope power systems and missions for which DOE needs to plan, it does not fundamentally change NASA's overall potential plutonium-238 requirements, or the expectation that the available U.S. inventory of this material would effectively be depleted by approximately 2005.<sup>3</sup>

---

<sup>3</sup> Applicable NASA mission planning correspondence is presented in Appendix R.

Although future space mission schedules over a long-term planning horizon of 10 to 35 years cannot be specified at this time, DOE anticipates that NASA space exploration missions conducted during this period will continue to require plutonium-238-fueled power systems. For example, NASA announced in a recent press conference (October 26, 2000) that mission launches in 2014 and 2016 for the long-term exploration of Mars would involve long-life rover vehicles. Radioisotope power systems would be required to provide the long-life capability.

Therefore, DOE proposes to reestablish a domestic capability for producing and processing this material. Because the SRS facilities previously used for plutonium-238 production are no longer available, DOE needs to evaluate other DOE irradiation and chemical processing facilities, as well as potential commercial light water reactors (CLWR), for this mission. Unless an assured domestic supply of plutonium-238 is established, DOE's ability to provide radioisotope power systems to support future NASA space exploration missions may be lost.

### **1.2.3 Civilian Nuclear Energy Research and Development**

Nuclear energy is an important contributor in reducing greenhouse gas emissions in the United States, Asia, and Europe. Globally, nuclear energy produces 17 percent of the world's electricity. In the United States, nuclear energy generated 20 percent of all electricity consumed in 1999. In view of these energy and environmental contributions, there is a renewed interest in nuclear power to meet an equivalent portion of the Nation's future expanding energy requirements.

In January 1997, President Clinton tasked his Committee of Advisors on Science and Technology (PCAST) to evaluate the current national energy research and development portfolio and to provide a strategy that ensures the United States has a program to address the Nation's energy and environmental needs for the next century. In its November 1997 report responding to this request, the PCAST Energy Research and Development Panel determined that restoring a viable nuclear energy option to help meet our future energy needs is important and that a properly focused research and development effort to address the potential long-term barriers to expanded use of nuclear power (e.g., nuclear waste, proliferation, safety, and economics) was appropriate. The PCAST panel further recommended that DOE reinvigorate its nuclear energy research and development activities to address these potential barriers.

Clean, safe, reliable nuclear power has a role today and in the future for our national energy security. Recognizing this need, two new significant nuclear energy research and development programs have been initiated: the Nuclear Energy Research Initiative (NERI) and Nuclear Energy Plant Optimization (NEPO). The NERI program, initiated in fiscal year 1999, sponsors new and innovative scientific and engineering research and development to address the potential long-term barriers identified by the PCAST panel affecting the future use of nuclear energy. The NEPO program, a cost-shared program with industry initiated in fiscal year 2000, sponsors applied research and development to ensure that current nuclear plants can continue to deliver adequate and affordable energy supplies up to and beyond their initial 40-year license period by resolving open issues related to plant aging and by applying new technologies to improve plant reliability, availability, and productivity.

The NERAC Subcommittee on Long-Term Planning for Nuclear Energy Research has set forth a recommended 20-year research and development plan to guide DOE's nuclear energy programs in areas of material research, nuclear fuel, and reactor technology development (NERAC 2000b). This plan stresses the need for DOE facilities to sustain the nuclear energy research mission in the years ahead. Such civilian nuclear energy research and development initiatives requiring an enhanced DOE nuclear facility infrastructure fall into three basic categories: materials research, nuclear fuel research, and advanced reactor development.

**Materials Research.** The high radiation fields, high temperatures, and corrosive environments in nuclear reactors (terrestrial or space) and other complex nuclear systems (e.g., accelerator transmutation of waste [ATW] systems) can accelerate the degradation of pressure vessels and structural material, component materials, material interfaces, and joints between materials (e.g., welds). Radiation effects in materials can cause a loss of mechanical integrity (fracture toughness and ductility) by embrittlement, dimensional changes (creep and swelling), and fatigue and cracking (irradiation-assisted stress corrosion cracking). Acquiring a fundamental understanding of radiation effects in current and future reactor materials (engineered steel alloys, ceramics, composites, and refractory metals), as well as the experimental validation of analytical models and computational methods, would require material irradiation testing over a range of neutron energies (thermal and fast flux) and doses. Material testing under simulated reactor conditions would be required to ensure the compatibility of advanced materials with the various moderators/coolants of future reactor concepts. In addition, the thermophysical properties and behaviors of liquid metal coolants being considered for advanced reactor (terrestrial or space) and ATW systems would require further irradiation testing. One key area of materials research that is important to plant safety and the license renewal of existing nuclear power plants is the accelerated aging of materials to simulate radiation effects over a plant lifetime. Researchers from the United States and many foreign countries use DOE's high-flux research reactors for materials testing and experimentation. These facilities have the capability to maintain a high density of neutrons in a given test volume for materials testing; shorten the time needed for such testing; tailor the neutron flux to simulate the different reactor types and conditions; and instrument the core for close monitoring of the test conditions.

**Nuclear Fuel Research.** Increasing demands are being placed on nuclear fuel and cladding material performance as the fuel burnup limits are extended in existing light water reactors to maximize plant performance and economic benefits. New fuel types and forms are being investigated that offer potential benefits such as enhanced proliferation resistance (uranium-thorium fuel), higher burnup, and improved waste forms for the new reactor concepts being researched and developed by DOE. In addition, plutonium-based mixed oxide fuels are being developed for the disposition of surplus weapons material, and high temperature, long-life fuels may be required for space reactors. Each of the various fuel and cladding types, forms, and material compositions would require research and irradiation testing under prototypical reactor conditions to fully understand fuel performance, cladding performance, cladding/fuel interaction, and cladding/coolant material compatibility. Fuel research includes a variety of thermal and fast spectrum power reactor fuel forms (ceramic, metal, hybrids such as cermet) and various fuel types (oxides, nitrides, carbides, and metallics). Irradiation experiments to characterize fuel performance would require the capability to test fuel pellets, pins, and fuel assemblies under steady-state and transient conditions in the higher temperature environments expected in future reactor designs. Reactor physics and criticality safety data for benchmarking computational codes and analytical methods used in fuel design and performance analysis would also be required.

**Advanced Reactor Development.** Certification and licensing of advanced reactor and complex nuclear systems would require the demonstration and validation of reactor and safety system thermal and fluid dynamic properties under steady-state and transient conditions. Typically, nonnuclear test loops are used to perform this research. However, because of the unique nature of some proposed advanced reactor concepts, test loop operation under prototypical temperature and neutron flux conditions would be necessary to adequately test and demonstrate coolant/moderator physics and thermal properties, heat transfer, fluid flow, and fuel-moderator performance.

### **1.3 DECISIONS TO BE MADE**

In reaching programmatic decisions regarding potential enhancements to its existing nuclear facility infrastructure, DOE will factor the analytical results of this NI PEIS together with the findings presented in the ancillary *Cost Report for Alternatives Presented in the Draft Programmatic Environmental Impact Statement for Accomplishing Expanded Civilian Nuclear Energy Research and Development and Isotope*

*Production Missions in the United States, Including the Role of the Fast Flux Test Facility (NI Cost Report) and Nuclear Infrastructure Nonproliferation Impact Assessment for Accomplishing Expanded Civilian Nuclear Energy Research and Development and Isotope Production Missions in the United States, Including the Role of the Fast Flux Test Facility (NI Nonproliferation Impact Assessment)*<sup>4</sup>, the *Nuclear Science and Technology Infrastructure Roadmap* (which will be updated periodically), recommendations of NERAC and its various subcommittees, public input, and other DOE policy and programmatic considerations.

With the benefit of this broad base of information, DOE intends to make the following decisions:

- Whether to enhance its current nuclear facility infrastructure to meet projected requirements for future medical and industrial isotope production, plutonium-238 production, and civilian nuclear energy research and development.
- If a decision is made to enhance DOE's existing nuclear facility infrastructure, whether to construct new facilities (one or two accelerators or a research reactor).
- Whether to restart the Fast Flux Test Facility (FFTF) at the Hanford Site in Richland, Washington, as part of a nuclear infrastructure enhancement program and, if not, whether to remove FFTF from standby mode and permanently deactivate it in preparation for its eventual decontamination and decommissioning.
- If DOE's existing nuclear facility infrastructure is not enhanced, select from existing operating facilities those needed to support the proposed plutonium-238 mission, or decide whether to continue purchasing plutonium-238 from Russia to support future NASA space missions. Existing operating facilities performing medical, research, and/or industrial isotope production missions and/or civilian nuclear energy research and development missions would continue to support existing missions at current levels.
- Whether DOE inventories of neptunium-237 should be relocated and stored for future plutonium-238 production needs.

The programmatic decisions reached in association with this NI PEIS will address isotope production and civilian nuclear energy research and development missions which are the responsibility of the DOE Office of Nuclear Energy, Science and Technology. In addition to the range of reasonable programmatic alternatives evaluated in this NI PEIS, DOE could choose to combine components of several alternatives in selecting the most appropriate strategy. For example, DOE could select a low-energy accelerator to produce certain medical, research, and industrial isotopes, and an existing operating reactor to produce plutonium-238 and conduct civilian nuclear energy research and development. If alternatives were selected involving the siting, construction, and operation of one or two new accelerators or a new research reactor, appropriate site- and project-specific NEPA documentation, tiered from this NI PEIS, would be prepared.

#### **1.4 ISSUES IDENTIFIED DURING THE SCOPING PROCESS**

On October 5, 1998, DOE published in the Federal Register (63 FR 53398) a Notice of Intent to prepare an environmental impact statement (EIS) on the proposed production of plutonium-238 for use in advanced radioisotope power systems for future space missions. With that announcement, DOE began preparing the

---

<sup>4</sup> The findings of the *NI Cost Report* and the *NI Nonproliferation Impact Assessment* are summarized in Appendixes P and Q, respectively.

*Environmental Impact Statement for the Proposed Production of Plutonium-238 for Use in Advanced Radioisotope Power Systems for Future Space Missions (Plutonium-238 Production EIS)*. The scope of the *Plutonium-238 Production EIS* was established through a public scoping process conducted from October 5, 1998, through January 4, 1999. As part of the scoping process for that draft, DOE announced that FFTF would not be considered a reasonable alternative for the plutonium-238 production mission unless restart of the facility were proposed for other reasons.

Since then, the Secretary of Energy announced on August 18, 1999, that DOE would prepare the NI PEIS. Because plutonium-238 production would be among the missions considered, the scope of the *Plutonium-238 Production EIS* in its entirety was incorporated within the scope of this NI PEIS, and preparation of the *Plutonium-238 Production EIS* as a separate NEPA review was terminated.

On September 15, 1999, DOE published in the Federal Register a Notice of Intent to prepare the NI PEIS (64 FR 50064). In the Notice, DOE invited the public to comment on the proposed actions during the 45-day NI PEIS scoping period that ended October 31, 1999. During this period, DOE held public scoping meetings at seven locations: Oak Ridge, Tennessee; Idaho Falls, Idaho; Richland and Seattle, Washington; Hood River and Portland, Oregon; and Washington, D.C. The written and oral comments, and the additional comments received via U.S. mail, electronic mail, and toll-free faxes and telephone calls, were reviewed and considered by DOE in preparing this NI PEIS. Similarly, DOE reviewed and considered all comments and input originally received from the public during the *Plutonium-238 Production EIS* scoping period in the preparation of this NI PEIS.

For the *Plutonium-238 Production EIS*, approximately 750 scoping comments were received by DOE. At the scoping meetings, the following general issues and concerns were raised:

- Additional irradiation service alternatives, such as CLWRs and accelerators
- Additional storage, target fabrication, and target processing alternatives, such as Argonne National Laboratory–West’s Hot Fuels Examination Facility and the SRS H-Canyon and HB-Line
- Generation of additional waste
- Costs of implementing the various alternatives

In general, the people who attended the meetings in Idaho and Tennessee were supportive of DOE’s proposed plans to produce plutonium-238 domestically for future space missions. However, in Richland, Washington, the meeting was attended by several stakeholder and environmental groups who voiced considerable opposition to DOE’s consideration of FFTF for plutonium-238 production.

At the meeting in Richland, Washington, the main concern was that DOE should not consider restarting FFTF; that DOE has worked hard over the years to change Hanford’s mission from “production” to “cleanup”; and that DOE should continue to honor its commitment to cleanup. There were concerns about the generation of additional waste at the site and the operational safety of FFTF. There was strong opposition to restart of FFTF for any mission.

For this NI PEIS, approximately 7,000 scoping comments were received by DOE. At the scoping meetings, the most prevalent concerns were:

- Status of and commitment to cleanup at Hanford and the impact of FFTF’s restart on the existing waste cleanup at Hanford

- Lack of justification for the identified missions
- Costs of implementing the various alternatives
- Need for an additional alternative calling for the permanent deactivation of FFTF coupled with the No Action Alternative elements; that is, no plutonium-238 production and no additional research and development or medical isotope production beyond existing operating levels

The number of people who commented at the scoping meetings conducted in Oak Ridge, Tennessee; Idaho Falls, Idaho; and Washington, D.C., was smaller in comparison to the meetings held in the Pacific Northwest. At the scoping meeting in Oak Ridge, Tennessee, a commentator was concerned with the relationship of this NI PEIS to other DOE programs and the relative merits of accelerator and reactor performance. The commentator stated that the NI PEIS should include an explanation of mixed oxide fuel disposition. In addition, the commentator supported medical isotope production in Oak Ridge because it is near a transportation hub and some medical isotopes are short-lived; therefore, transportation is key.

At the scoping meeting in Idaho Falls, Idaho, most commentators supported siting the new missions at INEEL. The commentators also stated that the socioeconomic impacts of the alternatives need to be considered in this NI PEIS. A commentator stated that decisions in regard to medical isotope production should be based on the needs of the Nation as a whole and not on perceived commercial needs. The commentator also stated that incremental DOE and commercial investments in the ATR would be sufficient to enhance reactor radioisotope production needs and meet the requirements of the nuclear medicine industry.

At the scoping meetings held in the states of Washington and Oregon, many of the comments concerned using FFTF to accomplish the proposed action. Many who attended the meetings in Seattle, Washington; Portland, Oregon; and Hood River, Oregon, were strongly opposed to the restart of FFTF. Many commentators stated that the Hanford cleanup mission would be jeopardized, especially when DOE has not met the cleanup milestones. Many of the comments received at the Richland, Washington, meeting supported restarting FFTF, stating that the restart would not hamper Hanford's cleanup mission, and further stating that the operation of FFTF could help save many lives by producing isotopes to be used in new ways to treat cancer, heart disease, and other illnesses. Commentors were also concerned about the potential generation of radioactive and hazardous wastes as a result of the proposed action, as well as DOE's commitment to ongoing cleanup programs, particularly at Hanford.

At the scoping meeting in Washington, D.C., the commentators supported the need for medical isotope production. Several commentators were against the restart of FFTF; others stated that DOE needs to consider partnerships with private industry to generate necessary funds for the restart. Some commentators thought a cost study should be prepared to include avoiding future health care costs as well as cost savings to the national Medicare and Medicaid programs that could be realized by using nuclear isotopes in medical applications. Proliferation concerns were also raised as some commentators stated that: (1) the United States would be sending the wrong message by restarting FFTF; (2) a change in the U.S. nonproliferation policy would be required to import German mixed oxide fuel; and (3) the use of highly enriched uranium would be contrary to existing U.S. nonproliferation policy. Other concerns included waste generation, the Hanford cleanup, and safety at FFTF.

Comments received during the scoping periods were systematically reviewed by DOE. As a means of summarizing the issues raised during the scoping process, those comments with similar or related topics were grouped into categories to identify specific issues of public concern. After these issues were identified, they were further evaluated to determine whether they fell within or outside the proposed scope of this NI PEIS.

In several instances, the original scope was expanded to accommodate additional issues resulting from the public scoping process.

Comments received that contributed to expansion of the scope included the following general areas:

- Deactivate FFTF: Alternative 5, Permanently Deactivate FFTF with no new missions at existing facilities, has been added to the scope of this NI PEIS.
- Cleanup at Hanford: although not within the scope of this NI PEIS, information is included about the cleanup mission at Hanford and land-use planning efforts.
- Environmental contamination at Hanford: information is included about the groundwater quality at the Hanford Site.
- Nonproliferation issues: the proposed import of German SNR-300 fuel is addressed, and a separate *NI Nonproliferation Impact Assessment* report was prepared and distributed to the public in September 2000.
- Transition of FFTF stewardship after it is deactivated: the appropriate transition information is included.
- Restart of FFTF and budget constraints: DOE has made a commitment that implementation of the Record of Decision will not divert or reprogram budgeted funds designated for Hanford cleanup.
- Tri-Party Agreement at Hanford: information about the Tri-Party Agreement and its relationship to this NI PEIS is included.

Public comments and materials submitted during the public scoping periods for both the *Plutonium-238 Production EIS* and this NI PEIS were logged and placed in the Administrative Record for this NI PEIS. Appendix N summarizes the comments received during both public scoping periods.

## **1.5 ISSUES RAISED DURING THE PUBLIC COMMENT PERIOD ON THE DRAFT NI PEIS**

DOE published the Draft NI PEIS in July 2000. In accordance with Council on Environmental Quality (CEQ) and DOE NEPA regulations, DOE announced the availability of the Draft NI PEIS in the Federal Register (65 FR 46443) and invited interested parties to provide comments on the Draft NI PEIS analysis and results. The Draft NI PEIS or Summary was distributed to approximately 6,000 individuals.

NEPA regulations mandate a minimum 45-day comment period after the U.S. Environmental Protection Agency's Notice of Availability of a draft EIS to provide an opportunity for the public to comment on the EIS analysis and results. The original 45-day comment period on the Draft NI PEIS began on July 28, 2000. To provide interested parties with additional time to comment, the deadline for transmittal of comments was changed from September 11, 2000 (as stated in the transmittal letter of the Draft PEIS and the Summary) to September 18, 2000. During the 52-day comment period, DOE held seven hearings to discuss the proposed action and to receive oral and written comments on the Draft NI PEIS. These hearings were held at Oak Ridge, Tennessee; Idaho Falls, Idaho; Hood River, Oregon; Portland, Oregon; Seattle, Washington; Richland, Washington; and Arlington, Virginia. In addition, the public was encouraged to submit comments via U.S. mail, e-mail, a toll-free phone line, and a toll-free fax line. During the public comment period, DOE received approximately 3,400 submittals containing over 6,200 comments. DOE has responded to all comments received during the public comment period. These comments are presented in Volume 3 of this Final NI PEIS.

DOE considered comments received after the close of the public comment period to the extent practicable (see Section 1.5.6).

The public comments received on the Draft NI PEIS addressed a wide range of issues. The following discusses the major issues raised, and DOE's responses to these issues. Changes made in response to comments received on the Draft NI PEIS are described in Section 1.8.

Major issues raised addressed purpose and need for the proposed action; impact of FFTF on Hanford cleanup; waste management and spent nuclear fuel; cost of the various alternatives; nuclear nonproliferation policy; public involvement; and environmental impacts. Aside from comments on the proposed action and its environmental impacts, many commentors expressed support for or opposition to FFTF restart, the major point of public controversy associated with the NI PEIS.

### **1.5.1 Purpose and Need for the Proposed Action**

Many commentors expressed the opinion that DOE failed to demonstrate a compelling argument for the projected need for medical isotopes, and that such medical isotopes could be produced or purchased elsewhere, particularly in Canada. In contrast, a large number of commentors expressed support for expanded isotope production by sharing personal stories of how medical isotopes had either saved a relative or friend, or could have saved them had isotopes been available. As presented in Section 1.2.1, DOE sought independent analysis of trends in the use of medical isotopes, and established two advisory bodies, the Expert Panel and the NERAC. DOE has adopted these growth projections as a planning tool for evaluating the potential capability of the existing nuclear facility infrastructure to meet programmatic requirements. In the period since the initial estimates were made, the actual growth of medical isotope use has tracked at levels consistent with the Expert Panel findings. While Canada currently provides a large amount of the medical radioisotopes used in the United States, it only supplies a limited number of economically attractive commercial isotopes (primarily molybdenum-99), and it does not supply research isotopes or the diverse array of medical and industrial isotopes considered in the NI PEIS.

A number of commentors also questioned the suitability of using FFTF for producing research isotopes in light of findings presented in the NERAC Subcommittee for Isotope Research and Production Planning Report (NERAC 2000a). While it would not be cost effective to restart FFTF for the singular purpose of producing small quantities of various research isotopes, sustained operation of FFTF for the production of larger quantities of both research and commercial isotopes would be viable if FFTF were operated in concert with producing plutonium-238 and conducting nuclear energy research and development for civilian applications. In recognition of these constraints on its operational feasibility, the NI PEIS only evaluates the use of FFTF for isotope production when coupled with these other missions.

Commentors also questioned the need for the United States to reestablish domestic production of plutonium-238. In particular, commentors pointed to the availability of plutonium-238 that could be purchased from Russia, and recent guidance from NASA stating that DOE no longer needed to support certain radioisotope power systems. As discussed in Section 1.2.2, DOE could purchase plutonium-238 from Russia. However, for supply reliability reasons and concern of nuclear nonproliferation, DOE's preference is to establish a domestic plutonium-238 production capability. Current NASA guidance to DOE is also discussed in Section 1.2.2. The May 22, 2000, correspondence from NASA identifies that it no longer has a planned requirement for Small Radioisotope Thermoelectric Generator (SRTG) power systems (NASA 2000a). This does not mean that NASA no longer requires DOE to provide the necessary plutonium-238 to support deep space missions. Rather, SRTG development efforts were stopped in order to permit reprogramming of funds to support development of a new radioisotope power system based on the SRPS technology. This new radioisotope power system, referred to in the subject correspondence, requires one-third less plutonium as its

fuel source. Because the SRPS technology is developmental, NASA has requested in a September 22, 2000, letter to DOE that the plutonium-238 needed for a large radioisotope thermoelectric generator be maintained as a backup (NASA 2000b).

### **1.5.2 Impact of FFTF Restart on Hanford Cleanup**

A number of commentors expressed concern that DOE's primary mission at Hanford needs to be cleanup, including compliance with the Tri-Party Agreement. Although beyond the scope of this NI PEIS, ongoing Hanford cleanup activities are high priority to DOE. Hanford environmental restoration activities are conducted in accordance with the Tri-Party (i.e., DOE's Richland Operations Office, EPA, and the State of Washington Department of Ecology) Agreement. This agreement specifies milestones and schedules for restoration of all parts of Hanford. FFTF milestones in the Tri-Party Agreement were placed in abeyance (suspension) by agreement of the three parties until a decision is made on the future of FFTF. Public meetings were held on this formal milestone change. DOE is fully committed to honoring this agreement.

A number of commentors also expressed concern that funding for Hanford cleanup would be diverted for FFTF restart and hamper the progress of cleanup activities. The U.S. Congress funds Hanford cleanup through the Office of the Assistant Secretary for Environmental Management. Congress also funds FFTF through the Office of Nuclear Energy, Science and Technology (NE). The nuclear infrastructure missions described in Section 1.2 would also be funded through NE, which has no funding connection to Hanford cleanup activities. As stated in Section N.3.2, implementation of the nuclear infrastructure alternatives would not divert or reprogram budgeted funds designated for Hanford cleanup, regardless of the alternative(s) selected.

### **1.5.3 Waste Management and Spent Nuclear Fuel**

A number of commentors expressed concern over the generation and disposition of waste resulting from the proposed action. In particular, commentors pointed to past DOE waste management practices and questioned whether wastes resulting from proposed NI PEIS activities would be properly managed. This NI PEIS addresses wastes produced for each alternative, as well as cumulative impacts related to waste production. Waste minimization programs at each of the alternative sites are also addressed. These programs would be implemented for the alternative selected in the Record of Decision. The waste generated from any of the alternatives considered in this NI PEIS would be managed (i.e., treated, stored, and disposed of) in a safe and environmentally protective manner and in compliance with all applicable Federal and state laws and regulations and applicable DOE orders.

A number of commentors expressed specific concern over the generation and disposition of waste resulting from FFTF restart and operation, and how this would impact Hanford's existing waste management infrastructure. Management of wastes that would be generated under implementation of Alternative 1 (Restart FFTF) is discussed in Section 4.3 (e.g., Section 4.3.1.1.13). Section 4.3.1.1.13 was revised to clarify that the Hanford waste management infrastructure is analyzed in this NI PEIS for the management of waste resulting from FFTF restart and operation. This analysis is consistent with policy and DOE Order 435.1, *Radioactive Waste Management*, that DOE radioactive waste shall be treated, stored, and in the case of low-level waste, disposed of at the site where the waste is generated, if practical, or at another DOE facility. However, if DOE determines that use of the Hanford waste management infrastructure or other DOE sites is not practical or cost effective, DOE may issue an exemption under DOE Order 435.1 for the use of non-DOE facilities (i.e., commercial facilities) to store, treat, and dispose of such waste generated from the restart and operation of FFTF. In addition, Sections 4.3.3.1.13 and 4.4.3.1.13 also address the potential impacts associated with the waste generated from the target fabrication and processing in the Fuels and Materials Examination Facility (FMEF) and how this waste would be managed at the site.

A number of commentors also raised concern that processing of irradiated targets for production of plutonium-238 would generate high-level radioactive waste. DOE Manual 435.1, *Radioactive Waste Management*, defines high-level radioactive waste as “the highly radioactive waste material resulting from the reprocessing of spent nuclear fuel, including liquid waste produced directly in reprocessing and any solid material derived from such liquid waste that contains fission products in sufficient concentrations; and other highly radioactive material that is determined, consistent with existing law, to require permanent isolation.” DOE has prepared an implementation guide to M 435.1 to assist in implementing the requirements contained in that manual. For this particular “requirement,” the definition of high-level radioactive waste, the guide is intended to facilitate the classification of indefinite waste as to whether or not they are high-level radioactive waste. It is recognized that the definition of high-level radioactive waste is not precise and is essentially a source-based definition that also alludes to concentrations of a given waste stream. Page II-8 of the guide notes that “For the purpose of managing high-level waste under DOE M 435.1-1 [sic], spent nuclear fuel includes spent driver elements and/or irradiated target elements that contain transuranium elements.” This statement was included in the guide because the concentrations of long-lived isotopes are likely to be somewhat high during reprocessing and it also meets the source-based definition. As a result of reviewing this guide and to address the comments raised, DOE is considering whether the waste from processing of irradiated neptunium-237 targets should be classified as high-level radioactive waste and not transuranic waste. As a result, the Waste Management sections (i.e., Sections 4.3.1.1.13, 4.3.2.1.13, 4.3.3.1.13, and 4.4.3.1.13) of this NI PEIS have been revised to reflect this different classification from what was assumed in the Draft NI PEIS. As discussed in these revised sections, irrespective of how the waste is classified (i.e., transuranic or high-level radioactive waste), the composition and characteristics are the same, and the waste management (i.e., treatment and onsite storage) for this NI PEIS would be the same. In addition, even if the waste were managed as high-level radioactive waste, it would have no impact on the existing high-level radioactive waste management infrastructure (e.g., high-level waste storage tanks) because the high-activity waste from processing the targets would be initially stored and vitrified within the processing facility (i.e., FMEF, the Radiochemical Engineering Development Center [REDC], or the Fluorinel Dissolution Process Facility [FDPF]).

Commentors also expressed concern over the potential impacts of spent nuclear fuel generation from FFTF restart and operation, particularly regarding human health risk. This NI PEIS estimates that about 16 metric tons of heavy metal spent nuclear fuel would be generated over 35 years of operation of FFTF. Hanford is currently managing about 2,000 metric tons of heavy metal spent nuclear fuel. As indicated in Table 4-173, the radiation risk to a maximally exposed individual from normal operational activities during management of the current stored spent nuclear fuel over 35 years is  $1.4 \times 10^{-8}$  latent cancer fatality. The risk to the maximally exposed individual that would be associated with the new nuclear infrastructure operations to restart FFTF and operate FMEF or the Radiochemical Processing Laboratory is  $9.5 \times 10^{-8}$  latent cancer fatality. Furthermore, only a small fraction of this risk would be attributable to management of the additional spent nuclear fuel at FFTF. The annual dose to the maximally exposed individual from all current and reasonably foreseeable activities at Hanford is less than 0.2 millirem. This dose is well within the DOE dose limits given in DOE Order 5400.5, *Radiation Protection of the Public and the Environment*. As discussed in that order, the dose limit from airborne emissions is 10 millirem per year, as required by EPA regulations under the Clean Air Act; the dose limit from drinking water is 4 millirem per year, consistent with the EPA drinking water criteria under the Safe Drinking Water Act; and the dose limit from all pathways combined is 100 millirem per year. The risk to the population from all activities at Hanford would be 0.21 latent cancer fatality over 35 years. DOE has committed to remove the spent nuclear fuel at Hanford for ultimate disposition in a geologic repository.

#### 1.5.4 Cost of the Various Alternatives

Commentors expressed opinions about the costs related to the stated missions. Commentors stated that a cost-benefit analysis was necessary to show the value of production of medical isotopes balanced against facility

costs, in particular, the restart of FFTF, and noted that perhaps facilities would be able to pay for themselves. There were concerns that FFTF restart would take funds away from the cleanup of Hanford. Commentors noted that the decommissioning costs were not included for the restart FFTF option in the *NI Cost Report*. Several commentors remarked that the expense of plutonium-238 production cannot be justified when DOE needs to clean up existing problems at its sites.

Although the costs of proposed actions are not required by NEPA and CEQ regulations to be included in a PEIS, DOE prepared a separate *NI Cost Report*. This report would provide additional pertinent information to the Secretary of Energy so that he may make an informed decision with respect to the alternatives presented in this Final NI PEIS. Pursuant to CEQ regulations (40 CFR Section 1505.1(e)), such documents comparing alternatives should be made available to the public prior to any decision being made. DOE mailed this document to more than 730 interested parties on August 24, 2000. This report was made available immediately upon release on the NE web site (<http://www.nuclear.gov>) and in the public reading rooms. DOE has also provided the summary of the *NI Cost Report* in Appendix P of this Final NI PEIS.

### **1.5.5 Nuclear Nonproliferation Policy**

Commentors expressed opinions about the nuclear nonproliferation implications of the proposed action. Commentors were concerned about keeping plutonium-238 out of the hands of third parties, and it was suggested that the purchase of plutonium-238 from Russia would stop proliferation of the material and the United States would know the disposition of the quantity purchased. Several commentors raised concerns about specific facilities described in the NI PEIS, including the FDPF and FFTF. The use of highly enriched uranium fuel in FFTF was questioned related to possible violation of U.S. nuclear nonproliferation policy. Conversely, the shutdown of FFTF that occurred previously was characterized as being done to discourage proliferation of nuclear weapons worldwide, but had instead weakened the U.S. position as a world leader in nuclear technology. There were comments about the timeliness of release of the *NI Nonproliferation Impact Assessment*, that no nonproliferation information was included in the Draft NI PEIS, and that nuclear nonproliferation policy should be considered by DOE in selection of its preferred alternative.

The plutonium being considered for production in the NI PEIS is plutonium-238, which is not the same isotope of plutonium that is used in nuclear weapons. The production of plutonium-238 does not present a nonproliferation concern. DOE developed the separate *NI Nonproliferation Impact Assessment*, published in September 2000, that analyzed the nonproliferation impacts of the actions considered in this PEIS and found that there are no U.S. nonproliferation policies, laws, regulations, or international agreements that preclude the use of any of the facilities in the manner described in the Draft NI PEIS. Although this policy analysis is not required under NEPA, it is an essential element in the decision-making process for the DOE nuclear infrastructure. A summary of the *NI Nonproliferation Impact Assessment* is included in Appendix Q of this Final NI PEIS. It is also available on the DOE NE web site (<http://www.nuclear.gov>).

### **1.5.6 Public Involvement**

Commentors expressed opinions about the length of the comment period on the Draft NI PEIS, and said they wanted additional time to obtain and review relevant documents, including the *NI Cost Report* and *NI Nonproliferation Impact Assessment*. As identified in Section 1.5, the deadline for transmittal of comments was changed from September 11, 2000 (as stated in the transmittal letter of the Draft NI PEIS and the Summary) to September 18, 2000. While the official comment period ended on September 18, 2000, DOE addressed late comments to the extent practicable and considered all comments received through October 31, 2000, in preparing this Final NI PEIS. Comments that were received through September 25, 2000, along with corresponding responses, have been included in Chapter 2 of the comment response volume. Direct responses are not included to comments that were received after September 25, 2000. However, all of these comments

were considered and are characterized by other comments received during the comment period (for which a response has been provided).

Many commentors expressed the opinion that public input is intended for “show only,” and that DOE has already made its decisions. Commentors also stated that they had given the same comments over and over again and that DOE representatives were not listening. DOE policy encourages effective public participation in its decision-making process. In compliance with NEPA and CEQ regulations, DOE provided opportunity to the public to comment on the scope of the NI PEIS and the environmental impact analysis of DOE’s proposed alternatives. DOE gave equal consideration to all comments. In preparing this Final NI PEIS, DOE carefully considered all comments received from the public.

Some commentors expressed opinions about the conduct of the hearings, both positive and negative. The public hearing format was designed to be fair. The public hearing format used was based on stakeholder input and was presented in the Notice of Availability (65 FR 46443 et seq.) for the Draft NI PEIS. This format was intended to encourage public participation, regardless of the motivation for attending the hearing. It provided an opportunity for the participants to meet, exchange information and share concerns with DOE personnel available throughout the course of each hearing to answer questions. The meetings were facilitated by an independent moderator to ensure that all persons wishing to speak had an opportunity to do so. Persons wishing to comment were selected at random from the audiences rather than according to the order in which they registered. This was accomplished by a random number drawing. In addition to the comment recorder stationed at the main hearing, a second recorder was available in an adjacent room to receive comments without the need to await selection at the main proceeding. The hearing format promoted open and equal representation by all individuals and groups.

### **1.5.7 Environmental Impacts**

A number of commentors questioned the results of the environmental impact analysis and cumulative impacts, specifically at Hanford. Many of these comments focused on concerns that the proposed action would result in negative impacts to the health of individuals residing in the Hanford region. The NI PEIS analyzes the impacts of the various alternatives, and the environmental impacts associated with all proposed nuclear infrastructure activities are addressed in detail in Chapter 4. Specifically, the environmental impacts associated with operation of the Hanford facilities during normal operations and from postulated accidents are presented in Section 4.3. These assessments were made using well-established and accepted analytical methods, as described in Appendixes G through L. The analytical methodology is conservative by nature; the actual impacts to the environment would be expected to be less than calculated. All impacts have been shown to be small. No fatalities among workers or the general public would be expected over the 35-year operational period. The impacts to the biosphere (air, water, and land) were also evaluated and determined to be small.

Some commentors raised specific concern over potential contamination of the Columbia River resulting from the restart of FFTF. However, FFTF is approximately 4.5 miles from the Columbia River. There are no discharges to the river from FFTF and no radioactive or hazardous discharges to groundwater. As indicated in analyses presented in Chapter 4 (e.g., Sections 4.3.1.1.4, 4.3.3.1.4, 4.4.3.1.4, 4.5.3.2.4, and 4.6.3.2.4), there would be no discernible impacts to groundwater or surface water quality at Hanford from operation of Hanford facilities that would support the nuclear infrastructure missions described in Section 1.2.

A number of commentors also expressed concern that DOE would expose individuals in the Pacific Northwest to risks associated with importing weapons-grade plutonium. None of the proposed alternatives involve the shipment of any weapons-grade plutonium to any port in the United States. Alternative 1 does postulate that DOE might decide at some point to import mixed oxide fuel from Europe to fuel FFTF. At this time, however, DOE has not proposed to import this fuel through any specific port. If DOE ultimately decides to import fuel

from Europe, it would perform a separate NEPA analysis to select a port. This review would address all relevant potential impacts of overseas and inland water transportation, shipboard fires, package handling, land transportation, as well as safeguards and security associated with the import of SNR-300 mixed oxide fuel through a variety of specific candidate ports on the west and east coasts. It would take into account all public comments, including local resolutions, concerning the desirability of bringing mixed oxide fuel into the proposed alternative ports.

In the event that DOE decides to enhance its nuclear infrastructure, it would not expose any population to high, unacceptable risks under any alternative. Any transportation activities that would be conducted by DOE would comply with U.S. Nuclear Regulatory Commission (NRC) and U.S. Department of Transportation regulations. Associated transatlantic shipments would comply with International Atomic Energy Agency requirements. In Section J.6.2, DOE reviewed the potential maximum impacts from the marine transportation of mixed oxide fuel from Europe to a representative military port (Charleston, South Carolina), and overland transportation to Hanford. Also in that section, the results of a bounding analysis show that the maximum potential radiological risks to the surrounding public from mixed oxide fuel shipments would be extremely small (e.g., less than 1 chance in a trillion for a latent cancer fatality per shipment from severe accidents at docks and in channels and less than 1 chance in 50 billion for a latent cancer fatality per shipment from overland highway accidents).

## **1.6 ALTERNATIVES EVALUATED IN THIS NI PEIS**

This NI PEIS analyzes the potential environmental impacts using various irradiation and processing facilities to meet the following projected DOE irradiation service mission needs for 35 years: (1) production of medical, research, and industrial isotopes; (2) production of up to 5 kilograms (11 pounds) per year of plutonium-238 for use in advanced radioisotope power systems for future NASA space missions; and (3) support for U.S. civilian nuclear energy research and development activities. The proposed irradiation facilities include those that are currently operating, those that could be brought online, or those that could be constructed and operated to meet DOE's nuclear facility infrastructure requirements. This NI PEIS evaluates a No Action Alternative and five programmatic alternatives:

No Action Alternative

Alternative 1—Restart FFTF

Alternative 2—Use Only Existing Operational Facilities

Alternative 3—Construct New Accelerator(s)

Alternative 4—Construct New Research Reactor

Alternative 5—Permanently Deactivate FFTF (with No New Missions)

Each of the alternatives in this NI PEIS would contribute to fulfilling some of the proposed missions. However, none of the alternatives can completely meet all of the projected nuclear infrastructure needs. It is possible during the Record of Decision process that a combination of the alternatives could be selected, for example, a low-energy accelerator in combination with the existing reactors to optimize research isotope production, or in combination with FFTF to optimize research and therapeutic isotope production. The alternatives, their associated facility options, and their relative capabilities are described in detail in Chapter 2. DOE's Preferred Alternative for accomplishing expanded civilian nuclear energy research and development and isotope production missions in the United States is Alternative 2, Use Only Existing Operational Facilities, Option 7. Under this alternative and option, DOE would reestablish domestic production of plutonium-238, as needed, using irradiation capabilities at both ATR at INEEL and HFIR at ORNL. REDC at ORNL would be used to store neptunium-237 and to fabricate and process the targets irradiated at ATR and HFIR. The production of medical and industrial isotopes and support of civilian nuclear energy research and development

would continue and increase to the extent possible under current reactor operating levels. FFTF at Hanford would be permanently deactivated.

## 1.7 RELATED NEPA REVIEWS

This section provides brief summaries of NEPA documents related to ongoing DOE programs, including documents that address other aspects of DOE's nuclear facility infrastructure, the management of various waste types across the DOE complex, and activities currently under way or planned at candidate sites that are analyzed in this NI PEIS.

The *Environmental Assessment, Shutdown of the Fast Flux Test Facility, Hanford Site, Richland, Washington*, (DOE/EA-0993, May 1995; Finding of No Significant Impact [FONSI], May 1995) analyzes the environmental impacts associated with permanent shutdown (deactivation) of FFTF and the activities required to support it. Based on the environmental assessment, DOE determined that the proposed shutdown would not result in significant environmental impacts as defined under NEPA. This NI PEIS summarizes the impacts presented in the environmental assessment for those alternatives that consider permanent deactivation of FFTF (i.e., Alternatives 2, 3, 4, and 5) (DOE 1995a).

The *Environmental Assessment of the Import of Russian Plutonium-238* (DOE/EA-0841, June 1993; FONSI, June 1993) addresses the environmental impacts of importing plutonium-238 from Russia to augment the U.S. inventory for NASA space missions. The proposed action considers shipping up to 40 kilograms (88.2 pounds) of plutonium-238 fuel from Russia to a U.S. port, transporting the plutonium-238 within the United States to either SRS or LANL in Los Alamos, New Mexico, and if necessary, processing the material at SRS to remove impurities from the fuel. The impacts analyzed in the environmental assessment are summarized in this NI PEIS for those alternatives that do not consider re-establishing a domestic plutonium-238 production capability (i.e., the No Action Alternative and Alternative 5) (DOE 1993).

The *Final Environmental Impact Statement, Interim Management of Nuclear Materials* (DOE/EIS-0220, October 1995) analyzes the potential environmental impacts of managing certain nuclear materials at SRS pending decisions on future use or ultimate disposition, as well as the impacts of constructing the SRS Actinide Packaging and Storage Facility. Five related Records of Decision have been issued since this Final EIS was published. On December 12, 1995, DOE issued a Record of Decision and a Notice of Preferred Alternatives (60 FR 65300) concerning interim management of several categories of nuclear materials at SRS. On February 8, 1996, DOE issued a Supplemental Record of Decision (61 FR 6633) concerning stabilization of two of the remaining categories of nuclear materials (Mark-16 and Mark-22 fuel and other aluminum-clad targets) analyzed in the Final EIS. After considering a DOE staff study and recommendation on canyon facility use, DOE issued a second Supplemental Record of Decision on September 6, 1996 (61 FR 48474), concerning stabilization of the neptunium-237 solutions, obsolete neptunium targets, and plutonium-239 solutions. On April 2, 1997, DOE issued a third Supplemental Record of Decision (62 FR 17790) related to stabilization in the F-Canyon and FB-Line facilities of the remaining Taiwan Research Reactor spent nuclear fuel. On October 31, 1997, DOE issued a fourth Supplemental Record of Decision (62 FR 61099) to add another method, processing and storage for vitrification in the Defense Waste Processing Facility, to those being used to manage plutonium and uranium stored in vaults and to amend its September 6, 1996, Supplemental Record of Decision to now enable use of the SRS H-Canyon facilities to stabilize the plutonium-239 and neptunium-237 solutions stored in H-Canyon and the obsolete neptunium-237 targets stored in K-Reactor into oxide forms. This neptunium-237 oxide serves as the target material for the plutonium-238 production mission analyzed in this NI PEIS (DOE 1995b).

The *Final Environmental Impact Statement, Medical Isotopes Production Project: Molybdenum-99 and Related Isotopes* (DOE/EIS-249, April 1996; Record of Decision, September 1996 [61 FR 48921]) analyzes

the proposed establishment of a domestic capability to produce molybdenum-99 (a short-lived isotope that decays into technetium-99, an isotope used extensively for medical imaging) and related medical isotopes such as iodine-131, xenon-133, and iodine-125. At the time of this review, the U.S. supply of molybdenum-99 depended on the production capacity of one aging reactor in Canada, so DOE proposed this action to ensure a reliable domestic source for this vital isotope. In the Record of Decision, DOE selected the Annular Core Research Reactor and the Hot Cell Facility at SNL, New Mexico, for the production of molybdenum-99 and the related isotopes. Since that time, the diversity and reliability of the world supply of molybdenum-99 have increased. DOE has determined that, because the vulnerability in supplies of molybdenum-99 has sufficiently diminished, the selected SNL facilities should be further developed for molybdenum-99 production using private funds. Negotiations toward that end are ongoing. Until an agreement is reached, the reactor and hot cell facilities are available for emergency molybdenum-99 production should that need arise. The reactor is also being used for the production of other isotopes such as iodine-125, and has been made available on a services basis to serve defense missions. Any nuclear facility infrastructure enhancements analyzed in this NI PEIS would be separate from, and in addition to, the existing capabilities of these facilities (DOE 1996a).

The *Final Environmental Impact Statement, Construction and Operation of the Spallation Neutron Source* (DOE/EIS-0247, April 1999; Record of Decision, June 1999 [64 FR 35140]) analyzes the potential environmental impacts of constructing and operating a state-of-the-art spallation neutron source facility at one of four sites: ORNL (Preferred Alternative); Argonne National Laboratory–East in Argonne, Illinois; Brookhaven National Laboratory in Upton, New York; and LANL. The spallation neutron source facility is designed to provide a high-flux, short-pulsed neutron source that would give the United States’ scientific and industrial research communities a much more intense source of pulsed neutrons than is currently available. Construction of this new facility would also ensure the future availability of a state-of-the-art facility as currently existing sources reach the end of their useful operating lives. In the associated Record of Decision, DOE designated ORNL as the chosen site for construction and operation of the spallation neutron source. The spallation neutron source is currently under construction, and the facility’s full capacity has been dedicated to support planned missions. The impacts of this action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action. However, the nuclear facility infrastructure enhancements analyzed in this NI PEIS would be separate from, and in addition to, the capabilities of this facility (DOE 1999a).

The *Final Waste Management Programmatic Environmental Impact Statement for Managing Treatment, Storage, and Disposal of Radioactive and Hazardous Waste (Waste Management PEIS)* (DOE/EIS-0200-F, May 1997; Transuranic Waste Record of Decision, January 1998 [63 FR 3629]; Hazardous Waste Record of Decision, August 1998 [63 FR 41810]; High-Level Radioactive Waste Record of Decision, August 1999 [64 FR 46661]; Low-Level Radioactive Waste and Mixed Low-Level Radioactive Waste Record of Decision, February 2000 [65 FR 10061] examines the potential environmental and cost impacts of selected strategic alternatives for managing five types of radioactive and hazardous waste that result from nuclear defense and research activities at sites throughout the United States. The *Waste Management PEIS* provides information on the impacts of the various siting configurations DOE will use to decide where to locate additional treatment, storage, and disposal capacity for each waste configuration. In the transuranic waste Record of Decision, DOE determined that those sites that currently have or will generate transuranic waste will prepare it for storage and store it on site, except SNL, which will transfer its transuranic waste to LANL. The hazardous waste Record of Decision states that DOE will continue the use of offsite facilities to treat nonwastewater hazardous waste, with the exception that Oak Ridge Reservation (ORR) and SRS will treat some of their own nonwastewater hazardous waste on site. The high-level radioactive waste Record of Decision states that immobilized high-level radioactive waste will be stored at Hanford, INEEL, SRS, and the West Valley Demonstration Project in New York until a geologic repository is licensed by the NRC. The low-level radioactive waste and mixed low-level radioactive waste Record of Decision states that DOE will minimally treat low-level radioactive waste at the generator sites, and that Hanford and the Nevada Test Site will be made available to

all DOE sites for low-level radioactive waste disposal. As part of this decision, DOE will treat mixed low-level radioactive waste at INEEL, ORR, and SRS; dispose of mixed low-level radioactive waste at the Nevada Test Site; and both treat and dispose of mixed low-level radioactive waste at Hanford. The impacts of this action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action. This NI PEIS analysis also assumes that waste generated as part of the NI PEIS proposed action would be managed in accordance with these decisions (DOE 1997a).

The *Draft Environmental Impact Statement for a Geologic Repository for the Disposal of Spent Nuclear Fuel and High-Level Radioactive Waste at Yucca Mountain, Nye County, Nevada*, (DOE/EIS-0250D, July 1999) analyzes the construction, operation and monitoring, and eventual closure of a potential geologic repository at Yucca Mountain to dispose of commercial and DOE spent nuclear fuel, high-level radioactive waste, and materials that NRC determines by rule require the same degree of isolation. National transportation, Nevada transportation, and waste packaging are evaluated as part of the analysis. Three implementing design alternatives based on thermal load—low, intermediate, and high—are examined. This NI PEIS assumes for analysis purposes that Yucca Mountain is a potential geologic repository site for spent nuclear fuel produced as a result of enhancing the U.S. nuclear facility infrastructure (DOE 1999b).

The *Tank Waste Remediation System, Hanford Site, Richland, Washington, Final Environmental Impact Statement* (DOE/EIS-0189, August 1996; Record of Decision, February 1997 [62 FR 8693]) satisfies the DOE commitment made in the *Disposal of Hanford Defense High-Level, Transuranic and Tank Waste Final Environmental Impact Statement* (DOE/EIS-0113, December 1987; Records of Decision March and April 1988) to prepare a supplemental NEPA analysis. The *Tank Waste Remediation System EIS* was prepared in response to several important changes subsequent to the Record of Decision, including a revised strategy for managing and disposing of tank waste and encapsulated cesium and strontium. As part of the proposed action, the *Tank Waste Remediation System EIS* evaluates continued operation and management of the tank farms, waste transfer system upgrades, and retrieval and treatment of the tank waste, including construction and operation of a facility to vitrify high-level radioactive waste and to vitrify or similarly immobilize low-level radioactive waste. DOE decided to implement the Preferred Alternative for retrieval, treatment, and disposal of tank waste and to defer a decision on the disposition of cesium and strontium capsules. Two supplemental analyses were prepared for the *Tank Waste Remediation System EIS*. The first was *Proposed Upgrades to the Tank Farm Ventilation, Instrumentation, and Electrical Systems under Project W-314 in Support of Tank Farm Restoration and Safe Operations* (DOE/EIS-0189-SA1, June 1997). Based on these supplemental analyses, it was determined that upgrades or planned upgrades to the tank farm do not pose any additional potential environmental impacts and, therefore, no additional NEPA analysis is required. The second supplemental analysis was for the *Tank Waste Remediation System* (DOE/EIS-0189-SA2, May 1998). This analysis provides information on the most recent inventory of chemical and radiological constituents in the tanks and the new waste to be sent to the tanks for treatment. Based on the new data, it was concluded that there would be minimal changes from the impacts identified in the *Tank Waste Remediation System EIS* and, therefore, no additional NEPA analysis is required. The impacts of this action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action (DOE 1996b).

The *Final Hanford Comprehensive Land Use Plan Environmental Impact Statement* (DOE/EIS-0222-F, September 1999; Record of Decision, November 1999 [64 FR 61615]) focuses on developing an overall strategy for future land use at Hanford and includes a proposed comprehensive land-use plan. The Preferred Alternative, which DOE selected in the Record of Decision, is to consolidate waste management operations in the Central Plateau; allow industrial development in the eastern and southern portions of the site; increase recreational access to the Columbia River; and expand Saddle Mountain National Refuge to include all of the Wahluke Slope, McGee Ranch, and Fitzner-Eberhardt Arid Lands Ecology Reserve. The impacts of this action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action (DOE 1999c).

The *Hanford Reach of the Columbia River Comprehensive River Conservation Study and Environmental Impact Statement* (National Park Service June 1994; Record of Decision, July 1996) evaluates impacts related to protection of the Hanford Reach of the Columbia River as a Wild and Scenic River, increased recreation access, and visitor interpretation and education. In the Record of Decision, the National Park Service recommended that Congress designate the Hanford Reach of the Columbia River, public land within one-quarter mile of the river, and all public land on the Wahluke Slope as a new National Wildlife Refuge and National Wild and Scenic River. The impacts of this action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action (NPS 1994).

The *Department of Energy Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs Final Environmental Impact Statement* (DOE/EIS-0203-F, April 1995; Record of Decision, May 1995 [60 FR 28680]) is a complex-wide evaluation of the alternatives for managing the existing and projected amounts of spent nuclear fuel within the DOE inventory through 2035. The EIS contains an analysis of the impacts of transporting spent nuclear fuel, as well as sitewide alternatives for environmental restoration and waste management programs at INEEL. In the associated Record of Decision, DOE designated Hanford, INEEL, and SRS for regional spent fuel storage and management and made decisions about environmental restoration and waste management activities at INEEL. In March 1996, DOE issued an amendment to the May 1995 Record of Decision to include a decision to regionalize the management of DOE-owned spent nuclear fuel by fuel type, including spent fuel currently stored at Hanford, INEEL, and SRS. The impacts of this action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action (DOE 1995c).

The *Final Environmental Impact Statement on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel* (DOE/EIS-0218F, February 1996; Record of Decision, July 1996 [61 FR 38720]) evaluates the adoption of a joint DOE/Department of State policy to manage spent nuclear fuel from foreign research reactors, including highly enriched uranium provided by the United States to other countries for research reactors. Management alternatives include a number of implementation options for port selection, transportation, and storage at DOE sites. In the Record of Decision, DOE selected a management policy that returned spent nuclear fuel from various foreign research reactors to the United States using two designated U.S. ports and the management at INEEL and SRS. A supplement analysis (DOE/EIS-0218-SA-2, August 1998) was prepared to examine acceptance of foreign research reactor spent nuclear fuel under three scenarios not specifically examined in the EIS: (1) accepting spent nuclear fuel not included in EIS-estimated inventories, (2) accepting spent nuclear fuel from countries in quantities greater than the quantities identified in the EIS, and (3) transporting more than eight casks of spent fuel on a single oceangoing vessel. The supplement analysis concluded that the potential environmental impacts of these actions are bounded by the analysis performed in the EIS and, therefore, no supplement to the EIS is needed. In turn, DOE issued a revision to the Record of Decision on July 19, 2000 (65 FR 44767) to allow the shipment of up to 16 casks of spent nuclear fuel on a single ocean-going vessel transporting foreign research reactor spent nuclear fuel to the United States. The impacts of this action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action (DOE 1996c).

The DOE INEEL *Advanced Mixed Waste Treatment Project Final Environmental Impact Statement* (DOE/EIS-0290, January 1999; Record of Decision, April 1999 [64 FR 16948]) evaluates four alternatives: (1) a No Action Alternative under which existing waste management operations, facilities, and projects would continue; (2) the proposed action/Preferred Alternative under which BNFL, Inc., would build and operate an advanced mixed waste treatment project facility using proposed thermal and nonthermal treatment technologies for certification and shipment to the Waste Isolation Pilot Plant or to another acceptable disposal facility; (3) a nonthermal treatment alternative under which some treatment of transuranic, alpha, and low-level mixed waste would occur at an advanced mixed waste treatment project facility at the same location as the proposed action, and waste that requires thermal treatment would be repackaged for storage; and (4) a treatment and storage

alternative that would include the same processes as the proposed action/Preferred Alternative, except the treated waste would be placed in Resource Conservation and Recovery Act–permitted storage units at the onsite Radioactive Waste Management Complex for long-term storage. In the Record of Decision, DOE selected the Preferred Alternative, although construction of the thermal treatment component of this alternative has been deferred pending the recommendation of a blue ribbon panel of experts assessing possible technology alternatives. The impacts of the proposed action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action (DOE 1999d).

The *Site-Wide Environmental Impact Statement for the Continued Operation of the Los Alamos National Laboratory* (DOE/EIS-0238, January 1999; Record of Decision, September 1999 [64 FR 50797]) evaluates ongoing and projected new operations and facilities at LANL in support of DOE missions, including the storage of plutonium-238. A decision was made in the LANL Record of Decision to implement the Preferred Alternative, which includes expansion of operations as necessary, increases in existing operations to the greatest reasonably foreseeable levels, and full implementation of the mission elements assigned to LANL. Because the remaining U.S. inventory of usable plutonium-238 is stored at LANL, the NI PEIS evaluates the transport to LANL of the plutonium-238 product resulting from an enhanced nuclear facility infrastructure (DOE 1999e).

The *Final Programmatic Environmental Impact Statement for Tritium Supply and Recycling* (DOE/EIS-0161, October 1995; Record of Decision, December 5, 1995 [60 FR 63878]) evaluates the siting, construction, and operation of tritium supply technology alternatives and recycling facilities at five candidate sites, as well as the use of a CLWR for producing tritium, a gaseous radioactive isotope of hydrogen considered essential to the operation of U.S. thermonuclear weapons. In the Record of Decision, DOE selected a dual-track approach. One track explores the purchase of an operating or partially complete CLWR, or the purchase of irradiation services from such a reactor. A second track would design, build, and test critical components of an accelerator system for production of tritium. The Record of Decision stated that DOE would select one of the alternatives at a later date to serve as the primary tritium source for the U.S. nuclear weapons stockpile, while the other alternative will be developed as a backup source, if feasible. The Record of Decision also stated that DOE would determine whether the operation of FFTF might be able to play any role in future tritium requirements. On December 22, 1998, the Secretary of Energy announced his selection of the CLWR as the primary tritium supply and that an accelerator would be developed but not constructed. In addition, DOE decided that FFTF would have no role in tritium supply plans. The impacts of this action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action. Since the accelerator for production of tritium would not be built, it was not considered as a reasonable alternative in the NI PEIS (DOE 1995d).

The *Disposition of Surplus Highly Enriched Uranium Final Environmental Impact Statement* (DOE/EIS-0240, June 1996; Record of Decision, July 1996 [61 FR 40619]) addresses the disposition of a nominal 220 tons of highly enriched uranium declared surplus to the national security needs of the United States. Alternatives include several approaches to blending down the highly enriched material to make it non-weapons-usable and suitable for fabrication into fuel for commercial nuclear reactors. The Record of Decision identifies DOE's intent to blend, over time, as much material as possible (up to 85 percent) for commercial use and blending the remainder for disposal as low-level radioactive waste. The impacts of the proposed action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action (DOE 1996d).

The *Storage and Disposition of Weapons-Usable Fissile Materials Final Programmatic Environmental Impact Statement* (DOE/EIS-0229, December 1996; Record of Decision, January 1997 [63 FR 43386]) analyzes the environmental impacts of alternatives considered for the long-term storage of weapons-usable fissile materials (highly enriched uranium and plutonium) and for the disposition of weapons-usable plutonium that has been declared surplus to national security needs. The Record of Decision encompasses two categories of plutonium

decisions: (1) the sites and facilities for the storage of nonsurplus plutonium and the storage of surplus plutonium pending disposition; and (2) the programmatic strategy for disposition of surplus plutonium. It also announces the decision to store surplus and nonsurplus highly enriched uranium in upgraded facilities at ORR. DOE studies indicated that significant cost savings could be realized from the transfer of nonpit materials from the Rocky Flats Environmental Technology Center and Hanford earlier than indicated in the *Storage and Disposition PEIS* Record of Decision. DOE issued an amended Record of Decision (August 1998) that supports the early closure of the Rocky Flats Environmental Technology Center and the early deactivation of plutonium storage facilities at Hanford. The amended Record of Decision includes decisions to accelerate shipment of all nonpit surplus plutonium from the Rocky Flats Environmental Technology Center to SRS and the relocation of all Hanford surplus plutonium to SRS, if SRS were selected as the immobilization site. A supplement analysis to the *Storage and Disposition PEIS*, the *Supplement Analysis for Storing Plutonium in the Actinide Packaging and Storage Facility and Building 105-K at the Savannah River Site*, was issued in July 1998. The impacts of the proposed action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action (DOE 1996e).

The *Surplus Plutonium Disposition Final Environmental Impact Statement* (DOE/EIS-0283, November 1999; Record of Decision, January 2000 [65 FR 1608]) was tiered from the *Storage and Disposition PEIS* and evaluated reasonable alternatives for the siting, construction, and operation of facilities required to implement DOE's disposition strategy for up to 50 metric tons of surplus plutonium. The disposition facilities analyzed in this EIS include a pit disassembly and conversion facility, a plutonium conversion and immobilization facility, and a mixed oxide fuel fabrication facility. The analyses also considered the potential impacts of fabricating a limited number of lead fuel assemblies for testing in a reactor. In the Record of Decision, DOE decided to provide for the safe, secure disposition using a hybrid approach of immobilizing approximately 17 metric tons (19 tons) and using up to 33 metric tons (36 tons) as mixed oxide fuel. DOE also decided to construct and operate each of the three disposition facilities at SRS, fabricate the lead assemblies at LANL, and conduct postirradiation examination of the lead assemblies at ORNL. The impacts of the proposed action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action (DOE 1999f).

The *Final Programmatic Environmental Impact Statement for Alternative Strategies for the Long-Term Management and Use of Depleted Uranium Hexafluoride* (DOE/EIS-0269, April 1999; Record of Decision, August 1999 [64 FR 43358]) evaluates the environmental impacts of six alternative strategies for the long-term management of DOE-owned depleted uranium hexafluoride currently stored at the East Tennessee Technology Park in Oak Ridge, Tennessee; the Paducah Gaseous Diffusion Plant near Paducah, Kentucky; and the Portsmouth Gaseous Diffusion Plant near Piketon, Ohio. These alternatives involve cylinder technology and design; conversion of depleted uranium hexafluoride to another chemical form; and materials use, storage, disposal, and transportation. As indicated in the Record of Decision, DOE selected the Preferred Alternative—to begin conversion of the depleted uranium hexafluoride as soon as possible, either to uranium oxide, uranium metal, or a combination of both, while allowing for future use of as much of this inventory as possible. This NI PEIS analyzes the conversion of depleted uranium hexafluoride from a representative site (Portsmouth) to uranium dioxide, which would be used as feedstock for immobilization and mixed oxide fuel and lead assembly fabrication. The impacts of the proposed action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action (DOE 1999g).

The *Final Programmatic Environmental Impact Statement for Stockpile Stewardship and Management* (DOE/EIS-0236, September 1996; Record of Decision, December 1996 [61 FR 68014]) evaluates the potential environmental impacts resulting from activities associated with nuclear weapons research, design, development, and testing, as well as the assessment and certification of their safety and reliability. The stewardship portion of the document analyzes the development of three new facilities to provide enhanced experimental capabilities. The stockpile management portion of the EIS concerns producing, maintaining,

monitoring, refurbishing, and dismantling the nuclear weapons stockpile at eight sites, including Pantex and SRS. In the Record of Decision, DOE selected to downsize a number of facilities for stockpile dismantlement and to build experimental facilities at Lawrence Livermore National Laboratory. A draft supplement analysis (DOE/EIS-0236-SA, June 1999) was prepared to examine the plausibility of a building-wide fire at LANL's plutonium facility and to examine new studies regarding seismic hazards at LANL. The draft supplement analysis was issued for public comment and a final supplemental analysis was issued on September 2, 1999. The supplement analysis concluded that there is no need to prepare a supplemental EIS. The impacts of the proposed action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action (DOE 1996f).

The *Final Environmental Impact Statement for the Treatment and Management of Sodium-Bonded Spent Nuclear Fuel* (DOE/EIS-0306, July 2000; Record of Decision, September 2000 [65 FR 56565]) evaluates strategies to remove or stabilize the reactive sodium contained in a portion of DOE's spent nuclear fuel inventory to prepare the spent nuclear fuel for disposal in a geologic repository. The EIS analyzes, under the proposed action, six alternatives that employ one or more of the following technology options at nuclear fuel management facilities at SRS or INEEL: electrometallurgical treatment; the plutonium-uranium extraction process; packaging in high-integrity cans; and the melt and dilute treatment process. In the Record of Decision, DOE decided to implement the preferred alternative of electrometallurgically treating the Experimental Breeder-II spent nuclear fuel and miscellaneous small lots of sodium-bonded spent nuclear fuel at Argonne National Laboratory–West at INEEL. Because of the different physical characteristics of the Fermi-1 sodium-bonded blanket spent nuclear fuel also analyzed in the EIS, DOE decided to continue to store this material while alternative treatments are evaluated. The impacts of the proposed action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action (DOE 2000b).

The *Final Environmental Impact Statement (EIS) for Treating Transuranic (TRU)/Alpha Low-Level Waste at the Oak Ridge National Laboratory, Oak Ridge, Tennessee* (DOE/EIS-0305-F, June 2000; Record of Decision, August 2000 [65 FR 48683]) evaluates alternatives to construct, operate, and decontaminate and decommission a transuranic waste treatment facility in Oak Ridge, Tennessee. Four types of waste would be treated at the proposed facility including remote-handled transuranic mixed waste sludge, liquid low-level radioactive waste associated with the sludge, contact-handled transuranic/alpha low-level radioactive waste solids, and remote-handled transuranic/alpha low-level radioactive waste solids. The EIS analyzes the potential environmental impacts associated with five alternatives—No Action; the Low-Temperature Drying Alternative, which is DOE's Preferred Alternative; the Vitrification Alternative; the Cementation Alternative; and the Treatment and Waste Storage at ORNL Alternative. In the Record of Decision, DOE selected the preferred alternative of constructing and operating a Transuranic (TRU) Waste Treatment Facility that will use a low-temperature drying process for treating TRU mixed waste sludge and associated low-level waste supernate, and that will treat TRU solid waste by sorting and compacting. Any solid waste containing hazardous constituents regulated under RCRA will be encapsulated. DOE will dispose of the treated TRU waste at the Waste Isolation Pilot Plant near Carlsbad, New Mexico, and treated low-level waste at DOE's Nevada Test Site. The impacts of the proposed action are factored into the assessment of potential cumulative impacts resulting from this NI PEIS proposed action (DOE 2000c).

The *Environmental Assessment of Melton Valley Storage Tanks Capacity Increase Project at the Oak Ridge National Laboratory in Oak Ridge, Tennessee* (DOE/EA-1044, April 1995) evaluates the potential impacts of the construction and maintenance of additional storage capacity at ORNL in Oak Ridge, Tennessee, for liquid low-level radioactive waste. New capacity would be provided by a facility partitioned into six individual tank vaults containing one 100,000-gallon liquid low-level radioactive waste storage tank each. Alternatives

considered include the No Action Alternative, ceasing generation, storage at other ORR storage facilities, source treatment, pretreatment, and storage at other DOE facilities. The impacts of the proposed action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action (DOE 1995e).

The *Environmental Assessment and FONSI for the Management of Spent Nuclear Fuel on the Oak Ridge Reservation Oak Ridge, Tennessee* (DOE/EA-1117, February 1996) evaluates the potential impacts of the management of spent nuclear fuel on the DOE Oak Ridge Reservation. Spent nuclear fuel would be retrieved from storage; transferred by truck to a hot cell facility, if segregation by fuel type and/or repackaging is required; loaded into containers/transport casks that meet regulatory requirements; and shipped via truck to offsite storage at either SRS or INEEL. The proposed action may also include construction and operation of a dry cask spent nuclear fuel storage facility on ORR to enable reactor operations to continue in the event of an interruption of offsite spent nuclear fuel shipment. In the No Action Alternative, neither construction of a dry cask storage facility nor shipment of spent nuclear fuel from ORR would occur. Spent nuclear fuel would remain at present storage locations on ORR. Due to space limitations, operations on ORR that generate spent nuclear fuel would have to cease, including operation of the High Flux Isotope Reactor. The impacts of the proposed action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action (DOE 1996g).

The *Final Environmental Impact Statement, Management of Spent Nuclear Fuel from the K Basins at the Hanford Site, Richland, Washington* (DOE/EIS-0245F, January 1996; Record of Decision, March 1996 [61 FR 10736]) analyzes the potential environmental impacts of alternatives for managing the spent nuclear fuel located in the K-East and K-West spent nuclear fuel storage basins at Hanford. In the Record of Decision, DOE decided to implement the preferred alternative evaluated in the FEIS with two modifications. The preferred alternative consists of removing the spent nuclear fuel from the basins, vacuum drying, conditioning and sealing it in inert-gas filled canisters for dry vault storage in a new facility, to be built at Hanford, for up to 40 years pending decisions on ultimate disposition. The K Basins will continue to be operated during the period over which the preferred alternative is implemented. The preferred alternative also includes transfer of the basin sludge to Hanford's double-shell tanks for management, disposal of non-spent-nuclear-fuel basin debris in a low-level burial ground at Hanford, disposition of the basin water, and deactivation of the basins pending decommissioning. The two modifications to the preferred alternative that were presented in the Record of Decision addressed the management of the sludge, and the timing of placement of the spent nuclear fuel into the transportation casks: (1) should it not be possible to put the sludge into the double-shell tanks, the sludge will either continue to be managed as spent nuclear fuel, or disposed of as solid waste; and (2) to reduce the radiation exposure to workers, the multiccanister overpacks will be placed inside the transportation casks before the spent nuclear fuel is loaded into them, instead of loading the spent nuclear fuel into the multiccanister overpacks prior to placing them inside the transportation casks. A supplement analysis (DOE/EIS-0245-SA-01, August 1998) was prepared to examine the potential impacts of deleting the hot conditioning/passivation step from the preferred alternative in the ROD. Based on this supplement analysis, DOE determined that there would be minimal changes from the impacts previously identified in the EIS, and therefore no additional NEPA analysis is required. The impacts of this action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action (DOE 1996h).

The *Environmental Assessment, Management of Hanford Site Non-Defense Production Reactor Spent Nuclear Fuel* (DOE/EA-1185, March 1997; FONSI, March 1997) assesses the environmental impacts associated with the management of nondefense production reactor spent nuclear fuel at Hanford, and associated activities to support this work. Under the proposed action, DOE would consolidate the site's inventory of this material, stored in various facilities throughout the site, in a cost-effective, radiologically and industrially safe and passive storage condition, pending final disposition. Alternatives considered in the review process included the No Action alternative; the preferred alternative to consolidate Hanford's inventory of nondefense

production reactor spent nuclear fuel in aboveground and vault storage in the 200 Area; and alternatives addressing aboveground dry cask storage in the 400 Area and vault storage in the 200 Area. The impacts of this action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action (DOE 1997b).

The *Environmental Assessment for Transportation of Low-Level Radioactive Waste from the Oak Ridge Reservation to Off-Site Treatment or Disposal Facilities* (DOE/EA-1315, April 2000) evaluates the potential impacts of the transportation of low-level radioactive waste from ORR in Tennessee for treatment or disposal at various locations in the United States. Low-level radioactive waste from three ORR facilities, ORNL, Oak Ridge Y-12 Plant, and East Tennessee Technology Park, is proposed to be loaded and transported to destinations representative of other DOE sites and licensed commercial nuclear waste treatment or disposal facilities. The treatment and/or disposal facilities include Envirocare of Utah, Inc.; Waste Control Specialists; commercial treatment or disposal facilities near SRS in Aiken, South Carolina; commercial facilities near ORR; commercial facilities near Hanford; and facilities at DOE sites such as the Nevada Test Site, the Hanford Reservation, and SRS. In the No Action Alternative, DOE would not ship and dispose of the existing and projected large quantities of ORR low-level radioactive waste at offsite radioactive waste disposal facilities. Relatively small volumes of ORR low-level radioactive waste would continue to be shipped to DOE or commercial disposal facilities under existing and previously approved categorical exclusions. Low-level radioactive waste would continue to be stored on the ORR site, eventually requiring additional low-level radioactive waste storage facilities. The impacts of the proposed action are factored into the assessment of potential cumulative impacts resulting from this NI PEIS proposed action (DOE 2000d).

The *Environmental Assessment for Selection and Operation of the Proposed Field Research Centers for the Natural and Accelerated Bioremediation Research (NABIR) Program* (DOE/EA-1196, March 2000; FONSI, April 2000) evaluates the potential impacts of adding a Field Research Center component to the existing NABIR Program. The NABIR Program is a 10-year fundamental research program designed to increase the understanding of fundamental biogeochemical processes that would allow the use of bioremediation approaches for cleaning up DOE's contaminated legacy waste sites. The Field Research Center would be integrated with the existing and future laboratory and field research and would provide a means of examining the fundamental biogeochemical processes that influence bioremediation under controlled small-scale field conditions. The environmental assessment analyzes the No Action Alternative and two alternative sites under the proposed action: ORNL/Y-12 Site, Oak Ridge, Tennessee, and Pacific Northwest National Laboratory/DOE Hanford 100-H Area, Richland, Washington. The impacts of the proposed action are factored into the assessment of potential cumulative impacts resulting from this NI PEIS proposed action (DOE 2000e).

The *Idaho High-Level Waste and Facilities Disposition Draft Environmental Impact Statement* (DOE/EIS-0287D, December 1999) analyzes the potential environmental consequences of managing two waste types at INEEL. The two waste types are high-level radioactive waste in a calcine form and liquid mixed transuranic waste, historically known as sodium-bearing waste and newly generated liquid waste. The disposition of existing and proposed high-level radioactive waste facilities after their missions have been completed is also analyzed. The waste processing alternatives are No Action, Continued Current Operations, Separations, Non-Separations, and Minimum INEEL Processing. The facilities' disposition alternatives are No Action, Clean Closure, Performance-Based Closure, Closure to Landfill Standards, Performance-Based Closure with Class A Grout Disposal, and Performance-Based Closure with Class C Grout Disposal. The impacts of the proposed action are factored into the assessment of potential impacts resulting from the NI PEIS proposed action (DOE 1999h).

The *Draft Environmental Assessment for Transportation of Low-Level Radioactive Mixed Waste from the Oak Ridge Reservation to Off-Site Treatment or Disposal Facilities* (DOE/EA-1317, July 2000) evaluates the potential impacts of transportation of low-level radioactive mixed waste from Oak Ridge, Tennessee, to

treatment and disposal facilities in various locations in the United States. Low-level radioactive mixed waste from three ORR facilities, East Tennessee Technology Park, ORNL, and the Y-12 Plant, is proposed to be packaged as required, loaded, and shipped to licensed, commercial nuclear waste treatment or disposal facilities. The treatment and/or disposal facilities include Envirocare of Utah, Inc.; Waste Control Specialists; Nevada Test Site; and commercial treatment or disposal facilities near SRS in Aiken, South Carolina, ORR, and the Hanford Site in Richland, Washington. The No Action Alternative of continuing to store most low-level radioactive mixed waste on site, and eventually requiring additional low-level radioactive mixed waste storage facilities is also analyzed. The impacts of the proposed action are factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action (DOE 2000f).

## **1.8 CHANGES FROM THE DRAFT NI PEIS**

In response to comments on the Draft NI PEIS and as a result of information that was unavailable at the time of its issuance, this Final NI PEIS contains revisions and new information. These revisions and new information are indicated by sidebars. A brief discussion of the most important changes included in this Final NI PEIS is provided in the following paragraphs.

### ***Chapter 1***

#### *Purpose and Need for Agency Action*

As a result of public comments, additional discussion was incorporated to address DOE's production of medical, research, and industrial isotopes relative to global isotope production and availability. In addition, the discussion of the need for plutonium-238 production for space missions was expanded and updated to reflect the most recent planning guidance provided by NASA to DOE.

#### *Issues Raised During the Public Comment Period on the Draft NI PEIS*

Section 1.5, Issues Raised During the Public Comment Period on the Draft NI PEIS, was added to this Final NI PEIS.

#### *Related NEPA Reviews*

The Final NI PEIS was revised to add descriptions of the *Final Environmental Impact Statement, Management of Spent Nuclear Fuel from the K Basins at the Hanford Site, Richland, Washington* (DOE/EIS-0245F), and the *Environmental Assessment, Management of Hanford Site Non-Defense Production Reactor Spent Nuclear Fuel* (DOE/EA-1185). The impacts of these NEPA actions were factored into the assessment of potential cumulative impacts resulting from the NI PEIS proposed action.

This Final NI PEIS was also revised to reflect recent Records of Decision that have been issued for the *Final Environmental Impact Statement on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel* (DOE/EIS-0218F), the *Final Environmental Impact Statement for Treating Transuranic (TRU)/Alpha Low-Level Waste at the Oak Ridge National Laboratory Oak Ridge, Tennessee* (DOE/EIS-0305), and the *Final Environmental Impact Statement for the Treatment and Management of Sodium-Bonded Spent Nuclear Fuel* (DOE/EIS-0306).

#### *Changes from the Draft NI PEIS*

Section 1.8, Changes from the Draft NI PEIS, was added to this Final NI PEIS.

## **Chapter 2**

### *Transportation Requirements*

Additional U.S. ports were named as candidates for receiving mixed oxide fuel from Europe.

### *Alternatives Considered and Dismissed*

Information was provided to explain why the Isotope Production Facility at LANL, the Brookhaven LINAC Isotope Producer and the Alternating Gradient Synchrotron accelerator complex at Brookhaven National Laboratory, and CLWRs were not considered reasonable alternatives for the production of medical isotopes.

Information was also provided to explain why increasing the power levels at ATR and/or HFIR or installing rapid radioisotope retrieval systems would be insufficient to meet the long-term growth projection needs and therefore were dismissed as reasonable alternatives.

### *Preferred Alternative*

The discussion of DOE's preferred alternative for accomplishing the proposed action, i.e., Alternative 2, Use Only Existing Operational Facilities, Option 7, is included in this Final NI PEIS.

### *Summary of Environmental Impacts*

Section 2.7 was revised in response to comments that it was difficult to compare environmental impacts among alternatives. Although estimates of the environmental impacts that would result from implementation of the alternatives are the same as those in the Draft NI PEIS, the tables and accompanying text were reformatted for ease in comparing environmental impacts among alternatives and among options within alternatives. Section 2.7 was also revised to focus on incremental impacts that would result from implementation of the alternatives. Baseline environmental impacts were removed from the comparisons among alternatives and options. This information is now presented in Chapter 3.

## **Chapter 3**

### *Affected Environment*

Additional information was provided on the environmental baseline at each site, including graphics to more clearly illustrate existing surface water and groundwater conditions. Estimates of existing impacts for current HFIR/REDC operations were added to Sections 3.2.3.2 (Air Quality), 3.2.9.1.2 (Radiation Exposure and Risk), and 3.2.11.1 (Waste Inventories and Activities). Similarly, estimates for current ATR operations were added to Sections 3.3.3.2 (Air Quality), 3.3.9.1.2 (Radiation Exposure and Risk), and 3.3.11.1 (Waste Inventories and Activities). Estimates of existing impacts of maintaining FFTF in standby were added to Section 3.4.3.1 (Air Quality). Information was also provided on the impacts of the range fires affecting Hanford and INEEL during the summer of 2000. In addition, site data were updated to reflect recent measurements and analyses.

In response to public comments on the Draft NI PEIS, additional information on health studies conducted in the Hanford area was also incorporated.

## **Chapter 4**

### *Air Quality*

Stack parameters used for the air quality modeling were added. In response to public comment, estimates of the ambient air quality concentrations from FFTF sources were added to the deactivation section.

### *Water Resources*

New water use and sanitary wastewater generation increments for REDC and FDPF were added to reflect the revised additional workforce required at these facilities and to be consistent with FMEF. Water use and wastewater generation rates for the new accelerator(s) and new research reactor alternatives were also revised. These changes were also incorporated into the waste management analyses.

### *Ecological and Cultural and Paleontological Resources*

These sections were updated to reflect that consultations concerning threatened and endangered species and cultural resources were conducted with appropriate Federal and state agencies. Consultations were also conducted with interested Native American tribes. No major issues were raised as a result of these consultations.

### *Socioeconomics*

Section 4.3.1.1.8 was revised to reflect changes in the number of workers associated with FFTF operations and deactivation. The associated impacts on community services were also incorporated. In addition, the number of workers at the Oak Ridge Reservation was revised to reflect the entire site workforce rather than just the number of workers at the Oak Ridge National Laboratory.

### *Normal Operations*

Based on more recent site data on occupational radiation exposure for workers at REDC, all worker health impacts for target processing at REDC, FMEF, and FDPF and for neptunium target storage at REDC, Chemical Processing Plant-651, and FMEF were updated. Also, low-energy accelerator source terms were modified to properly reflect normal operational emissions resulting in modifications to the population health impacts for all options of Alternative 3.

### *Facility Accidents*

The high-energy accelerator analysis was redone to incorporate a more accurate revised source term, and the incremental risks for currently operating reactors were added to the tables. An additional analysis addressing industrial accidents was also performed and incorporated into Chapter 4.

### *Transportation*

The neptunium inventory was revised to use the recently declassified actual inventory. The number of actual shipments from SRS to the processing facilities and the transportation risk estimates were modified accordingly.

### *Waste Management*

The analysis for the Draft NI PEIS assumed that the waste generated from the processing of irradiated neptunium-237 targets is transuranic waste. However, as a result of comments received during the public comment period, DOE is considering whether the waste from processing of irradiated neptunium-237 targets should be classified as high-level radioactive waste and not transuranic waste. The Waste Management sections (i.e., Sections 4.3.1.1.13, 4.3.2.1.13, 4.3.3.1.13, and 4.4.3.1.13) were revised to reflect this different classification from what was assumed in the Draft NI PEIS.

### *Spent Nuclear Fuel Management*

These sections were revised to quantify the generation of spent fuel from 35 years of operation and to state that dry spent nuclear fuel storage at the FFTF site is similar to NRC-approved methods currently being used for interim storage of commercial spent nuclear fuel. In addition, based on public comments, reference was added about the K Basins spent fuel storage.

### *Cumulative Impacts*

Cumulative impact tables in Section 4.8 were revised to present the contributions from each of the various site actions anticipated during the course of the operational period evaluated in this NI PEIS.

The air quality tables were also revised to incorporate the revised baseline from Chapter 3. In addition, waste management tables were revised to include the sites' treatment, storage, and disposal capacities for easier comparison of the waste generations by waste type to the waste management capacities at the sites.

## **Chapter 5**

In response to public comments, a list of organizations that DOE contacted during the consultation process was added.

### **Volume 2**

Summaries of the *NI Cost Report* and *NI Nonproliferation Impact Assessment* were added as Appendixes P and Q, respectively. NASA mission guidance correspondence was added as Appendix R.

### **Volume 3**

Volume 3 of the NI PEIS was added to present the comments received during the public review period for the Draft NI PEIS and DOE's responses to these comments.

## **1.9 STRUCTURE OF THIS NI PEIS**

This NI PEIS contains 9 chapters and 18 appendixes. The main analyses are included in the chapters in Volume 1, with additional project information provided in the appendixes in Volume 2. Comments received during the public comment period and DOE's associated responses are presented in Volume 3. A Summary of this NI PEIS is also included.

The nine chapters provide the following information:

Chapter 1—Introduction: Background; purpose and need for agency action; decisions to be made; issues identified during the public scoping process; issues raised during the public comment period on the Draft NI PEIS; alternatives evaluated; related NEPA documents; and changes from the Draft NI PEIS

Chapter 2—Program Description and Alternatives: Program missions; candidate facilities and proposed options to enhance U.S. nuclear infrastructure and provide the capabilities needed to meet DOE's mission requirements; operations required to implement DOE program missions and the candidate sites and facilities for these activities; transportation activities associated with the program missions; alternatives considered reasonable for detailed evaluation; alternatives and facilities considered and dismissed from evaluation; a summary of the environmental impacts; implementation schedules associated with the alternatives evaluated; a comparative evaluation of alternatives; and the description of the Preferred Alternative.

Chapter 3—Affected Environment: Aspects of the environment that could be affected by the NI PEIS alternatives

Chapter 4—Environmental Consequences: Analyses of the potential impacts of the NI PEIS alternatives on the environment

Chapter 5—Applicable Laws, Regulations, and Other Requirements: Environmental, safety, and health regulations that would apply to the alternatives of this NI PEIS, and agencies consulted for their expertise

Chapter 6—List of Preparers

Chapter 7—Distribution List

Chapter 8—Glossary

Chapter 9—Index

The 18 appendixes provide the following information:

Appendix A—Plutonium-238 Target Fabrication and Processing Operations

Appendix B—Neptunium-237 Target Irradiation Operations in Currently Operating Reactors for Plutonium-238 Production

Appendix C—Medical and Industrial Isotope Target Fabrication and Processing Operations and Civilian Nuclear Research and Development Targets

Appendix D—Fast Flux Test Facility Operations

Appendix E—Research Reactor Operations

Appendix F—New Accelerator(s)

Appendix G—Methods for Assessing Environmental Impacts

Appendix H—Evaluation of Human Health Effects from Normal Facility Operations

Appendix I—Evaluation of Human Health Effects from Facility Accidents

Appendix J—Evaluation of Human Health Effects of Transportation

Appendix K—Environmental Justice Analysis

Appendix L—Socioeconomics Analysis

Appendix M—Ecological Resources

Appendix N—Public Scoping Process

Appendix O—Contractor Disclosure Statement

Appendix P—*Nuclear Infrastructure Cost Report Summary* |

Appendix Q—*Nuclear Infrastructure Nonproliferation Impact Assessment Summary* |

Appendix R—NASA Mission Planning Correspondence |

## Chapter 2

### Program Description and Alternatives

Chapter 2 describes the program missions and the logic behind the structure of the program alternatives. Section 2.1 introduces the facility alternatives and options proposed to enhance the U.S. nuclear infrastructure and provide the capabilities needed to meet DOE's mission requirements. This section also presents the No Action Alternative and an alternative suggested by some of the public scoping comments. Sections 2.2 and 2.3, respectively, describe the operations necessary to implement DOE's program missions and the candidate sites and facilities where the operations would take place. Section 2.4 discusses the transportation activities associated with the program missions. Section 2.5 describes the alternatives that were considered reasonable for detailed evaluation. Section 2.6 explains why some other alternatives and facilities were considered and dismissed from evaluation in this NI PEIS. Section 2.7 summarizes the environmental impacts and implementation schedules associated with the alternatives that were evaluated and provides a comparative evaluation of these alternatives in terms of impacts and mission effectiveness. The chapter concludes with the description of the preferred alternative.

#### 2.1 INTRODUCTION

As discussed in Chapter 1, the U.S. Department of Energy (DOE) is proposing to enhance its existing nuclear facility infrastructure to accommodate new and expanding missions in the areas of civilian nuclear energy research and development and isotope production. DOE currently does not have sufficient steady-state neutron sources to meet its projected irradiation needs for: (1) isotopes for medical and industrial uses, (2) plutonium-238 for potential use in advanced radioisotope (radioactive isotope) power systems and heating units for future U.S. National Aeronautics and Space Administration (NASA) space exploration missions, and (3) other irradiation services to meet the Nation's civilian nuclear energy research and development needs.

The programmatic alternatives focus on the use of irradiation facilities that are currently operating, could be brought on line, or could be constructed and operated to meet DOE's irradiation needs. Thus, this *Final Programmatic Environmental Impact Statement for Accomplishing Expanded Civilian Nuclear Energy Research and Development and Isotope Production Missions in the United States, Including the Role of the Fast Flux Test Facility (Nuclear Infrastructure Programmatic Environmental Impact Statement [NI PEIS])* evaluates the following alternatives:

- **Alternative 1**, resuming operation of the Fast Flux Test Facility (FFTF) at the Hanford Site (Hanford) in Washington State
- **Alternative 2**, using existing irradiation facilities (the Advanced Test Reactor [ATR] at Idaho National Engineering and Environmental Laboratory [INEEL], and the High Flux Isotope Reactor [HFIR] at Oak Ridge National Laboratory [ORNL], or a generic commercial light water reactor [CLWR])
- **Alternative 3**, constructing and operating one or two new accelerators at an existing DOE site
- **Alternative 4**, constructing and operating a new research reactor at an existing DOE site

This NI PEIS also evaluates a **No Action Alternative** in which the status quo would be maintained; that is, DOE's existing facilities would continue to meet their current mission requirements within their operating levels, but DOE would not enhance existing U.S. nuclear facility infrastructure or expand its current missions to accommodate new missions. This NI PEIS also includes an additional alternative that would permanently deactivate Hanford's FFTF without enhancing U.S. nuclear facility infrastructure to accommodate new or expanded missions. **Alternative 5**, permanently deactivate FFTF, although a component of all alternatives

except No Action and Alternative 1, is included as a stand-alone alternative in response to numerous public comments received during the scoping period.

This NI PEIS evaluates several options under each alternative. These options primarily involve DOE facilities that could be used for the fabrication, storage, and postirradiation processing of the targets necessary for the program missions. Among the facilities proposed are: (1) the Radiochemical Engineering Development Center (REDC) at ORNL, (2) the Fluorinel Dissolution Process Facility (FDPF) and/or Building CPP-651 (storage only) at INEEL, (3) the Fuels and Materials Examination Facility (FMEF) at Hanford, (4) the Radiochemical Processing Laboratory (RPL) and Building 306-E at Hanford, and (5) a new facility to be constructed and operated at an existing DOE site to support the one or two new accelerators or new research reactor alternatives. **Table 2-1** provides an overview of the alternatives and 26 specific options for this NI PEIS.

Sections 2.2 through 2.4 describe: (1) the operations needed to implement the program missions, (2) the candidate sites and facilities where the operations would take place, and (3) the transportation activities associated with the program missions. In describing the facilities, the sections refer to the specific alternatives for which the individual facilities are proposed. Detailed descriptions of alternatives are provided in Section 2.5. Alternatives considered and dismissed are discussed in Section 2.6. Section 2.7 summarizes the environmental impacts and implementation schedules and provides a comparison of mission effectiveness between alternatives, and Section 2.8 presents the preferred alternative.

## **2.2 DESCRIPTION OF OPERATIONS**

### **2.2.1 Medical Isotopes Production**

Production of medical and industrial isotopes involves: (1) fabricating specially designed targets at a target fabrication facility, (2) irradiating the targets in an irradiation facility to generate specific medical isotopes, and (3) processing the targets at a target fabrication facility to prepare the medical isotopes for shipment to customers.

#### **2.2.1.1 Target Fabrication**

Each medical isotope would be produced using a target that is enriched in the appropriate target material for neutron irradiation. With the exception of the radium-226 target and those that use recycled materials, all of the targets use nonradioactive materials. Appendix C lists the types and forms of the target material used to produce each medical isotope.

After irradiation of the original target, radioactive impurities may remain with the target material after the medical isotope product is removed. Because of these impurities, reuse of the material can in some cases create targets that are radioactive. As a result, fabrication of targets from recycled target materials would require special handling and shielding.

Before beginning fabrication of a target for production of a particular medical isotope, a significant quantity of the element that makes up the target would be required. For nonradioactive targets, this material typically would be acquired from ORNL, where enrichment processes are conducted to produce target material that is sufficiently pure to support the generation of medical isotopes. The target form may be a metal, metallic oxide, or other chemical compound suitable for high-temperature irradiation, depending on engineering considerations such as material heat transfer characteristics, melting points, and metallurgical properties. The nonradioactive target material would be transported by truck from ORNL to the target fabrication facility. One candidate radioactive target material, radium-226, would not be supplied by ORNL. However, radium-226 could be supplied by a variety of sources (no decision on a proposed supplier or suppliers has been made at

Table 2–1 NI PEIS Alternatives and Options

	Option Number	Irradiation Facility	Plutonium-238 Production Mission		Medical and Industrial Isotopes Production and Nuclear Research and Development Mission

<b>Alternative 5: Permanently Deactivate FFTF (with No New Missions)</b>	–	–	–	–	–	–

a. Hanford FFTF would operate with mixed oxide fuel for 21 years and highly enriched uranium fuel for 14 years.

b. Hanford FFTF would operate with mixed oxide fuel for 6 years and highly enriched fuel for 29 years.

c. The new facility would not be required if a DOE site is selected with available support capability and infrastructure.

**Key:** ATR, Advanced Test Reactor at INEEL; CLWR, commercial light water reactor; CPP–651, INEEL Building CPP–651 Storage Vault; FDPF, Fluorinel Dissolution Process Facility at INEEL; FFTF, Fast Flux Test Facility at Hanford; FMEF, Fuels and Materials Examination Facility at Hanford; HFIR, High Flux Isotope Reactor at ORNL; REDC, Radiochemical Engineering Development Center at ORNL; RPL/306–E, Radiochemical Processing Laboratory at Hanford, Building 306–E.

this time). Once materials for the targets arrive on the site, they would be stored at the target fabrication facility until needed for fabrication into medical isotope targets.

Solid targets would be fabricated in gloveboxes using a series of mechanical and thermal processes. For the solid targets based on a powder, it is unknown at this time whether the powder would be loose or would be pressed and sintered into pellets. If the latter method were preferred, separate equipment would be required to press and sinter each type of solid target material to reduce the risk of cross-contaminating other target materials.

If pellets were used, the first major step in their preparation would be powder conditioning and pressing, which includes weighing, blending, and pressing the powder and binder into slugs. The slugs would be granulated, blended with binder addition, and pressed into pellets. The pellets would be transferred to the sintering/debind station, weighed, and subjected to a series of thermal processes to debind and sinter the pellets. The sintered pellets would be subject to characterization to ensure that specifications were met.

Acceptable pellets would be transferred to the loading and welding station to be visually inspected before inclusion into a capsule or pin. For both powder or pellet target materials, capsules and pins would be cleaned before final closure. The capsules would be leak-tested and inspected before being cleared for use.

### **2.2.1.2 Target Irradiation**

Production of medical or industrial isotopes is accomplished by irradiating target materials in the neutron flux of an irradiation facility such as a nuclear reactor. The desired isotopes are produced by neutron-induced reactions such as activation or transmutation.

Activation is the most common neutron-induced reaction and involves the capture of a neutron with the subsequent emission of a gamma ray. Because there is no change in the number of protons, the chemical identity of the target remains the same. For example, holmium-166 is produced by irradiating target material enriched in holmium-165 by activation.

Transmutation involves the capture of a neutron and the subsequent ejection of a proton or other particle that would change the chemical identity of the product. For example, phosphorus-32 is produced by irradiating a target material enriched in sulfur-32 by transmutation (proton ejection).

### **2.2.1.3 Postirradiation Target Processing**

Processing of irradiated targets to recover medical- and industrial-grade isotopes can be broken down into distinct steps: (1) transport of irradiated targets to a chemical separation facility and receipt at that facility; (2) chemical processing of the targets (using hot cells, shielded gloveboxes and appropriate open-faced hoods); (3) waste handling; (4) analysis of the products; (5) recycling of some of the target materials; and (6) shipment of the isotope products to customers.

Each of the medical isotope products evaluated for production in this NI PEIS is unique. Some targets would produce an isotope of the same element and would not require separation. Some targets would produce the same element, but would require some processing to remove impurities. Other target materials would produce different elements and would require chemical separation of the target material, the desired isotope product, and unwanted impurities. Details on postirradiation processing of the targets for medical and industrial isotope production are provided in Appendix C.

## 2.2.2 Plutonium-238 Production

Production of plutonium-238 involves (1) storing neptunium-237, (2) fabricating neptunium-237 targets, (3) irradiating the targets in an irradiation facility, and (4) processing the targets to separate the plutonium-238 and prepare the product for shipment to Los Alamos National Laboratory (LANL) where it would be fabricated into heat sources for radioisotope power systems. As stated in Section 1.2.2, a plutonium-238 production rate of 2 to 5 kilograms (4.4 to 11 pounds) per year would be sufficient to meet the projected need based on NASA space exploration missions. Evaluations presented in this NI PEIS are based on a plutonium-238 production goal of 5 kilograms (11 pounds) per year to bound the environmental impacts of the proposed plutonium-238 production mission.

### 2.2.2.1 Target Fabrication

The facility designated to fabricate neptunium-237 target elements for plutonium-238 production would receive the neptunium-237 oxide from the Savannah River Site (SRS) and would dissolve it in an acid solution prior to removal of protactinium-233, a decay daughter of neptunium-237. Protactinium-233 reaches 90 percent of its equilibrium activity approximately 90 days after purification and contributes significantly to radiation doses in the target fabrication line. The best approach for the removal of the protactinium-233, and possibly the easiest to implement, is to pass the neptunium solution through a column containing silica gel adsorbent (Wham et al. 1998). After protactinium-233 removal, the purified neptunium solution can be transferred to a target-fabrication glovebox line and reconversion of the neptunium to the oxide form can be initiated. The desired form of the oxide (microspheres) is obtained by loading the neptunium on a cation-exchange resin of the selected particle size range, washing the loaded resin, and using heated air to oxidize the resin and form the neptunium dioxide microspheres.

Current target designs for the ATR and HFIR reactors consist of neptunium dioxide blended with aluminum powder, pressed into a target core, and clad with aluminum. This type of target has been used in nearly all of the DOE production and research reactors (except for fast neutron flux reactors, e.g., FFTF) to produce isotopes in general and plutonium-238 specifically.

Three different techniques can be employed to fabricate such targets:

1. The neptunium dioxide and aluminum powders are blended and pressed into pellets. The pellets are then loaded into aluminum target tubes, which are seal-welded and hydrostatically compressed.
2. The neptunium dioxide and aluminum powders are blended and pressed into compacts. The compacts are then roll-milled between aluminum cladding, after which the aluminum-clad neptunium dioxide is seal-welded.
3. The neptunium dioxide and aluminum powders are blended and pressed into billets and assembled into welded and evacuated aluminum containers. The billets and containers are then coextruded to produce target tubes.

All three techniques have advantages and disadvantages. The coextrusion technique has been used successfully by SRS in its plutonium-238 program and other special isotope programs. Demonstrations of the fabrication techniques would be required to determine which techniques are best for the proposed irradiation facilities.

The target blanket for the high-energy accelerator consists of neptunium dioxide blended with aluminum powder, pressed into the required configuration, and clad with aluminum.

The CLWR targets would have stainless steel or Zircaloy cladding because of the higher operating temperatures. Targets for the new research reactor would also have stainless steel (Incoloy-800) cladding for material compatibility. The postirradiation processing of these targets would be different from the postirradiation processing of the aluminum-clad targets.

The targets used for production of plutonium-238 in FFTF would be similar to target concepts developed in studies performed in 1992 and 1993. The proposed target assembly would consist of 19 large-diameter pins that combine alternating thin pellets or wafers of neptunium dioxide and yttrium hydride moderator within a ferritic alloy steel cladding. The steel cladding is required for compatibility with the reactor sodium.

The conversion efficiency of neptunium-237 to plutonium-238 during target irradiation at FFTF, ATR, HFIR, or CLWR would be approximately 10 to 15 percent. Approximately 50 kilograms (110 pounds) per year of neptunium-237 would be fabricated into targets to meet the plutonium-238 production goal of 5 kilograms (11 pounds) per year. Following processing of the irradiated targets, approximately 40 kilograms (88 pounds) per year of the unconverted neptunium-237 would be stored in liquid form and recycled for the fabrication of new targets. The remainder would be process waste. Based on the current preconceptual designs, the conversion efficiency of neptunium-237 to plutonium-238 during target irradiation at the new high-energy accelerator and new research reactor would be significantly lower, approximately 2.8 percent and 1.4 percent respectively. To meet the plutonium-238 production goal of 5 kilograms (11 pounds) per year, approximately 180 kilograms (396 pounds) would be fabricated into targets annually for irradiation in the high-energy accelerator, and 380 kilograms (836 pounds) would be fabricated into targets for irradiation in the new research reactor. The neptunium-237 target fabrication requirements for the new research reactor could be reduced by a factor of 4 to 8 by refining the current target and reactor preconceptual designs presented in Appendix E.

Neptunium must be treated like uranium-235 under DOE safeguards and security requirements, which are based on the mass of neptunium and the attractiveness level of the physical and chemical form of the neptunium. This would require special security clearances for persons with access to the neptunium, as well as ongoing security reviews and audits during the time of possession of the neptunium (McCallum 1999). Safe, secure trailer/SafeGuards Transports (SST/SGTs) would be required to transport any significant quantity of neptunium. The neptunium containers would be stored in specially designed storage vaults to provide a secure, safe storage for the materials. DOE guidelines concerning safeguards and security would be followed whenever materials were being stored or processed.

### 2.2.2.2 Target Irradiation

Irradiation of neptunium-237 targets in neutron flux produces plutonium-238 according to the following equations:

The neptunium-237 target nuclide absorbs a neutron to become neptunium-238 (first equation), which in turn decays with a half-life of 2.1 days and emits a beta particle (or electron) to form plutonium-238 (second equation).

Irradiation of the neptunium-237 targets generates fission products in the targets. The irradiated targets would be cooled for at least 120 days to allow time for the decay of short-lived fission products (e.g., iodine-131). Following the cool-down period, the irradiated targets would be loaded into a shielded cask for transport to

the chemical processing facility. They would then be ready for chemical processing to separate the plutonium-238 content and unconverted neptunium-237 from radioactive waste products.

### 2.2.2.3 Postirradiation Target Processing

The flowsheet for processing irradiated neptunium-237 targets, recovering the unconverted neptunium-237, refabricating target elements, separating the plutonium-238 product, and shipping the plutonium-238 for fabrication into heat sources for radioisotope power systems is shown in **Figure 2–1**. Processing the irradiated neptunium-237 targets would be conducted inside heavily shielded hot cells to protect workers from high radiation doses. Hot cells are specially designed shielded vaults or areas used for the remote handling and manipulation of some radioactive materials. Certain chemical processing steps would be required to recover the plutonium-238 as product and to recover the neptunium-237 for recycle. At ORNL and Hanford this process would be accomplished in two steps:

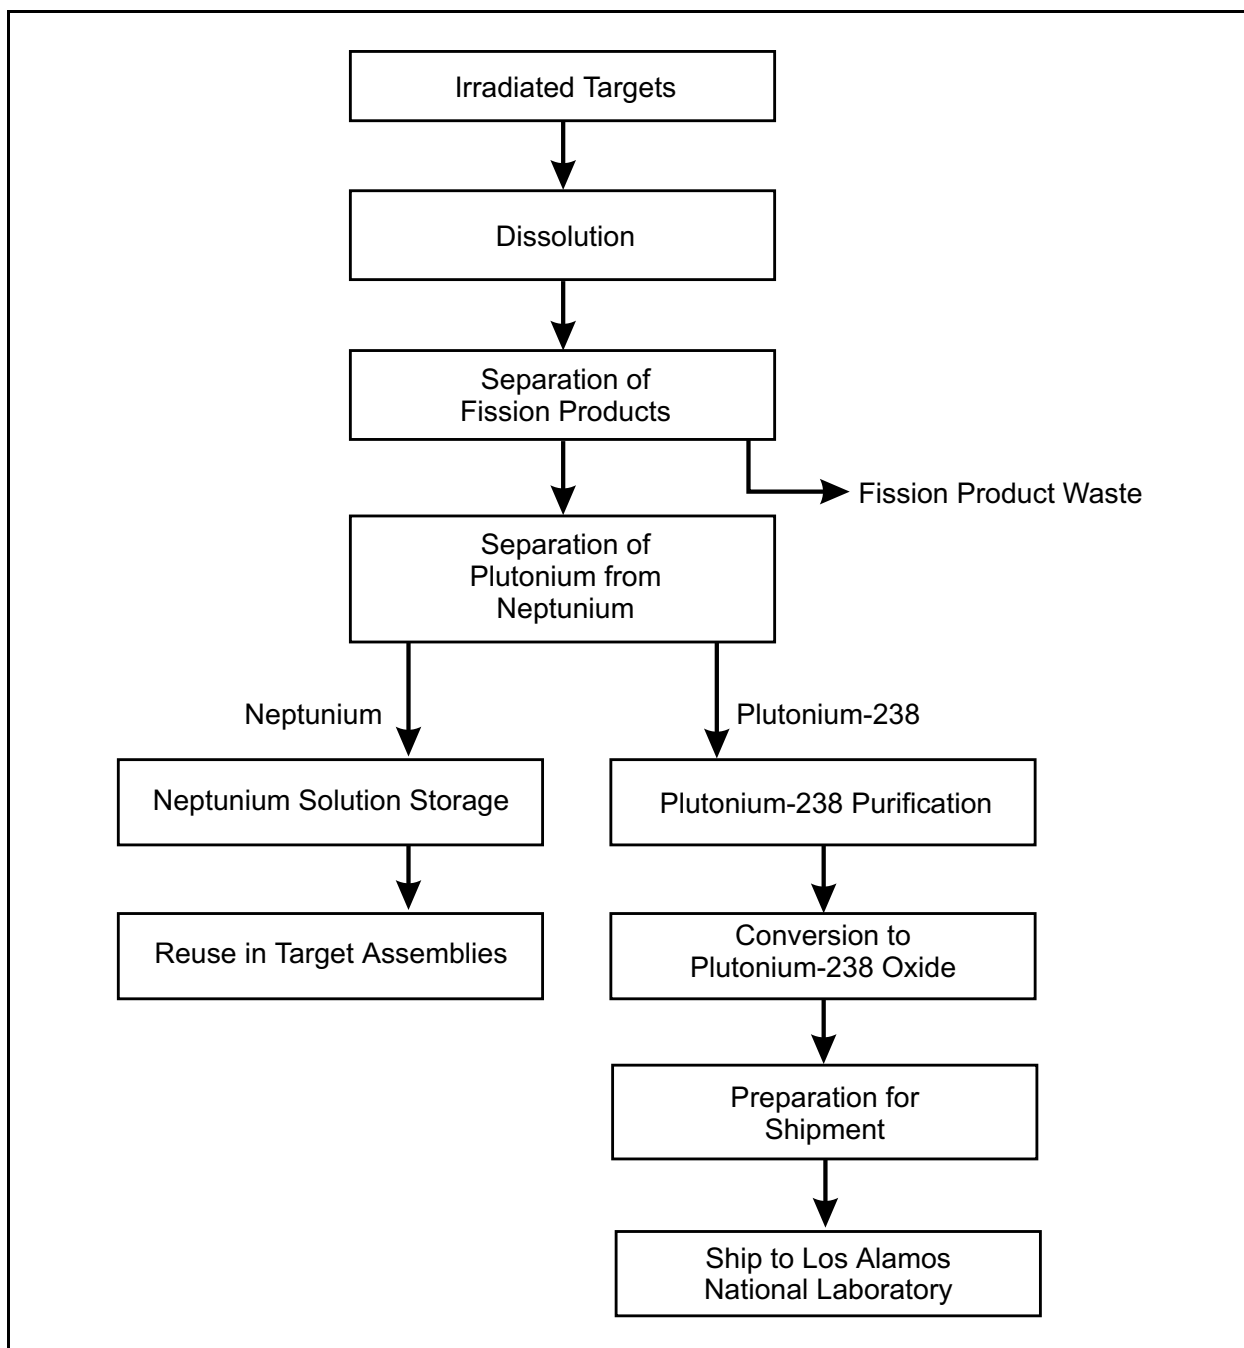

- For targets irradiated in ATR, HFIR, or the accelerator, caustic-nitrate solution would be used to dissolve the cladding, thereby separating the bulk of the aluminum and caustic-soluble fission products from the actinide products, including the neptunium and plutonium. For targets irradiated in FFTF, the new research reactor, or a CLWR, the first step in the target processing would be to chop the targets into small pieces for dissolution in acid (in the next step).
- Next, acid would be used to dissolve the actinide products and remaining fission products to prepare the feed for the first mainline separation process. The feed would be filtered prior to pH (acidity/alkalinity) adjustment to remove any solids that could complicate the solvent extraction process. For the FFTF, new research reactor, or CLWR targets, the undissolved cladding would be discarded as waste.

Dissolution of the irradiated targets at INEEL would be accomplished using a one-step target dissolution process in a nitric acid-fluoroboric acid solution instead of the two-step process for the ATR and HFIR targets that would be used at ORNL and Hanford. It would still be necessary to shear or chop the FFTF or CLWR targets at INEEL before the acid leach process.

Subsequent to target dissolution, a tributyl phosphate-based solvent extraction process would be used for three cycles of purification. The first cycle would decontaminate the neptunium and plutonium products from fission product wastes. The second cycle solvent extraction process would separate the neptunium from the plutonium, and the third-cycle process would remove trace plutonium from the neptunium product. The plutonium product would undergo further purification using anion exchange if the product did not meet specification.

Chemical conversion of the plutonium to an oxide would start with its precipitation from solution as an oxalate. The precipitate would be filtered and calcined (heated at high temperature) to an oxide product. The plutonium dioxide product would be further treated in an oxygen-exchange process to exchange its oxygen-17 and oxygen-18 components with oxygen-16, thereby reducing the neutron emission rate. The resulting oxide product would be packaged and shipped to LANL for fabrication into heat sources for radioisotope power systems.

The purified neptunium nitrate from the third-cycle solvent extraction process would be stored as a solution. A small quantity of neptunium oxide (6 to 8 kilograms [12 to 16 pounds]) would be removed from storage, dissolved, and purified to replace the neptunium-237 that was converted to plutonium-238. This material would be added to the neptunium solution recovered during postirradiation target processing, loaded onto a cation-exchange resin, and then calcined to produce oxide microspheres for re-use in target assemblies for

**Figure 2-1 Chemical Processing Flowsheet for Irradiated Neptunium-237 Target Processing**

irradiation. Waste-handling equipment would be used to minimize the activity in low-level radioactive liquid waste and to stabilize solid wastes into an acceptable waste form. The equipment would be included in the hot cells used for the chemical processing of irradiated targets.

### 2.2.3 Civilian Nuclear Energy Research and Development

As discussed in Section 1.2.3, civilian nuclear energy research and development initiatives requiring an enhanced DOE facility infrastructure fall into three basic categories: materials research, nuclear fuel research, and advanced reactor development.

## 2.3 DESCRIPTION OF FACILITIES

This section describes the facilities proposed by DOE for the production of medical and industrial isotopes, plutonium-238, and civilian nuclear energy research and development. Because the programmatic alternatives are structured around the use of the candidate irradiation facilities, they are discussed first in Section 2.3.1, followed by a discussion of the proposed target fabrication and processing facilities in Section 2.3.2. The proposed irradiation facility alternatives are (1) FFTF at Hanford, (2) ATR at INEEL, (3) HFIR at ORNL, (4) a generic CLWR, (5) one or two new accelerators at an existing DOE site, or (6) a new research reactor at an existing DOE site.

### 2.3.1 Target Irradiation Facilities

#### 2.3.1.1 Fast Flux Test Facility

FFTF is a 400-megawatt thermal, liquid-cooled (sodium) nuclear test reactor (**Figure 2–2**) owned by DOE and located at Hanford in southeastern Washington State near Richland, Washington. Figure 3–12 presents a map of Hanford that depicts the location of FFTF. In May 1972, the U.S. Atomic Energy Commission published an environmental statement for FFTF (AEC 1972). That document provided information on the potential environmental impacts associated with the construction and operation of FFTF. In the late 1970s, the Safety Analysis Report prepared for FFTF was reviewed by the U.S. Nuclear Regulatory Commission (NRC) and the Advisory Committee for Reactor Safeguards. Comments from both organizations were addressed in the FFTF Final Safety Analysis Report. The construction of FFTF was completed in 1978.

Following extensive testing, FFTF was started up in April 1982. During its operation, FFTF successfully tested advanced nuclear fuels, materials, components, operating protocols, and reactor safety designs. It also produced a wide variety of medical isotopes and made tritium for the U.S. fusion research program.

FFTF was originally designed and operated as a science test bed for U.S. liquid metal fast reactor programs. These programs, which were canceled in 1993, were key elements both in closed fuel cycle and actinide waste disposition technology development. In December 1993, DOE decided not to operate FFTF because of a lack of

**Figure 2–2 Fast Flux Test Facility**

economically viable missions at that time. In accordance with the National Environmental Policy Act (NEPA), DOE published an environmental assessment and Finding of No Significant Impact for the shutdown and deactivation of FFTF in May 1995 (DOE 1995a). The environmental assessment contained an evaluation of the environmental impacts associated with the actions necessary to place FFTF in a radiologically and industrially safe shutdown condition suitable for long-term surveillance and maintenance before final decontamination and decommissioning.

The FFTF complex includes the reactor, as well as equipment and structures for heat removal, containment, reactor safety and shutdown systems core component handling and examination, fuel offloading and storage, utilities, and other essential services. There are 100 systems supporting various functions of FFTF during operation. The central structure of FFTF is the reactor containment building, an all-welded cylindrical steel structure 41 meters (135 feet) in diameter and 57 meters (187 feet) high. The array of buildings and equipment that surround the containment building and comprise the FFTF complex is shown in **Figure 2-3**. The reactor is below grade in a shielded cell in the center of the containment structure. Heat is removed from the reactor by circulating liquid sodium under low pressure through three separate closed primary piping loops, which include pumps, piping, and intermediate heat exchangers. These loops are located within inerted cells (cells filled with inert gases) within the containment structure. **Figure 2-4** is a cutaway of the containment building showing the location of the reactor, primary pumps, and intermediate heat exchangers. Three secondary sodium loops transport reactor heat from the intermediate heat exchangers to the air-cooled tubes of the dump heat exchangers. From there, the heat dissipates into the atmosphere through the forced draft dump heat exchanger. Commercial nuclear power reactors use reactor heat to create steam, which turns a turbine to produce electricity. FFTF, however, does not generate electricity.

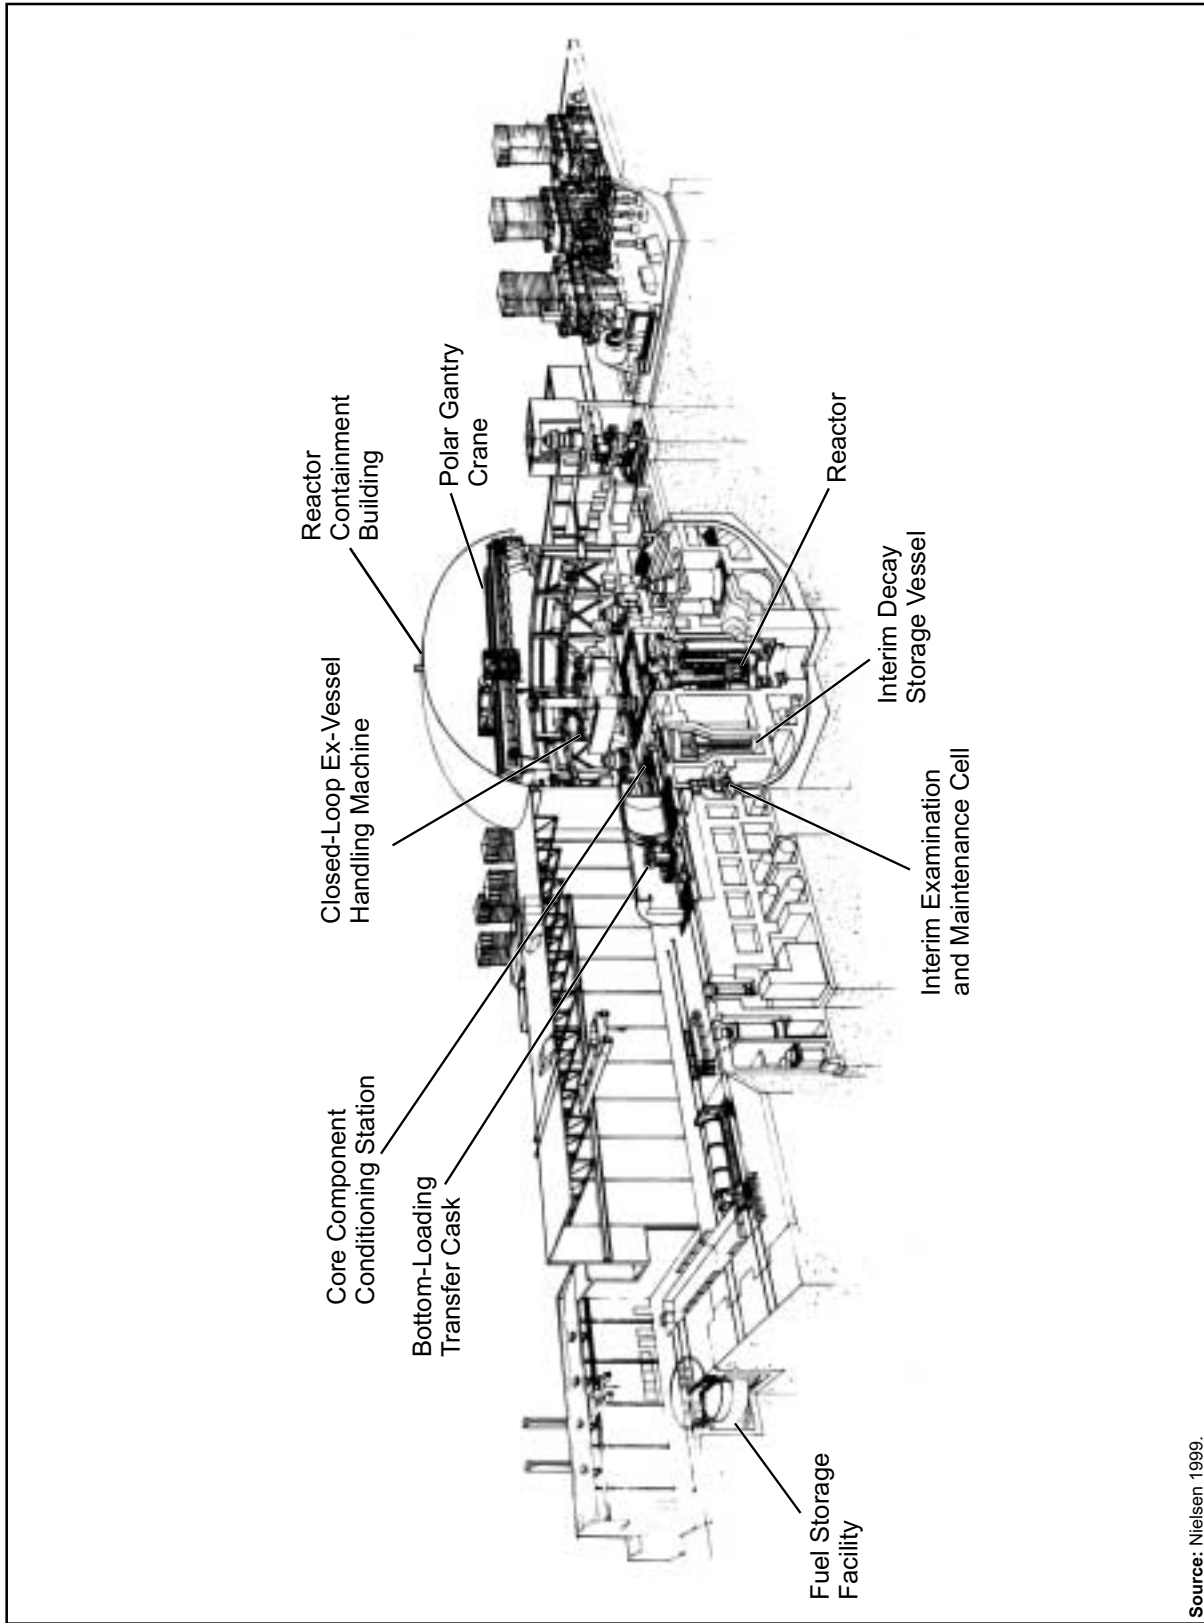

FFTF has demonstrated its capability to function as a nuclear science and irradiation services user facility. It has five distinct features: size, flux, test evaluation and irradiation capabilities, fuel type, and coolant type. In combination, these features provide a multipurpose facility suitable for medical and industrial isotopes production, plutonium-238 production, and civilian nuclear energy research and development purposes. Although FFTF was used primarily to evaluate reactor fuels and different fuel assembly materials during its 10 years of operation, the reactor facility has also supported large and varied test programs for industry, nuclear energy (domestic and international), medical isotope applications and research, space nuclear power, and fusion research programs. A more detailed description of FFTF and its capabilities is included in Appendix D.

#### **2.3.1.1.1 Maintenance of FFTF in Standby**

FFTF is currently defueled and is being maintained in a safe standby condition. FFTF would be maintained in the standby condition under the No Action Alternative. Seventy-seven of the 100 systems are operational; the other 23 are in a recoverable standby state. System integrity and configuration control are being maintained. The Main Heat Transport System is being operated at approximately 200 °C (400 °F) to keep the sodium coolant in the reactor liquefied and circulating. Essential systems, staffing, and support services are being maintained in a manner that would support potential restart.

#### **2.3.1.1.2 FFTF Restart and Operation**

FFTF is proposed to be restarted and operated under Alternative 1, FFTF Restart. If a decision were made to restart FFTF, several equipment upgrades are planned to return systems to operation, improve reliability, conform to current standards, improve efficiency, and minimize waste. Most of the required modifications would consist of either mechanical equipment upgrades or replacement of outdated control and computer

Source: Nielsen 1999.

Figure 2-3 FFTF Complex

Figure 2-4 Cutaway of the Reactor Containment Building

systems and would have minimal environmental consequences. The following is a brief list of the planned modifications if FFTF would be restarted (Battelle 1999):

- Upgrade of plant protection system (scram breakers, power supplies, and signal conditioners)
- Replacement of zero-time-outage motor generator sets with solid-state electronic units
- Upgrades of plant data systems computers
- Upgrade of conductivity metering system on three cooling towers and replacement of electronic sensors and controls
- Installation of two new electrical distribution transformers to replace the polychlorinated biphenyl-filled units that were removed during standby operations
- Establishment of a program to assess and replace elastomer seals during the startup period to take advantage of advancements in seal technology
- Upgrades of the plant simulator (A program to upgrade the existing simulator to reach commercial simulator standards was in progress, but was discontinued when FFTF was placed in standby.)

#### **2.3.1.1.3 FFTF Fuel Use Option**

This NI PEIS postulates that FFTF would operate at a nominal power level of 100 megawatts, one quarter of the reactor design power level, to meet the irradiation requirements of the proposed missions. Periodic increases in power level between 100 and 400 megawatts may be required to support civilian nuclear energy research and development activities. Operating FFTF at a nominal 100-megawatt power level would extend the reactor life and significantly reduce the generation rate of spent fuel. FFTF is currently designed to operate using mixed oxide fuel (i.e., plutonium-uranium); however, it can also be operated using highly enriched uranium fuel. FFTF has an onsite supply of mixed oxide fuel for approximately 6 years of operation at the 100-megawatt level proposed for the mission. When this onsite fuel is depleted, FFTF may continue to use mixed oxide fuel or may switch to a reactor core of highly enriched uranium fuel. DOE believes that an additional 15-year supply of mixed oxide fuel would be available from Germany under favorable economic terms, (i.e., no charge for the fuel). The fuel would be reconfigured into assemblies suitable for irradiation at FFTF before shipment to the United States. That is why this NI PEIS evaluates the operation of FFTF for two reactor core configurations for the 35-year evaluation period of operation common to all alternatives: (1) operation with a mixed oxide core for approximately 21 years followed by 14 years of operation with a highly enriched uranium core, and (2) operation with a mixed oxide core for approximately 6 years followed by 29 years of operation with a highly enriched uranium core.

In this NI PEIS, DOE has not evaluated the possibility of using low-enriched uranium fuel for operation of the FFTF because it makes programmatic and economic sense to use available mixed oxide fuel supplies before using uranium. U.S. nonproliferation policy (U.S. House of Representatives 1992 [Schumer Amendment]), strongly discourages the use of highly enriched uranium fuel in civilian research and test reactors. The Reduced Enrichment for Research and Test Reactors Program implements this policy by developing technical means to reduce and eventually eliminate the use of highly enriched uranium in research and test reactors throughout the world and in the United States without decreasing their safety or significantly affecting their performance and operating costs.

To be in compliance with these policy directives, the most appropriate fuel supply for FFTF in the out-years (beyond current Hanford mixed oxide and possible German SNR-300 mixed oxide supplies) must be determined by a technical study with the preferred fuel source being low-enriched uranium. Highly enriched uranium fuel should only be considered if low-enriched uranium is not technically feasible, or if there are significant impacts on safety, performance, or cost associated with using fuels other than highly enriched uranium.

In the event that a decision is made to restart the reactor, and to support these policy directives, DOE's Office of Nonproliferation and National Security would undertake a study to consider the technical feasibility of using low-enriched uranium fuel (under the Reduced Enrichment for Research and Test Reactors Program) for FFTF. If low-enriched uranium fuel is found infeasible, DOE would subsequently procure highly enriched uranium fuel in a manner consistent with U.S. nonproliferation policy. This study would be conducted, decisions would be implemented, and fuel would be made available during the time period between a Record of Decision indicating an FFTF restart and prior to the end of available Hanford mixed oxide and possible SNR-300 mixed oxide fuel supplies.

For the purposes of presenting a bounding analysis in this NI PEIS, DOE has analyzed the impacts of using highly enriched uranium fuel in FFTF after the available mixed oxide fuel supplies have been expended. These impacts would bound those of using a low-enriched uranium fuel form.

#### **2.3.1.1.4 FFTF Irradiation Operations**

There are eight locations available in the reactor core that are termed Open Test Assembly positions. These positions are located under spool pieces in the reactor head and allow the installation of 38-foot-long assemblies that extend from the reactor head down to the reactor core. These eight locations are unique from the rest of the reactor in that they allow direct contact instrumentation for remote monitoring during reactor operation. Within the 82 active core locations, there are up to 20 or more additional locations that could contain a standard length (3.6-meter or 12-foot) test assembly. These locations also have specific online outlet temperature and flow measurements from installed plant instrumentation. In addition to the test locations within the active fueled region of the core, there are 108 locations available in the surrounding reflector region where other tests could be inserted. These three basic testing configurations enable irradiation of large and/or very diverse quantities. The target designs vary according to the test requirements and the location of the test within the reactor.

To fulfill the mission, the FFTF core would be modified to include an array of target assemblies and rapid radioisotope retrieval systems capable of producing a number of long- and short-lived isotopes for medical and industrial applications and plutonium-238 for space power applications. In addition, reactor space would be provided for research and development test articles.

Fifteen plutonium-238 production targets would be included in the reflector region with an annual production rate of 5 kilograms. The residence time for these targets would be three 100-day cycles; five assemblies would be harvested at the end of each cycle.

Long-Term Irradiation Vehicles would be used to irradiate targets to produce long-lived isotopes. The Long-Term Irradiation Vehicles would be installed in the reactor during normal refueling operations and would be handled using standard FFTF component handling equipment. The Long-Term Irradiation Vehicle would consist of a bundle of target pins installed inside a nozzle, duct, and handling socket assembly similar in appearance to an FFTF 3.6-meter-long (12-foot-long) fuel assembly. Depending on the isotopes to be produced, the pin bundle could contain moderator pins and neutron shield pins. A design that would allow re-use of the long-term irradiation assembly nozzle, duct, and handling socket hardware would be considered

during the design process to reduce both costs and waste generation. It is assumed that 12 Long-Term Irradiation Vehicle assemblies for the production of long-lived medical and industrial isotopes would be installed. A detailed description of the Long-Term Irradiation Vehicles and their proposed use is included in Appendix D.

Rapid radioisotope retrieval systems would be installed in selected Open Test Assembly positions for the production of short-lived isotopes. These systems would extend from above the spool pieces in the reactor head down into and slightly below the active core region and would allow target materials to be inserted and withdrawn from the reactor core region while the reactor is operating. Systems for routinely inserting and removing irradiation targets, nuclear instrumentation, and research hardware have been in use for years at various research reactors throughout the world. Most of these systems use either a pneumatic rabbit-type system or a mechanical cable-type system for insertion and retrieval. There would be a maximum of eight systems in the core. One of the systems would be configured as a gas target to produce iodine-125 from xenon-124. The other seven systems would be used to produce solid short-lived medical isotopes. A detailed description of the rapid radioisotope retrieval systems and their proposed use is included in Appendix D.

FFTF would operate at a nominal power level of 100 megawatts. However, the accident analyses provided in this NI PEIS are based on the FFTF design power level of 400 megawatts and provide conservative estimates of operation at 400 megawatts-thermal and lower power levels.

Testing programs would be conducted for new materials and target designs to be irradiated in the reactor. A discussion of the types of testing that would be associated with the medical isotope and plutonium-238 production missions is included in Appendix D.

#### **2.3.1.1.5 FFTF Deactivation**

FFTF would be permanently deactivated in Alternative 2 (Use Only Existing Operational Facilities), Alternative 3 (Construct New Accelerator[s]), Alternative 4 (Construct New Research Reactor), and Alternative 5 (Permanently Deactivate FFTF [with No New Missions]). This would require placement of FFTF in a radiologically and industrially safe shutdown condition that is suitable for a long-term surveillance and maintenance phase prior to final decontamination and decommissioning. An *Environmental Assessment, Shutdown of the Fast Flux Test Facility, Hanford Site, Richland, Washington*, issued by DOE in 1995, addressed the environmental impacts associated with permanently deactivating FFTF (DOE 1995a).

If a decision were made to proceed with permanent deactivation of FFTF, the molten sodium (radioactive) would be removed from the reactor systems and transferred to an existing sodium storage facility that was specially constructed for this purpose. The sodium would be drained by pressure transfer to the maximum practical extent into tanks located in the sodium storage facility. Residual sodium would be accommodated to a stabilized condition so that long-term monitoring and surveillance could be conducted in a safe and environmentally sound manner. The current concept for accommodating residuals would be to maintain an inert gas atmosphere that prevents any chemical reactions during long-term surveillance and maintenance.

#### **2.3.1.2 Advanced Test Reactor**

ATR is a light-water-cooled and moderated reactor with a design thermal power of 250 megawatts that is owned by DOE and is in the Test Reactor Area in the southwest portion of INEEL. Figure 3–6 presents a map of INEEL that depicts ATR's location.

ATR would continue to operate and meet its current mission requirements, including naval reactor research and development, medical and industrial isotope production, and civilian nuclear energy research and

development activities, at its current operating levels under the No Action Alternative, Alternative 1 (FFTF Restart), Alternative 3 (Construct New Accelerator[s]), Alternative 4 (Construct New Research Reactor), Alternative 5 (Permanently Deactivate FFTF [with No New Missions]), and Alternative 2 (Use Only Existing Operational Facilities) when it is not providing irradiation services in support of the plutonium-238 production mission. When ATR is supporting the plutonium-238 production mission, it would fully support its primary mission—naval reactor research and development; however, it would support the medical and industrial isotope production and civilian nuclear energy research and development activities to the extent possible within its current reactor operating levels. Consideration must be given to the need to maintain appropriate levels of neutron flux to support ATR's primary mission. Neutron flux levels can be impacted by the placement of targets, such as neptunium-237 targets for the production of plutonium-238, in the reactor core. The production planning assumption for ATR is from 3 kilograms (6.6 pounds) of plutonium-238 per year (if used in conjunction with HFIR) to 5 kilograms (11 pounds) of plutonium-238 per year (if ATR were used alone). Thus, ATR alone could meet the program goal of up to 5 kilograms (11 pounds) per year and could be used in combination with any one of the three processing facilities for the plutonium-238 production mission.

Special features of ATR include high neutron flux levels (ranging from  $1 \times 10^{15}$  neutrons per square centimeter per second in the flux traps to  $1 \times 10^{13}$  neutrons per square centimeter per second in the outer reflector positions) and the ability to vary power to fit different experiment needs in different test positions. The primary user of ATR is the U.S. Naval Nuclear Propulsion Program. A variety of other users include other foreign and domestic government programs, a commercial isotope production company, industrial customers, and research and development interests. This facility description is based on information provided in the *Advanced Test Reactor Upgraded Final Safety Analysis Report* (LMIT 1997) and *Capabilities of the Test Reactor Area Featuring the Advanced Test Reactor* (LMIT 1995). A number of support facilities are important to the operation of ATR (LMIT 1997). Among these are the Advanced Test Reactor Critical Facility, which is used to baseline experiment impacts to the ATR flux profile, and the Nuclear Materials Inspection and Storage Facility, which is used to receive, store, and inspect reactor fuel prior to its placement in ATR (INEEL 1999, 2000; LMIT 1995).

The reactor, its primary coolant system, control room, and much of its auxiliary and experimental support equipment are in Test Reactor Area Building 670. ATR began operation in 1967 and is expected to continue operating for several decades. The reactor vessel is constructed entirely of stainless steel, and the core internals are replaced every 7 to 9 years. The most recent changeout was completed in 1994 (LMIT 1995). Buildings and structures in other parts of the Test Reactor Area provide additional support functions.

ATR is currently operating at approximately 140 megawatts or less. ATR operates with highly enriched uranium fuel. Typical operating cycles are 42 days or 49 days at power followed by a 7-day outage for refueling and changeout of experiments and isotope production targets. The core is 1.2 meters (4 feet) high and is surrounded by a 1.3-meter-diameter (4.25-foot-diameter) beryllium reflector. Beryllium is an excellent neutron reflector and is used to enhance the neutron flux essential to a test reactor. The location of the core in the ATR vessel is shown in **Figure 2–5**. ATR has nine flux traps in its core and achieves a close integration of flux traps and fuel by means of a serpentine fuel arrangement (**Figure 2–6**). When viewed from above, the ATR fuel region resembles a four-leaf clover. The four flux traps positioned within the four lobes of the reactor core are almost entirely surrounded by fuel, as is the center position. Four other flux trap positions between the lobes of the core have fuel on three sides. ATR's unique control device design permits large power shifts among the nine flux traps. Testing can be performed in test loops installed in some flux traps with individual flow and temperature control or in reflector irradiation positions with primary fluid as coolant. The curved fuel arrangement brings the fuel closer on all sides of the test loops than is possible in a rectangular grid.

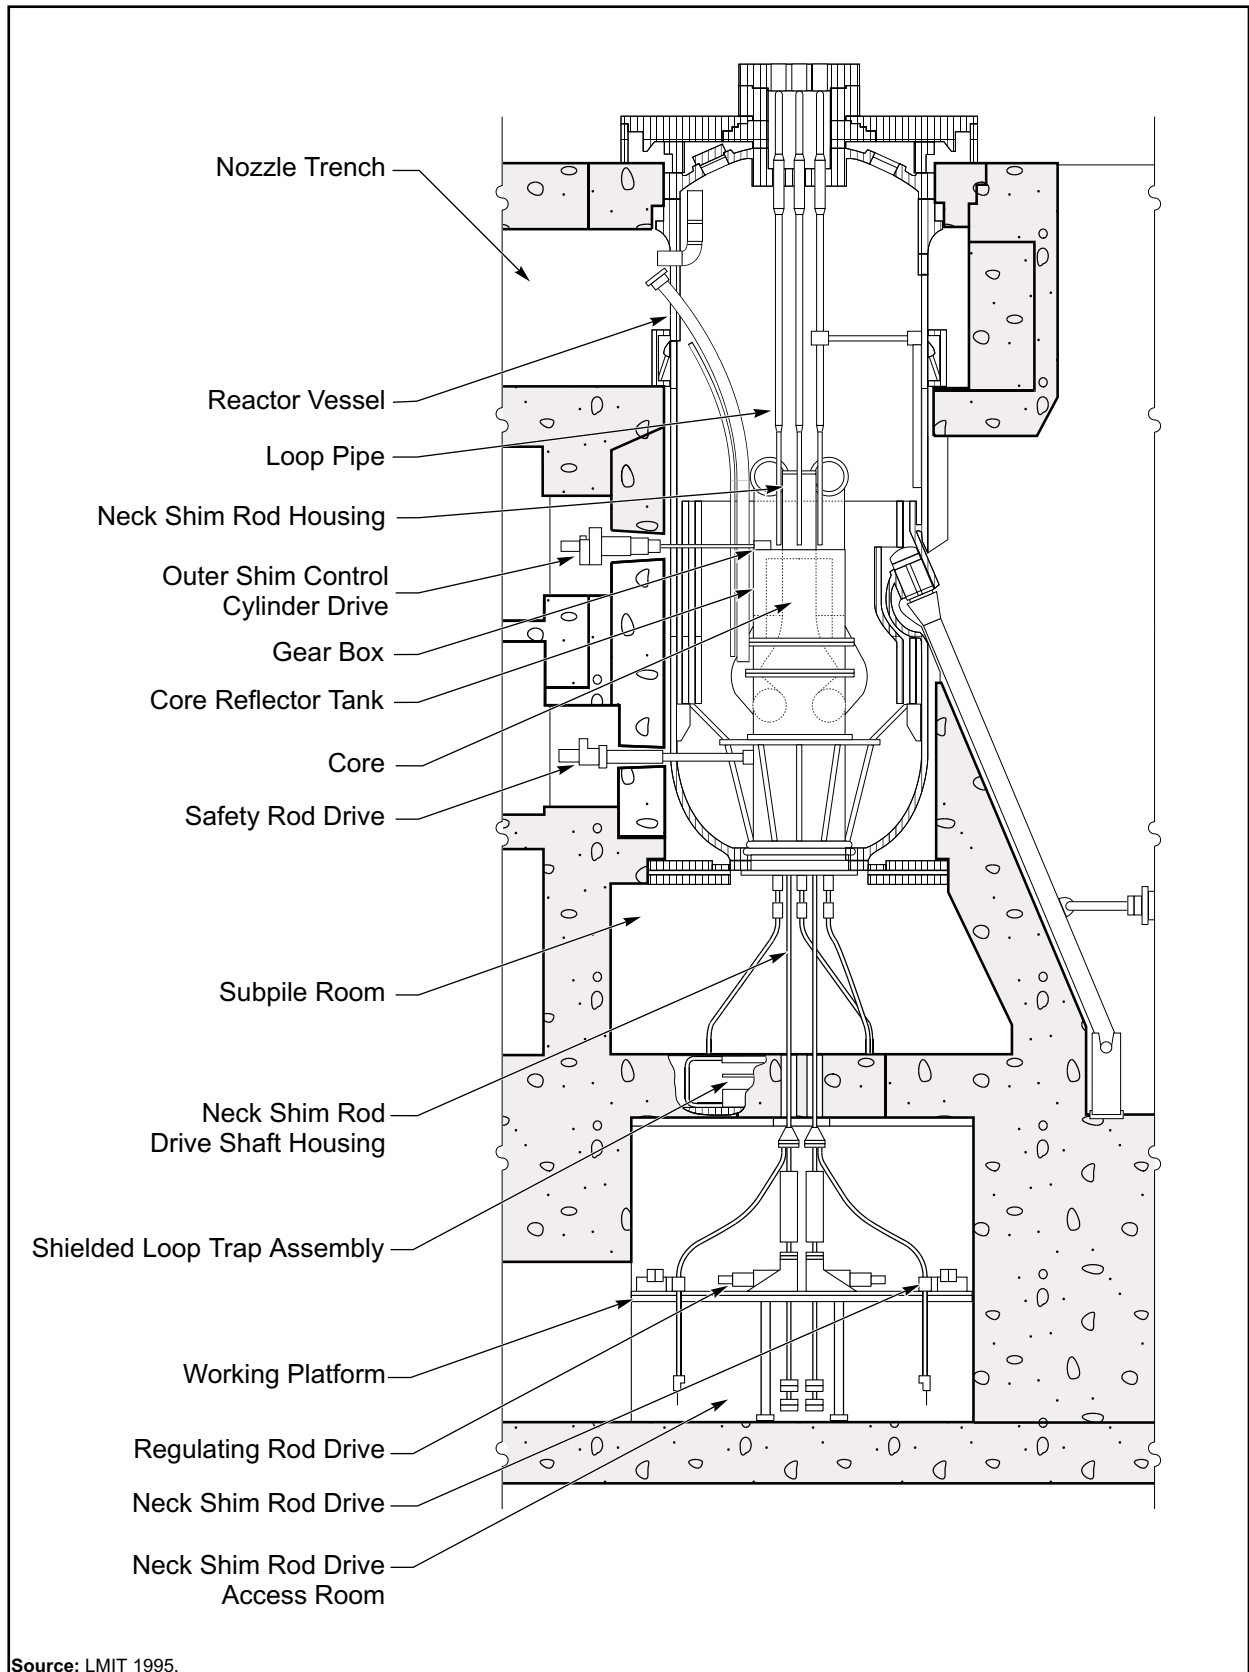

Figure 2-5 Vertical Cross Section of the ATR Vessel

Figure 2-6 Plan View (Cross Section) of ATR

Five out of the nine flux traps are configured with pressurized-water loops that allow for individual temperature, pressure, flow, and chemistry controls. The five test loops are used by the Naval Reactors program. Of the remaining four flux traps, one is dedicated to the Naval Reactors program, one is used for isotope production, one is used for low-specific-activity cobalt production, and the fourth has recently had the Irradiation Test Vehicle installed. The Irradiation Test Vehicle can be described as three small pressurized-gas test loops. The use of one of these three test loops was recently purchased by a British corporation; negotiations for use of the other two are currently under way.

In addition to the primary flux trap irradiation positions, there are some 70 irradiation positions in the beryllium reflector (and aluminum support structure) that are available for experiment irradiation and isotope production. These position diameters range from 1.6 centimeters (0.625 inch) to 12.7 centimeters (5 inches) with thermal neutron flux levels ranging from  $1 \times 10^{15}$  neutrons per square centimeter per second to  $1 \times 10^{13}$  neutrons per square centimeter per second. Approximately 25 percent of the high-flux test positions (A holes, B holes, and H holes) are currently used for iridium-192 production. The majority of the remaining high-flux test positions are used for cobalt-60 production. Occasionally, additional isotopes (e.g., strontium-89, nickel-63) are generated in small quantities. A private company leases the space for the production of these isotopes. A small number of positions are used by other companies or government programs for other materials irradiation projects. For the production of plutonium-238, neptunium-237 targets would be placed in the beryllium reflector positions. The proposed target design consists of neptunium dioxide blended with aluminum powder, pressed into a target core, and clad with aluminum. The basic ATR target should be similar in appearance to, but longer than, the typical transuranic isotope production target shown in **Figure 2-7**. The ATR target length would be sized for the 1.2-meter (4-foot) active core length of ATR. Beryllium reflector position sizes range from 1.6 centimeters (0.625 inch) in diameter to 12.7 centimeters (5 inches) in diameter.

ATR is equipped with numerous safety features, including extensive plant protective systems, standby power sources, experiment interlocks, computerized surveillance, confinement systems, safety rods, and an emergency firewater injection system. ATR's six safety rods provide fast shutdown of the reactor if potentially damaging conditions develop. A sudden rise in power or coolant temperature, a sudden drop in coolant flow or pressure, or the overheating of a test sample are examples of approximately 360 conditions that would automatically drop the safety rods into the core. The firewater injection system provides emergency core cooling and flooding of the reactor vessel in the event of a loss of primary coolant. ATR is connected by a water canal to the ATR Critical Facility. The ATR Critical Facility is a low-power, full-size nuclear duplicate of ATR that is used to provide data as needed for experiment loadings prior to irradiation of the actual experiments in ATR.

INEEL has privatized the production of medical and industrial isotopes through contracting with a commercial entity. International Isotopes Idaho, Inc. (I<sup>4</sup>), was selected in October 1996 as the commercial business for conducting these business operations. I<sup>4</sup> specializes in producing isotopes targets for irradiation in ATR and processing and distributing commercial-grade isotopes to their customers. Prior to commercialization, INEEL's isotope production operations were limited in types and quantities. Since the start of commercial activities, I<sup>4</sup> has expanded its commercial production to become a major world supplier of several important isotopes. I<sup>4</sup> has doubled the use of ATR irradiation positions for this purpose.

The major isotopes currently produced by INEEL and I<sup>4</sup> are iridium-192, 70 percent of the total U.S. demand; cobalt-60, 95 percent of the U.S. medical market; strontium-89, only U.S. supplier; and nickel-63, only U.S. supplier and producer of 50 percent of the world market.

Incremental investments have been identified for ATR that would make it a more versatile and capable reactor for isotope production. I<sup>4</sup> and another commercial company are in the discussion phase of investing in ATR to install an isotope rabbit (shuttle) system for the production of short-lived radioisotopes. Many of these

Figure 2-7 Typical Transuranic Isotope Production Target

short-lived radioisotopes are expected to be in growing demand for various cancer therapies. I<sup>4</sup> has also committed to keep part of the rabbit system available for other users.

### 2.3.1.3 High Flux Isotope Reactor

HFIR is a beryllium-reflected, light-water-moderated and -cooled reactor operating at a thermal power level of 85 megawatts. HFIR is owned by DOE and is in the 7900 Area of the ORNL site in the southern portion of the Oak Ridge Reservation (ORR). Figure 3–1 presents a map of ORR that depicts HFIR's location.

HFIR would continue to be operated to meet its primary mission of neutron science-based research for the DOE Office of Science. In addition, medical and industrial isotope production and civilian nuclear energy research and development activities would be performed on a not-to-interfere basis at the current operating level in the No Action Alternative, Alternative 1 (FFTF Restart), Alternative 3 (Construct New Accelerator[s]), Alternative 4 (Construct New Research Reactor), Alternative 5 (Permanently Deactivate FFTF [with No New Missions]), and Alternative 2 (Use Only Existing Operational Facilities). When HFIR is supporting the plutonium-238 production mission, it would fully support its primary mission, but would support the medical and industrial isotope production and civilian nuclear energy research and development activities to the extent possible within the current reactor operating levels. Consideration must be given to the need to maintain appropriate levels of neutron flux to support HFIR's primary mission. Neutron flux levels can be impacted by the placement of targets (such as neptunium-237 targets for the production of plutonium-238) in the reactor core. Under the planning assumptions for plutonium-238 production, HFIR could only produce from 1 to 2 kilograms (2.2 to 4.4 pounds) per year without impacting ongoing missions. As the program goal is to achieve a production rate of 5 kilograms (11 pounds) per year, production from HFIR would need to be augmented by the use of ATR to meet this goal. HFIR and ATR together could meet the program goal of up to 5 kilograms (11 pounds) per year and could be used in combination with any one of the three processing facilities for the plutonium-238 production mission.

HFIR was originally designed as both an isotope production and a research reactor with a thermal flux of 3 to  $5 \times 10^{15}$  neutrons per square centimeter per second and a full power level of 100 megawatts-thermal ( $3.4 \times 10^8$  British thermal units per hour). It is currently operating at a maximum authorized power level of 85 megawatts-thermal ( $2.9 \times 10^8$  British thermal units per hour) to extend the useful life of the reactor. Many experiment-irradiation facilities were provided for in the original design and several others have been added. The primary mission of HFIR is neutron science research. Isotope production is done on a not-to-interfere basis.

HFIR transfers its primary coolant heat load to secondary coolant through heat exchangers for dissipation to the atmosphere by an induced-draft cooling tower. The reactor uses highly enriched uranium and aluminum-clad plate fuel. The reactor vessel itself is immersed in a pool in a poured-concrete reactor building that also houses the primary coolant pumps and heat exchangers, a spent fuel pool, and experiment areas. The control and water wing of the reactor building contains the reactor control room; relay and amplifier areas; heating and ventilating equipment; pool and fire alarm equipment; instrumentation systems; and office and support rooms. A separate electrical building adjacent to the reactor building contains switchgear, diesel generators, and associated transformers that connect the facility to offsite power. The reactor building is essentially airtight and provides dynamic confinement. A special hot exhaust system exhausts air from potentially contaminated areas of the building through filters (two HEPA filters and two charcoal filters) before being released to the atmosphere through a 76-meter (250-foot) stack. The stack serves as the exhaust point for both HFIR and REDC at ORNL.

After the reactor completed 17.2 full-power years of its 20 full-power year design life in November 1986, several measures were taken to extend the useful life of the reactor, including reducing the

100 megawatts-thermal ( $3.4 \times 10^8$  British thermal units per hour) rated power level to 85 megawatts-thermal ( $2.9 \times 10^8$  British thermal units per hour); adjusting the primary coolant temperature and pressure; conducting periodic hydrostatic tests; establishing an irradiation embrittlement surveillance program; and installing an emergency depressurization system. Subsequent life extension programs can enable HFIR to provide support during the total 35-year evaluation period for operations.

A plan view of the reactor (**Figure 2–8**) provides a cross section of the reactor vessel depicting experiment irradiation capabilities. Available experiment irradiation facilities include (1) the hydraulic tube facility in the very high flux region of the flux trap that allows for insertion and removal of irradiation samples while the reactor is operating; (2) 30 target positions in the flux trap that normally contain transuranium production rods but can be used for the irradiation of other experiments (two instrumented target positions were provided by a recent modification); (3) six peripheral target positions at the outer edge of the flux trap; (4) numerous vertical irradiation facilities of various sizes located throughout the beryllium reflector; (5) two pneumatic tube facilities in the beryllium reflector that allow insertion and removal of irradiation samples while the reactor is operating for activation analysis; (6) four horizontal beam tubes that originate in the beryllium reflector; and (7) four slant access facilities, called “engineering facilities,” located adjacent to the outer edge of the beryllium reflector. In addition, spent fuel assemblies are used for gamma irradiation in the gamma irradiation facility in the reactor pool.

The reactor core assembly is contained in a 2.44-meter (8-foot) diameter pressure vessel in a pool of water. The top of the pressure vessel is 5.18 meters (17 feet) below the pool surface, and the reactor horizontal midplane is 8.38 meters (27.5 feet) below the pool surface. The control plate drive mechanisms are in a subpile room beneath the pressure vessel. These features provide the necessary shielding for working above the reactor core and greatly facilitate access to the pressure vessel, core, and reflector regions.

The neutron flux within HFIR is primarily a thermal neutron flux ranging from approximately  $2 \times 10^{15}$  neutrons per square centimeter per second in the flux trap to approximately  $4 \times 10^{14}$  neutrons per square centimeter per second in the outer regions of the beryllium reflector. Specially designed neutron beam tubes provide access to neutrons that supply intense neutron beams to various specialized instruments used for neutron scattering research.

ORNL produces a variety of medical isotopes using HFIR for irradiation and various hot cell and glovebox facilities for target fabrication and final product purification. **Table 2–2** presents a listing of HFIR-produced therapeutic radioisotopes. Key examples of the therapeutic radioisotopes currently produced in HFIR for distribution include dysprosium-166, rhenium-186, tin-117m, and tungsten-188 (parent of rhenium-188). The nine hydraulic tube positions in the central high flux region permit the insertion and removal of targets at any time during the operating cycle (22 to 24 days) and have traditionally been a major site for the production of medical radioisotopes.

In addition to providing radioisotopes for extramural research and development and commercial applications by distribution through the DOE Isotope Production and Distribution Program, there are medical radioisotope research and development programs at ORNL that depend on the availability of HFIR-produced radioisotopes.

The Isotopes Program at ORNL is totally funded by the DOE Office of Nuclear Energy, Science and Technology’s Isotope Production and Distribution Program. It provides enriched stable isotopes, selected radioisotopes, and related technical services for use in a wide variety of research, industrial, and especially medical applications. The scope of work not only includes the production of radioisotopes, but also the development of new methods and equipment to produce, recover, and purify isotope products.

Figure 2-8 Plan View (Cross Section) of HFIR

Table 2-2 Examples of HFIR-Produced Radioisotopes of Current Interest for Therapy

Radioisotope	Half-Life	Target	Comment
Palladium-103	17 days	Palladium-102	Therapy of prostatic carcinoma
Rhenium-186	3.77 days	Rhenium-185	Therapy of prostatic carcinoma
Samarium-153	1.93 days	Samarium-152	Antibodies/bone pain palliation
Tin-117m	13.6 days	Tin-116 or tin-117	Bone pain palliation
Arsenic-77 (from germanium-77)	1.62 days	Germanium-76	Bone pain palliation
Gold-199 (from platinum-199)	3.14 days	Platinum-198	Phosphorus analogue
Tungsten-188 (rhenium-188 daughter)	69 days	Tungsten-186	Bone pain/antibodies/ synovectomy
Dysprosium-166 (holmium-166 daughter)	3.4 days	Dysprosium-164	Synovectomy/bone pain

#### **2.3.1.4 Commercial Light Water Reactor**

A CLWR would continue to operate and meet its primary mission requirement, providing steam for the generation of electrical power, in the No Action Alternative, Alternative 1 (FFTF Restart), Alternative 3 (Construct New Accelerator[s]), Alternative 4 (Construct New Research Reactor), Alternative 5 (Permanently Deactivate FFTF [with No New Missions]), and Alternative 2 (Use Only Existing Operational Facilities) when it is not providing irradiation services in support of the plutonium-238 production mission. When the CLWR is supporting the plutonium-238 production mission, it would fully support its primary mission. The production planning assumption for the generic CLWR is 5 kilograms (11 pounds) per year of plutonium-238 or 7.5 kilograms (16.5 pounds) per 18-month operating cycle. Thus, the CLWR alone could meet the program goal of up to 5 kilograms (11 pounds) per year and could be used in combination with any one of the three processing facilities for the plutonium-238 production mission. The use of a CLWR for the medical and industrial isotope production mission and the DOE civilian nuclear energy research and development mission was not considered practical, as discussed in Section 2.6.1.

A typical pressurized water reactor core consists of 170 to 200 fuel assemblies arranged in the reactor vessel in an approximately cylindrical pattern. Most pressurized water reactors operating in the United States are licensed to operate at thermal power levels of 2,500 to 3,500 megawatts ( $8.5 \times 10^9$  to  $1.2 \times 10^{10}$  British thermal units per hour) for net station electrical outputs of 800 to 1,200 megawatts-electric ( $2.7 \times 10^9$  to  $4.1 \times 10^9$  British thermal units per hour).

The nuclear steam supply system powered by the pressurized water reactor is generally arranged as two heat transport loops, each with two primary coolant circulating pumps and one steam generator in which the primary coolant dissipates heat generated in the reactor core to the secondary fluid in the steam generator. In addition to serving as a heat transport medium, the primary coolant also serves as a neutron moderator and reflector and as a solvent for the soluble boron used in chemical reactivity control. All nuclear steam supply system components are designed to withstand the effects of earthquakes and loss-of-coolant accidents.

The containment for a pressurized-water reactor plant consists of two structures: (1) a steel containment vessel and (2) a reinforced-concrete shield building.

The containment, including all of its penetrations, is a low-leakage steel structure designed to withstand a postulated loss-of-coolant accident and to confine a postulated release of radioactive material. It houses the reactor pressure vessel, reactor coolant piping, pressurizer, pressurizer quench tank and coolers, reactor primary coolant pumps, steam generators, core flooding tanks, and letdown coolers. Safety systems directly associated with this vessel include the containment spray system, the containment air cooling system, and the containment isolation system. An annular space is provided between the wall of the containment vessel and the shield building. Overhead clearance from the dome of the shield building is also provided.

The shield building itself is a concrete structure surrounding the containment that is designed to provide biological shielding during both normal operations and hypothetical accident conditions. The shield building enables the collection and filtration of fission product leakage from the containment following a hypothetical accident by means of its emergency ventilation system. In addition, the shield building provides environmental protection for the containment from adverse atmospheric conditions and external missiles (e.g., tornado debris).

A complete reactor core of 177 fuel assemblies, arranged in a square lattice that approximates a cylinder, is shown in **Figure 2-9**. All fuel assemblies are identical in mechanical construction and are interchangeable in any core location. The basic fuel assembly (**Figure 2-10**) is normally composed of 208 fuel rods, 16 control rod guide tubes, and one centrally-located position for instrumentation—all within a 15- by 15-position square

Figure 2-9 Plan View (Cross Section) of a Generic CLWR

array. The fuel assembly is approximately 20.3 by 20.3 centimeters (8 by 8 inches) in cross section and has an overall length of 419 centimeters (165 inches).

The neptunium-237 targets can be placed in numerous locations within the reactor core region (i.e., fuel assembly region) and outside of the reactor core region to be irradiated for the production of plutonium-238. Three potential target arrangements were considered for evaluation in this NI PEIS: (1) all targets located in the center fuel assembly position in the reactor core, (2) all targets distributed within the reactor core region, and (3) all targets distributed outside the reactor core region. The center fuel assembly position was selected for evaluation in this NI PEIS because it was assumed that this would be the worst-case location during postulated beyond-design-basis accident conditions. This assumption conservatively postulated that during a beyond-design-basis core disruptive accident, temperatures in the center fuel assembly position would reach levels that would fail the cladding on all the neptunium-237 targets located in that position, resulting in worst-case releases.

Figure 2-10 CLWR Fuel Assembly

The substitution of target rods for fuel rod positions in the center fuel assembly would only minimally impact reactor operations. The fuel rods located in the center fuel assembly position normally would not be fresh fuel (i.e., fuel inserted within the first 18-month operating cycle in the reactor); instead, they would be in their second or third operating cycle. The normal power distribution within the core and reactor coolant flow and its distribution within the core would remain within existing technical specification limits.

### **2.3.1.5 New Accelerator(s)**

One or two new accelerators would be constructed and operated in Alternative 3 (Construct New Accelerator[s]). Preconceptual designs have been developed for a low-energy accelerator and a high-energy accelerator for evaluation in this NI PEIS (TechSource 2000). The low-energy accelerator would support the medical and industrial isotope production missions and the civilian nuclear energy research and development mission. This could effectively be accomplished with accelerator energies in the range of 30 to 70 million electron volts. The high-energy accelerator design would support the plutonium-238 production mission and the civilian nuclear energy research and development mission. An accelerator with an energy level of 1,000 million electron volts is required to support the plutonium-238 and nuclear research and development missions. The preconceptual design of the high-energy accelerator presented in Appendix F focused on supporting the plutonium-238 production mission. Although not analyzed in this NI PEIS, the design of the high-energy accelerator could be refined and expanded to perform additional missions such as the production of a select set of medical and industrial radioisotopes. In addition, DOE is aware of longer-term concepts that would apply high-energy accelerators to produce “tuneable” neutrons in a subcritical assembly. Such a facility could be used to address some of the missions more familiar to reactor facilities and may hold considerable promise for future science and technology research. A facility of this nature could provide unique capabilities in areas such as the testing of many different nuclear system coolant, fuel, and materials interactions.

The accelerators would be constructed and operated at one or two existing DOE sites. The low-energy accelerator would be located on the same DOE site as the new support facility or at a DOE site with an existing support facility. The high-energy accelerator could be located at a different DOE site. Alternative 3 site selection was not evaluated as part of this NI PEIS. Because Alternative 3 was evaluated at a generic DOE site, no credit was taken for any existing support infrastructure at the site, and it was postulated that a new support facility would be required to support operation of the low-energy accelerator and its missions and the high-energy accelerator civilian nuclear energy research and development missions if both accelerators were located on the same site. While this approach bounds the environmental impact assessment for the implementation of Alternative 3, it overstates the impacts because this NI PEIS integrates the impacts associated with constructing new support facilities and infrastructure that may be available at the existing DOE site. In the event that Alternative 3 or the low-energy accelerator alone is selected in the Record of Decision for subsequent consideration, follow-on NEPA reviews would evaluate potential locations for either both or one of the accelerators. It is unlikely that DOE would consider locating the new low-energy or high-energy accelerator on a DOE site that does not have an existing infrastructure capable of supporting all or most of the mission requirements. To determine the environmental impacts if Alternative 3 were implemented at a site with adequate support infrastructure, the environmental impacts for the construction of the support facility could be subtracted from the environmental impacts of Alternative 3 as presented in this NI PEIS. Section 4.5 of this NI PEIS presents the environmental impacts from construction and operation of the new support facility separately.

#### **2.3.1.5.1 Low-Energy Accelerator**

Three low-energy accelerator options would be available for the production of medical and industrial isotopes and to support nuclear energy research and development: (1) a high-current proton linear accelerator, (2) a

multiparticle cyclotron, or (3) a proton-only cyclotron. The proton-only cyclotron would have distinct technical advantages over the other two options and is described further in the sections that follow.

The proton-only cyclotron can be either a positive proton or negative ion type and is referred to as a proton cyclotron  $H^+$  or proton cyclotron  $H^-$ . A positive proton cyclotron would offer lower vacuum requirements and, with the latest technology, a high-extraction efficiency. Obtaining variable energy output would be complicated, however, because extraction can be done using only a single port and splitting the beam would require a complicated septum magnet. In comparison, the negative ion cyclotron would offer a continuous beam with high-current capacity using very simple high-efficiency extraction, a simple method to vary the particle energy, and the possibility of simultaneous irradiation of two different target arrays at different energies. The high-extraction efficiency would be achieved simply by passing the negatively charged beam through a thin foil that strips the electrons from the ion, creating a positive proton. The proton would be directly ejected from the machine by the existing magnetic field with high efficiency (greater than 98 percent). This feature would be important to minimize the activation of the cyclotron structure and thus reduce radiation exposure to the operational staff.

A high-beam current would be advantageous because more products could be prepared in a shorter time. In addition, a much higher specific-activity radioisotope could be prepared at the higher-beam current of the cyclotron. Specific activity is often a critical parameter in many nuclear medicine applications, including research and clinical use. The cyclotron could continuously tune the beam energy, which would be an advantage for research. The ability to tune the energy with precision could also help achieve high-purity isotope production by avoiding energies where impurity isotopes would be readily coproduced. These are important advantages for flexibility in research isotope production and are within the capabilities of commercially proven technology.

A new building with a 43-meter (140-foot) by 43-meter (140-foot) footprint would be constructed to house the cyclotron and the four beam lines. The walls of the facility would be 4.6 meters (15 feet) thick behind the target stations to minimize the neutron flux outside the building. The walls surrounding the cyclotron itself would be 3 meters (10 feet) thick. The mazes throughout the building would have walls 1.5 meters (5 feet) thick so that the total thickness surrounding the cyclotron area would be 3 meters (10 feet). The beam would be diverted to the four target stations by switching magnets located in the cyclotron vault. The beam would be directed through focusing and steering magnets to the target. In the isotope production beam line (northwest cave), the targets would be installed and removed vertically from a hot cell, which would be located on the second floor directly above the target station. The power supplies for the magnets would be housed with the power supplies for the cyclotron. The mechanical equipment for cooling water would be housed in a shielded mechanical room adjacent to the cyclotron vault. Recirculating water for cooling the targets and systems that could contain potentially radioactive material would be separated to prevent cross-contamination. These systems would be contained in mechanical equipment rooms near the respective target station. Piping would be contained in waterproof trenches with leak detection.

See Appendix F for additional details.

#### **2.3.1.5.2 High-Energy Accelerator**

In accelerator production of plutonium-238, an energetic beam of protons generated by a linear accelerator would be transported to a heavy metal target where spallation neutrons would be produced and moderated in a surrounding blanket. The blanket containing neptunium-237 would capture the slowed neutrons to produce plutonium-238 through the same nuclear sequence that occurs in a reactor. The accelerator would be housed in a concrete tunnel and buried below ground to provide radiation shielding for operating personnel. **Figure 2-11** presents the layout of the accelerator. A building to house radio frequency power systems and

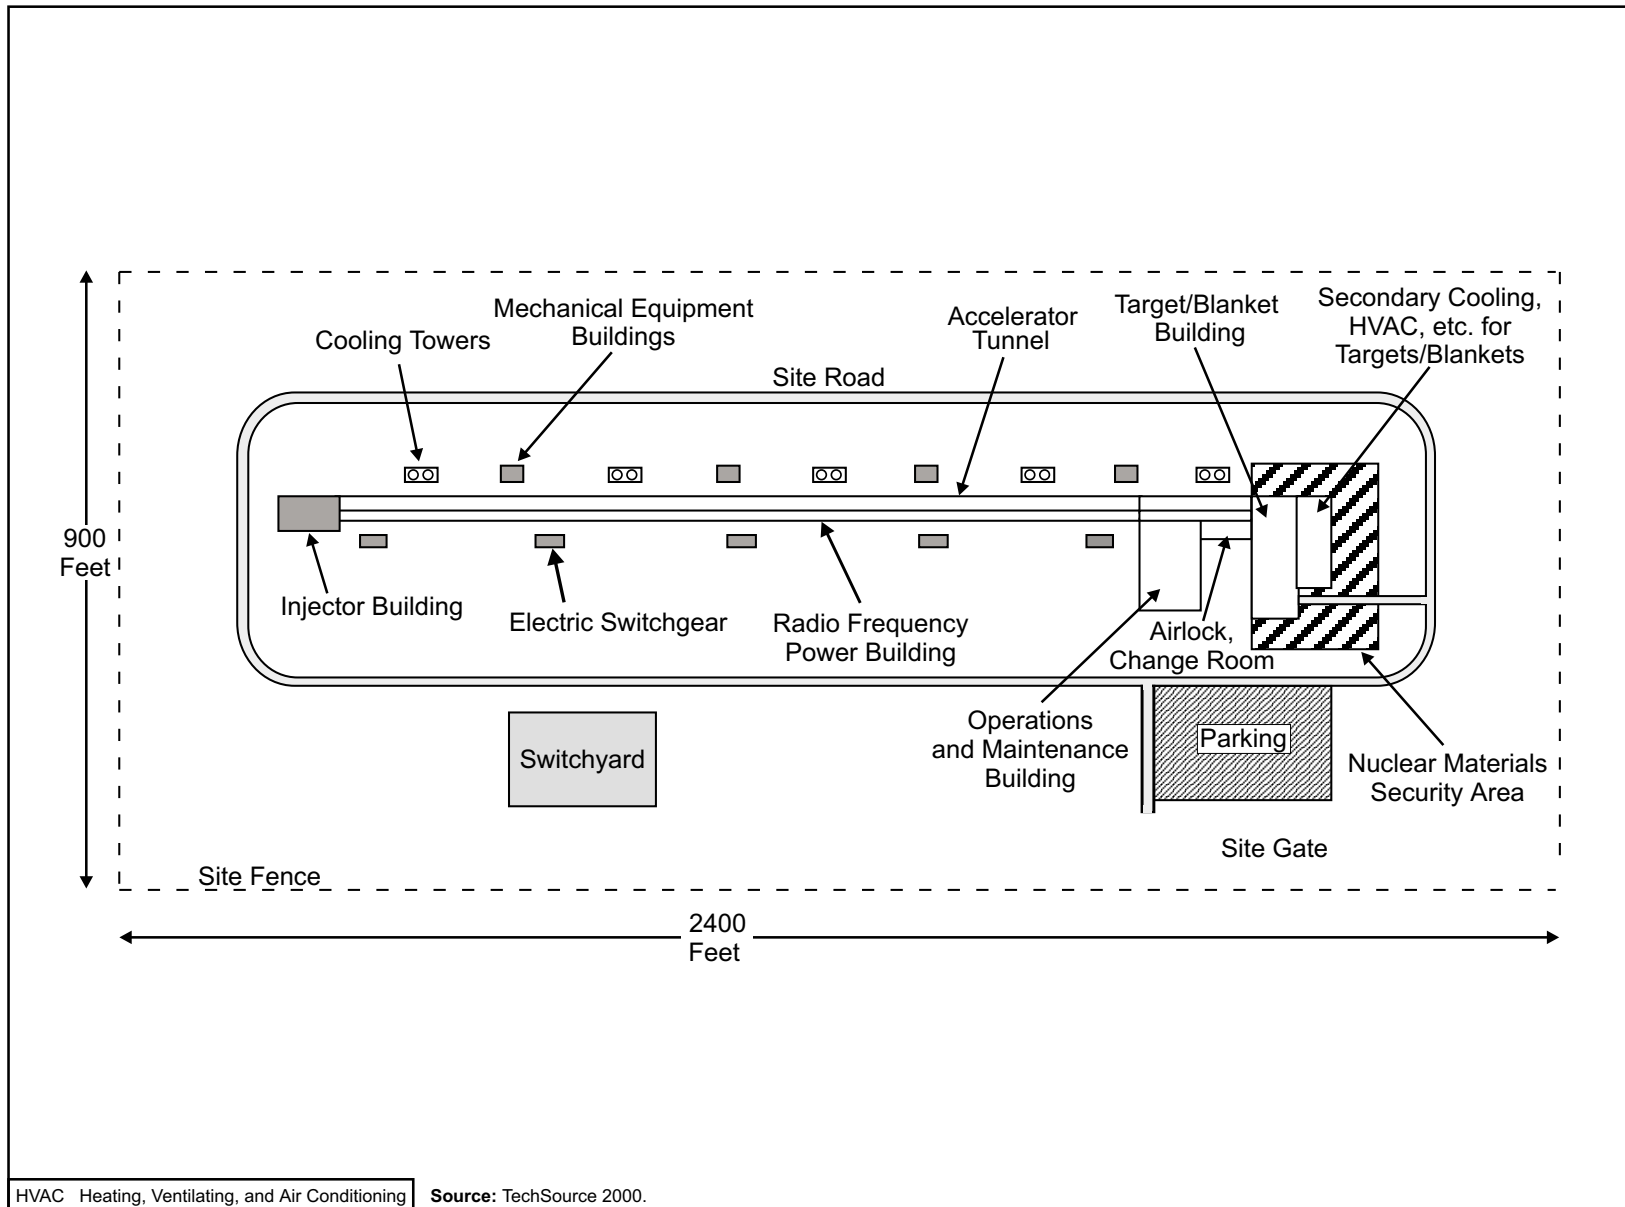

Figure 2-11 Accelerator Production of Plutonium Plant Layout

other equipment used to drive, monitor, and control the accelerator would be above ground close to the accelerator tunnel. The target and blanket assembly would be housed inside a steel and concrete shield within a multistory building that would contain appropriate service equipment. At the target, the small-diameter proton beam transported magnetically from the accelerator would be converted to a much larger cross section by a beam expander to reduce the power density to acceptable levels for the target cooling systems. A source of neutrons produced by an accelerator can be used to produce plutonium-238 from neptunium-237 feedstock through the capture-and-decay nuclear processes. A 1,000-million-electron-volt proton beam produced by a radio frequency linear accelerator would bombard a heavy metal (uranium-238) target, with each proton producing about 40 neutrons. A very preliminary target and blanket design has been developed for scoping purposes, based on the architecture employed in the accelerator production of tritium target and blanket design. It would use uranium-238 (cooled by heavy water) as the neutron-production target. The target would be surrounded by a blanket of neptunium-237 in a dilute mixture of aluminum and water coolant. Enclosing the blanket would be a beryllium reflector.

To meet the plutonium-238 production goal of up to 5 kilograms (11 pounds) per year, the high-energy accelerator facility would conduct three 4-month production campaigns. Each campaign would be divided into 100 days of production and 21 days for recycling the production blanket. A 90 percent plant availability during the scheduled operating periods is assumed. Based on operating experience at the Los Alamos Neutron Science Center Linear Accelerator, 90 percent plant availability would be achievable. See Appendix F for additional details.

The preconceptual design of the high-energy accelerator presented in Appendix F focused on supporting the plutonium-238 production mission. While not evaluated in this NI PEIS, the design of the high-energy accelerator could be refined and expanded to perform additional missions such as the production of a select set of medical and industrial radioisotopes. In addition, DOE is aware of longer-term concepts that would apply high-energy accelerators to produce “tuneable” neutrons in a subcritical assembly. Such a facility could be used to address some of the missions more familiar to reactor facilities and may hold considerable promise for future science and technology research. A facility of this nature could provide unique capabilities in areas such as the testing of many different nuclear system coolant, fuel, and materials interactions. The accelerator designs for Alternative 3 were developed to a level of detail that was adequate to assess the environmental impacts associated with the construction and operation of the proposed facilities and the technical feasibility of meeting the mission objectives. In the event that the NI PEIS Record of Decision selects Alternative 3, DOE would prepare conceptual, preliminary, and detailed designs and optimize the facility designs to accomplish the stated missions. Additional NEPA review would be required for site selection and to evaluate the environmental impacts of integrating the more refined accelerator designs with the existing site infrastructure(s).

#### **2.3.1.6 New Research Reactor**

A new research reactor would be constructed and operated in Alternative 4 (Construct New Research Reactor). A preconceptual design for a new research reactor was developed to meet the following DOE missions: (1) producing medical and industrial isotopes, (2) producing plutonium-238 (annual production of up to 5 kilograms [11 pounds]), and (3) supporting nuclear energy research and development. In accordance with U.S. nuclear nonproliferation policy, a design limitation of this new research reactor would be that it could only use low-enriched uranium with an enrichment of less than 20 percent uranium-235. This preconceptual design includes the basic elements of the research reactor facility, which are sufficient to support this NI PEIS, but does not include the design details (e.g., system and layout drawings, bill of materials, electrical and piping routing) commensurate with a complete preliminary reactor design.

The reactor design was developed to a level of detail that was adequate to assess the environmental impacts associated with the construction and operation of the proposed facilities and the technical feasibility of meeting the mission objectives. The design of the new research reactor is based on current research reactor designs that have been approved by both NRC and the International Atomic Energy Agency, as well as the nuclear regulatory authorities of many nations. Reactor core physics calculations were performed to evaluate three different nuclear fuel designs (described in Appendix E). Based on this analysis, the desired mission for this reactor, current nuclear fuel manufacturing capabilities, and safety considerations, a TRIGA (training, research, isotopes General Atomics) production reactor fuel design was selected for the new research reactor. The principal distinguishing features of the TRIGA fuel are its proven safety performance during power pulsing and its demonstrated long-term irradiation integrity.

To concurrently produce medical and industrial isotopes, meet the plutonium-238 production goal of up to 5 kilograms (11 pounds) per year, and provide irradiation services for civilian nuclear energy research and development, it was determined that a reactor core power of 50 megawatts-thermal would be necessary. Higher power levels and alternative target designs capable of meeting production requirements were also considered in the new research reactor design analysis but were not analyzed in this NI PEIS. For example, although not analyzed in this NI PEIS, operating at 100 megawatts-thermal could reduce the amount of neptunium-237 required to meet the plutonium-238 production requirements.

At the 50-megawatts-thermal power level, the core would require an active cooling system with forced coolant flow to maintain the fuel below its material thermal limits. The new research reactor cooling system would use a tank within a pool that is connected to primary coolant circulating pumps, heat exchangers, and an ultimate heat sink consisting of two cooling towers. The pool would be housed in a reactor building that also would enclose the pumps, heat exchangers, secondary systems, and spent nuclear fuel storage pool. The spent nuclear fuel storage pool, sized to store the reactor core's discharged spent nuclear fuel for its entire 35-year production period, could be hydraulically connected to the reactor core pool for refueling and emergency reflooding. The ultimate heat sink cooling towers, air exhaust stack, and emergency diesel generators would be located outside the reactor building.

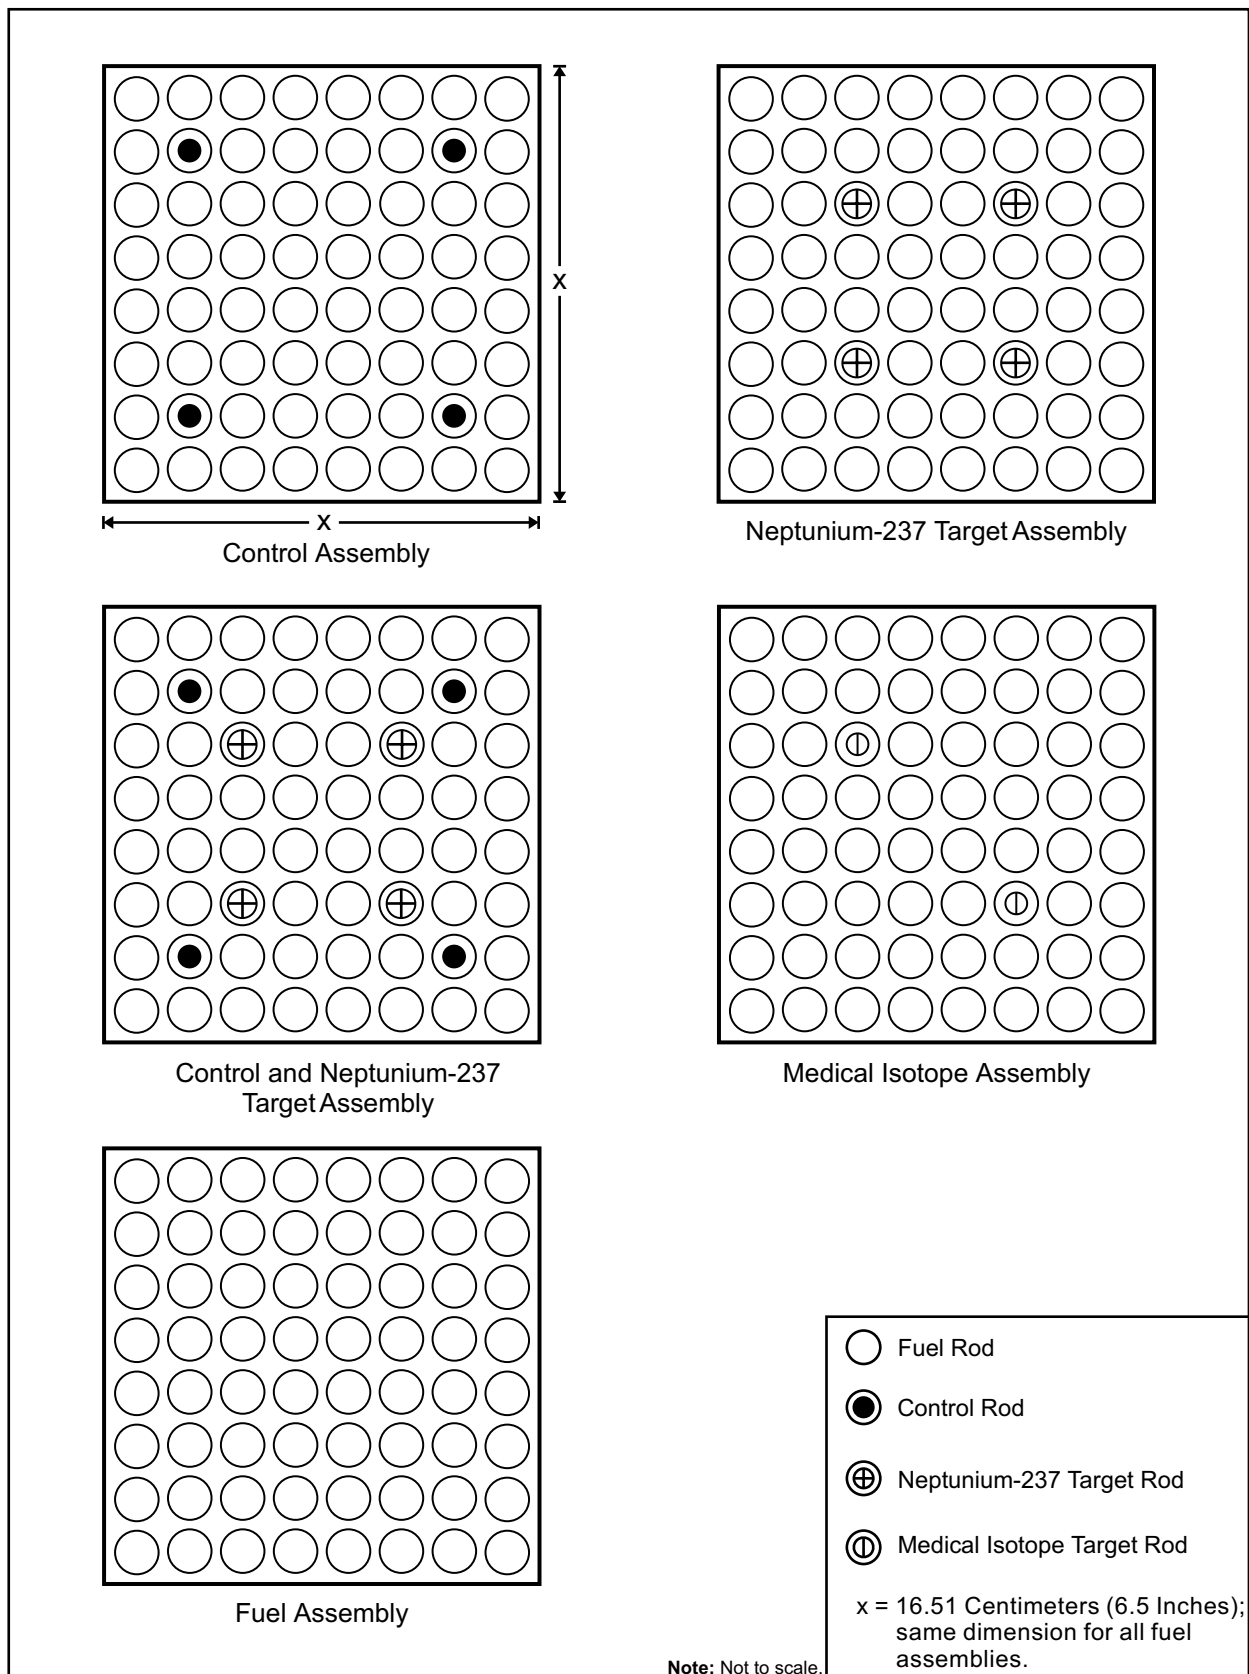

The fuel for the new research reactor would be based on an extension of currently licensed low-enriched uranium TRIGA fuel designs for 10- to 16-megawatts-thermal reactors. The new research reactor fuel design would be identical to current low-enriched uranium TRIGA fuel for higher power cores, except the new reactor fuel would have a larger assembly configuration array (i.e., 8 by 8 versus 4 by 4) and a longer active fuel length (153.7 centimeters [60.5 inches] versus 55.88 centimeters [22.0 inches]). The larger array and length were selected to meet the plutonium-238 production requirements and to maintain high safety factors with respect to fuel thermal performance.

Along with the fuel rods, the core would contain a number of medical and industrial isotope and plutonium-238 production target rods. These rods would occupy positions in a fuel assembly where a fuel rod would otherwise exist. Each of these positions would have an Incoloy-800 alloy guide tube with the same dimensions as the fuel rod cladding. The target rods would be inserted into these guide tubes for their design irradiation time period. In addition, some fuel rod positions in core fuel assemblies would be replaced with similar guide tubes to accommodate Incoloy-800-clad boron carbide control rods. Boron carbide is a widely used, proven, and accepted neutron absorber for control rods. **Figure 2–12** presents a representative illustration of the fuel rod; the neptunium-237, medical, or industrial radioisotope target rod; and the control rod. **Figure 2–13** shows a cross-sectional view of each type of fuel assembly in the core. The new research reactor core design would consist of 68 fuel assemblies, each of which would be enclosed in a square aluminum shroud for structural support and coolant flow control. Key design features of the core are provided in Appendix E.

Note: Not to scale.

Figure 2-12 Representative Illustration of Fuel Rod; Neptunium-237, Medical, or Industrial Radioisotope Target Rod; and Control Rod (New Research Reactor)

**Figure 2-13 Cross-Sectional View of Fuel Assemblies in the Core (New Research Reactor)**

The core would include eight rabbit tubes for short irradiation time production of medical or industrial isotopes and civilian nuclear energy research and development. These rabbit tubes would be located outside the fuel region of the core, but still within an area with a relatively high neutron flux. A cross-sectional view of the new research reactor core showing the layout of fuel assemblies, target rod assemblies, control rod assemblies, reflector, and rabbit tubes is presented in **Figure 2-14**.

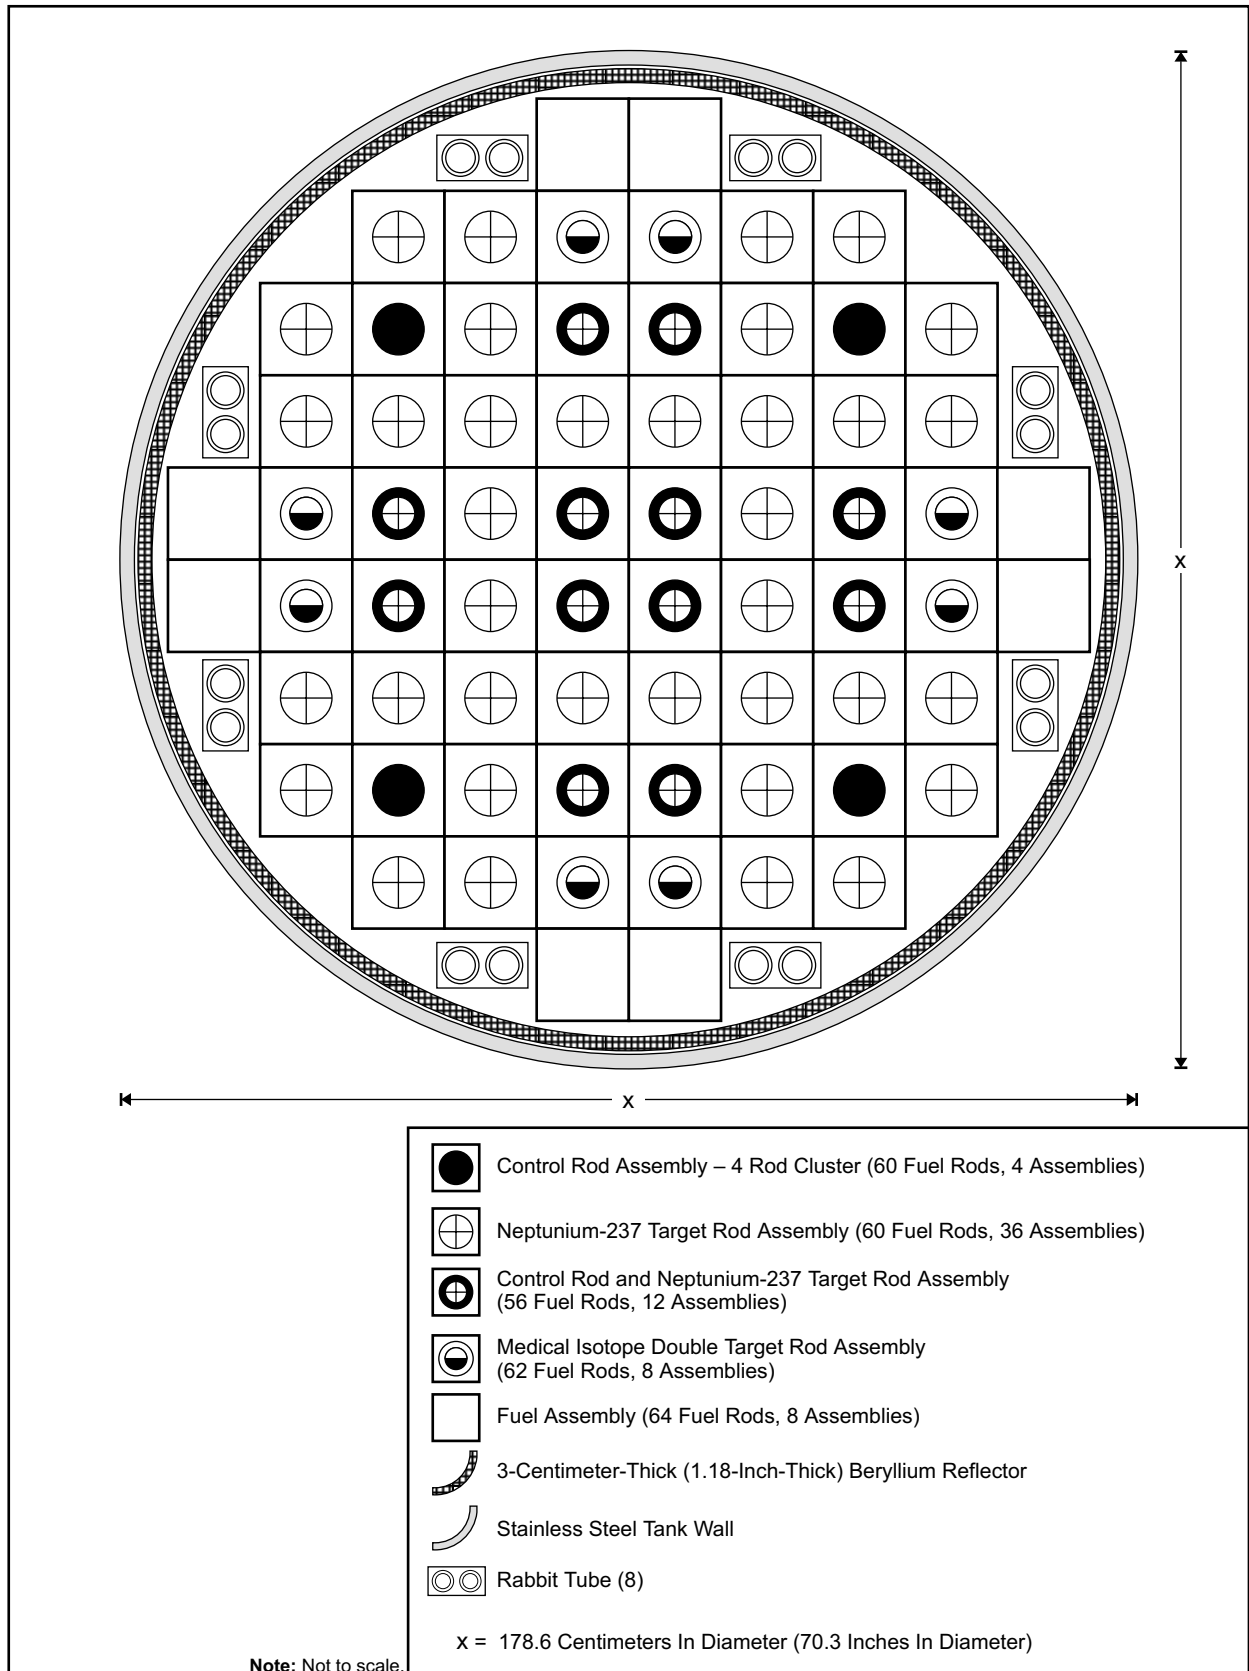

The new research reactor would be constructed and operated at an existing DOE site. Since the potential site has not been selected, it is evaluated in this NI PEIS as a generic DOE site. Because Alternative 4 was evaluated at a generic DOE site, no credit was taken for any existing support infrastructure at the site, and it was postulated that a new support facility would be required to support operation of the new research reactor and its medical isotope production and civilian nuclear energy research and development missions. While this approach bounds the environmental impact assessment for the implementation of Alternative 4, it overstates the impacts because this NI PEIS integrates the impacts associated with constructing new support facilities and infrastructure that may be available at the existing DOE site. In the event that Alternative 4 is selected in the Record of Decision for subsequent consideration, follow-on NEPA reviews would evaluate potential site locations. It is unlikely that DOE would consider locating the new research reactor on a DOE site that does not have an existing infrastructure capable of supporting all or most of the mission requirements. To determine the environmental impacts if Alternative 4 were implemented at a site with adequate support infrastructure, the environmental impacts for the construction of the support facility could be subtracted from the environmental impacts of Alternative 4 as presented in this NI PEIS. Section 4.6 of this NI PEIS presents the environmental impacts from construction and operation of the new support facility separately.

## **Reactor Operation**

Operation of the new research reactor would be similar to other research reactors except that the core would be maintained at full power for a minimum 80 percent of the year. At the beginning of a cycle of operation, neptunium-237 and medical isotope target rod assemblies that require a long irradiation time would be inserted into their appropriate fuel assembly sleeve locations. The target rods would be mechanically attached to a cluster spider assembly similar to that used for the control rod assembly. The neptunium-237 target rod assemblies would remain in the core for the entire annual fuel cycle. These target rod assemblies would be removed from the host fuel assembly without removing the fuel assembly from the core, and then would be transferred to the spent fuel storage pool using the transfer canal. Medical and industrial isotope target rods that require a 100-day irradiation cycle would be removed and replaced with new target rod assemblies during brief reactor shutdown periods. These target rod assemblies would be removed and transferred in a manner similar to that of the neptunium-237 target rod assemblies. Isotopes that require only a short irradiation time would be inserted into rabbit tubes for the required 10- to 25-day time period. The eight rabbit tubes would be located outside the core, but inside the reflector region. The insertion and removal of irradiation targets in the rabbit tubes would have no significant effect on core reactivity and would not affect power operation.

After an isotope-specific cooling time in the spent fuel pool, the medical and industrial isotope and neptunium-237 target assemblies would be transferred to a shipping cask in the spent fuel storage pool. Using the overhead crane in the spent fuel pool area, shipping casks would be placed onto a truck in the reactor building bay adjacent to the fuel storage pool for shipment to the processing facility. New targets would be shipped from the target preparation facility into the reactor building bay by truck, transferred into the spent fuel storage pool, and subsequently moved to the reactor core pool or rabbit tube area for insertion into the core.

The plutonium-238 annual production goal of up to 5 kilograms (11 pounds) was calculated to be achieved with a 300-day annual irradiation time, which corresponds to a capacity factor of approximately 80 percent. Key reactor annual resource requirements are presented in Appendix E.

**Figure 2–14 Cross-Sectional View of Research Reactor Core**

## **Reactor Construction**

Construction of the new research reactor facility was determined to require 4 years after design and licensing activities have been completed (AECL 1996; ANSTO 1999).

### **2.3.2 Target Fabrication and Postirradiation Processing Facilities**

The proposed DOE facilities that would be used for the fabrication, storage, and postirradiation processing of the targets necessary for the program mission are (1) REDC at ORNL, (2) FDPF and/or Building CPP-651 at INEEL, (3) FMEF at Hanford, (4) RPL/Building 306-E at Hanford, or (5) a new target fabrication and processing facility at an existing DOE site that would support medical and industrial isotope production for targets irradiated in the proposed new low-energy accelerator or research reactor facilities. REDC, FDPF, and CPP-651 would support plutonium-238 production; FMEF would support both plutonium-238 and medical and industrial isotope production. The RPL/306-E facilities and the new facility would support only medical and industrial isotope production.

#### **2.3.2.1 Radiochemical Engineering Development Center**

REDC at ORNL is a companion facility to HFIR. The REDC's two buildings house heavily shielded hot cells and analytical laboratories that are used for remote fabrication of rods and targets (for irradiation in HFIR) and processing of irradiated rods and targets for the separation and purification of transuranic elements, process development, and product purification and packaging.

ORNL's REDC Building 7930 is proposed for storage of neptunium-237 under one option of the No Action Alternative. It also is proposed for storage of neptunium-237, fabrication of neptunium-237 targets, and processing of irradiated neptunium-237 targets under two irradiation options in Alternative 1 (FFTF Restart), three irradiation options in Alternative 2 (Use Only Existing Operational Facilities), and one irradiation option each in Alternative 3 (Construct New Accelerator[s]) and Alternative 4 (Construct New Research Reactor). REDC's current radiochemical missions would not be impacted by the addition of the proposed storage of neptunium-237, fabrication of neptunium-237 targets, and the processing of irradiated neptunium-237 targets activities. REDC would have no role in support of Alternative 5 (Permanently Deactivate FFTF [with No New Missions]). Figure 3-1 presents a map of ORR that depicts REDC's location.

REDC Building 7930 is divided into four major areas: (1) a cell complex with seven cells, six shielded and one unshielded; (2) maintenance and service areas surrounding the cell complex; (3) an operating control area; and (4) an office area adjacent to, but isolated from, the operating areas. Utility services, ventilating systems, crane and manipulator systems, and liquid waste systems also are included. The proposed plutonium-238 processing and storage activities would require equipment installation in three main areas of the second floor of REDC Building 7930. A plan view of these areas is shown in **Figure 2-15**. REDC hot cell facilities that would be used for the proposed action have never been used. The activities required for target fabrication would take place in shielded gloveboxes. The mechanical operations involved in the final target fabrication process may present lesser hazards that permit them to be carried out in open boxes. Cell E would contain processing equipment to purify the separated plutonium-238 product, prepare the plutonium oxide, and transfer the oxide into shipping containers. Cell E would also contain vertical storage wells for dry storage of neptunium and other actinides.

Cell D activities would include receipt of irradiated targets, as well as target dissolution, chemical separation of neptunium and plutonium from fission products, and partitioning and purification of neptunium. Cell D

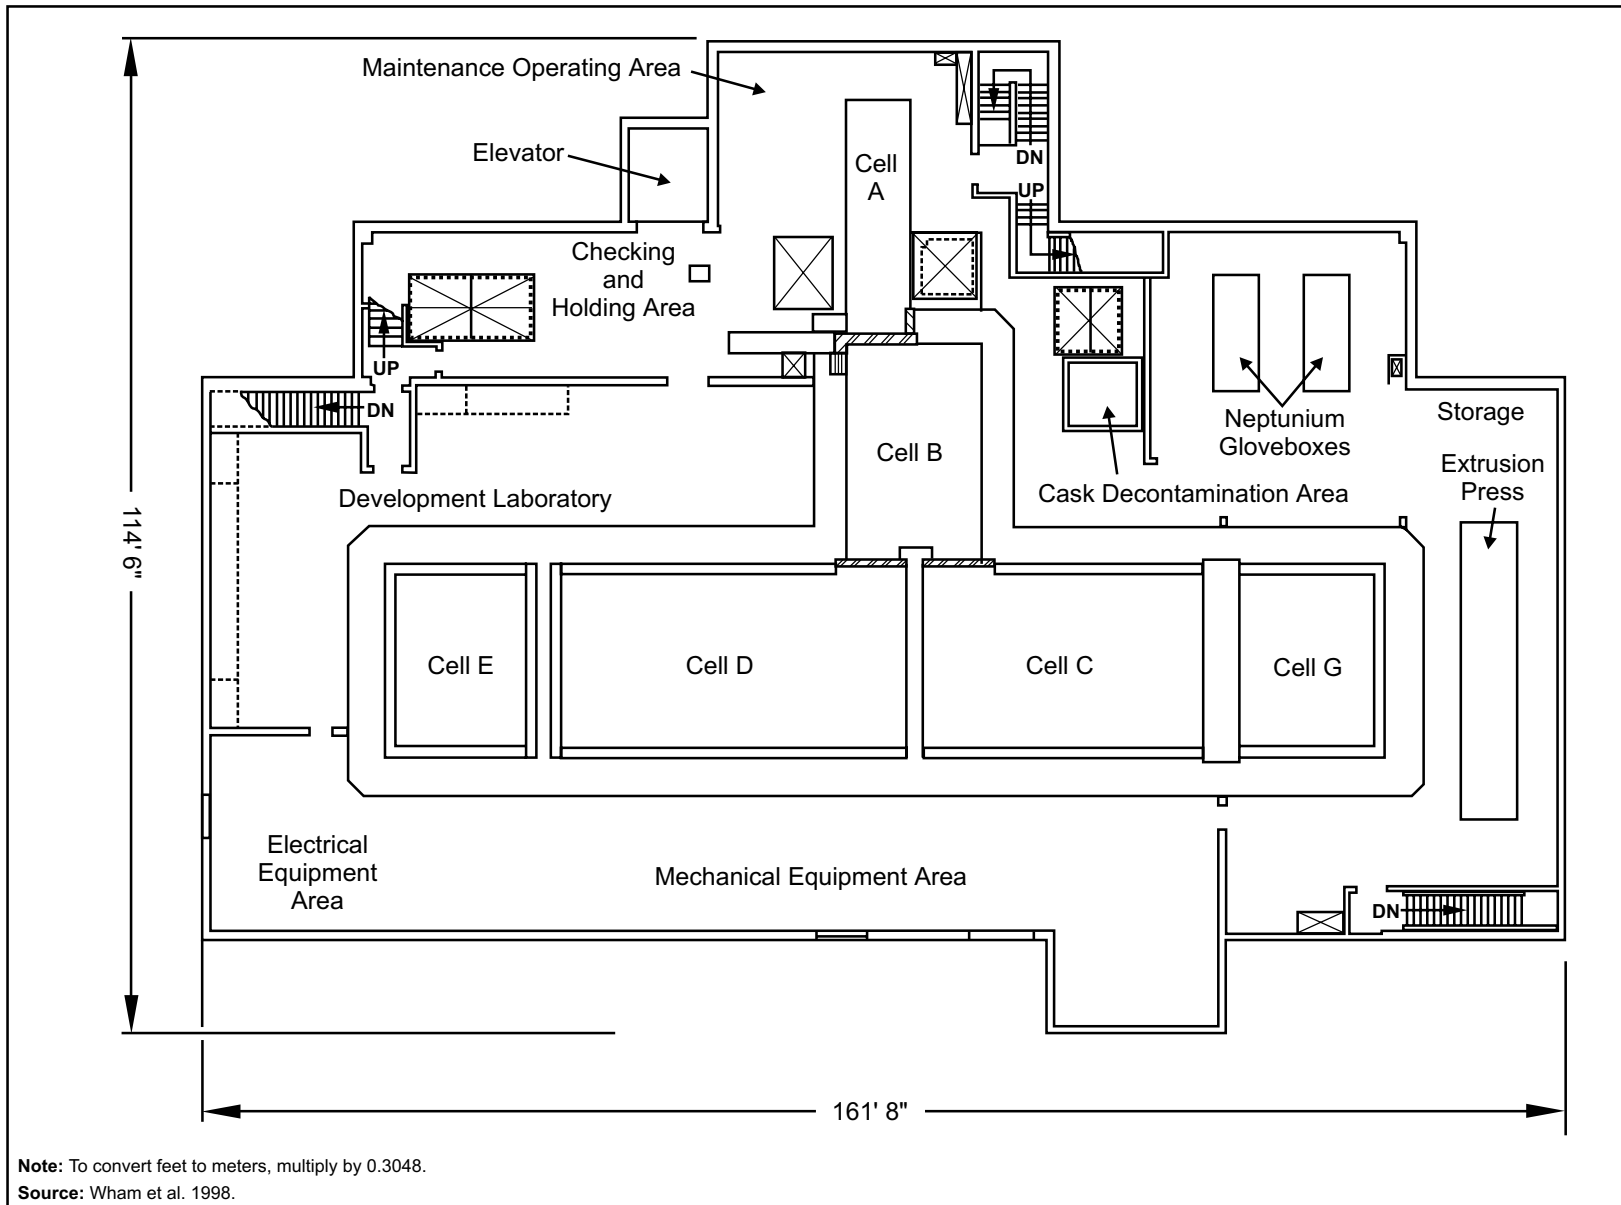

Figure 2-15 REDC Building 7930 Second Floor Plan View (Cross Section)

also contains process equipment for removing transuranic elements from the aqueous waste streams and vitrifying the waste.

The neptunium dioxide (NpO<sub>2</sub>) containers would be stored in specially designed storage vaults to provide secure, safe storage for the materials. DOE safeguards and security guidelines would be followed whenever the material is being stored, transported, or processed. Detailed descriptions of the facility and the processes associated with storage, target fabrication, and postirradiation processing are provided in Appendix A.

### **2.3.2.2 Fluorinel Dissolution Process Facility**

FDPF is in the Idaho Nuclear Technology and Engineering Center (INTEC) that is northeast of the Central Facilities Area at INEEL and approximately 3.2 kilometers (2 miles) southeast of ATR. FDPF is proposed for fabrication of neptunium-237 targets and processing of irradiated neptunium-237 targets under two irradiation options in Alternative 1 (FFTF Restart), three irradiation options in Alternative 2 (Use Only Existing Operational Facilities), and one irradiation option each in Alternative 3 (Construct New Accelerator[s]) and Alternative 4 (Construct New Research Reactor). Figure 3–6 presents a map of INEEL that depicts FDPF's location.

FDPF has no current mission. Historically, INTEC reprocessed spent nuclear fuel from U.S. Government reactors to recover reusable highly enriched uranium. After DOE announced in April 1992 that it would no longer reprocess spent fuel, reprocessing operations at INTEC ended. Two buildings at INTEC are candidate storage and processing sites for plutonium-238 production: Building CPP–651, the Unirradiated Fuel Storage Facility, and Building CPP–666, FDPF. Building CPP–651 was originally designed for the storage of special nuclear materials to support Defense Programs and is quite flexible in terms of the size and shape of special nuclear materials that it can receive and store. The 100 storage positions in the vault use the existing structural barriers of Building CPP–651 (earth and concrete) and provide supplemental security protection via their in-ground concrete storage silo design. Each storage position houses a rack that holds seven highly enriched uranium product cans. Racks are raised and lowered in their storage positions via an overhead 1-ton hoist.

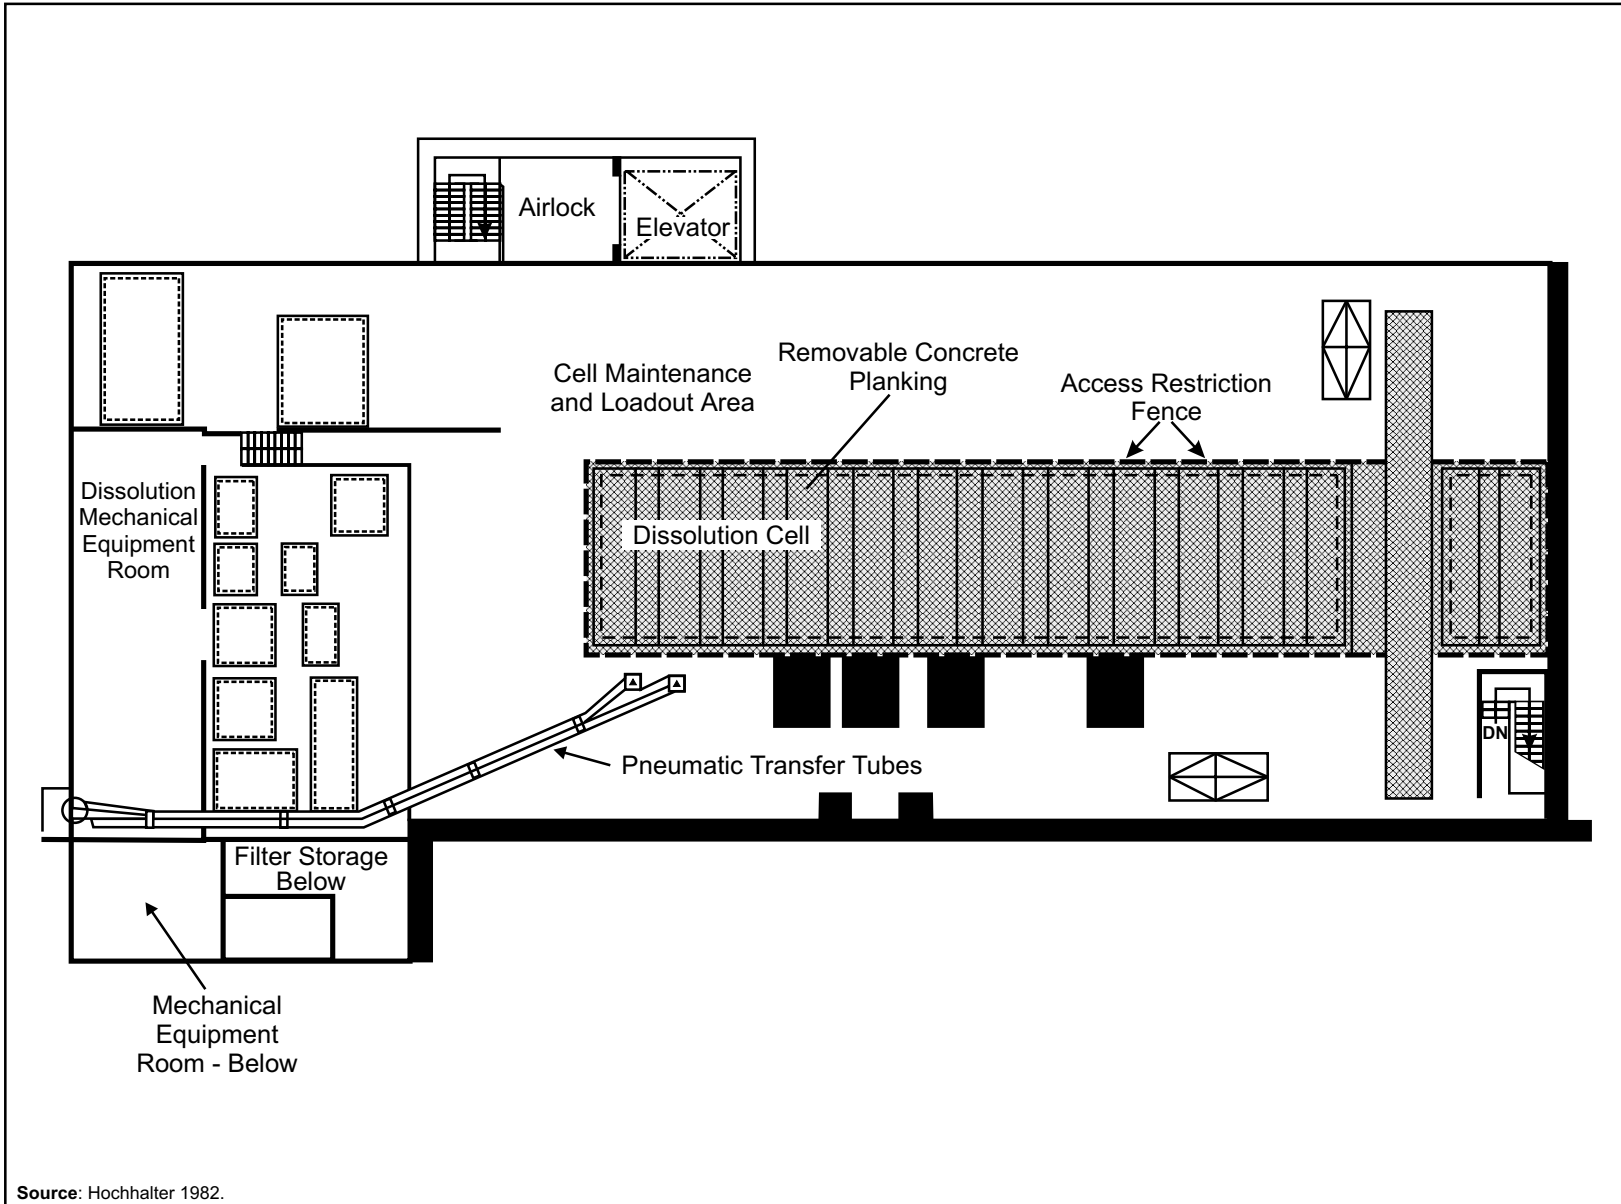

Building CPP–666 is divided into two parts, the Fuel Storage Facility and FDPF. The Fuel Storage Facility consists of receiving and unloading areas, a fuel unloading pool, and six storage pools for storing nuclear fuel.

FDPF was designed and built to process Navy fuel via three dissolver trains. When fuel reprocessing was discontinued, uranium and hazardous materials were flushed from FDPF, and the facility is currently under consideration for new missions. FDPF consists of a large hot cell and supporting areas with a total area of approximately 3,700 square meters (40,000 square feet). The facility is divided into five levels that are identified by their elevation relative to ground level (Hochhalter 1982). A floor plan of the plus 28-foot level, the proposed location for target fabrication activities, is shown in **Figure 2–16**.

The chemical separation would take place in the FDPF cell using small centrifugal contactors installed for that purpose. Storage of neptunium-237 would be performed in Building CPP–651, which is located within 100 meters (328 feet) of FDPF. There are 100 in-ground concrete-shielded storage well positions in this vault. Each storage well contains a rack that can be modified to house cans of neptunium-237.

The neptunium dioxide containers would be stored in specially designed storage vaults to provide secure, safe storage for the materials. DOE safeguards and security guidelines would be followed whenever the material is being stored, transported, or processed.

Source: Hochhalter 1982.

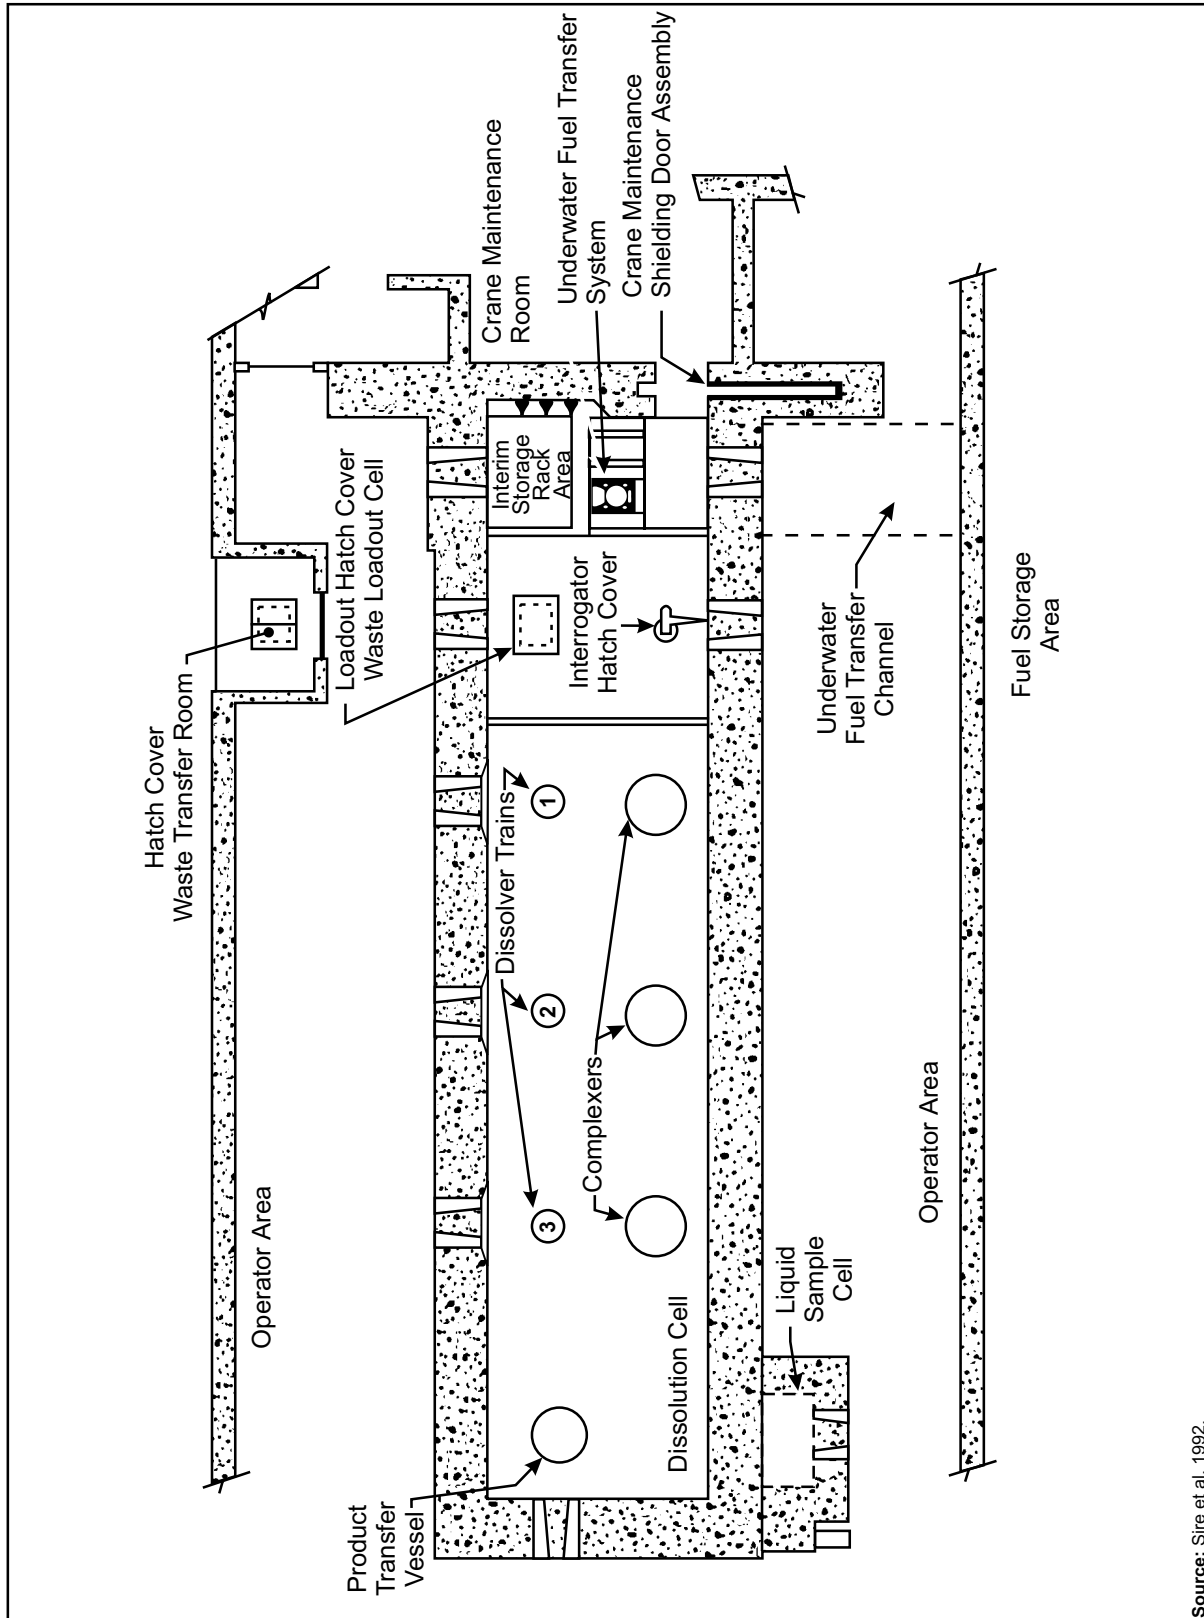

Figure 2-16 Fluorinel Dissolution Process Facility, Plus 28-Foot Level

The FDPF portion of INTEC includes a hot cell about 6.1 meters (20 feet) wide, 30.5 meters (100 feet) long, and 15.2 meters (50 feet) deep that is shielded by 1.8-meter-thick (6-foot-thick) concrete walls, as shown in **Figure 2–17**. The cell was designed to process Navy spent nuclear fuel via three dissolver trains, each of which consists of a 1,700-liter (450-gallon) Hastelloy C-4 dissolver and a 6,510-liter (1,720-gallon) Hastelloy C-4 complexer vessel in series. Each train is connected to a common 8,000-liter (2,110-gallon) stainless steel product transfer vessel that was used for accountability sampling prior to transferring the adjusted fuel dissolution product for solvent extraction separations. If the targets were dissolved in a continuous process, a small, 12.5-liter (3.3-gallon) dissolver would be skid-mounted on the grate at the level of the dissolver lids, and the dissolvers would be used for collecting the dissolution product of irradiated neptunium-237 targets. If a batch dissolution process were used, a small 200-liter (53-gallon) dissolver system designed for the small target dissolution throughput rate could be skid-mounted on the grate at the level of the dissolver lids for batch processing. Three complexer vessels in the cell could be used for waste or rework solution collection, or for the collection of condensate if a waste evaporator were employed. The head-end dissolution system is supported by remote manipulators (overhead and master/slave), as well as an underwater fuel transfer system and crane for target transfer and waste loadout. The dissolver offgas system scrubs potentially hazardous chemicals and filters radioactive particles from the offgases of the process vessels before releasing them into the heating, ventilating, and air conditioning exhaust system. The chemical separation would take place in the FDPF cell using small centrifugal contactors installed for that purpose. The storage of neptunium-237 would be performed in either FDPF or in a secure vault facility, Building CPP–651, located within 100 meters (328 feet) of FDPF. There are 100 in-ground concrete-shielded storage well positions in this vault. Each storage well contains a rack that can be modified to house cans of neptunium-237. Detailed descriptions of the facility and the processes associated with storage, target fabrication, and postirradiation processing are provided in Appendix A.

### **2.3.2.3 Fuels and Materials Examination Facility**

Use of Hanford's FMEF is proposed for storage of neptunium-237 under one option of the No Action Alternative. It also is proposed for storage of neptunium-237, fabrication of neptunium-237 targets, and processing of irradiated neptunium-237 targets under two irradiation options in Alternative 1 (FFTF Restart), three irradiation options in Alternative 2 (Use Only Existing Operational Facilities), and one irradiation option each in Alternative 3 (Construct New Accelerator[s]) and Alternative 4 (Construct New Research Reactor). In addition to the support of the plutonium-238 production mission activities in Alternative 1, FMEF would also support medical and industrial production mission and civilian nuclear energy research and development mission activities at Hanford. FMEF would have no role in supporting Alternative 5 (Permanently Deactivate FFTF [with No New Missions]). FMEF is adjacent to the west of FFTF in the 400 Area of Hanford. Figure 3–12 presents a map of Hanford that depicts FMEF's location.

FMEF was built during the late 1970s and early 1980s as a major addition to the breeder reactor technology development program at Hanford. Although it has never been used, the facility was constructed to perform fuel fabrication and development and postirradiation examination of breeder reactor fuels (DOE 1995b). FMEF is currently being maintained in a condition suitable for a future mission. In 1998, FMEF was placed into a partial layup condition to reduce the cost of maintaining the facility. Many systems were shut down and most hazardous materials were removed from the building. FMEF is considered clean and uncontaminated because no nuclear materials have been introduced (Hoyt et al. 1999). Some critical systems, such as the fire detection and protection systems, remain in operation. In order to avoid freezing of the fire protection water systems, limited heating and ventilating remain available. For example, the heating, ventilating, and air conditioning system has been modified to simplify its operation by blocking automatic dampers in appropriate configurations. Also, although the chillers have been laid up, including removal of the refrigerant, the chilled water system (containing an ethylene glycol-water mixture) remains available to help distribute heat within the building. Electrical power and lighting remain available, and the freight elevator remains in service to

Figure 2-17 Plan View of FDFPF Cell

support routine facility walkdowns and any required maintenance. FFTF staff conduct surveillance and maintenance of FMEF.

FMEF consists of a 30-meter-high (98-foot-high) Process Building that has an attached Mechanical Equipment Wing on the west side and an Entry Wing on the south (front) side. The Mechanical Equipment Wing houses utility and support equipment, including water treatment equipment, air compressors, and a portion of the air conditioning equipment.

The Entry Wing contains space for reactor fuel assembly (recently used as a training facility in support of the Hanford Site cleanup mission), lunchroom and change rooms, and heating and air conditioning equipment associated with the Entry Wing. Personnel access into the Process Building is provided via a Security Guard Station and automated personnel access control portals located on the first floor of the entry wing. Office space and administrative support areas are also housed on the second floor of the Entry Wing (DOE 1995b).

The Process Building is approximately 53.3 meters (175 feet) wide by 82.3 meters (270 feet) long and extends from around 10.7 meters (35 feet) below grade to 30 meters (98 feet) above grade. Total potential operating space is approximately 17,470 square meters (188,000 square feet). The Process Building contains several large interconnected hot cells and many smaller connected hot cells. Major cranes are available, but some cranes, windows, and manipulators were not installed because construction of FMEF was halted prior to completing work on the hot cell complex (Hoyt et al. 1999). Nevertheless, the building is divided into six operating floors or levels that are identified in the following manner by their elevation relative to ground level and their primary function:

- The top floor at the 21.3-meter (70-foot) elevation is called the Secure Automated Fabrication Level. This level contains the Secure Automated Fabrication Line, automated fabrication equipment originally designed to produce reactor fuel.
- The lower Fuel Fabrication Level at the 13-meter (42.5-foot) elevation consists of two separate operating areas—one designated as the Low Gamma Test Pin Fabrication and Development Area and the other as the Unit Process Cell. This level provides approximately 470 square meters (5,100 square feet) of potential operating space around the Unit Process Cell. This cell area is highly shielded by thick concrete walls and was intended for the future development of remote fabrication and maintenance equipment or for the production of high gamma test pins. However, this cell area is not equipped at this time.
- The lower Chemistry Level at the 6.5-meter (21.25-foot) elevation surrounds the upper portions of the Nondestructive Examination Cell and the Decontamination Cell, which extend upward from the floor below. This level was designed to contain equipment to perform the chemical analyses of fuel material necessary to support fuel fabrication work. Much of the work planned in this area was to be performed in gloveboxes to reduce personnel radiation exposures. Also located on this level is an automated system that is potentially available for handling and storing the special nuclear material, such as the feed material for the fuel fabrication processes. The area encompasses approximately 790 square meters (8,500 square feet) of potential operating space.
- The Entry Level at ground level is the main operating floor of the Nondestructive Examination Cell, which also extends into the floors above and below. The Nondestructive Examination Cell was designed to contain remotely operated equipment for the nondestructive examination of irradiation fuel assemblies and pins. Maintenance and decontamination of equipment were to be performed in the adjacent Decontamination Cell. The Entry Level also contains computer and operations control rooms and inert gas systems and building air exhaust equipment. The Shipping and Receiving Area,

which is approximately 500 square meters (5,400 square feet) of operating floor space, is at the extreme east end of the Process Building on the Entry Level. This area includes a liquid waste loadout station, a solid waste storage area, a truck lock, and a large high-bay material-handling area.

- The Equipment Level at the minus 5.3-meter (17.5-foot) elevation was designed to contain a variety of support equipment, including two separate electrical switchgear rooms, emergency air compressors, heating and ventilating system air supply equipment, Nondestructive Examination Cell inert atmosphere equipment, emergency batteries, analytical chemistry cell exhaust equipment, and building air filtering system components. Also included is the vacuum equipment associated with the vacuum and air sample vacuum systems.
- The DE Cell Level at the minus 10.7-meter (35-foot) elevation (see **Figure 2–18**) contains cells originally intended for destructive examination of fuels and materials samples. These cells are arranged in two parallel rows along a horizontal transfer corridor that was to be used to transfer equipment between individual cells. The DE Cell area is heavily shielded, and work in the cells was planned to be performed using remotely operated equipment. The Entry Tunnel extends from below the Shipping and Receiving Area floor (on the Entry Level) to the DE Cell Level (10.8 meters or 35.5 feet total height). The Entry Tunnel was designed to house a 75-ton rail-mounted transporter intended to transfer casks between the Shipping and Receiving hatch and the Decontamination Cell and Nondestructive Examination Cell Floor penetrations. The transporter rails are roughly halfway up the tunnel at the 5-meter (16.2-foot) elevation.

The use of FMEF for neptunium-237 target material storage, target fabrication, and postirradiation processing would require the construction of a new 76-meter (250-foot) stack. The neptunium dioxide (NpO<sub>2</sub>) containers would be stored in specially designed storage vaults to provide secure, safe storage for the materials. DOE safeguards and security guidelines would be followed whenever the material is being stored, transported, or processed. Detailed descriptions of the facility and the processes associated with storage, neptunium-237 target fabrication, and postirradiation processing in support of plutonium-238 production are provided in Appendix A.

#### **2.3.2.4 Radiochemical Processing Laboratory and Building 306–E**

Two Hanford 300 Area facilities are proposed to support medical and industrial isotope target fabrication and postirradiation: RPL and Building 306–E (RPL/Building 306–E). The facilities support the four irradiation options of Alternative 1 (FFTF Restart) that are not supported by FMEF. RPL and Building 306–E would be used to support medical and industrial isotope production and civilian nuclear energy research and development activities. These activities would not impact current missions at the facilities. RPL and Building 306–E have no role in support of the No Action Alternative, Alternative 2 (Use Only Existing Operational Facilities), Alternative 3 (Construct New Accelerator[s]), Alternative 4 (Construct New Research Reactor), and Alternative 5 (Permanently Deactivate FFTF [with No New Missions]). Figure 3–12 presents a map of Hanford that depicts the locations of RPL and Building 306–E. The following descriptions are based on the *Hanford Data Request for FFTF Operational Support Facilities* (BWHC 1999).

##### **2.3.2.4.1 Radiochemical Processing Laboratory**

The research and development activities of the Radiochemical Processing Group are conducted at RPL in the 300 Area of Hanford. RPL consists of a central area that contains general purpose laboratories designed for low-level radioactive work, a front wing that contains office space and shops, and two annexes that provide shielded enclosures with remote manipulators for high-level radiochemical work. The facility also contains

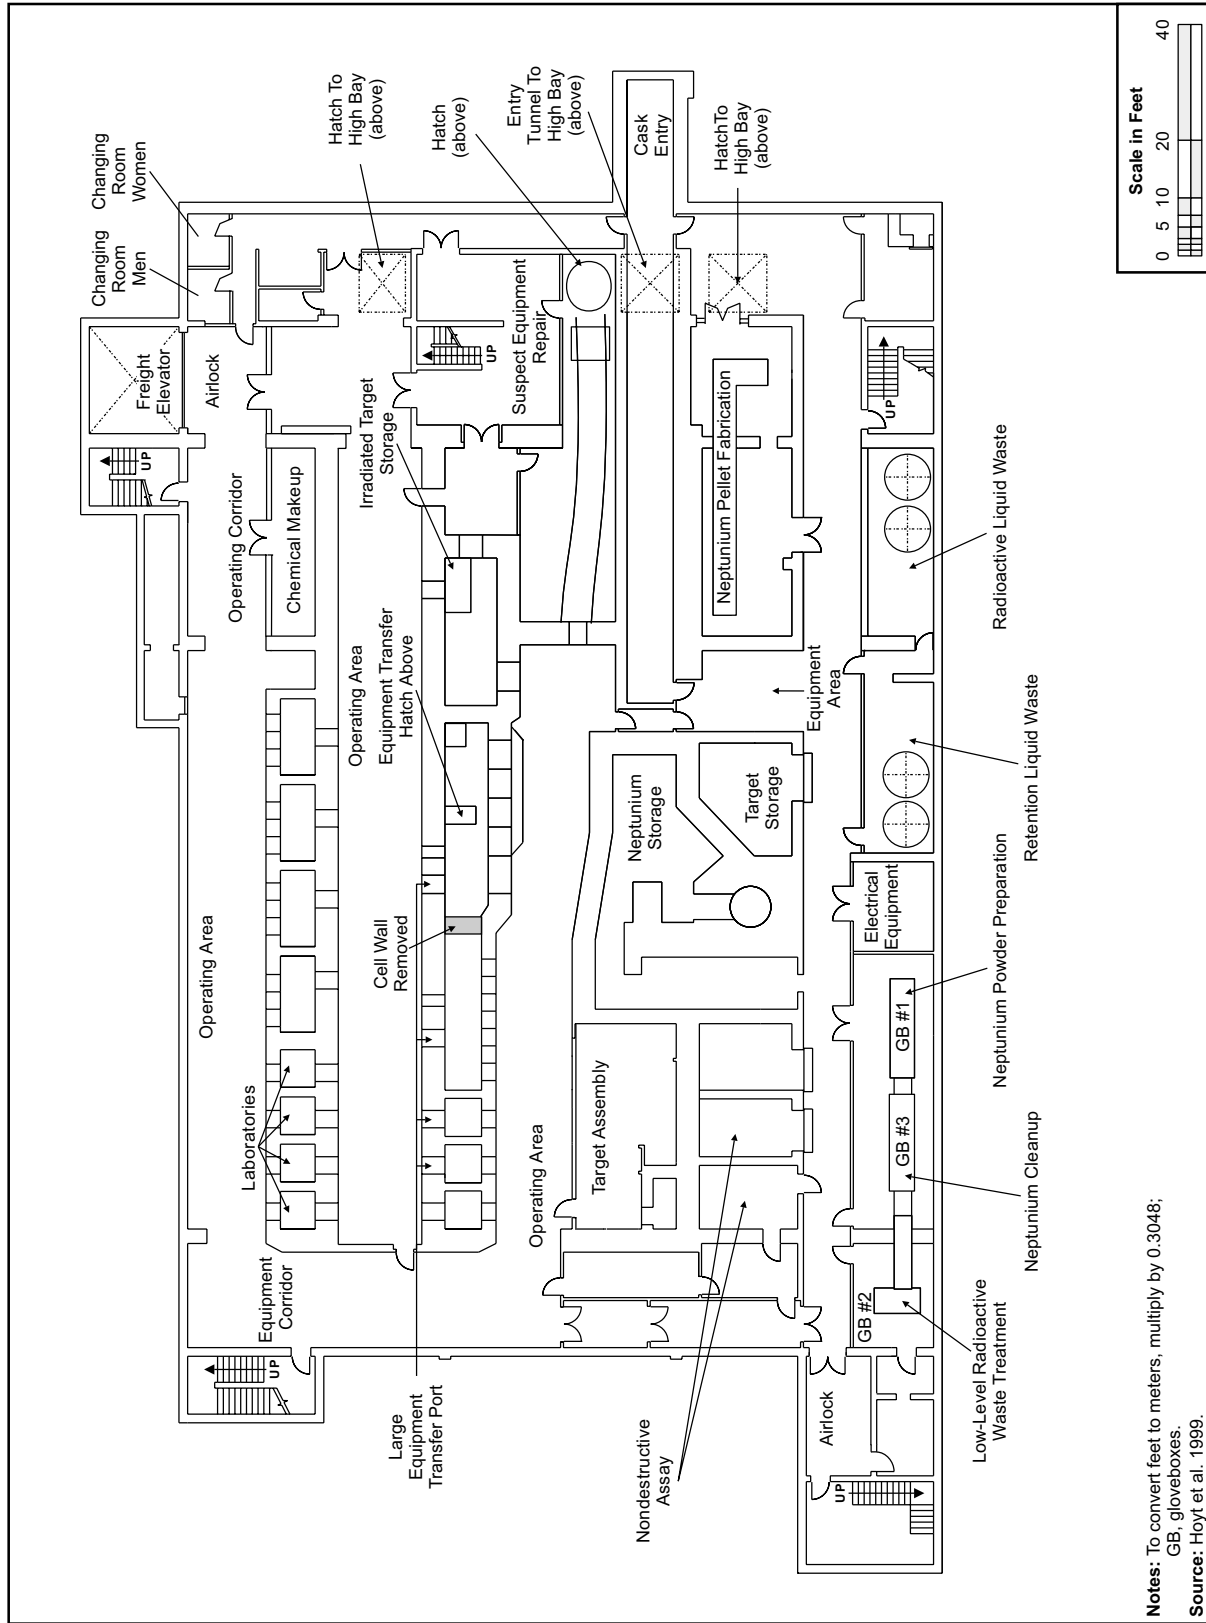

Figure 2-18 FMEF Layout, Minus 35-Foot Level

laboratories and specialized facilities designed for work with nonradioactive materials, microgram-to-kilogram quantities of fissionable materials, and up to megacurie quantities of radionuclides. RPL would be the primary site for fabricating the radioactive targets (i.e., targets containing radium-226 or recycled materials from previous irradiations). Total space within RPL is 13,350 square meters (143,700 square feet), of which 4,140 square meters (44,500 square feet) are occupied by general chemistry laboratories. The floor plans for the first floor and the basement of RPL are shown in **Figures 2–19** and **2–20**. A recent space utilization survey of RPL indicated that 646 square meters (6,950 square feet), representing 15.6 percent of the laboratories' area, are presently unoccupied. All of the occupied and nearly all of the unoccupied laboratories are functional and are fully equipped with standard utilities. Several of the laboratories, especially those used for radioanalytical work, have been renovated during the past few years. Upgrading and modernization of the equipment within the chemistry laboratories has been given a high priority during the past 2 years. During the space utilization survey at RPL, an assessment was made of the number of fume hoods and shielded gloveboxes (including several small hot cells) that are available in the chemistry laboratories for additional programmatic work. Of the 79 functional fume hoods and 23 shielded gloveboxes, 50 fume hoods and 15 gloveboxes are available for additional work.

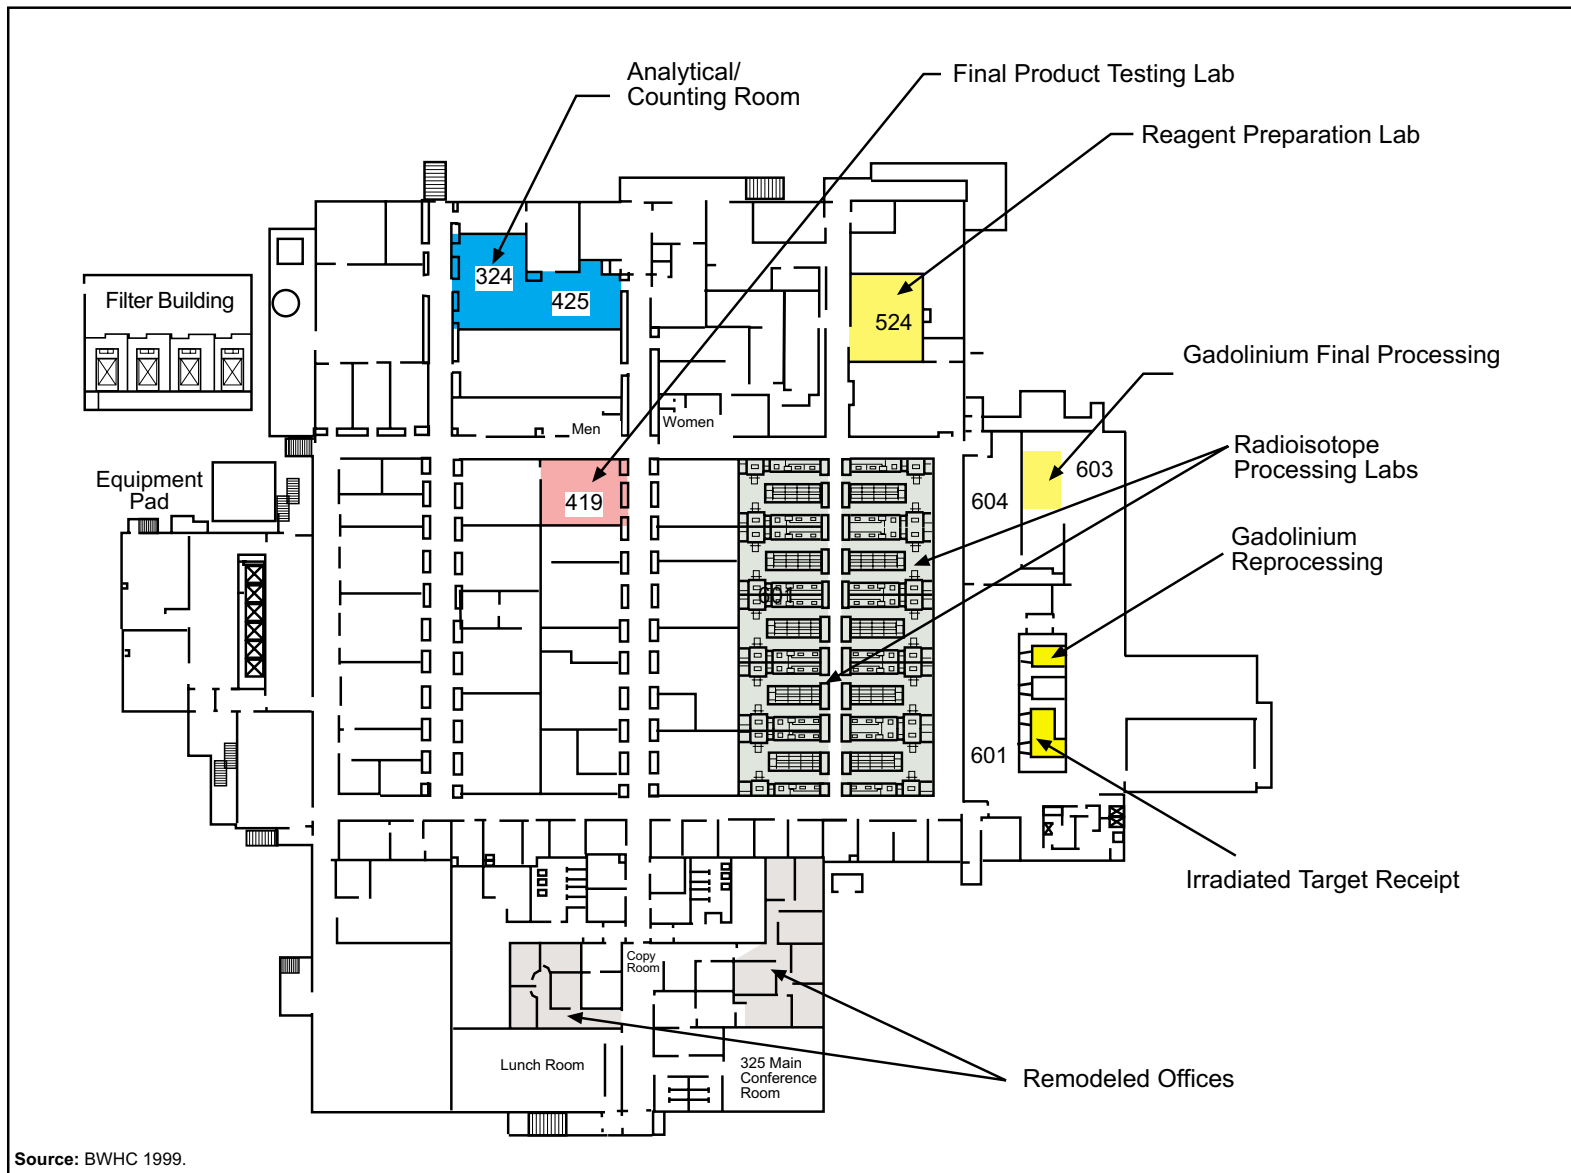

A special feature of RPL is the existence of two heavily shielded hot cell facilities located in annexes on the east and west sides of the building. These shielded facilities are the High-Level Radiochemistry Facility and the Shielded Analytical Laboratory. These two hot cell complexes are heavily used because they provide capabilities for conducting bench-scale to pilot-scale work with a wide variety of highly radioactive materials. Their capabilities include those required to conduct radiochemical separation and purification procedures, irradiated fuel or target sectioning and processing, metallography, physical properties testing of activated metals, thermal processing (including waste vitrification), and radioanalytical and preparatory chemistry operations.

The High-Level Radiochemistry Facility contains three large, interconnected hot cells designated as A-Cell, B-Cell, and C-Cell. Each of the three cells is 4.6 meters (15 feet) high and 2.1 meters (7.0 feet) deep. The A-Cell is 4.6 meters (15 feet) wide, and the B-Cell and C-Cell are each 1.8 meters (6.0 feet) wide. In-cell operations are performed using medium-duty electromechanical manipulators, and operators view their work through leaded-glass, oil-filled windows. Closed-circuit television cameras and videocassette recorders have been installed for detailed inspection work within the hot cells. The A-Cell and C-Cell also have overhead bridges that contain hoists with a 2,200-kilogram (4,840-pound) capacity. The hot cells are fully equipped with utilities and have shielded service penetrations at the front wall to allow insertion of special instruments. Each hot cell contains several process vessels located below the work deck that range in capacity from 4.0 to 320 liters (1.1 to 84.5 gallons). A large shielded door and a shielded double-door transfer port located in the rear wall of the cell provide access to each hot cell in the High-Level Radiochemistry Facility. Cask payloads weighing up to 2,200 kilograms (4,840 pounds) can be transferred into and out of the hot cells using a bridge crane located in the canyon behind the cells.

The Shielded Analytical Laboratory contains six interconnecting hot cells, each of which is 1.7 meters (5.5 feet) wide, 1.7 meters (5.5 feet) deep, and 2.9 meters (9.5 feet) high. Each hot cell is equipped with a pair of medium-duty manipulators. Turntables built into the rear walls of the hot cells provide rapid transfers of radioactive samples into and out of the cells. The Shielded Analytical Laboratory hot cells are equipped to perform a wide variety of analytical chemistry operations with highly radioactive samples.

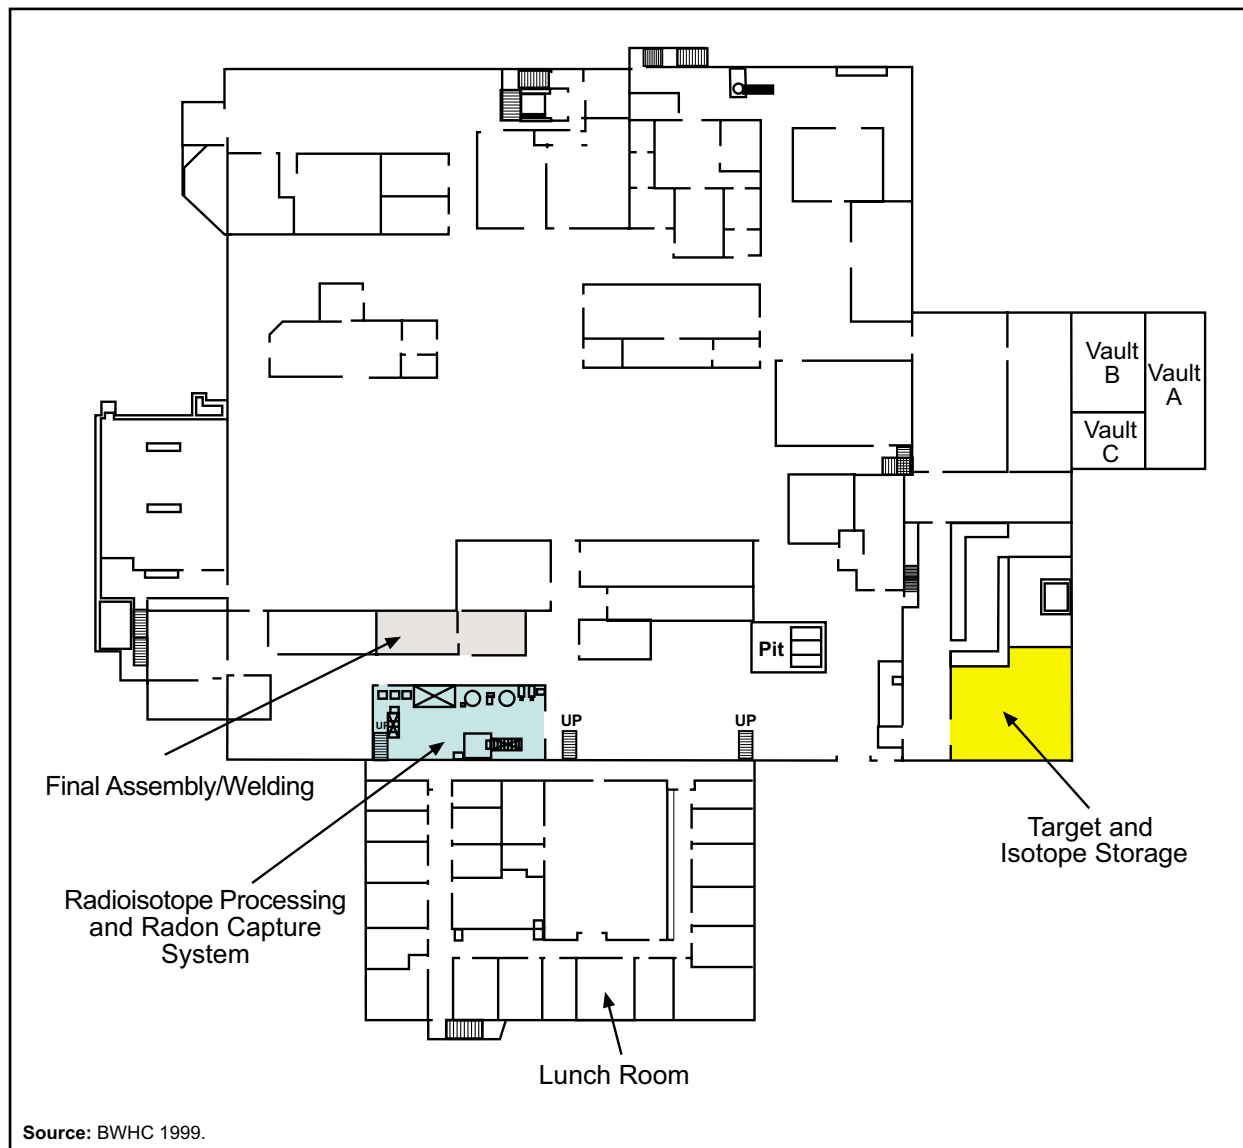

The primary features and functions of the laboratories within RPL that would be used for processing targets irradiated at FFTF are described below.

- A cluster of 10 laboratories would be available on the first floor of RPL. Each laboratory would contain a small hot cell, a shielded glovebox, and a fume hood with interconnecting transfer ports.

**Figure 2-19 RPL: Proposed First Floor Locations for Hot Cell Operations and Radiochemical and Radioanalytical Laboratories for FFTF Target Processing**

**Figure 2–20 RPL: Proposed Basement Locations for Assembly, Processing, and Storage of FFTF Targets; Also Shown: Laboratory with Radon Gas Capture System to be Used for Processing Radium-226 Targets**

- A transfer port for receiving casks containing irradiated targets into the A-Cell of the High-Level Radiochemistry Facility would be installed, and provision would be made in the C-cell for initial processing of highly radioactive targets (e.g., irradiated europium targets containing gadolinium-153 product).
- Target preparation and storage areas would be provided in the basement of RPL, in close proximity to the facilities where the radioactive and recycled targets would be assembled and welded.
- A 139.4-square-meter (1,500-square-foot) laboratory equipped with a radon gas capture system would be available in the basement of RPL to process radium-226 targets and the product isotopes generated by irradiation of these targets (all of these targets generate radon gas as intermediate products in their decay chains).

Detailed descriptions of the processes associated with medical and industrial isotope storage, target fabrication, and postirradiation processing are included in Appendix C.

#### **2.3.2.4.2 Building 306–E**

Building 306–E was constructed in 1956 as part of the nuclear material production program at Hanford and was used to develop the coextrusion process for N-Reactor fuel. Major upgrades and renovations were completed in the late 1960s and early 1970s to support the civilian reactor development program (Liquid Metal Reactor Program—FFTF). The building has 4,273 square meters (46,000 square feet) of floor space, with a 36.5-meter by 61-meter by 6.4-meter-high (120-foot by 200-foot by 21-foot-high) bay containing one 1.5-ton, one 5-ton, and three 10-ton cranes. The facility has electron beam and laser welding, certified nondestructive testing, a 3.7-meter by 3.7-meter (12-foot by 12-foot) vertical assembly and test station with a 24.4-meter (80-foot) hook height, a machine shop, and an instrument development laboratory. A description of the spaces is provided below; a view of the floor plan is provided in **Figure 2–21**.

<b><u>Function</u></b>	<b><u>Area (square feet)</u></b>
Offices	4,298
Laboratories	25,003
Shops	2,358
Conference	511
Common	14,133
Total	46,303

The building is serviced by three 1,416-cubic-meters-per-minute (50,000-cubic-feet-per-minute) supply units complete with filters, steam coils, and spray chambers. Two of the units have refrigeration coils for summer cooling. Two ceiling-mounted 1,012-cubic-meters-per-minute (35,750-cubic-feet-per-minute) recirculation fans with freon compressors provide additional cooling and air movement. Fume hoods have individual exhaust fans. Chemical and acid tanks exhaust through two 340-cubic-meters-per-minute (12,000-cubic-feet-per-minute) fume scrubbers to a 12.2-meter-high, 7.6-centimeter-diameter (40-foot-high, 3-inch-diameter) stainless steel exhaust stack. Equipment exhaust collects through a grid that leads to two 566-cubic-meters-per-minute (20,000-cubic-feet-per-minute) exhaust fans. Plastic hoods and duct work are provided for highly corrosive service.

Major equipment includes three industrial x-ray machines, a 6-kilowatt Hamilton Standard electron beam welder, five open face hoods, two inert gas welding chambers, and one electrolytic cutoff saw. Utilities include hot and cold water, deionized water, propane, helium, compressed air, argon, steam, and sanitary and process sewers as well as a special acid drain and neutralizing tank. Normal power is provided by a 1500-kilovolts ampere transformer with 150-kilovolts ampere backup power from an adjoining building and a 30-kilovolts ampere emergency transformer. The building is protected by redundant emergency alarm systems, fire gongs, and an evacuation siren.

#### **2.3.2.5 New Support Facility**

A new generic support facility would have the mission of preparing medical and industrial isotope targets for irradiation, processing irradiated targets, and housing the materials research and development activities in association with Alternatives 3 and 4. Siting of the generic support facility for medical and industrial isotope production would require the facility to be located in the same general vicinity (0.2 to 20 kilometers [0.12 to 12.4 miles]) as the new irradiation facility (accelerator or reactor). Colocation with the irradiation facility

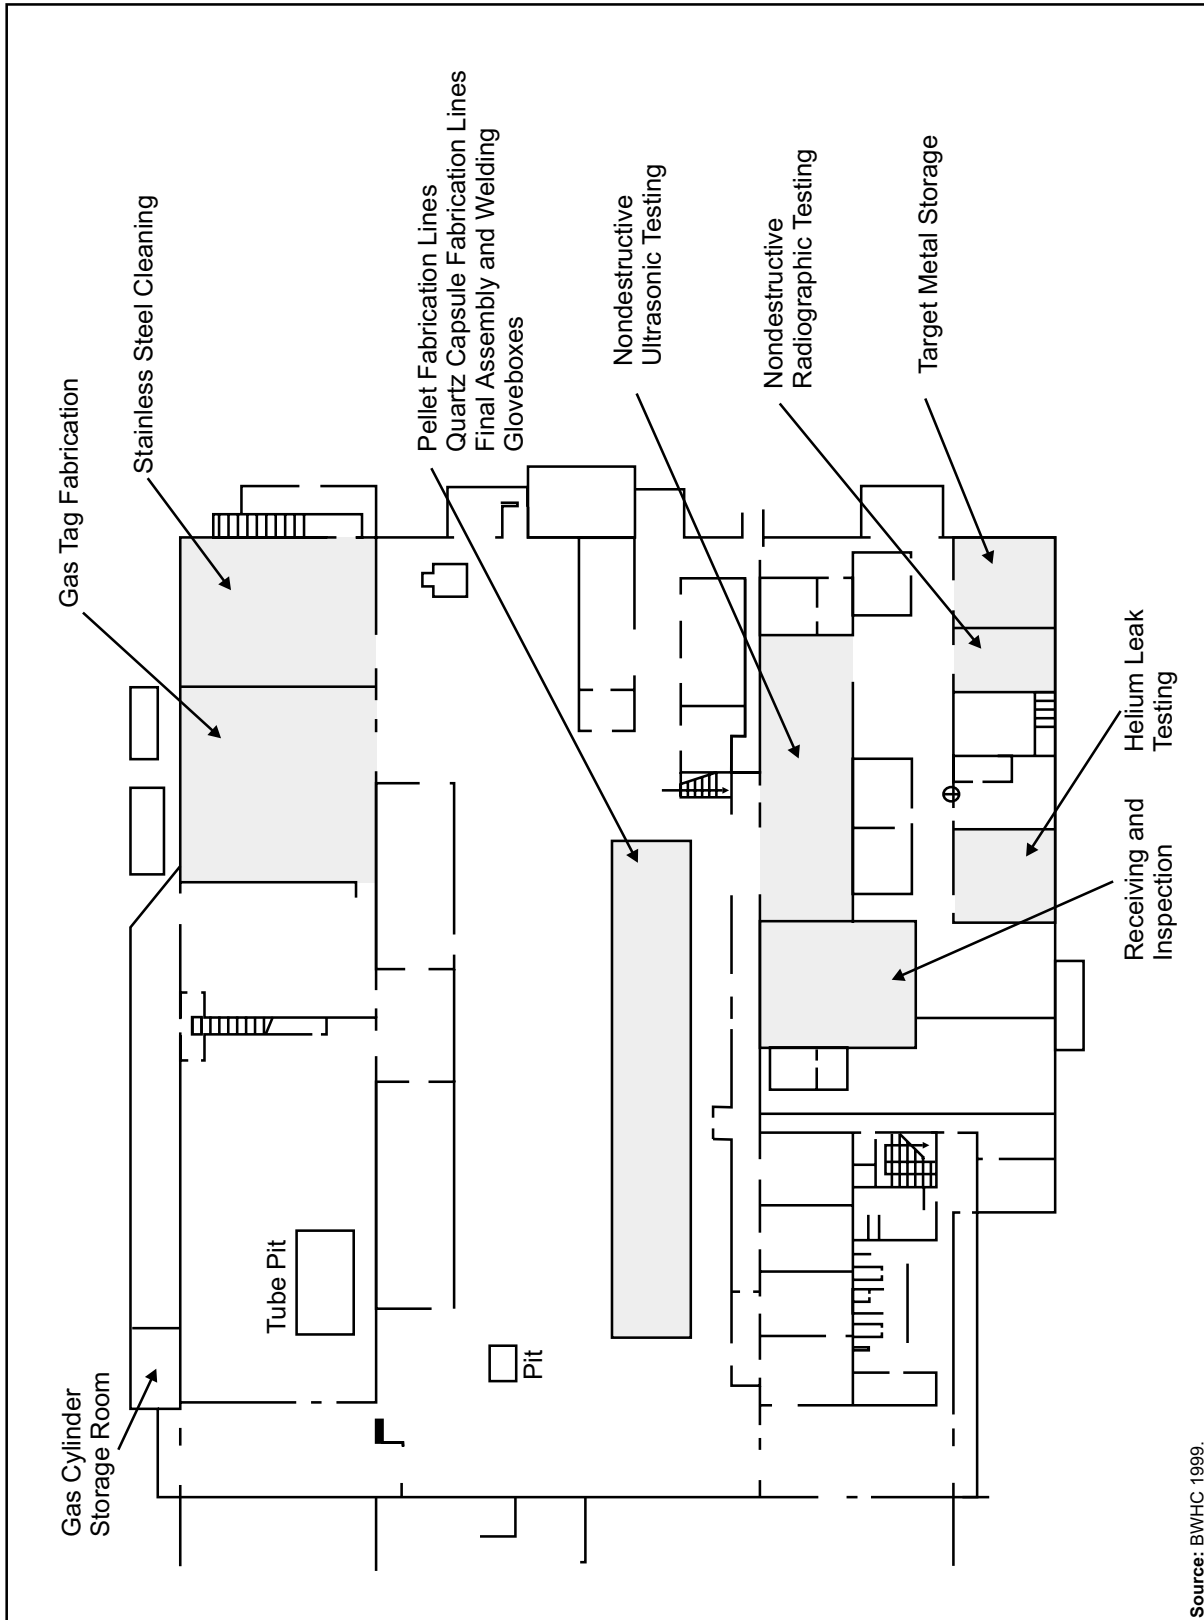

Figure 2-21 Building 306-E Floor Plan

Source: BWHC 1999.

would be needed to process some irradiated target materials promptly after removal from the reactor/accelerator because some isotopes have short half-lives. Colocation would also minimize transportation time. Although the facility could be located within the irradiation facility security protection area, the lack of a defense mission and fissile material in the generic support facility indicates that a high level of physical protection would not be warranted.

The generic support facility mission would be accommodated by a one-story, 3,345-square-meter (36,000-square-foot) above-grade building with a 1,490-square-meter (16,000-square-foot) basement area under a portion of the footprint (SAIC 2000). **Figure 2–22** provides the general layout of the building. The relative position and size of the processing, support, office, and research and development areas are shown on the diagram.

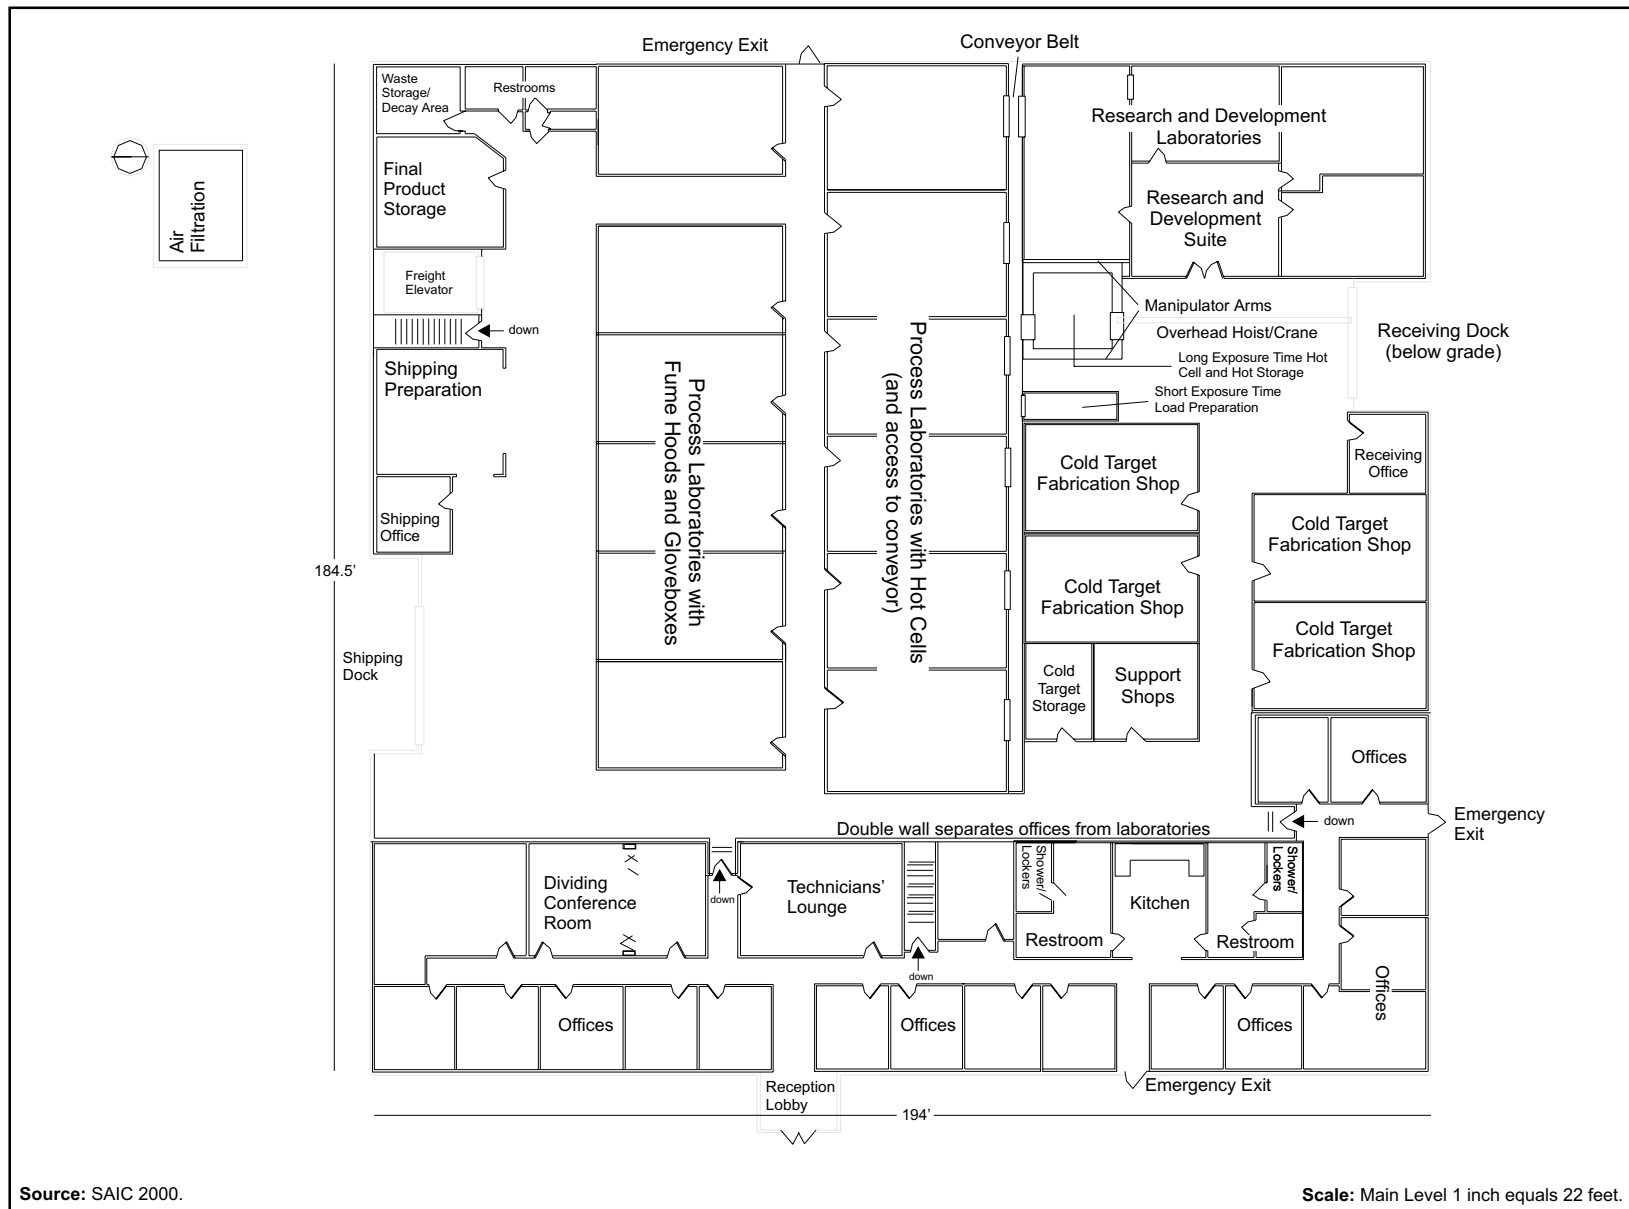

The facility is designed around a center area containing the highest-risk activities and the material inventories requiring the highest level of engineered controls. As can be seen in Figure 2–22, irradiated materials in casks or other shielded transport containers would enter a loading dock with a straight-line access to the primary facility hot cell. The hot sample entry area would be a high bay area with a high floor loading area between the loading dock and the hot cell access port. This configuration would allow transport cask access to the hot cell. In addition, an overhead hoist would be available to facilitate handling of materials and devices in the proximity of the hot cell.

The hot cell would accept high-radiation-level samples or those difficult to shield or manipulate (e.g., reactor core components containing samples). The hot cell would have access to a conveyor that can remotely transport samples to the hot process laboratories. In addition, samples from the hot cell could be transferred to the hot research and development laboratory gloveboxes for detailed analysis and testing. Hot cell manipulators would be located on both the operating gallery and the research and development sides of the hot cell. Adjacent to that would be the central receiving station for all other radioactive and short-exposure samples not contained in the reactor core components. This area, while not a hot cell, would provide personnel protection (i.e., shielding and controlled ventilation) for preliminary sample preparation and examination. It would also provide interim irradiated sample storage prior to delivery to the designated processing laboratory. When needed, samples would be transported remotely to the processing laboratories by the conveyor system. Samples requiring a lesser degree of control would be distributed for processing throughout the remaining process laboratory wing. After processing, the radiopharmaceuticals would be either stored or packaged and shipped immediately to offsite vendors.

Radioactive waste would be packaged and stored for eventual disposal. Those materials containing short-lived isotopes would be delivered to a decay/holding room so that, given appropriate decay time, they could be disposed of without a radioactive component. The process and research and development areas would be considered radiologically controlled areas, but no routinely occupied areas would require control as contaminated radiological areas. Radioactive contamination would be controlled at the hood or glovebox face. Due to this configuration, protective clothing and change rooms would be needed only for occasional maintenance activities when temporary radiological areas are established.

Cold sample (nonradioactive) preparation would be accomplished in a set of three large laboratories where radiological conditions are not anticipated. Completed samples would be stored in an adjacent room along with raw sample materials (nonradioactive).

Radioactive sample preparation and irradiated material recycling activities would be conducted in one of the laboratories adjacent to the conveyor.

Source: SAIC 2000.

Figure 2–22 Support Facility Layout

Irradiated research and development samples introduced into the hot cell could be processed or examined using manipulators within the hot cell. Samples could also enter the research and development suite of lab rooms through the hot cell port into a hot cell or glovebox. From there, they could be moved to additional research and development laboratory rooms within a controlled environment for detailed analysis and testing.

Support areas would include ventilation, maintenance, change rooms, quality assurance and quality control, lunch and break rooms, storage, conference rooms, basement stairwells, equipment elevators, and utility distribution. A small machine shop would accommodate light machining activities, but would not be intended to involve radioactive materials. A portion of the support functions, especially utilities, would be located in a basement portion of the building. The basement would be located under the half of the building that would not experience high weight loads (i.e., hot cell, cask receiving area).

Solid waste would be collected, packaged, and stored at a central location. Liquid waste would be processed at the point of generation (e.g., hood/glovebox) or would be collected in a retention tank for characterization and eventual transfer to the effluent treatment facility.

## **2.4 DESCRIPTION OF TRANSPORTATION ACTIVITIES**

### **2.4.1 Purchase of Plutonium-238 from Russia**

Under the No Action Alternative (see Section 2.5.1), DOE would continue exercising its option to purchase Russian plutonium-238 (if available) to meet the needs of future U.S. space exploration missions. In 1992, DOE signed a contract permitting the purchase from Russia of up to 40 kilograms (88.2 pounds) of plutonium-238. To date, DOE has purchased 9 kilograms (19.8 pounds). In 1997, DOE extended the contract for another 5 years, so this option remains viable. It is unclear, however, whether this option would remain reliable or viable once the existing contract expires (DOE 1997). The impacts associated with the purchase of plutonium-238 from Russia are discussed in Section 4.2.1.1.

### **2.4.2 Transportation of Plutonium-238 from St. Petersburg, Russia, to the Los Alamos National Laboratory**

Plutonium-238 purchased from Russia would have to be transported from St. Petersburg to a U.S. port of entry, and from there to LANL where it would be used in the fabrication of radioisotope power systems and heating units. The impacts of the transportation of a total of 40 kilograms (88.2 pounds) of plutonium-238 are estimated in the *Environmental Assessment of the Import of Russian Plutonium-238* (DOE 1993) and are summarized in Section 4.2.1.1 of this NI PEIS. The impacts associated with transporting 175 kilograms (385 pounds) (5 kilograms [11 pounds] per year for the 35-year evaluation period) of plutonium-238 have been determined by extrapolation and are included in the same section.

### **2.4.3 Transportation of Neptunium-237 from Savannah River Site to Candidate Storage Facilities**

Under the No Action Alternative (see Section 2.5.1) DOE would transport neptunium-237 oxide from SRS to a storage facility off site. Storage canisters containing the neptunium-237 oxide would be loaded into approved shielded shipping containers or casks at SRS and shipped to the designated storage facilities for long-term storage.

Truck transportation of neptunium-237 from SRS to the proposed storage facilities is assumed in this NI PEIS. The neptunium-237 would be transported in robust Type B transportation casks. Type B casks are used to transport nuclear materials with the highest radioactivity levels, and are designed to protect and retain their contents under transportation accident conditions. According to DOE policy, which requires compliance with

applicable Federal regulations regarding domestic shipments of radioactive materials, transportation of neptunium-237 in Type B casks would comply with the requirements of 10 CFR Part 71, “Packaging and Transportation of Radioactive Materials,” and 49 CFR Part 173, “Shippers - General Requirements for Shipments and Packagings.”

The container that would be used to transport neptunium-237 has not been proposed, but would be a Type B container similar to the Chalfont container 9975. The 9975 container includes a 132-liter (35-gallon) drum, insulation, a primary containment vessel, a secondary containment vessel, lead shielding, and aluminum honeycomb spacers. The neptunium-237 would be sealed into a can, which would be placed on a honeycomb spacer inside the stainless steel primary containment vessel. The primary containment vessel would be bolted closed and placed into a similarly constructed, but larger, secondary containment vessel. The secondary containment vessel would be bolted closed and loaded into a drum equipped with lead shielding to reduce radiation levels and fireboard insulation to protect the containment vessels in the unlikely event of a severe impact. A description of the Chalfont container 9975 is provided in Appendix J.

DOE anticipates that neptunium-237 would be transported through use of the Transportation Safeguards System and shipped using SST/SGTs. The SST/SGT, a fundamental component of the Transportation Safeguards System, is a specially designed component of an 18-wheel tractor-trailer vehicle. Although details of vehicle enhancements and some operational aspects are classified, key characteristics of the SST/SGT system include the following:

- Enhanced structural characteristics and a highly reliable tie-down system to protect cargo from impact
- Heightened thermal resistance to protect the cargo in case of fire (newer SST/SGT models)
- Established operational and emergency plans and procedures governing the shipment of nuclear materials
- Various deterrents to prevent unauthorized removal of cargo
- An armored tractor component that provides courier protection against attack and contains advanced communications equipment
- Specially designed escort vehicles containing advanced communications and additional couriers
- 24-hour-a-day real-time communications to monitor the location and status of all SST/SGT shipments via DOE’s Security Communication system
- Couriers, who are armed Federal officers, receive rigorous specialized training and are closely monitored through DOE’s Personnel Assurance Program
- Significantly more stringent maintenance standards than those for commercial transport equipment
- Conduct of periodic appraisals of the Transportation Safeguards System operations by the DOE Office of Defense Programs to ensure compliance with DOE orders and management directives, and continuous improvement in transportation and emergency management programs

Additional details are presented in Appendix J.

#### **2.4.4 Transportation of Mixed Oxide Fuel from Europe to the Fast Flux Test Facility**

As discussed in Section 2.3.1.1.3, a 15-year supply of mixed oxide fuel may be available from Germany to operate FFTF. Approximately 205 mixed oxide fuel assemblies were fabricated in Europe for use in Germany's SNR-300 sodium-cooled, breeder reactor before the German government suspended the reactor's operation. SNR-300 mixed oxide fuel is very similar in both composition and construction to FFTF fuel. The 205 SNR-300 mixed oxide fuel assemblies, if reconfigured for FFTF, could be used to fabricate about 150 to 160 FFTF fuel assemblies. This amount could supply two FFTF core loads for approximately 15 years of FFTF operation at the 100 megawatts thermal power level with occasional excursions to the 400 megawatts thermal power level on an as-needed basis (as proposed for this mission).

The inventory of unused SNR-300 mixed oxide fuel is now stored at Hanau, Germany, and Dounreay, Scotland. If a decision were made to use SNR-300 fuel in FFTF, security measures would be implemented to prevent unauthorized removal of the mixed oxide fuel during transportation to the United States. The requirements to ensure the safety and security of transatlantic mixed oxide fuel shipments are listed in: *The Convention on the Physical Protection of Nuclear Material*, International Atomic Energy Agency publication INFCIRC 274 (IAEA 1997); *The Physical Protection of Nuclear Material*, International Atomic Energy Agency publication INFCIRC 225 (IAEA 1999); the *Code for the Safe Carriage of Irradiated Nuclear Fuel, Plutonium and High-Level Radioactive Wastes in Flasks on Board Ships* (IMO 1993); DOE orders; and 10 CFR Part 73. DOE estimates that as many as 11 shipments from Europe would be required. The initial shipment would transport the FFTF mixed oxide fuel lead test assembly, and the following 5 to 10 shipments would transport the SNR-300 fuel assemblies reconfigured for FFTF use.

SNR-300 mixed oxide fuel could be brought into many U.S. commercial and military ports. A port-selection process was used by DOE in its *Final Environmental Impact Statement on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel (Foreign Research Reactor Spent Nuclear Fuel EIS)* (DOE 1996). The criteria used for screening ports in the *Foreign Research Reactor Spent Nuclear Fuel EIS* were: (1) appropriate port experience; (2) safe port transit to open ocean; (3) appropriate port facilities for safe receipt, handling, and transshipment; (4) ready intermodal access; and (5) low human population of the ports and along transportation routes. DOE used these same criteria to identify ports for receiving mixed oxide fuel from Europe. The application of these criteria for mixed oxide fuel is discussed in Section J.3.6.1.

In the *Foreign Research Reactor Spent Nuclear Fuel EIS* Record of Decision, DOE decided to use military ports to take advantage of their capabilities to increase the safety and security of the spent fuel transportation process. DOE concluded that the use of military ports provides additional confidence in the safety of shipments due to the increased security. Since the security issues are far greater for fresh mixed oxide fuel than for spent nuclear fuel because of the potential for proliferation, DOE would use a military port to bring the SNR-300 mixed oxide fuel into the country.

Based on a review of the *Foreign Research Reactor Spent Nuclear Fuel EIS* (DOE 1996), the following military ports were considered:

- In the eastern United States: Charleston Naval Weapons Station, South Carolina; Military Ocean Terminal Sunny Point, North Carolina; Mayport, Florida; Kings Bay, Georgia; Pensacola, Florida; Yorktown, Virginia; and Hampton Roads, Virginia
- In the western United States: Military Ocean Terminal Bay Area, California; Bremerton, Washington; Everett, Washington; Port Hueneme, California; and Port Townsend, Washington

Other military ports that could be considered in a formal port selection process include, but are not limited to: Naval Weapons Station Seal Beach, California; Naval Submarine Base, North Island, California; Naval Amphibious Base Coronado, California; Naval Station San Diego, California; Naval Station Ingleside, Texas; Naval Station Pascagola, Mississippi; Naval Air Station Pensacola, Florida; Naval Weapons Station Earle, New Jersey; and Naval Submarine Base New London, Connecticut.

The overland transportation impacts would be higher if mixed oxide fuel were accepted at an east coast port rather than a west coast port. However, accepting mixed oxide fuel at an east coast port would reduce time and eliminate the potential security risk when transiting the Panama Canal. Charleston Naval Weapons Station, an east coast port, was used for the purpose of transportation impact analysis (see Section J.6.2). If Alternative 1 (Restart FFTF) were selected for implementation, and if it were decided to import mixed oxide fuel, DOE would conduct an appropriate NEPA review prior to importation of mixed oxide fuel. The analysis would consider a variety of ports on the east and west coasts. It also would consider the potential impacts of traversing both global commons (i.e., portions of the ocean not within the territorial boundary of any nation), in accordance with Executive Order 12114 (44 FR 1957), and inland waters (such as Puget Sound), as well as shipboard fires, package handling, truck transportation, and logistical and safeguard and security concerns associated with transporting mixed oxide fuel.

Use of a military port to receive SNR-300 mixed oxide fuel would require shipment via chartered ships. The ships that would be used to transport SNR-300 mixed oxide fuel to the United States would be of the type used to transport spent nuclear fuel or mixed oxide fuel internationally. These specially equipped ships are called purpose-built vessels.

Purpose-built vessels, as used in this NI PEIS, are those vessels specifically designed to transport nuclear fuel casks. These vessels operate as dedicated vessels and, therefore, are not used to transport any other cargoes. Casks are loaded directly into the holds of the vessels because the cargo compartments contain hardware that mates to the tie-down fixtures on the casks. If a vessel has no crane, dockside cranes are used for loading and unloading. The cargo compartments are typically intended to handle a specific type of cask, and other cask types cannot be used without making modifications to the tie-down hardware.

The purpose-built vessels are equipped with double bottoms and hulls, watertight compartments, special firefighting systems, and collision-damage-resisting structures within the main hull, as well as special security features and satellite tracking systems. The crew is trained in appropriate cargo-handling techniques and in emergency response.

At present, purpose-built vessels are operated by Pacific Nuclear Transport Services of Japan, by British Nuclear Fuels, Limited, and by the Swedish Nuclear Fuel and Waste Management Company. They are used to move nuclear fuel between operating nuclear power plants and nuclear fuel reprocessing facilities operated by Cogema and British Nuclear Fuels, Limited, or in Sweden's case, the repository in Forsmark. Beginning in 1998, purpose-built vessels have transported spent nuclear fuel from foreign research reactors to the Charleston Naval Weapons Station. Additionally, in 1999 purpose-built vessels delivered mixed oxide fuel from the United Kingdom to Japan. There are no U.S.-owned purpose-built vessels for nuclear fuel transport.

DOE anticipates that the SNR-300 mixed oxide fuel would be transported overland from the seaport to FFTF using the same Transportation Safeguards System that would be required for the transportation of neptunium-237 (see Section 2.4.3).

The environmental impacts associated with importing SNR-300 mixed oxide fuel from Europe are discussed in Section 4.3 and Appendix J.

#### **2.4.5 Transportation of Neptunium-237 from Savannah River Site to Target Fabrication Facilities**

The neptunium-237 required for target fabrication in the production of plutonium-238 is currently stored at SRS. Therefore, transportation of neptunium-237 oxide from SRS to target fabrication facilities off site (REDC, FDPF, FMEF) would be required. Storage canisters containing the neptunium-237 would be loaded into approved shielded shipping containers or casks at SRS and shipped to the target fabrication facilities. Transportation of neptunium-237 from SRS to these facilities for long-time storage is discussed in Section 2.4.3.

#### **2.4.6 Transportation of Nonirradiated and Irradiated Targets**

Transportation of nonirradiated neptunium-237 targets from the target fabrication facility to the irradiation facility and irradiated targets from the irradiation facility back to the fabrication facility for processing would use Type B casks certified for the safe shipments of the neptunium-237 targets. The casks used would be similar in size and construction to a spent nuclear fuel cask. Nonirradiated neptunium-237 targets would be transported in SST/SGTs. Irradiated neptunium-237 targets could be transported in commercial trucks. The analysis in this NI PEIS assumes transportation in commercial trucks to maximize the environmental impacts. The cask selection and environmental issues are discussed in Appendix J.

#### **2.4.7 Transportation of Plutonium-238 Product to the Los Alamos National Laboratory**

After postirradiation processing at the target processing facility, the plutonium-238 product in oxide form would be packaged and shipped to LANL. The 5320 package, designed for surface transportation of americium or plutonium, would be used to carry plutonium oxide to LANL. The 5320 package is a dome-topped upright cylinder that is mounted on a baseplate supported by casters. As explained in Appendix J, Section J.3.3.3, the plutonium-238 would be loaded into an EP-60 product canister, a stainless steel shell confinement vessel used to load the product into the package safely and conveniently. The EP-60 would be seal-welded into the removable stainless steel shell primary containment vessel, the EP-61. The EP-61 would be placed into the secondary containment vessel, the EP-62. The stainless steel EP-62 has a removable bolted closure lid. The gasketed flange of the EP-62 satisfies the containment requirements for both normal transport and hypothetical accident conditions. Plutonium oxide would be transported using the Transportation Safeguards System and would be shipped using SST/SGT (see Section 2.4.3).

#### **2.4.8 Transportation of Materials for Medical Isotope Production**

The raw material for target fabrication would typically be acquired from ORNL, where enrichment processes are conducted to produce high purity target material suitable for production of medical isotopes. The raw material would be shipped from ORNL to Hanford or to the new generic support facility at an existing but undefined DOE site.

Transportation of materials for medical and industrial isotope production and research and development would take place at Hanford between FFTF and the Hanford RPL/306-E facilities or FMEF. At the existing DOE site, transportation would take place between the new generic support facility and either the new low-energy accelerator or the new research reactor.

At Hanford, two different target irradiation vehicle assemblies would be used—the Long-Term Irradiation Vehicle Assembly (up to 3.7 meters [12 feet] in length) and the Rapid Radioisotope Retrieval System Target Carrier (less than 30 centimeters [1 foot] in length). Irradiated pins or short target carriers would be shipped from the irradiation facility to the processing facility using a Type B, accident-resistant shipping cask. The elements (or pins) for the Long-Term Target Irradiation Vehicle Assemblies would be segmented in the FFTF

Interim Examination and Maintenance cell, if necessary, or could be inserted directly into the shipping cask. The Rapid Retrieval System Target Vehicle Assemblies would be inserted into a smaller “shielded pig” package, which would be inserted into the shipping cask or, ideally and as a design goal, the irradiated target carriers would be loaded directly into the shipping cask from the reactor.

At the existing DOE site, irradiated targets and research and development material would be transported in a “shielded pig” package from either the new low-energy accelerator or the new research reactor to the new generic support facility.

A variety of casks would be used to ship the separated isotopes from the processing facility to the destination (i.e., the pharmaceutical distributor). Some land and air shipments would use DOT-specified casks such as CI-20WC-2, and others would require larger Type B casks.

An existing licensed irradiated fuel shipping cask (the T-3) is available to transport material used for research and development. This cask can accommodate shipments of pins or FFTF fuel assemblies as well as nonfuel experiments and materials.

## **2.5 DESCRIPTION OF ALTERNATIVES**

A perspective on the programmatic activities associated with the options under each alternative is presented in **Table 2–3**. Individual alternatives are described in the following sections. The environmental impacts associated with each alternative and its options are discussed in Chapter 4 and are summarized in Section 2.7.1.

**Table 2-3 Alternatives and Options Matrix**

Activity	Irradiation Facility and Site	Target Fabrication and Processing Facility Site	No Action Alternative	Alternative 1 <sup>a</sup>						Alternative 2 <sup>b</sup>									Alternative 3 <sup>c</sup>			Alternative 4 <sup>d</sup>			Alternative 5 <sup>e</sup>			
			Options				Options						Options									Options						
			1	2	3	4	1	2	3	4	5	6	1	2	3	4	5	6	7	8	9	1	2	3		1	2	3
Store neptunium-237 as oxide		REDC at ORNL		●

Maintain FFTF in standby status	FFTF at Hanford		●	●	●	●																						
Deactivate FFTF	FFTF at Hanford																									●		

- a. Alternative 1, Restart FFTF.
- b. Alternative 2, Use Only Existing Operational Facilities.
- c. Alternative 3, Construct New Accelerator(s).
- d. Alternative 4, Construct New Research Reactor.
- e. Alternative 5, Permanently Deactivate FFTF (with No New Missions).
- f. CPP-651 would be used only for storage.

### 2.5.1 No Action Alternative

Under the No Action Alternative (maintain status quo), FFTF would be maintained in standby status for all or a portion of the 35-year evaluation period for operations covered in this NI PEIS. For the purpose of analysis in this NI PEIS, the maximum period of 35 years was assumed. Ongoing operations at existing facilities (as described in Chapter 3, Affected Environment) would continue under this alternative. DOE would not establish a domestic plutonium-238 production capability, but could instead continue to purchase Russian plutonium-238 to meet the needs of future U.S. space missions. For the purpose of analysis in this NI PEIS, DOE assumed that it would continue to purchase plutonium-238 to meet the space mission needs for the 35-year evaluation period. DOE recognizes, however, that any purchase beyond what is currently available to the United States through the existing contract will require additional NEPA review. DOE would continue its medical and industrial isotope production and civilian nuclear energy research and development activities at the current operating levels of existing facilities. A consequence of a No Action decision would be the need to determine the future of the neptunium-237 stored at SRS. Therefore, the impacts of possible future transportation and storage of neptunium-237 are evaluated as part of the No Action Alternative. Four options are identified. If DOE decides not to establish a domestic plutonium-238 production capability in the future, then neptunium-237 would have no programmatic value and Option 1 would be selected. Conversely, if DOE decides to maintain the capability to establish a domestic plutonium-238 capability in the future, the inventory of neptunium-237 must be retained. In this case, Option 2, 3, or 4 could be selected.

- **Option 1.** Under this option, DOE would follow its current stabilization strategy for the neptunium-237, currently stored in solution form at SRS. The current plan is to stabilize the material to oxide, as described in the Supplemental Record of Decision for the *Final Environmental Impact Statement, Interim Management of Nuclear Materials at SRS* (DOE 1995c; 62 FR 61099). This Record of Decision would be amended or new NEPA analysis would be performed, if necessary.
- **Options 2 through 4.** Under these options, the neptunium-237 oxide would be transported from SRS to one of three candidate DOE sites for up to 35 years of storage. For the purpose of analysis in this NI PEIS, the maximum period of 35 years was assumed. Option 2 would provide storage at ORNL's REDC facility, Option 3 at INEEL's Building CPP-651, and Option 4 at Hanford's FMEF.

### 2.5.2 Alternative 1—Restart FFTF

Under Alternative 1, FFTF at Hanford would be restarted and operated for the 35-year evaluation period. FFTF would be used to irradiate targets for medical and industrial isotopes production, plutonium-238 production, and civilian nuclear energy research and development irradiation requirements. Ongoing operations at existing facilities (as described in Chapter 3, Affected Environment) would continue.

Targets for medical and industrial isotope production would be fabricated in one or more facilities at Hanford. Target material would typically be acquired from ORNL, where enrichment processes are conducted to produce high-purity target material suitable for production of medical isotopes. The targets would be irradiated at FFTF and then returned to the fabrication facility for postirradiation processing. From there, the isotope products would be sent directly to commercial pharmaceutical distributors.

Targets for plutonium-238 production would be fabricated in one of three candidate facilities at ORNL, INEEL, or Hanford. The material needed for target fabrication (neptunium-237) would be transported from SRS. The nonirradiated targets would be transported and irradiated at FFTF and then transported back to the fabricating facilities for postirradiation processing. The separated plutonium-238 would be transported to LANL for fabrication into radioisotope power systems and heating units.

Under Alternative 1, raw materials, nonirradiated targets, irradiated targets, and processed materials would be transported among the locations selected for raw target material acquisition, material storage, target fabrication, target irradiation, and postirradiation processing, and eventually to the final destinations for the medical and industrial isotopes and the plutonium-238 product or various research and development test sites.

FFTF could produce high-energy neutrons and a large flux level ( $10^{15}$  neutrons per square centimeter per second) that can be tailored to nearly any desired energy level. FFTF would provide the greatest flexibility for both isotope production and nuclear-based research and development among the baseline configurations for all of the proposed alternatives. Due to its large core size, flux spectrum, demonstrated testing capability, and rated power level, it would be able to concurrently support the projected plutonium-238 production needs, production of medical and industrial isotopes, and civilian nuclear energy research and development related to a broad range of materials, advanced reactors, advanced fuels, and waste transmutation.

The six options under this alternative are associated with the type of nuclear fuel to be used for FFTF operations and the specific facilities to be used for target fabrication and processing. The first three options (Options 1 through 3) would involve operating FFTF with a mixed oxide fuel core for the first 21 years and a highly enriched uranium fuel core for the remaining 14 years. The last three options (Options 4 through 6) would involve operating FFTF with a mixed oxide fuel core for the first 6 years and a highly enriched uranium fuel core for the remaining 29 years. FFTF can provide similar irradiation services with either a mixed oxide fuel core or a highly enriched uranium fuel core. The reasons for these options in FFTF core fuel are provided in Section 2.3.1.1.3. Potential impacts from the deactivation of FFTF at the end of its operating life are not explicitly covered under this alternative, but are addressed under Alternative 5 (Section 2.5.6).

The options involving storage, fabrication, postirradiation processing, and transportation are discussed below.

- **Options 1 and 4.** REDC at ORNL would be used to fabricate and process the neptunium-237 targets required for plutonium-238 production. The neptunium-237 transported from SRS to ORNL would be stored in REDC. The plutonium-238 product would be transported from ORNL to LANL. Hanford's RPL/306-E facilities would be used to fabricate and process targets for medical and industrial isotope production and for research and development, as well as to store the materials needed to fabricate these targets.
- **Options 2 and 5.** FDPF at INEEL would be used to fabricate and process the neptunium-237 targets for plutonium-238 production. The neptunium-237 transported from SRS to INEEL would be stored in FDPF or Building CPP-651 at INEEL. The plutonium-238 product would be transported from INEEL to LANL. Hanford's RPL/306-E facilities would be used to fabricate and process targets for medical and industrial isotope production and for research and development, as well as to store the materials needed to fabricate these targets.
- **Options 3 and 6.** FMEF at Hanford would be used to fabricate and process both neptunium-237 targets for plutonium-238 production and targets for the production of medical and industrial isotopes. The neptunium-237 transported from SRS to Hanford and the other target materials transported from other offsite facilities to Hanford would be stored in FMEF. The plutonium-238 product would be transported from Hanford to LANL for fabrication into heat sources for radioisotope power systems.

### **2.5.3 Alternative 2—Use Only Existing Operational Facilities**

Under Alternative 2, DOE would use existing operating DOE reactors or U.S. commercial nuclear power plants to produce plutonium-238 for future space missions. The production of medical and industrial isotopes

and support of civilian nuclear energy research and development in DOE reactors and accelerators would continue at the No Action Alternative levels.

The currently operating DOE reactors, HFIR and ATR, cannot fully meet the projected long-term needs for medical isotope production and civilian nuclear energy research and development with or without adding the plutonium-238 production mission. Depending on the combination of facilities used in Alternative 2, HFIR and ATR could continue their current support of the medical and industrial isotope and research and development missions, including some near-term growth, while accommodating the production of plutonium-238. Under other scenarios, some near-term growth in medical and industrial isotope production and civilian nuclear energy research and development could be limited by the addition of plutonium-238 production. In any case, non-DOE use of these facilities would be affected by the addition of the plutonium-238 mission. If a commercial reactor were used for plutonium-238 production, the DOE facilities would be unaffected and would continue operating as discussed under the No Action Alternative.

Another component of Alternative 2 is permanent deactivation of FFTF. Permanent deactivation of FFTF (Alternative 5) would occur in conjunction with any of the options under Alternatives 2, 3, or 4. Ongoing operations at existing facilities (as described in Chapter 3, Affected Environment) would continue under Alternative 2.

Targets for plutonium-238 production would be fabricated in one of three facilities at ORNL, INEEL, or Hanford. The material needed for target fabrication (neptunium-237) would be processed and transported from SRS to the fabrication facilities. The targets would be irradiated at existing reactor facilities (HFIR, ATR, a CLWR, as described in Section 2.3.1) and would be transported back to the fabricating facilities for postirradiation processing.

Under Alternative 2, nonirradiated targets, irradiated targets, and processed materials would be transported among the locations selected for storage, target fabrication, target irradiation, and postirradiation processing, and the plutonium-238 product would be transported to LANL.

Nine options are proposed under this alternative. Options 1 through 3 involve the irradiation of targets in ATR at INEEL. Options 4 through 6 involve the irradiation of targets in a generic CLWR. Options 7 through 9 involve the irradiation of targets in both INEEL's ATR and ORNL's HFIR. These options and the associated target fabrication, postirradiation processing, and transportation activities are discussed below.

- **Option 1.** REDC at ORNL would be used to store the neptunium-237 transported from SRS to ORNL and to fabricate and process the targets irradiated at ATR. Option 1 also would involve transportation of the neptunium-237 targets from ORNL to INEEL for irradiation in ATR, transportation of the irradiated targets from INEEL back to ORNL for postirradiation processing, and subsequent transportation of the plutonium-238 product from ORNL to LANL following postirradiation processing.
- **Option 2.** FDPF at INEEL would be used to store the neptunium transported from SRS to INEEL and to fabricate and process the targets (irradiated at ATR). Building CPP-651 would be used for storage. Option 2 also would involve transportation of the plutonium-238 product from INEEL to LANL following postirradiation processing.
- **Option 3.** FMEF at Hanford would be used to fabricate and process the targets (irradiated at ATR) and to store the neptunium-237 transported from SRS to Hanford. Option 3 also would involve transportation of the neptunium-237 to Hanford for target fabrication, transportation of the targets

from Hanford to INEEL for irradiation, transportation of the irradiated targets back to Hanford for postirradiation processing in FMEF, and subsequent transportation of the plutonium-238 product from Hanford to LANL.

- **Option 4.** REDC at ORNL would be used to store the neptunium-237 transported from SRS to ORNL and to fabricate and process the targets (irradiated at a generic CLWR). Option 4 also would involve transportation of the neptunium-237 targets from ORNL to the generic CLWR location for irradiation, transportation of the irradiated targets back to ORNL for postirradiation processing, and transportation of the plutonium-238 product from ORNL to LANL.
- **Option 5.** FDPF at INEEL would be used to store the neptunium transported from SRS to INEEL and to fabricate and process the targets (irradiated at a generic CLWR). Building CPP-651 would also be used for storage. In addition, Option 5 would involve transportation of the neptunium-237 targets from INEEL to the generic CLWR location for irradiation, transportation of the irradiated targets back to INEEL for postirradiation processing, and transportation of the plutonium-238 product from INEEL to LANL.
- **Option 6.** FMEF at Hanford would be used to store the neptunium-237 transported from SRS to Hanford and to fabricate and process the targets (irradiated at a generic CLWR). Option 6 also would involve transportation of neptunium-237 to Hanford for target fabrication, transportation of the targets from Hanford to the generic CLWR location for irradiation, transportation of the irradiated targets back to Hanford for postirradiation processing, and transportation of the plutonium-238 product from Hanford to LANL.
- **Option 7.** REDC at ORNL would be used to store the neptunium-237 transported from SRS to ORNL and to fabricate and process the targets (irradiated at ATR and HFIR). Option 7 also would involve transportation of the neptunium-237 targets from ORNL to the reactors for irradiation, transportation of the irradiated targets back to ORNL for processing, and transportation of the plutonium-238 product from ORNL to LANL.
- **Option 8.** FDPF at INEEL would be used to store the neptunium transported from SRS to INEEL and to fabricate and process the targets (irradiated at ATR and HFIR). Building CPP-651 would be used for storage. Option 8 also would involve transportation of the neptunium-237 targets from INEEL to the reactors for irradiation, transportation of the irradiated targets back to INEEL for postirradiation processing, and transportation of the plutonium-238 product from INEEL to LANL.
- **Option 9.** FMEF at Hanford would be used to store the neptunium-237 transported from SRS to Hanford and to fabricate and process the targets (irradiated at ATR and HFIR). Option 9 also would involve transportation of neptunium-237 to Hanford for target fabrication, transportation of the targets from Hanford to the reactors for irradiation, transportation of the irradiated targets back to Hanford for postirradiation processing, and transportation of the plutonium-238 product from Hanford to LANL.

#### **2.5.4 Alternative 3—Construct New Accelerator(s)**

Under Alternative 3, one or two new accelerators would be used for target irradiation for the evaluation period of 35 years. The new accelerator(s), which would be constructed at an existing DOE site(s), would be used to irradiate all of the targets (i.e., for production of plutonium-238, isotopes for medical and industrial uses, and materials testing for research and development). Ongoing operations at existing facilities as described in Chapter 3, Affected Environment, would continue.

The targets for plutonium-238 production would be fabricated in one of the three candidate facilities at ORNL, INEEL, or Hanford. The material needed for the target fabrication (neptunium-237) would be transported from SRS to the fabrication facilities. The targets would be irradiated at the new high-energy accelerator facility and transported back to the target fabrication facilities for postirradiation processing.

Targets for medical and industrial isotope production would be fabricated in a new support facility located at the same site as the low-energy accelerator. The targets would be irradiated in the low-energy accelerator and returned to the new support facility for postirradiation processing. Site selection for Alternative 3 is not evaluated as part of this NI PEIS. Because Alternative 3 is evaluated at a generic DOE site, no credit was taken for any support infrastructure existing at the site, and it was postulated that a new support facility would be required to support operation of the low-energy accelerator and its missions and the high-energy accelerator civilian nuclear energy research and development missions if both accelerators were located on the same site. While this approach bounds this NI PEIS for the implementation of Alternative 3, it overstates the impacts because this NI PEIS integrates the impacts associated with constructing new support facilities and infrastructure that may be available at the existing DOE site. In the event that Alternative 3 or the low-energy accelerator alone were selected by the Record of Decision for subsequent consideration, follow-on NEPA reviews would evaluate potential locations for either one or both of the accelerators. It is unlikely that DOE would consider locating the new low-energy or high-energy accelerator on a DOE site that does not have existing infrastructure capable of supporting all or most of the mission requirements.

Under Alternative 3, nonirradiated targets, irradiated targets, and processed materials would be transported between the locations selected for storage, target fabrication, target irradiation, postirradiation processing, and the final destination of the plutonium-238. Alternative 3 also would include decontamination and decommissioning of the accelerator(s) and the support facility when the missions are completed, as well as deactivation of FFTF at Hanford.

The low-energy accelerator would serve as a dedicated isotope production facility. Due to the nature of this type of accelerator, it could only produce a limited number of isotopes (listed in Table 1–1), has no ability to satisfy the plutonium-238 needs, and has a very limited ability to support the proposed nuclear-based research and development needs. The preconceptual design of the high-energy accelerator presented in Appendix F focused on supporting the plutonium-238 production mission. The design of the high-energy accelerator could be refined and expanded to perform additional missions such as the production of a select set of medical and industrial radioisotopes. In addition, DOE is aware of longer-term concepts that would apply high-energy accelerators to produce “tuneable” neutrons in a subcritical assembly. Such a facility could be used to address some of the missions more familiar to reactor facilities and may hold considerable promise for future science and technology research. A facility of this nature could provide unique capabilities in areas such as the testing of many different nuclear system coolant, fuel, and material interactions. The changes required to add additional capability to the high-energy accelerator could be provided, but they would increase the size of the facility, add complexity to the facility design and operation, increase the cost of construction and operation, and potentially require more time for design and construction.

The three options under this alternative and their associated target fabrication, postirradiation processing, and transportation activities are discussed below.

- **Option 1.** REDC at ORNL would be used to fabricate and process the neptunium-237 targets required for plutonium-238 production. The neptunium-237 transported from SRS to ORNL would be stored at REDC. The plutonium-238 product would be transported from ORNL to LANL for use in radioisotope power systems for future U.S. space missions. A new support facility at an existing

DOE site would be used to fabricate and process the targets required for the production of medical and industrial and research isotopes and to store the materials needed for target fabrication.

- **Option 2.** FDPF at INEEL would be used to fabricate and process the neptunium-237 targets associated with plutonium-238 production. The neptunium-237 transported from SRS to INEEL would be stored in FDPF or Building CPP-651 at INEEL. The plutonium-238 product would be transported from INEEL to LANL for use in radioisotope power systems for future U.S. space missions. A new support facility at an existing DOE site would be used to fabricate and process the targets required to produce medical and industrial and research isotopes and to store the materials needed for target fabrication.
- **Option 3.** FMEF at Hanford would be used to fabricate and process the neptunium-237 targets for plutonium-238 production. The neptunium-237 transported from SRS to Hanford would be stored in FMEF. The plutonium-238 product would be transported from Hanford to LANL. A new support facility at an existing DOE site would be used to fabricate and process the targets required for the production of medical and industrial and research isotopes and to store the materials needed for target fabrication.

### **2.5.5 Alternative 4—Construct New Research Reactor**

Under Alternative 4, a new research reactor would be used for target irradiation for the evaluation period of 35 years. The new research reactor, to be constructed at an existing DOE site, would be used to irradiate all targets (i.e., for the production of plutonium-238, isotopes for medical and industrial uses, and materials testing for civilian nuclear energy research and development). Ongoing operations at existing facilities as described in Chapter 3, Affected Environment, would continue.

The targets for plutonium-238 production would be fabricated in one of the three candidate facilities at ORNL, INEEL, or Hanford. The material needed for the target fabrication (neptunium-237) would be transported from SRS to the fabrication facilities. The targets would be irradiated at the new research reactor facility and transported back to the target fabrication facilities for postirradiation processing.

Targets for medical and industrial isotope production would be fabricated in a new support facility located at the same site as the new research reactor. The targets would be irradiated in the new research reactor and returned to the new support facility for postirradiation processing.

Alternative 4 site selection is not evaluated as part of this NI PEIS. Because Alternative 4 is evaluated at a generic DOE site, no credit was taken for any existing support infrastructure existing at the site and it was postulated that a new support facility would be required to support operation of the new research reactor and its missions. While this approach bounds this NI PEIS for the implementation of Alternative 4, it overstates the impacts because this NI PEIS integrates the impacts associated with constructing new support facilities and infrastructure that may be available at the existing DOE site. In the event that Alternative 4 were selected by the Record of Decision for subsequent consideration, follow-up NEPA reviews would evaluate potential locations for the new research reactor. It is unlikely that DOE would consider locating the new research reactor on a DOE site that does not have existing infrastructure capable of supporting all or most of the proposed medical and industrial isotope production and nuclear research and development mission requirements.

Under Alternative 4, nonirradiated targets, irradiated targets, and processed materials would be transported between the locations selected for storage, target fabrication, target irradiation, postirradiation processing, and the final destination of the plutonium-238. Alternative 4 also would include the decontamination and

decommissioning of both the research reactor and the support facility when the missions are completed, as well as deactivation of FFTF at Hanford.

The proposed new research reactor would provide ample neutrons for the production of plutonium-238 and for many of the isotopes listed in Table 1–1. The thermal flux would limit the new research reactor’s ability to produce a number of isotopes requiring fast or high-energy neutrons. Its lower flux levels ( $10^{13}$  neutrons per square centimeter per second) and predominantly thermal flux may limit its ability to support many of the projected nuclear-based research and development needs.

The three options under this alternative and their associated target fabrication, postirradiation processing, and transportation activities are discussed below.

- **Option 1.** REDC at ORNL would be used to fabricate and process the neptunium-237 targets associated with plutonium-238 production. The neptunium-237 transported from SRS to ORNL would be stored at REDC. The plutonium-238 product would be transported from ORNL to LANL. A new support facility at an existing DOE site would be used to fabricate and process the targets required to produce medical and industrial and research isotopes and to store the materials needed for target fabrication.
- **Option 2.** FDPF at INEEL would be used to fabricate and process the neptunium-237 targets associated with plutonium-238 production. The neptunium-237 transported from SRS to INEEL would be stored in FDPF or Building CPP–651. The plutonium-238 product would be transported from INEEL to LANL. A new support facility at an existing DOE site would be used to fabricate and process the targets required to produce medical and industrial and research isotopes and to store the materials needed for target fabrication.
- **Option 3.** FMEF at Hanford would be used to fabricate and process neptunium-237 targets for plutonium-238 production. The neptunium-237 transported from SRS to Hanford would be stored in FMEF. The plutonium-238 product would be transported from Hanford to LANL. A new support facility at an existing DOE site would be used to fabricate and process the targets required for the production of medical and industrial and research isotopes and to store the materials needed for target fabrication.

### 2.5.6 Alternative 5—Permanently Deactivate FFTF (with No New Missions)

Under Alternative 5, DOE would permanently deactivate FFTF, with no new missions. Medical and industrial isotope production and civilian nuclear energy research and development missions, at the existing facilities described in Chapter 3, would continue. DOE’s nuclear facilities infrastructure would not be enhanced.

## 2.6 ALTERNATIVES CONSIDERED AND DISMISSED

In developing a range of reasonable alternatives, DOE examined the capabilities and available capacities of the existing and planned nuclear research facilities (accelerators, reactors, and processing [hot] cells) that potentially could be used to support one or all of the proposed isotope production and research missions (DOE 2000a). The following facilities were initially considered, but were subsequently dismissed as reasonable alternatives for meeting DOE’s proposed nuclear infrastructure mission requirements.

### **2.6.1 Irradiation Facilities Dismissed**

DOE evaluated the irradiation capabilities of existing government, university, and commercial irradiation facilities to determine whether they could significantly support the proposed expanded nuclear infrastructure missions. **Table 2–4** presents irradiation facilities that were initially considered but dismissed from further evaluation because they lacked technical capability or available capacity. Reasons for lacking technical capability include that the facility has been permanently shut down, it does not possess the capability to produce steady-state neutrons, or that it could not maintain sufficient power levels to adequately support steady-state neutron production. Facilities were similarly dismissed if existing capacity was fully dedicated to existing missions, or if use of existing capacity to support this NI PEIS proposed action would impact existing missions. Although a number of facilities shown in Table 2–4 have some available capacity, their combined available capacity is a very small percentage of the capacity needed to support the missions evaluated in this NI PEIS.

Two of these facilities, the Brookhaven LINAC Isotope Producer (BLIP) at the Brookhaven National Laboratory and the Isotope Production Facility (IPF) at the Los Alamos Neutron Science Center (LANSCE), were identified in the NI PEIS Notice of Intent as existing facilities that could potentially support the proposed nuclear infrastructure missions. IPF produces radioisotopes using LANSCE's half-mile accelerator that delivers medium-energy protons. IPF's three major products include germanium-68, strontium-82, and sodium-22. As a result of changing DOE missions, the production of radioisotopes at target area "A" of the LANSCE has been rendered inoperable. DOE is currently in the process of upgrading the LANSCE facility with a new 100-million-electron-volt IPF. The facility is scheduled for completion in 2001. After completion of the LANSCE upgrade, the existing capability at these two facilities will be twice the current need for accelerator-generated medical isotopes. Thus, no new accelerator capacity is needed in the short term. Should isotope demand grow consistent with the Expert Panel Report, there will be a need for expanded isotope production capacity for those isotopes generated by IPF and BLIP. IPF and BLIP were dismissed as reasonable alternatives for the production of medical isotopes because they cannot meet the projected future demand for accelerator-produced isotopes.

The Alternating Gradient System (AGS) accelerator complex at the Brookhaven National Laboratory was evaluated for meeting the mission requirements of medical and industrial isotope production, plutonium-238 production, and civilian nuclear energy research and development. AGS presently accelerates up to  $7 \times 10^{13}$  protons to 24 giga-electron volts with a cycle time of approximately 2.5 seconds. This corresponds to a beam power of approximately 100 kilowatts. The complex was dismissed as a reasonable alternative because the potential neutron flux generated by the facility in the required configuration (i.e., with a spallation target) would not be adequate to meet the mission goals and, in addition, operating the complex in the required configuration would not be compatible with the present primary mission of the facility (Kovar 2000).

Two existing operating DOE facilities, ATR and HFIR, were evaluated as components of Alternative 2, Use Only Existing Operational Facilities. These two facilities currently provide isotope production capabilities and were examined for their abilities to meet the isotope production and nuclear research and development requirements of the proposed expanded missions. In addition, DOE considered whether production from ATR and HFIR could be enhanced by increasing power levels at the reactors or through other modifications to the facilities, which included the installation of rapid radioisotope retrieval systems for the production of isotopes with a short half-life. In general, the installation of rapid radioisotope retrieval systems in reactors does not increase the ability of reactors to produce larger quantities of isotopes; it enables the reactors to produce a broader spectrum of isotopes. While some growth is possible in isotope production at ATR and HFIR, such growth would be insufficient to meet the long-term growth projections discussed in Section 1.2.1. Further growth could only be enabled by increasing reactor power levels. At ATR, increases in power level are possible to the extent that priority DOE Office of Naval Reactor missions are not impacted. Raising ATR

**Table 2-4 Irradiation Facilities Considered but Dismissed from Further Evaluation**

Reasons for Dismissal	Facility
Facilities lacking sufficient neutron production capacity to support the NI PEIS proposed action without impacting existing missions	Neutron Radiographic Reactor Argonne National Laboratory–West

**Source:** DOE 2000a.

power would only delay the point in time at which capacity is reached. The power level at HFIR is already at 100 percent of its current Authorization Basis (85 megawatts), and modification of this Authorization Basis would be required to increase to full-design power (100 megawatts). Increasing the power levels at ATR and/or HFIR will enhance the isotope production capability of these reactors. However, the enhancement in production capability would not be adequate to meet the future demand for isotope production; it would only delay the point in time at which the United States' reactor isotope production capacity is reached. Therefore, increasing the power levels at ATR and/or HFIR was dismissed as a reasonable alternative for meeting the requirements of the DOE missions.

Modification of CLWRs to enable online insertion and retrieval of targets for the medical and industrial isotope production missions was evaluated and dismissed as a reasonable alternative. This decision was made because the required facility modifications would be significant and would include penetrations into the reactor vessel and, potentially, the containment vessel. Additional facility modifications would be required to enable loading of the targets into a shielded cask for transport to a processing facility. Performing these facility modifications would require an extended refueling outage (with a resulting loss of power generation revenue to the CLWR owner) and could potentially extend subsequent maintenance or refueling outages to inspect, test, and maintain the insertion and retrieval system, reactor vessel penetrations, and potential containment vessel penetrations. CLWRs were considered for the production of medical isotopes with moderate and long half-lives by

irradiating targets in the CLWR vessel but outside the reactor core region (i.e., outside of the fuel assembly region). Only one of the isotopes listed in the Expert Panel Report, *Expert Panel: Forecast Future Demand for Medical Isotopes* (Wagner et al. 1998), strontium-89, was considered a potential candidate for production in a CLWR, outside of the reactor core region. Strontium-89 has a half-life of 50.5 days. Irradiated targets containing strontium-89 could only be harvested from a CLWR every 18 to 24 months during a scheduled reactor refueling outage. Approximately 10 CLWRs with refueling outages scheduled every 2 to 3 months would be required to support a program to ensure a continuous and reliable supply of strontium-89. Due to the CLWR's ability to irradiate targets for only a very limited array of medical isotopes (only one isotope in current demand was identified), it was not considered a reasonable alternative for expanding the U.S. infrastructure to provide an overall enhancement of the medical isotope production missions. CLWRs were also considered for the proposed DOE civilian nuclear energy research and development missions. CLWRs will continue to support the commercial industry research and development activities by providing a test bed for industry-sponsored lead test assemblies and other related research. CLWRs cannot meet most of the requirements for supporting the DOE civilian nuclear energy research and development missions and, therefore, were dismissed as a reasonable alternative for supporting these missions.

CANDU reactors, operating in Canada, were considered for supplying irradiation services for the plutonium-238 production mission. (Note: Canada is currently the major supplier of medical radioisotopes used in the United States.) Since use of the CANDU reactors does not meet the programmatic issue being addressed in this NI PEIS, that is, the enhancement of the United States infrastructure to support the proposed missions, the CANDU reactors were considered but were dismissed as a reasonable alternative. However, the environmental impacts associated with transporting the nonirradiated and irradiated neptunium-237 targets between the CANDU reactors and the target fabrication and processing facilities in the United States are bound by the evaluations presented in this NI PEIS for the CLWR options of Alternative 2 (Use Only Existing Operational Facilities).

Some facilities listed in Table 2-4 do not have the capacity to support the proposed missions without impacting existing missions, but do have some existing medical or industrial isotope production or nuclear research and development missions. These facilities will continue to support their existing missions at current levels.

### 2.6.2 Processing Facilities Dismissed

Numerous existing U.S. processing hot cell facilities possess the capabilities and capacities to support the proposed missions. Given this general availability, only existing processing facilities that are collocated at DOE's candidate irradiation facility sites (i.e., ORNL, INEEL, and Hanford) were evaluated in this NI PEIS. Although multiple processing facilities exist at each of these sites, only the most suitable facilities in terms of capability, capacity, and availability were given further consideration. The processing facilities that were dismissed from evaluation are listed in **Table 2-5**.

Based on public comments on the scope of the proposed *Plutonium-238 Production EIS*, the H-Canyon and HB-Line facilities at SRS that previously performed the processing for the plutonium-238 production mission were reconsidered as potential processing facilities for the proposed plutonium-238 production mission even though the facilities are not collocated with a proposed irradiation facility. After reviewing the plutonium-238 production target fabrication and processing requirements, the capabilities and capacities of the facilities, and the modifications and resources required to support the plutonium-238 production mission, use of the H-Canyon and HB-Line facilities was dismissed as a reasonable alternative because:

1. DOE plans to shut down these facilities following completion of their current missions to stabilize and prepare for disposition of Cold War legacy nuclear materials and certain spent nuclear fuel, and a

determination that a new nonchemical processing technology is capable of preparing aluminum-clad research reactor spent nuclear fuel for ultimate disposition.

2. The cost to extend the operating lives of these facilities to support plutonium-238 production for the proposed 35-year evaluation period would be approximately one order of magnitude higher than the costs associated with the processing facilities evaluated in this NI PEIS.

A commentator also proposed using the H-Canyon and HB-Line for a short campaign to produce all of the required plutonium-238. Based on prior production rates, it would take approximately 7 years to produce 175 kilograms (385 pounds) of plutonium-238, the total plutonium-238 production goal. The target fabrication and irradiation requirements to support this processing campaign to produce 25 kilograms (55 pounds) per year of plutonium-238 would be significant but feasible. The irradiation requirements could be supported by operating five CLWRs or operating FFTF at the 400-megawatt power level. However, a concern about the short campaign option is that the plutonium-238 would be stored a long time before use and because of natural decay may not meet the specification requirements when finally needed. This alternative was dismissed

because of the uncertainty that over time the plutonium-238 produced may not meet the required specification for NASA missions.

## **2.7 SUMMARY OF ENVIRONMENTAL IMPACTS, SCHEDULES, AND MISSION EFFECTIVENESS**

The following sections summarize the environmental impacts and schedules associated with the alternatives and options and compare the impacts among the alternatives described in Sections 4.2 through 4.7. Chapter 4 shows construction impacts that would result from implementation of Alternative 3 and 4, as well as operational impacts for all of the alternatives. Section 2.7.1 compares the environmental impacts and risks among the alternatives. Section 2.7.2 summarizes the implementation schedules for each alternative. Mission effectiveness is discussed in Section 2.7.3.

As discussed in Section 1.8, tables and text in this section have been revised in response to comments about the difficulty of comparing environmental impacts among the alternatives in the Draft NI PEIS. Tables and figures in this section now focus on estimated environmental impacts that would result from implementation of the alternatives. Baseline environmental data for the sites and for the candidate facilities are now given in Chapter 3. In this NI PEIS, Option 1 of the No Action Alternative is used as a basis for the comparison of impacts at candidate sites.

Numerical values are assigned to environmental impacts that include radiological and nonradiological risks to the public and workers at the candidate sites and along representative transportation routes, potential quantities of waste generated, and potential quantities of spent nuclear fuel generated. These numerical values reflect the degree to which the proposed activities would increase the environmental impacts of current activities and operations at the candidate sites. It should be noted that most of the options being considered under the various alternatives involve the use of more than one site, so the numerical values presented are the sums of the values for all of the relevant sites or transportation routes. There are two exceptions—the health risks to the maximally exposed individual and the noninvolved worker. For these two exceptions, the numerical value presented is the maximum value among all relevant sites.

### **2.7.1 Summary of Environmental Impacts**

#### **2.7.1.1 Radiological and Hazardous Chemical Impacts**

##### **RADIOLOGICAL IMPACTS**

**Table 2–6** summarizes radiological and hazardous chemical risks that could occur under implementation of the alternatives from operations at fabrication, processing, and irradiation facilities. Radiological risks to the maximally exposed individual are listed in columns 2 and 5 for normal operations and accidents, respectively. Similarly, columns 3 and 6 display radiological risks to the public for normal operations and accidents, and columns 4 and 7 show radiological risks to workers at candidate irradiation facilities and processing and fabrication facilities. As indicated in the table, Option 1 of the No Action Alternative is the basis for comparing impacts that would result from implementation of the other alternatives and options. Impact values for Option 1 of the No Action Alternative are set to zero and provide a reference point for comparing impacts that would result from implementation of the other alternatives and options. Negative values in the table indicate a decrease in risk with respect to Option 1 of the No Action Alternative.

The risk values presented are the sum of individual risk values from operational activities in the fabrication, processing, and irradiation facilities used under each alternative and option. For Alternatives 2 through 4, where FFTF would be permanently deactivated, the values presented also include the reduction in risk from

- a. For descriptions of the options under each alternative, see Section 2.5.
- b. Accident risks include accident likelihood over 35 years and the consequences.
- c. Probability that an individual would develop cancer from exposure to hazardous (carcinogenic) chemicals.
- d. A measure of hazard from exposure to multiple toxic (noncarcinogenic) chemicals. If this value is less than 1, the exposure is unlikely to produce an adverse toxic effect.
- e. Baseline conditions for the comparison of impacts is Option 1 of the No Action Alternative.
- f. These alternatives include FFTF deactivation impacts. The deactivation would lead to negative impacts (reduced risk); see Alternative 5.
- g. The reduction in impacts from deactivating FFTF would affect the impacts to the population and workforce for Alternatives 2 through 4 and to the maximally exposed individual only for those options within Alternatives 2 through 4 that use FMEF.
- Note:** Refer to the text for a discussion on how the risk values in this table have been generated.
- Key:** LCF, latent cancer fatalities.

FFTF deactivation, where applicable. For example, the radiological risk to the population from normal operations for Option 3 of Alternative 2 (i.e., irradiation at ATR, fabrication and processing at FMEF, and deactivation of FFTF) is given as  $-4.7 \times 10^{-4}$  latent cancer fatality. This value was calculated by adding the population risks from fabrication and processing at FMEF and irradiation at ATR,  $7.7 \times 10^{-7}$  latent cancer fatality (see Table 4–77), and Alternative 5 (Permanently Deactivate FFTF [with No New Missions]),  $-4.7 \times 10^{-4}$  latent cancer fatality. The latter risk is the sum of the population risk associated with the activities during permanent deactivation of FFTF,  $1.8 \times 10^{-5}$  latent cancer fatality (see Section 4.4.1.2), and that resulting from not keeping FFTF in standby for 35 years,  $-4.9 \times 10^{-4}$  latent cancer fatality (the negative value reflects the reduction in risk) (see Section 4.2.1). The radiological risks for accident conditions are the sum of accident risks evaluated for each option. For each accident, the risk value is the product of the accident consequences and its occurrence likelihood over 35 years of operation. Chapter 4, Appendix H, and Appendix I provide the details on public and occupational risk calculations.

A comparison of radiological risks estimated to result from normal operations over 35 years (columns 2 and 3 of Table 2–6) shows that implementation of the alternatives would result in a small risk of a latent cancer fatality among the general public. Radiological accident risks to the public over 35 years (columns 5 and 6 of Table 2–6) are estimated to be less than one latent cancer fatality. **Figure 2–23** shows estimated latent cancer fatalities among the population at risk from potential accidents at candidate sites. Each bar in Figure 2–23 represents the estimated latent cancer fatalities for a given option.

For example, there are six bars shown above the alternative labeled “Restart FFTF.” The first of the six bars represents the estimated latent cancer fatalities for implementation of Option 1, the second bar represents the estimated latent cancer fatalities for implementation of Option 2, etc. As discussed in Section 4.2, storage containers for neptunium-237 targets would not be expected to rupture under the most severe accident evaluated in this NI PEIS. Therefore, no latent cancer fatalities would be expected under implementation of the No Action Alternative. Deactivation of FFTF (with no new missions) would result in a small reduction in radiological accident risks in comparison with the No Action Alternative. Differences in the radiological accident risks among alternatives and among options within a given alternative are driven by accident risks at the target fabrication and processing facilities. This point is illustrated in **Figure 2–24**.

Figure 2–24 shows risks to the public that would result from radiological accidents at candidate fabrication and processing facilities and candidate irradiation facilities. Latent cancer fatalities estimated for candidate fabrication and processing facilities are shown to the left of the dividing line in Figure 2–24, and the estimated latent cancer fatalities for candidate irradiation facilities appear on the right side of the dividing line. The estimated latent cancer fatalities for FMEF under Options 3 and 6 of Alternative 1 are labeled “FMEF (Hanford).” Under Options 3 and 6 of Alternative 1, FMEF would serve as the fabrication and processing facility for all targets. If FMEF were selected to fabricate and process neptunium-237 targets only, the radiological risk to the public would be reduced by approximately a factor of two, as shown by the bar labeled “FMEF (Hanford, neptunium-237 targets only)” in Figure 2–24. Among the candidate fabrication and processing facilities, accident risks to the public range from a low of 0.029 latent cancer fatality at FDPF (INEEL) to 0.377 latent cancer fatality at RPL (Hanford). Although all of the accident risks shown in Figure 2–24 are less than one latent cancer fatality, risks to the public that would be expected from radiological accidents at candidate fabrication and processing facilities are relatively large in comparison to those for candidate irradiation facilities.

Figure 2–23 Public Risks Due to Radiological Accidents at Candidate Sites (35 Years)

Figure 2–24 Public Risks Due to Radiological Accidents at Candidate Facilities (35 Years)

Prevailing weather conditions, the geographical distribution of the population at risk, and the type of target(s) processed (neptunium-237 only, other isotopes only, or both) all contribute to variations in the radiological risk to the public. Calculations of accident consequences and risks include populations residing within 80 kilometers (50 miles) of the accident site, although the consequences and risks decrease noticeably with increasing distance from the accident site. As shown in **Figure 2–25**, RPL (Hanford) and REDC (ORR) have the largest populations residing within 16 kilometers (10 miles) of candidate sites, while FDPF (INEEL) has the smallest. Because the total population residing within 16 kilometers (10 miles) of FDPF is relatively small, the curve representing populations residing near FDPF is nearly coincident with the horizontal axis in Figure 2–25. Comparing Figures 2–24 and 2–25, it is clear that accident risks due to fabrication and processing activities are driven by both the type of processing activities and the total population residing near the facilities. In turn, variations in accident risks among the alternatives, as well as variations among options within an alternative, are driven by the selection of fabrication and processing facilities. The choice for irradiation facility would have little effect on radiological accident risks to the public.

### **HAZARDOUS CHEMICAL IMPACTS**

Columns 8 and 9 of Table 2–6 display cancer risks and hazard indexes that could result from airborne emissions of hazardous chemicals from candidate processing facilities. As discussed in Section H.3, cancer risk factors listed in column 8 of Table 2–6 are estimates of an upper-bound lifetime probability of an individual developing cancer due to exposure to carcinogenic chemicals. For all alternatives and options, the maximum cancer risk factor is  $2.6 \times 10^{-7}$  (or a likelihood of approximately 1 in 3,800,000) or less. Different carcinogens can cause or promote different forms of cancer. In general, cancer risk factors for different carcinogens are not additive because there are potential synergistic or antagonistic chemical interactions in multiple-substance exposures (EPA 1989). Therefore, column 8 of the table lists the maximum cancer risk factor for each alternative. Hazard indexes listed in column 9 of Table 2–6 estimate the potential for adverse toxic (noncancerous) health effects due to exposure to hazardous chemicals. If the hazard index is less than one, adverse (noncancerous) health effects would not be expected. For all of the alternatives and options, hazard indexes are 0.0064 or less. The results (presented in columns 8 and 9 of Table 2–6) indicate that no adverse toxic health or cancer effects would be expected from exposure to hazardous chemicals released under the implementation of any of the alternatives.

Figure 2-25 Population Residing Within 16 Kilometers (10 Miles) of Candidate Fabrication and Processing Facilities

### 2.7.1.2 Generation and Disposition of Waste and Spent Nuclear Fuel

**Table 2–7** summarizes the estimated amount of waste and spent nuclear fuel that would be generated under implementation of the nuclear infrastructure alternatives. As discussed in Chapter 4, waste that would result from implementation of the alternatives would be relatively small in comparison to current waste generation at the candidate sites. Current waste management practices at the candidate sites would be sufficient to manage waste that would result from the nuclear infrastructure alternatives.

#### TRANSURANIC WASTE/HIGH-LEVEL RADIOACTIVE WASTE

The analysis for the Draft NI PEIS assumed that the waste generated from the processing of irradiated neptunium-237 targets is transuranic waste. However, as a result of comments received during the public comment period, DOE is considering whether the waste from processing of irradiated neptunium-237 targets should be classified as high-level radioactive waste. Irrespective of how the waste is classified (i.e., transuranic or high-level radioactive), the waste composition and characteristics are the same, and the waste management (i.e., treatment and onsite storage) as described in this NI PEIS would be the same. In addition, either waste type would require disposal in a suitable repository. As shown in column 2 of Table 2–7, between 240 and 380 cubic meters (314 and 497 cubic yards) of transuranic waste or high-level radioactive waste would result from implementation of Alternatives 1 through 4. This waste would result from processing irradiated neptunium-237 targets to harvest plutonium-238. Approximately 380 cubic meters (497 cubic yards) of waste per year for 35 years (see Table 2–7) would be generated for all options under Alternatives 1 through 4, except those for which target fabrication and processing would be conducted at FDPF at INEEL. If FDPF were selected for neptunium target fabrication and processing, then approximately 240 cubic meters (314 cubic yards) of waste would be generated during the program.

#### LOW-LEVEL AND MIXED LOW-LEVEL WASTE

Columns 3 and 4 of Table 2–7 summarize the total low-level radioactive waste and mixed low-level radioactive waste generation that would be expected from implementation of the alternatives. Low-level radioactive waste would be generated at the irradiation facilities and at the fabrication and processing facilities. As shown, the low-level radioactive waste generation that would result under Alternative 2 would be less than half of that for Alternatives 1, 3, and 4, and mixed low-level radioactive waste generation would be almost half. This is because under Alternative 2 currently operational facilities would be used for target irradiation and these facilities would generate little additional low-level and mixed low-level radioactive waste. Also under Alternative 2, no waste generation would result from production of additional medical and industrial isotopes.

DOE's approach for managing low-level and mixed low-level radioactive waste is provided in the Record of Decision for its Waste Management Program (65 FR 10061). The Record of Decision states that for the management of low-level radioactive waste, minimal treatment will be performed at all sites, and disposal will continue to the extent practicable, on site at INEEL, LANL, ORR, and SRS. In addition, Hanford and the Nevada Test Site will be available to all DOE sites for low-level radioactive waste disposal. The Record of Decision does not preclude the use of commercially licensed low-level radioactive waste disposal facilities. Low-level radioactive waste generated at Hanford would be disposed of on site. However, if DOE determines that use of the Hanford waste management infrastructure or other DOE sites is not practical or cost effective, DOE may issue an exemption under DOE Order 435.1 for the use of non-DOE facilities (i.e., commercial facilities) to store, treat, and dispose of such waste generated from the restart and operation of FFTF.

**Table 2–7 Comparison of Waste and Spent Nuclear Fuel Generation Among Alternatives**

Options <sup>a</sup>	Waste Generation in Cubic Meters (35 Years)					Spent Nuclear Fuel in Metric Tons

<b>Alternative 5: Permanently Deactivate FFTF (with No New Missions)</b>						
	0.0	0.0	(b)	2,500 <sup>d</sup>	0.0	0

a. For descriptions of the options under each alternative, see Section 2.5.

b. The deactivation of FFTF would result in the removal of approximately 980,000 liters (260,000 gallons) of sodium. This sodium would be evaluated for alternate uses and is therefore not included in mixed low-level radioactive waste for Alternatives 2 through 5.

c. 2,500 cubic meters of these materials would be evaluated for radioactive contamination and would be reused or recycled if possible.

d. These materials would be evaluated for radioactive contamination and would be reused or recycled if possible.

**Key:** NA, not applicable.

Solid low-level radioactive waste generated at ORR eventually would have to be disposed of off site due to lack of low-level waste disposal capacity at ORR. Low-level radioactive waste generated at INEEL would be disposed of on site. At some future time, low-level radioactive waste would be disposed of off site.

In compliance with the Waste Management Program Record of Decision, DOE's mixed low-level radioactive waste will be treated at: Hanford, INEEL, ORR, and SRS, and disposed of at Hanford and the Nevada Test Site. Existing candidate sites analyzed in this NI PEIS all have treatment facilities for mixed low-level radioactive waste (see Section 3.2.11 [ORR], Section 3.3.11 [INEEL], and Section 3.4.11 [Hanford]). Solid mixed low-level radioactive waste generated at ORR and INEEL would have to eventually be disposed of off site due to lack of onsite mixed low-level radioactive waste disposal capacity.

### **HAZARDOUS WASTE**

Hazardous waste that would result from implementation of the nuclear infrastructure alternatives is shown in column 5 of Table 2-7. The amount of hazardous waste generated under the alternatives is relatively small in comparison to hazardous waste currently generated at the candidate sites: ORR (Table 3-11), INEEL (Table 3-25), and Hanford (Table 3-34). Estimated amounts of hazardous waste that would be generated under Alternatives 2 through 4 include the hazardous waste that would be generated under Alternative 5 (Permanently Deactivate FFTF [with No New Missions]).

Based on the Record of Decision for hazardous waste issued on August 5, 1998 (63 FR 41810), nonwastewater hazardous waste would be treated and disposed of at offsite commercial facilities. As discussed in Chapter 4, hazardous waste generated under the nuclear infrastructure alternatives would be stored in onsite facilities permitted under the Resource Conservation and Recovery Act or generator accumulation areas prior to shipment to a commercial facility permitted to manage hazardous waste.

### **NONHAZARDOUS WASTE**

Nonhazardous waste that would be expected from implementation of the nuclear infrastructure alternatives is listed in column 6 of Table 2-7. Nonhazardous waste that would be expected under implementation of Alternative 3 (Construct New Accelerator[s]) is at least a factor of six larger than the nonhazardous waste estimated for the other alternatives. As indicated in Sections 4.5.1.1.12 and 4.5.1.2.13, nonhazardous waste that would be produced under Alternative 3 would be driven by sanitary waste and process wastewater resulting from construction and operation of accelerators and the new support facility.

As indicated in Sections 4.3.1.1.13 and 4.3.2.1.13, nonhazardous solid waste that would be generated at ORR and INEEL would represent less than 0.5 percent of the generating site's onsite nonhazardous waste disposal capacity. Nonhazardous solid waste that would be generated at Hanford under the nuclear infrastructure alternatives would be recycled or sent off site for disposal as industrial waste. Nonhazardous process wastewater at the candidate sites would represent a small fraction of the generating sites capacity and would be treated on site. Sanitary wastewater would be treated on site as necessary prior to offsite disposition.

### **SPENT NUCLEAR FUEL**

Changes in the generation of spent nuclear fuel would occur only under implementation of Alternatives 1 (Restart FFTF) and 4 (Construct New Research Reactor). Spent nuclear fuel that would be generated under Alternative 1 would be less than 1 percent (by weight) of the current spent nuclear fuel inventory at Hanford. As discussed in Section 4.3.1.1.14, spent nuclear fuel that would be generated at Hanford under implementation of Alternative 1 would be placed in facility storage vessels and onsite dry storage pending ultimate disposal in a geologic repository. Spent nuclear fuel generated under Alternative 4 would be stored on site in wet storage pending ultimate disposal in a geologic repository (Section 4.6.1.2.14).

### **2.7.1.3 Water Use**

#### **CONSTRUCTION**

For construction of new facilities under Alternatives 3 (Construct New Accelerator[s]) and 4 (Construct New Research Reactor), water is expected to be required for such uses as mixing concrete, dust control, washing activities, and potable and sanitary needs. Water use for facility construction is estimated at 22.7 million liters (6 million gallons) for the high-energy accelerator, 14 million liters (3.7 million gallons) for the low-energy accelerator, 11.7 million liters (3.1 million gallons) for the new research reactor, and 14.6 million liters (3.85 million gallons) for the new support facility on an annualized (construction-year) basis.

#### **OPERATIONS**

**Figure 2–26** shows the annual water use that would be expected to occur under the nuclear infrastructure alternatives. As discussed in Section 2.5.1 under the No Action Alternative, FFTF would remain in standby and DOE’s nuclear infrastructure would not be enhanced. In standby condition, the FFTF uses approximately 197 million liters (52 million gallons) of groundwater per year. In Figure 2–26, the No Action Alternative is used as a basis for comparison of water use among the alternatives. Therefore, water use for the No Action Alternative is shown as zero. The water use shown in Figure 2–26 for Alternative 1 (Restart FFTF) is the additional groundwater use that would result from operation of the FFTF. Under Alternatives 2 through 5, FFTF would be deactivated, thus saving approximately 197 million liters (52 million gallons) per year in groundwater required for maintaining FFTF in standby. As a result, the water use is negative for Alternatives 2 (Use Only Existing Operational Facilities) and 5 (Permanently Deactivate FFTF [with No New Missions]). The negative increment in water use would be more than offset by the increase in water use estimated for Alternatives 3 (Construct New Accelerator[s]) and 4 (Construct New Research Reactor).

### **2.7.1.4 Air Quality**

#### **CONSTRUCTION**

Under Alternatives 3 (Construct New Accelerator[s]) and 4 (Construct New Research Reactor), new irradiation and support facilities would be constructed to support DOE’s nuclear missions. Facility construction would not be required under the other alternatives. **Tables 2–8** and **2–9** show the estimated concentrations of air pollutants that would be expected during construction conducted under Alternatives 3 and 4, respectively. Since no specific site has yet been selected for the new accelerator[s] or the new research reactor, Federal standards are used in column 3 of the tables. As discussed in Section 4.5.1.1.3, the effects of constructing the new high-energy accelerator were used to characterize air quality impacts under Alternative 3 (Construct New Accelerator[s]). Construction impacts of the low-energy accelerator and support facilities would add relatively small concentrations to those shown in column 4 of Table 2–8. If Alternative 3 and/or Alternative 4 were selected for implementation, site-specific environmental documentation would be prepared prior to site selection.

The negative increment in water use would be more than offset by the increase in water use estimated for Alternatives 3 (Construct New Accelerator[s]) and 4 (Construct New Research Reactor).

Figure 2-26 Annual Water Use Under the Nuclear Infrastructure Alternatives

Table 2-8 Air Pollutant Concentrations Resulting from Construction of a High-Energy Accelerator Under All Options of Alternative 3

Pollutant	Averaging Period	Most Stringent Standard or Guideline (micrograms per cubic meter) <sup>a</sup>	Modeled Increment (microgram per cubic meter)
Carbon monoxide	8 hours	10,000	436
	1 hour	40,000	623
Nitrogen oxide	Annual	100	42
PM <sub>10</sub>	Annual	50	3
	24 hours	150	69
Sulfur dioxide	Annual	80	3
	24 hours	365	64
	3 hours	1,300	143

a. The more stringent of the Federal and state standards is presented if both exist for the averaging period. The National Ambient Air Quality Standards (NAAQS) (40 CFR Part 50), other than those based on annual averages, are not to be exceeded more than once per year. The annual arithmetic mean PM<sub>10</sub> standard is attained when the expected annual arithmetic mean concentration is less than or equal to the standard.

Source: Modeled increments are based on SCREEN3 computer code (EPA 1995); data from TechSource 2000.

**Table 2–9 Air Pollutant Concentrations Resulting from Construction of a New Research Reactor Under All Options of Alternative 4**

<b>Pollutant</b>	<b>Averaging Period</b>	<b>Most Stringent Standard or Guideline (micrograms per cubic meter)<sup>a</sup></b>	<b>Modeled Increment (microgram per cubic meter)</b>
Carbon monoxide	8 hours	10,000	72
	1 hour	40,000	103
Nitrogen oxide	Annual	100	1
PM <sub>10</sub>	Annual	50	3
	24 hours	150	88

a. The more stringent of the Federal and state standards is presented if both exist for the averaging period. The National Ambient Air Quality Standards (NAAQS) (40 CFR Part 50), other than those based on annual averages, are not to be exceeded more than once per year. The annual arithmetic mean PM<sub>10</sub> standard is attained when the expected annual arithmetic mean concentration is less than or equal to the standards.

**Source:** Modeled increments are based on the SCREEN3 computer code (EPA 1995); data from Appendix E. Missions]).

As shown in Tables 2–8 and 2–9, construction of the new irradiation and support facilities would not be expected to exceed Federal standards and guidelines for ambient air quality. However, in comparison with air pollutant concentrations expected from facility operations (discussed in Section 2.7.1.5.2 below), concentrations of air pollutants that would be expected during construction are relatively large. If the new facilities were constructed in an area with existing high background concentrations, construction activities could produce enough air pollutant emissions to exceed ambient air quality standards

## **OPERATIONS**

### **No Action Alternative**

Under the No Action Alternative (Section 2.5.1), FFTF would remain in standby and DOE’s nuclear infrastructure would not be enhanced to meet the nuclear infrastructure missions described in Section 1.2. Air quality effects that would be expected from transportation of neptunium-237 oxide to REDC (Option 2), FDPF (Option 3), or FMEF (Option 4) are summarized in Section 2.7.1.6.

### **Alternatives 1 through 5**

**Oak Ridge Reservation.** Under Alternatives 1 (Options 1 and 4), 2 (Options 1, 4, and 7), 3 (Option 1), and 4 (Option 1), air quality impacts at ORR would result from the production of plutonium-238 at REDC. Concentrations of air pollutants that would be expected from facility operations conducted under these alternatives and options are shown in column 4 of **Table 2–10**. All of the expected concentrations are small in comparison with the most stringent ambient air quality standards shown in column 3 of Table 2–11. Operation of REDC in support of plutonium-238 production would not be expected to significantly affect air quality or to result in air pollutant concentrations in excess of ambient air quality standards. No air quality impacts would result from operation of HFIR under Alternative 2 (Use Only Existing Operational Facilities).

**Idaho National Engineering and Environmental Laboratory.** Under Alternatives 1 (Options 2 and 5), 2 (Options 2, 5, and 8), 3 (Option 2) and 4 (Option 2), air quality impacts at INEEL would result from the production of plutonium-238 at FDPF. Concentrations of air pollutants that would be expected from facility operations conducted under these alternatives and options are shown in column 4 of **Table 2–11**. All of the expected concentrations are small in comparison with the most stringent ambient air quality standards shown in column 3 of the table. Operation of FDPF in support of plutonium-238 production would not be expected to significantly affect air quality or to result in air pollutant concentrations in excess of ambient air quality

**Table 2–10 Air Pollutant Concentrations Expected from Operation of the Radiochemical Engineering Development Center Under Alternatives 1 Through 4**

Pollutant	Averaging Period	Most Stringent Standard or Guideline (micrograms per cubic meter) <sup>a</sup>	Modeled Increment (micrograms per cubic meter)
Nitrogen dioxide	Annual	100	1.99×10 <sup>-4</sup>

	24 hours	365	0.31
	3 hours	1,300	0.70

a. For comparison with ambient air quality standards.

**Source:** Modeled increments are based on the SCREEN3 computer code (EPA 1995); 40 CFR Part 50.

**Table 2–11 Air Pollutant Concentrations Expected from Operation of the Fluorinel Dissolution Process Facility Under Alternatives 1 Through 4**

Pollutant	Averaging Period	Most Stringent Standard or Guideline (micrograms per cubic meter) <sup>a</sup>	Modeled Increment (micrograms per cubic meter)
<b>Criteria pollutants</b>			
Nitrogen dioxide	Annual	100	3.66×10 <sup>-4</sup>
Sulfur dioxide	Annual	80	0.024
	24 hours	365	0.19
	3 hours	1,300	0.43
<b>Toxic air pollutants</b>			
Methanol	24 hours	13,000	0.0048
Nitric acid	24 hours	250	0.0097
Paraffin hydrocarbons	24 hours	100	0.44
Tributyl phosphate	24 hours	110	0.25

a. For comparison with ambient air quality standards.

**Source:** Modeled increments are based on the SCREEN3 computer code (EPA 1995); 40 CFR Part 50; WDEC 1998.

standards. No air quality impacts would result from operation of ATR under Alternative 2 (Use Only Existing Operational Facilities).

**Hanford Site.** If Alternative 1 were selected for implementation, impacts on air quality at Hanford would result from operation of FFTF (all options), RPL (Options 1, 2, 4, and 5), and FMEF (Options 3 and 6). FMEF could also be used for production of plutonium-238 under Alternatives 2 (Options 3, 6, and 9), 3 (Option 3), and 4 (Option 3). Concentrations of air pollutants that would be expected from facility operations conducted under these alternatives and options are shown in **Table 2–12**. Numbers in the third row of Table 2–12 are the most stringent state or Federal standard for each averaging period. FFTF would be deactivated under Alternatives 2 through 5. Deactivation would, in turn, result in the shutdown of diesel-driven fire pumps, oil-fired preheaters, and a gas turbine that currently support FFTF's standby condition. If any of Alternatives 2 through 5 were selected for implementation, emissions from this supporting equipment would cease, thereby improving the air quality near FFTF. Emissions of air pollutants from FMEF are relatively small in comparison to those associated with FFTF supporting equipment. Therefore, all the air concentrations shown in Table 2–12 for Alternatives 2 through 5 are negative to represent an overall decrease in the emission of air pollutants.

Air quality concentrations for FFTF and FMEF were calculated with the SCREEN3 model developed by EPA. The model is intended to provide conservative estimates of the concentrations of air pollutants emitted from point or extended sources. Concentrations shown under Alternatives 2 through 5 were obtained by summing estimated emissions from the diesel-driven oil pumps, the oil-fired preheaters, and the gas turbine. Because

a. The more stringent of the Federal and state standards is presented if both exist for the averaging period. The National Ambient Air Quality Standards (NAAQS) (40 CFR Part 50), other than those for ozone, particulate matter, and lead, and those based on annual averages, are not to be exceeded more than once per year. The 24-hour PM<sub>10</sub> (particulate matter with an aerodynamic diameter less than or equal to 10 micrometers) standard is attained when the expected number of days with a 24-hour average concentration above the standard is equal to or less than 1. The annual arithmetic mean PM<sub>10</sub> standard is attained when the expected annual arithmetic mean concentration is less than or equal to the standard.

b. Federal and state standard.

c. Federal standard currently under litigation.

d. State standard.

e. For descriptions of the options under each alternative, see Section 2.5.

**Source:** Modeled increments are based on the SCREEN3 computer code (EPA 1995); additional data from Nielsen 2000.

these sources operate intermittently and do not necessarily operate at the same time, estimates of the concentrations of air pollutants shown in Table 2–12 are conservative because they were obtained under the assumption that all supporting equipment for FFTF would operate simultaneously, which is considered a worst-case scenario.

**Generic Site for the New Accelerator(s).** Under Alternative 3 (all options), air quality impacts at the site for the new accelerator(s) would result from the operation of emergency diesel generators for the high-energy accelerator and any support facilities. The low-energy accelerator would not require emergency diesel power, and it was assumed in the analysis that air quality effects of the low-energy accelerator could be ignored. Air quality impacts of the support facilities would be assessed if Alternative 3 (Construct New Accelerator[s]) were selected for implementation. Column 4 of **Table 2–13** shows estimated air pollutant concentrations at the

generic site that would result from operation of emergency diesel generators. In comparison with the air quality concentrations that would be expected during construction (Table 2–8), air quality impacts resulting from operation of the diesel generators would be relatively small. All of the expected concentrations resulting from operation of emergency generators would be small in comparison with the most stringent ambient air quality standards shown in column 3 of Table 2–13, and would not be expected to result in air pollutant concentrations in excess of ambient air quality standards. If the new accelerator(s) were located in an area that has high background pollutant concentrations, diesel emissions could result in pollutant concentrations in excess of the ambient standards. If Alternative 3 were selected for implementation, site-specific environmental documentation would be prepared prior to site selection.

**Table 2–13 Air Pollutant Concentrations Expected from Operation of the Emergency Diesel Generators for the High-Energy Accelerator**

Pollutant	Averaging Period	Most Stringent Standard or Guideline (micrograms per cubic meter) <sup>a</sup>	Modeled Increment (micrograms per cubic meter)
Carbon monoxide	8 hours	10,000	94
	1 hour	40,000	135
Nitrogen oxide	Annual	100	0.47
PM <sub>10</sub>	Annual	50	0.03
	24 hours	150	17.7
Sulfur dioxide	Annual	80	0.03
	24 hours	365	16.5
	3 hours	1,300	37.2

### 2.7.1.5 Socioeconomics

As discussed in Chapter 4, implementation of the nuclear infrastructure alternatives would have no significant impact on regional economic areas or community services at Hanford, INEEL, and ORR. Socioeconomic impacts at the generic sites could not be evaluated in detail because areas potentially affected under Alternatives 3 and 4 could vary widely in demographic and economic composition. If Alternatives 3 or 4 were selected for implementation, site-specific environmental analysis would be conducted prior to site selection. **Table 2–15** shows the number of direct jobs that would be generated under implementation of the nuclear infrastructure alternatives. Deactivation of FFTF under Alternatives 2 through 5 would result in the loss of 242 jobs that are required to keep the facility in standby condition. That loss would be offset under alternatives and options for which FMEF would support the production of plutonium-238 (62 direct jobs).

### 2.7.1.6 Transportation Impacts

As stated in Section 2.4.2 and explained in Section 4.2.1.1, the transportation impacts for Option 1 of the No Action Alternative are those resulting from transporting 175 kilograms (385 pounds) (5 kilograms [11 pounds] per year for the 35-year evaluation period) of plutonium-238 from Russia to LANL. The impacts were obtained by extrapolating the impact analysis presented in the *Environmental Assessment of the Import of Russian Plutonium-238* (DOE 1993) for the purchase of 40 kilograms (88.2 pounds) of plutonium-238. The impacts presented for the other options of the No Action Alternative include those of Option 1 plus the impact from transporting neptunium oxide from SRS to the selected facilities at ORNL, INEEL, and Hanford. Because the assumptions and data used to assess the transportation impacts in the above environmental assessment are different from those used in this NI PEIS, incremental transportation impacts compared to the baseline condition (Option 1 of the No Action Alternative) can only be presented for the options under the No Action Alternative. Therefore, the transportation impacts presented in this section are not compared to the baseline condition.

Radiological and nonradiological transportation impacts over the 35-year program duration are summarized in **Table 2–16**. Risks to the public and workers due to incident-free transportation are shown in columns 3 through 5 of the table. Columns 6 and 7 summarize radiological and nonradiological risks to the public that could result from transportation accidents. Chapter 4 and Appendix J discuss transportation impacts in more detail.

**Table 2–15 Comparisons Among Alternatives: Change in Direct Jobs Under the Nuclear Infrastructure Alternatives**

a. For descriptions of the options under each alternative, see Section 2.5.

## RADIOLOGICAL TRANSPORTATION RISKS

**Figure 2–27** illustrates the data listed in column 6 of Table 2–16. The results indicate a large risk to the public due to transportation accidents that could occur over 35 years under implementation of Alternatives 1 (Restart of FFTF), 3 (Construct New Accelerator[s]), and 4 (Construct New Research Reactor) as compared to those from implementation of Alternative 2 (Use Only Existing Operational Facilities). This large difference is due to the more than 8,000 medical isotope shipments by air transport considered under Alternatives 1, 3, and 4, and not under Alternative 2. As explained in Appendix J and the Transportation sections in Chapter 4, nearly all of the radiological and traffic accident risk are due to those involving medical and industrial isotope shipments. No enhancement of medical and industrial isotope production is considered under Alternative 2.

Implementation of Alternative 5 (Permanently Deactivate FFTF [with No New Mission]) would not result in any new transportation activities.

**Table 2–16 Comparison Among Alternatives: Impacts of Transportation on Occupational and Public Health and Safety**

Options <sup>a</sup>	Transportation Distance (millions of kilometers)	Incident-Free Transportation over 35 Years			Transportation Accidents over 35 Years

a. For descriptions of the options under each alternative, see Section 2.5

b. No radiological spill.

c. No new transportation activities would occur under Alternative 5.

**Key:** LCF, latent cancer fatalities.

**Figure 2–27 Public Risks Due to Radiological Transportation Accidents (35 Years)**

**Figure 2–28** shows the radiological risks to the public that could result from incident-free transportation over 35 years (column 3 of Table 2–16). For all of the alternatives and options, incident-free radiological transportation risks are approximately 0.2 latent cancer fatality over 35 years. As shown in column 4 of Table 2–16, radiological risks to workers due to incident-free transportation are less than approximately 0.012 latent cancer fatality for all alternatives and options.

#### NONRADIOLOGICAL TRANSPORTATION RISKS

Column 7 of Table 2–16 shows the risks of traffic fatalities that would be expected to result from vehicular collisions in which there is no radiological spill. Under all alternatives and options, the expected number of traffic fatalities would be less than approximately 0.2. Data listed in column 5 of the same table indicates that less than approximately 0.03 fatality would be expected from vehicular exhaust emissions. Fatalities that would be expected to result from both vehicular collisions and exhaust emissions are closely correlated with the estimated highway mileage that would be traveled under implementation of the alternatives (see column 2 of Table 2–16 and **Figure 2–29**). As discussed in Appendix J, traffic accident rates depend on the type of carrier. Both commercial trucks and DOE’s SST/SGTSs would be used for the highway transport of isotopes. Accident rates for the safe, secure trailer system are less than those for commercial trucks by at least a factor of five. As a result, expected collision fatalities for any option would increase the total distance traveled, but the impacts would also depend on relative amounts of transportation by commercial truck and the SST/SGTs.

Figure 2–28 Radiological Risks to the Public Due to Incident-Free Transportation (35 Years)

Figure 2–29 Highway Distances That Would Be Traveled Under the Alternatives (35 Years)

### **2.7.1.7 Resource Areas Discussed in Less Detail**

As discussed in Chapter 4, implementation of the nuclear infrastructure alternatives at existing candidate sites would be expected to have little effect on land use, visual resources, noise, water quality, geology and soils, ecology, cultural resources, and environmental justice. Implementation of the alternatives at one or more generic sites could potentially result in significant impacts in one or more of these resource areas. However, these impacts are site-specific and could not be evaluated in detail in this programmatic document. If Alternative 2 (Options 4, 5, and 6), 3, or 4 were selected for implementation, site-specific environmental documentation would be prepared prior to site selection.

#### **2.7.1.7.1 Land Use**

Implementation of the nuclear infrastructure alternatives at existing operational candidate sites at Hanford, INEEL, and ORR would be consistent with ongoing activities and current land use at these sites. Irradiation of neptunium targets at an existing CLWR would also be consistent with the land use at the reactor site. If Alternatives 3 or 4 were selected for implementation, a site-specific evaluation of land use would be conducted prior to site selection. Deactivation of the FFTF under Alternatives 2 through 5 would have no effect on ongoing land use in the 400 Area of Hanford.

#### **2.7.1.7.2 Visual Resources**

Existing sites that are candidates for implementation of the nuclear infrastructure alternatives are rated Class IV under the U.S. Bureau of Land Management classification guidelines for visual resources (DOI 1986). Selection of one or more of the existing candidate sites for implementation would not affect their visual resource classification as areas in which industrial development dominates the landscape. Use of a CLWR for irradiation of neptunium targets would not alter the appearance of the reactor or the surrounding landscape. Implementation of Alternative 3 (Construct New Accelerator[s]) or 4 (Construct New Research Reactor) could result in reclassification under U.S. Bureau of Land Management guidelines. If Alternative 3 or 4 were selected for implementation, a site-specific evaluation of visual resources would be conducted prior to site selection. Deactivation of FFTF under Alternatives 2 through 5 would not significantly alter the overall landscape in the 400 Area of Hanford.

#### **2.7.1.7.3 Noise**

Noise associated with target fabrication and processing and irradiation at existing candidate sites would be similar to currently existing onsite noise and would not be audible beyond site boundaries. These activities would not produce sudden, loud noises that would startle wildlife. Noise levels that would be generated at a CLWR under Alternative 2 (options 4, 5, and 6) would be the same as those currently existing at the reactor site. Implementation of Alternative 3 (Construct New Accelerator[s]) or 4 (Construct New Research Reactor) would result in construction activities that could disturb nearby residents or wildlife. If Alternative 3 or 4 were selected for implementation, a site-specific NEPA review would be prepared, and an evaluation of potential noise impacts would be conducted prior to site selection. Deactivation of FFTF under Alternative 5 would not significantly alter the noise levels in the 400 Area of Hanford.

#### **2.7.1.7.4 Water Quality**

Under Alternative 1 (Restart FFTF), there would be no liquid radiological effluent pathways to the environment from FFTF. Process wastewater from cooling tower blow-down would be ultimately discharged to the 400 Area Pond (i.e., the 4608 B/C percolation ponds). No impact on the quality of ground or surface

water would be expected. Irradiation of neptunium targets at existing reactors and a generic CLWR would have no measurable effect on the quantity or quality of discharged effluents. Use of existing facilities for target fabrication and processing would not result in direct effluent discharge to the environment, and additional wastewater generation would be relatively small in comparison to existing wastewater treatment volumes at the sites. If Alternative 3 (Construct New Accelerator[s]) or 4 (Construct New Research Reactor) were selected for implementation, construction and operation of new facilities would not be anticipated to significantly impact water quality. While the water quality impacts are expected to be small, a site-specific environmental evaluation of potential water quality impacts and mitigation measures would be conducted prior to site selection. Sodium removal during deactivation of FFTF under Alternatives 2 through 5 would result in approximately 7,600 liters (2,000 gallons) of wastewater that would be disposed of in existing wastewater treatment facilities at Hanford. Deactivation of FFTF would not be expected to impact water quality.

#### **2.7.1.7.5 Geology and Soils**

Except for Alternatives 3 (Construct New Accelerator[s]) and 4 (Construct New Research Reactor), activities conducted under the nuclear infrastructure alternatives would not require construction of new facilities. No soil would be disturbed, and there would be no impacts on the geology of potentially affected sites. Construction of new accelerators and support facilities under Alternative 3 would be expected to disturb up to approximately 27 hectares (66 acres) of soil. If Alternative 4 were selected for implementation, construction of the new reactor and support facility would be expected to disturb approximately 4 hectares (10 acres) of soil. If Alternative 3 or 4 were selected for implementation, a site-specific environmental evaluation would be conducted prior to site selection. Deactivation of FFTF under Alternatives 2 through 5 would take place on previously disturbed land. Impacts of deactivation on geology and soils would be negligible.

#### **2.7.1.7.6 Ecology**

Activities that would be conducted under the nuclear infrastructure alternatives at candidate existing facilities and the generic CLWR would not involve construction of new facilities or significant changes in traffic, noise, air quality, or water quality. In addition, irradiation and processing activities would take place in established industrial areas. Impacts on terrestrial resources and wetlands would be negligible.

Under Alternatives 3 (Construct New Accelerator[s]) and 4 (Construct New Research Reactor), construction of new facilities at a yet-to-be-determined site could potentially have a significant effect on wildlife and wetlands. If Alternative 3 or 4 were selected for implementation, site-specific ecological evaluations would be conducted prior to site selection. The evaluation would include consultation with the U.S. Fish and Wildlife Service and appropriate state authorities concerning threatened and endangered species. Deactivation of FFTF under Alternatives 2 through 5 would take place on previously disturbed land in the 400 Area. No threatened or endangered species are known to reside in the 400 Area, and noise impacts on local wildlife would be temporary.

#### **2.7.1.7.7 Cultural Resources**

Existing candidate facilities that would host activities under the nuclear infrastructure alternatives are located within areas that contain National Historic Landmarks or structures that are eligible for nomination to the National Register of Historic Places. Several candidate facilities are eligible for nomination to the National Register, including the Reactor Containment Building and the Control Building for FFTF at Hanford, RPL at Hanford, and ATR at INEEL. Selection of these facilities to support the nuclear infrastructure missions would not alter their eligibility.

Under the nuclear infrastructure alternatives, activities at candidate existing sites and the generic CLWR would be conducted within existing facilities. Use of the FMEF at Hanford for target fabrication and processing would require construction of a 76-meter-high (250-foot-high) stack on previously disturbed land. Similarly, construction of a support facility for deactivation of the FFTF would take place on previously disturbed land in the 400 Area. Thus, except for Alternatives 3 (Construct New Accelerator[s]) and 4 (Construct New Research Reactor), no disturbance of archeological resources would be expected under the nuclear infrastructure alternatives.

Implementation of Alternative 3 or 4 would require construction on potentially undisturbed lands. If Alternative 3 or 4 were selected for implementation, a site-specific NEPA review would be prepared, and an environmental evaluation of cultural resources would be conducted prior to site selection. The evaluation would include consultation with State Historic Preservation Offices and potentially affected Native American tribes.

#### **2.7.1.7.8 Environmental Justice**

The objective of the environmental justice analysis was to determine whether or not implementation of the nuclear infrastructure alternatives would result in significant environmental impacts that disproportionately affect low-income or minority populations. As discussed throughout Chapter 4, normal operations at the candidate sites and incident-free transportation pose no significant radiological risks to the public or to maximally exposed offsite individuals among the public.

Portions of the Fort Hall Indian Reservation and the Yakama Indian Reservation lie within potentially affected areas surrounding INEEL and Hanford, respectively. As discussed in Appendixes H and I, calculations of radiological risks considered human exposures due to inhalation and ingestion of radioactive materials. Ingestion of contaminated fish, vegetation, and/or wildlife is an environmental justice consideration due to potential patterns of subsistence consumption for minority or low-income populations (CEQ 1997:sec 4-4). Radiological health models used in the environmental evaluation assumed accidents at the irradiation facilities or the fabrication and processing facilities would contaminate all of the food produced in the area, and that all of the contaminated food would be consumed by persons residing in the potentially affected area. As discussed in Sections K.5.1 through K.5.3, the expected risk that would result from ingestion of radiologically contaminated food for persons residing near Hanford would be approximately 0.004 latent cancer fatality and essentially zero for persons residing near the INEEL or ORR. Thus, no credible pattern of food consumption would be expected to result in a significant health risk to low-income or minority populations residing within potentially affected areas surrounding the existing candidate sites. As explained in various parts of Section 2.7.1 and detailed in Chapter 4, implementation of the alternatives would not be expected to result in significant environmental impacts in any of the environmental resource areas. Thus, no disproportionately high and adverse impacts on minority and low-income populations would be expected to result from implementation of the alternatives.

As discussed in Chapter 4, accidents at candidate fabrication and processing facilities and during transportation of radioisotopes by aircraft were found to pose the largest risks to the public. Under conservative assumptions described in Appendix I, no latent cancer fatalities due to accidents would be expected at the existing sites. Accidents during air transport of radioisotopes could occur anywhere along the flight path and would not place any identifiable group within the general population at disproportionate risk.

The density and distribution of total, low-income, and minority populations varies from site to site, so that evaluations of environmental justice are necessarily site-specific. If Alternatives 3 (Construct New Accelerator[s]) or 4 (Construct New Research Reactor) were selected for implementation, a site-specific NEPA

review would be prepared, and an evaluation of environmental justice would be conducted prior to site selection. The evaluation would include patterns of food consumption that could result in disproportionately high and adverse effects on low-income or minority populations at risk.

### 2.7.1.8 Industrial Safety

Estimates of potential industrial impacts to workers during construction, irradiation, fabrication and processing were evaluated based on DOE and Bureau of Labor Statistics data. Impacts are classified into two groups: total recordable cases and fatalities. A recordable case includes work-related death, illness, or injury which resulted in loss of consciousness, restriction of work or motion, transfer to another job, or required medical treatment beyond first aid. The industrial safety evaluation is discussed in more detail in Section I.3.

The average occupational total recordable cases and fatality rates for construction and operation activities are presented in **Table 2–17**.

**Table 2–17 Average Occupational Total Recordable Cases and Fatality Rates (per worker-year)**

Labor Category	Total Recordable Cases	Fatalities
Construction	0.053	$1.3 \times 10^{-4}$
Operation	0.033	$1.3 \times 10^{-5}$

The expected impacts (both annual and for the duration of the activity) to workers at each facility for construction and operation are presented in **Table 2–18**.

**Table 2–18 Industrial Safety Impacts from Construction and Operation**

Facility	Estimated Number of Workers	Construction or Operation Duration (years)	Expected Annual Total Recordable Cases	Expected Activity Duration Total Recordable Cases	Annual Fatalities	Activity Duration Fatalities
<b>Construction</b>						
Low-energy accelerator	75	3	4.0	12	0.010	0.030

a. No additional workers would be required for the proposed activities evaluated in this NI PEIS.

No fatalities would be expected from either construction or operation of any facility.

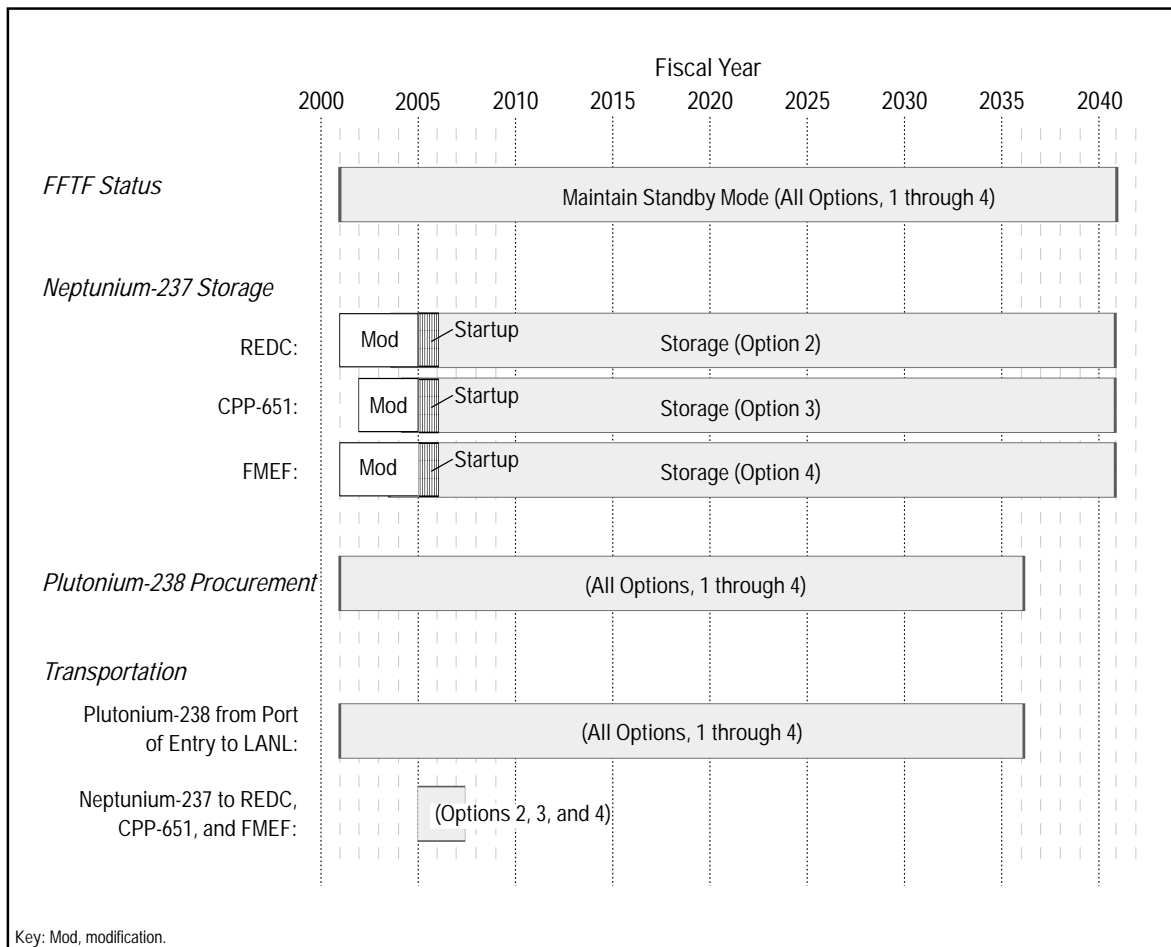

### 2.7.2 Implementation Schedule

The implementation schedules for the alternatives in this NI PEIS are presented in **Figures 2–30** through **2–35**.

#### No Action Alternative

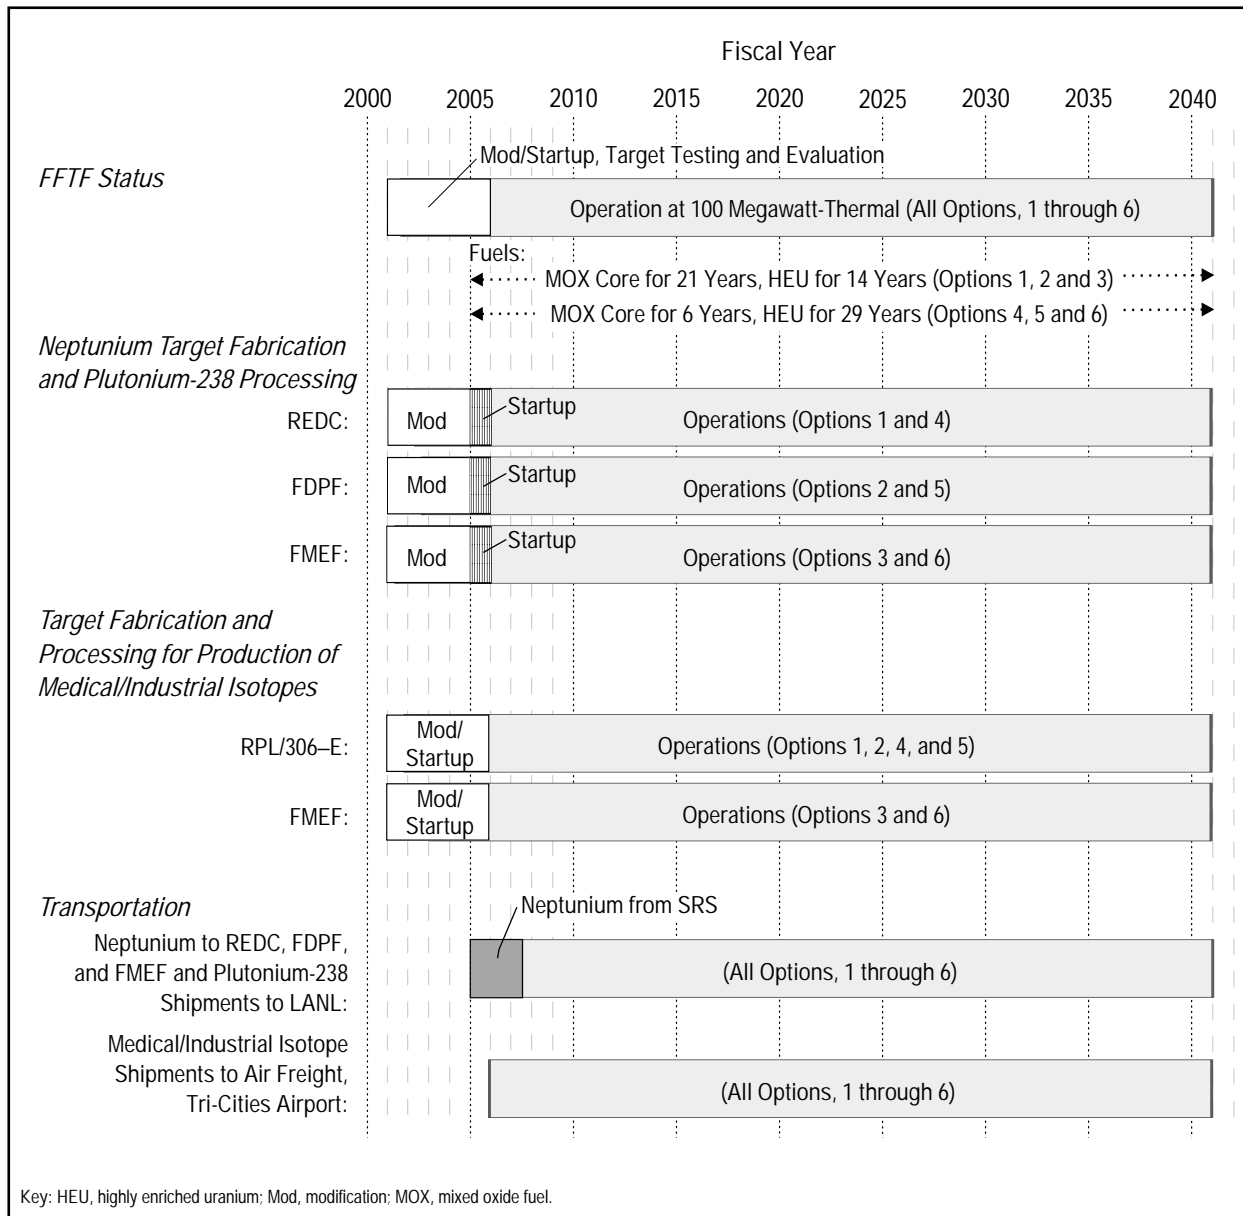

The implementation schedule for the No Action Alternative is shown in **Figure 2–30**. As indicated, the design and construction for the storage facilities would start during fiscal years 2001 and 2002 and would be completed during fiscal year 2004. Neptunium-237 shipments from SRS would take place during fiscal years 2005 to 2007. The purchase of plutonium-238 from Russia would start during fiscal year 2001.

**Figure 2–30 Implementation Schedule for No Action Alternative**

#### Alternative 1—Restart FFTF

The planned implementation schedule for Alternative 1 is shown in **Figure 2–31**. As indicated, facility modification, design, and construction at target fabrication and processing facilities would take place during fiscal years 2001 to 2005.

**Figure 2-31 Implementation Schedule for Alternative 1**

As shown in Figure 2-31, target fabrication and processing at REDC, FDPF, and FMEF were assumed to begin in fiscal year 2006 and would continue through fiscal year 2040 in conjunction with target irradiation at FFTF. Target testing and evaluation and facility testing and startup were assumed to take place in fiscal year 2005 at FFTF.

### Alternative 2—Use Only Existing Operational Facilities

The planned implementation schedule for Alternative 2 is shown in **Figure 2-32**. As indicated, facility modification, design, and construction at storage and target fabrication and processing facilities would take place during fiscal years 2001 to 2004. It was assumed that reactor facilities would not require any modifications to irradiate targets.

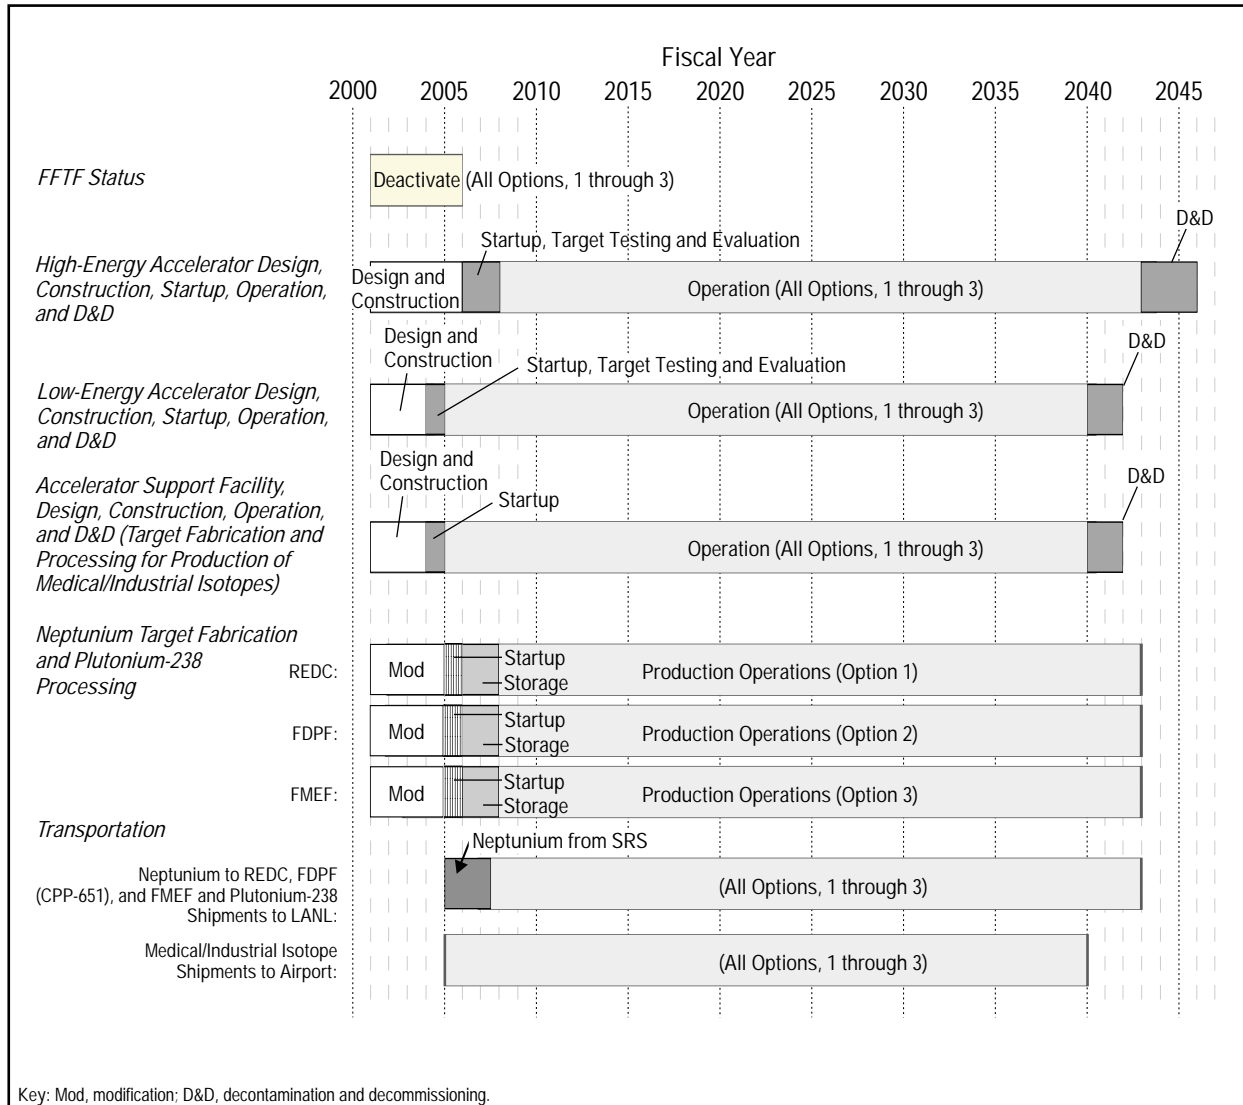

**Figure 2–32 Implementation Schedule for Alternative 2**

As shown in Figure 2–32, target fabrication and processing at REDC, FDPF, and FMEF were assumed to begin in fiscal year 2006 and would continue through fiscal year 2040 in conjunction with target irradiation at HFIR and/or ATR, and through fiscal year 2042 in conjunction with target irradiation at the CLWR. Target testing and evaluation and facility testing and startup were assumed to begin in fiscal year 2005 for each of the nuclear reactors and to continue to fiscal year 2006 at HFIR and/or ATR, and to fiscal year 2008 at the CLWR. Irradiation operations at nuclear reactor facilities would occur from fiscal year 2006 through fiscal year 2040 at HFIR and/or ATR, and from fiscal year 2008 through fiscal year 2042 at the CLWR.

Deactivation of FFTF would begin in fiscal year 2001 and continue through fiscal year 2006.

### Alternative 3—Construct New Accelerator(s)

The planned implementation schedule for Alternative 3 is shown in **Figure 2–33**.

**Figure 2–33 Implementation Schedule for Alternative 3**

The new low-energy accelerator design and construction were assumed to begin fiscal year 2001 and continue to 2004, startup would be completed during fiscal year 2004, and full operation would commence fiscal year 2005. The new support facility schedule is driven by the reactor schedule and has similar schedule milestones. The new low-energy accelerator and support facility would be decontaminated and decommissioned within 2 years after completion of the missions.

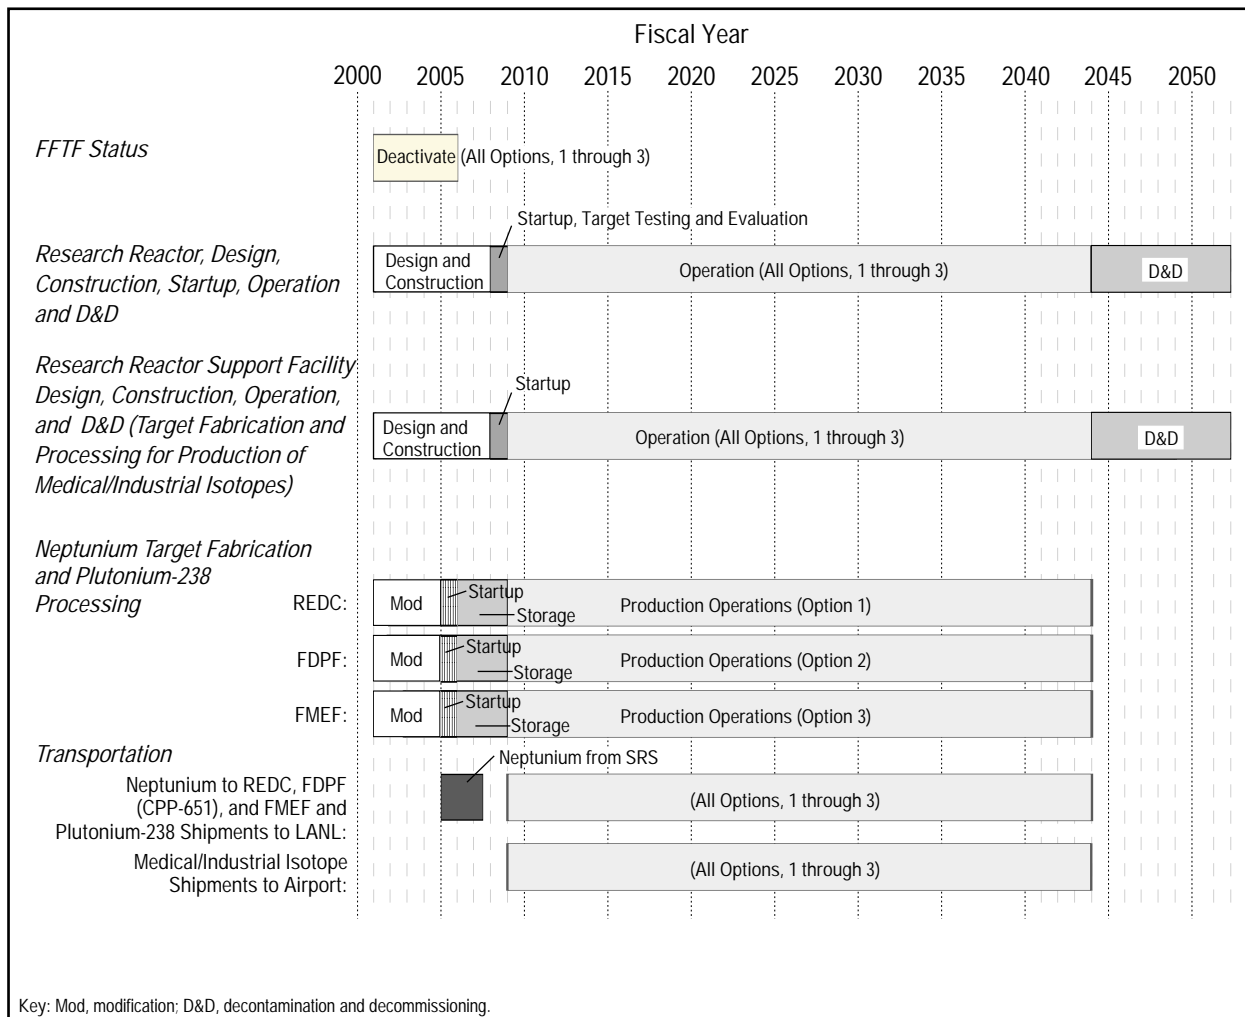

As shown in Figure 2–33, the new high-energy accelerator design and construction were assumed to begin fiscal year 2001 and continue through 2006. The 2-year startup period would be completed during fiscal year 2007, and full operation would commence fiscal year 2008. The neptunium-238 target fabrication and processing facility (REDC, FDPF, or FMEF) modification design would take place during fiscal years 2001

to 2004 and start receiving neptunium-237 from SRS during fiscal year 2005. These facilities would be in full operation supporting the new high-energy accelerator irradiation of the neptunium-237 targets during fiscal year 2008. The new high-energy accelerator would be decontaminated and decommissioned within 3 years after completion of the mission.

Deactivation of FFTF would begin in fiscal year 2001 and continue through fiscal year 2006.

### Alternative 4—Construct New Research Reactor

The planned implementation schedule for Alternative 4 is shown in **Figure 2–34**.

**Figure 2–34 Implementation Schedule for Alternative 4**

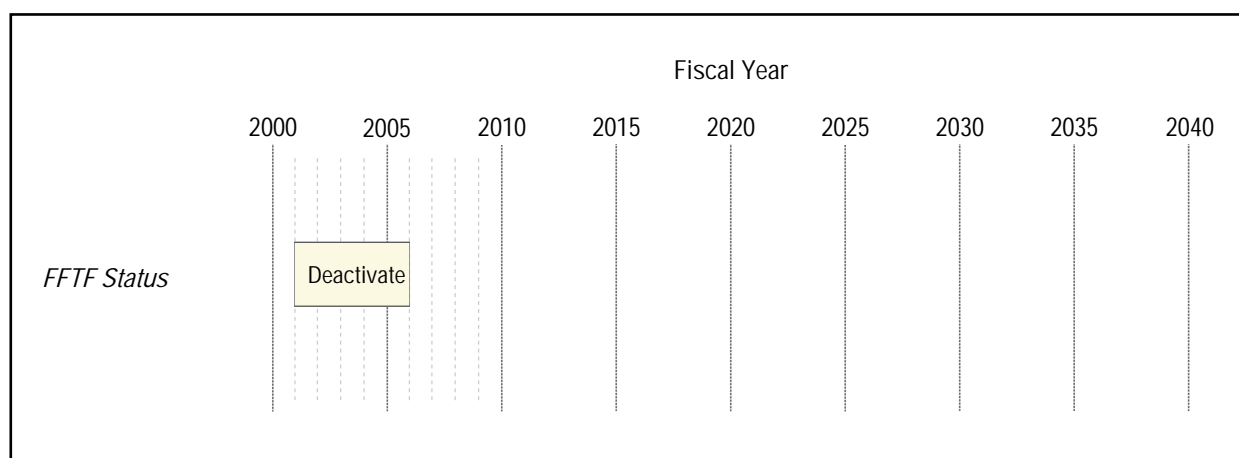

The new research reactor design and construction were assumed to begin fiscal year 2001 and continue to 2008, startup would be completed during fiscal year 2008, and full operation would commence fiscal year 2009. The new support facility schedule is driven by the reactor schedule and has similar schedule milestones.

As shown in Figure 2–34, the neptunium-238 target fabrication and processing facility (REDC, FDPF, or FMEF) modification design would take place during fiscal years 2001 to 2004 and start receiving neptunium-237 from SRS during fiscal year 2005. These facilities would be in full operation supporting the new reactor irradiation of the neptunium-237 targets during fiscal year 2009. The new research reactor and support facility would be decontaminated and decommissioned within 8 years after completion of the missions.

Deactivation of FFTF would begin in fiscal year 2001 and continue through fiscal year 2006.

**Alternative 5—Permanently Deactivate FFTF (with No New Missions)**

The planned implementation schedule for Alternative 5 is shown in **Figure 2–35**. As indicated, deactivation of FFTF would take place over 5 years (Battelle 1999).

**Figure 2–35 Implementation Schedule for Alternative 5**

**2.7.3 Comparison of Mission Effectiveness Among Alternatives**

This section compares the effectiveness of Alternatives 1, 2, 3, and 4 in supporting the three missions evaluated in this NI PEIS:

- Medical and industrial isotope production
- Plutonium-238 production to support NASA space missions
- Nuclear energy research and development for civilian applications

**Table 2–19** lists the medical isotopes that were included in the Expert Panel’s forecast of future demands (Wagner et al. 1998), and identifies their means of production using accelerators, reactors, or separation from existing stockpiles of radioisotopes. Consistent with the panel’s report, the list of isotopes is presented in three categories: proven medical isotopes currently used in clinical applications, those under development for clinical applications, and radioisotopes that have shown promise during medical research. Some are most suited for production in an accelerator, some in a nuclear reactor, and some are harvested by chemical separation from existing stockpiles of long-lived radioactive isotopes. Those isotopes that can be harvested from existing stockpiles of radioactive isotopes require only hot cells for the extraction process; neither accelerators or nuclear reactors are necessary for their production.

No single production method would satisfy all of the Expert Panel’s projected requirements for medical isotopes. Isotopes produced by neutron capture are typically provided by a reactor, but could be produced by

**Table 2–19 Medical Isotopes and Their Means of Production**

Isotope <sup>a</sup>	Accelerator-Produced	Reactor-Produced	Separation from Existing Stockpiles of Radioactive Isotopes
<b>Proven Isotopes Currently Used in Clinical Applications That Face Supply and Cost Concerns</b>

Bismuth-213	(b)	●	● <sup>e</sup>
Radium-223	(b)	●	● <sup>f</sup>

a. Wagner et al. 1998.

b. These isotopes are produced by neutron capture and could be produced in a high-energy accelerator. However, this capability has not been included in the design, analysis, or cost estimates of Alternative 3.

c. Sufficient supplies of this isotope are available from Canadian suppliers.

d. Bismuth-212 is a progeny of thorium-232.

e. Bismuth-213 is a progeny of uranium-233.

f. Radium-233 is a progeny of protactinium-231.

**Key:** α, efficient means of production with an alpha particle accelerator; ●, efficient means of production.

a high-energy accelerator with a spallation neutron source. Accelerator production of these isotopes would be relatively inefficient, and might not be practical to provide the large quantities needed to meet clinical demands. The proposed high-energy accelerator described in this NI PEIS could be modified to provide such capability, but this would add to the design, construction, and operating complexity, would require an increase in particle energy greater than 1 gigaelectron volts, and would increase the capital and operating costs.

Bismuth and radium isotopes, which were identified as promising medical isotopes by the Expert Panel, are currently harvested from existing stockpiles of long-lived radioisotopes and can also be readily produced in a reactor.

### **Alternative 1—Restart FFTF**

FFTF would produce high-energy neutrons and a large flux level ( $10^{15}$  neutrons per square centimeter per second) that can be tailored to nearly any desired energy level. FFTF would provide the greatest flexibility for both isotope production and nuclear-based research and development among the baseline configurations for all of the proposed alternatives. Due to its large core size, flux spectrum, demonstrated testing capability, and rated power level, it would be able to concurrently support the projected plutonium-238 needs, production of medical and industrial isotopes, and civilian nuclear energy research and development related to a broad range of materials, advanced reactors, advanced fuels, and waste transmutation.

### **Alternative 2—Use Only Existing Operational Facilities**

Due to current mission commitments at the existing DOE facilities, a large portion of the reactor irradiation space is committed to existing users. The existing reactors are able to provide for the current plutonium-238 needs. However, fulfilling this requirement with these facilities would use most, if not all, excess capacity, and may require some non-Federal missions to be terminated. The ability to expand the medical and industrial isotope production would require some current missions to be postponed or terminated. If the CLWR were used for plutonium-238 production, then the existing facilities would gain additional margin for medical and industrial isotope production and limited civilian nuclear energy research and development activities. These facilities have primary missions with sponsors who reserve the right to dictate to what degree and the times the facility could be used.

### **Alternative 3—Construct New Accelerator(s)**

One or two accelerators, a low-energy accelerator and/or a high-energy accelerator, are proposed for Alternative 3. The low-energy accelerator would serve as a dedicated isotope production facility. Due to the nature of this type of accelerator, it could only produce a limited number of the isotopes listed in Table 2–19, it has no ability to satisfy the plutonium-238 needs, and a limited ability to support the proposed nuclear-based research and development needs. The preconceptual design of the high-energy accelerator presented in Appendix F focused on supporting the plutonium-238 production mission. The design of the high-energy accelerator could be refined and expanded to perform additional missions such as the production of a select set of medical and industrial radioisotopes. In addition, DOE is aware of longer-term concepts that would apply high-energy accelerators to produce “tunable” neutrons in a subcritical assembly. Such a facility could be used to address some of the missions more familiar to reactor facilities and may hold considerable promise for future science and technology research. A facility of this nature could provide unique capabilities in areas such as the testing of many different nuclear system coolant, fuel, and material interactions. The changes required to add additional capability to the high-energy accelerator could be provided, but they would increase the size of the facility, add complexity to the facility design and operation, increase the cost of construction and operation, and potentially require more time for design and construction.

### **Alternative 4—Construct New Research Reactor**

The proposed new research reactor would provide ample neutrons for the production of plutonium-238 and for many of the isotopes listed in Table 2–19. The thermal flux would limit the new research reactor's ability to produce a number of isotopes requiring fast or high-energy neutrons. Its lower flux levels ( $10^{13}$  neutrons per

square centimeter per second) and predominantly thermal flux would limit its ability to support many of the projected nuclear-based research and development needs.

## 2.8 PREFERRED ALTERNATIVE

The Council on Environmental Quality (CEQ) regulations require an agency to identify its preferred alternative(s) in the final programmatic environmental impact statement (40 CFR 1502.14(e)). The preferred alternative is the alternative that the agency believes would fulfill its statutory mission, giving consideration to environmental, economic, technical, and other factors. Consequently, to identify a preferred alternative, DOE has developed information on potential environmental impacts, costs, policy issues, technical risks, and schedule risks for the alternatives under consideration. This NI PEIS provides information on the environmental impacts. Cost, nonproliferation policy, and various technical reports have also been prepared and are available in the appropriate DOE Reading Rooms for public review.

Based on the analysis discussed above, DOE's Preferred Alternative is to apply its existing infrastructure to the extent possible to pursue the missions outlined in this NI PEIS, that is, Alternative 2, Option 7. Under this approach, DOE proposes to consider opportunities to enhance its existing facilities to maximize the agency's ability to address future mission needs.

The Preferred Alternative also addresses the future of FFTF. While DOE recognizes that this facility has unique capabilities, the Department did not receive the commitments from the private sector or other governments that would clearly justify the restart of the facility. Lacking such commitment, DOE would permanently deactivate FFTF under the Preferred Alternative.

Finally, under the Preferred Alternative, DOE proposes to reestablish domestic production of plutonium-238, as needed, to support U.S. space exploration. ATR in Idaho and HFIR in Tennessee would be used, as appropriate, to irradiate targets for this purpose without interfering with either reactor's primary mission. The Preferred Alternative includes processing the irradiated plutonium-238 targets at REDC at ORNL.

In view of the lack of commitments that would justify the restart of FFTF or the construction of new facilities as proposed under Alternatives 3 and 4, DOE anticipates that its current infrastructure will serve the needs of the research and isotope communities for the next several years. In particular, DOE will consider opportunities to enhance its effort to provide medical and research isotopes. If significantly larger amounts of isotopes are required in the future, DOE would rely on the private sector to fulfill these needs.

As a potential option for the longer-term future, DOE proposes to work over the next 2 years to establish a conceptual design for an Advanced Accelerator Applications (AAA) facility. Such a facility, which would be used to evaluate spent fuel transmutation, conduct various nuclear research missions, and ensure a viable backup technology for the production of tritium for national security purposes, was proposed and initial work funded in the fiscal year 2001 Energy and Water Appropriation. If DOE proposes specific enhancements of existing facilities or development of the AAA facility, further NEPA review would be conducted.

## Chapter 3

### Affected Environment

In Chapter 3, the affected environment descriptions are presented to provide the context for understanding the environmental consequences described in Chapter 4. As such, they serve as a baseline from which any environmental changes that may be brought about by implementing the proposed action and alternatives can be identified and evaluated; the baseline conditions are the currently existing conditions. The affected environments at each site are described for the following impact areas: land resources, noise, air quality, water resources, geology and soils, ecological resources, cultural and paleontological resources, socioeconomics, existing human health risk, environmental justice, waste management, and spent nuclear fuel.

#### 3.1 APPROACH TO DEFINING THE AFFECTED ENVIRONMENT

For this *Final Programmatic Environmental Impact Statement for Accomplishing Expanded Civilian Nuclear Energy Research and Development and Isotope Production Missions in the United States, Including the Role of the Fast Flux Test Facility (Nuclear Infrastructure Programmatic Environmental Impact Statement [NI PEIS])*, the candidate sites for neptunium-237 storage, target fabrication, and irradiated target processing facilities to recover plutonium-238 are the Oak Ridge Reservation (ORR), the Idaho National Engineering and Environmental Laboratory (INEEL), and the Hanford Site (Hanford). As described in Chapter 2, the candidate facilities for neptunium-237 storage, target fabrication, and irradiated target processing are the Radiochemical Engineering Development Center (REDC) at ORR, Building 651 and the Fluorinel Dissolution Process Facility (FDPF) at INEEL, and the Fuels and Materials Examination Facility (FMEF) at Hanford. The facilities being considered for irradiation of the neptunium-237 targets are the High Flux Isotope Reactor (HFIR) at ORR, the Advanced Test Reactor (ATR) at INEEL, the Fast Flux Test Facility (FFTF) at Hanford, a generic commercial light water reactor (CLWR), and one or two new accelerators or a nuclear research reactor that would be located at an unspecified existing U.S. Department of Energy (DOE) site.

As described in Chapter 2, the candidate sites for target fabrication and irradiated target processing facilities for industrial and medical isotope production and for research and development are Hanford, and the unspecified DOE site, where one or two new accelerators or a research reactor would be located. The candidate facilities for these target fabrication and irradiated target processing activities would be FMEF in the Hanford 400 Area, other existing processing facilities in the Hanford 300 Area, and a new processing facility located at an existing DOE site where one or two new accelerators or research reactor would be constructed. The sites being considered for research and development irradiation activities and for irradiation of targets for the production of industrial and medical isotopes are Hanford, where FFTF is located, and an unspecified existing DOE site where one or two new accelerators or research reactor would be located.

The affected environment is described for the candidate sites for the following resource areas: land use, visual resources, noise, air quality, water resources, geology and soils, ecological resources, cultural and paleontological resources, socioeconomics, existing human health risk, environmental justice, waste management, and spent nuclear fuel management. No additional spent nuclear fuel would be generated by the operation of HFIR, ATR, or a generic CLWR for neptunium-237 target irradiation; as they would be operating, even if they were not irradiating targets discussed in this NI PEIS. Additional spent nuclear fuel would be generated by the operation of FFTF or a new reactor located on an existing DOE site. Operation of the existing HFIR, ATR, or generic CLWR would continue to generate spent nuclear fuel, which is managed under current planning. New spent nuclear fuel would be generated by the restart of FFTF or a new research reactor located on an existing DOE site. Accordingly, spent nuclear fuel management is addressed in this chapter only in the sections for Hanford and an existing DOE site where a new research reactor would be located.

DOE evaluated the environmental impacts of certain research and development activities, and of industrial isotope, medical isotope, and plutonium-238 production alternatives within defined regions of influence at each

of the candidate sites and along potential transportation routes. The regions of influence are specific to the type of effect evaluated, and encompass geographic areas within which any significant impact would be expected to occur. For example, human health risks to the general public from exposure to airborne contaminant emissions were assessed for an area within an 80-kilometer (50-mile) radius of the proposed facilities. The human health risks of shipping materials between sites were evaluated for populations living along roadways linking the DOE sites. Economic effects such as job and income changes were evaluated within a socioeconomic region of influence that include the county in which the site is located, and nearby counties in which a substantial portion of the site’s workforce reside. Brief descriptions of the regions of influence are given in **Table 3–1**. More detailed descriptions of the region of influence and the methods used to evaluate impacts are presented in Appendix G.

**Table 3–1 General Regions of Influence for the Affected Environment**

Environmental Resources	Region of Influence
Land use and visual resources	The site and the areas immediately adjacent to the site
Noise	The site, nearby offsite areas, access routes to the sites, and the transportation corridors between the sites
Air quality	The site, nearby offsite areas within local air quality control regions, and the transportation corridors between the sites
Water resources	Onsite and adjacent surface water bodies and groundwater
Geology and soils	Geologic and soil resources within the site and nearby offsite areas
Ecological resources	The site and adjacent areas where ecological resources may be affected by construction and/or operation
Cultural and paleontological resources	The area within the site and adjacent to the site boundary
Socioeconomics	The counties where at least 90 percent of site employees reside
Existing human health risk	The site, nearby offsite areas (within 80 kilometers [50 miles] of the site, and the transportation corridors between the sites) where worker and general population radiation, radionuclide, and hazardous chemical exposures may occur
Environmental justice	The minority and low-income populations within 80 kilometers (50 miles) of the site, and along the transportation corridors between the sites
Waste management	Waste management facilities on the site
Spent fuel management	Spent fuel management facilities on the site

At each of the candidate sites, baseline conditions for each environmental resource area were determined for ongoing operations from information provided in previous environmental studies, relevant laws and regulations, and other government reports and data bases. More detailed information of the affected environment at the candidate sites can be found in annual site environmental reports and site National Environmental Policy Act (NEPA) documents.

## **3.2 OAK RIDGE RESERVATION**

ORR, established in 1943 as one of the three original Manhattan Project sites, is located on 13,949 hectares (34,424 acres) in Oak Ridge, Tennessee, and includes the Oak Ridge National Laboratory (ORNL), the Y-12 Plant (Y-12), and the East Tennessee Technology Park. It extends over parts of Anderson and Roane counties. The primary focus of ORNL is to conduct basic and applied scientific research and technology development. Y-12 engages in national security activities and manufacturing outreach to U.S. industries. The mission of the East Tennessee Technology Park is to maintain the infrastructure until decommissioning activities have been completed.

ORNL is one of the country's largest multidisciplinary and multiprogram laboratories and research facilities. Its primary mission is to perform leading-edge nonweapons research and development in energy, health, and the environment. Other missions include production of radioactive and stable isotopes, not available from other production sources; fundamental and applied research and development in sciences and materials development; research involving hazardous and radioactive materials; environmental research; and radioactive waste disposal. These activities are primarily sponsored by various offices within DOE, including the Office of Science; Office of Environmental Management; Office of Environment, Safety and Health; and Office of Nuclear Energy, Science and Technology.

Activities at ORR that are sponsored by the DOE Office of Defense Programs are performed at Y-12, and include storage of uranium and lithium materials and weapons parts; maintenance of the capability to fabricate components for nuclear weapons; dismantlement of nuclear weapon components returned from the national stockpile; processing of special nuclear materials; and special production support to DOE design agencies and other DOE programs.

Environmental management activities are in progress at each of the major facilities within ORR. These activities consist of environmental remediation and restoration, decontamination and decommissioning of surplus facilities, and waste management.

Non-DOE activities conducted at ORR include National Oceanic and Atmospheric Administration missions and programs, which conducts meteorological and atmospheric diffusion research, sponsored by itself and DOE. This work is performed at the Atmospheric Turbulence and Diffusion Laboratory and at field sites on ORR. This laboratory also provides services to DOE contractors and operates the Weather Instrument Telemetry Monitoring System for DOE. ORR also provides support to other Federal agencies such as the U.S. Nuclear Regulatory Commission (NRC), U.S. Environmental Protection Agency (EPA), and others, and private industry in conducting basic scientific research, engineering technology development and transfer, and educational research in the areas of health, environment, and energy.

### **3.2.1 Land Resources**

Land resources include land use and visual resources. Each of these resource areas is described for the site as a whole, as well as for the locations of the proposed activities.

#### **3.2.1.1 Land Use**

Land use may be characterized by its current use and potential for the location of human activities. Natural resource attributes and other environmental characteristics could make a site more suitable for some land uses than for others. Changes in land use may have both beneficial and adverse effects on other resources such as ecological, cultural, geological, aquatic, and atmospheric.

### 3.2.1.1.1 General Site Description

Land bordering ORR is predominantly rural and is used primarily for residences, small farms, forest land, and pasture land. The city of Oak Ridge has a typical urban mix of residential, public, commercial, and industrial land uses. It also includes almost all of ORR. There are four residential areas along the northern boundary of ORR, several of which have houses located within 30 meters (98 feet) of the site boundary.

Generalized land uses at ORR are shown in **Figure 3–1**. Land uses at the site include industrial, mixed industrial, institutional/research, institutional/environmental laboratory, and mixed research/future initiatives. Industrial and mixed industrial areas of the site include ORNL, Y–12, and the East Tennessee Technology Park. The institutional/research category applies to land occupied by central research facilities at ORNL and the Natural and Accelerated Bioremediation Field Research Center in Bear Creek Valley near Y–12. The institutional/environmental laboratory category includes the Oak Ridge Institute for Science and Education. Land within the mixed research/future initiative category includes land that is used or available for use in field research and land reserved for future DOE initiatives. Most mixed research and future initiatives areas are forested. Undeveloped forested lands on ORR are managed for multiple use and sustained yield of quality timber products. Although soils that would be identified as prime farmland occur on the site, that designation is waived because they are within the city of Oak Ridge (DOE 1999a). Only a small fraction of ORR has been disturbed by Federal activities, including the construction and operation of facilities, roadways, or other structures.

A large number of reservation-wide land uses overlay the primary land use categories and are officially designated as mixed uses. The largest mixed use is biological and ecological research in the Oak Ridge National Environmental Research Park, which is on 8,090 hectares (20,000 acres). The National Environmental Research Park, established in 1980, is used by the nation’s scientific community as an outdoor laboratory for environmental science research on the impact of human activities on the eastern deciduous forest ecosystem (DOE 1996b; ORNL 1999). Recently, the Three Bend Scenic and Wildlife Management Refuge Area, on 1,215 hectares (3,000 acres), was set aside by DOE as a conservation and wildlife management area. The area is located in the ORR buffer zone, on Freels, Gallaher, and Solway Bends on the north shore of Melton Hill Lake (DOE 1999b). Additional details on land use plans at the site are provided in the *Oak Ridge National Laboratory Land and Facilities Plan* (LMER 1999).

Proposed short-range projects at ORR include the Composite Materials Laboratory; Laboratory for Comparative and Functional Genomics; Mixed Waste Treatment Facility; Transuranic Waste Treatment Project Facility; Recycle and Materials Processing Facility; Process Waste Treatment Facility; Industrial Landfill Expansion and Upgrades; and Steam Plant Waste Water Treatment Facility. The Spallation Neutron Source Project and the Environmental Management of Waste Management Facility are in early stages of development. DOE completed an environmental assessment for economic development leasing of 387 hectares (957 acres) of land located to the northeast of the East Tennessee Technology Park (DOE 1996a:S-1). The lease is for 40 years (DOE 2000e). The Community Reuse Organization of East Tennessee is currently developing the site as an industrial park. The locations of selected, planned, or proposed projects at ORR are shown in Figure 3–1.

Almost all of ORR lies within the city of Oak Ridge. A small portion of the northwest corner of the site lies outside the city in Roane County. The Oak Ridge Area Land Use Plan (city of Oak Ridge) designates ORR with the following land uses: residential, office/institutional, industrial, public, and undesignated. The city of Oak Ridge zoning ordinance classifies the entire ORR as a Forest, Agriculture, Industry, and Research District. The Roane County zoning ordinance does not classify ORR land; rather, it identifies ORR as a DOE Reservation.

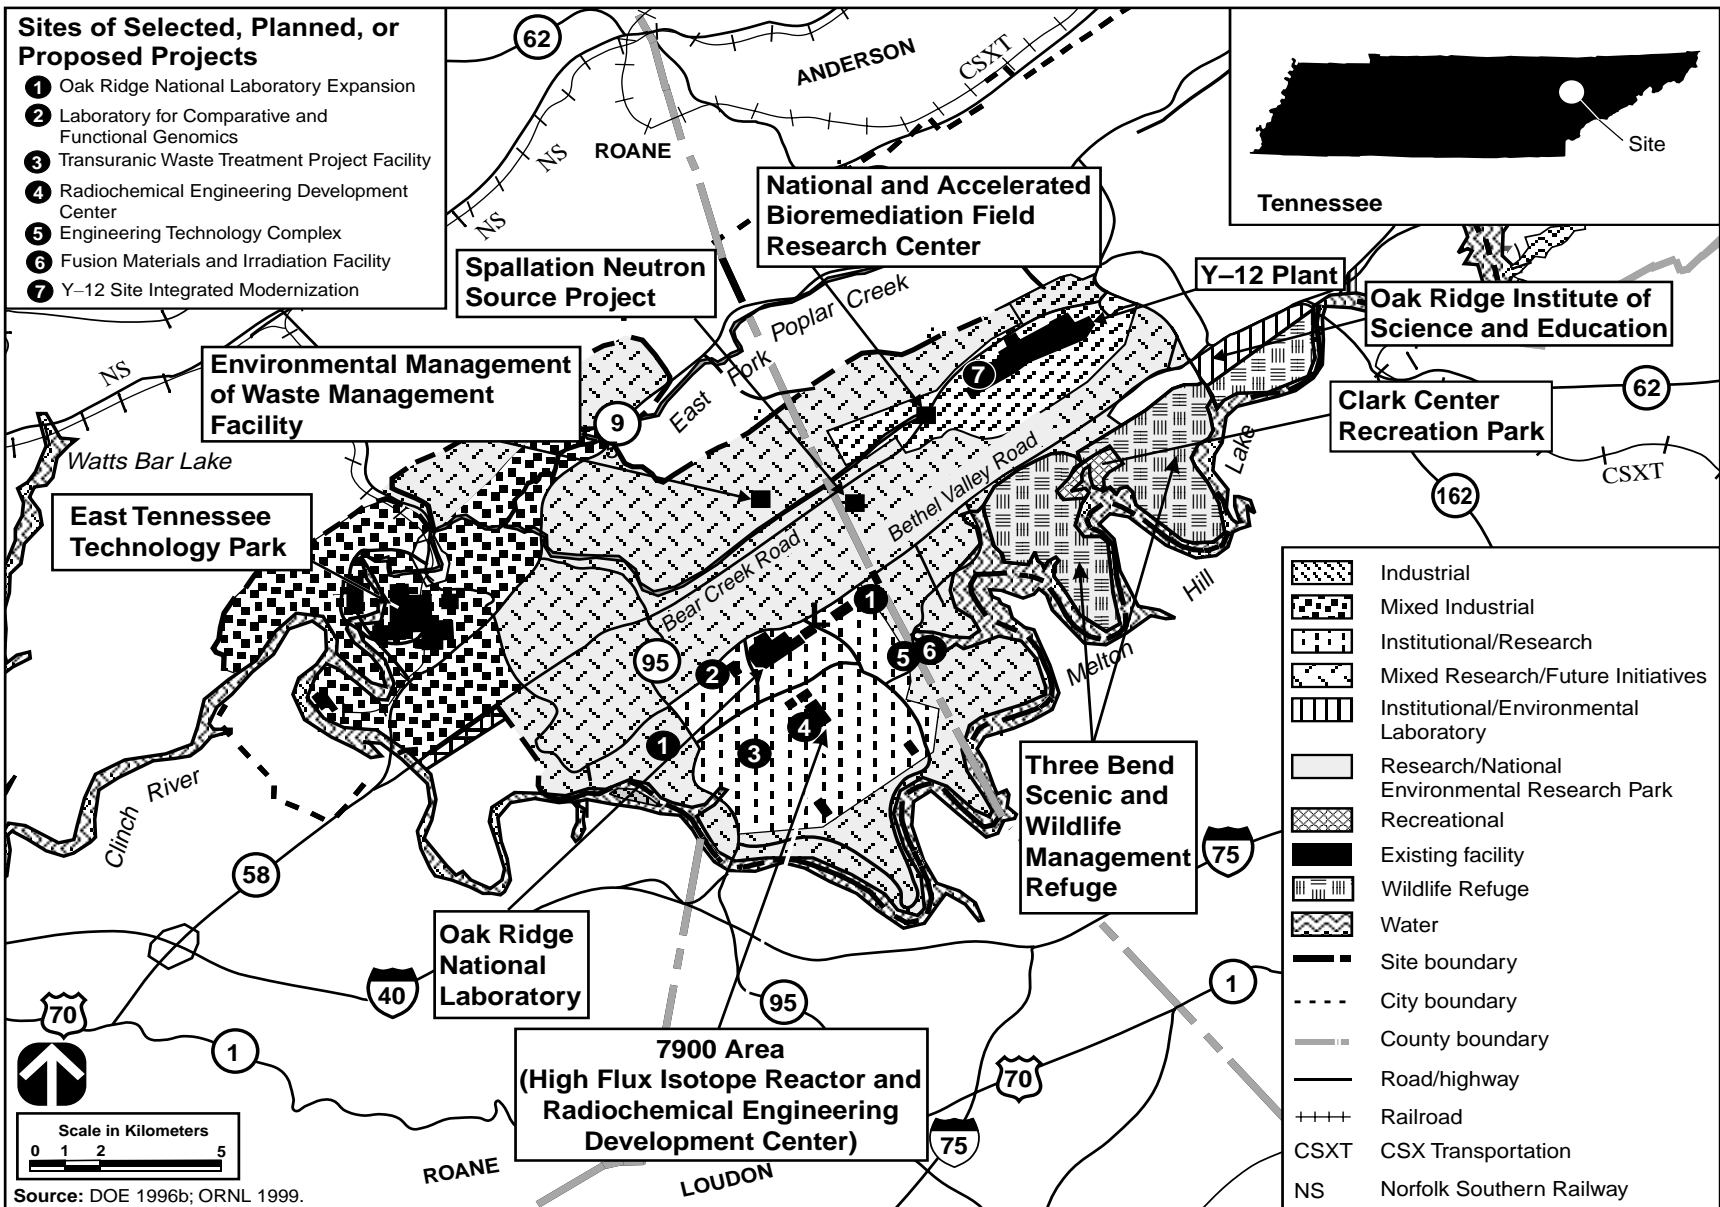

Figure 3-1 Generalized Land Use at Oak Ridge Reservation and Vicinity

### **3.2.1.1.2 Location of Proposed Activities**

ORNL is primarily located within Bethel Valley between Haw and Chestnut Ridges, and covers 1,720 hectares (4,250 acres) of land (ORNL 1999). The site is classified as an industrial area that encompasses a number of facilities dedicated to energy research. REDC and HFIR are in the 7900 Area of ORNL. The 7900 Area is situated on a low ridge in Melton Valley, just to the southwest of Haw Ridge. The nearest public access to the 7900 Area, Bethel Valley Road, is located about 1,500 meters (4,920 feet) to the north, and the nearest residential area is about 4,100 meters (13,450 feet) to the southwest. Land surrounding ORNL is largely forested and is classified as mixed research/future initiatives.

### **3.2.1.2 Visual Resources**

Visual resources are natural and human-created features that give a particular landscape its character and aesthetic quality. Landscape character is determined by the visual elements of form, line, color, and texture. All four elements are present in every landscape. The stronger the influence exerted by these elements in a landscape, the more interesting the landscape.

#### **3.2.1.2.1 General Site Description**

The ORR landscape is characterized by a series of ridges and valleys that trend in a northeast-to-southwest direction. The vegetation is dominated by deciduous forest mixed with some coniferous forest. Most of the original open field areas on the site have been planted in shortleaf and loblolly pine, although smaller areas have been planted in a variety of deciduous and coniferous trees. The DOE facilities are brightly lit at night, making them especially visible. The developed areas of ORR are consistent with the Bureau of Land Management's Visual Resource Management Class IV rating in which management activities dominate the view and are the focus of viewer attention (DOI 1986). The remainder of ORR ranges from a Visual Resource Management Class II to Class III rating. Management activities within these classes may be seen, but should not dominate the view.

The viewshed consists mainly of rural land. The city of Oak Ridge is the only adjoining urban area. Sensitive viewpoints affected by DOE facilities are primarily associated with Interstate 40, State Highways 58, 62, and 95, and Bethel Valley and Bear Creek Roads. The Clinch River/Melton Hill Lake, and the bluffs on the opposite side of the Clinch River also have views of ORR, but views of most of the existing DOE facilities are blocked by terrain and/or vegetation. Although only a small portion of State Highway 62 crosses ORR, it is a major route for traffic to and from Knoxville and other communities. The hilly terrain, heavy vegetation, and generally hazy atmospheric conditions limit views. Partial views of the city of Oak Ridge water treatment plant can be seen from the urban areas of the city of Oak Ridge.

#### **3.2.1.2.2 Location of Proposed Activities**

ORNL is one of several highly developed areas of ORR. As noted above, such areas are consistent with the Bureau of Land Management Visual Resource Management Class IV rating. While a large part of ORNL is visible from Bethel Valley Road, it is not visible to persons in offsite locations because of the presence of the Haw and Chestnut Ridges. The 7900 Area, which is located to the south of the main ORNL complex, is not visible from any public area.

### **3.2.2 Noise**

Noise is unwanted sound that interferes or interacts negatively with the human or natural environment. Noise may disrupt normal activities or diminish the quality of the environment.

### **3.2.2.1 General Site Description**

Major noise emission sources within ORR include various industrial facilities, equipment, and machines (e.g., cooling systems, transformers, engines, pumps, boilers, steam vents, paging systems, construction and materials-handling equipment, and vehicles). Most ORR industrial facilities are a sufficient distance from the site boundary that noise levels at the boundary from these sources are not measurable, or are barely distinguishable from background noise levels (DOE 1996b:3-192).

Sound level measurements have been recorded at various locations within and near ORR in the process of testing sirens and preparing support documentation for the Atomic Vapor Laser Isotope Separation site. The acoustic environment along the ORR site boundary in rural areas and at nearby residences away from traffic noise is typical of a rural location, with average day-night sound levels in the range of 35 to 50 decibels A-weighted (dBA). Areas near the site within Oak Ridge are typical of a suburban area, with the average day-night sound levels in the range of 53 to 62 dBA. Traffic is the primary source of noise at the site boundary and at residences located near roads. During peak hours, the plant traffic is a major contributor to traffic noise levels in the area (DOE 1996b:3-192).

The State of Tennessee has not established specific community noise standards applicable to ORR. The city of Oak Ridge has specific acceptable sound levels at property lines (City of Oak Ridge 1999). EPA guidelines for environmental noise protection recommend a day-night average sound level of 55 dBA as sufficient to protect the public from the effects of broadband environmental noise in typically quiet outdoor and residential areas (EPA 1974:29). Land use compatibility guidelines adopted by the Federal Aviation Administration and the Federal Interagency Committee on Urban Noise indicate that yearly day-night average sound levels less than 65 dBA are compatible with residential land uses (14 CFR Part 150). These guidelines further indicate that noise levels up to 75 dBA are compatible with residential uses if suitable noise reduction features are incorporated into structures. It is expected that for most residences near ORR, the day-night average sound level is less than 65 dBA, and is compatible with the residential land use, although for some residences along major roadways noise levels may be higher.

### **3.2.2.2 Location of Proposed Activities**

No distinguishing noise characteristics within ORNL have been identified. The ORNL 7900 Area is 2.5 kilometers (1.6 miles) from the site boundary; thus, the noise levels at the site boundary from these sources are barely distinguishable from background noise levels.

## **3.2.3 Air Quality**

Air pollution refers to the introduction, directly or indirectly, of any substance into the air that could endanger human health, harm living sources and ecosystems and material property, and impair or interfere with the comfortable enjoyment of life or other legitimate uses of the environment. Air pollutants are transported, dispersed, or concentrated by meteorological and topographical conditions. Air quality is affected by air pollutant emission characteristics, meteorology, and topography.

### **3.2.3.1 General Site Description**

The climate at ORR may be classified as humid continental, but is moderated by the influence of the Cumberland and Great Smoky Mountains. Winters are mild and summers are warm, with no noticeable extremes in precipitation, temperature, or winds (DOE 1996b:3-192). The average annual temperature is 13.7 °C (56.6 °F); average monthly temperatures range from a minimum of 2.2 °C (36 °F) in January to a maximum of 24.9 °C (76.8 °F) in July. The average annual precipitation is 138.5 centimeters (54.5 inches).

Prevailing winds at ORR generally follow the valley, up the valley from the southwest daytime, or down the valley from the northeast nighttime. The wind speed is less than 11.9 kilometers per hour (7.4 miles per hour) 75 percent of the time; tornadoes and winds exceeding 30 kilometers per hour (18 miles per hour) are rare (Hamilton et al. 1999:1-4).

ORR is located in the Eastern Tennessee and Southwestern Virginia Interstate Air Quality Control Region #207. The areas within this Air Quality Control Region are in attainment with respect to the National Ambient Air Quality Standards (NAAQS) for criteria pollutants (40 CFR Section 81.343). Applicable NAAQS and Tennessee State ambient air quality standards are presented in **Table 3–2**.

**Table 3–2 Comparison of Modeled Ambient Air Concentrations from Oak Ridge Reservation Sources with Most Stringent Applicable Standards or Guidelines, 1998**

Pollutant	Averaging Period	Most Stringent Standard or Guideline (micrograms per cubic meters) <sup>a</sup>	ORR Concentration (micrograms per cubic meters)
<b>Criteria pollutants</b>			
Carbon monoxide	8 hours	10,000 <sup>b</sup>	8.05
	1 hour	40,000 <sup>b</sup>	27.1
Nitrogen dioxide	Annual	100 <sup>b</sup>	1.58
Ozone	1 hour	235 <sup>c</sup>	(d)
PM <sub>10</sub>	Annual	50 <sup>b</sup>	1.6
	24 hours	150 <sup>b</sup>	12.7
Sulfur dioxide	Annual	80 <sup>b</sup>	4.86
	24 hours	365 <sup>b</sup>	35.7
	3 hours	1,300 <sup>b</sup>	112.0
<b>Other regulated pollutants</b>			
Total suspended particulates	24 hours	150 <sup>e</sup>	2 <sup>f</sup>

- a. The more stringent of the Federal and state standards is presented if both exist for the averaging period. The National Ambient Air Quality Standards (NAAQS) (40 CFR Part 50), other than those for ozone, particulate matter, and lead, and those based on annual averages, are not to be exceeded more than once per year. The annual arithmetic mean particulate matter with an aerodynamic diameter less than or equal to 10 microns (PM<sub>10</sub>) standard is attained when the expected annual arithmetic mean concentration is less than or equal to the standard.
- b. Federal and state standard.
- c. Federal 8-hour standard is currently under litigation.
- d. Not directly emitted or monitored by the site.
- e. State standard.
- f. Based on stack emissions of particulate matter only.

**Note:** Emissions of hazardous air pollutants not listed here have been identified at ORR, but are not associated with any alternative evaluated. EPA revised the ambient air quality standards for particulate matter and ozone in 1997 (62 FR 38856, 62 FR 38652); however, these standards are under litigation, but could become enforceable during the life of this project.

**Source:** 40 CFR Part 50; Hamilton et al. 1999; TDEC 1999a; modeled site boundary concentrations using 1998 meteorological data and 1998 emissions data.

One Prevention of Significant Deterioration Class I area can be found in the vicinity of ORR. A Class I area is one in which very little increase in pollution is allowed due to the pristine nature of the area. This area, the Great Smoky Mountains, is located 48.3 kilometers (30 miles) southeast of ORR. ORR and its vicinity are classified as a Class II area in which more moderate increases in pollution are allowed. Since the creation of the Prevention of Significant Deterioration program in 1977, no Prevention of Significant Deterioration permits have been issued for any emission source at ORR (DOE 1996b:3-192).

The primary sources of criteria air pollutants at ORR are the steam plants at ORNL, Y-12, and the East Tennessee Technology Park. Other emission sources include the Toxic Substances Control Act incinerator;

various process sources; vehicles, temporary emissions from construction activities; and fugitive particulate emissions from coal piles (DOE 1996b:3-192; Hamilton et al. 1999).

The existing ambient air pollutant concentrations attributable to sources at ORR are presented in Table 3-2. These concentrations are based on dispersion modeling, using emissions for the year 1998 (Hamilton et al. 1999). Only those pollutants that would be emitted by any of the alternatives evaluated in this NI PEIS are presented. As shown in Table 3-2, modeled concentrations associated with ORR emission sources represent a small percentage of the ambient air quality standard.

The closest offsite monitors are operated by the Tennessee Department of Environment and Conservation in Anderson County and the city of Knoxville. In 1999, these monitors reported a maximum 8-hour average carbon monoxide concentration of 4,466 micrograms per cubic meter and maximum 1-hour average concentration of 12,712 micrograms per cubic meter. An annual average particulate matter with an aerodynamic diameter less than or equal to 10 microns (PM<sub>10</sub>) concentration of 30.0 micrograms per cubic meter and a maximum 24-hour average concentration of 71 micrograms per cubic meter were reported. Annual, 24-hour, and 3-hour average sulfur dioxide maximum concentrations of 7.9 micrograms per cubic meter, 78.5 micrograms per cubic meter, and 293 micrograms per cubic meter, respectively, were also reported in 1999 (EPA 2000).

Because ORR sources are limited or background concentrations of criteria pollutants are well below ambient standards, ORR emissions should not result in air pollutant concentrations that violate the ambient air quality standards.

### 3.2.3.2 Location of Proposed Activities

HFIR and REDC are located in the 7900 Area of ORNL. The 7900 Area is situated in Melton Valley, south of the main portion of ORNL, between the Cumberland Mountains to the northwest, and the Great Smoky Mountains to the southeast. Terrain generally consists of ridges and valleys oriented southwest-northeast. The prevailing winds tend to follow this flow (LMER 1998:2.3-1, 2.3-2).

Current nonradiological emissions from the HFIR/REDC facilities are minimal, and result from wet chemistry and laboratory scale activities located at the facility. Additional nonradiological emissions result from maintenance activities inside the facility and in a small shop located adjacent to HFIR/REDC and testing of emergency diesel generators. Current Tennessee Department of Environment and Conservation air pollution control rules do not require that these emissions be permitted or quantified (Smith 2000). The existing ambient air pollutant concentrations attributable to sources at HFIR and REDC are presented in **Table 3-3**. These concentrations are estimated using SCREEN3 and are expected to over estimate the contribution to site boundary concentrations.

The primary sources of nonradiological air pollutants at ORNL include the facility steam plant, discussed in Section 3.2.3.1, and two small oil-fired boilers, which account for 98 percent of all allowable emissions. ORNL has 21 air permits covering 201 air emission sources. In 1998, the Tennessee Department of Environment and Conservation inspected all permitted sources and found them to be in compliance (Hamilton et al. 1999:2-23).

**Table 3–3 Comparison of Modeled Ambient Air Concentrations from Sources at HFIR and REDC with Most Stringent Applicable Standards or Guidelines**

Pollutant	Averaging Period	Most Stringent Standard or Guideline (micrograms per cubic meters) <sup>a</sup>	HFIR/REDC Concentration (micrograms per cubic meters)
<b>Criteria pollutants</b>			
Carbon monoxide	8 hours	10,000 <sup>b</sup>	31.5
	1 hour	40,000 <sup>b</sup>	45.1
Nitrogen dioxide	Annual	100 <sup>b</sup>	0.0072
Ozone	1 hour	235 <sup>c</sup>	(d)
PM <sub>10</sub>	Annual	50 <sup>b</sup>	0.0005
	24 hours	150 <sup>b</sup>	5.96
Sulfur dioxide	Annual	80 <sup>b</sup>	0.0005
	24 hours	365 <sup>b</sup>	5.51
	3 hours	1,300 <sup>b</sup>	12.4
<b>Other regulated pollutants</b>			
Total suspended particulates	24 hours	150 <sup>e</sup>	5.96

- a. The more stringent of the Federal and state standards is presented if both exist for the averaging period. The National Ambient Air Quality Standards (NAAQS) (40 CFR Part 50), other than those for ozone, particulate matter, and lead, and those based on annual averages, are not to be exceeded more than once per year. The annual arithmetic mean particulate matter with an aerodynamic diameter less than or equal to 10 microns (PM<sub>10</sub>) standard is attained when the expected annual arithmetic mean concentration is less than or equal to the standard.
- b. Federal and state standard.
- c. Federal 8-hour standard is currently under litigation.
- d. Not directly emitted or monitored by the site.
- e. State standard.

### 3.2.4 Water Resources

Water resources include all forms of surface water and subsurface groundwater.

#### 3.2.4.1 Surface Water

Surface water includes marine or freshwater bodies that occur above the ground surface, including rivers, streams, lakes, ponds, rainwater catchments, embayments, and oceans.

##### 3.2.4.1.1 General Site Description

The major surface water feature in the immediate vicinity of ORR is the Clinch River, which borders the site to the south and west. There are four major sub-drainage basins on ORR that flow into the Clinch River and are affected by site operations: Poplar Creek, East Fork Poplar Creek, Bear Creek, and White Oak Creek. Several smaller drainage basins, including Ish Creek, Grassy Creek, Bearden Creek, McCoy Branch, Kerr Hollow Branch, and Raccoon Creek, drain directly to the Clinch River (**Figure 3–2**). Each drainage basin takes the name of the major stream flowing through the area. The three major facilities at ORR each affect

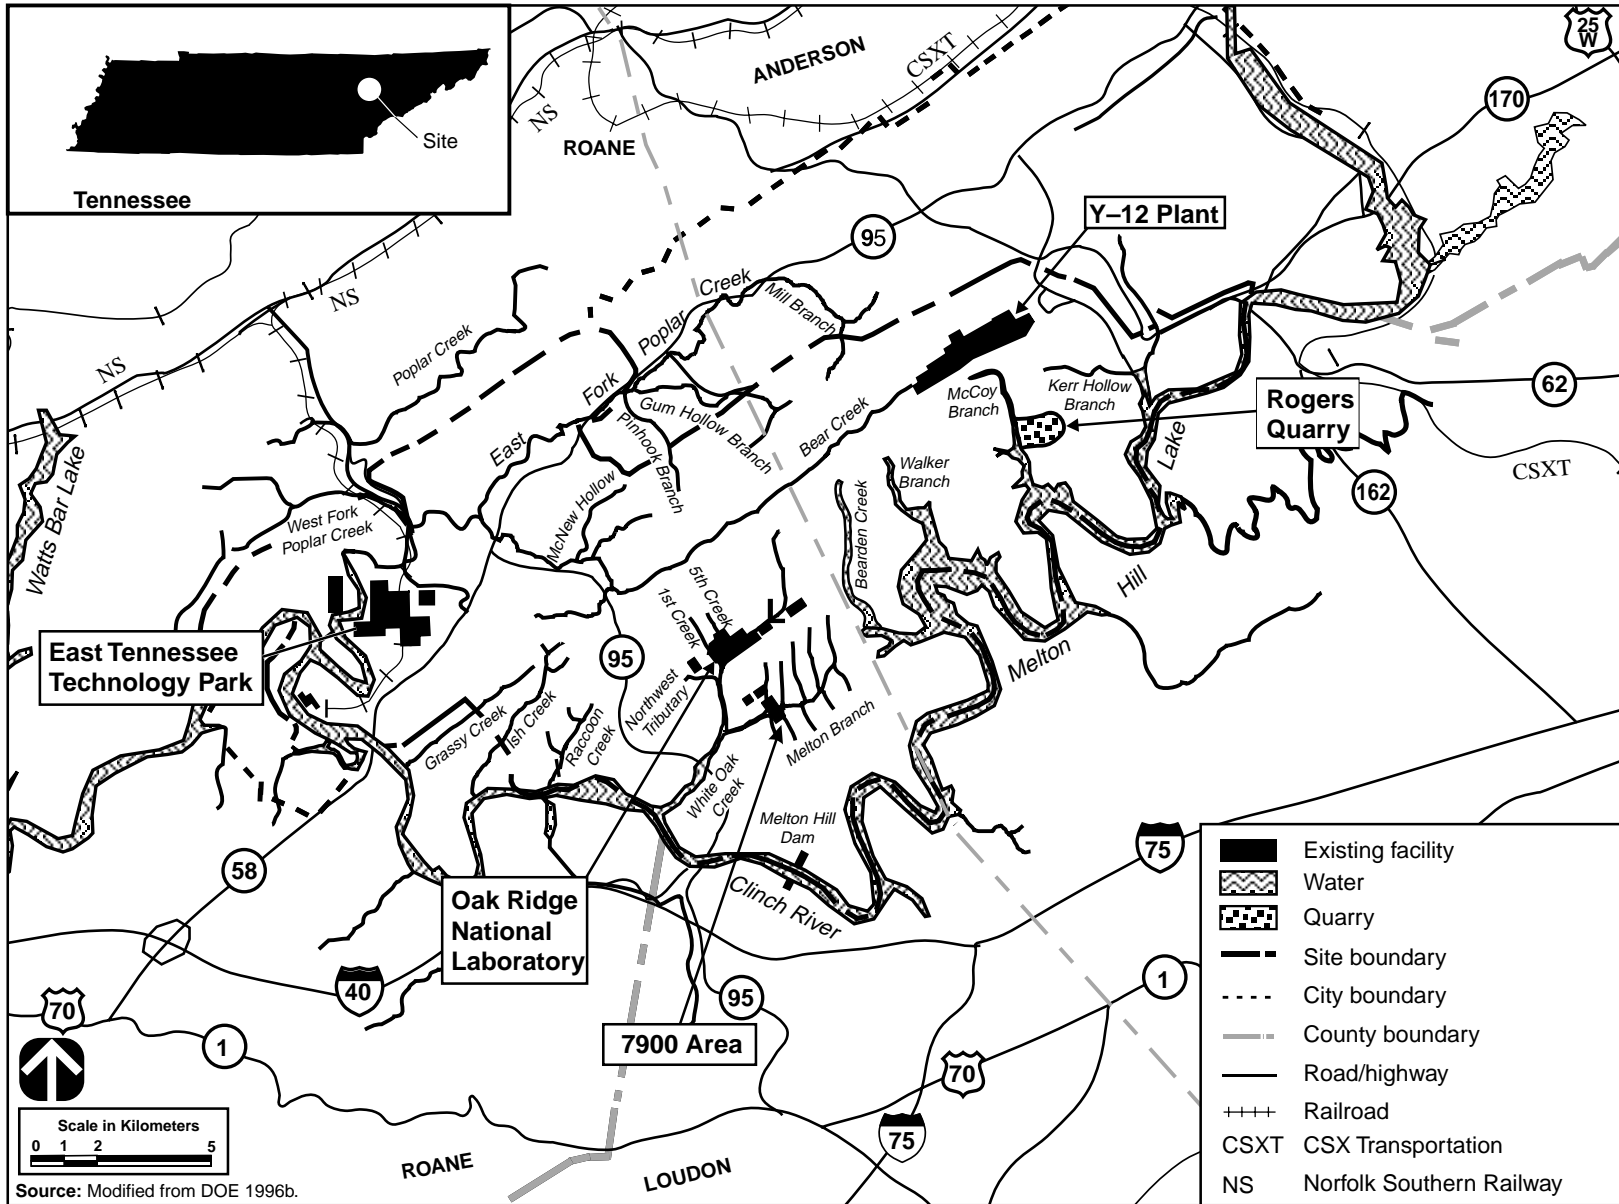

Figure 3-2 Surface Water Features at Oak Ridge Reservation

different basins of the Clinch River. Drainage from Y-12 enters both Bear Creek and East Fork Poplar Creek; the East Tennessee Technology Park drains mainly into Poplar Creek; and ORNL drains into White Oak Creek (DOE 1996b:3-194).

The Clinch River and connected waterways supply the raw water for ORR. The Clinch River has an average flow rate of 132 cubic meters (4,647 cubic feet) per second, as measured at the downstream side of Melton Hill Dam. The average flow rates of Grassy, Ish, and Bear Creeks in the ORR area are 0.08 cubic meters (2.8 cubic feet) per second, 0.05 cubic meters (1.8 cubic feet) per second, and 0.11 cubic meters (3.9 cubic feet) per second, respectively. The average flow rate at East Fork Poplar Creek is 1.46 cubic meters (51.4 cubic feet) per second. Y-12 uses 7,530 million liters (1,989 million gallons) per year of water, and ORR uses 14,210 million liters (3,754 million gallons) per year (DOE 1996b:3-194). The ORR water supply system, which includes the city of Oak Ridge treatment facility (formerly the DOE treatment facility) and the East Tennessee Technology Park treatment facility, has a capacity of 90.8 to 121.5 million liters (24 to 32.1 million gallons) per day (DOE 1996b:3-194; LMER 1999:3-24).

The Clinch River water levels in the vicinity of ORR are regulated by a system of dams operated by the Tennessee Valley Authority. Melton Hill Dam controls the flow of the Clinch River along the northeast and southeast sides of ORR. Watts Bar Dam on the Tennessee River near the lower end of the Clinch River controls the flow of the Clinch River along the southwest side of ORR (DOE 1996b:3-194).

The surface streams of Tennessee are classified by the Tennessee Department of Environmental Conservation according to the Use Classifications for Surface Waters. Classifications are based on water quality, beneficial uses, and resident aquatic biota. The Clinch River is the only surface water body on or near ORR classified for domestic water supply. Unless otherwise specified in these rules, all streams in Tennessee are classified for use for fish and aquatic life, recreation, irrigation, and for livestock watering and wildlife. In addition, the Clinch River and a short segment of Poplar Creek from its confluence with the Clinch River are also classified for industrial water supply use. White Oak Creek and Melton Branch are the only streams on ORR not classified for irrigation (TDEC 1999b). East Fork Poplar Creek is posted by the State of Tennessee with warnings against fishing and contact recreation (O'Donnell 2000).

Wastewater treatment facilities are located throughout ORR, including six treatment facilities at Y-12 that discharge to East Fork Poplar Creek, and three treatment facilities at ORNL that discharge into White Oak Creek Basin. These discharge points are included in existing National Pollutant Discharge Elimination System (NPDES) permits. Y-12 also has a permit to discharge wastewater to the city of Oak Ridge Treatment Facility. The East Tennessee Technology Park operates one sanitary sewage system discharging to Poplar Creek (DOE 1996b:3-196).

There are more than 400 NPDES-permitted outfalls at ORR associated with the three major facilities (Y-12 Plant, East Tennessee Technology Park, and ORNL); many of these are storm water outfalls. ORNL is currently operating under NPDES Permit TN0002941, which was renewed by the Tennessee Department of Environmental Conservation on December 6, 1996, and went into effect on February 3, 1997. This permit lists 164 point-source discharges that require compliance monitoring. Approximately 100 of these are storm drains, roof drains, and parking lot drains. Compliance was determined by approximately 6,500 laboratory analyses and measurements in 1998, in addition to numerous field observations by ORNL field technicians. The NPDES permit compliance rate was nearly 100 percent with only three permit exceedances. The NPDES permit limit compliance rate for all discharge points for the three major facilities in 1998 was over 99 percent (Hamilton et al. 1999:2-18, 2-19).

Compared with the previous permit, the new ORNL NPDES permit includes more stringent limits based on water quality criteria at a number of outfalls. The new permit also requires ORNL to conduct detailed

characterization of numerous storm water outfalls, conduct an assessment and evaluation for the modification of the Radiological Monitoring Plan, develop and implement a Storm Water Pollution Prevention Plan, implement a revised Biological Monitoring and Abatement Program Plan, and develop and implement a Chlorine Control Strategy (Hamilton et al. 1999:2-19).

At ORR, water samples are collected and analyzed from 22 locations around the reservation to assess the impact of past and current DOE operations on the quality of local surface water. Sampling locations include streams, both upstream and downstream of ORR waste sources, and public water intakes. Samples are collected and analyzed for general water quality parameters at all locations, and are screened for radioactivity and analyzed for specific radionuclides, when appropriate. Based on 1998 sampling data, radionuclides were detected at all but two surface water locations, which were dry when sampling was attempted. High levels of radioactivity (gross alpha, gross beta, and total radioactive strontium) relative to applicable standards or criteria detected at First Creek within ORNL are attributed to leakage to backfill and soil from underground waste storage Tank W-1A at ORNL. Uranium isotopes were determined to be the primary alpha emitters. Excluding the First Creek site, the highest levels of gross beta, total radioactive strontium and tritium were detected at White Oak Creek at White Oak Dam and at White Oak Creek and Melton Branch, both downstream from ORNL. These data are consistent with historical data and with process or legacy activities nearby or upstream from these sites. Elevated levels of gross beta and total radioactive strontium have also been detected at Raccoon Creek and Northwest Tributary. Locations that were checked for volatile organic compounds showed either low or undetectable levels. Polychlorinated biphenyls were not detected at either of the two sites sampled. Except for lead in 1 sample, and zinc in 3 samples out of 12 respectively, at the Clinch River upstream from all DOE inputs, no metals of human health concern were detected (Hamilton et al. 1999:7-6, 7-10, 7-11, D-5, D-8, D-11, D-13, D-14).

In Tennessee, the state's water right laws are established under the Water Quality Control Act. In effect, water rights are similar to riparian rights, in that designated usages of a water body cannot be impaired. Before withdrawing water from available supplies, a U.S. Army Corps of Engineers permit to construct intake structures would need to be obtained (DOE 1996b:3-196). In addition, projects and activities with the potential to affect aquatic resources could require permits from the Tennessee Department of Environment and Conservation and the Tennessee Valley Authority (Hamilton et al. 1999:2-20).

The Tennessee Valley Authority has conducted flood studies along the Clinch River, Bear Creek, and East Fork Poplar Creek. Portions of Y-12 lie within the 100- and 500-year floodplain boundaries of East Fork Poplar Creek. Studies have not been performed to delineate the 100- or 500-year floodplain boundaries of Grassy, Ish, and Bear Creeks in the western half of the site (DOE 1996b:3-194).

The Tennessee Valley Authority has performed probable maximum flood studies along the Clinch River. The probable maximum flood is the flood that can be expected from the most severe combination of critical hydrometeorological conditions that are reasonably possible over the entire watershed. The probable maximum flood level along the Clinch River at the mouth of Bearden Creek occurred at elevation 248.3 meters (814.7 feet), while the probable maximum flood level at the mouth of White Oak Creek occurred at elevation 237.5 meters (779.3 feet). Based on the studies, most of ORR is above the probable maximum flood elevation along the Clinch River (LMER 1999:2-8).

#### **3.2.4.1.2 Location of Proposed Activities**

HFIR and REDC are in the 7900 Area on a low ridge in Melton Valley. HFIR overlooks Melton Branch, a tributary of White Oak Creek, with the REDC complex (Buildings 7920 and 7930) just north and upslope of HFIR (LMER 1998:2.4-1). Two reservoir systems supply water to ORNL facilities in Melton Valley and the 7900 Area, in particular, and also to facilities in Bethel Valley. The first is to the north of the 7900 Area on

Chestnut Ridge and consists of a concrete storage reservoir with a capacity of 11.4 million liters (3 million gallons). A project to construct a second 3.8-million-liter (1-million-gallon) storage reservoir adjacent to the existing one is planned. The second system is on Haw Ridge and consists of two steel reservoir tanks, each with a storage capacity of 5.7 million liters (1.5 million gallons). These tanks are designated to provide reserve capacity for HFIR, REDC, and other facilities in Melton Valley. Water usage by ORNL Melton Valley facilities ranges from 9.5 million liters (2.5 million gallons) per day in the winter to a maximum of 18.9 million liters (5 million gallons) per day in the summer. The reservoir distribution system can supply 26.5 million liters (7 million gallons) per day (LMER 1999:3-25). These reservoirs are supplied by the city of Oak Ridge water treatment plant, which receives its water from the Melton Hill Reservoir via a pumping station upstream from HFIR. Either of the two reservoirs is capable of supplying the normal 3,785 liters (1,000 gallons) per minute cooling water requirements of HFIR (Building 7900) (LMER 1998:2.4-1). Based on the most recent water use survey, the HFIR complex (i.e., Buildings 7900–7903, 7910, and 7916) uses a total of approximately 6.1 million liters (1.6 million gallons) of water per day or about 2.23 billion liters (589 million gallons) annually. REDC (Buildings 7920 and 7930) uses approximately 294,000 liters (77,800 gallons) of water per day or 107 million liters (28.4 million gallons) per year (Wham 2000c). The major water demand by both HFIR and REDC is for cooling purposes.

Sanitary wastewater from the 7900 Area is conveyed to the ORNL Sewage Treatment Plant, which provides primary, secondary, and tertiary sewage treatment. The Sewage Treatment Plant has a treatment capacity of 1.1 million liters (300,000 gallons) per day. Since 1997, treated flows have ranged from about 685,000 to 821,000 liters (181,000 to 217,000 gallons) per day (LMER 1999:3-62, 3-63). Specifically, the HFIR complex is estimated to generate about 7.3 million liters (1.93 million gallons) of sanitary wastewater per year with REDC generating an additional 3.1 million liters (828,000 gallons) annually (Wham 2000a).

Process wastewater from HFIR and REDC is collected and conveyed to storage tanks prior to processing in the Process Waste Treatment Complex. Continuous monitoring of the wastewater in the collection system is used to route the wastewater to the appropriate treatment process. The Process Waste Treatment Complex consists of two facilities, Buildings 3544 and 3608, which provide both nonradiological and radiological effluent treatment. Treatment in Building 3608 consists of precipitation, filtration, air stripping, and neutralization to remove particulates, heavy metals, and organics, and to control pH before discharge. A clarifier is also used to perform process wastewater softening prior to transfer to Building 3544 for further treatment. Treatment capacity is 4.2 million liters (1.1 million gallons) per day. Treatment in Building 3544 consists of precipitation, filtration, and ion exchange. The maximum treatment capacity is about 1.9 million liters (504,000 gallons) per day (LMER 1999:3-64, 3-65).

All wastewater treated at Buildings 3544 and 3608 is ultimately discharged to White Oak Creek through a single NPDES-permitted outfall (Outfall X12). The flow rate from this outfall averages about 2.08 million liters (550,000 gallons) per day, of which approximately 66,245 liters (17,500 gallons) per day are attributable to process wastewater from HFIR and REDC. The treated effluent from Outfall X12 meets NPDES water quality-based limits for metals and organics and DOE Derived Concentration Guides (DOE Order 5400.5), and is not toxic to aquatic species based on NPDES-required toxicity testing. HFIR and REDC also discharge dechlorinated cooling water and cooling tower blowdown to Melton Branch through NPDES-permitted outfalls 081 and 281. Discharge from Outfall 281, which is predominantly HFIR cooling tower blowdown, averages about 378,500 liters (100,000 gallons) per day in the warm months. The discharge rate from Outfall 081 averages approximately 265,000 liters (70,000 gallons) per day during the warm months and consists primarily of REDC cooling water (Valentine 2000). Waste management activities and facilities are discussed in greater detail under Section 3.2.11.

Melton Branch, the primary stream in the immediate vicinity of HFIR and REDC, was analyzed to assess the potential for flooding from a locally intense storm, based on probable maximum precipitation events. The

analysis determined that the relatively high elevation of the terrain and slope of the 7900 Area ensures that locally intense precipitation would not cause the Melton Branch to flood equipment at the HFIR site and vicinity. Likewise, the occurrence of a probable maximum flood at the mouth of White Oak Creek or along Melton Branch due to probable maximum precipitation events would not inundate the HFIR and vicinity. Surface runoff and facility drainage flows to either of two headwater tributaries of Melton Branch on the east and west sides, respectively, of the 7900 Area (LMER 1998:2.4-6, 2.4-7).

### 3.2.4.2 Groundwater

Aquifers are classified by Federal and state authorities according to use and quality. The Federal classifications include Classes I, II, and III groundwater. Class I groundwater is either the sole source of drinking water, or is ecologically vital. Classes IIA and IIB are current or potential sources of drinking water (or other beneficial use), respectively. Class III is not considered a potential source of drinking water and is of limited beneficial use.

#### 3.2.4.2.1 General Site Description

ORR is in an area of sedimentary rocks of widely varying hydrologic character. Groundwater flow occurs at shallow depths with discharge to nearby surface waters. Depth to groundwater is generally 5 to 9 meters (16 to 30 feet), but may be as little as 1.5 meters (5 feet). All aquifers are considered Class II (DOE 1996b:3-196).

Two broad hydrologic regimes have been characterized at ORR, each having fundamentally different hydrologic characteristics. The Knox Group and the Maynardville Limestone of the Conasauga Group constitute the Knox aquifer, in which flow is dominated by solution conduits formed along fractures and bedding planes. The less permeable ORR aquitard units constitute the second regime, in which flow is dominated by fractures (DOE 1999a:4-12; Hamilton et al. 1999:1-5, 1-6). These hydrologic groupings and the geologic units comprising them are illustrated in **Figure 3-3**. The combination of fractures and solution conduits in the dolostones and limestones of the Knox aquifer control flow over substantial areas, and rather large quantities of water may move relatively long distances. The Knox aquifer is the primary source of groundwater to many streams (base-flow), and most large springs on ORR receive discharge from the Knox aquifer. Yields of some wells penetrating larger solution conduits are reported to exceed 3,785 liters (1,000 gallons) per minute. Units at ORR constituting the ORR aquitards include the Rome Formation, the Conasauga Group below the Maynardville Limestone, and the Chickamauga Group, and consist mainly of siltstone, shale, sandstone, and thinly bedded limestone of low to very low permeability. The typical yield of a well in the aquitards is less than 3.8 liters (1 gallon) per minute, and the base flows of streams draining areas underlain by the aquitards are poorly sustained because of such low flow rates (Hamilton et al. 1999:1-5).

Subsurface flow in both the Knox aquifer and in the aquitards is recharged mainly on ridges and is discharged into lakes, streams, springs, and seeps (DOE 1999a:4-12). Within ORR, the Knox aquifer underlies some of the major ridges (e.g., Chestnut and Copper Ridge) and aquitard units predominate under the valleys (e.g., Bear Creek, Bethel, and Melton valley) (Hamilton et al. 1999:1-7, 1-8) (**Figure 3-4**). Because of the abundance of surface water and its proximity to the points of use, very little groundwater is used at ORR. Only one water supply well exists on ORR; it provides a supplemental water supply to an ORNL aquatic biology laboratory during extended droughts (DOE 1996b:3-196).

Groundwater samples are collected quarterly from representative wells selected from more than 1,000 monitoring wells throughout ORR. Samples collected from monitoring wells are analyzed for a standard set of parameters, including trace metals, volatile organic compounds, radioactive materials, and acidity/basicity. Background groundwater quality at ORR is generally good in the near-surface aquifer zones, and poor in the bedrock aquifer at depths greater than 305 meters (1,000 feet), due to high total dissolved

Age		Group	Formation	Thickness, meters	Hydrologic Unit	
Ordovician	Upper	Chickamauga Group	Moccasin Formation	100–170	Aquitard	
			Witten Formation	105–110		
			Bowen Formation	5–10		
	Middle		Benbolt/Wardell Formation	110–115	Aquifer	
			Rockdell Formation	80–85

Note: To convert meters to feet multiply by 3.281.

**Figure 3–3 Stratigraphic Column for the Oak Ridge Reservation**

solids (DOE 1996b:3-197). Information on more recent groundwater monitoring and chemical analysis is presented in the annual site environmental report (Hamilton et al. 1999).

Groundwater in the Bear Creek Valley near Y-12 and in the ORNL and East Tennessee Technology Park areas has been locally contaminated by hazardous chemicals and radionuclides from past process activities. The contaminated sites include past waste disposal sites, waste storage tanks, spill sites, and contaminated inactive facilities (DOE 1996b:3-197).

Industrial and drinking water supplies are primarily taken from surface water sources. However, single-family wells are common in adjacent rural areas not served by the public water supply system. Most of the residential wells in the immediate vicinity of ORR are south of the Clinch River (DOE 1996b:3-197).

**Figure 3-4 Geologic Cross Section of the Oak Ridge Reservation**

Groundwater rights in the State of Tennessee are traditionally associated with the Reasonable Use Doctrine. Under this doctrine, landowners can withdraw groundwater as long as they exercise their rights reasonably in relation to the rights of others (DOE 1996b:3-199).

#### 3.2.4.2.2 Location of Proposed Activities

Groundwater sampling performed in 1998 at 11 monitoring wells located in waste area groupings 8 and 9 in Melton Valley, encompassing HFIR and REDC, showed evidence of radioactivity attributable to former effluent-handling practices in the 7900 Area (Smith 2000). Two of the sampled wells exceeded Federal drinking water standards: one well for tritium contamination, and a second well for gross beta activity and total radioactive strontium contamination. Gross alpha activity ranged from undetectable to 6.7 picocuries per liter; the drinking water standard is 15 picocuries per liter. Gross beta activity ranged from undetectable to 1,400 picocuries per liter; the drinking water standard is 50 picocuries per liter. Total radioactive strontium ranged from undetectable to 630 picocuries per liter; the drinking water standard is 8 picocuries per liter. Tritium ranged from undetectable to 53,000 picocuries per liter; the drinking water standard is 20,000 picocuries per liter (Hamilton et al. 1999:5-27, 5-33). Note that groundwater is not used for drinking water at ORNL (Hamilton et al. 1999:5-28). In general, contaminant plumes in groundwater at ORNL and elsewhere at ORR are relatively small in areal extent as contaminant sources are discretely located, and flow paths to surface water outlets are short (Hamilton et al. 1999:1-9, 5-28, 5-30).

#### 3.2.5 Geology and Soils

Geologic resources are consolidated or unconsolidated earth materials, including ore and aggregate materials, fossil fuels, and significant landforms. Soil resources are the loose surface materials of the earth in which plants grow, usually consisting of disintegrated rock, organic matter, and soluble salts.

### 3.2.5.1 General Site Description

ORR is in the southwestern portion of the Valley and Ridge physiographic province in east-central Tennessee. The topography consists of alternating valleys and ridges that have a southwest-northeast trend, with most ORR facilities occupying the valleys (DOE 1996b:3-200). The topography reflects the underlying geology, which consists of a sequence of sedimentary rocks deformed by a series of major southeast-dipping thrust faults (Figures 3-3 and 3-4). The ridges are underlain by relatively erosion-resistant rocks, while weaker rock strata underlie the valleys (DOE 1999a:4-1, 4-3). Y-12 is in Bear Creek Valley between Pine and Chestnut Ridges, East Tennessee Technology Park is located along Poplar Creek between McKinney and Pine Ridges, and the ORNL main site is in Bethel Valley between Haw and Chestnut Ridges. The 7900 Area of ORNL is on a low ridge in Melton Valley, south of Haw Ridge. ORNL and the East Tennessee Technology Park are underlain primarily by calcareous siltstones and silty to clean limestone of the Chickamauga Group of upper and middle Ordovician age (about 440 to 480 million years old). The Conasauga Group underlies Y-12 and the 7900 Area; it is comprised of shales, calcareous siltstones, and silty-to-clean limestones of upper and middle Cambrian age (about 505 to less than 550 million years old). Pine Ridge and Haw Ridge are underlain by the Rome Formation, which consists of sandstone with thin shale interbeds. Chestnut Ridge is underlain by the cherty dolomite of the Knox Group. The Knox Group typically has well-developed karst features such as sinkholes, large solution cavities, and caves (DOE 1996b:3-200; 1999a:4-3-4-5). Structurally, two major thrust faults factor into the subsurface geology of ORR. Chestnut Ridge and Bethel Valley are underlain by the Whiteoak Mountain thrust fault. Haw Ridge and Melton Valley are underlain by the Copper Creek thrust fault (Figure 3-4). These faults formed during the Permian-Pennsylvanian periods (occurring about 245 to 320 million years ago) but have not been historically active (DOE 1999a:4-3-4-5). The present topography of the valleys is a result of stream action preferentially eroding the softer shales and limestones; the ridges are composed of relatively more resistant sandstones and dolomites. With the exception of strata suited to hard-rock quarrying for stone and aggregate (e.g., limestone, shale), no economically viable geologic resources have been identified at ORR (DOE 1996b:3-200).

There is no evidence of capable faults in the Valley and Ridge physiographic province, or within the rocks comprising the Appalachian Basin structural feature, where ORR is located. A capable fault is one that has had movement at or near the ground surface at least once within the past 35,000 years, or recurrent movement within the past 500,000 years (10 CFR Part 100, Appendix A). The nearest capable faults are approximately 480 kilometers (298 miles) northwest in the New Madrid (Reelfoot rift) fault zone. Historical earthquakes occurring in the Valley and Ridge are not attributable to fault structures in underlying sedimentary rocks, but rather occur at depth in basement rock (DOE 1999a:4-9; LMER 1998:2.5-19, 2.5-20).

The historical seismicity of the southeastern United States relative to ORR has been extensively reviewed in recent years. Since the New Madrid earthquakes of 1811-1812, at least 27 other earthquakes with a Modified Mercalli Intensity of III to VI (**Table 3-4**) have been felt in the Oak Ridge area (DOE 1996b:3-200; LMER 1998:2.5-16, 2.5-17, 2.5-29, 2.5-30). Second to the New Madrid earthquakes in intensity, the Charleston, South Carolina, earthquake of 1886, located about 515 kilometers (320 miles) from ORR, is estimated to have produced effects at ORR equivalent to Modified Mercalli Intensity VI (LMER 1998:2.5-29). One of closest and most intense seismic events occurred in 1930, approximately 8 kilometers (5 miles) from ORR, and had a Modified Mercalli Intensity of V at the site. The largest most recent earthquake in eastern Tennessee registered 4.6 on the Richter scale and occurred on November 30, 1973, in Maryville, Tennessee, about 32 kilometers (20 miles) southeast of ORR. This earthquake produced a Modified Mercalli Intensity of V to VI at ORR (as estimated at HFIR) (DOE 1996b:3-200; LMER 1998: 2.5-17, 2.5-30). The region has continued to be seismically active, with 42 earthquakes recorded within a radius of 90 kilometers (56 miles) of ORNL since 1973. In 1987, a magnitude 4.2 earthquake occurred about 38 kilometers (24 miles) from ORR producing a Modified Mercalli Intensity of VI at its epicenter. Since 1995, two earthquakes with a reported

**Table 3–4 The Modified Mercalli Intensity Scale of 1931, with Approximate Correlations to Richter Scale and Maximum Ground Acceleration<sup>a</sup>**

Modified Mercalli Intensity <sup>b</sup>	Observed Effects of Earthquake	Approximate Richter Magnitude <sup>c</sup>	Maximum Ground Acceleration <sup>d</sup> (g)
I	Usually not felt	Less than 2	Negligible
II	Felt by persons at rest on upper floors or favorably placed	2 to 3	Less than 0.003
III	Felt indoors; hanging objects swing; vibration like passing of light truck occurs; might not be recognized as earthquake	3	0.003 to 0.007
IV	Felt noticeably by persons indoors, especially in upper floors; vibration occurs like passing of heavy truck; jolting sensation; standing automobiles rock; windows, dishes, and doors rattle; wooden walls and frames may creak	4	0.007 to 0.015
V	Felt by nearly everyone; sleepers awoken; liquids disturbed and may spill; some dishes break; small unstable objects are displaced or upset; doors swing; shutters and pictures move; pendulum clocks stop or start	Between 4 and 5	0.015 to 0.03
VI	Felt by all; many are frightened; persons walk unsteadily; windows and dishes break; objects fall off shelves, pictures fall off shelves and walls; furniture moves or overturns; weak masonry cracks; small bells ring; trees and bushes shake	5	0.03 to 0.09
VII	Difficult to stand; noticed by car drivers; furniture breaks; damage moderate in well built ordinary structures; poor quality masonry cracks and breaks; chimneys break at roof line; loose bricks, stones, and tiles fall; waves appear on ponds and water is turbid with mud; small earthslides; large bells ring	6	0.07 to 0.22
VIII	Automobile's steering affected; some walls fall; twisting and falling of chimneys, stacks, and towers; frame houses shift if on unsecured foundations; damage slight in specially designed structures, considerable in ordinary substantial buildings; changes in flow of wells or springs; cracks appear in wet ground and steep slopes	Between 6 and 7	0.15 to 0.3
IX	General panic; masonry heavily damaged or destroyed; foundations damaged; serious damage to frame structures, dams and reservoirs; underground pipes break; conspicuous ground cracks	7	0.03 to 0.7
X	Most masonry and frame structures destroyed; some well built wooden structures and bridges destroyed; serious damage to dams and dikes; large landslides; rails bent	8	0.45 to 1.5
XI	Rails bent greatly; underground pipelines completely out of service	Between 8 and 9	0.5 to 3
XII	Damage nearly total; large rock masses displaced; objects thrown into air; lines of sight distorted	9	0.5 to 7

a. This table illustrates the approximate correlation between the Modified Mercalli Intensity scale, the Richter scale, and maximum ground acceleration.

b. Intensity is a unitless expression of observed effects.

c. Magnitude is an exponential function of seismic wave amplitude, related to the energy released.

d. Acceleration is expressed in relation to the earth's gravitational acceleration (g).

**Source:** DOE 1996b:3-39.

Modified Mercalli Intensity of at least III and two with a Modified Mercalli Intensity of V have occurred within approximately 90 kilometers (56 miles) of ORR. The most recent of those events occurred on June 17, 1998, with an epicenter within ORR near the East Tennessee Technology Park, registering a magnitude 3.6 (USGS 2000a, 2000c). Based on historical observations, the maximum earthquake for ORR would be a Modified Mercalli Intensity VIII event, having an epicenter at ORR (DOE 1999a:4-9, 4-10). Numerous studies have been conducted as part of establishing the design-basis earthquake for evaluating and designing new ORR facilities. For this purpose, an earthquake producing an effective peak-ground acceleration of 0.15g has been established and calculated to have an annual probability of occurrence of about 1 in 1,000

(LMER 1998:2.5-18, 2.5-59). For comparison, an earthquake with a peak acceleration of 0.32g has an annual probability of occurrence of 1 in 5,000 (Barghusen and Feit 1995:2.8-14).

Measures of peak (ground) acceleration are indicative of what an object on the ground would experience during an earthquake. This motion is customarily expressed in units of g (percent of gravity). While peak acceleration is generally adequate to approximate what a short structure would experience in terms of horizontal force during an earthquake, it does not account for the range of energies experienced by a building during an earthquake, particularly for taller buildings. Thus, building design based on peak acceleration alone does not provide a uniform margin against collapse. However, the U.S. Geological Survey (USGS) has developed new seismic hazard maps as part of the National Seismic Hazard Mapping Project that are based on response spectral acceleration.

Spectral acceleration maps account for the natural period of vibration of structures (i.e., short buildings have short natural periods [up to 0.6 second] and taller buildings longer periods [less than or equal to 0.7 second]) (USGS 2000b). These maps have been adapted for use in the new *International Building Code* (ICC 2000) (Figures 1615(1) and 1615(2) in the code) and depict maximum considered earthquake ground motion of 0.2- and 1.0-second spectral response acceleration, respectively, based on a 2 percent probability of exceedance in 50 years. This corresponds to an annual recurrence interval of about 1 in 2,500. ORR lies within the 0.50g to 0.60g mapping contours for a 0.2-second spectral response acceleration and the 0.10g to 0.15g contours for a 1.0-second spectral response acceleration.

There is no volcanic hazard at ORR. The area has not experienced volcanic activity within the last 230 million years (DOE 1996b:3-200).

Four general soil map units occur on ORR. These are described based on the Anderson County soil survey (Moneymaker 1981:5-7). The soil survey for Roane County has not been updated since 1942 (Swann et al. 1942) and does not specifically identify general soil map units. The four soil map units of ORR are Fullerton-Claiborne-Bodine; Collegedale-Gladeville-Rock outcrop; Lehew-Armuchee-Muskingum; and Armuchee-Montevallo-Hamblen units. Soils of the Fullerton-Claiborne-Bodine unit may be described as deep, rolling-to-steep, well-drained cherty and noncherty soils underlain by dolomite. They occur on rolling ridgetops and on all aspects of steep side slopes. The Collegedale-Gladeville-Rock outcrop soil unit consists of deep and shallow, rolling and hilly well-drained soils that are underlain by limestone and have many outcrops of limestone. Soils of this group occur on uplands. Soils of the Lehew-Armuchee-Muskingum unit are moderately deep, steep, well-drained soils underlain by multicolored shale, siltstone, and sandstone. This unit is found on high winding ridges. The Armuchee-Montevallo-Hamblen soil unit is made up of shallow-to-deep, steep to nearly level, well-drained and moderately well-drained soils underlain by shale. This unit occurs on uplands and bottomlands.

Prime farmland is land with the best combination of physical and chemical characteristics for producing food, feed, forage, fiber, and oilseed crops, and is available for these uses. While there are soils that would be classified as prime farmland on ORR, that designation is waived within the city limits of Oak Ridge and ORR (DOE 1999a:4-7).

### **3.2.5.2 Location of Proposed Activities**

| There are no capable faults on or near ORR. As noted above, the ORNL main site is underlain primarily by calcareous siltstones and silty-to-clean limestone of the Chickamauga Group. Melton Valley, and the  
| 7900 Area in particular, are underlain by the interbedded limestones and shales of the Conasauga Group. Most  
| of the 7900 Area is mapped as underlain by the Maryville Limestone with the southern limits of the site  
| bordering the Nolichucky Shale (DOE 1999a:4-4, 4-5; LMER 1998:2.5-48) (Figures 3-3 and 3-4). In

particular, the bedrock beneath the HFIR complex is described as a dark-gray, calcareous clay shale overlain by up to 6 meters (20 feet) of saprolite (weathered bedrock) with only a thin topsoil (LMER 1998:2.5-16). Karst features are less developed in the Chickamauga Group than in the Knox Group. Cavities encountered are smaller and often clay-filled, and caves are sparse and typically small, with the same observation expected for the Conasauga Group (LMER 1999:2-8). Soils of ORNL, including the 7900 Area, are highly disturbed and would be classified as Urban Land. Urban Land includes areas where more than 80 percent of the surface is covered with industrial plants, paved parking lots, and other impervious surfaces (Moneymaker 1981:44).

### **3.2.6 Ecological Resources**

Ecological resources include terrestrial resources, wetlands, aquatic resources, and threatened and endangered species.

#### **3.2.6.1 Terrestrial Resources**

This section addresses the plant and animal communities of ORR and includes a plant community map of the site. Terrestrial resources are described for the site as a whole, as well as the proposed facility locations.

##### **3.2.6.1.1 General Site Description**

Plant communities at ORR are characteristic of the intermountain regions of central and southern Appalachia. Only a small fraction of ORR has been disturbed by Federal activities; the remainder of the site has reverted to or been planted with natural vegetation. The vegetation of ORR has been categorized into seven plant communities (**Figure 3-5**). Pine and pine-hardwood forest is the most extensive plant community on the site. Another abundant community is the oak-hickory forest, which is commonly found on ridges throughout ORR. Northern hardwood forest and hemlock-white pine-hardwood forest are the least common forest community types on the site. Forest resources on ORR are managed for multiple use and sustained yield of quality timber products (DOE 1996b). Over 1,100 vascular plants species are found on ORR (LMER 1999).

Animal species found on ORR include 59 amphibians and reptiles, 260 birds, and 38 mammals (LMER 1999). Animals commonly found on the site include the American toad, eastern garter snake, Carolina chickadee, northern cardinal, white-footed mouse, and raccoon. Most of ORR is within the Oak Ridge Wildlife Management Area. Wildlife management is carried out by the Tennessee Wildlife Resources Agency in cooperation with ORNL's Environmental Sciences Division. The whitetail deer and wild turkey are the only species hunted on site; however, other game animals are also present (LMER 1999). Raptors, such as the northern harrier and great horned owl, and carnivores, such as the gray fox and mink, are ecologically important groups on ORR. A variety of migratory birds have been found at ORR.

##### **3.2.6.1.2 Location of Proposed Activities**

Vegetative communities in the vicinity of the 7900 Area are typical of ORR as a whole, with pine, pine-hardwood forests, cedar, cedar-pine, cedar hardwood, and oak-hickory forests being the predominant community types (Figure 3-5). Fauna of the area are similar to that found throughout ORR. The 7900 Area itself is highly developed and provides minimal wildlife habitat.

#### **3.2.6.2 Wetlands**

Wetlands include “those areas that are inundated or saturated by surface or groundwater at a frequency and duration sufficient to support, and that under normal circumstances do support a prevalence of vegetation

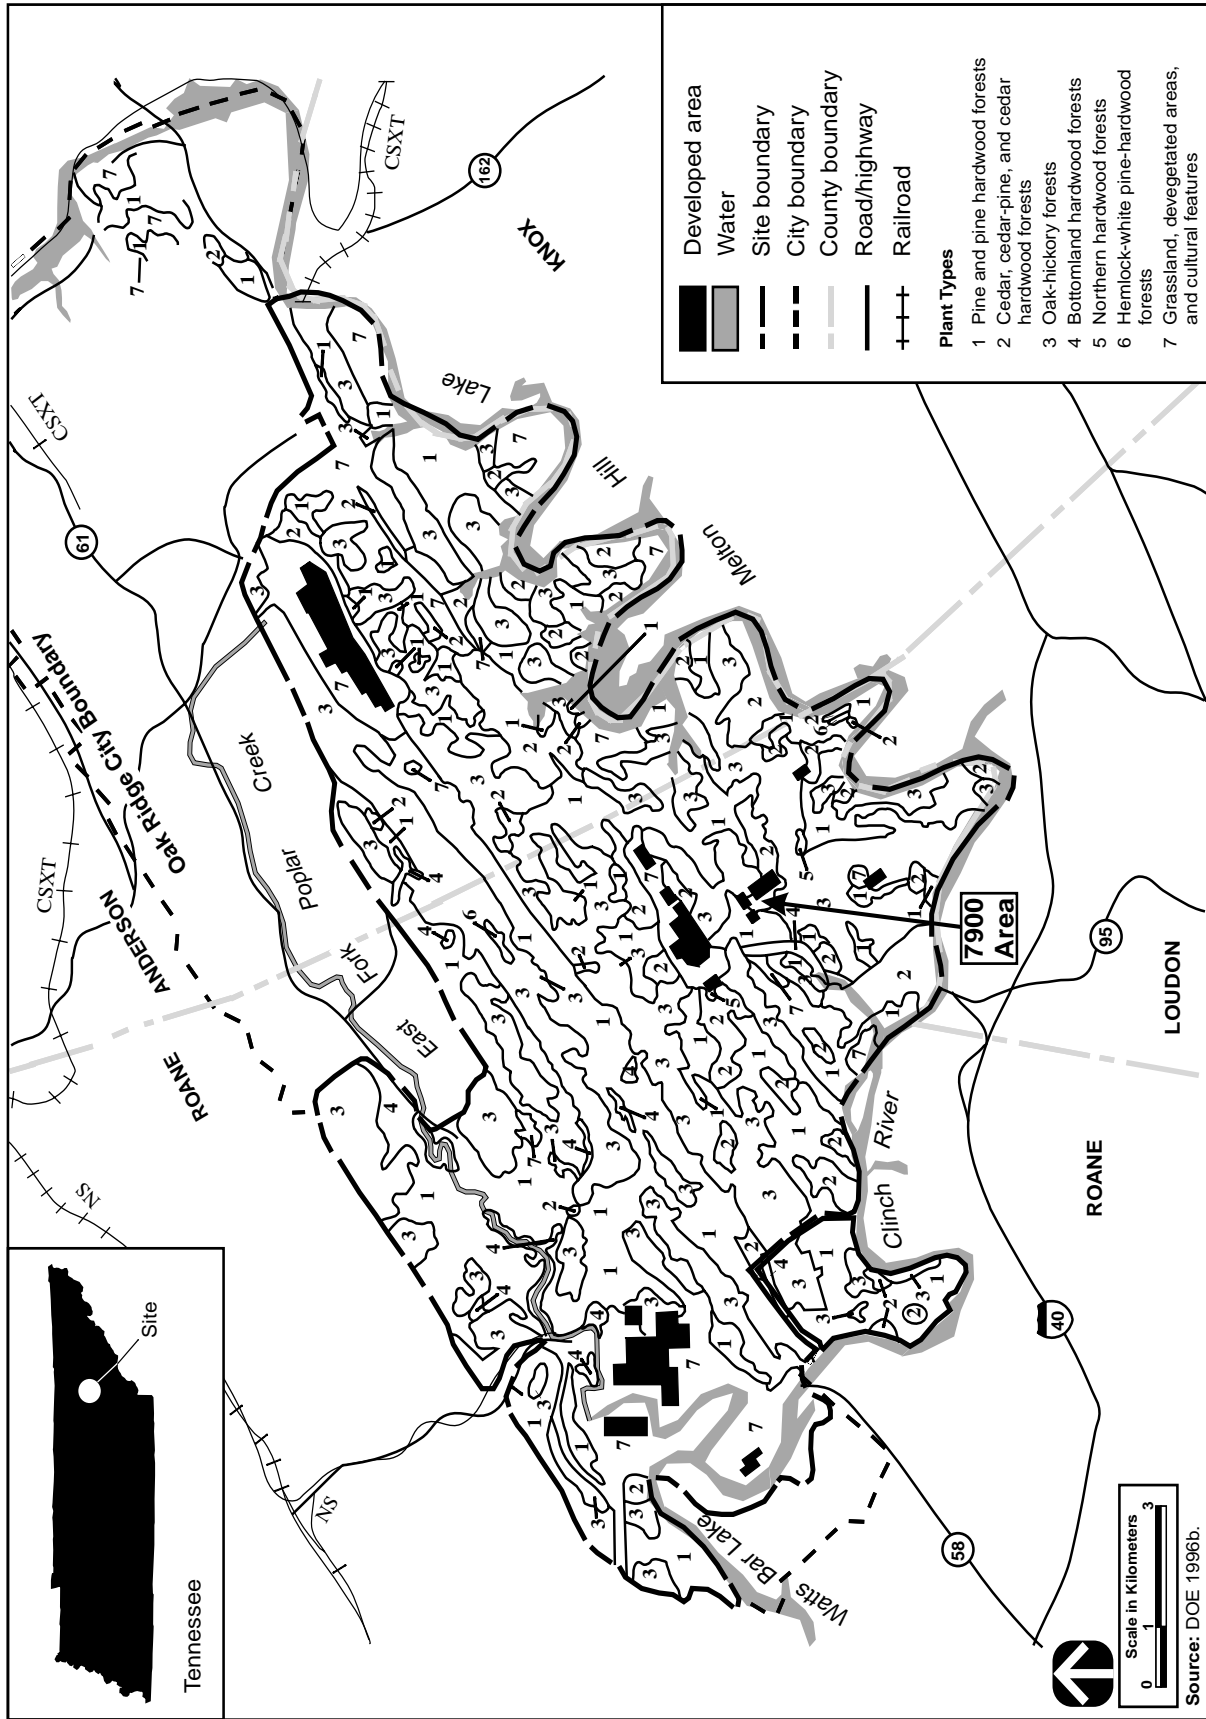

Figure 3-5 Distribution of Plant Communities at the Oak Ridge Reservation

typically adapted for life in saturated soil conditions” (33 CFR Section 328.3). Wetlands are described for ORR as a whole, as well as for the proposed facility locations.

### **3.2.6.2.1 General Site Description**

Approximately 235 hectares (580 acres) of wetlands occur on ORR (LMER 1999). These include emergent, scrub and shrub, and forested wetlands associated with bays (embayments) of the Melton Hill and Watts Bar Lake, areas bordering major streams and their tributaries (riparian), old farm ponds, and groundwater seeps. Well-developed communities of emergent wetland plants in the shallow embayments of the two reservoirs typically intergrade into forested wetland plant communities, which extend upstream through riparian areas associated with streams and their tributaries. Old farm ponds on ORR vary in size and support diverse plant communities and fauna. Although most riparian wetlands on ORR are forested, areas within utility rights-of-way, such as those in Bear Creek and Melton Valley, support emergent wetland vegetation.

### **3.2.6.2.2 Location of Proposed Activities**

There are six wetlands in the vicinity of the 7900 Area, including one small, unclassified wetland (Rosensteel 1996:25, 42); however, none are within the developed area. These wetlands, which were identified using the criteria and methods set forth in the *Corps of Engineers Wetland Delineation Manual* (Environmental Laboratory 1987), are generally classified as palustrine forested broad-leaved deciduous wetlands, although one also includes areas of emergent vegetation. Not including the unclassified wetland, the size of these areas range from 0.14 hectare (0.3 acre) to 1.23 hectares (3.0 acres). Mowing routinely disturbs two of the six wetlands.

### **3.2.6.3 Aquatic Resources**

Aquatic resources at ORR are described for the site as a whole, as well as for the proposed facility locations.

#### **3.2.6.3.1 General Site Description**

Aquatic habitat on or adjacent to ORR ranges from small, free flowing streams in undisturbed watersheds to larger streams with altered flow patterns due to dam construction. These aquatic habitats include tailwaters, impoundments, reservoir embayments, and large and small perennial streams. Aquatic areas in ORR also include seasonal and intermittent streams and old farm ponds.

Sixty-three fish species have been collected on ORR (LMER 1999). The minnow family has the largest number of species and is numerically dominant in most streams. Fish species representative of the Clinch River in the vicinity of ORR are shad, herring, common carp, catfish, bluegill, crappie, and freshwater drum. The most important fish species taken commercially in the ORR area are common carp and catfish. Commercial fishing is permitted on the Clinch River downstream from Melton Hill Dam. Area recreational species consist of crappie, largemouth bass, sauger, sunfish, and catfish. Sport fishing is not permitted within ORR.

#### **3.2.6.3.2 Location of Proposed Activities**

ORNL is drained by White Oak Creek. The upper portion of the creek is similar to the upper reaches of other streams originating on Chestnut Ridge. These streams typically have alternating riffle and pool habitats. The stoneroller and blacknose dace are the fish species most commonly collected; 24 taxa of macroinvertebrates are present. Historically, operations at ORNL have had an adverse ecological effect on White Oak Creek. For

example, the influence of ORNL is reflected in the fact that benthic macroinvertebrate populations are less diverse downstream of the site than upstream (DOE 1999a).

There are three Aquatic Reference Areas and one Reference Area in the ORNL area: Aquatic Reference Areas 3, 4, and 5, and Reference Area 28 (Pounds, Parr, and Ryon 1993:5,15-17). Reference Areas are areas that are representative of the communities of the southern Appalachian region or that possess unique biotic features. Aquatic Reference Area 3, Northwest Tributary, is a second-order, frequently intermittent stream that flows along the wooded base of Haw Ridge, but with mowed fields, parking lots, and experimental ponds on the opposite bank. Aquatic Reference Area 4, First Creek, and Aquatic Reference Area 5, Fifth Creek, are first-order, spring-fed streams that flow out of Chestnut Ridge. Each area has rich benthic fauna, but is somewhat more limited with regard to the number of fish species present. Reference Area 28, Spring Pond, is a small spring-fed pond with unusually clear water for ponds on ORR; it is dominated by Nutall waterweed.

#### **3.2.6.4 Threatened and Endangered Species**

Endangered species are those plants and animals in danger of extinction throughout all or a large portion of their range. Threatened species are those species likely to become endangered within the foreseeable future. Threatened and endangered species are described for ORR as a whole, as well as for the proposed facility locations.

##### **3.2.6.4.1 General Site Description**

Forty Federal and state-listed threatened, endangered, and other special status species have been found on ORR; additional species that occur near the site may also be present (ORNL 2000). The gray bat (endangered) and bald eagle (threatened, but proposed to be delisted) are the only federally listed threatened or endangered species observed on or near ORR. The bald eagle has been seen on Melton Hill and Watts Bar Lakes (DOE 1996b). A dead gray bat was found several years ago at Y-12 (Barclay 1999). The Indiana bat (endangered) has not been reported from the site (Mitchell et al. 1996a; ORNL 2000). State-listed threatened or endangered species observed on ORR include the gray bat, bald eagle, peregrine falcon, osprey, and 10 plant species. No critical habitat for threatened or endangered species, as defined in the Endangered Species Act, exists on ORR or adjacent lakes. Consultation to comply with Section 7 of the Endangered Species Act was conducted with the U.S. Fish and Wildlife Service. Consultation was also conducted with the state. The results of these consultations are presented in Chapter 4.

##### **3.2.6.4.2 Location of Proposed Activities**

No threatened, endangered, or sensitive plant or animal species have been recorded at or in the vicinity of the 7900 Area. Further, there is no potential habitat for such species confirmed in close proximity to the area (Parr 1999).

#### **3.2.7 Cultural and Paleontological Resources**

Cultural resources are human imprints on the landscape and are defined and protected by a series of Federal laws, regulations, and guidelines. The three general categories of cultural resources addressed in this section are prehistoric, historic, and Native American. Paleontological resources are the physical remains, impressions, or traces of plants or animals from a former geological age, and may be sources of information on paleoenvironments and the evolutionary development of plants and animals.

### **3.2.7.1 Prehistoric Resources**

Prehistoric resources are physical properties that remain from human activities that predate written records.

#### **3.2.7.1.1 General Site Description**

More than 20 cultural resources surveys have been conducted at ORR. About 90 percent of ORR has received at least some preliminary walkover or archival-level study, but less than 5 percent has been intensively surveyed. Most cultural resources studies have occurred along the Clinch River and adjacent tributaries. Prehistoric sites recorded at ORR include villages, potential burial mounds, camps, quarries, a chipping station, limited activity locations, and shell scatters. More than 45 prehistoric sites have been recorded at ORR to date. At least 13 prehistoric sites are considered potentially eligible for the National Registry of Historic Places, but most of these sites have not yet been evaluated. Additional prehistoric sites may be anticipated in the unsurveyed portions of ORR. In 1994, a Programmatic Agreement concerning the management of historic and cultural properties at ORR was executed among the DOE Oak Ridge Operation Office, the Tennessee State Historic Preservation Officer, and the Advisory Council on Historic Preservation. This agreement was executed to satisfy DOE's responsibilities regarding Sections 106 and 110 of the National Historic Preservation Act, and resulted in DOE preparing a cultural resources management plan for ORR (Souza, DuVall, and Tinker 1997).

#### **3.2.7.1.2 Location of Proposed Activities**

No prehistoric properties have been located within or immediately adjacent to the 7900 Area (Souza, DuVall, and Tinker 1997:F-5).

### **3.2.7.2 Historic Resources**

Historic resources consist of physical properties that postdate the existence of written records. In the United States, historic resources are generally considered to be those that date no earlier than 1492.

#### **3.2.7.2.1 General Site Description**

Several historic resources surveys have been conducted at ORR. Historic resources identified at ORR include both archaeological remains and standing structures. Documented log, wood frame, or fieldstone structures include cabins, barns, churches, gravehouses, springhouses, storage sheds, smokehouses, log cribs, privies, henhouses, and garages. Archaeological remains consist primarily of foundations, roads, and trash scatters. A total of 32 cemeteries are located within the present boundaries of ORR (Souza, DuVall, and Tinker 1997). More than 240 historic resources have been recorded at ORR, and 38 of those sites may be considered potentially eligible for listing on the National Registry of Historic Places. Freel's Cabin and two church structures, George Jones Memorial Baptist Church and the New Bethel Baptist Church, are listed on the National Registry. These structures date from before the establishment of the Manhattan Project. National Registry sites associated with the Manhattan Project include the Graphite Reactor at ORNL, listed on the National Registry of Historic Places as a National Historic Landmark, and three traffic checkpoints, Bear Creek Road, Bethel Valley Road, and Oak Ridge Turnpike Checking Stations (DOE 1999a). Many other buildings and facilities at ORR are associated with the Manhattan Project and are eligible for the National Registry. Historic building surveys have been completed for the Oak Ridge Townsite, ORNL, Y-12, the East Tennessee Technology Park, and the Oak Ridge Institute for Science and Education (Souza, DuVall, and Tinker 1997). Additional historic sites may be anticipated in the unsurveyed portions of ORR. Consultation to comply with Section 106 of the National Historic Preservation Act was initiated with the State Historic Preservation Office. The results of this consultation are presented in Chapter 4.

### **3.2.7.2.2 Location of Proposed Activities**

A survey was conducted in 1993 to identify properties at ORNL that are included or are eligible for inclusion in the National Register of Historic Places. Eligible properties include the ORNL Historic District; Buildings 7001 and 7002 in the ORNL East Support Area; the Molten Salt Reactor Experiment Facility (Building 7503, previously known as the Aircraft Reactor Experiment Building); the Tower Shielding Facility; and White Oak Lake and Dam. Of these structures, the Molten Salt Reactor Experiment Facility is the closest eligible property to the 7900 Area. It is located about 0.4 kilometer (0.25 mile) to the north of REDC and HFIR (Souza, DuVall, and Tinker 1997:3-70).

### **3.2.7.3 Native American Resources**

Native American resources are sites, areas, and materials important to Native Americans for religious or heritage reasons. In addition, cultural values are placed on natural resources such as plants, which have multiple purposes within various Native American groups. Concepts of sacred space that create the potential for land use conflicts are of primary concern.

#### **3.2.7.3.1 General Site Description**

The Overhill Cherokee Tribe occupied portions of the Tennessee, Hiwassee, Clinch, and Little Tennessee River Valleys in the 1700s. Overhill Cherokee villages consisted of a large townhouse, a summer pavilion, and a plaza, and residences had both summer and winter structures. Subsistence was based on hunting, gathering, and horticulture. The Cherokee were relocated to the Oklahoma territory in 1838, although some individuals refused to be moved and some Cherokee later returned to the area from Oklahoma. Resources that may be sensitive to Native American groups include remains of prehistoric and historic villages, ceremonial lodges, cemeteries, burials, and traditional plant gathering areas. Apart from prehistoric archaeological sites, to date no Native American resources have been identified at ORR.

#### **3.2.7.3.2 Location of Proposed Activities**

No Native American sacred sites or cultural items have been located within or immediately adjacent to the 7900 Area (Souza, DuVall, and Tinker 1997:3-66, 3-69, F-5).

### **3.2.7.4 Paleontological Resources**

Paleontological resources are the physical remains, impressions, or traces of plants or animals from a former geological age. Paleontological remains consist of fossils and their associated geological information.

#### **3.2.7.4.1 General Site Description**

The majority of geological units with surface exposures at ORR contain paleontological materials. Paleontological materials consist primarily of invertebrate remains, and these have relatively low research potential.

#### **3.2.7.4.2 Location of Proposed Activities**

Paleontological resources at ORNL would not be expected to differ from those found elsewhere on ORR.

### 3.2.8 Socioeconomics

Statistics for employment and regional economy are presented for the regional economic area, as defined in Appendix G.8, which encompasses 15 counties around ORR in Tennessee. Statistics for population, housing, community services, and local transportation are presented for the region of influence, a four-county area in which 89.9 percent of all ORR employees reside (**Table 3–5**). In 1998, ORR employed 14,215 persons (about 3.4 percent of the regional economic area civilian labor force) (DOE 1999c).

**Table 3–5 Distribution of Employees by Place of Residence in the ORR Region of Influence, 1998**

County	Number of Employees	Total Site Employment (percent)
Anderson	4,061	28.6
Knox	5,615	39.5
Loudon	828	5.8
Roane	2,275	16.0
Region of influence total	12,779	89.9

Source: DOE 1999c.

#### 3.2.8.1 Regional Economic Characteristics

Between 1990 and 1998, the civilian labor force in the ORR regional economic area increased 17.6 percent to the 1998 level of 484,774. In 1998, the unemployment rate in the regional economic area was 4.1 percent, which was slightly less than the unemployment rate for Tennessee (4.2 percent) (DOL 2000).

In 1993, services represented the largest sector of employment in the regional economic area (26 percent), followed by retail (19 percent), and manufacturing (18 percent). In Tennessee, the services sector comprised 26 percent of total employment, followed by manufacturing (19 percent), and retail (17 percent) (DOE 1996b).

#### 3.2.8.2 Population and Housing

In 1998, the ORR region of influence population totaled 528,017. From 1990 to 1998, the region of influence population grew by 9.4 percent, compared to 10.9 percent growth in Tennessee (Forstall 1995; DOC 1999). Between 1980 and 1990, the number of housing units in the region of influence increased by about 13.8 percent, nearly 2 percent less than the increase for the entire State of Tennessee. In 1998, the total number of owner and rental housing units within the region of influence was 225,636. In 1990, the homeowner and rental vacancy rates for the region of influence were 1.7 percent, compared to the state's rate of 8.5 percent (DOE 1996b; State of Tennessee 2000; DOC 1992).

#### 3.2.8.3 Community Services

##### 3.2.8.3.1 Education

School districts providing public education in the ORR region of influence operated at capacities ranging from 74.7 to 100 percent. Total student enrollment in the region of influence in 2000 was 70,493. The average student-to-teacher ratio was 16.7:1 (Davis 2000; Garza 2000; Groover 2000; McKinney 2000; Pierce 2000).

##### 3.2.8.3.2 Public Safety

In 1999, a total of 1,501 sworn police officers served the four-county region of influence. The average officer-to-population ratio was 2.8 officers per 1,000 persons (HPI 1999). In 1998, 1,293 paid and volunteer

firefighters provided fire protection services in the ORR region of influence. The average firefighter-to-population ratio was 2.4 firefighters per 1,000 persons (State of Tennessee 1998).

### **3.2.8.3.3 Health Care**

In 1995, a total of 1,525 physicians served the ORR region of influence, with the majority practicing in Knox County (Randolph, Seidman, and Pasko, 1995). The average physician-to-population ratio was 3.0 physicians per 1,000 persons. In 1994, there were 13 hospitals serving the region of influence with a total of 2,833 beds (AHA 1995).

### **3.2.8.4 Local Transportation**

Vehicles access ORR via three state routes. State Route 95 forms an interchange with Interstate 40, and enters the reservation from the south. State Route 58 enters the reservation from the west, and passes just south of the East Tennessee Technology Park. State Route 162 extends from Interstate 75 and Interstate 40 just west of Knoxville, and provides eastern access to ORR (Figure 3-1).

Within ORR, several routes are used to transfer traffic from the state routes to the main plant areas. Bear Creek Road, north of Y-12, flows in an east-west direction and connects Scarboro Road on the east end of the plant with State Road 95 and State Road 58. Bear Creek Road has restricted access around Y-12, and is not a public thoroughfare. Bethel Valley Road, a public roadway, provides access to ORNL, and extends from the east end of ORR at State Road 62 to the west end at State Route 95. Access to the 7900 Area is provided by secondary roads with controlled access: First Street, which runs north-south from Bethel Valley Road, and Melton Valley Road, which runs east-west and passes the 7900 Area entry road (McGee 2000).

Two main branches provide rail service for ORR. The CSX Transportation line at Elza (just east of Oak Ridge) serves Y-12 and the Office of Science and Technological Information in east Oak Ridge. The Norfolk and Southern main line from Blair provides easy access to the East Tennessee Technology Park. The Clinch River has a barge facility located on the west end of ORR near the East Tennessee Technology Park and is occasionally used to receive shipments that are too large or too heavy to be transported by rail or truck. McGhee Tyson Airport, 37 kilometers (23 miles) from ORR, is the nearest airport serving the region, with major carriers providing passenger and cargo service. A private airport, Atomic Airport, Inc., is the closest air transportation facility to Oak Ridge. Oak Ridge has a part-time public transportation system (DOE 1996b).

## **3.2.9 Existing Human Health Risk**

Existing human health risk issues include the determination of potentially adverse effects on human health that result from acute and chronic exposures to ionizing radiation and hazardous chemicals.

### **3.2.9.1 Radiation Exposure and Risk**

#### **3.2.9.1.1 General Site Description**

Major sources and levels of background radiation exposure to individuals in the vicinity of ORR are shown in **Table 3-6**. Annual background radiation doses to individuals are expected to remain constant over time. The total dose to the population, in terms of person-rem, changes as the population size changes. Background radiation doses are unrelated to ORR operations.

**Table 3–6 Sources of Radiation Exposure to Individuals  
in the ORR Vicinity Unrelated to ORR Operations**

Source	Effective Dose Equivalent (millirem per year)
<b>Natural background radiation<sup>a</sup></b>	
Cosmic radiation	36
External terrestrial radiation	51
Internal terrestrial radiation	39
Radon in homes (inhaled)	200
<b>Other background radiation<sup>b</sup></b>	
Diagnostic x-rays and nuclear medicine	53
Weapons test fallout	Less than 1
Air travel	1
Consumer and industrial products	10
<b>Total</b>	<b>390</b>

a. Hamilton et al. 1999.

b. NCRP 1987.

**Note:** Value of radon is an average for the United States.

Releases of radionuclides to the environment from ORR operations provide another source of radiation exposure to individuals in the vicinity of ORR. Types and quantities of radionuclides released from ORR normal operations in 1998 are listed in the *Oak Ridge Reservation Annual Site Environmental Report for 1998* (Hamilton et al. 1999). The doses to the public resulting from these releases are presented in **Table 3–7**. These doses fall within radiological limits per DOE Order 5400.5 and are much lower than those of background radiation.

**Table 3–7 Radiation Doses to the Public from ORR Normal Operations in 1998  
(Total Effective Dose Equivalent)**

Members of the Public	Atmospheric Releases		Liquid Releases		Total	
	Standard <sup>a</sup>	Actual	Standard <sup>a</sup>	Actual	Standard <sup>a</sup>	Actual
Maximally exposed individual (millirem)	10	0.73	4	2.6 <sup>b</sup>	100	4.4 <sup>c</sup>
Population within 80 kilometers (person-rem) <sup>d</sup>	None	12.3	None	48	100	60.3
Average individual within 80 kilometers (millirem) <sup>e</sup>	None	0.014	None	0.055	None	0.069

a. The standards for individuals are given in DOE Order 5400.5. As discussed in that order, the 10-millirem-per-year limit from airborne emissions is required by the Clean Air Act, and the 4-millirem-per-year limit is required by the Safe Drinking Water Act; for this NI PEIS, the 4-millirem-per-year value is conservatively assumed to be the limit for the sum of doses from all liquid pathways. The total dose of 100 millirem per year is the limit from all pathways combined. The 100-person-rem value for the population is given in proposed 10 CFR Part 834, as published in 58 FR 16268. If the potential total dose exceeds the 100-person-rem value, it is required that the contractor operating the facility notify DOE.

b. These doses are mainly from drinking water (approximately 0.35 millirem) and eating fish from the Clinch River section of Poplar Creek.

c. This total dose includes a conservative value of 1 millirem per year from direct radiation exposure to a cesium field near the Clinch River.

d. Based on a population of about 880,000 in 1998.

e. Obtained by dividing the population dose by the number of people living within 80 kilometers (50 miles) of the site.

**Source:** Hamilton et al. 1999.

Using a risk estimator of 500 cancer deaths per 1 million person-rem to the public (Appendix H), the risk of a latent cancer fatality to the maximally exposed member of the public due to radiological releases from ORR operations in 1998 is estimated to be  $2.2 \times 10^{-6}$ . That is, the estimated probability of this person dying of cancer

at some point in the future from radiation exposure associated with 1 year of ORR operations is approximately 2 in 1 million, as it takes several to many years from the time of radiation exposure for a cancer to manifest itself.

According to the same risk estimator, 0.030 excess latent cancer fatality is projected in the population living within 80 kilometers (50 miles) of ORR from normal operations in 1998. To place this number in perspective, it may be compared with the number of cancer fatalities expected in the same population from all causes. The 1997 mortality rate associated with cancer for the entire U.S. population was 0.2 percent per year (Famighetti 1998:964). Based on this mortality rate, the number of cancer fatalities expected during 1998 from all causes in the population living within 80 kilometers (50 miles) of ORR was 1,760, which was much higher than the 0.030 latent cancer fatality estimated from ORR operations in 1998.

ORR workers receive the same doses as the general public from background radiation, but they also receive an additional dose from working in facilities with nuclear materials. The average dose to the individual worker and the cumulative dose to all workers at ORR from operations in 1998 are presented in **Table 3–8**. These doses fall within the radiological regulatory limits of 10 CFR Part 835. According to a risk estimator of 400 cancer fatalities per 1 million person-rem among workers (Appendix H), the number of projected latent cancer fatalities among ORR workers from normal operations in 1998 is 0.041.

**Table 3–8 Radiation Doses to Workers from ORR Normal Operations in 1998  
(Total Effective Dose Equivalent)**

Occupational Personnel	Onsite Releases and Direct Radiation	
	Standard <sup>a</sup>	Actual
Average radiation worker (millirem)	None <sup>b</sup>	47
Total workers (person-rem) <sup>c</sup>	None	103

a. The radiological limit for an individual worker is 5,000 millirem per year. However, DOE’s goal is to maintain radiological exposure as low as is reasonably achievable. It has therefore established the Administrative Control Level of 2,000 millirem per year; the site must make reasonable attempts to maintain individual worker doses below this level.

b. No standard is specified for an “average radiation worker”; however, the maximum dose that this worker may receive is limited to that given in footnote “a.”

c. Based on a worker population of 2,187 with measurable doses in 1998.

**Source:** 10 CFR Section 835.202; DOE 1999p.

A more detailed presentation on the radiation environment, including background exposures and radiological releases and doses, is presented in the *Oak Ridge Reservation Annual Site Environmental Report for 1998* (Hamilton et al. 1999). The concentrations of radioactivity in various environmental media (including air, water, and soil) in the site region (on and off site) are also presented in the report.

### 3.2.9.1.2 Location of Proposed Activities

Radiological health effects resulting from the release of radionuclides from the stack that serves HFIR and REDC are shown in **Table 3–9**. Estimates shown in the table are based on the 1997 through 1999 release data discussed in Appendix H. Doses listed in Table 3–9 show that the risk of a latent cancer fatality to the maximally exposed member of the public due to emissions from HFIR and REDC would be  $2.3 \times 10^{-7}$ . The risk of an excess cancer fatality among the public residing within 80 kilometers (50 miles) of ATR would be 0.0042.

**Table 3–9 Radiation Doses to the Public from Normal Operations at HFIR and REDC in 1999  
(Total Effective Dose Equivalent)**

Members of the Public	Atmospheric Releases		Liquid Releases		Total	
	Standard	Actual	Standard	Actual	Standard	Actual
Maximally exposed individual (millirem)	10	0.46	4	0	100	0.46
Population within 80 kilometers (person-rem)	None	8.4	None	0	100	8.4
Average individual within 80 kilometers (millirem) <sup>a</sup>	None	$7.4 \times 10^{-3}$	None	0.00	None	$7.4 \times 10^{-3}$

a. For an affected population of 1,134,000.

**Table 3–10** lists average annual radiation doses to HFIR and REDC workers for the years 1998 and 1999. The average risk of an excess cancer fatality among workers at HFIR and REDC due to onsite releases and direct radiation for each of the two years would be  $1.5 \times 10^{-5}$  and  $6.6 \times 10^{-5}$ , respectively.

**Table 3–10 Radiation Doses to Workers from HFIR and REDC Normal Operations  
(Total Effective Dose Equivalent)**

Occupational Personnel	Onsite Releases and Direct Radiation	
	Standard <sup>a</sup>	Actual (1998 through 1999 average)
Average HFIR worker (millirem)	None <sup>b</sup>	38
Average REDC worker (millirem)	None <sup>b</sup>	165

a. The radiological limit for an individual worker is 5,000 millirem per year. However, DOE's goal is to maintain radiological exposure as low as is reasonably achievable. It has therefore established the Administrative Control Level of 2,000 millirem per year; the site must make reasonable attempts to maintain individual worker doses below this level.

b. No standard is specified for an "average radiation worker"; however, the maximum dose that this worker may receive is limited to that given in footnote "a."

**Source:** Boyd 2000a; Wham 2000d.

### 3.2.9.2 Chemical Environment

The background chemical environment important to human health consists of the atmosphere, which may contain hazardous chemicals that can be inhaled; drinking water, which may contain hazardous chemicals that can be ingested; and other environmental media through which people may come in contact with hazardous chemicals (e.g., surface water during swimming, soil through direct contact, or food). Hazardous chemicals can cause cancer and other adverse health effects.

**Carcinogenic Effects.** Health effects in this case are estimated as the incremental probability of an individual developing cancer over a lifetime as a result of exposure to the potential carcinogen. This could be incremental or excess individual lifetime cancer risk.

**Noncarcinogenic Effects.** Health effects in this case are determined by the ratio between the calculated, or measured concentration of the chemical in the air and the reference concentration or dose. This ratio is known as the Hazard Quotient. Hazard Quotients for noncarcinogens are summed to obtain the Hazard Index. If the Hazard Index is less than 1, no adverse health effects would be expected.

Effective administrative and design controls that decrease hazardous chemical releases to the environment and help achieve compliance with permit requirements (e.g., air emissions and NPDES permit requirements) contribute to minimizing health impacts on the public. The effectiveness of these controls is verified through the use of monitoring information and inspection of mitigation measures. Health impacts on the public may

occur by inhaling air containing hazardous chemicals released to the atmosphere during normal ORR operations. Risks to public health from other possible pathways, such as ingestion of contaminated drinking water or direct exposure, are lower than those via the inhalation pathway.

Baseline concentrations are estimates of the highest existing offsite concentrations and represent the highest concentrations to which members of the public could be exposed from normal operations at ORR. These concentrations are in compliance with applicable guidelines and regulations. Information on estimating the health impacts of hazardous chemicals is presented in Appendix H.

Exposure pathways to ORR workers during normal operation may include inhaling contaminants in the workplace atmosphere and through direct contact with hazardous materials. The potential for health impacts varies among facilities and workers, and available information is insufficient for a meaningful estimate of impacts. However, workers are protected from workplace hazards through appropriate training, protective equipment, monitoring, substitution, and engineering and management controls. ORR workers are also protected by adherence to Occupational Safety and Health Administration (OSHA) and EPA standards that limit the workplace atmospheric and drinking water concentrations of potentially hazardous chemicals. Appropriate monitoring that reflects the frequency and amounts of chemicals used in the operational processes ensure that these standards are not exceeded. Additionally, DOE requires that conditions in the workplace be as free as possible from recognized hazards that cause, or are likely to cause, illness or physical harm.

### **3.2.9.3 Health Effects Studies**

Two epidemiologic studies were conducted to determine whether ORR contributed to any excess cancers in communities surrounding the facility. One study found no excess cancer mortality in the population living in counties surrounding ORR, when compared to the control populations in other nearby counties and elsewhere in the United States. The other study found slight excess cancer incidences of several types in the counties near ORR, but less than the number of expected cancers incidences for other types of cancers.

A pilot study on mercury contamination conducted by the Tennessee Department of Health and Environment showed no difference in urine or hair mercury levels between individuals with potentially high mercury exposures compared to those with little potential for exposure. However, soil analysis showed that the mercury in soil is inorganic, which decreases the likelihood of a toxic accumulation in living tissue (bioaccumulation) and adverse health effects. Studies are continuing on the long-term effects of exposure to mercury and other hazardous chemicals.

More epidemiologic studies have been conducted to assess health effects on the population working at ORR than any other site reviewed for this document. Excess cancer mortalities have been reported and linked to specific job categories, age, and length of employment, as well as to the levels of exposure to radiation.

For a more detailed description of the epidemiologic studies, refer to Appendix M.4.6 of the *Storage and Disposition PEIS* (DOE 1996b:M-235 to M-242).

### **3.2.9.4 Accident History**

There have been no safety-related accidents causing significant injury or harm to workers, or posing any sort of harm to the offsite public, at HFIR or REDC during their operational lifetimes (DOE 1999e).

In addition, there have been no accidents with a measurable impact on offsite population during nearly 50 years of Y-12 operations at ORR. The most noteworthy accident in Y-12's history was a 1958 criticality accident, which resulted in temporary radiation sickness for a few ORR employees. In 1989, there was a one-time

accidental release of xylene into the ORR sewer system with no offsite impacts. Accidental releases of anhydrous hydrogen fluoride occurred in 1986, 1988, and 1992, with little onsite and negligible offsite impacts. The hydrogen fluoride system where these accidents occurred is being modified to reduce the probability of future releases, and to minimize the potential consequences if a release does occur.

### **3.2.9.5 Emergency Preparedness**

Each DOE site has established an emergency management program that would be activated in the event of an incident that threatens the health and safety of workers and the public. This program has been developed and maintained to ensure adequate response to most incident conditions and to provide response efforts for incidents not specifically considered. The emergency management program includes emergency planning, preparedness, and response.

DOE has overall responsibility for emergency planning and operations at ORR. However, DOE has delegated primary authority for event response to the operating contractor. Although the contractor's primary response responsibility is on site, the contractor does provide offsite assistance, if requested, under the terms of existing mutual aid agreements. If a hazardous materials event with offsite impacts occurs at a DOE facility, elected officials and local governments are responsible for the state's response efforts. The Tennessee Emergency Management Agency is the established agency responsible for coordinating state emergency services. When a hazardous materials event occurring at DOE facilities is beyond the capability of local government and assistance is requested, the Tennessee Emergency Management Agency Director may direct state agencies to provide assistance to the local governments. To accomplish this task and ensure prompt initiation of emergency response actions, the Director may cause the state Emergency Operations Center and Field Coordination Center to be activated. City or county officials may activate local Emergency Operations Centers in accordance with existing emergency plans.

DOE has specified actions to be taken at all DOE sites to implement lessons learned from the emergency response to an accidental explosion at Hanford in May 1997.

### **3.2.10 Environmental Justice**

Under Executive Order 12898, *Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations*, Federal agencies are responsible for identifying and addressing the possibility of disproportionately high and adverse health, economic, and environmental impacts of programs and activities on minority and low-income populations in potentially affected areas. Minority populations refer to persons of any race self-designated as Asian, Black, Native American, or Hispanic. Low-income populations refer to households with incomes below the Federal poverty thresholds. In the case of ORR, the potentially affected area includes parts of Tennessee, North Carolina, and Kentucky.

The potentially affected area surrounding ORNL is defined by a circle with an 80-kilometer (50-mile) radius centered at HFIR/REDC (latitude 35° 55'8" N, longitude 84° 18'14" W). The total population residing within that area in 1990 was 881,987, while the minority population was 6.1 percent of that (DOC 1992). In 1990, approximately one-fourth of the total national population was comprised of persons self-designated as members of a minority group. Percentage minority populations residing in the States of Tennessee, North Carolina, and Kentucky were 17.4 percent, 25.0 percent, and 8.3 percent, respectively.

At the time of the 1990 census, Blacks were the largest minority group within the potentially affected area, constituting 4.7 percent of the total population. Asians made up 0.5 percent, Hispanics, 0.5 percent, and Native Americans made up 0.4 percent of the population (DOC 1992).

In 1990, the poverty threshold was \$9,981 for a family of three with one related child under 18 years of age. A total of 137,708 persons (16 percent of the total population) residing within the potentially affected area around ORNL reported incomes below that threshold (DOC 1992). Data obtained during the 1990 census show that of the total population of the contiguous United States, 13.1 percent reported incomes below the poverty threshold. Percentages for those below the poverty threshold in Tennessee, North Carolina, and Kentucky were 19.0 percent, 13.1 percent, and 15.7 percent, respectively.

A more detailed description of the environmental justice analysis is given in Appendix K.

### **3.2.11 Waste Management**

Waste management includes minimization, characterization, treatment, storage, transportation, and disposal of waste generated from ongoing DOE activities. The waste is managed using appropriate treatment, storage and disposal technologies and in compliance with all Federal and state statutes and DOE orders. Disposal and management of previously generated ORR waste, known as legacy waste, is the responsibility of DOE's environmental management contractor, which is working to repackaging, remove, and dispose of the existing legacy waste and newly generated wastes. The strategy is to dispose of current inventories of all waste types and close many of the existing storage facilities. The long-range strategy is to rely on a combination of onsite and offsite facilities to dispose of newly generated waste.

#### **3.2.11.1 Waste Inventories and Activities**

ORR manages the following types of waste: transuranic, mixed transuranic, low-level radioactive, mixed low-level radioactive, hazardous, and nonhazardous. Waste generation rates and the inventory of stored waste from activities at ORR are provided in **Table 3-11**. Waste generation rates specifically for HFIR and REDC activities are provided in **Table 3-12**. ORR waste management capabilities are summarized in **Table 3-13**. More detailed descriptions of the waste management system capabilities at ORR are included in the *Storage and Disposition PEIS* (DOE 1996b:3-219, E-63).

DOE is working with Federal and state regulatory authorities to address compliance and cleanup obligations arising from its past operations at ORR. DOE is engaged in several activities to bring its operations into full regulatory compliance. These activities are set forth in negotiated agreements that contain schedules for achieving compliance with applicable requirements and financial penalties for nonachievement of agreed-upon milestones.

EPA placed ORR on the National Priorities List, which identifies sites for possible long-term remedial action under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), on November 21, 1989. DOE, EPA Region IV, and the Tennessee Department of Environment and Conservation completed a Federal Facility Agreement, effective January 1, 1992. This agreement coordinates ORR inactive site assessment and remedial actions. Portions of the Federal Facility Agreement are applicable to operating waste management systems. Existing actions are conducted under the Resource Conservation and Recovery Act (RCRA) and applicable state laws that minimize duplication, expedite response actions, and achieve a comprehensive remediation of the site. More information on regulatory requirements for waste disposal is provided in Chapter 5.

**Table 3–11 Waste Generation Rates and Inventories at ORR and ORNL**

Waste Type	Generation Rates (cubic meters per year)		Inventory (cubic meters)	
	ORR <sup>a</sup>	ORNL	ORR <sup>a</sup>	ORNL
<b>Transuranic</b>				
Contact handled	12	12	1,000	1,000
Remotely handled	10	10	550	550
Remotely handled sludge (tank waste)	1.5	1.5	900	900
<b>Low-level radioactive</b>				
Liquid <sup>b</sup>	12,500 (total)	1,200	20,000 <sup>c</sup> (total)	1,600
Solid		2,400		3,614
Process waste	283,900	283,900	0 <sup>d</sup>	0 <sup>d</sup>
<b>Mixed low-level radioactive</b>				
Liquid	(e)	(e)	(e)	(e)
Solid	1,600	475	26,000	3,000
<b>Hazardous</b>	36,000 kg/yr	–	1,689	–
<b>Nonhazardous</b>				
Liquid	269,000	60,600	NA <sup>f</sup>	NA <sup>f</sup>
Solid	29,500	5,700	NA <sup>f</sup>	NA <sup>f</sup>

- a. Represents entire waste generated or managed at ORR, including ORNL.  
b. Liquid low-level radioactive waste is processed through an evaporator for volume reduction, and the evaporator bottoms are stored as a concentrated solution.  
c. Excludes waste from DOE environmental restoration activities.  
d. This inventory is zero because the process waste is treated and discharged.  
e. Mixed liquid low-level radioactive waste is reported as low-level radioactive waste. Certain contents are mixed-permit-by-rule.  
f. Generally, this waste is not held in long-term storage.

**Note:** To convert from cubic meters to cubic yards, multiply by 1.308. To convert from kilograms to pounds, multiply by 2.2.

**Key:** kg/yr, kilograms per year; NA, not applicable.

### 3.2.11.2 High-Level Radioactive Waste

ORR does not manage high-level radioactive waste at the site.

### 3.2.11.3 Transuranic Waste

Although ORNL is the only current generator of transuranic wastes on ORR, other sites at ORR have produced small quantities of transuranic wastes in the past and are likely to do so again during decontamination and decommissioning activities. Transuranic waste includes contact-handled transuranic and remotely handled transuranic. Normally, contact-handled transuranic waste consists primarily of miscellaneous waste from glovebox operations (e.g., paper, glassware, plastic, shoe covers, and wipes), discarded high-efficiency particulate air filters, and discarded equipment (e.g., gloveboxes and processing equipment). Contact-handled transuranic waste has a surface dose rate that does not exceed 200 millirem per hour. Generally, contact-handled transuranic waste is contained within polyethylene bags inside 208-liter (55-gallon) stainless steel drums. Metal paint cans, plastic buckets, and other similar containers are also used to package waste inside the drums.

Remotely handled transuranic waste consists primarily of miscellaneous hot cell waste (e.g., paper, glass, plastic tubing, and wipes), high efficiency particulate air filters, and discarded equipment (e.g., processing racks, vacuum pumps, and furnaces). Unshielded remotely handled transuranic waste packages typically have radiation levels that measure between 10 and 2,000 rem per hour; however, most are below 100 rem per hour. Shielding generally reduces the levels at the surface of the container to approximately 1 rem per hour. Remotely handled transuranic waste contains activation and fission products that decay and emit neutron and gamma radiation on the surface of the packaging that exceeds 200 millirem per hour. The activation materials are transuranium radionuclides ranging from plutonium-238 to californium-252, but are usually dominated by curium-244 which contributes to the neutron dose from spontaneous fission and alpha-n reactions. The alpha-n reactions contribute to the external dose rate measured at the surface of a container for both the contact-handled transuranic and remotely handled transuranic solid waste.

Remotely handled transuranic wastes are usually contained in concrete casks (1.4 meters [4.5 feet] in diameter by 2.3 meters [7.5 feet] high). The wall thicknesses of the casks are currently either 15 centimeters (6 inches) or 30.5 centimeters (12 inches) thick, depending on the radiation level of the contents. A large polyethylene bag is placed inside the cask for additional contamination control prior to use. Most remotely handled transuranic wastes inside the concrete casks are also contained inside polyethylene bags. Smaller waste packages such as 11-liter (2.9-gallon) plastic buckets, 3.7-liter (0.98-gallon) paint cans, and 18.9-liter (5.0-gallon) metal cans are packaged within the polyethylene bags. Fiber drums and carbon and steel drums have also been used to package waste inside the concrete cask. Intermediate-sized items that will not fit in the previously mentioned packages are generally placed in vinyl bags, then placed inside the lined waste cask. Large cask items may be placed directly in the cask.

As of January 1999, approximately 1,000 cubic meters (1,310 cubic yards) of contact-handled transuranic waste was in retrievable drum storage in the Bunker and Earthen Trenches. The amount of remotely handled transuranic waste was about 550 cubic meters (719 cubic yards) (64 FR 4079). Current activities center around certification of contact-handled waste, designing of a repackaging and certification facility for remote-handled wastes, and planning for shipment of waste to the Waste Isolation Pilot Plant (WIPP) or another suitable geologic repository for disposal.

#### **3.2.11.4 Low-Level Radioactive Waste**

Solid low-level radioactive waste is compactible radioactive waste such as paper, plastic, cloth, glass, cardboard, filters, floor sweepings, styrofoam, clothing, ceiling tile, and miscellaneous radioactively contaminated trash. The waste may include up to 20 percent lightweight or non-smeltable metal items. The solid low-level radioactive waste normally generated at ORNL consists primarily of radioactively contaminated personnel protection equipment, paper debris, trapping media, and process equipment. The Interim Waste Management Facility at ORNL only accepts low-level radioactive waste generated at ORNL. However, the Interim Waste Management Facility is at two-thirds of capacity, and access to this facility for the proposed plutonium-238 production, new medical and industrial isotope production, or new nuclear reasearch and development activities is not expected. Solid low-level radioactive waste is being stored at the East Tennessee Technology Park and Y-12 for future disposal. Contaminated scrap metal is stored above ground at the K-770 scrap metal facility, the old salvage yard at Y-12, and at ORNL which is being managed by the DOE scrap metal program until further disposal methods are evaluated.

The basic low-level radioactive waste strategy is to:

1. Use the Interim Waste Management Facility for legacy waste until it is filled to capacity.

2. Stage low-level radioactive waste at all sites, with emphasis on storage at the East Tennessee Technology Park until a disposal site is available.
3. Ship waste to the Nevada Test Site, Hanford, or a commercial disposal site as access is approved, and according to site-specific waste acceptance criteria.

### **3.2.11.5 Mixed Low-Level Radioactive Waste**

RCRA mixed low-level radioactive waste is in storage at Y-12, East Tennessee Technology Park, and ORNL. Because prolonged storage of these wastes exceeded the one-year limit imposed by RCRA, ORR entered into a Federal Facility Compliance Agreement for RCRA Land Disposal Restriction wastes with EPA on June 12, 1992. This agreement was terminated with the issuance of the Tennessee Department of Environmental Conservation Commissioner's Order, effective October 1, 1995, which requires DOE to comply with the Site Treatment Plan prepared by ORR. The plan contains milestones and target dates for DOE to characterize and treat its inventory of mixed wastes at ORR. Sludges contaminated with low-level radioactivity are generated by settling and scrubbing operations, and in the past were stored in K-1407-C ponds at the East Tennessee Technology Park.

Sludges have been removed from these ponds and a portion has been fixed in concrete at the K-1419 Sludge Treatment Facility, and stored at the K-33 building. The concreted sludges are being shipped off site for disposal. The raw sludges are stored in the K-1065 building, pending further treatment. Mixed waste sludges are also generated at Y-12 in the treatment of nitrate waste from purification and recycling of uranium and in the treatment of plating shop waste.

The primary facility generator of liquid mixed waste is the K-1435 Toxic Substances Control Act Incinerator from the wet scrubber blowdown. This waste is currently being treated at the Central Neutralization Facility, which provides pH adjustment and chemical precipitation. Treated effluents are discharged through a NPDES outfall. The contaminated sludges are stored as mixed waste at the East Tennessee Technology Park.

The East Tennessee Technology Park Toxic Substances Control Act Incinerator has a design capacity to incinerate 909 kilograms (2,000 pounds) per hour of mixed liquid waste and up to 455 kilograms (1,000 pounds) per hour of solids and sludge (91 kilograms [200 pounds] per hour maximum sludge content). The Toxic Substances Control Act Incinerator is capable of incineration of both Toxic Substances Control Act- and RCRA-mixed wastes. The Toxic Substances Control Act Incinerator capacity utilization for incinerable solids is limited to ORR wastes to support the completion of enforceable milestones required by the ORR Site Treatment Plan. Because of permit limits (Toxic Substances Control Act, RCRA, State of Tennessee), the incinerator is not running at full capacity. In 1994, approximately 2,590 cubic meters (683,000 gallons) of mixed liquid waste was incinerated (DOE 1996b:3-226).

The major type of mixed waste generated at ORNL is mixed waste oils. Mixed waste oils are generated when oils are removed from systems that have operated in radiation environments. Radiation levels in these oils are typically low (less than or equal to 10 millirem per hour). Generally, these wastes consist of vacuum pump oil, axle oil, refrigeration oil, mineral oil, or oil/water mixtures. The principal components of scintillation fluids are toluene and/or xylene, culture medium, and miscellaneous organics. Other mixed wastes generated at ORNL include organic wastes, carcinogenic wastes, mercury-contaminated solid waste, waste solvents, corrosives, poisons, and other process waste. Because of the diversity of the mixed waste generated at ORNL, quantities are usually small.

Radioactive wastes contaminated with polychlorinated biphenyl are being stored because of lack of treatment and disposal capacities. DOE and EPA signed a Federal Facility Compliance Agreement, effective

December 16, 1996, to bring East Tennessee Technology Park into compliance with Toxic Substances Control Act regulations for use, storage, and disposal of polychlorinated biphenyls. It also addressed the approximately 10,000 pieces of nonradioactive polychlorinated biphenyls-containing dielectric equipment used in the shutdown of diffusion plant operations.

#### **3.2.11.6 Hazardous Waste**

RCRA-regulated wastes are generated by ORR in laboratory research, electroplating operations, painting operations, descaling, demineralizer regeneration, and photographic processes. Certain other wastes (e.g., spent photographic processing solutions) are processed on site into a nonhazardous state. Those wastes that are safe to transport, and have been certified as having no radioactivity added, are shipped off site to RCRA-permitted commercial treatment and disposal facilities. Small amounts of reactive chemical explosives that would be dangerous to transport off site, such as aged picric acid, are processed on site in the Chemical Detonation Facility at ORNL.

#### **3.2.11.7 Nonhazardous Waste**

Nonhazardous wastes are generated from numerous ORR activities. For example, the steam plant produces nonhazardous sludge. Scrap metals are discarded from maintenance and renovation activities and are recycled when appropriate. Construction and demolition projects produce nonhazardous industrial wastes. Other nonhazardous wastes include paper, plastic, glass, can, cafeteria wastes, and general trash. All nonradioactive medical wastes are autoclaved to render them noninfectious and are sent to the Y-12 Sanitary Landfill. Remedial action projects also produce wastes requiring proper management. The State of Tennessee permitted landfill (Construction Demolition Landfill VI) receives nonhazardous industrial materials such as fly ash and construction debris. Asbestos and general refuse are managed in Industrial and Sanitary Landfill V located at Y-12.

#### **3.2.11.8 Waste Minimization**

The DOE Oak Ridge Operations Office has an active waste minimization and pollution prevention program to reduce the total amount of waste generated and disposed of at ORR. This is accomplished by eliminating waste through source reduction or material substitution; recycling potential waste materials that cannot be minimized or eliminated; and treating waste generated to reduce its volume, toxicity, or mobility prior to storage or disposal. Implementing pollution prevention projects reduced the amount of waste generated at ORR in 1998 by approximately 64,900 cubic meters (84,000 cubic yards). Examples of pollution prevention projects completed in 1998 at the Oak Ridge Operations Office include: reducing cleanup/stabilization of low-level radioactive waste by approximately 395 cubic meters (517 cubic yards), mixed low-level radioactive waste by approximately 119 cubic meters (156 cubic yards), and hazardous waste by approximately 83 metric tons (91 tons) by providing incentives in contracts for projects to turn over vacant and decontaminated buildings to the DOE Oak Ridge Operation Office; reducing routine operations mixed low-level radioactive waste by approximately 693 cubic meters (906 cubic yards) by selling various scrap metals (including clean and contaminated carbon steel and copper) to an outside vendor for cleaning and recycling; and reducing transuranic waste generation by less than 1 cubic meter (1.3 cubic yards) per year by replacing three oil-lubricated vacuum pumps with dry pumps, which eliminated the transuranic-contaminated waste oil stream and associated waste (DOE 1999f:56).

### 3.2.11.9 Waste Management PEIS Records of Decision

The *Final Waste Management Programmatic Environmental Impact Statement for Managing Treatment, Storage, and Disposal of Radioactive and Hazardous Waste (Waste Management PEIS)* Records of Decision affecting ORR are shown in **Table 3–14** for the waste types analyzed in this NI PEIS. Decisions on the various waste types are being announced in a series of Records of Decision that have been issued on the *Waste Management PEIS*. The transuranic waste Record of Decision was issued on January 20, 1998 (63 FR 3629); the hazardous waste Record of Decision was issued on August 5, 1998 (63 FR 41810); the high-level radioactive waste Record of Decision was issued on August 12, 1999 (64 FR 46661); and the low-level radioactive waste and mixed low-level radioactive waste Record of Decision was issued on February 18, 2000 (65 FR 10061). The transuranic waste Record of Decision states that DOE will develop and operate mobile and fixed facilities to characterize and prepare transuranic waste for disposal at WIPP. Each DOE site that has or will generate transuranic waste will, as needed, prepare and store its transuranic waste on site. The hazardous waste Record of Decision states that most DOE sites will continue to use offsite facilities for the treatment and disposal of major portions of the nonwastewater hazardous waste, with ORR and the Savannah River Site (SRS) continuing to treat some of their own nonwastewater hazardous waste on site in existing facilities, where this is economically favorable. The high-level radioactive waste Record of Decision states that immobilized high-level radioactive waste will be stored at the site of generation until transfer to a geologic repository. The low-level radioactive waste and mixed low-level radioactive waste Record of Decision states that for the management of low-level radioactive waste, minimal treatment will be performed at all sites and disposal will continue, to the extent practicable, on site at INEEL, Los Alamos National Laboratory (LANL), ORR, and SRS. In addition, Hanford and the Nevada Test Site will be available to all DOE sites for low-level radioactive waste disposal. Mixed low-level radioactive waste will be treated at Hanford, INEEL, ORR, and SRS and disposed of at Hanford and the Nevada Test Site. More detailed information concerning DOE's preferred alternatives for the future configuration of waste management facilities at ORR is presented in the *Waste Management PEIS* and the high-level radioactive waste, transuranic waste, hazardous waste, and low-level radioactive and mixed low-level radioactive waste Records of Decision.

**Table 3–14 Waste Management PEIS Records of Decision Affecting ORR**

Waste Type	Preferred Action
High-level radioactive	ORR does not currently manage high-level radioactive waste. <sup>a</sup>
Transuranic and mixed transuranic	DOE has decided that ORR should prepare and store its transuranic waste on site pending disposal at WIPP <sup>b</sup> or another suitable geologic repository.
Low-level radioactive	DOE has decided to treat ORR's liquid low-level radioactive waste on site. <sup>c</sup> Separate from the <i>Waste Management PEIS</i> , DOE prefers offsite management of ORR's solid low-level radioactive waste after temporary onsite storage.
Mixed low-level radioactive	DOE has decided to regionalize treatment of mixed low-level radioactive waste at ORR. <sup>c</sup> This includes the onsite treatment of ORR's waste and could include treatment of some mixed low-level radioactive waste generated at other sites.
Hazardous	DOE has decided to use commercial and onsite ORR facilities for treatment of ORR nonwastewater hazardous waste. DOE will also continue to use onsite facilities for wastewater hazardous waste. <sup>d</sup>

### 3.3 IDAHO NATIONAL ENGINEERING AND ENVIRONMENTAL LABORATORY

INEEL is on 230,700 hectares (570,000 acres) in southeastern Idaho and is 55 kilometers (34 miles) west of Idaho Falls, 61 kilometers (38 miles) northwest of Blackfoot, and 35 kilometers (22 miles) east of Arco. INEEL is owned by the Federal Government and administered, managed, and controlled by DOE. It is primarily within Butte County, but portions of the site are also in Bingham, Jefferson, Bonneville, and Clark counties. The site is roughly equidistant from Salt Lake City, Utah, and Boise, Idaho.

There are approximately 450 buildings and 2,000 support structures at INEEL, with more than 279,000 square meters (3,000,000 square feet) of floor space in varying conditions of utility. INEEL has approximately 25,100 square meters (270,000 square feet) of covered warehouse space and an additional 18,600 square meters (200,000 square feet) of fenced yard space. The total area of the various machine shops is 3,035 square meters (32,665 square feet).

Fifty-two research and test reactors have been designed and deployed at INEEL over the years to test reactor systems, develop fuel and target designs, and test the overall safety of reactor systems. In addition to nuclear reactor research, other INEEL facilities are operated to support reactor operations. These facilities include high-level radioactive and low-level radioactive waste processing and storage sites; hot cells; nuclear materials storage vaults; analytical laboratories; machine shops; laundry, railroad, and administrative facilities. Other activities include management of one of DOE's largest storage sites for low-level radioactive waste, transuranic waste, and spent nuclear fuel (both highly enriched and low-enriched uranium).

#### 3.3.1 Land Resources

Land resources include land use and visual resources. Each of these resource areas is described for the site as a whole, as well as for the locations of the proposed activities.

##### 3.3.1.1 Land Use

Land may be characterized by its potential for the location of human activities (land use). Natural resource attributes and other environmental characteristics could make a site more suitable for some land uses than for others. Changes in land use may have both beneficial and adverse effects on other resources such as ecological, cultural, geological, aquatic, and atmospheric.

##### 3.3.1.1.1 General Site Description

The Federal Government, the State of Idaho, and private parties own lands surrounding INEEL. Regional land uses include grazing, wildlife management, mineral and energy production, recreation, and crop production. Approximately 60 percent of the surrounding area is used by sheep and cattle for grazing. Small communities and towns near the INEEL boundaries include Mud Lake to the east; Arco, Butte City, and Howe to the west; and Atomic City to the south. Two National Natural Landmarks border INEEL: Big Southern Butte (2.4 kilometers [1.5 miles] south) and Hell's Half Acre (2.6 kilometers [1.6 miles] southeast). A portion of Hell's Half Acre National Natural Landmark is designated as a Wilderness Study Area. The Black Canyon Wilderness Study Area is also adjacent to INEEL.

Land use categories at INEEL include facility operations, grazing, general open space, and infrastructure such as roads. Generalized land uses at INEEL and vicinity are shown in **Figure 3-6**. Facility operations include industrial and support operations associated with energy research and waste management activities. Land is also used for recreation and environmental research associated with the designation of INEEL as a National

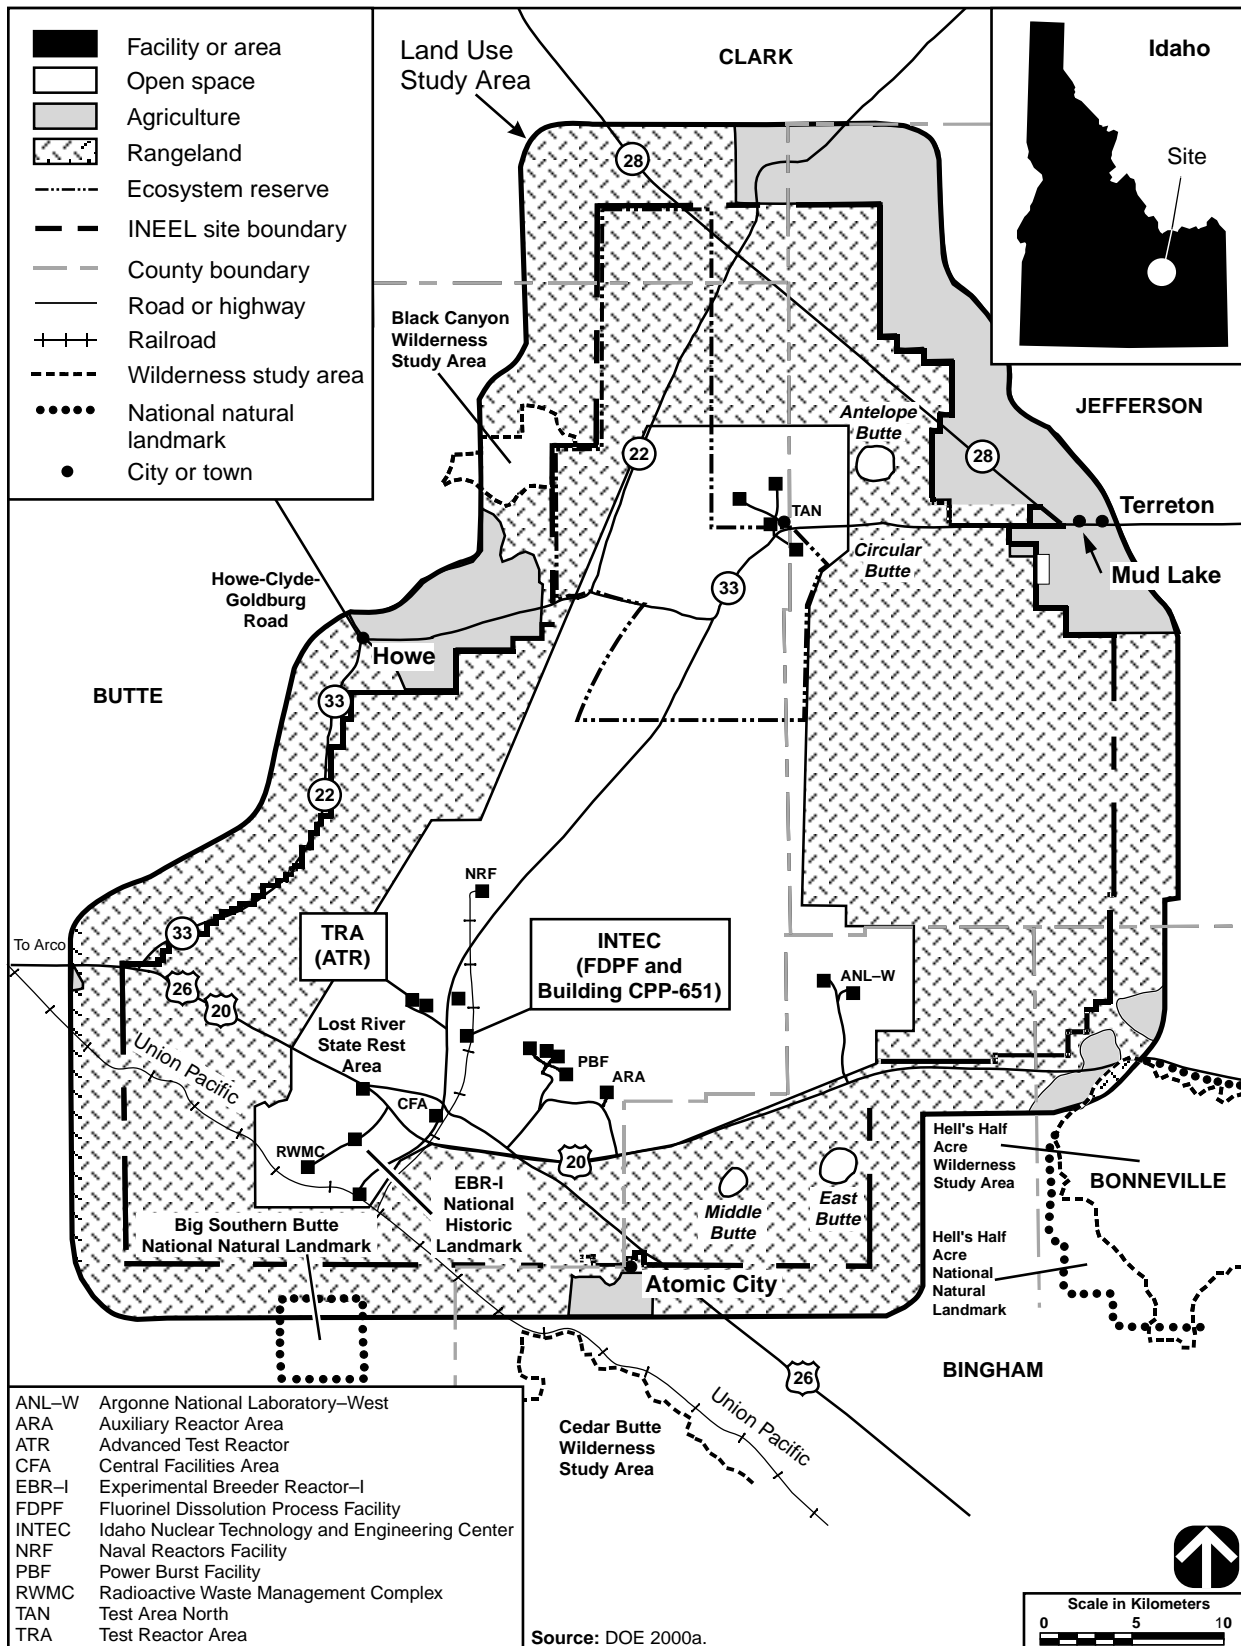

Figure 3-6 Generalized Land Use at Idaho National Engineering and Environmental Laboratory and Vicinity

Environmental Research Park. Much of INEEL is open space that has not been designated for specific use. Some of this space serves as a buffer zone between INEEL facilities and other land uses. Recently, 29,950 hectares (74,000 acres) of open space in the north central portion of the site has been designated as the INEEL Sagebrush Steppe Ecosystem Reserve (DOE 1999g). This area represents one of the last sagebrush steppe ecosystems in the United States and provides a home for a number of rare and sensitive species of plants and animals. Approximately 2 percent of the total INEEL site area (4,600 hectares [11,400 acres]) is used for facilities and operations. Facilities are sited within a central core area of about 93,100 hectares (230,000 acres) (Figure 3–6). Public access to most facilities is restricted. DOE land use plans and policies applicable to INEEL are discussed in the *Department of Energy Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs Final Environmental Impact Statement* (DOE 1995a:vol. 2, part A, 4.2-1–4.2-4).

All county plans and policies encourage development adjacent to previously developed areas to minimize the need for infrastructure improvements and to avoid urban sprawl. Because INEEL is remote from most developed areas, its lands and adjacent areas are not likely to experience residential and commercial development, and no new development is planned near the site. Recreational and agricultural uses, however, are expected to increase in the surrounding area in response to greater demand for recreational areas and the conversion of rangeland to cropland (DOE 1999e:3-82).

The Fort Bridger Treaty of July 3, 1868, secured the Fort Hall Reservation as the permanent homeland of the Shoshone-Bannock Peoples. According to the treaty, tribal members reserved rights to hunting, fishing, and gathering on surrounding unoccupied lands of the United States. While INEEL is considered occupied land, it was recognized that certain areas on the INEEL site have significant cultural and religious significance to the tribes. A *1994 Memorandum of Agreement with the Shoshone-Bannock Tribes* (DOE 1994) provides tribal members access to the Middle Butte to perform sacred or religious ceremonies or other educational or cultural activities.

### **3.3.1.1.2 Locations of Proposed Activities**

#### **IDAHO NUCLEAR TECHNOLOGY AND ENGINEERING CENTER**

Land within Idaho Nuclear Technology and Engineering Center (INTEC) is highly disturbed, and is used to store spent nuclear fuel and radioactive wastes, treat radioactive wastes, and develop waste management technologies. The area includes about 85 hectares (210 acres) within the perimeter fence and an additional 22 hectares (54 acres) outside the fence (DOE 1997b:31, 95–111). A number of wastewater and percolation ponds are also present on the site. INTEC is 12 kilometers (7.5 miles) north of the site boundary, and 0.8 kilometer (0.5 mile) southeast of the Big Lost River. Facilities at INTEC include spent fuel storage and processing areas, a waste solidification facility and related high-level waste storage facilities, remote analytical laboratories, and a coal-fired steam-generating plant that is in standby.

#### **TEST REACTOR AREA**

The Test Reactor Area is in the southwestern portion of INEEL (Figure 3–6). Land in the Test Reactor Area is currently disturbed, and is designated for reactor operations. The area includes about 15 hectares (37 acres) within the security fence, plus several sewage and waste ponds outside of the fence. The Test Reactor Area is about 11 kilometers (6.8 miles) southeast of the nearest site boundary and about 2.6 kilometers (1.6 miles) northwest of the Big Lost River. The Materials Test Reactor and Engineering Test Reactor (both shut down), the Test Reactor Area Hot Cells, and ATR, which achieved initial criticality in 1967, are in the Test Reactor Area. In addition, numerous support facilities (i.e., storage tanks, maintenance buildings, warehouses), laboratories, and sanitary and radioactive waste treatment facilities are in the area (DOE 1997b:32, 189–201).

### **3.3.1.2 Visual Resources**

Visual resources are natural and human-created features that give a particular landscape its character and aesthetic quality. Landscape character is determined by the visual elements of form, line, color, and texture. All four elements are present in every landscape. The stronger the influence exerted by these elements in a landscape, the more interesting the landscape.

#### **3.3.1.2.1 General Site Description**

The Bitterroot, Lemhi, and Lost River mountain ranges border INEEL on the north and west. Volcanic buttes near the southern boundary of INEEL can be seen from most locations on the site. INEEL generally consists of open desert land predominantly covered by big sagebrush and grasslands. Pasture and farmland border much of the site.

Ten facility areas are on the INEEL site. Although INEEL has a comprehensive facility and land use plan (DOE 1997b), no specific visual resource standards have been established. INEEL facilities have the appearance of low-density commercial/industrial complexes widely dispersed throughout the site. Structure heights generally range from 3 to 30 meters (10 to 100 feet); a few stacks and towers reach 76 meters (250 feet). Although many INEEL facilities are visible from highways, most facilities are more than 0.8 kilometer (0.5 mile) from public roads. The operational areas are well defined at night by the security lights.

Lands adjacent to INEEL, under Bureau of Land Management jurisdiction, are designated as Visual Resource Management Class II areas. Lands within the INEEL site are designated as Visual Resource Management Class II and III. Management activities within these classes may be seen but should not dominate the review (DOI 1986). The Black Canyon Wilderness Study Area, adjacent to INEEL, is under consideration by Bureau of Land Management for Wilderness Area designation, approval of which would result in an upgrade of its Visual Resource Management rating from Class II to Class I. The Hell's Half Acre Wilderness Study Area is 2.6 kilometers (1.6 miles) southeast of INEEL's eastern boundary. This area, famous for its lava flow and hiking trails, is managed by the Bureau of Land Management. The Craters of the Moon Wilderness Area is about 20 kilometers (12 miles) southwest of INEEL's western boundary.

#### **3.3.1.2.2 Locations of Proposed Activities**

##### **IDAHO NUCLEAR TECHNOLOGY AND ENGINEERING CENTER**

While the Fuel Processing Facility is the largest building at INTEC, the tallest structure is the main stack, which is 76 meters (250 feet) tall. The Visual Resource Management rating of INTEC is Class IV, which means management activities dominate the view and are the focus of the viewers attention. INTEC is visible in the middle ground from State Highways 20 and 26, with Saddle Mountain in the background. Natural features of visual interest within a 40-kilometer (25-mile) radius include Big Lost River at 0.8 kilometer (0.5 mile), Middle Butte at 18 kilometers (11 miles), Big Southern Butte National Natural Landmark at 20 kilometers (11 miles), East Butte at 23 kilometers (14 miles), Hell's Half Acre Wilderness Study Area at 33 kilometers (21 miles), and Saddle Mountain at 40 kilometers (25 miles).

##### **TEST REACTOR AREA**

The tallest structure at ATR within the Test Reactor Area is the main stack, which can be seen from Highways 20, 26, and 22. Developed areas within the Test Reactor Area are consistent with a Visual Resource Management Class IV rating. Natural features of visual interest within a 40-kilometer (25-mile) radius include

Big Lost River at 2.6 kilometers (1.6 miles), Middle Butte at 20 kilometers (12 miles), Big Southern Butte National Natural Landmark at 18 kilometers (11 miles), East Butte at 23 kilometers (14 miles), Hell’s Half Acre Wilderness Study area at 35 kilometers (22 miles), and Saddle Mountain at 40 kilometers (25 miles).

### **3.3.2 Noise**

Noise is unwanted sound that interferes or interacts negatively with the human or natural environment. Noise may disrupt normal activities or diminish the quality of the environment.

#### **3.3.2.1 General Site Description**

Major noise emission sources within INEEL include various industrial facilities, equipment, and machines (e.g., cooling systems, transformers, engines, pumps, boilers, steam vents, paging systems, construction and materials-handling equipment, and vehicles). Most INEEL industrial facilities are far enough from the site boundary that noise levels at the boundary from these sources are not measurable, or are barely distinguishable from background levels (DOE 1996b:3-112).

Existing INEEL-related noises of public significance are from the transportation of people and materials to and from the site and in-town facilities via buses, trucks, private vehicles, and freight trains. Noise measurements along U.S. Route 20, about 15 meters (50 feet) from the roadway, indicate that the sound levels from traffic range from 64 to 86 dBA, and that the primary source is buses (71 to 80 dBA). While few people reside within 15 meters (50 feet) of the roadway, the results indicate that INEEL traffic noise might be objectionable to members of the public residing near principal highways or busy bus routes. Noise levels along these routes may have decreased somewhat due to reductions in employment and bus service at INEEL in the last few years. The acoustic environment along the INEEL site boundary in rural areas and at nearby areas away from traffic noise is typical of a rural location; the average day-night sound level is in the range of 35 to 50 dBA. Except for the prohibition of nuisance noise, neither the State of Idaho nor local governments have established any regulations that specify acceptable community noise levels applicable to INEEL (DOE 1996b:3-114). The EPA guidelines for environmental noise protection recommend an average day-night sound level of 55 dBA as sufficient to protect the public from the effects of broadband environmental noise in typically quiet outdoor and residential areas (EPA 1974:29). Land use compatibility guidelines adopted by the Federal Aviation Administration and the Federal Interagency Committee on Urban Noise indicate that yearly day-night average sound levels less than 65 dBA are compatible with residential land uses (14 CFR Part 150). These guidelines further indicate that levels up to 75 dBA are compatible with residential uses if suitable noise reduction features are incorporated into structures. It is expected that for most residences near INEEL, the day-night average sound levels are compatible with the residential land use, although for some residences along major roadways, noise levels may be higher than 65 dBA.

#### **3.3.2.2 Locations of Proposed Activities**

##### **IDAHO NUCLEAR TECHNOLOGY AND ENGINEERING CENTER**

No distinguishing noise characteristics at INTEC have been identified. INTEC is far enough from the site boundary (12 kilometers [7.5 miles]) that noise levels at the boundary from these sources are not measurable or are barely distinguishable from background levels.

## TEST REACTOR AREA

No distinguishing noise characteristics at the Test Reactor Area have been identified. The Test Reactor Area is far enough from the site boundary (11 kilometers [6.8 miles]) that noise levels at the site boundary from these sources are not measurable or are barely distinguishable from background levels.

### 3.3.3 Air Quality

Air pollution refers to the introduction, directly or indirectly, of any substance into the air that could endanger human health, harm living resources and ecosystems as well as material property, and impair or interfere with the comfortable enjoyment of life or other legitimate uses of the environment. Air pollutants are transported, dispersed, or concentrated by meteorological and topographical conditions. Air quality is affected by air pollutant emission characteristics, meteorology, and topography.

#### 3.3.3.1 General Site Description

The climate at INEEL and the surrounding region is characterized as that of a semiarid steppe. The average annual temperature at INEEL is 5.6 °C (42 °F); average monthly temperatures range from a minimum of -8.8 °C (16.1 °F) in January to a maximum of 20 °C (68 °F) in July. The average annual precipitation is 22 centimeters (8.7 inches) (Clawson, Start, and Ricks 1989:55, 77). Prevailing winds at INEEL are southwest or northeast (DOE 1999h:4.7-1). The annual average wind speed is 3.4 meters per second (7.5 miles per hour) (DOE 1996b:3-112).

INEEL is within the Eastern Idaho Intrastate Air Quality Control Region #61. None of the areas within INEEL and its surrounding counties are designated as nonattainment areas with respect to the NAAQS for criteria air pollutants (40 CFR Section 81.313). The nearest nonattainment area for particulate matter is in Pocatello, about 80 kilometers (50 miles) to the south. Applicable NAAQS and Idaho State ambient air quality standards are presented in **Table 3-15**.

The primary sources of air pollutants at INEEL include calcination of sodium-bearing waste, combustion of coal for steam, and combustion of fuel oil for heating. Other emission sources include waste burning, coal piles, industrial processes, stationary diesel engines, vehicles, and fugitive dust from waste burial and construction activities. The existing ambient air concentrations attributable to sources at INEEL are presented in Table 3-15. These concentrations are based on dispersion modeling at the INEEL site boundary centered at the INTEC facility, performed for the *High-Level Waste and Facilities Disposition Draft EIS* using 1997 actual emissions and excluding Argonne National Laboratory-West; dispersion modeling at the INEEL site boundary centered on Argonne National Laboratory-West using 1997 actual emissions for Argonne National Laboratory-West; and meteorological data from 1991-1992 (DOE 1999i, 2000a). The estimated concentrations are conservative and bound the actual INEEL contribution to ambient levels, as some of the modeled sources are currently in standby. Concentrations shown in Table 3-15 represent a small percentage of the ambient air quality standards. Concentrations of any hazardous and toxic compounds would be well below regulatory levels.

Because INEEL sources are limited and background concentrations of criteria pollutants are well below ambient standards, INEEL emissions should not result in air pollutant concentrations that violate the ambient air quality standards.

**Table 3–15 Comparison of Modeled Ambient Air Concentrations from INEEL Sources with Most Stringent Applicable Standards or Guidelines**

Pollutant	Averaging Period	Most Stringent Standard or Guideline (micrograms per cubic meters) <sup>a</sup>	INEEL Concentration without ANL–W (micrograms per cubic meters)	ANL–W Concentration (micrograms per cubic meters)
<b>Criteria pollutants</b>				
Carbon monoxide	8 hours	10,000 <sup>b</sup>	78	41
	1 hour	40,000 <sup>b</sup>	206	59
Nitrogen dioxide	Annual	100 <sup>b</sup>	0.46	13
Ozone	1 hour	235 <sup>c</sup>	(d)	(d)
PM <sub>10</sub>	Annual	50 <sup>b</sup>	0.49	0.14
	24 hours	150 <sup>b</sup>	12	1.1
Sulfur dioxide	Annual	80 <sup>b</sup>	0.14	3.3
	24 hours	365 <sup>b</sup>	5.3	27
	3 hours	1,300 <sup>b</sup>	24	60

- a. The more stringent of the Federal and state standards is presented if both exist for the averaging period. The NAAQS (40 CFR Part 50), other than those for ozone, particulate matter, and lead, and those based on annual averages, are not to be exceeded more than once per year. The annual arithmetic PM<sub>10</sub> mean standard is attained when the expected annual arithmetic mean concentration is less than or equal to the standard.
- b. Federal and state standard.
- c. Federal 8-hour standard is currently under litigation.
- d. Not directly emitted or monitored by the site.

**Note:** NAAQS also include standards for lead. No sources of lead emissions have been identified for any alternative evaluated. Emissions of hazardous air pollutants not listed here have been identified at INEEL, but are not associated with any of the alternatives evaluated. EPA revised the ambient air quality standards for particulate matter and ozone in 1997 (62 FR 38856, 62 FR 38652); however, these standards are currently under litigation, but could become enforceable during the life of this project.

**Source:** 40 CFR Part 50; DOE 1999i, 2000a; ID DHW 1998.

The nearest Prevention of Significant Deterioration Class I area to INEEL is Craters of the Moon Wilderness Area, Idaho, 53 kilometers (33 miles) west-southwest from the center of the site. A Class I area is one in which very little increase in pollution is allowed due to the pristine nature of the area. There are no other Class I areas within 100 kilometers (62 miles) of INEEL. INEEL and its vicinity are classified as a Class II area in which more moderate increases in pollution are allowed (DOE 1996b:3-112).

EPA has established Prevention of Significant Deterioration increments for certain pollutants: sulfur dioxide, nitrogen dioxide and particulate matter less than or equal to 10 microns in diameter. The increments specify a maximum allowable increase above a certain baseline concentration for a given averaging period, and apply only to sources constructed or modified after a specified baseline date. These sources are known as increment-consuming sources. The baseline date is the date of submittal of the first application for a Prevention of Significant Deterioration permit in a given area.

Prevention of Significant Deterioration permits have been obtained for the coal-fired steam-generating facility next to the Idaho Nuclear Technology and Engineering Center and Fuel Processing Facility, which is not expected to be operated (DOE 1996b). In addition to this facility, INEEL has other increment consuming sources on site. The current amounts of Prevention of Significant Deterioration increment consumption in Class I and Class II areas by INEEL's increment-consuming sources based on dispersion modeling analyses are specified in **Tables 3–16** and **3–17**, respectively.

**Table 3–16 Prevention of Significant Deterioration Increment Consumption at Craters of the Moon Wilderness (Class I) Area by Existing (1996) and Projected Sources Subject to Prevention of Significant Deterioration Regulation**

Pollutant	Averaging Period	Allowable Prevention of Significant Deterioration Increment <sup>a</sup> (micrograms per cubic meter)	Amount of Prevention of Significant Deterioration Increment Consumed (micrograms per cubic meter)
Nitrogen dioxide	Annual	2.5	0.06
Respirable particulates <sup>b</sup>	Annual	4	0.008
	24 hours	8	0.7
Sulfur dioxide	Annual	2	0.09
	24 hours	5	1.9
	3 hours	25	6.2

a. All increments specified are State of Idaho standards (ID DHW 1998).

b. Data on particulate size are not available for most sources. For purposes of comparison to the respirable particulate increments, it is conservatively assumed that all particulates emitted are of respirable size (i.e., 10 microns or less in diameter).

**Note:** Estimated increment consumption includes existing sources, projected increases from planned projects, including the Advanced Mixed Waste Treatment Project, and excludes the New Waste Calcining Facility.

**Source:** DOE 1999i.

**Table 3–17 Prevention of Significant Deterioration Increment Consumption at Class II Areas by Existing (1996) and Projected Sources Subject to Prevention of Significant Deterioration Regulation at INEEL**

Pollutant	Averaging Period	Allowable Prevention of Significant Deterioration Increment <sup>a</sup> (micrograms per cubic meter)	Amount of Prevention of Significant Deterioration Increment Consumed (micrograms per cubic meter)
Nitrogen dioxide	Annual	25	1.6
Respirable particulates <sup>b</sup>	Annual	17	0.92
	24 hours	30	17
Sulfur dioxide	Annual	20	2.4
	24 hours	91	31
	3 hours	512	140

a. All increments specified are State of Idaho standards (ID DHW 1998).

b. Data on particulate size are not available for most sources. For purposes of comparison to the respirable particulate increments, it is conservatively assumed that all particulates emitted are of respirable size (i.e., 10 microns or less in diameter).

**Note:** Estimated increment consumption includes existing sources, projected increases from planned projects, including the Advanced Mixed Waste Treatment Project, and excludes the New Waste Calcining Facility.

**Source:** DOE 1999i.

Routine offsite monitoring for nonradiological air pollutants is generally only performed for particulates. Monitoring for PM<sub>10</sub> is performed by the Environmental Science and Research Foundation at the site boundary and at communities beyond the boundary. In 1998, 55 samples were collected at Rexburg (about 60 kilometers [19.3 miles] east of the site) by the Foundation. The mean PM<sub>10</sub> concentration at Rexburg for 1998 was 27 micrograms per cubic meter. Forty-eight samples were collected at the Mountain View Middle School in Blackfoot, with a mean concentration of 23 micrograms per cubic meter. Forty-four samples were collected at Atomic City in 1998, with a mean concentration of 21 micrograms per cubic meter (Saffle et al. 2000).

Some monitoring data has also been collected by the National Park Service at the Craters of the Moon Wilderness Area. The monitoring program has shown no exceedances of the 1-hour ozone standard, low levels of sulfur dioxide (except for one exceedance of the 24-hour standard in 1985), and total suspended particulates within applicable standards (DOE 1999h). Note that the total suspended particulate standards have been replaced with PM<sub>10</sub> standards.

### 3.3.3.2 Locations of Proposed Activities

The meteorological conditions for INEEL are considered to be representative of the INTEC and Test Reactor Area sites.

#### IDAHO NUCLEAR TECHNOLOGY AND ENGINEERING CENTER

Primary sources of nonradiological air pollutants include the New Waste Calcining Facility and coal-fired steam-generating facility. Both of these facilities are in standby. These facilities are sources of carbon monoxide, nitrogen dioxide, sulfur dioxide, and PM<sub>10</sub>. The New Waste Calcining Facility is a large source of nitrogen dioxide at INEEL.

#### TEST REACTOR AREA

The ATR facility operates a diesel generator as a source of backup electrical power. This generator is a source of nonradioactive air emissions at ATR. Other diesel engines are also operated periodically and contribute to air emissions (LMIT 1997:11–23). The existing ambient air pollutant concentrations attributable to sources at ATR are presented in **Table 3–18**. These concentrations are estimated using SCREEN3 and are expected to overestimate the contribution to site boundary concentrations.

**Table 3–18 Comparison of Modeled Ambient Air Concentrations from ATR Sources with Most Stringent Applicable Standards or Guidelines**

Pollutant	Averaging Period	Most Stringent Standard or Guideline (micrograms per cubic meters) <sup>a</sup>	ATR Concentration (micrograms per cubic meters)
<b>Criteria pollutants</b>			
Carbon monoxide	8 hours	10,000 <sup>b</sup>	33.6
	1 hour	40,000 <sup>b</sup>	48
Nitrogen dioxide	Annual	100 <sup>b</sup>	9.19
Ozone	1 hour	235 <sup>c</sup>	(d)
PM <sub>10</sub>	Annual	50 <sup>b</sup>	4.72
	24 hours	150 <sup>b</sup>	37.7
Sulfur dioxide	Annual	80 <sup>b</sup>	1.50
	24 hours	365 <sup>b</sup>	12
	3 hours	1,300 <sup>b</sup>	26.9

a. The more stringent of the Federal and state standards is presented if both exist for the averaging period. The NAAQS (40 CFR Part 50), other than those for ozone, particulate matter, and lead, and those based on annual averages, are not to be exceeded more than once per year. The annual arithmetic mean PM<sub>10</sub> standard is attained when the expected annual arithmetic mean concentration is less than or equal to the standard.

b. Federal and state standard.

c. Federal 8-hour standard is currently under litigation.

d. Not directly emitted or monitored by the site.

**Source:** Modeled concentrations using SCREEN3 and emissions estimates for diesel generators.

### 3.3.4 Water Resources

Water resources include all forms of surface water and subsurface groundwater.

### **3.3.4.1 Surface Water**

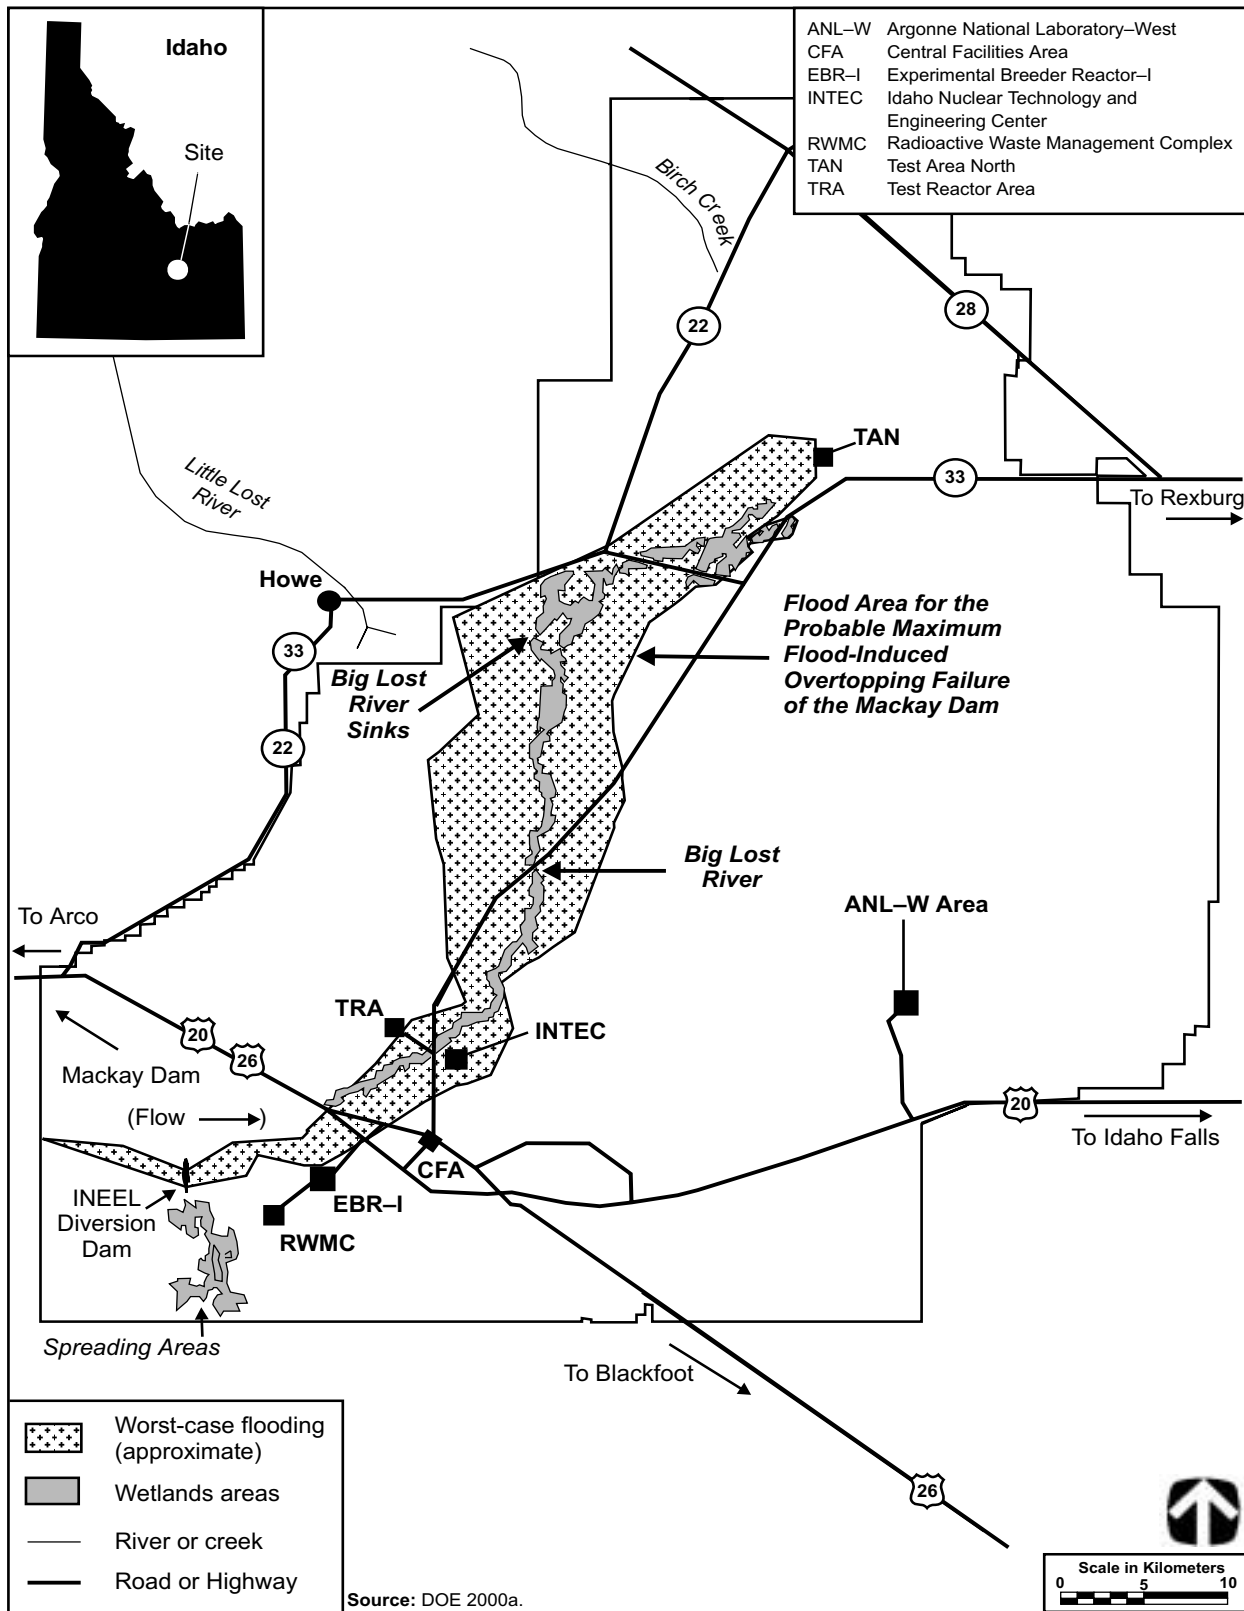

Surface water includes marine or freshwater bodies that occur above the ground surface, including rivers, streams, lakes, ponds, rainwater catchments, embayments, and oceans.

#### **3.3.4.1.1 General Site Description**

INEEL is in the Mud Lake-Lost River Basin (also known as the Pioneer Basin). This closed drainage basin includes three main streams—the Big and Little Lost Rivers and Birch Creek (**Figure 3–7**). These three streams are essentially intermittent and drain the mountain areas to the north and west of INEEL, although most flow is diverted for irrigation in the summer months before it reaches the site boundaries. Flow that reaches INEEL infiltrates the ground surface along the length of the stream beds, in the spreading areas at the southern end of INEEL and, if the stream flow is sufficient, in the ponding areas (playas or sinks) in the northern portion of INEEL. During dry years, there is little or no surface water flow on INEEL. Because the Mud Lake-Lost River Basin is a closed drainage basin, water does not flow off INEEL but rather infiltrates the ground surface to recharge the aquifer or is consumed by evapotranspiration. The Big Lost River flows southeast from Mackay Dam, past Arco and onto the Snake River Plain. On INEEL, near the southwestern boundary, a diversion dam prevents flooding of downstream areas during periods of heavy runoff by diverting water to a series of natural depressions or spreading areas. During periods of high flow or low irrigation demand, the Big Lost River continues northeastward past the diversion dam, passes within about 60 meters (200 feet) of INTEC and ends in a series of playas 24 to 32 kilometers (15 to 20 miles) northeast of INTEC and the Test Reactor Area, where the water infiltrates the ground surface.

Flow from Birch Creek and the Little Lost River infrequently reaches INEEL. The water in Birch Creek and Little Lost River is diverted in summer months for irrigation prior to reaching INEEL. During periods of unusually high precipitation or rapid snow melt, water from Birch Creek and Little Lost River may enter INEEL from the northwest and infiltrate the ground, recharging the underlying aquifer (DOE 1999i:4-50, 4-51). Other than the three intermittent streams, the only other surface water bodies on the site include natural wetland-like ponds and manmade percolation and evaporation ponds (DOE 1999h:4.8-1).

Big Lost River, Little Lost River, and Birch Creek have been classified by the State of Idaho for irrigation for agriculture, cold water biota development, salmon spawning, and primary and secondary recreation (DOE 1999h:4.8-9). Surface waters, however, are not used for drinking water on the site, nor is effluent discharged directly to them; thus, there are no surface water rights issues at INEEL (DOE 1996b:3-115). Although there are no routine wastewater discharges to surface waters, an NPDES permit application has been filed with EPA Region 10 for minor discharges from INTEC production wells to the Big Lost River. However, these discharges are subject to Idaho water quality standards and criteria. INEEL facilities are also covered by EPA's multisector general stormwater permit issued in 1998 (63 FR 52430). Stormwater is managed via the INEEL Storm Water Pollution Prevention Plan (first implemented in 1993). Annual stormwater evaluations are conducted as part of the plan, and stormwater is monitored in accordance with the permit and DOE Orders. In 1998, INEEL also submitted a Notice of Intent to EPA for renewal of the site's General Permit for Storm Water Discharges from Construction Sites. As for industrial activities, a pollution prevention plan covering construction activities is maintained. Application has been made to the State of Idaho for Wastewater Land Application Permits for all existing wastewater treatment facilities on the site (e.g., percolation ponds and sewage treatment irrigation systems); four permits have been issued (Saffle et al. 2000:2-6, 2-7).

**Figure 3-7 Surface Water Features at the Idaho National Engineering and Environmental Laboratory**

None of the rivers on or near INEEL have been classified as a Wild and Scenic River. The INEEL diversion dam constructed in 1958 and enlarged in 1984 secured INEEL from the 300-year flood of the Big Lost River by directing flow through a diversion channel into four spreading areas (DOE 1995a:4.8-3, 4.8-4, 4.8-13; 1996b:3-115).

#### **3.3.4.1.2 Locations of Proposed Activities**

There are no named streams within INTEC and the Test Reactor Area; there are only unnamed drainage ditches that carry storm flows away from buildings and facilities at the site. Outside INTEC and the Test Reactor Area, the only surface water is a stretch of Big Lost River. As described above, this is an intermittent stream that flows past the diversion dam and across INEEL near INTEC and the Test Reactor Area mainly during wet periods such as when it carries snowmelt from the nearby mountains, and/or when upstream irrigation demand is low (Abbott, Crockett, and Moor 1997:5; DOE 1999i:4-50). The stream channel is immediately adjacent to the northwest corner of INTEC and is 1,365 meters (4,480 feet) from the southeast corner of the Test Reactor Area fenced boundary (LMIT 1997:2-47). During the period September 1995 to July 1996, flow of the Big Lost River on INEEL averaged 1.51 cubic meters (53.5 cubic feet) per second with the highest one-day flow of 10.36 cubic meters (366 cubic feet) per second (DOE 1999h:4.8-1). A summary of water quality data for Big Lost River in the vicinity of INEEL is provided in the *Storage and Disposition PEIS* and shows no unusual concentrations of the parameters analyzed (DOE 1996b:3-115–3-117). In general, the water quality of Big Lost River, Little Lost River, and Birch Creek is similar with the chemical quality reflecting the carbonate mineral composition of the mountain ranges drained by them, along with the quality of irrigation water return flows (DOE 1995a:4.8-4; 1999i:4-54).

### **IDAHO NUCLEAR TECHNOLOGY AND ENGINEERING CENTER**

Sanitary waste with no potential for radioactive contamination is treated in the INTEC Sewage Treatment Facility (CPP-615) and associated treatment lagoons. This facility has a Wastewater Land Application Permit from the State of Idaho for discharge to infiltration trenches, located on the northeast corner of INTEC, after treatment and does not discharge to surface waters. The only effluent criteria associated with flows to the sewage treatment ponds are for total suspended solids and nitrogen. All compliance points for the ponds are in wells downgradient from the ponds, and the maximum allowable concentrations are similar to those in the National Primary and Secondary Drinking Water Standards (Abbott, Crockett, and Moor 1997:9, 10, 13; DOE 1999i:4-52, 4-58). In 1998, INTEC generated and disposed of about 60.4 million liters (15.95 million gallons) of sanitary wastewater (French, Tallman, and Taylor 1999a:INTEC-12).

Drainage from corridors, roof and floor drains, and condensate from process heating, and heating, ventilation, and air conditioning systems, with very low potential for radiological contamination are routed to the INTEC service waste system. This system discharges under a Wastewater Land Application Permit to two percolation ponds located on the south side of the INTEC complex. Service Waste Pond 1 has a surface area of about 18,400 square meters (198,000 square feet) and is 4.9 meters (16 feet) deep. It has a disposal capacity of 5.7 million liters (1.5 million gallons) per day. Service Waste Pond 2, immediately west of Service Waste Pond 1, has a surface area of approximately 23,100 square meters (248,700 square feet). It has a disposal capacity of 11 million liters (2.9 million gallons) per day. Both ponds are fenced to keep out wildlife (Abbott, Crockett, and Moor 1997:9). Approximately 1.96 billion liters (517 million gallons) of process wastewater was discharged to the service waste percolation ponds in 1998 (French, Tallman, and Taylor 1999a:INTEC-7, 12). Based on 1998 monitoring results from the INTEC service waste system, none of the parameter concentrations exceeded applicable standards that would define the effluent as hazardous (Saffle et al. 2000:7-5).

Consideration is being given to relocating the percolation pond to reduce the potential impacts on a contaminated perched water zone. Consideration is also being given to obtaining an NPDES permit to allow direct discharge into Big Lost River. These actions are independent of the proposed action analyzed in this NI PEIS and would be preceded by appropriate NEPA documentation (Abbott, Crockett, and Moor 1997:10). Waste management activities and facilities are discussed in greater detail under Section 3.3.11.

Flooding scenarios that involve the failure of MacKay Dam and high flows in the Big Lost River have been evaluated. The results indicate that in the event of a failure of this dam, flooding would occur at INTEC. The flood area calculated for this worse-case event is shown on Figure 3-7. The low velocity and shallow depth of the water, however, would not pose a threat of structural damage to most facilities (Barghusen and Feit 1995:2.3-21; DOE 1999i:4-51, 4-53, 4-54). Localized flooding can occur due to rapid snowmelt and frozen ground conditions, but none has been reported at INTEC (Barghusen and Feit 1995:2.3-23).

A separate flood study conducted by USGS and published in 1998 calculated that the 100-year flood would produce a flow at the Arco gauging station of about 205.6 cubic meters (7,260 cubic feet) per second, resulting in failure of the INEEL Diversion Dam and inundating the northern third of INTEC (DOE 1999i:4-54, 4-55). A 1999 Bureau of Reclamation paleoflood study confirms that while INTEC is potentially subject to flooding by the Big Lost River, it is predominantly sited on geomorphic surfaces that are well in excess of 10,000 years of age, indicating that the hazard of significant flooding is low under natural channel conditions. However, extensive modification of the Big Lost River channel throughout much of INEEL indicates that the characterization of flood stage due to Big Lost River flows will require a detailed assessment of channel stability and behavior for different flows (DOI 1999). Nevertheless, the results of the Bureau of Reclamation study indicate that neither the 100- or 500-year flood would inundate any more than the northern-most portion of INTEC. The study did not, however, consider dam failure (DOE 1999i:4-54, 4-56, 4-57). No flood maps are available from the Federal Emergency Management Agency.

### **TEST REACTOR AREA**

Sanitary wastewater from Test Reactor Area facilities is collected by the sanitary sewer system and discharged to two sewage evaporation lagoons located just to the east of the Test Reactor Area (i.e., Test Reactor Area Sanitary Waste Ponds) (Saffle et al. 2000:7-6). In 1998, the Test Reactor Area generated and disposed of about 42.4 million liters (11.2 million gallons) of sanitary wastewater (French, Tallman, and Taylor 1999a:TRA-12).

Radiological liquid effluents at the Test Reactor Area result from canal wastewater, primary coolant leakage, and activities associated with ATR power monitoring. This process wastewater is treated by the ATR Warm Waste Treatment Facility system. The resultant wastewater, containing tritium, limited concentrations of activation, and fission products below the volatile and nonvolatile release limits established by the State of Idaho, is released to the Test Reactor Area Warm Waste Evaporation Ponds, Test Reactor Area-715. As a result, there is no direct discharge to groundwater. Nevertheless, this released wastewater is also below applicable requirements for nonradiological hazardous constituents specified in the pond operating permit (LMIT 1997:11-10, 11-11, 11-42; Moor and Peterson 1999:7). The ATR Warm Waste Treatment Facility has a design flow rate of 567.8 liters (150 gallons) per minute or about 817,646 liters (216,000 gallons) per day (LMIT 1997:11-41, 11-43). Effluent discharges to the Warm Waste Evaporation Ponds totaled approximately 15.8 million liters (4.17 million gallons) in 1998 (French, Tallman, and Taylor 1999a:TRA-8).

Nonradiological process waste effluents (primary ATR secondary cooling water) collect at the cold well sump (Test Reactor Area-703) and sampling station (Test Reactor Area-764) where they are collected continuously, sampled daily, and pumped out to the Cold Waste Pond (Test Reactor Area-702) located outside the Test Reactor Area fence. Sampling data indicate that during routine operation, the Test Reactor Area cold waste

effluent is characterized as nonhazardous industrial wastewater (LMIT 1997:11-10–11-12; Moor and Peterson 1999:7; Saffle et al. 2000:7-6, 7-7). Approximately 793.7 million liters (209.67 million gallons) of process wastewater was discharged to the Cold Waste Pond in 1998 (French, Tallman, and Taylor 1999a:TRA-5). Waste management activities and facilities are discussed in greater detail under Section 3.3.11.

Flooding scenarios that involve the failure of MacKay Dam have been evaluated and the results indicate that flood waters would not reach ATR, even if the failure was concurrent with the probable maximum flood (Figure 3–7). The effects of intense local precipitation and snowmelt runoff have also been evaluated and are not expected to result in flood damage to ATR because the reactor building main floor is at a higher elevation than its surroundings (LMIT 1997:2-47-2-51).

The 1998 USGS and 1999 Bureau of Reclamation flood studies described earlier also evaluated the potential for flooding at Test Reactor Area with the results indicating that none of the scenarios evaluated would result in inundation of the Test Reactor Area.

### **3.3.4.2 Groundwater**

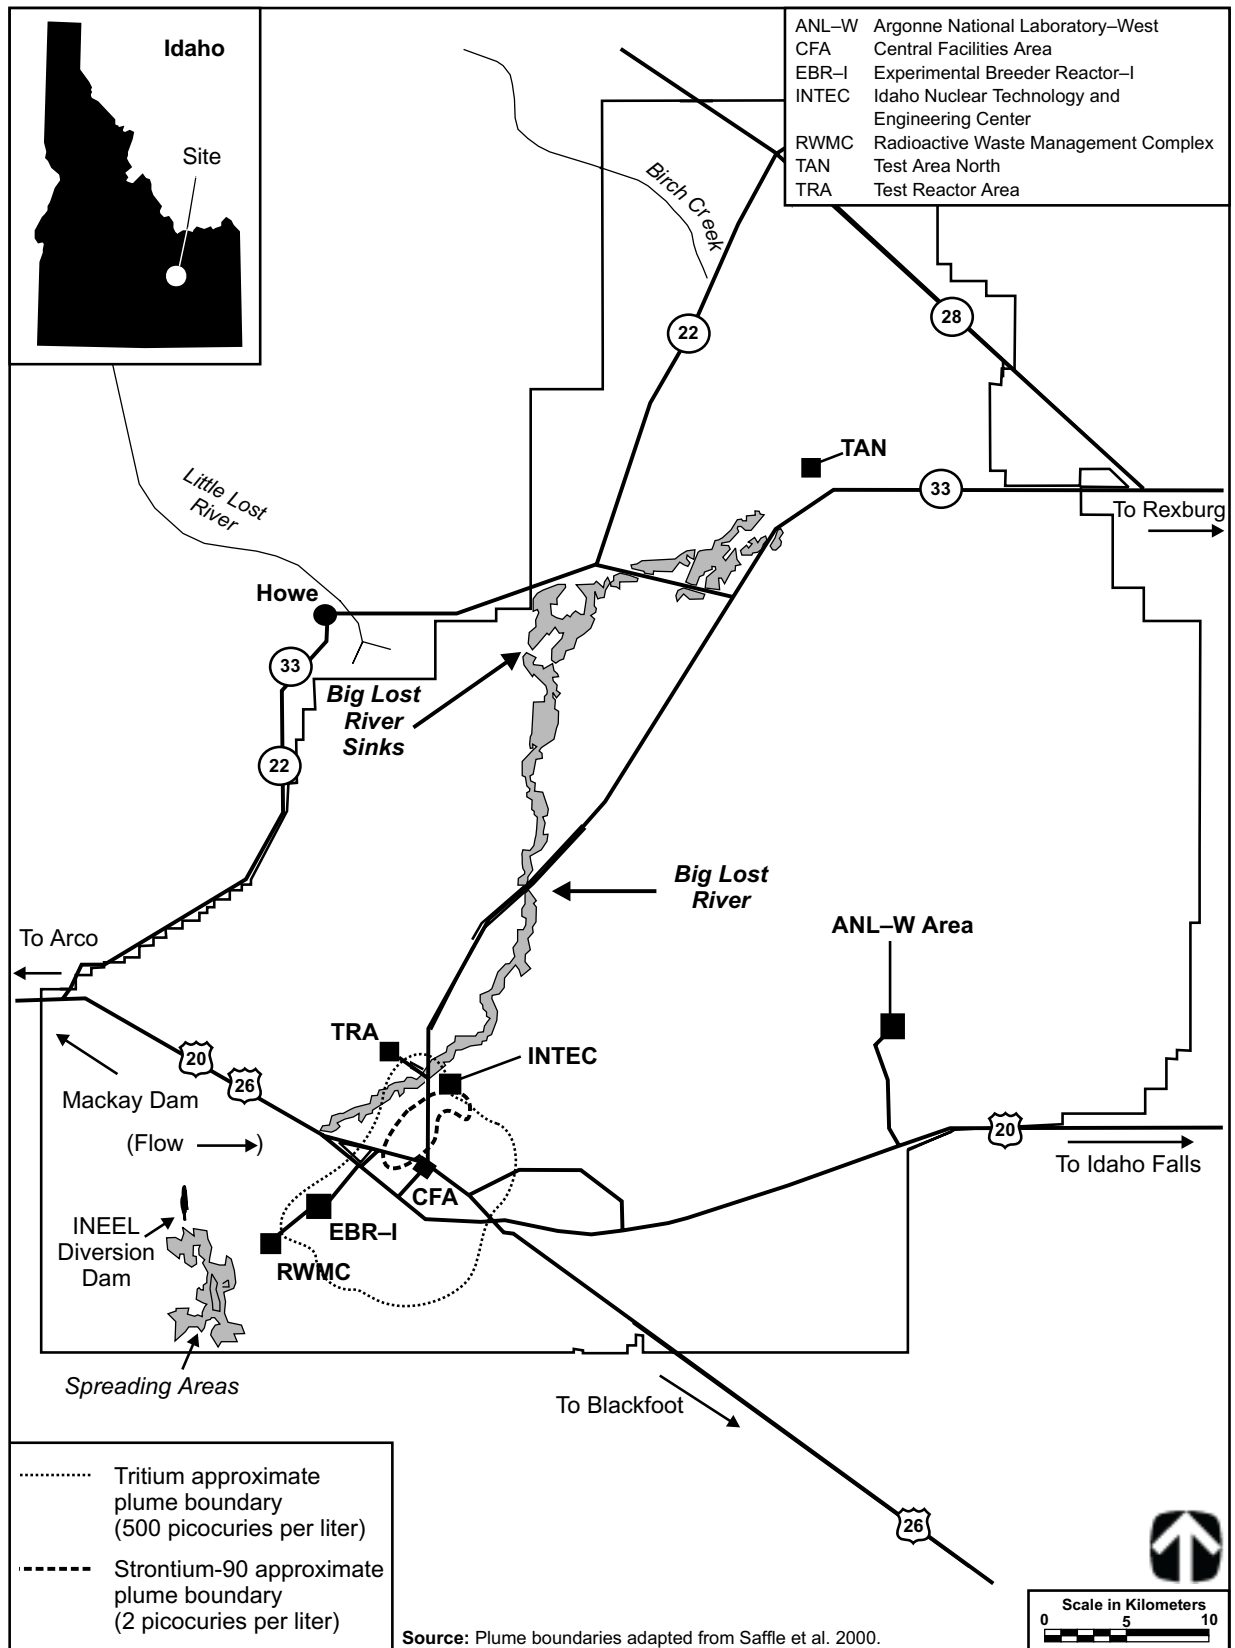

Aquifers are classified by Federal and state authorities according to use and quality. The Federal classifications include Classes I, IIA, IIB, and III groundwater. Class I groundwater is either the sole source of drinking water or is ecologically vital. Classes IIA and IIB are current or potential sources of drinking water or other beneficial use, respectively. Class III is not considered a potential source of drinking water and is of limited beneficial use.

#### **3.3.4.2.1 General Site Description**

The Snake River Plain aquifer is classified by EPA as a Class I sole source aquifer. It lies below the INEEL site and covers about 2,486,000 hectares (6,143,000 acres) in southeastern Idaho. This aquifer serves as the primary drinking water source in the Snake River Basin and is believed to contain 1.2 quadrillion to 2.5 quadrillion liters (317 trillion to 660 trillion gallons) of water. The aquifer consists of 610 to 3,048 meters (2,000 to 10,000 feet) of interbedded sediments, lava flows, and rhyolite. Recharge of the groundwater comes from Henry's Fork of the Snake River, Big Lost River, Little Lost River, and Birch Creek. Rainfall and snowmelt also contribute to the aquifer's recharge (DOE 1996b:3-115–3-117). Groundwater generally flows laterally at a rate of 1.5 to 6.1 meters (5 to 20 feet) per day. Groundwater flow is toward the south-southwest. It emerges in springs along the Snake River from Milner to Bliss, Idaho. Depth to the groundwater table ranges from about 60 meters (200 feet) below ground in the northeast corner of the site, to about 300 meters (1,000 feet) in the southeast corner (DOE 1995a:4.8-5; 1996b:3-117). Perched water tables also occur below the site. These perched water tables tend to slow the migration of pollutants that might otherwise reach the Snake River Plain aquifer (DOE 1996b:3-117). Perched water tables have been detected beneath INTEC and the Test Reactor Area mainly attributable to disposal ponds (DOE 1995a:4.8-8).

INEEL has a large network of monitoring wells that are maintained and monitored by USGS. This network includes 125 observation wells in the Snake River Plain aquifer and 45 drilled to monitor perched aquifers. An additional 120 auger holes have been drilled for monitoring shallow perched groundwater (Saffle et al. 2000:3-34, 3-35). INEEL's management and operations contractor also routinely monitors drinking water quality via 17 production wells and 10 distribution systems (Saffle et al. 2000:3-27).

Historical waste disposal practices have produced localized plumes of radiochemical and chemical constituents in the Snake River Plain Aquifer at INEEL. Of principal concern over the years has been the movements of the tritium and strontium-90 plumes. The general extent of these plumes beneath INEEL are shown in **Figure 3–8**.

**Figure 3–8 Extent of Tritium and Strontium-90 Plumes within the Snake River Plain Aquifer on the Idaho National Engineering and Environmental Laboratory (1995)**

The main sources of tritium contamination of groundwater have been the injection of wastewater through the INTEC disposal well and the discharge of wastewater to the infiltration/percolation ponds at INTEC and Test Reactor Area. Since 1984, wastewater has been discharged only to the infiltration ponds, and since 1993 principally to lined evaporation ponds at the Test Reactor Area. The extent of the tritium contamination plume has remained about the same since 1991; however, concentrations in well water within the plume have decreased significantly. This is attributed to radioactive decay and a decrease in tritium disposal rates (Saffle et al. 2000:6-10, 6-12, 6-13).

The extent of the strontium-90 contaminant plume, also originating from INTEC, as well as the concentrations of strontium-90 have remained essentially constant since 1991. This is attributed to a lack of groundwater recharge from the Big Lost River that would otherwise dilute concentrations, and to the disposal of other chemicals in the INTEC infiltration ponds which may have decreased strontium-90 adsorption to soil and rock causing more to remain in the liquid phase (Saffle et al. 2000:6-13). Other known contaminants include cesium-137, iodine-129, strontium-90, and nonradioactive compounds such as trichloroethylene. Components of nonradioactive waste entered the aquifer as a result of past waste disposal practices. Elimination of groundwater injection exemplifies a change in disposal practices that has reduced the amount of these constituents in the groundwater (DOE 1996b:3-117, 3-119). Information on more recent groundwater monitoring and chemical analysis is presented in the annual site environmental report (Saffle et al. 2000).

From 1982 to 1985, INEEL used about 7.9 billion liters (2.1 billion gallons) per year from the Snake River Plain aquifer, the only source of water at INEEL. This represents less than 0.3 percent of the groundwater withdrawn from that aquifer. Since 1950, DOE has held a Federal Reserved Water Right for the INEEL site that permits a pumping capacity of approximately 2.3 cubic meters (80 cubic feet) per second, with a maximum water consumption of 43 billion liters (11.4 billion gallons) per year. Total groundwater withdrawal at INEEL historically averages between 15–20 percent of that permitted amount (DOE 1996b:3-119; Moor and Peterson 1999:6). In 1998, INEEL's production well system withdrew a total of about 4.83 billion liters (1.276 billion gallons) of water. Most of the groundwater withdrawn for use by INEEL facilities is returned to the subsurface via percolation ponds (French, Tallman, and Taylor 1999a:v).

#### **3.3.4.2.2 Locations of Proposed Activities**

##### **IDAHO NUCLEAR TECHNOLOGY AND ENGINEERING CENTER**

Water for INTEC is supplied by two deep wells (CPP-01 and CPP-02) in the northwest corner of the area. The wells are about 180 meters (590 feet) deep and about 36 centimeters (14 inches) in diameter (Abbott, Crockett, and Moor 1997:9, 13). These wells can each supply up to approximately 11,400 liters per minute (3,000 gallons per minute) of water for use in the INTEC fire water, potable water, treated water, and demineralized water systems (Werner 1997). INTEC withdrew approximately 2.20 billion liters (581 million gallons) of groundwater in 1998 (French, Tallman, and Taylor 1999a:INTEC-12). Water use by individual facilities within INTEC (e.g., FDPF or CPP-651) is not generally metered (Folk 2000). Pumping has little effect on the level of the groundwater, because the withdrawals are small relative to the volume of water in the aquifer and the amount of recharge available. The production wells at INTEC have historically contained measurable quantities of strontium-90 (Barghusen and Feit 1995:2.3-23–2.3-29).

Water from the potable production well system at INTEC was sampled and analyzed in 1998 for lead, copper, and nitrogen as nitrate, with maximum levels measuring 0.004, 0.3, and 2.0 milligrams per liter, respectively. None of these constituents were above the EPA maximum contaminant levels or the State of Idaho drinking water limits of 0.015, 1.3, and 10 milligrams per liter, respectively. Also, routine sampling and analysis in 1998 of the potable water distribution system serving INTEC for purgeable organic compounds revealed the presence of total trihalomethanes (i.e., trichloromethane [chloroform], dibromochloromethane,

bromodichloromethane, and tribromomethane [bromoform]) and total xylenes at maximum levels of 11.3 and 0.3 micrograms per liter, respectively. However, these concentrations are well below the corresponding maximum contaminant levels for these contaminants of 100 and 10,000 micrograms per liter. Monitoring was also conducted in 1998 for radiochemical contaminants in INEEL production well and distribution systems. Of the 59 samples analyzed in 1998, seven revealed detectable gross alpha activity with the highest level (7 picocuries per liter) at INEEL from the INTEC distribution system. This is below the maximum contaminant level of 15 picocuries per liter. Tritium was also detected in several wells and distribution systems sampled in 1998. The maximum tritium concentration was 15,700 picocuries per liter (maximum contaminant level of 20,000 picocuries per liter) in the Central Facilities Area; the maximum concentration measured from an INTEC production well was 500 picocuries per liter (Saffle et al. 2000:6-10–15).

Purgeable (volatile) organics such as 1,1-dichloroethylene, toluene, and 1,1,1-trichloroethane have also historically been detected in monitoring wells within and near INTEC but at levels below maximum contaminant levels. Maximum values for tritium in samples from INTEC wells previously averaged 23,700 picocuries per liter, and maximum strontium-90 values averaged 53 picocuries per liter (Abbott, Crockett, and Moor 1997:11, 12). These values exceed the drinking water standards for tritium and strontium-90 of 20,000 picocuries per liter and 8 picocuries per liter, respectively. Selected USGS monitoring wells were sampled in 1998 for volatile organics with measurable quantities found in four wells downgradient (southwest) of INTEC. Contaminants found included 1,1,1-trichloroethane (maximum contaminant level of 200 micrograms per liter) in two wells at a maximum concentration of 0.4 micrograms per liter and dichlorodifluoromethane in four wells at a maximum concentration of 0.2 micrograms per liter (no established maximum contaminant level) (Saffle et al. 2000:6-8, 6-9). Based on the most recently published data for USGS monitoring wells, concentrations in the tritium plume originating at INTEC have continued to decrease with the concentration in well 77 south of INTEC decreasing from about 41,700 picocuries per liter in 1991 to 25,100 picocuries per liter in 1995. In contrast, strontium-90 concentrations have remained relatively constant since 1991 with concentrations between 1992 and 1995 ranging from 2.6 to 76 picocuries per liter. Nevertheless, while sampling has historically found detectable levels of strontium-90 in INTEC production wells, no strontium-90 was detected in INTEC production wells based on 1998 sampling results (Saffle et al. 2000:6-12–6-14). The general extent of the tritium and strontium-90 plumes is depicted in Figure 3–8.

### **TEST REACTOR AREA**

All water used at Test Reactor Area is groundwater from the Snake River Plain aquifer tapped by three deep wells (TRA-01, TRA-02, and TRA-03). The depth to the groundwater at the Test Reactor Area is approximately 140 meters (460 feet). In general, Test Reactor Area, encompassing the ATR complex, uses approximately 190 million liters (50 million gallons) per month of water (Moor and Peterson 1999:6; LMIT 1997:2-59). In 1998, groundwater withdrawals from these three wells for Test Reactor Area uses totaled approximately 1.80 billion liters (475.5 million gallons) (French, Tallman, and Taylor 1999a:TRA-11). For 1999, total groundwater production was similar at about 1.78 billion liters (471 million gallons) (Perry 2000). Water use by individual facilities within the Test Reactor Area is not generally metered (Folk 2000).

As part of routine potable production well system monitoring, water from the Test Reactor Area distribution system was sampled and analyzed in 1998 for copper and nitrogen as nitrate, with concentrations measuring 1.2 and 1.1 milligrams per liter, respectively; results were below the established maximum contaminant levels (Saffle et al. 2000:6-11, 6-12). In 1998, the Test Reactor Area distribution system was also monitored for purgeable organics such as total trihalomethanes with a maximum detected concentration of 0.3 micrograms per liter, below the maximum contaminant level of 100 micrograms per liter. The tritium concentration measured in the Test Reactor Area potable water distribution system during 1998 was much lower than at INTEC and other sites with a maximum concentration of 30 picocuries per liter (maximum contaminant level of 20,000 picocuries per liter). USGS monitoring well data for tritium indicate that tritium concentrations

continue to decrease, as observed near INTEC, with the concentration in well 65 south of the Test Reactor Area decreasing from about 37,800 picocuries per liter in 1991 to 21,200 picocuries per liter in 1995 (Saffle et al. 2000:6-12, 6-15).

### **3.3.5 Geology and Soils**

Geologic resources are consolidated or unconsolidated earth materials, including ore and aggregate materials, fossil fuels, and significant landforms. Soil resources are the loose surface materials of the earth in which plants grow, usually consisting of disintegrated rock, organic matter, and soluble salts.

#### **3.3.5.1 General Site Description**

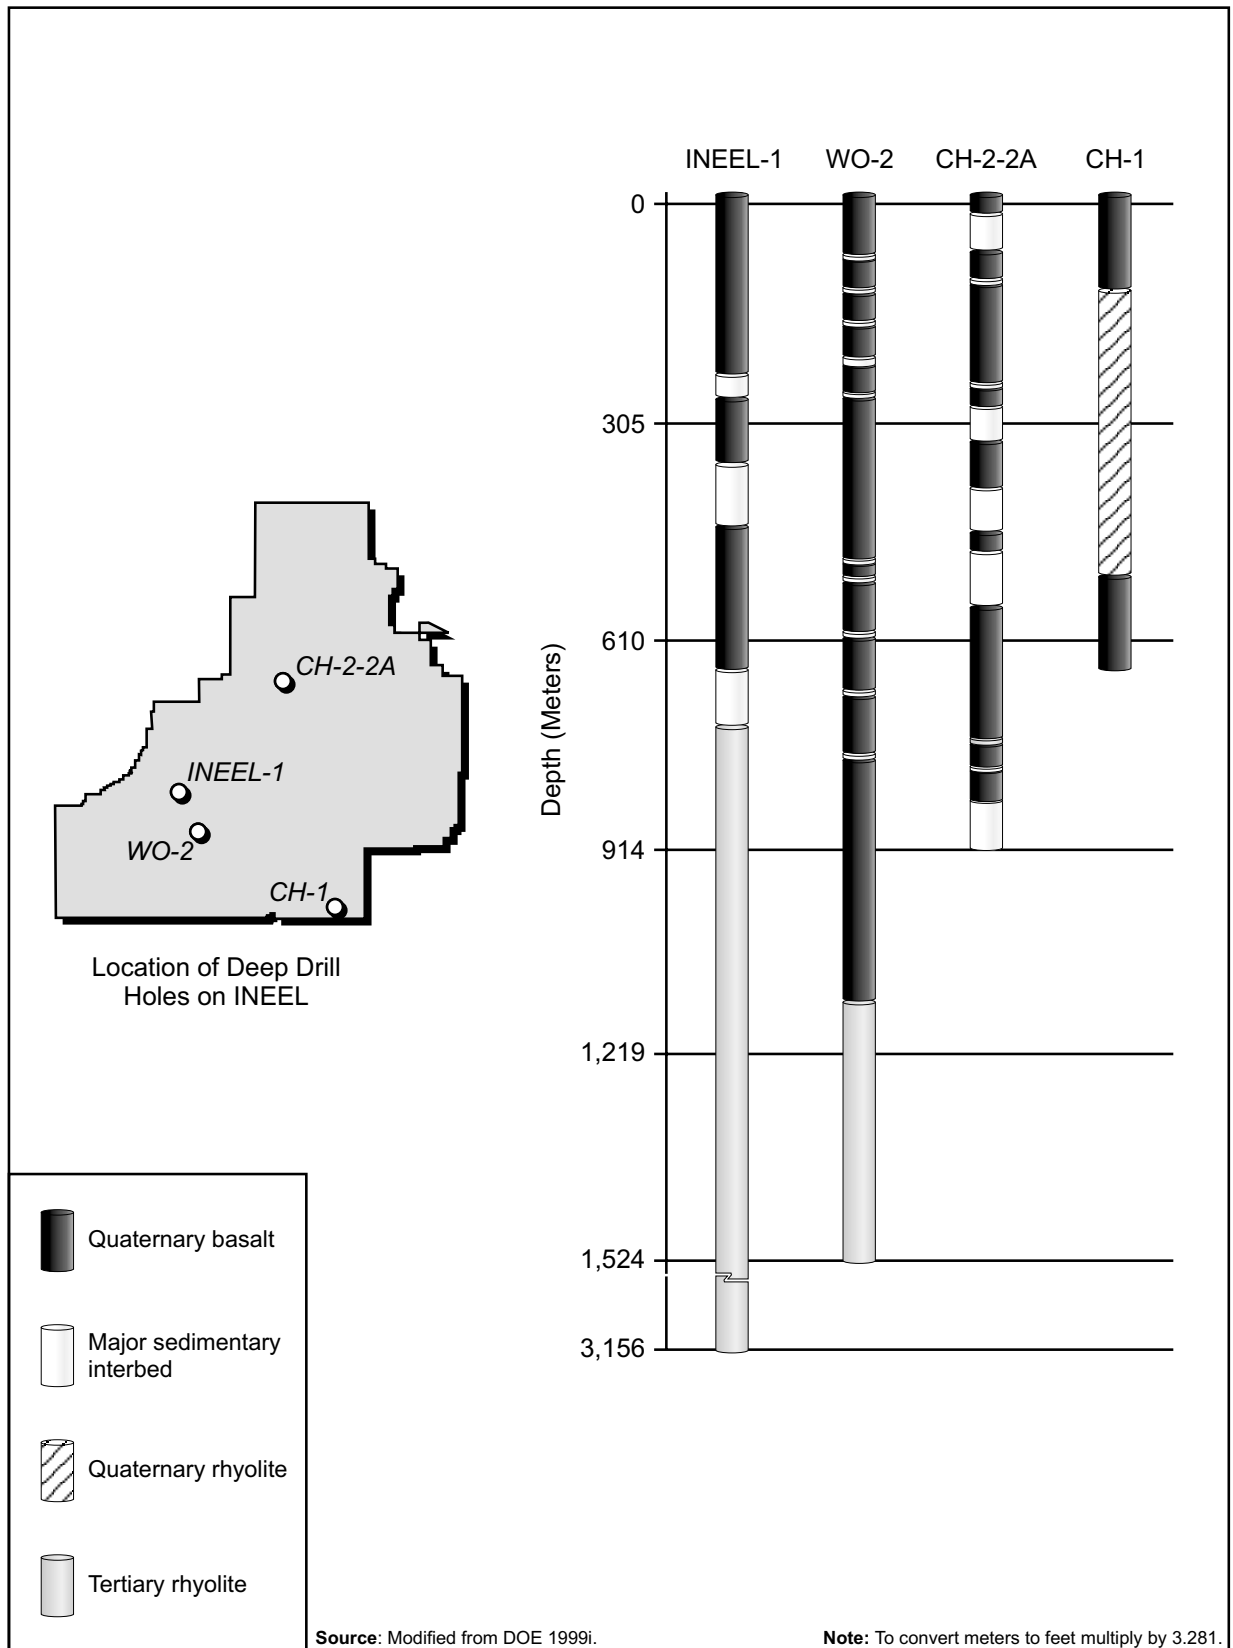

INEEL is on the northwestern edge of the eastern Snake River Plain that is bounded on the north and south by north to northwest trending mountains and valleys of the Basin and Range physiographic province (DOE 1999h:4.6-1; LMIT 1997:2A-3). The upper 1 to 2 kilometers (0.6 to 1.2 miles) of the crust beneath INEEL is composed of a sequence of Quaternary age (recent to 2 million years old) basalt lava flows and poorly consolidated sedimentary interbeds collectively called the Snake River Group. The sediments are composed of fine-grained silts that were deposited by wind; silts, sands, and gravels deposited by streams; and clays, silts, and sands deposited in lakes. Rhyolitic (granite-like) volcanic rocks of unknown thickness lie beneath the basalt sediment sequence. The rhyolitic volcanic rocks were erupted between 4.3 and 6.5 million years ago during the upper Tertiary Period (Barghusen and Feit 1995:2.3-17; LMIT 1997:2A-15, 2A-16). The variability of the volcanic-sedimentary sequences underlying INEEL is illustrated by logs of deep drill holes completed at INEEL (**Figure 3-9**). Lava tubes, which could have similar adverse effects as karst, occur in the INEEL area (Abbott, Crockett, and Moor 1997:10).

Within INEEL, economically viable sand, gravel, pumice, silt, clay, and aggregate resources exist. Several quarries supply these materials to various onsite construction and maintenance projects (DOE 1999h:4.6-4). Geothermal resources are potentially available in parts of the Eastern Snake River Plain, but neither of two boreholes drilled near INTEC encountered rocks with significant geothermal potential (Abbott, Crockett, and Moor 1997:12).

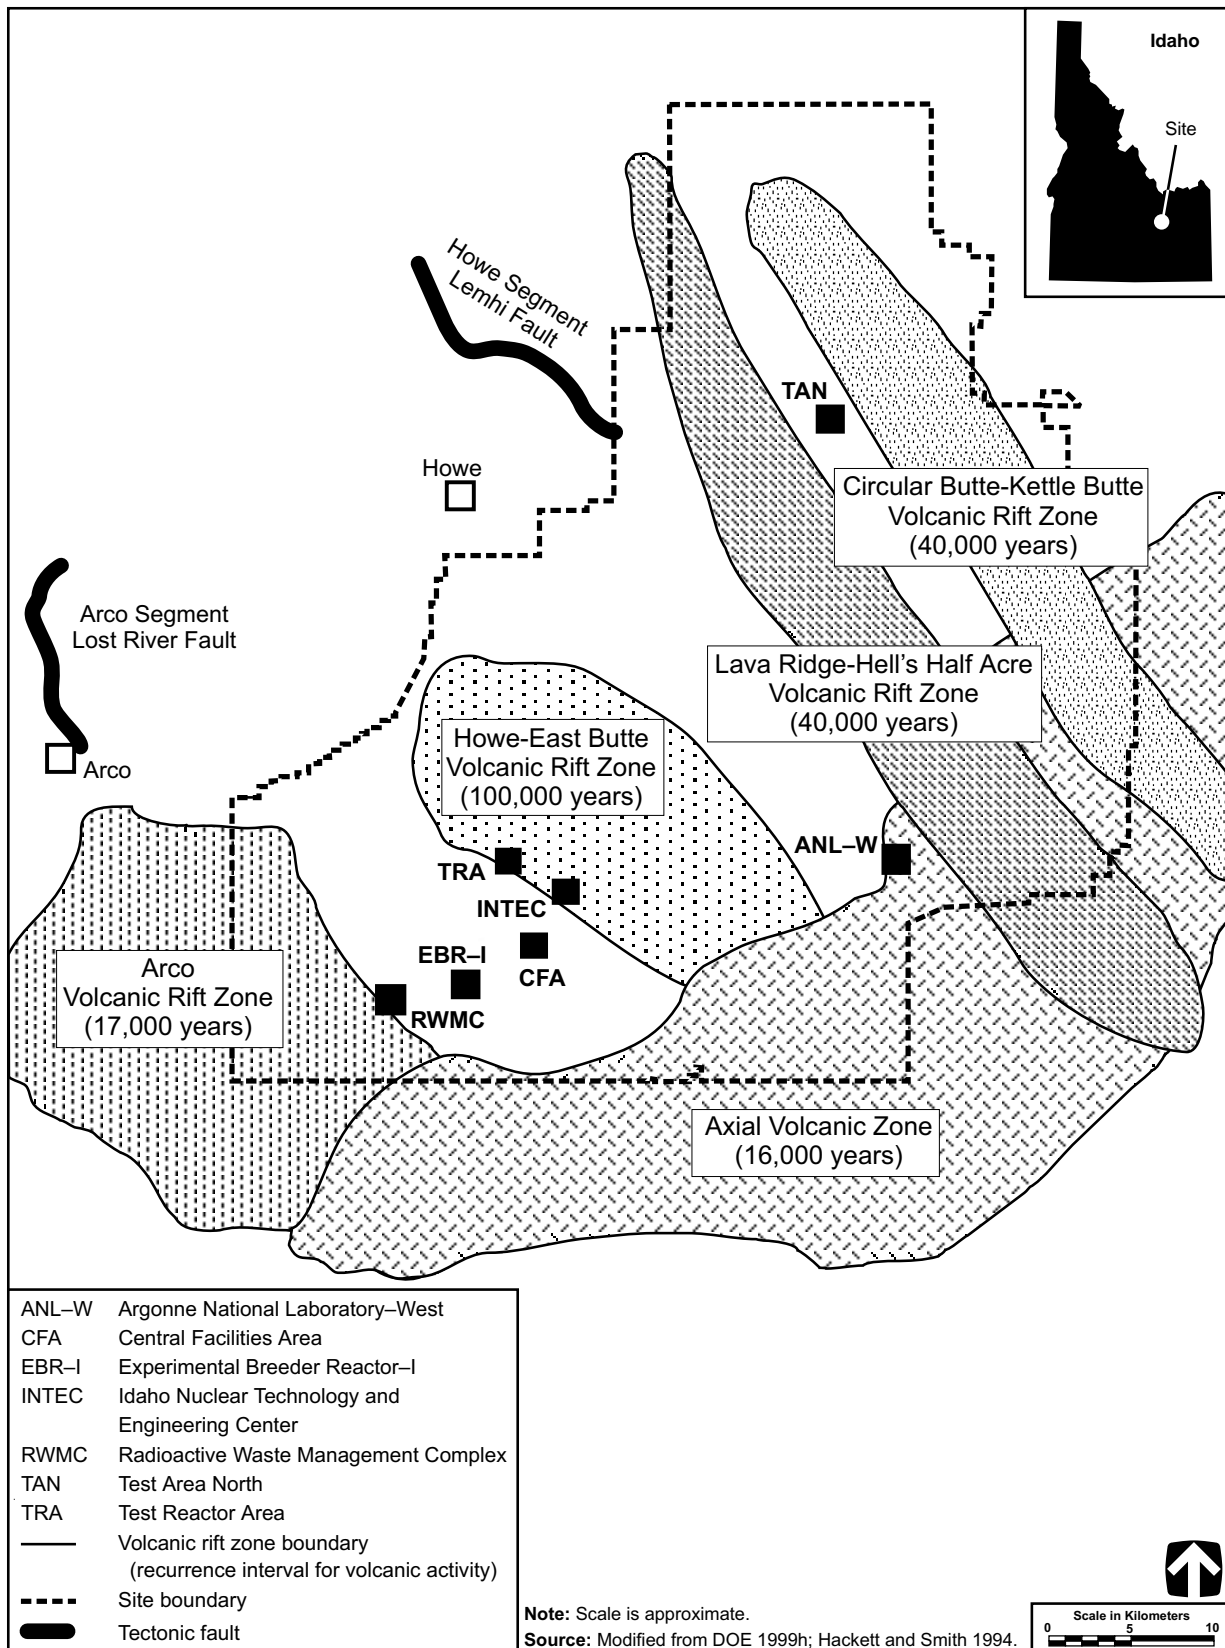

The Arco Segment of the Lost River Fault is thought to terminate about 7 kilometers (4.3 miles) from the INEEL boundary. The Howe Segment of the Lemhi Fault terminates near the northwest boundary of the site (LMIT 1997:2A-44, 2A-45, 2A-77) (**Figure 3-10**). Both segments are considered capable. A capable fault is one that has had movement at or near the ground surface at least once within the past 35,000 years, or recurrent movement within the past 500,000 years (10 CFR Part 100, Appendix A).

The seismic characteristics of the Eastern Snake River Plain and the adjacent Basin and Range Province are different; the Snake River Plain has historically experienced few and small earthquakes (DOE 1999h:4.6-1). Monitoring by the INEEL seismic network has detected relatively few microearthquakes (magnitude less than 1.5) as having occurred on or near the site (Barghusen and Feit 1995:2.3-17; Jackson et al. 1993:680-695). Since 1973, there have been a total of nine small earthquakes (ranging in magnitude from 3.0 to 3.6) recorded within a radius of 90 kilometers (56 miles) of central INEEL (INTEC and Test Reactor Area), with none closer than 75 kilometers (47 miles) (USGS 2000c).

The largest historic earthquake near INEEL took place in October 1983, about 90 kilometers (56 miles) to the northwest, near Borah Peak in the Lost River Range. It occurred on the middle portion of the Lost River Fault. The earthquake had a surface-wave magnitude of 7.3 (moment magnitude of 6.9) producing peak horizontal accelerations of 0.022g to 0.078g at INEEL (DOE 1999h:E-2-1; Jackson 1985:385; USGS 2000c). The reported Modified Mercalli Intensity was VII at the event's epicenter (USGS 2000c). The Test Reactor Area

**Figure 3-9 Lithologic Logs of Deep Drill Holes on Idaho National Engineering and Environmental Laboratory**

**Figure 3–10 Major Geologic Features of the Idaho National Engineering and Environmental Laboratory**

(i.e., ATR) experienced a Modified Mercalli Intensity of VI during this event with no damage to ATR found upon inspection (LMIT 1997:2A-29). An earthquake with a maximum horizontal acceleration of 0.15g is calculated to have an annual probability of occurrence of 1 in 5,000 at a central INEEL location (Barghusen and Feit 1995:2.3-17).

As discussed in more detail in Section 3.2.5.1, USGS has developed new seismic hazard maps as part of the National Seismic Hazard Mapping Project that are based on response spectral acceleration. These maps have been adapted for use in the new *International Building Code* (ICC 2000) (Figures 1615 (1) and 1615(2) in the code) and depict maximum considered earthquake ground motion of 0.2- and 1.0-second spectral response acceleration, respectively, based on a 2 percent probability of exceedance in 50 years. INEEL lies within the 0.35g to 0.40g mapping contours for a 0.2-second spectral response acceleration and the 0.10g to 0.15g contours for a 1.0-second spectral response acceleration.

Basaltic volcanic activity occurred from about 2,100 to 4 million years ago in the INEEL site area. Although no eruptions have occurred on the Eastern Snake River Plain during recorded history, lava flows of the Hell's Half Acre lava field erupted near the southern INEEL boundary as recently as 5,400 years ago. The most recent eruptions within the site area occurred about 2,100 years ago 30 kilometers (19 miles) southwest of the site at the Craters of the Moon Wilderness Area. Five volcanic zones have been identified on INEEL. The estimated recurrence interval for volcanism in these zones ranges from 16,000 to 100,000 years (DOE 1999h:4.6-3, 4.6-4; Hackett and Smith 1994:9, 12, 14, 20). These zones are depicted in Figure 3-10.

Four basic soils exist at INEEL: river-transported sediments deposited on alluvial plains, fine-grained sediments deposited into lake or playa basins, colluvial sediments originating from bordering mountains, and wind-blown sediments over lava flows. The alluvial deposits follow the courses of the modern Big Lost River and Birch Creek. The playa soils are in the north-central part of the site. The colluvial sediments are along the western edge of INEEL. Wind-blown sediments (silt and sand) covering lava plains occupy the rest of the landscape of the site (DOE 1997b:52-54). The thickness of surficial sediments ranges from less than 0.3 meters (1 foot) at basalt outcrops east of INTEC to 95 meters (312 feet) near the Big Lost River sinks (DOE 1999h:4.6-1). No prime farmland lies within INEEL boundaries (DOE 1999e:3-71).

### 3.3.5.2 Locations of Proposed Activities

#### IDAHO NUCLEAR TECHNOLOGY AND ENGINEERING CENTER

The nearest capable fault to INTEC is the Howe Segment of the Lemhi Fault, located about 19 kilometers (12 miles) north of the site (Abbott, Crockett, and Moor 1997:10; LMIT 1997:2A-82). Surficial geologic materials at INTEC include alluvial materials deposited by the Big Lost River. These alluvial deposits are a mixture of gravel, sand, and silt ranging in thickness from approximately 7.6 to 19.8 meters (25 to 65 feet) and locally interbedded with silt and clay deposits up to 2.9 meters (9.5 feet) thick (DOE 1999i:4-31). These surficial materials overlie the interbedded basaltic lavas of the Snake River Group. While lava tubes do occur in the INEEL area, extensive drilling in the INTEC area has not revealed any lava tubes below the site. All soil near INTEC was originally fine loam over a sand or sand-cobble mix deposited in the floodplain of the Big Lost River. However, all natural soils within INTEC fences have been disturbed. The soils beneath INTEC area are not subject to liquefaction because of the high content of gravel mixed with the alluvial sands and silts. In addition, the sediments are not saturated (Abbott, Crockett, and Moor 1997:10, 12; LMIT 1997:2A-83).

## TEST REACTOR AREA

The nearest capable fault to the Test Reactor Area is the Howe Segment of the Lemhi Fault, which is about 19 kilometers (12 miles) north-northeast of ATR (LMIT 1997:2A-82). Surficial materials within the site area, like INTEC, consist of Big Lost River alluvium comprised mostly of gravel, gravelly sands, and sands ranging from 9 to 15 meters (30 to 50 feet) in depth. A relatively thin layer of silt and clay underlies the alluvium in some locations creating a low-permeability layer at the basalt bedrock interface. These sediments overlie the interbedded basalts of the Snake River Group, with basaltic rock exposed at the surface to the north and west of the Test Reactor Area. The sedimentary interbeds of the Snake River Group consist mainly of silts, clayey silts, and sandy silts (LMIT 1997:2A-17, 2A-18). There is no potential for unstable conditions due to lava tubes at the site. Soils on the site, although highly disturbed by existing facilities, are derived from the Big Lost River alluvium. The soils and sediments are not subject to liquefaction (LMIT 1997:2A-17, 2A-83; Moor and Peterson 1999:7).

### 3.3.6 Ecological Resources

Ecological resources include terrestrial resources, wetlands, aquatic resources, and threatened and endangered species. Material presented in this section, unless otherwise noted, is from the *Storage and Disposition PEIS* (DOE 1996b).

#### 3.3.6.1 Terrestrial Resources

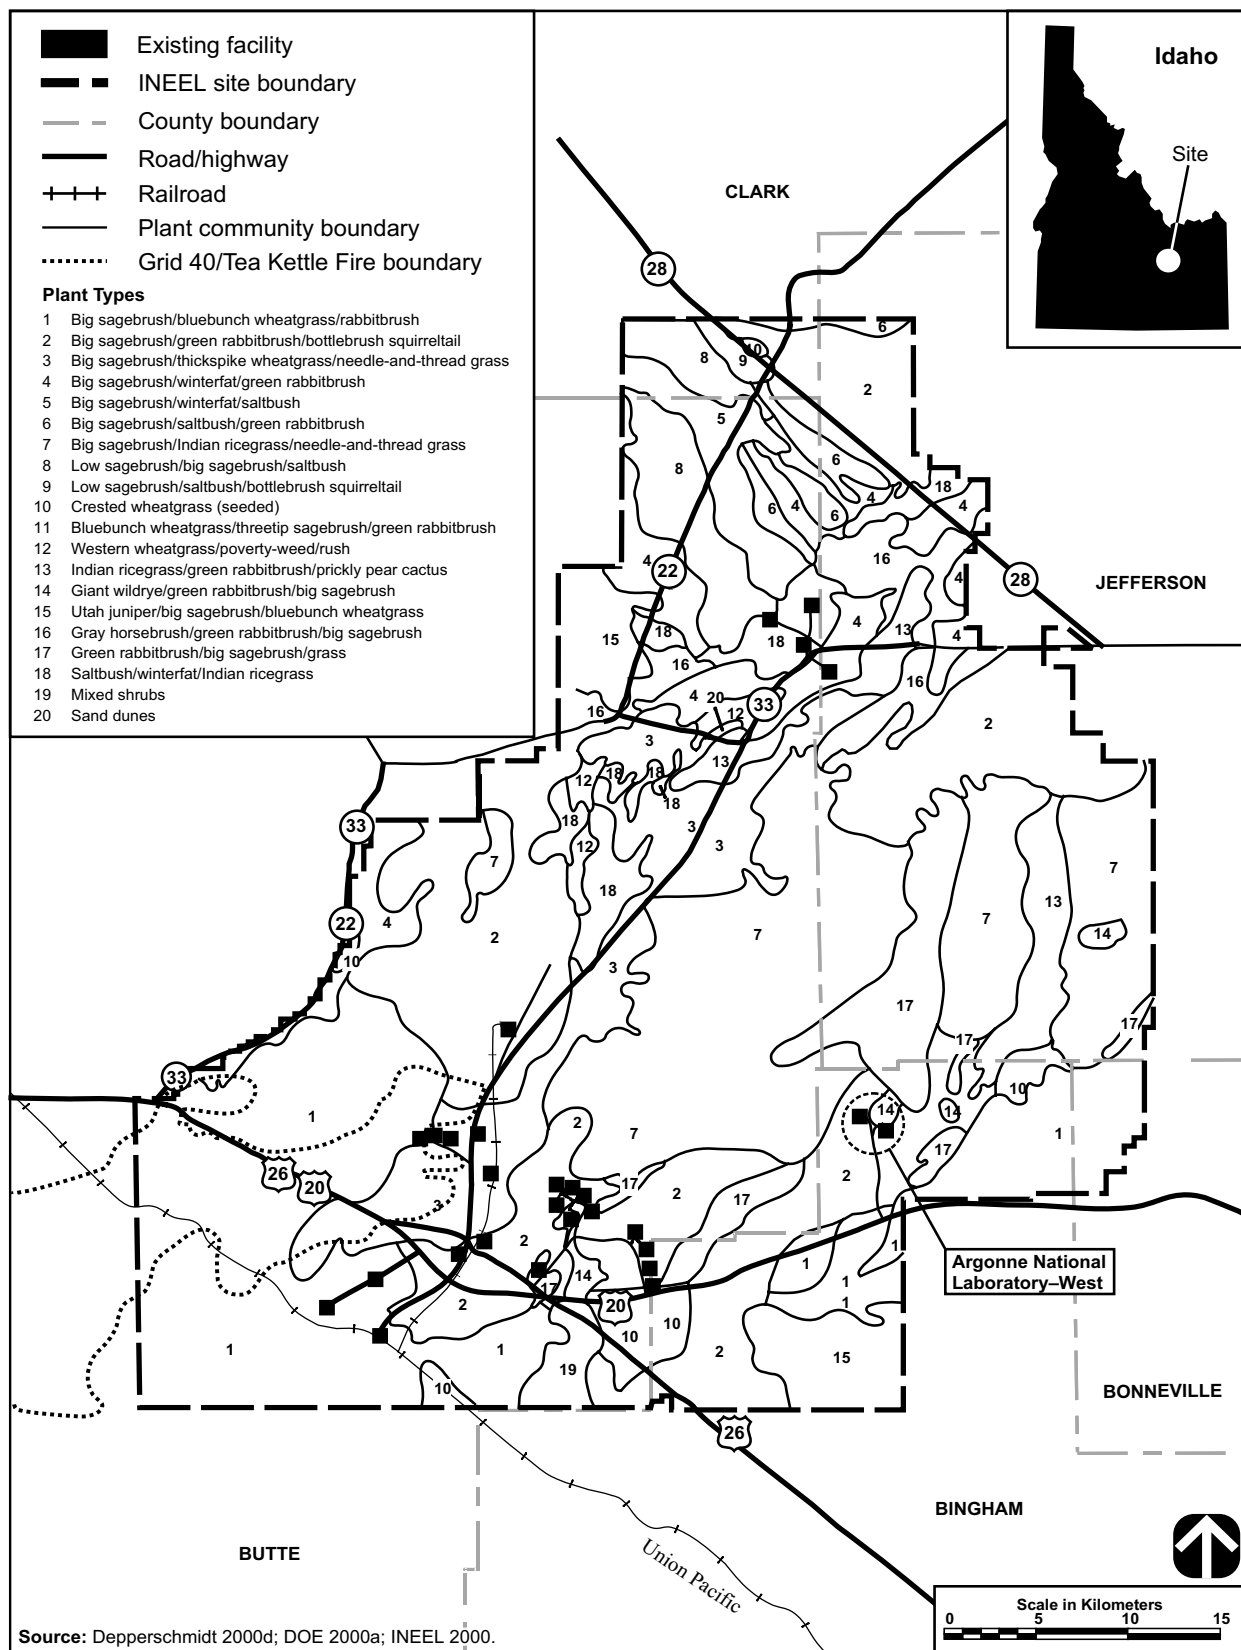

This section addresses the plant and animal communities of INEEL and includes a plant community map of the site. Terrestrial resources are described for the site as a whole, as well as for the proposed facility locations.

##### 3.3.6.1.1 General Site Description

INEEL lies in a cool desert ecosystem dominated by shrub-steppe communities. Most land within the site is relatively undisturbed and provides important habitat for species native to the region. Facilities and operating areas occupy 2 percent of INEEL; approximately 60 percent of the area around the periphery of the site is grazed by sheep and cattle. Although sagebrush communities occupy about 80 percent of INEEL, a total of 20 plant communities have been identified (**Figure 3-11**). In total, 398 plant taxa have been documented at INEEL.

The interspersed low and big sagebrush communities in the northern portion of INEEL, and juniper communities in the northwestern and southeastern portions of the site are considered sensitive habitats. The former provides critical winter and spring range for sage grouse and pronghorn, while the latter is important to nesting raptors and songbirds. Riparian vegetation, primarily cottonwood and willow along the Big Lost River and Birch Creek provides nesting habitat for hawks, owls, and songbirds. Recently, approximately 29,950 hectares (74,000 acres) of open space in the north central portion of the site have been designated as the INEEL Sagebrush Steppe Ecosystem Reserve (DOE 1999g). The area represents some of the last sagebrush steppe habitat in the United States and provides habitat for numerous rare and sensitive plants and animals.

INEEL supports numerous animal species, including two amphibian, 11 reptile, 225 bird, and 44 mammal species (Reynolds 1999). Common animals on INEEL include the short-horned lizard, gopher snake, sage sparrow, Townsend's ground squirrel, and black-tailed jackrabbit. Important game animals include the sage grouse, mule deer, elk, and pronghorn. During some winters, 4,500 to 6,000 pronghorn, or about 30 percent of Idaho's total pronghorn population, may be found on INEEL. Pronghorn wintering areas are located in the northeastern portion of the site, in the area of the Big Lost River sinks, in the west-central portion of the site

**Figure 3–11 Distribution of Plant Communities at Idaho National Engineering and Environmental Laboratory**

along the Big Lost River, and in the south-central portion of the site (DOE 1996b:3-125). Hunting elk and pronghorn is permitted only within 0.8 kilometers (0.5 miles) of the site boundary on INEEL lands adjacent to agricultural lands (DOE 1997b). Numerous raptors, such as the golden eagle and prairie falcon, and carnivores, such as the coyote and mountain lion, are also found on INEEL. A variety of migratory birds have been found at INEEL.

On July 27 and 28, 2000, a wildfire, known as the Grid 40/Tea Kettle Fire, burned across the southwestern portion of INEEL (Figure 3-11). The total burn area encompassed an estimated 19,830 hectares (49,000 acres) (Depperschmidt 2000a). The immediate effect of the fire on ecological resources on INEEL, aside from plants and animals that perished as a direct result of the fire, was the displacement of animals from their habitat. A longer-term concern for plant communities affected by fire and the animals that depend on them is that nonnative, invasive plant species may have a better competitive advantage at the expense of the native grasses and shrubs.

### **3.3.6.1.2 Locations of Proposed Activities**

#### **IDAHO NUCLEAR TECHNOLOGY AND ENGINEERING CENTER**

INTEC is within an area dominated by big sagebrush communities. The site itself is developed with little vegetation, other than that associated with landscaped areas. In fact, bare ground comprises 85 percent of the site, while facilities and pavement make up 13 percent of the area. Animal species present at INTEC are primarily limited to those adapted to disturbed industrial areas, such as mice, rabbits, sparrows, finches, and lizards (DOE 1999e:3.3.8.1.2). Wastewater ponds associated with INTEC attract a variety of wildlife (Cieminski and Flake 1995:105).

#### **TEST REACTOR AREA**

Vegetative communities in which big sagebrush is the dominant plant occur in the vicinity of the Test Reactor Area (Figure 3-11). Grasslands comprised primarily of wheat grasses also occur in the area. The Test Reactor Area itself is a developed area with little or no vegetation. Lawns and ornamental vegetation are used by a number of species such as songbirds, raptors, rabbits, and mule deer. Ponds in and around the Test Reactor Area are known to be frequented by waterfowl, shorebirds, swallow, passerines, and to a limited extent, by raptors such as the American kestrel, ferruginous hawk, and northern harrier. Mammals have been observed at the disposal ponds despite perimeter fences, and amphibians have been reported at Test Reactor Area industrial waste and sewage disposal ponds (Moor and Peterson 1999:9).

### **3.3.6.2 Wetlands**

Wetlands include “those areas that are inundated or saturated by surface or groundwater at a frequency and duration sufficient to support, and that under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions” (33 CFR Section 328.3). Wetlands are described for INEEL as a whole, as well as for the proposed facility locations.

#### **3.3.6.2.1 General Site Description**

National Wetland Inventory maps prepared by the U.S. Fish and Wildlife Service have been completed for most of INEEL. These maps indicate that the primary wetland areas are associated with the Big Lost River, the Big Lost River spreading areas, and the Big Lost River sinks, although smaller (less than about 0.4 hectares [1 acre]) isolated wetlands also occur. Wetlands associated with the Big Lost River are classified as riverine/intermittent, indicating a defined stream channel with flowing water during only part of the year. The

only area of jurisdictional wetland is the Big Lost River sinks (Evans et al. 1998:2-7). Wetland areas on INEEL are shown in Figure 3-11.

### **3.3.6.2.2 Locations of Proposed Activities**

#### **IDAHO NUCLEAR TECHNOLOGY AND ENGINEERING CENTER**

The Big Lost River spreading areas and Big Lost River sinks are seasonal wetlands and are approximately 14 kilometers (8.7 miles) southwest, and 25 kilometers (15.5 miles) north of INTEC. These areas can provide more than 809 hectares (2,000 acres) of wetland habitat during wet years. Riparian wetland vegetation exists along the Big Lost River and along Birch Creek. Plants found along the Big Lost River, which is about 0.8 kilometer (0.5 mile) northwest of the site, are in poor condition due to recent years of only intermittent flows. There are no wetlands within the immediate INTEC area (Abbott, Crockett, and Moor 1997:15).

#### **TEST REACTOR AREA**

The Big Lost River, Big Lost River spreading areas, and the Big Lost River sinks are about 2 kilometers (1.2 miles) southeast, 13 kilometers (8 miles) southwest, and 21 kilometers (13 miles) north-northeast of the Test Reactor Area. Natural wetlands do not occur in the immediate vicinity of the Test Reactor Area.

### **3.3.6.3 Aquatic Resources**

Aquatic resources at INEEL are described for the site as a whole, as well as for the proposed facility location.

#### **3.3.6.3.1 General Site Description**

Aquatic habitat on INEEL is limited to the Big Lost River, Little Lost River, Birch Creek, and a number of liquid waste disposal ponds. All three streams are intermittent and drain into four sinks in the north-central part of the site. Six species of fish have been observed within water bodies located on site (Reynolds 1999). Species observed in the Big Lost River include: brook trout, rainbow trout, mountain whitefish, speckled dace, shorthead sculpin, and kokanee salmon. The Little Lost River and Birch Creek, northwest and northeast of the Test Reactor Area, respectively, enter INEEL only during periods of high flow. Surveys of fish in these surface water bodies have not been conducted. The liquid waste disposal ponds on INEEL, while considered aquatic habitat, do not support fish.

#### **3.3.6.3.2 Locations of Proposed Activities**

#### **IDAHO NUCLEAR TECHNOLOGY AND ENGINEERING CENTER**

There is no natural aquatic habitat on the INTEC site. The nearest such habitat is the Big Lost River which is about 0.8 kilometer (0.5 mile) to the northwest. Disposal ponds in the vicinity of INTEC do not support populations of fish. However, these ponds do support a variety of aquatic invertebrates (Cieminski and Flake 1995).

#### **TEST REACTOR AREA**

Although a number of disposal ponds occur in the vicinity of the Test Reactor Area, they do not support populations of fish. Aquatic invertebrates, however, are supported by habitat provided by the ponds (Moor and Peterson 1999:9). The Big Lost River is 2 kilometers (1.2 miles) southeast of the Test Reactor Area.

### **3.3.6.4 Threatened and Endangered Species**

Endangered species are those plants and animals in danger of extinction throughout all or a large portion of their range. Threatened species are those species likely to become endangered within the foreseeable future. Threatened and endangered species are described for INEEL as a whole, as well as for the proposed facility locations.

#### **3.3.6.4.1 General Site Description**

Fifteen Federal and state-listed threatened, endangered, and other special status species occur, or possibly occur, on INEEL (see Table 4–18 of the *Idaho High-Level Waste Facilities Disposition Draft Environmental Impact Statement* [DOE 1999i]). The bald eagle is listed by the U.S. Fish and Wildlife Service as threatened (but has been proposed to be delisted) and by the State of Idaho as endangered. The bald eagle has rarely been seen in the western and northern portions of INEEL. The gray wolf (listed endangered, experimental population) has been sighted several times on INEEL since 1993. On July 27 and 28, 2000, a wildland fire called the Grid 40/Tea Kettle fire burned across 19,830 hectares (49,000 acres) of the southwestern portion of INEEL. DOE is currently assessing the impacts of that fire on threatened and endangered species and species of concern (e.g., sage grouse) (Depperschmidt 2000a, 2000c). No critical habitat for threatened or endangered species, as defined in the Endangered Species Act, exists on INEEL. Consultation to comply with Section 7 of the Endangered Species Act was conducted with the U.S. Fish and Wildlife Service. Consultation was also conducted with the state. The results of these consultations are presented in Chapter 4.

#### **3.3.6.4.2 Locations of Proposed Activities**

##### **IDAHO NUCLEAR TECHNOLOGY AND ENGINEERING CENTER**

No threatened, endangered or other special status plant or wildlife species have been recorded at or within 0.5 kilometer (0.3 mile) of INTEC (Abbott, Crockett, and Moor 1997:15). The common loon, listed by Idaho as a species of special concern, was observed once at a percolation pond during a 3-year study in the early 1990s (Werner 1997:7). Other state species of special concern potentially occurring in the vicinity of the site include the black tern, loggerhead shrike, northern goshawk, trumpeter swan, pygmy rabbit, and Townsend's western big-eared bat. A complete list of threatened, endangered, or other special status species potentially occurring in areas surrounding INTEC is provided in the *Surplus Plutonium Disposition EIS* (DOE 1999e).

##### **TEST REACTOR AREA**

No threatened, endangered, or other special status plant or wildlife species have been recorded at or near the Test Reactor Area. However, one federally listed species, the bald eagle, and a number of state-listed species of special concern potentially occur in the area. State species of special concern include the northern goshawk, loggerhead shrike, black tern, trumpeter swan, pygmy rabbit, and Townsend's western big-eared bat. Of these species, only the loggerhead shrike is commonly seen in areas surrounding the Test Reactor Area (Moor and Peterson 1999:10-11).

### **3.3.7 Cultural and Paleontological Resources**

Cultural resources are human imprints on the landscape and are defined and protected by a series of Federal laws, regulations, and guidelines. INEEL has a well-documented record of cultural and paleontological resources. Guidance for the identification, evaluation, recordation, curation, and management of these resources is included in the *Idaho National Engineering Laboratory Management Plan for Cultural Resources (Final Draft)* (Miller 1995). Past studies, which covered 4 percent of the site, identified 1,506 cultural

resource sites and isolated finds including 688 prehistoric sites, 38 historic sites, 753 prehistoric isolates, and 27 historic isolates (DOE 1996b). As of January 1998, approximately 7 percent of INEEL had been surveyed, raising the number of potential archeological sites to 1,839 (DOE 1999h). Most surveys have been conducted near major facility areas in conjunction with major modification, demolition, or abandonment of site facilities.

Cultural sites are often occupied continuously or intermittently over substantial time spans. For this reason, a single location may contain evidence of use during both historic and prehistoric periods. In the discussions that follow, the numbers of prehistoric and historic resources are presented. However, the sum of these resources may be greater than the total number of sites reported due to this dual-use history at sites. Therefore, where the total number of sites reported is less than the sum of prehistoric and historic sites, certain locations were used during both periods. DOE is currently evaluating the impacts to cultural resources from fire suppression activities during the Grid 40/Tea Kettle fire that burned across 19,830 hectares (49,000 acres) of the southwestern portion of INEEL on July 27 and 28, 2000 (Depperschmidt 2000a, 2000c).

### **3.3.7.1 Prehistoric Resources**

Prehistoric resources are physical properties that remain from human activities that predate written records.

#### **3.3.7.1.1 General Site Description**

Prehistoric resources identified at INEEL are generally reflective of Native American hunting and gathering activities. Resources appear to be concentrated along the Big Lost River and Birch Creek, atop buttes, and within craters or caves. They include residential bases, campsites, caves, hunting blinds, rock alignments, and limited-activity locations such as lithic and ceramic scatters, hearths, and concentrations of fire-affected rock. Most sites have not been formally evaluated for nomination to the National Register of Historic Places, but are considered to be potentially eligible. Given the rather high density of prehistoric sites at INEEL, additional sites are likely to be identified as surveys continue.

#### **3.3.7.1.2 Locations of Proposed Activities**

##### **IDAHO NUCLEAR TECHNOLOGY AND ENGINEERING CENTER**

The INTEC area has been subjected to a number of archaeological survey projects over the past two decades. Most of these investigations have been concentrated around the perimeter of the site and along existing roadways or power line corridors. Survey coverage within 1 kilometer (0.6 mile) of Building 691, located roughly in the center of INTEC, is complete. Archaeological resources identified within the surveyed area include prehistoric isolates such as camp sites and isolated artifacts reflecting Native American hunting and gathering activities. These resources are not likely to yield additional information and are, therefore, not likely to be potentially eligible for National Register nomination (Abbott, Crockett, and Moor 1997:16).

##### **TEST REACTOR AREA**

A variety of archaeological survey projects have been completed in the Test Reactor Area. During a 1984 examination of a 100-meter-wide (328-foot-wide) corridor surrounding the fenced perimeter of the Test Reactor Area, no prehistoric resources were identified. It is also unlikely that undisturbed prehistoric resources are present within the fenced perimeter of the facility, although no specific archaeological surveys have been conducted inside the fence. Although no prehistoric sites are known to occur around the periphery of the Test Reactor Area, significant sites have been documented in the vicinity, including a multi-component archaeological site, and smaller Native American campsites (Moor and Peterson 1999:12).

### **3.3.7.2 Historic Resources**

Historic resources consist of physical properties that postdate the existence of written records. In the United States, historic resources are generally considered to be those that date no earlier than 1492.

#### **3.3.7.2.1 General Site Description**

Thirty-eight historic sites and 27 historic isolates have been identified at INEEL. These resources are representative of European-American activities, including fur trapping and trading, immigration, transportation, mining, agriculture, and homesteading, as well as more recent military and scientific/engineering research and development activities. Examples of historic resources include Goodale's Cutoff (a spur of the Oregon Trail), remnants of homesteads and ranches, irrigation canals, and a variety of structures from the World War II era. The Experimental Breeder Reactor-I, the first reactor to achieve a self-sustaining chain reaction using plutonium instead of uranium as the principal fuel component, is listed on the National Register of Historic Places and is designated as a National Historic Landmark. Many other INEEL structures built between 1949 and 1974 are considered eligible for the National Register because of their exceptional scientific and engineering significance, and their major role in the development of nuclear science and engineering since World War II. Additional historic sites are likely to exist in unsurveyed portions of INEEL. Consultation to comply with Section 106 of the National Historic Preservation Act was initiated with the State Historic Preservation Office. The results of this consultation are presented in Chapter 4.

#### **3.3.7.2.2 Locations of Proposed Activities**

##### **IDAHO NUCLEAR TECHNOLOGY AND ENGINEERING CENTER**

Two historic sites that may be eligible for nomination to the National Register of Historic Places, a homestead and nearby trash dump, have been identified near INTEC. These sites are potential sources of information on Carey Act-sponsored agricultural activities in the region. This act, which was passed in 1894, was designed to aid in the reclamation (through irrigation) and settlement of desert lands. In addition, six historic structures associated with INTEC have been identified. An historic resource inventory of all buildings within INTEC is being conducted and will likely identify additional historic structures built between 1949 and 1974 (Abbott, Crockett, and Moor 1997:16).

##### **TEST REACTOR AREA**

All three of the major reactors within the Test Reactor Area (the Materials Test Reactor, the Engineering Test Reactor, and ATR), along with numerous support facilities, are considered eligible for listing on the National Register of Historic Places. As a result of an historic building inventory conducted in 1997, 59 Test Reactor Area buildings are considered to be eligible for the National Register (Moor and Peterson 1999:13).

### **3.3.7.3 Native American Resources**

Native American resources are sites, areas, and materials important to Native Americans for religious or heritage reasons. In addition, cultural values are placed on natural resources such as plants, which have multiple purposes within various Native American groups. Of primary concern are concepts of sacred space that create the potential for land use conflicts.

### **3.3.7.3.1 General Site Description**

Native American resources at INEEL are associated with the two groups of nomadic hunters and gatherers that used the region at the time of European-American contact: the Shoshone and Bannock. Both of these groups used the area that now encompasses INEEL, as they harvested plant and animal resources and obsidian from Big Southern Butte and Howe Point. Because INEEL is considered part of the Shoshone-Bannock Tribes' ancestral homeland, it contains many localities that are important for traditional, cultural, educational, and religious reasons. This includes not only prehistoric archaeological sites which are important in a religious or cultural heritage context, but also includes features of the natural landscape and air, plant, water, and animal resources that have special significance. Consultation was conducted with the Shoshone and Bannock Tribes. The results of this consultation are presented in Chapter 4.

### **3.3.7.3.2 Locations of Proposed Activities**

#### **IDAHO NUCLEAR TECHNOLOGY AND ENGINEERING CENTER**

Although INTEC and the surrounding area may contain Native American resources (Abbott, Crockett, and Moor 1997:16), it is unlikely that undisturbed Native American resources exist within the fenced perimeter of the site.

#### **TEST REACTOR AREA**

Over the past two decades, efforts have been underway to assemble complete inventories of cultural resources in the vicinity of major operating facilities at INEEL. A variety of survey projects have been completed near the Test Reactor Area, including a 1984 examination of a 100-meters-wide (328-foot-wide) corridor surrounding the fenced perimeter of the site. No Native American resources were identified within the surveyed area, and it is unlikely that undisturbed Native American resources are present within the fenced perimeter of the Test Reactor Area, although no specific surveys have been conducted. Cultural resource surveys in the vicinity of the Test Reactor Area have identified small Native American campsites, and an area that may be of traditional and cultural importance to the Shoshone-Bannock Tribes (Moor and Peterson 1999:12).

### **3.3.7.4 Paleontological Resources**

Paleontological resources are the physical remains, impressions, or traces of plants or animals from a former geological age. Paleontological remains consist of fossils and their associated geologic information.

#### **3.3.7.4.1 General Site Description**

The region encompassing INEEL has abundant and varied paleontological resources, including plant, vertebrate, and invertebrate remains in soils, lake and river sediments, and organic materials found in caves and archaeological sites. Vertebrate fossils recovered from the Big Lost River floodplain consist of isolated bones and teeth from large mammals of the Pleistocene or Ice Age. These fossils were discovered during excavations and well drilling operations. Fossils have been recorded in the vicinity of the Naval Reactors Facility. Occasional skeletal elements of fossil mammoth, horse, and camel have been retrieved from the Big Lost River diversion dam and Radioactive Waste Management Complex on the southwestern side of INEEL, and from river and alluvial fan gravels and Lake Terreton sediments near Test Area North (DOE 1999e). In total, 24 paleontological localities have been identified in INEEL (Miller 1995).

### 3.3.7.4.2 Locations of Proposed Activities

#### IDAHO NUCLEAR TECHNOLOGY AND ENGINEERING CENTER

Vertebrate fossils recovered from the Big Lost River floodplain consist of isolated bones or teeth from large mammals of the Pleistocene or Ice Age. These fossils were discovered during excavations and well-drilling operations. A single mammoth tooth was salvaged during the excavation of a percolation pond located to the south of INTEC (Abbott, Crockett, and Moor 1997:16).

#### TEST REACTOR AREA

A mammoth tooth dating from the late Pleistocene has been recovered from the Test Reactor Area (Miller 1995:J-15).

### 3.3.8 Socioeconomics

Statistics for employment and regional economy are presented for the regional economic area, as defined in Appendix G.8, which encompasses 13 counties around INEEL located in Idaho and Wyoming. Statistics for population, housing, community services, and local transportation are presented for the region of influence, a four-county area in Idaho in which 94.4 percent of all INEEL employees reside, as shown in **Table 3–19**. In 1997, INEEL employed 8,291 persons (about 5.5 percent of the regional economic area civilian labor force) (DOE 1999e).

**Table 3–19 Distribution of Employees by Place of Residence in the INEEL Region of Influence, 1997**

County	Number of Employees	Total Site Employment (percent)
Bonneville	5,553	67.0
Bingham	1,077	13.0
Bannock	615	7.4
Jefferson	583	7.0
Region of influence total	7,828	94.4

Source: DOE 1999e.

#### 3.3.8.1 Regional Economic Characteristics

Between 1990 and 1996, the civilian labor force in the regional economic area increased 26 percent, to the 1996 level of 150,835. In 1996, the annual unemployment average in the regional economic area was 4.8 percent, which was slightly less than the annual unemployment average for Idaho (5.2 percent) and Wyoming (5.0 percent) (DOE 1999e).

In 1995, service activities represented the largest sector of employment in the regional economic area (27.1 percent). This was followed by retail trade (20.4 percent), and government (19.5 percent). The totals for these employment sectors in Idaho were 21.5 percent, 19.6 percent, and 18.7 percent, respectively. The totals for these employment sectors in Wyoming were 21.1 percent, 20.8 percent, and 25 percent, respectively (DOE 1999e).

#### 3.3.8.2 Population and Housing

In 1996, the region of influence population totaled 213,547. Between 1990 and 1996, the region of influence population increased by 10.6 percent, compared to a 17.5 percent increase in Idaho's population. Between

1980 and 1990, the number of housing units in the region of influence increased by 6.7 percent, compared to a 10.2 percent increase in Idaho. The total number of housing units in the region of influence in 1990 was 69,760. The 1990 region of influence homeowner vacancy rate was 2.1 percent, compared to Idaho's rate of 2 percent. The region of influence rental vacancy rate was 8.3 percent compared to Idaho's rate of 7.3 percent (DOE 1999e).

### **3.3.8.3 Community Services**

#### **3.3.8.3.1 Education**

In 1997, thirteen school districts providing public education in the INEEL region of influence were operating at capacities between 50 percent and 100 percent. Total student enrollment in the region of influence in 1997 was 50,168, and the student-to-teacher ratio in the region of influence averaged 18.8:1. In 1990, Idaho's average student-to-teacher ratio was 12.8:1 (DOE 1999e).

#### **3.3.8.3.2 Public Safety**

In 1997, a total of 475 sworn police officers served the four-county region of influence. In 1997, the average region of influence officer-to-population ratio was 2.2 officers per 1,000 persons, compared to the 1990 state average of 1.5 officers per 1,000 persons. In 1997, 560 paid and volunteer firefighters provided fire protection services in the INEEL region of influence. The region of influence firefighter-to-population ratio in 1997 was 2.6 firefighters per 1,000 persons, compared to the 1990 state average of 1.2 firefighters per 1,000 persons (DOE 1999e).

#### **3.3.8.3.3 Health Care**

In 1996, a total of 329 physicians served the region of influence. The average region of influence physician-to-population ratio was 1.5 physicians per 1,000 persons, compared to the 1996 state average of 1.7 physicians per 1,000 persons. In 1997, there were five hospitals serving the four-county region of influence. The hospital bed-to-population ratio was 4.6 hospital beds per 1,000 persons, compared to the 1990 state average of 3.3 hospital beds per 1,000 persons (DOE 1999e).

### **3.3.8.4 Local Transportation**

Vehicular access to INEEL is provided by U.S. Routes 20 and 26 to the south, and State Routes 22 and 33 to the north. U.S. Routes 20 and 26, and State Routes 22 and 33 all share rights-of-way west of INEEL (Figure 3-6).

There are two road segments that could be affected by the alternatives considered in this NI PEIS; U.S. Route 20 from U.S. Routes 26 and 91 at Idaho Falls to U.S. Route 26 East, and U.S. Routes 20 and 26 from U.S. Route 26 East to State Routes 22 and 33.

There are at least 10 pending projects to be completed by the Idaho Transportation Department that could impact access into INEEL as well as within the INEEL site. The type of work includes laying new base, widening and rehabilitation, and pavement rehabilitation, which are all very extensive. Some projects only include a new seal coat, which can be completed in 2 weeks. The projects include: (1) a base and resurfacing and minor widening project scheduled for late in the summer of 2000 for U.S. Route 20 from Brunt Road to Cinder Butte Road; (2) a minor widening and pavement rehabilitation for State Highway 22 from the Butte County line to the Clark County line scheduled for October 2000; (3) a minor widening and rehabilitation and base resurfacing project for State Highway 33 on the INEEL site at the Test Reactor Area NE in Jefferson

County scheduled for October 2000; (4) a minor widening and restoration and paving rehabilitation project for State Highway 22 on the INEEL site from the junction of State Highway 33 to the Clark County line scheduled for July 2001; (5) a new seal coat will be placed on State Highway 33 at Terreton East and West scheduled after July 2000; (6) a new seal coat for U.S. Route 20 leading into the INEEL site at Arco East scheduled for October 2000; (7) a paving rehabilitation and restoration and new base and resurfacing for State Highway 22 located off site from the Jefferson County line to Mile Post 52.24 scheduled in July 2002; (8) a new seal coat for U.S. Route 20 leading into the site just above the Bonneville County line scheduled for October 2002; (9) a new seal coat for State Highway 22 leading into the site from the junction of State Highway 28 to Medicine Lodge scheduled for July 2003; (10) a new seal coat for State Highway 33 on the INEEL site from Mile Post 38.5 to the junction of State Highway 28 in Jefferson County scheduled for 2003 (Cole 2000).

DOE buses provide transportation between INEEL facilities and Idaho Falls for DOE and contractor personnel. The major railroad in the region of influence is the Union Pacific Railroad. The railroad's Blackfoot-to-Arco Branch provides rail service to the southern portion of INEEL. A DOE-owned spur connects the Union Pacific Railroad to INEEL by a junction at Scoville Siding. There are no navigable waterways within the region of influence capable of accommodating waterborne transportation of material shipments to INEEL. Fanning Field in Idaho Falls and Pocatello Municipal Airport in Pocatello provide jet air passenger and cargo service for both national and local carriers. Numerous smaller private airports are located throughout the region of influence (DOE 1999e).

### 3.3.9 Existing Human Health Risk

Existing human health risk issues include the determination of potentially adverse effects on human health that result from acute and chronic exposures to ionizing radiation and hazardous chemicals.

#### 3.3.9.1 Radiation Exposure and Risk

##### 3.3.9.1.1 General Site Description

Major sources and levels of background radiation exposure to individuals in the vicinity of INEEL are shown in **Table 3-20**. Annual background radiation doses to individuals are expected to remain constant over time. The total dose to the population, in terms of person-rem, changes as the population size changes. Background radiation doses are unrelated to INEEL operations.

Releases of radionuclides to the environment from INEEL operations provide another source of radiation exposure to individuals in the vicinity of INEEL. Types and quantities of radionuclides released from INEEL operations in 1998 are listed in the *Idaho National Engineering and Environmental Laboratory Site Environmental Report for Calendar Year 1998* (Saffle et al. 2000:8-4, 8-8). The doses to the public resulting from these releases are presented in **Table 3-21**. These doses fall within radiological limits per DOE Order 5400.5, and are much lower than those of background radiation.

Using a risk estimator of 500 cancer deaths per 1 million person-rem to the public (Appendix H), the risk of a latent cancer fatality to the maximally exposed member of the public due to radiological releases from INEEL operations in 1998 is estimated to be  $4 \times 10^{-9}$ . That is, the estimated probability of this person dying of cancer at some point in the future from radiation exposure associated with 1 year of INEEL operations is less than 1 in 200 million. It takes several to many years from the time of radiation exposure for a cancer to manifest itself.

**Table 3–20 Sources of Radiation Exposure to Individuals in the INEEL Vicinity Unrelated to INEEL Operations**

Source	Effective Dose Equivalent (millirem per year)
<b>Natural background radiation<sup>a</sup></b>	
Cosmic radiation	48
External terrestrial radiation	71
Internal radiation	40
Radon in homes (inhaled)	200
<b>Other background radiation<sup>b</sup></b>	
Diagnostic x-rays and nuclear medicine	53
Weapons test fallout	Less than 1
Air travel	1
Consumer and industrial products	10
<b>Total</b>	<b>424</b>

a. Saffle et al. 2000.

b. NCRP 1987:11, 40, 53.

**Note:** Value of radon is an average for the United States.

**Table 3–21 Radiation Doses to the Public from INEEL Normal Operations in 1998 (Total Effective Dose Equivalent)**

Members of the Public	Atmospheric Releases		Liquid Releases		Total	
	Standard <sup>a</sup>	Actual	Standard <sup>a</sup>	Actual	Standard <sup>a</sup>	Actual
Maximally exposed individual (millirem)	10	0.008	4	0	100	0.008
Population within 80 kilometers (person-rem) <sup>b</sup>	None	0.075	None	0	100	0.075
Average individual within 80 kilometers (millirem) <sup>c</sup>	None	$6.2 \times 10^{-4}$	None	0	None	$6.2 \times 10^{-4}$

a. The standards for individuals are given in DOE Order 5400.5. As discussed in that order, the 10-millirem-per-year limit from airborne emissions is required by the Clean Air Act, and the 4-millirem-per-year limit is required by the Safe Drinking Water Act; for this NI PEIS, the 4-millirem-per-year value is conservatively assumed to be the limit for the sum of doses from all liquid pathways. The total dose of 100 millirem per year is the limit from all pathways combined. The 100-person-rem value for the population is given in proposed 10 CFR Part 834, as published in 58 FR 16268. If the potential total dose exceeds the 100-person-rem value, it is required that the contractor operating the facility notify DOE.

b. Based on a population of about 121,500 in 1998.

c. Obtained by dividing the population dose by the number of people living within 80 kilometers (50 miles) of the site.

**Source:** Saffle et al. 2000.

According to the same risk estimator,  $3.8 \times 10^{-5}$  excess cancer fatality is projected in the population living within 80 kilometers (50 miles) of INEEL from normal operations in 1998. To place this number in perspective, it may be compared with the number of cancer fatalities expected in the same population from all causes. The 1997 mortality rate associated with cancer for the entire U.S. population was 0.2 percent per year (Famighetti 1998:964). Based on this mortality rate, the number of cancer fatalities expected during 1998 from all causes in the population living within 80 kilometers (50 miles) of INEEL was 243. This expected number of cancer fatalities is much higher than the  $3.8 \times 10^{-5}$  cancer fatality estimated from INEEL operations in 1998.

INEEL workers receive the same doses as the general public from background radiation, but they also receive an additional dose from working in facilities with nuclear materials. The average dose to the individual worker and the cumulative dose to all workers at INEEL from operations in 1998 are presented in **Table 3–22**. These doses fall within the radiological regulatory limits of 10 CFR Section 835.202. According to a risk estimator

**Table 3–22 Radiation Doses to Workers from INEEL Normal Operations in 1998  
(Total Effective Dose Equivalent)**

Occupational Personnel	Onsite Releases and Direct Radiation	
	Standard <sup>a</sup>	Actual
Average radiation worker (millirem)	None <sup>b</sup>	87 <sup>c</sup>
Total workers (person-rem) <sup>d</sup>	None	65 <sup>c</sup>

- The radiological limit for an individual worker is 5,000 millirem per year. However, DOE's goal is to maintain radiological exposure as low as is reasonably achievable. It has therefore established the Administrative Control Level of 2,000 millirem per year; the site must make reasonable attempts to maintain individual worker doses below this level.
- No standard is specified for an "average radiation worker"; however, the maximum dose that this worker may receive is limited to that given in footnote "a."
- Does not include doses received at the Naval Reactors Facility. The impacts associated with this facility fall under the jurisdiction of the Navy as part of the Nuclear Propulsion Program.
- Based on a worker population of 743 with measurable doses in 1998.

**Source:** 10 CFR Section 835.202; DOE 1999p.

of 400 cancer fatalities per 1 million person-rem among workers (Appendix H), the number of projected latent cancer fatalities among INEEL workers from normal operations in 1998 is 0.026.

A more detailed presentation on the radiation environment, including background exposures and radiological releases and doses, is presented in the *Idaho National Engineering and Environmental Laboratory Site Environmental Report for Calendar Year 1998* (Saffle et al. 2000). The concentrations of radioactivity in various environmental media (including air, water, and soil) in the site region (on and off site) are also presented in that report.

### 3.3.9.1.2 Locations of Proposed Activities

#### IDAHO NUCLEAR TECHNOLOGY AND ENGINEERING CENTER

External radiation doses and concentrations of gross alpha and beta in air have been measured in the vicinity of INTEC. In 1998, the annual average dose within INTEC was about 171 millirem. This is about 40 millirem higher than the average dose measured at the offsite control locations. This onsite dose would affect workers only and is well below annual worker dose limits as identified in Table 3–22. Concentrations in air of gross alpha and beta were  $1.1 \times 10^{-15}$  microcuries per milliliter and  $2.4 \times 10^{-14}$  microcuries per milliliter, respectively (Saffle et al. 2000:4-4, 4-5, 4-15, 4-20).

#### TEST REACTOR AREA

Radiological health effects resulting from the release of radionuclides from the stack that serves ATR and the ATR Critical Facility are shown in **Table 3–23**. Estimates shown in the table are based on 1999 release data discussed in Appendix H. Doses listed in Table 3–23 show that the risk of a latent cancer fatality to the maximally exposed member of the public due to emissions from ATR and the ATR Critical Facility in 1999 would be  $6.5 \times 10^{-10}$ . The risk of an excess cancer fatality among the public residing within 80 kilometers (50 miles) of ATR would be  $6.5 \times 10^{-6}$ .

**Table 3–24** lists radiation doses to average Test Reactor Area and ATR workers in 1998. The average risk of an excess cancer fatality among workers at the Test Reactor Area and ATR due to onsite releases and direct radiation in 1999 would be  $4.2 \times 10^{-5}$  and  $5.0 \times 10^{-5}$ , respectively.

**Table 3–23 Radiation Doses to the Public from Normal Operations at ATR and ATR Critical Facility in 1999 (Total Effective Dose Equivalent)**

Members of the Public	Atmospheric Releases		Liquid Releases		Total	
	Standard	Actual	Standard	Actual	Standard	Actual
Maximally exposed individual (millirem)	10	$1.3 \times 10^{-3}$	4	0	100	$1.3 \times 10^{-3}$
Population within 80 kilometers (person-rem)	None	0.013	None	0	100	0.013
Average individual within 80 kilometers (millirem)	None	$7.9 \times 10^{-4}$	None	0.00	None	$7.9 \times 10^{-4}$

**Table 3–24 Radiation Doses to Workers from the Test Reactor Area and ATR Normal Operations in 1998 (Total Effective Dose Equivalent)**

Occupational Personnel	Onsite Releases and Direct Radiation	
	Standard <sup>a</sup>	Actual
Average Test Reactor Area worker (millirem)	None <sup>b</sup>	105
Average ATR worker (millirem)	None <sup>b</sup>	126

- a. The radiological limit for an individual worker is 5,000 millirem per year. However, DOE's goal is to maintain radiological exposure as low as is reasonably achievable. It has therefore established the Administrative Control Level of 2,000 millirem per year; the site must make reasonable attempts to maintain individual worker doses below this level.
- b. No standard is specified for an "average radiation worker"; however, the maximum dose that this worker may receive is limited to that given in footnote "a."

Source: DOE 1999p.

### 3.3.9.2 Chemical Environment

The background chemical environment important to human health consists of the atmosphere, which may contain hazardous chemicals that can be inhaled; drinking water, which may contain hazardous chemicals that can be ingested; and other environmental media through which people may come in contact with hazardous chemicals (e.g., surface water during swimming, soil through direct contact, or food). Hazardous chemicals can cause cancer and other adverse health effects.

**Carcinogenic Effects.** Health effects in this case are estimated as the incremental probability of an individual developing cancer over a lifetime as a result of exposure to the potential carcinogen. This could be incremental or excess individual lifetime cancer risk.

**Noncarcinogenic Effects.** Health effects in this case are determined by the ratio between the calculated, or measured concentration of the chemical in the air and the reference concentration or dose. This ratio is known as the Hazard Quotient. Hazard Quotients for noncarcinogens are summed to obtain the Hazard Index. If the Hazard Index is less than 1, no adverse health effects would be expected.

Effective administrative and design controls that decrease hazardous chemical releases to the environment and help achieve compliance with permit requirements (e.g., air emissions and NPDES permit requirements) contribute to minimizing health impacts on the public. The effectiveness of these controls is verified through the use of monitoring information and inspection of mitigation measures. Health impacts on the public may occur through inhaling air containing hazardous chemicals released to the atmosphere during normal INEEL operations. Risks to public health from other possible pathways, such as ingestion of contaminated drinking water or direct exposure, are lower than those via the inhalation pathway. At INEEL, the risk to public health from water ingestion and direct exposure pathways is low because surface water is not used for drinking or as a receptor for wastewater discharges.

Baseline air emission concentrations and applicable standards for hazardous chemicals are addressed in Section 3.3.3.

The baseline concentrations are estimates of the highest existing offsite concentrations and represent the highest concentrations to which members of the public could be exposed. These concentrations are in compliance with applicable guidelines and regulations. Information on estimating the health impacts of hazardous chemicals is presented in Appendix H.

Exposure pathways to INEEL workers during normal operations may include inhaling contaminants in the workplace atmosphere and direct contact with hazardous materials. The potential for health impacts varies among facilities and workers, and available information is insufficient for a meaningful estimate of impacts. However, workers are protected from workplace hazards through appropriate training, protective equipment, monitoring, substitution, and engineering and management controls. INEEL workers are also protected by adherence to OSHA and EPA standards that limit workplace atmospheric and drinking water concentrations of potentially hazardous chemicals. Appropriate monitoring that reflects the frequency and amounts of chemicals used in the operational processes ensures that these standards are not exceeded. Additionally, DOE requires that conditions in the workplace be as free as possible from recognized hazards that cause, or are likely to cause, illness or physical harm.

### **3.3.9.3 Health Effects Studies**

Epidemiological studies were conducted on communities surrounding INEEL to determine whether there are excess cancers in the general population. Two of these are described in more detail in Appendix M.4.4 of the *Storage and Disposition PEIS* (DOE 1996b:M-233, M-234). No excess cancer mortality was reported, and although excess cancer incidence was observed, no association thereof with INEEL was established. A study by the State of Idaho completed in June 1996, found excess brain cancer incidence in the six counties surrounding INEEL, but a follow-up survey concluded that “No common factors were identified that clearly linked the cases, and individuals expressed varying concerns about possible exposures or causes for brain cancer” (ID DHW 1997).

No occupational epidemiological studies have been completed at INEEL to date, but several worker health studies have been initiated recently at INEEL. Researchers from the Boston University School of Public Health, in cooperation with the National Institute of Occupational Safety and Health, are investigating the effects of workforce restructuring (downsizing) in the nuclear weapons industry. The health of displaced workers will be studied. Under a National Institute of Occupational Safety and Health cooperative agreement, the epidemiologic evaluation of childhood leukemia and paternal exposure to ionizing radiation now includes INEEL as well as other DOE sites. Another study, begun in October 1997, *Medical Surveillance for Former Workers at INEEL*, is being carried out by a group of investigators from the Oil, Chemical, and Atomic Workers International Union, Mt. Sinai School of Medicine, the University of Massachusetts at Lowell, and the Alice Hamilton College. DOE has implemented an epidemiologic surveillance program to monitor the health of current INEEL workers. A discussion of this program is given in Appendix M.4.4 of the *Storage and Disposition PEIS* (DOE 1996b:M-233, M-234).

### **3.3.9.4 Accident History**

DOE conducted a study, the Idaho National Engineering Laboratory Historical Dose Evaluation, to estimate the potential offsite radiation doses for the entire operating history of INEEL (DOE 1996b:3-139). Releases resulted from a variety of tests and experiments as well as a few accidents at INEEL. The study concluded that these releases contributed to the total radiation dose during test programs of the 1950s and early 1960s. The frequency and size of releases have declined since that time. There have been no serious unplanned or

accidental releases of radioactive or other hazardous substances at INEEL facilities in the 10 years of operation prior to 1998. However, in July 1998, an incident occurred at INEEL's Test Reactor Area. One fatality and several injuries resulted from an accidental release of fire retardant carbon dioxide during routine maintenance operation. No nuclear materials were involved and there was no threat to public safety (DOE 1998a, 1998b, 1998c, 1998d).

### **3.3.9.5 Emergency Preparedness**

Each DOE site has established an emergency management program that would be activated in the event of an accident. This program has been developed and maintained to ensure adequate response to most accident conditions and to provide response efforts for accidents not specifically considered. The emergency management program includes emergency planning, preparedness, and response.

Government agencies whose plans are interrelated with the INEEL emergency plan for action include the State of Idaho, Bingham County, Bonneville County, Butte County, Clark County, Jefferson County, the Bureau of Indian Affairs, and the Fort Hall Indian Reservation. INEEL contractors are responsible for responding to emergencies at their facilities. Specifically, the emergency action director is responsible for recognition, classification, notification, and protective action recommendations. At INEEL, emergency preparedness resources include fire protection from onsite and offsite locations and radiological and hazardous chemical material response. Emergency response facilities include an emergency control center at each facility, the INEEL Warning Communication Center, and the INEEL site Emergency Operations Center. Seven INEEL medical facilities are also available to provide routine and emergency service.

DOE has specified actions to be taken at all DOE sites, implementing lessons learned from the emergency response to an accidental explosion at Hanford in May 1997.

### **3.3.10 Environmental Justice**

Under Executive Order 12898, *Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations*, Federal agencies are responsible for identifying and addressing the possibility of disproportionately high and adverse health, economic, and environmental impacts of programs and activities on minority and low-income populations in potentially affected areas. Minority populations refer to persons of any race self-designated as Asian, Black, Native American, or Hispanic. Low-income populations refer to households with incomes below the Federal poverty thresholds. In the case of INEEL, the potentially affected area includes only parts of central Idaho.

The potentially affected area surrounding ATR is defined by a circle with an 80-kilometer (50-mile) radius centered at the Test Reactor Area (latitude 43° 35'8" N, longitude 112° 57'47" W). The total population residing within that area in 1990 was 105,939. Minorities made up 10.1 percent of the total population. In 1990, approximately one-fourth of the total population was comprised of persons self-designated as members of a minority group; minorities made up 7.8 percent of the State of Idaho's total population.

At the time of the 1990 census, Hispanics and Native Americans were the largest minority groups within the potentially affected area, accounting for 6.2 percent and 2.7 percent of the total population, respectively. Asians constituted about 1.1 percent, and Blacks, about 0.3 percent (DOC 1992).

In 1990, the poverty threshold was \$9,981 for a family of three with one related child under 18 years of age. A total of 13,188 persons (12.6 percent of the total population) residing within the potentially affected area around ATR reported incomes below that threshold (DOC 1992). Data obtained during the 1990 census also

show that of the total population of the contiguous United States, 13.1 percent reported incomes below the poverty threshold. The corresponding percentage for Idaho was 13.3 percent.

The potentially affected area surrounding FDPF is defined by an 80-kilometer (50-mile) circle centered at INTEC (latitude 43° 34'12.5" N, longitude 112° 55'55.4" W). The total population residing within the potentially affected area in 1990 was 121,472. Approximately 10 percent of the total population was comprised of persons self-designated as members of a minority. Data from the 1990 census show that minorities represented approximately 24 percent of the national population, and approximately 8 percent of the population of the State of Idaho. Hispanics (6.2 percent) and Native Americans (2.7 percent) were the largest minority groups within the population at risk. Asians (1.1 percent) and Blacks (0.3 percent) made up the remainder of the minority population at risk. Approximately 12 percent of the population at risk reported incomes below the poverty threshold of 1990.

### 3.3.11 Waste Management

Waste management includes minimization, characterization, treatment, storage, transportation, and disposal of waste generated from ongoing DOE activities. The waste is managed using appropriate treatment, storage, and disposal technologies, and in compliance with all applicable Federal and state statutes and DOE orders.

#### 3.3.11.1 Waste Inventories and Activities

INEEL manages the following types of waste: high-level radioactive, transuranic, mixed transuranic, low-level radioactive, mixed low-level radioactive, hazardous, and nonhazardous. Waste generation rates and the inventory of stored waste from activities at INEEL are provided in **Table 3-25**.

**Table 3-25 Waste Generation Rates and Inventories at INEEL**

Waste Type	Generation Rate (cubic meters per year)	Inventory (cubic meters)
High-level radioactive	0 <sup>a</sup>	4,200 <sup>b</sup>
Transuranic and mixed transuranic	0 <sup>a,c</sup>	65,000 <sup>d,e</sup>
Sodium-bearing waste	0 <sup>a</sup>	5,300 <sup>b</sup>
Low-level radioactive	6,400 <sup>f</sup>	6,000 <sup>g</sup>
Mixed low-level radioactive <sup>h</sup>	230	1,700
Hazardous	835 <sup>c,i</sup>	NA <sup>j</sup>
Nonhazardous		
Liquid	2,000,000 <sup>c,k</sup>	NA <sup>j</sup>
Solid	62,000 <sup>c</sup>	NA <sup>j</sup>

- a. Refer to the text.
- b. DOE 1999i. The sodium-bearing waste is managed by the high-level radioactive waste program.
- c. Moor and Peterson 1999:chap. 3.
- d. Includes both alpha low-level radioactive waste and transuranic waste.
- e. DOE 1995a:4.14-2.
- f. Willson 1998:2-9 and 2-10.
- g. Bright 1999.
- h. DOE 1998e:4-5.
- i. Includes 760 cubic meters that is recyclable.
- j. Generally, hazardous and nonhazardous wastes are not held in long-term storage.
- k. Projected annual average generation amounts for 1997–2006.

**Note:** To convert from cubic meters to cubic yards, multiply by 1.308.

**Key:** NA, not applicable.

Waste generation rates specifically for ATR and FDPF activities are provided in **Table 3–26**. The INEEL waste management capabilities are summarized in **Table 3–27**. More detailed descriptions of the waste management system capabilities at INEEL are included in the *Storage and Disposition PEIS* (DOE 1996b:3-141–145, E-33–E-48) and the *Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs Final Environmental Impact Statement* (DOE 1995a:2.2-30).

**Table 3–26 Waste Generation Rates at ATR and FDPF**

Waste Type	ATR <sup>a</sup> (cubic meters per year)	FDPF (cubic meters per year)
High-level radioactive	0	0
Transuranic	0	0
Low-level radioactive	404	0
Mixed low-level radioactive	<1	0
Hazardous	190	0
Nonhazardous		
Process wastewater	794,000	0
Sanitary wastewater	42,000	0
Solid	4,208	0

a. The data includes all facilities within the Test Reactor Area, which includes ATR.

**Note:** To convert from cubic meters to cubic yards, multiply by 1.308.

**Source:** Depperschmidt 2000b; French, Tallman, and Taylor 1999a, 1999b.

EPA placed INEEL on the National Priorities List on December 21, 1989. In accordance with CERCLA, DOE entered into a consent order with EPA and the State of Idaho to coordinate cleanup activities at INEEL under one comprehensive strategy. This agreement integrates DOE's CERCLA response obligations with RCRA corrective action obligations. Aggressive plans are in place to achieve early remediation of sites that represent the greatest risk to workers and the public. The goal is to complete remediation of contaminated sites at INEEL to support delisting from the National Priorities List by 2019 (DOE 1996b:3-141). More information on regulatory requirements for waste disposal is provided in Chapter 5.

### 3.3.11.2 High-Level Radioactive Waste

High-level radioactive waste at INEEL was generated in the process of extracting useful isotopes from spent nuclear fuel at INTEC. Most of this fuel was from the Naval Reactors Program. Most aqueous solutions from spent nuclear fuel processing and isotope extraction were concentrated by evaporation and separated into low-level and high-level radioactive waste streams in the Process Equipment Waste Evaporator. The liquid high-level radioactive waste was stored in subsurface tanks and then transformed by calcination into solid metallic oxides in a granular form. This calcination was completed in February 1998. The calcine is stored in stainless steel bins in near-surface concrete vaults where it awaits further processing into a form suitable for emplacement in a Federal repository. INEEL met the requirements of a December 1991 consent order with the State of Idaho and EPA to calcine all the high-level radioactive waste by June 30, 1998. Subsequently, the calcined waste will be treated to meet RCRA provisions on a schedule to be negotiated with the State of Idaho under the Federal Facility Compliance Act.

Although sodium-bearing waste is not high-level radioactive waste as specified in the Nuclear Waste Policy Act of 1982, it has been historically managed as high-level radioactive waste at INEEL. This is because some

of the physical and chemical properties of these two waste types are similar (e.g., both are acidic and both contain similar radionuclides, including transuranics) (DOE 1999i:1-11). About 5,300 cubic meters ( $1.4 \times 10^6$  gallons) of liquid-sodium-bearing waste remain in the INTEC Tank Farm. New treatment processes for the remaining liquid-sodium-bearing wastes are being analyzed in the *Idaho High-Level Waste and Facilities Disposition Environmental Impact Statement*.

### **3.3.11.3 Transuranic and Mixed Transuranic Waste**

Transuranic waste generated since 1972 is segregated into contact-handled and remotely handled categories and stored at the Radioactive Waste Management Complex in a form designed for eventual retrieval (DOE 1996b:3-144). Some transuranic waste is also stored at the Radioactive Scrap and Waste Facility at Argonne National Laboratory–West (DOE 1995a:2.2-36). There is virtually no transuranic waste generated at INEEL. Most of the transuranic waste in storage was received from the Rocky Flats Environmental Technology Site (DOE 1996b:3-144). Transuranic waste is currently being stored, pending shipment to WIPP. Transuranic waste will be treated to meet WIPP waste acceptance criteria, packaged in accordance with DOE and Department of Transportation (DOT) requirements, and transported to WIPP for disposal (DOE 1996b:3-144) or a suitable geologic repository. The first shipment of transuranic waste from INEEL was received at WIPP on April 28, 1999 (DOE 1999j).

The existing treatment facilities for transuranic waste at INEEL are limited to testing, characterization, and repackaging. The Advanced Mixed Waste Treatment Project will be operated as a private sector treatment facility after its construction is completed (Moor and Peterson 1999). This facility will (1) treat waste to meet the most current requirements; (2) reduce waste volume and life-cycle cost to DOE; and (3) perform tasks in a safe and environmentally compliant manner (Saffle et al. 2000:3-11). The construction of the incinerator component of this facility has been deferred, pending the recommendation of a blue ribbon panel of experts. This panel of experts will assess and recommend new technology alternatives to incineration. The panel's recommendation is expected in December 2000 (DOE 2000b).

Waste containing between 10 and 100 nanocuries of alpha activity per gram of transuranic radionuclides is called alpha low-level radioactive waste. Although this waste is technically considered low-level radioactive waste rather than transuranic waste, it cannot be disposed of at INEEL because it does not meet all of the INEEL low-level radioactive waste disposal facility acceptance criteria. Alpha low-level radioactive waste and alpha mixed low-level radioactive waste are managed together as part of the transuranic waste program. It is expected that these wastes will be treated by the Advanced Mixed Waste Treatment Project and then be disposed of at WIPP (DOE 1995a:2.2-34, 2.2-35).

### **3.3.11.4 Low-Level Radioactive Waste**

Liquid low-level radioactive waste is solidified before disposal (DOE 1996b:E-35). INTEC has the capability to treat aqueous low-level radioactive waste. Liquid low-level radioactive waste is concentrated at the INTEC Process Equipment Waste Evaporator, with the condensed vapor processed by the Liquid Effluent Treatment and Disposal Facility. The concentrated materials remaining after evaporation are stored in the Chemical Processing Plant–604 storage tanks. The Waste Experimental Reduction Facility was required to shutdown by November 2, 2000. In addition, aqueous low-level radioactive wastes are discharged to the two double-lined ponds at the Test Reactor Area for evaporation (DOE 1995a:2.2-39). The two Test Reactor Evaporation Ponds have a capacity of 36,790 cubic meters (48,100 cubic yards) each with a flow rate of 30 liters (8 gallons) per minute.

Low-level radioactive waste disposal occurs in pits and concrete-lined soil vaults in the subsurface disposal area of the Radioactive Waste Management Complex (DOE 1995a:2.2-39). Approximately 60 percent of the

low-level radioactive waste generated at INEEL is treated for volume reduction prior to disposal at the Radioactive Waste Management Complex. Additionally, some low-level radioactive waste is shipped off site to be incinerated, and the residual ash is returned to INEEL for disposal. The Radioactive Waste Management Complex is expected to be filled to capacity by the year 2030 (Mitchell et al. 1996b:3-26), although some proposals would close the low-level radioactive waste disposal facility by 2006 (DOE 1998f:B-4).

### **3.3.11.5 Mixed Low-Level Radioactive Waste**

Mixed low-level radioactive waste is divided into two categories for management purposes: alpha mixed low-level radioactive waste and beta-gamma mixed low-level radioactive waste. Most of the alpha mixed low-level radioactive waste stored at INEEL is waste that has been reclassified from mixed transuranic waste and is managed as part of the transuranic waste program. Therefore, this section deals only with beta-gamma mixed low-level radioactive waste (DOE 1995a:2.2-39, 2.2-40).

Mixed low-level radioactive waste, including polychlorinated biphenyl-contaminated low-level radioactive waste, is stored at several onsite areas awaiting the development of treatment methods (DOE 1996b:3-144). Mixed low-level radioactive waste is stored at the Mixed Waste Storage Facility (or Waste Experimental Reduction Facility Waste Storage Building) and in portable storage units at the Power Burst Facility area. In addition, smaller quantities of mixed low-level radioactive waste are stored in various facilities at INEEL, including the Hazardous Chemical/Radioactive Waste Facility at INTEC, and the Radioactive Sodium Storage Facility and Radioactive Scrap and Waste Storage Facility at Argonne National Laboratory–West (DOE 1995a:2.2-41). Although mixed wastes are stored in many locations at INEEL, the bulk of that volume is solid waste stored at the Radioactive Waste Management Complex (DOE 1996b:E-38).

As part of the INEEL Site Treatment Plan and Consent Order required by the Federal Facility Compliance Act, preferred treatment options have been identified to eliminate the hazardous waste component for many types of mixed low-level radioactive waste (DOE 1995a:2.2-42). Mixed low-level radioactive waste is or will be processed to RCRA Land Disposal Restrictions treatment standards through several treatment facilities. Those treatment facilities and their operational status are: (1) Waste Experimental Reduction Facility Incinerator (shutdown), (2) Waste Experimental Reduction Facility Stabilization (operational), (3) Test Area North cask dismantlement (operational), (4) Sodium Process Facility (operational), (5) High-Efficiency Particulate Air Filter Leach (operational), (6) Waste Reductions Operations Complex Macroencapsulation (March 2001), (7) Debris Treatment (operational), and (8) Advanced Mixed Waste Treatment Project (March 2003). Commercial treatment facilities are also being considered, as appropriate. Currently, limited amounts of mixed low-level radioactive waste are disposed of at Envirocare of Utah (DOE 1999e:3-57).

### **3.3.11.6 Hazardous Waste**

Approximately 1 percent of the total waste generated at INEEL (not including liquid nonhazardous waste) is hazardous waste. Most of the hazardous waste generated annually at INEEL is transported off site for treatment and disposal (DOE 1995a:2.2-45). Offsite shipments are surveyed to determine that the wastes have no radioactive content, and therefore are not mixed waste (DOE 1996b:3-145).

Highly reactive or unstable materials, such as waste explosives, are addressed on a case-by-case basis, and are either stored, burned, or detonated, as appropriate. The Waste Handling Facility Project at Argonne National Laboratory–West will be implemented to handle Argonne National Laboratory–West hazardous waste (DOE 1996b).

### **3.3.11.7 Nonhazardous Waste**

Approximately 90 percent of the solid waste generated at INEEL is classified as industrial waste and is disposed of on site in a landfill complex in the Central Facilities Area and off site at the Bonneville County landfill (DOE 1995a:2.2-47). The onsite landfill complex contains separate areas for petroleum-contaminated media, industrial waste, and asbestos waste (Werner 1997). The onsite landfill is 4.8 hectares (12 acres), and is being expanded by 91 hectares (225 acres) to provide capacity for at least 30 years (DOE 1996b:3-145).

Sewage is disposed of in surface impoundments in accordance with terms of the October 7, 1992 Consent Order. Waste in the impoundments is allowed to evaporate, and the resulting sludge is placed in the landfill. Solids are separated and reclaimed where possible (DOE 1996b:3-145). Nonhazardous service wastewater generated at INTEC is disposed of in percolation ponds at a flow rate of 3.8 million to 7.6 million liters (1 million to 2 million gallons) per day (Werner 1997). The INTEC sanitary sewer system collects and transfers sanitary waste to the sewage treatment lagoons east of INTEC for treatment and disposal. This system has a capacity of 3,200,000 cubic meters (4,190,000 cubic yards) per year (DOE 1999e:3-58). The Test Reactor Area Cold Waste Pond disposes of about 1,500 liters (400 gallons) per minute of nonhazardous wastewater with a capacity of 33,960 cubic meters (44,400 cubic yards). The TRA sanitary sewer system collects and transfers about 98 liters (26 gallons) per minute of sanitary wastewaters to the sewage treatment lagoons east of the Test Reactor Area for treatment and disposal. This system has a capacity of 20,600 cubic meters (26,900 cubic yards).

### **3.3.11.8 Waste Minimization**

The DOE Idaho Operations Office has an active waste minimization and pollution prevention program to reduce the total amount of waste generated and disposed of at INEEL. This is accomplished by eliminating waste through source reduction or material substitution; by recycling potential waste materials that cannot be minimized or eliminated; and by treating all waste that is generated to reduce its volume, toxicity, or mobility prior to storage or disposal. The Idaho Operations Office published its first Waste Minimization Plan in 1990, which defined specific goals, methodology, responsibility, and achievements of programs and organizations. The achievements and progress have been updated at least annually. Implementing pollution prevention projects reduced the total amount of waste generated at INEEL in 1998 by approximately 1,100 cubic meters (1,400 cubic yards). Examples of pollution prevention projects completed in 1998 at INEEL include: reduction of routine operations hazardous waste by approximately 55 metric tons (61 tons) by collecting engine oil by a recycling vendor for energy recovery; reducing cleanup/stabilization of hazardous waste by approximately 20 metric tons (22 tons) by dismantling the Mobile Test Assembly Cask and sending the clean lead to the clean lead storage area for recycling; and reducing both routine operations and cleanup/stabilization low-level radioactive waste by approximately 19 cubic meters (25 cubic yards) by recycling depleted uranium scrap metal from both normal facility operations and deactivation of a facility (DOE 1999f:44).

### **3.3.11.9 Waste Management PEIS Records of Decision**

The *Waste Management PEIS* Records of Decision affecting INEEL are shown in **Table 3-28** for the waste types analyzed in this NI PEIS. Decisions on the various waste types were announced in a series of Records of Decisions that have been issued on the *Waste Management PEIS*. The transuranic waste Record of Decision was issued on January 20, 1998 (63 FR 3629); the hazardous waste Record of Decision was issued on August 5, 1998 (63 FR 41810); the high-level radioactive waste Record of Decision was issued on August 12, 1999 (64 FR 46661); and the low-level radioactive and mixed low-level radioactive waste Record of Decision was issued on February 18, 2000 (65 FR 10061). The transuranic waste Record of Decision states that DOE will develop and operate mobile and fixed facilities to characterize and prepare transuranic waste

**Table 3–28 Waste Management PEIS Records of Decision Affecting INEEL**

Waste Type	Preferred Action
High-level radioactive	DOE has decided that INEEL should store its immobilized high-level radioactive waste on site until transfer to a geologic repository. <sup>a</sup>
Transuranic and mixed transuranic	DOE has decided that INEEL should prepare and store its transuranic waste on site pending disposal at WIPP <sup>b</sup> or another suitable geologic repository.
Low-level radioactive	DOE has decided to treat INEEL's low-level radioactive waste on site. <sup>c</sup>
Mixed low-level radioactive	DOE has decided to regionalize treatment of mixed low-level radioactive waste at INEEL. <sup>c</sup> This includes the onsite treatment of INEEL's wastes and could include treatment of some mixed low-level radioactive waste generated at other sites.
Hazardous	DOE has decided to continue to use commercial facilities for treatment of INEEL nonwastewater hazardous waste. DOE will also continue to use onsite facilities for wastewater hazardous waste. <sup>d</sup>

a. From the Record of Decision for high-level radioactive waste (64 FR 46661).

b. From the Record of Decision for transuranic waste (63 FR 3629).

c. From the Record of Decision for low-level radioactive and mixed low-level radioactive waste (65 FR 10061).

d. From the Record of Decision for hazardous waste (63 FR 41810).

**Source:** 63 FR 3629; 63 FR 41810; 64 FR 46661; 65 FR 10061.

for disposal at WIPP. Each DOE site that has or will generate transuranic waste will, as needed, prepare and store its transuranic waste on site. The hazardous waste Record of Decision states that most DOE sites will continue to use offsite facilities for the treatment and disposal of major portions of the nonwastewater hazardous waste with ORR and SRS continuing to treat some of their own nonwastewater hazardous waste, on site in existing facilities, where this is economically feasible. The high-level radioactive waste Record of Decision states that immobilized high-level radioactive waste will be stored at the site of generation until transfer to a geologic repository. The low-level radioactive waste and mixed low-level radioactive waste Record of Decision states that for the management of low-level radioactive waste, minimal treatment will be performed at all sites, and disposal will continue, to the extent practicable, on site at INEEL, LANL, ORR, and SRS. In addition, Hanford and the Nevada Test Site will be available to all DOE sites for low-level radioactive waste disposal. Mixed low-level radioactive waste will be treated at Hanford, INEEL, ORR, and SRS, and disposed of at Hanford and the Nevada Test Site. More detailed information concerning DOE's decisions for the future configuration of waste management facilities at INEEL is presented in the high-level radioactive waste, transuranic waste, hazardous waste, and low-level radioactive waste and mixed low-level radioactive waste Records of Decision.

### 3.4 HANFORD SITE

Hanford, established in 1943 as one of the three original Manhattan Project sites, is located on approximately 148,000 hectares (365,000 acres) in Washington State, just north of Richland. It extends over parts of Adams, Benton, Grant, and Franklin counties. Hanford was a U.S. Government defense materials production site that included nuclear reactor operation, uranium and plutonium processing, storage and processing of spent nuclear fuel, and management of radioactive and hazardous and state dangerous wastes. Present Hanford programs are diversified and include management of radioactive wastes, cleanup of waste sites, soil, and groundwater related to past releases, stabilization and storage of spent nuclear fuel, renewable energy technologies, waste disposal technologies, contamination cleanup, and plutonium stabilization and storage (DOE 1999k). The primary emphasis at the site is on cleanup activities.

Hanford is owned and used primarily by DOE, but portions of it are owned, leased, or administered by other Government agencies. Public access is limited to travel on the Route 4 and Route 10 access roads as far as the Wye Barricade, State Routes 24 and 240, and the Columbia River. By restricting access to the site, the public is buffered from areas formerly used for production of nuclear materials and currently used for waste storage and disposal. Only about 6 percent of the land area has been disturbed and is actively used, leaving mostly vacant land with widely scattered facilities. On June 9, 2000, the President issued a proclamation that established the 78,900-hectare (195,000-acre) Hanford Reach National Monument (65 FR 37253). This proclamation recognizes the unique character and biological diversity of the area, as well as its geological, paleontological, historic, and archaeological significance. The monument includes not only land adjacent to the Columbia River, but also other areas on the Hanford Site as depicted on **Figure 3-12**. The U.S. Fish and Wildlife Service will manage the monument under existing agreements with DOE. Land within the monument that is not subject to existing agreements will be managed by DOE; however, DOE will consult with the Secretary of the Interior when developing any management plans affecting these lands.

Hanford includes extensive production, service, research, and development areas. Onsite programmatic and general purpose facilities, many of which are inactive, total approximately 799,000 square meters (8.6 million square feet) of space. Fifty-one percent (408,000 square meters [4.4 million square feet]) is general purpose space, including offices, laboratories, shops, warehouses, and other support facilities. The remaining 392,000 square meters (4.2 million square feet) of space are programmatic facilities including processing, evaporation, filtration, waste recovery, waste treatment, waste storage facilities, and research and development laboratories. More than half of the general purpose and programmatic facilities are more than 30 years old. Facilities designed to perform previous missions are being evaluated for reuse in the cleanup mission. The existing facilities are grouped into the following numbered operational areas (DOE 1996b:3-20, 3-21).

The 100 Areas, in the northern part of the site on the southern shore of the Columbia River, are the site of eight retired plutonium production reactors and the dual-purpose N Reactor, all of which have been permanently shut down since 1991. Waste sites throughout the 100 Areas are currently undergoing remediation, consisting of excavating contaminated soils and structural materials. Contaminated groundwater in the 100 Areas is being treated via both ex situ and in situ methods. Approximately 2,000 metric tons (2,200 tons) of spent nuclear fuel are currently stored in indoor basins in the 100 Areas pending approval and storage in the 200 Areas. The 100 Areas cover about 1,100 hectares (2,720 acres).

The 200-West and 200-East Areas are in the center of the site and are about 8 and 11 kilometers (5 and 6.8 miles), respectively, south of the Columbia River. The 200-West and 200-East Areas are also about 20 and 12 kilometers (12.2 and 7.3 miles), respectively, west of the Columbia River. Historically, these areas have been used for fuel processing; plutonium processing, fabrication, and storage; and waste management and disposal activities. DOE has constructed the Environmental Restoration Disposal Facility in the 200 Area to provide disposal capacity for environmental remediation waste (e.g., low-level, mixed low-level, and

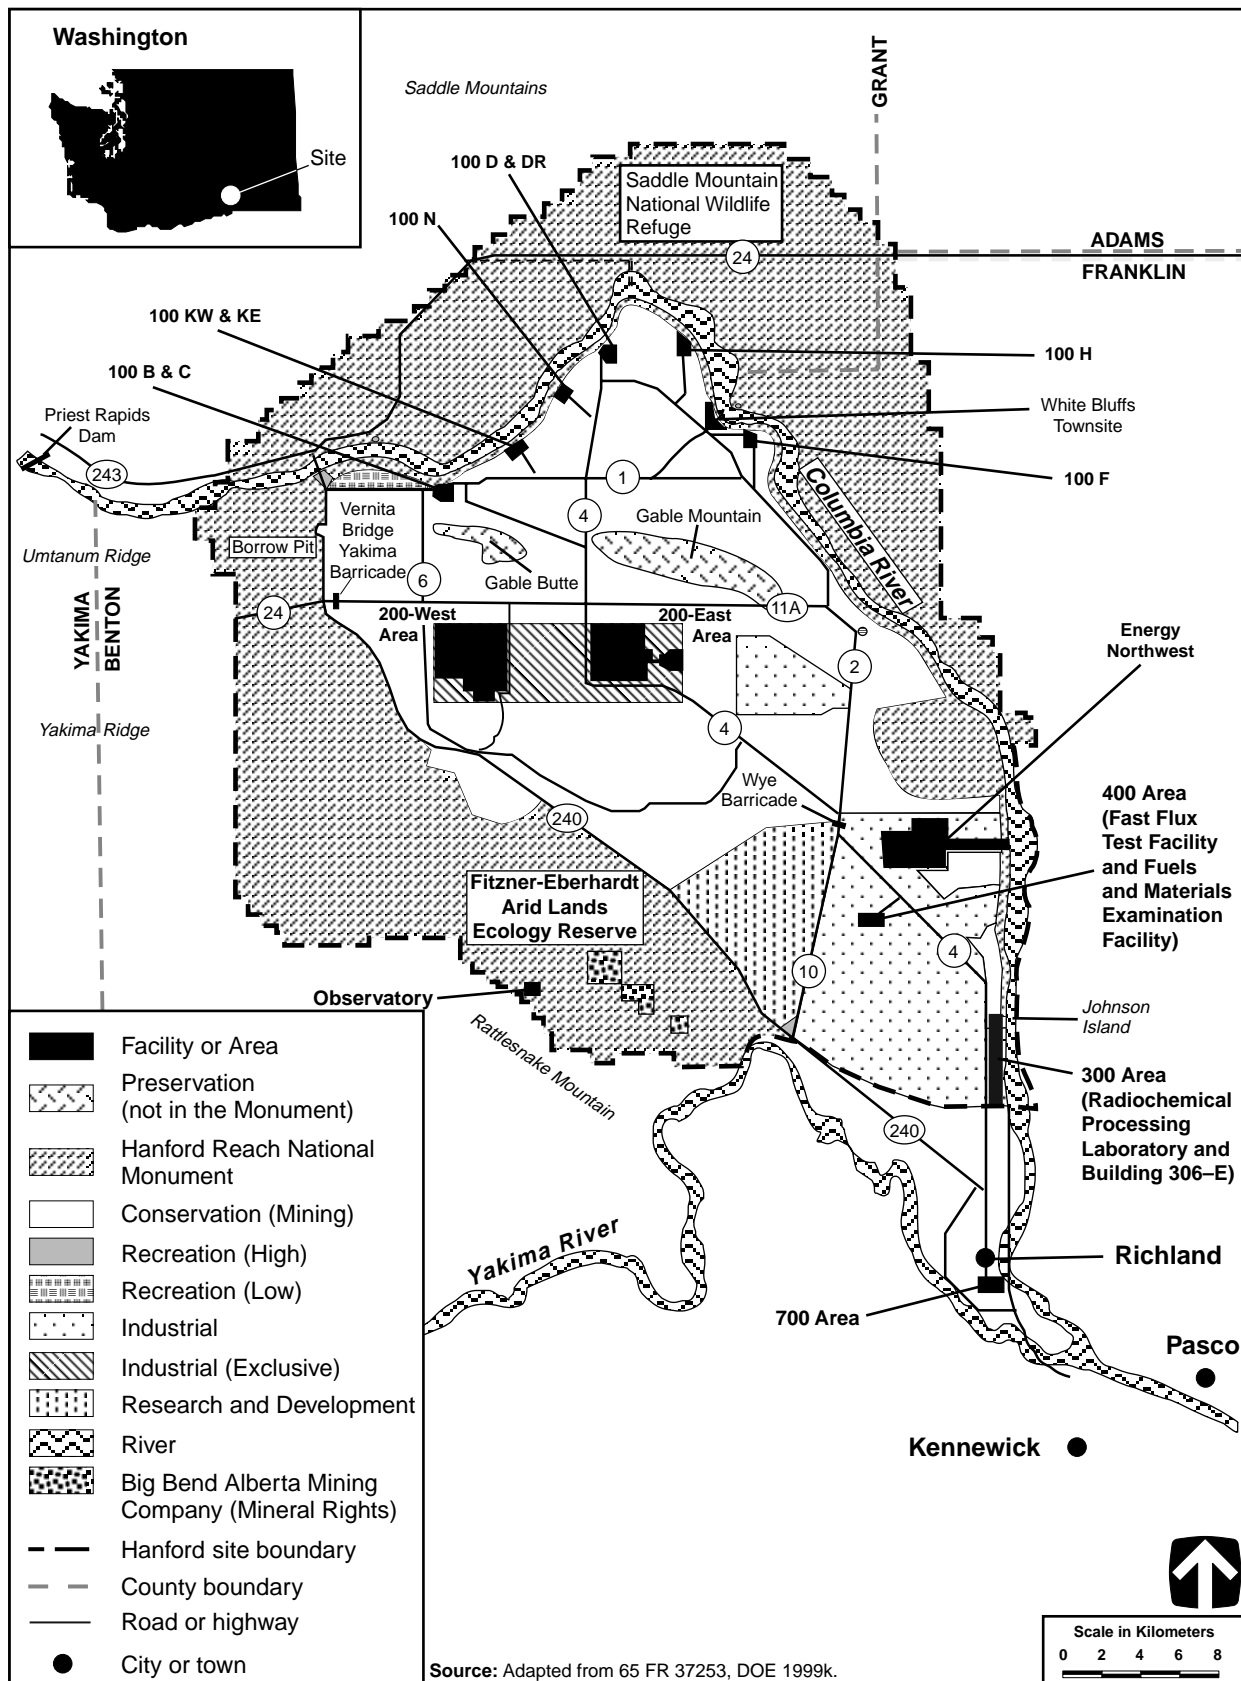

Figure 3-12 Generalized Land Use at the Hanford Site and Vicinity

dangerous wastes) generated during remediation of the 100, 200, and 300 Areas of the Hanford Site. The facility currently covers about 130 hectares (320 acres) and can be expanded up to 414 hectares (1,020 acres) as additional waste disposal capacity is required (DOE 1999k). The 200 Areas cover about 1,600 hectares (3,950 acres).

The 300 Area is in the southern part of the site, just north of the city of Richland. A few of the facilities continue to support nuclear and nonnuclear research and development of the Pacific Northwest National Laboratory. Many of the facilities in the 300 Area are in the process of being deactivated. The Environmental Molecular Sciences Laboratory and associated research programs provide research capability to advance technologies in support of DOE's environmental remediation and waste management programs (DOE 1999k). Waste sites in the 300 Area are currently undergoing remediation, consisting of excavating contaminated soils and structural materials. The 300 Area has also been proposed for accelerated remediation of waste sites and inactive buildings to support future non-DOE uses. The 300 Area covers 150 hectares (370 acres). The Radiochemical Processing Laboratory (RPL) (Building 325) and the Development Fabrication Test Laboratory (Building 306-E) are located in this area and would be used under certain alternatives under this NI PEIS.

The 400 Area, 8 kilometers (5 miles) northwest of the 300 Area, is the location of FFTF and FMEF. FFTF was designed and built as a liquid-metal (sodium) cooled reactor to be the nation's leading test reactor for development and testing of materials and equipment for the Liquid Metal Fast Breeder Reactor Programs. The reactor was neither designed nor operated as a breeder reactor itself. FFTF operated for about 10 years (1982–1992) as a national research facility testing advanced nuclear fuels, materials, components, active and passive reactor safety technologies, and gaining operating experience for the next generation of nuclear reactors. FFTF also produced a wide variety of medical isotopes and made tritium for the U.S. fusion research program. In 1995, FFTF was in the process of being shutdown, but was directed in 1997 to maintain a standby condition. The final decision on this reactor is to be determined in the Record of Decision for this NI PEIS.

FMEF, located in the 400 Area adjacent to the west of FFTF, was constructed in the late 1970s and early 1980s to perform fuel fabrication and development and postirradiation examination of breeder reactor fuels. FMEF was never operated and is currently in a lay-up condition suitable for a future mission. The building is clean and uncontaminated, as no nuclear materials were ever introduced into the building. The six-level process building (Building 427) is the main structure of FMEF and encloses about 17,400 square meters (188,000 square feet) of operating area. FMEF also consists of several connected buildings. The exterior walls are reinforced concrete and the cell walls are constructed of high-density concrete. The facility was designed and constructed for spent fuel examination and was equipped for mixed oxide fuel fabrication.

Other areas at Hanford include Energy Northwest facilities and a section of land currently owned by Washington State for the disposal of hazardous substances. Energy Northwest currently operates Washington Nuclear Plant Number 2 on leased land approximately 4 kilometers (2.5 miles) northeast of the 400 Area. Originally leased for the operation of three nuclear power plants, construction of two of the plants was stopped and now other industrial options are being considered. Other facilities at Hanford include a specialized training center, the Hazardous Materials Management and Emergency Response (HAMMER) Volpentest Training and Education Center, which is used to train hazardous materials response personnel. It is located in the southeastern portion of the site and covers about 32 hectares (80 acres). The Hanford Patrol Training Academy, a regional law-enforcement training facility, provides classrooms, library resources, practice shoot houses, an exercise gym, and an obstacle course. The Laser Interferometer Gravitational Wave Observatory, a national research facility, built by the National Science Foundation for scientific research, is designed to detect cosmic gravitational waves. The facility consists of two optical tube arms, each 4 kilometers (2.5 miles) long, arrayed in an "L" shape, and extremely sensitive to vibrations (DOE 1999k). The 700 Area is the administrative center in downtown Richland and consists of Government-owned buildings (e.g., the Federal Building).

In addition, there are DOE-leased facilities and DOE contractor-owned facilities that support Hanford operations. These facilities are on private land south of the 300 Area and outside of the 1100 and 3000 Areas (DOE 1996b:3-21).

DOE has transferred the 1100 Area (which served as a procurement, central warehousing, vehicle maintenance, transportation, and distribution center for the Hanford Site) and the smaller 3000 Area to the Port of Benton for use in economic development and diversification (DOE 1998g, 1998h, 1998i).

### **3.4.1 Land Resources**

Land resources include land use and visual resources. Each of these resource areas is described for the site as a whole, as well as for the locations of the proposed activities.

#### **3.4.1.1 Land Use**

Land may be characterized by its potential for the location of human activities (land use). Natural resource attributes and other environmental characteristics could make a site more suitable for some land uses than for others. Changes in land use may have both beneficial and adverse effects on other resources such as ecological, cultural, geological, aquatic, and atmospheric.

##### **3.4.1.1.1 General Site Description**

The Tri-Cities area southeast of Hanford includes residential, commercial, and industrial land use. This area, encompassing the cities of Richland, Kennewick, and Pasco, is the population center closest to Hanford. Additional cities near the southern boundary of Hanford include Benton City, Prosser, and West Richland. Agriculture is a major land use in the remaining areas surrounding Hanford. In 1996, wheat was the largest crop in terms of area planted in Benton, Franklin, and Grant counties. Alfalfa, apples, asparagus, cherries, corn, grapes, and potatoes are some of the other major crops in Benton, Franklin, and Grant counties.

DOE has designated the entire Hanford Site as a National Environmental Research Park, an outdoor laboratory for ecological research to study the environmental effects of energy development. The Hanford National Environmental Research Park is a shrub-steppe habitat that contains a wide range of semiarid land ecosystems and offers the opportunity to examine linkages between terrestrial, subsurface, and aquatic environments.

Land use designations at Hanford include preservation, conservation, recreation, industrial, and research and development (Figure 3–12). Approximately 6 percent of the site has been disturbed and is occupied by DOE facilities (Neitzel 1999). Hanford contains a variety of widely dispersed facilities, including retired reactors, research and development facilities, and various deactivated production and processing plants. Preservation and conservation are the largest land use categories at Hanford. Industrial areas include the 200 Areas, an area to the east of the 200 Areas, and most of the southeast corner of the site.

Important areas within the preservation land use category include the Hanford Reach National Monument, that incorporates a portion of the Columbia River corridor, as well as the Fitzner-Eberhardt Arid Lands Ecology Reserve to the south and west, and portions of the Hanford Site north of the Columbia River (65 FR 37253). Other special status land in the vicinity include McNary National Wildlife Refuge, administered by the U.S. Fish and Wildlife Service, and the Columbia River Islands Area of Critical Environmental Concern and McCoy Canyon, both administered by the Bureau of Land Management. The Columbia River, which is adjacent to and runs through the Hanford Site, is used for numerous purposes including public boating, water skiing, fishing, hunting, transportation, irrigation, and municipal water supply. Public access is allowed on certain islands, while other areas are considered sensitive because of unique habitats and the presence of

cultural resources. The area known as the Hanford Reach includes the quarter-mile strip of public land on either side of the last free-flowing, nontidal segment of the Columbia River. On June 9, 2000, the President issued a proclamation that established the Hanford Reach National Monument (65 FR 37253) covering 78,900 hectares (195,000 acres). This proclamation recognizes the unique character and biological diversity of the area, as well as its geological, paleontological, historic, and archaeological significance. The U.S. Fish and Wildlife Service will manage the monument under existing agreements with DOE. Land within the monument that is not subject to existing agreements will be managed by DOE; however, DOE will consult with the Secretary of the Interior when developing any management plans affecting these lands.

On June 27, 2000, a fire known as the 24 Command Fire, was started by a fatal motor vehicle accident on State Route 24, about 2 miles west of the State Route 240 intersection. As a result of high winds and temperatures and low humidity, the fire spread rapidly and eventually consumed 66,322 hectares (163,884 acres) of Federal, state, and private lands. A total of 24,384 hectares (60,254 acres) within Hanford burned, including lands within the Hanford Reach National Monument, most of the Arid Lands Ecology Reserve, and areas near former production sites (Figures 3–12 and 3–21). The fire was declared controlled on July 2, 2000. Fire suppression impacts included construction of 66 kilometers (41 miles) of bulldozed fire lines, widened dirt roads, and cut fences (DOI 2000). Wind and sheet and rill erosion are likely due to the loss of vegetation and fire fighting activities. Impacts to the land should not be permanent because rehabilitation measures, including revegetation and fence repair, are being implemented.

The Hanford Site has developed a comprehensive land use plan to define how to best use the land at the site for the next 50 years (DOE 1999k). The plan provides the framework within which future use of the site's lands and resources will occur. This framework consists of four basic elements including: a land use map depicting land uses for the site; land use definitions describing the purpose, intent, and principal uses of each land use designation; a set of policies directing land use actions; and implementing procedures. Figure 3–12 reflects the land use categories developed in the *Hanford Comprehensive Land-Use Plan EIS* (DOE 1999k) as modified by the designation of the Hanford Reach National Monument.

Under separate treaties signed in 1855, lands occupied by the present Hanford Site were ceded to the United States by the Confederated Tribes and Bands of the Yakama Indian Nation, the Confederated Tribes of the Umatilla Indian Reservation, and the Nez Perce Tribe of Western Idaho. Under these treaties, the tribes retained the right to fish in their usual and accustomed places, hunt, gather roots and berries, and pasture horses and cattle on open, unclaimed lands. Tribal fishing rights have been recognized as effective within the Hanford Reach. Tribal governments and DOE, however, disagree over the applicability of tribal member's treaty-reserved rights to hunt, gather plants, and pasture livestock on the Hanford Site. The tribes and DOE have proceeded with the land use planning process, while reserving all rights to assert their respective positions regarding treaty rights (DOE 1999k).

#### **3.4.1.1.2 Locations of Proposed Activities**

##### **300 AREA**

The *Hanford Comprehensive Land-Use Plan EIS* (DOE 1999k) and Record of Decision (64 FR 61615) have designated the 300 Area as an industrial area for the foreseeable future. An industrial area is defined in that EIS as an area that is suitable and desirable for activities such as reactor operations, transport facilities, mining, manufacturing, warehousing, and distribution operations. The 300 Area, which is just north of the city of Richland and west of the Columbia River, covers 150 hectares (371 acres). It is the site of former reactor fuel fabrication facilities and is also the principal location of nuclear research and development facilities serving the Hanford Site. The RPL/306–E buildings are in the 300 Area.

## 400 AREA

Under the *Hanford Comprehensive Land-Use Plan EIS* (DOE 1999k) and Record of Decision (64 FR 61615) land in the 400 Area is designated for industrial use, including reactor operations, for the foreseeable future. The 400 Area occupies 60 hectares (150 acres) and is 7 kilometers (4.3 miles) to the west of the nearest site boundary. It is the site of FFTF and FMEF. FFTF is a test reactor that was used for the development and testing of materials and equipment for the liquid metal breeder reactor program. FMEF is an unused building designed and constructed for spent fuel examination and equipped for mixed oxide fuel fabrication.

### 3.4.1.2 Visual Resources

Visual resources are natural and human-created features that give a particular landscape its character and aesthetic quality. Landscape character is determined by the visual elements of form, line, color, and texture. All four elements are present in every landscape. The stronger the influence exerted by these elements in a landscape, the more interesting the landscape.

#### 3.4.1.2.1 General Site Description

Hanford is in the Pasco Basin of the Columbia Plateau north of the city of Richland, where the Yakima and Columbia Rivers join. The topography of land in the vicinity of Hanford ranges from generally flat to gently rolling. Rattlesnake Mountain, rising to 1,060 meters (3,480 feet) above mean sea level, forms the southwestern boundary of the site. Gable Mountain and Gable Butte are the highest land forms within the site, rising approximately 60 meters (200 feet) and 180 meters (590 feet), respectively. The Columbia River flows through the northern part of the site and, turning south, forms part of the eastern site boundary. White Bluffs, steep whitish-brown bluffs adjacent to the Columbia River and above the northern boundary of the river in this region, are a striking feature of the landscape.

Typical of the regional shrub-steppe desert, the site is dominated by widely spaced, low-brush grasslands. A large area of unvegetated, stabilized sand dunes extends along the east boundary, and unvegetated blowouts are scattered throughout the site. Hanford is characterized by mostly undeveloped land, with widely spaced clusters of industrial buildings along the southern and western banks of the Columbia River and at several interior locations.

Between June 27 and July 2, 2000, a fire known as the 24 Command Fire burned 66,322 hectares (163,884 acres) of Federal, state, and private lands, including 24,384 hectares (60,254 acres) within Hanford (DOI 2000). Areas burned included land within the Hanford Reach National Monument, most of the Arid Lands Ecology Reserve, and areas near former production sites (see Figure 3–12). Firefighting activities resulted in the construction of 66 kilometers (41 miles) of bulldozed fire lines, widened dirt roads, and cut fences. Thus, both the fire and the activities required to control it resulted in dramatic changes to the visual character of affected portions of the site. Visual resources would likely also be affected by dust storms resulting from exposed soil. These alterations to the visual character of Hanford will change over time as rains promote the growth of vegetation, fire lines are rehabilitated, and fences are repaired. Because of the slow regeneration of sagebrush, however, it will be years before the visual character of the landscape will mirror pre-fire conditions.

The adjacent visual landscape consists primarily of rural rangeland and farms. The city of Richland, part of the Tri-Cities area, is the only adjoining urban area. Viewpoints affected by DOE facilities are primarily associated with the public access roadways (including State Routes 24 and 240, Hanford Road, Horn Rapids Road, Route 4 South, and Steven Drive), the bluffs, and the northern edge of the city of Richland. The Energy Northwest (formerly known as the Washington Public Power Supply System) nuclear reactors and DOE

facilities are brightly lit at night and are highly visible from many areas. Developed areas are consistent with a Bureau of Land Management Visual Resource Management Class IV rating, while the remainder of the Hanford Site ranges in Visual Resource Management rating from Class II to Class III (DOI 1986). Management activities within Class II and III areas may be seen, but should not dominate the view, while management activities in Class IV areas dominate the view and are the focus of viewer attention.

#### **3.4.1.2.2 Locations of Proposed Activities**

##### **300 AREA**

The tallest structures within the 300 Area vicinity are the water towers, with a height of 40 meters (130 feet), and the meteorological tower with a height of 61 meters (200 feet) in height. The 300 Area is visible from Route 4, which runs in a north-south direction along the western boundary of the site (Nielsen 2000). Because the 300 Area is a highly developed industrial area, it has a Visual Resource Management Class IV rating. Natural features of visual interest within a 40-kilometer (25-mile) radius include the Columbia River immediately to the east, Rattlesnake Mountain at 24 kilometers (15 miles), Gable Mountain at 27 kilometers (17 miles), and Gable Butte at 35 kilometers (22 miles).

##### **400 AREA**

FMEF, the tallest building in the 400 Area, is 30 meters (100 feet) tall and can be seen from State Route 240. Developed areas within the 400 Area are consistent with a Visual Resource Management Class IV rating. Natural features of visual interest within a 40-kilometer (25-mile) radius include the Columbia River at 6.8 kilometers (4.2 miles), Rattlesnake Mountain at 17 kilometers (11 miles), Gable Mountain at 19 kilometers (12 miles), and Gable Butte at 27 kilometers (17 miles).

#### **3.4.2 Noise**

Noise is unwanted sound that interferes or interacts negatively with the human or natural environment. Noise may disrupt normal activities or diminish the quality of the environment.

##### **3.4.2.1 General Site Description**

Major noise sources within the Hanford Site include various facilities, equipment, and machines (e.g., cooling systems, transformers, engines, pumps, boilers, steam vents, paging systems, construction and materials-handling equipment, and vehicles). Wind has been identified as a major source of background sound levels at Hanford. Data from two noise surveys indicate that background noise levels (measured as the 24-hour equivalent sound level) at Hanford range from 30 to 60.5 dBA. The 24-hour background sound level in undeveloped areas at Hanford ranges from 24 to 36 dBA, except when high winds elevate sound levels. The primary source of noise at the site and nearby residences is traffic. Most Hanford industrial facilities are far enough from the site boundary that noise levels at the boundary from these sources are not measurable, or are barely distinguishable from background noise levels. Hanford is currently in compliance with state noise regulations. Noise sources, existing noise levels at Hanford, and noise standards are described in the *Storage and Disposition PEIS* (DOE 1996b:3-29–3-31, F-31, F-32) and in the 1999 *Hanford Site National Environmental Policy Act (NEPA) Characterization* (Neitzel 1999:4.137-138).

The potential impact of traffic noise resulting from activities at Hanford was evaluated for a draft EIS addressing the siting of the proposed New Production Reactor (Neitzel 1999:4.138). Estimates were made of baseline traffic noise along two major access routes: State Route 24, leading from the Hanford Site west to Yakima, and State Route 240, south of the site and west of Richland, where it handles maximum traffic

volume. About 9 percent of the employees at Hanford commute by vanpool or bus. Modeled traffic noise levels (equivalent sound level [1-hour]) at 15 meters (50 feet) from State Route 24 for both peak and offpeak periods were 62 dBA. Traffic noise levels from State Route 240 for both peak and offpeak periods were 70 dBA. These traffic noise levels were projections based on employment levels about 30 percent higher than actual levels at Hanford in 1997. Existing traffic noise levels may be different as a result of changes in site employment and ride-sharing activities (DOE 1999e:3-8; Neitzel 1999:4.138-4.141).

Washington State has established noise standards for different source and receiving areas. Hanford belongs to source area Class C (industrial). The maximum allowable noise level for residential, commercial, and industrial areas is 50 to 70 dBA (DOE 1996b:3-29 and 3-31, Neitzel 1999:4.138). The EPA guidelines for environmental noise protection recommend a day-night average sound level of 55 dBA as sufficient to protect the public from the effects of broadband environmental noise in typically quiet outdoor and residential areas (EPA 1974:29). Land use compatibility guidelines adopted by the Federal Aviation Administration and the Federal Interagency Committee on Urban Noise indicate that yearly day-night average sound levels less than 65 dBA are compatible with residential land uses (14 CFR Part 150). These guidelines further indicate that noise levels up to 75 dBA are compatible with residential uses if suitable noise reduction features are incorporated into structures. It is expected that for most residences near Hanford, the day-night average sound level is less than 65 dBA and is compatible with the residential land use, although for some residences along major roadways noise levels may be higher.

### **3.4.2.2 Locations of Proposed Activities**

#### **300 AREA**

No distinguishing noise characteristics in the 300 Area have been identified. The 300 Area is just north of Richland and adjacent to the site boundary along the Columbia River. No sound level data have been collected in this area except for measurements that reflect traffic noise levels.

#### **400 AREA**

No distinguishing noise characteristics in the 400 Area have been identified. The 400 Area is far enough away from the site boundary, 7 kilometers (4.3 miles), that noise levels at the site boundary from these sources are not measurable or are barely distinguishable from background levels.

### **3.4.3 Air Quality**

Air pollution refers to the introduction, directly or indirectly of any substance into the air that could endanger human health, harm living resources and ecosystems as well as material property, and impair or interfere with the comfortable enjoyment of life or other legitimate uses of the environment. Air pollutants are transported, dispersed, or concentrated by meteorological and topographical conditions. Air quality is affected by air pollutant emission characteristics, meteorology, and topography.

#### **3.4.3.1 General Site Description**

The climate at Hanford and the surrounding region is characterized as that of a semiarid steppe. The humidity is low and winters are mild. The average annual temperature is 11.8 °C (53.3 °F); average monthly temperatures range from a minimum of -0.4 °C (31.3 °F) in January to a maximum of 24.6 °C (76.2 °F) in July. The average annual precipitation is 16 centimeters (6.3 inches). Prevailing winds at the Hanford Meteorological Station are from the west-northwest. The average annual wind speed is 3.4 meters per second (7.6 miles per hour) (Dirkes, Hanf, and Poston 1999:7.5; DOE 1999e:3-5).

Most of Hanford is within the South-Central Washington Intrastate Air Quality Control Region #230, but a small portion of the site is in the Eastern Washington-Northern Idaho Interstate Air Quality Control Region #62. None of the areas within Hanford and its surrounding counties are designated as nonattainment areas, with respect to NAAQS for criteria air pollutants (40 CFR Section 81.348). However, particulate matter concentrations can reach relatively high levels in eastern Washington State because of extreme natural events, such as dust storms, volcanic eruptions, and large brush fires. Washington State ambient air quality standards have not considered “rural fugitive dust” from exceptional natural events when estimating the maximum background concentrations of particulates in the area east of the Cascade Mountain crest. In June 1996, EPA adopted the policy that allows dust storms to be treated as uncontrollable natural events. The air quality impact of dust storms can therefore be excluded during the determination of whether this area is in nonattainment for atmospheric particulates (Neitzel 1999). Applicable NAAQS and Washington State ambient air quality standards are presented in **Table 3–29**.

The primary sources of air pollutants at Hanford include emissions from power generation and chemical processing (Neitzel 1999:4.30). Other sources include vehicles, construction, environmental remediation, and waste management activities (Wisness 2000). The existing ambient air pollutant concentrations at the site boundary attributable to sources at Hanford are presented in Table 3–29. These concentrations are based on dispersion modeling using emissions for Hanford, excluding the 400 Area for 1999 (Wisness 2000). The 400 Area emissions during FFTF standby are estimated using the EPA Standard AP-42 guideline. The concentrations at the site boundary for the 400 Area were calculated using EPA’s SCREEN3 dispersion model; however, the concentrations from the other sources at the site were calculated using the ISCST3 dispersion model. SCREEN3 estimates of maximum concentrations are conservative when compared to the ISCST3 estimates. The ISCST3 modeling was performed using the 1999 meteorological data for Hanford, whereas the SCREEN3 modeling was performed using a set of worst-case meteorological conditions. Although the location for maximum concentrations may be different, for the purpose of this NI PEIS, it was assumed to be occurring at the same location.

Only those pollutants that would be emitted by any of the alternatives evaluated in this NI PEIS are presented. Hanford sources are limited and background concentrations of criteria pollutants are well below ambient standards. As shown in Table 3–29, these modeled concentrations from Hanford sources represent a small percentage of the ambient air quality standards. Hanford emissions should not result in air pollutant concentrations that violate the ambient air quality standards for criteria pollutants. Detailed information on emissions of other pollutants at Hanford is discussed in the *Hanford Site NEPA Characterization* (Neitzel 1999:4.27–4.32).

There are no Prevention of Significant Deterioration Class I areas within 100 kilometers (62 miles) of Hanford. A Class I area is one in which very little increase in pollution is allowed due to the pristine nature of the area. Hanford and its vicinity are classified as a Class II area in which more moderate increases in pollution are allowed. Hanford operates under a Prevention of Significant Deterioration permit issued in 1980. New emission sources require a Prevention of Significant Deterioration increment consumption analysis. The recent designation of the Hanford Reach as a national monument (65 FR 37253) might lead to a proposal to redesignate this area, that includes part of Hanford and adjoining areas, as Prevention of Significant Deterioration Class I, although that appears unlikely at this time due to a variety of political and technical issues.

**Table 3–29 Comparison of Modeled Ambient Air Concentrations from Hanford Sources with Most Stringent Applicable Standards or Guidelines**

Pollutant	Averaging Period	Most Stringent Standard or Guideline (micrograms per cubic meter) <sup>a</sup>	Maximum Hanford Concentration Excluding 400 Area (micrograms per cubic meter) <sup>b</sup>	Maximum 400 Area Concentration (micrograms per cubic meter)
<b>Criteria pollutants</b>				
Carbon monoxide	8 hours	10,000 <sup>c</sup>	23.8	3.5
	1 hour	40,000 <sup>c</sup>	58.2	5.1
Nitrogen dioxide	Annual	100 <sup>c</sup>	0.634	0.032
Ozone	1 hour	235 <sup>d</sup>	(e)	(e)
PM <sub>10</sub>	Annual	50 <sup>c</sup>	0.0162	0.002
	24 hours	150 <sup>c</sup>	0.112	0.898
Sulfur dioxide	Annual	50 <sup>f</sup>	0.0114	0.164
	24 hours	260 <sup>f</sup>	0.365	29.8
	3 hours	1,300 <sup>c</sup>	2.41	67.0
	1 hour	1,000 <sup>f</sup>	5.02	74.4
	1 hour	660 <sup>f,g</sup>	5.02	74.4
<b>Other regulated pollutants</b>				
Total suspended particulates	Annual	60	0.0162	0.002
	24 hours	150	0.112	0.898

- a. The more stringent of the Federal and state standards is presented if both exist for the averaging period. The National Ambient Air Quality Standards (NAAQS) (40 CFR Part 50), other than those for ozone, particulate matter, and lead, and those based on annual averages, are not to be exceeded more than once per year. The annual arithmetic mean PM<sub>10</sub> standard is attained when the expected annual arithmetic mean concentration is less than or equal to the standard.
- b. Site contributions based on a 1999 emissions inventory, excluding the 400 Area.
- c. Federal and state standard.
- d. Federal 8-hour standard is currently under litigation.
- e. Not directly emitted or monitored by the site.
- f. State standard.
- g. Not to be exceeded more than twice in any 7 consecutive days.

**Note:** NAAQS also includes standards for lead. No sources of lead emissions have been identified at the site. Emissions of other air pollutants not listed here have been identified at Hanford, but are not associated with any alternative evaluated. EPA revised the ambient air quality standards for particulate matter and ozone in 1997; however, these standards were under litigation. In 1999, new standards, effective on September 16, 1997, could not be enforced. The ozone standard is a 1-hour concentration of 235 micrograms per cubic meter (0.12 parts per million) (62 FR 38856). The 8-hour standard could not be enforced. For particulate matter, the current PM<sub>10</sub> annual standard is retained (62 FR 38652).

**Source:** 40 CFR Part 50; WDEC 1998; Wisness 2000.

A sitewide air operating permit is being developed for Hanford, scheduled to be issued as a draft by the end of 2000, in accordance with Title V of the Clean Air Act and Amendments of 1990 and the Federal and state programs under 40 CFR Part 70 and WAC 173-401, respectively (WDEC 1997). The Hanford air operating permit will include a compilation of requirements for both radioactive emissions now covered by the existing state license and nonradioactive emissions. The primary effects of the air operating permit will be to consolidate approval orders and applicable requirements into one permit, require the permitted party to conduct periodic monitoring to show continuous compliance with permit conditions and applicable requirements, require biannual reporting and annual certification of continuous compliance, and increase the state's and EPA's enforcement position.

Based on 1996 monitoring conducted off site by the Washington State Department of Ecology, the annual and 24-hour PM<sub>10</sub> standards were not exceeded (Neitzel 1999:4.29). Ambient air quality at Hanford is discussed in more detail in the *Hanford Site Environmental Report for Calendar Year 1998* (Dirkes, Hanf, and Poston 1999).

Routine monitoring of most nonradiological pollutants is not conducted at the site. Monitoring of nitrogen oxides and total suspended particulates at Hanford has been discontinued as a result of phasing out programs for which the monitoring was required. Carbon monoxide, sulfur dioxide, and nitrogen dioxide have been monitored periodically in communities and commercial areas southeast of Hanford. In 1995, air samples of semivolatile organic compounds were collected on the site and at an offsite location, and the results are discussed in the site's annual environmental report. All concentrations of these compounds were below the applicable risk-based concentrations.

### **3.4.3.2 Locations of Proposed Activities**

#### **300 AREA**

Prevailing winds in the 300 Area are from the southwest. The 300 Area emits various nonradiological air pollutants from power generation and process sources (Neitzel 1999:4.30, 4.31).

#### **400 AREA**

Prevailing winds in the 400 Area are from the south-southwest, with a secondary maximum from the northwest. The 400 Area emits various nonradiological air pollutants (see Sections 3.4.3.1 and 4.4.1.2.3) (Neitzel 1999:4.30).

### **3.4.4 Water Resources**

Water resources include all forms of surface water and subsurface groundwater.

#### **3.4.4.1 Surface Water**

Surface water includes marine or freshwater bodies that occur above the ground surface, including rivers, streams, lakes, ponds, rainwater catchments, embayments, and oceans.

##### **3.4.4.1.1 General Site Description**

Major surface water features at Hanford include the Columbia River, Columbia riverbank seepage, springs, and ponds (**Figure 3-13**). In addition, the Yakima River flows along a short section of the southern boundary of the site. The Columbia River is the second largest river in the contiguous United States in terms of total flow and is the dominant surface water feature on the site. Flow of the Columbia River is regulated by several dams, seven upstream and four downstream from the site. The nearest dam upstream from Hanford is the Priest Rapids Dam, and the closest downstream dam is the McNary Dam. The Hanford Reach is the portion of the Columbia River that extends from Priest Rapids Dam to the upstream edge of Lake Wallula behind McNary Dam. Because the flows are regulated, flow rates in the Hanford Reach can vary considerably; it is the last remaining free-flowing, nontidal section of the river. The average daily flow rate at Priest Rapids Dam is 3,360 cubic meters (118,700 cubic feet) per second. Peak flows generally occur from April through June corresponding to runoff from snowmelt. Due to larger than normal snowpacks, the peak flow rate in 1997 was nearly 11,750 cubic meters (415,000 cubic feet) per second. The width of the river varies from approximately 300 to 1,000 meters (1,000 to 3,300 feet) within the Hanford Site (Neitzel 1999:4.55, 4.56).

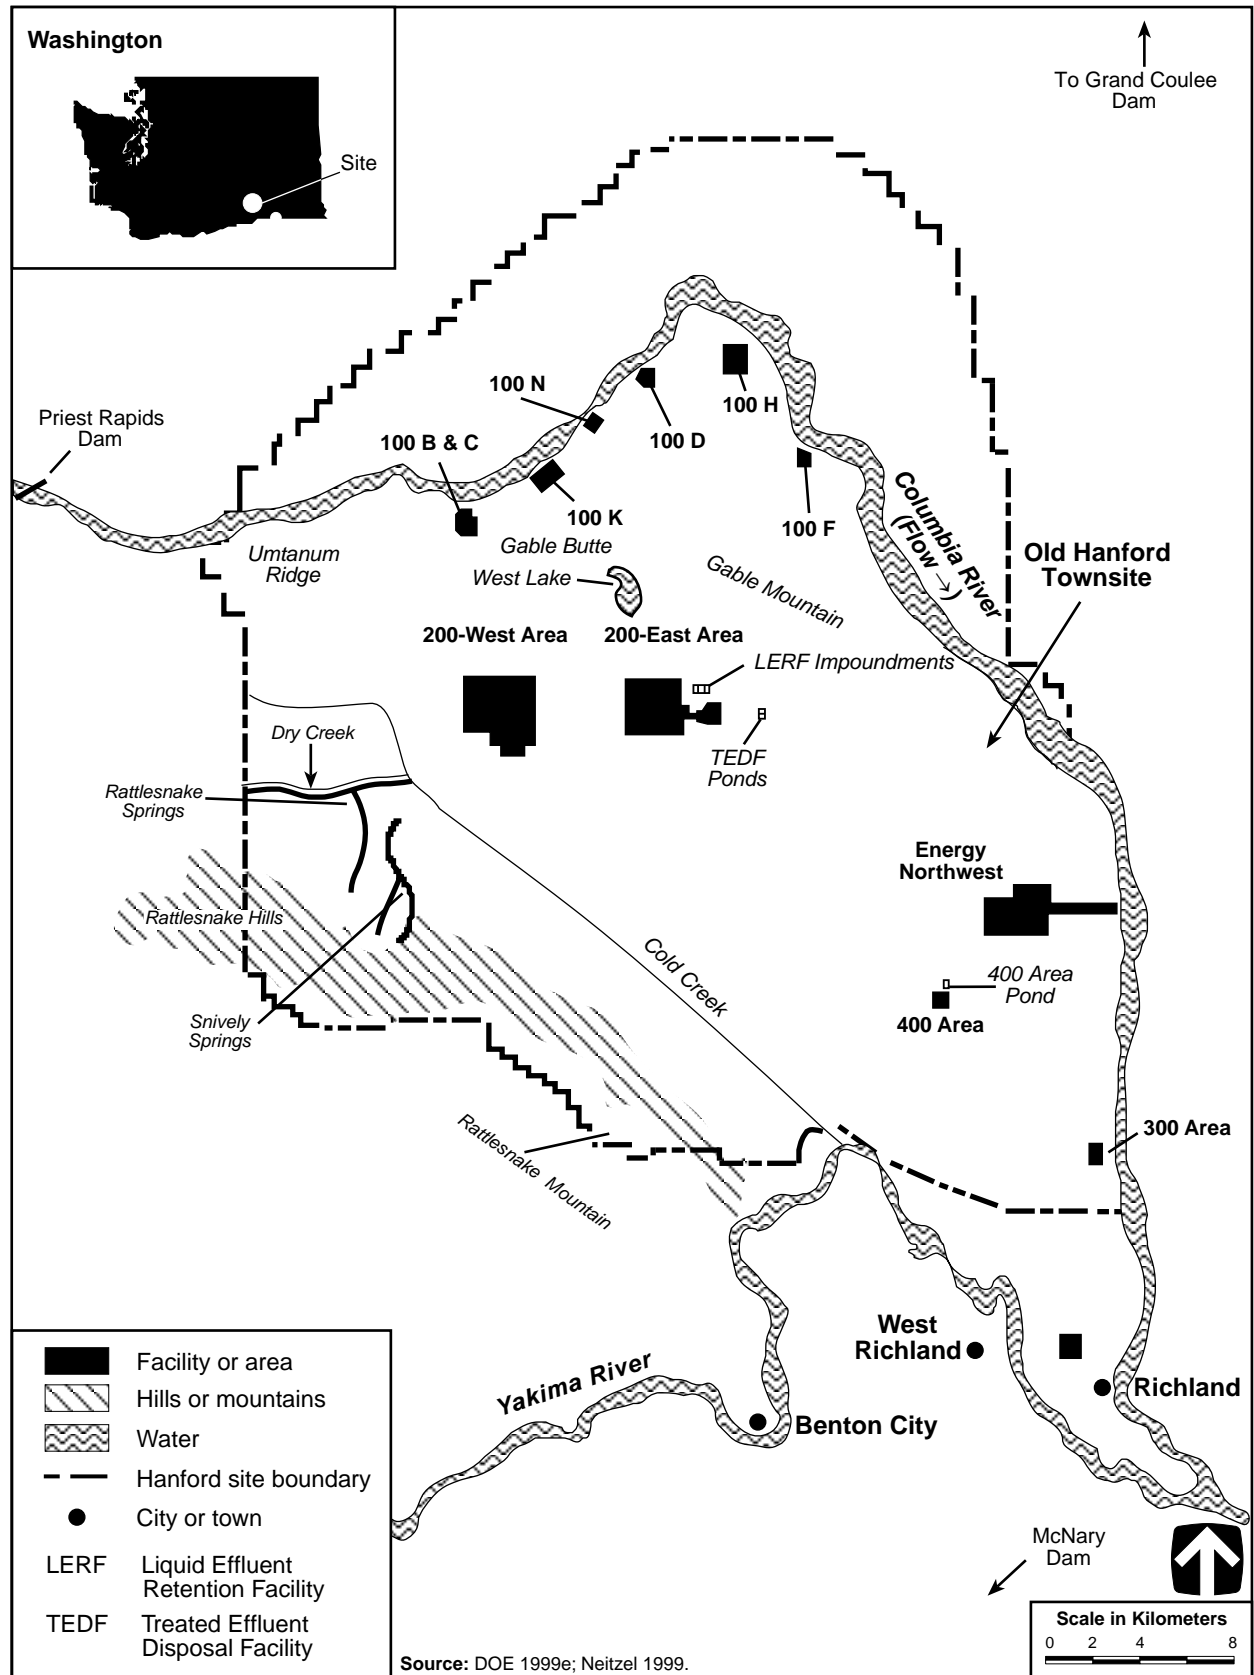

Figure 3-13 Surface Water Features at the Hanford Site

Primary uses of the Columbia River include hydroelectric power generation, irrigation of crops in the Columbia Basin, and barge transportation. The Hanford Reach is the upstream navigable limit of barge traffic. The Columbia River is also used extensively for recreation, including fishing, hunting, boating, sailboarding, water-skiing, diving, and swimming. In addition to a water supply source for the Hanford Site, several communities use the Columbia River as their source of drinking water (Neitzel 1999:4.56). Nine of the 12 DOE-owned, contractor-operated water plants on the Hanford Site use water from the Columbia River (Dirkes, Hanf, and Poston 1999:4.47–4.49).

The Washington State Department of Ecology classifies the Columbia River, from Grand Coulee to the Washington-Oregon border and encompassing the Hanford Reach, as Class A (excellent). Class A waters are suitable for essentially all uses, including raw drinking water, recreation, and wildlife habitat. Federal and state drinking water standards, and DOE Order 5400.5, apply to the Columbia River and are currently being met (DOE 1999k:4-35). Although no federally designated Wild and Scenic Rivers exist in the Hanford Site vicinity, the Hanford Reach is being considered for listing under the National Wild and Scenic Rivers Act as part of broader resource conservation initiatives (DOE 1999k:4-5; Neitzel 1999:6.10). The Hanford Reach was recently proclaimed a National Monument (refer to Section 3.4.1.1.1).

DOE continues to assert a federally reserved water withdrawal right for the Columbia River. Hanford withdraws approximately 13.5 billion liters (3.6 billion gallons) per year from the Columbia River (DOE 1999e:3-30).

About one-third of the Hanford Site drains into the Yakima River. The average daily flow rate for the Yakima River is 104 cubic meters (3,670 cubic feet) per second. The peak average daily flow rate in 1997 was nearly 1,300 cubic meters (45,900 cubic feet) per second (Neitzel 1999:4.58).

Rattlesnake Springs and Snively Springs are in the western portion of the site and flow into intermittent streams that infiltrate rapidly into the surface sediments (Figure 3–13). Water discharged from Rattlesnake Springs flows down Dry Creek, a tributary to Cold Creek, for about 3 kilometers (1.9 miles) before infiltrating into the ground. An alkaline spring has also been documented at the east end of Umtanum Ridge. Several springs are also found on the slopes of Rattlesnake Mountain along the western and southwestern edges of the site (DOE 1999k:4-30; Neitzel 1999:4.58). The seepage of groundwater into the Columbia River was documented along the Hanford Reach long before Hanford Site operations began. This seepage occurs both below the river surface and on the exposed riverbank. These relatively small seeps flow intermittently, influenced primarily by changes in river level. Hanford-origin contaminants have been documented in these discharges along the Hanford Reach (DOE 1999k:4-30; Neitzel 1999:4.65).

Other naturally occurring surface water features include West Lake and three previously undocumented clusters of approximately 20 vernal ponds or pools. The clusters are located on the eastern end of Umtanum Ridge, in the central part of Gable Butte, and at the eastern end of Gable Mountain. The ponds appear to form during the relatively wetter winter ponds in shallow depressions underlain by a layer of basalt (DOE 1999k:4-31; Neitzel 1999:4.67).

Artificial ponds also exist on the site primarily associated with waste management activities. These include: water storage ponds in the 100 K-Area, the two Treated Effluent Disposal Facility (TEDF) disposal ponds and the three Liquid Effluent Retention Facility impoundments adjacent to the 200-East Area, and the 400 Area Pond (FFTF Pond or 4608 B/C ponds) used by FFTF and other facilities (Figure 3–13) (DOE 1999k:4-31; Neitzel 1999:4.57, 4.67). While West Lake, a natural pond located north of the 200 Areas that predates Hanford operations, has not received effluents, it was sustained by the artificially elevated water table beneath much of Hanford, attributable to historic waste management activities and current wastewater disposal in the 200 Areas. Although not accessible to the public, these ponds are accessible by waterfowl (DOE 1999k:4-32;

Neitzel 1999:4.67, 4.88). In addition to these features, there are irrigation ponds and wetlands located in the northwest portion of the site and north of the Columbia River (Neitzel 1999:4.57, 4.67).

In 1998, the Hanford Site had two NPDES permits: Permit #WA-000374-3 and Permit #WA-002591-7. Permit #WA-000374-3 included four inactive outfalls in the 100-N Area and three active outfalls (two in the 100-K Area and one in the 300 Area). There were two instances of noncompliance for these outfalls in 1998. Permit #WA-002591-7 covered one outfall located at the 300 Area TEDF. The 300 Area TEDF had 14 exceedances in 1998. This disposal facility was in normal operation and meeting design specifications at the time of these events. All indications suggest that the facility is unable to consistently meet the restrictions of the facility's NPDES permit, despite the use of the best available technology. An application for a permit modification was submitted to EPA in November 1997 (Dirkes, Hanf, and Poston 1999:2.24, 2.25). The modification requested transfer of the two active 100-K Area outfalls from Permit #WA-000374-3 to Permit #WA-002591-7, among other items. A revised permit was issued April 2, 1999, and became effective May 5, 1999 (Chapin 1999). Revised effluent limits for the 300 Area TEDF were established under the modified Permit #WA-002591-7 (Dirkes, Hanf, and Poston 1999:2.25). Permit #WA-000374-3 has lapsed.

Hanford was covered by two industrial stormwater permits (WAR-00-000F, WAR-10-000F) in 1998. An annual comprehensive site compliance evaluation was performed and documented in 1998. In accordance with the September 30, 1998, Federal Register (63 FR 52430), the stormwater general permit for industrial activity (WAR-00-000F) was terminated and replaced by the multisector general stormwater permit (WAR-10-000F). On December 28, 1998, a Notice of Intent was submitted to EPA for coverage under the NPDES multisector permit (WAR-10-000F) (Dirkes, Hanf, and Poston 1999:2.25).

DOE Richland Operations Office has a pretreatment permit (CR-IU005) from the city of Richland for the discharge of wastewater from the Environmental Molecular Sciences Laboratory in the 300 Area. Also, there are numerous sanitary waste discharges to the ground through sanitary systems permitted by the Washington State Department of Health, as well as 400 Area sanitary waste discharges to the Energy Northwest treatment facility. Sanitary waste from the 300 Area and other facilities north of and in Richland discharge to the city of Richland treatment facility (Dirkes, Hanf, and Poston 1999:2.25).

Hanford is subject to a Washington State Department of Ecology liquid effluent consent order that regulates liquid effluent discharges to the ground. All state waste discharge permit applications for discharges covered under the consent order have been submitted. One new state waste discharge permit was issued on May 1, 1998, by the Washington State Department of Ecology (Permit ST-4509 for Hanford cooling water and condensate discharges). In 1998, there were eight noncompliances in three of the seven state waste discharge permits currently in place at Hanford. One of these was for exceeding the permit limit for manganese in the cooling water discharge to the 400 Area Pond. The exceedance was attributed to the naturally high levels of the metal in the source water (Dirkes, Hanf, and Poston 1999:2.25, 2.26).

All radiological contaminant concentrations measured in the Columbia River in 1998 were lower than the DOE Derived Concentration Guides and Washington State ambient surface water quality criteria. For nonradiological parameters, applicable standards for Class A—designated surface water were met, with results comparable to those over the past 5 years. During 1998, there was no evidence of deterioration in water quality attributable to Hanford operations along the Hanford Reach (Dirkes, Hanf, and Poston 1999:4.22, 4.27–4.29).

The Columbia River is also the primary discharge area for the unconfined aquifer underlying Hanford. The site conducts sampling of these groundwater seeps during low flow and refers to them as riverbank springs. Water samples were collected from eight Columbia River shoreline spring areas in 1998. All samples were analyzed for gamma-emitting radionuclides, gross alpha, gross beta, and tritium. Samples from selected

springs were analyzed for strontium-90; technetium-99; iodine-129; and uranium-234, 235, and 238. Samples were also analyzed for metals and anions (Dirkes, Hanf, and Poston 1999:4.20, 4.34–4.36).

All radiological contaminant concentrations measured in 1998 were less than the DOE Derived Concentration Guides. Tritium in riverbank springs water at the Old Hanford Townsite (refer to Figure 3–13 for locations) and the 100-N Area exceeded the state ambient surface water quality criterion (20,000 picocuries per liter), with the maximum of 120,000 picocuries per liter observed at the Old Hanford Townsite. Gross beta activities in riverbank springs water at the 100-H Area exceeded the ambient criterion (50 picocuries per liter), with a maximum observed value of 72 picocuries per liter. While there are no ambient surface water quality criteria directly applicable to uranium, total uranium levels exceeded the site-specific proposed EPA drinking water standard in the 300 Area (equivalent to 13.4 picocuries per liter), with a maximum total uranium activity of 58 picocuries per liter. Gross alpha activity exceeded the ambient surface water quality criterion of 15 picocuries per liter in riverbank springs water at the 300 Area, with a maximum observed value of 56 picocuries per liter. This is consistent with the elevated uranium levels. All other radionuclide activities in 300 Area springs water were less than ambient surface water quality criteria (Dirkes, Hanf, and Poston 1999:4.36, A.10, A.11, C.3). Elevated uranium activities exist in the unconfined aquifer beneath the 300 Area in the vicinity of uranium fuel fabrication facilities and inactive waste sites. Elevated tritium activities have also been measured in the 300 Area riverbank springs and are indicators of the contaminated groundwater plume emanating from the 200 Areas. However, in 1998, the maximum observed activity level was 9,600 picocuries per liter and below the ambient surface water quality criterion (Dirkes, Hanf, and Poston 1999:4.38, C.4).

Nonradiological contaminants measured in riverbank springs located on the Hanford shoreline in 1998 were below the applicable Washington State ambient surface water criteria except for chromium concentrations in 100-B, 100-K, 100-D, and 100-H Area springs exceeding the acute toxicity level of 16 micrograms per liter (Dirkes, Hanf, and Poston 1999:4.38, C.4).

Flooding of the site has occurred along the Columbia River, but chances of recurrence have been greatly reduced by the construction of dams to regulate river flow. Major floods are typically due to the melting of the winter snowpack combined with above normal precipitation (Neitzel 1999:4.60). No maps of flood-prone areas have been produced by the Federal Emergency Management Agency. The Federal Emergency Management Agency produces these maps for areas capable of being developed, and the Hanford Site is not designated for commercial or residential development (DOE 1999k:4-34). However, analyses have been completed to determine the potential for the probable maximum flood. This is determined through hydrologic factors, including the amount of precipitation within the drainage basin, snow melt, and tributary conditions. The probable maximum flood for the Columbia River below the Priest Rapids Dam has been calculated at 40,000 cubic meters (1.4 million cubic feet) per second, which is greater than the 500-year flood (DOE 1999k:4-34; Neitzel 1999:4.60). The extent of the 1948 flood, and the extent of the probable maximum flood, are shown in **Figure 3–14**. Potential flooding due to dam failure has been evaluated by the U.S. Army Corps of Engineers. Upstream failures could have any number of causes, the magnitude of the resultant flooding depending on the size of the breach in the dam. The U.S. Army Corps of Engineers evaluated various scenarios for failure of the Grand Coulee Dam, located approximately 130 kilometers (80 miles) from Hanford, and assumed flow conditions of about 11,300 cubic meters (400,000 cubic feet) per second. The worst-case scenario assumed a 50 percent breach in the dam (**Figure 3–15**). The flood wave from an instantaneous 50 percent breach was calculated to be 600,000 cubic meters (21 million cubic feet) per second. In addition to the areas affected by the probable maximum flood, the remainder of the 100 Area, the 300 Area, and nearly all of Richland, Washington, would be flooded. Determinations were not made for larger instantaneous breaches in the Grand Coulee Dam, because the 50 percent scenario was believed to be the largest conceivable flow from a natural or manmade breach. It was not considered credible that a structure as large as the Grand

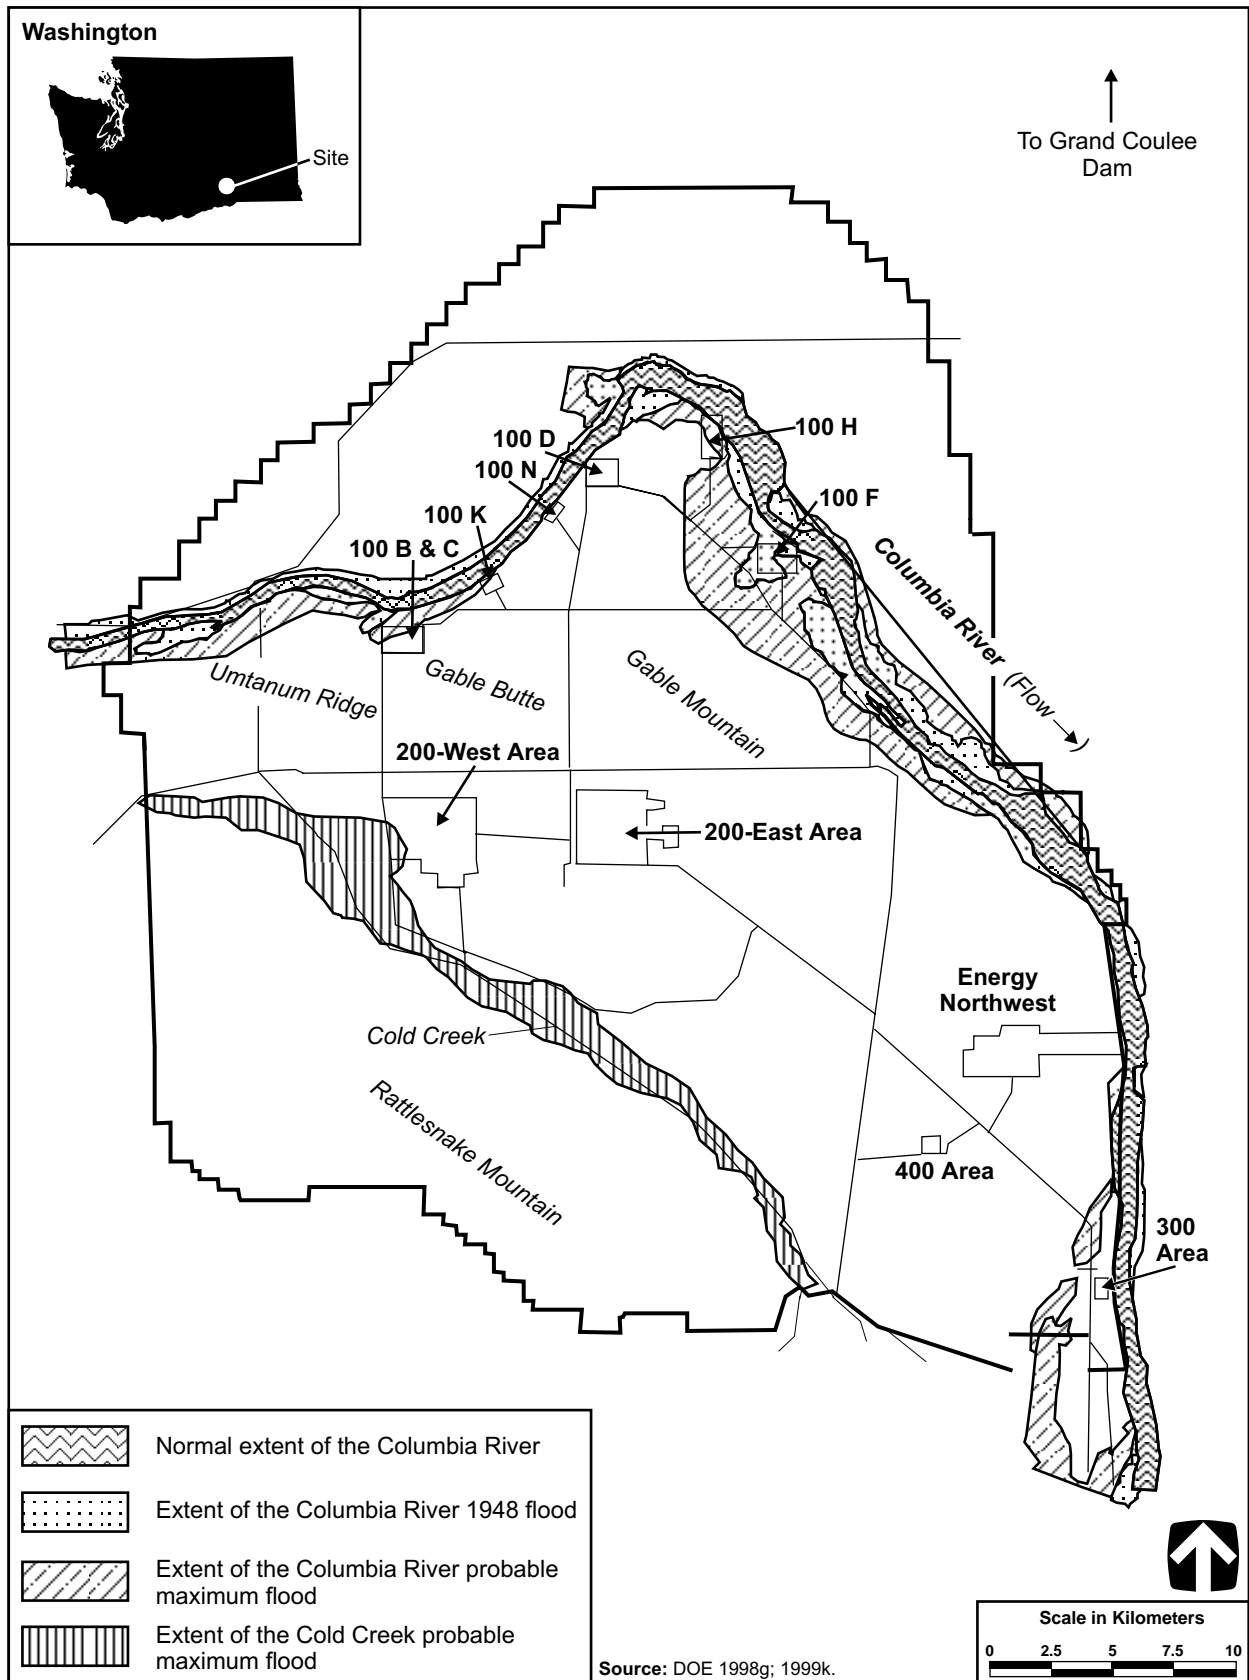

Figure 3-14 Flood Area for the Probable Maximum Flood and Columbia River 1948 Flood

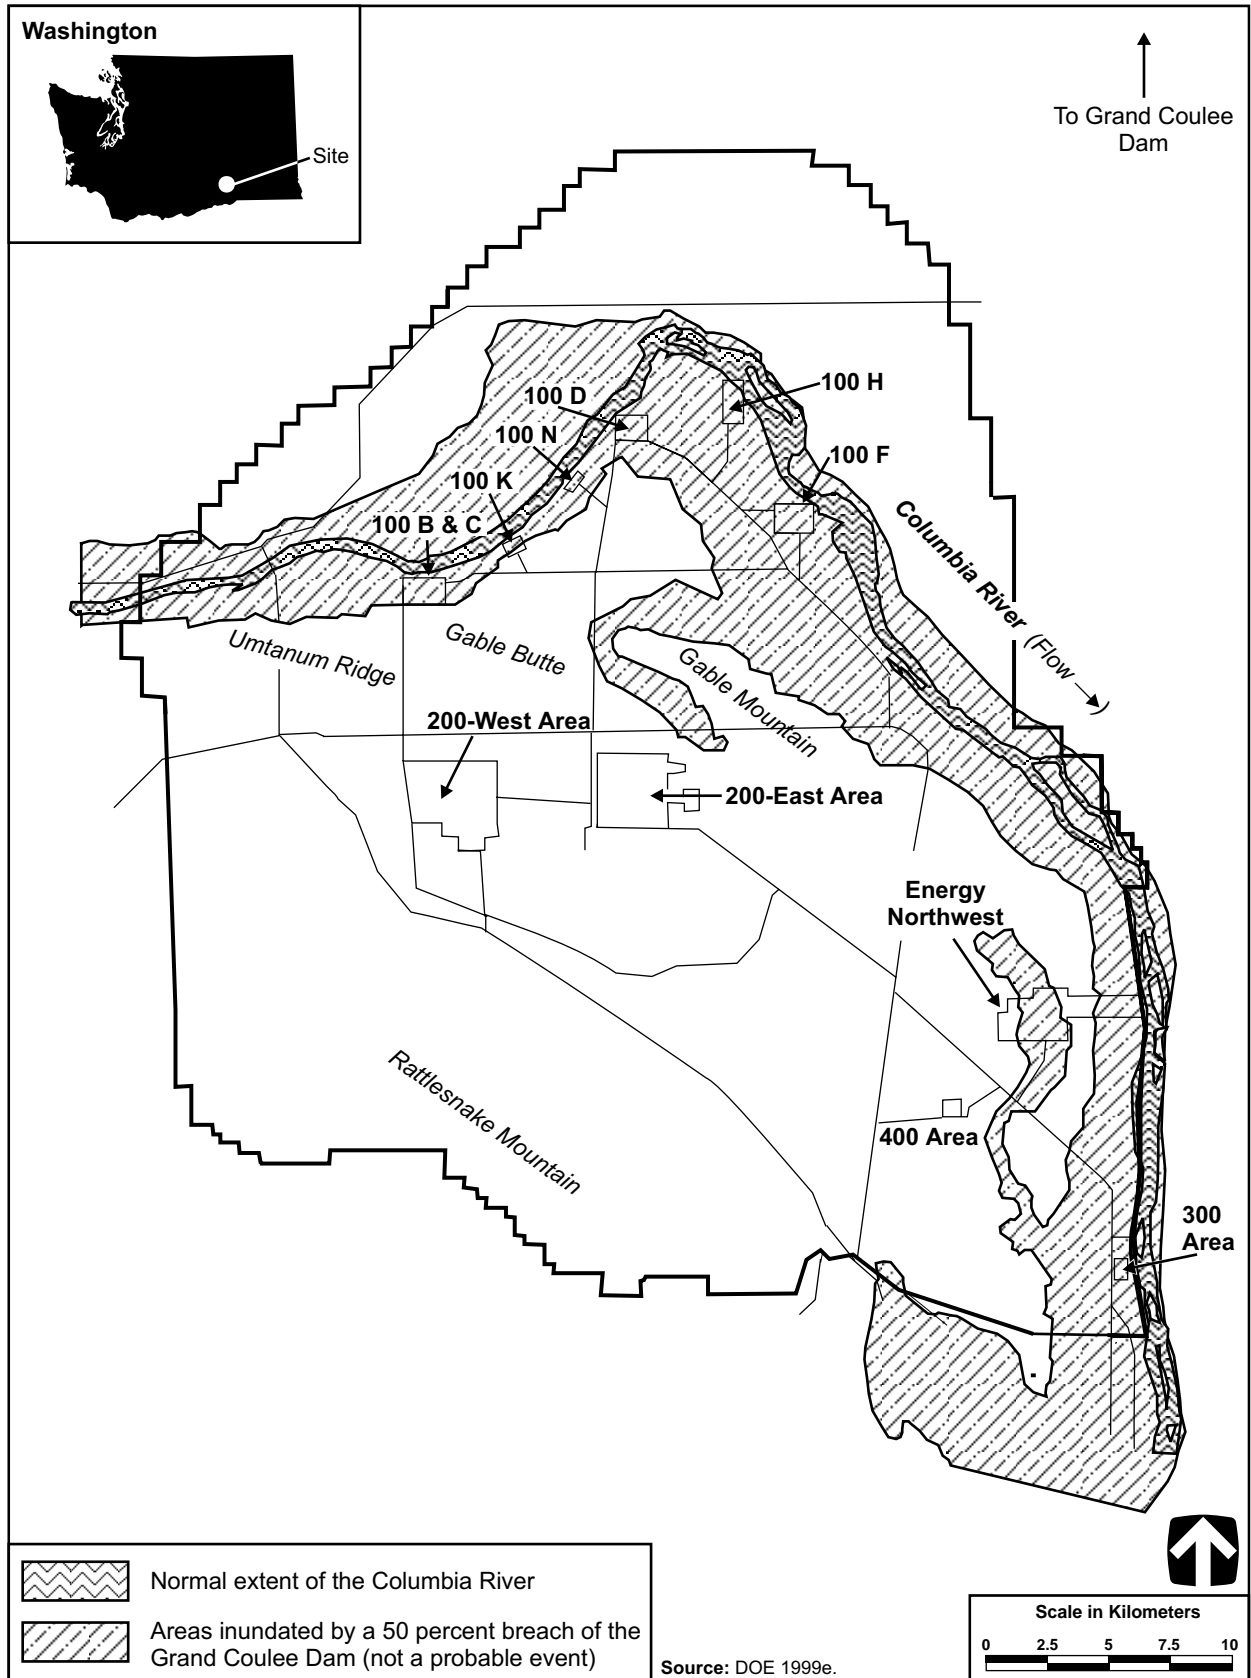

Figure 3-15 Flood Area of a 50 Percent Breach of the Grand Coulee Dam

Coulee Dam could be 100 percent destroyed instantaneously. The analysis also assumed that the 50 percent breach would occur only as the result of direct explosive detonation, and not because of some natural event such as an earthquake (DOE 1999k:4.34; Neitzel 1999:4.60, 4.65).

### 3.4.4.1.2 Locations of Proposed Activities

#### 300 AREA

The 300 Area is located in the southeast corner of the site adjacent to the Columbia River. Although no site-specific flood analysis is available for the 300 Area, analyses have been completed for the site as a whole, as previously discussed. The 300 Area does not lie within the area postulated to be affected by the probable maximum flood, but locations just to the west of the area would be affected (Figure 3–14). However, the 300 Area would be inundated from a 50 percent breach of the Grand Coulee Dam (Figure 3–15). Water for the 300 Area, including for RPL/306–E, is provided by the city of Richland, which obtains about two-thirds of its water from the Columbia River (FDH 1999:3; Neitzel 1999:4.133). Water consumption in the 300 Area is approximately 594 million liters (157 million gallons) per year (FDH 1999:3). Sanitary wastewater from the 300 Area is discharged to the city of Richland treatment facility (Dirkes, Hanf, and Poston 1999:2.25).

RPL is connected to the 300 Area sanitary sewer system and to a separate retention process sewer system. This system collects equipment cooling water, laboratory waste liquids, and other liquids that have a slight potential for radioactive contamination. The retention process sewer system routes process wastewater to the 307 basins at the 340 Complex and ultimately to the 300 Area TEDF, which operates under NPDES Permit WA002591-7. The system is monitored for radioactivity and, if an alarm is triggered, the effluent is diverted to a dedicated basin at the 340 Complex. Otherwise, the effluent is screened at the 307 basins before being conveyed to the 300 Area TEDF. Direct sampling and analysis of the system is also conducted as needed (DOE 1997c: 4-58; 2000c:C-2, C-3). Historically, RPL has generated an average of 1.13 million liters (300,000 gallons) of sanitary wastewater annually and 2.27 million liters (600,000 gallons) of process wastewater per year (DOE 1997c: 4-58). RPL currently generates an average of 3.98 million liters (1.05 million gallons) of sanitary wastewater annually and 3.6 million liters (950,000 gallons) per year of process wastewater (DOE 2000c:C-3; Tenforde 2000). Liquid, low-level radioactive waste generation has averaged less than 3,800 liters (1,000 gallons) per year (DOE 1997c:4-58, 4-59). Building 306–E is also served by the sanitary sewer and process sewer systems. For Building 306–E, sanitary wastewater generation averages 995,000 liters (262,000 gallons) on an annual basis and process wastewater generation averages 24.9 million liters (6.57 million gallons) per year (Tenforde 2000). Process wastewater with the potential for radioactive contamination is not routinely generated at the facility (DOE 1997c:4-60, B.2-2). Waste management activities and facilities are discussed in greater detail under Section 3.4.11.

#### 400 AREA

The 400 Area is located 6.3 kilometers (3.9 miles) from the west bank of the Columbia River. No specific flooding analyses have been completed for the 400 Area, but analyses have been completed for the site as a whole. According to the sitewide data, the elevation of the ground surface in the 400 Area is about 30 meters (100 feet) above that of the maximum calculated flood from a 50 percent breach of the Grand Coulee Dam (Mecca 1997a:4) (Figure 3–15). Also, the 400 Area is above the elevation of the maximum historical floods of 1894 (Neitzel 1999:4.61) and 1948 (Figure 3–14).

The only surface water body in the vicinity of the 400 Area is the 400 Area Pond (i.e., FFTF Pond or 4608 B/C ponds) located just north of the 400 Area (DOE 1999k:4-31; Neitzel 1999:4.67). It is designed and used to dispose of nonradioactive process wastewater collected by the process sewer system from four 400 Area facilities including FFTF, FMEF, the Maintenance and Storage Facility, and the water pumphouse. The

400 Area Pond consists of two cells measuring 15 by 30 meters (50 by 100 feet) with 1.2-meter (4-foot) walls. The majority of the wastewater discharged to the pond system is cooling tower blowdown from FFTF's eight auxiliary cooling towers and FMEF's three cooling towers (currently inactive). Individual effluent streams are collected at a central drain line that runs to the ponds, with the effluent monitored before discharge. Wastewater rapidly percolates into the ground, leaving the ponds dry under normal conditions. The discharges are regulated under State Waste Discharge Permit No. ST-4501, and the effluent is periodically sampled and analyzed for permit compliance. Approximately 76 million liters (20 million gallons) per year of process wastewater is discharged to the ponds. Also, about 3.8 million liters (1 million gallons) of sanitary wastewater is discharged annually from 400 Area facilities to the Energy Northwest system for treatment (DOE 2000c:11; Nielsen 1999:38, 39, 41). There are no radiological liquid effluent pathways to the environment from either FFTF or FMEF under normal operations (DOE 1997c:4-6, 4-29). Liquid, low-level radioactive waste from equipment washing is generated during standby operations at a maximum rate of about 3,785 liters (1,000 gallons) per year. It is collected in tanks and transported to the 200 Area Effluent Treatment Facility for treatment and disposal (DOE 1997c:4-54; Nielsen 1999:39).

FMEF is also equipped with a separate retention/radioactive liquid waste system for handling wastewater not conveyed to the sanitary system due to the slight potential for radioactive contamination of some wastewater streams. Wastewater first flows to two 22,700-liter (6,000-gallon) collection tanks, where the wastewater can be sampled and either discharged by operator command to the process sewer system or, if contaminated, can be trucked to the 200 Area Effluent Treatment Facility, or other suitable facility, for processing (DOE 1997c:B.1-11; 2000c:7). Waste management activities and facilities are discussed in greater detail under Section 3.4.11.

### **3.4.4.2 Groundwater**

Aquifers are classified by Federal and state authorities according to use and quality. The Federal classifications include Classes I, II, and III groundwater. Class I groundwater is either the sole source of drinking water or is ecologically vital. Classes IIA and IIB are current or potential sources of drinking water (or other beneficial use), respectively. Class III is not considered a potential source of drinking water and is of limited beneficial use.

#### **3.4.4.2.1 General Site Description**

Groundwater under Hanford occurs in confined and unconfined aquifer systems. The hydrostratigraphic (water bearing) units comprising these systems are illustrated in **Figure 3-16**. The unconfined aquifer system, referred to as the suprabasalt aquifer system, lies within the glacioalluvial sands and gravels of the Hanford Formation and, to a greater degree, the fluvial and lacustrine sediments of the Ringold Formation. Groundwater generally flows eastward across the site from recharge areas in the higher elevations on the western site boundary, with discharge primarily to the Columbia River (**Figure 3-17**) (DOE 1999e:3-31; Neitzel 1999:4.68). The Yakima River is also considered a source of recharge (Neitzel 1999:4.68). Because of site wastewater disposal practices, however, the water table has risen as much as 27 meters (89 feet) in the 200 West Area. This has caused groundwater mounding with radial and northward flow components in the 200 Area, although groundwater elevations have declined since 1984 due to decreased wastewater disposal (DOE 1999e:3-31; Neitzel 1999:4.70). Depth to groundwater across the site ranges from 0.3 meters (1 foot) along the Columbia River to more than 106 meters (348 feet) near the center of the site (Dirkes, Hanf, and Poston 1999:6.10). Daily river level fluctuations may result in water table fluctuations of up to 3 meters (10 feet) near the Columbia River (Neitzel 1999:4.68).

Figure 3–16 Stratigraphic Column for the Pasco Basin and Hanford Site

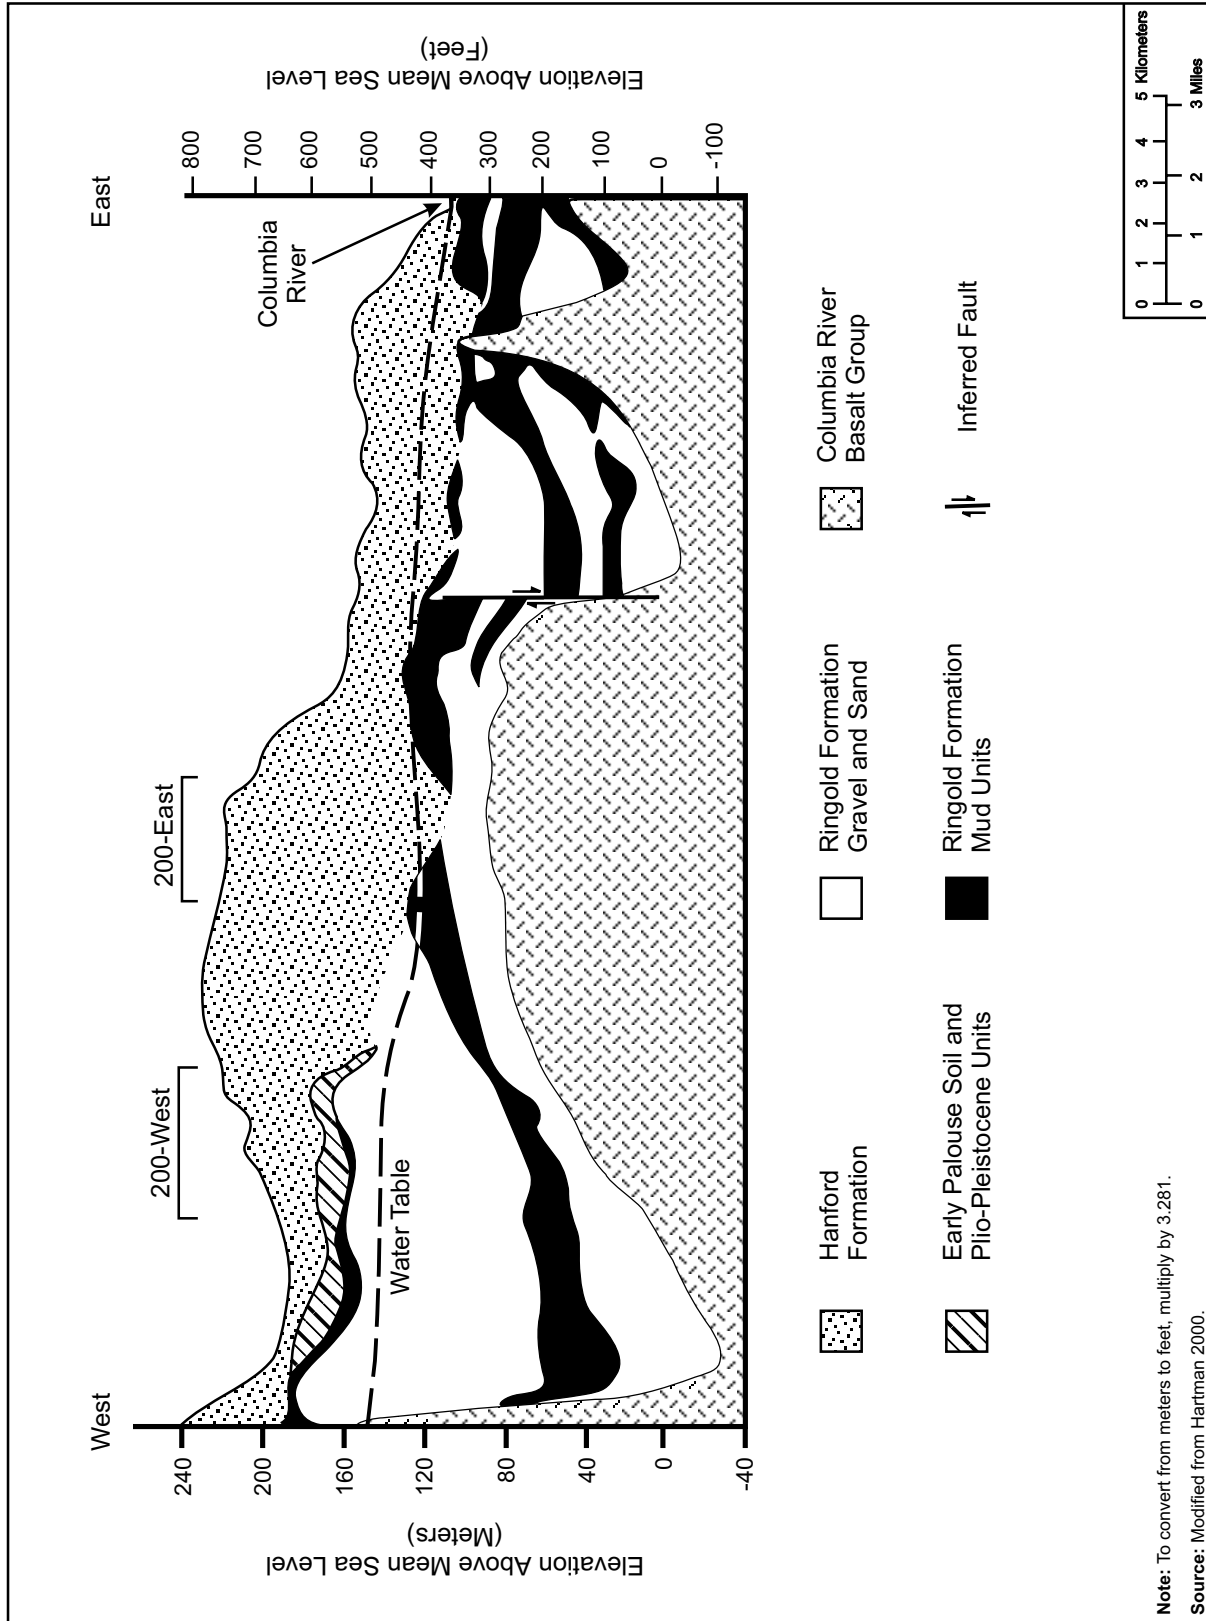

Figure 3-17 Geologic Cross Section of the Hanford Site

The confined aquifer system at Hanford consists of sedimentary interbeds and interflow zones that occur between basalt flows in the Columbia River Basalt Group. Aquifer thickness varies from several centimeters to at least 52 meters (171 feet). Recharge of the confined aquifer occurs where the basalt formations are near ground level, and thus surface water is allowed to infiltrate them. Groundwater in the confined aquifer system discharges to the Columbia River, but in some places, moves toward areas of vertical interconnection with the overlying unconfined aquifer system. One such area is near the Gable Mountain anticline (DOE 1999e:3-32; Neitzel 1999:4-68).

Water use in the Pasco Basin, which includes Hanford, is primarily via surface water diversion; groundwater accounts for less than 10 percent of water use (DOE 1999k:4-49). While most of the water used by Hanford is surface water withdrawn from the Columbia River, some groundwater is used. One of the principal users of groundwater was FFTF, which used about 697,000 liters (184,000 gallons) per day when it operated. In addition to the 400 Area, other facilities that use groundwater are the Yakima Barricade and the Patrol Training Academy (Barghusen and Feit 1995:2.2-22). DOE currently asserts an unlimited federally reserved groundwater withdrawal right with respect to existing Hanford operations, and withdraws about 197 million liters (52 million gallons) per year (DOE 1999e:3-32).

Groundwater quality beneath large portions of the Hanford Site has been affected by past liquid waste discharges, primarily to ditches, trenches, and ponds and from spills, injection wells, and leaks from waste storage tanks (Neitzel 1999:4.72). The unconfined aquifer system contains radiological and nonradiological contaminants at levels exceeding water quality criteria and standards. During fiscal year 1999 (October 1998 to September 1999), 623 wells were sampled for radiological and chemical constituents. Tritium and iodine-129 are the most widespread radiological contaminants in the unconfined aquifer system, with tritium exceeding the drinking water standard in the 100, 200, 400, and 600 Areas in 1998 and fiscal year 1999. Tritium levels are expected to decrease over time because of dispersion and radioactive decay. Nitrate, chromium, and carbon tetrachloride are the most widely distributed nonradiological contaminants (Dirkes, Hanf, and Poston 1999:6.27, 6.49; Hartman, Morasch, and Webber 2000:2.5–2.8). Tritium, iodine-129, and nitrate are the most widespread groundwater contaminants associated with Hanford legacy activities. Their distribution in the unconfined aquifer system are illustrated in **Figures 3–18, 3–19, and 3–20**, respectively. The figures also depict the locations of former waste management sites (e.g., Gable Mt. Pond, U Pond, B Pond, effluent disposal cribs) and burial grounds. Also shown are locations of active waste management and treatment facilities such as the State Approved Land Disposal Site, the Effluent Treatment Facility, the 200 Areas TEDF, and the Environmental Restoration Disposal Facility. Information on groundwater monitoring and chemical analysis is summarized in the annual site environmental report with detailed results in the site groundwater monitoring report (Dirkes, Hanf, and Poston 1999; Hartman, Morasch, and Webber 2000). Contamination in the confined aquifer system is typically limited to areas of exchange with the unconfined aquifer system (Dirkes, Hanf, and Poston 1999:6.65). No aquifers have been designated sole-source aquifers (Barghusen and Feit 1995:2.2-22).

#### **3.4.4.2.2 Locations of Proposed Activities**

##### **300 AREA**

Groundwater flow direction and the water table in the unconfined aquifer system beneath the 300 Area are greatly affected by fluctuations in the level of the Columbia River. During low to average river level conditions, groundwater in the unconfined aquifer system converges beneath the 300 Area from the northwest and southwest and flows in a west to east or northwest to southeast direction, with discharge to the river. High river flows cause the water table to rise above the Hanford-Ringold formation contact and groundwater temporarily flows in a generally southwest to south direction. The unconfined aquifer system consists mainly of Hanford Formation gravels and sands, and Ringold Formation gravels and sands with varying amounts of

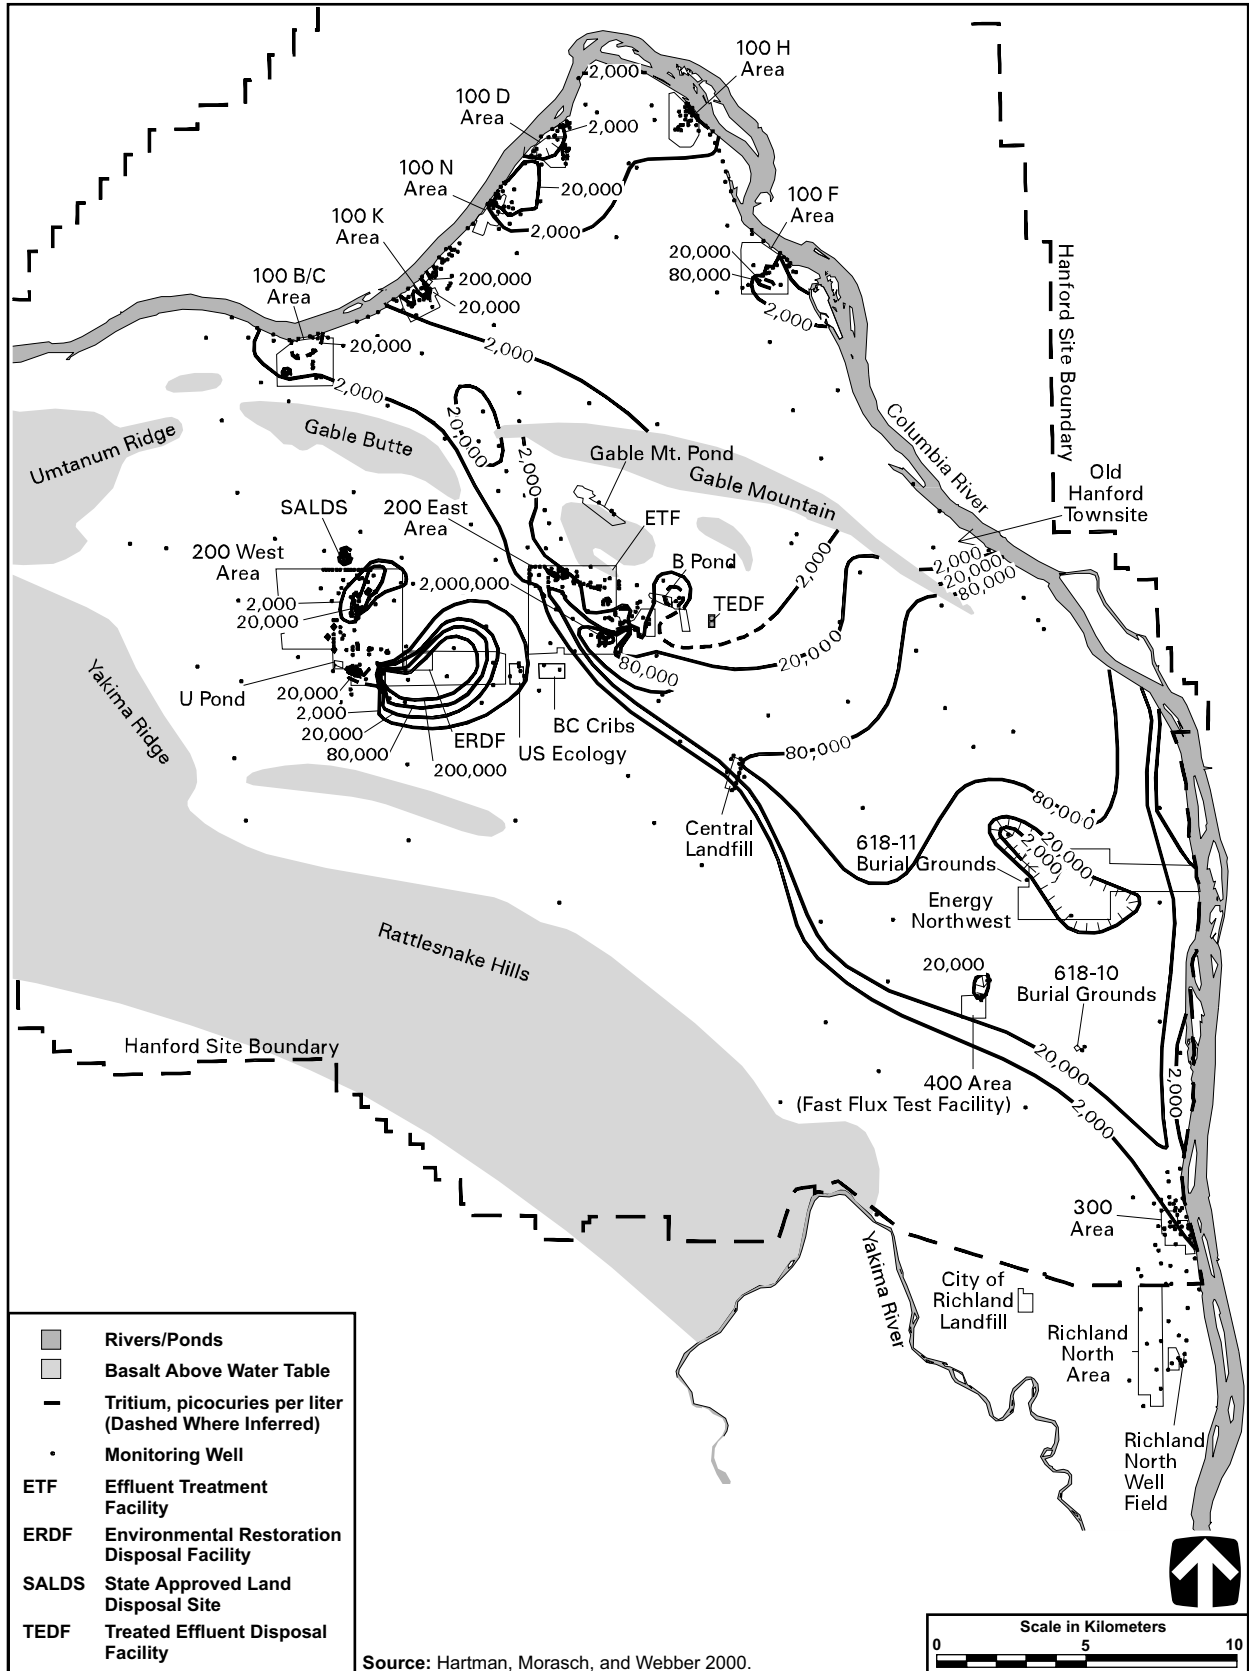

Figure 3-18 Average Tritium Concentrations on the Hanford Site, Top of Unconfined Aquifer

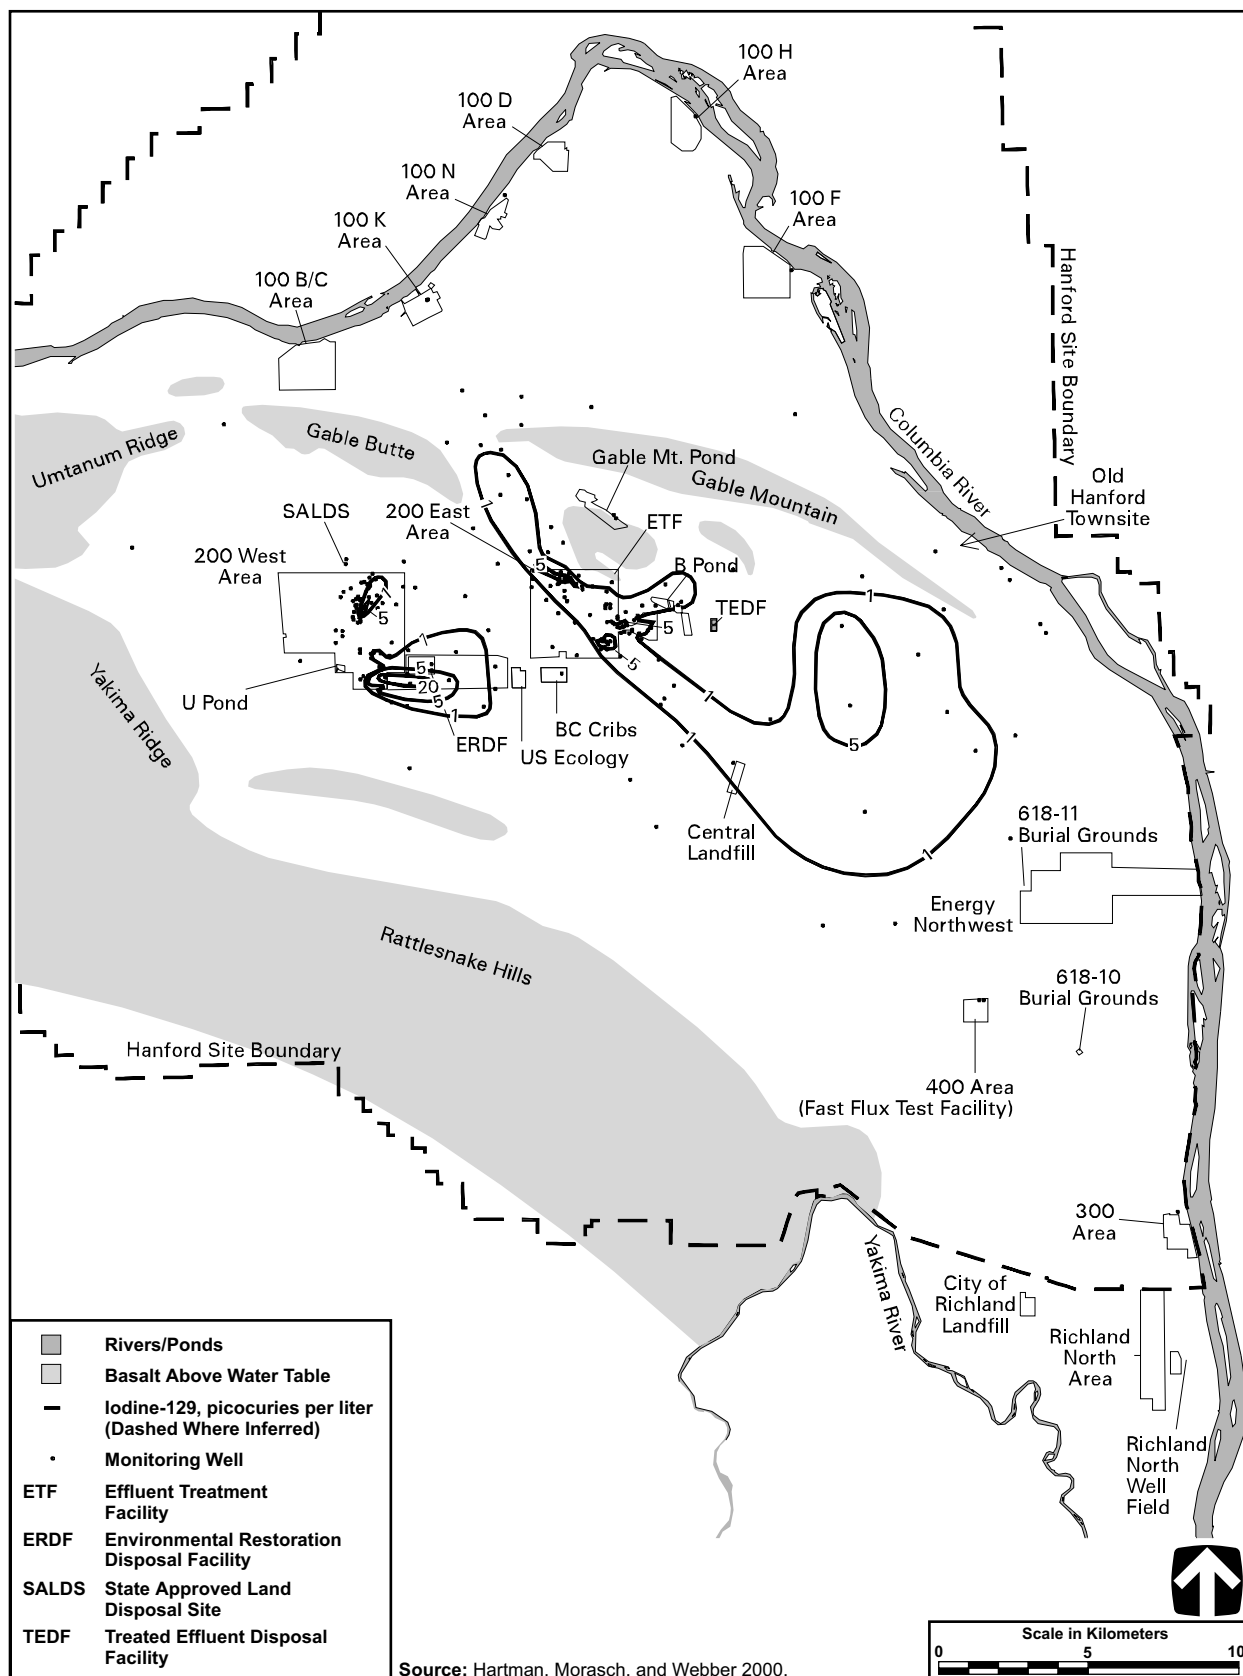

Figure 3-19 Average Iodine-129 Concentrations on the Hanford Site, Top of Unconfined Aquifer

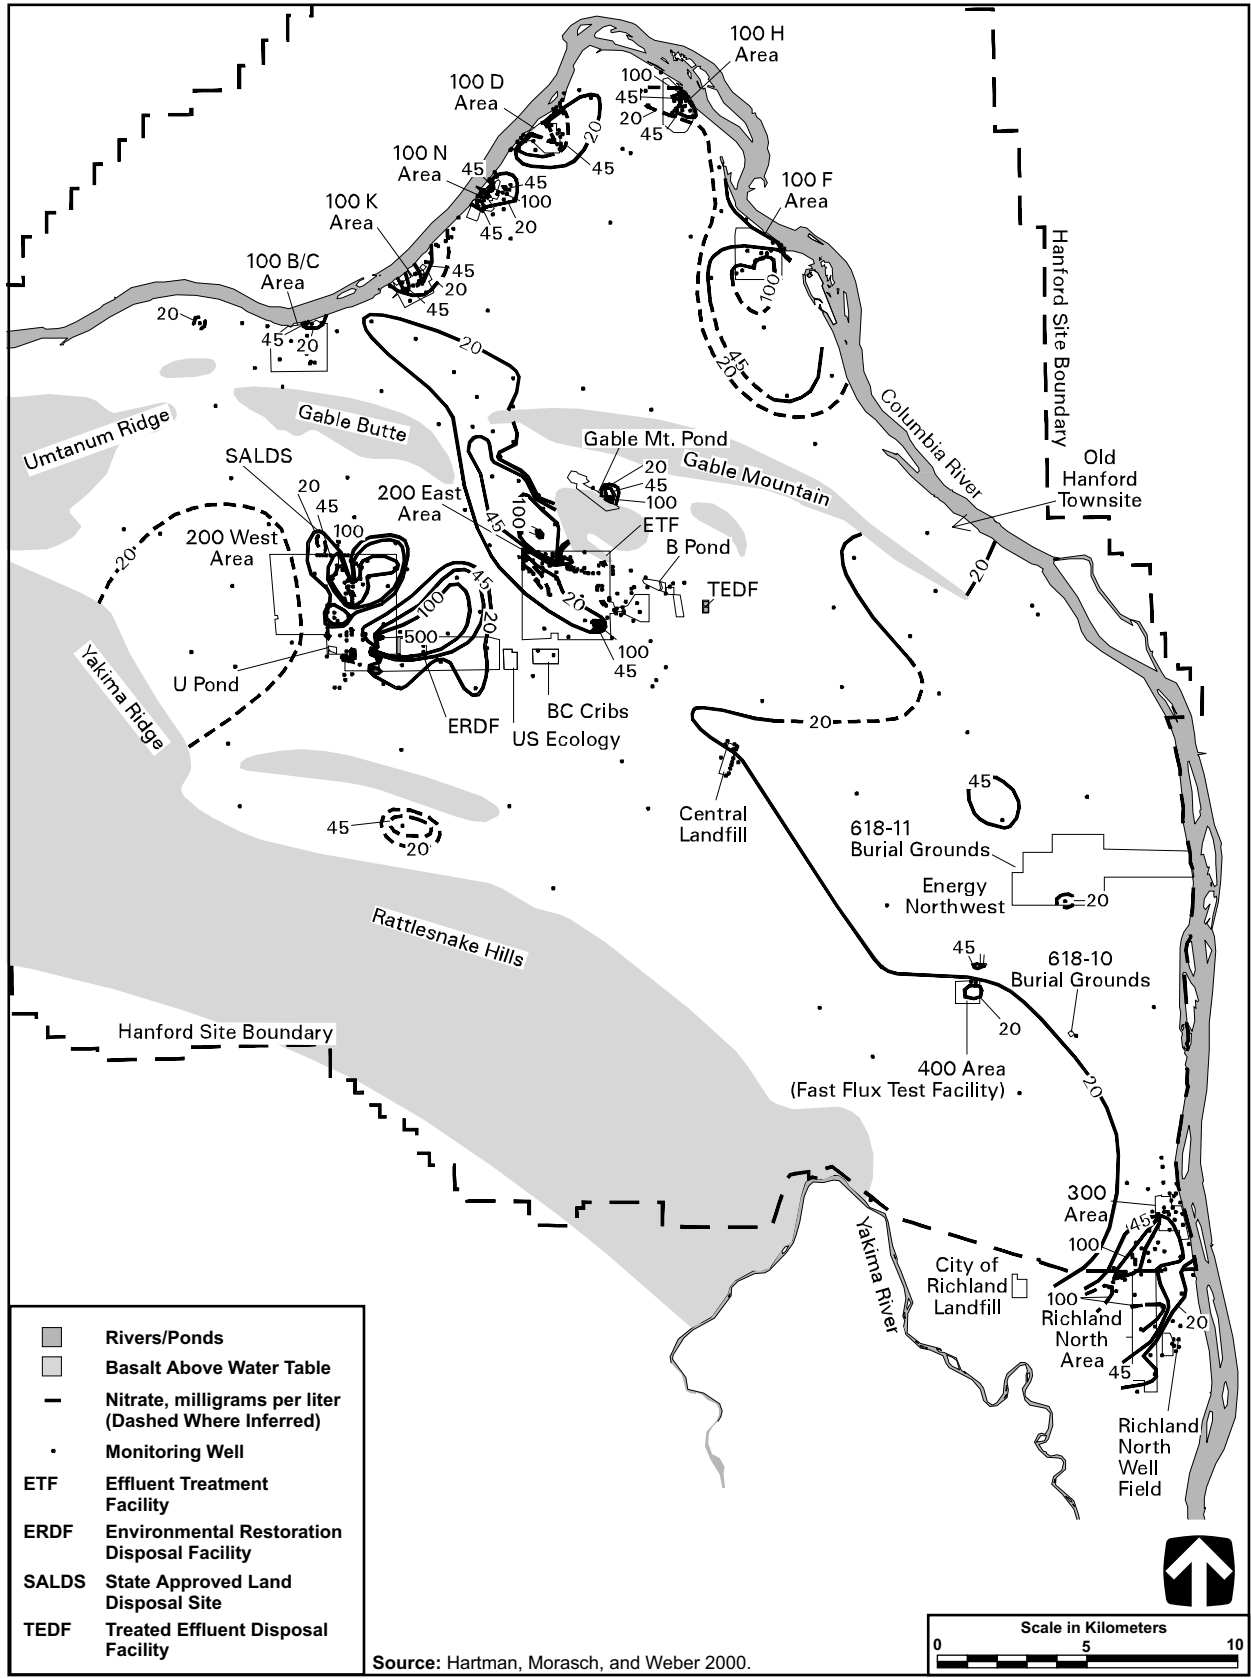

Figure 3-20 Average Nitrate Concentrations on the Hanford Site, Top of Unconfined Aquifer

silt and clay. The water table lies within the Hanford Formation in most of the 300 Area. The depth to the water table beneath the 300 Area ranges from less than 1 meter (3 feet) near the Columbia River to 18 meters (59 feet) further inland (Hartman 2000:4.27, 4.28).

Groundwater quality in the 300 Area has primarily been affected by the uranium fuel fabrication facility and related cooling and sanitary wastewater discharges to the former 316-1 and 316-2 process ponds and subsequently to the 316-5 process trenches (Hartman 2000:4.28, 4.29). Uranium is the major contaminant of concern in the 300 Area with a plume in the upper unconfined aquifer system extending from the northeast and north-central portions of the 300 Area and south and east across the area to the Columbia River. In fiscal year 1999, uranium was detected at levels above the proposed drinking water maximum contaminant level (20 micrograms per liter) over much of the northeastern and eastern parts of the 300 Area, with a high of 322 micrograms per liter detected in one well (Hartman, Morasch, and Webber 2000:2.256, 2.260). Other groundwater contaminants detected at levels above their maximum contaminant levels (5 and 70 micrograms per liter, respectively) in the bottom of the unconfined aquifer system in the 300 Area during 1999 include trichloroethylene and cis-1,2-dichloroethylene in one well, with concentrations of 6 and 180 micrograms per liter, respectively. Tetrachloroethylene was detected above the maximum contaminant level (5 micrograms per liter) in one well in the upper part of the unconfined aquifer east and southeast of the 316-5 process trenches at a concentration of 7 micrograms per liter. Nitrate was above the maximum contaminant level (45 milligrams per liter) in two wells in the southern and southwestern portions of the 300 Area, with a maximum concentration of 110 milligrams per liter. This contaminant has been attributed to offsite industry and agriculture. The southward migrating tritium plume originating in the 200-East Area has also impacted the unconfined aquifer in the 300 Area, but with levels below the interim drinking water standard of 20,000 picocuries per liter (Hartman, Morasch, and Webber 2000:2.255, 2.257, 2.258, 2.265, 2.267, A-78).

#### **400 AREA**

Groundwater flow across the 400 Area is generally from west to east. The Hanford Formation immediately underlying the area consists mainly of the sand-dominated sediments. The water table is located near the contact between the Hanford and Ringold Formations, with the depth to the water table in the 400 Area ranging from about 45 to 50 meters (148 to 164 feet). Hanford Formation sediments dominate groundwater flow in the 400 Area because of their relatively high permeability, compared to that of the Ringold Formation sediments. The Ringold Formation consists of gravelly sands, sandy gravel, silty sands and fluvial gravels and overbank and lacustrine silt and clay. The saturated thickness of this aquifer system is about 140 meters (460 feet) (Hartman 2000:4.25).

The 400 Area receives its water from three supply wells, each with a pumping capacity of 833 liters (220 gallons) per minute (FDH 1999:3-4). One well (499-S1-8J) serves as the primary supply well for all 400 Area needs, including potable, process, and fire protection uses. The second and third wells (499-S0-8 and 499-S0-7) provide backup and emergency supply, respectively. Chlorination is the only water treatment provided to these wells (FDH 1999:4; Dirkes, Hanf, and Poston 1999:4.48, 4.49, 6.8). All of the wells are completed in the unconfined (Hanford/Ringold) aquifer system. The primary production well was installed in 1985 in the lower unconfined aquifer system after tritium contamination was detected in the original two wells, completed near the top of the aquifer (Hartman 2000:4.25). Water usage in the 400 Area ranges from about 284 to 681 liters (75 to 180 gallons) per minute on a seasonal basis. Water is stored in three aboveground storage tanks with a total capacity of about 3 million liters (800,000 gallons) (FDH 1999:4). Average annual groundwater use in the 400 Area is currently about 197 million liters (52 million gallons) (Nielsen 1999:41).

Nitrate is the only significant contaminant attributable to 400 Area operations. Elevated nitrate concentrations in excess of the drinking water maximum contaminant level have been attributed to the former sanitary sewage

lagoon located west and upgradient of the 400 Area process ponds. The maximum concentration in fiscal year 1999 was 92 milligrams per liter; the maximum contaminant level is 45 milligrams per liter. As disposal to the lagoon has been discontinued and the lagoon backfilled, nitrate contamination from this source should diminish with time. Elevated levels of tritium in 400 Area wells continued in 1999 and are associated with the groundwater plume from the vicinity of the Plutonium Uranium Extraction Plant in the 200-East Area. Tritium was found at levels at or above the interim drinking water standard (20,000 picocuries per liter) in samples from the 400 Area backup supply wells (wells 499-S0-7 and 499-S0-8). The maximum in the backup water supply in fiscal year 1999 was 68,400 picocuries per liter (Hartman, Morasch, and Webber 2000:2.8, 2.235, 2.236). All samples collected from the primary supply well (499-S1-8J) were below the drinking water standard for tritium. Tritium activities were also below the drinking water standard, and the 4-millirem-per-year dose equivalent in the drinking water supply (sampled at the tap), for all sampling events in fiscal year 1998. Nitrate levels also remained below the maximum contaminant level in fiscal year 1999 for the water-supply wells. Fiscal year 1999 and past data from 400 Area and surrounding wells indicates no other constituents are present at levels above drinking water maximum contaminant levels (Hartman, Morasch, and Webber 2000:2.236).

One recent finding based on groundwater monitoring for nearby areas is particularly noteworthy with regard to tritium concentrations near the 400 Area. In January 1999, a sample from well 699-13-3A, located along the eastern (downgradient) fence line of the 618-11 burial ground and about 4 kilometers (2.5 miles) southeast of the 400 Area, contained 1.86 million picocuries per liter of tritium. The result was confirmed via reanalysis and represents the first time that tritium has been detected in this well. This value is also much higher than data from the surrounding wells. A January 2000 sample contained 8.1 million picocuries per liter of tritium. This is the highest concentration of tritium detected onsite in recent years. A special investigation of the groundwater at the 618-11 burial ground was to be undertaken in fiscal year 2000 to determine the source of the high tritium results (Hartman, Morasch, and Webber 2000:2.246). The results should be available in time to be published in the fiscal year 2000 groundwater monitoring report.

### **3.4.5 Geology and Soils**

Geologic resources are consolidated or unconsolidated earth materials, including ore and aggregate materials, fossil fuels, and significant landforms. Soil resources are the loose surface materials of the earth in which plants grow, usually consisting of disintegrated rock, organic matter, and soluble salts.

#### **3.4.5.1 General Site Description**

Hanford lies within the Pasco Basin of the Columbia Plateau that is encompassed by the Columbia Intermontane physiographic province (Barghusen and Feit 1995:2.2-12). The rocks beneath Hanford consist of Miocene age (5 to 24 million years old) and younger rocks that overlay older Cenozoic sedimentary and volcanic basement rocks. The major geologic units underlying Hanford are, in ascending order: subbasalt (basement) rocks; the Columbia River Basalt Group; and the Ringold Formation, the Plio-Pleistocene unit, early "Palouse" soil, and the Hanford Formation, collectively known as the Suprabasalt Sediments (Figures 3-16 and 3-17).

The Columbia River Basalt Group consists of sequences of continental flood basalts of Miocene age that cover an extensive area across Washington, Oregon, and Idaho. Nearly all of the flood basalts were erupted in a span dating from approximately 14.5 to 17 million years ago. Volcaniclastic (volcanic-sedimentary) and fluvial (stream deposited) sedimentary materials of the Ellensburg Formation are interbedded within the group. Airfall tuff (consolidated volcanic ash) is the dominant volcaniclastic material at the Hanford Site. The Ringold Formation is exposed in the White Bluffs east of the Columbia River on the site and consists of sedimentary deposits dominated by fluvial gravel and sand deposits along with lake-deposited sand, silt, and

clay. The Plio-Pleistocene unit is locally derived, consisting of alluvium, colluvium, and/or calcium-cemented soil material (caliche). Wind-deposited sand and silt characterizes the early “Palouse” soil. This unit occurs in the western portion of the site. Because it is hard to distinguish from overlying and underlying units, it is generally grouped together with the Plio-Pleistocene unit. Gravel, sand, and silt deposits, comprising the unit informally designated as the Hanford Formation, are the products of cataclysmic floods that inundated the Pasco Basin and the Hanford Site during the Pleistocene between about 13,000 and 1 million years ago. Younger surficial materials also include alluvium deposited by streams and rivers, as well as active sand dune fields (i.e., north of Energy Northwest) (DOE 1999k:4.12–4-22; Hartman 2000:3.1–3.4; Neitzel 1999:4.35–4.44).

Basalt outcrops are exposed on ridges at Gable Mountain, Gable Butte, and the Saddle Mountains in the northern part of Hanford, and on Rattlesnake Hills and Yakima Ridge, overlapping the western and southwestern edges of the site. Other than crushed rock, sand, and gravel, no economically viable geologic resources have been identified at Hanford (DOE 1999e:3-24).

Known faults in the Hanford area include those on Gable Mountain and the Rattlesnake-Wallula alignment. The faults in Central Gable Mountain are considered capable, although there is no observed seismicity on or near Gable Mountain. The Rattlesnake-Wallula alignment is interpreted as possibly being capable because there appear to be active portions of the fault system 56 kilometers (35 miles) southwest of the central part of Hanford (Barghusen and Feit 1995:2.2-13, 2.2-14). A capable fault is one that has had movement at or near the ground surface at least once within the past 35,000 years, or recurrent movement within the past 500,000 years (10 CFR Part 100, Appendix A).

Seismicity of the Columbia Plateau, as determined by the rate of earthquakes per area and the historical magnitude of these events, is lower than that of other regions in the Pacific Northwest. The two largest earthquakes near Hanford occurred in 1918 and 1973; each had an approximate Richter magnitude of 4.4 and a Modified Mercalli Intensity of V (Table 3–3). They occurred in the central portion of the Columbia Plateau north of Hanford, with the December 20, 1973, event epicentered approximately 22 kilometers (14 miles) northwest of the Hanford Site boundary (Neitzel 1999:4.52; USGS 2000c). There have been 45 small earthquakes (ranging in magnitude from 2.5 to 3.9) recorded within a radius of 90 kilometers (56 miles) of the Hanford Site 400 Area since the 1973 earthquake. The closest of these was a magnitude 3.3 event that occurred on June 12, 1995, and had an epicenter about 8 kilometers (5 miles) southeast of the 400 Area (Chapin 2000; USGS 2000c). Based on the most recent seismic analyses, an earthquake with a maximum horizontal acceleration of 0.2g is calculated to have an annual probability of occurrence of 1 in 2,500 at Hanford (Neitzel 1999:4.55). While evidence has been mounting since at least the early 1990s that great earthquakes, with a magnitude of 8 to 9, have occurred in the past in association with the Cascadia Subduction Zone off the coast of the Pacific Northwest, the increased risk is primarily to Western Washington (USGS 1995).

As discussed in more detail in Section 3.2.5.1, USGS has developed new seismic hazard maps as part of the National Seismic Hazard Mapping Project that are based on response spectral acceleration. These maps have been adapted for use in the new *International Building Code* (ICC 2000) (Figures 1615 (1) and 1615(2) in the code) and depict maximum considered earthquake ground motion of 0.2- and 1.0-second spectral response acceleration, respectively, based on a 2 percent probability of exceedance in 50 years. Hanford lies within the 0.40g to 0.50g mapping contours for a 0.2-second spectral response acceleration and the 0.10g to 0.15g contours for a 1.0-second spectral response acceleration.

There is some potential for slope failure at Hanford, although only the slopes of Gable Mountain and White Bluffs are steep enough to warrant landslide concern. White Bluffs, east of the Columbia River, poses the greatest concern. This risk is in part attributable to the largely unconsolidated and uncemented nature of the

Ringold sediments comprising much of the bluffs, the discharge of irrigation water atop the bluffs and subsequent percolation through the sediments, and the general dip of the sediments toward the Columbia River (DOE 1999k:4-18, 4-21; Neitzel 1999:4.43). A large landslide along White Bluffs could fill the Columbia River channel and divert water onto Hanford. Calculations of the potential impacts of such a landslide indicate a flood area similar to the probable maximum flood (Neitzel 1999:4.64, 4.65).

Several major volcanoes are in the Cascade Range west of Hanford, including Mount Adams and Mount St. Helens, located 165 kilometers (102 miles) and 220 kilometers (137 miles) from the site, respectively. Ashfalls from at least three Cascade volcanoes have blanketed the central Columbia Plateau since the late Pleistocene epoch. Generally, ashfall layers have not exceeded more than a few centimeters (less than 1.5 inches) in thickness, with the exception of the Mount Mazama (Crater Lake, Oregon) eruption, when as much as 10 centimeters (3.9 inches) of ash fell over western Washington (Barghusen and Feit 1995:2.2-14).

Fifteen different soil types occur at Hanford. These soils vary from sand to silty and sandy loam. The dominant soil types are the Quincy (Rupert) sand, Burbank loamy sand, Ephrata sandy loam, and the Warden silt loam. No soils at Hanford are currently classified as prime farmlands because there are no current soil surveys, and the only prime farmland soils in the region are irrigated. The Quincy (Rupert) sand is the most widespread soil type at Hanford, but particularly encompasses much of the southeast and east-central portions of the site (south and east of the 200 Areas). It developed from sandy alluvial deposits mantled by wind-blown sand. Burbank loamy sand soils mainly occur north of the 200 Areas and south of the Columbia River along with Ephrata sandy loams. Both soils are underlain by gravelly material. The Warden silt loam occurs in a broad band in the south and southwestern portions of the site, running from the south boundary of the site and downslope of Rattlesnake Mountain (DOE 1999k:4.23–4.27; Neitzel 1999:4.48–4.51). More detailed descriptions of the geology and the soil conditions at Hanford are included in the *Hanford Site NEPA Characterization* (Neitzel 1999) and the *Hanford Comprehensive Land-Use Plan Environmental Impact Statement* (DOE 1999k).

### **3.4.5.2 Locations of Proposed Activities**

#### **300 AREA**

The Central Gable Mountain fault is the nearest capable fault to the 300 Area and is located 28 kilometers (17 miles) away (DOE 1999k:4-19; Mecca 1997a:6, 78, 79). The surficial stratigraphy of the 300 Area is dominated by the gravel and sands of the Hanford Formation that overlie the sediments of the Ringold Formation. Total thickness of these units is approximately 52 meters (171 feet) (Hartman 2000:4.27, 4.28; Neitzel 1999:4.45). The predominant soil type is the Quincy (Rupert) sand, and the soils and surface sediments are not subject to liquefaction or other instabilities (Mecca 1997a:6; Neitzel 1999:4.49).

#### **400 AREA**

The nearest capable fault to the 400 Area (Central Gable Mountain fault) is 19 kilometers (12 miles) away (Mecca 1997a:6, 78, 79). 400 Area stratigraphy consists of sand-dominated sediments of the Hanford Formation which attain a thickness of about 50 meters (164 feet) beneath the site. Locally, surface sediments also consist of stabilized sands deposited in dune fields (Hartman 2000:4.25; Neitzel 1999:4.44). The predominant soil type in the 400 Area is the Quincy (Rupert) sand, and the soils and surface sediments are not subject to liquefaction or other instabilities (Mecca 1997a:6; Neitzel 1999:4.49).

### 3.4.6 Ecological Resources

Ecological resources include terrestrial resources, wetlands, aquatic resources, and threatened and endangered species. Material presented in this section, unless otherwise noted, is from the *Storage and Disposition PEIS* (DOE 1996b:3-83-3-87).

#### 3.4.6.1 Terrestrial Resources

This section addresses the plant and animal communities of Hanford and includes a plant community map of the site. Terrestrial resources are described for the site as a whole, as well as for the proposed facility locations.

##### 3.4.6.1.1 General Site Description

Vegetation at Hanford has been characterized as shrub-steppe. Shrub-steppe ecosystems are typically dominated by a shrub overstory with a grass understory. Present site development consists of clusters of large buildings that are found at widely spaced locations. Developed areas encompass about 6 percent of the site. The remaining areas of the site can be divided into 10 major plant communities (**Figure 3-21**). Hanford is dominated by plant communities in which big sagebrush is a major component. Other plant communities contain a variety of grasses and herbaceous plants. Areas previously disturbed by agricultural activities are dominated by nonnative species, such as cheatgrass. Trees are uncommon on the site, but those that are present include cottonwood and willow, which are both found near water bodies, and a few other deciduous species which were originally planted near farmsteads as windbreaks. Five hundred ninety species of plants have been identified at Hanford (Neitzel 1999).

Unique habitats on the Hanford Site include bluffs, dunes, and islands within the Columbia River. The White Bluffs, Umtanum Ridge, and Gable Mountain include rock outcrops that occur infrequently on the site. Vegetation on basalt outcrops includes snow buckwheat and Sandberg's bluegrass. The terrain of the dune habitat rises and falls between 3 and 5 meters (10 and 16 feet). The dune are vegetated by bitterbrush, dune scurfpea, and thickspike wheatgrass. Riparian vegetation that characterizes the islands of the Columbia River includes willow, white mulberry, snow buckwheat, lupine, yarrow, and thickspike wheatgrass among others (Neitzel 1999).

Hanford provides suitable habitat for numerous animal species, including over 1,500 species of insects, 4 species of amphibians, 9 species of reptiles, 246 species of birds, and 40 species of mammals. Grasshoppers and darkling beetles are among the more conspicuous groups of insects, and along with other insects, are an important food source for local birds and mammals (Neitzel 1999:4.87). Common animal species at Hanford include the side-blotched lizard, gopher snake, western meadowlark, horned lark, Great Basin pocket mouse, black-tailed jackrabbit, and mule deer. Trees planted around former farmsteads serve as nesting platforms for several species of birds, including hawks, owls, ravens, magpies, and great blue herons; these trees also serve as night roosts for bald eagles. The Hanford Reach of the Columbia River, including several sparsely vegetated islands, provides nesting habitat for the Canada goose, ring-billed gull, Forster's tern, and great blue heron. Several game animals are found at Hanford. Hunting is permitted on site north of the Columbia River. Numerous raptors, such as the Swainson's hawk and red-tailed hawk, and carnivores, such as the coyote and bobcat, are found on Hanford. A variety of migratory birds have been found at Hanford.

Unique habitats on the Hanford Site provide habitat for a number of species of wildlife. Bluff areas provide nesting habitat for prairie falcons, red-tailed hawks, and several species of swallows and roosting habitat for bald eagles. Mule deer, burrowing owls, and coyotes, as well as many transient species, may be found in dune habitat. Islands in the Columbia River provide nesting habitat for Canada geese, California gulls, ring-billed gulls and Forster's tern (Neitzel 1999).

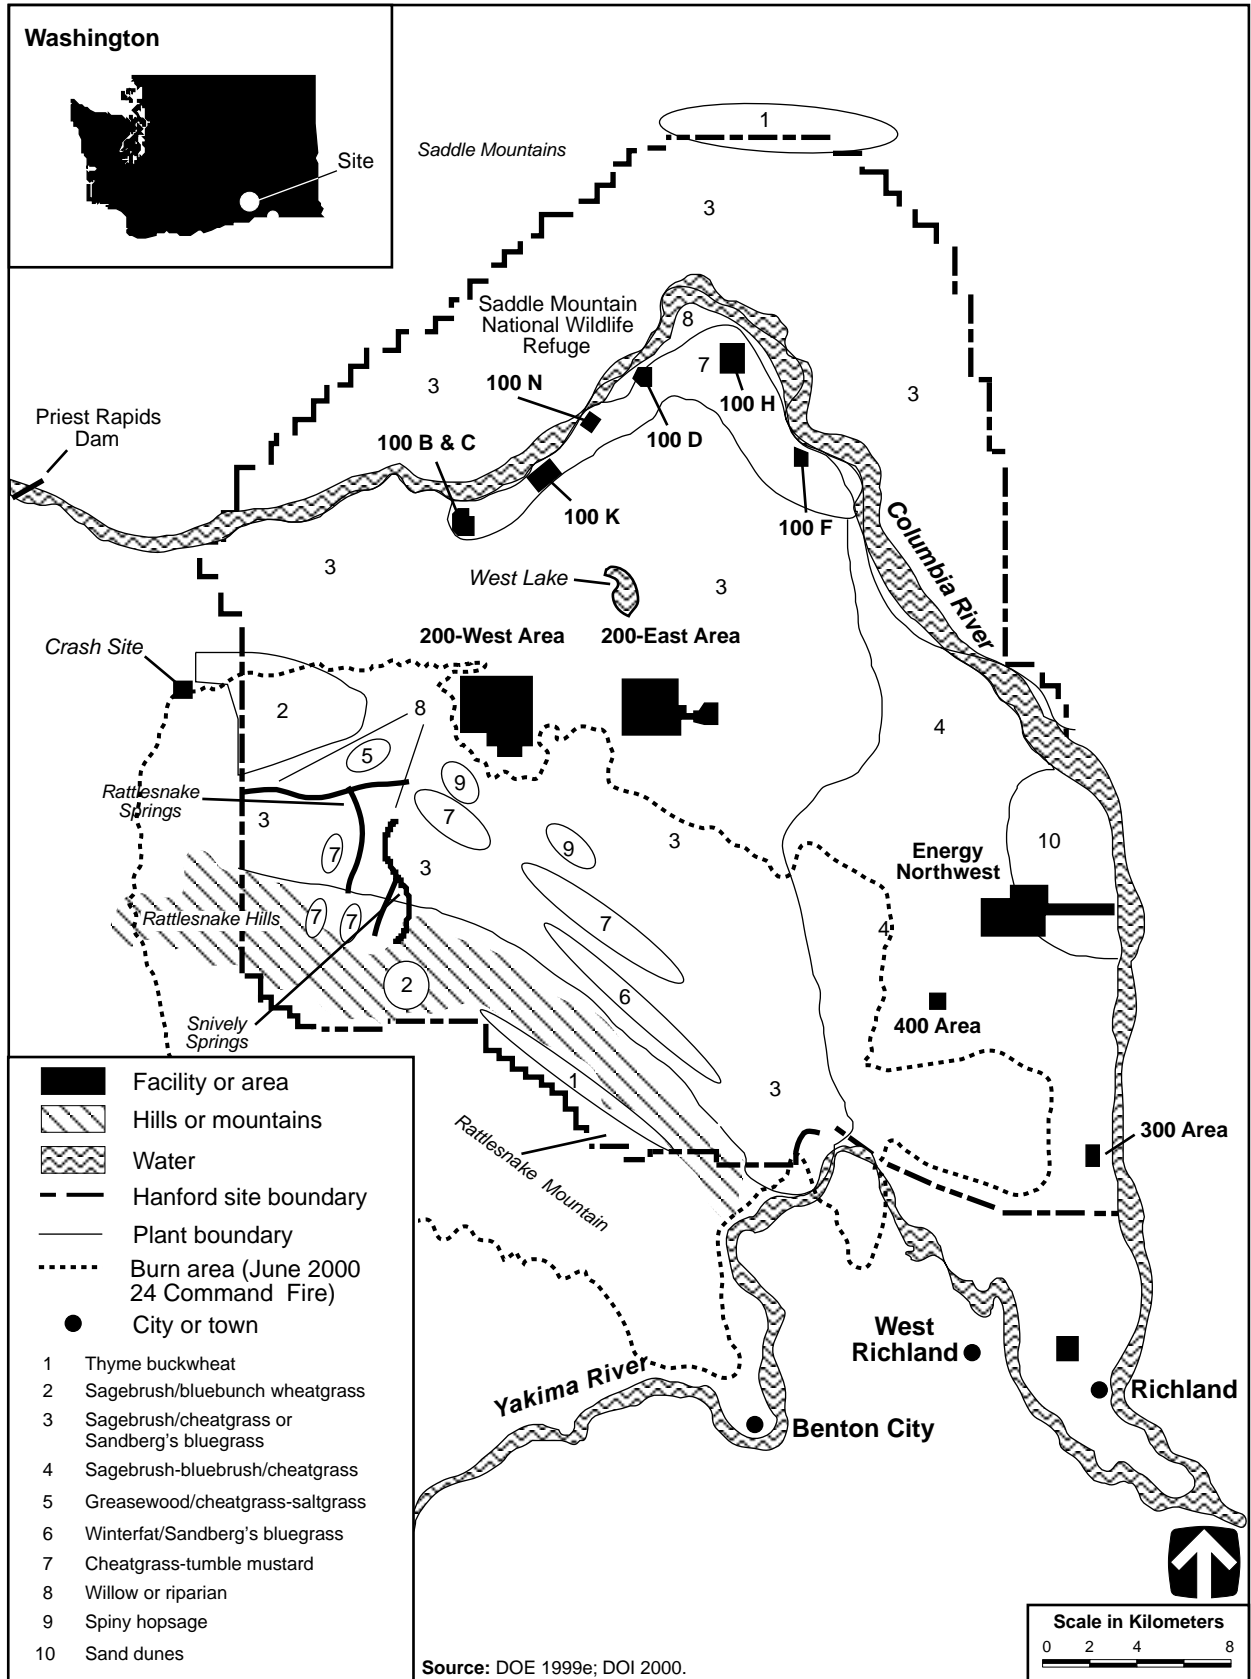

Figure 3-21 Distribution of Plant Communities at the Hanford Site

On June 27, 2000, a fire known as the 24 Command Fire was started by a fatal motor vehicle accident on State Route 24, about 2 miles west of the State Route 240 intersection. As a result of high winds and temperatures and low humidity, the fire spread rapidly and eventually consumed 66,322 hectares (163,884 acres) of Federal, state, and private lands. A total of 24,384 hectares (60,254 acres) within Hanford burned, including lands within the Hanford Reach National Monument, most of the Arid Lands Ecology Reserve, and areas near former production sites (Figures 3–12 and 3–21). The fire was declared controlled on July 2, 2000 (DOI 2000).

The USFWS has prepared a *Burned Area Emergency Rehabilitation Plan* in which resource issues and impacts were assessed and recommendations outlined (DOI 2000). Due to the extremely dry conditions and high winds, vegetation resources were significantly reduced on about 85 percent of the fire area. However, because of the relatively fast passage of the fire over any one area, soils showed little damage and seed bank sources in the soil were not adversely impacted. While this will aid natural vegetation, recovery of some plant associations (e.g., sagebrush) may require planting and could take years. Plant associations extensively affected by the fire include those containing big sagebrush, bluebunch wheatgrass, and three-tipped sage. Some riparian vegetation was also impacted. Fire suppression tactics, including construction of firebreaks and backfire operations, also adversely affected plant communities. Potential long-term impacts from the fire include the establishment of noxious weeds and changes in natural plant communities.

The 24 Command Fire had immediate direct impacts on wildlife, including loss of individual animals, especially smaller less mobile species and young of the year, as well as displacement of more mobile animals to unaffected areas. However, displacement itself can lead to an increase in mortality due to road kills, and in the case of elk, this has already occurred. Additionally, long-term impacts to wildlife due to loss of food, cover, and breeding habitat are expected as a result of the fire (DOI 2000).

#### **3.4.6.1.2 Locations of Proposed Activities**

##### **300 AREA**

While the 300 Area is located within the big sagebrush/bunchgrasses–cheatgrass vegetation community, it is heavily developed (DOE 1999k). Vegetation within the 300 Area is characteristic of disturbed areas consisting of sparse amounts of cheatgrass and Russian thistle (Nielsen 2000). Due to the disturbed nature of most of the 300 Area, wildlife use of developed portions of the areas is limited.

##### **400 AREA**

The 400 Area is located within postfire shrub-steppe habitat dominated by cheatgrass and small shrubs, including gray and green rabbitbrush. Due to past disturbances and human occupancy in the 400 Area, wildlife is limited. Several animal species may be found in the area, including the gopher snake, northern Pacific rattlesnake, burrowing owl, Swainson's hawk, western meadowlark, black-tailed jackrabbit, and Great Basin pocket mouse (DOE 1999e:3-35).

#### **3.4.6.2 Wetlands**

Wetlands include “those areas that are inundated or saturated by surface or groundwater at a frequency and duration sufficient to support, and that under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions” (33 CFR Section 328.3). Wetlands are described for Hanford as a whole, as well as for the proposed facility locations.

### **3.4.6.2.1 General Site Description**

Primary wetland areas at Hanford are found in the riparian zone along the Columbia River. The extent of this zone varies, but includes large stands of willows, grasses, and other plants. This area has been extensively affected by hydropower operations at Priest Rapids Dam (Neitzel 1999).

Other large areas of wetlands at Hanford can be found north of the Columbia River within the Saddle Mountain National Wildlife Refuge and the Wahluke Wildlife Unit Columbia Basin Area. These two areas encompass all the lands extending from the north bank of the Columbia River northward to the site boundary and east of the Columbia River down to Ringold Springs. Wetland habitat in these areas consists of fairly large ponds resulting from irrigation runoff. These ponds have extensive stands of cattails and other emergent aquatic vegetation surrounding the open water regions. They are extensively used as nesting sites by waterfowl (Neitzel 1999).

On the western side of Hanford, Rattlesnake Springs supports a riparian zone of 3.0 kilometers (1.9 miles) in length, featuring watercress, bulrush, spike rush, cattail and peachleaf willow. Snively Springs also contains a diverse biotic community similar to Rattlesnake Springs (Neitzel 1999). The 24 Command Fire affected approximately 18 hectares (44 acres) of willow riparian habitat, including areas around Rattlesnake Spring, Snively Canyon, Benson Springs, and the Yakima River (DOI 2000). Several semi-permanent artificial ponds and ditches that receive cooling water or irrigation wastewater are also present on Hanford. These waterbodies provide a source of water for terrestrial animals (Neitzel 1999).

### **3.4.6.2.2 Locations of Proposed Activities**

#### **300 AREA**

The 300 Area is bounded on the eastern side by the Columbia River. The riparian zone bordering the river is the only wetland area associated with the site (Nielsen 2000). The general nature of this zone is discussed in Section 3.4.6.2.1.

#### **400 AREA**

There are no natural wetlands in the 400 Area, although a small cooling and wastewater pond does contain some wetland vegetation. Wildlife species observed using the site include a variety of mammals and waterfowl (DOE 1999e:3-36).

### **3.4.6.3 Aquatic Resources**

Aquatic resources at Hanford are described for the site as a whole, as well as for the proposed facility locations.

#### **3.4.6.3.1 General Site Description**

Aquatic resources on Hanford include the Columbia River, ephemeral streams, springs, surface ponds, and ditches. The Columbia River flows along the northern and eastern edges of the site. The Hanford Reach supports 44 anadromous and resident species of fish. Many of the fish species present in the Hanford Reach are dependent upon flowing water and rocky substrate for at least part of their life cycles. Fall chinook salmon, steelhead trout, mountain whitefish, and smallmouth bass spawn in this area. The destruction of other mainstream Columbia River spawning areas by dams has increased the relative importance of the Hanford Reach for spawning (Neitzel 1999).

The Hanford Reach provides a migration route to upstream spawning areas for spring, summer, and fall adult chinook salmon, coho salmon, sockeye salmon, and steelhead trout. It also provides rearing habitat for the salmonid juveniles in their downstream migration to the sea. Principal resident fish species sought by anglers in the Hanford Reach include mountain whitefish, white sturgeon, smallmouth bass, crappie, catfish, walleye, and yellow perch (Neitzel 1999).

The Yakima River borders the southern portion of Hanford. Game fish found in the river in the vicinity of the site are smallmouth bass, steelhead trout, and channel catfish. Cold Creek and its tributary, Dry Creek, are ephemeral streams within the Yakima River drainage system along the southern boundary of Hanford. These streams do not support any fish populations.

There are several springs at Hanford. Rattlesnake Springs and Snively Springs, which are in the western portion of the site, form short streams that seep into the ground. None of the springs support any fish populations.

### **3.4.6.3.2 Locations of Proposed Activities**

#### **300 AREA**

The 300 Area is immediately to the west of the Columbia River. There are no aquatic resources on the site itself (Nielsen 2000).

#### **400 AREA**

Although no natural aquatic habitat occurs in the 400 Area, a small cooling and wastewater pond is present (DOE 1999e:3-36). The 400 Area is 6.8 kilometers (4.2 miles) west of the Columbia River.

### **3.4.6.4 Threatened and Endangered Species**

Endangered species are those plants and animals in danger of extinction throughout all or a large portion of their range. Threatened species are those species likely to become endangered within the foreseeable future. Threatened and endangered species are described for Hanford as a whole, as well as for the proposed facility locations.

#### **3.4.6.4.1 General Site Description**

Eighty-one Federal- and state-listed threatened, endangered, and other special status species may be found on Hanford. These are listed in Tables 4–6 and 4–7 of the *Hanford Comprehensive Land-Use Plan Environmental Impact Statement* (DOE 1999k). Nineteen of these are Federal- or state-listed as threatened or endangered, while the remainder are listed by the state within one of several special status classifications.

The threatened bald eagle, which has been proposed to be delisted, is the only federally listed species known to be found regularly at Hanford, although there are occasional sightings of the threatened Aleutian Canada goose. The bald eagle, which is also listed by the state as endangered, is a regular winter resident along the Hanford Reach where it forages for salmon and waterfowl. Trees in the historic Hanford Townsite area are used by eagles for perching. Recently, eagles have attempted to nest on the site. The peregrine falcon, listed as endangered by the state, is a migrant in the Hanford area (Dirkes and Hanf 1997:F.1; DOE 1996b:3-44; Neitzel 1999). The Upper Columbia River run of steelhead and Upper Columbia River spring run of Chinook salmon are listed as endangered and the Middle Columbia River run of steelhead are listed as threatened by the Federal government. Spring-run chinook salmon do not spawn in the Hanford Reach but use it as a

migration corridor. Little is known about the quality and quantity of steelhead spawning, rearing, and adult holding habitat in the Hanford Reach and Upper Columbia River (DOE 1999k). Recently, the Hanford Reach has been designated as critical habitat for Upper Columbia River spring-run chinook salmon and Upper Columbia River steelhead (65 FR 7764). Consultation to comply with Section 7 of the Endangered Species Act was conducted with the U.S. Fish and Wildlife Service and National Marine Fisheries Service. Consultation was also conducted with the state. The results of these consultations are presented in Chapter 4.

The 24 Command Fire burned 24,384 hectares (60,254 acres) of Hanford resulting in potential impacts to a number of threatened, endangered, or other special status species. A total of 9 plant and 12 animal special status species could potentially be found in the burn area (DOI 2000). A post-fire survey determined that suitable habitat for the threatened Ute ladies'-tresses, the only federally listed plant species, did not exist in the burn area. The fire could have directly or indirectly affected seven state-listed plants. Direct effects could include loss of plants and seed stock. Indirect effects could include adverse impacts such as competition from invasive plant species, potential loss of soil productivity due to wind erosion, and loss of seed viability. Indirect effects could also be of a beneficial nature and include release of nutrients back into the soil and reduction in competition for soil nutrients, sun, and soil moisture. With respect to wildlife, the 24 Command Fire was determined to have had no effect on any federally listed species. Potential direct impacts to state-listed species include direct loss of adults and young, while indirect effects include loss of habitat used for feeding, cover, and raising young. Monitoring special status species will be necessary to determine the exact nature and extent to which plants and animals were impacted by the fire.

#### **3.4.6.4.2 Locations of Proposed Activities**

##### **300 AREA**

A survey of the 300 Area made in conjunction with an environmental assessment of RPL did not locate any Federal- or state-listed threatened or endangered plant or animal species within the site (DOE 1997d). However, more recently, the peregrine falcon and bald eagle have been observed in the area (Nielsen 2000).

##### **400 AREA**

No Federal- or state-listed threatened or endangered plants or animals reside in the vicinity of the 400 Area (DOE 1999e), although potential exists for the incidental occurrence of some migratory species, such as the peregrine falcon. State sensitive plant species have not been found in the 400 Area, although Piper's daisy does occur in the vicinity. A fire also burned the area in the mid 1980s, leaving it dominated by cheatgrass and some small shrubs (Mecca 1997b; Schinner 1999).

#### **3.4.7 Cultural and Paleontological Resources**

Cultural resources are human imprints on the landscape and are defined and protected by a series of Federal laws, regulations, and guidelines. The three general categories of cultural resources addressed in this section are prehistoric, historic, and Native American. Paleontological resources are the physical remains, impressions, or traces of plants or animals from a former geological age, and may be sources of information on paleoenvironments and the evolutionary development of plants and animals.

Hanford has a well-documented record of cultural and paleontological resources. The *Hanford Cultural Resources Management Plan* (Battelle 1989), establishes guidance for identifying, evaluating, recording, curating, and managing these resources. There are approximately 930 cultural resource sites and isolated finds recorded (Neitzel 1999:4.104). Forty-eight archaeological sites and one building are included on the National Register of Historic Places. Nominations have been prepared for several archaeological districts and sites

considered to be eligible for listing on the National Register. While many significant cultural resources have been identified, only about 6 percent of the Hanford Site has been surveyed, and few of the known sites have been evaluated for their eligibility for listing on the National Register. Cultural resource reviews are conducted whenever projects are proposed in previously unsurveyed areas. In recent years, reviews have exceeded 500 per year.

Cultural sites are often occupied continuously or intermittently over substantial time spans. For this reason, a single location may contain evidence of use during both historic and prehistoric periods. In the discussions that follow, the numbers of prehistoric and historic resources are presented. The sum of these resources may be greater than the total number of sites reported due to this dual-use history at sites. Therefore, where the total number of sites reported is less than the sum of prehistoric and historic sites, certain locations were used during both periods.

The 24 Command Fire burned 24,384 hectares (60,254 acres) of Hanford, resulting in potential impacts to cultural resources. A preliminary assessment of possible effects to cultural resources determined that a minimum of 190 previously recorded historic and prehistoric archaeological sites may have been affected (DOI 2000). These sites range from lithic scatters to can scatters, Indian hunting sites to ranch buildings, and spirit quest monuments to gas production wells. The preliminary assessment found that wooden structures (e.g., a corral) were destroyed, but that other surface and subsurface artifacts such as glass and lithic debris were not severely altered by the fire. Post-fire surface visibility has been greatly enhanced, which presents opportunities for archaeologists and historians to refine the boundaries of known sites and locate new sites, but also increases the potential for looting and vandalism.

### **3.4.7.1 Prehistoric Resources**

Prehistoric resources are physical properties that remain from human activities that predate written records.

#### **3.4.7.1.1 General Site Description**

About 365 prehistoric archaeological sites and isolated finds have been recorded on Hanford. Of 48 sites included on the National Register of Historic Places, two are individual sites (Hanford Island Site and Paris Site), and the remainder are located in seven archaeological districts. In addition, four other archaeological districts have been nominated or are planned to be nominated for the National Register. A number of sites have been identified along the Middle Columbia River and in inland areas away from the river, but near other water sources. Some evidence of human occupation has been found in the arid lowlands. Sites include remains of numerous pithouse villages, various types of open campsites, graves along the riverbanks, spirit quest monuments (rock cairns), hunting camps, game drive complexes, quarries in mountains and rocky bluffs, hunting and kill sites in lowland stabilized dunes, and small temporary camps near perennial sources of water away from the river (Neitzel 1999).

More than 10,000 years of prehistoric human activity in the largely arid environment of the Middle Columbia River region have left extensive archaeological deposits. Archaeological surveys have been conducted at Hanford since 1926; however, little excavation has been conducted at any of the sites. Surveys have included studies of Gable Mountain, Gable Butte, Snively Canyon, Rattlesnake Mountain, Rattlesnake Springs, and a portion of the Basalt Waste Isolation Project Reference Repository location. Most of the surveys have focused on islands and on a 400-meter (1,312-foot) wide area on either side of the river. From 1991 through 1993, the 100 Areas were surveyed, and new sites were identified. Excavations have been conducted at several sites on the riverbanks and islands and at two unnamed sites. Test excavations have been conducted at the Wahluke, Vernita Bridge, and Tsulim sites and at other sites in Benton County (Neitzel 1999).

### 3.4.7.1.2 Locations of Proposed Activities

#### 300 AREA

Much of the 300 Area has been highly disturbed by industrial activities and is unlikely to contain intact prehistoric sites (Neitzel 1999). The *Hanford Cultural Resources Management Plan* (Battelle 1989) provides for survey work before construction, and has contingency guidelines for handling the discovery of previously unknown archaeological resources encountered during construction.

#### 400 AREA

Most of the 400 Area has been highly disturbed and is unlikely to contain intact prehistoric sites. A cultural resources survey found only 12 hectares (30 acres) that were undisturbed, and no sites were identified either within the 400 Area or within 2 kilometers (1.2 miles) of the 400 Area. The *Hanford Cultural Resources Management Plan* (Battelle 1989) provides for survey work before construction, and has contingency guidelines for handling the discovery of previously unknown archaeological resources encountered during construction.

### 3.4.7.2 Historic Resources

Historic resources consist of physical properties that postdate the existence of written records. In the United States, historic resources are generally considered to be those that date no earlier than 1492.

#### 3.4.7.2.1 General Site Description

Five hundred seventeen historic archaeological sites associated with the pre-Hanford Site and the Cold War eras, including an assortment of farmstead, corrals, dumps, and military sites, have been recorded since 1977 (Neitzel 1999). Of these sites, one is included on the National Register of Historic Places as a historic site, and 56 are listed as archaeological sites. Sites and localities that predate the Hanford era include homesteads, ranches, trash scatters, dumps, gold mine tailings, roads, and townsites, including the Hanford townsite and the East White Bluffs townsite and ferry landing. More recent historic structures include the defense reactors and associated materials-processing facilities that played an important role in the Manhattan Project and the Cold War era. A Programmatic Agreement for the maintenance, deactivation, alteration, and demolition of the built environment on Hanford has been reached between DOE, the Advisory Council on Historic Preservation, and the Washington State Historic Preservation Office (DOE 1996d).

Lewis and Clark were some of the first European Americans to visit the Hanford region during their 1804 to 1806 expedition. They were followed by fur trappers, military units, and miners. It was not until the 1860s that merchants set up stores, a freight depot, and the White Bluffs Ferry on the Hanford Reach, and Chinese gold miners began to work the gravel bars. Cattle ranches opened in the 1880s, and farmers soon followed. Several small thriving towns, including Hanford, White Bluffs, and Ringold, grew up along the riverbanks in the early 20th century. Other ferries were established at Wahluke and Richland. These towns, and nearly all other structures, were razed after the U.S. Government acquired the land for the original Hanford Engineer Works in the early 1940s (part of the Manhattan Project). Plutonium produced at the 100 B-Reactor was used in the first nuclear explosion at the White Sands Missile Range in New Mexico, and later in the bomb that destroyed Nagasaki, Japan, to help end World War II. The Hanford 100 B-Reactor is listed on the National Register and is designated a National Mechanical Engineering Landmark, a National Historic Civil Engineering Landmark, and a National Nuclear Engineering Landmark. Consultation to comply with Section 106 of the National Historic Preservation Act was conducted with the State Historic Preservation Office. The results of this consultation are presented in Chapter 4.

### **3.4.7.2.2 Locations of Proposed Activities**

#### **300 AREA**

The 300 Area has been highly disturbed by industrial activities. Five recorded archaeological sites, including campsites, housepits, and historic trash scatter, are located at least partially within the 300 Area; many more may be located in subsurface deposits. Twenty-seven archaeological sites and 13 isolated artifacts have been recorded within 2 kilometers (1.2 miles) of the site. The historic archaeological sites contain debris scatters and roadbeds associated with farmsteads. One site has been tested and is recognized as eligible for listing on the National Register of Historic Places. One hundred fifty-eight buildings or structures in the 300 Area have been inventoried and of that number, 47 have been determined eligible for the National Register as contributing properties within the Historic District recommended for mitigation, including RPL/306-E (DOE 1996d; Neitzel 1999).

#### **400 AREA**

Most of the 400 Area has been so disrupted by construction activities, that a 1978 archaeological survey found only 12 hectares (30 acres) that were undisturbed. No cultural resources were located in those 12 hectares (30 acres). No archaeological sites are known to be located within 2 kilometers (1.2 miles) of the 400 Area.

All of the building and structures in the 400 Area were constructed during the Cold War era. Six buildings/structures have been determined eligible for the National Register of Historic Places as contributing properties within the Historic District recommended for mitigation. These include the 405 Reactor Containment Building, 436 Training Facility, 4621-W Auxiliary Equipment Facility, 4703 Fast Flux Test Facility Control Building, 4710 Operation Support Building, and the 4790 Patrol Headquarters (DOE 1996d).

### **3.4.7.3 Native American Resources**

Native American resources are sites, areas, and materials important to Native Americans for religious or heritage reasons. In addition, cultural values are placed on natural resources such as plants, which have multiple purposes within various Native American groups. Of primary concern are concepts of sacred space that create the potential for land use conflicts.

#### **3.4.7.3.1 General Site Description**

In prehistoric and early historic times, Native Americans of various tribal affiliations heavily populated the Hanford Reach. The Wanapum and the Chamnapum lived along the Columbia River at what is now Hanford. Some of their descendants still live nearby at Priest Rapids, northwest of Hanford. Palus People, who lived on the lower Snake River, joined the Wanapum and Chamnapum to fish the Hanford Reach, and some inhabited the east bank of the river. Walla Walla and Umatilla People also make periodic visits to fish in the area. These people retain traditional secular and religious ties to the region, and many have knowledge of the ceremonies and lifeways of their culture. The Washani, or Seven Drums religion, which has ancient roots and originated among the Wanapum, is still practiced by many people on the Yakama, Umatilla, Warm Springs, and Nez Perce Reservations. Native plant and animal foods, some of which can be found at Hanford, are used in the ceremonies performed by tribal members.

Consultation is required, and was conducted, to identify the traditional cultural properties that are important in maintaining the cultural heritage of Native American tribes. The results of this consultation are presented in Chapter 4. Under separate treaties signed in 1855, the Confederated Tribes and Bands of the Yakama Nation and the Confederated Tribes of the Umatilla Indian Reservation ceded lands to the United States that

include the present Hanford Site. Under the treaties, the tribes reserved the right to fish at usual and accustomed places in common with the citizens of the territory, and retained the privilege of hunting, gathering roots and berries, and pasturing horses and cattle upon open, unclaimed land. The Treaty of 1855 with the Nez Perce Tribe includes similar reservations of rights, and the Nez Perce have identified the Hanford Reach as the location of usual and accustomed places for fishing. The Wanapum People are not signatory to any treaty with the United States and are not a federally recognized tribe; however, they live about 8 kilometers (5 miles) west of the Hanford boundary, they were historical residents of Hanford, and their interests in the area have been acknowledged.

All of these tribes are active participants in decisions regarding Hanford and have expressed concerns about hunting, fishing, pasture rights, and access to plant and animal communities and important sites. Sites sacred to Native Americans at Hanford include remains of prehistoric villages, burial grounds, ceremonial longhouses or lodges, rock art, fishing stations, and vision quest sites. Culturally important localities and geographic features include Rattlesnake Mountain, Gable Mountain, Gable Butte, Goose Egg Hill, Coyote Rapids, and the White Bluffs portion of the Columbia River.

#### **3.4.7.3.2 Locations of Proposed Activities**

##### **300 AREA**

One documented locality with great importance to the historic Wanapum is near the 300 Area. Certain areas near the 300 Area have been found to be of great importance to Native Americans and are fenced (Neitzel 1999).

##### **400 AREA**

The 400 Area is not known to contain any Native American resources.

#### **3.4.7.4 Paleontological Resources**

Paleontological resources are the physical remains, impressions, or traces of plants or animals from a former geological age.

##### **3.4.7.4.1 General Site Description**

Remains from the Pliocene and Pleistocene Ages have been identified at Hanford. The Upper Ringold Formation dates to the Late Pliocene Age and contains fish, reptile, amphibian, and mammal fossil remains. Late Pleistocene Touchet beds have yielded mammoth bones. These beds are composed of fluvial sediments deposited along ridge slopes that surround Hanford.

##### **3.4.7.4.2 Locations of Proposed Activities**

##### **300 AREA**

Paleontological resources are limited in the vicinity of the 300 Area, and no such resources have been located within the site itself (Nielsen 2000).

## 400 AREA

No paleontological resources have been reported in the 400 Area. Late Pleistocene Touchet beds, which have yielded mammoth bones, are located at distances greater than 5 kilometers (3.1 miles) from the 400 Area.

### 3.4.8 Socioeconomics

Statistics for employment and regional economy are presented for the regional economic area, as defined in Appendix G.8, which encompasses nine counties surrounding Hanford in Washington. Statistics for population, housing, community services, and local transportation are presented for the region of influence, a two-county area in which 91 percent of all Hanford employees reside (**Table 3–30**). In 1997, Hanford employed 12,882 persons, 3.8 percent of the regional economic area civilian labor force (DOE 1999e).

**Table 3–30 Distribution of Employees by Place of Residence in the Hanford Region of Influence, 1997**

County	Number of Employees	Total Site Employment (percent)
Benton	10,563	82.0
Franklin	1,159	9.0
Region of influence total	11,722	91.0

Source: DOE 1999e.

#### 3.4.8.1 Regional Economic Characteristics

Between 1990 and 1996, the civilian labor force in the regional economic area increased 34.6 percent, to the 1996 level of 342,941. In 1996, the annual unemployment average in the regional economic area was 11.1 percent, significantly higher than the annual unemployment average of 6.5 percent in Washington State (DOE 1999e).

In 1995, service activities represented the largest sector of employment in the regional economic area (22.3 percent). This was followed by agriculture (19.6 percent) and government (17.4 percent). Overall, the state total for these employment sectors was 25.0 percent, 3.7 percent, and 18.0 percent, respectively (DOE 1999e).

#### 3.4.8.2 Population and Housing

In 1996, the region of influence population totaled 179,949. Between 1990 and 1996, the region of influence population increased 18.9 percent, compared with the 12.9 percent increase experienced in Washington. Between 1980 and 1990, the number of housing units in the region of influence increased by 4.6 percent, compared with a 20.3 percent increase in Washington. The 1990 homeowner vacancy rates for the region of influence was 1.4 percent, compared with the state's rate of 1.3 percent. The region of influence renter vacancy rate was 5.5 percent, compared with 5.8 percent for the state (DOE 1999e).

#### 3.4.8.3 Community Services

##### 3.4.8.3.1 Education

In 1997, ten school districts providing public education in the Hanford region of influence were operating at capacities ranging from 65 to 100 percent. Total student enrollment in the region of influence in 1997 was 38,206 and the student-to-teacher ratio in the region of influence averaged 16:1. In 1990, the average student-to-teacher ratio for Washington was 11.4:1 (DOE 1999e).

### **3.4.8.3.2 Public Safety**

In 1997, a total of 281 sworn police officers were serving the region of influence. The region of influence average officer-to-population ratio was 1.6 officers per 1,000 persons. This compares with the 1990 state average of 1.7 police officers per 1,000 persons. In 1997, 616 paid and volunteer firefighters provided fire protection services in the Hanford region of influence. The average firefighter-to-population ratio in 1997 in the region of influence was 3.4 firefighters per 1,000 persons. This compares with the 1990 state average of 1 firefighter per 1,000 persons (DOE 1999e).

### **3.4.8.3.3 Health Care**

In 1996, a total of 257 physicians served the region of influence. The average physician-to-population ratio in the region of influence was 1.4 physicians per 1,000 persons compared with the 1996 state average of 3.7 per 1,000 persons. In 1997, there were four hospitals serving the region of influence. The hospital bed-to-population ratio averaged 2.1 beds per 1,000 persons. This compares with a state 1991 average of 2.4 beds per 1,000 persons (DOE 1999e).

### **3.4.8.4 Local Transportation**

Vehicle access to Hanford is provided by State Routes 240, 243, and 24. State Route 240 connects to the Richland bypass highway, which interconnects with I-182. State Route 243 exits the site's northwestern boundary and serves as a primary link between the site and I-90. State Route 24 enters the site from the west and continues eastward across the northernmost portion of the site and intersects State Route 26 about 16 kilometers (10 miles) east of the site boundary (Figure 3-12) (DOE 1999e). Only routine preservation projects are planned by the Washington State Department of Transportation for the state routes listed above and are not considered to impact access into the site (Trepanier 2000).

The local intercity transit system, Ben Franklin Transit, supplies bus service between the Tri-Cities and Hanford, although bus service is provided only to the 300 Area and Energy Northwest. Both private interests and Ben Franklin Transit provide van pooling opportunities in the region of influence.

There is presently no rail service at Hanford, except for a spur to Energy Northwest. Onsite rail transport was formerly provided by a short-line railroad that connected with the Union Pacific line just south of the Yakima River. The Union Pacific line interchanges with the Burlington Northern-Santa Fe at the city of Kennewick. The Hanford railroad is still intact and service could be restored if needed.

In the region of influence, the Columbia River is used as an inland waterway for barge transportation from the Pacific Ocean. The Port of Benton provides a barge slip where shipments arriving at Hanford may be off-loaded.

Tri-Cities Airport, near the city of Pasco, provides jet air passenger and cargo service by both national and local carriers. Numerous smaller private airports are located throughout the region of influence (DOE 1999e).

### **3.4.9 Existing Human Health Risk**

Existing human health risk issues include the determination of potentially adverse effects on human health that result from acute and chronic exposures to ionizing radiation and hazardous chemicals.

### 3.4.9.1 Radiation Exposure and Risk

#### 3.4.9.1.1 General Site Description

Major sources and levels of background radiation exposure to individuals in the vicinity of Hanford are shown in **Table 3–31**. Annual background radiation doses to individuals are expected to remain constant over time.

**Table 3–31 Sources of Radiation Exposure to Individuals in the Hanford Vicinity  
Unrelated to Hanford Operations**

Source	Effective Dose Equivalent (millirem per year)
<b>Natural background radiation<sup>a</sup></b>	
Cosmic radiation	30
External terrestrial radiation	30
Internal radiation	40
Radon in homes (inhaled)	200
<b>Other background radiation<sup>b</sup></b>	
Diagnostic x-rays and nuclear medicine	53
Weapons test fallout	Less than 1
Air travel	1
Consumer and industrial products	10
<b>Total</b>	<b>365</b>

a. Dirkes, Hanf, and Poston 1999.

b. NCRP 1987:11, 40, 53.

**Note:** Value of radon is an average for the United States.

The total dose to the population, in terms of person-rem, changes as the population size changes. Background radiation doses, as identified in Table 3–31, are unrelated to Hanford operations.

Releases of radionuclides to the environment from Hanford operations provide another source of radiation exposure to individuals in the vicinity of Hanford. Types and quantities of radionuclides released from Hanford operations in 1998 are listed in the *Hanford Site Environmental Report for Calendar Year 1998* (Dirkes, Hanf, and Poston 1999:5.5–5.10). Doses to the public resulting from these releases are presented in **Table 3–32**. These doses fall within radiological limits per DOE Order 5400.5 and are much lower than those of background radiation.

Using a risk estimator of 500 cancer deaths per 1 million person-rem to the public (Appendix H), the risk of a latent cancer fatality to the maximally exposed member of the public due to radiological releases from Hanford operations in 1998 is estimated to be  $1.1 \times 10^{-8}$ . That is, the estimated probability of this person dying of cancer at some point in the future from radiation exposure associated with 1 year of Hanford operations is approximately 1 in 100 million. It takes several to many years from the time of radiation exposure for a cancer to manifest itself.

According to the same risk estimator,  $1 \times 10^{-4}$  excess latent cancer fatality are projected in the population of 370,000 living within 80 kilometers (50 miles) of Hanford from normal operations in 1998. To place this number in perspective, it may be compared with the number of cancer fatalities expected in the same population from all causes. The 1997 mortality rate associated with cancer for the entire U.S. population was 0.2 percent per year. Based on this mortality rate, the number of cancer fatalities expected during 1998 from all causes in the population living within 80 kilometers (50 miles) of Hanford was 740. This expected number of cancer fatalities (which excludes any radiation dose contribution from Hanford) is much higher than the  $1 \times 10^{-4}$  latent cancer fatality estimated from Hanford operations in 1998.

**Table 3–32 Radiation Doses to the Public from Hanford Normal Operations in 1998  
(Total Effective Dose Equivalent)**

Members of the Public	Atmospheric Releases <sup>a</sup>		Liquid Releases		Total	
	Standard <sup>b</sup>	Actual	Standard <sup>b</sup>	Actual	Standard <sup>b</sup>	Actual
Maximally exposed individual (millirem)	10	0.015	4	0.0077 <sup>c</sup>	100	0.022
Population within 80 kilometers (person-rem) <sup>d</sup>	None	0.084	None	0.11	100	0.19
Average individual within 80 kilometers (millirem) <sup>e</sup>	None	3.4×10 <sup>-4</sup>	None	2.9×10 <sup>-4</sup>	None	5.0×10 <sup>-4</sup>

- a. Includes direct radiation dose from surface deposits of radioactive material.
- b. The standards for individuals are given in DOE Order 5400.5. As discussed in that order, the 10-millirem-per-year limit from airborne emissions is required by the Clean Air Act, and the 4-millirem-per-year limit is required by the Safe Drinking Water Act; for this NI PEIS, the 4-millirem-per-year value is conservatively assumed to be the limit for the sum of doses from all liquid pathways. The total dose of 100-millirem-per-year is the limit from all pathways combined. The 100-person-rem value for the population is given in proposed 10 CFR Part 834, as published in 58 FR 16268. If the potential total dose exceeds the 100-person-rem value, it is required that the contractor operating the facility notify DOE.
- c. Includes the drinking water dose.
- d. Based on a population of about 380,000 in 1998.
- e. Obtained by dividing the population dose by the number of people living within 80 kilometers (50 miles) of the site.
- Source:** Dirkes, Hanf, and Poston 1999:5.9, 5.10.

Hanford workers receive the same dose as the general public from background radiation, but they also receive an additional dose from working in facilities with nuclear materials. The average dose to the individual worker and the cumulative dose to all workers at Hanford from operations in 1998 are presented in **Table 3–33**. These doses fall within the radiological regulatory limits of 10 CFR Part 835. According to a risk estimator of 400 cancer fatalities per 1 million person-rem among workers<sup>1</sup> (Appendix H), the number of projected latent cancer fatalities among Hanford workers from normal operations in 1998 is 0.072.

**Table 3–33 Radiation Doses to Workers from Hanford Normal Operations in 1998  
(Total Effective Dose Equivalent)**

Occupational Personnel	Onsite Releases and Direct Radiation	
	Standard <sup>a</sup>	Actual
Average radiation worker (millirem)	None <sup>b</sup>	102
Total workers <sup>c</sup> (person-rem)	None	181

- a. The radiological limit for an individual worker is 5,000 millirem per year. However, DOE's goal is to maintain radiological exposure as low as is reasonably achievable. It has therefore established the Administrative Control Level of 2,000 millirem per year; the site must make reasonable attempts to maintain individual worker doses below this level.
- b. No standard is specified for an "average radiation worker"; however, the maximum dose that this worker may receive is limited to that given in footnote "a."
- c. 1,772 with measurable doses in 1998.
- Source:** 10 CFR Section 835.202; DOE 1999p.

A more detailed presentation of the radiation environment, including background exposures and radiological releases and doses, is presented in the *Hanford Site Environmental Report for Calendar Year 1998* (Dirkes, Hanf, and Poston 1999). The concentrations of radioactivity in various environmental media (including air, water, and soil) in the site region (on and off site) are also presented in that report.

<sup>1</sup> The risk estimator for workers is lower than the estimator for the public because of the absence from the workforce of the more radiosensitive infant and child age groups.

### 3.4.9.1.2 Locations of Proposed Activities

#### 300 AREA

External radiation doses have been measured in the 300 Area. In 1998, the annual dose in the 300 Area was about 83 millirem. This is about 5 to 12 millirem higher than the value measured at the off site control locations. This onsite dose affects workers only, and is well below limits identified in Table 3–33. No measurements of plutonium concentrations in air were reported for the 300 Area (Dirkes, Hanf, and Poston 1999:4.84, 4.85).

#### 400 AREA

External radiation doses have been measured in the 400 Area. In 1998, the annual dose in the 400 Area was about 83 millirem. This is about 5 to 12 millirem higher than the value measured at the offsite control locations. This onsite dose affects workers only, and is well below limits identified in Table 3–33. No measurements of plutonium concentrations in air were reported for the 400 Area (Dirkes, Hanf, and Poston 1999:4.84, 4.85).

### 3.4.9.2 Chemical Environment

The background chemical environment important to human health consists of the atmosphere which may contain hazardous chemicals that can be inhaled; drinking water, which may contain hazardous chemicals that can be ingested; and other environmental media through which people may come in contact with hazardous chemicals (e.g., surface water during swimming, soil through direct contact, or food). Hazardous chemicals can cause cancer and noncancer health effects.

**Carcinogenic Effects.** Health effects in this case are estimated as the incremental probability of an individual developing cancer over a lifetime as a result of exposure to the potential carcinogenic. This could be incremental or excess individual lifetime cancer risk.

**Noncarcinogenic Effects.** Health effects in this case are determined by the ratio between the calculated or measured concentration of the chemical in the air and the reference concentration or dose. This ratio is known as the Hazard Quotient. Hazard Quotients for noncarcinogens are summed to obtain the Hazard Index. If the Hazard Index is less than 1, no adverse health effects would be expected.

Effective administrative and design controls that decrease hazardous chemical releases to the environment and help achieve compliance with permit requirements (e.g., air emissions and NPDES permit requirements) contribute to minimizing health impacts on the public. The effectiveness of these controls is verified through the use of monitoring information and inspection of mitigation measures. Health impacts on the public may occur by inhaling air containing hazardous chemicals released to the atmosphere during normal Hanford operations. Risks to public health from other possible pathways, such as ingestion of contaminated drinking water or direct exposure, are lower than those via the inhalation pathway.

Baseline air emission concentrations and applicable standards for hazardous chemicals are addressed in Section 3.4.3. The baseline concentrations are estimates of the highest existing offsite concentrations and represent the highest concentrations to which members of the public could be exposed. These concentrations are in compliance with applicable guidelines and regulations.

Exposure pathways to Hanford workers during normal operations may include inhaling contaminants in the workplace atmosphere and direct contact with hazardous materials. The potential for health impacts varies

among facilities and workers, and available information is insufficient for a meaningful estimate of impacts. However, workers are protected from workplace hazards through appropriate training, protective equipment, monitoring, substitution, and engineering and management controls. They are also protected by adherence to OSHA and EPA standards that limit workplace atmospheric and drinking water concentrations of potentially hazardous chemicals. Appropriate monitoring that reflects the frequency and amounts of chemicals used in the operational processes ensures that these standards are not exceeded. Additionally, DOE requires that conditions in the workplace be as free as possible from recognized hazards that cause, or are likely to cause, illness or physical harm.

### **3.4.9.3 Health Effects Studies**

The question of whether or not the population surrounding Hanford is subject to elevated rates of cancer incidence or cancer mortality is unresolved. Existing studies and data suggest that cancer mortality rates among populations residing near Hanford are not elevated. A survey sponsored by the National Cancer Institute and published in the *Journal of the American Medical Association* in 1991 (Jablon, Hrubec, and Boice 1991:1403–1408) detected no general increase in the risk of cancer death for people living in 107 counties adjacent to or containing 62 nuclear facilities. Hanford, INEEL, and ORR were included in the survey. The study used cancer mortality data from Benton, Franklin, and Grant counties in the survey for Hanford. The methodology used in the survey did not attempt to estimate actual exposures to ionizing radiation or hazardous chemicals and did not allow identification of areas within a given county that might have increased or decreased cancer rates relative to the country as a whole. The authors of the study concluded that if any excess cancer mortality risk were present in U.S. counties with nuclear facilities, it was too small to be detected with the methods employed.

Sixteen counties are within 80 kilometers (50 miles) of the Hanford boundary—13 counties in Washington and 3 in Oregon. Prevailing winds at Hanford blow toward Grant County, Washington, from the south (14 percent of the time) and south-southwest (11.5 percent of the time). Therefore, Grant County would be expected to bear the major burden of wind-borne contamination from Hanford. Cancer mortality data published by the National Cancer Institute ([www.nci.nih.gov/atlas](http://www.nci.nih.gov/atlas)) for white female and white male residents for all U.S. counties from 1970 to 1994 show no elevated cancer rates for white residents of Grant County. Cancer mortality rates among white females in the 16 counties ranged from a low of 80.1 per 100,000 person-years in Gilliam County, Oregon, to a high of 149.5 per 100,000 person-years in Lincoln County, Washington. Adams, Klickitat, and Lincoln counties were found to have cancer mortality rates among white females above the National cancer mortality rate for white females of 135.9 per 100,000 person-years. The remaining 13 counties have cancer mortality rate for white females below the National cancer mortality rate for white females. Cancer mortality rates among white males in the 16 counties range from a low of 161.9 per 100,000 person-years in Gilliam County, Oregon, to a high of 211.8 per 100,000 person-years in Morrow County, Oregon. Morrow County was found to have a cancer mortality rate among white males above the National cancer mortality rate for white males of 209.5 per 100,000 person-years. The remaining 15 counties were found to have cancer mortality rates below the National cancer mortality rate for white males. The data does not include estimates of human exposures to ionizing radiation or hazardous chemicals.

Two studies of birth defects in Benton and Franklin counties were published in 1988 (Sever et al. 1988a:226–241; 1988b:243–254). The studies focused on congenital malformations among infants born from 1968 to 1980. The studies showed a statistically significant association between parental preconception exposure to ionizing radiation and neural tube defects in their infants. Other defects in the infant studies showed no statistically significant association with parental radiation exposure.

Many epidemiological studies have been carried out on the Hanford workers over the years. The studies have consistently shown a statistically significant elevated risk of death from multiple myeloma associated with

radiation exposure among Hanford male workers. The elevated risk was observed only among workers exposed to 10 rads (approximately 10 rem) or more. Other studies have also identified an elevated risk of death from pancreatic cancers, but a recent reanalysis did not conclude there was an elevated risk. Studies of female Hanford workers have shown an elevated risk of deaths from musculoskeletal system and connective tissue conditions. For a more detailed description of the studies reviewed and their findings, and for a discussion of the epidemiologic surveillance program implemented by DOE to monitor the health of current workers, refer to Appendix M.4.2 of the *Storage and Disposition PEIS* (DOE 1996b:M-224–M-230).

#### 3.4.9.4 Accident History

DOE maintains a safe and healthy workplace in accordance with DOE P 450.4, *Safety Management Systems Policy*; DOE Order 420.1, *Facility Safety*; DOE Order 151.1A, *Comprehensive Emergency Management System*; 29 CFR 1910.119, *Process Safety Management of Highly Hazardous Chemicals*; 29 CFR 1910.120, *Hazardous Waste Operations and Emergency Response*; and the Washington Administrative Code 267-247. There are three tiers of safety organizations at Hanford: the DOE Operations Office, Fluor Hanford, and project-specific organizations. Each safety organization is responsible for protection of the public, workers, and the environment. Information concerning safety-related events at Hanford and other sites is available from the DOE occurrence reporting system on the Internet at [tis.eh.doe.gov/oeaf/orps.html](http://tis.eh.doe.gov/oeaf/orps.html).

Hanford implements corrective actions for all safety-related incidents. For example, although unrelated to candidate facilities discussed in this NI PEIS, a chemical explosion occurred at the Hanford Plutonium Reclamation Plant in a room where nonradioactive bulk chemicals were mixed for the now-discontinued plutonium recovery process. The direct cause of the accident was the concentration by evaporation of the dilute solution in a tank to the point where a spontaneous reaction occurred, creating a rapid gas evolution that over-pressurized the tank beyond its physical design limitations. No one was injured and no radioactive materials were released to the environment (DOE 1997h). Eight workers outside the plant at the time of the explosion complained of symptoms that included headaches, dizziness, and an unidentified metallic taste. All eight workers were transferred to a nearby medical center where they were examined and released. The explosion caused significant localized damage to the facility. Corrective actions focused on improving shutdown planning to maintain the facility in a safe condition, consistent with the approved safety authorization documentation, and improving emergency preparedness and response. As discussed in Section 3.4.9.5, lessons learned from this event were implemented across the DOE complex to improve emergency preparedness and response.

There have been no nuclear-related accidents or accidental releases of hazardous or radioactive materials causing injury or harm to workers, or posing any threat to the offsite public at FFTF or at the candidate Hanford support facilities evaluated in this NI PEIS. Examples of the most severe safety incidents that have occurred at these facilities are discussed below. In all cases, corrective actions were completed to address the cause of each event, and there were no long-term programmatic consequences:

- A loss of contamination control event occurred in February 1990 at a maintenance facility adjacent to FFTF during a filter replacement on the bottom-loading transfer cask (an FFTF fuel-handling machine) resulting in contamination spread to the adjacent area within the facility. The contamination was successfully cleaned up and the facility was restored to normal access and work control. Corrective actions to prevent similar occurrences included (1) training program changes and additional training of plant personnel on job controls and planning for these types of hazards, (2) strengthened requirements for pre-job briefings and Person-in-Charge responsibilities, and (3) more detailed requirements for the various types of radiological control areas.

- A sodium pump developed a leak in 1984. As a result of the leak, 75 gallons of sodium spilled in a closed room filled with inert gas. It was determined that the hole was created by two conditions: tube wall thinning due to cavitation and rapid heatup during a previous meltout. Enhanced leak detection was installed on all normally inaccessible pumps, and a visual inspection was conducted on the remaining pumps. Procedural flow restrictions were placed on the pumps to preclude any additional cavitation conditions, and changes were made to the meltout procedures to reduce the allowable heatup rate. The sodium was removed and the pump was replaced with a spare.
- Two unplanned tritium releases occurred at RPL in 1998 because of equipment failure or operator error. These releases were within the levels specified by the facility's air operating permit and did not result in the exposure of site personnel or members of the public in excess of regulatory standards. Corrective actions included the redesign of a sampling system to permit more effective leak testing, and implementation of administrative controls to eliminate operator error.

#### **3.4.9.5 Emergency Preparedness**

Each DOE site has established an emergency management program that would be activated in the event of an accident. This program has been developed and maintained to ensure adequate response to most accident conditions and to provide response efforts for accidents not specifically considered. The emergency management program includes emergency planning, preparedness, and response.

Accordingly, the DOE Richland Operations Office has developed and maintains a comprehensive set of emergency preparedness plans and procedures for Hanford to support onsite and offsite emergency management actions in the event of an accident. The DOE Richland Operations Office also provides technical assistance to other Federal agencies and to state and local governments. Hanford contractors are responsible for ensuring that emergency plans and procedures are prepared and maintained for all facilities, operations, and activities under their jurisdiction, and for directing implementation of those plans and procedures during emergency conditions. The DOE Richland Operations Office, contractor, and state and local government plans are fully coordinated and integrated. Emergency control centers have been established by the DOE Richland Operations Office and its contractors for the principal work areas to provide oversight and support to emergency response actions within those areas.

Following the May 1997 explosion at Hanford discussed in Section 3.4.9.4, a review of the emergency management response indicated that multiple programs and systems failed in the hours following the accident. In a letter to Secretarial Offices, Secretary of Energy Federico Peña identified actions to be taken at all DOE sites for implementing lessons learned from the emergency response. The actions involve the following elements:

- Improve training for facility and site emergency personnel
- Ensure that equipment and qualified personnel are ready for the wide variety of potential radiological and chemical hazards
- Improve coordination with local medical communities
- Have in place comprehensive procedures to attend to personnel who are potentially affected by an accident

#### **3.4.10 Environmental Justice**

Under Executive Order 12898, *Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations*, Federal agencies are responsible for identifying and addressing the possibility of disproportionately high and adverse health, economic, and environmental impacts of programs and activities

on minority and low-income populations in potentially affected areas. Minority populations refer to persons of any race self-designated as Asian, Black, Native American, or Hispanic. Low-income populations refer to households with incomes below the Federal poverty thresholds. In the case of Hanford, the potentially affected area includes parts of Washington and Oregon.

The potentially affected area surrounding the 400 Area is defined by a circle with an 80-kilometer (50-mile) radius centered at FMEF (latitude 46° 26'7" N, longitude 119° 21'55" W). The total population residing within that area in 1990 was 277,515; minorities made up 25.4 percent of the total population (DOE 1999e). In 1990, approximately one-fourth of the total national population was comprised of persons self-designated as members of a minority group, and minorities made up 13.2 percent of Washington State's total population and 9.2 percent of Oregon's total population.

According to the 1990 census, the racial and ethnic composition of the minority population in the potentially affected area around FMEF are as follows: Hispanics were the largest minority group, constituting 21.5 percent of the total population; Asians comprised 1.4 percent of the total population, Native Americans 1.4 percent, and Blacks 1.0 percent (DOE 1999e).

In 1990, the poverty threshold was \$9,981 for a family of three with one related child under 18 years of age. A total of 45,820 persons, 17.3 percent of the total population, residing within the potentially affected area around the 400 Area reported incomes below the poverty threshold. Data obtained during the 1990 census also show that of the total population of the contiguous United States, 13.1 percent reported incomes below the poverty threshold, corresponding percentages for Washington and Oregon were 10.9 and 12.4 percent, respectively.

### **3.4.11 Waste Management**

Waste management includes minimization, characterization, treatment, storage, transportation, and disposal of waste generated from ongoing DOE activities. The waste is managed using appropriate treatment, storage, and disposal technologies and in compliance with all applicable Federal and state statutes and DOE orders.

#### **3.4.11.1 Waste Inventories and Activities**

Hanford manages the following types of waste: high-level, transuranic, mixed transuranic, low-level radioactive, mixed low-level radioactive, hazardous, and nonhazardous. Waste generation rates and the inventory of stored waste from activities at Hanford are provided in **Table 3-34**. Waste generation rates specifically for FFTF in standby and RPL/306-E activities are provided in **Table 3-35**. The Hanford waste management capabilities are summarized in **Table 3-36**. More detailed descriptions of the waste management system capabilities at Hanford are included in the *Storage and Disposition PEIS* (DOE 1996b:3-61, E-12).

EPA placed Hanford on the National Priorities List on November 3, 1989. In accordance with CERCLA, DOE entered into a Tri-Party Agreement with EPA and the Washington State Department of Ecology to govern the environmental compliance and cleanup of Hanford. This agreement meets the legal requirements specified under the Federal Facility Compliance Act. An aggressive environmental restoration program is under way using priorities established in the Tri-Party Agreement (DOE 1996b:3-61). More information on regulatory requirements for waste disposal is provided in Chapter 5.

**Table 3–34 Waste Generation Rates and Inventories at Hanford**

Waste Type	Generation Rate (cubic meters per year)	Inventory (cubic meters)
<b>High-level radioactive</b>	0	213,000
<b>Transuranic and mixed transuranic</b>		
Contact handled	450	11,450
Remotely handled	72	273
<b>Low-level radioactive</b>	3,902 <sup>a</sup>	0
<b>Mixed low-level radioactive</b>		
RCRA	840	8,170
TSCA	7	103
<b>Hazardous</b>	560	NA <sup>b</sup>
<b>Nonhazardous</b>		
Liquid	200,000	NA <sup>b</sup>
Solid	43,000	NA <sup>b</sup>

a. Excludes waste from DOE environmental restoration activities.

b. Generally, hazardous and nonhazardous wastes are not held in long-term storage.

**Note:** To convert from cubic meters to cubic yards, multiply by 1.308.

**Key:** NA, not applicable; RCRA, Resource Conservation and Recovery Act; TSCA, Toxic Substances Control Act.

**Source:** LMER 1996e:15, 16, except high-level radioactive waste (DOE 1997a), hazardous and nonhazardous solid wastes (DOE 1996b:3-62, E-19), and nonhazardous liquid wastes (Teal 1997).

**Table 3–35 Waste Generation Rates at FFTF and RPL/306–E**

Waste Type	FFTF (cubic meters per year)	RPL/306–E (cubic meters per year)
<b>High-level radioactive</b>	0	0
<b>Transuranic</b>	0	8
<b>Low-level radioactive</b>

### **3.4.11.2 High-Level Radioactive Waste**

High-level radioactive waste was generated in the recovery of uranium and plutonium from spent fuel generated in the production reactors. All of this radioactive waste is considered mixed waste because of its toxic and hazardous constituents as defined by RCRA. It must be remotely handled because of its high radiation levels. The waste was generated as liquids and sludges and stored in underground tanks where the sludges and salts in the liquid have precipitated out of solution as porous solids (called salt cake) and settled to the bottom of the tanks. The liquid above the solids has been pumped from the older, single-shelled tanks into newer, double-shelled tanks. The liquids that remain in the porous salt cake will be removed by boring holes through the salt cake and extracting liquids from near the tank bottoms. The wastes are segregated and handled according to their hazardous nature (corrosivity, chemical stability, heat generation rates), and require special monitoring and venting. Cooling is needed for some of these wastes. The wastes are concentrated by evaporation and returned to the tanks for storage until final processing to a form suitable for disposal in a geologic repository. It is planned to vitrify high-level radioactive waste water-soluble sludges and selected radionuclides separated from liquids retrieved from the tanks. In addition to this liquid and solid high-level radioactive waste, an inventory of encapsulated cesium and strontium is stored in the Waste Encapsulation and Storage Facility in a water-cooled pool. Some of this material was used as irradiation sources in, for example, radiography and food irradiation (DOE 1996:3-65).

### **3.4.11.3 Transuranic and Mixed Transuranic Waste**

All generated contact-handled transuranic waste is being placed in above-grade storage buildings at the Hanford Central Waste Complex (DOE 1996b:3-64). Transuranic waste will be maintained in storage until it is shipped to WIPP in Carlsbad, New Mexico, for disposal, or to a suitable geologic repository. The new Waste Receiving and Processing Facility has the capability to certify drummed or small container transuranic waste for shipment to WIPP (Dirkes and Hanf 1996:10). Transuranic wastes to be transported to WIPP will be packaged and shipped to WIPP for disposal in accordance with DOE and DOT requirements and WIPP waste acceptance criteria. Mixed transuranic wastes are included in the transuranic waste category because these wastes are expected to go to WIPP for ultimate disposal (DOE 1996b:3-64). The first shipment of transuranic waste from Hanford was received at WIPP on July 14, 2000 (DOE 2000d:2).

### **3.4.11.4 Low-Level Radioactive Waste**

Solid low-level radioactive waste is compacted and sent to the Low-level Radioactive Waste Burial Ground in the 200 West Area for disposal in trenches. Additional low-level radioactive waste is received from offsite generators and disposed of at the Low-level Radioactive Waste Burial Ground. Low-level radioactive waste resulting from the River Protection Project-tank waste treatment will be vitrified. The vitrified low-level radioactive waste will be disposed of on site in the 200 Area as part of the tank waste remediation system program (DOE 1996b:3-64). Low-level radioactive waste resulting from CERCLA cleanup activities are disposed of on site at the Environmental Restoration Disposal Facility.

U.S. Ecology operates a licensed commercial low-level radioactive waste Burial Ground on a site southwest of the 200-East Area that is leased to the State of Washington. The facility is not a DOE facility and is not considered part of DOE's Hanford operations (DOE 1996b:E-17).

### **3.4.11.5 Mixed Low-Level Radioactive Waste**

Miscellaneous dilute aqueous low-level radioactive and liquid mixed low-level radioactive wastes are temporarily stored in the Liquid Effluent Retention Facility until treated in the Liquid Effluent Treatment Facility. The Liquid Effluent Retention Facility consists of three RCRA-compliant surface impoundments for

storing process condensate from the 242-A Evaporator. This facility provides equalization of the flow and pH to the Liquid Effluent Treatment Facility. The Liquid Effluent Treatment Facility provides ultraviolet light/peroxide destruction of organic compounds, reverse osmosis to remove dissolved solids, and ion exchange to remove the last traces of contaminants. Discharge of the treated effluent is via a dedicated pipeline to an underground drain field. The effluent treatment process produces a mixed low-level radioactive waste sludge that is concentrated, dried, packaged in 208-liter (55-gallon) drums, and transferred to the Central Waste Complex. This secondary waste is stored prior to treatment, if necessary, and disposed in the Mixed Waste Trench (Dirkes and Hanf 1996:10, 45, 46).

The Waste Receiving and Processing Facility, near the Central Waste Complex in the 200 West Area, provides analyses, characterization, and preparation of drums and boxes for disposal of Hanford's mixed waste. The Waste Receiving and Processing Facility is designed to process 6,800 drums of waste annually and to prepare retrieved and stored transuranic waste for disposal (Dirkes and Hanf 1996:40).

The Radioactive Mixed Waste Disposal Facilities are in the Hanford Low-level Radioactive Waste Burial Ground and are designated as 218-W-5, Trench 31, and Trench 34. The facilities consist of rectangular trenches with approximate dimensions of 76 by 30 meters (250 by 100 feet). These facilities are RCRA compliant, with double liners and leachate collection and removal systems (Dirkes and Hanf 1996:40).

#### **3.4.11.6 Hazardous Waste**

There are no treatment facilities for hazardous waste at Hanford; therefore, the wastes are accumulated in satellite storage areas for less than 90 days, or at interim RCRA-permitted facilities, such as the 305-B Waste Storage Facility. The common practice for newly generated hazardous waste is to ship it off site by truck using DOT-approved transporters for treatment, recycling, recovery, and disposal at RCRA-permitted commercial facilities (DOE 1999e:3-11, 12).

#### **3.4.11.7 Nonhazardous Waste**

Sanitary wastewater is discharged to onsite treatment facilities such as septic tanks, subsurface soil adsorption systems, and wastewater treatment plants. These facilities treat an average of 600,000 liters (158,000 gallons) per day of sewage (DOE 1996b:E-19).

The 200 Area TEDF industrial sewer collects the treated wastewater streams from various plants in the 200 Areas and disposes of the clean effluent at two 2-hectare (5-acre) ponds permitted by the State of Washington (DOE 1996b:E-19). The design capacity of the facility is approximately 8,700 liters (2,300 gallons) per minute, although the discharge permit presently limits the average monthly flow to about 2,400 liters (640 gallons) per minute (Dirkes and Hanf 1996:46).

Nonhazardous solid wastes include construction debris, office trash, cafeteria wastes, furniture and appliances, nonradioactive friable asbestos, powerhouse ash, and nonradioactive/nonhazardous demolition debris. Until 1997, nonhazardous solid wastes were disposed of in the 600 Area central landfill. Under an agreement between DOE and the city of Richland, most of the site's nonregulated and nonradioactive solid wastes are now sent to the Richland Sanitary Landfill for disposal (DOE 1996b:3-65, E-19). The Richland Sanitary Landfill is at the southern edge of the Hanford Site boundary. Nonradioactive friable asbestos and medical waste are shipped off site for disposal to a commercial facility (DOE 1999e:3-12).

### 3.4.11.8 Waste Minimization

The Hanford Site Pollution Prevention Program is a comprehensive and continual effort to systematically reduce the quantity and toxicity of hazardous, radioactive, mixed, and sanitary wastes; conserve resources and energy; reduce hazardous substance use; and prevent or minimize pollutant releases to all environmental media from all operations and site cleanup activities. In accordance with sound environmental management, preventing pollution through source reduction is the first priority in the Hanford Site Pollution Prevention Program, and the second priority is environmentally safe recycling. Implementation of pollution prevention projects reduced the total amount of waste generated at Hanford in 1998 by approximately 17,500 cubic meters (23,000 cubic yards). Examples of pollution prevention projects completed in 1998 at Hanford include: the reduction of cleanup and stabilization of mixed low-level radioactive waste by approximately 170 cubic meters (220 cubic yards) by decontaminating numerous items (including process tanks, machinery, floors, and associated equipment and piping) to low-level radioactive waste status, avoiding a mixed low-level radioactive wastestream and associated disposal costs; the reduction of hazardous waste by 22 metric tons (24 tons) by removing CFC-12 refrigerant from four of eight chillers and selling it to a vendor for reuse; and the reduction of cleanup and stabilization of mixed low-level radioactive waste by approximately 11 cubic meters (14 cubic yards) by recycling scrap metal from an underground tank system for use as radiation shielding blocks (DOE 1999f:64).

DOE has developed a draft *Waste Minimization and Management Plan for FFTF* to incorporate pollution prevention and waste minimization practices in its consideration of the future of FFTF (DOE 2000c). If a decision were made to restart FFTF, this plan would be used to ensure that optimum opportunities are provided for characterizing potential waste streams, identifying source reduction and recycling strategies, evaluating disposition options, developing sustainable designs, and implementing effective management strategies. This plan identifies DOE's preferred options for management, treatment, and/or disposition of all waste streams related to the restart and operation of FFTF. These preferred options primarily use commercial waste handling and disposal facilities.

### 3.4.11.9 Waste Management PEIS Records of Decision

The *Waste Management PEIS* Records of Decision affecting Hanford are shown in **Table 3-37** for the waste types analyzed in this NI PEIS. Decisions on the various waste types were announced in a series of Records of Decision that have been issued on the *Waste Management PEIS*. The transuranic waste Record of Decision was issued on January 20, 1998 (63 FR 3629); the hazardous waste Record of Decision was issued on August 5, 1998 (63 FR 41810); the high-level radioactive waste Record of Decision was issued on August 12, 1999 (64 FR 46661); and the low-level radioactive waste Record of Decision was issued on February 18, 2000 (65 FR 10061). The transuranic waste Record of Decision states that DOE will develop and operate mobile and fixed facilities to characterize and prepare transuranic waste for disposal at WIPP.

Each DOE site that has or will generate transuranic waste will, as needed, prepare and store its transuranic waste on site. The hazardous waste Record of Decision states that most DOE sites will continue to use offsite facilities for the treatment and disposal of major portions of the nonwastewater hazardous waste, with ORR and SRS continuing to treat some of their own nonwastewater hazardous waste on site in existing facilities where this is economically favorable. The high-level radioactive waste Record of Decision states that immobilized high-level radioactive waste will be stored at the site of generation until transfer to a geologic repository. The low-level radioactive waste and mixed low-level radioactive waste Record of Decision states that for the management of low-level radioactive waste, minimal treatment will be performed at all sites, and disposal will continue, to the extent practicable, on site at INEEL, LANL, ORR, and SRS. In addition,

**Table 3–37 Waste Management PEIS Records of Decision Affecting Hanford**

Waste Type	Preferred Action
High-level radioactive	DOE has decided that Hanford should store its high-level radioactive waste on site until transfer to a geologic repository <sup>a</sup>
Transuranic and mixed transuranic	DOE has decided that Hanford should prepare and store its transuranic waste on site pending disposal at WIPP or another suitable geologic repository. <sup>b</sup>
Low-level radioactive	DOE has decided to treat Hanford's low-level radioactive waste on site. Hanford has been selected as one of the regional disposal sites for low-level radioactive waste. <sup>c</sup>
Mixed low-level radioactive	DOE has decided to regionalize treatment at Hanford. This includes the onsite treatment of Hanford's wastes and could include treatment of some mixed low-level radioactive waste generated at other sites. Hanford has been selected as one of the regional disposal sites for mixed low-level radioactive waste. <sup>c</sup>
Hazardous	DOE has decided to continue to use commercial facilities for treatment of Hanford nonwastewater hazardous waste. DOE will also continue to use onsite facilities for wastewater hazardous waste. <sup>d</sup>

a. From the Record of Decision for high-level radioactive waste (65 FR 46661).

b. From the Record of Decision for transuranic waste (63 FR 3629).

c. From the Record of Decision for low-level radioactive and mixed low-level radioactive waste (65 FR 10061).

d. From the Record of Decision for hazardous waste (63 FR 41810).

**Source:** 63 FR 3629; 63 FR 44810; 64 FR 46661; 65 FR 10061.

Hanford and the Nevada Test Site will be available to all DOE sites for low-level radioactive waste disposal. Mixed low-level radioactive waste will be treated at Hanford, INEEL, ORR, and SRS, and disposed of at Hanford and the Nevada Test Site. More detailed information concerning DOE's alternatives for the future configuration of waste management facilities at Hanford is presented in the *Waste Management PEIS* and the transuranic waste, hazardous waste, and low-level radioactive and mixed low-level radioactive waste Records of Decision.

### 3.4.12 Spent Nuclear Fuel

When nuclear assemblies can no longer be used in the nuclear reactor, they are designated as "spent nuclear fuel," which is removed from the reactor and stored in the spent fuel storage pool, vessel, or basin. The Nuclear Waste Policy Act of 1982, as amended, assigned the Secretary of Energy the responsibility for developing of a repository for the disposal of high-level radioactive waste and spent nuclear fuel. When such a repository is available, spent nuclear fuel would be transferred for disposal from nuclear reactor site to the repository. Until a repository is available, spent nuclear fuel is stored in the reactor vessel, or in another acceptable method, such as in a dry cask storage system.

The current inventory of spent nuclear fuel at FFTF is approximately 11 metric tons of heavy metal, predominantly mixed plutonium-uranium oxide encapsulated in stainless steel. About 3 percent, (i.e., 0.3 metric tons of heavy metal) is of sodium-bonded spent nuclear fuel. In addition, there is 0.02 metric tons of heavy metal of training, research, isotopes General Atomics (TRIGA) spent nuclear fuel. This constitutes less than 1 percent of the cumulative spent nuclear fuel (about 2,133 metric tons of heavy metal), including defense and nondefense fuel at Hanford. DOE is managing this spent fuel in accordance with the Environmental Assessment, *Management of Hanford Site Non-Defense Production Reactor Spent Nuclear Fuel* and the associated Finding of No Significant Impact (DOE 1997f, 1997g).

### **3.5 GENERIC COMMERCIAL LIGHT WATER REACTOR SITE**

Existing CLWRs use both pressurized water and boiling water technologies. Previous studies for the tritium supply program showed that, of the two types of commercial reactors, pressurized-water reactors are more readily adaptable than boiling-water reactors to the production of isotopes by target irradiation (DOE 1995b). DOE published a request for Expressions of Interest in the January 4, 1999, *Commerce Business Daily* for the production of plutonium-238 for space missions (DOE 1999n). No responses by the commercial nuclear industry to DOE's request for Expressions of Interest were provided by, or on behalf of, boiling-water reactor owners. The evaluation of CLWRs in this NI PEIS, therefore, will only be based on the use of pressurized-water reactors.

The use of CLWRs is not appropriate for the production of medical and industrial isotopes or to support civilian nuclear research and development because CLWRs operate on a 9- to 18-month cycle between refueling outages. Many medical and industrial isotopes have short half-lives and would decay before they could be removed from the reactors. In addition, CLWRs are not good irradiation sources for many civilian nuclear research tests because the range of neutron fluxes present in CLWR is limited, and the flux is optimized for power production rather than research. Accordingly, CLWRs are not appropriate irradiation sources for either medical and industrial isotope production or civilian nuclear research and development.

Because it is unreasonable for this NI PEIS to analyze all CLWRs, the environmental baseline was developed for a generic CLWR site description that is representative of existing reactor sites in the contiguous United States. The generic CLWR analysis in this NI PEIS is not site specific. Any one of the commercial, operating pressurized-water reactors is a potential candidate for the plutonium-238 production mission. Currently, 72 pressurized-water reactors are located at 42 sites in 27 states. The commercial, pressurized-water reactors operating in the United States that would be representative of the CLWR described and analyzed in this NI PEIS are shown in **Figure 3-22**. If an alternative were selected that involves the use of an existing CLWR site, site-specific environmental conditions would be identified in tiered NEPA documentation.

#### **3.5.1 Land Resources**

Land resources include land use and visual resources. Each of these resources is described below.

##### **3.5.1.1 Land Use**

Land may be characterized by its potential for the location of human activities (land use). Natural resource attributes and other environmental characteristics could make a site more suitable for some land uses than for others. Changes in land use may have both beneficial and adverse effects on other resources such as ecological, cultural, geological, aquatic, and atmospheric.

CLWR site areas within the United States range from 34 to 12,000 hectares (84 to 29,700 acres). Almost 60 percent of the plant sites encompass from 200 to 800 hectares (490 to 1,980 acres). Approximately half of the sites contain two or three nuclear units per site. Larger land use areas are associated with plant cooling systems that include reservoirs, artificial lakes, and buffer areas. Plant facilities are typically sited on 3 to 9 percent of the total site area. For sites that use cooling ponds instead of cooling towers, facilities could occupy a larger percentage, 67 to 76 percent, of the total site area (DOE 1996b). Typically, nuclear power plant sites are on and near flat-to-rolling countryside in wooded or agricultural areas. More than 50 percent of the sites have 80-kilometer (50-mile) population densities of fewer than 77 persons per square kilometer (200 persons per square mile) and more than 80 percent have 80-kilometer (50-mile) densities of fewer than 193 persons per square kilometer (500 persons per square mile) (DOE 1996b).

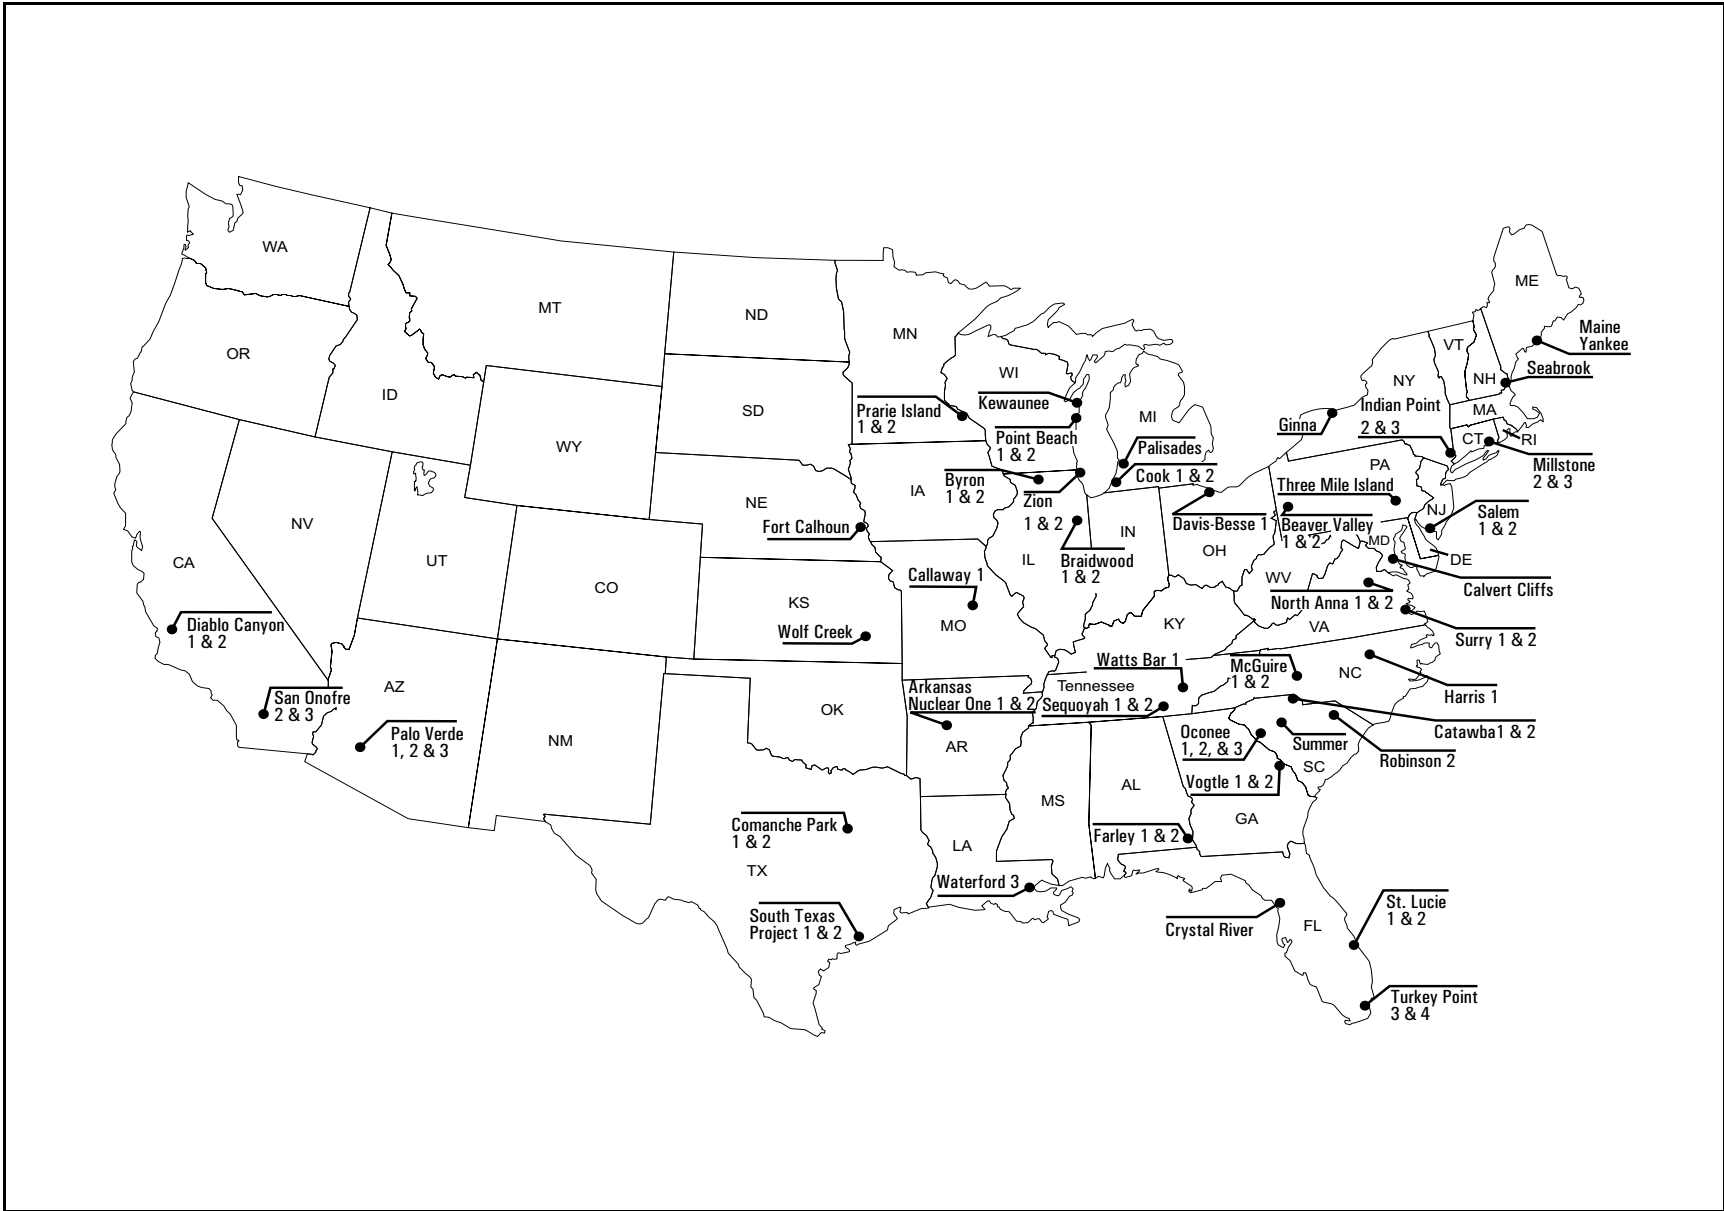

Figure 3–22 Commercial Pressurized-Water Reactors Operating in the United States

The location of a generic CLWR site would range between 3 and 55 kilometers (2 and 34 miles) from the nearest city, and most likely be further from the closest metropolitan area than 80 kilometers (50 miles). The site would likely be located adjacent to a large water body, such as a lake, river, or bay.

### **3.5.1.2 Visual Resources**

Visual resources are natural and human-created features that give a particular landscape its character and aesthetic quality. Landscape character is determined by the visual elements of form, line, color, and texture. All four elements are present in every landscape. The stronger the influence exerted by these elements in a landscape, the more interesting the landscape.

The visual environment of a generic CLWR site would likely be characterized by flat to gently rolling topography adjacent to a large water body. The site would be a developed area that contains facilities and activities, surrounded by an undeveloped buffer area. The viewshed would likely include a small-to-medium sized urbanized area with surrounding forest and agricultural use. Depending on topography, atmospheric conditions, vegetation, and distance, the facilities of a generic existing CLWR site could be visible from adjacent viewpoints. Stack plumes from cooling towers could be visible under most meteorological conditions. Median visible plume lengths would usually range from less than 500 meters (1,640 feet) in summer to 1,000 meters (3,280 feet) in winter. The facilities would be brightly lit at night. The range of public viewpoints could include public access roadways, urbanized areas, and recreation and scenic areas with high user volumes. Since the site would be adjacent to a large water body, it would be likely that distance zones would range from foreground to middleground. The developed areas of a generic existing CLWR site would likely be consistent with a Bureau of Land Management Visual Resource Management Class IV rating indicating that the level of change to the characteristic landscape is high and that management activities dominate the view and are the major focus of view attention (DOE 1996b).

### **3.5.2 Noise**

Principal noise sources at nuclear power plants include cooling towers and transformers. The impacts of these and other sources at the plants have been found to be small and generally not noticed by the public (NRC 1996:17). In most cases, noise sources are sufficiently distant from sensitive receptors that noise is attenuated to nearly ambient levels, although at some sites, sensitive receptors were identified during licensing at which noise levels would be greater than 10 decibels above ambient (NRC 1996:139). An area near a CLWR site would be essentially rural in character and would have typically low background sound levels. Typical day-night average sound levels in the range of 35 to 50 dBA can be expected for such a rural location where noise sources may include wind, insect activity, aircraft, and agricultural activity. Existing industrial noise sources and traffic noise at the site would result in higher background noise levels near the site and along site access routes (DOE 1996b:3-387).

### **3.5.3 Air Quality**

Air pollution refers to the introduction, directly or indirectly, of any substance into the air that could endanger human health, harm living resources and ecosystems as well as material property, and impair or interfere with the comfortable enjoyment of life or other legitimate uses of the environment.

Ambient air quality conditions at CLWR sites in the United States could include a wide range of pollutants and conditions. The baseline air concentrations for criteria pollutants at a generic CLWR site are presented in **Table 3-38**. These concentrations are based on ambient monitoring data collected near a representative CLWR site. Some potential CLWR sites are near or within nonattainment areas for PM<sub>10</sub>, ozone, and carbon monoxide. The maximum ground-level pollutant concentrations that would result from CLWR emissions are

**Table 3–38 Comparison of Baseline Air Concentrations with Most Stringent Applicable Regulations or Guidelines at the Generic CLWR Site**

Criteria Pollutant	Averaging Period	Most Stringent Regulation or Guideline <sup>a</sup> (micrograms per cubic meter)	Baseline Concentration (micrograms per cubic meter)
Carbon monoxide	8 hours	10,000	1,250
	1 hour	40,000	1,250
Lead	Calendar quarter	1.5	0.03
Nitrogen dioxide	Annual	100	26.3
Ozone	1 hour	235	(b)
PM <sub>10</sub>	Annual	50	20.3
	24 hours	150	39,000
Sulfur dioxide	Annual	80	10.5
	24 hours	365	65.5
	3 hours	1300	204

a. The Federal standards are presented.

b. Ozone, as a criteria pollutant, is not directly emitted or monitored by the sites.

**Key:** PM<sub>10</sub>, particulate matter with an aerodynamic diameter less than or equal to 10 microns.

**Source:** DOE 1999o.

low when compared to NAAQS. However, if the CLWR is in an area that may already have high background pollutant concentrations, resultant pollutant concentrations could approach or exceed NAAQS. As a result, regulatory compliance will need to be assessed on a case-by-case basis.

### 3.5.4 Water Resources

Major surface water features near a generic CLWR site could range from a large navigable river to a large lake. These surface waters would be classified and protected by regulation for specified uses, such as water supply. CLWRs would also have NPDES permits that specify the concentrations of pollutants and temperature permissible for liquid effluents and stormwater runoff discharged to surface waters. Other surface water bodies could include ponds and/or site-bordering ephemeral or perennial streams (DOE 1996b:3-388).

CLWRs withdraw large amounts of mainly surface water to meet a variety of plant needs. Water withdrawal rates from adjacent bodies of water for plants with once-through cooling systems are large. Flow through the condenser for a 1,000 megawatt plant may be 2.6 million to 3.8 million liters (700,000 to 1 million gallons) per minute. Water lost by evaporation from the heated discharge is about 60 percent of that which is lost through cooling towers. Additional water needs for service water, auxiliary systems, and radioactive waste systems account for 1 to 15 percent of that needed for condenser cooling (DOE 1995b:4-510).

Water withdrawal from adjacent bodies of water for plants with closed-cycle cooling systems is 5 to 10 percent of that with once-through cooling systems, with much of this water being used for makeup of water by evaporation. With once-through cooling systems, evaporative losses are about 40 percent less but occur externally in the adjacent body of water instead of in the closed-cycle system. The average makeup water withdrawals for several of the more recently constructed plants having closed-cycle cooling, normalized to 1,000 megawatts, are about 53,000 to 68,000 liters (14,000 to 18,000 gallons) per minute. Variation is due to cooling tower design, concentration factor of recirculated water, climate at the site, plant operating conditions, and other plant-specific factors. Consumptive loss normalized to 1,000 megawatts is about 42,400 liters (11,200 gallons) per minute, which is about 80 percent of the water volume taken in (DOE 1995b:4-510).

These consumptive water losses remove surface water from other uses downstream. In those areas experiencing water availability problems, nuclear power plant consumption may conflict with other existing or potential closed-cycle uses (e.g., municipal and agricultural water withdrawals) and in-stream uses (e.g., adequate in-stream flows to protect aquatic biota, recreation, and riparian communities) (DOE 1995b:4-510).

Some CLWRs use groundwater as an additional source of water. The rate of usage varies greatly among users. Many plants use groundwater only for the potable water system and require less than 380 liters (100 gallons) per minute; however, withdrawals at other sites can range from 1,500 to 11,000 liters (400 to 3,000 gallons) per minute (DOE 1995b:4-510).

### **3.5.5 Geology and Soils**

The physiography of a CLWR site could range from a flat nearly featureless plain to a highly dissected plain of arid to humid environments. The geology could range from alluvium to thick sequences of unconsolidated marine sediments, glaciofluvial material, and crystalline and sedimentary bedrock. These materials could range in age from Cenozoic to Precambrian (recent to over 600 million years) (DOE 1996b:3-389).

The generic CLWR site could be located in regions that may have a low to moderate seismic risk as a result of an earthquake based on historical seismic activity. The location of the nearest capable fault could range from within the site boundaries to 350 kilometers (217 miles) away from CLWR sites. The nearest known epicenter of a damaging earthquake could be approximately 350 kilometers (217 miles) from existing CLWR sites (DOE 1996b:3-389).

The CLWR sites are not within a region of active volcanism; however, a generic CLWR site could be within 164 kilometers (102 miles) of a volcano (DOE 1996b:3-389).

The CLWR sites could be located where the predominant soil types are loamy clays to gravel silty loams. These soils range from moderate to well drained soils. The erosion potential could range from minor to severe in those areas with slopes greater than 25 percent and which have been eroded in the past. Shrink-swell potential could range from low to severe, which is acceptable for standard construction techniques, depending upon the engineering controls employed. Wind erosion potential ranges from minor to severe (DOE 1996b:3-389).

### **3.5.6 Ecological Resources**

Ecological resources include terrestrial resources, wetlands, aquatic resources, and threatened and endangered species. The nature of these resources in the vicinity of a CLWR is highly dependent upon the specific location of an existing reactor. All CLWR sites were developed within the requirements of applicable Federal and state natural resource laws and regulations.

#### **3.5.6.1 Terrestrial Resources**

Terrestrial resources in the vicinity of a generic CLWR site would include those plant and animal communities typical of the ecoregion within which the facility is located. Ecoregions are characterized by distinctive flora, fauna, climate, landform, soil, vegetation, and ecological climax (Bailey 1976). Within such a region, ecological relationships between plant species, and soil and climate are essentially similar. Provinces are subdivisions that are a broad vegetation region with the same type or types of zonal soils. Provinces within which a CLWR could be located may include, but are not limited to the eastern deciduous forest; southeastern mixed forest; outer coastal plain forest; prairie parkland; Great Plains short-grass prairie; tall-grass prairie;

American desert; and California chaparral. These provinces are further subdivided by Bailey (1976) based on specific climax vegetation.

### **3.5.6.2 Wetlands**

Since the need for cooling water is an important operational requirement, most CLWRs are constructed near rivers, lakes, reservoirs, or oceans. In each case, the presence of wetlands in the vicinity of the facility may be expected. Major types of wetlands, which could occur near a generic CLWR, include tidal salt marshes, freshwater marshes, northern peatlands, shrub swamps, and forested wetlands. Wetlands serve a variety of important functions including maintaining water quality, controlling floodwaters, stabilizing shorelines, and providing recreational uses such as hunting and fishing. Wetlands are also important in providing habitat for terrestrial and aquatic organisms including migratory birds and threatened and endangered plants and animals.

### **3.5.6.3 Aquatic Resources**

Nearly all CLWRs are constructed near a source of cooling water such as a river, lake, reservoir, or ocean. The abiotic and biotic characteristics of each type of water body vary with its geographic location.

### **3.5.6.4 Threatened and Endangered Species**

Threatened and endangered species could be present in each of the ecoregions within which a generic CLWR could be located. At present, there are 1,233 federally listed threatened and endangered species in the United States (FWS 2000). States also typically identify threatened and endangered, as well as other special status species, found within their borders. Endangered plants and animals often rely on sensitive environments, such as wetlands, for habitat. Critical habitats, areas that are considered essential to the conservation of a species and that could require special management considerations or protection, can be designated and protected under the Endangered Species Act. Protection of threatened and endangered species and their habitat is important for maintaining biodiversity.

### **3.5.7 Cultural and Paleontological Resources**

Cultural and paleontological resources include prehistoric resources, historic resources, Native American resources, and paleontological resources. The presence or absence of such resources is highly dependent upon the location of a specific existing CLWR. In accordance with applicable Federal and state laws and regulations, all existing sites would have been surveyed for such resources prior to site construction. Further, consultation with the State Historic Preservation Officer and tribal governments would have been required.

#### **3.5.7.1 Prehistoric Resources**

Prehistoric resources in the vicinity of the generic CLWR may include sites, districts, or isolated artifacts. Archaeological sites may represent occupation during the Archaic through later prehistoric periods and can include hunting and butchering sites, cemeteries, campsites, and tool manufacturing areas. They may yield artifacts such as stone tools and associated manufacturing debris, and ceramic potsherds. Some sites may be included on the National Register of Historic Places, while others may be eligible for listing.

#### **3.5.7.2 Historic Resources**

Historic resources may include cemeteries, remains of commercial or residential structures, or standing structures. While some sites may already be listed on the National Register of Historic Places, others may be eligible for listing.

### **3.5.7.3 Native American Resources**

Native American resources can include cemeteries, geological or geographic elements such as mountains or creeks, certain species of animals or plants, architectural structures, such as pueblos; battlefields, or trails. Such resources are important to Native American groups for religious or historical reasons.

### **3.5.7.4 Paleontological Resources**

Paleontological resources are the physical remains, impressions, or traces of plants or animals from a former geological age. Paleontological remains consist of fossils and their associated geological information. The presence of such resources at a generic CLWR site is dependent upon the past geologic history of the site.

### **3.5.8 Socioeconomics**

The CLWR site could potentially affect the socioeconomic environment of a given regional economic area or region of influence. The characteristics of the regional economic area, region of influence, and community are dependent upon geographic location. For employment and income, the economic area would be based upon industry interaction and linkages in the region. The anticipated residential distribution of project-related employees and their families would determine the region of influence. This region of influence would contain all principal jurisdictions and school districts likely to be affected by the proposed activity.

Socioeconomic characteristics described for the generic CLWR site include employment and local economy, population and housing, and local transportation. Four hypothetical sites (A, B, C, and D) have been developed for the generic CLWR for purposes of making these characterizations. Site A, which had a nearby 1992 population of 2,604, was located about 160 kilometers (100 miles) from a large metropolitan area. Site B, with a nearby 1992 population of 5,236, was located approximately 8 kilometers (5 miles) from a small community and approximately 64 kilometers (40 miles) from a large metropolitan area. Site C, with a nearby 1992 population of 44,384, was located approximately 16 kilometers (10 miles) from a medium-size community and approximately 48 kilometers (30 miles) from a large metropolitan area. Site D, with a nearby 1992 population of 34,201 and a total urban population of more than 100,000. Statistics for employment and local economy were based on the regional economic area for each site. Statistics for the remaining socioeconomic characteristics were based on the sites' regions of influence (DOE 1996b).

#### **3.5.8.1 Regional Economic Characteristics**

Employment and regional economy statistics for each representative site's regional economic area are discussed in this section. Between 1980 and 1990, the civilian labor force in the region of economic area encompassing Site A increased 7.7 percent to the 1990 level of 4,811,800, and for Site B increased 49.6 percent to the 1990 level of 1,162,300. The civilian labor force for Site C, located near a large metropolitan area, increased 21.9 percent to the 1990 level of 862,500. The civilian labor force for Site D, located in an urbanized area, increased 9.9 percent to 254,800 persons. The 1994 unemployment rates in the two small hypothetical communities' (A and B) regional economic areas were 5.6 percent and 5.2 percent, respectively. Sites C and D had unemployment of 4.3 percent and 9.1 percent, respectively.

For the two small representative communities, the portions of total employment involving farming in the regional economic areas were about 1 percent. Governmental activities for Sites A and B represented about 12 percent and 14 percent, respectively. Manufacturing was 16 percent of the total employment for site A and 10 percent for site B. Retail trade accounted for 16 percent and 18 percent of the total sector employment for Sites A and B, respectively. Service activities represented a 30 percent share of the total employment for Sites A and B.

For Sites C and D, the portion of total employment was about 1 percent and 12 percent for farming and 11 and 15 percent for governmental activities, respectively. The nonfarm private sector activities of retail trade and services were 16 and 22 percent of total employment, respectively, for Site C and 16 and 26 percent, respectively, for Site D. Employments for manufacturing were 23 and 8 percent of total employment for Sites C and D, respectively (DOE 1996b).

### 3.5.8.2 Population and Housing

Between 1980 and 1994 the region of influence population increase for the two small hypothetical communities, A and B, was 6.4 percent (average annual increase of 0.5 percent) and 54.6 percent (average annual increase of 3.9 percent), respectively. The number of housing units in the region of influence increased 8.9 percent for Site A and 55.8 percent for Site B between 1980 and 1990. The 1990 region of influence homeowner vacancy rates were 1.1 and 3.9 percent, while the renter vacancy rates were 5.9 and 16.4 percent for Sites A and B, respectively.

The regions of influence surrounding Sites C and D experienced a 31.8 percent (average annual increase of 2.3 percent) and 19.8 percent (average annual increase of 1.4 percent) increase in population, between 1980 and 1994, and a 32.7 and 5.4 percent increase, respectively, in the number of housing units between 1980 and 1990.

The 1990 homeowner and renter vacancy rates were 2.0 and 8.9 percent for Site C and 1.3 and 5.6 percent for Site D (DOE 1996b).

### 3.5.8.3 Community Services and Local Transportation

These characteristics are dependent upon geographic location. The region of influence would determine all principal jurisdictions and school districts likely to be affected by the proposed activity. Local transportation would be the existing principal road, air, and rail networks required to support the project activities (DOE 1996b).

## 3.5.9 Existing Human Health Risk

### 3.5.9.1 Radiation Exposure and Risk

Major sources and levels of background radiation exposure to individuals in the vicinity of the CLWR site are shown in **Table 3-39**. Annual background radiation doses to individuals are expected to remain constant over time. The total dose to the population size changes as the population size changes. Background radiation doses are unrelated to CLWR site operations.

Releases of radionuclides to the environment from CLWR site operations provide another source of radiation exposure to individuals in the vicinity of CLWR sites. Types and quantities of radionuclides released from CLWR site operations are listed in the annual radiological effluent release reports for the reference sites. The doses to the public resulting from these releases are presented in **Table 3-40**. These doses fall within radiological guidelines and limits (10 CFR Part 50, Appendix I, and 40 CFR Part 190) and are small (less than 0.01 percent) in comparison to background radiation.

Based on a risk estimator of 500 cancer deaths per 1 million person-rem to the public, the latent cancer fatality risk to the maximally exposed member of the public due to radiological releases from operations at the CLWR site is estimated to range from  $3.9 \times 10^{-9}$  to  $7.0 \times 10^{-7}$  per year. That is, the estimated probability of this person

**Table 3-39 Sources of Radiation Exposure to Individuals in the Vicinity Unrelated to Operation at the CLWR Site**

Source	Effective Dose Equivalent (millirem per year)
<b>Natural background radiation</b>	
Cosmic radiation	27 to 29
Cosmogenic radiation	1
External terrestrial radiation	29 to 30
Radon in homes (inhaled)	200
Internal terrestrial radiation	39
<b>Other background radiation</b>	
Diagnostic x rays and nuclear medicine	53
Weapons test fallout	Less than 1
Air travel	1
Consumer and industrial products	10
<b>Total</b>	<b>361 to 364</b>

**Note:** Value of radon is an average for the United States.

**Source:** DOE 1996b.

**Table 3-40 Radiation Doses to the Public from Normal Operation in 1994 at the Generic Existing CLWR Site (Committed Effective Dose Equivalent)**

Members of the Public	Atmospheric Releases		Liquid Releases		Total	
	Standard <sup>a</sup>	Actual	Standard <sup>a</sup>	Actual	Standard <sup>a</sup>	Actual <sup>b</sup>
Maximally exposed individual (millirem)	5	0.0013 to 1.10	3 per reactor	0 to 0.29	25	0.0078 to 1.39
Population within 80 kilometers <sup>c</sup> (person-rem)	None	0.016 to 13.3	None	0 to 1.28	None	0.020 to 13.3
Average individual within 80 kilometers <sup>d</sup> (millirem)	None	$6.3 \times 10^{-5}$ to $6.8 \times 10^{-3}$	None	0 to $8 \times 10^{-4}$	None	$7.9 \times 10^{-5}$ to $6.8 \times 10^{-3}$

- The standards for individuals are given in 10 CFR Part 50, Appendix I, and 40 CFR Part 190. As discussed in Appendix I of 10 CFR Part 50, the 5-millirem-per-year value is an airborne emission guideline, and the 3-millirem-per-year per reactor value is a liquid release guideline. Meeting these guideline values serves as a numerical demonstration that doses are as low as is reasonably achievable. The total dose of 25 millirem per year is the limit from all pathways combined as given in 40 CFR Part 190.
- Totals cannot be obtained by summing the atmospheric and liquid release components since these component entries can be for different reactor sites.
- This population ranges from 252,000 to 1,960,000.
- Obtained by dividing the population dose by the number of people living within 80 kilometers (50 miles) of the site.

**Source:** DOE 1996b:3-398.

dying of cancer at some point in the future from radiation exposure associated with 1 year of CLWR site operation ranges from about 4 in 1 billion to 7 in 10 million. Note that it takes several to many years from the time of exposure to radiation for a cancer to manifest itself.

Based on the same risk estimator, a range of  $1.0 \times 10^{-5}$  to  $6.7 \times 10^{-3}$  excess fatal cancers is projected in the population living within 80 kilometers (50 miles) of the CLWR site from normal operations. To place these numbers into perspective, they can be compared with the numbers of fatal cancers expected in these populations from all causes. The 1990 mortality rate associated with cancer for the entire U.S. population was 0.2 percent per year. Based on this mortality rate, the number of fatal cancers expected from all causes in the population living within 80 kilometers (50 miles) of the CLWR site ranged from 505 to 3,920. These numbers of expected fatal cancers are much higher than the estimated range of  $1.0 \times 10^{-5}$  to  $6.7 \times 10^{-3}$  fatal cancers that could result from operations at the CLWR site.

At the CLWR site, workers receive the same dose as the general public from background radiation but also receive an additional dose from working at the site. The range of the average worker and total worker dose from operations at the generic existing CLWR site are presented in **Table 3–41**. These doses fall within radiological regulatory limits (10 CFR Part 20). Based on a risk estimator of 400 fatal cancers per 1 million person-rem among workers, the number of excess fatal cancers to CLWR site workers from operations is estimated to range from 0.16 to 0.34 per year (DOE 1996b).

**Table 3–41 Annual Doses to Workers from Normal Operation at the Generic CLWR Site  
(Committed Effective Dose Equivalent)**

Occupational Personnel	Onsite Releases and Direct Radiation	
	Standard <sup>a</sup>	Actual
Average worker (millirem)	ALARA <sup>b</sup>	114 to 322
Total workers <sup>c</sup> (person-rem)	ALARA	396 to 854

a. NRC's goal is to maintain radiological exposures as low as is reasonably achievable.

b. As low as is reasonably achievable.

c. The number of badged workers ranges from 2,650 to 4,370.

Source: DOE 1996b:3-399.

### 3.5.9.2 Chemical Environment

The background chemical environment important to human health consists of the atmosphere, which may contain hazardous chemicals that can be inhaled; drinking water, which may contain hazardous chemicals that can be ingested; and other environmental media with which people may come in contact (e.g., surface waters during swimming and soil through direct contact or via the food pathway).

**Carcinogenic Effects.** Health effects in this case are estimated as the incremental probability of an individual developing cancer over a lifetime as a result of exposure to the potential carcinogen. This could be incremental or excess individual lifetime cancer risks.

**Noncarcinogenic Effects.** Health effects in this case are determined by the ratio between the calculated or measured concentration of the chemical in the air and the reference concentration or dose. This ratio is known as the Hazard Quotient. Hazard Quotients for noncarcinogens are summed to obtain the Hazard Index. If the Hazard Index is less than 1, no adverse health effects would be expected.

Effective administrative and design controls that decrease hazardous chemical releases to the environment and help achieve compliance with permit requirements, for example, air emissions and NPDES permit requirements contribute toward minimizing potential health impacts to the public. The effectiveness of these controls is verified through the use of monitoring information and inspection of mitigation measures. Health impacts to the public may occur during normal operations at CLWR sites via inhalation of air containing hazardous chemicals released to the atmosphere by site operations. Risks to public health from other possible pathways, such as ingestion of contaminated drinking water or direct exposure, are low relative to the inhalation pathway.

Exposure pathways for CLWR site workers during normal operation may include inhaling the workplace atmosphere and direct contact with hazardous material associated with work assignments. Occupational exposure varies from facility to facility and from worker to worker, and available information is not sufficient to allow a meaningful estimation and summation of these impacts. However, workers are protected from hazards specific to the workplace through appropriate training, protective equipment, monitoring, and management controls. At the CLWR site, workers are also protected by adherence to OSHA and EPA standards that limit workplace atmospheric and drinking water concentrations of potentially hazardous

chemicals. Appropriate monitoring that reflects the frequency and amounts of chemicals used in the operational processes ensures that these standards are not exceeded (DOE 1996b).

### **3.5.9.3 Health Effects Studies**

CLWRs have been operating for many years. Site-specific epidemiological studies may be available, and these studies would be reviewed for specific CLWR locations. Epidemiologic studies will be considered in the future.

### **3.5.9.4 Accident History**

CLWRs have been operating in the United States for many years. Accident information for these reactors, where applicable, can be found in documentation available from NRC.

### **3.5.9.5 Emergency Preparedness**

The CLWR site would have an NRC-approved emergency management program that would be activated in the event of an accident. The programs are compatible with other Federal, state, and local plans and are thoroughly coordinated with all interested groups.

### **3.5.10 Environmental Justice**

As discussed in Appendix K, Executive Order 12898 directs Federal agencies to address disproportionately high and adverse health or environmental effects of alternatives on minority and low-income populations. The Executive order does not alter prevailing statutory interpretations under NEPA or existing case law. Regulations prepared by the Council on Environmental Quality remain the foundation for preparing environmental documentation in compliance with NEPA (40 CFR Parts 1500 through 1508) and the Council's guidelines for inclusion of environmental justice under NEPA (CEQ 1997). As the present document is a programmatic EIS, environmental justice issues would be addressed in a site-specific EIS if an option using a CLWR were to be selected.

### **3.5.11 Waste Management**

Waste management includes minimization, characterization, treatment, storage, transportation, and disposal of waste generated from ongoing CLWR activities. The waste is managed using appropriate treatment, storage, and disposal technologies, and in compliance with all NRC and other applicable governmental regulations.

#### **3.5.11.1 Waste Inventories and Activities**

The amounts of waste generated are reported on a quarterly basis by each nuclear utility. The waste volumes of CLWRs are given in **Table 3-42**. These volumes are based on site-specific data (DOE 1996b and DOE 1999o). Because high-level radioactive waste as defined by DOE Order 435.1 would not be generated by neptunium-237 target irradiation activities at the generic CLWR site, it is not included in this table or discussed any further in this section.

Waste management and activities specific to each category of waste are discussed in the following sections.

**Table 3–42 Existing Pressurized-Light Water Reactor Site Waste Management Characteristics**

Characteristic	Range	Average
Low-level radioactive waste shipped (cubic meters per year)	57.04 to 636.85	178.22
Number of low-level radioactive waste shipments per year	6.00 to 31.00	16.17
Stored mixed low-level radioactive waste per 1,000 megawatt (cubic meters per year)	Not reported	101.90 <sup>a</sup>
Hazardous waste generation (cubic meters per year)	11.4 to 29	23
Nonhazardous waste generation (cubic meters per year)		
Liquids	682 to 60,794	37,072
Solids	909 to 10,400	4,148

a. This is the average of both pressurized-water reactors and boiling-water reactors. A value was not specifically reported for the pressurized-water reactor category.

**Note:** To convert from cubic meters to cubic yards, multiply by 1.308.

**Source:** DOE 1996b:3-401 for low-level radioactive waste and mixed low-level radioactive waste; DOE 1999o:chap. 3 for hazardous and nonhazardous waste.

### 3.5.11.2 Transuranic Waste

Transuranic elements are contained within spent nuclear fuel. Transuranic waste is not generated or managed at CLWR sites.

### 3.5.11.3 Low-Level Radioactive Waste

Liquid low-level radioactive waste generated in CLWRs could be classified as either clean waste, dirty waste, turbine building floor drain water, or steam generator blowdown. Clean wastes come from equipment leaks and drains, certain valve and pump seal leakoffs not collected in the reactor coolant drain tank, and other aerated leakage sources. Primary coolant is also considered a clean waste. Liquid wastes collected in the containment building sump, auxiliary building sumps and drains, laboratory drains, sample station drains, and other miscellaneous floor drains are termed dirty wastes because of their moderate conductivity. Clean and dirty wastes will have variable radioactivity content. Detergent wastes, which consist of laundry wastes and personnel and equipment decontamination wastes, normally have a low radioactivity content. Turbine building floor drain water usually exhibits high conductivity with low radionuclide content. Depending on the amount of primary-to-secondary leakage, steam generator blowdown could have relatively high concentrations of radionuclides. The chemical and radionuclide content of the waste would determine the type and degree of treatment before storage for reuse or discharge to the environment. Operating plants have steadily increased the degree of processing, storing, and recycling of liquid radioactive waste (DOE 1996b:3-402).

Solid low-level radioactive waste is generated by removal of radionuclides from liquid waste streams, filtration of airborne gaseous emissions, and removal of contaminated material from various reactor areas. Liquid contaminated with radionuclides comes from primary and secondary coolant systems, spent-fuel pools, decontaminated wastewater, and laboratory operations. Concentrated liquids, filter sludges, waste oils, and other liquid sources are segregated by type, flushed to storage tanks, stabilized for packaging in a solid form by dewatering, and slurried into 208-liter (55-gallon) steel drums prior to disposal. High efficiency particulate air filters are used to remove radioactive material from gaseous plant effluents. These filters are compacted and disposed of as solid low-level radioactive waste. Other solid low-level radioactive waste includes contaminated protective clothing, paper, rags, glassware, compactible and noncompactible trash, and nonfuel irradiated reactor components and equipment. Tools and other material exposed to the reactor environment would also be considered solid low-level radioactive waste. Compactible solid low-level radioactive waste

is taken to an offsite or onsite volume reduction facility before disposal. Solid low-level radioactive waste is stored in shielded prefabricated steel buildings or other facilities until suitable for disposal at an approved low-level radioactive waste disposal facility (DOE 1996b:3-402).

#### **3.5.11.4 Mixed Low-Level Radioactive Waste**

Mixed low-level radioactive waste generated by a nuclear power plant covers a broad spectrum of waste types. The vast majority of mixed waste in storage at nuclear plants is chlorinated fluorocarbons and waste oil. Mixed low-level radioactive waste is stored on site until treatment and disposal is available at an offsite RCRA-permitted facility. Because of the occupational exposure from testing radioactive wastes to determine if they are chemically hazardous, the utilities have been looking at ways to eliminate, or at least minimize, the generation of mixed wastes. These efforts include removing and separating hazardous constituents from radioactive streams by remote methods; minimizing the use of solvents exposed to the reactor environment; relying on substitute processes; and recycling and reusing cleaning materials, resins, and waste oils (DOE 1996b). Stored mixed low-level radioactive waste per 1,000 megawatt averages about 100 cubic meters (130 cubic yards) per year for the existing plants studied.

#### **3.5.11.5 Hazardous Waste**

Hazardous wastes are generated from nonradioactive materials such as wipes contaminated with oils, lubricants, and cleaning solvents that are used outside the reactor environment. Hazardous wastes are packaged and shipped to offsite RCRA-permitted treatment and disposal facilities.

#### **3.5.11.6 Nonhazardous Waste**

Nonhazardous wastes include boiler blowdown, water treatment wastes, boiler metal cleaning wastes, floor and yard drain wastes, storm water runoff, and sewage wastes. Depending on the design of the individual reactor, other small volumes of wastewater are released from other plant systems or combined with the cooling water discharges. Sanitary wastes that cannot be processed by onsite waste treatment systems are collected by independent contractors and trucked to offsite treatment facilities (DOE 1996b:3-402).

#### **3.5.11.7 Waste Minimization**

Because of the increased disposal costs for low-level radioactive waste, utility companies have undertaken major volume reduction and waste minimization efforts. These efforts include segregation, decontamination, minimizing the exposure of materials and tools to the contaminated environment, and sorting. Compacting, consolidating, and monitoring waste streams to reduce the volume of low-level radioactive waste requiring storage, and lessening the exposure of routine equipment to the reactor environment, have been the most effective volume reduction strategies. Current industry-wide volume reduction practices include ultra-high pressure compaction of waste drums, incineration of waste oils and resins, mobile thin-film evaporation, waste crystallization, and asphalt solidification of resins and sludges (DOE 1996b:3-400).

Nuclear power plants typically have waste minimization programs in place to minimize both the volume and cost impact of waste generation. In existing operating plants, a number of the design considerations that affect the plant waste streams are already in place, and improvements in waste management are continually being implemented. Waste minimization steps include more economical use of disposables or elimination of disposables in favor of recyclables. Process improvements aimed at more efficient use of ion exchange resins and reductions of waste streams from the waste processes are being implemented. In general, wastes generated by operating plants have been decreasing in recent years.

### **3.6 DOE SITE FOR NEW ACCELERATOR(S) OR A NEW RESEARCH REACTOR**

Under Alternative 3, DOE would construct one or two new accelerators for medical and industrial production, plutonium-238 production, and civilian nuclear energy research and development. In addition, DOE would construct a support facility for the processing of medical and industrial isotopes and for processing associated with research and development activities. Under Alternative 4, DOE would construct a new research reactor and support facility for this same purpose. Processing activities associated with plutonium-238 production would be performed at an existing DOE facility. The new accelerator(s), research reactor, and support facility would be located at an existing DOE site. No DOE site has been identified as the location of these facilities. If DOE were to select these alternatives, a follow-on EIS would be required to select the specific DOE site where the new accelerator(s), research reactor, and support facility would be located. In that document, DOE would identify site-specific environmental conditions, as well as evaluate the environmental impacts of facility construction and operation on the DOE sites being considered.

Because it is unreasonable for this NI PEIS to analyze all DOE sites, the environmental baseline was developed for a generic DOE site description that is representative of existing DOE sites. The generic DOE analysis does not include a specific DOE site for analysis in this NI PEIS. Any existing DOE site is a potential candidate for the new accelerator(s) or research reactor to support DOE's civilian missions for nuclear research and development and isotope production. One factor that would be considered in identifying candidate DOE sites would be the availability of existing facilities and infrastructure at the sites for support of the accelerator(s), research reactor, and support facility.

#### **3.6.1 Land Resources**

Land resources include land use and visual resources. Each of these resource areas is described for the site as a whole, as well as for the proposed facility locations.

##### **3.6.1.1 Land Use**

Land may be characterized by its potential for the location of human activities (land use). Natural resource attributes and other environmental characteristics could make a site more suitable for some land uses than for others. Changes in land use may have both beneficial and adverse effects on other resources such as ecological, cultural, geological, aquatic, and atmospheric.

DOE sites range from 165 hectares (408 acres) to 350,000 hectares (865,000 acres) in size. While these sites were established for a variety of reasons including nuclear weapons research, development, production, and testing, and energy research and development, the extent of development within each site varies greatly. Facilities located within smaller sites typically occupy a greater percentage of the site than on the larger sites, where from 1 to 25 percent of the site is developed. Undeveloped portions of the sites are used as buffers and in many cases represent land that has remained largely undisturbed since it first came under the jurisdiction of the Federal government. Depending upon the site, undeveloped land may be used for forestry, grazing, wildlife management, or for ecological research. For example, a number of the sites have areas designated as National Environmental Research Parks within their borders. These areas are devoted to research by the nation's scientific community on the impact of human activities on the natural environment. Land uses bordering DOE sites varies from developed urban areas to open spaces in which forestry, wildlife management, farming, grazing, and other rural land uses predominate. Many sites have developed land use plans and recently some have released land for redevelopment by the private sector.

### **3.6.1.2 Visual Resources**

Visual resources are natural and human-created features that give a particular landscape its character and aesthetic quality. Landscape character is determined by the visual elements of form, line, color, and texture. All four elements are present in every landscape. The stronger the influence exerted by these elements in a landscape, the more interesting the landscape.

The visual environment of DOE sites is extremely varied. Certain sites are more highly developed and located near urban areas, while others are only sparsely developed and located many miles from human settlement. Smaller sites and developed portions of larger sites would have a Bureau of Management Visual Resource Management Class IV rating, indicating that the level of change to the characteristic landscape is high and that management activities dominate the view and are the major focus of viewer attention. The Visual Resource Management rating of undeveloped portions of larger DOE sites may range from Class II to Class III. In general, these ratings are characteristic of a less developed landscape and, although management activities may be seen, they should not attract the attention of the casual observer or dominate the view. Views of developed portions of sites located within the eastern United States are often limited due to screening by vegetation and terrain. In the western United States vegetation is generally more sparse and in many cases the landscape is relatively flat. Thus, developed portions of these sites are typically visible from greater distances. Sites located near urban areas are viewed by more people than are the more isolated sites.

### **3.6.2 Noise**

Existing noise sources and characteristics at a DOE site where the new accelerator(s), research reactor, and support facility might be sited can be expected to be similar to existing DOE sites and are generally described as follows. Major noise emission sources include various industrial facilities, equipment, and machines (e.g., cooling systems, transformers, engines, pumps, boilers, steam vents, construction and materials-handling equipment, and vehicles). Most industrial facilities are a sufficient distance from the site boundary that noise levels at the boundary from these sources are not measurable, or are barely distinguishable from background noise levels.

Existing site-related noises of public significance would be from the transportation of people and materials to and from the site. Noise measurements taken near the site would likely indicate that noise levels are consistent with nearby land uses which are primarily rural. Noise levels along roads and access routes to the site would be higher and may result in some annoyance at residences and other noise sensitive land uses near the roads, especially during peak traffic hours.

### **3.6.3 Air Quality**

Ambient air quality at a generic DOE site would be expected to be in compliance with the NAAQS and with the state ambient air quality regulations. A range of ambient air concentrations for criteria pollutants representative of existing DOE sites are presented in **Table 3-43**.

| The primary sources of criteria air pollutants could include steam and power generation facilities, incinerators, waste processing sources, various other process sources, vehicles, temporary emissions from construction activities, and fugitive dust from coal piles, construction activities, and waste disposal operations.

**Table 3–43 Comparison of Baseline Ambient Air Concentrations with NAAQS at a Generic DOE Site**

Pollutant	Averaging Period	NAAQS (micrograms per cubic meter) <sup>a</sup>	Baseline Concentration Range (micrograms per cubic meter)
<b>Criteria pollutants</b>			
Carbon monoxide	8 hours	10,000	8 to 119
	1 hour	40,000	27 to 265
Lead	Calendar quarter	1.5	0.05
Nitrogen dioxide	Annual	100	1 to 14
Ozone	1 hour	235	(b)
PM <sub>10</sub>	Annual	50	1 to 2
	24 hours	150	1 to 13
Sulfur dioxide	Annual	80	1 to 5
	24 hours	365	1 to 36
	3 hours	1,300	2 to 112

a. NAAQS (40 CFR Part 50), other than those for ozone, particulate matter, and lead, and those based on annual averages, are not to be exceeded more than once per year. The annual arithmetic PM<sub>10</sub> mean standard is attained when the expected annual arithmetic mean concentration is less than or equal to the standard.

b. Not directly emitted or monitored by the site.

**Note:** EPA revised the ambient air quality standards for particulate matter and ozone in 1997 (62 FR 38856, 62 FR 38652); however, these standards are currently under litigation, but could become enforceable during the life of this project.

**Source:** 40 CFR Part 50.

### 3.6.4 Water Resources

Major surface water features in the vicinity of a generic DOE site could range from seasonally ephemeral (intermittent) streams to perennial streams and rivers more characteristic of an eastern site. These surface waters would be classified and protected by regulation for specified uses (e.g., water supply, agriculture, fish and wildlife uses, recreation). Existing facilities would have NPDES permits that specify the concentrations of pollutants for liquid effluents and stormwater runoff discharged to surface waters. However, some surface waters could have been impacted from historic waste management activities. Process and sanitary effluents from existing facilities would be managed by wastewater treatment plants and/or by seepage or evaporation ponds. Routine and compliance monitoring of discharges would be conducted with results reported in annual site environmental reports. Some generic DOE site locations could potentially be affected by flooding (DOE 1996b:3-115, 3-194–3-196).

Groundwater could occur in aquifers comprised of strata ranging from interbedded volcanic rocks and sediments to sedimentary rocks consisting of limestone, sandstone, siltstone, and shale. Classifications of major aquifers range from Class I to Class II. Groundwater could also occur as perched groundwater. Depth to groundwater could average from about 60 to 300 meters (200 to 1,000 feet) at a western generic DOE site to about 5 to 9 meters (16 to 30 feet) beneath eastern sites. Portions of some aquifer systems, and perched groundwater tables, could have been impacted by radiological and nonradiological contaminants. Like surface waters, routine monitoring of groundwater would be conducted with results reported in annual site environmental reports (DOE 1996b:3-115–3-117, 3-196–3-199).

Water supply for a generic DOE site could be obtained from either surface water or groundwater sources (DOE 1996b:3-115, 3-194).

### 3.6.5 Geology and Soils

The physiography of a generic DOE site could range from the high, flat to rolling plateaus and plains underlain by nearly horizontal rock strata of the western physiographic provinces to the alternating valleys and ridges

comprised of weakly to strongly folded strata of the eastern Valley and Ridge physiographic province. Surficial geology could range from relatively young (Miocene to Holocene) strata consisting of interlayered volcanic rocks (basalt, rhyolite) and unconsolidated sediments to the older (Cambrian to Ordovician), consolidated sedimentary rocks (limestone, sandstone, shale) of the eastern valleys and ridges (DOE 1996b:3-121–3-123, 3-200; 1999e:3-69, 3-70).

The generic DOE site could be located in regions that may have a low to moderate seismic risk as a result of an earthquake based on historical seismic activity. The location of the nearest capable fault could range from about 19 kilometers (12 miles) to more than 480 kilometers (298 miles) (DOE 1996b:3-200; 1999e:3-70, 3-71). The nearest known center of a potentially damaging earthquake to an accelerator(s) or research reactor at a generic DOE site could range from less than 10 kilometers (6 miles) to more than 100 kilometers (62 miles) away (DOE 1996b:3-200; 1999e:3-70, 3-71). New seismic hazard maps have been developed as part of the National Seismic Hazard Mapping Project which have been adapted for use in the new *International Building Code* (ICC 2000) (Figures 1615(1) and 1615(2) in the code) (see Section 3.2.5.1). These maps depict maximum considered earthquake ground motion of 0.2- and 1.0-second spectral response acceleration, respectively, based on a 2 percent probability of exceedance in 50 years. Based on these maps, a generic DOE accelerator(s) or reactor site could be located anywhere within the 0.35g to 0.60g mapping contours for a 0.2-second spectral response acceleration and the 0.10g to 0.15g contours for a 1.0-second spectral response acceleration.

Future risks of volcanic activity affecting a generic site range from a low risk in the west to no risk in the east, with the closest volcanic features occurring 20 kilometers (12 miles) away from a DOE site (DOE 1996b:3-200; 1999e:3-71).

Soil types could range from sands to loams and clays with depths ranging from shallow to deep. The soils developed from materials ranging from volcanic to sedimentary rocks including limestone, sandstone, shale, and siltstone. The soils are largely well drained. Shrink-swell potential generally ranges from low to moderate. In general, most soils are acceptable for standard construction techniques (Barghusen and Feit 1995:2.3-20, 2.8-14, 2.8-15; DOE 1996b:3-123, 3-200).

### **3.6.6 Ecological Resources**

Ecological resources include terrestrial resources, wetlands, aquatic resources, and threatened and endangered species. The nature of these resources in the vicinity of a generic DOE site is highly dependent upon site location. Therefore, the following discussion addresses only the broad ecological characteristics of the regions within which potential DOE sites fall. If the new accelerator(s) or research reactor alternative were selected, site-specific details would be addressed in NEPA documentation tiered to this NI PEIS.

#### **3.6.6.1 Terrestrial Resources**

Terrestrial resources in the vicinity of a generic DOE site would include those plant and animal communities typical of the ecoregion within which the facility is located. Ecoregions are characterized by distinctive flora, fauna, climate, landform, soil, vegetation, and ecological climax (Bailey 1976). Within such a region, ecological relationships between plant species, and soil and climate are essentially similar. Provinces are subdivisions that are a broad vegetation region with the same type or types of zonal soils. DOE sites are located in a broad range of provinces, including, but not limited to: Eastern deciduous forest, Southeastern mixed forest, Great plains short-grass prairie, Rocky Mountain forest, Colorado plateau, and Intermountain sagebrush. These provinces are further subdivided by Bailey (1976), based on specific climax vegetation.

### **3.6.6.2 Wetlands**

The presence of wetlands on DOE sites vary, depending upon whether the site is located in the eastern United States where rainfall is plentiful or the western part of the country where it is sparse. Wetlands are common at eastern sites and generally uncommon at western locations. Major types of wetlands which could occur at a generic DOE site include freshwater marshes, shrub swamps, and wooded swamps. Wetlands may be either permanent or intermittent depending upon local rainfall and soil conditions. The existence of manmade wetlands associated with some sites is dependent on continued site operations. Wetlands serve a variety of important functions including maintaining water quality, controlling floodwaters, stabilizing shorelines, and providing recreational uses such as hunting and fishing. They are also important in providing habitat for terrestrial and aquatic organisms including migratory birds and threatened and endangered plants and animals.

### **3.6.6.3 Aquatic Resources**

Aquatic resources vary greatly between potential DOE sites located in the eastern United States and those located in the western part of the country. In the eastern United States, ample rainfall results in the presence of permanent water bodies varying from small streams to major rivers. Natural and manmade ponds and reservoirs are more prominent on or in the vicinity of eastern sites. Numerous species of aquatic flora and fauna occur at these sites. DOE sites located in the western United States typically experience limited rainfall and therefore, have few aquatic resources. In many cases the only water bodies present are evaporation and waste ponds, although major rivers do occur in the vicinity of some sites. Western sites typically have fewer species of aquatic organisms than eastern sites.

### **3.6.6.4 Threatened and Endangered Species**

Threatened and endangered species could be present at a generic DOE site; however, the species involved would be highly dependent on site location. At present, there are 1,233 federally listed threatened and endangered species in the United States (FWS 2000). States also typically identify threatened and endangered, as well as other special status species, found within their borders. Endangered plants and animals often rely on sensitive environments, such as wetlands, for habitat. Critical habitats, areas that are considered essential to the conservation of a species and that could require special management consideration or protection, can be designated and protected under the Endangered Species Act. Protection of threatened and endangered species and their habitat is important for maintaining biodiversity, which is essential for full ecological function.

### **3.6.7 Cultural and Paleontological Resources**

Cultural and paleontological resources include prehistoric resources, historic resources, Native American resources, and paleontological resources. The presence or absence of such resources at a generic accelerator(s) or research reactor site is highly dependent upon the specific location of the DOE site involved. In accordance with applicable Federal and state laws and regulations, any site selected for the accelerator(s) or research reactor would have to be surveyed before construction could begin. Also, consultation with State Historic Preservation Officers and tribal representatives would be required.

#### **3.6.7.1 Prehistoric Resources**

Prehistoric resources in the vicinity of a generic DOE site may include sites, districts, or isolated artifacts. Archaeological sites may represent occupation during the Archaic through later prehistoric periods and can include hunting and butchering sites, cemeteries, campsites, and tool manufacturing areas. They may yield

artifacts such as stone tools and associated manufacturing debris, and ceramic potsherds. Some prehistoric sites may be included on the National Register of Historic Places, while others may be eligible for listing.

### **3.6.7.2 Historic Resources**

Historic resources potentially present on a generic DOE site include cemeteries, remains of commercial or residential structures, standing structures, or routes used by settlers during westward expansion. While some of these sites may already be on the National Register of Historic Places, others may be eligible for listing. DOE sites may also contain more recent structures of historic significance including those associated with the Manhattan Project and the Cold War era.

### **3.6.7.3 Native American Resources**

Native American resources can include cemeteries, geological or geographic elements (such as mountains or creeks), certain species of animals or plants, architectural structures (such as pueblos), battlefields, or trails. Such resources are important to Native American groups for religious or historical reasons. Many DOE sites contain Native American resources and some sites have signed agreements with local tribes that designate certain rights to those tribes.

### **3.6.7.4 Paleontological Resources**

Paleontological resources are the physical remains, impressions, or traces of plant or animals from a former geological age. Paleontological remains consist of fossils and their associated geological information. The presence of such resources at a generic DOE site is dependent upon the past geologic history of the site.

### **3.6.8 Socioeconomics**

The socioeconomic characteristics of a generic DOE site will vary widely depending on whether the site is located near a large urbanized area or in a remote rural area. Statistics for employment and regional economy are defined for the regional economic area. Statistics for population, housing and community services are defined for the region of influence, which include the counties where nearly 90 percent of the DOE site's employees reside. Since the region of influence population for a generic DOE site could range from nearly 2,000,000 people for a site located in a large metropolitan area, to less than 200,000 for a site located in a small rural community, the socioeconomic impacts of the proposed action will vary immensely. The construction and operation of one or two new accelerators or a new research reactor at a generic DOE site are more likely to have an impact on housing and community services in a remote rural community than one located near a large metropolitan area. Likewise, the impacts on the regional economy and employment could also vary widely. Taking the unemployment rate into account, siting the new accelerator(s) or research reactor at a generic DOE site located in a rural area would have more of an impact on the economy than one located near a large metropolitan area.

If DOE were to select an alternative to build one or two new accelerators or a new research reactor, another EIS would be required to select the specific DOE site to locate the facility. In that document, DOE would perform a thorough evaluation of the socioeconomic impacts of the sites under consideration.

### 3.6.9 Existing Human Health Risk

#### 3.6.9.1 Radiation Exposure and Risk

Major sources and levels of background radiation exposure to individuals in the vicinity of the generic site where the new accelerator(s) and research reactor could be located are shown in **Table 3–44**. Annual background radiation doses to individuals are expected to remain constant over time. The total dose to the population changes as the population size changes. Background radiation doses are unrelated to accelerator(s) or reactor site operations.

**Table 3–44 Sources of Radiation Exposure to Individuals in the Vicinity Unrelated to Operation at the Accelerator(s) or Reactor Site**

Source	Effective Dose Equivalent (millirem per year)
<b>Natural background radiation</b>	
Cosmic radiation	27 to 48
External terrestrial radiation	28 to 74
Radon in homes (inhaled)	200
Internal terrestrial radiation	40
<b>Other background radiation</b>	
Diagnostic x-rays and nuclear medicine	53
Weapons test fallout	Less than 1
Air travel	1
Consumer and industrial products	10
<b>Total</b>	360 to 427

**Note:** Value of radon is an average for the United States.

**Source:** Evans et al. 1998:4-19; Hamilton et al. 1999.

Releases of radionuclides to the environment from accelerator(s) or reactor site operations provide another source of radiation exposure to individuals in the vicinity of the site. Types and quantities of radionuclides released from accelerator(s) or reactor site operations are listed in the annual radiological effluent release reports for the reference sites. The doses to the public resulting from these releases are presented in **Table 3–45**. (The data provides a range of consequences to the public based on those associated with DOE sites whose offsite consequences are expected to bound those from the accelerator(s) or reactor site.) These doses fall within radiological guidelines and limits (DOE Order 5400.5) and are small in comparison to background radiation.

Based on a risk estimator of 500 cancer deaths per 1 million person-rem to the public, the latent cancer fatality risk to the maximally exposed member of the public due to radiological releases from operations at the accelerator(s) or reactor site is estimated to range from  $1.1 \times 10^{-8}$  to  $2.2 \times 10^{-6}$  per year. That is, the estimated probability of this person dying of cancer at some point in the future from radiation exposure associated with 1 year of accelerator(s) or reactor site operations ranges from about 1 in 90 million to 1 in 450,000. Note that it takes several to many years from the time of exposure to radiation for a cancer to manifest itself.

Based on the same risk estimator, a range of  $1.2 \times 10^{-4}$  to  $3.0 \times 10^{-2}$  excess fatal cancers is projected in the population living within 80 kilometers (50 miles) of the accelerator(s) or reactor site from normal operations. To place these numbers into perspective, they can be compared with the numbers of fatal cancers expected in these populations from all causes. The 1990 mortality rate associated with cancer for the entire U.S. population was 0.2 percent per year. Based on this mortality rate, the number of fatal cancers expected from all causes in the population living within 80 kilometers (50 miles) of the accelerator(s) or reactor site

**Table 3–45 Radiation Doses to the Public from Normal Operation at the Accelerator(s) or Reactor Site (Committed Effective Dose Equivalent)**

Members of the Public	Atmospheric Releases		Liquid Releases		Total	
	Standard <sup>a</sup>	Actual	Standard <sup>a</sup>	Actual <sup>b</sup>	Standard <sup>a</sup>	Actual
Maximally exposed individual (millirem)	10	0.021 to 0.73	4	0 to 2.7	100	0.021 to 4.4 <sup>c</sup>
Population within 80 kilometers (person-rem)	None	0.23 to 12.3	None	0 to 48	None	0.23 to 60.3
Average individual within 80 kilometers (millirem) <sup>d</sup>	None	0.0019 to 0.014	None	0 to 0.055	None	0.0019 to 0.069

- The standards for individuals are given in DOE Order 5400.5. As discussed in that order, the 10-millirem-per-year limit from airborne emissions is required by the Clean Air Act, and the 4-millirem-per-year limit is required by the Safe Drinking Water Act; for this NI PEIS, the 4-millirem-per-year value is conservatively assumed to be the limit for the sum of doses from all liquid pathways. The total dose of 100 millirem per year is the limit from all pathways combined. The 100-person-rem value for the population is given in proposed 10 CFR Part 834, as published in 58 FR 16268. If the potential total dose exceeds the 100-person-rem value, it is required that the contractor operating the facility notify DOE.
- These doses are mainly from drinking water and eating fish.
- This total dose includes a conservative value of 1 millirem per year from direct radiation exposure.
- Obtained by dividing the population dose by the number of people living within 80 kilometers (50 miles) of the site.

Source: Evans et al. 1998:4-19; Hamilton et al. 1999.

ranged from 243 to 1,760. These numbers of expected fatal cancers are much higher than the estimated range of  $1.2 \times 10^{-4}$  to 0.030 fatal cancers that could result from operations at the accelerator(s) or reactor site.

At the accelerator(s) or reactor site, workers receive the same dose as the general public from background radiation but also receive an additional dose from working at the site. The range of the average worker and total worker dose from operations at the accelerator(s) or reactor site are presented in **Table 3–46**. These doses fall within radiological regulatory limits (10 CFR Part 20). Based on a risk estimator of 400 fatal cancers per 1 million person-rem among workers, the number of excess fatal cancers to accelerator(s) or reactor site workers from operations is estimated to range from 0.031 to 0.046 per year (DOE 1999d).

**Table 3–46 Annual Doses to Workers from Normal Operation at the Accelerator(s) or Reactor Site (Committed Effective Dose Equivalent)**

Occupational Personnel	Onsite Releases and Direct Radiation	
	Standard <sup>a</sup>	Actual
Average worker (millirem)	ALARA <sup>b</sup>	48 to 101
Total workers <sup>c</sup> (person-rem)	ALARA	78 to 115

- The radiological limit for an individual worker is 5,000 millirem per year. However, DOE's goal is to maintain radiological exposure as low as is reasonably achievable. It has therefore established the Administrative Control Level of 2,000 millirem per year; the site must make reasonable attempts to maintain individual worker doses below this level.
- As low as is reasonably achievable.
- The number of badged workers ranges from 1,141 to 1,614.

Source: 10 CFR Section 835.202; DOE 1999d.

### 3.6.9.2 Chemical Environment

The background chemical environment important to human health consists of the atmosphere, which may contain hazardous chemicals that can be inhaled; drinking water, which may contain hazardous chemicals that can be ingested; and other environmental media with which people may come in contact, for example, surface waters during swimming and soil through direct contact or via the food pathway.

**Carcinogenic Effects.** Health effects in this case are estimated as the incremental probability of an individual developing cancer over a lifetime as a result of exposure to the potential carcinogen. This could be incremental or excess individual lifetime cancer risks.

**Noncarcinogenic Effects.** Health effects in this case are determined by the ratio between the calculated or measured concentration of the chemical in the air and the reference concentration or dose. This ratio is known as the Hazard Quotient. Hazard Quotients for noncarcinogens are summed to obtain the Hazard Index. If the Hazard Index is less than 1, no adverse health effects would be expected.

Effective administrative and design controls that decrease hazardous chemical releases to the environment and help achieve compliance with permit requirements, such as air emissions and NPDES permit requirements, contribute toward minimizing potential health impacts to the public. The effectiveness of these controls is verified through the use of monitoring information and inspection of mitigation measures. Health impacts to the public may occur during normal operations at the accelerator(s) or reactor site via inhalation of air containing hazardous chemicals released to the atmosphere by site operations. Risks to public health from other possible pathways, such as ingestion of contaminated drinking water or direct exposure are low, relative to the inhalation pathway.

Exposure pathways for accelerator(s) or reactor site workers during normal operations may include inhaling the workplace atmosphere and direct contact with hazardous material associated with work assignments. Occupational exposure varies from facility to facility and from worker to worker, and available information is not sufficient to allow a meaningful estimation and summation of these impacts. However, workers are protected from hazards specific to the workplace through appropriate training, protective equipment, monitoring, and management controls. At the accelerator(s) or reactor site, workers are also protected by adherence to OSHA and EPA standards that limit workplace atmospheric and drinking water concentrations of potentially hazardous chemicals. Appropriate monitoring that reflects the frequency and amounts of chemicals used in the operational processes, ensures that these standards are not exceeded. Worker health conditions at the generic existing accelerator(s) or reactor site are expected to be substantially better than required by the standards.

### **3.6.9.3 Health Effects Studies**

Under Alternatives 3 and 4 of this NI PEIS, DOE would construct one or two accelerators or a research reactor at a generic DOE site for irradiation of targets to produce isotopes or for research. Once the specific sites are identified, DOE would review epidemiologic studies for the specific sites under consideration.

### **3.6.9.4 Accident History**

Accelerators and research reactors have been operating in the United States for many years. Accident information for these accelerators and research reactors, where applicable, can be found in documentation available from DOE and NRC. Estimates of potential accidents and their consequences can also be found in safety analysis reports and probabilistic risk assessments prepared by the accelerator or reactor owners and filed with NRC.

### **3.6.9.5 Emergency Preparedness**

The generic DOE accelerator(s) or reactor site would have a DOE-approved emergency management program that would be activated in the event of an accident. The programs are compatible with other Federal, state, and local plans and are thoroughly coordinated with all interested groups.

### **3.6.10 Environmental Justice**

As discussed in Appendix K, Executive Order 12898 directs Federal agencies to address disproportionately high and adverse health or environmental effects of alternatives on minority and low-income populations. The Executive order does not alter prevailing statutory interpretations under NEPA or existing case law. Regulations prepared by the Council on Environmental Quality remain the foundation for preparing environmental documentation in compliance with NEPA (40 CFR Parts 1500 through 1508) and the Council's guidelines for inclusion of environmental justice under NEPA (CEQ 1997). Specific locations must be designated before detailed reviews of Environmental Justice can be conducted.

### **3.6.11 Waste Management**

Waste management includes minimization, characterization, treatment, storage, transportation, and disposal of waste generated from ongoing DOE activities. The waste is managed using appropriate treatment, storage, and disposal technologies and in compliance with all applicable Federal and state statutes and DOE orders.

#### **3.6.11.1 Waste Inventories and Activities**

DOE facilities manage the following types of waste: high-level, transuranic, mixed transuranic, low-level radioactive, mixed low-level radioactive, hazardous, and nonhazardous. The volume of high-level radioactive waste currently stored in addition to expected generation for individual DOE sites ranges from 0 to about 213,000 cubic meters (280,000 cubic yards) (DOE 1997a:summary, 71). The volume of transuranic and mixed transuranic waste currently stored and projected through the year 2033 for individual DOE sites ranges from 0 to about 80,000 cubic meters (100,000 cubic yards). These volumes include estimates from environmental restoration, decontamination and decommissioning, and future Departmental missions, such as the disposition of weapons-usable plutonium at SRS (DOE 1997e:3).

Based on current inventories and 20 year projections, the disposal volume for low-level radioactive waste for individual DOE sites ranges from 0 to about 3.5 million cubic meters (4.6 million cubic yards) and the disposal volume for mixed low-level radioactive waste for individual DOE sites ranges from 0 to about 320,000 cubic meters (420,000 cubic yards). These volumes include waste resulting from waste management operations and environmental restoration activities (DOE 1998k:app. A). Hazardous waste is generated or exists at most DOE facilities. The annual volume for individual DOE sites ranges from 0 to about 640,000 metric tons per year. These volumes include both wastewater and nonwastewater, RCRA-defined waste only (it does not include Toxic Substance Control Act regulated hazardous waste, state-regulated hazardous waste, and environmental restoration-generated hazardous waste) (DOE 1997a:summary, 80).

Waste management and activities specific to each category of waste are discussed in the following sections.

#### **3.6.11.2 High-Level Radioactive Waste**

High-level radioactive waste is the highly radioactive waste resulting from the reprocessing of spent nuclear fuel including liquid waste produced directly in reprocessing and any solid material derived from the liquid waste that contains fission products in sufficient concentrations; and other highly radioactive material that is determined, consistent with existing law, to require permanent isolation (DOE Order 435.1). High-level waste is also a mixed waste because it contains hazardous constituents that are regulated under RCRA (DOE 1997a:1-27). Although the proposed plutonium-238 production, new medical and industrial isotope production, or new nuclear energy research and development activities would not generate high-level radioactive waste, some DOE facilities manage its transuranic waste as high-level waste. The high-level

radioactive waste Record of Decision issued on August 12, 1999 (64 FR 46661) states that immobilized high-level radioactive waste will be stored at the DOE site of generation until transfer to a geologic repository.

### **3.6.11.3 Transuranic and Mixed Transuranic Waste**

Transuranic waste is waste containing more than 100 nanocuries of alpha-emitting transuranic isotopes per gram of waste, with half-lives greater than 20 years and atomic number greater than 92, except for (a) high-level radioactive waste, (b) waste that the Secretary of Energy has determined, with the concurrence of the Administrator, does not need the degree of isolation required by the disposal regulations, or (c) waste that NRC has approved for disposal on a case-by-case basis in accordance with 10 CFR Part 61. Transuranic waste is produced during reactor fuel assembly, nuclear weapons production, research and development, and spent nuclear fuel processing. The transuranic waste Record of Decision, issued on January 20, 1998 (63 FR 3629), states that DOE will develop and operate mobile and fixed facilities to characterize and prepare transuranic waste for disposal at WIPP. Each DOE site that has or will generate transuranic waste will, as needed, prepare and store its transuranic waste on site.

### **3.6.11.4 Low-Level Radioactive Waste**

Low-level radioactive waste includes all radioactive wastes that is not classified as high-level radioactive waste, spent nuclear fuel, transuranic waste, uranium and thorium mill tailing, or waste from processed ore. Most low-level radioactive waste consists of relatively large amounts of waste materials contaminated with small amounts of radionuclides, such as contaminated equipment (e.g., gloveboxes, ventilation ducts, shielding, and laboratory equipment), protective clothing, paper, rags, packing material, and solidified sludges. Test specimens of fissionable material irradiated for research and development, only, and not for the production of power or plutonium, may be classified as low-level radioactive waste, provided the concentration of transuranics is less than 100 nanocuries per gram of waste. Low-level radioactive waste is subject to the Atomic Energy Act and is categorized as contact handled or remote handled, and as alpha or nonalpha on the basis of the types and levels of radioactivity present. However, most low-level radioactive waste contains short-lived radionuclides and generally can be handled without additional shielding or remote handling equipment (DOE 1997a:1-24). Currently, DOE sites which manage low-level radioactive waste treat and/or dispose of the waste on site or off site either at another DOE facility or commercial facility. The low-level radioactive waste and mixed low-level radioactive waste Record of Decision issued on February 18, 2000 (65 FR 10061), states that for the management of low-level radioactive waste, minimal treatment will be performed at all sites, and disposal will continue, to the extent practicable, on site at INEEL, LANL, ORR, and SRS. In addition, Hanford and the Nevada Test Site will be available to all DOE sites for low-level radioactive waste disposal.

### **3.6.11.5 Mixed Low-Level Radioactive Waste**

Mixed low-level radioactive waste contains both hazardous and low-level radioactive components. The hazardous component in mixed low-level radioactive waste is subject to RCRA, whereas the radioactive components are subject to the Atomic Energy Act (42 U.S.C. 2011 et seq.). Mixed low-level radioactive waste is characterized as either contact handled or remote handled and as alpha or nonalpha. Mixed low-level radioactive waste results from a variety of activities, including the processing of nuclear materials used in nuclear weapons production, and energy research and development activities. Although there are some commercial and DOE treatment facilities available, commercial and DOE facilities are insufficient to treat DOE's inventory of mixed low-level radioactive waste (DOE 1997a:1-24). Most of DOE's mixed low-level radioactive waste is being stored on site awaiting the development of treatment methods. DOE is subject to the requirements mandated by the Federal Facility Compliance Act of 1992, and most DOE facilities that currently store or generate mixed low-level radioactive waste have either a state-approved or EPA

region-approved Site Treatment Plan or another type of agreement. Each Site Treatment Plan or agreement requires treatment of mixed waste, including mixed low-level radioactive waste, in accordance with its provisions.

The low-level radioactive waste and mixed low-level radioactive waste Record of Decision, issued on February 18, 2000 (65 FR 10061), states that mixed low-level radioactive waste will be treated at Hanford, INEEL, ORR, and SRS and disposed of at Hanford and the Nevada Test Site.

#### **3.6.11.6 Hazardous Waste**

The quantities and types of hazardous waste generated as a result of DOE activities vary considerably and include acids, metals, industrial solvents, paints, oils, rags contaminated with hazardous cleaning compounds, and other hazardous materials that are byproducts of routine maintenance and operations. About 99 percent of DOE's hazardous waste is wastewater and is treated at DOE sites. Treatment residues and the remaining 1 percent, predominantly solvents and cleaning agents, are treated at commercial facilities. The hazardous waste Record of Decision, issued on August 5, 1998 (63 FR 41810), states that most DOE sites will continue to use offsite facilities for treatment and disposal of major portions of the nonwastewater hazardous waste, with ORR and SRS continuing to treat some of their own nonwastewater hazardous waste on site in existing facilities, where this is economically favorable.

#### **3.6.11.7 Nonhazardous Waste**

Nonhazardous and nonradioactive sanitary and industrial waste requires limited handling and can be treated or disposed of in properly designed facilities or used in energy production. DOE currently manages sanitary and industrial waste on a site-by-site basis. Some DOE sites dispose of this waste in onsite landfills that have permits issued by appropriate State agencies, while other sites use commercial landfills (DOE 1997a:1-29).

#### **3.6.11.8 Waste Minimization**

The DOE complex-wide waste reduction goals for achievement by December 31, 1999 (compared to the 1993 Baseline) are to reduce low-level radioactive waste, mixed low-level radioactive waste, and hazardous waste generation by 50 percent, and nonhazardous waste by 33 percent (DOE 1999f:1).

#### **3.6.12 Spent Nuclear Fuel**

The operation of the new reactor will generate nuclear spent fuel at a rate of about 0.31 metric tons of heavy metal per year (Appendix E of this NI PEIS). The Nuclear Waste Policy Act of 1982, as amended, assigned the Secretary of Energy the responsibility for the development of a repository for the disposal of high-level radioactive waste and spent nuclear fuel. When such a repository is available, spent nuclear fuel would be transferred for disposal from the nuclear reactor site to the repository. Until a repository is available, spent nuclear fuel generated from the operation of the new reactor is expected to be stored on site in the reactor spent fuel pool, which provides the capacity for spent fuel generated from 35 years of operation.

## Chapter 4

# Environmental Consequences

The impact analyses in Chapter 4 focus on those areas where the potential exists for effects on the environment. Each of the options, including the four options under the No Action Alternative, the six options under the Restart Fast Flux Test Facility Alternative, the nine options under the Use Only Existing Operational Facilities Alternative, the three options under the Construct New Accelerator(s) Alternative, the three options under the Construct New Research Reactor Alternative, and the one option under the Permanently Deactivate Fast Flux Test Facility (with No New Missions) Alternative, is discussed separately in Sections 4.2 through 4.7. The cumulative impacts associated with the alternatives are presented in Section 4.8. A detailed discussion of each alternative is given in Chapter 2; a comparison of the environmental effects among alternatives and among options within alternatives is presented in Section 2.7.1.

### 4.1 INTRODUCTION

In this *Final Programmatic Environmental Impact Statement for Accomplishing Expanded Civilian Nuclear Energy Research and Development and Isotope Production Missions in the United States, Including the Role of the Fast Flux Test Facility (Nuclear Infrastructure Programmatic Environmental Impact Statement [NI PEIS])*, the impact analyses assess all disciplines where the potential exists for effects on the environment, as follows:

- Land resources
- Noise
- Air quality
- Water resources
- Geology and soils
- Ecological resources
- Cultural and paleontological resources
- Socioeconomics
- Public and occupational health and safety (associated with normal operations, facility accidents, and transportation)
- Environmental justice
- Waste management
- Spent nuclear fuel management

These disciplines are analyzed in a manner commensurate with their importance under a specific option—the sliding-scale assessment approach. For example, under all options of Alternative 2 (Use Only Existing Operational Facilities), the U.S. Department of Energy (DOE) has determined that minimal or no impacts would be associated with land resources, noise, water resources, geology and soils, ecological resources, and cultural and paleontological resources. This is because existing facilities in developed areas would be used, no new land disturbance would take place, proposed activities would be consistent with current operations, and wastewater discharges would continue through permitted outfalls. Therefore, impacts associated with these resources are assessed in less detail. Where construction and decommissioning are integral parts of an option (all options under both Alternative 3 [Construct New Accelerator(s)] and Alternative 4 [Construct New Research Reactor]), the impacts associated with such construction and decommissioning are included in the assessments, and disciplines such as land resources and noise are assessed in more detail. The sliding-scale assessment approach has been applied in the evaluation of all the options addressed in this NI PEIS.

The environmental consequences associated with the alternatives assessed in this NI PEIS were generally calculated using appropriate computer models and by applying facility operational characteristics from

Appendixes A through F. The analyses were performed in accordance with the impact assessment methods described in Appendix G. More detailed descriptions of the development of the impacts for some resource areas are presented in Appendixes H through L, as follows:

- Appendix H, Evaluation of Human Health Effects from Normal Facility Operations
- Appendix I, Evaluation of Human Health Effects from Facility Accidents
- Appendix J, Evaluation of Human Health Effects of Transportation
- Appendix K, Environmental Justice Analysis
- Appendix L, Socioeconomic Analysis

The results of the assessments of environmental consequences associated with the various alternatives and their options are presented in this chapter. For brevity, numerical results are often rounded. Portions of some alternative options are equivalent. For example, for Alternative 2 (Use Only Existing Operational Facilities), the Radiochemical Engineering Development Center (REDC) at the Oak Ridge Reservation (ORR) would be used to fabricate and process the neptunium-237 targets under Options 1, 4, and 7. Therefore, the activities at REDC would be virtually the same for these three alternative options. The organization of Chapter 4 takes advantage of these equivalencies. When the impacts have already been described for a previous alternative or alternative option, the later impacts discussion provides a reference to the earlier section, rather than repeating the information.

## 4.2 NO ACTION ALTERNATIVE

Under the No Action Alternative (maintain status quo), Fast Flux Test Facility (FFTF) would be maintained in standby status for all or a portion of the 35-year evaluation period for operations covered in this NI PEIS. For the purpose of analysis in this NI PEIS, the maximum period of 35 years was assumed. Ongoing operations at existing facilities as described in Chapter 3, Affected Environment, would continue under this alternative. DOE would not establish a domestic plutonium-238 production capability, but could, instead, continue to purchase Russian plutonium-238 to meet the needs of future U.S. space missions. For the purpose of analysis in this NI PEIS, DOE assumed that it would continue to purchase plutonium-238 to meet the space mission needs for the 35-year evaluation period. DOE would continue its medical and industrial isotope production and civilian nuclear energy research and development activities at the current operating levels of existing facilities. A consequence of a No Action decision would be the need to determine the future of the neptunium-237 stored at the Savannah River Site (SRS). Therefore, the impacts of possible future transportation and storage of neptunium-237 are evaluated as part of the No Action Alternative. Four options are identified. If DOE decides not to establish a domestic plutonium-238 production capability in the future, the neptunium-237 would have no programmatic value and Option 1 would be selected. Conversely, if DOE decides to maintain the capability to establish a domestic plutonium-238 capability in the future, the inventory of neptunium-237 must be retained. In this case, Option 2, 3, or 4 could be selected.

- **Option 1.** Under this option, DOE would reconsider its stabilization strategy for the neptunium-237, currently stored in solution form at SRS, possibly leading to final disposition. The current plan is to stabilize the material to oxide, as described in the Supplemental Record of Decision for the *Final Environmental Impact Statement, Interim Management of Nuclear Materials at SRS* (62 FR 61099). This Record of Decision would be amended or new NEPA analysis performed, if necessary.
- **Options 2 through 4.** Under these options, the neptunium-237 oxide would be transported from SRS to one of three candidate DOE sites for up to 35 years of storage. For the purpose of analysis in this NI PEIS, the maximum period of 35 years was assumed. Option 2 would provide storage at the Oak Ridge National Laboratory's (ORNL) REDC facility, Option 3 at Idaho National Engineering and Environmental Laboratory's (INEEL) Building CPP-651, and Option 4 at the Hanford Site's (Hanford) Fuels and Materials Examination Facility (FMEF).

Each of the four options under the No Action Alternative includes importing plutonium-238 from Russia and maintaining FFTF in standby. Option 1 includes no other activities, whereas the other three options include the transportation of neptunium-237 from SRS to, and storage at, another DOE site. Under Option 2, this neptunium would be stored at ORR in REDC, under Option 3 at INEEL in Building CPP-651, and under Option 4 at Hanford in FMEF.

### 4.2.1 No Action Alternative—Option 1

Under Option 1, the United States would continue to purchase the plutonium-238 from Russia that is needed to fabricate radioisotope power systems for future U.S. space missions. As part of this option, FFTF at Hanford would be maintained in standby. This option does not include the transportation of neptunium-237 from SRS and its storage at another DOE site, as do the other three options under the No Action Alternative.

#### 4.2.1.1 Importation of Plutonium-238 from Russia

Activities and impacts associated with transporting plutonium-238 to the United States from Russia are evaluated in two other NEPA documents: *Environmental Assessment of the Import of Russian Plutonium-238* (*Russian Plutonium-238 EA*) (DOE 1993a), and *Finding of No Significant Impact for Import of Russian*

*Plutonium-238 Fuel* (DOE 1993b). The proposed action in the *Russian Plutonium-238 EA* is to import up to 40 kilograms (88 pounds) of plutonium-238 fuel (isotopic mass) in dioxide form from Russia to supplement the current U.S. inventory. The action includes the transportation by ship of Russian plutonium-238 in 5-kilogram (11-pound) increments from St. Petersburg, Russia, to a U.S. port of entry. From the U.S. port of entry, the plutonium-238 would be ground transported by DOE safe, secure trailer/SafeGuards Transport (SST/SGT) to Los Alamos National Laboratory (LANL) in New Mexico and would be added to LANL's portion of the existing U.S. plutonium-238 inventory. As of November 2000, two shipments have been safely and securely transported to LANL.

The dose to transportation workers associated with importing 40 kilograms (88 pounds) of plutonium-238 to LANL was reported to be 2.6 person-rem; the dose to the public would be 4.5 person-rem. Accordingly, incident-free transportation of plutonium-238 would result in 0.0011 latent cancer fatality among transportation workers and 0.0023 latent cancer fatality in the total affected population over the duration of the transportation activities. The number of nonradiological fatalities from vehicular emissions was not reported (DOE 1993a).

The reported transportation accident risks under this option are as follows: a radiological dose to the population of 0.2 person-rem, resulting in  $1.0 \times 10^{-4}$  latent cancer fatality; and traffic accidents resulting in 0.0032 traffic fatality. These estimates include the risk to the crew, handlers, and the public during both ocean and highway transportation. DOE considered the environmental consequences on global commons (i.e., portions of the ocean not within the territorial boundary of any nation) in accordance with Executive Order 12114 (44 FR 1957) (DOE 1993a).

The risk estimated for importing 40 kilograms (88 pounds of plutonium-238) can be scaled to estimate the risk of importing 175 kilograms (5 kilograms per year times 35 years) (385 pounds) of plutonium-238 over the 35-year period covered by this NI PEIS. Approximately 35 shipments of plutonium-238 would be made by DOE. The total distance traveled on public roads by trucks carrying radioactive materials would be 114,000 kilometers (71,000 miles); and at sea by ships carrying plutonium-238, 298,000 kilometers (161,000 nautical miles).

The transportation impacts analysis is described in detail in Appendix J.

**IMPACTS OF INCIDENT-FREE TRANSPORTATION.** The dose to transportation workers from all transportation activities entailed by this option has been estimated at 12 person-rem; the dose to the public would be 20 person-rem. Accordingly, incident-free transportation of radioactive material would result in 0.0046 latent cancer fatality among transportation workers and 0.0099 latent cancer fatality in the total affected population over the duration of the transportation activities. Latent cancer fatalities associated with radiological releases were estimated by multiplying the occupational (worker) dose by  $4.0 \times 10^{-4}$  latent cancer fatality per person-rem of exposure, and the public accident and accident-free doses by  $5.0 \times 10^{-4}$  latent cancer fatality per person-rem of exposure (ICRP 1991). The estimated number of nonradiological fatalities from vehicular emissions associated with this option is  $4.7 \times 10^{-4}$ .

**IMPACTS OF ACCIDENTS DURING TRANSPORTATION.** Estimates of the total ground transportation accident risks under this option are as follows: a radiological dose to the population of 0.88 person-rem, resulting in  $4.4 \times 10^{-4}$  latent cancer fatality; and traffic accidents resulting in 0.014 traffic fatality.

#### **4.2.1.2 Maintenance of FFTF in Standby**

The environmental impacts associated with maintaining FFTF in standby for 35 years are discussed in the following sections.

#### 4.2.1.2.1 Land Resources

**LAND USE.** Maintaining FFTF in standby would not change land use in the 400 Area for 35 years because maintenance activities would not require the development of additional land areas. Further, maintenance activities are consistent with the site's industrial nature.

**VISUAL RESOURCES.** Impacts on visual resources would not change for 35 years because no new construction or modification of existing structures would be required. Since there would be no change in the appearance of FFTF, the current Visual Resource Management Class IV rating for the 400 Area would continue for 35 years.

#### 4.2.1.2.2 Noise

Maintaining FFTF in standby would not involve any new construction, major change in activities, or change in employment. Thus, there would be no change in noise impacts on wildlife around the 400 Area or on people near Hanford and this would be expected to continue for the next 35 years to the extent it is dependent on activities at FFTF.

#### 4.2.1.2.3 Air Quality

Maintaining FFTF in standby for 35 years would not involve any new construction, change in activities, or change in employment. Thus, there would be no change in nonradiological air quality at Hanford. Emissions from maintaining FFTF in standby would be expected to continue for the next 35 years.

#### 4.2.1.2.4 Water Resources

Impact on water resources associated with maintaining FFTF in standby for 35 years would include the continuation of groundwater withdrawals and process and sanitary wastewater discharges associated with Hanford 400 Area facilities (**Table 4–1**). Specifically, groundwater withdrawals by 400 Area facilities (mainly FFTF) would continue to average about 197 million liters (52 million gallons) per year. The discharge of approximately 76 million liters (20 million gallons) per year of FFTF cooling water to the 400 Area process sewer system and the 400 Area Pond (i.e., 4608 B/C percolation ponds) would continue. Also, it is expected that 400 Area sanitary wastewater flows of about 3.8 million liters (1 million gallons) annually could continue to be discharged to Energy Northwest for treatment. However, as groundwater use during standby would not be expected to affect regional groundwater levels and effluents would continue to be discharged to appropriate treatment facilities, the overall impact on water resources at Hanford should be negligible (DOE 2000a:11; Nielsen 1999:38, 39, 41). Further information on current water usage, effluent discharge, and water quality at Hanford is presented in Section 3.4.4.

**Table 4–1 Water Use and Wastewater Generation Associated with Maintaining FFTF in Standby Under All Options of the No Action Alternative**

Indicator (million liters per year)	Hanford 400 Area
	FFTF
Water use	197
Process wastewater generation	76
Sanitary wastewater generation	3.8

**Note:** To convert from liters per year to gallons per year, multiply by 0.264.

**Source:** DOE 2000a:11; Nielsen 1999:38, 39, 41.

#### **4.2.1.2.5 Geology and Soils**

Maintaining FFTF in standby for 35 years would not involve new construction. Therefore, geologic and soil resources in the 400 Area would not be disturbed. In the *Storage and Disposition of Weapons-Usable Fissile Materials Final Programmatic Environmental Impact Statement (Storage and Disposition PEIS)* (DOE 1996a:4-45), hazards from large-scale geologic conditions at Hanford, such as earthquakes and volcanoes, were evaluated. That analysis was reviewed in the *Surplus Plutonium Disposition Final Environmental Impact Statement (Surplus Plutonium Disposition EIS)* (DOE 1999a:4-260). Further review of the data and analyses presented in these referenced documents and the site-specific data presented in this NI PEIS indicates that the large-scale geologic conditions continue to present a low risk to FFTF. Ground shaking of Modified Mercalli Intensity V to VII (refer to Table 3–4) associated with postulated earthquakes would be expected to primarily affect the integrity of inadequately designed or nonreinforced structures. Damage to properly or specially designed or upgraded facilities would not be expected. Also, only minimal effects (e.g., ashfall) would be expected from postulated volcanic events in the Cascade Region. The potential for other nontectonic events to affect the facility is also low.

As stated in DOE Order 420.1, DOE requires that nuclear or nonnuclear facilities be designed, constructed, and operated so that the public, the workers, and the environment are protected from the adverse impacts of natural phenomena hazards, including earthquakes. DOE Order 420.1, Section 4.4, as supplemented by DOE Guide 420.1-2, stipulates the natural phenomena hazards mitigation requirements for DOE facilities and specifically provides for the reevaluation and upgrade of existing DOE facilities when there is a significant degradation in the safety basis for the facility. DOE uses the requirements of the latest model building codes and national standards to mitigate the consequences of natural phenomena hazards. Further, the natural phenomena hazards mitigation requirements of DOE Order 420.1 are consistent with the guidance for seismic design and construction contained in the National Earthquake Hazards Reduction Program 1997 provisions (BSSC 1997). In addition, DOE Guide 420.1-2 was recently issued to recognize the consolidation of the three previous U.S. model building codes, including the Uniform Building Code, into the *International Building Code* (ICC 2000). The DOE requirements for seismic engineering have followed the Uniform Building Code, unless the importance of achieving a high level of protection warrants the use of more demanding methods and criteria (DOE Guide 420.1-2). As necessary, the need to evaluate and upgrade existing DOE facilities with regard to natural geologic hazards would be assessed in accordance with DOE Order 420.1.

#### **4.2.1.2.6 Ecological Resources**

Maintaining FFTF in standby for 35 years would not involve new construction or other disturbance to the natural environment. As noted in Section 4.2.1.2.2, there would be no change in noise impacts on wildlife. Impacts on wetlands and aquatic resources (associated with manmade ponds on the site) would not change because water usage and wastewater discharge would not change. Due to the developed nature of the area and because no construction would take place, impacts on threatened and endangered species would not occur.

Consultation letters concerning threatened and endangered species were sent to the U.S. Fish and Wildlife Service, the National Marine Fisheries Service, the Washington State Department of Natural Resources, and the State of Washington Department of Fish and Wildlife (see Table 5–3). Each agency was asked to provide information on potential impacts of the proposed action on threatened and endangered species. Both the Washington State Department of Natural Resources and the State of Washington Department of Fish and Wildlife provided lists of state species of concern that occur in the vicinity of the project area. As noted above, no impacts to any threatened or endangered species are expected, including those of concern to these agencies. While DOE has made additional contacts with the U.S. Fish and Wildlife Service and the National Marine Fisheries Service, responses are pending from these agencies. Although no federally listed species are

expected to be impacted by the proposed action, no action would be taken relative to the use of facilities at Hanford prior to the receipt of input from these Federal agencies.

#### **4.2.1.2.7 Cultural and Paleontological Resources**

Maintaining FFTF in standby for 35 years would not involve new construction and, thus, would not disturb cultural and paleontological resources in the 400 Area. No prehistoric, historic, or paleontological sites have been identified either in the 400 Area or within 2 kilometers (1.2 miles) of the 400 Area. Six buildings in the 400 Area, including two FFTF structures (the Reactor Containment Building and the FFTF Control Building), are eligible for the National Register of Historic Places as contributing properties in the Historic District recommended for mitigation. Maintaining FFTF in standby for 35 years would not affect the status of these structures. No Native American resources are known to occur in the 400 Area.

Consultation to comply with Section 106 of the National Historic Preservation Act was conducted with the State Historic Preservation Office (see Table 5–3) and resulted in concurrence by the State Historic Preservation Office that the proposed action would have no effect on historic properties at Hanford. Consultation was also conducted with interested Native American tribes that resulted in comments at public hearings by members representing the Nez Perce and Confederated Tribes of the Umatilla Indian Reservation. Responses to their specific comments are addressed in Volume 3.

#### **4.2.1.2.8 Socioeconomics**

Under the No Action Alternative, FFTF would continue to be maintained in standby for 35 years. Current employment of approximately 242 workers would be continued for the next 35 years (Nielsen 1999). No new employment or in-migration of workers would be required. Thus, there would be no additional impact on the socioeconomic conditions around Hanford.

#### **4.2.1.2.9 Public and Occupational Health and Safety—Normal Standby Activities**

Assessments of radiological and chemical impacts associated with this option are presented in this section. Supplemental information is provided in Appendix H.

**RADIOLOGICAL IMPACTS.** Potential radiological doses to three receptor groups are given in **Table 4–2**: the population within 80 kilometers (50 miles) of FFTF in the year 2020 (approximate midlife of the nuclear infrastructure activities assessed in this NI PEIS), the maximally exposed member of the public, and the average exposed member of the public. The projected number of latent cancer fatalities in the surrounding population and the latent cancer fatality risk to the maximally and average exposed individuals are also presented in the table.

**Table 4–2 Radiological Impacts on the Public Around Hanford from Maintaining FFTF in Standby Under All Options of the No Action Alternative**

Receptor	Standby
<b>Population within 80 kilometers (50 miles) in the year 2020</b>	
Dose (person-rem)	0.028
35-year latent cancer fatalities	$4.9 \times 10^{-4}$
<b>Maximally exposed individual</b>	
Annual dose (millirem)	$1.4 \times 10^{-4}$
35-year latent cancer fatality risk	$2.4 \times 10^{-9}$
<b>Average exposed individual within 80 kilometers (50 miles)</b>	
Annual dose <sup>a</sup> (millirem)	$5.7 \times 10^{-5}$
35-year latent cancer fatality risk	$9.9 \times 10^{-10}$

a. Obtained by dividing the population dose by the number of people projected to live within 80 kilometers (50 miles) of FFTF in the year 2020 (503,300).

**Source:** Model results, using the GENII computer code (Napier et al. 1988).

Probability coefficients for determining the likelihood of a latent cancer fatality, given a dose, are taken from the *1990 Recommendations of the International Commission on Radiological Protection* (ICRP 1991). A probability coefficient of  $5 \times 10^{-4}$  latent cancer fatality per rem is applied for the public, and a coefficient of  $4 \times 10^{-4}$  latent cancer fatality per rem is applied for workers. The value for workers is lower due to the absence of children and the elderly, who are more radiosensitive.

A collective dose of 0.028 person-rem would be incurred by the surrounding population in the year 2020. The corresponding number of latent cancer fatalities in this population from 35 years of maintaining FFTF in standby would be  $4.9 \times 10^{-4}$ . Here, and throughout this document, a latent cancer fatality value of less than one can be related to the statistical probability of a latent cancer fatality. The most probable outcome of a population dose of 0.028 person-rem would be no latent cancer fatalities. However, in a small number of cases, this dose would result in a latent cancer fatality. The lower the number of cases, the less likely is this outcome. This issue is addressed in more detail in Appendix H.

An annual dose of  $1.4 \times 10^{-4}$  millirem is shown for the maximally exposed individual. From 35 years of standby activities, the corresponding risk of a latent cancer fatality to this individual would be  $2.4 \times 10^{-9}$ .

The expected average dose to a worker involved with storage activities while FFTF is maintained in standby and the associated expected dose to the total storage workforce would be 3.5 millirem and 0.69 person-rem, respectively (refer to **Table 4–3**). The associated risk of a latent cancer fatality to the average worker from 35 years of standby activities would be  $4.9 \times 10^{-5}$ , and the estimated number of latent cancer fatalities in the total workforce from 35 years of operations would be 0.0097.

**Table 4–3 Radiological Impacts on FFTF Workers from Maintaining FFTF in Standby Under All Options of the No Action Alternative**

Receptor—No Action Workers <sup>a</sup>	Standby
Total dose (person-rem per year)	0.69 <sup>b</sup>
35-year latent cancer fatalities	0.0097
Average worker dose (millirem per year)	3.5
35-year latent cancer fatality risk	$4.9 \times 10^{-5}$

a. The radiological limit for an individual worker is 5,000 millirem per year (10 CFR Part 835). However, the maximum dose to a worker involved with storage operations would be kept below the DOE Administrative Control Level of 2,000 millirem per year (DOE 1999j). Further, DOE recommends that facilities adopt a more limiting, 500 millirem per year, Administrative Control Level (DOE 1999j). To reduce doses to levels that are as low as is reasonably achievable (ALARA), an effective ALARA program would be enforced.

b. Based on an estimated 200 workers.

Source: Nielsen 1999.

**HAZARDOUS CHEMICAL IMPACTS.** No new chemicals would be introduced by maintaining FFTF in standby. Thus, there would be no change in impacts from emissions of hazardous chemicals. Emissions of hazardous air pollutants from maintaining FFTF in standby, would be expected to continue for the next 35 years.

#### 4.2.1.2.10 Public and Occupational Health and Safety—Standby Accidents

In its current standby condition, FFTF is defueled with slightly radioactive sodium circulating through the primary heat transport system. A primary heat transport system sodium spill would be the accident with the highest consequences. A detailed description of the accident analysis is provided in Appendix I.

Estimates of radiological consequences have been developed for the maximally exposed individual, the offsite population within 80 kilometers (50 miles) of FFTF, and a noninvolved worker at a distance of 640 meters (0.4 miles) from the release point. Consequences are presented in terms of radiological dose (in rem) and the probability that the dose would result in a latent cancer fatality. Accident risk is defined as the product of the accident probability (i.e., accident frequency) and the accident consequence. In this NI PEIS, risk is expressed as the increased likelihood of a latent cancer fatality per unit of time (i.e., 1 year or 35 years) for an individual (the maximally exposed offsite individual or a noninvolved worker), and as the increased number of latent cancer fatalities per unit of time (i.e., 1 year or 35 years) in the offsite population.

Consequences to involved workers are addressed Appendix I, Section I.1.7.

Probability coefficients for determining the likelihood of a latent cancer fatality, given a dose, are taken from the *1990 Recommendations of the International Commission on Radiological Protection* (ICRP 1991). For low doses or dose rates, a probability coefficient of  $4 \times 10^{-4}$  latent cancer fatality per rem is applied for workers, and  $5 \times 10^{-4}$  latent cancer fatality per rem for the public. For high doses received at a high rate, probability coefficients of  $8 \times 10^{-4}$  and 0.001 latent cancer fatality per rem are applied for workers and the public, respectively. These higher probability coefficients apply for doses above 20 rads and dose rates above 10 rads per hour.

Potential consequences and associated risks are presented in **Tables 4–4** and **4–5**, respectively.

**Table 4–4 FFTF Standby Accident Consequences Under All Options of the No Action Alternative**

Accident	Maximally Exposed Individual		Population to 80 Kilometers (50 Miles)		Noninvolved Worker	
	Dose (rem)	Latent Cancer Fatality <sup>a</sup>	Dose (person-rem)	Latent Cancer Fatalities <sup>b</sup>	Dose (rem)	Latent Cancer Fatality <sup>a</sup>
Primary heat transport system sodium spill	$1.34 \times 10^{-7}$	$6.70 \times 10^{-11}$	$9.99 \times 10^{-3}$	$4.99 \times 10^{-6}$	$1.62 \times 10^{-8}$	$6.48 \times 10^{-12}$

a. Likelihood of a latent cancer fatality.

b. Number of latent cancer fatalities.

Source: Model results, using the MACCS2 computer code (Chanin and Young 1997).

**Table 4–5 FFTF Standby Accident Risks Under All Options of the No Action Alternative**

Accident (Frequency)	Maximally Exposed Individual <sup>a</sup>	Population to 80 Kilometers (50 Miles) <sup>b</sup>	Noninvolved Worker <sup>a</sup>
Annual primary heat transport system sodium spill risk ( $1 \times 10^{-4}$ )	$6.70 \times 10^{-15}$	$4.99 \times 10^{-10}$	$6.48 \times 10^{-16}$
35-year risk	$2.35 \times 10^{-13}$	$1.75 \times 10^{-8}$	$2.27 \times 10^{-14}$

a. Increased likelihood of a latent cancer fatality.

b. Increased number of latent cancer fatalities.

Source: Model results, using the MACCS2 computer code (Chanin and Young 1997).

With FFTF in standby for 35 years, the increased risk of a latent cancer fatality to the maximally exposed individual and to a noninvolved worker would be  $2.35 \times 10^{-13}$  and  $2.27 \times 10^{-14}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be  $1.75 \times 10^{-8}$ .

The 35-year risks are conservative because they are based on current primary sodium radioactivity levels. The radioisotopes contained in the primary sodium are sodium-22, cesium-137, plutonium-239, and tritium. Examining the current inventories, half-lives, and dose conversion factors of these isotopes, it was determined that currently 99 percent of the dose is attributable to plutonium-239 and sodium-22, with sodium-22 accounting for 78 percent of the total dose. Plutonium-239 has a 24,400-year half-life and would have only decayed 0.1 percent after 35 years. Sodium-22, however, has a 2.6-year half-life and would have decayed over 99.99 percent after 35 years. In year 35, only 21 percent of the original total dose level would remain. The annual risks would decrease each year due mainly to the radioactive decay of sodium-22. Therefore, if the annual risks were recalculated for each subsequent year based on lower activity levels and then summed for the 35-year period, the resulting risks would be lower than those presented.

Maintaining FFTF in standby would not introduce any additional operations that require the use of hazardous chemicals. Thus, there would be no postulated hazardous chemical accidents attributable to maintaining FFTF in standby.

#### 4.2.1.2.11 Public and Occupational Health and Safety—Transportation

There would be no transportation impacts associated with maintaining FFTF in standby.

#### 4.2.1.2.12 Environmental Justice

As discussed in other parts of Section 4.2.1.2, normal and incident-free operations required to maintain FFTF in standby pose no significant risks to the public. For 35 years of normal standby operations, FFTF would be a small contributor to baseline emissions from the Hanford Site. Chemical emissions would not be altered and no transportation impacts are associated with maintenance of FFTF in standby. As discussed in Appendix K,

under the conservative assumption that all food consumed in the potentially affected area during the 35-year operational period would be radioactively contaminated, no credible pattern of food consumption would pose a significant radiological health risk due to ingestion of contaminated food supplies. Radiological risks to the public due to accidents occurring at FFTF while in standby would be essentially zero. Thus, maintaining FFTF in standby would pose no disproportionately high and adverse risks to minority or low-income populations.

#### 4.2.1.2.13 Waste Management

The expected generation rates of waste at Hanford that would be associated with maintaining FFTF in standby for 35 years are compared with Hanford's treatment, storage, and disposal capacities in **Table 4-6**. The impacts on the Hanford waste management systems, in terms of managing the waste, are discussed in this section. Radiological and chemical impacts on workers and the public from waste management activities are included in the public and occupational health and safety impacts that are given in Sections 4.2.1.2.9 through 4.2.1.2.11.

**Table 4-6 Waste Management Impacts of Maintaining FFTF in Standby Under All Options of the No Action Alternative**

Waste Type <sup>a</sup>	Estimated Waste Generation for FFTF in Standby (cubic meters per year)	Estimated Waste Generation as a Percent of <sup>b</sup>		
		Onsite Treatment Capacity	Onsite Storage Capacity	Onsite Disposal Capacity
<b>Low-level radioactive waste</b>				
Liquid	<6	(c)	(c)	(c)
Solid	17	NA	NA	0.03
<b>Mixed low-level radioactive waste</b>	<0.5	NA	0.11	0.13
<b>Hazardous</b>	4 <sup>d</sup>	NA	NA	NA
<b>Nonhazardous</b>				
Process wastewater	76,000	(c)	(c)	(c)
Sanitary wastewater	3,800	1.6 <sup>e</sup>	NA	NA
Solid	120	NA	NA	NA

a. See definitions in Section G.9.

b. The estimated amounts of waste generated annually are compared with the annual site treatment capacities. The estimated total amounts of waste generated over the assumed 35-year operational period are compared with the site storage and disposal capacities.

c. Refer to the text.

d. Represents both liquid and solid hazardous waste.

e. Percent of capacity of the Energy Northwest Sewage Treatment Facility.

**Note:** To convert from cubic meters per year to cubic yards per year, multiply by 1.308; < means "less than."

**Key:** NA, not applicable (i.e., the majority of this waste is not routinely treated, stored, or disposed of on site; refer to the text).

**Source:** DOE 2000a; Nielsen 1999.

In accordance with the Records of Decision for the *Final Waste Management Programmatic Environmental Impact Statement for Managing Treatment, Storage, and Disposal of Radioactive and Hazardous Waste (Waste Management PEIS)* (DOE 1997a), waste could be treated and disposed of on site at Hanford or at other DOE sites or commercial facilities. Based on the Record of Decision for hazardous waste issued on August 5, 1998 (63 FR 41810), nonwastewater hazardous waste would continue to be treated and disposed of at offsite commercial facilities. Based on the Record of Decision for low-level radioactive waste and mixed low-level radioactive waste issued on February 18, 2000 (65 FR 10061), minimal treatment of low-level radioactive waste will be performed at all sites and, to the extent practicable, onsite disposal of low-level radioactive waste will continue. Hanford and the Nevada Test Site will be made available to all DOE sites for disposal of low-level radioactive waste. Mixed low-level radioactive waste analyzed in the *Waste Management*

PEIS will be treated at Hanford, INEEL, ORR, and SRS and will be disposed of at Hanford and the Nevada Test Site.

It is also assumed in this NI PEIS that low-level radioactive waste, mixed low-level radioactive waste, hazardous waste, and nonhazardous waste would be treated, stored, and disposed of in accordance with current and developing site practices. No high-level radioactive waste or transuranic waste would be associated with maintaining FFTF in standby.

Solid low-level radioactive waste associated with maintaining FFTF in standby would continue to be compacted, if possible, and packaged in appropriate containers or burial casks, certified, and transferred for disposal in the existing onsite low-level radioactive Burial Grounds.

Six hundred cubic meters (780 cubic yards) of solid low-level radioactive waste would be generated over the 35-year period as a result of maintaining FFTF in standby. This solid low-level radioactive waste represents approximately 0.03 percent of the 1.74-million-cubic-meter (2.28-million-cubic-yard) capacity of the low-level radioactive Burial Grounds. Using the 3,480-cubic-meter-per-hectare (1,842-cubic-yard-per-acre) disposal land usage factor for Hanford published in the *Storage and Disposition PEIS* (DOE 1996a:E-9), 600 cubic meters (780 cubic yards) of waste would require 0.17 hectare (0.42 acre) of disposal space at Hanford. The impacts of managing this low-level radioactive waste at Hanford would be minimal.

Maintaining FFTF in standby would result in 210 cubic meters (275 cubic yards) of liquid low-level radioactive waste over the 35-year period. Liquid low-level radioactive waste associated with maintaining FFTF in standby would continue to be stored in FFTF or the Maintenance and Storage Facility and transported, as necessary, to the 200 Area Effluent Treatment Facility for processing and disposal. This liquid low-level radioactive waste resulting from maintaining FFTF in standby represents a very small amount of waste that can be managed by the 200 Area Liquid Effluent Treatment Facility, which has a capacity of 0.57 cubic meter per minute (0.75 cubic yard per minute).

Mixed low-level radioactive waste would be stabilized, packaged, and stored on site for treatment and disposal in a manner consistent with the Tri-Party Agreement (EPA et al. 1989) for Hanford. Over the 35-year period, it is estimated that less than 18 cubic meters (24 cubic yards) of mixed low-level radioactive waste would be generated as a result of maintaining FFTF in standby. This mixed low-level radioactive waste is expected to be treated at a nearby commercial facility. This waste is also estimated to be less than 0.11 percent of the 16,800-cubic-meter (22,000-cubic-yard) storage capacity of the Central Waste Complex and less than 0.13 percent of the 14,200-cubic-meter (18,600-cubic-yard) planned disposal capacity of the Radioactive Mixed Waste Disposal Facility. Therefore, this waste would only have a minimal impact on the management of mixed low-level radioactive waste at Hanford.

Hazardous waste generated during maintaining FFTF in standby would be packaged in U.S. Department of Transportation (DOT)-approved containers and shipped off site to permitted commercial recycling, treatment, and disposal facilities. The waste load generated during the 35-year period would have only a minimal impact on the Hanford hazardous waste management system.

Nonhazardous solid waste would be packaged and transported in conformance with standard industrial practice. Solid waste such as office paper, metal cans, and plastic and glass bottles that can be recycled would be sent off site for that purpose. The remaining solid sanitary waste would be sent for offsite disposal in a municipal landfill. This waste load would have only a minimal impact on the nonhazardous solid waste management system at Hanford.

Nonhazardous process wastewater, which is composed mainly of blowdown water from the eight FFTF cooling towers and would continue to be discharged into the 400 Area Ponds. This discharge is regulated by State Waste Discharge Permit ST-4501.

Nonhazardous sanitary wastewater would continue to be discharged from the 400 Area, which is connected to the Energy Northwest Treatment System. Nonhazardous sanitary wastewater generated from maintaining FFTF in standby would represent 1.6 percent of the 235,000-cubic-meter-per-year (307,000-cubic-yard-per-year) capacity of the Energy Northwest Sewage Treatment Facility.

The generation rates of waste at Hanford that are associated with maintaining FFTF in standby (refer to Table 4–6) can be compared with the current total waste generation rates at the site, given in Table 3–34 (Section 3.4.11). The waste generation rates associated with maintaining FFTF in standby is a small fraction of the current total waste generation rates at the site.

#### **4.2.1.2.14 Spent Nuclear Fuel Management**

Ongoing surveillance and minimum maintenance would continue while FFTF is in standby, and no irradiated nuclear fuel would be transferred to dry storage (WHC 1994).

The current inventory of spent nuclear fuel at FFTF is approximately 11 metric tons (24,200 pounds) of heavy metal, composed predominantly of mixed plutonium-uranium oxide encapsulated in stainless steel cladding (DOE 1995a). The spent nuclear fuel is stored in the sodium-filled vessels and in the dry cask storage system. Spent nuclear fuel stored at FFTF during standby, would continue to be stored there under existing conditions. There is no radiological liquid released to the environment from spent nuclear fuel storage. During operation, the airborne releases from FFTF, including spent nuclear fuel storage, resulted in an annual total effective dose equivalent to the public of less than  $1.0 \times 10^{-4}$  millirem (Nielsen 1999). This dose is negligible compared with the U.S. Environmental Protection Agency's (EPA) Clean Air Act standard of 10 millirem per year.

### **4.2.2 No Action Alternative—Option 2**

Under Option 2 of the No Action Alternative, the United States would continue to purchase the plutonium-238 from Russia that is needed to fabricate radioisotope power systems for future U.S. space missions. However, to allow for potential future production of plutonium-238, neptunium-237 that could be used in targets would be transported from SRS to a new storage facility. This option evaluates REDC at ORR as that storage facility.

FFTF at Hanford would be maintained in standby as part of this option.

#### **4.2.2.1 Importation of Plutonium-238 from Russia**

The environmental impacts associated with importing the plutonium-238 from Russia are given in Section 4.2.1.1.

#### **4.2.2.2 Transportation and Storage**

The environmental impacts associated with transporting neptunium-237 oxide from SRS to ORR and storing it in REDC are addressed in the following sections.

#### **4.2.2.2.1 Land Resources**

**LAND USE.** REDC is an existing facility in the 7900 Area of ORNL. The use of this facility for storing neptunium-237 for 35 years would require internal modifications, but no new facilities would be built. Since no additional land would be disturbed and the use of REDC for neptunium-237 storage would be compatible with its present mission, there would be no change in land use at ORR.

**VISUAL RESOURCES.** All activities associated with storing neptunium-237 would take place over a 35-year period in REDC. Because REDC is an existing facility that would require no external modifications, there would be no change in its appearance. Thus, the current Visual Resource Management Class IV rating for the 7900 Area would continue for 35 years. Since there would be no change in the appearance of REDC or of the 7900 Area, there would be no impact on visual resources.

#### **4.2.2.2.2 Noise**

Neptunium-237 storage would generate noise levels similar to those presently associated with REDC operations, as well as other operations in the 7900 Area. Onsite noise impacts would be expected to be minimal, and changes in offsite noise levels would not be noticeable since the nearest site boundary is 2.5 kilometers (1.6 miles) to the southeast. Changes in traffic volume going to and from REDC would be small, and would result in only minor changes to existing onsite and offsite noise levels. There would be no loud noises associated with neptunium-237 storage that would adversely impact wildlife. Noise impacts from this option would be expected to be the same over the next 35 years.

#### **4.2.2.2.3 Air Quality**

There would be no additional nonradiological air pollutant emissions associated with the storage of neptunium-237 at REDC over the next 35 years; thus, there would be no change in nonradiological air quality impacts at ORR (Wham 1999a).

The air quality impacts of transportation are presented in Section 4.2.2.2.11.

#### **4.2.2.2.4 Water Resources**

There would be no additional impact on water resources associated with the storage of neptunium-237 at REDC over 35 years because there would be no incremental use of surface water or groundwater, and there would be no change in the quantity or quality of effluents discharged to surface water or groundwater (Wham 1999a). Information on current water usage, effluent discharge, and water quality at ORR is presented in Section 3.2.4.

#### **4.2.2.2.5 Geology and Soils**

Using REDC for storing neptunium-237 would not involve new construction. Therefore, geologic and soil resources in the 7900 Area of ORNL would not be disturbed. Hazards from large-scale geologic conditions at ORR, such as earthquakes and volcanoes, were previously evaluated in the *Storage and Disposition PEIS* (DOE 1996a:4-260). The analysis determined that these hazards present a low risk to long-term storage facilities. Further review of the data and analyses presented in the referenced document and the site-specific data presented in this NI PEIS indicates that the large-scale geologic conditions likewise present a low risk to REDC. This is based on the fact that there is no evidence of capable faults on or near ORR and no volcanic hazard exists. Ground shaking of Modified Mercalli Intensity VI (refer to Table 3-4) associated with postulated earthquakes would be expected to primarily affect the integrity of inadequately designed or

nonreinforced structures. Damage to properly or specially designed or upgraded facilities would not be expected. While sinkholes are present in the Knox Group, the 7900 Area is underlain by the Conasauga Group, in which karst features are less well-developed. Thus, sinkholes do not present a geologic hazard to REDC. As necessary, the need to evaluate and upgrade existing DOE facilities with regard to natural geologic hazards would be assessed in accordance with DOE Order 420.1, which is described in Section 4.2.1.2.5.

#### **4.2.2.2.6 Ecological Resources**

Because no new construction is planned, direct disturbance to ecological resources, including wetlands, would not occur. As noted in Section 4.2.2.2.2, wildlife would not be adversely affected by noise associated with neptunium-237 storage. There would be no change in impacts on aquatic resources for 35 years because water usage and wastewater discharge would not change from current values (Section 4.2.2.2.4). Due to the developed nature of the area and because no new construction would take place, impacts on threatened and endangered species would not occur.

Consultation to comply with Section 7 of the Endangered Species Act was conducted with the U.S. Fish and Wildlife Service (see Table 5–3) and resulted in the Service concluding that it does not anticipate adverse effects to federally listed endangered species that occur near the project area. DOE has also consulted with the Tennessee Department of Environment and Conservation; a response concerning state-listed species is pending from this agency. Although no state-listed species are expected to be impacted by the proposed action, no action would be taken relative to the use of facilities at ORR prior to the receipt of input from the state.

#### **4.2.2.2.7 Cultural and Paleontological Resources**

Because no new construction is planned, impacts on cultural and paleontological resources would not occur. One structure on ORNL, the Graphite Reactor, is listed on the National Register of Historic Places as a National Historic Landmark. Additionally, several other structures proposed for listing on the National Register of Historic Places are found on or near ORNL. However, neither the Graphite Reactor nor any of the other structures is in the 7900 Area; thus, the status of cultural resources would not change for 35 years as a result of using REDC for neptunium-237 storage.

Consultation to comply with Section 106 of the National Historic Preservation Act was initiated with the State Historic Preservation Office (see Table 5–3). While DOE has made additional contact with the State Historic Preservation Office, a response is pending from this office. Although impacts to cultural resources are not expected as a result of the proposed action, no action would be taken relative to the use of facilities at ORR prior to the receipt of input from the State Historic Preservation Office.

#### **4.2.2.2.8 Socioeconomics**

The existing storage facilities at ORR would remain operational. The effort associated with this option can be filled from within the currently projected site employment of 16,276. No new employment or in-migration of workers would be required. Thus, there would be no additional impacts on the socioeconomic conditions in the region around ORR.

#### **4.2.2.2.9 Public and Occupational Health and Safety—Normal Operations**

Assessments of incremental radiological and chemical impacts associated with this option are presented in this section. Supplemental information is provided in Appendix H.

**RADIOLOGICAL IMPACTS.** Upper-bounding radiological doses to three receptor groups over a 35-year period are given in **Table 4–7**: the population within 80 kilometers (50 miles) of REDC in the year 2020, the maximally exposed member of the public, and the average exposed member of the public. For purposes of this evaluation, it is conservatively assumed that the doses from neptunium-237 storage would be 10 percent of the doses from neptunium-237 target fabrication and processing (refer to Appendix H). The projected number of latent cancer fatalities in the surrounding population and the latent cancer fatality risk to the maximally and average exposed individuals are also presented in the table.

**Table 4–7 Radiological Impacts on the Public Around ORR from Storage in REDC Under Option 2 of the No Action Alternative**

Receptor	Storage in REDC <sup>a</sup>
<b>Population within 80 kilometers (50 miles) in the year 2020</b>	
Dose (person-rem)	$8.0 \times 10^{-6}$
35-year latent cancer fatalities	$1.4 \times 10^{-7}$
<b>Maximally exposed individual</b>	
Annual dose (millirem)	$1.7 \times 10^{-7}$
35-year latent cancer fatality risk	$3.0 \times 10^{-12}$
<b>Average exposed individual within 80 kilometers (50 miles)</b>	
Annual dose <sup>b</sup> (millirem)	$7.1 \times 10^{-9}$
35-year latent cancer fatality risk	$1.2 \times 10^{-13}$

- a. Because exposure data are not available for neptunium-237 storage exclusively, values are conservatively estimated to be 10 percent of the fabrication and processing component of the total neptunium-237 target fabrication, processing, and storage doses (see Table H–12). These values serve as an upper-bounding representation of the potential impacts that could be incurred from neptunium-237 storage (refer to Appendix H). Realistically, these values would be expected to be virtually zero.
- b. Obtained by dividing the population dose by the number of people projected to live within 80 kilometers (50 miles) of REDC in the year 2020 (1,134,200).

**Source:** Model results, using the GENII computer code (Napier et al. 1988).

A probability coefficient of  $5 \times 10^{-4}$  latent cancer fatality per rem is applied for the public, and a coefficient of  $4 \times 10^{-4}$  latent cancer fatality per rem is applied for workers (ICRP 1991). The value for workers is lower due to the absence of children and the elderly, who are more radiosensitive.

A collective dose of  $8.0 \times 10^{-6}$  person-rem would be incurred by the surrounding population in the year 2020. The corresponding number of latent cancer fatalities in this population from 35 years of storage would be  $1.4 \times 10^{-7}$ . A bounding annual dose of  $1.7 \times 10^{-7}$  millirem is shown for the maximally exposed individual. From 35 years of storage, the corresponding risk of a latent cancer fatality to this individual would be  $3.0 \times 10^{-12}$ .

The upper-bound estimate of the average dose to a worker involved with neptunium-237 storage operations and the corresponding upper-bound dose to the total storage workforce would be 17 millirem and 1.2 person-rem, respectively (refer to **Table 4–8**). The associated risk of a latent cancer fatality to the average worker from 35 years of storage operations would be  $2.3 \times 10^{-4}$ , and the estimated number of latent cancer fatalities in the total storage workforce from 35 years of operations would be 0.017. The total workforce dose presented in Table 4–8 was assumed to be 10 percent of the annual average worker doses reported at REDC for the years 1998 and 1999 (Wham 2000). This reduction factor was applied because the values given in that document include dose components associated with all REDC activities required for neptunium-237 processing, and not just the storage of neptunium-237 (refer to Appendix H). The resulting dose still serves as a conservative representation of potential worker impacts associated with neptunium-237 storage.

**Table 4–8 Radiological Impacts on ORR Workers from Operational Facilities Under Option 2 of the No Action Alternative**

Receptor—No Action Workers <sup>a</sup>	Storage in REDC <sup>b</sup>
Total dose (person-rem per year)	1.2 <sup>c</sup>
35-year latent cancer fatalities	0.017
Average worker dose (millirem per year)	17
35-year latent cancer fatality risk	$2.3 \times 10^{-4}$

- a. The radiological limit for an individual worker is 5,000 millirem per year (10 CFR Part 835). However, the maximum dose to a worker involved with storage operations would be kept below the DOE Administrative Control Level of 2,000 millirem per year (DOE 1999j). Further, DOE recommends that facilities adopt a more limiting, 500 millirem per year, Administrative Control Level (DOE 1999j). To reduce doses to levels that are as low as is reasonably achievable (ALARA), an effective ALARA program would be enforced.
- b. Because exposure data are not available for neptunium-237 storage exclusively, values are conservatively estimated to be 10 percent of the total dose from neptunium-237 target fabrication/processing and neptunium-237 storage, given in Section 4.4.1.1.9 (Table 4–57), and serve as an upper-bounding representation of the potential impacts that could be incurred from neptunium-237 storage (refer to Appendix H).
- c. Based on an estimated 75 badged workers.

**Source:** Wham 1999b, 2000.

**HAZARDOUS CHEMICAL IMPACTS.** Hazardous chemical impacts would be unchanged from baseline site operations because no new chemicals would be used at REDC (Wham 1999a). Ongoing emissions of hazardous chemicals would be expected to continue for the next 35 years.

#### 4.2.2.2.10 Public and Occupational Health and Safety—Facility Accidents

There would be no consequences from postulated accidents for neptunium-237 storage in REDC. The most severe accident evaluated in this NI PEIS is the beyond-design-basis catastrophic earthquake. Although the building would be expected to collapse, the hot cells would be expected to remain intact, but with cracked walls. In addition, one or more of the shielded viewing windows could be cracked or broken. The neptunium-237 is stored in double steel cans, with both the inner and outer cans sealed. The double cans are stacked in an array of seismically supported steel storage tubes inside the hot cell. The storage tube array would maintain geometry and not be damaged by equipment dislodged in the hot cell during the earthquake. The storage cans would not be stressed to a level that would breach the double containment of the can design. Therefore, no neptunium would be released from the storage cans.

Storage of neptunium-237 at REDC would not require the introduction of hazardous chemicals. Thus, there would be no hazardous chemical accidents associated with the storage of neptunium-237 at REDC.

#### 4.2.2.2.11 Public and Occupational Health and Safety—Transportation

Transportation impacts may be divided into two parts: the impacts of incident-free or routine transportation, and the impacts of transportation accidents. Incident-free transportation and transportation accident impacts are divided into two components: nonradiological and radiological. Incident-free transportation impacts include radiological impacts on the public and the crew from the radiation field that surrounds the package; nonradiological impacts are from vehicular emissions. Nonradiological impacts of potential transportation accidents include traffic accident fatalities. Only as a result of a severe fire and/or a powerful collision, which are of extremely low probability, could a transportation package of the type used to transport radioactive material be so damaged that there could be a release of radioactivity to the environment.

The impact of a specific accident is expressed in terms of probabilistic risk, which is defined as the accident probability (i.e., accident frequency) multiplied by the accident consequences. The overall risk is obtained by summing the individual risks from all reasonably conceivable accidents. The risks for radiological accidents

are expressed as additional latent cancer fatalities, and for nonradiological accidents as additional immediate fatalities. The risks of incident-free effects are expressed in additional latent cancer fatalities.

The first step in the analysis was to determine the incident-free and accident risk factors, on a per-shipment basis, for ground transportation of the various materials. Calculation of risk factors was accomplished by using the HIGHWAY (Johnson et al. 1993) computer code to choose representative routes in accordance with DOT regulations. This code provides population estimates so that the RADTRAN 5 (Neuhauser and Kanipe 2000) code could be used to determine the radiological risk factors. This analysis is described in Appendix J.

Neptunium-237 would be transported from storage at SRS to REDC at ORR. The neptunium-237 would be shipped in Type B packages. Plutonium-238 would be imported from Russia and shipped to LANL. No other shipments of neptunium-237 or waste are anticipated.

Approximately 59 shipments of radioactive materials would be made by DOE under this option. The total distance traveled on public roads by trucks carrying radioactive materials would be 128,000 kilometers (80,000 miles), and at sea by ships carrying plutonium-238 would be 298,000 kilometers (161,000 nautical miles).

**IMPACTS OF INCIDENT-FREE TRANSPORTATION.** The dose to transportation workers from all transportation activities entailed by this option has been estimated at 12 person-rem; the dose to the public would be 21 person-rem. Accordingly, incident-free transportation of radioactive material would result in 0.005 latent cancer fatality among transportation workers and 0.011 latent cancer fatality in the total affected population over the duration of the transportation activities. Latent cancer fatalities associated with radiological releases were estimated by multiplying the occupational (worker) dose by  $4.0 \times 10^{-4}$  latent cancer fatality per person-rem of exposure, and the public accident and accident-free doses by  $5.0 \times 10^{-4}$  latent cancer fatality per person-rem of exposure (ICRP 1991). The estimated number of nonradiological fatalities from vehicular emissions associated with this option is  $5.9 \times 10^{-4}$ .

**IMPACTS OF ACCIDENTS DURING TRANSPORTATION.** The maximum foreseeable offsite transportation accident under this option (probability of occurrence: more than 1 in 10 million per year) would not breach the transportation package. The consequences of more severe accidents that could breach the transportation package and release radioactive material were evaluated and estimated to have probabilities of less than 1 in 10 million per year.

Estimates of the total ground transportation accident risks under this option are as follows: a radiological dose to the population of 0.88 person-rem, resulting in  $4.4 \times 10^{-4}$  latent cancer fatality; and traffic accidents resulting in 0.014 traffic fatality.

#### **4.2.2.2.12 Environmental Justice**

As discussed in other parts of Section 4.2.2.2, neptunium-237 storage operations at REDC would pose no significant health or other environmental risks to the public.

**NORMAL OPERATIONS.** For 35 years of normal operations, the likelihood of a radiological latent cancer fatality among the population residing within 80 kilometers (50 miles) of REDC would be essentially zero (derived from information in Table 4-7). There would be no significant incremental impact associated with emissions of hazardous chemicals at REDC (Section 4.2.2.2.9). As discussed in Section 4.2.2.2.11, no radiological or nonradiological fatalities would be expected to result from incident-free transportation.

**ACCIDENTS.** Postulated accidents that would affect neptunium-237 storage were found to have no radiological consequences because the storage containers would not be breached (Section 4.2.2.2.10). Accidents during ground transportation were found to have essentially no radiological consequences because credible transportation accidents would not breach the transportation packages for neptunium-237. As discussed in Section 4.2.2.2.11, a fatal vehicle collision would be unlikely.

The implementation of this option would not pose significant radiological or other environmental risks to the public. Under the conservative assumption that all food consumed in the potentially affected area during the 35-year operational period would be radioactively contaminated, no credible pattern of food consumption would pose a significant radiological health risk due to ingestion of contaminated food supplies (see Appendix K). The transportation of neptunium-237 to ORR and storage at REDC would pose no disproportionately high and adverse risks for minority or low-income populations.

#### **4.2.2.2.13 Waste Management**

The only anticipated waste generated would be from the decontamination of the shipping containers used to transport neptunium-237 from SRS to ORR for storage at REDC. The minor amounts of low-level radioactive waste that would be generated—less than 10 cubic meters (13.1 cubic yards) over a 35-year period (Brunson 1999a)—could be managed under the existing waste management practices discussed in Section 3.2.11. Incremental impacts on the environment would be negligible.

#### **4.2.2.3 Maintenance of FFTF in Standby**

The environmental impacts associated with maintaining FFTF in standby for 35 years are addressed in Section 4.2.1.2.

#### **4.2.3 No Action Alternative—Option 3**

Under Option 3 of the No Action Alternative, the United States would continue to purchase the plutonium-238 from Russia that is needed to fabricate radioisotope power systems for future U.S. space missions. However, to allow for potential future production of plutonium-238, neptunium-237 that could be used in targets would be transported from SRS to a new storage facility. This option evaluates the Building CPP-651 vault at INEEL as that storage facility. The CPP-651 vault is within 91 meters (100 yards) of the Fluorine Dissolution Process Facility (FDPF). This vault has 100 in-ground concrete storage silo positions sealed with 5.1-centimeter (2-inch) stainless steel shielding plugs. The neptunium-237 storage cans would be placed in a rack inside the silo.

FFTF at Hanford would be maintained in standby as part of this option.

##### **4.2.3.1 Importation of Plutonium-238 from Russia**

The environmental impacts associated with importing the plutonium-238 from Russia are given in Section 4.2.1.1.

##### **4.2.3.2 Transportation and Storage**

The environmental impacts associated with transporting neptunium-237 oxide from SRS to INEEL and storing it in the Building CPP-651 vault are addressed in this section.

#### **4.2.3.2.1 Land Resources**

**LAND USE.** Building CPP-651 is in the Idaho Nuclear Technology and Engineering Center (INTEC) area of INEEL. The use of this facility for storing neptunium-237 for 35 years would require internal modifications of the facility, but no new facilities would be built. Since no additional land would be disturbed and the use of Building CPP-651 for neptunium-237 storage would be compatible with the missions for which it was designed, there would be no change in land use at INEEL.

**VISUAL RESOURCES.** All activities associated with storing neptunium-237 would take place in Building CPP-651. Because this facility would not require external modifications, there would be no change in its appearance. Thus, the current Visual Resource Management Class IV rating for INTEC would continue for 35 years. Since there would be no change in the appearance of Building CPP-651 or INTEC, there would be no impact on visual resources.

#### **4.2.3.2.2 Noise**

Neptunium-237 storage in Building CPP-651 would generate noise levels similar to those presently associated with operations conducted in INTEC. Onsite noise impacts would be expected to be minimal, and changes in offsite noise levels should not be noticeable since the nearest site boundary is 12 kilometers (7.5 miles) to the south. Changes in traffic volume going to and from INTEC would be small and would result in only minor changes to onsite and offsite noise levels. There would be no loud noises associated with neptunium-237 storage that would adversely impact wildlife. Noise impacts from this option would be expected to be the same over the next 35 years.

#### **4.2.3.2.3 Air Quality**

There would be no additional nonradiological air pollutant emissions associated with the storage of neptunium-237 at INEEL over the next 35 years; thus, there would be no change in nonradiological air quality impacts.

The air quality impacts of transportation are presented in Section 4.2.3.2.11.

#### **4.2.3.2.4 Water Resources**

There would be no additional impact on water resources associated with the storage of neptunium-237 in Building CPP-651 for 35 years because there would be no incremental use of surface water or groundwater, and there would be no change in the quantity or quality of effluents discharged to surface water or groundwater. Information on current water usage, effluent discharge, and water quality at INEEL is presented in Section 3.3.4

#### **4.2.3.2.5 Geology and Soils**

Building CPP-651 would be used to store neptunium-237. Because this is an existing facility, there would be no disturbance to either geologic or soil resources at INTEC. Hazards from large-scale geologic conditions at INEEL, such as earthquakes and volcanoes, were previously evaluated in the *Storage and Disposition PEIS* (DOE 1996a:4-148). The analysis determined that these hazards present a low risk to long-term storage facilities. That analysis was reviewed in the *Surplus Plutonium Disposition EIS* (DOE 1999a:4-267-268). Further review of the data and analyses presented in these referenced documents and the site-specific data presented in this NI PEIS indicates that the large-scale geologic conditions likewise present a low risk to the proposed INTEC facilities. Ground shaking of Modified Mercalli Intensity VI to VII (refer to Table 3-4)

associated with postulated earthquakes would be expected to primarily affect the integrity of inadequately designed or nonreinforced structures. Damage to properly or specially designed or upgraded facilities would not be expected. Also, the likelihood of future volcanic activity during the 35-year storage period is considered low. The potential for other nontectonic events to affect INEEL facilities is also low. As necessary, the need to evaluate and upgrade existing DOE facilities with regard to natural geologic hazards would be assessed in accordance with DOE Order 420.1, which is described in Section 4.2.1.2.5.

#### **4.2.3.2.6 Ecological Resources**

Because no new construction is planned, direct disturbance to ecological resources would not occur. As noted in Section 4.2.3.2.2, wildlife would not be affected by noise associated with neptunium-237 storage. There would be no impact on aquatic resources for 35 years because water usage and wastewater discharge would not change from current values (Section 4.2.3.2.4). Due to the developed nature of the area and the fact that no new construction would take place, impacts on threatened and endangered species would not occur.

Consultation letters to comply with Section 7 of the Endangered Species Act were sent to the U.S. Fish and Wildlife Service and the Idaho Department of Fish and Game (see Table 5–3). Each agency was asked to provide information on potential impacts of the proposed action on threatened and endangered species. The Idaho Department of Fish and Game indicated that their database contained no known occurrences of special status plants or animals near the project area. While DOE has made additional contact with the U.S. Fish and Wildlife Service, a response is pending from this agency. Although no federally listed species are expected to be impacted by the proposed action, no action would be taken relative to the use of facilities at INEEL prior to the receipt of input from the Service.

#### **4.2.3.2.7 Cultural and Paleontological Resources**

Because no new construction is planned, impacts on cultural and paleontological resources at INTEC would not occur. The use of Building CPP–651 to store neptunium-237 for 35 years would not change the status of six historic structures located at INTEC. Also, Native American resources occurring in the vicinity of INTEC would not be impacted by the storage of neptunium-237.

Consultation to comply with Section 106 of the National Historic Preservation Act was initiated with the State Historic Preservation Office (see Table 5–3). The State Historic Preservation Office indicated that Building CPP-651 is likely to be eligible for the National Register of Historic Places as a contributory property in a potential historic district of exceptional significance. However, at this time, the State Historic Preservation Office has determined that more information is needed prior to assisting DOE in evaluating this property. The State Historic Preservation Office also indicated that since there would be no new construction, there is little potential for effects on archaeological properties. DOE would provide additional information as required to the Idaho State Historic Preservation Office prior to the use of any facility at INEEL for the proposed project. Consultation was conducted with interested Native American tribes; however, responses are pending.

#### **4.2.3.2.8 Socioeconomics**

The existing storage facilities at INEEL would remain operational. The effort associated with this option can be filled from within the currently projected site employment of 7,993. No new employment or in-migration of workers would be required. Thus, there would be no additional impacts on the socioeconomic conditions in the region around INEEL.

#### 4.2.3.2.9 Public and Occupational Health and Safety—Normal Operations

Assessments of incremental and chemical impacts associated with this option are presented in this section. Supplemental information is provided in Appendix H.

**RADIOLOGICAL IMPACTS.** Under this option, INEEL would store neptunium-237 in CPP-651 in the INTEC area. Upper-bounding radiological doses to three receptor groups are given in **Table 4-9**: the population within 80 kilometers (50 miles) of INTEC in the year 2020, the maximally exposed member of the public, and the average exposed member of the public. For purposes of this evaluation, it is conservatively assumed that the doses from neptunium-237 storage would be 10 percent of the doses from neptunium-237 target fabrication and processing (refer to Appendix H). The projected number of latent cancer fatalities in the surrounding population and the latent cancer fatality risk to the maximally and average exposed individuals are also presented in the table.

**Table 4-9 Radiological Impacts on the Public Around INEEL from Operational Facilities Under Option 3 of the No Action Alternative**

Receptor	Storage in CPP-651 <sup>a</sup>
<b>Population within 80 kilometers (50 miles) in the year 2020</b>	
Dose (person-rem)	$3.5 \times 10^{-7}$
35-year latent cancer fatalities	$6.1 \times 10^{-9}$
<b>Maximally exposed individual</b>	
Annual dose (millirem)	$2.4 \times 10^{-8}$
35-year latent cancer fatality risk	$4.2 \times 10^{-13}$
<b>Average exposed individual within 80 kilometers (50 miles)</b>	
Annual dose <sup>b</sup> (millirem)	$1.9 \times 10^{-9}$
35-year latent cancer fatality risk	$3.3 \times 10^{-14}$

a. Because exposure data are not available for neptunium-237 storage exclusively, values are conservatively estimated to be 10 percent of the fabrication and processing component of the total neptunium-237 target fabrication, processing, and storage doses (see Table H-12). These values serve as an upper-bounding representation of the potential impacts that could be incurred from neptunium-237 storage (refer to Appendix H). Realistically, these values would be expected to be virtually zero.

b. Obtained by dividing the population dose by the number of people projected to live within 80 kilometers (50 miles) of INTEC in the year 2020 (188,400).

**Source:** Model results, using the GENII computer code (Napier et al. 1988).

A probability coefficient of  $5 \times 10^{-4}$  latent cancer fatality per rem is applied for the public, and a coefficient of  $4 \times 10^{-4}$  latent cancer fatality per rem is applied for workers (ICRP 1991). The value for workers is lower due to the absence of children and the elderly, who are more radiosensitive.

A collective dose of  $3.5 \times 10^{-7}$  person-rem would be incurred in the surrounding population in the year 2020. The corresponding number of latent cancer fatalities in this population from 35 years of storage would be  $6.1 \times 10^{-9}$ . A bounding annual dose of  $2.4 \times 10^{-8}$  millirem is shown for the maximally exposed individual. From 35 years of storage, the corresponding risk of a latent cancer fatality to this individual would be  $4.2 \times 10^{-13}$ .

The upper-bound estimate of the average dose to a worker involved with neptunium-237 storage operations and the corresponding upper-bound dose to the total storage workforce would be 17 millirem and 1.2 person-rem, respectively (refer to **Table 4-10**). The associated risk of a latent cancer fatality to the average worker from 35 years of storage operations would be  $2.3 \times 10^{-4}$ , and the estimated number of latent cancer fatalities in the total storage workforce from 35 years of operations would be 0.017. The total workforce dose presented in Table 4-10 was assumed to be 10 percent of the annual average worker doses reported at REDC for the years 1998 and 1999 (Wham 2000). This reduction factor was applied because the values given in that document include dose components associated with all REDC activities, and not just the storage of

neptunium-237 (refer to Appendix H). The resulting dose still serves as a conservative representation of potential worker impacts associated with neptunium-237 storage.

**Table 4–10 Radiological Impacts on INEEL Workers from Operational Facilities Under Option 3 of the No Action Alternative**

Receptor—No Action workers <sup>a</sup>	Storage in CPP–651 <sup>b</sup>
Total dose (person-rem per year)	1.2 <sup>c</sup>
35-year latent cancer fatalities	0.017
Average worker dose (millirem per year)	17
35-year latent cancer fatality risk	$2.3 \times 10^{-4}$

- The radiological limit for an individual worker is 5,000 millirem per year (10 CFR Part 835). However, the maximum dose to a worker involved with storage operations would be kept below the DOE Administrative Control Level of 2,000 millirem per year (DOE 1999j). Further, DOE recommends that facilities adopt a more limiting, 500 millirem per year, Administrative Control Level (DOE 1999j). To reduce doses to levels that are as low as is reasonably achievable (ALARA), an effective ALARA program would be enforced.
- Because exposure data are not available for neptunium-237 storage exclusively, values are conservatively estimated to be 10 percent of the total dose from neptunium-237 target fabrication/processing and neptunium-237 storage, given in Section 4.4.2.1.9 (Table 4–69), and serve as an upper-bounding representation of the potential impacts that could be incurred from neptunium-237 storage (refer to Appendix H).
- Based on an estimated 75 badged workers.

**Source:** Wham 1999b, 2000.

**HAZARDOUS CHEMICAL IMPACTS.** Hazardous chemical impacts at INEEL would be unchanged from baseline site operations because no new chemicals would be emitted to the air at INEEL. Ongoing emissions would be expected to continue for the next 35 years.

#### 4.2.3.2.10 Public and Occupational Health and Safety—Facility Accidents

At INEEL, neptunium-237 would be stored in the Building CPP–651 vault, which is within 91 meters (100 yards) of FDPF. The Building CPP–651 vault has 100 in-ground concrete storage silo positions sealed with 5.1-centimeter (2-inch) stainless steel shielding plugs. The neptunium-237 storage cans would be placed in a rack inside the silo. While the postulated beyond-design-basis earthquake may cause portions of the facility to collapse, none of the storage cans in the in-ground storage silos would be breached. The storage cans would not be stressed to a level that would breach the double containment of the can design.

Storage of neptunium-237 in Building CPP–651 would not require the introduction of hazardous chemicals. Thus, there would be no hazardous chemical accidents associated with the storage of neptunium-237 in Building CPP–651.

#### 4.2.3.2.11 Public and Occupational Health and Safety—Transportation

Neptunium-237 would be transported from storage at SRS to the Building CPP–651 vault at INEEL. The neptunium-237 would be shipped in Type B packages. Plutonium-238 would be imported from Russia and shipped to LANL. No other shipments of neptunium-237 and no shipments of waste are anticipated. The analysis is described in Appendix J.

Approximately 59 shipments of radioactive materials would be made by DOE. The total distance traveled on public roads by trucks carrying radioactive materials would be 203,000 kilometers (127,000 miles), and at sea by ships carrying plutonium-238 would be 298,000 kilometers (161,000 nautical miles).

**IMPACTS OF INCIDENT-FREE TRANSPORTATION.** The dose to transportation workers from all transportation activities entailed by this option has been estimated at 12 person-rem; the dose to the public would be 28 person-rem. Accordingly, incident-free transportation of radioactive material would result in 0.005 latent cancer fatality among transportation workers and 0.014 latent cancer fatality in the total affected population over the duration of the transportation activities. The estimated number of nonradiological fatalities from vehicular emissions associated with this option is 0.0009.

**IMPACTS OF ACCIDENTS DURING TRANSPORTATION.** The maximum foreseeable offsite transportation accident under this option (probability of occurrence: more than 1 in 10 million per year) would not breach the transportation package. The consequences of more severe accidents that could breach the transportation package and release radioactive material were evaluated and estimated to have probabilities of less than 1 in 10 million per year.

Estimates of the total ground transportation accident risks under this option are as follows: a radiological dose to the population of 0.88 person-rem, resulting in  $4.4 \times 10^{-4}$  latent cancer fatality; and traffic accidents resulting in 0.014 traffic fatality.

#### **4.2.3.2.12 Environmental Justice**

As discussed in other parts of Section 4.2.3.2, neptunium-237 storage operations would pose no significant health or other environmental risks to the public.

**NORMAL OPERATIONS.** For 35 years of normal storage operations, the likelihood of a radiological latent cancer fatality among the population residing within 80 kilometers (50 miles) of neptunium storage facilities at INEEL would be essentially zero (derived from information in Table 4-9). There would be no significant incremental impact associated with emissions of hazardous chemicals (Section 4.2.3.2.9). As discussed in Section 4.2.3.2.11, incident-free transportation activities conducted under this option would not be expected to result in fatalities.

**ACCIDENTS.** Postulated accidents that would affect neptunium-237 storage were found to have no radiological consequences because the storage containers would not be breached (Section 4.2.3.2.10). Accidents during ground transportation were found to have essentially no radiological consequences because credible transportation accidents would not breach the transportation packages for neptunium-237. No fatalities due to vehicle collisions would be expected.

The implementation of this option would pose no significant radiological or other environmental risks to the public. Under the conservative assumption that all food consumed in the potentially affected area during the 35-year operational period would be radioactively contaminated, no credible pattern of food consumption would pose a significant radiological health risk due to ingestion of contaminated food supplies (see Appendix K). The transportation of neptunium-237 to INEEL and storage in Building CPP-651 would pose no disproportionately high and adverse risks for minority or low-income populations.

#### **4.2.3.2.13 Waste Management**

The only anticipated waste associated with this option would be from decontamination of the shipping containers used to transport neptunium-237 from SRS to INEEL for storage. The minor amounts of low-level radioactive waste that would be generated—less than 10 cubic meters (13.1 cubic yards) over a 35-year period (Brunson 1999a)—could be managed under the existing waste management practices discussed in Section 3.3.11. Incremental impacts on the environment would be negligible.

### **4.2.3.3 Maintenance of FFTF in Standby**

The environmental impacts associated with maintaining FFTF in standby for 35 years are addressed in Section 4.2.1.2.

### **4.2.4 No Action Alternative—Option 4**

Under Option 4 of the No Action Alternative, the United States would continue to purchase the plutonium-238 from Russia that is needed to fabricate radioisotope power systems for future U.S. space missions. However, to allow for potential future production of plutonium-238, neptunium-237 that could be used in targets would be transported from SRS to a new storage facility. This option evaluates FMEF at Hanford as that storage facility.

FFTF at Hanford would be maintained in standby as part of this option.

#### **4.2.4.1 Importation of Plutonium-238 from Russia**

The environmental impacts associated with importing the plutonium-238 from Russia are given in Section 4.2.1.1.

#### **4.2.4.2 Transportation and Storage**

The environmental impacts associated with transporting neptunium-237 oxide from SRS to Hanford and storing it at FMEF are addressed in this section.

##### **4.2.4.2.1 Land Resources**

**LAND USE.** FMEF is in the 400 Area of Hanford. The use of this facility for storing neptunium-237 for 35 years would require internal modifications, but no new facilities would be built. Since no additional land would be disturbed and the use of FMEF for neptunium-237 storage would be compatible with the mission for which it was designed, there would be no change in land use at Hanford.

**VISUAL RESOURCES.** All activities associated with storing neptunium-237 would take place over 35 years in FMEF. Because FMEF would require no external modifications, there would be no change in its appearance. Therefore, the current Visual Resource Management Class IV rating for the 400 Area would continue for 35 years. Since there would be no change in the appearance of FMEF or that of the 400 Area, there would be no impact on visual resources.

##### **4.2.4.2.2 Noise**

Neptunium-237 storage would generate noise levels similar to those presently associated with operations in the 400 Area. Onsite noise impacts would be expected to be minimal, and changes in offsite noise levels should not be noticeable since the nearest site boundary is 7 kilometers (4.3 miles) to the east. Changes in traffic volume going to and from FMEF would be small and would result in only minor changes to onsite and offsite noise levels. There would be no loud noises associated with neptunium-237 storage that would adversely impact wildlife. Noise impacts from this option would be expected to be the same over the next 35 years.

#### 4.2.4.2.3 Air Quality

There would be no additional nonradiological air pollutant emissions associated with the storage of neptunium-237 at Hanford over the next 35 years; thus, there would be no change in nonradiological air quality impacts.

The air quality impacts of transportation from SRS to Hanford are presented in Section 4.2.4.2.11.

#### 4.2.4.2.4 Water Resources

There would be no additional impact on water resources associated with the storage of neptunium-237 in FMEF for 35 years because there would be no incremental use of surface water or groundwater, and there would be no change in the quantity or quality of effluents discharged to surface water or groundwater. Information on current water usage, effluent discharge, and water quality at Hanford is presented in Section 3.4.4.

#### 4.2.4.2.5 Geology and Soils

Because the neptunium-237 would be stored in FMEF, an existing facility, there would be no disturbance to either geologic or soil resources in the 400 Area. Hazards from large-scale geologic conditions at Hanford, such as earthquakes and volcanoes, were previously evaluated in the *Storage and Disposition PEIS* (DOE 1996a:4-45). The analysis determined that these hazards present a low risk to long-term storage facilities. That analysis was reviewed in the *Surplus Plutonium Disposition EIS* (DOE 1999a:4-260). Further review of the data and analyses presented in these referenced documents and the site-specific data presented in this NI PEIS indicates that the large-scale geologic conditions likewise present a low risk to FMEF. Ground shaking of Modified Mercalli Intensity V to VII (refer to Table 3–4) associated with postulated earthquakes would be expected to primarily affect the integrity of inadequately designed or nonreinforced structures. Damage to properly or specially designed or upgraded facilities would not be expected. Also, only minimal effects (e.g., ashfall) would be expected from postulated volcanic events in the Cascade Region. The potential for other nontectonic events to affect the facility is also low. As necessary, the need to evaluate and upgrade existing DOE facilities with regard to natural geologic hazards would be assessed in accordance with DOE Order 420.1, which is described in Section 4.2.1.2.5.

#### 4.2.4.2.6 Ecological Resources

Because no new construction is planned in the 400 Area, direct disturbance to ecological resources would not occur. As noted in Section 4.2.4.2.2, wildlife would not be affected by noise associated with neptunium-237 storage. Because water usage and wastewater discharge would not change from current values, there would be no change in impacts on aquatic habitat or wetlands associated with the Columbia River for 35 years (Section 4.2.4.2.4). Due to the developed nature of the area and the fact that no new construction would take place, impacts on threatened and endangered species would not occur.

Consultation letters concerning threatened and endangered species were sent to the U.S. Fish and Wildlife Service, the National Marine Fisheries Service, the Washington State Department of Natural Resources, and the State of Washington Department of Fish and Wildlife (see Table 5–3). Each agency was asked to provide information on potential impacts of the proposed action on threatened and endangered species. Both the Washington State Department of Natural Resources and the State of Washington Department of Fish and Wildlife provided lists of state species of concern that occur in the vicinity of the project area. As noted above, no impacts to any threatened or endangered species are expected, including those of concern to these agencies. While DOE has made additional contacts with the U.S. Fish and Wildlife Service and the National Marine

Fisheries Service, responses are pending from these agencies. Although no federally listed species are expected to be impacted by the proposed action, no action would be taken relative to the use of facilities at Hanford prior to the receipt of input from these Federal agencies.

#### 4.2.4.2.7 Cultural and Paleontological Resources

Because FMEF is an existing facility in the highly disturbed 400 Area and new construction would not be required, there would be no change in the status of cultural and paleontological resources. No prehistoric, historic, or paleontological sites have been identified either in the 400 Area or within 2 kilometers (1.2 miles) of the 400 Area. Six buildings in the 400 Area have been determined to be eligible for listing on the National Register of Historic Places as contributing properties in the Historic District recommended for mitigation. The use of FMEF to store neptunium-237 for 35 years would not affect the eligibility of these structures for the National Register of Historic Places. No Native American resources are known to occur in the 400 Area.

Consultation to comply with Section 106 of the National Historic Preservation Act was conducted with the State Historic Preservation Office (see Table 5–3) and resulted in concurrence by the State Historic Preservation Office that the proposed action would have no effect on historic properties at Hanford. Consultation was also conducted with interested Native American tribes that resulted in comments at public hearings by members representing the Nez Perce and Confederated Tribes of the Umatilla Indian Reservation. Responses to their specific comments are addressed in Volume 3.

#### 4.2.4.2.8 Socioeconomics

The existing storage facilities at Hanford would remain operational. The effort associated with this option can be filled from within the currently projected site employment of 16,005. No new employment or in-migration of workers would be required. Thus, there would be no additional impacts on the socioeconomic conditions in the region around Hanford.

#### 4.2.4.2.9 Public and Occupational Health and Safety—Normal Operations

Assessments of incremental and chemical impacts associated with this option are presented in this section. Supplemental information is provided in Appendix H.

**RADIOLOGICAL IMPACTS.** This option involves the storage of neptunium-237 at FMEF. Upper-bounding radiological doses to three receptor groups are given in **Table 4–11**: the population within 80 kilometers (50 miles) of FMEF in the year 2020, the maximally exposed member of the public, and the average exposed member of the public. For purposes of this evaluation, it is conservatively assumed that the doses from neptunium-237 storage would be 10 percent of the doses from neptunium-237 target fabrication and processing (refer to Appendix H). The projected number of latent cancer fatalities in the surrounding population and the latent cancer fatality risk to the maximally and average exposed individuals are also presented in the table.

A probability coefficient of  $5 \times 10^{-4}$  latent cancer fatality per rem is applied for the public, and a coefficient of  $4 \times 10^{-4}$  latent cancer fatality per rem is applied for workers (ICRP 1991). The value for workers is lower due to the absence of children and the elderly, who are more radiosensitive.

A collective dose of  $4.0 \times 10^{-6}$  person-rem would be incurred in the surrounding population in the year 2020. The corresponding number of latent cancer fatalities in this population from 35 years of storage would be  $7.0 \times 10^{-8}$ . A bounding annual dose of  $4.3 \times 10^{-8}$  millirem is shown for the maximally exposed individual. From 35 years of storage, the corresponding risk of a latent cancer fatality to this individual would be  $7.5 \times 10^{-13}$ .

**Table 4–11 Radiological Impacts on the Public Around Hanford from Operational Facilities Under Option 4 of the No Action Alternative**

Receptor	Storage in FMEF <sup>a</sup>
<b>Population within 80 kilometers (50 miles) in the year 2020</b>	
Dose (person-rem)	$4.0 \times 10^{-6}$
35-year latent cancer fatalities	$7.0 \times 10^{-8}$
<b>Maximally exposed individual</b>	
Annual dose (millirem)	$4.3 \times 10^{-8}$
35-year latent cancer fatality risk	$7.5 \times 10^{-13}$
<b>Average exposed individual within 80 kilometers (50 miles)</b>	
Annual dose <sup>b</sup> (millirem)	$8.1 \times 10^{-9}$
35-year latent cancer fatality risk	$1.4 \times 10^{-13}$

a. Because exposure data are not available for neptunium-237 storage exclusively, values are conservatively estimated to be 10 percent of the fabrication and processing component of the total neptunium-237 target fabrication, processing, and storage doses (see Table H–12). These values serve as an upper-bounding representation of the potential impacts that could be incurred from neptunium-237 storage (refer to Appendix H). Realistically, these values would be expected to be virtually zero.

b. Obtained by dividing the population dose by the number of people projected to live within 80 kilometers (50 miles) of FMEF in the year 2020 (494,400).

**Source:** Model results, using the GENII computer code (Napier et al. 1988).

The upper-bound estimate of the average dose to a worker involved with neptunium-237 storage operations and the corresponding upper-bound dose to the total storage workforce would be 17 millirem and 1.2 person-rem, respectively (refer to **Table 4–12**). The associated risk of a latent cancer fatality to the average worker from 35 years of storage operations would be  $2.3 \times 10^{-4}$ , and the estimated number of latent cancer fatalities in the total storage workforce from 35 years of operations would be 0.017. The total workforce dose presented in Table 4–12 was assumed to be 10 percent of the average annual workforce doses reported at REDC for the years 1998 and 1999 (Wham 2000). This reduction factor was applied because the values given in that document include dose components associated with all REDC activities, and not just the storage of neptunium-237 (refer to Appendix H). The resulting dose still serves as a conservative representation of potential worker impacts associated with neptunium-237 storage.

**Table 4–12 Radiological Impacts on Hanford Workers from Operational Facilities Under Option 4 of the No Action Alternative**

Receptor—No Action Workers <sup>a</sup>	Storage in FMEF <sup>b</sup>
Total dose (person-rem per year)	1.2 <sup>c</sup>
35-year latent cancer fatalities	0.017
Average worker dose (millirem per year)	17
35-year latent cancer fatality risk	$2.3 \times 10^{-4}$

a. The radiological limit for an individual worker is 5,000 millirem per year (10 CFR Part 835). However, the maximum dose to a worker involved with storage operations would be kept below the DOE Administrative Control Level of 2,000 millirem per year (DOE 1999j). Further, DOE recommends that facilities adopt a more limiting, 500 millirem per year, Administrative Control Level (DOE 1999j). To reduce doses to levels that are as low as is reasonably achievable (ALARA), an effective ALARA program would be enforced.

b. Because exposure data are not available for neptunium-237 storage exclusively, values are conservatively estimated to be 10 percent of the total dose from neptunium-237 target fabrication/processing and neptunium-237 storage, given in Section 4.4.3.1.9 (Table 4–78), and serve as an upper-bounding representation of the potential impacts that could be incurred from neptunium-237 storage (refer to Appendix H).

c. Based on an estimated 75 badged workers.

**Source:** Wham 1999b, 2000.

**HAZARDOUS CHEMICAL IMPACTS.** Hazardous chemical impacts would be unchanged from baseline site operations because no new chemicals would be emitted to the air at Hanford. Ongoing emissions associated with storage at FMEF would be expected to continue for the next 35 years.

#### 4.2.4.2.10 Public and Occupational Health and Safety—Facility Accidents

There would be no consequences from postulated accidents for neptunium-237 storage in FMEF. The most severe accident evaluated in this NI PEIS is the beyond-design-basis catastrophic earthquake. Although the building would be expected to collapse, the hot cells would be expected to remain intact, but with cracked walls. In addition, one or more of the shielded viewing windows could be cracked or broken. The neptunium-237 is stored in double steel cans, with both the inner and outer cans sealed. The double cans are stacked in an array of seismically supported steel storage tubes inside the hot cell. The storage tube array would maintain geometry and not be damaged by equipment dislodged in the hot cell during the earthquake. The storage cans would not be stressed to a level that would breach the double containment of the can design. Therefore, no neptunium would be released from the storage cans.

Storage of neptunium-237 at FMEF would not require the introduction of hazardous chemicals. Thus, there are no hazardous chemical accidents associated with the storage of neptunium-237 at FMEF.

#### 4.2.4.2.11 Public and Occupational Health and Safety—Transportation

Neptunium-237 would be transported from storage at SRS to FMEF at Hanford. The neptunium-237 would be shipped in Type B packages. Plutonium-238 would be imported from Russia and shipped to LANL. No other shipments of neptunium-237 and no shipments of waste are anticipated.

Approximately 59 shipments of radioactive materials would be made by DOE under this option. The total distance traveled on public roads by trucks carrying radioactive materials would be 220,000 kilometers (137,000 miles), and at sea by ships carrying plutonium-238 would be 298,000 kilometers (161,000 nautical miles).

**IMPACTS OF INCIDENT-FREE TRANSPORTATION.** The dose to transportation workers from all transportation activities entailed by this option has been estimated at 12 person-rem; the dose to the public, 29 person-rem. Accordingly, incident-free transportation of radioactive material would result in 0.005 latent cancer fatality among transportation workers and 0.014 latent cancer fatality in the total affected population over the duration of the transportation activities. The estimated number of nonradiological fatalities from vehicular emissions associated with this alternative is 0.0009.

**IMPACTS OF ACCIDENTS DURING TRANSPORTATION.** The maximum foreseeable offsite transportation accident under this option (probability of occurrence: 1 in 10 million) would not breach the transportation package. The consequences of more severe accidents that could breach the transportation package and release radioactive material were evaluated and estimated to have probabilities of less than 1 in 10 million per year.

Estimates of the total ground transportation accident risks under this option are as follows: a radiological dose to the population of 0.88 person-rem, resulting in  $4.4 \times 10^{-4}$  latent cancer fatality; and traffic accidents resulting in 0.014 traffic fatality.

#### 4.2.4.2.12 Environmental Justice

As discussed in other parts of Section 4.2.4.2, neptunium-237 storage operations at FMEF would pose no significant health or other environmental risks to the public.

**NORMAL OPERATIONS.** For 35 years of normal storage operations, the likelihood of a radiological latent cancer fatality among the population residing within 80 kilometers (50 miles) of neptunium storage facilities at Hanford would be essentially zero (derived from information in Table 4–11). There would be no significant incremental impact associated with emissions of hazardous chemicals at Hanford (Section 4.2.4.2.9). No fatalities would be expected from incident-free transportation (Section 4.2.4.2.11).

**ACCIDENTS.** Postulated accidents that would affect neptunium-237 storage were found to have no radiological consequences because the storage containers would not be breached (Section 4.2.4.2.10). Accidents during ground transportation were found to have essentially no radiological consequences because credible transportation accidents would not breach the transportation packages for neptunium-237. No fatal vehicle collisions would be expected.

The implementation of this option would pose no significant radiological or other environmental risks to the public. Under the conservative assumption that all food consumed in the potentially affected area during the 35-year operational period would be radioactively contaminated, no credible pattern of food consumption would pose a significant radiological health risk due to ingestion of contaminated food supplies (see Appendix K). The transportation of neptunium-237 to Hanford and storage in FMEF would pose no disproportionately high and adverse risks to minority or low-income populations.

#### **4.2.4.2.13 Waste Management**

The only anticipated waste associated with this option would be from decontamination of the shipping containers used to transport neptunium-237 from SRS to Hanford for storage at FMEF. The minor amounts of low-level radioactive waste that would be generated—less than 10 cubic meters (13.1 cubic yards) over a 35-year period (Brunson 1999a)—could be managed under the existing waste management practices discussed in Section 3.4.11. Incremental impacts on the environment would be negligible.

#### **4.2.4.3 Maintenance of FFTF in Standby**

The environmental impacts associated with maintaining FFTF in standby for 35 years are addressed in Section 4.2.1.2.

### 4.3 ALTERNATIVE 1—RESTART FFTF

Under Alternative 1, FFTF at Hanford would be restarted and operated for the 35-year evaluation period. FFTF would be used to irradiate targets for medical and industrial isotopes production, plutonium-238 production, and civilian nuclear energy research and development irradiation requirements. Ongoing operations at existing facilities as described in Chapter 3, Affected Environment, would continue.

Targets for medical and industrial isotope production would be fabricated in one or more facilities at Hanford. Target material would typically be acquired from ORNL, where enrichment processes are conducted to produce high purity target material suitable for production of medical isotopes. The targets would be irradiated at FFTF and then returned to the fabrication facility for postirradiation processing. From there, the isotope products would be sent directly to commercial pharmaceutical distributors.

Targets for plutonium-238 production would be fabricated in one of three candidate facilities at ORNL, INEEL, or Hanford. The material needed for target fabrication (neptunium-237) would be transported from SRS. The nonirradiated targets would be transported and irradiated at FFTF and transported back to the fabricating facilities for postirradiation processing. The separated plutonium-238 would be transported to LANL for fabrication into heat sources for radioisotope power systems.

Under Alternative 1, raw materials, nonirradiated targets, irradiated targets, and processed materials would be transported between the locations selected for raw target material acquisition, material storage, target fabrication, target irradiation, and postirradiation processing and the final destination for the isotopes and the plutonium-238 product or various research and development test sites.

FFTF could produce high-energy neutrons and a large flux level ( $10^{15}$  neutron per square centimeters per second) that can be tailored to nearly any desired energy level. FFTF would provide the greatest flexibility for both isotope production and nuclear-based research and development among the baseline configurations for all of the proposed alternatives. Due to its large core size, flux spectrum, demonstrated testing capability, and rated power level, it would be able to concurrently support the projected plutonium-238 needs, production of medical and industrial isotopes (including those isotopes normally produced in particle accelerators), and civilian nuclear energy research and development related to a broad range of materials, advanced reactors, advanced fuels and waste transmutation.

The six options under this alternative are associated with the type of nuclear fuel to be used for FFTF operations and the specific facilities to be used for target fabrication and processing. The first three options (Options 1 through 3) would involve operating FFTF with a mixed oxide fuel core for the first 21 years and a highly enriched uranium fuel core for the remaining 14 years. The last three options (Options 4 through 6) would involve operating FFTF with a mixed oxide fuel core for the first 6 years and a highly enriched uranium fuel core for the remaining 29 years. FFTF can provide similar irradiation services with either a mixed oxide core or a highly enriched uranium core. The reasons for these options in FFTF core fuel are provided in Section 2.3.1.1.3.

The options involving storage, fabrication, postirradiation processing, and transportation are discussed below.

- **Options 1 and 4.** REDC at ORNL would be used to fabricate and process the neptunium-237 targets required for plutonium-238 production. The neptunium-237 transported from SRS to ORNL would be stored in REDC. The plutonium-238 product would be transported from ORNL to LANL. Hanford's Radiochemical Processing Laboratory (RPL)/306-E facilities would be used to fabricate and process targets for medical and industrial isotope production and for research and development, as well as to store the materials needed to fabricate these targets.

- **Options 2 and 5.** FDPF at INEEL would be used to fabricate and process the neptunium-237 targets for plutonium-238 production. The neptunium-237 transported from SRS to INEEL would be stored in FDPF or Building CPP-651 at INEEL. The plutonium-238 product would be transported from INEEL to LANL. Hanford's RPL/306-E facilities would be used to fabricate and process targets for medical and industrial isotope production and for research and development, as well as to store the materials needed to fabricate these targets.
- **Options 3 and 6.** FMEF at Hanford would be used to fabricate and process neptunium-237 targets for plutonium-238 production, targets for the production of medical and industrial isotopes, and targets for research and development. The neptunium-237 transported from SRS to Hanford and the other target materials transported from other offsite facilities to Hanford would be stored in FMEF. The plutonium-238 product would be transported from Hanford to LANL for fabrication into heat sources for radioisotope power systems.

As described in Section 1.2.3, the civilian nuclear energy research and development initiatives requiring an enhanced DOE nuclear infrastructure fall into three basic categories: materials research, nuclear fuels research, and advanced reactor development.

- Materials research involves irradiating materials in a high-flux field to determine the radiation effect during reactor normal operating conditions or to perform accelerated life-cycle testing. This form of testing would not introduce material into FFTF that would result in additional releases during normal operation or accident conditions.
- Nuclear fuels research involves irradiating test fuel pellets, fuel pins, and fuel assemblies in high-temperature environments expected in future reactor designs. When the test specimens are inserted into FFTF, there would be no significant increase of fissile material in the FFTF core inventory that would result in additional releases during normal operation or accident conditions.
- Advanced reactor development involves test loop experiments under prototypical reactor conditions. When the test loop is operating in the FFTF core, there would be no significant increase of fissile material in the core inventory that would result in additional releases during normal operation or accident conditions.

The environmental impacts associated with implementation of the proposed civilian nuclear energy research and development missions cannot be distinguished from the impacts of operating FFTF without the civilian nuclear energy research and development mission.

#### **4.3.1 Alternative 1 (Restart FFTF)—Option 1**

Option 1 involves operating FFTF at Hanford to irradiate all targets and materials associated with plutonium-238 production, medical and industrial isotope production, and research and development; operating REDC at ORR to fabricate and process neptunium-237 targets and to process the plutonium-238 product; and operating facilities in the Hanford 300 Area to fabricate and process the other targets and materials and to process the associated products. This option includes storage in REDC of the neptunium-237 transported to ORR from SRS and storage in the Hanford 300 Area facilities of the other target materials transported to Hanford from other offsite facilities.

The transportation of the mixed oxide and highly enriched uranium fuel to Hanford for use in FFTF, the transportation of the neptunium-237 to ORR and then to Hanford, the transportation of the other target material

to Hanford, and the transportation of the product materials following irradiation and postirradiation processing are also part of this option.

Under Option 1, FFTF would operate with a mixed oxide fuel core for the first 21 years and with a highly enriched uranium fuel core for the next 14 years.

#### **4.3.1.1 Operations and Transportation**

The environmental impacts associated with storage, processing, and irradiation operations and with all transportation activities are assessed in this section.

##### **4.3.1.1.1 Land Resources**

**LAND USE.** FFTF is in the 400 Area of Hanford. For the foreseeable future, land use in the 400 Area is anticipated to be industrial, which is defined to include FFTF operations. The use of the facility for the irradiation services assessed in this NI PEIS would be compatible with the mission for which the facility was originally built. Although internal modifications could be required, no new facilities would be built and thus, there would be no change in land use in the 400 Area.

REDC at ORR would be used for neptunium-237 storage, target fabrication, and processing. REDC is an existing operating facility in the 7900 Area of ORNL, and use of this facility would require internal modifications, but no new facilities would be built. Because no additional land would be disturbed and the use of REDC for neptunium-237 storage, target fabrication, and processing would be compatible with its present mission, there would be no change in land use at ORR.

RPL and Building 306–E in the 300 Area of Hanford would be used for the fabrication and processing of targets associated with the medical and industrial isotope production and civilian nuclear energy research and development missions. These buildings are existing structures that would require only internal modifications. Because no additional land would be disturbed and target fabrication and processing would be compatible with their present mission, there would be no impact on land use at Hanford.

**VISUAL RESOURCES.** The use of FFTF would not require any external modifications that would alter the appearance of the facility. Thus, the current Visual Resource Management Class IV rating for the 400 Area would not change. Since there would be no change in the appearance of FFTF or that of the 400 Area, there would be no additional impact on visual resources.

All activities associated with neptunium-237 storage, target fabrication, and processing would take place in REDC at ORR. Because REDC is an existing facility that would require no external modifications, there would be no change in its appearance. Therefore, the current Visual Resource Management Class IV rating for the 7900 Area would not change, and there would be no impact on visual resources.

RPL/306–E in the 300 Area of Hanford would be used for the fabrication and processing of targets associated with the medical and industrial isotope production and civilian nuclear energy research and development missions. These existing structures would require no external modifications. Because the appearance of these buildings would remain unchanged, the current Visual Resource Management Class IV rating for the 300 Area would not change; thus, there would be no impact on visual resources.

#### **4.3.1.1.2 Noise**

No new construction would be required at FFTF under Option 1. Noise sources from FFTF operations would be similar to those during standby. Therefore, the change in noise levels from operation activities would be expected to be small. FFTF operations would not be expected to result in any change in noise impacts on wildlife around the 400 Area, and offsite noise impacts would also be minor because the nearest site boundary is 7 kilometers (4.3 miles) to the east. Operations would be expected to result in a minimal change in noise impacts on people near Hanford as a result of changes in employee and truck traffic levels.

REDC at ORR would be used for neptunium-237 target-material storage, target fabrication, and processing. Interior modifications of these facilities in the 7900 Area of ORNL would be expected to result in little change in noise impacts on wildlife around this area. REDC operations would not be expected to result in any change in noise impacts on wildlife around the 7900 Area, and offsite noise impacts would be small because the nearest site boundary is 2.5 kilometers (1.6 miles) to the southeast. Operations would be expected to result in minimal change in noise impacts on people near ORR as a result of changes in employee and truck traffic levels.

RPL/306-E in the 300 Area of Hanford would be used for the fabrication and processing of targets associated with the medical and industrial isotope production and civilian nuclear energy research and development missions. Interior modifications of these facilities would be expected to result in little change in noise impacts on wildlife around this area and people near Hanford. Operation of these facilities for target fabrication and processing would not be expected to result in any change in noise impacts on wildlife around the 300 Area and people near Hanford. Operations would be expected to result in minimal change in noise impacts on people near Hanford as a result of changes in employee and truck traffic levels.

#### **4.3.1.1.3 Air Quality**

There are no planned FFTF outdoor construction activities associated with the restart of FFTF. No airborne constituents are currently measured or have been required to be monitored during previous reactor operations (Nielsen 2000). Several air pollutant sources are operating at FFTF, including the gas turbine emergency generator, the diesel-driven fire pump, and the oil-fired preheaters. They would continue to operate at the existing frequency. The emergency diesel generators are not currently operated or tested. The operation of FFTF would require the emergency diesel generators to be tested approximately 30 minutes each month to ensure operability (Nielsen 2000). Criteria pollutants were modeled for a stack 9.22 meters (30.3 feet) in height at a distance of 7,200 meters (23,600 feet) east of FFTF and compared with the most stringent standards for the Hanford area. The concentrations are based on a dispersion-modeling screening analysis conducted with maximum expected emission rates and a set of worst-case meteorological conditions.

The concentrations at Hanford from FFTF attributable to this option are presented in **Table 4-13**. Only those air pollutants expected to be emitted that have ambient air quality standards are presented in the table. The concentrations were determined to be small and would be below the applicable ambient standards even when ambient monitored values and contributions from other site activities were included.

There would be no change in air quality impacts from target processing at the Hanford 300 Area. Emissions of target material would be minimal due to efficient filtration and measures taken to prevent losses of expensive target material. Fugitive dust from employee and truck traffic could increase slightly.

The concentrations at Hanford attributable to this option are compared with the Prevention of Significant Deterioration Class II increments for sulfur dioxide and nitrogen dioxide in **Table 4-14**.

**Table 4–13 Incremental Hanford Concentrations Associated with Alternative 1 (Restart FFTF)—Option 1**

Pollutant	Averaging Period	Most Stringent Standard or Guideline (micrograms per cubic meter) <sup>a</sup>	Modeled Increment (micrograms per cubic meter)
Carbon monoxide	8 hours	10,000 <sup>b</sup>	52.1
	1 hour	40,000 <sup>b</sup>	74.4
Nitrogen dioxide	Annual	100 <sup>b</sup>	0.0118
PM <sub>10</sub>	Annual	50 <sup>c</sup>	8.4×10 <sup>-4</sup>
	24 hours	150 <sup>c</sup>	9.84
Sulfur dioxide	Annual	50 <sup>d</sup>	7.86×10 <sup>-4</sup>
	24 hours	260 <sup>d</sup>	9.1
	3 hours	1,300 <sup>b</sup>	20.5
	1 hour	660 <sup>d</sup>	22.8

- a. The more stringent of the Federal and state standards is presented if both exist for the averaging period. The National Ambient Air Quality Standards (NAAQS) (40 CFR Part 50), other than those for ozone, particulate matter, and lead, and those based on annual averages, are not to be exceeded more than once per year. The 24-hour PM<sub>10</sub> (particulate matter with an aerodynamic diameter less than or equal to 10 micrometers) standard is attained when the expected number of days with a 24-hour average concentration above the standard is equal to or less than 1. The annual arithmetic mean PM<sub>10</sub> standard is attained when the expected annual arithmetic mean concentration is less than or equal to the standard.
- b. Federal and state standard.
- c. Federal standard currently under litigation.
- d. State standard.

**Source:** Modeled increments are based on the SCREEN3 computer code (EPA 1995); additional data from Nielsen 2000.

**Table 4–14 PSD Class II Increments Compared to Hanford Concentrations Associated with FFTF Under Alternative 1 (Restart FFTF)—Option 1**

Pollutant	Averaging Period	Allowable PSD Increment (micrograms per cubic meter)	Modeled Increment (micrograms per cubic meter)
Nitrogen dioxide	Annual	25	0.0118
Sulfur dioxide	Annual	20	7.86×10 <sup>-4</sup>
	24 hours	91	9.1
	3 hours	512	20.5

**Key:** PSD, Prevention of Significant Deterioration.

**Source:** Modeled PSD increments are based on the SCREEN3 computer code (EPA 1995).

The air pollutant concentrations at ORR attributable to this option at REDC are presented in **Table 4–15**. The concentrations are based on a dispersion-modeling screening analysis conducted with maximum expected emission rates and a set of worst-case meteorological conditions. Criteria pollutants were modeled for a stack height of 76.2 meters (250 feet) at the boundary limit of 4,988 meters (16,370 feet). Only those air pollutants expected to be emitted that have ambient air quality standards are presented in the table.

**Table 4–15 Incremental ORR Concentrations<sup>a</sup> Associated with Alternative 1 (Restart FFTF)—Option 1**

Pollutant	Averaging Period	Most Stringent Standard or Guideline (micrograms per cubic meter) <sup>a</sup>	Modeled Increment (micrograms per cubic meter)
Nitrogen dioxide	Annual	100	1.99×10 <sup>-4</sup>
Sulfur dioxide	Annual	80	0.04
	24 hours	365	0.31
	3 hours	1,300	0.70

- a. For comparison with ambient air quality standards.

**Source:** Modeled increments are based on the SCREEN3 computer code (EPA 1995).

There are no Prevention of Significant Deterioration increment-consuming sources at ORR; therefore, a Prevention of Significant Deterioration increment consumption analysis was not conducted. Health effects from hazardous chemicals associated with this option are addressed in Section 4.3.1.1.9.

The change in ambient concentrations of these pollutants would be minimal compared to the baseline. Concentrations off site would be expected to stay well below the ambient standards even when ambient monitored values and the contribution from other site activities were included.

The air quality impacts of transportation are presented in Section 4.3.1.1.11.

#### 4.3.1.1.4 Water Resources

For the restart of FFTF, an existing facility, there would be no construction-related impacts on water bodies, floodplains, or on surface water or groundwater quality.

Incremental effects on key water resource indicators under this option are summarized in **Table 4–16**. During current standby operations, annual average groundwater withdrawal by 400 Area facilities is about 197 million liters (52 million gallons). Should FFTF be restarted, FFTF operations would increase water use by about 61 million liters (16 million gallons) to a total annual withdrawal of approximately 258 million liters (68 million gallons) (Nielsen 1999:38, 41). In addition to higher process cooling demands at FFTF from cooling tower operation, this increase reflects additional staffing and associated potable and sanitary water demands in the 400 Area (DOE 2000a:11; Nielsen 1999:38, 41). This volume of 258 million liters (68 million gallons) per year is approximately 65 percent of the 400 Area groundwater production capacity of about 398 million liters (105.1 million gallons) per year (DOE 1999a:4-262). However, no impact on regional groundwater levels would be expected from increased withdrawals (Nielsen 1999:38). Resumption of groundwater withdrawals could potentially affect the direction of groundwater flow in the unconfined aquifer system on a localized basis. Surface water would not be used for operation of the 400 Area facilities; thus, there would be no impact on the availability of surface water from the Columbia River.

**Table 4–16 Incremental Water Use and Wastewater Generation Associated with Operating FFTF and RPL/306–E at Hanford and REDC at ORR Under Alternative 1 (Restart FFTF)—Option 1**

Indicator (million liters per year)	Hanford			
	FFTF Operations <sup>a</sup>	FFTF Increment Over Standby <sup>b</sup>	RPL/306–E	ORR REDC
Water use	258	61	~ 0.016 <sup>c</sup>	2.86
Process wastewater generation	98	22	0.016	0.023
Sanitary wastewater generation	5.7	1.9	0	2.83

a. These estimates represent total projected operational impacts after restart.

b. Incremental impacts of FFTF restart and operation over standby operations (see Table 4–1).

c. Water use for RPL/306–E operations is estimated to be approximately equal to the process wastewater estimate, as no other additional demands on water use are expected.

**Note:** To convert from liters per year to gallons per year, multiply by 0.264; ~ means “approximately.”

**Source:** DOE 2000a:11, C-3; Nielsen 1999:38, 41; Wham 1999c.

Additional staffing required to support the restart of FFTF would also increase annual sanitary wastewater generation in the 400 Area by approximately 1.9 million liters (502,000 gallons) over standby to about 5.7 million liters (1.5 million gallons) per year during operations (DOE 2000a:11). Sanitary wastewater from the 400 Area is conveyed to the Energy Northwest treatment system (Nielsen 1999:39). The Energy Northwest treatment system has a treatment capacity of approximately 235 million liters (62 million gallons) per year with sufficient excess capacity to accommodate increased flow from the 400 Area (DOE 1999a:4-41).

There are no radiological liquid effluent pathways to the environment from FFTF. Process (nonradioactive) wastewater from 400 Area facilities is discharged to the 400 Area process sewer system and ultimately to the 400 Area Pond (i.e., 4608 B/C percolation ponds). These discharges are regulated under State Waste Discharge Permit No. ST-4501. This system is further described in Section 3.4.4.1.2. Process wastewater discharges from FFTF would increase by about 22 million liters (5.8 million gallons) annually over standby to approximately 98 million liters (26 million gallons) per year during operations. Increased process wastewater volume would mainly consist of cooling tower blowdown from FFTF's eight cooling towers. However, chemical usage required to control scaling and biofouling of the cooling water systems would not increase (DOE 2000a:11; Nielsen 1999:38). Therefore, as the chemical quality of the process wastewater would not change, no impact on groundwater quality would be expected.

Small quantities of liquid, low-level radioactive waste would be generated during operations associated with washing residual sodium from reactor components in FFTF's Interim Examination and Maintenance Cell and decontamination activities at the 400 Area Maintenance and Storage Facility. Approximately 6,000 liters (1,600 gallons) of liquid, low-level radioactive waste would be generated annually, which would be collected and transported to the 200 Area Effluent Treatment Facility for treatment and disposal (DOE 2000a:7; Nielsen 1999:39, 41).

REDC in the 7900 Area of ORNL at ORR would be used for neptunium-237 storage, target fabrication, and processing in support of plutonium-238 production with proposed activities similar to the current mission of REDC. As existing facilities would be used, there would be no construction-related impacts on water bodies, floodplains, or on surface water or groundwater quality. As summarized in Table 4-16, a relatively small increase in water use and sanitary wastewater generation is projected mainly to support the additional staffing required at REDC (see Section 4.3.1.1.8). The only other measurable increase would be an additional 23,000 liters (6,100 gallons) per year of process wastewater associated with target processing (Wham 1999c). Changes in the quantity or quality, if any, of process and sanitary wastewater discharges would be very small compared to that of other activities with no radiological liquid effluent discharge to the environment under normal operations (Wham 1999a; LMER 1997). Specifically, the anticipated additional 23,000 liters (6,100 gallons) of process wastewater generated per year would be negligible relative to the total volume of process wastewater generated and treated at the ORNL Process Waste Treatment Complex, approximately 2.08 million liters (550,000 gallons) per day (Section 3.2.4.1.2). All wastewaters would be discharged to designated collection and treatment systems as described in Section 3.2.4.1.2. Overall, no measurable impact on water resources at ORR is expected.

RPL/306-E in the 300 Area of Hanford would be used for the fabrication and processing of targets associated with the medical and industrial isotope production and civilian nuclear energy research and development missions. However, radiological activities would be confined to RPL, with Building 306-E providing support to activities not involving radioactive materials (DOE 2000a:C-1). As existing facilities would be used requiring no external modifications, there would be no construction-related impacts on water bodies, floodplains, or on surface water or groundwater quality. Little measurable increase in water use is anticipated to support target fabrication and processing for medical, industrial, and research and development isotope production, with no radiological liquid effluent discharge to the environment under normal operations (DOE 1997b:4-28, 4-29). Also, changes in the quantity or quality of process and sanitary wastewater discharges would be negligible compared to that of other RPL activities, with the only projected increase resulting from equipment washing of nonradiological target materials (DOE 1997b:4-30). Process wastewater discharge from washing activities at RPL is projected to increase by about 16,000 liters (4,200 gallons) per year from a current annual average of approximately 3.6 million liters (950,000 gallons) (DOE 2000a:C-3). This is an increase of less than 1 percent. The only increase in water use expected would be to support this minor increase in processing activity. Process wastewater is discharged to the 300 Area retention process

sewer system (Section 3.4.4.1.2). Thus, impacts on water resources at Hanford are expected to be negligible overall.

Waste management aspects of this option and their effects are further discussed in Section 4.3.1.1.13.

#### **4.3.1.1.5 Geology and Soils**

Since no new construction is planned under the proposed restart of FFTF, there would be no disturbance to either geologic or soil resources in the 400 Area of Hanford. As discussed in Section 4.2.1.2.5, hazards from large-scale geologic conditions at Hanford, such as earthquakes and volcanoes, were previously evaluated in the *Storage and Disposition PEIS* (DOE 1996a:4-45). The analysis determined that these hazards present a low risk to properly or specially designed or upgraded facilities. That analysis was reviewed in the *Surplus Plutonium Disposition EIS* (DOE 1999a:4-260). Further review of the data and analyses presented in these referenced documents and the site-specific data presented in this NI PEIS indicates that the large-scale geologic conditions likewise present a low risk to proposed FFTF operations. This is based on the relatively low seismic risk of the area to such specially designed facilities and the expected minimal effects from postulated volcanic events in the Cascade Region.

RPL/306-E in the 300 Area of Hanford would be used for the fabrication and processing of targets associated with the medical and industrial isotope production and civilian nuclear energy research and development missions. Because existing structures would be used, there would be no disturbance to geologic or soil resources in the 300 Area. Hazards from large-scale geologic conditions at Hanford were previously evaluated as discussed above for FFTF and determined to present a low risk to existing facilities. For the reasons previously described, the large-scale geologic conditions likewise present a low risk to the subject 300 Area facilities. As necessary, the need to evaluate and upgrade existing DOE facilities with regard to natural geologic hazards would be assessed in accordance with DOE Order 420.1, which is described in Section 4.2.1.2.5.

Because the existing REDC facility would be used for neptunium-237 storage, target fabrication, and processing, geologic and soil resources in the 7900 Area of ORR would not be disturbed. Hazards from large-scale geologic conditions at ORR, such as earthquakes and volcanoes, were previously analyzed as discussed in Section 4.2.2.2.5 and determined to present a relatively low risk to REDC.

#### **4.3.1.1.6 Ecological Resources**

Terrestrial resources would not be adversely affected by the restart of FFTF because it is in the highly disturbed and fenced 400 Area and no new construction is planned. Further, as noted in Section 4.3.1.1.2, there would be no change in noise impacts on wildlife. Because additional surface water would not be used and wastewater discharge chemistry would not be expected to change, there would be no change in impacts on aquatic habitat or wetlands associated with the Columbia River (Section 4.3.1.1.4). Due to the developed nature of the area and the fact that no new construction would take place, impacts on threatened and endangered species would not occur.

RPL/306-E in the 300 Area of Hanford would be used for the fabrication and processing of targets associated with the medical and industrial isotope production and civilian nuclear energy research and development missions. Because use of these buildings would not involve any new construction, direct disturbance to ecological resources would not occur. As noted in Section 4.3.1.1.2, wildlife would not be adversely affected by noise associated with target fabrication and processing activities. Because water usage and wastewater discharge would be small fractions of current values and discharge chemistry would not be expected to change, there would be no change in impacts on aquatic habitat or wetlands associated with the Columbia River

(Section 4.3.1.1.4). Due to the developed nature of the area and the fact that no new construction would take place, impacts on threatened and endangered species would not occur.

Consultation letters concerning threatened and endangered species were sent to the U.S. Fish and Wildlife Service, the National Marine Fisheries Service, the Washington State Department of Natural Resources, and the State of Washington Department of Fish and Wildlife (see Table 5–3). Each agency was asked to provide information on potential impacts of the proposed action on threatened and endangered species. Both the Washington State Department of Natural Resources and the State of Washington Department of Fish and Wildlife provided lists of state species of concern that occur in the vicinity of the project area. As noted above, no impacts to any threatened or endangered species are expected, including those of concern to these agencies. While DOE has made additional contacts with the U.S. Fish and Wildlife Service and the National Marine Fisheries Service, responses are pending from these agencies. Although no federally listed species are expected to be impacted by the proposed action, no action would be taken relative to the use of facilities at Hanford prior to the receipt of input from these Federal agencies.

The existing REDC at ORR would be used for neptunium-237 storage, target fabrication, and processing. No new construction would take place; thus, direct disturbance to ecological resources, including wetlands, would not occur. As noted in Section 4.3.1.1.2, there would be no change in noise impacts on wildlife. Because there are no wetlands in or directly adjacent to the 7900 Area, this resource would not be affected. There would be no change in impacts on aquatic resources because no additional water would be withdrawn from or discharged to site surface waters and discharge chemistry would not be expected to change (Section 4.3.1.1.4). Threatened and endangered species would not be impacted because an existing facility in the developed area would be used.

Consultation to comply with Section 7 of the Endangered Species Act was conducted with the U.S. Fish and Wildlife Service (see Table 5–3) and resulted in the Service concluding that it does not anticipate adverse effects to federally listed endangered species that occur near the project area. DOE has also consulted with the Tennessee Department of Environment and Conservation; a response concerning state-listed species is pending from this agency. Although no state-listed species are expected to be impacted by the proposed action, no action would be taken relative to the use of facilities at ORR prior to the receipt of input from the state.

#### **4.3.1.1.7 Cultural and Paleontological Resources**

Because FFTF is in the highly disturbed 400 Area and new construction would not be required, no direct impacts on cultural and paleontological resources would be expected. No prehistoric, historic, or paleontological sites have been identified either in the 400 Area or within 2 kilometers (1.2 miles) of the 400 Area. Six buildings in the 400 Area, including two FFTF structures (the Reactor Containment Building and FFTF Control Building), have been determined to be eligible for the National Register of Historic Places as contributing properties in the Historic District recommended for mitigation. The restart of FFTF would be consistent with the purpose for which the reactor was built and would not affect the status of the aforementioned structures.

RPL/306–E in the 300 Area of Hanford would be used for the fabrication and processing of targets associated with the medical and industrial isotope production and civilian nuclear energy research and development missions. Although a number of archaeological sites have been located at least partially within the 300 Area, none would be disturbed because new construction would not be required. Additionally, both buildings have been determined eligible for the National Register of Historic Places as contributing properties within the Historic District recommended for mitigation (Section 3.4.7.2.2); however, they would not be substantially altered by use for target fabrication and processing, and thus, their status would not change. Areas near the 300 Area that are of importance to Native Americans would not be affected by the proposed action.

Consultation to comply with Section 106 of the National Historic Preservation Act was conducted with the State Historic Preservation Office (see Table 5–3) and resulted in concurrence by the State Historic Preservation Office that the proposed action would have no effect on historic properties at Hanford. Consultation was also conducted with interested Native American tribes that resulted in comments at public hearings by members representing the Nez Perce and Confederated Tribes of the Umatilla Indian Reservation. Responses to their specific comments are addressed in Volume 3.

Neptunium-237 storage, target fabrication, and processing would take place at the existing REDC facility, which is in the 7900 Area of ORNL. Because no new construction would take place, direct impacts on cultural and paleontological resources would not occur. One structure within ORNL, the Graphite Reactor, is listed on the National Register of Historic Places as a National Historic Landmark. Additionally, several other structures proposed for listing on the National Register of Historic Places are found within or near ORNL. However, neither the Graphite Reactor nor any of the other structures is in the 7900 Area and, thus, their status would not change by the use of REDC for target fabrication and processing.

Consultation to comply with Section 106 of the National Historic Preservation Act was initiated with the State Historic Preservation Office (see Table 5–3). While DOE has made additional contact with the State Historic Preservation Office, a response is pending from this office. Although impacts to cultural resources are not expected as a result of the proposed action, no action would be taken relative to the use of facilities at ORR prior to the receipt of input from the State Historic Preservation Office.

#### **4.3.1.1.8 Socioeconomics**

Operating FFTF and target fabrication and processing of all other targets at Hanford 300 Area facilities would require about 218 additional workers to operate these facilities (DOE 1997b; Hoyt et al. 1999). This level of employment would generate about 552 indirect jobs in the region around Hanford. The potential total employment increase of 770 direct and indirect jobs in the Hanford region represents an approximate 0.3 percent increase in the projected regional economic area workforce. It would have no noticeable impact on the regional economic area.

Additional employment resulting from this option would not have any noticeable impact on community services in the Hanford region of influence. Assuming that 91 percent of the new employment associated with this option would reside in Hanford’s region of influence (Section 3.4.8), 701 new jobs could increase the region’s population by approximately 1,346 persons. This increase, in conjunction with normal population growth forecasted by the State of Washington, would not have any noticeable impact on the availability of housing and/or the price of housing in the region of influence. Given the current population-to-student ratio in the region of influence, this would likely result in an increase of about 279 students, requiring local school districts to slightly increase the number of classrooms to accommodate them.

Community services in the region of influence would be expected to change to accommodate the population growth as follows: 17 new teachers would be needed to maintain the current student-to-teacher ratio of 16:1; 2 new police officers would be needed to maintain the current officer-to-population ratio of 1.5:1000; 5 new firefighters would need to be added to maintain the current firefighter-to-population ratio of 3.4:1000; and 2 new doctors would be needed to maintain the current doctor-to-population ratio of 1.4:1000. Thus, an additional 26 positions would have to be created to maintain community services at current levels. Hospitals in the region of influence would not experience any change from the 2.1 beds per 1,000 persons currently available. Additionally, the average school enrollment would increase from 92.5 percent to 93.1 percent. None of these projected changes should have a major impact on the level of community services currently offered in the region of influence.

Target fabrication and processing of neptunium-237 targets at ORR would require about 41 additional workers to operate these facilities (Wham et al. 1998). This level of employment would generate approximately 105 indirect jobs in the region around Oak Ridge. The potential total employment increase of 146 direct and indirect jobs represents less than 0.1 percent of the projected regional economic area workforce. It would have no noticeable impact on the regional economic area.

Additional employment resulting from this option would not have any noticeable impact on community services in the ORR region of influence. Assuming that 89.9 percent of the new employment associated with this option would reside in ORR's region of influence (Section 3.2.8), 146 total new jobs could increase the region's population by approximately 248 persons. This increase, in conjunction with normal population growth forecasted by the State of Tennessee, would have no noticeable effect on the availability of housing and/or the price of housing in the region of influence. The public would experience little or no change in the level of community services currently offered in the region of influence.

#### 4.3.1.1.9 Public and Occupational Health and Safety—Normal Operations

Assessments of incremental radiological and chemical impacts associated with this option are presented in this section. Supplemental information is provided in Appendix H.

During normal operations, there would be incremental radiological and hazardous chemical releases to the environment and also incremental direct in-plant exposures. The resulting doses and potential health effects to the public and workers for this option are described below.

**RADIOLOGICAL IMPACTS.** Incremental radiological doses to three receptor groups from startup, processing, and operations are given in **Table 4-17** for FFTF and RPL at Hanford and REDC at ORR: the population within 80 kilometers (50 miles) in the year 2020, the maximally exposed member of the public, and the average exposed member of the public. The projected number of latent cancer fatalities in the surrounding population and the latent cancer fatality risk to the maximally and average exposed individuals are also presented in the table.

A probability coefficient of  $5 \times 10^{-4}$  latent cancer fatality per rem is applied for the public, and a coefficient of  $4 \times 10^{-4}$  latent cancer fatality per rem is applied for workers (ICRP 1991). The value for workers is lower due to the absence of children and the elderly, who are more radiosensitive.

To represent a bounding annual dose scenario at Hanford, it is assumed that a full-year's isotopic release would occur from target processing at RPL concurrently with a full-year's release from FFTF operations at 400 megawatts; the impacts presented in Table 4-17 assume a full-year's release resulting from FFTF and RPL preoperational testing and startup activities. To represent a bounding annual dose scenario at ORR, it is assumed that a full year's release would occur from neptunium-237 target processing at REDC.

As a result of annual operations, the bounding projected total incremental population dose in the year 2020 for the populations surrounding Hanford and ORR would be 0.25 person-rem. The corresponding number of latent cancer fatalities in these populations from 35 years of operations would be 0.0044. The bounding total incremental dose to the maximally exposed member of the public from annual operations at Hanford would be 0.0054 millirem. From 35 years of operations, the corresponding risk of a latent cancer fatality to this individual would be  $9.5 \times 10^{-8}$ . The incremental dose to the maximally exposed member of the public from annual operations at ORR would be  $1.9 \times 10^{-6}$  millirem. From 35 years of operations, the corresponding risk of a latent cancer fatality to this individual would be  $3.3 \times 10^{-11}$ .

**Table 4–17 Incremental Radiological Impacts on the Public Around ORR and Hanford from Operational Facilities Under Alternative 1 (Restart FFTF)—Option 1**

Receptor	ORR REDC Processing <sup>a</sup>	Hanford FFTF Preoper. Activities <sup>b</sup>	Hanford RPL Preoper. Activities <sup>b</sup>	Hanford FFTF Operations	Hanford RPL Target Processing <sup>a</sup>	Hanford Operations and Processing Total <sup>c</sup>
<b>Population within 80 kilometers (50 miles) in the year 2020</b>						
Dose (person-rem)	$8.8 \times 10^{-5}$	0.028	$1.0^d$	0.044	0.21	0.25
1-year latent cancer fatalities	–	$1.4 \times 10^{-5}$	$5.0 \times 10^{-4}$	–	–	–
35-year latent cancer fatalities	$1.5 \times 10^{-6}$	–	–	$7.7 \times 10^{-4}$	0.0037	0.0044
<b>Maximally exposed individual</b>						
Annual dose (millirem)	$1.9 \times 10^{-6}$	$1.4 \times 10^{-4}$	$0.043^c$	$4.1 \times 10^{-4}$	0.0050	0.0054
1-year latent cancer fatality risk	–	$6.8 \times 10^{-11}$	$2.2 \times 10^{-8}$	–	–	–
35-year latent cancer fatality risk	$3.3 \times 10^{-11}$	–	–	$7.2 \times 10^{-9}$	$8.8 \times 10^{-8}$	$9.5 \times 10^{-8}$
<b>Average exposed individual within 80 kilometers (50 miles)</b>						
Annual dose <sup>e</sup> (millirem)	$7.8 \times 10^{-8}$	$5.7 \times 10^{-5}$	$2.0 \times 10^{-3}^c$	$8.8 \times 10^{-5}$	$4.2 \times 10^{-4}$	$5.0 \times 10^{-4}$
1-year latent cancer fatality risk	–	$2.8 \times 10^{-11}$	$9.9 \times 10^{-10}$	–	–	–
35-year latent cancer fatality risk	$1.4 \times 10^{-12}$	–	–	$1.5 \times 10^{-9}$	$7.3 \times 10^{-9}$	$8.8 \times 10^{-9}$

- Target storage, processing, and fabrication activities are performed at the facility. Impacts are for all facility target activities and are dominated by processing activity impacts.
- For conservatism as well as consistency with other radiological impacts evaluated in this NI PEIS, these values were assessed for the year 2020 even though these activities would commence prior to that year.
- Represents upper-bounding values.
- Annual emissions during preoperational activities were assumed to be the same as the 1998 releases for RPL (BWHC 1999). The majority of this dose is due to tritium releases.
- Obtained by dividing the population dose by the number of people projected to live within 80 kilometers (50 miles) of the facilities in the year 2020 (about 505,000 for Hanford and 1,134,200 for ORR).

**Source:** Model results, using the GENII computer code (Napier et al. 1988).

Incremental doses to involved workers from normal operations are given in **Table 4–18**; these workers are defined as those directly associated with all process and operational activities. The incremental annual average dose to REDC workers would be 170 millirem; the incremental annual average dose to FFTF workers (during startup) would be 3.5 millirem; the incremental annual average dose to FFTF workers (during operations) would be 6.6 millirem; the incremental annual average dose to RPL workers (during startup) would be 81 millirem; and the incremental annual average dose for RPL workers (during processing) is estimated to be approximately 160 millirem. The incremental annual dose received by the total site workforce for each of these facilities (at the different phases) would be approximately 12, 0.69, 1.3, 3.2, and 4.8 person-rem, respectively. The risks and numbers of latent cancer fatalities among the different workers are included in Table 4–18. Doses to individual workers would be kept to minimal levels by instituting badged monitoring and ALARA programs.

**Table 4–18 Incremental Radiological Impacts on Involved REDC, FFTF, and RPL Workers Under Alternative 1 (Restart FFTF)—Option 1**

Receptor—Involved Workers <sup>a</sup>	ORR REDC Processing <sup>b</sup>	Hanford FFTF Preoper. Activities	Hanford RPL Preoper. Activities	Hanford FFTF Operations	Hanford RPL Target Processing <sup>b</sup>	Hanford Operations & Processing Total

- a. The radiological limit for an individual worker is 5,000 millirem per year (10 CFR Part 835). However, the maximum dose to a worker involved with operations would be kept below the DOE Administrative Control Level of 2,000 millirem per year (DOE 1999j). Further, DOE recommends that facilities adopt a more limiting, 500 millirem per year, Administrative Control Level (DOE 1999j). To reduce doses to levels that are as low as is reasonably achievable (ALARA), an effective ALARA program would be enforced.
- b. Target storage, processing, and fabrication activities are performed at this facility. Impacts, dominated by processing activities, include impacts from all facility target activities.
- c. Based on an estimated 75 badged workers.
- d. Based on an estimated 200 badged workers.
- e. Based on an estimated 40 badged workers.
- f. Based on an estimated 30 badged workers.

**Key:** NA, not applicable.

**Source:** BWHC 1999; Nielsen 1999; Wham 1999b, 2000.

**HAZARDOUS CHEMICAL IMPACTS.** No new hazardous chemical impacts would be expected at RPL/306–E in the 300 Area of Hanford. The quantities of chemicals used for target fabrication and processing would change little from ongoing operations in the 300 Area, and emissions and air quality impacts would be expected to be unchanged.

FFTF restart would require emergency diesel generators to be tested. Hazardous chemical impacts are summarized in **Table 4–19**.

**Table 4–19 Incremental Hazardous Chemical Impacts Associated with FFTF Emergency Diesel Generators at Hanford Under Alternative 1 (Restart FFTF)—Option 1**

Chemical	Modeled Annual Increment (micrograms per cubic meter)	Reference Concentration (micrograms per cubic meter)	Unit Cancer Risk (risk per micrograms per cubic meter)	Hazard Quotient	Cancer Risk
Benzene	2.5×10 <sup>-6</sup>	NA	7.8×10 <sup>-6</sup>	NA	1.96×10 <sup>-11</sup>
Toluene	1.10×10 <sup>-6</sup>	400	NA	2.74×10 <sup>-9</sup>	NA
Propylene	6.92×10 <sup>-6</sup>	NA	3.7×10 <sup>-6</sup>	NA	2.56×10 <sup>-11</sup>
Formaldehyde	3.17×10 <sup>-6</sup>	NA	0.000013	NA	4.12×10 <sup>-11</sup>
Acetaldehyde	2.06×10 <sup>-6</sup>	NA	2.2×10 <sup>-6</sup>	NA	4.53×10 <sup>-12</sup>

**Key:** NA, not applicable (the chemical is not a known carcinogen or it is a carcinogen and only unit cancer risk will apply).

**Source:** EPA 1999; model results, using the Screen3 computer model (EPA 1995).

At ORR, both carcinogenic and noncarcinogenic health effects from exposure to hazardous chemicals were evaluated. It was assumed that under normal operating conditions, the primary exposure pathway for members of the public would be from air emissions released through the 7911 stack. Emissions of chemicals were estimated based on anticipated chemical usage. A worst-case dispersion-modeling screening analysis was performed to estimate annual concentrations for each chemical, based on their emission rates.

The annual concentration for each noncarcinogenic chemical was divided by the corresponding inhalation reference concentration to estimate the Hazard Quotient for each chemical. The Hazard Quotients were summed to give the Hazard Index from all noncarcinogenic chemicals associated with this option. A Hazard Index of less than one indicates that adverse health effects from non-cancer-causing agents are not expected. For carcinogens, the annual concentration was multiplied by the unit cancer risk to estimate the increased cancer risk from that chemical. Hazardous chemical health effects are summarized in **Table 4–20**.

**Table 4–20 Incremental Hazardous Chemical Impacts on the Public Around ORR Under Alternative 1 (Restart FFTF)—Option 1**

Chemical	Modeled Annual Increment (milligrams per cubic meter)	Reference Concentration Inhalation (milligrams per cubic meter)	Unit Cancer Risk (risk per milligrams per cubic meter)	Hazard Quotient	Cancer Risk
Diethyl benzene	$3.37 \times 10^{-5}$	1	0.0078	$3.37 \times 10^{-5}$	$2.63 \times 10^{-7}$
Methanol	$1.23 \times 10^{-6}$	1.75	NA	$7.03 \times 10^{-7}$	NA
Nitric acid	$1.53 \times 10^{-6}$	0.1225	NA	$1.25 \times 10^{-5}$	NA
Tributyl phosphate	$6.34 \times 10^{-5}$	0.01	NA	0.00634	NA
Hazard Index =				0.00639	

**Note:** For diethyl benzene, the reference concentration for ethyl benzene and the unit cancer risk for benzene were used to estimate Hazard Quotient and cancer risk because no information was available for diethyl benzene. For tributyl phosphate, the reference concentration for phosphoric acid was used to estimate the Hazard Quotient because no information was available for tributyl phosphate. Propylene oxide cancer unit was used for propylene.

**Key:** NA, not applicable (the chemical is not a known carcinogen or it is a carcinogen and only unit cancer risk will apply).

**Source:** DOE 1996a; EPA 1999; model results, using the SCREEN3 computer code (EPA 1995).

#### 4.3.1.1.10 Public and Occupational Health and Safety—Facility Accidents

Impacts from postulated accidents associated with FFTF target irradiation, REDC neptunium-237 target processing, and RPL medical, industrial, research and development isotope processing are presented in this section. Detailed descriptions of the accident analyses are provided in Appendix I.

The accident analysis incorporates external events (e.g., earthquakes, fires) as well as internal events (e.g., equipment failure, human errors). A recent external event of concern is the threat of wildfires. While two large range fires at Hanford in 1984 and in June 2000 burned very close to FFTF, neither caused any damage or operational difficulties at the facility. Several features of FFTF make it well equipped to deal with a large range fire. A more detailed discussion is provided in Section I.1.1.4.1.

Estimates of radiological consequences have been developed for the maximally exposed individual, the offsite population within 80 kilometers (50 miles) of the facility, and a noninvolved worker at a distance of 640 meters (0.4 mile) from the release point. Consequences are presented in terms of radiological dose (in rem) and the probability that the dose would result in a latent cancer fatality. Accident risk is defined as the product of the accident probability (i.e., accident frequency) and the accident consequence. In this NI PEIS, risk is expressed as the increased likelihood of a latent cancer fatality per year for an individual (the maximally exposed individual or a noninvolved worker), and as the increased number of latent cancer fatalities per year in the

offsite population. The probability coefficients for determining the likelihood of a latent cancer fatality, given a dose, are presented in Section 4.2.1.2.10. Consequences to involved workers are addressed in Section I.1.7.

To provide a better indication of risks from the postulated accidents, the risks are summed for each facility and also for each option. Although the summation provides the combined risk for the spectrum of accidents analyzed, it does not indicate total risk. To determine total risk from accidents, a full-scope probabilistic risk analysis would be required for each facility. Since full-scope probabilistic risk analyses are not available to incorporate in this NI PEIS, the summation of the spectrum of accident risks was considered appropriate for the purposes of this NI PEIS. Details of the risk summation calculations are provided in Appendix I.

Consequences and associated risks are presented in **Tables 4–21** and **4–22**, respectively.

FFTF would operate for 21 years with a mixed oxide core followed by 14 years with a highly enriched uranium core. As shown in Table 4–21, the beyond-design-basis core melt accident would result in the largest radiological consequences among FFTF accidents. To incorporate internal and external initiators, the accident frequency of  $1 \times 10^{-6}$  was selected for the beyond-design-basis core melt accident. For 35 years of operation, the increased risk of a latent cancer fatality to the maximally exposed individual and to a noninvolved worker would be  $1.23 \times 10^{-8}$  and  $1.20 \times 10^{-8}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.00127.

For 35 years of REDC neptunium-237 target fabrication and processing, the increased risk of a latent cancer fatality to the maximally exposed individual and of an early fatality to a noninvolved worker would be  $5.71 \times 10^{-5}$  and  $3.50 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.157.

For 35 years of RPL medical, industrial, and research and development target fabrication and processing, the increased risk of a latent cancer fatality to the maximally exposed individual and to a noninvolved worker would be  $4.51 \times 10^{-4}$  and  $3.50 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.377.

For 35 years under this option, the increased risk of a latent cancer fatality to the maximally exposed individual and of a fatality to a noninvolved worker would be  $4.51 \times 10^{-4}$  and  $3.50 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.535.

The irradiation of medical, industrial, research and development, and neptunium-237 targets at FFTF would not introduce any additional operations that require the use of hazardous chemicals. Thus, there are no postulated hazardous chemical accidents attributable to the irradiation of medical, industrial, research and development, or neptunium-237 targets at FFTF.

Processing associated with the plutonium-238 production program at REDC, including storage of neptunium-237 and plutonium-238, neptunium-237 target fabrication, postirradiation processing to extract plutonium-238 and to recycle the unconverted neptunium-237 into new targets, does not require the introduction of hazardous chemicals that are not in current use in the facility. The quantities of in-process hazardous chemicals for the plutonium-238 production program are bounded by the quantities of the material currently stored in the facility. The impacts of in-process hazardous chemical accidents associated with the plutonium-238 production are bounded by the impacts of hazardous chemical accidents for existing storage facilities at REDC.

<b>35-year Option risk<sup>d</sup></b>	$4.51 \times 10^{-4}$	0.535	$3.50 \times 10^{-4}$

a. Increased likelihood of a latent cancer fatality.

b. Increased number of latent cancer fatalities.

c. Risk of an early fatality.

d. Individual risks are summed only for collocated individuals. The highest individual risk was used to represent the 35-year option risk.

**Key:** BLTC, bottom-loading transfer cask; HEU, highly enriched uranium core; MOX, mixed oxide core.

**Source:** Model results, using the MACCS2 (Chanin and Young 1997) and GENII (Napier et al. 1988) computer codes.

Processing associated with the medical, industrial, and research and development isotope production program at RPL, including target fabrication and postirradiation processing, would not require the introduction of hazardous chemicals that are not in current use in the facility. The quantities of in-process hazardous chemicals for the medical and industrial isotope production program are bounded by the quantities of the material currently stored in the facility. The impacts of in-process hazardous chemical accidents associated with the medical and industrial isotope production are bounded by the impacts of hazardous chemical accidents for existing storage facilities at RPL.

#### **4.3.1.1.11 Public and Occupational Health and Safety—Transportation**

DOE would transport neptunium-237 from storage at SRS to the REDC target fabrication facility at ORR. DOE would transport the unirradiated neptunium-237 targets from REDC to FFTF. Following irradiation in FFTF, the targets would be returned to REDC for processing. After this processing, the plutonium-238 product would be shipped to LANL. FFTF would receive highly enriched uranium fuel from a U.S. fuel fabrication facility and mixed oxide fuel from Europe. Additionally, medical and industrial isotopes would be shipped from FFTF to a local airport, and from there to locations throughout the country.

Approximately 38,000 shipments of radioactive materials would be made by DOE. The total distance traveled on public roads by trucks carrying radioactive materials would be 8.0 million kilometers (5.0 million miles); at sea by ships carrying mixed oxide fuel, 96,000 kilometers (52,000 nautical miles); and in the air carrying medical isotopes, 23 million kilometers (14 million miles).

The transportation impact analysis is described in detail in Appendix J.

**IMPACTS OF INCIDENT-FREE TRANSPORTATION.** The dose to transportation workers from all transportation activities entailed by this option has been estimated at 31 person-rem; the dose to the public, 299 person-rem. Accordingly, incident-free transportation of radioactive material associated with this option would result in 0.012 latent cancer fatality among transportation workers and 0.15 latent cancer fatality in the total affected population over the duration of the transportation activities. The estimated number of nonradiological fatalities from vehicular emissions associated with this option would be 0.03. About half of the crew risk, about 2 percent of the public risk, and most of the emissions risk would result from shipping medical and industrial isotopes.

**IMPACTS OF ACCIDENTS DURING TRANSPORTATION.** The maximum foreseeable offsite transportation accident under this option (probability of occurrence: 1 in 10 million per year) is a shipment of irradiated neptunium-237 targets to REDC with a severity Category V accident in an urban population zone under neutral (average) weather conditions. The accident could result in a dose of 0.61 person-rem to the public with an associated  $3.1 \times 10^{-4}$  latent cancer fatality, and 2.6 millirem to the hypothetical maximally exposed individual with a latent cancer fatality risk of  $1.3 \times 10^{-6}$ . No fatalities would be expected to occur. The probability of more severe accidents, different weather conditions at the time of the accident, or occurrence while carrying neptunium-237 (unirradiated) or plutonium-238 was also evaluated and estimated to have a probability of less than 1 in 10 million per year.

Estimates of the total transportation accident risks under this option are as follows: a radiological dose to the population of 1,063 person-rem, resulting in 0.53 latent cancer fatality; and traffic accidents resulting in 0.19 traffic fatality. Nearly all of the radiological and traffic accident risk would result from shipping medical and industrial isotopes.

**IMPACTS OF MARINE TRANSPORTATION.** The potential impacts of marine transport of mixed oxide fuel on the global commons (i.e., portions of the ocean not within the territorial boundary of any nation) were

evaluated in accordance with Executive Order 12114 (44 FR 1957). Following a hypothetical severe accident, radioactive particles dispersed over the ocean would not be in large enough amounts to have a measurable impact on the environment. The risks of accidents approaching and docking at the port have been estimated to be less than  $1 \times 10^{-9}$  person-rem, resulting in less than  $1 \times 10^{-12}$  latent cancer fatality. The radiological doses associated with incident-free transportation, which include the exposure of the ship's crew to low levels of radiation during transport and handling of the packages, have been estimated to be approximately 0.03 person-rem for a route to an east coast port and 0.06 person-rem for a route to a west coast port. These doses would result in  $1.2 \times 10^{-5}$  and  $2.4 \times 10^{-5}$  latent cancer fatalities, respectively.

#### 4.3.1.1.12 Environmental Justice

**NORMAL OPERATIONS.** The number of expected latent cancer fatalities among the population residing within 80 kilometers (50 miles) of REDC at ORR and FFTF and RPL at Hanford would be less than 0.005 for 35 years of normal operations (Table 4–17). As shown in Tables 4–19 and 4–20, the release of hazardous chemicals at Hanford and ORR would pose no significant risk of cancer or toxic effects among the public. As discussed in Sections K.5.2 and K.5.3, the expected latent cancer fatalities that would result from the ingestion of food that could be radiologically contaminated due to normal operations would be approximately 0.002 at Hanford and essentially zero at ORR. No credible pattern of food consumption by persons residing in potentially affected areas would result in significant health risks due to radiological contamination of food supplies near Hanford or ORR. As discussed in Section 4.3.1.1.11, incident-free transportation would not be expected to result in fatalities.

**ACCIDENTS.** Expected latent cancer fatalities among populations at risk due to radiological accidents listed in Table 4–22 would be approximately 0.5. In the event a radiological accident were to occur at REDC and winds were from the southwest, the predominantly minority population of the Scarboro Community adjacent to the northern boundary of ORR would lie in the path of highest potential radiological exposure (see Figure K–6). If the winds were from the west, the predominantly minority populations in Knoxville, Tennessee, would lie in the path of exposure. Because the accidents that could occur under the implementation of this option would not be expected to result in significant offsite exposures to any exposed offsite individual or populations, neither situation would result in a disproportionately high and adverse risk to any group or individuals within the population. If a radiological accident were to occur at FFTF or the 300 Area at Hanford and northeasterly winds prevailed at the time of the accident, radiological contamination from the accident would be directed toward the Yakama Indian Reservation (see Figure K–11). However, accidents that could occur under the implementation of this option would not be expected to result in a latent cancer fatality among the population or maximally exposed individual residing within the boundary of the Yakama Indian Reservation.

The number of expected latent cancer fatalities resulting from transportation accidents with radiological emissions was found to be approximately 0.5. As discussed in Appendix J, this risk is driven by accidents that could occur during air transportation of medical and industrial isotopes and the conservative assumptions used in the analysis of such accidents. Such accidents could occur anywhere along the flight paths and would not place any identifiable group within the general population at disproportionate risk. As discussed in Section 4.3.2.1.11 and Appendix J, expected fatalities due to a fatal traffic collision would be approximately 0.2.

In summary, normal operations and accidents that could result from the implementation of this option would pose no significant radiological or nonradiological risks to the public, and implementation would pose no disproportionately high and adverse risks to any group within the population.

### 4.3.1.1.13 Waste Management

The expected generation rates of waste at Hanford that would be generated from the operation of FFTF for irradiating targets and RPL/306-E for processing and fabricating target materials for the research and development support and medical and industrial isotope production are compared with Hanford’s treatment, storage, and disposal capacities in **Table 4–23**. The expected generation rates of waste at ORR that would be associated with the operation of REDC to fabricate and process the neptunium-237 targets for plutonium-238 production are compared with ORR’s treatment, storage, and disposal capacities in **Table 4–24**.

Sanitary wastewater	2,832	0.0068	NA	NA
Solid	148	NA <sup>n</sup>	NA <sup>n</sup>	0.42

- a. See definitions in Section G.9.
- b. The estimated additional amounts of waste generated annually are compared with the annual site treatment capacities. The estimated total amounts of additional waste generated over the assumed 35-year operational period are compared with the site storage and disposal capacities.
- c. Refer to the text for a discussion on waste classification and treatment.
- d. This waste would be stored on site pending availability of a suitable repository. It is assumed this waste would be remotely handled.
- e. Liquid low-level radioactive waste is processed through an evaporator for volume reduction. The evaporator bottoms are stored as a concentrated solution.
- f. The solid low-level radioactive waste would not be treated on site.
- g. Refer to the text for a discussion of potential limitations of the onsite storage capacity for solid low-level radioactive waste and the probable solution.
- h. It is anticipated that solid low-level radioactive waste and solid mixed low-level radioactive waste would be disposed of at an off site facility.
- i. Reported as low-level radioactive waste.
- j. In the short-term, the Toxic Substances Control Act Incinerator would be used for the treatment of solid mixed low-level radioactive waste. If this facility is shut down, the site's management and integration contractor would identify other options for treatment of this waste.
- k. Refer to the text for a discussion of potential limitations of the onsite storage capacity for solid mixed low-level radioactive waste and the probable solution.
- l. Although there is some treatment and storage capacity for hazardous waste, this waste would be shipped off site to permitted commercial facilities.
- m. The nonhazardous process wastewater would be discharged to a permitted outfall or otherwise disposed of off site after onsite treatment.
- n. Solid nonhazardous waste would be taken to the Oak Ridge Y-12 landfill for disposal.

**Note:** To convert from cubic meters per year to cubic yards per year, multiply by 1.308; to convert from kilograms to pounds, multiply by 2.20; < means "less than."

**Key:** NA, not applicable.

**Source:** Brunson 1999b; Wham 1999c, 1999d, 1999e.

The impacts on the Hanford and ORR waste management systems in terms of managing the additional waste are discussed in this section. This analysis is consistent with policy and DOE Order 435.1, that DOE radioactive waste shall be treated, stored, and in the case of low-level waste, disposed of at the site where the waste is generated, if practical, or at another DOE facility. However, if DOE determines that use of the Hanford waste management infrastructure or other DOE sites is not practical or cost effective, DOE may issue an exemption under DOE Order 435.1 for the use of non-DOE facilities (i.e., commercial facilities) to store,

treat, and dispose of such waste generated from the restart and operation of FFTF. Radiological and chemical impacts on workers and the public from waste management activities are included in the public and occupational health and safety impacts that are given in Sections 4.3.1.1.9 through 4.3.1.1.11.

Canisters used to transport neptunium-237 to ORR would constitute a very small additional amount of solid low-level radioactive waste—less than 10 cubic meters (13.1 cubic yards) over the 35-year operational period, even if no credit is taken for volume reduction by compaction (Brunson 1999a). The annual generation of this waste would fall within the range of accuracy of the generation rate of solid low-level radioactive waste given in Table 4–24, and its management need not be addressed separately.

In accordance with the Records of Decision for the *Waste Management PEIS* (DOE 1997a), waste could be treated and disposed of on site at Hanford or at other DOE sites or commercial facilities. Based on the Record of Decision for high-level radioactive waste issued on August 12, 1999 (64 FR 46661), immobilized high-level radioactive waste would be stored on site until transfer to a geologic repository. Based on the Record of Decision for transuranic waste issued on January 20, 1998 (63 FR 3629), transuranic waste would be certified on site and eventually shipped to a suitable geologic repository for disposal. Based on the Record of Decision for hazardous waste issued on August 5, 1998 (63 FR 41810), nonwastewater hazardous waste would continue to be treated and disposed of at offsite commercial facilities. Based on the Record of Decision for low-level radioactive waste and mixed low-level radioactive waste issued on February 18, 2000 (65 FR 10061), minimal treatment of low-level radioactive waste will be performed at all sites and, to the extent practicable, onsite disposal of low-level radioactive waste will continue. Hanford and the Nevada Test Site will be made available to all DOE sites for disposal of low-level radioactive waste. Mixed low-level radioactive waste analyzed in the *Waste Management PEIS* (DOE 1997a) will be treated at Hanford, INEEL, ORR, and SRS and will be disposed of at Hanford and the Nevada Test Site.

No high-level radioactive waste or transuranic waste would be generated from merely operating FFTF or from target fabrication and processing in RPL/306–E.

Solid low-level radioactive waste generated from target irradiation at FFTF and fabrication and processing in RPL/306–E would be packaged in appropriate containers or burial casks, certified, and transferred for additional treatment and disposal in the existing onsite low-level radioactive Burial Grounds. Liquid low-level radioactive waste generated from target irradiation at FFTF and fabrication and processing in RPL/306–E would be transported to the 200 Area Effluent Treatment Facility for processing and ultimate disposal.

An additional 2,200 cubic meters (2,900 cubic yards) of solid low-level radioactive waste would be generated over the 35-year operational period as a result of target irradiation at FFTF as compared to the current standby mode for FFTF. Target fabrication and processing at RPL/306–E would generate about 700 cubic meters (920 cubic yards) of solid low-level radioactive waste over the 35-year operational period. The total amount of additional solid low-level radioactive waste resulting from operations at FFTF and RPL/306–E represents approximately 0.17 percent of the 1.74-million-cubic-meter (2.28-million-cubic-yard) capacity of the low-level radioactive Burial Grounds. Using the 3,480-cubic-meter-per-hectare (1,842-cubic-yard-per-acre) disposal land usage factor for Hanford published in the *Storage and Disposition PEIS* (DOE 1996a:E-9), 2,900 cubic meters (3,800 cubic yards) of waste would require 0.83 hectares (2.1 acres) of disposal space at Hanford. The impacts of managing this additional low-level radioactive waste at Hanford would be minimal.

There would be no increase in liquid low-level radioactive waste generation as a result of target irradiation at FFTF as compared to the current standby mode for FFTF, nor for target fabrication and processing at the RPL/306–E.

Mixed low-level radioactive waste would be stabilized, packaged, and stored on site for treatment and disposal in a manner consistent with the Tri-Party Agreement (EPA et al. 1989) for Hanford. Over the 35-year operational period, no additional mixed low-level radioactive waste would be generated as a result of target irradiation at FFTF as compared to the current standby mode. Mixed low-level radioactive waste generated at RPL/306-E associated with target fabrication and processing is estimated over the 35-year operation period to be about 140 cubic meters (180 cubic yards). This mixed low-level radioactive waste is expected to be treated at a nearby commercial facility. This additional waste is estimated to be about 0.83 percent of the 16,800-cubic-meter (22,000-cubic-yard) storage capacity of the Central Waste Complex and about 0.98 percent of the 14,200-cubic-meter (18,600-cubic-yard) planned disposal capacity of the Radioactive Mixed Waste Disposal Facility. Therefore, this additional waste would only have a minimal impact on the management of mixed low-level radioactive waste at Hanford.

Hazardous waste generated during operation would be packaged in DOT-approved containers and shipped off site to permitted commercial recycling, treatment, and disposal facilities. The additional waste load generated during the 35-year operational period would have only a minimal impact on the Hanford hazardous waste management system.

Nonhazardous solid waste would be packaged and transported in conformance with standard industrial practice. Solid waste such as office paper, metal cans, and plastic and glass bottles that can be recycled would be sent off site for that purpose. The remaining solid sanitary waste would be sent for offsite disposal. This additional waste load would have only a minimal impact on the nonhazardous solid waste management system at Hanford.

Nonhazardous sanitary wastewater from FFTF operations would be discharged to the 400 Area sanitary sewer system, which connects to the Energy Northwest Sewage Treatment Facility. Nonhazardous sanitary wastewater generated at FFTF would represent about 0.81 percent of the 235,000-cubic-meter-per-year (307,000-cubic-yard-per-year) capacity of the Energy Northwest Sewage Treatment Facility.

Nonhazardous process wastewater from FFTF would be discharged into the 400 Area Ponds. This discharge is regulated by State Waste Discharge Permit ST-4501. Nonhazardous process wastewater generated from target fabrication and processing in RPL/306-E would be discharged to the 300 Area Treated Effluent Disposal Facility.

The generation rates of waste at Hanford that would be associated with this option (refer to Table 4-23) can be compared with the current waste generation rates at the site, given in Table 3-34 (Section 3.4.11). The waste generation rates would be much smaller than the current waste generation rates at the site.

The analysis for the Draft NI PEIS assumed that the waste generated from the processing of irradiated neptunium-237 targets is transuranic waste. However, as a result of comments received during the public comment period, DOE is considering whether the waste from processing of irradiated neptunium-237 targets should be classified as high-level radioactive waste and not transuranic waste. Irrespective of how the waste is classified (i.e., transuranic or high-level radioactive waste), the composition and characteristics are the same, and the waste management activities (i.e., treatment and onsite storage) as described in this NI PEIS would be the same. In addition, either waste type would require disposal in a suitable repository. If it is transuranic waste, it would be nondefense waste and could not be disposed of at WIPP under current law. Because nondefense transuranic waste has no current disposal path, DOE Headquarters' approval would be necessary before a decision were made to generate such waste, as required by DOE Order 435.1. If the waste is classified as high-level radioactive waste, it is assumed for the purposes of this analysis that Yucca Mountain, Nevada, if approved, would be the final disposal site for DOE's high-level radioactive waste. The other differences between these two waste classifications are that a high-level radioactive waste repository requires a much more

rigorous waste-form qualification process than a transuranic waste repository and there is a slightly different set of requirements for high-level radioactive waste than for transuranic waste delineated in DOE Manual 435.1.

Target fabrication and processing in REDC would generate a total of 385 cubic meters (504 cubic yards) of transuranic or high-level radioactive waste over the 35-year operational period. As described in Section 3.4.5 of the *Preconceptual Design Planning for Chemical Processing to Support Pu-238 Production* (Wham 1998), the waste would be vitrified into a glass matrix at a glass melter installed within REDC. The resulting glass matrix would be stored on site pending availability of a suitable repository. This additional waste would represent approximately 18 percent of the available 2,169-cubic-meter (2,837-cubic-yard) storage capacity in facilities 7572, 7574, 7826, 7878, 7879, and 7883. The impacts of managing the additional quantities of this waste at ORR would be minimal.

Low-level radioactive waste at ORR would be treated, packaged, certified, and accumulated before transfer for additional treatment and disposal at onsite and offsite facilities. Annual liquid low-level radioactive waste generation (including mixed low-level radioactive waste—refer to Table 4–24) that would be associated with neptunium-237 target fabrication and processing in REDC is estimated to be 0.13 percent of the 19,908-cubic-meter-per-year (26,040-cubic-yard-per-year) site treatment capacity. If all the liquid low-level radioactive waste generated over the 35-year operational period were stored on site, the amount would represent 24 percent of the 3,646-cubic-meter (4,769-cubic-yard) storage capacity at ORR, and 46 percent of the estimated onsite disposal capacity of 1,894 cubic meters (2,477 cubic yards) of tank storage for liquid low-level radioactive waste from the Liquid Low-Level Waste Evaporator Facility Building 2531. Solid low-level radioactive waste would not be treated on site. If all the solid low-level radioactive waste generated over the 35-year operational period were stored on site, the amount would represent 2.6 percent of the 47,000-cubic-meter (61,500-cubic-yard) storage capacity at ORR. If account is taken of the existing inventory of solid low-level radioactive waste (41,000 cubic meters [53,600 cubic yards]) and of its present generation rate (7,000 cubic meters [9,160 cubic yards] per year), sufficient storage capacity probably would not be available. However, this should be considered only an interim situation. Arrangements are being made that would allow the solid low-level radioactive waste to be treated and disposed of off site at another DOE site or at a commercial facility, thereby eliminating any onsite storage problems, including the storage capacity limitations at ORR. A draft *Environmental Assessment for Transportation of Low-Level Radioactive Waste from the Oak Ridge Reservation to Off-Site Treatment and Disposal Facilities* (DOE 2000d) was issued by the Oak Ridge Operations Office.

The management of the additional low-level radioactive waste from 35 years of operating REDC to fabricate and process neptunium-237 targets would not have a major impact on ORR's ability to manage low-level radioactive waste.

Mixed low-level radioactive waste associated with neptunium-237 target fabrication and processing at ORR would be stabilized, packaged, and stored on site for treatment and disposal in a manner consistent with the site treatment plan. Liquid mixed low-level radioactive waste is reported as low-level radioactive waste; the generation and management of this waste are covered under the low-level radioactive waste discussion above. Solid mixed low-level radioactive waste generation is estimated to be less than 2.2 percent of the 227-cubic-meter-per-year (297-cubic-yard-per-year) site treatment capacity. If all the solid mixed low-level radioactive waste generated over the 35-year operational period were stored on site, the amount would represent less than 0.57 percent of the 30,780-cubic-meter (40,260-cubic-yard) storage capacity at ORR. However, if account is taken of the existing inventory of solid mixed low-level radioactive waste (24,964 cubic meters [32,700 cubic yards]) and of its present generation rate (801 cubic meters [1,050 cubic yards] per year), part or all of the storage capacity may not be available. As is the case for the solid low-level radioactive waste, arrangements are being made that would allow the solid mixed low-level radioactive waste to be disposed of

off site at another DOE site or at a commercial facility, thereby eliminating any onsite storage problems, including the storage capacity limitations at ORR. A draft *Environmental Assessment for Transportation of Low-Level Radioactive Mixed Waste from the Oak Ridge Reservation to Off-Site Treatment or Disposal Facilities* (DOE 2000e) was developed by the Oak Ridge Operations Office.

Managing the small additional quantities of mixed waste that would be generated at ORR would not impact ORR's management of this type of waste.

At ORR, hazardous waste associated with the fabrication and processing of neptunium-237 targets at REDC would be packaged in DOT-approved containers, and shipped off site to permitted commercial recycling, treatment, and disposal facilities. The additional waste load generated during the operational period would only have a minimal impact on ORR's management of hazardous waste.

Nonhazardous solid waste associated with neptunium-237 target fabrication and processing in REDC would be packaged in conformance with standard industrial practices and disposed of in the onsite landfills. If all the nonhazardous solid waste generated over the 35-year operational period were disposed of in Industrial Landfills V and VI, only 0.42 percent of the 1,219,000-cubic-meter (1,594,000-cubic-yard) total capacity of these landfills would be needed. Nonhazardous sanitary wastewater from REDC operations would be discharged to the sanitary wastewater treatment facility. Nonhazardous process wastewater would be processed, as necessary, in the wastewater treatment facilities before discharge to an outfall or other offsite disposition facility. The additional solid and liquid waste loads would only have a minimal impact on nonhazardous waste management at ORR.

The generation rates of waste at ORR that would be associated with this option (Table 4–24) can be compared with the current waste generation rates at the site, given in Table 3–11 (Section 3.2.11). The waste generation rates associated with plutonium-238 production would be much smaller than the current waste generation rates at the site. However, if the waste resulting from processing irradiated neptunium-237 is classified as high-level radioactive waste, although ORR does not currently manage high-level radioactive waste, the impacts to the waste management infrastructure would be minimal.

#### 4.3.1.1.14 Spent Nuclear Fuel Management

Data on spent nuclear fuel generation and storage under all options of Alternative 1 are presented in Table 4–25.

**Table 4–25 Data for Spent Nuclear Fuel Generation and Storage Under All Options of Alternative 1 (Restart FFTF)**

Data Parameter	At FFTF
Operating duration (years)	35
Operating power level (megawatts)	100
Existing spent nuclear fuel inventory (metric tons of heavy metal)	11 <sup>a</sup>
Method of storage	Sodium-cooled vessels and dry storage casks
Number of spent nuclear fuel assemblies generated annually	About 12 to 15 (i.e., 2 casks per year)
Spent nuclear fuel generated in 35 years (metric tons of heavy metal)	16

a. The total spent nuclear fuel inventory at Hanford is 2,133 metric tons of heavy metal.

**Note:** To convert from metric tons to pounds, multiply by 2,200.

**Source:** DOE 2000a.

The operation of FFTF would generate about 0.46 metric ton heavy metal (1,012 pounds) of spent nuclear fuel per year. For the 35-year mission at 100 megawatts, this would equate to a total of 16 metric tons of heavy

metal (35,200 pounds) of spent nuclear fuel, which is less than 1 weight-percent of the total spent nuclear fuel inventory presently stored at Hanford.

The currently authorized storage modes for the FFTF spent nuclear fuel include two sodium-filled storage vessels within the facility and the interim storage area located at the northeast corner of the FFTF site which now is capable of accommodating spent nuclear fuel in 49 aboveground dry storage casks. It is projected that these storage modes will provide enough capacity at the reactor site for 35 years of reactor operation. This projection is based on the assumption that the nonfuel irradiated components are disposed of and do not remain in storage. If it is conservatively assumed that this hardware remains in storage, the number of spaces available for spent nuclear fuel storage would be reduced. With this worst-case assumption, it is projected that the current storage modes would support 24 years of reactor operation. Since the operation of FFTF would result in the generation of 12 to 15 spent nuclear fuel assemblies per year and each dry storage cask is capable of storing 7 assemblies, the additional storage capacity for years 25 through 35 of reactor operation could be provided by loading 2 additional dry storage casks per year.

Upon cessation of reactor operation, or earlier, the spent nuclear fuel would be packaged in acceptable containers and shipped to a geologic repository for disposal. Refer to Section 4.6.1.3.13 for further information on the geologic repository.

**CONSTRUCTION IMPACTS.** The interim storage area is currently authorized for spent nuclear fuel storage in 49 dry storage casks. Prior to standby, 30 dry storage casks were procured, 18 of which are storing spent nuclear fuel and 12 of which are currently empty. It is anticipated that with additional cask procurement, the interim storage area, as currently authorized, would provide enough capacity for 35 years of reactor operation. As such, no construction impacts associated with expanding the dry cask storage capability of the interim storage area would be incurred.

However, based on the worst case assumption that all the irradiated nonfuel hardware would remain in storage, it is possible that the interim storage area would need to accommodate 20 additional dry storage casks. The construction impact of providing an additional concrete storage pad north of the existing concrete pad would be minimal.

**OPERATIONAL IMPACTS.** Operation of the sodium-filled storage vessels and the dry storage casks would not result in significant releases of radionuclides to the environment. The airborne radionuclides emitted from overall FFTF operations have always been at levels practically indistinguishable from natural background radiation. During the last year of reactor operations (1992), the overall radionuclide releases from the entire FFTF complex resulted in a total effective dose equivalent to the maximally exposed member of the public of less than  $1.0 \times 10^{-4}$  millirem (DOE 2000a). This dose is well below EPA's Clean Air Act standard of 10 millirem per year that is cited in DOE Order 5400.5. Any dose contribution from the storage vessels would be expected to be only a small fraction of the overall dose. No radionuclide releases from the dry cask storage system would occur because the spent nuclear fuel is contained in a sealed confinement.

Although no radionuclides are expected to be released from the dry storage cask, the cask would be a source of direct and skyline-scattered radiation that would penetrate the thick concrete shielding of the cask. The direct radiation is from neutron and gamma sources emitted from the spent nuclear fuel, with the greatest contribution coming from the gamma source. Based on the operating experience of the Independent Spent Fuel Storage Installation (ISFSI) facilities (BGE 1989; NRC 1986; Duke 1988; NRC 1985), the direct radiation dose to an individual 100 meters from the cask was calculated to be in the range of 0.01 to 0.1 millirem per hour. This direct radiation would have an effect only on onsite workers; the radiation dose is greatly reduced to insignificant levels beyond the site boundary. The whole body dose to an offsite

individual (at about or more than 1,000 meters [0.62 mile] from the site) for these ISFSIs is normally less than 1 millirem per year.

The operation of the dry storage system would generate a small quantity of decay heat, which is removed by natural air convection and would not have any effect on the offsite environment.

There would be no liquid releases to the environment associated with spent nuclear fuel management. The environmental impacts associated with the dry spent nuclear fuel storage system are summarized in **Table 4–26**. The dry spent fuel storage at the FFTF site is similar to NRC-approved methods currently being used for interim storage of commercial spent nuclear fuel.

**Table 4–26 Environmental Impact of Dry Spent Nuclear Fuel Storage System Under All Options of Alternative 1 (Restart FFTF)**

Environmental Parameter	Environmental Impact
Radiological impacts (normal operation)	Dose of less than 0.1 millirem per year, well below EPA's Clean Air Act standard of 10 millirem per year
Effect of decay heat on the site	Equivalent to 210 light bulbs (100 watts each); no offsite effect
Facility water use	Small
Liquid and solid radwaste generated	Small; no discharges to the environment
Chemical and biocide generated	Minimal (if any)
Effect of sanitary waste discharges	Minimal
Noise and traffic impacts	Minimal
Effect of maintenance of the electrical system	Minimal
Effect on ecology	Minimal
Socioeconomics	Small; fewer than five additional people would be employed

Source: BGE 1989; Duke 1988; NRC 1985; NRC 1986.

### 4.3.2 Alternative 1 (Restart FFTF)—Option 2

Option 2 involves operating FFTF at Hanford to irradiate all targets and materials associated with plutonium-238 production, medical and industrial isotope production, and research and development; operating FDPF at INEEL to fabricate and process neptunium-237 targets and to process the plutonium-238 product; and operating facilities in the Hanford 300 Area to fabricate and process the other targets and materials and to process the associated products. This option includes storage in Building CPP–651 or FDPF of the neptunium-237 transported from SRS to INEEL and storage in RPL/306–E of the other target materials transported to Hanford from other offsite facilities.

The transportation of the mixed oxide and highly enriched uranium fuel to Hanford for use in FFTF, the transportation of the neptunium-237 to INEEL and then to Hanford, the transportation of the other target material to Hanford, and the transportation of the product materials following irradiation and postirradiation processing are also part of this option.

Under Option 2, FFTF would operate with a mixed oxide fuel core for the first 21 years and with a highly enriched uranium fuel core for the next 14 years.

#### 4.3.2.1 Operations and Transportation

The environmental impacts associated with storage, processing, and irradiation operations and with all transportation activities are assessed in this section.

#### **4.3.2.1.1 Land Resources**

**LAND USE.** The restart of FFTF would not result in impacts on land use at Hanford for the reasons described in Section 4.3.1.1.1.

Building CPP-651 and/or FDPF, which are both in the INTEC area of INEEL, would be used for neptunium-237 storage, and FDPF for target fabrication and processing. The use of either facility would require internal modifications, but no new facilities would be built. Because additional land would not be disturbed and the use of Building CPP-651 and/or FDPF would be compatible with the missions for which they were designed, there would be no change in land use at INEEL.

Using RPL/306-E for research and development support and medical and industrial isotope target fabrication and processing would not result in impacts on land use at Hanford for the reasons described in Section 4.3.1.1.1.

**VISUAL RESOURCES.** The restart of FFTF would not result in impacts on visual resources at Hanford for the reasons described in Section 4.3.1.1.1.

All activities associated with neptunium-237 storage, target fabrication, and processing would take place in Building CPP-651 and/or FDPF. Because neither facility would require external modification, there would be no change in appearance. Therefore, the current Visual Resource Management Class IV rating for INTEC would not change. Because there would be no change in the appearance of either of these facilities or the INTEC area, there would be no impact on visual resources.

Using RPL/306-E for research and development support and medical and industrial isotope target fabrication and processing would not result in impacts on visual resources at Hanford for the reasons described in Section 4.3.1.1.1.

#### **4.3.2.1.2 Noise**

For the restart of FFTF, the change in noise impacts from construction and operation would be expected to be small as described in Section 4.3.1.1.2.

Building CPP-651 and/or FDPF, both in the INTEC area of INEEL, would be used for neptunium-237 target-material storage, and FDPF for target fabrication and processing. Interior modifications of these facilities in the INTEC area of INEEL would be expected to result in little change in noise impacts on wildlife around this area. The operation of these facilities would not be expected to result in any change in noise impacts on wildlife around the INTEC area and offsite noise impacts would be small because the nearest site boundary is 12 kilometers (7.5 miles) to the south. Operation would be expected to result in minimal change in noise impacts on people near the INEEL as a result of changes in employee and truck traffic levels.

RPL/306-E in the 300 Area of Hanford would be used for the fabrication and processing of targets associated with the medical and industrial isotope production and civilian nuclear energy research and development missions. Interior modifications of these facilities and operation would be expected to result in little change in noise impacts on wildlife around this area and people near Hanford as described in Section 4.3.1.1.2.

### 4.3.2.1.3 Air Quality

Under this option, air quality impacts due to the restart and operation of FFTF would be the same as under Option 1 (Section 4.3.1.1.3). Air quality impacts from target fabrication and processing in the Hanford 300 Area facility would be the same as under Option 1 (Section 4.3.1.1.3).

The concentrations at INEEL attributable to FDPF operations under this option are presented in **Table 4–27**. The concentrations are based on a dispersion-modeling screening analysis conducted with maximum expected emission rates and a set of worst-case meteorological conditions. Criteria and toxic air pollutants were modeled for a stack height of 48.8 meters (160 feet) at a boundary limit of 6,800 meters (22,300 feet). Only those air pollutants expected to be emitted that have ambient air quality standards are presented in the table. The change in concentrations of these pollutants would be small and would be below applicable ambient standards even when ambient monitored values and the contribution from other site activities were included.

**Table 4–27 Incremental INEEL Concentrations<sup>a</sup> Associated with Alternative 1 (Restart FFTF)—Option 2**

Pollutant	Averaging Period	Most Stringent Standard or Guideline (micrograms per cubic meter)	Modeled Increment (micrograms per cubic meter)
<b>Criteria pollutants</b>			
Nitrogen dioxide	Annual	100	$3.66 \times 10^{-4}$
Sulfur dioxide	Annual	80	0.024
	24 hours	365	0.19
	3 hours	1,300	0.43
<b>Toxic air pollutants</b>			
Methanol	24 hours	13,000	0.0048
Nitric acid	24 hours	250	0.0097
Paraffin hydrocarbons	24 hours	100	0.44
Tributyl phosphate	24 hours	110	0.25

a. For comparison with ambient air quality standards.

**Note:** Toxic air pollutant standards apply to new or modified sources only.

**Source:** 40 CFR Part 50; ID DHW 1998; modeled increments are based on the SCREEN3 computer code (EPA 1995).

The concentrations at INEEL attributed to this option are compared with the Prevention of Significant Deterioration Class II increments for nitrogen dioxide and sulfur dioxide in **Table 4–28**.

**Table 4–28 PSD Class II Increments Compared to INEEL Concentrations Associated with Alternative 1 (Restart FFTF)—Option 2**

Pollutant	Averaging Period	Allowable PSD Increment (micrograms per cubic meter)	Modeled Increment (micrograms per cubic meter)
Nitrogen dioxide	Annual	25	$3.66 \times 10^{-4}$
Sulfur dioxide	Annual	20	0.024
	24 hours	91	0.19
	3 hours	512	0.43

**Key:** PSD, Prevention of Significant Deterioration.

**Source:** Modeled PSD increments are based on the SCREEN3 computer code (EPA 1995).

Health impacts from FDPF chemical releases are discussed in Section 4.3.2.1.9.

The air quality impacts of transportation are presented in Section 4.3.2.1.11.

#### 4.3.2.1.4 Water Resources

Impacts on water resources at Hanford associated with the restart of FFTF would be substantially the same as those described in Section 4.3.1.1.4.

Building CPP-651 and/or FDPF, which are both located within the INTEC area of INEEL, would be used for neptunium-237 storage with target fabrication and processing in support of plutonium-238 production conducted in FDPF. The projected incremental effects on key water resource indicators are summarized in **Table 4-29**. As existing facilities would be used, there would be no construction-related impacts on water bodies, floodplains, or on surface water or groundwater quality. A relatively small increase in water use and sanitary wastewater generation is projected mainly attributable to the additional staffing required at FDPF (see Section 4.3.2.1.8). The only other measurable increase would be an additional 23,000 liters (6,100 gallons) per year of process wastewater associated with target processing in FDPF (Kirkham 1999; Wham 1999c). All wastewater would be discharged to designated collection and treatment systems as described in Section 3.3.4.1.2. There would be no radiological liquid effluent discharge to the environment under normal operations, and no measurable impact on water resources at INEEL would be expected.

**Table 4-29 Incremental Water Use and Wastewater Generation Associated with Operating FDPF at INEEL Under Alternative 1 (Restart FFTF)—Option 2**

Indicator (million liters per year)	INEEL
	FDPF
Water use	1.68
Process wastewater generation	0.023
Sanitary wastewater generation	1.66

**Note:** To convert from liters per year to gallons per year, multiply by 0.264.

**Source:** Kirkham 1999; Wham 1999c.

RPL/306-E in the 300 Area of Hanford would be used for the fabrication and processing of targets associated with the medical and industrial isotope production and civilian nuclear energy research and development missions. As a result, it is expected that impacts on water resources at Hanford would be negligible as previously described in Section 4.3.1.1.4.

Waste management aspects of this option and their effects are further discussed in Section 4.3.2.1.13.

#### 4.3.2.1.5 Geology and Soils

The restart of FFTF would not be expected to result in impacts on geologic and soil resources at Hanford, nor be jeopardized by large-scale geologic conditions, for the reasons described in Sections 4.2.1.2.5 and 4.3.1.1.5.

Because existing facilities (i.e., Building CPP-651 and/or FDPF) would be used, there would be no disturbance to either geologic or soil resources at INTEC. Hazards from large-scale geologic conditions, such as earthquakes and volcanoes, were previously evaluated as discussed in Section 4.2.3.2.5. The analysis determined that these hazards present a low risk for neptunium-237 storage in INTEC facilities. Likewise, large-scale geologic conditions do not present a substantial risk to use of the proposed facilities for neptunium-237 storage, target fabrication, and processing.

Using RPL/306-E for research and development support and medical and industrial isotope target fabrication and processing would not be expected to result in impacts on geologic resources at Hanford, nor be jeopardized by large-scale geologic conditions, for the reasons described in Sections 4.2.1.2.5 and 4.3.1.1.5. As necessary,

the need to evaluate and upgrade existing DOE facilities with regard to natural geologic hazards would be assessed in accordance with DOE Order 420.1, which is described in Section 4.2.1.2.5.

#### **4.3.2.1.6 Ecological Resources**

The restart of FFTF would not be expected to result in impacts on ecological resources at Hanford for the reasons described in Section 4.3.1.1.6.

Because no new construction is planned, the use of Building CPP-651 and/or FDFP at INEEL would not result in direct disturbance to ecological resources. As noted in Section 4.3.2.1.2, there would be little change in noise impacts on wildlife. Because additional water usage and wastewater discharge would be small fractions of current values, and discharge chemistry would not be expected to change, there would be no impact on aquatic resources (Section 4.3.2.1.4). Due to the developed nature of the area and the fact that no new construction would take place, impacts on threatened and endangered species would not occur.

Consultation letters to comply with Section 7 of the Endangered Species Act were sent to the U.S. Fish and Wildlife Service and the Idaho Department of Fish and Game (see Table 5-3). Each agency was asked to provide information on potential impacts of the proposed action on threatened and endangered species. The Idaho Department of Fish and Game indicated that their database contained no known occurrences of special status plants or animals near the project area. While DOE has made additional contact with the U.S. Fish and Wildlife Service, a response is pending from this agency. Although no federally listed species are expected to be impacted by the proposed action, no action would be taken relative to the use of facilities at INEEL prior to the receipt of input from the Service.

Using RPL/306-E for research and development support and medical and industrial isotope target fabrication and processing would not result in impacts on ecological resources at Hanford for the reasons described in Section 4.3.1.1.6.

#### **4.3.2.1.7 Cultural and Paleontological Resources**

The restart of FFTF would not result in impacts on cultural resources at Hanford for the reasons described in Section 4.3.1.1.7.

No new construction is planned; therefore, direct impacts on cultural and paleontological resources at INTEC would not occur. The use of Building CPP-651 and/or FDFP to store neptunium-237 or FDFP to fabricate and process neptunium-237 targets would not change the status of six historic structures located at INTEC. Also, Native American resources occurring in the vicinity of INTEC would not be impacted.

Consultation to comply with Section 106 of the National Historic Preservation Act was initiated with the State Historic Preservation Office (see Table 5-3). The State Historic Preservation Office indicated that Building CPP-651 and FDFP are likely to be eligible for the National Register of Historic Places as contributory properties in a potential historic district of exceptional significance. However, at this time, the State Historic Preservation Office has determined that more information is needed prior to assisting DOE in evaluating these properties. The State Historic Preservation Office also indicated that since there would be no new construction, there is little potential for effects on archaeological properties. DOE would provide additional information as required to the Idaho State Historic Preservation Office prior to the use of any facility at INEEL for the proposed project. Consultation was conducted with interested Native American tribes; however, responses are pending.

Using RPL/306–E for research and development support and medical and industrial isotope target fabrication and processing would not result in impacts on cultural resources at Hanford for the reasons described in Section 4.3.1.1.7.

#### **4.3.2.1.8 Socioeconomics**

The socioeconomic impacts associated with restarting and operating FFTF to irradiate all targets, and operating RPL/306–E to fabricate and process all other targets are addressed in Section 4.3.1.1.8.

Target fabrication and processing of neptunium-237 targets at INEEL would require approximately 24 additional workers (Hill et al. 1999). This level of employment could generate 64 indirect jobs in the region around INEEL. The potential total employment increase of 88 direct and indirect jobs in the INEEL region represents less than 0.1 percent of the projected regional economic area workforce. It would have no noticeable impact on the regional economic area.

Additional employment resulting from this option would not have any noticeable impact on community services in the INEEL region of influence. Assuming 94 percent of the new employment associated with this alternative would reside in INEEL's region of influence (Section 3.3.8), 83 new jobs could increase the region's population by approximately 161 persons. This increase in conjunction with normal population growth forecasted by the State of Idaho would not have any noticeable effect on the availability of housing and/or the price of housing in the region of influence. The public would experience little or no change in the level of community services currently offered in the region of influence.

#### **4.3.2.1.9 Public and Occupational Health and Safety—Normal Operations**

Assessments of incremental radiological and chemical impacts associated with this option are presented in this section. Supplemental information is provided in Appendix H.

During normal operations, there would be incremental radiological and hazardous chemical releases to the environment and also incremental direct in-plant exposures. The resulting doses and potential health effects to the public and workers for this option are described below.

**RADIOLOGICAL IMPACTS.** Incremental radiological doses to three receptor groups from startup, processing, and operations are given in **Table 4–30** for FFTF and RPL at Hanford and FDPF at INEEL: the population within 80 kilometers (50 miles) in the year 2020, the maximally exposed member of the public, and the average exposed member of the public. The projected number of latent cancer fatalities in the surrounding population and the latent cancer fatality risk to the maximally and average exposed individuals are also presented in the table.

A probability coefficient of  $5 \times 10^{-4}$  latent cancer fatality per rem is applied for the public, and a coefficient of  $4 \times 10^{-4}$  latent cancer fatality per rem is applied for workers (ICRP 1991). The value for workers is lower due to the absence of children and the elderly, who are more radiosensitive.

To represent a bounding annual dose scenario at Hanford, it is assumed that a full-year's isotopic release would occur from target processing at RPL concurrently with a full-year's release from FFTF operations at 400 megawatts; the impacts presented in Table 4–30 also assume a full-year's release resulting from FFTF and RPL preoperational testing and startup activities. To represent a bounding annual dose scenario at INEEL, it is assumed that a full year's release would occur from neptunium-237 target processing at FDPF.

**Table 4–30 Incremental Radiological Impacts on the Public Around INEEL and Hanford from Operational Facilities Under Alternative 1 (Restart FFTF)—Option 2**

Receptor	INEEL FDPF Processing <sup>a</sup>	Hanford Preoperational Activities <sup>b</sup>		Hanford FFTF Operations	Hanford RPL Target Processing <sup>a</sup>	Hanford Operations and Processing Total <sup>c</sup>
		FFTF	RPL			
<b>Population within 80 kilometers (50 miles) in the year 2020</b>						
Dose (person-rem)	$3.9 \times 10^{-6}$	0.028	$1.0^d$	0.044	0.21	0.25
1-year latent cancer fatalities	–	$1.4 \times 10^{-5}$	$5.0 \times 10^{-4}$	–	–	–
35-year latent cancer fatalities	$6.7 \times 10^{-8}$	–	–	$7.7 \times 10^{-4}$	0.0037	0.0044
<b>Maximally exposed individual</b>						
Annual dose (millirem)	$2.6 \times 10^{-7}$	$1.4 \times 10^{-4}$	$0.043^c$	$4.1 \times 10^{-4}$	0.0050	0.0054
1-year latent cancer fatality risk	–	$6.8 \times 10^{-11}$	$2.2 \times 10^{-8}$	–	–	–
35-year latent cancer fatality risk	$4.6 \times 10^{-12}$	–	–	$7.2 \times 10^{-9}$	$8.8 \times 10^{-8}$	$9.5 \times 10^{-8}$
<b>Average exposed individual within 80 kilometers (50 miles)</b>						
Annual dose <sup>e</sup> (millirem)	$2.0 \times 10^{-8}$	$5.7 \times 10^{-5}$	$0.0020^c$	$8.8 \times 10^{-5}$	$4.2 \times 10^{-4}$	$5.0 \times 10^{-4}$
1-year latent cancer fatality risk	–	$2.8 \times 10^{-11}$	$9.9 \times 10^{-10}$	–	–	–
35-year latent cancer fatality risk	$3.6 \times 10^{-13}$	–	–	$1.5 \times 10^{-9}$	$7.3 \times 10^{-9}$	$8.8 \times 10^{-9}$

- a. Target storage, processing, and fabrication activities are performed at the facility. Impacts are for all facility target activities and are dominated by processing activity impacts.
- b. For conservatism as well as consistency with other radiological impacts evaluated in this NI PEIS, these values were assessed for the year 2020 even though these activities would commence prior to that year.
- c. Represents upper-bounding values.
- d. Annual emissions during preoperational activities were assumed to be the same as the 1998 releases for RPL (BWHC 1999). The majority of this dose is due to tritium releases.
- e. Obtained by dividing the population dose by the number of people projected to live within 80 kilometers (50 miles) of the facilities in the year 2020 (about 505,000 for Hanford and 188,400 for INEEL).

**Source:** Model results, using the GENII computer code (Napier et al. 1988).

As a result of annual operations, the bounding projected total incremental population dose in the year 2020 for the populations surrounding Hanford and INEEL would be 0.25 person-rem. The corresponding number of latent cancer fatalities in these populations from 35 years of operations would be 0.0044. The bounding total incremental dose to the maximally exposed member of the public from annual operations at Hanford would be 0.0054 millirem. From 35 years of operations, the corresponding risk of a latent cancer fatality to this individual would be  $9.5 \times 10^{-8}$ . The incremental dose to the maximally exposed member of the public from annual operations at FDPF would be  $2.6 \times 10^{-7}$  millirem. From 35 years of operations, the corresponding risk of a latent cancer fatality to this individual would be  $4.6 \times 10^{-12}$ .

Incremental doses to involved workers from normal operations are given in **Table 4–31**; these workers are defined as those directly associated with all process and operational activities. The incremental annual average dose to FDPF workers would be 170 millirem; the incremental annual average dose to FFTF workers (during startup) would be 3.5 millirem; the incremental annual average dose to FFTF workers (during operations) would be 6.6 millirem; the incremental annual average dose to RPL workers (during startup) would be 81 millirem; and the incremental annual average dose for RPL workers (during processing) would be approximately 160 millirem. The incremental annual dose received by the total workforce for each of these

facilities (at the different phases) would be approximately 12, 0.69, 1.3, 3.2, and 4.8 person-rem, respectively. The risks and numbers of latent cancer fatalities among the different workers are included in Table 4–31. Doses to individual workers would be kept to minimal levels by instituting badged monitoring and ALARA programs.

**Table 4–31 Incremental Radiological Impacts on Involved FDPF, FFTF, and RPL Workers Under Alternative 1 (Restart FFTF)—Option 2**

Receptor—Involved Workers <sup>a</sup>	INEEL FDPF Processing <sup>b</sup>	Hanford Preoperational Activities		Hanford		
		FFTF	RPL	FFTF Operations	RPL Target Processing <sup>b</sup>	Operations and Processing Total
Total dose (person-rem per year)	12 <sup>c</sup>	0.69 <sup>d</sup>	3.2 <sup>e</sup>	1.3 <sup>d</sup>	4.8 <sup>f</sup>	6.1
1-year latent cancer fatalities	–	2.8×10 <sup>-4</sup>	0.0013	–	–	–
35-year latent cancer fatalities	0.17	–	–	0.018	0.067	0.086
Average worker dose (millirem per year)	170	3.5	81	6.6	160	NA
1-year latent cancer fatality risk	–	1.4×10 <sup>-6</sup>	3.2×10 <sup>-5</sup>	–	–	–
35-year latent cancer fatality risk	0.0023	–	–	9.2×10 <sup>-5</sup>	0.0022	NA

a. The radiological limit for an individual worker is 5,000 millirem per year (10 CFR Part 835). However, the maximum dose to a worker involved with operations would be kept below the DOE Administrative Control Level of 2,000 millirem per year (DOE 1999j). Further, DOE recommends that facilities adopt a more limiting, 500 millirem per year, Administrative Control Level (DOE 1999j). To reduce doses to levels that are as low as is reasonably achievable (ALARA), an effective ALARA program would be enforced.

b. Target storage, processing, and fabrication activities are performed at this facility. Impacts, dominated by processing activities, include impacts from all facility target activities.

c. Based on an estimated 75 badged workers.

d. Based on an estimated 200 badged workers.

e. Based on an estimated 40 badged workers.

f. Based on an estimated 30 badged workers.

**Key:** NA, not applicable.

**Source:** BWHC 1999; Mecham 1999; Nielsen 1999; Wham 1999b, 2000.

**HAZARDOUS CHEMICAL IMPACTS.** Hazardous chemical impacts associated with FFTF restart and target fabrication and processing in the 300 Area at Hanford were determined to be the same as for Option 1 (Section 4.3.1.1.9). Hazardous chemical impacts associated with processing in FDPF at INEEL are presented in **Table 4–32** and show little effect from air pollutant releases associated with this option.

#### 4.3.2.1.10 Public and Occupational Health and Safety—Facility Accidents

Impacts from postulated accidents associated with FFTF target irradiation, FDPF neptunium-237 target processing, and RPL medical and industrial target processing are presented in this section. Detailed descriptions of the accident analyses are provided in Appendix I.

Estimates of radiological consequences have been developed for the maximally exposed individual, the offsite population within 80 kilometers (50 miles) of the facility, and a noninvolved worker at a distance of 640 meters (0.4 mile) from the release point. Consequences are presented in terms of radiological dose (in rem) and the probability that the dose would result in a latent cancer fatality. Accident risk is defined as the product of the

**Table 4–32 Incremental Hazardous Chemical Impacts on the Public Around INEEL Under Alternative 1 (Restart FFTF)—Option 2**

Chemical	Modeled Annual Increment (micrograms per cubic meter)	RfC (micrograms per cubic meter)	Unit Cancer Risk (risk per micrograms per cubic meter)	Hazard Quotient	Cancer Risk
Diethyl benzene	0.0165	1,000	$7.80 \times 10^{-6}$	$1.65 \times 10^{-5}$	$1.29 \times 10^{-7}$
Methanol	$6.02 \times 10^{-4}$	1,750	NA	$3.44 \times 10^{-7}$	NA
Nitric acid	0.00121	122.5	NA	$9.86 \times 10^{-6}$	NA
Tributyl phosphate	0.031	10	NA	0.0031	NA
Hazard Index =				0.0031	

**Note:** For diethyl benzene, the reference concentration for ethyl benzene and the unit cancer risk for benzene were used. For tributyl phosphate, the reference concentration for phosphoric acid was used to estimate the Hazard Quotient because no information was available for tributyl phosphate.

**Key:** NA, not applicable (the chemical is not a known carcinogen); RfC, Reference Concentration.

**Source:** DOE 1996a; EPA 1999; model results, using the SCREEN3 computer code (EPA 1995).

accident probability (i.e., accident frequency) and the accident consequence. In this NI PEIS, risk is expressed as the increased likelihood of a latent cancer fatality per year for an individual (the maximally exposed individual or a noninvolved worker), and as the increased number of latent cancer fatalities per year in the offsite population. The probability coefficients for determining the likelihood of a latent cancer fatality, given a dose, are presented in Section 4.2.1.2.10. Consequences to involved workers are addressed in Section I.1.7.

To provide a better indication of risks from the postulated accidents, the risks are summed for each facility and also for each option. Although the summation provides the combined risk for the spectrum of accidents analyzed, it does not indicate total risk. To determine total risk from accidents, a full-scope probabilistic risk analysis would be required for each facility. Since full-scope probabilistic risk analyses are not available to incorporate in this NI PEIS, the summation of the spectrum of accident risks was considered appropriate for the purposes of this NI PEIS. Details of the risk summation calculations are provided in Appendix I.

Consequences and associated risks are presented in **Tables 4–33** and **4–34**, respectively.

FFTF would operate for 21 years with a mixed oxide core followed by 14 years with a highly enriched uranium core. As shown in Table 4–33, the beyond-design-basis core melt accident would result in the largest radiological consequences among FFTF accidents. To incorporate internal and external initiators, the accident frequency of  $1 \times 10^{-6}$  was selected for the beyond-design-basis core melt accident. For 35 years of operation, the increased risk of a latent cancer fatality to the maximally exposed individual and to a noninvolved worker would be  $1.23 \times 10^{-8}$  and  $1.20 \times 10^{-8}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.00127.

For 35 years of FDPF neptunium-237 target fabrication and processing, the increased risk of a latent cancer fatality to the maximally exposed individual and of an early fatality to a noninvolved worker would be  $1.49 \times 10^{-5}$  and  $3.50 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.0287.

For 35 years of RPL medical, industrial, and research and development target fabrication and processing, the increased risk of a latent cancer fatality to the maximally exposed individual and to a noninvolved worker would be  $4.51 \times 10^{-4}$  and  $3.50 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.377.

Medical and industrial isotopes glovebox explosion ( $1 \times 10^{-4}$ )	$5.00 \times 10^{-6}$	0.00230	$3.92 \times 10^{-6}$
<b>35-year RPL risk</b>	$4.51 \times 10^{-4}$	0.377	$3.50 \times 10^{-4}$
<b>35-year Option risk<sup>d</sup></b>	$4.51 \times 10^{-4}$	0.407	$3.50 \times 10^{-4}$

a. Increased likelihood of a latent cancer fatality.

b. Increased number of latent cancer fatalities.

c. Risk of an early fatality.

d. Individual risks are summed only for collocated individuals. The highest individual risk was used to represent the 35-year option risk.

**Key:** BLTC, bottom-loading transfer cask; HEU, highly enriched uranium core; MOX, mixed oxide core.

**Source:** Model results, using the MACCS2 (Chanin and Young 1997) and GENII (Napier et al. 1988) computer codes.

For 35 years under this option, the increased risk of a latent cancer fatality to the maximally exposed individual and of a fatality to a noninvolved worker would be  $4.51 \times 10^{-4}$  and  $3.50 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.407.

The irradiation of medical, industrial, research and development, and neptunium-237 targets at FFTF would not introduce any additional operations that require the use of hazardous chemicals. Thus, there are no postulated hazardous chemical accidents attributable to the irradiation of medical, industrial, or neptunium-237 targets at FFTF.

No chemical processing activities are currently performed at FDPF and no chemicals are stored in this facility. Processing activities in support of plutonium-238 production would require the introduction of hazardous chemicals, specifically nitric acid and nitric oxide. Potential health impacts from accidental releases of nitric acid were assessed by comparing estimated airborne concentrations of the chemicals to Emergency Response Planning Guidelines (ERPG) developed by the American Industrial Hygiene Association. The ERPG-1 value (0.5 part per million) is the maximum airborne concentration below which nearly all individuals could be exposed for up to 1 hour, resulting in only mild, transient, and reversible adverse health effects. The ERPG-2 value (10 parts per million) is protective of irreversible or serious health effects or impairment of an individual's ability to take protective action. The ERPG-3 value (25 parts per million) is indicative of potentially life-threatening health effects.

The maximum distances, in meters, needed to reach the ERPG values for nitric acid releases at FDPF for Stability Classes D and F are shown in **Table 4-35**. Two separate atmospheric conditions were evaluated, Stability Classes D and F. Stability Class D represents average meteorological conditions while Stability Class F represents worst-case meteorological conditions. The number of involved and noninvolved workers potentially exposed would vary with a number of factors, such as the time of day and whether they are sheltered within buildings at the time of release. Individuals at the nearest highway (5,800 meters [3.6 miles]) and at the nearest site boundary (13,952 meters [8.7 miles]) from FDPF would be exposed to levels well below ERPG-1.

**Table 4-35 ERPG Distances for Nitric Acid Releases at FDPF**

Evaluation Parameter	Stability Class D (meters)	Stability Class F (meters)
ERPG-3	375	450
ERPG-2	500	600
ERPG-1	2,000	3,000

**Note:** To convert from meters to miles, multiply by  $6.22 \times 10^{-4}$ .

**Key:** ERPG, Emergency Response Planning Guideline.

There are no ERPG values for nitric oxide. For nitric oxide accidents, the level of concern has been estimated by using one-tenth of the "Immediately Dangerous to Life and Health" level published by the National Institute for Occupational Safety and Health. The Immediately Dangerous to Life and Health value for nitric oxide is 100 parts per million. The level of concern value used for this PEIS is 10 parts per million. The level of concern is defined as the concentration of an extremely hazardous substance in air above which there may be serious irreversible health effects as a result of a single exposure for a relatively short period of time.

For FDPF, the maximum distances needed to reach the level of concern for nitric oxide releases for Stability Classes D and F are 500 and 2,000 meters (1,640 and 6,560 feet), respectively. The number of involved and noninvolved workers potentially exposed would vary with a number of factors such as the time of day and whether they are sheltered within buildings at the time of release. Individuals at the nearest highway (5,800 meters [3.6 miles]) and at the nearest site boundary (13,952 meters [8.7 miles]) from FDPF would be exposed to levels well below the level of concern for nitric oxide.

Potential health impacts from the accidental release of the hazardous chemicals were assessed for a noninvolved worker, offsite individuals who are members of the public located at the nearest site boundary, and onsite individuals who are members of the public located at the nearest highway access onsite.

The impacts associated with the accidental release of nitric acid and nitric oxide at FDPF are presented in **Table 4–36**.

**Table 4–36 FDPF Hazardous Chemical Accident Impacts Under Alternative 1 (Restart FFTF)—Option 2**

Receptor	Evaluation Parameter	Nitric Acid		Nitric Oxide	
		Stability Class D	Stability Class F	Stability Class D	Stability Class F
Noninvolved worker (640 meters)	Parts per million Level of concern Potential health effects	3.3 <ERPG-2 Mild, transient	8.4 <ERPG-2 Mild, transient	4.2 <LOC Mild, transient	67.5 >LOC Serious
Nearest highway maximally exposed individual	Parts per million Level of concern Potential health effects	0.05 < ERPG-1 None	0.15 ERPG-1 Mild, transient	0.09 < LOC None	0.87 < LOC None
Site boundary maximally exposed individual	Parts per million Level of concern Potential health effects	<<0.05 < ERPG-1 None	<<0.15 ERPG-1 Mild, transient	<<0.09 < LOC None	<<0.87 < LOC None

**Note:** < means “less than”; << means “much less than.”

**Key:** ERPG, Emergency Response Planning Guideline; LOC, level of concern.

**Source:** Model results.

Processing associated with the medical, industrial, and research and development isotope production program at RPL, including target fabrication and postirradiation processing, would not require the introduction of hazardous chemicals that are not in current use in the facility. The quantities of in-process hazardous chemicals for the medical and industrial isotope production program are bounded by the quantities of the material currently stored in the facility. The impacts of in-process hazardous chemical accidents associated with the medical, industrial, and research and development isotope production are bounded by the impacts of hazardous chemical accidents for existing storage facilities at RPL.

#### 4.3.2.1.11 Public and Occupational Health and Safety—Transportation

DOE would transport neptunium-237 from storage at SRS to the FDPF target fabrication facility at INEEL. DOE would transport the unirradiated neptunium-237 targets from FDPF to FFTF. Following irradiation in FFTF, the targets would be returned to FDPF for processing. After this processing, the plutonium-238 product would be shipped to LANL. FFTF would receive highly enriched uranium fuel from a U.S. fuel fabrication facility and mixed oxide fuel from Europe. Additionally, medical and industrial isotopes would be shipped from FFTF to a local airport, and from there to locations throughout the country.

Approximately 38,000 shipments of radioactive materials would be made by DOE. The total distance traveled on public roads by trucks carrying radioactive materials would be 6.2 million kilometers (3.9 million miles); at sea by ships carrying mixed oxide fuel, 96,000 kilometers (52,000 nautical miles); and in the air carrying medical isotopes, 23 million kilometers (14 million miles).

The transportation impacts analysis is described in detail in Appendix J.

**IMPACTS OF INCIDENT-FREE TRANSPORTATION.** The dose to transportation workers from all transportation activities entailed by this option has been estimated at 21 person-rem; the dose to the public, 88 person-rem. Accordingly, incident-free transportation of radioactive material associated with this option would result in 0.008 latent cancer fatality among transportation workers and 0.044 latent cancer fatality in the total affected population over the duration of the transportation activities. The estimated number of nonradiological fatalities from vehicular emissions associated with this option would be 0.024. About half of the crew risk, about 8 percent of the public risk, and most of the emissions risk would result from shipping medical and industrial isotopes.

**IMPACTS OF ACCIDENTS DURING TRANSPORTATION.** The maximum foreseeable offsite transportation accident under this option (probability of occurrence: 1 in 10 million per year) is a shipment of irradiated neptunium-237 targets to FDPF with a severity Category V accident in an urban population zone under neutral (average) weather conditions. The accident could result in a dose of 0.61 person-rem to the public with an associated  $3.1 \times 10^{-4}$  latent cancer fatality, and 2.6 millirem to the hypothetical maximally exposed individual with a latent cancer fatality risk of  $1.3 \times 10^{-6}$ . No fatalities would be expected to occur. The probability of more severe accidents, different weather conditions at the time of the accident, or occurrence while carrying neptunium-237 (unirradiated) or plutonium-238 was also evaluated and estimated to have a probability of less than 1 in 10 million per year.

Estimates of the total transportation accident risks under this option are as follows: a radiological dose to the population of 1,063 person-rem, resulting in 0.53 latent cancer fatality; and traffic accidents resulting in 0.13 traffic fatality. Nearly all of the radiological and traffic accident risk would result from shipping medical and industrial isotopes.

**IMPACTS OF MARINE TRANSPORTATION.** The potential impacts of marine transport of mixed oxide fuel on the global commons (i.e., portions of the ocean not within the territorial boundary of any nation) were evaluated in accordance with Executive Order 12114 (44 FR 1957). Following a hypothetical severe accident, radioactive particles dispersed over the ocean would not be in large enough amounts to have a measurable impact on the environment. The risks of accidents approaching and docking at the port have been estimated to be less than  $1 \times 10^{-9}$  person-rem, resulting in less than  $1 \times 10^{-12}$  latent cancer fatality. The radiological doses associated with incident-free transportation, which include the exposure of the ship's crew to low levels of radiation during transport and handling of the packages, have been estimated to be approximately 0.03 person-rem for a route to an east coast port and 0.06 person-rem for a route to a west coast port. These doses would result in  $1.2 \times 10^{-5}$  and  $2.4 \times 10^{-5}$  latent cancer fatalities, respectively.

#### **4.3.2.1.12 Environmental Justice**

**NORMAL OPERATIONS.** The number of expected latent cancer fatalities among the populations residing within 80 kilometers (50 miles) of FDPF at INEEL and FFTF and RPL at Hanford would be less than 0.005 for 35 years of normal operations (Table 4-30). As shown in Table 4-32, the release of hazardous chemicals at INEEL would pose no significant risk of cancer or toxic effects among the public. As discussed in Sections K.5.1 and K.5.3, the expected latent cancer fatalities that would result from the ingestion of food that could be radiologically contaminated due to normal operations would be approximately 0.002 at Hanford and essentially zero at INEEL. No credible pattern of food consumption by persons residing in potentially affected areas would result in significant health risks due to radiological contamination of food supplies near Hanford or INEEL. As shown in Section 4.3.2.1.11, incident-free transportation would not be expected to result in fatalities.

**ACCIDENTS.** The number of expected latent cancer fatalities among populations at risk due to radiological accidents listed in Table 4-34 would be approximately 0.41. In the event a radiological accident were to occur

at FDPF and northwesterly winds prevailed at the time of the accident, radiological contamination would be directed toward the Fort Hall Indian Reservation (see Figure K-2). If a radiological accident were to occur at FFTF or the 300 Area at Hanford and northeasterly winds prevailed at the time of the accident, radiological contamination from the accident would be directed toward the Yakama Indian Reservation (see Figure K-11). However, accidents that could occur under the implementation of this option would not be expected to result in a latent cancer fatality among the populations or a maximally exposed individuals residing within the boundaries of the Fort Hall Indian Reservation or Yakama Indian Reservation.

The number of expected latent cancer fatalities resulting from transportation accidents with radiological emissions was found to be approximately 0.5. As discussed in Appendix J, this risk is driven by accidents that could occur from air transportation of medical and industrial isotopes and the conservative assumptions used in the analysis of such accidents. Such accidents could occur anywhere along the flight paths and would not place any identifiable group within the general population at disproportionate risk. As discussed in Section 4.3.2.1.11 and Appendix J, expected fatalities due to a traffic collision would be approximately 0.14.

In summary, normal operations and accidents that could result from the implementation of this option would pose no significant radiological or nonradiological risks to the public, and implementation would pose no disproportionately high and adverse risks to any group within the population.

#### 4.3.2.1.13 Waste Management

The impacts of managing waste generated from irradiating targets in FFTF and processing and fabricating target materials for the research and development support and medical and industrial isotope production in RPL/306-E are assumed to be the same as for Option 1 (Section 4.3.1.1.13). This is because the same amount of plutonium-238 production, medical and industrial isotope production, and civilian nuclear energy research and development support would be accomplished annually. As discussed in that section, the impacts on Hanford's waste management systems would be minimal.

The expected generation rates of waste that would be associated with the operation of FDPF to fabricate and process neptunium-237 targets are compared with INEEL's treatment, storage, and disposal capacities in **Table 4-37**. The impacts on the INEEL waste management systems, in terms of managing the additional waste, are discussed in this section. Radiological and chemical impacts on workers and the public from waste management activities are included in the public and occupational health and safety impacts that are given in Sections 4.3.2.1.9 through 4.3.2.1.11.

Canisters used to transport neptunium-237 to INEEL would constitute a very small additional amount of solid low-level radioactive—less than 10 cubic meters (13.1 cubic yards) over the 35-year operational period, even if no credit is taken for volume reduction by compaction (Brunson 1999a). The annual generation of this waste would fall within the range of accuracy of the generation rate of solid low-level radioactive waste given in Table 4-37, and its management need not be addressed separately.

In accordance with the Records of Decision for the *Waste Management PEIS* (DOE 1997a), waste could be treated and disposed of on site at INEEL or at other DOE sites or commercial facilities. Based on the Record of Decision for high-level radioactive waste issued on August 12, 1999 (64 FR 46661), immobilized high-level radioactive waste would be stored on site until transfer to a geologic repository. Based on the Record of Decision for transuranic waste issued on January 20, 1998 (63 FR 3629), transuranic waste would be certified on site and eventually shipped to a suitable geologic repository for disposal. Based on the Record of Decision for hazardous waste issued on August 5, 1998 (63 FR 41810), nonwastewater hazardous waste would continue to be treated and disposed of at offsite commercial facilities. Based on the Record of Decision for low-level radioactive waste and mixed low-level radioactive waste issued on February 18, 2000 (65 FR 10061), minimal

**Table 4–37 Incremental Waste Management Impacts of Operating FDFP at INEEL Under Alternative 1 (Restart FFTF)—Option 2**

Waste Type <sup>a</sup>	Estimated Additional Waste Generation (cubic meters per year)	Estimated Additional Waste Generation as a Percent of <sup>b</sup>		
		Onsite Treatment Capacity	Onsite Storage Capacity	Onsite Disposal Capacity
<b>Transuranic waste/High-level radioactive<sup>c</sup></b>	7	(c)	(c)	NA
<b>Low-level radioactive</b>

Sanitary wastewater	1,658	0.00052	NA	NA
Solid	148	NA	NA	0.31

- a. See definitions in Section G.9.
- b. Estimated additional annual waste generation is compared with annual site treatment and disposal capacities. Additional waste generation over the assumed 35-year operational period is compared with site storage capacities.
- c. Refer to the text for a discussion on waste classification, treatment, and storage. This waste would be stored on site pending availability of a suitable repository. It is assumed this waste would be remotely handled.
- d. Mixed liquid low-level radioactive waste is included under liquid low-level radioactive waste because these wastes are processed together.
- e. Refer to the text. The impact on the waste management system would be minimal.
- f. Percent of capacity of the two INTEC percolation ponds.

**Note:** To convert from cubic meters per year to cubic yards per year, multiply by 1.308; to convert from kilograms to pounds, multiply by 2.20; < means “less than.”

**Key:** INTEC, Idaho Nuclear Technology and Engineering Center; NA, not applicable (i.e., the majority of this waste is not routinely treated, or is not routinely stored, or is not routinely disposed of on site; refer to the text).

**Source:** Brunson 1999b; DOE 1999a; Kirkham 1999; Wham 1999d.

treatment of low-level radioactive waste will be performed at all sites and, to the extent practicable, onsite disposal of low-level radioactive waste will continue. Hanford and the Nevada Test Site will be made available to all DOE sites for disposal of low-level radioactive waste. Mixed low-level radioactive waste analyzed in the *Waste Management PEIS* will be treated at Hanford, INEEL, ORR, and SRS and will be disposed of at Hanford and the Nevada Test Site.

The analysis for the Draft NI PEIS assumed that the waste generated from the processing of irradiated neptunium-237 targets is transuranic waste. However, as a result of comments received during the public comment period, DOE is considering whether the waste from processing of irradiated neptunium-237 targets should be classified as high-level radioactive waste and not transuranic waste. Irrespective of how the waste is classified (i.e., transuranic or high-level radioactive waste), the composition and characteristics are the same and the waste management activities (i.e., treatment and onsite storage) as described in this NI PEIS would be the same. In addition, either waste type would require disposal in a suitable repository. If it is transuranic waste, it would be nondefense waste and could not be disposed of at WIPP under current law. Because nondefense transuranic waste has no current disposal path, DOE Headquarters’ approval would be necessary before a decision were made to generate such waste, as required by DOE Order 435.1. If the waste is classified as high-level radioactive waste, it is assumed for the purposes of this analysis that Yucca Mountain, Nevada,

if approved, would be the final disposal site for DOE's high-level radioactive waste. The other differences between these two waste classifications are that a high-level radioactive waste repository requires a much more rigorous waste-form qualification process than a transuranic waste repository and there is a slightly different set of requirements for high-level radioactive waste than for transuranic waste delineated in DOE Manual 435.1.

Target fabrication and processing in FDPF would generate a total of 245 cubic meters (320 cubic yards) of transuranic or high-level radioactive waste over the 35-year operational period. As described in Sections 3.4.5 of the *Preconceptual Design Planning for Chemical Processing to Support Pu-238 Production* (Wham 1998), the waste would be vitrified into a glass matrix at a glass melter installed within FDPF. The resulting glass matrix would be stored at FDPF pending availability of the suitable repository. The impacts of managing the additional quantities of this waste at INEEL would be minimal.

At INEEL, low-level radioactive waste from neptunium-237 fabrication and processing would be packaged, certified, and accumulated at FDPF before transfer for additional treatment as necessary, by compaction, size reduction, or stabilization on site or by incineration off site and then sent for disposal in existing onsite facilities. Annual liquid low-level radioactive waste generation, including mixed liquid low-level radioactive waste that would be associated with neptunium-237 target fabrication and processing in FDPF, is estimated to be 0.23 percent of the 13,000-cubic-meter-per-year (17,000-cubic-yard-per-year) capacity of the INTEC Process Equipment Waste evaporator. The condensate from this evaporator is processed by the Liquid Effluent Treatment and Disposal System evaporator and released to the main stack as steam. After any appropriate treatment, liquid waste generated by the neptunium-237 fabrication and processing would eventually be grouted for final disposition.

The annual amount of solid low-level radioactive waste that would be generated at FDPF as the result of neptunium-237 target fabrication and processing is estimated as 0.093 percent of the 37,700-cubic-meter-per-year (49,300-cubic-yard-per-year) disposal capacity of the Radioactive Waste Management Complex. A total of 1,225 cubic meters (1,602 cubic yards) of solid low-level radioactive waste would be generated over the 35-year operational period. Using the 6,264-cubic-meter-per-hectare (3,316-cubic-yard-per-acre) disposal land usage factor for INEEL published in the *Storage and Disposition PEIS* (DOE 1996a:E-9), 1,225 cubic meters (1,602 cubic yards) of waste would require 0.20 hectares (0.48 acres) of disposal space at INEEL. At some future time, low-level radioactive waste would be disposed of off site. The impacts of managing the additional low-level radioactive waste at INEEL would be minimal.

At INEEL, mixed solid low-level radioactive waste would be stabilized, packaged, and stored on site for treatment and disposal in a manner consistent with the site treatment plan. Mixed low-level radioactive waste is currently treated on site with some waste shipped to Envirocare of Utah for disposal. The additional mixed solid low-level radioactive waste that would be generated at FDPF is estimated to be less than 0.077 percent of the 6,500-cubic-meter-per-year (8,500-cubic-yard-per-year) planned capacity of the Advanced Mixed Waste Treatment Project. Over the 35-year operational period, the amount of this waste generated would represent less than 0.099 percent of the 177,300-cubic-meter (231,900-cubic-yard) storage capacity of the Radioactive Waste Management Complex. Therefore, the management of this additional waste at INEEL would have only a minimal impact on the management of mixed low-level radioactive waste at INEEL.

Hazardous waste generated during the operation of FDPF would be packaged in DOT-approved containers and shipped off site to permitted commercial recycling, treatment, and disposal facilities. Hazardous waste generated from 35 years of operating FDPF to fabricate and process the neptunium-237 targets is estimated to represent about 2.4 percent of the 9,600-cubic-meter (12,560-cubic-yard) capacity of the hazardous waste storage buildings (including staging). Management of the additional hazardous waste at INEEL would have only a minimal impact on the hazardous waste management system.

Nonhazardous solid waste would be packaged and transported in conformance with standard industrial practice. Solid waste such as office paper, metal cans, and plastic and glass bottles that can be recycled would be sent off site for that purpose. The remaining solid sanitary waste would be sent to the onsite landfill. This additional waste load would have only a minimal impact on the nonhazardous solid waste management system at INEEL. The annual amount of nonhazardous solid waste that would be generated is estimated to represent 0.31 percent of the 48,000-cubic-meter-per-year (63,000-cubic-yard-per-year) capacity of the Central Facilities Area Landfill Complex.

At INEEL, nonhazardous process wastewater generated by FDPF would be discharged to the INTEC service waste system, which then discharges to the two INTEC percolation ponds. Nonhazardous process wastewater generated as the result of neptunium-237 target fabrication and processing is estimated to be 0.14 percent of the 16,700-cubic-meter-per-year (21,800-cubic-yard-per-year) capacity of the INTEC percolation ponds. Nonhazardous sanitary wastewater from FDPF operations would be discharged to the INTEC Sewage Treatment Plant. Sanitary wastewater generated is estimated to be 0.00052 percent of the 3,200,000-cubic-meter-per-year (4,200,000-cubic-yard-per-year) capacity of the INTEC Sewage Treatment Plant. Therefore, management of nonhazardous liquid waste at INEEL would have only a minimal impact on the management system.

The generation rates of waste at INEEL that would be associated with this option (Table 4–37) can be compared with the current waste generation rates at the site, given in Table 3–25 (Section 3.3.11). Except for transuranic waste, which currently is not being generated at INEEL, the waste generation rates associated with plutonium-238 production would be much smaller than the current waste generation rates at the site.

#### **4.3.2.1.14 Spent Nuclear Fuel Management**

Impacts associated with spent nuclear fuel management would be the same as for Option 1, and are given in Section 4.3.1.1.14.

### **4.3.3 Alternative 1 (Restart FFTF)—Option 3**

Option 3 involves operating FFTF at Hanford to irradiate all targets and materials associated with plutonium-238 production, medical and industrial isotope production, and research and development, and also operating FMEF at Hanford to fabricate and process these targets and materials and the associated irradiated products. This option includes storage in FMEF of the neptunium-237 transported to Hanford from SRS and of the other target materials transported to Hanford from other offsite facilities.

The transportation of the mixed oxide and highly enriched uranium fuel to Hanford for use in FFTF, the transportation of the neptunium-237 and other target material to Hanford, and the transportation of the product materials following postirradiation processing are also part of this option.

Under Option 3, FFTF would operate with a mixed oxide fuel core for the first 21 years and with a highly enriched uranium fuel core for the next 14 years.

#### **4.3.3.1 Operations and Transportation**

The environmental impacts associated with storage, processing, and irradiation operations and with all transportation activities are assessed in this section.

#### 4.3.3.1.1 Land Resources

**LAND USE.** The restart of FFTF would not result in impacts on land use at Hanford for the reasons described in Section 4.3.1.1.1.

FMEF, which is in the 400 Area of Hanford, would be used for target material storage, target fabrication, and processing. The use of this facility would require the construction of a new 76-meter (250-foot) stack. Because the stack would be placed on previously disturbed land, and use of FMEF would be compatible with the mission for which it was designed, land use impacts in the 400 Area would be minimal.

**VISUAL RESOURCES.** The restart of FFTF would not result in impacts on visual resources at Hanford for the reasons described in Section 4.3.1.1.1.

The use of FMEF for target material storage, target fabrication, and processing would involve the construction of a 76-meter (250-foot) stack. While the stack would be visible from surrounding areas, it would not change the overall appearance of the 400 Area or its Visual Resource Management Class IV rating. Thus, impacts on visual resources would be minimal.

#### 4.3.3.1.2 Noise

The change in noise impacts from FFTF restart and operation would be expected to be small as described in Section 4.3.1.1.2.

FMEF would be used for target material storage, target fabrication, and processing. A new 76-meter (250-foot) stack would be required for neptunium-237 target processing at FMEF. Activities associated with construction of a new stack would be typical of small construction projects and would result in some temporary increase in noise. Noise sources associated with this construction would not be expected to be loud impulsive sources and would not be expected to result in disturbance of wildlife around the 400 Area. FMEF operations would not be expected to result in any change in noise impacts on wildlife around the 400 Area, and offsite noise impacts would also be minor because the nearest site boundary is 7 kilometers (4.3 miles) to the east. Operations would be expected to result in minimal change in noise impacts on people near Hanford as a result of changes in employee and truck traffic levels.

#### 4.3.3.1.3 Air Quality

The restart and operation of FFTF under this option would have the same air quality impacts as under Option 1 (Section 4.3.1.1.3), and are presented in **Table 4–38**. The concentrations at Hanford from FMEF attributable to this option are also presented in Table 4–38. Changes in concentrations were determined to be small and would be below the applicable ambient standards even when ambient monitored values and the contributions from the other site activities were included. Hazardous chemical impacts are addressed in Section 4.3.3.1.9.

The concentrations at Hanford attributable to this option are compared with the Prevention of Significant Deterioration Class II increments for sulfur dioxide and nitrogen dioxide in **Table 4–39**.

The air quality impacts of transportation are presented in Section 4.3.3.1.11.

**Table 4–38 Incremental Hanford Concentrations Associated with Alternative 1 (Restart FFTF)—Option 3**

Pollutant	Averaging Period	Most Stringent Standard or Guideline (micrograms per cubic meter) <sup>a</sup>	Modeled Increment (micrograms per cubic meter)	
			FFTF	FMEF
<b>Criteria pollutants</b>				
Carbon monoxide	8 hours	10,000 <sup>b</sup>	52.1	0
	1 hour	40,000 <sup>b</sup>	74.4	0
Nitrogen dioxide	Annual	100 <sup>b</sup>	0.0118	4.43×10 <sup>-5</sup>
PM <sub>10</sub>	Annual	50 <sup>c</sup>	8.4×10 <sup>-4</sup>	0
	24 hours	150 <sup>c</sup>	9.84	0
Sulfur dioxide	Annual	50 <sup>d</sup>	7.86×10 <sup>-4</sup>	0.0087
	24 hours	260 <sup>d</sup>	9.1	0.069
	3 hours	1,300 <sup>b</sup>	20.5	0.16
	1 hour	660 <sup>d</sup>	22.8	0.17
<b>Toxic air pollutants</b>				
Methanol	24 hours	870	0	0.0018
Nitric acid	24 hours	17	0	0.0022
Paraffin hydrocarbons	24 hours	7	0	0.16
Tributyl phosphate	24 hours	7.3	0	0.090

a. The more stringent of the Federal and state standards is presented if both exist for the averaging period. The National Ambient Air Quality Standards (NAAQS) (40 CFR Part 50), other than those for ozone, particulate matter, and lead, and those based on annual averages, are not to be exceeded more than once per year. The 24-hour PM<sub>10</sub> (particulate matter with an aerodynamic diameter less than or equal to 10 micrometers) standard is attained when the expected number of days with a 24-hour average concentration above the standard is equal to or less than 1. The annual arithmetic mean PM<sub>10</sub> standard is attained when the expected annual arithmetic mean concentration is less than or equal to the standard.

b. Federal and state standard.

c. Federal standard currently under litigation.

d. State standard.

#### 4.3.3.1.4 Water Resources

The restart of FFTF for isotope production and the use of FMEF for target material storage, target fabrication, and processing, both existing facilities located in the Hanford 400 Area, would not have any construction-related impacts on water bodies, floodplains, or on surface water or groundwater quality.

Operational impacts on water resources associated with the restart of FFTF would be substantially the same as those discussed in Section 4.3.1.1.4, with only a small incremental impact associated with FMEF operations. Total projected 400 Area and incremental effects of this option on key water resource indicators are summarized in **Table 4–40**. Annual average groundwater withdrawal during standby by 400 Area facilities

is about 197 million liters (52 million gallons) (Section 4.3.1.1.4). The restart of FFTF combined with the use of FMEF would increase annual water use to a total of 277 million liters (73 million gallons). This is a total increase of about 80 million liters (21 million gallons) per year. This includes some 15 million liters (4 million gallons) per year to support FMEF cooling needs and approximately 3.8 million liters (1 million gallons) per year for increased sanitary and potable water needs (Chapin 2000). This volume of 277 million liters (73 million gallons) per year is approximately 70 percent of the 400 Area groundwater production capacity of about 398 million liters (105.1 million gallons) per year (DOE 1999a:4-262).

**Table 4-40 Incremental Water Use and Wastewater Generation Associated with Operating FFTF and FMEF at Hanford Under Alternative 1 (Restart FFTF)—Option 3**

Indicator (million liters per year)	Hanford			
	Total 400 Area <sup>a</sup>	FFTF Operations <sup>b</sup>	FFTF Increment Over Standby <sup>c</sup>	FMEF Increment <sup>d</sup>
Water use	277	258	61	19
Process wastewater generation	113	98	22	15
Sanitary wastewater generation	9.5	5.7	1.9	3.8

a. Total projected operational impacts in the Hanford 400 Area (FFTF and FMEF operations combined).

b. These estimates represent total projected operational impacts after restart (FFTF only).

c. Incremental impacts of FFTF restart and operation over standby operations (see Table 4-1).

d. Incremental impacts of FMEF operations only.

**Note:** To convert from liters per year to gallons per year, multiply by 0.264.

**Source:** Chapin 2000; DOE 2000a:11; Nielsen 1999:38, 41.

Additional staffing required to support both the restart of FFTF and use of FMEF would also increase annual sanitary wastewater generation in the 400 Area by a total of 5.7 million liters (1.5 million gallons) over standby to about 9.5 million liters (2.5 million gallons) per year during operation. FMEF alone would contribute 3.8 million liters (1 million gallons) annually to this increase (Chapin 2000). Nevertheless, the Energy Northwest treatment system has sufficient excess capacity to accommodate this increased flow from the 400 Area (Section 4.3.1.1.4).

Process (nonradioactive) wastewater discharge from the 400 Area (mainly FFTF and FMEF) would increase by a total of approximately 37 million liters (9.8 million gallons) over standby to about 113 million liters (29.8 million gallons) per year as a result of FFTF and FMEF operations. FMEF would contribute about 15 million liters (4 million gallons) annually based on a conservative estimate of cooling water discharges and blowdown from FMEF's three cooling towers (currently inactive) (Chapin 2000; Nielsen 1999:38). This additional volume includes approximately 38,000 liters (10,000 gallons) per year of process wastewater resulting from target fabrication and processing activities (Chapin 2000). This wastewater would be discharged to the 400 Area process sewer system and ultimately to the 400 Area Pond, with no impact on groundwater quality expected for the same reasons cited in Section 4.3.1.1.4.

Waste management aspects of this option and their effects are further discussed in Section 4.3.3.1.13.

#### 4.3.3.1.5 Geology and Soils

The restart of FFTF would not be expected to result in impacts on geologic and soil resources at Hanford, nor be jeopardized by large-scale geologic conditions, for the reasons described in Sections 4.2.1.2.5 and 4.3.1.1.5.

FMEF would be used for target material storage, target fabrication, and processing. Additionally, a new 76-meter (250-foot) stack would be constructed (Nielsen 1999:24). Because FMEF is an existing facility and the stack would be located on previously disturbed land, impacts on geologic resources and soils would be negligible. As referenced above, and in Section 4.2.4.2.5, hazards from large-scale geologic conditions at

Hanford were previously evaluated and were reviewed in this NI PEIS and found to present a low risk to FMEF. As necessary, the need to evaluate and upgrade existing DOE facilities with regard to natural geologic hazards would be assessed in accordance with DOE Order 420.1, which is described in Section 4.2.1.2.5.

#### **4.3.3.1.6 Ecological Resources**

The restart of FFTF would not be expected to result in impacts on ecological resources at Hanford for the reasons described in Section 4.3.1.1.6.

FMEF, an existing facility, would be used for target material storage, target fabrication, and processing. Impacts on ecological resources resulting from the use of FMEF would not occur for the same reasons noted above for FFTF, which is also in the 400 Area. While a new 76-meter (250-foot) stack would be built, it would be placed on previously disturbed land in the 400 Area; thus, no natural terrestrial habitat would be lost.

#### **4.3.3.1.7 Cultural and Paleontological Resources**

The restart of FFTF would not be expected to result in impacts on cultural resources at Hanford for the reasons described in Section 4.3.1.1.7.

Target material storage, target fabrication, and processing would take place at FMEF in the 400 Area. Impacts on cultural resources resulting from the use of FMEF would not occur for the same reasons noted above for FFTF, which is also in the 400 Area. Although a new 76-meter (250-foot) stack would be built, it would be placed on previously disturbed land in the 400 Area; thus, impacts on cultural and paleontological resources would not be expected.

#### **4.3.3.1.8 Socioeconomics**

The irradiation of all isotopes at FFTF, and the fabrication and processing of all targets at FMEF would annually require about 292 additional workers at Hanford (Hoyt et al. 1999; DOE 1997b). This level of employment would generate about 739 indirect jobs in the region around Hanford. The potential total employment increase of 1,031 direct and indirect jobs in the Hanford region represents a less than 0.5 percent increase in the projected regional economic area workforce. It would have no noticeable impact on the regional economic area.

Additional employment resulting from this option would not have any noticeable impact on community services in the Hanford region of influence. Assuming that 91 percent of the new employment would reside in Hanford's region of influence (refer to Section 3.4.8), 938 new jobs could increase the region's population by approximately 1,803 persons. This increase, in conjunction with the normal population growth forecasted by the State of Washington, would not have any noticeable impact on the availability of housing and/or the price of housing in the region of influence. Given the current population-to-student ratio in the region of influence, this would likely result in an increase of about 373 students, requiring local school districts to slightly increase the number of classrooms to accommodate them.

Community services in the region of influence would be expected to change to accommodate the population growth as follows: 23 new teachers would be needed to maintain the current student-to-teacher ratio of 16:1; 3 new police officers would need to be added to maintain the current officer-to-population ratio of 1.5:100; 6 new firefighters would need to be added to maintain the current firefighter-to-population ratio of 3.4:1000; and 3 new doctors would be added to maintain the current physician-to-population ratio of 1.4:1000. Thus, an additional 35 positions would have to be created to maintain community services at current levels. Hospitals in the region of influence would not experience any change from the 2.1 beds per 1,000 persons

currently available. Moreover, average school enrollment would increase to 94.5 percent from the current 92.5 percent unless additional classrooms were built. None of these projected changes should have a major impact on the level of community services currently offered in the region of influence.

#### 4.3.3.1.9 Public and Occupational Health and Safety—Normal Operations

Assessments of incremental radiological and chemical impacts associated with this option are presented in this section. Supplemental information is provided in Appendix H.

During normal operations, there would be incremental radiological and hazardous chemical releases to the environment and also incremental direct in-plant exposures. The resulting doses and potential health effects to the public and workers for this option are described below.

**RADIOLOGICAL IMPACTS.** Incremental radiological doses to three receptor groups from startup, processing, and operations are given in **Table 4–41**: the population within 80 kilometers (50 miles) of FFTF and FMEF in the year 2020, the maximally exposed member of the public, and the average exposed member of the public. The projected number of latent cancer fatalities in the surrounding population and the latent cancer fatality risk to the maximally and average exposed individuals are also presented in the table.

**Table 4–41 Incremental Radiological Impacts on the Public Around Hanford from Operational Facilities Under Alternative 1 (Restart FFTF)—Option 3**

Receptor	FFTF Preoperational Activities <sup>a</sup>	FFTF Operations	FMEF Target Processing <sup>b</sup>	Operations and Processing Total <sup>c</sup>
<b>Population within 80 kilometers (50 miles) in the year 2020</b>				
Dose (person-rem)	0.028	0.044	0.085	0.13
1-year latent cancer fatalities	$1.4 \times 10^{-5}$	–	–	–
35-year latent cancer fatalities	–	$7.7 \times 10^{-4}$	0.0015	0.0023
<b>Maximally exposed individual</b>				
Annual dose (millirem)	$1.4 \times 10^{-4}$	$4.1 \times 10^{-4}$	$3.0 \times 10^{-4}$	$7.0 \times 10^{-4}$
1-year latent cancer fatality risk	$6.8 \times 10^{-11}$	–	–	–
35-year latent cancer fatality risk	–	$7.2 \times 10^{-9}$	$5.3 \times 10^{-9}$	$1.2 \times 10^{-8}$
<b>Average exposed individual within 80 kilometers (50 miles)</b>				
Annual dose <sup>d</sup> (millirem)	$5.7 \times 10^{-5}$	$8.8 \times 10^{-5}$	$1.7 \times 10^{-4}$	$2.6 \times 10^{-4}$
1-year latent cancer fatality risk	$2.8 \times 10^{-11}$	–	–	–
35-year latent cancer fatality risk	–	$1.5 \times 10^{-9}$	$3.0 \times 10^{-9}$	$4.5 \times 10^{-9}$

- For conservatism as well as consistency with other radiological impacts evaluated in this NI PEIS, these values were assessed for the year 2020 even though these activities would commence prior to that year.
- Target storage, processing, and fabrication activities are performed at the facility. Impacts are for all facility target activities and are dominated by processing activity impacts.
- Represents upper-bounding values.
- Obtained by dividing the population dose by the number of people projected to live within 80 kilometers (50 miles) of FFTF and FMEF in the year 2020 (about 500,000).

**Source:** Model results, using the GENII computer code (Napier et al. 1988).

A probability coefficient of  $5 \times 10^{-4}$  latent cancer fatality per rem is applied for the public, and a coefficient of  $4 \times 10^{-4}$  latent cancer fatality per rem is applied for workers (ICRP 1991). The value for workers is lower due to the absence of children and the elderly, who are more radiosensitive.

To represent a bounding annual dose scenario, it is assumed that a full-year's isotopic release would occur from target processing at FMEF concurrently with a full-year's release from FFTF operations at 400 megawatts. The impacts presented in Table 4–41 assume a full-year's release resulting from FFTF

preoperational testing and startup activities. As a result of annual operations, the bounding projected total incremental population dose in the year 2020 would be 0.13 person-rem. The corresponding number of latent cancer fatalities in the population surrounding Hanford from 35 years of operations would be  $2.3 \times 10^{-3}$ . The bounding total incremental dose to the maximally exposed member of the public from annual operations of FFTF and FMEF would be  $7.0 \times 10^{-4}$  millirem. From 35 years of operations, the corresponding risk of a latent cancer fatality to this individual would be  $1.2 \times 10^{-8}$ .

Incremental doses to involved workers from normal operations are given in **Table 4-42**; these workers are defined as those directly associated with all process and operational activities. The incremental annual average dose to FFTF workers during startup would be 3.5 millirem; the incremental annual average dose during operations, 6.6 millirem. For FMEF workers, the incremental annual average dose is estimated to be approximately 160 millirem. The incremental annual dose received by the total site workforce for each of these facilities would be approximately 0.69, 1.3, and 17 person-rem, respectively. The risks and numbers of latent cancer fatalities among the different workers are included in Table 4-42. Doses to individual workers would be kept to minimal levels by instituting badged monitoring and ALARA programs.

**Table 4-42 Incremental Radiological Impacts on Involved FFTF and FMEF Workers Under Alternative 1 (Restart FFTF)—Option 3**

Receptor—Involved Workers <sup>a</sup>	FFTF Preoperational Activities	FFTF Operations	FMEF Target Processing <sup>b</sup>	Operations and Processing Total
Total dose (person-rem per year)	0.69 <sup>c</sup>	1.3 <sup>c</sup>	17 <sup>d</sup>	18
1-year latent cancer fatalities	$2.8 \times 10^{-4}$	—	—	—
35-year latent cancer fatalities	—	0.018	0.24	0.26
Average worker dose (millirem per year)	3.5	6.6	160	NA
1-year latent cancer fatality risk	$1.4 \times 10^{-6}$	—	—	—
35-year latent cancer fatality risk	—	$9.2 \times 10^{-5}$	0.0023	NA

- The radiological limit for an individual worker is 5,000 millirem per year (10 CFR Part 835). However, the maximum dose to a worker involved with operations would be kept below the DOE Administrative Control Level of 2,000 millirem per year (DOE 1999j). Further, DOE recommends that facilities adopt a more limiting, 500 millirem per year, Administrative Control Level (DOE 1999j). To reduce doses to levels that are as low as is reasonably achievable (ALARA), an effective ALARA program would be enforced.
- Doses are based on a weighted average from historical data associated with plutonium processing and other radiochemical processing. Target storage, processing, and fabrication activities are performed at this facility. Impacts, dominated by processing activities, include impacts from all facility target activities.
- Based on an estimated 200 badged workers.
- Based on an estimated 105 badged workers.

**Key:** NA, not applicable.

**Source:** BWHC 1999; Mecham 1999; Nielsen 1999; Wham 1999b, 2000.

**HAZARDOUS CHEMICAL IMPACTS.** At FMEF, both carcinogenic and noncarcinogenic health effects from exposure to hazardous chemicals were evaluated and are presented in **Table 4-43**. It was assumed that under normal operating conditions, the primary exposure pathway for members of the public would be from airborne emissions released through the new 76-meter (250-foot) stack. Emissions of chemicals were estimated based on anticipated chemical usage. A worst-case dispersion-modeling screening analysis was performed to estimate annual concentrations for each chemical.

The annual concentration of each noncarcinogenic chemical was divided by the corresponding inhalation reference concentration to estimate the Hazard Quotient for each of the noncarcinogenic chemicals associated with this option. The Hazard Quotients were then summed to determine the Hazard Index. A Hazard Index of less than one indicates that adverse health effects from non-cancer-causing agents are not expected. For carcinogens, the annual concentration was multiplied by the unit cancer risk to estimate the increased cancer risk from that chemical.

**Table 4–43 Incremental Hazardous Chemical Impacts on the Public at Hanford Under Alternative 1 (Restart FFTF)—Option 3**

Chemical	Modeled Annual Increment (micrograms per cubic meter)	Reference Concentration (micrograms per cubic meter)	Unit Cancer Risk (risk per micrograms per cubic meter)	Hazard Quotient	Cancer Risk
<b>FFTF emergency diesel generators</b>					
Benzene	$2.5 \times 10^{-6}$	NA	$7.8 \times 10^{-6}$	NA	$1.96 \times 10^{-11}$
Toluene	$1.10 \times 10^{-6}$	400	NA	$2.74 \times 10^{-9}$	NA
Propylene	$6.92 \times 10^{-6}$	NA	$3.7 \times 10^{-6}$	NA	$2.56 \times 10^{-11}$
Formaldehyde	$3.17 \times 10^{-6}$	NA	$1.3 \times 10^{-5}$	NA	$4.12 \times 10^{-11}$
Acetaldehyde	$2.06 \times 10^{-6}$	NA	$2.2 \times 10^{-6}$	NA	$4.53 \times 10^{-12}$
<b>FMEF</b>					
Nitric acid	$2.73 \times 10^{-4}$	122.5	NA	$2.22 \times 10^{-6}$	NA
Diethyl benzene	0.00601	1000	$7.8 \times 10^{-6}$	$6.01 \times 10^{-6}$	$4.69 \times 10^{-8}$
Methanol	$2.19 \times 10^{-4}$	1750	NA	$1.25 \times 10^{-7}$	NA
Tributyl phosphate	0.0113	10	NA	0.00113	NA
Hazard Index =				0.00114	

**Note:** For diethyl benzene, the reference concentration for ethyl benzene and the unit cancer risk for benzene were used. For tributyl phosphate, the reference concentration for phosphoric acid was used to estimate the Hazard Quotient because no information was available for tributyl phosphate. The propylene oxide unit cancer risk factor was used for propylene.

**Key:** NA, not applicable (the chemical is not a known carcinogen or it is a carcinogen and only unit risk will apply).

**Source:** DOE 1996a; EPA 1999; model results, using the SCREEN3 computer code (EPA 1995).

#### 4.3.3.1.10 Public and Occupational Health and Safety—Facility Accidents

Impacts from postulated accidents associated with FFTF target irradiation and FMEF target fabrication and processing are presented in this section. Detailed descriptions of the accident analyses are provided in Appendix I.

Estimates of radiological consequences have been developed for the maximally exposed individual, the offsite population within 80 kilometers (50 miles) of the facility, and a noninvolved worker at a distance of 640 meters (0.4 mile) from the release point. Consequences are presented in terms of radiological dose (in rem) and the probability that the dose would result in a latent cancer fatality. Accident risk is defined as the product of the accident probability (i.e., accident frequency) and the accident consequence. In this NI PEIS, risk is expressed as the increased likelihood of a latent cancer fatality per year for an individual (the maximally exposed individual or a noninvolved worker), and as the increased number of latent cancer fatalities per year in the offsite population. The probability coefficients for determining the likelihood of a latent cancer fatality, given a dose, are presented in Section 4.2.1.2.10. Consequences to involved workers are addressed in Section I.1.7.

To provide a better indication of risks from the postulated accidents, the risks are summed for each facility and also for each option. Although the summation provides the combined risk for the spectrum of accidents analyzed, it does not indicate total risk. To determine total risk from accidents, a full-scope probabilistic risk analysis would be required for each facility. Since full-scope probabilistic risk analyses are not available to incorporate in this NI PEIS, the summation of the spectrum of accident risks was considered appropriate for the purposes of this NI PEIS. Details of the risk summation calculations are provided in Appendix I.

Consequences and associated risks are presented in **Tables 4–44** and **4–45**, respectively.

**Table 4-44 FFTF and FMEF Accident Consequences Under Alternative 1 (Restart FFTF)—Option 3**

Accident	Maximally Exposed Individual		Population to 80 Kilometers (50 Miles)		Noninvolved Worker

<b>35-year FMEF risk</b>	$6.79 \times 10^{-6}$	0.208	$4.17 \times 10^{-4}$
<b>35-year Option Risk<sup>d</sup></b>	$6.80 \times 10^{-6}$	0.209	$4.17 \times 10^{-4}$

a. Increased likelihood of a latent cancer fatality.

b. Increased number of latent cancer fatalities.

c. Risk of an early fatality.

d. Individual risks are summed only for colocated individuals. The highest individual risk was used to represent the 35-year option risk.

**Key:** BLTC, bottom-loading transfer cask; HEU, highly enriched uranium core; MOX, mixed oxide core.

**Source:** Model results, using the MACCS2 (Chanin and Young 1997) and GENII (Napier et al. 1988) computer codes.

FFTF would operate for 21 years with a mixed oxide core followed by 14 years with a highly enriched uranium (HEU) core. As shown in Table 4–44, the beyond-design-basis core melt accident would result in the largest radiological consequences among FFTF accidents. In order to incorporate internal and external initiators, the accident frequency of  $1 \times 10^{-6}$  was selected for the beyond-design-basis core melt accident. For 35 years of operation, the increased risk of a latent cancer fatality to the maximally exposed individual and to a noninvolved worker would be  $1.23 \times 10^{-8}$  and  $1.20 \times 10^{-8}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.00127.

For 35 years of FMEF target fabrication and processing, the increased risk of a latent cancer fatality to the maximally exposed individual and of an early fatality to a noninvolved worker would be  $6.79 \times 10^{-6}$  and  $4.17 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.208.

For 35 years under this option, the increased risk of a latent cancer fatality to the maximally exposed individual and of a fatality to a noninvolved worker would be  $6.80 \times 10^{-6}$  and  $4.17 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.209.

The irradiation of medical, industrial, research and development, and neptunium-237 targets at FFTF would not introduce any additional operations that require the use of hazardous chemicals. Thus, there are no postulated hazardous chemical accidents attributable to the irradiation of medical, industrial, or neptunium-237 targets at FFTF.

No chemical processing activities are currently performed at FMEF and no chemicals are stored in this facility. Processing activities in support of medical, industrial, research and development isotope and plutonium-238 production would require the introduction of hazardous chemicals, specifically nitric acid and nitric oxide. Potential health impacts from accidental releases of nitric acid were assessed by comparing estimated airborne concentrations of the chemicals to ERPG developed by the American Industrial Hygiene Association. The ERPG-1 value (0.5 parts per million) is the maximum airborne concentration below which nearly all individuals could be exposed for up to one hour, resulting in only mild, transient, and reversible adverse health effects. The ERPG-2 value (10 parts per million) is protective of irreversible or serious health effects or impairment of an individual's ability to take protective action. The ERPG-3 value (25 parts per million) is indicative of potentially life-threatening health effects.

The maximum distances, in meters, needed to reach the ERPG values for nitric acid releases at the FMEF for Stability Classes D and F are shown in **Table 4-46**. Two separate atmospheric conditions were evaluated, Stability Classes D and F. Stability Class D represents average meteorological conditions while Stability Class F represents worst-case meteorological conditions. The number of involved and noninvolved workers potentially exposed would vary with a number of factors such as the time of day and whether they are sheltered within buildings at the time of release. Individuals at the nearest highway (7,100 meters [4.4 miles]) and at the nearest site boundary (7,210 meters [4.5 miles]) from FMEF would be exposed to levels well below ERPG-1.

**Table 4-46 ERPG Distances for Nitric Acid Releases at FMEF**

Evaluation Parameter	Stability Class D (meters)	Stability Class F (meters)
ERPG-3	375	450
ERPG-2	500	600
ERPG-1	2,000	3,000

**Note:** To convert from meters to miles, multiply by  $6.22 \times 10^{-4}$ .

**Key:** ERPG, Emergency Response Planning Guideline.

There are no ERPG values for nitric oxide. For nitric oxide accidents, the level of concern has been estimated by using one-tenth of the "Immediately Dangerous to Life and Health" level published by the National Institute for Occupational Safety and Health. The Immediately Dangerous to Life and Health value for nitric oxide is 100 parts per million. The level of concern value used for this NI PEIS is 10 parts per million. The level of concern is defined as the concentration of an extremely hazardous substance in air above which there may be serious irreversible health effects as a result of a single exposure for a relatively short period of time.

For FMEF, the maximum distances needed to reach the level of concern for nitric oxide releases for Stability Classes D and F are 500 and 1,900 meters (1,640 and 6,560 feet), respectively. The number of involved and noninvolved workers potentially exposed would vary with a number of factors such as the time of day and whether they are sheltered within buildings at the time of release. Individuals at the nearest highway (7,100 meters [4.4 miles]) and at the nearest site boundary (7,210 meters [4.5 miles]) from FMEF would be exposed to levels well below the level of concern for nitric oxide.

Potential health impacts from the accidental release of the hazardous chemicals were assessed for a noninvolved worker, offsite individuals who are members of the public located at the nearest site boundary and onsite individuals who are members of the public located at the nearest highway access.

The impacts associated with the accidental release of nitric acid and nitric oxide at FMEF are presented in **Table 4-47**.

**Table 4-47 FMEF Hazardous Chemical Accident Impacts Under Alternative 1 (Restart FFTF)—Option 3**

Receptor	Evaluation Parameter	Nitric Acid		Nitric Oxide	
		Stability Class D	Stability Class F	Stability Class D	Stability Class F
Noninvolved worker (640 meters)	Parts per million	3.3	8.6	4.2	66
	Level of concern	<ERPG-2	<ERPG-2	<LOC	>LOC
	Potential health effects	Mild, transient	Mild, transient	Mild, transient	Serious
Nearest highway maximally exposed individual	Parts per million	0.03	0.1	0.09	0.55
	Level of concern	< ERPG-1	ERPG-1	< LOC	< LOC
	Potential health effects	None	Mild, transient	None	None
Site boundary maximally exposed individual	Parts per million	0.03	0.1	0.09	0.53
	Level of concern	< ERPG-1	ERPG-1	< LOC	< LOC
	Potential health effects	None	Mild, transient	None	None

**Note:** < means “less than.”

**Key:** ERPG, Emergency Response Planning Guideline; LOC, level of concern.

**Source:** Model results.

#### 4.3.3.1.11 Public and Occupational Health and Safety—Transportation

DOE would transport neptunium-237 from storage at SRS to the FMEF target fabrication facility at Hanford. DOE would transport the unirradiated neptunium-237 targets from FMEF to FFTF. Following irradiation in FFTF, the targets would be returned to FMEF for processing. After this processing, the plutonium-238 product would be shipped to LANL. FFTF would receive highly enriched uranium fuel from a U.S. fuel fabrication facility and mixed oxide fuel from Europe. Additionally, medical and industrial isotopes would be shipped from FFTF to a local airport, and from there to locations throughout the country.

Approximately 38,000 shipments of radioactive materials would be made by DOE. The total distance traveled on public roads by trucks carrying radioactive materials would be 5.6 million kilometers (3.5 million miles); at sea by ships carrying mixed oxide fuel, 96,000 kilometers (52,000 nautical miles); and in the air by aircraft carrying medical isotopes, 23 million kilometers (14 million miles).

The transportation impact analysis is described in detail in Appendix J.

**IMPACTS OF INCIDENT-FREE TRANSPORTATION.** The dose to transportation workers from all transportation activities entailed by this option has been estimated at 18 person-rem; the dose to the public, 19 person-rem.

Accordingly, incident-free transportation of radioactive material associated with this option would result in 0.0072 latent cancer fatality among transportation workers and 0.009 latent cancer fatality in the total affected population over the duration of the transportation activities. The estimated number of nonradiological fatalities from vehicular emissions associated with this option would be 0.023. About half of the crew risk, about 40 percent of the public risk, and most of the emissions risk would result from shipping medical and industrial isotopes.

**IMPACTS OF ACCIDENTS DURING TRANSPORTATION.** The maximum foreseeable offsite transportation accident under this option (probability of occurrence: 1 in 10 million per year) is a shipment of mixed oxide fuel to FFTF with a severity Category V accident in a suburban population zone under neutral (average) weather conditions. The accident could result in a dose of 0.40 person-rem to the public with an associated  $2.0 \times 10^{-4}$  latent cancer fatality, and 3.3 millirem to the hypothetical maximally exposed individual with a latent cancer fatality risk of  $1.7 \times 10^{-6}$ . No fatalities would be expected to occur. The probability of more severe accidents, different weather conditions at the time of the accident, or occurrence while carrying neptunium-237 (unirradiated), irradiated targets or plutonium-238 was also evaluated and estimated to have a probability of less than 1 in 10 million per year.

Estimates of the total transportation accident risks under this option are as follows: a radiological dose to the population of 1,063 person-rem, resulting in 0.53 latent cancer fatality; and traffic accidents resulting in 0.12 traffic fatality. Nearly all of the radiological and traffic accident risk would result from shipping medical and industrial isotopes.

**IMPACTS OF MARINE TRANSPORTATION.** The potential impacts of marine transport of mixed oxide fuel on the global commons (i.e., portions of the ocean not within the territorial boundary of any nation) were evaluated in accordance with Executive Order 12114 (44 FR 1957). Following a hypothetical severe accident, radioactive particles dispersed over the ocean would not be in large enough amounts to have a measurable impact on the environment. The risks of accidents approaching and docking at the port have been estimated to be less than  $1 \times 10^{-9}$  person-rem, resulting in less than  $1 \times 10^{-12}$  latent cancer fatalities. The radiological doses associated with incident-free transportation, which include the exposure of the ship's crew to low levels of radiation during transport and handling of the packages, have been estimated to be approximately 0.03 person-rem for a route to an east coast port and 0.06 person-rem for a route to a west coast port. These doses would result in  $1.2 \times 10^{-5}$  and  $2.4 \times 10^{-5}$  latent cancer fatalities, respectively.

#### **4.3.3.1.12 Environmental Justice**

**NORMAL OPERATIONS.** The number of expected latent cancer fatalities among the population residing within 80 kilometers (50 miles) of FFTF and FMEF would be less than 0.003 for 35 years of normal operations (Table 4-41). As shown in Table 4-43, the release of hazardous chemicals at FFTF and FMEF would pose no significant risk of cancer or toxic effects among the public. As discussed in Section K.5.3, the expected latent cancer fatalities that would result from the ingestion of food that could be radiologically contaminated due to normal operations at FFTF and FMEF would be approximately 0.001. No credible pattern of food consumption by persons residing in potentially affected areas would result in significant health risks due to radiological contamination of food supplies near Hanford. As discussed in Section 4.3.1.1.11, incident-free transportation would not be expected to result in fatalities.

**ACCIDENTS.** The number of expected latent cancer fatalities among the populations at risk due to radiological accidents listed in Table 4-45 would be approximately 0.2. If a radiological accident were to occur at FFTF or FMEF at Hanford and northeasterly winds prevailed at the time of the accident, radiological contamination from the accident would be directed toward the Yakama Indian Reservation (see Figure K-11). However, accidents that could occur under the implementation of this option would not be expected to result in a latent

cancer fatality among the population or maximally exposed individual residing within the boundary of the Yakama Indian Reservation.

The number of expected latent cancer fatalities resulting from transportation accidents with radiological emissions was found to be approximately 0.5. As discussed in Appendix J, this risk is driven by accidents that could occur during the air transportation of medical and industrial isotopes and the conservative assumptions used in the analysis of such accidents. Such accidents could occur anywhere along the flight paths and would not place any identifiable group within the general population at disproportionate risk. As discussed in Section 4.3.3.1.11 and Appendix J, expected fatalities due to a traffic collision would be approximately 0.1.

In summary, normal operations and accidents that could result from the implementation of this option would pose no significant radiological or nonradiological risks to the public, and implementation would pose no disproportionately high and adverse risks to any group within the population.

#### 4.3.3.1.13 Waste Management

The expected generation rates of waste at Hanford that would be generated from the operation of FFTF for irradiating targets and with the operation of FMEF for target fabrication and processing are compared with Hanford's treatment, storage, and disposal capacities in **Table 4-48**. The impacts on the Hanford waste management systems, in terms of managing the additional waste, are discussed in this section. Radiological and chemical impacts on workers and the public from waste management activities are included in the public and occupational health and safety impacts that are given in Sections 4.3.3.1.9 through 4.3.3.1.11.

Canisters used to transport neptunium-237 to the site would constitute a very small additional amount of solid low-level radioactive waste—less than 10 cubic meters (13.1 cubic yards) over the 35-year operational period, even if no credit is taken for volume reduction by compaction (Brunson 1999a). The annual generation of this waste would fall within the range of accuracy of the generation rate of solid low-level radioactive waste given in Table 4-48, and its management need not be addressed separately.

In accordance with the Records of Decision for the *Waste Management PEIS* (DOE 1997a), waste could be treated and disposed of on site at Hanford or at other DOE sites or commercial facilities. Based on the Record of Decision for high-level radioactive waste issued on August 12, 1999 (64 FR 46661), immobilized high-level radioactive waste would be stored on site until transfer to a geologic repository. Based on the Record of Decision for transuranic waste issued on January 20, 1998 (63 FR 3629), transuranic waste would be certified on site and eventually shipped to a suitable geologic repository for disposal. Based on the Record of Decision for hazardous waste issued on August 5, 1998 (63 FR 41810), nonwastewater hazardous waste would continue to be treated and disposed of at offsite commercial facilities. Based on the Record of Decision for low-level radioactive waste and mixed low-level radioactive waste issued on February 18, 2000 (65 FR 10061), minimal treatment of low-level radioactive waste will be performed at all sites and, to the extent practicable, onsite disposal of low-level radioactive waste will continue. Hanford and the Nevada Test Site will be made available to all DOE sites for the disposal of low-level radioactive waste. Mixed low-level radioactive waste analyzed in the *Waste Management PEIS* will be treated at Hanford, INEEL, ORR, and SRS and will be disposed of at Hanford and the Nevada Test Site.

The analysis for the Draft NI PEIS assumed that the waste generated from the processing of irradiated neptunium-237 targets is transuranic waste. However, as a result of comments received during the public comment period, DOE is considering whether the waste from processing of irradiated neptunium-237 targets should be classified as high-level radioactive waste and not transuranic waste. Irrespective of how the waste is classified (i.e., transuranic or high-level radioactive waste), the composition and characteristics are the same, and the waste management activities (i.e., treatment and onsite storage) as described in this NI PEIS would

**Table 4–48 Incremental Waste Management Impacts of Operating FFTF and FMEF at Hanford Under Alternative 1 (Restart FFTF)—Option 3**

Waste Type <sup>a</sup>	Estimated Additional Waste Generation for FFTF (cubic meters per year)	Estimated Total Waste Generation for FFTF Operation <sup>b</sup> (cubic meters per year)	Estimated Additional Waste Generation for FMEF (cubic meters per year)	Estimated Additional Waste Generation (both FFTF and FMEF) as a Percent of <sup>c</sup>		
				Onsite Treatment Capacity	Onsite Storage Capacity	Onsite Disposal Capacity
Transuranic/High-level radioactive <sup>d</sup>	0	0	11	(d)	(d)	NA
<b>Low-level radioactive</b>						
Liquid	0	<6	6	(e)	(e)	(e)

Solid	130	250	170	NA	NA	NA

- a. See definitions in Section G.9.
- b. These estimates represent the sum of the standby waste generation amounts provided for the No Action Alternative (Table 4–6) and the additional waste generation amounts given in the first column of this table (Table 4–48).
- c. The estimated additional amounts of waste generated annually are compared with the annual site treatment capacities. The estimated total amounts of additional waste generated over the assumed 35-year operational period are compared with the site storage and disposal capacities.
- d. Refer to the text for a discussion on waste classification and treatment. This waste would be stored at FMEF pending availability of a suitable repository. It is assumed that this waste would be remotely handled.
- e. Refer to the text.
- f. Percent of capacity of the Energy Northwest Sewage Treatment Facility.

**Note:** To convert from cubic meters per year to cubic yards per year, multiply by 1.308; < means “less than.”

**Key:** NA, not applicable (i.e., the majority of this waste is not routinely treated, stored, or disposed of on site).

**Source:** Chapin 2000; DOE 2000a; Nielsen 1999.

be the same. In addition, either waste type would require disposal in a suitable repository. If it is transuranic waste, it would be nondefense waste and could not be disposed of at WIPP under current law. Because nondefense transuranic waste has no current disposal path, DOE Headquarters’ approval would be necessary before a decision were made to generate such waste, as required by DOE Order 435.1. If the waste is classified as high-level radioactive waste, it is assumed for the purposes of this analysis that Yucca Mountain, Nevada, if approved, would be the final disposal site for DOE’s high-level radioactive waste. The other differences between these two waste classifications are that a high-level radioactive waste repository requires a much more rigorous waste-form qualification process than a transuranic waste repository and there is a slightly different set of requirements for high-level radioactive waste than for transuranic waste delineated in DOE Manual 435.1.

Target fabrication and processing in FMEF would generate a total of 385 cubic meters (504 cubic yards) of transuranic or high-level radioactive waste over the 35-year operational period. As described in Section 3.4.5 of the *Preconceptual Design Planning for Chemical Processing to Support Pu-238 Production* (Wham 1998), the waste would be vitrified into a glass matrix at a glass melter installed within FMEF. The resulting glass matrix would be stored at FMEF pending availability of a repository for permanent disposal. The impacts of managing the additional quantities of this waste at Hanford would be minimal.

No high-level radioactive or transuranic waste would be generated from merely operating FFTF. The waste described above would result from processing targets that had been irradiated in FFTF.

Solid low-level radioactive waste generated from target irradiation at FFTF and target fabrication and processing in FMEF would be packaged in appropriate containers or burial casks, certified, and transferred for additional treatment and disposal in the existing onsite low-level radioactive Burial Grounds.

An additional 2,200 cubic meters (2,900 cubic yards) of solid low-level radioactive waste would be generated over the 35-year operational period as a result of target irradiation at FFTF as compared to the current standby mode for FFTF. Target fabrication and processing at FMEF would generate about 2,600 cubic meters (3,400 cubic yards) of solid low-level radioactive waste over the 35-year operational period. The total amount of additional solid low-level radioactive waste resulting from operations at FFTF and FMEF represents approximately 0.28 percent of the 1.74-million-cubic-meter (2.28-million-cubic-yard) capacity of the low-level radioactive Burial Grounds. Using the 3,480-cubic-meter-per-hectare (1,842-cubic-yard-per-acre) disposal land usage factor for Hanford published in the *Storage and Disposition PEIS* (DOE 1996a:E-9), 4,800 cubic meters (6,300 cubic yards) of waste would require 1.4 hectares (3.5 acres) of disposal space at Hanford. The impacts of managing this additional low-level radioactive waste at Hanford would be minimal.

Liquid low-level radioactive waste generated from target irradiation at FFTF and target fabrication and processing in FMEF would be transported to the 200 Area Effluent Treatment Facility for processing and ultimate disposal.

There would be no increase in liquid low-level radioactive waste generation as a result of target irradiation at FFTF as compared to the current standby mode for FFTF. Target fabrication and processing at FMEF would generate about 210 cubic meters (270 cubic yards) of liquid low-level radioactive waste over the 35-year operational period. This total amount of additional liquid low-level radioactive waste resulting from operations at FFTF and FMEF represents a small amount of waste that can be managed by the 200 Area Liquid Effluent Treatment Facility, which has an operating capacity of 0.57 cubic meter (0.75 cubic yard) per minute.

Mixed low-level radioactive waste would be stabilized, packaged, and stored on site for treatment and disposal in a manner consistent with the Tri-Party Agreement (EPA et al. 1989) for Hanford. Over the 35-year operational period, no additional mixed low-level radioactive waste would be generated as a result of target irradiation at FFTF as compared to the current standby mode. Mixed low-level radioactive waste generated at FMEF that is associated with target fabrication and processing is estimated over the 35-year operation period to be about 320 cubic meters (420 cubic yards). This mixed low-level radioactive waste is expected to be treated at a nearby commercial facility. This additional waste is also estimated to be about 1.9 percent of the 16,800-cubic-meter (22,000-cubic-yard) storage capacity of the Central Waste Complex and about 2.2 percent of the 14,200-cubic-meter (18,600-cubic-yard) planned disposal capacity of the Radioactive Mixed Waste Disposal Facility. Therefore, this additional waste would only have a minimal impact on the management of mixed low-level radioactive waste at Hanford.

Hazardous waste generated during operation would be packaged in DOT-approved containers and shipped off site to permitted commercial recycling, treatment, and disposal facilities. The additional waste load generated during the 35-year operational period would have only a minimal impact on the Hanford hazardous waste management system.

Nonhazardous solid waste would be packaged and transported in conformance with standard industrial practice. Solid waste such as office paper, metal cans, and plastic and glass bottles that can be recycled would be sent off site for that purpose. The remaining solid sanitary waste would be sent for offsite disposal. This

additional waste load would have only a minimal impact on the nonhazardous solid waste management system at Hanford.

Nonhazardous process wastewater would be discharged into the 400 Area Ponds. This discharge is regulated by State Waste Discharge Permit ST-4501.

Nonhazardous sanitary wastewater would be discharged to the 400 Area sanitary sewer system, which connects to the Energy Northwest Sewage Treatment Facility. Nonhazardous sanitary wastewater generated at FFTF from target irradiation and at FMEF from target fabrication and processing would represent 2.4 percent of the 235,000-cubic-meter-per-year (307,000-cubic-yard-per-year) capacity of the Energy Northwest Sewage Treatment Facility.

The generation rates of waste at Hanford that would be associated with this option (refer to Table 4–48) can be compared with the current waste generation rates at the site, given in Table 3–34 (Section 3.4.11). The waste generation rates associated with this alternative would be much smaller than the current waste generation rates at the site.

#### **4.3.3.1.14 Spent Nuclear Fuel Management**

Impacts associated with spent nuclear fuel management would be the same as for Option 1 and are given in Section 4.3.1.1.14.

#### **4.3.4 Alternative 1 (Restart FFTF)—Option 4**

Option 4 involves operating FFTF at Hanford to irradiate all targets and materials associated with plutonium-238 production, medical and industrial isotope production, and research and development; operating REDC at ORR to fabricate and process neptunium-237 targets and to process the plutonium-238 product; and operating facilities in RPL/306–E to fabricate and process the other targets and materials and to process the associated products. This option includes storage in REDC of the neptunium-237 transported from SRS to ORR and storage in RPL/306–E of the other target materials transported from other offsite facilities to Hanford.

The transportation of the highly enriched uranium fuel to Hanford for use in FFTF, the transportation of the neptunium-237 to ORR and then to Hanford, the transportation of the other target material to Hanford, and the transportation of the product materials following irradiation and postirradiation processing are also part of this option.

FFTF would operate with a mixed oxide fuel core for the first 6 years and with a highly enriched uranium fuel core for the next 29 years.

#### **4.3.4.1 Operations and Transportation**

The environmental impacts associated with storage, processing, and irradiation operations, and with all transportation activities, are assessed in this section.

##### **4.3.4.1.1 Land Resources**

**LAND USE.** The restart of FFTF would not result in impacts on land use at Hanford for the reasons described in Section 4.3.1.1.1.

Neptunium-237 target fabrication and processing at REDC would not result in impacts on land use at ORR for the reasons described in Section 4.3.1.1.1.

Using RPL/306–E for research and development support and medical and industrial isotope target fabrication and processing would not result in impacts on land use at Hanford for the reasons described in Section 4.3.1.1.1.

**VISUAL RESOURCES.** The restart of FFTF would not result in impacts on visual resources at Hanford for the reasons described in Section 4.3.1.1.1.

Impacts on visual resources would not occur at ORR for the reasons described in Section 4.3.1.1.1.

Using RPL/306–E for research and development support and medical and industrial isotope target fabrication and processing would not result in impacts on visual resources at Hanford for the reasons described in Section 4.3.1.1.1.

#### **4.3.4.1.2 Noise**

For the restart of FFTF, the change in noise impacts from construction and operation would be expected to be small as described in Section 4.3.1.1.2.

Noise impacts from neptunium-237 target fabrication and processing at the REDC at ORNL would be expected to be small as described in Section 4.3.1.1.2.

Noise impacts from research and development support and medical and industrial isotope target fabrication and processing at RPL/306–E at Hanford would be expected to be small as described in Section 4.3.1.1.2.

#### **4.3.4.1.3 Air Quality**

Air quality impacts would be the same as under Option 1 (Section 4.3.1.1.3).

#### **4.3.4.1.4 Water Resources**

Impacts on water resources at Hanford associated with the restart of FFTF would be the same as those described in Section 4.3.1.1.4.

REDC in the 7900 Area of ORNL would be used for neptunium-237 storage, target fabrication, and processing in support of plutonium-238 production with impacts on ORR water resources the same as those described in Section 4.3.1.1.4.

RPL/306–E in the 300 Area of Hanford would be used for the fabrication and processing of targets associated with the medical and industrial isotope production and civilian nuclear energy research and development missions. Impacts on water resources at Hanford from use of RPL/306–E would be the same as those described in Section 4.3.1.1.4.

#### **4.3.4.1.5 Geology and Soils**

The restart of FFTF would not be expected to result in impacts on geology and soils at Hanford, nor be jeopardized by large-scale geologic conditions, for the reasons described in Sections 4.2.1.2.5 and 4.3.1.1.5.

Neptunium-237 target fabrication and processing at REDC would not likely result in impacts on geology and soils at ORR, nor be jeopardized by large-scale geologic conditions, for the reasons described in Sections 4.2.2.2.5 and 4.3.1.1.5.

Using RPL/306–E for research and development support and medical and industrial isotope target fabrication and processing would not be expected to result in impacts on geology or soils at Hanford, nor be jeopardized by large-scale geologic conditions, for the reasons described in Sections 4.2.1.2.5 and 4.3.1.1.5. As necessary, the need to evaluate and upgrade existing DOE facilities with regard to natural geologic hazards would be assessed in accordance with DOE Order 420.1, which is described in Section 4.2.1.2.5.

#### **4.3.4.1.6 Ecological Resources**

The restart of FFTF would not result in impacts on ecological resources at Hanford for the reasons described in Section 4.3.1.1.6.

Impacts on ecological resources would not occur at ORR for the reasons described in Section 4.3.1.1.6.

Using RPL/306–E for research and development support and medical and industrial isotope target fabrication and processing would not result in impacts on ecological resources at Hanford for the reasons described in Section 4.3.1.1.6.

#### **4.3.4.1.7 Cultural and Paleontological Resources**

The restart of FFTF would not result in impacts on cultural resources at Hanford for the reasons described in Section 4.3.1.1.7.

Impacts on cultural resources would not occur at ORR for the reasons described in Section 4.3.1.1.7.

Using RPL/306–E for research and development support and medical and industrial isotope target fabrication and processing would not result in impacts on cultural resources at Hanford for the reasons described in Section 4.3.1.1.7.

#### **4.3.4.1.8 Socioeconomics**

Impacts associated with this option would be the same as those addressed in Section 4.3.1.1.8.

#### **4.3.4.1.9 Public and Occupational Health and Safety—Normal Operations**

Impacts associated with this option would be the same as those presented in Section 4.3.1.1.9.

#### **4.3.4.1.10 Public and Occupational Health and Safety—Facility Accidents**

Impacts from postulated accidents associated with FFTF target irradiation, REDC neptunium-237 target processing, and RPL medical and industrial isotope processing are presented in this section. Detailed descriptions of the accident analyses are provided in Appendix I.

Estimates of radiological consequences have been developed for the maximally exposed individual, the offsite population within 80 kilometers (50 miles) of the facility, and a noninvolved worker at a distance of 640 meters (0.4 mile) from the release point. Consequences are presented in terms of radiological dose (in rem) and the probability that the dose would result in a latent cancer fatality. Accident risk is defined as the product of the

accident probability (i.e., accident frequency) and the accident consequence. In this NI PEIS, risk is expressed as the increased likelihood of a latent cancer fatality per year for an individual (the maximally exposed individual or a noninvolved worker), and as the increased number of latent cancer fatalities per year in the offsite population. The probability coefficients for determining the likelihood of a latent cancer fatality, given a dose, are presented in Section 4.2.1.2.10. Consequences to involved workers are addressed in Section I.1.7.

To provide a better indication of risks from the postulated accidents, the risks are summed for each facility and also for each option. Although the summation provides the combined risk for the spectrum of accidents analyzed, it does not indicate total risk. To determine total risk from accidents, a full-scope probabilistic risk analysis would be required for each facility. Since full-scope probabilistic risk analyses are not available to incorporate in this NI PEIS, the summation of the spectrum of accident risks was considered appropriate for the purposes of this NI PEIS. Details of the risk summation calculations are provided in Appendix I.

Consequences and associated risks are presented in **Tables 4-49** and **4-50**, respectively.

FFTF would operate for 6 years with a mixed oxide core followed by 29 years with a highly enriched uranium core. As shown in Table 4-49, the beyond-design-basis core melt accident would result in the largest radiological consequences among FFTF accidents. In order to incorporate internal and external initiators, the accident frequency of  $1 \times 10^{-6}$  was selected for the beyond-design-basis core melt accident. For 35 years of operation, the increased risk of a latent cancer fatality to the maximally exposed individual and to a noninvolved worker would be  $1.06 \times 10^{-8}$  and  $9.37 \times 10^{-9}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.00122.

For 35 years of REDC neptunium-237 target processing, the increased risk of a latent cancer fatality to the maximally exposed individual and of an early fatality to a noninvolved worker would be  $5.71 \times 10^{-5}$  and  $3.50 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.157.

For 35 years of RPL medical, industrial, and research and development target fabrication and processing, the increased risk of a latent cancer fatality to the maximally exposed individual and to a noninvolved worker would be  $4.51 \times 10^{-4}$  and  $3.50 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.377.

For 35 years under this option, the increased risk of a latent cancer fatality to the maximally exposed individual and of a fatality to a noninvolved worker would be  $4.51 \times 10^{-4}$  and  $3.50 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.535.

The consequences associated with chemical accidents would be the same as for Option 1 (Section 4.3.1.1.10).

#### **4.3.4.1.11 Public and Occupational Health and Safety—Transportation**

DOE would transport neptunium-237 from storage at SRS to the REDC target fabrication facility at ORR. DOE would transport the unirradiated neptunium-237 targets from REDC to FFTF. Following irradiation in FFTF, the targets would be returned to REDC for processing. After this processing, the plutonium-238 product would be shipped to LANL. FFTF would receive highly enriched uranium fuel from a U.S. fuel fabrication facility. Additionally, medical and industrial isotopes would be shipped from FFTF to a local airport, and from there to locations throughout the country.

a. Increased likelihood of a latent cancer fatality.

b. Increased number of latent cancer fatalities.

c. Risk of an early fatality.

d. Individual risks are summed only for collocated individuals. The highest individual risk was used to represent the 35-year option risk.

**Key:** BLTC, bottom-loading transfer cask; HEU, highly enriched uranium core; MOX, mixed oxide core.

**Source:** Model results, using the MACCS2 (Chanin and Young 1997) and GENII (Napier et al. 1988) computer codes.

Approximately 38,000 shipments of radioactive materials would be made by DOE. The total distance traveled on public roads by trucks carrying radioactive materials would be 7.9 million kilometers (4.9 million miles); and in the air carrying medical isotopes, 23 million kilometers (14 million miles).

The transportation impact analysis is described in detail in Appendix J.

**IMPACTS OF INCIDENT-FREE TRANSPORTATION.** The dose to transportation workers from all transportation activities entailed by this option has been estimated at 31 person-rem; the dose to the public, 298 person-rem. Accordingly, incident-free transportation of radioactive material associated with this option would result in 0.012 latent cancer fatality among transportation workers and 0.15 latent cancer fatality in the total affected population over the duration of the transportation activities. The estimated number of nonradiological fatalities from vehicular emissions associated with this option would be 0.029. About half of the crew risk, about 2 percent of the public risk, and most of the emissions risk would result from shipping medical and industrial isotopes.

**IMPACTS OF ACCIDENTS DURING TRANSPORTATION.** The maximum foreseeable offsite transportation accident under this option (probability of occurrence: 1 in 10 million per year) is a shipment of irradiated neptunium-237 targets to REDC with a severity Category V accident in an urban population zone under neutral (average) weather conditions. The accident could result in a dose of 0.61 person-rem to the public with an associated  $3.1 \times 10^{-4}$  latent cancer fatality, and 2.6 millirem to the hypothetical maximally exposed individual with a latent cancer fatality risk of  $1.3 \times 10^{-6}$ . No fatalities would be expected to occur. The probability of more severe accidents, different weather conditions at the time of the accident, or occurrence while carrying neptunium-237 (unirradiated) or plutonium-238 was also evaluated and estimated to have a probability of less than 1 in 10 million per year.

Estimates of the total transportation accident risks under this option are as follows: a radiological dose to the population of 1,063 person-rem, resulting in 0.53 latent cancer fatality; and traffic accidents resulting in 0.18 traffic fatality. Nearly all of the radiological and traffic accident risk would result from shipping medical and industrial isotopes.

#### **4.3.4.1.12 Environmental Justice**

Environmental effects that would result from the implementation of Option 4 are nearly identical to those that would result from the implementation of Option 1 (Section 4.3.1.1.12). No disproportionately high and adverse radiological or nonradiological risks to minority or low-income populations would be expected to result from the implementation of Option 4.

#### **4.3.4.1.13 Waste Management**

The impacts of managing waste associated with irradiating targets in FFTF, with processing and fabricating target materials for research and development support and medical and industrial isotope production in RPL/306-E, and with fabricating and processing neptunium-237 targets for plutonium-238 production in REDC at ORR are all assumed to be the same as for Option 1 (Section 4.3.1.1.13). This is because the waste generation would not be affected by the type of fuel used (i.e., mixed oxide or highly enriched uranium), and the same amount of plutonium-238 production, medical and industrial isotope production, and civilian nuclear energy research and development support would be accomplished annually. As discussed in that section, the impacts on Hanford and ORR's waste management systems would be minimal.

#### **4.3.4.1.14 Spent Nuclear Fuel Management**

Impacts associated with spent nuclear fuel management would be the same as for Option 1 and are given in Section 4.3.1.1.14.

#### **4.3.5 Alternative 1 (Restart FFTF)—Option 5**

Option 5 involves operating FFTF at Hanford to irradiate all targets and materials associated with plutonium-238 production, medical and industrial isotope production, and research and development; operating FDPF at INEEL to fabricate and process neptunium-237 targets and to process the plutonium-238 product; and RPL/306–E in the Hanford 300 Area to fabricate and process the other targets and materials and to process the associated products. This option includes storage in Building CPP–651 or FDPF of the neptunium-237 transported to INEEL from SRS and storage in RPL/306–E of the other target materials transported to Hanford from other offsite facilities.

The transportation of the highly enriched uranium to Hanford for use in FFTF, the transportation of the neptunium-237 to INEEL and then to Hanford, the transportation of the other target material to Hanford, and the transportation of the product materials following irradiation and postirradiation processing are also part of this option.

FFTF would operate with a mixed oxide fuel core for the first 6 years and with a highly enriched uranium fuel core for the next 29 years.

#### **4.3.5.1 Operations and Transportation**

The environmental impacts associated with storage, processing, and irradiation operations, and with all transportation activities, are assessed in this section.

##### **4.3.5.1.1 Land Resources**

**LAND USE.** The restart of FFTF would not result in impacts on land use at Hanford for the reasons described in Section 4.3.1.1.1.

Neptunium-237 storage in Building CPP–651 or FDPF and target fabrication and processing in FDPF would not result in impacts on land use at INEEL for the reasons described in Section 4.3.2.1.1.

Using RPL/306–E for research and development support and medical and industrial isotope target fabrication and processing would not result in impacts on land use at Hanford for the reasons described in Section 4.3.1.1.1.

**VISUAL RESOURCES.** The restart of FFTF would not result in impacts on visual resources at Hanford for the reasons described in Section 4.3.1.1.1.

Impacts on visual resources would not occur at INEEL for the reasons described in Section 4.3.2.1.1.

Using RPL/306–E for research and development support and medical and industrial isotope target fabrication and processing would not result in impacts on visual resources at Hanford for the reasons described in Section 4.3.1.1.1.

#### **4.3.5.1.2 Noise**

For the restart of FFTF, the change in noise impacts from construction and operation would be expected to be small as described in Section 4.3.1.1.2.

Noise impacts from neptunium-237 target fabrication and processing at Building CPP-651 and/or FDPF at INEEL would be expected to be small as described in Section 4.3.2.1.2.

Noise impacts from research and development support and medical and industrial isotope target fabrication and processing at RPL/306-E at Hanford would be expected to be small as described in Section 4.3.1.1.2.

#### **4.3.5.1.3 Air Quality**

Air quality impacts would be the same as under Option 2 (Section 4.3.2.1.3).

#### **4.3.5.1.4 Water Resources**

Impacts on water resources at Hanford associated with the restart of FFTF would be the same as those described in Section 4.3.1.1.4.

Building CPP-651 and/or FDPF in the INTEC area of INEEL would be used for neptunium-237 storage, with target fabrication and processing in support of plutonium-238 production in FDPF. Impacts on water resources at INEEL would be the same as those described in Section 4.3.2.1.4.

RPL/306-E in the 300 Area of Hanford would be used for the fabrication and processing of targets associated with the medical and industrial isotope production and civilian nuclear energy research and development missions. Impacts on water resources at Hanford would be the same as those described in Section 4.3.1.1.4.

#### **4.3.5.1.5 Geology and Soils**

The restart of FFTF would not be expected to result in impacts on geology and soils at Hanford, nor be jeopardized by large-scale geologic conditions, for the reasons described in Sections 4.2.1.2.5 and 4.3.1.1.5.

Neptunium-237 storage at Building CPP-651 and/or FDPF and target fabrication, and processing in FDPF would not likely result in impacts on geology and soils at INEEL, nor be jeopardized by large-scale geologic conditions, for the reasons described in Sections 4.2.3.2.5 and 4.3.2.1.5.

Using RPL/306-E for research and development support and medical and industrial isotope target fabrication and processing would not be expected to result in impacts on geology or soils at Hanford, nor be jeopardized by large-scale geologic conditions, for the reasons described in Sections 4.2.1.2.5 and 4.3.1.1.5. As necessary, the need to evaluate and upgrade existing DOE facilities with regard to natural geologic hazards would be assessed in accordance with DOE Order 420.1, which is described in Section 4.2.1.2.5.

#### **4.3.5.1.6 Ecological Resources**

The restart of FFTF would not result in impacts on ecological resources at Hanford for the reasons described in Section 4.3.1.1.6.

Impacts on ecological resources would not occur at INEEL for the reasons described in Section 4.3.2.1.6.

Using RPL/306–E for research and development support and medical and industrial isotope target fabrication and processing would not result in impacts on ecological resources at Hanford for the reasons described in Section 4.3.1.1.6.

#### **4.3.5.1.7 Cultural and Paleontological Resources**

The restart of FFTF would not result in impacts on cultural resources at Hanford for the reasons described in Section 4.3.1.1.7.

Impacts on cultural resources would not occur at INEEL for the reasons described in Section 4.3.2.1.7.

Using RPL/306–E for research and development support and medical and industrial isotope target fabrication and processing would not result in impacts on cultural resources at Hanford for the reasons described in Section 4.3.1.1.7.

#### **4.3.5.1.8 Socioeconomics**

Impacts associated with this option would be the same as those addressed in Section 4.3.2.1.8.

#### **4.3.5.1.9 Public and Occupational Health and Safety—Normal Operations**

Impacts associated with this option would be the same as those presented in Section 4.3.2.1.9.

#### **4.3.5.1.10 Public and Occupational Health and Safety—Facility Accidents**

Impacts from postulated accidents associated with FFTF target irradiation, FDFP neptunium-237 target processing, and RPL medical and industrial target processing are presented in this section. Detailed descriptions of the accident analyses are provided in Appendix I.

Estimates of radiological consequences have been developed for the maximally exposed individual, the offsite population within 80 kilometers (50 miles) of the facility, and a noninvolved worker at a distance of 640 meters (0.4 miles) from the release point. Consequences are presented in terms of radiological dose (in rem) and the probability that the dose would result in a latent cancer fatality. Accident risk is defined as the product of the accident probability (i.e., accident frequency) and the accident consequence. In this NI PEIS, risk is expressed as the increased likelihood of a latent cancer fatality per year for an individual (the maximally exposed individual or a noninvolved worker), and as the increased number of latent cancer fatalities per year in the offsite population. The probability coefficients for determining the likelihood of a latent cancer fatality, given a dose, are presented in Section 4.2.1.2.10. Consequences to involved workers are addressed in Section I.1.7.

To provide a better indication of risks from the postulated accidents, the risks are summed for each facility and also for each option. Although the summation provides the combined risk for the spectrum of accidents analyzed, it does not indicate total risk. To determine total risk from accidents, a full-scope probabilistic risk analysis would be required for each facility. Since full-scope probabilistic risk analyses are not available to incorporate in this NI PEIS, the summation of the spectrum of accident risks was considered appropriate for the purposes of this NI PEIS. Details of the risk summation calculations are provided in Appendix I.

Consequences and associated risks are presented in **Tables 4–51** and **4–52**, respectively.

a. Likelihood of a latent cancer fatality.

b. Number of latent cancer fatalities.

c. Early fatality due to radiation dose. A radiation dose of 450 to 500 rem causes fatalities in 50 percent of those exposed. Early fatalities are expected for exposures greater than 600 rem.

**Key:** BLTC, bottom-loading transfer cask; HEU, highly enriched uranium core; MOX, mixed oxide core.

**Source:** Model results, using the MACCS2 (Chanin and Young 1997) and GENII (Napier et al. 1988) computer codes.

**Table 4–52 FFTF, FDFP, and RPL Accident Risks Under Alternative 1  
(Restart FFTF)—Option 5**

Accident (Frequency)	Maximally Exposed Individual <sup>a</sup>	Population to 80 Kilometers (50 Miles) <sup>b</sup>	Noninvolved Worker <sup>a</sup>
<b>Annual FFTF risks</b>			
Design-basis-accident primary sodium spill (MOX) ( $1 \times 10^{-4}$ )	$5.65 \times 10^{-11}$	$3.93 \times 10^{-6}$	$1.25 \times 10^{-10}$

<b>35-year RPL risk</b>	$4.51 \times 10^{-4}$	0.377	$3.50 \times 10^{-4}$
<b>35-year Option risk<sup>d</sup></b>	$4.51 \times 10^{-4}$	0.407	$3.50 \times 10^{-4}$

a. Increased likelihood of a latent cancer fatality.

b. Increased number of latent cancer fatalities.

c. Risk of an early fatality.

d. Individual risks are summed only for collocated individuals. The highest individual risk was used to represent the 35-year option risk.

**Key:** BLTC, bottom-loading transfer cask; HEU, highly enriched uranium core; MOX, mixed oxide core.

**Source:** Model results, using the MACCS2 (Chanin and Young 1997) and GENII (Napier et al. 1988) computer codes.

FFTF would operate for 6 years with a mixed oxide core followed by 29 years with a highly enriched uranium core. As shown in Table 4–51, the beyond-design-basis core melt accident would result in the largest radiological consequences among FFTF accidents. In order to incorporate internal and external initiators, the accident frequency of  $1 \times 10^{-6}$  was selected for the beyond-design-basis core melt accident. For 35 years of operation, the increased risk of a latent cancer fatality to the maximally exposed individual and to a noninvolved worker would be  $1.06 \times 10^{-8}$  and  $9.37 \times 10^{-9}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.00122.

For 35 years of FDPF neptunium-237 target processing, the increased risk of a latent cancer fatality to the maximally exposed individual and of an early fatality to a noninvolved worker would be  $1.49 \times 10^{-5}$  and  $3.50 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.0287.

For 35 years of RPL medical, industrial, and research and development target fabrication and processing, the increased risk of a latent cancer fatality to the maximally exposed individual and to a noninvolved worker would be  $4.51 \times 10^{-4}$  and  $3.50 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.377.

For 35 years under this option, the increased risk of a latent cancer fatality to the maximally exposed individual and of a fatality to a noninvolved worker would be  $4.51 \times 10^{-4}$  and  $3.50 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.407.

The consequences associated with chemical accidents would be the same as for Option 2 (Section 4.3.2.1.10).

#### **4.3.5.1.11 Public and Occupational Health and Safety—Transportation**

DOE would transport neptunium-237 from storage at SRS to the FDPF target fabrication facility at INEEL. DOE would transport the unirradiated neptunium-237 targets from FDPF to FFTF. Following irradiation in FFTF, the targets would be returned to FDPF for processing. After this processing, the plutonium-238 product would be shipped to LANL. FFTF would receive highly enriched uranium fuel from a U.S. fuel fabrication facility. Additionally, medical and industrial isotopes would be shipped from FFTF to a local airport, and from there to locations throughout the country.

Approximately 38,000 shipments of radioactive materials would be made by DOE. The total distance traveled on public roads by trucks carrying radioactive materials would be 6.1 million kilometers (3.8 million miles); and in the air carrying medical isotopes, 23 million kilometers (14 million miles).

The transportation impact analysis is described in detail in Appendix J.

**IMPACTS OF INCIDENT-FREE TRANSPORTATION.** The dose to transportation workers from all transportation activities entailed by this option has been estimated at 21 person-rem; the dose to the public, 88 person-rem. Accordingly, incident-free transportation of radioactive material associated with this option would result in 0.008 latent cancer fatality among transportation workers and 0.044 latent cancer fatality in the total affected population over the duration of the transportation activities. The estimated number of nonradiological fatalities from vehicular emissions associated with this option would be 0.023. About half of the crew risk, about 8 percent of the public risk, and most of the emissions risk would result from shipping medical and industrial isotopes.

**IMPACTS OF ACCIDENTS DURING TRANSPORTATION.** The maximum foreseeable offsite transportation accident under this option (probability of occurrence: 1 in 10 million per year) is a shipment of irradiated

neptunium-237 targets to FDFP with a severity Category V accident in an urban population zone under neutral (average) weather conditions. The accident could result in a dose of 0.61 person-rem to the public with an associated  $3.1 \times 10^{-4}$  latent cancer fatality, and 2.6 millirem to the hypothetical maximally exposed individual with a latent cancer fatality risk of  $1.3 \times 10^{-6}$ . No fatalities would be expected to occur. The probability of more severe accidents, different weather conditions at the time of the accident, or occurrence while carrying neptunium-237 (unirradiated) or plutonium-238 was also evaluated and estimated to have a probability of less than 1 in 10 million per year.

Estimates of the total transportation accident risks under this option are as follows: a radiological dose to the population of 1,063 person-rem, resulting in 0.53 latent cancer fatality; and traffic accidents resulting in 0.13 traffic fatality. Nearly all of the radiological and traffic accident risk would result from shipping medical and industrial isotopes.

#### **4.3.5.1.12 Environmental Justice**

Environmental effects that would result from the implementation of Option 5 are nearly identical to those that would result from the implementation of Option 2 (Section 4.3.2.1.12). No disproportionately high and adverse radiological or nonradiological risks to minority or low-income populations would be expected to result from the implementation of Option 5.

#### **4.3.5.1.13 Waste Management**

The impacts of managing waste associated with irradiating targets in FDFP, with processing and fabricating target materials for the research and development support and medical and industrial isotope production in RPL/306-E, and with fabricating and processing neptunium-237 targets for plutonium-238 production in FDFP, are all assumed to be the same as for Option 2 (Section 4.3.2.1.13). This is because the waste generation would not be affected by the type of fuel used (i.e., mixed oxide or highly enriched uranium) and the same amount of plutonium-238 production, medical and industrial isotope production, and civilian nuclear energy research and development support would be accomplished annually. As discussed in that section, the impacts on Hanford's and INEEL's waste management systems would be minimal.

#### **4.3.5.1.14 Spent Nuclear Fuel Management**

Impacts associated with spent nuclear fuel management would be the same as for Option 1 and are given in Section 4.3.1.1.14.

### **4.3.6 Alternative 1 (Restart FDFP)—Option 6**

Option 6 involves operating FDFP at Hanford to irradiate all targets and materials associated with plutonium-238 production, medical and industrial isotope production, and research and development, and also operating FMEF at Hanford to fabricate and process these targets and materials and the associated irradiated products. This option includes storage in FMEF of the neptunium-237 transported to Hanford from SRS and of the other target materials transported to Hanford from other offsite facilities.

The transportation of the highly enriched uranium fuel to Hanford for use in FDFP, the transportation of the neptunium-237 and other target material to Hanford, and the transportation of the product materials following postirradiation processing are also part of this option.

FDFP would operate with a mixed oxide fuel core for the first 6 years and with a highly enriched uranium fuel core for the next 29 years.

#### **4.3.6.1 Operations and Transportation**

The environmental impacts associated with storage, processing, and irradiation operations, and with all transportation activities, are assessed in this section.

##### **4.3.6.1.1 Land Resources**

**LAND USE.** The restart of FFTF would not result in impacts on land use at Hanford for the reasons described in Section 4.3.3.1.1.

Impacts on land use at Hanford from target material storage, target fabrication, and processing at FMEF would be minimal for the reasons described in Section 4.3.3.1.1.

**VISUAL RESOURCES.** The restart of FFTF would not result in impacts on visual resources at Hanford for the reasons described in Section 4.3.3.1.1.

Impacts on visual resources at Hanford from target material storage, target fabrication, and processing at FMEF would be minimal for the reasons described in Section 4.3.3.1.1.

##### **4.3.6.1.2 Noise**

For the restart of FFTF, the change in noise impacts from construction and operation would be expected to be small as described in Section 4.3.1.1.2.

Noise impacts from target material storage, target fabrication, and processing at the FMEF would be expected to be small as described in Section 4.3.3.1.2.

##### **4.3.6.1.3 Air Quality**

Air quality impacts would be the same as under Option 3 (Section 4.3.3.1.3).

##### **4.3.6.1.4 Water Resources**

Impacts on water resources at Hanford associated with the restart of FFTF and the operation of FMEF for target material storage, target fabrication, and processing would be the same as those described in Section 4.3.3.1.4.

##### **4.3.6.1.5 Geology and Soils**

The restart of FFTF would not be expected to result in impacts on geologic and soil resources at Hanford, nor be jeopardized by large-scale geologic conditions, for the reasons described in Sections 4.2.1.2.5 and 4.3.1.1.5.

Impacts on geologic resources and soils at Hanford from the operation of FMEF for target material storage, target fabrication, and processing would not be expected for the reasons described in Section 4.3.3.1.5. Likewise, large-scale geologic conditions would not be expected to jeopardize FMEF. As necessary, the need to evaluate and upgrade existing DOE facilities with regard to natural geologic hazards would be assessed in accordance with DOE Order 420.1, which is described in Section 4.2.1.2.5.

#### **4.3.6.1.6 Ecological Resources**

The restart of FFTF would not result in impacts on ecological resources at Hanford for the reasons described in Section 4.3.1.1.6.

Impacts on ecological resources at Hanford from target material storage, target fabrication, and processing at FMEF would not be expected for the reasons described in Section 4.3.3.1.6.

#### **4.3.6.1.7 Cultural and Paleontological Resources**

The restart of FFTF would not be expected to result in impacts on cultural resources at Hanford for the reasons described in Section 4.3.1.1.7.

Impacts on cultural resources at Hanford from target material storage, target fabrication, and processing at FMEF would not be expected for the reasons described in Section 4.3.3.1.7.

#### **4.3.6.1.8 Socioeconomics**

Impacts associated with this option would be the same as those presented in Section 4.3.3.1.8.

#### **4.3.6.1.9 Public and Occupational Health and Safety—Normal Operations**

Impacts associated with this option would be the same as those presented in Section 4.3.3.1.9.

#### **4.3.6.1.10 Public and Occupational Health and Safety—Facility Accidents**

Impacts from postulated accidents associated with FFTF target irradiation and FMEF target processing are presented in this section. Detailed descriptions of the accident analyses are provided in Appendix I.

Estimates of radiological consequences have been developed for the maximally exposed individual, the offsite population within 80 kilometers (50 miles) of the facility, and a noninvolved worker at a distance of 640 meters (0.4 miles) from the release point. Consequences are presented in terms of radiological dose (in rem) and the probability that the dose would result in a latent cancer fatality. Accident risk is defined as the product of the accident probability (i.e., accident frequency) and the accident consequence. In this NI PEIS, risk is expressed as the increased likelihood of a latent cancer fatality per year for an individual (the maximally exposed individual or a noninvolved worker), and as the increased number of latent cancer fatalities per year in the offsite population. The probability coefficients for determining the likelihood of a latent cancer fatality, given a dose, are presented in Section 4.2.1.2.10. Consequences to involved workers are addressed in Section I.1.7.

To provide a better indication of risks from the postulated accidents, the risks are summed for each facility and also for each option. Although the summation provides the combined risk for the spectrum of accidents analyzed, it does not indicate total risk. To determine total risk from accidents, a full-scope probabilistic risk analysis would be required for each facility. Since full-scope probabilistic risk analyses are not available to incorporate in this NI PEIS, the summation of the spectrum of accident risks was considered appropriate for the purposes of this NI PEIS. Details of the risk summation calculations are provided in Appendix I.

Consequences and associated risks are presented in **Tables 4–53** and **4–54**, respectively.

**Table 4-53 FFTF and FMEF Accident Consequences Under Alternative 1 (Restart FFTF)—Option 6**

Accident	Maximally Exposed Individual		Population to 80 Kilometers (50 Miles)		Noninvolved Worker	
	Dose (rem)	Latent Cancer Fatality <sup>a</sup>	Dose (person-rem)	Latent Cancer Fatalities <sup>b</sup>	Dose (rem)	Latent Cancer Fatality <sup>a</sup>
<b>FTTF accidents</b>

<b>35-year Option risks<sup>d</sup></b>	$6.80 \times 10^{-6}$	0.209	$4.17 \times 10^{-4}$

a. Increased likelihood of a latent cancer fatality.

b. Increased number of latent cancer fatalities.

c. Risk of an early fatality.

d. Individual risks are summed only for colocated individuals. The highest individual risk was used to represent the 35-year option risk.

**Key:** BLTC, bottom-loading transfer cask; HEU, highly enriched uranium core; MOX, mixed oxide core.

**Source:** Model results, using the MACCS2 (Chanin and Young 1997) and GENII (Napier et al. 1988) computer codes.

FFTF would operate for 6 years with a mixed oxide core followed by 29 years with a highly enriched uranium core. As shown in Table 4–53, the beyond-design-basis core melt accident would result in the largest radiological consequences among FFTF accidents. In order to incorporate internal and external initiators, the accident frequency of  $1 \times 10^{-6}$  was selected for the beyond-design-basis core melt accident. For 35 years of operation, the increased risk of a latent cancer fatality to the maximally exposed individual and to a noninvolved worker would be  $1.06 \times 10^{-8}$  and  $9.37 \times 10^{-9}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.00122.

For 35 years of FMEF target fabrication and processing, the increased risk of a latent cancer fatality to the maximally exposed individual and of an early fatality to a noninvolved worker would be  $6.79 \times 10^{-6}$  and  $4.17 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.208.

For 35 years under this option, the increased risk of a latent cancer fatality to the maximally exposed individual and of a fatality to a noninvolved worker would be  $6.80 \times 10^{-6}$  and  $4.17 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.209.

The consequences associated with chemical accidents would be the same as for Option 3 (Section 4.3.3.1.10).

#### **4.3.6.1.11 Public and Occupational Health and Safety—Transportation**

DOE would transport neptunium-237 from storage at SRS to the FMEF target fabrication facility at Hanford. DOE would transport the unirradiated neptunium-237 targets from FMEF to FFTF. Following irradiation in FFTF, the targets would be returned to FMEF for processing. After this processing, the plutonium-238 product would be shipped to LANL. FFTF would receive highly enriched uranium fuel from a U.S. fuel fabrication facility. Additionally, medical and industrial isotopes would be shipped from FFTF to a local airport, and from there to locations throughout the country.

Approximately 38,000 shipments of radioactive materials would be made by DOE. The total distance traveled on public roads by trucks carrying radioactive materials would be 5.5 million kilometers (3.4 million miles); and in the air carrying medical isotopes, 23 million kilometers (14 million miles).

The transportation impact analysis is described in detail in Appendix J.

**IMPACTS OF INCIDENT-FREE TRANSPORTATION.** The dose to transportation workers from all transportation activities entailed by this option has been estimated at 18 person-rem; the dose to the public, 18 person-rem. Accordingly, incident-free transportation of radioactive material associated with this option would result in 0.0071 latent cancer fatality among transportation workers and 0.009 latent cancer fatality in the total affected population over the duration of the transportation activities. The estimated number of nonradiological fatalities from vehicular emissions associated with this option would be 0.023. About half of the crew risk, about 40 percent of the public risk, and most of the emissions risk would result from shipping medical and industrial isotopes.

**IMPACTS OF ACCIDENTS DURING TRANSPORTATION.** The maximum foreseeable offsite transportation accident under this option (probability of occurrence: 1 in 10 million per year) would not breach the transportation package. The probability of severe accidents, different weather conditions at the time of the accident, or occurrence while carrying neptunium-237 (unirradiated) or plutonium-238 was evaluated and estimated to have a probability of less than 1 in 10 million per year.

Estimates of the total transportation accident risks under this option are as follows: a radiological dose to the population of 1,063 person-rem, resulting in 0.53 latent cancer fatality; and traffic accidents resulting in 0.11 traffic fatality. Nearly all of the radiological and traffic accident risk would result from shipping medical and industrial isotopes.

#### **4.3.6.1.12 Environmental Justice**

Environmental effects that would result from the implementation of Option 6 are nearly identical to those that would result from the implementation of Option 3 (Section 4.3.3.1.12). No disproportionately high and

adverse radiological or nonradiological risks to minority or low-income populations would be expected to result from the implementation of Option 6.

#### **4.3.6.1.13 Waste Management**

Impacts of managing waste associated with irradiating targets in FFTF, and with processing and fabricating target materials for the research and development support and medical and industrial isotope production and plutonium-238 production in FMEF, are assumed to be the same as for Option 3 (Section 4.3.3.1.13). This is because the waste generation would not be affected by the type of fuel used (i.e., mixed oxide or highly enriched uranium) and the same amount of plutonium-238 production, medical and industrial isotope production and civilian nuclear energy research and development support would be accomplished annually. As discussed in that section, the impacts on Hanford's waste management systems would be small.

#### **4.3.6.1.14 Spent Nuclear Fuel Management**

Impacts associated with spent nuclear fuel management would be the same as for Option 1 and are given in Section 4.3.1.1.14.

#### **4.4 ALTERNATIVE 2—USE ONLY EXISTING OPERATIONAL FACILITIES**

Under Alternative 2, DOE would use existing operating DOE reactors or U.S. commercial nuclear power plants to produce plutonium-238 for future space missions. The production of medical and industrial isotopes and support of civilian nuclear energy research and development in DOE reactors and accelerators would continue at the No Action Alternative levels. However, the currently operating DOE reactors, HFIR and ATR, cannot fully meet the projected long-term needs for medical isotope production and civilian nuclear energy research and development with or without adding the plutonium-238 production mission.

Depending on the combination of facilities used in Alternative 2, HFIR and ATR could continue their current support of the medical and industrial isotope and research and development missions, including some near-term growth, while accommodating the production of plutonium-238. Under other scenarios, some of the near-term growth in medical and industrial isotope production and civilian nuclear energy research and development, possible in these reactors, could be limited by the addition of the plutonium-238 production. In any case, non-DOE use of these facilities would be affected by the addition of the plutonium-238 mission. If a commercial reactor were used for plutonium-238 production, the DOE facilities would be unaffected and would continue operating as discussed under the No Action Alternative.

Another component of Alternative 2 is permanent deactivation of FFTF. Permanent deactivation of FFTF (Alternative 5) could occur in conjunction with any of the options under Alternatives 2, 3, or 4. Ongoing operations at existing facilities as described in Chapter 3, Affected Environment, would continue under Alternative 2.

Targets for plutonium-238 production would be fabricated in one of three facilities at ORNL, INEEL, or Hanford. The material needed for target fabrication (neptunium-237) would be processed and transported from SRS to the fabrication facilities. The targets would be irradiated at existing reactor facilities (HFIR, ATR, and a commercial light water reactor [CLWR] as described in Section 2.3.1) and would be transported back to the fabricating facilities for postirradiation processing.

Under Alternative 2, nonirradiated targets, irradiated targets, and processed materials would be transported between the locations selected for storage, target fabrication, target irradiation, and postirradiation processing, as well as transportation of the plutonium-238 product to LANL.

Nine options are proposed under this alternative. Options 1 through 3 involve the irradiation of targets in ATR at INEEL. Options 4 through 6 involve the irradiation of targets in a generic CLWR. Options 7 through 9 involve the irradiation of targets in both INEEL's ATR and ORNL's HFIR. These options and the associated target fabrication, postirradiation processing, and transportation activities are discussed below.

- **Option 1.** REDC at ORNL would be used to store the neptunium-237 transported from SRS to ORNL and to fabricate and process the targets irradiated at ATR. Option 1 also involves transportation of the neptunium-237 targets from ORNL to INEEL for irradiation in ATR, transportation of the irradiated targets from INEEL back to ORNL for postirradiation processing, and subsequent transportation of the plutonium-238 product from ORNL to LANL following postirradiation processing.
- **Option 2.** FDPF at INEEL would be used to store the neptunium transported from SRS to INEEL and to fabricate and process the targets (irradiated at ATR). Building CPP-651 would also be used for storage. Option 2 also involves transportation of the plutonium-238 product from INEEL to LANL following postirradiation processing.

- **Option 3.** FMEF at Hanford would be used to fabricate and process the targets (irradiated at ATR) and to store the neptunium-237 transported from SRS to Hanford. Option 3 also involves transportation of the neptunium-237 to Hanford for target fabrication, transportation of the targets from Hanford to INEEL for irradiation, transportation of the irradiated targets back to Hanford for postirradiation processing in FMEF, and subsequent transportation of the plutonium-238 product from Hanford to LANL.
- **Option 4.** REDC at ORNL would be used to store the neptunium-237 transported from SRS to ORNL and to fabricate and process the targets (irradiated at a generic CLWR). Option 4 also involves transportation of the neptunium-237 targets from ORNL to the generic CLWR location for irradiation, transportation of the irradiated targets back to ORNL for postirradiation processing, and transportation of the plutonium-238 product from ORNL to LANL.
- **Option 5.** FDPF at INEEL would be used to store the neptunium transported from SRS to INEEL and to fabricate and process the targets (irradiated at a generic CLWR). Building CPP-651 would also be used for storage. In addition, Option 5 involves transportation of the neptunium-237 targets from INEEL to the generic CLWR location for irradiation, transportation of the irradiated targets back to INEEL for postirradiation processing, and transportation of the plutonium-238 product from INEEL to LANL.
- **Option 6.** FMEF at Hanford would be used to store the neptunium-237 transported from SRS to Hanford and to fabricate and process the targets (irradiated at a generic CLWR). Option 6 also involves transportation of neptunium-237 to Hanford for target fabrication, transportation of the targets from Hanford to the generic CLWR location for irradiation, transportation of the irradiated targets back to Hanford for postirradiation processing, and transportation of the plutonium-238 product from Hanford to LANL.
- **Option 7.** REDC at ORNL would be used to store the neptunium-237 transported from SRS to ORNL and to fabricate and process the targets (irradiated at ATR and HFIR). Option 7 also involves transportation of the neptunium-237 targets from ORNL to the reactors for irradiation, transportation of the irradiated targets back to ORNL for processing, and transportation of the plutonium-238 product from ORNL to LANL.
- **Option 8.** FDPF at INEEL would be used to store the neptunium transported from SRS to INEEL and to fabricate and process the targets (irradiated at ATR and HFIR). Building CPP-651 would also be used for storage. Option 8 also involves transportation of the neptunium-237 targets from INEEL to the reactors for irradiation, transportation of the irradiated targets back to INEEL for postirradiation processing, and transportation of the plutonium-238 product from INEEL to LANL.
- **Option 9.** FMEF at Hanford would be used to store the neptunium-237 transported from SRS to Hanford and to fabricate and process the targets (irradiated at ATR and HFIR). Option 9 also involves transportation of neptunium-237 to Hanford for target fabrication, transportation of the targets from Hanford to the reactors for irradiation, transportation of the irradiated targets back to Hanford for postirradiation processing, and transportation of the plutonium-238 product from Hanford to LANL.

#### 4.4.1 Alternative 2 (Use Only Existing Operational Facilities)—Option 1

Option 1 involves operating the Advanced Test Reactor (ATR) at INEEL to irradiate neptunium-237 targets to produce plutonium-238, and operating the REDC facility at ORR to both fabricate and process these targets and to store the neptunium-237 transported to ORR from SRS.

The transportation of the neptunium-237 from SRS to ORR for processing and fabrication into neptunium-237 targets in REDC, the transportation of these targets from ORR to INEEL for irradiation in ATR, the transportation of the irradiated targets from INEEL back to ORR for postirradiation processing in REDC, and the transportation of the plutonium-238 product from ORR to LANL also constitute part of this option.

All options under this alternative include the permanent deactivation of FFTF at Hanford.

#### **4.4.1.1 Operations and Transportation**

The environmental impacts associated with storage, processing, and irradiation operations, and with all transportation activities, are assessed in this section.

##### **4.4.1.1.1 Land Resources**

**LAND USE.** ATR is an operating facility in the Test Reactor Area at INEEL; use of the facility for neptunium-237 target irradiation would be compatible with its current mission. Further, because it is an existing facility, no new construction would be required, and thus, there would be no change in land use in the Test Reactor Area or INEEL.

REDC would be used for neptunium-237 storage, target fabrication, and processing. REDC is an existing operating facility in the 7900 Area of ORNL, and the use of this facility would require internal modifications, but no new facilities would be built. Because no additional land would be disturbed and the use of REDC for neptunium-237 target fabrication and processing would be compatible with its present mission, there would be no change in land use at ORR.

**VISUAL RESOURCES.** The irradiation of neptunium-237 targets would take place in the existing ATR at INEEL. The use of ATR would not require any external modifications that would alter the appearance of the facility. Therefore, the current Visual Resource Management Class IV rating for the Test Reactor Area would not change. Because there would be no change in the appearance of ATR or the Test Reactor Area, there would be no additional impact on visual resources.

All activities associated with neptunium-237 storage, target fabrication, and processing would take place in REDC at ORR. Because REDC is an existing facility that would require no external modifications, there would be no change in its appearance. Therefore, the current Visual Resource Management Class IV rating for the 7900 Area would not change, and there would be no impact on visual resources.

##### **4.4.1.1.2 Noise**

Noise associated with neptunium-237 target irradiation in ATR would be similar to sound levels generated by current reactor operations, as well as other operations in the Test Reactor Area. Onsite noise impacts would be expected to be minimal, and changes in offsite noise levels would not be noticeable because the nearest site boundary is 11 kilometers (6.8 miles) to the northwest. Noise levels associated with increased traffic going to and from the facility would be low, and would result in only minor changes to existing onsite and offsite noise levels. Neptunium-237 target irradiation in ATR would not produce any sudden loud noises that would adversely affect wildlife.

Noise associated with neptunium-237 storage, target fabrication, and processing would be similar to sound levels generated by present REDC operations, as well as other operations in the 7900 Area. Onsite noise impacts would be expected to be minimal, and changes in offsite noise levels would not be noticeable because the nearest site boundary is 2.5 kilometers (1.6 miles) to the southeast. Changes in traffic volume going to and

from REDC would be minor, and would not lead to noticeable changes in noise levels either on site or off site. There would be no loud noises associated with target fabrication and processing that would adversely impact wildlife.

#### 4.4.1.1.3 Air Quality

It is estimated that there would be no measurable increases in nonradiological air pollutant emissions at INEEL associated with this option (Moor and Peterson 1999). The baseline air quality at INEEL would be unchanged.

The air pollutant concentrations at ORR attributable to REDC are presented in **Table 4–55**. The concentrations are based on a dispersion-modeling screening analysis conducted with maximum expected emission rates and a set of worst-case meteorological conditions. Only those air pollutants expected to be emitted that have ambient air quality standards are presented in the table. The changes in concentrations were determined to be small and would be below the applicable standard even when ambient monitored values and the contribution from other site activities were included. There are no Prevention of Significant Deterioration increment-consuming sources at ORR; therefore, a Prevention of Significant Deterioration increment consumption analysis was not conducted. Health effects from hazardous chemicals associated with this option are addressed in Section 4.4.1.1.9.

**Table 4–55 Incremental ORR Concentrations<sup>a</sup> Associated with Alternative 2  
(Use Only Existing Operational Facilities)—Option 1**

Pollutant	Averaging Period	Most Stringent Standard or Guideline (micrograms per cubic meter)	Modeled Increment (micrograms per cubic meter)
Nitrogen dioxide	Annual	100	$1.99 \times 10^{-4}$
Sulfur dioxide	Annual	80	0.04
	24 hours	365	0.31
	3 hours	1,300	0.70

a. For comparison with ambient air quality standards.

**Source:** Modeled increments are based on the SCREEN3 computer code (EPA 1995).

The air quality impacts of transportation among SRS, INEEL, ORR, and LANL are presented in Section 4.4.1.1.11.

#### 4.4.1.1.4 Water Resources

The production of plutonium-238 would not measurably increase groundwater usage from the Snake River Plain aquifer or measurably affect the quantity or quality of effluents discharged from ATR (Moor and Peterson 1999:6). Information on current water usage, effluent discharge, and water quality for INEEL is presented in Section 3.3.4.

REDC, an existing facility in the 7900 Area of ORNL at ORR, would be used for neptunium-237 storage, target fabrication, and processing in support of plutonium-238 production with impacts on ORR water resources indicators the same as those described in Section 4.3.1.1.4. In summary, a small increase in water use and sanitary wastewater generation is anticipated, mainly attributable to increased staffing levels. Also, there would be a very small increase in process wastewater generation, but there would be no radiological liquid effluent discharge to the environment under normal operations.

#### 4.4.1.1.5 Geology and Soils

ATR, an existing facility, would be used for the irradiation of neptunium-237 targets. Since no new construction is planned, there would be no disturbance to either geologic or soil resources in the Test Reactor Area. As previously summarized in Section 4.2.3.2.5, hazards from large-scale geologic conditions at INEEL, such as earthquakes and volcanoes, were evaluated in the *Storage and Disposition PEIS* (DOE 1996a:4-148). The analysis determined that these hazards present a low risk to INEEL facilities. That analysis was reviewed in the *Surplus Plutonium Disposition EIS* (DOE 1999a: 4-267-268). Further review of the data and analyses presented in these referenced documents and the site-specific data presented in this NI PEIS indicates that the large-scale geologic conditions likewise present a low risk to proposed ATR operations. This is because regional seismic conditions do not preclude the safe operation of properly or specially designed or upgraded facilities and the potential for future volcanic activity is low. The potential for nontectonic events to threaten INEEL facilities is also low.

Because the existing REDC facility would be used for neptunium-237 storage, target fabrication, and processing under this option, there would be no disturbance to either geologic or soil resources in the 7900 Area of ORNL. Hazards from large-scale geologic conditions at ORR were previously analyzed as discussed in Section 4.2.2.2.5 and determined to present a low risk to REDC.

As necessary, the need to evaluate and upgrade existing DOE facilities with regard to natural geologic hazards would be assessed in accordance with DOE Order 420.1, which is described in Section 4.2.1.2.5.

#### 4.4.1.1.6 Ecological Resources

The existing ATR facility at INEEL would be used to irradiate neptunium-237 targets. Terrestrial resources would not be adversely affected because ATR is in the highly disturbed and fenced Test Reactor Area, and no new construction is planned. Further, as noted in Section 4.4.1.1.2, there would be no sudden loud noises that would adversely affect wildlife. Because there would be no measurable increase in water use or wastewater discharge, and discharge chemistry would not be expected to change, there would be no impact on aquatic habitat (Section 4.4.1.1.4). Due to the developed nature of the area, and because no new construction would take place, impacts on threatened and endangered species would not occur.

Consultation letters to comply with Section 7 of the Endangered Species Act were sent to the U.S. Fish and Wildlife Service and the Idaho Department of Fish and Game (see Table 5–3). Each agency was asked to provide information on potential impacts of the proposed action on threatened and endangered species. The Idaho Department of Fish and Game indicated that its database contained no known occurrences of special status plants or animals near the project area. While DOE has made additional contact with the U.S. Fish and Wildlife Service, a response is pending from this agency. Although no federally listed species are expected to be impacted by the proposed action, no action would be taken relative to the use of facilities at INEEL prior to the receipt of input from the Service.

REDC, an existing facility at ORR, would be used for neptunium-237 storage, target fabrication, and processing. No new construction would take place; thus, direct disturbance to ecological resources would not occur. As noted in Section 4.4.1.1.2, there would be no sudden loud noises that would adversely affect wildlife. There would be no change in impacts on aquatic resources because additional water usage and wastewater discharge would be small fractions of current values and discharge chemistry would not be expected to change (Section 4.4.1.1.4). Threatened and endangered species would not be impacted because an existing facility in the developed area would be used.

Consultation to comply with Section 7 of the Endangered Species Act was conducted with the U.S. Fish and Wildlife Service (see Table 5–3) and resulted in the Service concluding that it does not anticipate adverse effects to federally listed endangered species that occur near the project area. DOE has also consulted with the Tennessee Department of Environment and Conservation; a response concerning state-listed species is pending from this agency. Although no state-listed species are expected to be impacted by the proposed action, no action would be taken relative to the use of facilities at ORR prior to the receipt of input from the state.

#### **4.4.1.1.7 Cultural and Paleontological Resources**

The irradiation of neptunium-237 targets would take place in ATR. Because no new construction is planned, impacts on cultural and paleontological resources would not occur. The Materials Test Reactor, the Engineering Test Reactor, and ATR, as well as a number of support facilities, are potentially eligible for nomination to the National Register of Historic Places. The use of ATR would not affect the potential eligibility of these structures for listing.

Consultation to comply with Section 106 of the National Historic Preservation Act was initiated with the State Historic Preservation Office (see Table 5–3). The State Historic Preservation Office indicated that ATR is likely to be eligible for the National Register of Historic Places as a contributory property in a potential historic district of exceptional significance. However, at this time, the State Historic Preservation Office has determined that more information is needed prior to assisting DOE in evaluating this property. The State Historic Preservation Office also indicated that since there would be no new construction, there is little potential for effects on archaeological properties. DOE would provide additional information as required to the Idaho State Historic Preservation Office prior to the use of any facility at INEEL for the proposed project. Consultation was conducted with interested Native American tribes; however, responses are pending.

Neptunium-237 storage, target fabrication, and processing would take place at the existing REDC facility in the 7900 Area of ORNL. Because no new construction would take place, impacts on cultural and paleontological resources would not occur. One structure within ORNL, the Graphite Reactor, is listed on the National Register of Historic Places as a National Historic Landmark. Additionally, several other structures proposed for listing on the National Register of Historic Places are found within or near ORNL. However, neither the Graphite Reactor nor any of the other structures is in the 7900 Area and, thus, their status would not change by the use of REDC for target fabrication and processing.

Consultation to comply with Section 106 of the National Historic Preservation Act was initiated with the State Historic Preservation Office (see Table 5–3). While DOE has made additional contact with the State Historic Preservation Office, a response is pending from this office. Although impacts to cultural resources are not expected as a result of the proposed action, no action would be taken relative to the use of facilities at ORR prior to the receipt of input from the State Historic Preservation Office.

#### **4.4.1.1.8 Socioeconomics**

After facility modifications, startup, and testing of the plutonium-238 reactor operation facilities at INEEL and target fabrication/processing facilities at ORR, approximately 41 additional workers would be required to operate these facilities (none at INEEL and approximately 41 at ORR [Wham et al. 1998]). The socioeconomic impacts at ORR are the same as those addressed in Section 4.3.1.1.8.

#### **4.4.1.1.9 Public and Occupational Health and Safety—Normal Operations**

Assessments of incremental radiological and chemical impacts associated with Alternative 2, Option 1 are presented in this section. Supplemental information is provided in Appendix H.

During normal operations, there would be incremental radiological and hazardous chemical releases to the environment and also incremental direct in-plant exposures. The resulting doses and potential health effects to the public and workers for this option are described below.

**RADIOLOGICAL IMPACTS.** Incremental radiological doses to three receptor groups from operations are given in **Table 4–56** for INEEL and ORR: the population within 80 kilometers (50 miles) in the year 2020, the maximally exposed member of the public, and the average exposed member of the public. The projected number of latent cancer fatalities in the surrounding population and the latent cancer fatality risk to the maximally and average exposed individuals are also presented in the table.

**Table 4–56 Incremental Radiological Impacts on the Public Around INEEL and ORR from Operational Facilities Under Alternative 2 (Use Only Existing Operational Facilities)—Option 1**

Receptor	INEEL ATR	ORR REDC	Total
<b>Population within 80 kilometers (50 miles) in the year 2020</b>			
Dose (person-rem)	0	$8.8 \times 10^{-5}$	$8.8 \times 10^{-5}$
35-year latent cancer fatalities	0	$1.5 \times 10^{-6}$	$1.5 \times 10^{-6}$
<b>Maximally exposed individual</b>			
Annual dose (millirem)	0	$1.9 \times 10^{-6}$	NA <sup>a</sup>
35-year latent cancer fatality risk	0	$3.3 \times 10^{-11}$	NA <sup>a</sup>
<b>Average exposed individual within 80 kilometers (50 miles)</b>			
Annual dose <sup>b</sup> (millirem)	0	$7.8 \times 10^{-8}$	NA <sup>a</sup>
35-year latent cancer fatality risk	0	$1.4 \times 10^{-12}$	NA <sup>a</sup>

- a. A “Total” cannot be given in this case because the same individual cannot be located at two different sites simultaneously.  
 b. Obtained by dividing the population dose by the number of people projected to live within 80 kilometers (50 miles) of REDC in the year 2020 (1,134,200).

**Key:** NA, not applicable.

**Source:** Model results, using the GENII computer code (Napier et al. 1988).

A probability coefficient of  $5 \times 10^{-4}$  latent cancer fatality per rem is applied for the public, and a coefficient of  $4 \times 10^{-4}$  latent cancer fatality per rem is applied for workers (ICRP 1991). The value for workers is lower due to the absence of children and the elderly, who are more radiosensitive.

As a result of annual operations of ATR at INEEL and REDC at ORR, the projected total incremental population dose in the year 2020 would be  $8.8 \times 10^{-5}$  person-rem. The corresponding number of latent cancer fatalities in the populations surrounding INEEL and ORR from 35 years of operations would be  $1.5 \times 10^{-6}$ . The total incremental dose to the maximally exposed member of the public from annual ATR operations would be 0 millirem because there would be no increase in radiological releases to the environment from ATR associated with this option. From 35 years of operations, the corresponding risk of a latent cancer fatality to this individual would, therefore, be zero. The incremental dose to the maximally exposed member of the public from annual REDC operations would be  $1.9 \times 10^{-6}$  millirem. From 35 years of operations, the corresponding risk of a latent cancer fatality to this individual would be  $3.3 \times 10^{-11}$ .

Incremental doses to involved workers from normal operations are given in **Table 4–57**; these workers are defined as those directly associated with all process activities. The incremental annual average dose to ATR workers would be 0 millirem; for REDC workers, the incremental annual average dose would be approximately 170 millirem. The incremental annual dose received by the total site workforce for each of these facilities would be 0 and approximately 12 person-rem, respectively. The risks and numbers of latent cancer fatalities among the different workers from 35 years of operations are included in Table 4–57. Doses to individual workers would be kept to minimal levels by instituting badged monitoring and ALARA programs.

**Table 4–57 Incremental Radiological Impacts on Involved INEEL and ORR Workers from Operational Facilities Under Alternative 2 (Use Only Existing Operational Facilities)—Option 1**

Receptor—Involved Workers <sup>a</sup>	INEEL ATR	ORR REDC	Total
Total dose (person-rem per year)	0	12 <sup>b</sup>	12
35-year latent cancer fatalities	0	0.17	0.17
Average worker dose (millirem per year)	0	170	NA <sup>c</sup>
35-year latent cancer fatality risk	0	0.0023	NA <sup>c</sup>

a. The radiological limit for an individual worker is 5,000 millirem per year (10 CFR Part 835). However, the maximum dose to a worker involved with operations would be kept below the DOE Administrative Control Level of 2,000 millirem per year (DOE 1999j). Further, DOE recommends that facilities adopt a more limiting, 500 millirem per year, Administrative Control Level (DOE 1999j). To reduce doses to levels that are as low as is reasonably achievable (ALARA), an effective ALARA program would be enforced.

b. Based on an estimated 75 badged workers.

c. Values cannot be given for the average worker because the workers would be at two different facilities and sites.

**Key:** NA, not applicable.

**Source:** Mecham 1999; Wham 1999b, 2000.

**HAZARDOUS CHEMICAL IMPACTS.** Hazardous chemical impacts at INEEL would be the same as those of current site operations because no new chemicals are expected to be emitted at ATR.

At ORR, both carcinogenic and noncarcinogenic health effects from exposure to hazardous chemicals were evaluated. It was assumed that under normal operating conditions, the primary exposure pathway for members of the public would be from air emissions released through the 7911 stack. Emissions of chemicals were estimated based on anticipated chemical usage. A worst-case dispersion modeling screening analysis was performed to estimate annual concentrations for each chemical, based on the emissions.

The annual concentration for each noncarcinogenic chemical was divided by the corresponding inhalation reference concentration to estimate the Hazard Quotient for each chemical. The Hazard Quotients were summed to give the Hazard Index from all noncarcinogenic chemicals associated with this option. A Hazard Index of less than one indicates that adverse health effects from non-cancer-causing agents are not expected. For carcinogens, the annual concentration was multiplied by the unit cancer risk to estimate the increased cancer risk from that chemical. Hazardous chemical health effects are summarized in **Table 4–58**.

**Table 4–58 Incremental Hazardous Chemical Impacts on the Public Around ORR Under Alternative 2 (Use Only Existing Operational Facilities)—Option 1**

Chemical	Modeled Annual Increment (milligrams per cubic meter)	RfC - Inhalation (milligrams per cubic meter)	Unit Cancer Risk (risk per milligram per cubic meter)	Hazard Quotient	Cancer Risk
Diethyl benzene	$3.37 \times 10^{-5}$	1	0.0078	$3.37 \times 10^{-5}$	$2.63 \times 10^{-7}$
Methanol	$1.23 \times 10^{-6}$	1.75	NA	$7.03 \times 10^{-7}$	NA
Nitric acid	$1.53 \times 10^{-6}$	0.1225	NA	$1.25 \times 10^{-5}$	NA
Tributyl phosphate	$6.34 \times 10^{-5}$	0.01	NA	0.00634	NA
Hazard Index =				0.00639	

**Note:** For diethyl benzene, the reference concentration for ethyl benzene and the unit cancer risk for benzene were used to estimate Hazard Quotient and cancer risk because no information was available for diethyl benzene. For tributyl phosphate, the reference concentration for phosphoric acid was used to estimate the Hazard Quotient because no information was available for tributyl phosphate.

**Key:** NA, not applicable (the chemical is not a known carcinogen or it is a carcinogen and only unit risk will apply); RfC, reference concentration.

**Source:** DOE 1996a; EPA 1999; modeled increments are based on the SCREEN3 computer code (EPA 1995).

#### **4.4.1.1.10 Public and Occupational Health and Safety—Facility Accidents**

Impacts from postulated accidents associated with ATR target irradiation and REDC target processing are presented in this section. Detailed descriptions of the accident analyses are provided in Appendix I.

Estimates of radiological consequences have been developed for the maximally exposed individual, the offsite population within 80 kilometers (50 miles) of the facility, and a noninvolved worker at a distance of 640 meters (0.4 miles) from the release point. Consequences are presented in terms of radiological dose (in rem) and the probability that the dose would result in a latent cancer fatality. Accident risk is defined as the product of the accident probability (i.e., accident frequency) and the accident consequence. In this NI PEIS, risk is expressed as the increased likelihood of a latent cancer fatality per year for an individual (the maximally exposed individual or a noninvolved worker), and as the increased number of latent cancer fatalities per year in the offsite population. The probability coefficients for determining the likelihood of a latent cancer fatality, given a dose, are given in Section 4.2.1.2.10. Consequences to involved workers are addressed in Section I.1.7.

To provide a better indication of risks from the postulated accidents, the risks are summed for each facility and also for each option. Although the summation provides the combined risk for the spectrum of accidents analyzed, it does not indicate total risk. To determine total risk from accidents, a full-scope probabilistic risk analysis would be required for each facility. Since full-scope probabilistic risk analyses are not available to incorporate in this NI PEIS, summing the spectrum of accident risks was considered appropriate for the purposes of this NI PEIS. Details of the risk summation calculations are provided in Appendix I.

Consequences and associated risks are presented in **Tables 4–59** and **4–60**, respectively. Because ATR is currently operating, the consequences and risks are presented for both the current reactor configuration without neptunium-237 targets and for the worst-case neptunium-237 target-loading reactor configuration. Baseline accident risks attributed to ATR operations refer to accidents that could occur under the current ATR configuration (without neptunium-237 targets). Baseline accident risks are obtained from the data in Table 4–60 by summing the annual risks in columns 2, 3, or 4 for the baseline ATR configuration (0 kilograms per year plutonium-238 production), and then multiplying the sum by 35. The baseline ATR accident risk to the public would be 0.089 latent cancer fatality. Baseline ATR accident risks to the maximally exposed offsite individual and a noninvolved worker would be  $8.2 \times 10^{-7}$  and  $7.2 \times 10^{-6}$  latent cancer fatalities, respectively.

For 35 years of ATR target irradiation, the increased risk of a latent cancer fatality to the maximally exposed individual and to a noninvolved worker would be  $2.45 \times 10^{-7}$  and  $3.48 \times 10^{-6}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.00140.

For 35 years of REDC target processing, the increased risk of a latent cancer fatality to the maximally exposed individual and of an early fatality to a noninvolved worker would be  $5.71 \times 10^{-5}$  and  $3.50 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.157.

For 35 years under this option, the increased risk of a latent cancer fatality to the maximally exposed individual and of a fatality to a noninvolved worker would be  $5.71 \times 10^{-5}$  and  $3.50 \times 10^{-4}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be 0.158.

The irradiation of neptunium-237 targets to produce plutonium-238 at ATR would not introduce any additional operations that require the use of hazardous chemicals. Thus, there are no postulated hazardous chemical accidents attributable to the irradiation of neptunium-237 targets at ATR.

**Table 4–59 ATR and REDC Accident Consequences Under Alternative 2  
(Use Only Existing Operational Facilities)—Option 1**

Accident	Maximally Exposed Individual		Population to 80 Kilometers (50 Miles)		Noninvolved Worker	
	Dose (rem)	Latent Cancer Fatality <sup>a</sup>	Dose (person-rem)	Latent Cancer Fatalities <sup>b</sup>	Dose (rem)	Latent Cancer Fatality <sup>a</sup>
<b>ATR accidents</b>						
Large-break LOCA with 0 kg/yr plutonium-238 production	0.465	$2.33 \times 10^{-4}$	$5.11 \times 10^4$	25.5	5.15	0.00206
Large-break LOCA with 5 kg/yr plutonium-238 production	0.604	$3.02 \times 10^{-4}$	$5.17 \times 10^4$	25.9	7.61	0.00304
Target handling with 0 kg/yr plutonium-238 production <sup>c</sup>	0.0	0.0	0.0	0.0	0.0	0.0
Target handling with 5 kg/yr plutonium-238 production	$2.05 \times 10^{-4}$	$1.03 \times 10^{-7}$	0.128	$6.41 \times 10^{-5}$	0.00324	$1.30 \times 10^{-6}$
<b>REDC accidents</b>

<b>35-year Option risk<sup>g</sup></b>	$5.71 \times 10^{-5}$	0.158	$3.50 \times 10^{-4}$

- Increased likelihood of a latent cancer fatality.
- Increased number of latent cancer fatalities.
- The incremental risk from irradiation of neptunium-237 targets in a currently operating reactor is determined by subtracting the risk of operating without targets from the risk of operating with targets.
- There would be no neptunium-237 targets for the zero-production case. Thus, the 5-kg/yr production rate target-handling risks are the incremental risks.
- The 35-year risk is determined by summing the incremental annual risks and then multiplying by 35.
- Risk of an early fatality.
- Individual risks are summed only for colocated individuals. The highest individual risk was used to represent the 35-year option risk.

**Note:** To convert from kilograms per year to pounds per year, multiply by 2.20.

**Key:** kg/yr, kilograms per year; LOCA, loss-of-coolant accident.

**Source:** Model results, using the MACCS2 (Chanin and Young 1997) and GENII (Napier et al. 1988) computer codes.

Processing associated with the plutonium-238 production program at REDC, including storage of neptunium-237 and plutonium-238, neptunium-237 target fabrication, postirradiation processing to extract plutonium-238 and to recycle the unconverted neptunium-237 into new targets, would not require the introduction of hazardous chemicals that are not in current use in the facility. The quantities of in-process hazardous chemicals for the plutonium-238 production program are bounded by the quantities of the material currently stored in the facility. The impacts of in-process hazardous chemical accidents associated with the

plutonium-238 production are bounded by the impacts of hazardous chemical accidents for existing storage facilities at REDC.

#### 4.4.1.1.11 Public and Occupational Health and Safety—Transportation

DOE would transport neptunium-237 from storage at SRS to the REDC target fabrication facility at ORR. DOE would transport the unirradiated neptunium-237 targets from REDC to ATR at INEEL. Following irradiation in ATR, the targets would be returned to REDC for processing. After processing, the plutonium-238 product would be shipped to LANL. The analysis is described in Appendix J.

Approximately 689 shipments of radioactive materials would be made by DOE under this option. The total distance traveled on public roads by trucks carrying radioactive materials would be 2.2 million kilometers (1.4 million miles).

**IMPACTS OF INCIDENT-FREE TRANSPORTATION.** The dose to transportation workers from all transportation activities entailed by this option has been estimated at 12 person-rem; the dose to the public, 240 person-rem. Accordingly, incident-free transportation of radioactive material associated with this option would result in 0.005 latent cancer fatality among transportation workers and 0.12 latent cancer fatality in the total affected population over the duration of the transportation activities. The estimated number of nonradiological fatalities from vehicular emissions associated with this option is 0.0064.

**IMPACTS OF ACCIDENTS DURING TRANSPORTATION.** The maximum foreseeable offsite transportation accident under this option (probability of occurrence: 1 in 10 million per year) is a shipment of irradiated neptunium-237 targets to REDC with a severity category V accident in an urban population zone under neutral (average) weather conditions. The accident could result in a dose of 0.61 person-rem to the public with an associated  $3.1 \times 10^{-4}$  latent cancer fatality, and 2.6 millirem to the hypothetical maximally exposed individual with a latent fatal cancer risk of  $1.3 \times 10^{-6}$ . No fatalities would be expected to occur. The probability of more severe accidents, different weather conditions at the time of the accident, or occurrence while carrying neptunium-237 (unirradiated) or plutonium-238 were also evaluated and estimated to have a probability of less than 1 in 10 million per year.

Estimates of the total ground transportation accident risks are as follows: a radiological dose to the population of 0.088 person-rem, resulting in  $4.4 \times 10^{-5}$  latent cancer fatality; and traffic accidents resulting in 0.06 traffic fatality.

#### 4.4.1.1.12 Environmental Justice

**NORMAL OPERATIONS.** The risk of latent cancer fatalities among populations residing within 80 kilometers (50 miles) of ATR and REDC would be less than  $2 \times 10^{-6}$  for 35 years of normal operations (derived from information in Table 4-56). As shown in Table 4-58, the release of hazardous chemicals at ORR would pose no significant risk of cancer or toxic effects among the public. As discussed in Section K.5.1, the likelihood that a latent cancer fatality would result from the ingestion of food that could be radiologically contaminated due to normal operations would be essentially zero at INEEL and ORR. No credible pattern of food consumption by persons residing in potentially affected areas would result in significant health risks due to radiological contamination of food supplies near INEEL or ORR. As discussed in Section 4.4.1.1.11, no fatalities would be expected for incident-free transportation.

**ACCIDENTS.** The number of expected latent cancer fatalities among populations at risk due to radiological accidents listed in Table 4-60 would be approximately 0.16. If a radiological accident were to occur at ATR and northwesterly winds prevailed at the time of the accident, radiological contamination from the accident

would be directed toward the Fort Hall Indian Reservation (see Figure K–2). However, accidents that could occur under the implementation of this option would not be expected to result in a latent cancer fatality among the population or maximally exposed individual residing within the boundary of the Fort Hall Indian Reservation. In the event a radiological accident were to occur at REDC and southerly winds prevailed at the time of the accident, radiological contamination would be directed toward the predominately minority population of the Scarboro community adjacent to the northern boundary of ORR (see Figure K–6). If the winds were blowing from the west-southwest at the time of the accident, radiological contamination would be directed toward minority populations residing in Knoxville, Tennessee. Accidents that could occur under the implementation of this option would not be expected to result in a latent cancer fatality among the minority populations or maximally exposed individuals residing in the Scarboro community or Knoxville.

As discussed in Section 4.4.1.1.11, no fatalities due to transportation accidents would be expected.

In summary, the implementation of this option would pose no significant radiological risk to persons residing in potentially affected areas or along representative transportation routes. Under the conservative assumption that all food consumed in potentially affected areas during the 35-year operational period would be radioactively contaminated, no credible pattern of food consumption would pose a significant radiological health risk due to the ingestion of contaminated food supplies. As discussed in other parts of Section 4.4.1.1, the implementation of this option would not result in significant nonradiological impacts on populations at risk. Thus, implementation would not pose significant and adverse environmental risks to persons residing within potentially affected areas, including minority and low-income persons.

#### **4.4.1.1.13 Waste Management**

Virtually no additional waste would be generated as a result of irradiating the neptunium-237 targets in ATR because this reactor would already be operating for other purposes. Only the devices that position the neptunium-237 targets in the core would add to the ATR waste stream. The incremental amount of this waste is anticipated to be very small (about 1 cubic meter [1.3 cubic yards] per year of solid low-level radioactive waste), and therefore, no impacts on the waste management systems at INEEL would be anticipated. However, there would be impacts on ORR's waste management systems as a result of the operation of REDC to fabricate and process the neptunium-237 targets.

The impacts of managing waste associated with neptunium-237 target fabrication and processing in REDC are assumed to be the same as for Option 1 under Alternative 1 (Section 4.3.1.1.13) because the same amount of plutonium-238 would be produced annually. As shown in that section, the impacts on the waste management systems at ORR would be minimal.

#### **4.4.1.1.14 Spent Nuclear Fuel Management**

Under all options of this alternative, no additional spent nuclear fuel would be generated from reactor operations specific to neptunium-237 target irradiation. The reactor(s) would already be operating to provide other irradiation services (refer to Appendix B). Thus, there would be no incremental impacts associated with the management of spent nuclear fuel.

#### **4.4.1.2 Permanent Deactivation of FFTF**

The environmental impacts associated with the permanent deactivation of FFTF are analyzed in *Environmental Assessment, Shutdown of the Fast Flux Test Facility, Hanford Site, Richland, Washington*, DOE/EA-0993 (DOE 1995a). Summaries of these impacts are given in the following sections. Activities associated with final

decontamination and decommissioning are not within the scope of this NI PEIS. They would be addressed in subsequent NEPA documentation.

#### 4.4.1.2.1 Land Resources

**LAND USE.** Activities associated with the permanent deactivation of FFTF would not affect land use in the 400 Area because the industrial nature of the area would not change.

**VISUAL RESOURCES.** The permanent deactivation of FFTF would not involve the removal of existing structures with only minimal construction of small support structures in previously disturbed area facilities; thus, visual resources would not be affected, and the Visual Resource Management Class IV rating of the 400 Area would not change.

#### 4.4.1.2.2 Noise

Noise associated with the permanent deactivation of FFTF would be similar to sound levels generated by current activities in the 400 Area. Onsite noise impacts from deactivation would be expected to be minimal, and changes in offsite noise levels would not be noticeable since the nearest site boundary is 6.1 kilometers (3.8 miles) to the east. Noise levels associated with traffic during deactivation may be slightly higher as a result of moving fuel assemblies, equipment, and materials. When deactivation is complete, noise levels associated with traffic may decrease somewhat if the FFTF shutdown results in a decrease in the Hanford workforce (DOE 1995a). The contribution of FFTF deactivation activities to traffic noise levels on site and off site would be minor and would not lead to noticeable changes in noise levels either on site or off site. There would be no loud noises associated with the deactivation of FFTF that would adversely affect wildlife.

#### 4.4.1.2.3 Air Quality

Several sources of air pollutants are operated to support FFTF during standby: an emergency gas turbine generator, a diesel-driven fire pump, and oil-fired preheaters. If any of Alternatives 2 through 5 were selected for implementation, then these sources would be shut down. Concentrations of air pollutants at the Hanford Site boundary resulting from these sources were estimated from a dispersion-modeling screening analysis conducted with maximum expected emission rates and worst-case meteorological conditions. Although these sources are operated intermittently, and they are not necessarily operated simultaneously, concentrations of air pollutants from all three sources were summed to give the conservative estimate of air quality impacts of maintaining FFTF in standby shown in **Table 4–61**. Concentrations of air pollutants listed in Table 4–61 are negative to indicate that they represent a decrease in adverse impacts relative to air quality with FFTF in standby, although the decrease would be less than the conservative estimate for standby.

#### 4.4.1.2.4 Water Resources

The permanent deactivation of FFTF would eventually result in the cessation of sanitary and process wastewater discharges (i.e., cooling tower blowdown) from the facility because auxiliary systems would be shut down following hot sodium drainage. This would eliminate the annual discharge of 76 million liters (20 million gallons) of nonradioactive process wastewater to the 400 Area process sewer system and ultimately to the 400 Area Pond (i.e., 4608 B/C percolation ponds). The FFTF component (3.8 million liters [1 million gallons] per year) of 400 Area sanitary wastewater discharges to the Energy Northwest treatment system would also be eliminated. In addition, groundwater withdrawals by 400 Area facilities during standby of approximately 197 million liters (52 million gallons) per year would be greatly reduced or eliminated entirely (see Section 4.2.1.2.4). As part of the sodium-removal process, residual sodium would be washed from fuel assemblies and other reactor components, including instrumentation assemblies from the reactor core. This

**Table 4-61 Incremental Hanford Concentrations Associated with All Options of Alternatives 2 through 5**

Pollutant	Averaging Period	Most Stringent Standard or Guideline (micrograms per cubic meter) <sup>a</sup>	Modeled Increment (micrograms per cubic meter)
Carbon monoxide	8 hours	10,000 <sup>b</sup>	-3.5
	1 hour	40,000 <sup>b</sup>	-5.1
Nitrogen dioxide	Annual	100 <sup>b</sup>	-0.032
PM <sub>10</sub>	Annual	50 <sup>c</sup>	-0.002
	24 hours	150 <sup>c</sup>	-0.898
Sulfur dioxide	Annual	50 <sup>d</sup>	-0.164
	24 hours	260 <sup>d</sup>	-29.8
	3 hours	1,300 <sup>b</sup>	-67.0
	1 hour	660 <sup>d</sup>	-74.4

- a. The more stringent of the Federal and state standards is presented if both exist for the averaging period. The National Ambient Air Quality Standards (NAAQS) (40 CFR Part 50), other than those for ozone, particulate matter, and lead, and those based on annual averages, are not to be exceeded more than once per year. The 24-hour PM<sub>10</sub> (particulate matter with an aerodynamic diameter less than or equal to 10 micrometers) standard is attained when the expected number of days with a 24-hour average concentration above the standard is equal to or less than 1. The annual arithmetic mean PM<sub>10</sub> standard is attained when the expected annual arithmetic mean concentration is less than or equal to the standard.
- b. Federal and state standard.
- c. Federal standard currently under litigation.
- d. State standard.

**Source:** Modeled increments are based on the SCREEN3 computer code (EPA 1995); additional data from Nielsen 2000.

would be conducted in FFTF's Interim Examination and Maintenance Cell using the existing process and equipment designed for this purpose. Ion exchange would reduce the entire volume of radioactive wastewater generated to less than 7,600 liters (2,000 gallons). This wastewater would be disposed of at existing onsite waste management facilities; spent ion exchange resin would be packaged and properly disposed of as well (DOE 1995a:3-9, 3-15).

#### 4.4.1.2.5 Geology and Soils

No facilities would be demolished to effect permanent deactivation of FFTF. Any necessary ground disturbance would be confined to previously disturbed areas immediately adjacent to the FFTF complex. As a result, the impact on geologic and soil resources in the 400 Area of Hanford would be expected to be negligible. Activities associated with final decontamination and decommissioning and related activities that could impact geologic or soil resources to a greater degree would be addressed in subsequent NEPA documentation.

#### 4.4.1.2.6 Ecological Resources

Activities associated with the permanent deactivation of FFTF would not impact the limited ecological resources present in the 400 Area. No threatened and endangered species reside in the vicinity of the 400 Area; consequently, no adverse impacts on such species would occur from the proposed action.

#### 4.4.1.2.7 Cultural and Paleontological Resources

The 400 Area is highly disturbed with little potential for the occurrence of cultural and paleontological resources. For this reason and because there would be no ground disturbance beyond previously disturbed areas associated with the permanent deactivation of FFTF, impacts on cultural and paleontological resources from the proposed action would not occur.

#### 4.4.1.2.8 Socioeconomics

The deactivation of FFTF would result in a loss of about 242 jobs at Hanford (DOE 1997b). However, it should coincide with an increase in overall site employment at Hanford in connection with construction of the tank waste remediation system. The personnel who had worked at FFTF would be absorbed into other operations at Hanford. If this were not the case, the loss of 242 jobs would result in the loss of 613 indirect jobs in the region around Hanford. The potential employment loss of 855 direct and indirect jobs represents less than 0.4 percent of the projected regional economic area workforce and, therefore, would not result in a noticeable impact on the regional economic area.

In the region of influence, the loss of employment resulting from this alternative would not significantly impact community services in the Hanford region of influence. Assuming that 91 percent of those losing their jobs left the Hanford region of influence with their families (refer to Section 3.4.8), the region's population would decrease by approximately 1,494 persons. Given the current population-to-student ratio in the region of influence, this would likely result in a decrease of about 309 students, dropping the average school enrollment from 92.8 percent to 91.8 percent.

Community services in the region of influence may change to accommodate the population decrease as follows: 19 less teachers would be needed if the current student-to-teacher ratio of 16.0:1 was maintained; 2 less police officers would be needed to maintain the current officer-to-population ratio of 1.5:1000; 5 less firefighters would be needed to maintain the current firefighter-to-population ratio of 3.4:1000; and 2 less doctors would be needed to maintain the current physician-to-population ratio of 1.4:1000. Thus, 28 additional positions could be lost if community services were maintained at current levels. Hospitals in the region of influence would not experience any change from the 2.1 beds per 1,000 persons currently available. None of these projected changes should have a major impact on the level of community services currently offered in the region of influence.

#### 4.4.1.2.9 Public and Occupational Health and Safety—Normal Deactivation Activities

Assessments of incremental radiological and chemical impacts associated with the permanent deactivation of FFTF are presented in this section. Supplemental information is provided in Appendix H. During normal operations, there would be incremental radiological and hazardous chemical releases to the environment and also incremental direct in-plant exposures. The resulting doses and potential health effects to the public and workers are described below.

**RADIOLOGICAL IMPACTS.** Incremental radiological doses to three receptor groups from deactivation of FFTF at Hanford are given in **Table 4-62**: the population within 80 kilometers (50 miles), the maximally exposed member of the public, and the average exposed member of the public. The projected number of latent cancer fatalities in the surrounding populations and the latent cancer fatality risk to the maximally and average exposed individuals are also presented in the table.

A probability coefficient of  $5 \times 10^{-4}$  latent cancer fatality per rem is applied for the public, and a coefficient of  $4 \times 10^{-4}$  latent cancer fatality per rem is applied for workers (ICRP 1991). The value for workers is lower due to the absence of children and the elderly, who are more radiosensitive.

As a result of annual deactivation activities, the projected estimated total incremental population dose is estimated to be 0.036 person-rem. The corresponding number of latent cancer fatalities in the population surrounding Hanford would be  $1.8 \times 10^{-5}$ . The total annual incremental dose to the maximally exposed member of the public from deactivation activities would be  $2.6 \times 10^{-4}$  millirem. The corresponding risk of a latent cancer fatality to this individual would be  $1.3 \times 10^{-10}$ .

**Table 4–62 Incremental Radiological Impacts on the Public Around Hanford from FFTF Deactivation Activities**

Receptor	FFTF Deactivation
<b>Estimated population within 80 kilometers (50 miles)</b>	
Dose (person-rem)	0.036
1-year latent cancer fatalities	$1.8 \times 10^{-5}$
<b>Maximally exposed individual</b>	
Annual dose (millirem)	$2.6 \times 10^{-4}$
1-year latent cancer fatality risk	$1.3 \times 10^{-10}$
<b>Average exposed individual within 80 kilometers (50 miles)</b>	
Annual dose <sup>a</sup> (millirem)	$7.2 \times 10^{-5}$
1-year latent cancer fatality risk	$3.6 \times 10^{-11}$

a. Obtained by dividing the estimated population dose by the number of people projected to live within 80 kilometers (50 miles) of FFTF (about 500,000).

Source: DOE 1995a.

Estimated incremental doses to involved workers associated with annual deactivation activities are given in **Table 4–63**; these workers are defined as those directly associated with all planned deactivation activities. Under this alternative, the incremental annual average dose to FFTF deactivation workers is estimated not to exceed 6 millirem. The incremental annual dose received by the FFTF deactivation workforce is estimated not to exceed 0.06 person-rem. The risks and numbers of latent cancer fatalities among these workers from annual operations are included in Table 4–63. Doses to individual workers would be kept to minimal levels by instituting badged monitoring and ALARA programs.

**Table 4–63 Incremental Radiological Impacts on Involved FFTF Workers from Deactivation Activities**

Receptor	FFTF Deactivation
<b>Involved workers<sup>a</sup></b>	
Total dose (person-rem per year)	$<0.06^b$
1-year latent cancer fatalities	$<2.4 \times 10^{-5}$
Average worker dose (millirem per year)	$<6$
1-year latent cancer fatality risk	$<2.4 \times 10^{-6}$

a. The radiological limit for an individual worker is 5,000 millirem per year (10 CFR Part 835). However, the maximum dose to a worker involved with operations will be kept below the DOE Administrative Control Level of 2,000 millirem per year (DOE 1999j). Further, DOE recommends that facilities adopt a more limiting, 500 millirem per year, Administrative Control Level (DOE 1999j). To reduce doses to levels that are as low as is reasonably achievable (ALARA), an effective ALARA program will be enforced.

b. Based on an estimated 10 badged workers.

Note: < means “less than.”

Source: DOE 1995a.

**HAZARDOUS CHEMICAL IMPACTS.** No hazardous chemicals are anticipated to be released in substantial quantities from activities associated with permanently deactivating FFTF when compared to the annual amount routinely generated throughout Hanford. The deactivation of FFTF would result in a decrease of both near-term and long-term exposures (DOE 1995a).

#### 4.4.1.2.10 Public and Occupational Health and Safety—Deactivation Accidents

Impacts from a postulated accident associated with the permanent deactivation of FFTF are presented in this section. The FFTF shutdown environmental assessment (DOE 1995a) describes several accident scenarios and their consequences. Rather than a summary of the environmental assessment accidents, a reevaluation of

a limiting deactivation accident was performed. The reevaluation was performed because the current FFTF status is significantly different than at the time the environmental assessment was completed.

FFTF is currently defueled; therefore, accidents related to defueling need not be considered. Also because of defueling and decay of radioactivity over time, the current sodium radionuclide inventories are much less than when the environmental assessment was completed. Considering the current FFTF conditions, it was determined that a primary heat transport system sodium drain accident would be the accident with the highest consequences. A detailed description of the accident analysis is provided in Appendix I.

Estimates of radiological consequences have been developed for the maximally exposed individual, the offsite population within 80 kilometers (50 miles) of the facility, and a noninvolved worker at a distance of 640 meters (0.4 miles) from the release point. Consequences are presented in terms of radiological dose (in rem) and the probability that the dose would result in a latent cancer fatality. Accident risk is defined as the product of the accident probability (i.e., accident frequency) and the accident consequence. In this NI PEIS, risk is expressed as the increased likelihood of a latent cancer fatality per year for an individual (the maximally exposed individual or a noninvolved worker), and as the increased number of latent cancer fatalities per year in the offsite population. The probability coefficients for determining the likelihood of a latent cancer fatality, given a dose, are given in Section 4.2.1.2.10.

The FFTF deactivation accident is a sodium spill during the transfer of primary sodium to a treatment tank. The accident frequency is the probability of a sodium spill during the transfer process. The frequency is per event (sodium transfer) rather than per year. Since the risk remains constant for any time period, the 35-year risk is the same as the accident risk presented.

Consequences and associated risks are presented in **Tables 4–64** and **4–65**, respectively.

**Table 4–64 Consequences of FFTF Deactivation Accident**

Accident	Maximally Exposed Individual		Population to 80 Kilometers (50 Miles)		Noninvolved Worker	
	Dose (rem)	Latent Cancer Fatality <sup>a</sup>	Dose (person-rem)	Latent Cancer Fatalities <sup>b</sup>	Dose (rem)	Latent Cancer Fatality <sup>a</sup>
Primary heat transport system sodium drain accident	$4.75 \times 10^{-10}$	$2.38 \times 10^{-13}$	$3.64 \times 10^{-5}$	$1.82 \times 10^{-8}$	$3.88 \times 10^{-9}$	$1.55 \times 10^{-12}$

a. Likelihood of a latent cancer fatality.

b. Number of latent cancer fatalities.

**Source:** Model results, using the MACCS2 computer code (Chanin and Young 1997).

**Table 4–65 Risks of FFTF Deactivation Accident**

Accident (Frequency) <sup>a</sup>	Maximally Exposed Individual <sup>b</sup>	Population to 80 Kilometers (50 Miles) <sup>c</sup>	Noninvolved Worker <sup>b</sup>
Primary heat transport system sodium drain accident (0.10)	$2.38 \times 10^{-14}$	$1.82 \times 10^{-9}$	$1.55 \times 10^{-13}$

a. Per event.

b. Increased likelihood of a latent cancer fatality.

c. Increased number of latent cancer fatalities.

**Source:** Model results, using the MACCS2 computer code (Chanin and Young 1997).

For an FFTF deactivation accident, the increased risk of a latent cancer fatality to the maximally exposed individual and to a noninvolved worker would be  $2.38 \times 10^{-14}$  and  $1.55 \times 10^{-13}$ , respectively. The increased number of latent cancer fatalities in the surrounding population would be  $1.82 \times 10^{-9}$ .

Deactivating FFTF would not introduce any additional operations that require the use of hazardous chemicals. Thus, there are no postulated hazardous chemical accidents attributable to deactivating FFTF.

#### **4.4.1.2.11 Public and Occupational Health and Safety—Transportation**

There would be no transportation impacts associated with permanently deactivating FFTF.

#### **4.4.1.2.12 Environmental Justice**

**NORMAL OPERATIONS.** For deactivation activities at Hanford, the number of expected latent cancer fatalities among populations residing within 80 kilometers (50 miles) of FFTF would be less than  $2 \times 10^{-5}$  (derived from information in Table 4–62). As discussed in Section 4.4.1.2.9, the release of hazardous chemicals at FFTF would pose no significant risk of cancer or toxic effects among the public. There would be no intersite transportation associated with deactivation activities, and therefore, no transportation effects on the public.

**ACCIDENTS.** Accidents at FFTF also pose no significant environmental risk to the public. As shown, in Table 4–65, the risk of a public fatality associated with a sodium drain accident at FFTF would be essentially zero.

In summary, deactivating FFTF would have no significant environmental effects on the public. Thus, the deactivation would pose no disproportionately high and adverse risks for minority or low-income populations.

#### **4.4.1.2.13 Waste Management**

As discussed in the *Environmental Assessment, Shutdown of the Fast Flux Test Facility, Hanford Site, Richland, Washington* (DOE 1995a), the hazardous materials (e.g., solvents, glycols, polychlorinated biphenyls, asbestos) which may be removed or stabilized as a result of the deactivation of FFTF would be managed and reused, recycled, or disposed of in accordance with applicable Federal and state regulations. Such materials include approximately 360,000 liters (94,000 gallons) of ethylene glycol, 32,000 liters (8,500 gallons) of polychlorinated biphenyls, transformer oil, and 370,000 liters (99,000 gallons) of fuel oil. Approximately 8,200 drums of sodium sulfate (at approximately 208 liters or 55 gallons, each) could be generated for disposal. None of the materials would be anticipated to be generated in substantial quantities when compared to the annual amount routinely generated throughout Hanford (DOE 1995a:5-12).

The inventory of bulk metallic sodium (approximately 980,000 liters [260,000 gallons]) would undergo appropriate excess evaluations to determine if alternative sponsors and/or uses were available. In the event no viable use were determined, the bulk metallic sodium would be converted to an acceptable stable form (e.g., sodium sulfate), dried, collected into containers, and transported to an appropriate facility at Hanford for disposal (DOE 1995a:ES-2).

#### **4.4.1.2.14 Spent Nuclear Fuel Management**

Under deactivation, the irradiated FFTF assemblies and pin containers have been, or would be, placed into dry storage casks and transferred to storage at the site's Interim Storage Area (ISA). Each fuel assembly or pin container would be limited to a maximum decay heat value of 250 watts (850 BTU per hour) for fuel offload handling. At this heat level, no active cooling would be required, and many of the fission products and noble gases would have decayed substantially.

A typical FFTF spent nuclear fuel-handling sequence is as follows: sodium-wetted fuel assemblies are washed using existing FFTF process equipment; the spent nuclear fuel is subjected to a moist argon atmosphere to

slowly react residual sodium in a controlled manner; several water rinses of the fuel are conducted; the fuel receives a final dry; the fuel is transferred to the dry storage casks for interim storage in the Interim Storage Area. The dry casks subsequently would be transferred to the Canister Storage Building Complex in the 200-East Area for storage of the spent nuclear fuel pending disposition (DOE 1997b). When the geologic repository becomes available, the spent nuclear fuel would be transferred from the 200-East Area to the repository for disposal.

#### **4.4.2 Alternative 2 (Use Only Existing Operational Facilities)—Option 2**

Option 2 involves operating ATR at INEEL to irradiate neptunium-237 targets, and operating FDPF at INEEL to fabricate and process these targets. This alternative also includes storage of the neptunium-237 transported to INEEL from SRS in Building CPP-651 or FDPF.

The transportation of the neptunium-237 from SRS to INEEL for processing and fabrication into neptunium-237 targets in FDPF, and the transportation of the plutonium-238 product from INEEL to LANL following postirradiation processing in FDPF also constitute part of this option.

All options under this alternative include the permanent deactivation of FFTF at Hanford.

##### **4.4.2.1 Operations and Transportation**

The environmental impacts associated with storage, processing, and irradiation operations, and with all transportation activities, are assessed in this section.

###### **4.4.2.1.1 Land Resources**

**LAND USE.** The use of ATR to irradiate neptunium-237 targets would not result in impacts on land use at INEEL for the reasons described in Section 4.4.1.1.1.

Building CPP-651 or FDPF at INEEL would be used for neptunium-237 storage, and FDPF for target fabrication and processing. These are existing facilities in the INTEC area. The use of these facilities would require internal modifications, but no new facilities would be built. Because no additional land would be disturbed and use of the facilities would be compatible with the missions for which they were designed, there would be no change in land use at INEEL.

**VISUAL RESOURCES.** The use of ATR to irradiate neptunium-237 targets would not result in impacts on visual resources at INEEL for the reasons described in Section 4.4.1.1.1.

All activities associated with neptunium-237 storage, target fabrication, and processing would take place in existing facilities that would require no external modifications. Thus, there would be no change in appearance. The current Visual Resource Management Class IV rating for INTEC would not change, and there would be no impact on visual resources.

###### **4.4.2.1.2 Noise**

The irradiation of neptunium-237 targets in ATR would not be expected to result in noise impacts at INEEL for the reasons described in Section 4.4.1.1.2.

Neptunium-237 storage in Building CPP-651 or FDPF, and target fabrication and processing at FDPF would generate noise levels similar to those presently associated with operations in INTEC. Onsite noise impacts

would be expected to be minimal, and changes in offsite noise levels should not be noticeable because the nearest site boundary is 12 kilometers (7.5 miles) to the south. Changes in traffic volume going to and from INTEC would be small and would result in only minor changes to onsite and offsite noise levels. There would be no loud noises associated with neptunium-237 storage that would adversely impact wildlife.

#### 4.4.2.1.3 Air Quality

The concentrations at INEEL attributable to this option are presented in **Table 4–66**. The concentrations for the option are based on a dispersion modeling screening analysis conducted with maximum expected emission rates and a set of worst-case meteorological conditions.

**Table 4–66 Incremental INEEL Concentrations<sup>a</sup> Associated with Alternative 2 (Use Only Existing Operational Facilities)—Option 2**

Pollutant	Averaging Period	Most Stringent Standard or Guideline (micrograms per cubic meter)	Modeled Increment (micrograms per cubic meter)
<b>Criteria pollutants</b>			
Nitrogen dioxide	Annual	100	$3.66 \times 10^{-4}$
Sulfur dioxide	Annual	80	0.024
	24 hours	365	0.19
	3 hours	1,300	0.43
<b>Toxic air pollutants</b>			
Methanol	24 hours	13,000	0.0048
Nitric acid	24 hours	250	0.0097
Paraffin hydrocarbons	24 hours	100	0.44
Tributyl phosphate	24 hours	110	0.25

a. For comparison with ambient air quality standards.

**Source:** 40 CFR Part 50; ID DHW 1998; modeled increments are based on the SCREEN3 computer code (EPA 1995).

Only those air pollutants expected to be emitted that have ambient air quality standards are presented in the table. The change in concentrations of these pollutants would be small and would be below the applicable ambient air quality standards even when ambient monitoring values and the contribution from other site activities are included.

The concentrations at INEEL attributed to this option are compared to the Prevention of Significant Deterioration Class II increments for nitrogen dioxide and sulfur dioxide in **Table 4–67**.
