
Notes and Brief Reports

Long-Range Projection Of Average Benefits Under OASDI*

In its long-range projections of expenditures under the Old-Age, Survivors, and Disability Insurance (OASDI) system, the Office of the Actuary considers benefit payments, administrative expenses, net transfers under the Railroad Retirement interchange, and vocational rehabilitation expenses for the next 75 years. Benefit payments are by far the largest element, accounting for over 97 percent of all OASDI outgo. In preparing the projections, benefit payments are split primarily by type of benefit, such as old-age and auxiliary benefits (retired worker, wife/husband, and child), survivors benefits (widow/widower, disabled widow/widower, child, mother/father, and aged parent), and disabled-worker and auxiliary benefits (disabled worker, wife/husband, and child). For each type of benefit, the number of beneficiaries and the corresponding average benefit payable are projected for each fifth year for 75 years. (The short-range projections, covering the first 10 years of the period, are not discussed here.) This note describes how the "average benefit payable" is projected.

It is important to distinguish between average newly awarded benefits and average benefits being paid. Benefits being paid in any given year are made up of benefits awarded in that year (the prospective beneficiary having applied and met the requirements for the benefit), benefits awarded in the previous year, in the year prior to that, and so on. To project the average benefit payable, the average benefit awarded in each prior year is first projected. From these figures, the average benefit payable is calculated using a procedure described later.

Historical Development

The methodology used to project average benefits has become increasingly complex, because of the growing availability of computers and the increasingly complicated questions about future costs that must be answered. (Of course, these two factors are closely

*By Steven F. McKay, Office of the Actuary, Social Security Administration. This note was originally published as Actuarial Note No. 108, September 1981.

related.) Before 1970, dynamic factors such as average wage increases and Consumer Price Index (CPI) increases were not considered in the projection of average benefits. Average benefits were projected based on two representative earnings histories, one with constant earnings equal to the average earnings of all men in the most recent year, and a similar one based on the average earnings for women. In 1972, when Amendments to the Social Security Act provided that the earnings base would be tied automatically to average wage changes and that benefit increases would be tied to CPI increases, such economic factors had to be introduced into the projection of benefits.

Briefly, in the methodology established at that time, benefits for OASI and for DI were projected separately, with each based on the projected earnings of a series of cohorts consisting of five hypothetical steady earners assumed to be awarded benefits in each future year. All of the five workers in these sets were assumed to be men; each worker's yearly earnings were a constant proportion of the actual or projected average for all men working in that year; and the five proportions were designed to cover a reasonable range of possible earnings. The average of the calculated Primary Insurance Amounts (PIA's) awarded in each future year (to the workers in the simulation) was compared with the calculated average award in the base year (again, to workers in the simulation) to compute an index of benefit growth. The resulting index was then applied to the actual average benefits to be awarded in the base year (to actual Social Security beneficiaries, not to the simulated earners) to obtain the projected average benefits to be awarded in the future. The average benefit to be paid in each future year was then calculated as the weighted average of awards of previous years, in which the weights represented the distribution of the beneficiaries by duration of benefits. Benefits for female earners and for auxiliary and survivor beneficiaries were assumed to increase in proportion to benefits for male earners, with adjustments made in some benefit categories when there were reasons to believe future growth in benefits would not be exactly proportional.

Since 1972, the methodology has become more complex, but the basic idea of calculating an index to be applied to the actual average award in the base year to obtain awards in future years has continued to be a fundamental part of the projection procedure. A num-

ber of significant improvements have been made, however, primarily in the development of the cohorts of simulated workers. The number of earners in the simulation model was increased, first to 100 and later to 200 per cohort, for both the OASI and DI models, to improve the resolving power of the procedure. Nonsteady earnings histories were substituted for the steady ones in order to reflect more accurately the effects of the lengthening computation period. The nonsteady earnings histories included both years of zero earnings and fluctuations in nonzero earnings, in which the probability of a year of zero earnings depended on the existence or nonexistence of a neighboring year of zero earnings. Assumed earnings above the earnings base were also projected, to allow better estimates of the effect of changing the base.

The most recent revision of this methodology, described below, further increases the size of the cohorts and attempts to refine some of the characteristics of the workers in them. There is now little room left for expansion of the sample because of the computer time required to perform the projection. Since time is often critical when responding to questions, a timely but less-accurate response is generally preferable to a more accurate but delayed response. Future improvements are expected to be either minor or else at the expense of some other parts of the methodology, until new computer capabilities allow more significant changes.

Basic Sample of Earnings Histories

The current projection methodology uses an actual sample of earnings histories as a basis for the projected cohorts of workers. The first step in the construction of this sample was the extraction of a subsample of records from the Continuous Work History Sample (CWHS).¹ The CWHS is a 1-percent sample of all persons, living or deceased, with Social Security numbers; thus, it contains records for more than 2 million persons. The subsample drawn for the awards projection consists of all persons in the CWHS who were not receiving OASDI benefits at the end of 1976 but were receiving benefits (aged worker, disabled worker, or survivor) at the end of 1977. This sample was reduced to 7 percent of the original 1 percent (in other words, to a 0.07 percent sample) to have a more manageable number of beneficiaries. Dependents of retired and disabled workers are not included in the subsample because their benefits are assumed to be proportional to those of the primary beneficiaries. The "raw" subsample as drawn from the

CWHS includes records on 1,378 beneficiaries, of whom 851 are aged workers (503 men and 348 women), 326 are disabled workers (243 men and 83 women), and 201 are survivors (174 receiving benefits based on earnings of men and 27 based on earnings of women). For each beneficiary, information available from the CWHS includes PIA and benefit amount in December 1977, cumulative 1937-50 earnings and year-by-year 1951-77 earnings from the associated earnings record, sex, date of birth, first year of eligibility, and other benefit information.

The raw subsample is drawn from a sample of beneficiaries and therefore is not representative of the population as a whole. If, during the projection period, the composition of the group of beneficiaries should change significantly as compared with the population as a whole, considering only a 1977 sample could give misleading results. For example, the percentage of all women with enough earnings to be eligible for aged worker benefits is projected to rise by approximately 50 percent in the future, while that for men is projected to remain about constant. If the average benefits of the "newly eligible" women should differ significantly from those for women already insured, the average overall benefits of women would be affected. Therefore, it is important for the sample to include persons who were not insured in 1977 so that the projections for future years would include the "newly eligible" workers. Thus, the next step in constructing the basic sample was to complete the raw subsample of aged beneficiaries to make it more representative of the population as a whole. This was not done for disabled workers, due to the slower growth projected in the percentage of female workers receiving disability insurance and to the complexity of the task. It was also not done for survivors, since, as noted below, the survivor portion of the basic sample is not currently being used in the long-range projection.

Two additions were made to the raw subsample of aged workers to complete it. First, persons with some earnings, but not enough to be insured for retired worker benefits (fully-insured status), and persons of retirement age in 1977 were added to the sample. For this purpose, a subsample was drawn from the Current Population Survey-Internal Revenue Service-Social Security Administration (CPS-IRS-SSA) Exact Match File² of 200 such persons aged 62-65. Of the 200 records drawn, 174 represent women and 26 represent men. Second, 111 theoretical records for persons with no earnings, all assumed to be age 62, were added to the

¹ For more information on the CWHS, see Warren Buckler and Preston Smith, **Continuous Work History Sample (CWHS), Description and Contents**, a paper prepared for the meeting of American Statistical Association on August 11-14, 1980, Houston, Texas. Copies are available from the authors at the Office of Research and Statistics, Social Security Administration.

² For more information on the CPS-IRS-SSA Exact Match File, see Faye Aziz, Beth Kilss, and Frederick Scheuren, "1973 Current Population Survey-Administrative Record Exact Match File Codebook, Part I—Code Counts and Item Definitions," **Studies from Interagency Data Linkages** (Report No. 8), Office of Research and Statistics, Social Security Administration, November 1978.

sample. Of the 111 records added, 106 represent women and 5 represent men. As a result, the basic sample includes, in addition to the records of disability and survivor beneficiaries unchanged from the raw subsample, a total of 1,162 records of retired workers, of which 534 represent men and 628 represent women.

Projection of the Basic Sample

Once the basic sample was constructed, a similar sample was developed for each single year in the projection period up to 1990, and quinquennially thereafter to the end of the projection period (1995 to 2055). For each such year, the number of earners in the sample is the same as in the basic sample, and the age and sex characteristics remain the same for each earner, but the earnings have been updated to represent those of beneficiaries being awarded benefits in that year. The updating of the earnings was done in two parts: first, for years of award up to 2000, and second, for years of award from 2005 onward.

As the year of award moves from 1977 to 2000, the length of the earnings record of each earner increases. For instance, a retiree aged 65 in 1977 has year-by-year earnings in the basic sample from 1951 to 1977, representing earnings from age 39 to age 65; his or her prior earnings were simply aggregated in the pre-1951 total. The parallel retiree in the projected sample for the year 2000 would have to be assigned earnings for each year from 1951 to 2000, representing earnings from age 16 to age 65. To accomplish the lengthening of the year-by-year earnings record while retaining as many as possible of the characteristics of the earner in the basic sample, the year-by-year earnings record was expanded by duplicating some randomly selected years of earnings; however, earnings near the time of retirement were not considered in the random selection for duplication because, for many purposes, the exact pattern of earnings before retirement is important. Earnings records of awardees under age 48 in 1977 (disability and survivor cases) were not expanded because, in general, they had no pre-1951 earnings and had a full earnings record by 1977. In all cases, the year-by-year earnings in the projected earnings records were adjusted, after any expansion of the earnings record, to reflect the past or assumed future increases in average wages.

Before expansion of the earnings record could be accomplished, some other problems had to be resolved. The first relates to the basic sample including only earnings up to the earnings base. Because of the ad hoc increases in the earnings base included in the 1977 Amendments to the Social Security Act, and because of the automatic adjustment mechanism, the base is estimated to be higher during the projection period than during 1951-77 (after adjustment for inflation). Thus, it

was necessary to approximate earnings over the earnings base for the year-by-year earnings in the basic sample. This approximation was accomplished with a random selection procedure, using a statistical distribution of earnings in excess of the earnings base provided by the Social Security Administration's Office of Research and Statistics. Second, the lump-sum total of earnings before 1951 had to be projected to future years of award. Such total earnings were projected to decrease linearly, by year of award, to zero by 1990, or by an earlier year if the earner in the basic sample were younger than age 62.

By the year 2000, the earnings records in all cases were assumed to cover a full working life. The year 2000 projection was taken as a starting point for projections after that year, with the level of earnings adjusted to reflect assumed future increases in average wages.

The earnings for each calendar year in the constructed samples were further adjusted to reflect the overall projected changes in rates of participation for men and women in Social Security covered employment, in fully insured rates, and in earnings differentials. In general, earnings levels of women were increased and earnings levels of men were slightly decreased to narrow, but not to eliminate, the differential in earnings between the sexes. Some of the years with no earnings were randomly selected to become years with positive earnings on earnings records of women to produce increasing overall rates of participation in Social Security covered employment and increasing fully insured rates for women in the constructed samples.

Adjustments were also made to account for year-by-year earnings not being available before 1951, thus the expansion of the earnings records from the basic sample was performed on the basis of earnings at ages 35 and above (no retiree in 1977 could be younger than age 35 in 1951). Earnings, in general, are lower at the younger ages, even after accounting for general wage increases; therefore, adjustments were necessary as earnings were projected for younger persons to assure that the overall average coverage rates and the resulting earnings levels were reasonable.

Calculated Amounts

For each constructed sample, the operations of the OASDI system were simulated to calculate the benefit payable for each earnings record in the sample. Benefits in future years depend on a number of variables that, in turn, depend on changes in the CPI and on changes in average wages. Annual benefit increases for those on the rolls and those eligible for benefits, and for the special minimum PIA's generally equal annual increases in the CPI. The PIA formula bend points, the wage-indexing amount, the earnings base, and the amount required for a quarter of coverage are all tied to changes in the

average wage.³ Table 1 presents the average wage and CPI increase assumptions from the 1981 OASDI Trustees Report⁴ for the four long-range sets of assumptions. Based on those assumptions, the necessary program variables were projected.

In the simulation for each constructed sample, the earnings in each earnings record were checked to see if they were sufficient to produce the insured status necessary for the type of benefit applicable to that record. (Fully insured status is required for retirement benefits, fully or currently insured status for young survivor benefits, fully insured status for aged survivor benefits, and fully and disability insured status for disability benefits. The three insured statuses require a varying number of quarters of coverage, in which quarters of coverage are earned in each year with covered earnings. Before 1978, one quarter of coverage was credited for each calendar quarter in which \$50 of wages was paid. Beginning in 1978, quarters of coverage are credited on an annual basis. Currently, one quarter of coverage is credited for each \$340 of annual earnings in 1982, up to a maximum of four quarters of coverage. Fully insured status requires one quarter of coverage for each year after the later of 1950 or the year of attainment of age 21, and before the earliest of the year of attainment of age 62, disability, or death, with a minimum of six quarters required. The quarters of coverage can be earned at any time. Currently insured status requires six quarters earned in the preceding 13 quarters. Disability insured status requires 20 quarters earned in the preceding 40 quarters, or one-half the quarters in a progressively shorter period at ages under 31.) The year-by-year earnings in each record were compared with the yearly quarter of coverage amount to compute the yearly quarters of coverage earned, and the appropriate insured status test was applied.

If the insured status was met, the PIA was computed for that earnings record. Under the normal PIA computation procedure,⁵ an average of a specified number of highest years of indexed earnings is computed and designated the Average Indexed Monthly Earnings (AIME). The number of years of earnings required depends on the year of eligibility of the earner. For retirees, the year

¹ From the 1981 OASDI Trustees Report.

² By law, automatic benefit increases that would be less than 3 percent do not go into effect; instead, they are combined with the succeeding years increases until there is a combined increase of at least 3 percent. This facet of the law was modeled through 1990; thus, there are no benefit increases in 1987 and 1989, and the 1988 and 1990 increases each represent 2 years of benefit increases. Beginning in 1991, the 3-percent trigger was ignored.

Note: Alternative I is the most optimistic alternative in terms of its economic and demographic assumptions and its net effect on the status of the trust funds; Alternative III is the most pessimistic. Alternatives II-A and II-B are intermediate assumptions; they share the same demographic assumptions, but Alternative II-A assumes more robust economic performance.

of eligibility is the year of attainment of age 62; for disabled workers, it is the year of disability onset. In either case, the year of eligibility must be before or the same as the year of award. For constructed samples, the year of eligibility for each record was assumed to precede the year of award by the same number of years that eligibility preceded award in the parallel record in the basic sample.

Once the AIME for each record was computed, the applicable PIA formula (including benefit increases after eligibility) was applied to produce the PIA at award. In all cases, the special minimum PIA was calculated, and, if greater, it became the PIA at award. In some cases, other PIA calculation methods were considered. If there were any earnings before 1950, the 1977 simplified old-start PIA was considered. (The 1977 simplified old-start PIA is derived from the benefit formula in the 1939 Act. In this method, an average monthly earnings figure is computed using earnings back to 1937, and a benefit formula is used to calculate an intermediate benefit amount. Finally, a conversion table incorporated in the current PIA table is used to determine the actual PIA.) If eligibility was before 1979, the PIA was

³ For more information on the average wage series, see Eli N. Donkar, *Average Wages for Indexing under the Social Security Act and the Automatic Determinations for 1979-81* (Actuarial Note No. 103), Office of the Actuary, Social Security Administration, May 1981.

⁴ 1981 Annual Report of the Board of Trustees of the Federal Old-Age and Survivors Insurance and Disability Insurance Trust Fund, 1981.

⁵ For more information on the PIA computation procedures, see Steven F. McKay, *Computing a PIA after the 1977 Amendments* (Actuarial Note No. 100), Office of the Actuary, Social Security Administration, February 1980; and Steven F. McKay and Bruce D. Schobel, *Effects of the Various Social Security Benefit Computation Procedures* (Actuarial Study No. 86), Office of the Actuary, Social Security Administration, July 1981.

calculated by pre-1977 law methods. If a retiree in a constructed sample was born between 1917 and 1921, the transitional guarantee PIA was calculated. (The transitional guarantee PIA method is similar to the pre-1977 law PIA table method. Two differences serve to limit the amount of the transitional guarantee PIA: (1) earnings in and after the year of attainment of age 62 cannot be used in the calculation of the average monthly earnings figure, and (2) benefit increases are not applied to the December 1978 PIA table for years before the year of attainment of age 62.) In each case, the highest applicable PIA became the PIA at award.

Average Awards and Benefits

Once the PIA's were calculated for each record in each constructed sample, the weighted average PIA's were found for each of the following four groups: Male retired workers, female retired workers, male disabled workers, and female disabled workers. Because the categories were already arranged by sex, the weights attempted to adjust the average awards in future years for changing age distributions at the time of award. For retirees, the age cells considered went by a single year, from age 62 to age 69, with a final cell for ages 70 and over. For disabled workers the age cells went by 5-year age groups, from ages 25-29 to ages 60-64, with a beginning cell for those under age 25. Average awards were found for each age cell, and then average awards over all ages were found by applying the weights projected for the category of beneficiary and the appropriate year of award.

The indexes of awarded-benefit growth were established for each of the four groups of beneficiaries by comparing the average award computed for each constructed sample after 1980 to the corresponding average award for the 1980 constructed sample. Applying these indexes to the actual 1980 average award produced the projected average awards. Table 2 summarizes the results that were obtained under Alternative II-B assumptions from the 1981 OASDI Trustees Report.⁶

The next step was to calculate the average benefit being paid to all beneficiaries of the four beneficiary groups in each calendar year, given the average benefit of newly awarded beneficiaries. Again, weighted averages were calculated; in this case, the weights were projected distributions of beneficiaries in each future year by years elapsed since award. The weights for each year were applied to the average awards of previous years, brought forward by any intervening general benefit increases, increased slightly due to earnings after retirement and to differential mortality, and summed. Table

Note: The average annual benefits exclude retroactive payments and payments attributable to dual entitlement to a secondary benefit.

⁶ 1981 Annual Report of the Board of Trustees of the Federal Old-Age and Survivors Insurance and Disability Insurance Trust Fund, op. cit.

3 summarizes the results obtained under the Alternative II-B assumptions.

The final step was to calculate the average benefit being paid to the remaining beneficiary groups. Benefits to auxiliary beneficiaries (wives, husbands, and children) of retired workers were assumed to increase at the same rate as for the category of retired worker on whose record the benefit would be payable. Benefits to survivors of male or female deceased workers (widows, widowers, children, and parents) were also assumed to increase at the same rate as for the corresponding category of retired worker. Benefits to some dually entitled beneficiaries (entitled to both retired-worker and wife/husband benefits, or retired-worker and widow/widower benefits), however, were adjusted to account for the complex interaction of projected changes in the distributions of benefits to men and women by size of PIA. Average benefits to auxiliary beneficiaries of disabled workers were related to the benefits of the correspond-

ing disabled workers, but adjustments were made to account for the prospective effects (assuming a base year of 1980) of the 1980 Disability Amendments that changed the rules for computing the maximum family benefit in disability cases.

Comparison of Alternative Assumptions

Average benefits to be awarded and paid in future years are projected to vary significantly, depending on the assumptions. Tables 4 and 5 summarize the average awards and benefits paid, respectively, under all four sets of long-range assumptions in the 1981 Trustees Report. Besides the economic assumptions shown in table 1, the figures in tables 4 and 5 depend on varying assumptions regarding mortality, fertility, and disability incidence rates, and other factors. For more information on the assumptions, methodology, and results of the long-range cost estimates, see the 1981 Trustees Report.⁷
