# Water Supply Assessment

## 1.0 Introduction

The *Plan of Study*, provided in appendix 1 of the *Status Report*, states that the purpose of the Colorado River Basin Water Supply and Demand Study (Study) is to conduct a comprehensive study to define current and future imbalances in water supply and demand in the Colorado River Basin (Basin) and the adjacent areas of the seven Colorado River Basin States<sup>1</sup> (Basin States) that receive Colorado River water over the next 50 years, and to develop and analyze adaptation and mitigation strategies to resolve those imbalances. The Study contains four major elements to accomplish this goal: Water Supply Assessment, Water Demand Assessment, System Reliability Analysis, and Development and Evaluation of Opportunities for Balancing Supply and Demand.

The purpose of the Water Supply Assessment is to determine the probable magnitude and variability of historical and future natural flows in the Basin. Natural flow represents the flow that would have occurred at a location, had depletions and reservoir regulation not been present upstream of that location.

Because the magnitude and variability of future water supply is uncertain, a set of future water supply scenarios has been developed to capture the uncertainty, including the potential effects of future climate variability and climate change. The water supply projections will be used to analyze future reliability of the river system to meet water demands, with and without future adaptation and mitigation strategies. The water supply assessment draws on the expertise of researchers and analysts worldwide who have been investigating the hydrology of the Basin and the dynamics of global climate change.

This report was initially published in June 2011 under Interim Report No. 1 and has been since updated to reflect the comments received on Interim Report No. 1, technical developments, and the ongoing input of stakeholders.

Substantive changes made to this report since its first publication as part of Interim Report No. 1 are noted below by section.

- Historical Supply (Section 4) – Information related to watershed elevation was added and discussion related to the Pacific Decadal Oscillation and El Nino-Southern Oscillation relationships to streamflow in the Colorado River was expanded. Recent updates to the observed natural flow record for the Colorado River at Lees Ferry, Arizona resulted in a reclassification of the recent drought.
- Future Supply under Downscaled General Circulation Model (GCM) Projected Scenario (Section 8) – Evaluation of biases in GCM-projected precipitation and temperature and streamflow simulated by the Variable Infiltration Capacity (VIC) hydrology model. Application of a correction to account for the biases in the VIC-simulated streamflows was applied. Additionally, the method to generate daily precipitation and temperature for input to the VIC model was modified. A more in-depth analysis was conducted to better understand 1) the relative sensitivity of results

---

<sup>1</sup>Arizona, California, Colorado, New Mexico, Nevada, Utah, and Wyoming.

- to emission scenarios driving the GCM output and 2) extreme high annual flows projected under this scenario.
- Supplemental Water Supply Data and Methods (Appendix B2) – Consolidates discussion previously included in separate appendices.
  - Supplemental Analysis of Future Climate Data (Appendix B3) – New appendix that describes supplemental analysis of biases in GCM-projected precipitation and temperature and its potential influence on streamflow.
  - VIC Hydrologic Modeling Methods and Simulations (Appendix B4) – Consolidates discussion previously included in separate appendices. A discussion was added to describe the model validation results and the newly applied streamflow bias correction method.
  - Watershed-based Climate and Hydrologic Process Changes (Appendix B6) – Updated watershed-based hydrologic flux figures to be consistent with updates to modeling data sets.

## 2.0 Approach to Water Supply Scenario Development

A scenario planning process was implemented to examine the uncertainty in future water supply and demand and is detailed in *Technical Report A - Scenario Development*. As noted in that report, a collaborative process that engages stakeholders is essential to the successful development of future scenarios. For the Water Supply Assessment, numerous organizations have participated, including representatives of the Bureau of Reclamation (Reclamation), Reclamation’s Technical Service Center, the Basin States, U.S. Fish and Wildlife Service, National Oceanic and Atmospheric Administration (NOAA), Native American tribes and communities, environmental organizations, and others interested in the Basin. This collaboration has been accomplished through a variety of means, including participation in a Water Supply Sub-Team and direct contact with the organizations listed above. The Water Supply Sub-Team members and the points of contact are identified in appendix B1 of this report.

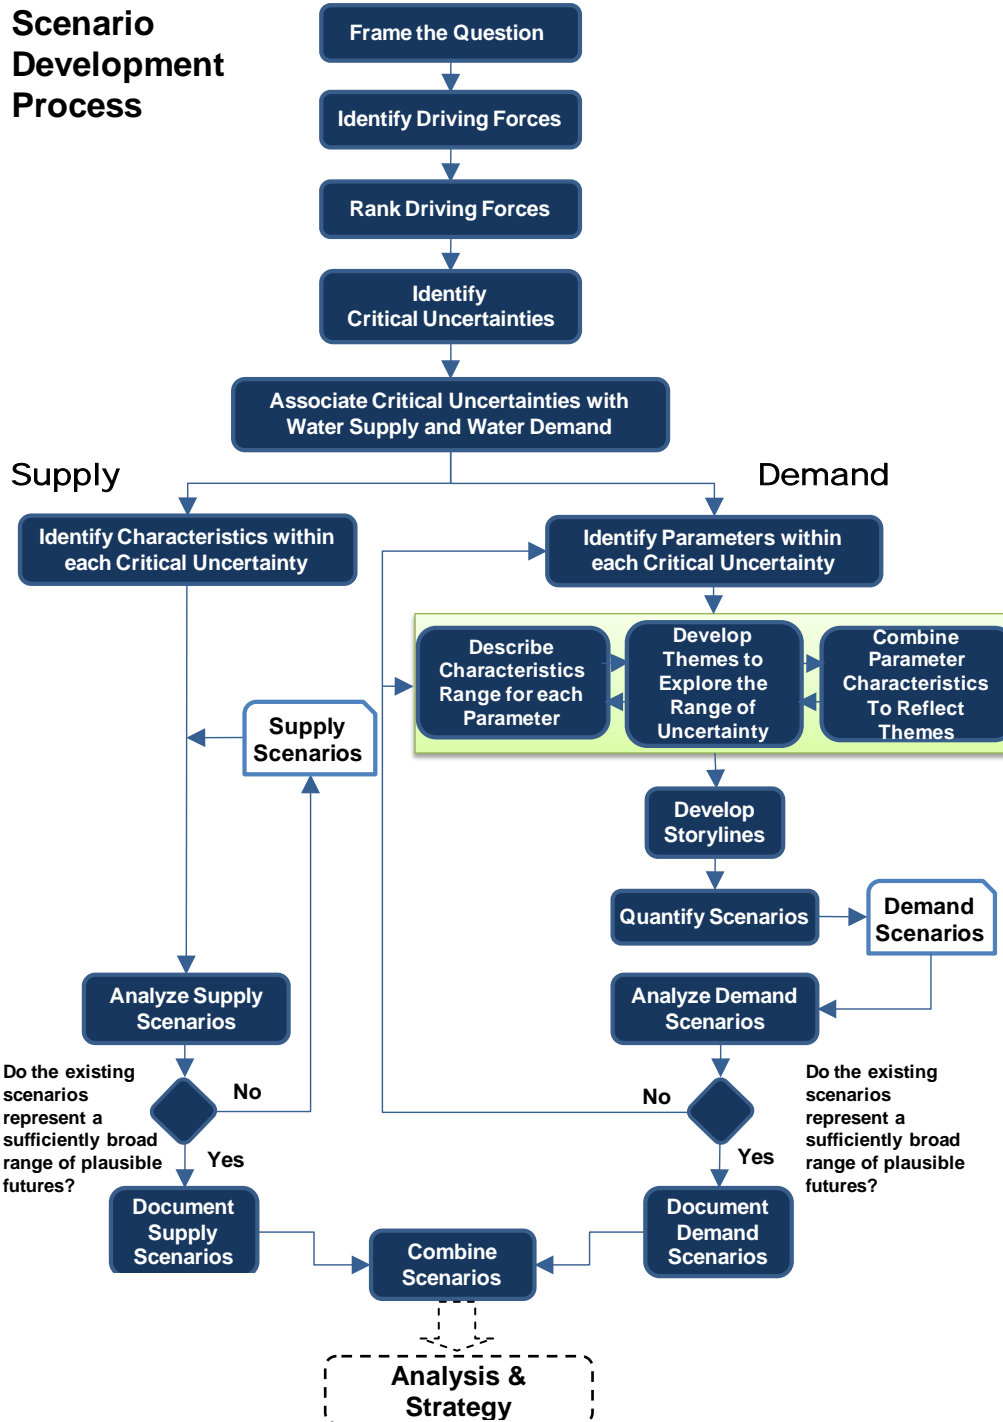

A scenario is an alternative view of how the future might unfold. Scenarios are not predictions or forecasts of the future. The scenario planning process involved identifying the key driving forces (i.e., the factors that will likely have the greatest influence on the future state of the system and thereby the performance of the system over time), ranking the driving forces as to their relative importance and relative uncertainty, and associating the highly uncertain and highly important driving forces, identified as critical uncertainties, with either water supply or water demand. The process is shown in figure B-1, which is also presented in *Technical Report A - Scenario Development*. The critical uncertainties that were identified and associated with water supply (the step, “Associate Critical Uncertainties with Water Supply and Demand,” shown in figure B-1) are:

- Changes in streamflow variability and trends
- Changes in climate variability and trends

See *Technical Report C – Water Demand Assessment* for a discussion of the critical uncertainties associated with water demand.

The subsequent process (shown on the left-hand side of figure B-1 and labeled “Supply”) was used by the Water Supply Sub-Team to move from the critical uncertainties to supply scenarios. Each step of this process is described in the following sub-sections.

FIGURE B-1  
Scenario Development Process

## 2.1 Identify Characteristics within each Critical Uncertainty

Characteristics can be either qualitative or quantitative descriptions of the trend or values over time that describe the trajectory of the critical uncertainty. In 2004, Reclamation initiated a multi-faceted research and development program to enable the use of methods beyond those that use the observed record for projecting possible future inflow sequences for Colorado River Basin planning studies. Through this effort, two additional water supply scenarios were developed and have been used in previous Colorado River Basin planning studies; these scenarios assume that characteristics of the water supply critical uncertainties are represented by the observed and paleo-reconstructed streamflow records. These scenarios have most recently been published in appendix N of the *Interim Guidelines for Lower Basin Shortages and Coordinated Operations for Lake Powell and Lake Mead Final Environmental Impact Statement* (2007 Interim Guidelines Final EIS) (Reclamation, 2007).

For purposes of the Study, it was determined that these previously used scenarios did not represent a sufficiently broad range of plausible futures because they did not include the consideration of changing climate beyond what has occurred in history. As such, a fourth scenario was developed that assumes the characteristics of the critical uncertainties, “changes in streamflow variability and trends,” and “changes in climate variability and trends,” are indicated by downscaled general circulation model (GCM) projections and simulated hydrology.

## 2.2 Water Supply Scenarios

The following scenarios and associated themes are being considered in the Study:

- **Observed Record Trends and Variability (Observed Resampled):** Future hydrologic trends and variability are similar to the past approximately 100 years.
- **Paleo Record Trends and Variability (Paleo Resampled):** Future hydrologic trends and variability are represented by reconstructions of streamflow for a much longer period in the past (nearly 1,250 years) that show expanded variability.
- **Observed Record Trends and Increased Variability (Paleo Conditioned):** Future hydrologic trends and variability are represented by a blend of the wet-dry states of the longer paleo reconstructed period (nearly 1,250 years), but magnitudes are more similar to the observed period (about 100 years).
- **Downscaled GCM Projected Trends and Variability (Downscaled GCM Projected):** Future climate will continue to warm with regional precipitation and temperature trends represented through an ensemble of future Downscaled GCM Projections and simulated hydrology.

The scenarios each represent a plausible future of water supply conditions. The Observed Resampled, Paleo Resampled, and Paleo Conditioned scenarios use approaches previously developed to represent a range of hydroclimatic variability (annual to decadal scales) under a broad retrospective view. Future changes in climate variability and trends, and their influence on streamflow and Colorado River Basin water supply, have been studied by several researchers in recent years. The Study represents the first time future climate scenarios have been included in Reclamation’s Colorado River Basin planning studies. For these reasons, greater detail is provided for the Downscaled GCM Projected scenario in this report.

However, each of the scenarios in the Study represents a plausible future condition and is informative for future Colorado River Basin planning.

### 3.0 Summary of the Water Supply Assessment Approach

A plausible range of future water supply scenarios, sufficiently broad to capture the significant uncertainty of the estimates, must be considered to analyze the future reliability of the system. An assessment of historical supply conditions was performed to facilitate an understanding of how the projected future supply conditions under each scenario differ from historical supply conditions. This section describes the water supply indicator groups analyzed for historical and future conditions and also includes a summary of published research related to Basin supply.

#### 3.1 Tools and Methods

The assessment of historical and future supply conditions focused on four main groups of water supply indicators, presented in figure B-2. The water supply indicator groups are interrelated: climate influences hydrologic processes; hydrologic processes generate streamflow; and teleconnections (defined below) influence the oscillation of climate patterns.

FIGURE B-2  
Water Supply Indicator Groups Used in the Study

Although the primary indicator of water supply in the Basin is streamflow, a fundamental understanding of the processes that influence the quantity, location, and timing of streamflow is beneficial. Comparisons for each indicator group are made between historical supply and future supply under the Downscaled GCM Projected scenario because this scenario assumes a changing climate. For the Observed Resampled, Paleo Resampled, and Paleo Conditioned scenarios, which assume a climate similar to the past, streamflow is the primary indicator. Methods applied to project streamflow under the future supply scenarios are described in their respective sections.

Climate indicators considered in this assessment are temperature and precipitation. Hydrologic process indicators are runoff, evapotranspiration (ET), snowpack accumulation (snow water equivalent, or SWE), and soil moisture. Climate and hydrologic process indicators were primarily derived from gridded data sets (Maurer et al. 2002; Maurer et al. 2007; Reclamation 2011), and spatial averaging was performed for selected sub-basins

associated with Reclamation's natural flow computation points. The sub-basin averaging of climate and hydrologic process information allows assessment of broader regions of the Basin than the detailed grid cell calculations.

Climate teleconnection indicators are the El Nino Southern Oscillation (ENSO), Pacific Decadal Oscillation (PDO), and Atlantic Multi-decadal Oscillation (AMO) indices. Teleconnections refer to the linkage between large-scale, ocean-atmosphere patterns (such as ENSO, PDO, and AMO) and weather or climate changes within a separate region of the globe (e.g., precipitation patterns in the Colorado River Basin). Finally, streamflow indicators are natural flows at select locations in the Basin.

Natural flow represents the flow that would have occurred at the location had depletions and reservoir regulation not been present upstream of that location. Natural flow is computed historically by Reclamation<sup>2</sup> and is currently available for 29 locations throughout the Basin: 20 locations in the Upper Basin upstream of and including the Lees Ferry gaging station in Arizona; and nine additional locations below Lees Ferry, including the Paria River and other inflow points in the Lower Basin. These locations are shown in figure B-3. At this time, Basin-wide, natural flow records extend from 1906 through 2008<sup>3</sup>. Although all gages were not in place back to 1906, the existing records were extended back to 1906 using methods described in Lee et al. (2006).

For some tributaries in the Lower Basin (specifically the Little Colorado River, Virgin River, and Bill Williams River), U.S. Geological Survey (USGS)-gaged flows at specific locations near the confluence of the tributary and the Colorado River mainstream have been used in place of natural flows. This approach is also taken for the Paria River, which joins the Colorado River just downstream of Lees Ferry, Arizona. In addition, the Gila River is not included in the Colorado River Simulation System (CRSS) and is therefore not included in the 29 locations where natural flow is estimated throughout the Basin. See *Technical Report C – Water Demand Assessment, Appendix C5, Modeling of Lower Basin Tributaries in the Colorado River Simulation System*, for further discussion.

CRSS is Reclamation's primary Basin-wide simulation model used for long-term planning studies and, in its current configuration, requires natural flow inputs at these 29 locations on a monthly time step over the Study's planning horizon. This report describes the specific methods used to quantify, and results of, the water supply scenarios considered in this Study.

Additional information related to water supply data and methods is provided in appendix B2.

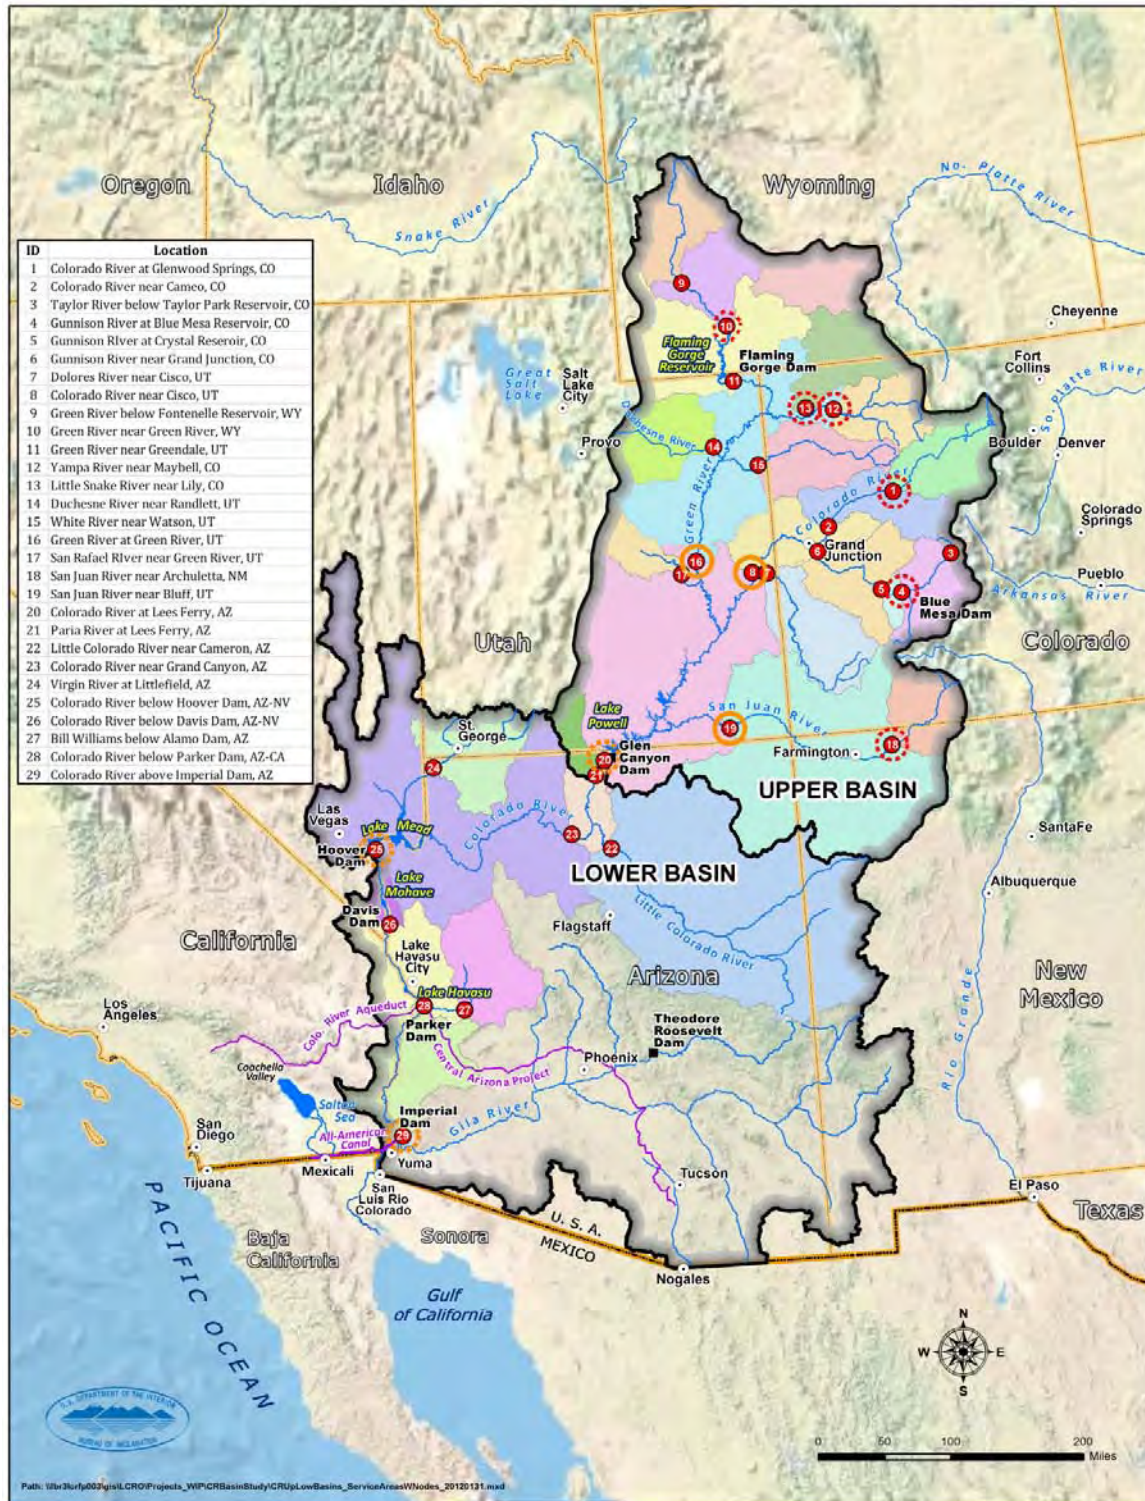

---

<sup>2</sup>Additional information, documentation, and the natural flow data are available at <http://www.usbr.gov/lc/region/g4000/NaturalFlow/index.html>.

<sup>3</sup>At the time the analysis for this report was performed, natural flow data were available only through 2007.

**FIGURE B-3**  
 Colorado River Basin and 29 Natural Flow Locations (Source: Reclamation, 2011)  
*Circled stations are used for climate and streamflow in this report; dashed circles are used to describe climate, and solid circled stations are used to describe streamflows.*

## 3.2 Sources of Data and Information

An extensive review of relevant literature, water supply studies, and hydroclimatic data was performed as part of the Water Supply Assessment. The Basin supply has been studied by numerous researchers, and a wealth of information is available on which to build upon, including several recent studies directly relevant to the Study. Relevant hydroclimate data were collected throughout the Water Supply Assessment, with particular emphasis on gridded climate data sets and natural flows for the 29 natural flow locations in the Basin.

### 3.2.1 Literature Review

Due to its strategic importance as a source of water for the western United States, the Colorado River is one of the most studied river systems in the world. The Basin water supply has been assessed using a variety of hydrologic analyses for many decades, but efforts accelerated in the 1990s with the availability of GCMs and observed increased streamflow variability (Pagano and Garen, 2005). Reclamation published an extensive literature review of Colorado River climate and hydrology studies in appendix U of the 2007 Interim Guidelines Final EIS (Reclamation 2007). This appendix summarizes the state of the science in 2007. In 2011, Reclamation's Technical Service Center published a second edition of the *Literature Synthesis on Climate Change Implications for Water and Environmental Resources* (Reclamation, 2011) that summarizes relevant research through the summer of 2010. Provided below is a brief summary of past efforts and research to assess Basin supply.

- The following studies: Gleick (1987); Nash and Gleick (1991, 1993); Hamlet and Lettenmaier (1999); McCabe and Wolock (1999); Wilby et al. (1999); and Wolock and McCabe (1999) discuss climate change impacts on the hydrology and water resources of western U.S. river basins. All these studies assume or predict increasing temperatures, but disagree about both the magnitude and direction of precipitation changes.
- Nash and Gleick (1991) evaluate prescribed changes of +2 degrees Celsius (°C) and +4 °C, coupled with precipitation reductions of 10 and 20 percent. The 2 °C increase/10 percent precipitation decrease resulted in a 20 percent streamflow reduction, while the 4 °C increase/20 percent precipitation decrease resulted in a 30 percent runoff decrease.
- Christensen et al. (2004) project average projected temperature increases of 1.0 °C, 1.7 °C, and 2.4 °C, and precipitation decreases of 3, 6, and 3 percent for the Basin for the periods 2010–2039, 2040–2069, and 2070–2099, respectively, relative to the period 1950–1999 means. The temperature and precipitation changes lead to reductions of April 1 SWE of 24, 29, and 30 percent, and runoff reductions of 14, 18, and 17 percent for the three periods.
- Updated analyses by Christensen and Lettenmaier (2007) using a larger ensemble of climate projections, result in smaller mean projected reductions in Lees Ferry flows (less than 11 percent).
- Hoerling et al. (2009), in an attempt to reconcile streamflow estimates by several researchers, summarize the recent hydroclimatic analyses of the Basin and find that the projections range from 5 to 20 percent reduction in streamflow by 2050.

- A recently released *Colorado River Water Availability Study* (Colorado Water Conservation Board Draft Report, 2010) focuses on the State of Colorado’s hydrometeorological contribution to the Colorado River system. The study describes the tools available to simulate river hydrology, agricultural demands, water allocation, and decision support.
- Several papers in a recent special issue of the Proceedings of the National Academy of Sciences on *Climate Change and Water in Southwestern North America* (Sabo et al., 2010) focus on the climate and water supply in the Basin. Cayan et al. (2010) provide an analysis of the current Colorado River drought and suggest that, although the current drought is exceptional in the observed record, future droughts in the Basin may be more severe and longer in duration. Woodhouse et al. (2010) provide the 1,200-year perspective on Southwestern drought, draw linkages of warming to paleo drought severity, and place the drought in context with the medieval period worst-case drought. Seager and Vecchi (2010) attribute the current and future Southwest drying to a broader expansion of the Hadley cell that causes storms to track farther north. It is important to note that the latter study (Seager and Vecchi, 2010) suggests decreases in winter (October–March) precipitation, although many other studies (including Cayan et al., 2010) suggest increases during this same period for much of the Basin. It is not clear whether this discrepancy is due to the large domain (southwest North America, from southern Mexico to the Oregon–California border and from the Pacific Ocean to the High Plains) that is being averaged, or due to the lack of regional/local spatial resolution of the GCM-based information.
- Das et al. (2011) further evaluate the effect of seasonal differences in warming on Colorado River streamflow changes. The Intergovernmental Panel on Climate Change (IPCC) 4th Assessment Report (AR4) group of climate models indicates that climate warming over the Colorado River Basin may be greater in summer than in winter. Das et al. (2011) find that annual Colorado River streamflow is more sensitive to warm season (April–September) warming than cold season warming (October–March), and is the most sensitive of the four western river basins evaluated. A 3 °C warming in the warm season results in a 13.3 percent reduction in annual flow, while the same warming applied during the cool season results in an annual flow reduction of only 3.5 percent. Climate warming, especially if amplified in summer as projected, may drive significant reductions in available supply, even if there is no reduction in precipitation.

Across almost all research is the projection of continued and increased warming in the Basin and very likely increases in the severity of future droughts. However, the research suggests continued uncertainty in projections of the magnitude and direction of potential future changes in annual precipitation. Effective treatment of this uncertainty is important in making credible estimates of future water supply.

### **3.2.2 Data Sources**

The Water Supply Assessment relied on a variety of peer-reviewed datasets collected by Reclamation, other recognized federal sources, and hydrologic modeling results obtained from Reclamation’s West-Wide Climate Risk Assessment study (Reclamation, 2011). The

data sources and methods are described further in subsequent sections of this report and a complete listing is collectively included in appendices B2, B3, and B4.

## 4.0 Historical Supply

An assessment of the Basin's historical climate and hydrology is critical for a robust understanding of the projected changes associated with each of the four future water supply scenarios. For this reason, an assessment of the historical supply of the Basin is first presented. This presentation begins with a discussion of the methods used to perform the assessment, followed by the results for the four groups of water supply indicators: climate, hydrologic processes, climate teleconnections, and streamflow.

### 4.1 Methods

Historical daily temperature and precipitation data for 1950–2005 (Maurer et al., 2002<sup>4</sup>) were processed into average temperature and total precipitation for each month and year of the period. Monthly, seasonal, and annual statistics were computed for each grid cell (1/8<sup>th</sup>-degree resolution, or about 12 kilometers [km]) of the gridded meteorological dataset for the 1971–2000 historical period to represent the historical climatology and compare to future projected climates. The historical dataset is derived from individual NOAA Cooperative Observer (COOP) station observations and gridded to the 1/8<sup>th</sup>-degree using mapping algorithms that account for station elevation, orographic effects, and other characteristics (Maurer et al., 2002).

Climate is defined by the World Meteorological Organization (WMO 2011) as the “average weather,” or a statistical description in terms of the mean and variability of variables such as temperature, precipitation, and wind. Climate change is the shift in the average weather, or trend, that a region experiences. Thus, climate change cannot be represented by single annual events or individual anomalies. That is, a single large flood event or particularly hot summer is not an indication of climate change, although a series of floods or warm years that statistically change the average precipitation or temperature over time may indicate climate change. The WMO recommends the use of a 30-year period for evaluating climate. At the time this study was initiated, the established 30-year climatological period as described by NOAA (2011) was the 1971–2000 historical period. This period was used in the study to define the historical base climate. While NOAA has recently updated its climatological period to 1981–2010, climate and hydrologic information from various sources is not yet available to support this assessment for the Basin.

The historical climatological period allows for the averaging of individual year and multi-year variability over a longer period to capture the average conditions. A longer period could have been selected as the historical base period, but ensuring consistency with NOAA's period definition, and establishing a period consistent with tracking future changes (desire to estimate future changes for similar 30-year time slices), were considered important to define time-varying changes in this analysis. The seasons are defined as follows: Fall (October, November, and December); Winter (January, February, and March); Spring (April, May, and June); and Summer (July, August, and September).

---

<sup>4</sup> Subsequent to Maurer et al., (2002), the climate dataset was extended to 2005 using identical methods.

Historical hydrologic parameter data were generated by the Variable Infiltration Capacity (VIC) model for the period 1950–2005. The VIC model (Liang et al., 1994; Liang et al., 1996; and Nijssen et al., 1997) is a spatially distributed macro-scale hydrologic model that solves the water balance at each model grid cell. The VIC model is populated with the historical temperature and precipitation data to simulate historical hydrologic parameters (Maurer et al., 2002). Appendix B4 provides details on the VIC model and its application in the Study. The simulated hydrologic parameters include ET, runoff (surface runoff), baseflow (subsurface runoff), soil moisture (in each of three soil layers), and SWE. Representative statistics describing these parameters were generated on monthly, seasonal, and annual bases. The statistical analysis was conducted on both grid cell and watershed bases. The results of the grid cell analysis produce the most informative map graphics and clearly show spatial variation at the greatest resolution possible, while the watershed basis provides an aggregate graphic of the variation across a natural flow station's watersheds.

Climate teleconnections were analyzed first by selecting indices that could have potential influence in streamflow changes for the Basin. Published research (Redmond and Koch, 1991; Diaz and Kiladis, 1992; and McCabe et al., 2004, etc.) indicates that the strongest correlations with Basin flows were observed with the ENSO and PDO indices. For ENSO, data were collected for both the ocean component (sea surface temperature anomalies) and the atmospheric component (sea level pressure anomalies). The sea surface temperature anomalies indicate the relative temperature state of the tropical Pacific Ocean as compared to normal (warm phase indicating El Niño conditions), while the sea level pressure anomalies are one measure of large-scale fluctuations in air pressure occurring between the western and eastern tropical Pacific. The two components are highly correlated, and combined, describe ENSO. The Southern Oscillation Index (SOI) was the primary dataset used in the Study to describe ENSO due to the longer period of data availability. Therefore, the quantitative teleconnections analysis was based on these SOI and the PDO indices. Only a qualitative discussion of the AMO is included in this report. For additional information pertaining to indices choice, refer to appendix B2.

Annual average values for the SOI were computed using different annual windows. The average SOI presented in the Study refers to the June–November period, which was identified as a strong indicator of ENSO events (Redmond and Koch, 1991). Once the SOI averages were computed, ENSO events were determined by years where the averaged SOI was below -1 (classified as an El Niño year) or above 1 (classified as a La Niña year). Annual averages of the PDO on a water year basis were calculated and compared with the same water year annual flows. A warm PDO was defined as a value greater than or equal to 0.0 and a cold PDO was a PDO value less than 0.0.

Two historical streamflow data sets, the observed record spanning the period 1906–2007, and the paleo reconstructed record spanning the period 762–2005 (Meko et al., 2007), were used in the Study to characterize historical streamflow patterns and variability. Period comparisons are made between the full extent of the data and a more recent period. For the observed dataset spanning 1906–2007, the second comparison period (1978–2007) was selected as the most recent 30-year period. For the paleo dataset spanning 762–2005, the second comparison period was selected as 1906–2005 so that direct comparisons could be made of the observed and paleo timeframes.

## **4.2 Results**

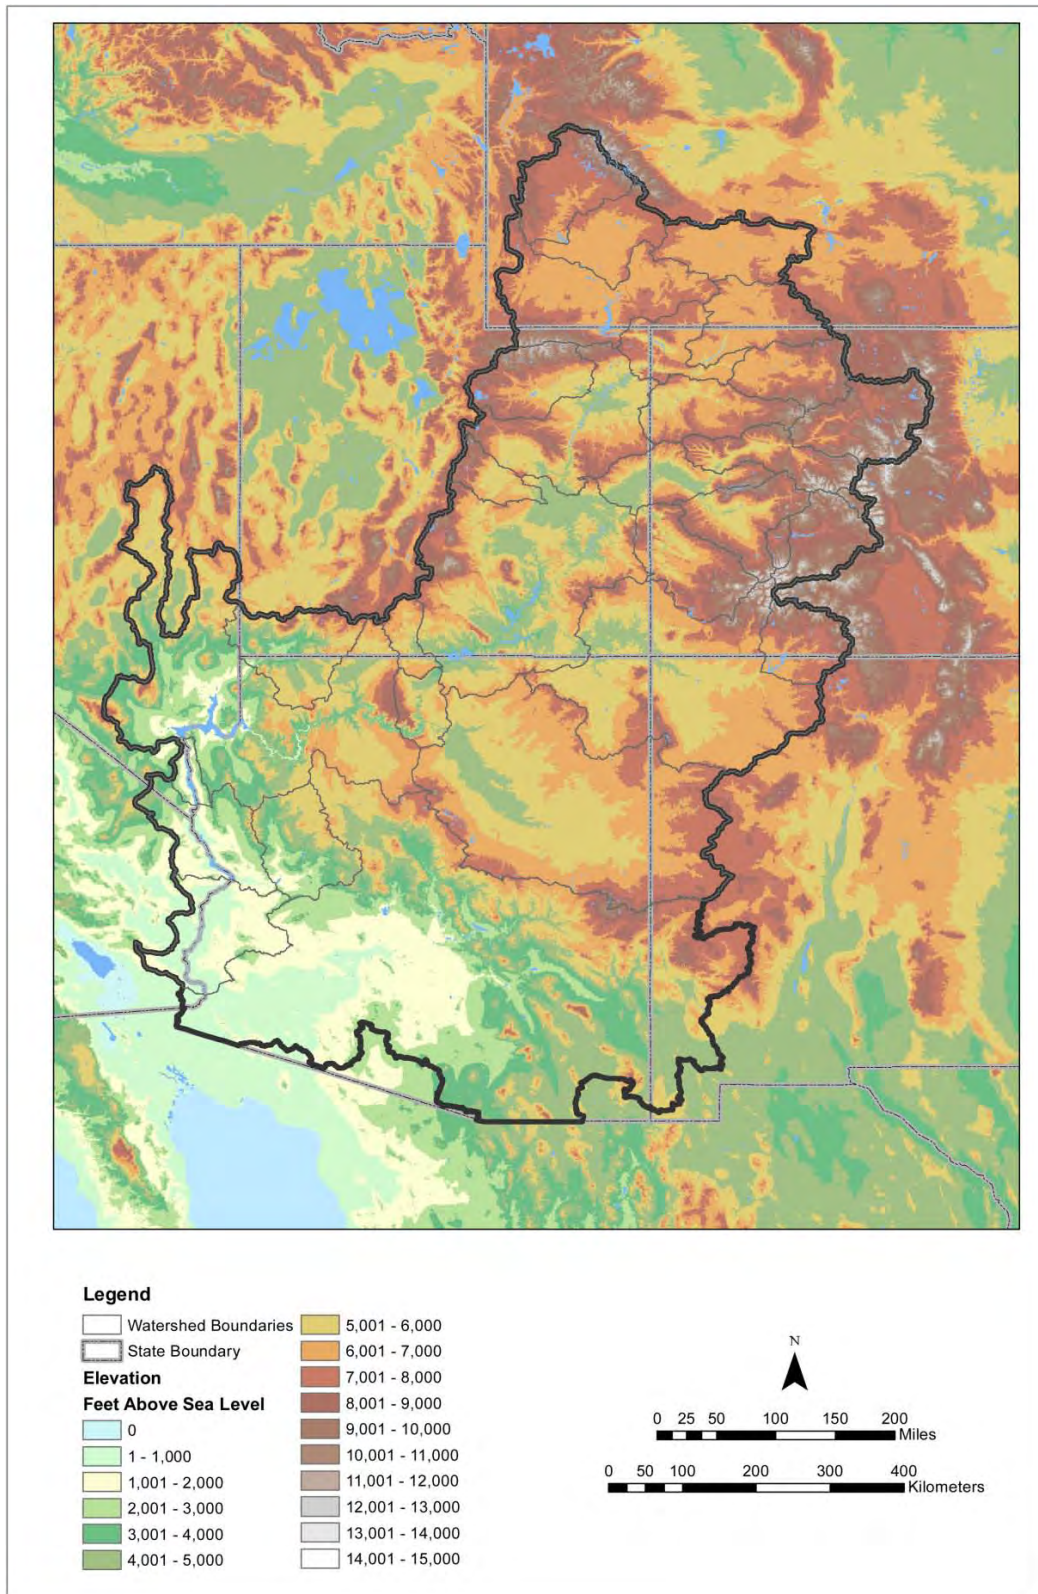

### **4.2.1 Climate**

The Basin contains climate zones ranging from alpine to desert and is fundamentally influenced by climate variability from seasonal to millennial scales (National Research Council [NRC], 2007). The Basin water supply, as is typical in many western river systems, strongly depends on snowmelt from high elevation portions (figure B-4) of the Upper Basin, with about 15 percent of the watershed area producing about 85 percent of the entire Basin's average annual runoff. Annual precipitation ranges from 84 millimeters (less than 4 inches) in southwestern Arizona to nearly 1,600 millimeters (63 inches) in the headwaters of Colorado, Utah, and Wyoming, as shown in figure B-5. Average temperatures vary considerably by season, Basin location, and elevation, as also shown in figure B-5. Warmest temperatures are seen in the southwestern Arizona summer and coolest in the headwaters during the winter.

**FIGURE B-4**

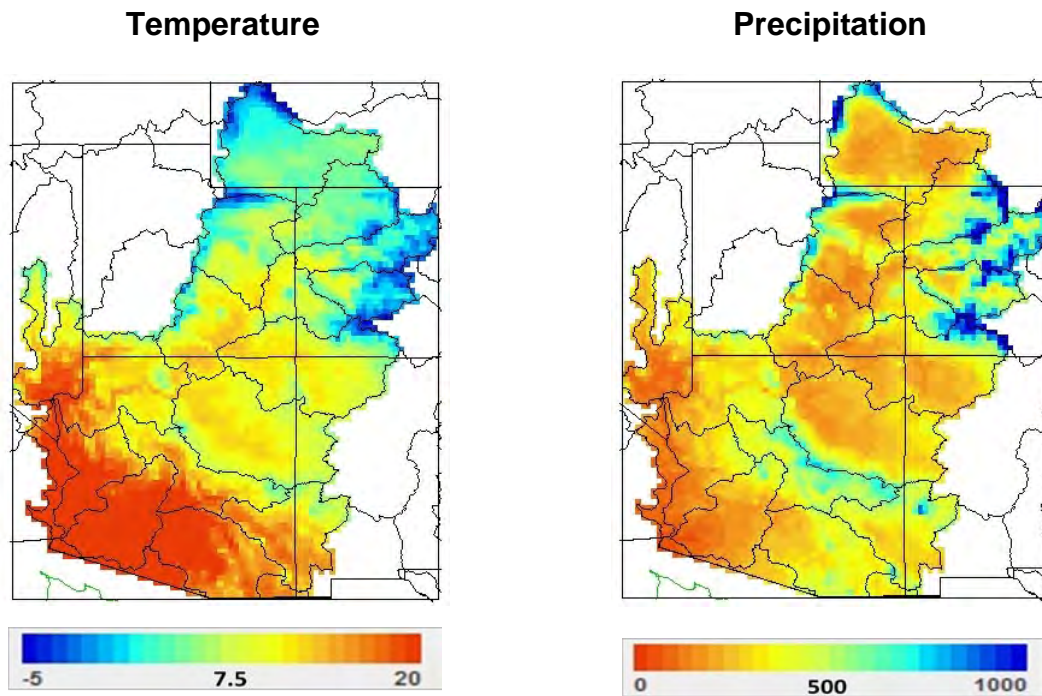

Colorado River Basin Elevation (feet above mean sea level)

Derived from National Elevation Dataset, U.S. Geological Survey [USGS], ([HTTP://NED.USGS.GOV](http://ned.usgs.gov)).

**FIGURE B-5**

Average Annual Temperature (°C) and Average Annual Precipitation (millimeters) for the Period 1971–2000  
 Derived from Maurer et al., 2002.

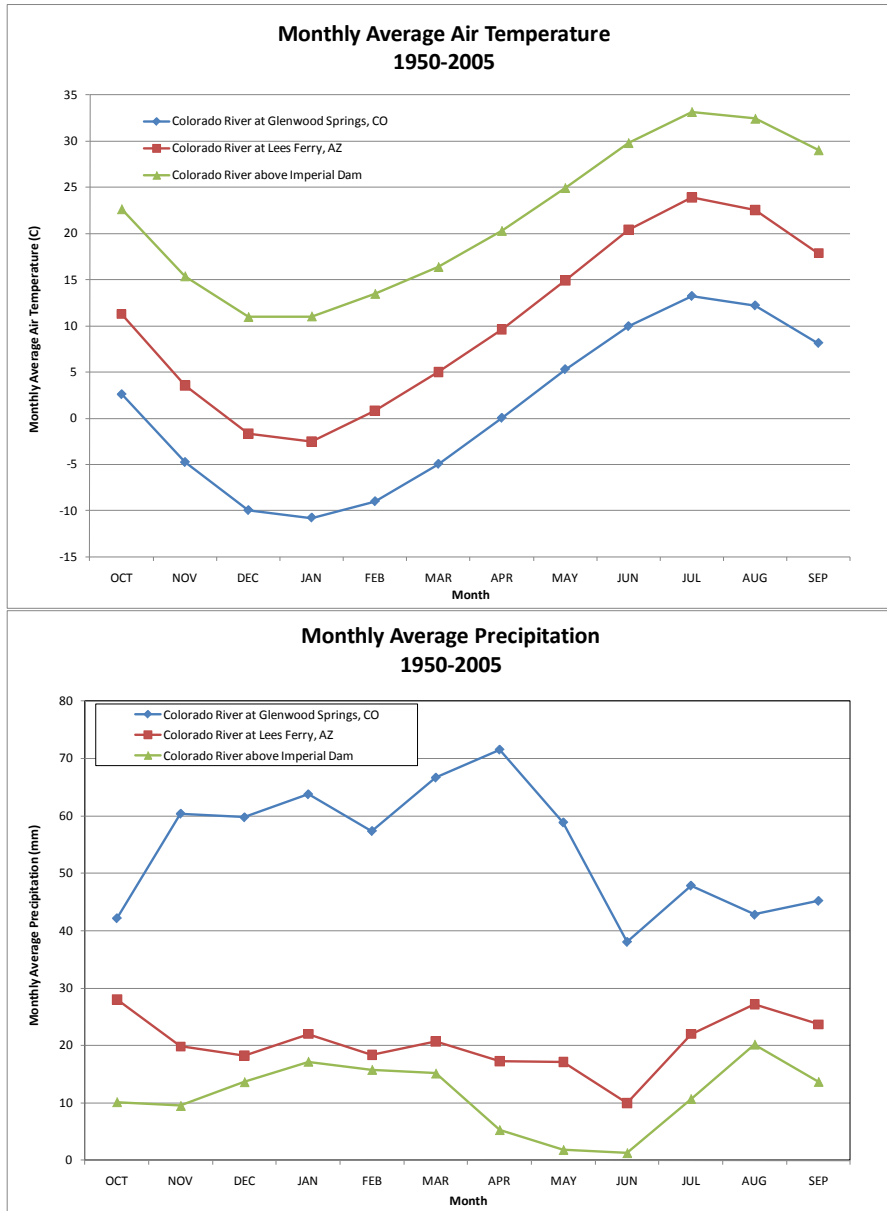

The climate of the Basin exhibits important spatial and seasonal variability. To illustrate this variability, figure B-6 shows monthly average temperature and precipitation as watershed averages for the areas immediately upstream of the Colorado River near Glenwood Springs (Colorado), Colorado River at Lees Ferry (Arizona), and Colorado River above Imperial Dam (Arizona/California). These three locations reflect a coarse transect of the Basin from the headwaters to Imperial Dam.

As illustrated in figure B-6, the average temperature varies by more than 20 °C seasonally at each of the three locations and similarly across the Basin within seasons. Cool winter temperatures at the higher elevation portions of the Upper Basin cause much of the precipitation to fall in the form of snow. At lower elevations, warmer conditions exist and liquid precipitation is the dominant form. For most regions, the majority of the precipitation occurs in the cool season (fall and winter). Warmer temperatures in the spring and summer induce snowmelt at the higher elevations, and storms tend to be short and intense. The summer precipitation does not contribute a significant portion of the Basin annual total. However, in the southwest portions of the Basin (Arizona, California, and Nevada), summer precipitation is locally important. The North American monsoon season plays a significant role in bringing moisture from the sub-tropical Pacific and Gulf of California and causes intense summer storms in the southwestern desert. The monsoon influence extends into Upper Basin states as well and can contribute to significant summer precipitation in New Mexico, Utah, and Colorado.

**FIGURE B-6**

Monthly Average Temperature and Precipitation for Three Representative Locations in the Colorado River Basin  
 Derived from daily gridded observed meteorology (Maurer et al., 2002) and averaged for the local watershed immediately upstream of the indicated point.

Trends in temperature and precipitation for the Basin have been studied by Groisman et al. (2001), McCabe et al. (2002), Piechota et al. (2004), Hamlet et al. (2005), Pagano and Garen (2005), Regonda et al. (2005), Andreasdis et al. (2006), Fassnacht (2006), Mote (2006), Christensen et al. (2007), and several others. Long-term trends are summarized in the 2007 NRC summary report on hydroclimatic variability in the Basin (NRC, 2007). The long-term annual temperatures and precipitation amounts from the period 1895–2005 are shown in figure B-7. A significant increase in temperature is apparent in this figure, although periods of cooling have occurred historically. Most important is the significant warming trend that

has occurred since the 1970s. This warming trend is consistent with trends in both the Upper and Lower Basins and with observed North American and global trends.

Annual precipitation shows substantial variability and periods of dry and wet spells. Most notable in the precipitation record is the lack of a significant long-term annual trend, yet the annual variability appears to be increasing. Both the highest and lowest annual precipitation years appear in the most recent 30-year record.

FIGURE B-7

Annual Average Surface Air Temperature for the Colorado River Basin, 1895–2005 (top); and Annual Water Year Average Precipitation for the Colorado River Basin above Lees Ferry, Arizona (bottom)

Note: red lines show annual values; blue lines show the 11-year running mean. Source: NRC 2007 and Western Regional Climate Center.

A 2008 publication by Miller and Piechota summarizes Basin temperature, precipitation, and streamflow trends and also examines the possibility that a “step change” in these parameters occurred during the mid 1970s. The step-change time series data were divided into the first 24 years of data (1951–1974) and the later 31 years of data (1975–2005) for temperature and precipitation datasets. Miller and Piechota (2008) find that increasing temperature trends and step changes were observed consistently throughout the year, often times at greater than a

95 percent confidence level. Temperature trends were most significant in the first quarter of the year, January–March. Precipitation trends and step changes were not as evident as those for temperature. An increasing precipitation trend was observed January–March, but not at all stations and not significant for other months.

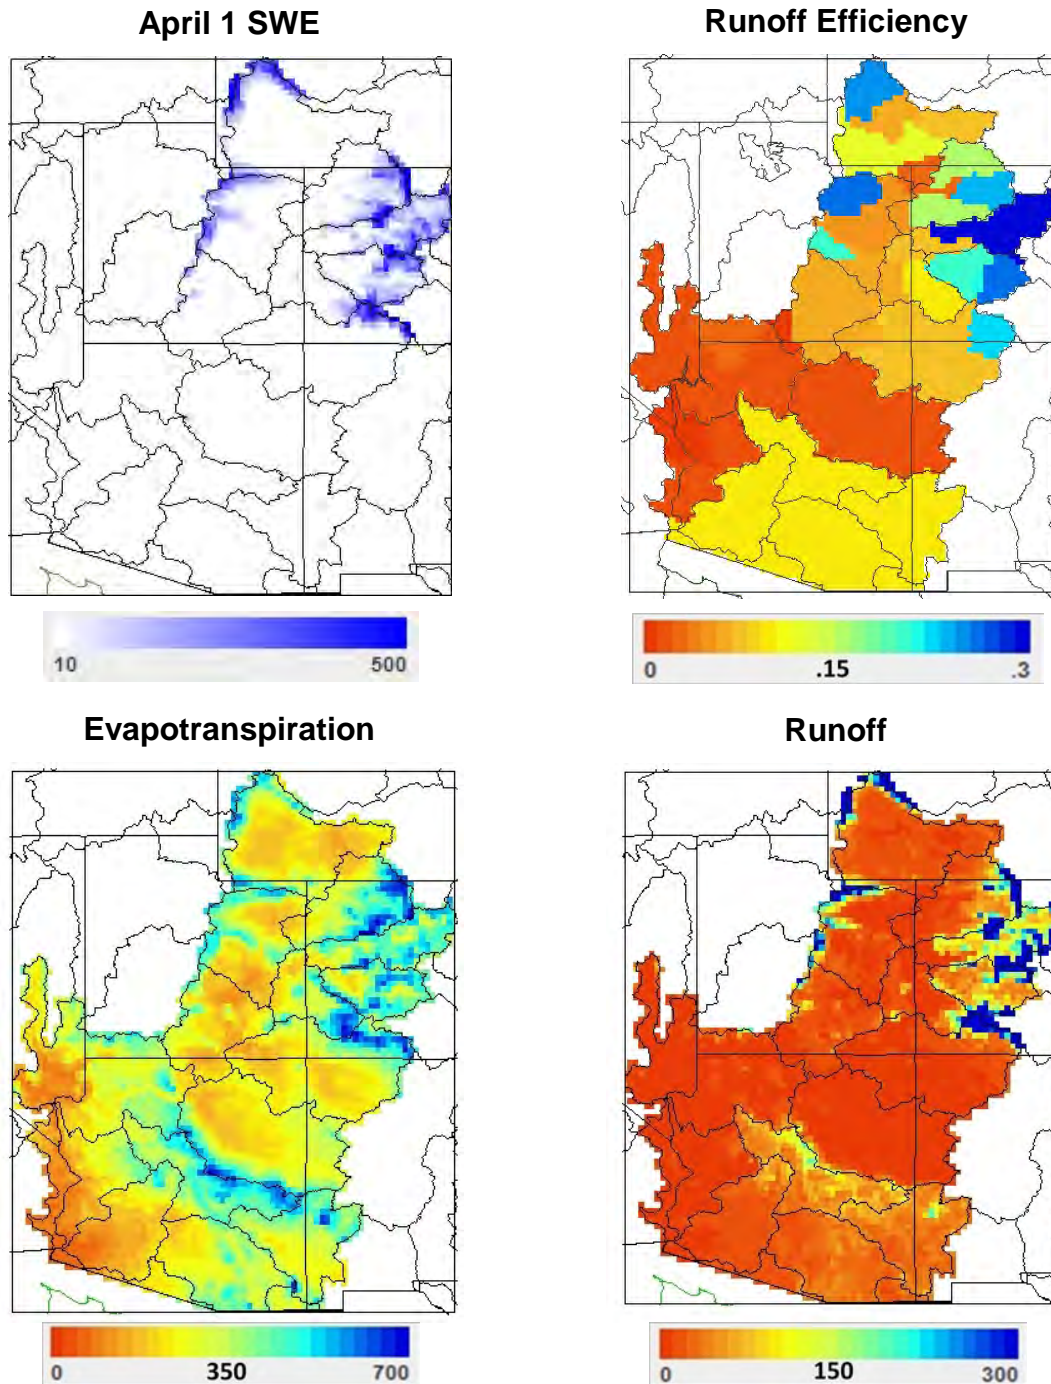

#### **4.2.2 Hydrologic Processes**

The hydrologic processes that describe the interaction between climate and the watershed landscape are critically important in determining water availability and the manner in which the Basin response may change under future climate. The regions of greatest precipitation in the Basin are those at high elevation in the headwaters of the Green, Colorado, and San Juan Rivers. Due to cold temperatures, these areas accumulate substantial snowpack that is critical to the Basin supply. Figure B-8 provides an estimate of the average spatially distributed April 1 SWE for the period 1971–2000 derived from a historical simulation of the VIC hydrology model. Important in this figure is the relatively small portion of the watershed that offers significant seasonal water storage in the form of snowpack. Although snow falls in other portions of the Basin, temperatures are generally not sufficiently cold to retain the snowpack for any great length of time. The remainder of this lower elevation portion of the watershed is primarily dominated by rainfall.

One way to synthesize many complex hydrologic processes at the watershed scale is to introduce the concept of runoff efficiency. Runoff efficiency is a measure of the effectiveness of a particular watershed in converting precipitation into runoff. Watersheds with very high runoff efficiencies dominate the overall contribution toward streamflow and have relatively lower losses. Watersheds with low runoff efficiencies have high losses and tend to be dominated by infiltration to soil moisture and consumptive use through ET. ET is the sum of evaporation from the land surface and plant transpiration. As can be seen in figure B-8, the watersheds with the highest efficiencies are the headwaters of the Colorado, Green, and San Juan Rivers. These watersheds are able to convert about 20–30 percent of the precipitation into runoff and baseflow. However, even in the headwater regions there is considerable variability in runoff efficiencies, with some values less than 10 percent. In the Lower Basin, average runoff efficiencies are all less than 10 percent and many watersheds have runoff efficiencies less than 5 percent. The runoff efficiency Basin-wide is about 12 percent.

ET is the dominant hydrologic flux on the annual scale, consuming more than 70 percent of the precipitation supply. As can be seen in figure B-8, ET is highest in regions with greatest precipitation. This is not to say that the ET demand is highest in these regions, but rather that ET tends to be supply-limited in the Basin. The ET demand (potential ET) is actually higher in the warmer climate of the Lower Basin, but water supply in the form of soil moisture is less and what is available is depleted earlier than in the Upper Basin watersheds.

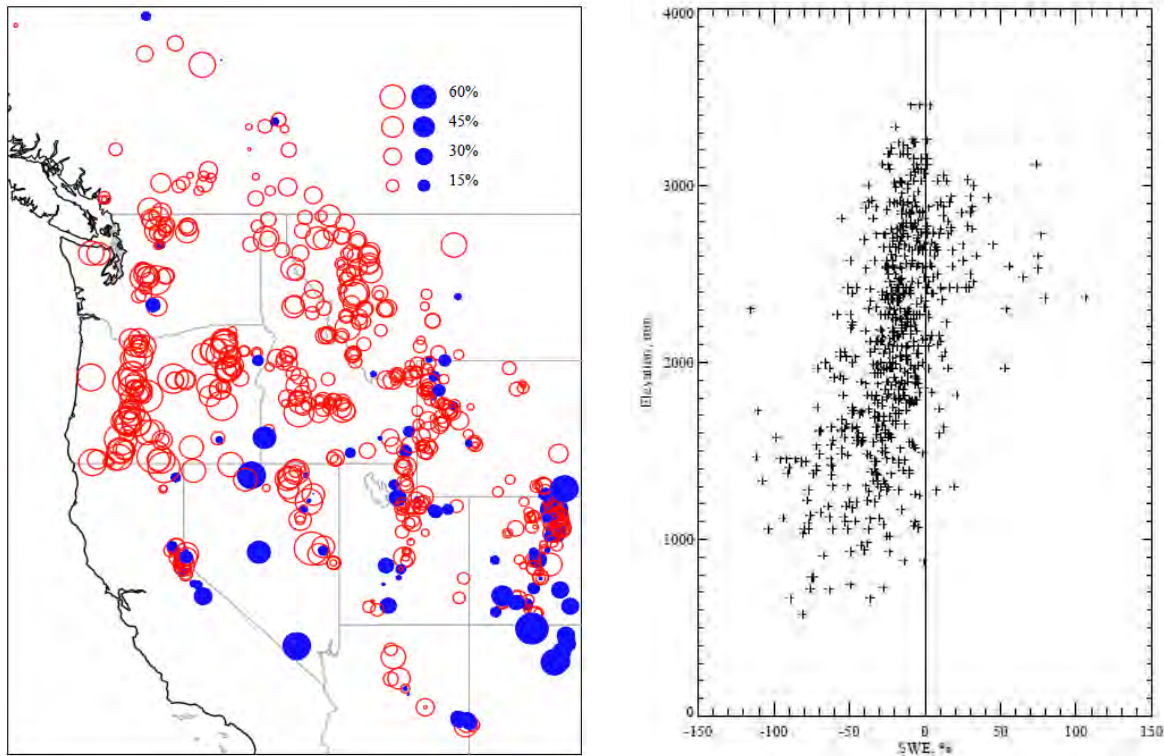

**FIGURE B-8**  
 Estimated Average Annual ET and Runoff (millimeters), April 1 SWE (millimeters), and Annual Average Runoff Efficiency (fraction of precipitation converted into runoff) for 1971–2000  
 Derived from historical VIC simulations.

Previously published research was relied on to assess observed snowpack trends in the Basin. Research by Mote (2003, 2008), Clark et al. (2001), and Cayan et al. (2001) indicate a general decline in April 1 SWE for Pacific Northwest and northern Rocky Mountain locations, and increases in parts of the Great Basin and southern Rockies, as shown in figure B-9.

**FIGURE B-9**

Left panel: Linear Trends in April 1 SWE at 594 Locations in the Western United States and Canada, 1950–2000 (Mote, et al., 2008) (Negative trends are shown by open circles, positive by solid circles.)  
 Right panel: April 1 SWE Trends (1950–2000) Plotted against Altitude of Snow Course (Mote et al., 2008) (Units on y-axis are incorrectly labeled as millimeters [mm] and should be meters.)

Widespread decreases in springtime snowpack are observed with consistent results across the lower elevation northern latitudes of the western United States. The high-elevation Rockies do not consistently produce decreasing trends for SWE. To assess the vertical characteristics of SWE, Mote plotted April 1 SWE trends (1950–2000) against altitude of snow course (figure B-9). Losses of SWE tend to be largest at low elevations and strongly suggest a temperature-related effect.

Finally, Mote et al. (2008) used the VIC model to simulate SWE accumulation and depletion for western U.S. basins. From this analysis, it was clear that changes in SWE are not simply linear, but fluctuate on decadal time scales. SWE was estimated to have declined from 1915 to the 1930s, rebounded in the 1940s and 1950s, and despite a peak in the 1970s, declined since mid-century.

Additionally, recent research demonstrates dust-on-snow events have the ability to alter the timing and magnitude of runoff (Painter et al., 2010). Dust-on-snow events reduce snow albedo, or reflectivity, thereby increasing the solar radiation that reaches and warms the snow, potentially contributing to changes in timing of snowmelt and seasonal streamflows.

### **4.2.3 Climate Teleconnections**

Research indicates a relationship between Pacific Ocean climate indices and Basin streamflow (Redmond and Koch 1991, Webb and Betancourt 1992, Cayan et al. 1999, Mo et al. 2009, and others). The June–November SOI is identified by Redmond and Koch (1991) as

a strong indicator of ENSO events. For the Study, relationships between the PDO and ENSO and natural flows in the Upper Basin were examined. Figure B-10 presents the annual PDO index and indicates when June–November SOI average values are below -1.0 or above 1.0. The solid red bars indicate a positive PDO index, or warm PDO phase, while the solid blue bars indicate the cold PDO phase. The light red and blue shading indicate the SOI condition. Evident in this figure is the low frequency phasing of the PDO (multi-decadal scales) and the significant year-to-year variability in the ENSO events. Indicated by the line on this figure is the 11-year, center-weighted annual flow departure from long-term mean for the Colorado River at Lees Ferry, Arizona. Correlation between the low frequency PDO and decadal scale Colorado River flows appears prominent since the mid-1940s with lower decadal-scale flows during cool PDO phases and higher flows during warm PDO phases. However, significant variability exists even at these scales and prior to the mid-1940s, the correlation is poor.

There are other climate teleconnections that appear to influence multi-decadal variations in precipitation patterns (e.g., AMO) and others that can modify the characteristics of seasonal precipitation (e.g., Madden-Julian Oscillation and Arctic Oscillation) (Becker et al., 2011; Bond and Vecchi, 2003; Hu and Feng, 2010). However, the understanding of the influence of these teleconnections on the Colorado River precipitation, and their usefulness as an indicator, is still evolving.

FIGURE B-10  
Plot of Water-Year Average PDO Values and ENSO Events Defined by SOI Averages for the Period June–November

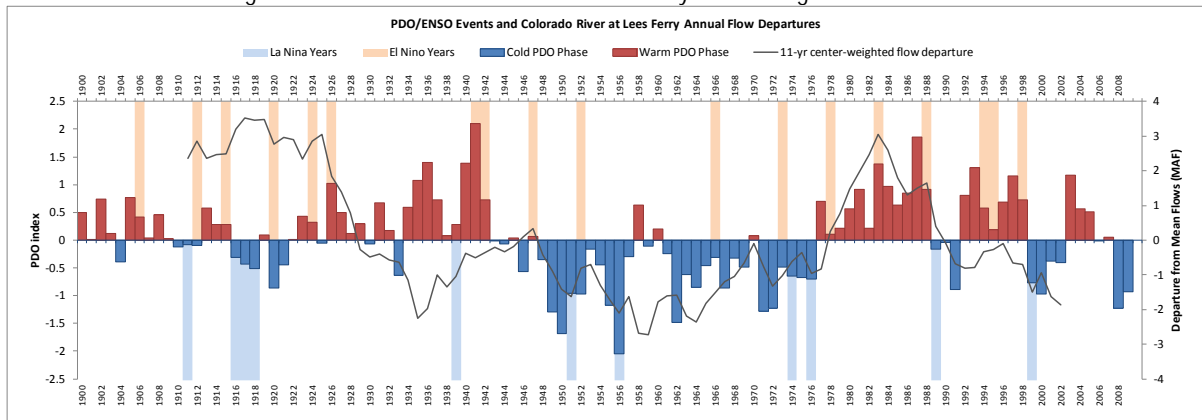

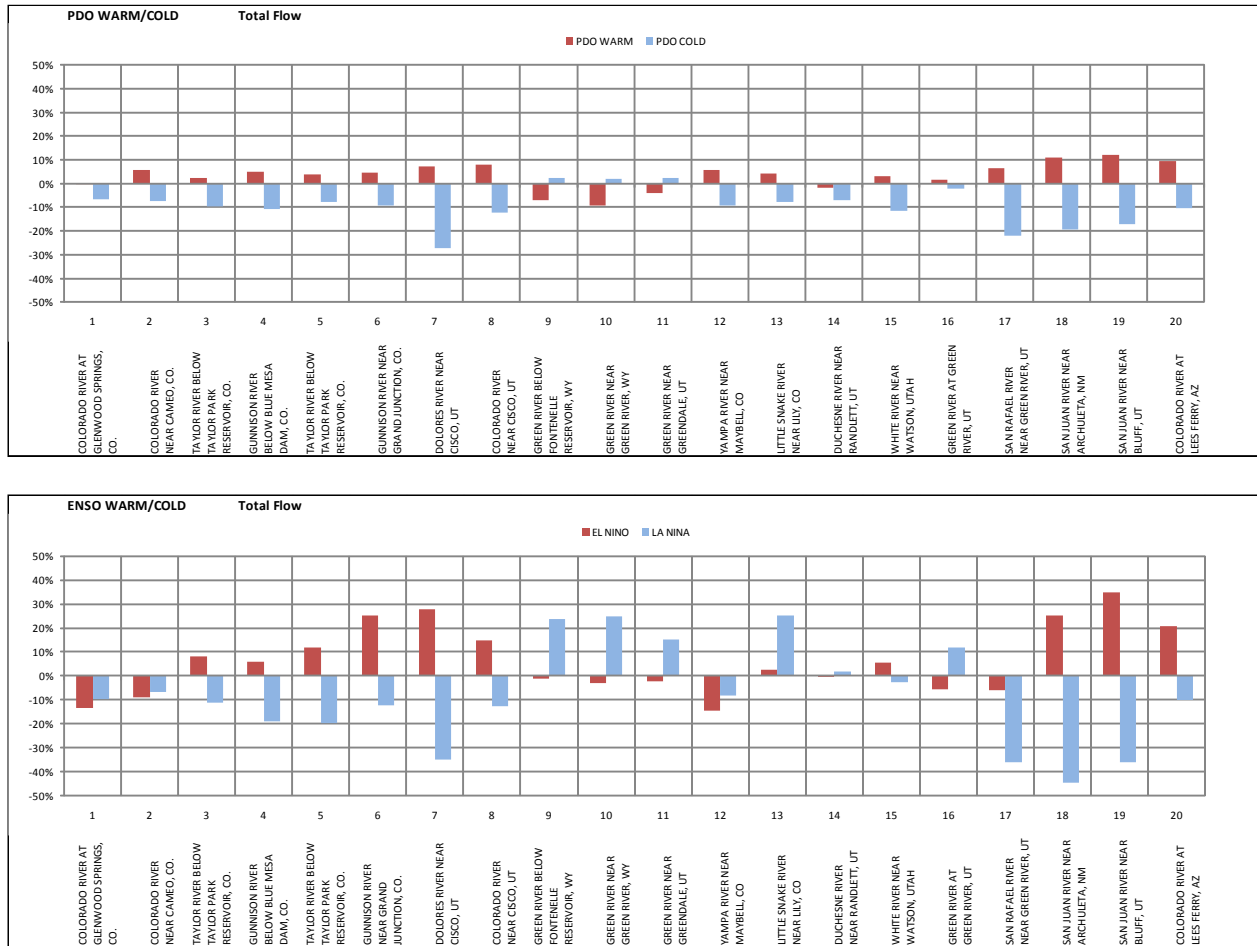

Figure B-11 illustrates water year departure from median streamflows in percent during warm and cold PDO and ENSO periods sampled from the period 1906–2007 for Upper Basin natural flow locations. The red bars indicate the streamflow departures for the warm phase of PDO (top) and ENSO (bottom), while the blue bars reflect the departures during the cool phases. Although significant streamflow variability exists from year to year, the majority of the flows are higher than normal during the warm PDO and ENSO (El Niño) phases. Conversely, the majority of the flows are lower than normal during the cool PDO and ENSO (La Niña) phases. It should be noted that the PDO and ENSO relationship is essentially inverted for the northern Basin in Wyoming (Green River Basin) where flows tend to be higher during the cool PDO and ENSO (La Niña) phase. The dividing line separating typical ENSO influence varies considerably from year to year, but is often referred to as a line from San Francisco to Cheyenne (Edwards and Redmond 2005).

Overall, the natural inter-annual variability in streamflow tends to be more dominant than the relationships to either ENSO or PDO. ENSO has considerably more skill (strength as a

predictor of seasonal precipitation or streamflow) in the coastal watersheds of the Pacific, than over the Basin. PDO, on the other hand, is a low-frequency signal (multi-decadal scale) that limits the number of events that could be correlated. However, it is important to note that in 2011–2012, the climate is entering a strong combined cool phase of both ENSO and PDO. The alignment of both signals in the cool phase suggests a propensity for continued drying trends in the coming years.

**FIGURE B-11**  
Median Change in Flows from Long-term Average for Warm and Cold PDO (top) and ENSO (bottom) Years

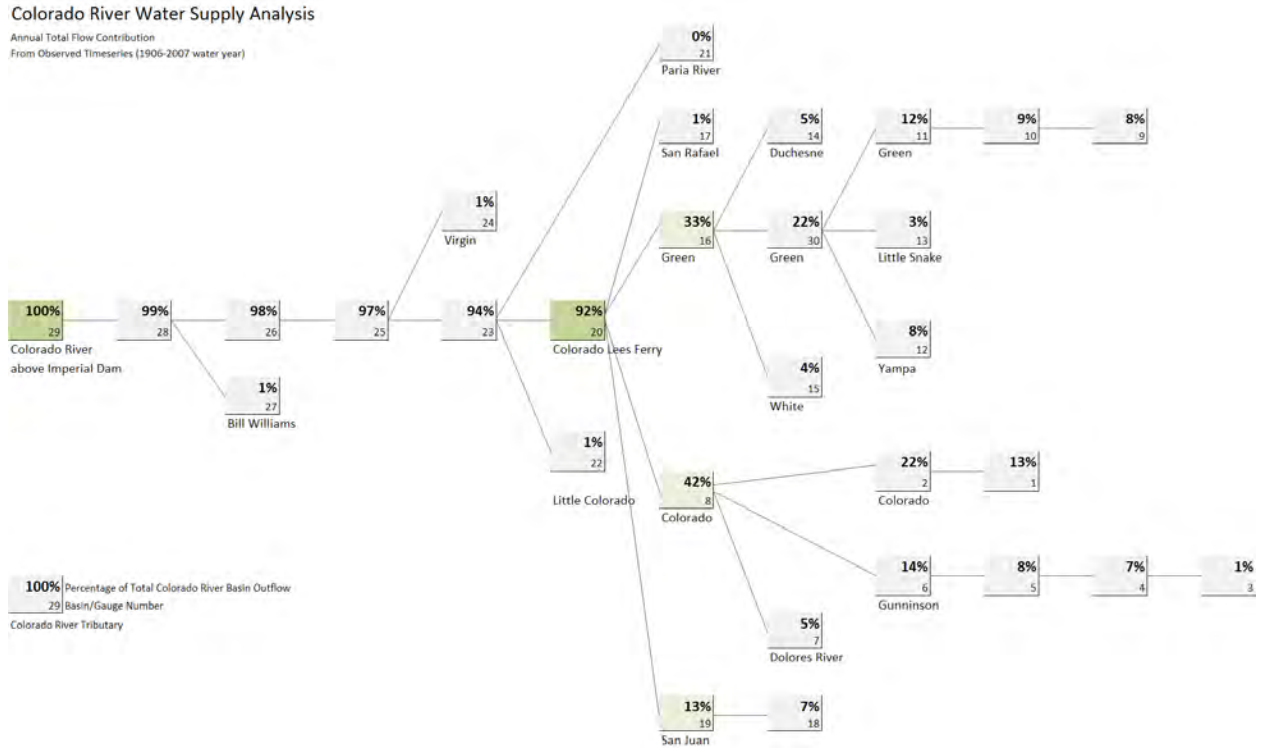

#### 4.2.4 Streamflow

Analysis of streamflow records for the 29 natural flow locations indicated that about 92 percent of the total Colorado River natural flow is contributed by runoff upstream of Lees Ferry, Arizona (figure B-12). As shown graphically in figure B-12, the Green River contributes about 33 percent of the total natural flow, the Colorado River at Cisco, Utah about 42 percent, and the San Juan River about 13 percent based on long-term annual natural flows from 1906–2007. Due to the importance of these rivers to the overall supply, they were selected as key locations for historical assessment. In addition, the Colorado River at Lees Ferry, Arizona is used because approximately 92 percent of the Basin flow has accumulated there.

**FIGURE B-12**

Colorado River Basin Average Annual Natural Flow Contribution (% of total) for each of the 29 Natural Flow Locations *Streamflow derived from the observed period (1906-2007)*. See figure B-2 for names of locations.

The mean annual flows for 1906–2007 at each of the 20 Upper Basin natural flow locations are shown in figure B-13. Also shown is the variability of annual flows as “box-whisker” ranges. The mean annual flow of the Colorado River at Lees Ferry, Arizona (location 20) is approximately 15.0 million acre-feet (maf), but ranged from 5.6 maf (1977) to 25.2 maf (1984) over this period. The upper Colorado River at Cisco, Utah (location 8), Green River at Green River, Utah (location 16), and San Juan River at Bluff, Utah (location 19) have mean annual flows of 6.8 maf, 5.4 maf, and 2.1 maf, respectively.

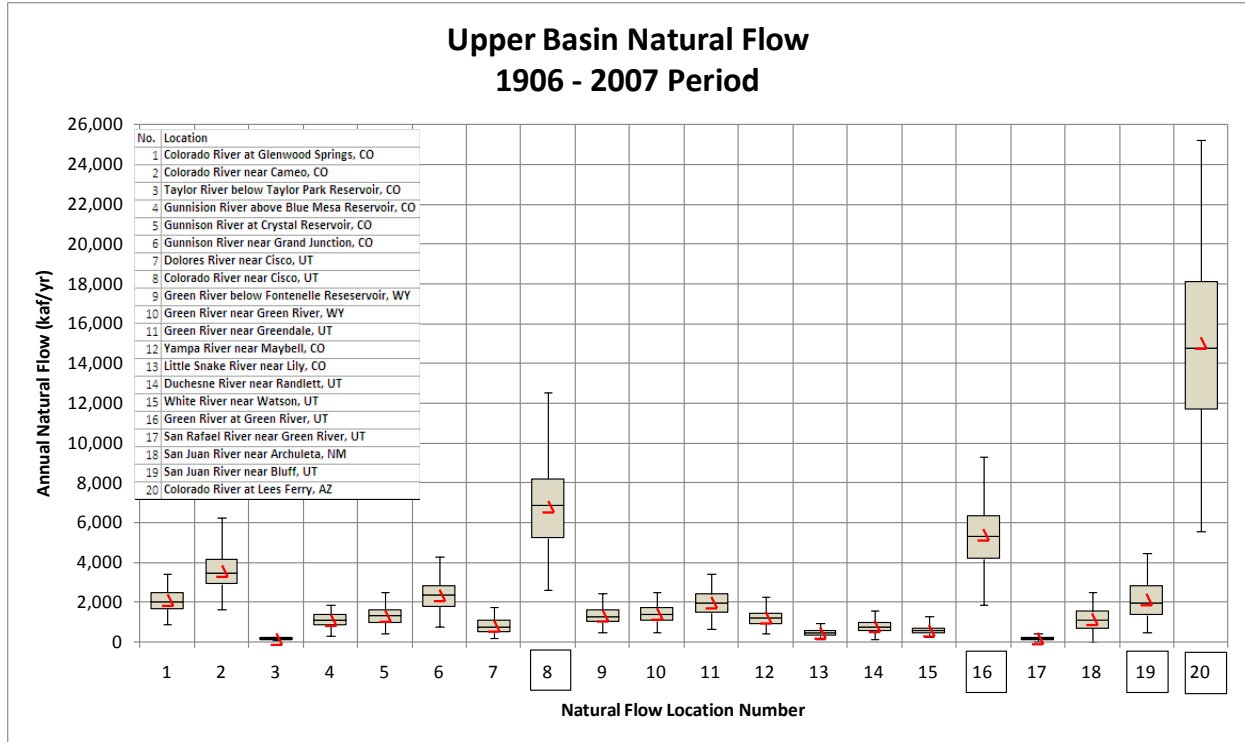

FIGURE B-13

Upper Basin Average Annual Total Natural Flows

Box represents the 25th, 50th, and 75th percentiles; whiskers represent the maximum [max] and minimum [min], and triangle represents the mean flow.

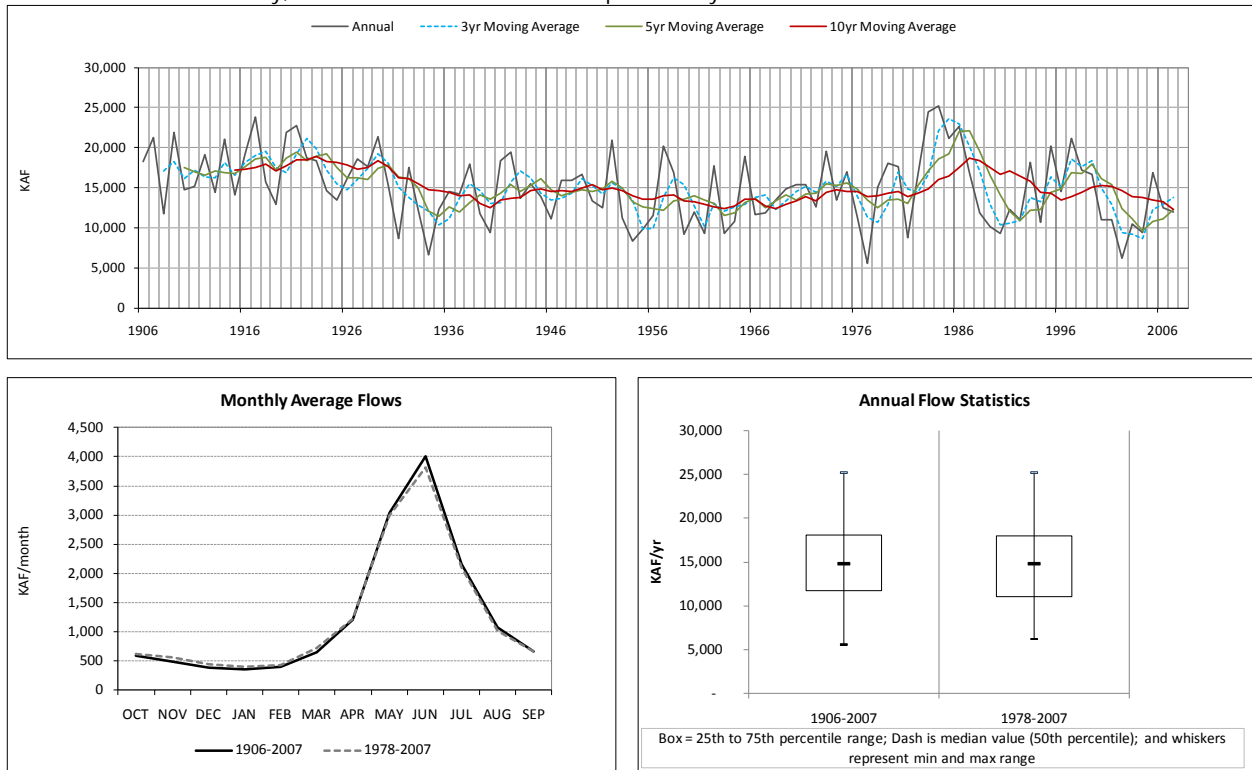

Streamflow derived from the observed period (1906–2007).

Streamflow analysis summaries (“snapshots”) were prepared for all 29 natural flow locations to evaluate the trends and variability of flows. Four snapshot summaries are presented in this report for the following key locations: Colorado River near Cisco, Utah (location 8); Green River at Green River, Utah (location 16); San Juan River near Bluff, Utah (location 19); and Colorado River at Lees Ferry, Arizona (location 20). Additional streamflow analysis figures for each of the major contributing flow locations are included in appendix B5. This supplemental material includes a table reporting specific monthly streamflow averages, annual averages including minimum and maximum values with the years they occurred, and a more-detailed analysis of deficit/surplus periods.

The snapshot results were developed from the natural flows dataset using data for water years 1906–2007 (figures B-14 to B-17). The top plot in each figure shows the annual flow volumes and the moving averages for 3, 5, and 10 years. This plot provides a visual assessment of streamflow variability, minimum and maximum flows, and long-term trends. For most selected locations, more variability and extreme events are observed after 1976. Generally lower flows are observed from the mid 1930s to mid 1960s and a slightly downward trend in flows is observed in all locations for this time period. As an example, the Colorado River at Lees Ferry, Arizona plot (figure B-14) shows a period of generally below average streamflow and a period of moderate variability for the period 1930–1976. Beginning in 1977, streamflow amplitude and variability increased, with a decrease in streamflows beginning in approximately 1986.

**FIGURE B-14**  
 Colorado River at Lees Ferry, Arizona Natural Streamflow Snapshot Analysis

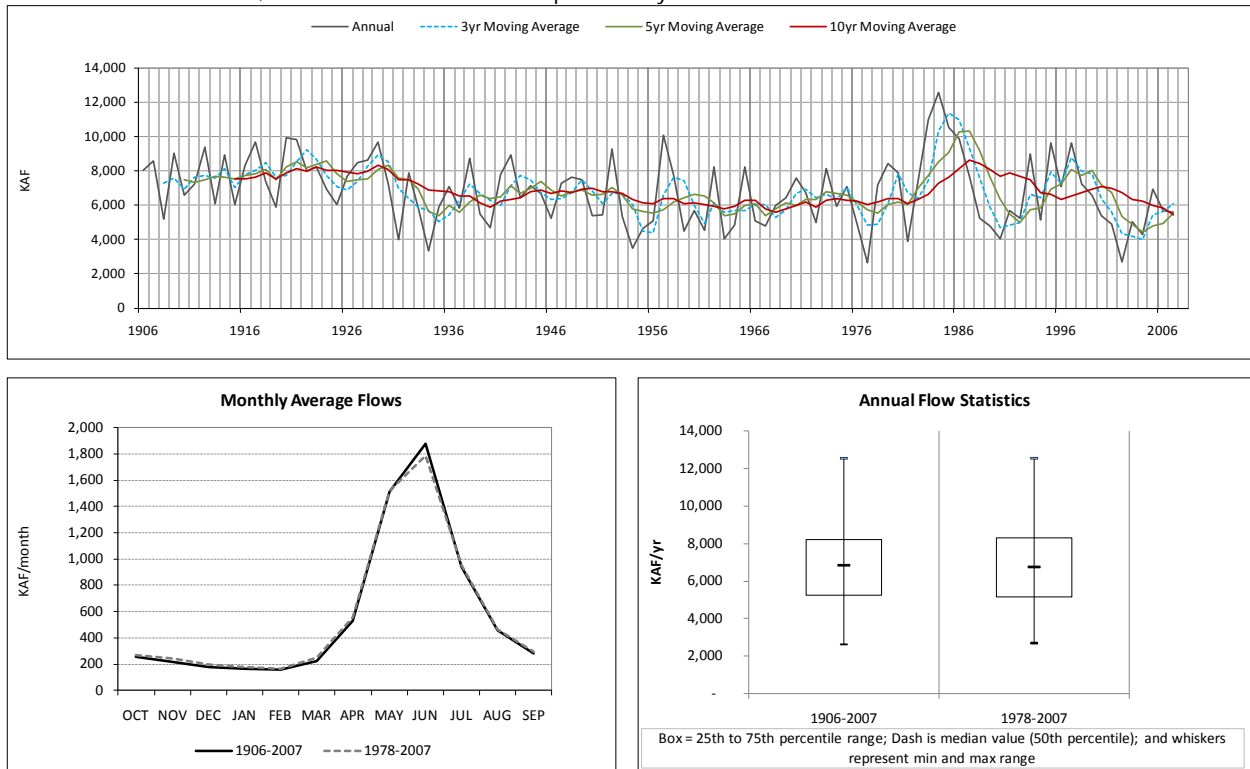

The bottom left plot shows a two-period comparison of monthly average streamflow. The first period spans 1906–2007, while the second period captures the more recent 30-year period, 1978–2007. For the period 1978–2007, all selected locations exhibit a reduction in late spring streamflows and a slight increase in winter streamflows when compared to the long-term (1906–2007) averages. The annual mean flow was slightly lower at most of the Upper Basin locations during the 1978–2007 period, while annual variability, based on the inter-quartile (25<sup>th</sup> to 75<sup>th</sup> percentile) range of flows, was higher during this period. The mean annual flow for the 1978–2007 period is 14.6 maf—about 3 percent lower than the 1906–2007 period mean annual flow of 15.0 maf. The increase in variability can be explained largely by the two significant high-flow periods (the early-mid 1980s and the late 1990s) and the recent extended drought conditions during this period. The two periods show similar maximums and minimums for the 1-, 3-, and 5-year averages because the annual flow extremes (both high and low) have mostly occurred in the most recent 30-year period and are thus represented in both periods (the most recent period is also included in the long-term period). This finding is consistent with precipitation trends that show increased variability in the recent period. However, these changes are not universal. For example, the Colorado River at Cisco, Utah station shows an increase in variability in the more recent period, but also a slight increase in annual mean flow. Conversely, the San Juan River near Bluff, Utah station shows a lower mean flow, but a slightly lower variability in the recent period as compared to the longer 1906–2007 period. The two highest flows at this location occurred in 1941 and 1973.

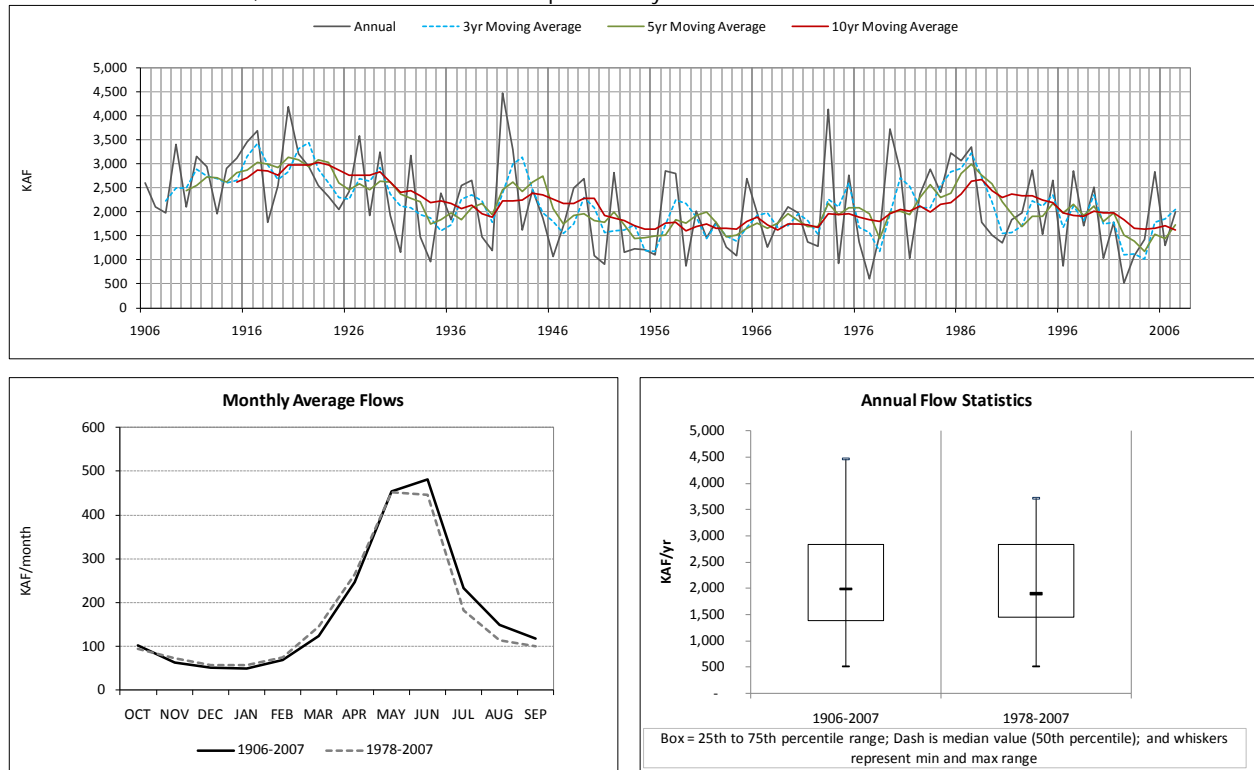

**FIGURE B-15**  
Green River at Green River, Utah Natural Streamflow Snapshot Analysis

**FIGURE B-16**  
Colorado River near Cisco, Utah Natural Streamflow Snapshot Analysis

**FIGURE B-17**  
 San Juan River near Bluff, Utah Natural Streamflow Snapshot Analysis

As with temperature and precipitation, Miller and Piechota (2008) also evaluated streamflow trends and explored the significance of a step change in streamflow, which occurred during the mid 1970s. The step change time series data were divided into the first 69 years of data (1906–1974) and the latter 31 years of data (1975–2005). Increasing streamflow trends in January–March and decreasing streamflow trends during peak runoff months (April–July) were reported in the authors’ study. The authors also note that decreasing streamflow trends were apparent at the 99 percent confidence level throughout the Basin during the traditional peak flow months, despite the high variability of streamflow rates that historically occurred in the Basin (e.g., Pagano and Garen, 2005; Woodhouse and Lukas, 2006). Because streamflow trends are more apparent than precipitation trends, the authors speculate that it is possible that the state (rain or snow) and interaction of precipitation (e.g., evaporation and seepage losses) are changing. Based on these studies, a general warming in the Basin is shifting winter precipitation to a higher rain-snow ratio when compared to historical data. These changes can correspond to earlier peak streamflows in the spring.

The inter-annual variability of climate and hydrology within the Basin produces frequent periods when the mean flow during that period is below the long-term mean. These occurrences are referred to as periods of streamflow deficit or deficits for the purpose of this report. As part of the analysis conducted for this report, different averaging periods for determining and measuring deficits were considered. The use of a 1-year averaging period was discarded because it implied that any 1 year above 15 maf of natural flow at Lees Ferry, Arizona would break a multi-year deficit. The use of a 2-year averaging period implies that it may take 2 consecutive, above-normal years (or 1 extremely wet year) to end a deficit. The definition used in the remainder of this report is the following: a deficit occurs whenever the

2-year average flow falls below 15 maf, the long-term mean annual flow of the 1906–2007 period.

Applying this definition, figure B-18 presents the severity of deficits in the observed record. For each year of the 1906–2010 period<sup>5</sup>, the 2-year running average annual flow was calculated. The difference between the 2-year running average flow and the long-term mean annual flow was computed. If the difference was negative, it was labeled “deficit” and the volumes were accumulated until the difference was once again positive. The deficit length and cumulative amount were recorded for each year. Three significant deficit spells that occurred in the observed period beginning in 1931 (7-year deficit), 1959 (7-year deficit), and 2000 (9-year deficit) are shown on the figure in green, orange, and red, respectively. As can be seen from the figure, the deficit that began in 2000 accumulated a 9-year deficit of more than 28 maf. This recent deficit is more severe than any other deficit in the observed period.

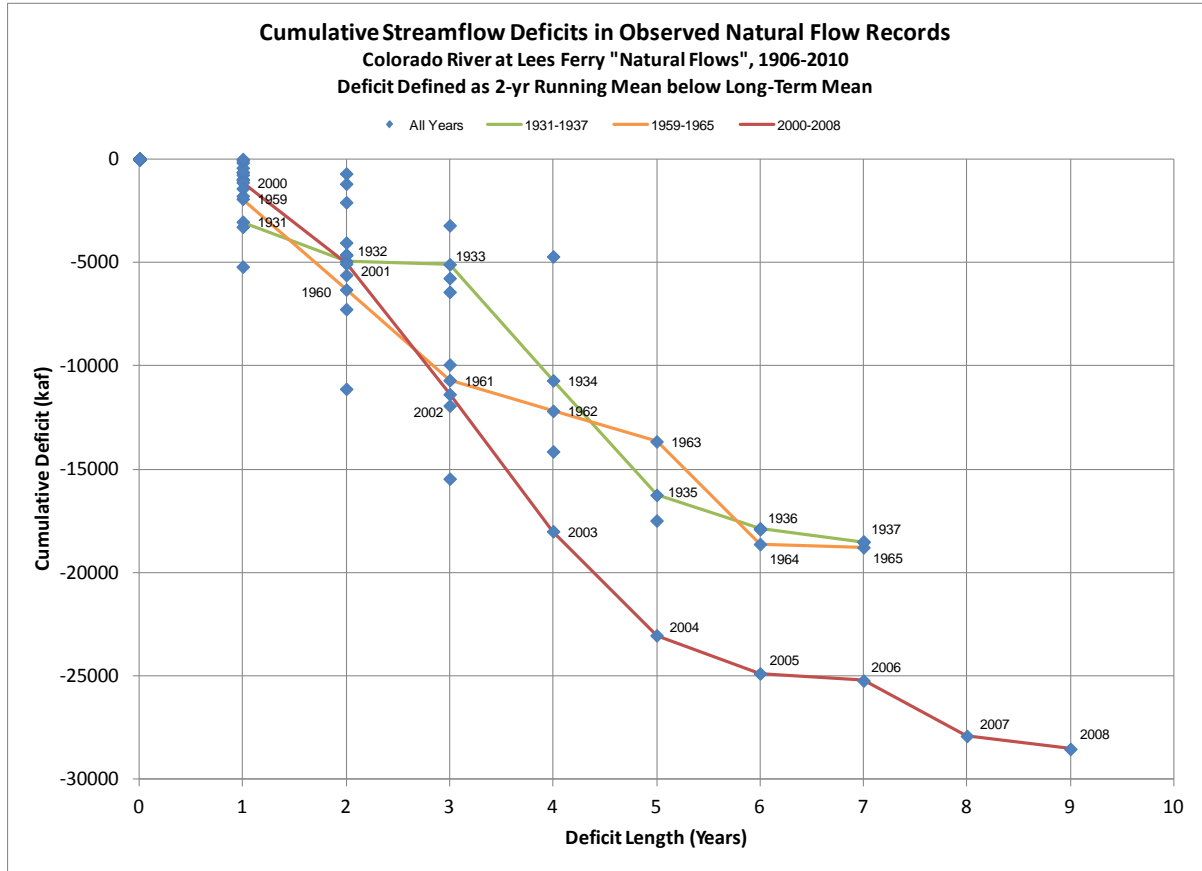

For comparative purposes, the periods of significant surplus (using the 2-year average above 15 maf criteria) occurred in six periods over the 1906–2010 timeframe. With the exception of the 1912–1918 surplus period, the remaining surplus periods were 5 or fewer years in length. The maximum surplus spell was observed during the 1983–1987 period and resulted in a cumulative surplus of about 32 maf. The remaining surplus periods resulted in individual cumulative surpluses of less than 23 maf. For the observational period, surplus periods generally persisted for a shorter duration than the deficit periods.

---

<sup>5</sup>The natural flow at Lees Ferry, Arizona extended to 2010, based on provisional natural flow estimates (James Prairie, Bureau of Reclamation, personal communication, November, 2010), is used here to better reflect the current state of streamflow deficit.

FIGURE B-18

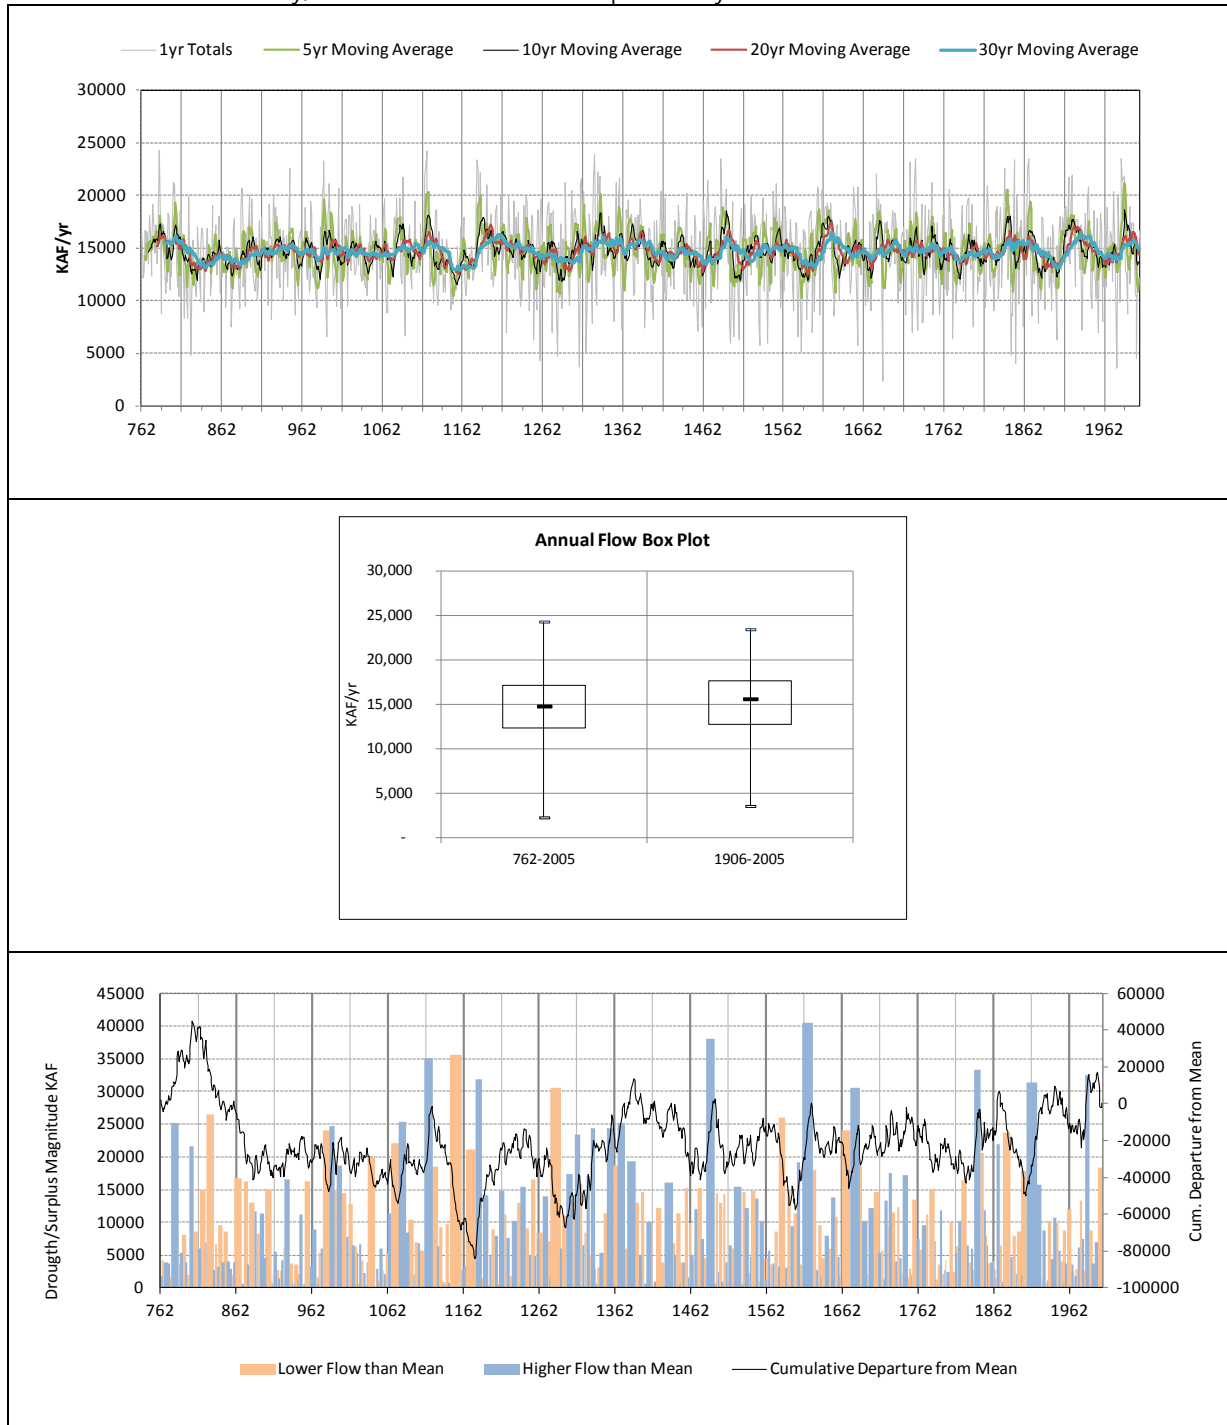

Cumulative Streamflow Deficits (defined as 2-year running mean below 15 maf) for the Colorado River at Lees Ferry, Arizona  
 Note: 2008-2010 natural flows are provisional.

### 4.3 Paleo Reconstruction of Streamflow

A summary of the snapshot results for Colorado River at Lees Ferry, Arizona from the paleo-reconstructed 762–2005 period is shown in figure B-19. The top plot shows the annual flow volumes and the moving averages for 3, 5, 10, 20, and 30 years for the period of record. This plot provides a visual assessment of streamflow variability, minimum and maximum flows, and long-term trends. Period comparisons between long-term paleo reconstruction (762–2005) and a segment of the observed record (1906–2005) are shown. The annual flow box plot shows the minimum, 75th, 50th, and 25th percentiles, and maximum annual streamflows for the two analysis periods. The minimum, 25th percentile, median, and 75th percentile are all slightly less in the paleo reconstructed record, indicating that the paleo reconstructed streamflows are lower than the observed record. Variability is increased in the paleo reconstructed record, as illustrated by the broader inter-quartile range and minimum/maximum values. Finally, the bottom panel shows the annual (left axis) and cumulative (right axis) deviations from the mean annual flow to illustrate the wet and dry periods in this long-term record.

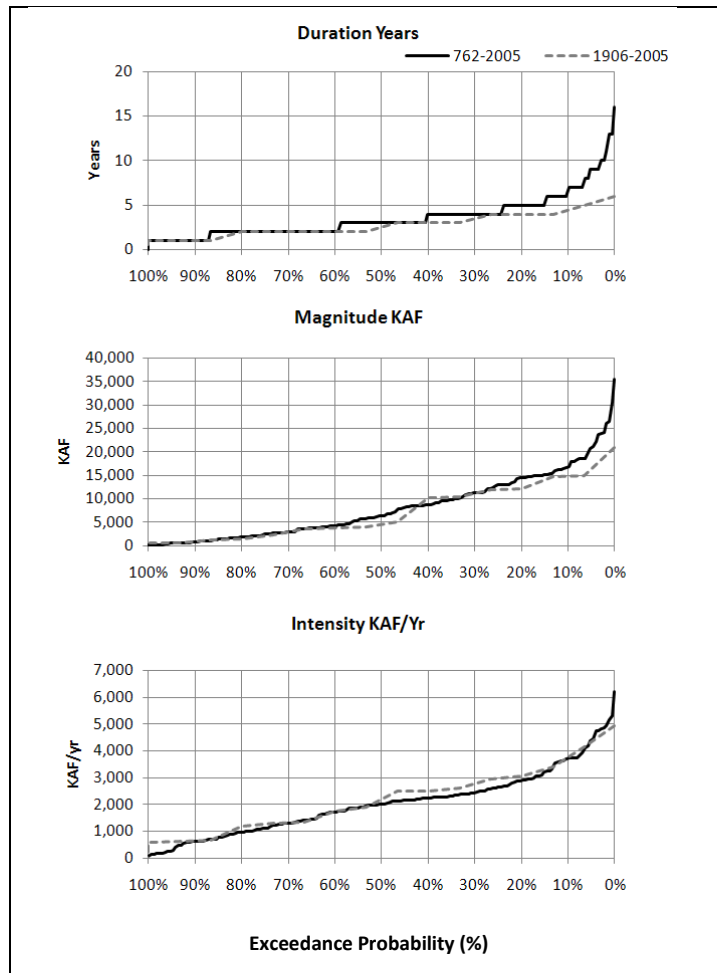

**FIGURE B-19**  
Colorado River at Lees Ferry, Arizona Paleo Streamflow Snapshot Analysis

Streamflow deficits using the same methods as described in the previous section were similarly computed for the 762–2005 period and the 1906–2005 period, and statistics are presented in three exceedance plots (duration, magnitude, and intensity) in figure B-20. The 762–2005 period contains deficits that are longer in duration (16 years) and larger (as much as 35 maf) than those in the 1906–2005 period. Thus, the sequences of wet-dry from the

much longer paleo record suggest that deficits of greater severity than the recent deficit are possible. Interestingly, the deficit intensity (defined as the cumulative deficit divided by the duration of the deficit, which can give an indication of the annual severity of deficits) is similar between the two periods, suggesting that the paleo record produces longer deficits, but that they may not be any more intense on an annual basis than the observed record.

**FIGURE B-20**  
 Comparison of Drought Characteristics between a Segment of the Observed Period (1906–2005) and the Paleo Period (762–2005)

In summary, the trends over the observed period and over the recent climatological regime suggest declining streamflows, increases in variability, and seasonal shifts in streamflow that are likely linked to warming. The paleo reconstruction indicates a slightly lower mean than the observed record. The paleo reconstruction suggests the annual and inter-annual flows have been more variable in terms of both wet and dry sequences, as compared with the observed record period. Deficits of longer duration and greater magnitude can be expected based on the paleo record, although the paleo record shows that past deficits were not significantly more intense than the observed record.

## 5.0 Future Supply under the Observed Resampled Scenario

### 5.1 Methods

Used by Reclamation in several past planning studies, the Observed Resampled<sup>6</sup> scenario is quantified by applying the Indexed Sequential Method (ISM) (Ouarda et al., 1997) to the 1906–2007 observed natural flow record to generate 102 sequences, each 50 years in length. ISM is a stochastic resampling method that creates a number of different future hydrologic sequences (or realizations). The length of the hydrologic sequence is determined by the simulation horizon (2011–2060, or 50 years in the Study) and the number of sequences is determined by the length of the record that is being resampled (1906–2007, or 102 years in this scenario). The ISM cycles through the observed record generating 102 hydrologic sequences, based on the assumption that the record “wraps around” at the end (i.e., 2007, 1906, and 1907).

Strengths of this method are that it is based on the best available measured data, provides the basis for a quantification of the uncertainty and an assessment of risk with respect to future inflows, and is widely accepted by Basin stakeholders. The major drawback of this approach is that future scenarios are limited to the magnitudes and sequencing that occurred in the observed record, with the exception of new sequences generated as a result of the wrap. Therefore, a wider range of plausible future streamflows (including flow magnitudes and wet and dry sequences not seen in the observed record) are not possible in the Observed Resampled scenario.

### 5.2 Results

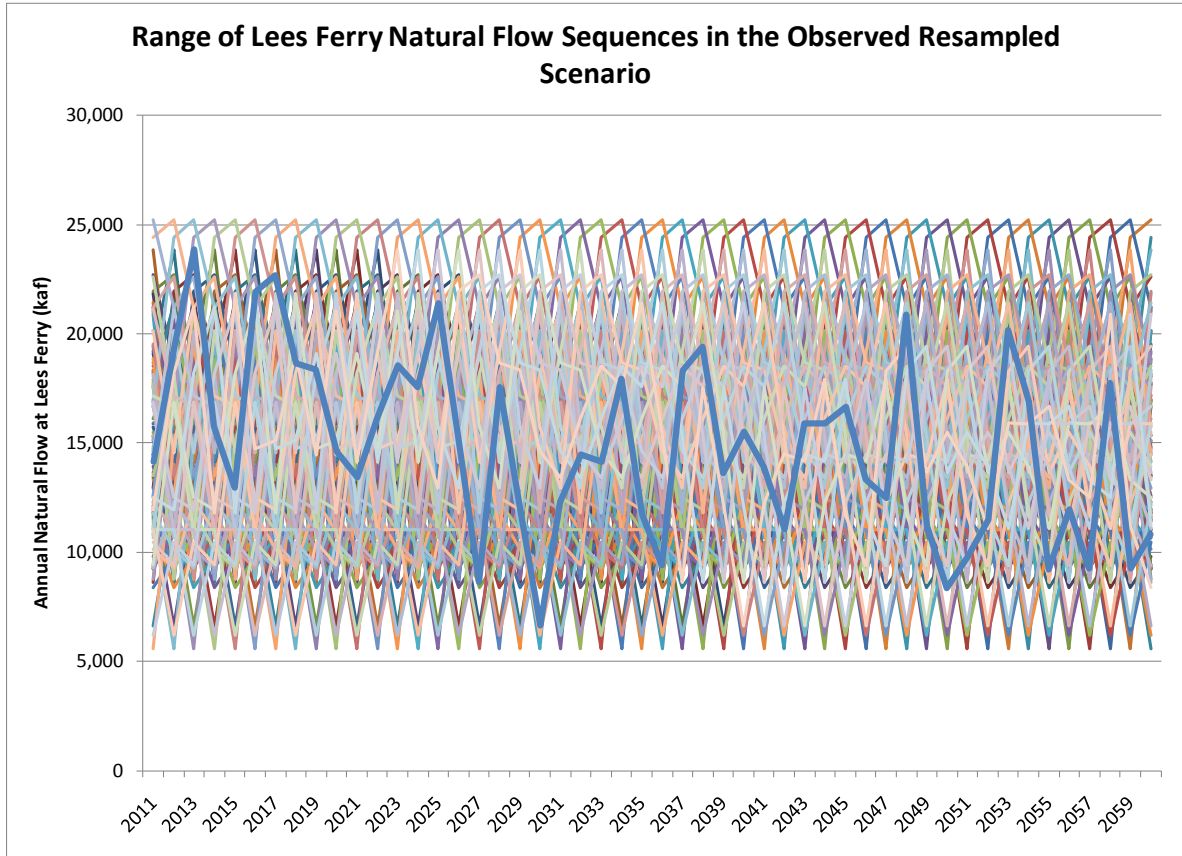

The results for the Observed Resampled scenario are presented as summary figures for annual and monthly flows at Colorado River at Lees Ferry, Arizona in figures B-21 through B-24. Because each supply scenario includes multiple hydrologic sequences, there is a range associated with the flow statistics. Figure B-21 displays all of the individual 102 sequences in the Observed Resampled scenario. The sequence bolded in figure B-21 also appears in figure B-22, which is a representative trace of the 102 sequences for illustration purposes. Figure B-22 depicts the annual range of natural flows when applying the ISM technique, and figure B-23 provides the annual statistics.

Annual natural flows are generally in the range of 5 to 25 maf, with a mean of approximately 15 maf. The standard deviation is almost one-third of the mean annual flow, providing a representation of the inter-annual variability of this flow record. Skew is a measure of the shape of the annual flow distribution. A skew of zero implies a normal distribution in which wetter years and magnitudes are evenly balanced with drier years. The skew and backward lag correlation indicate that the flows are slightly biased to the lower side of the distribution (more dry years than wet years) and that year-to-year correlation of flows is relatively high.

---

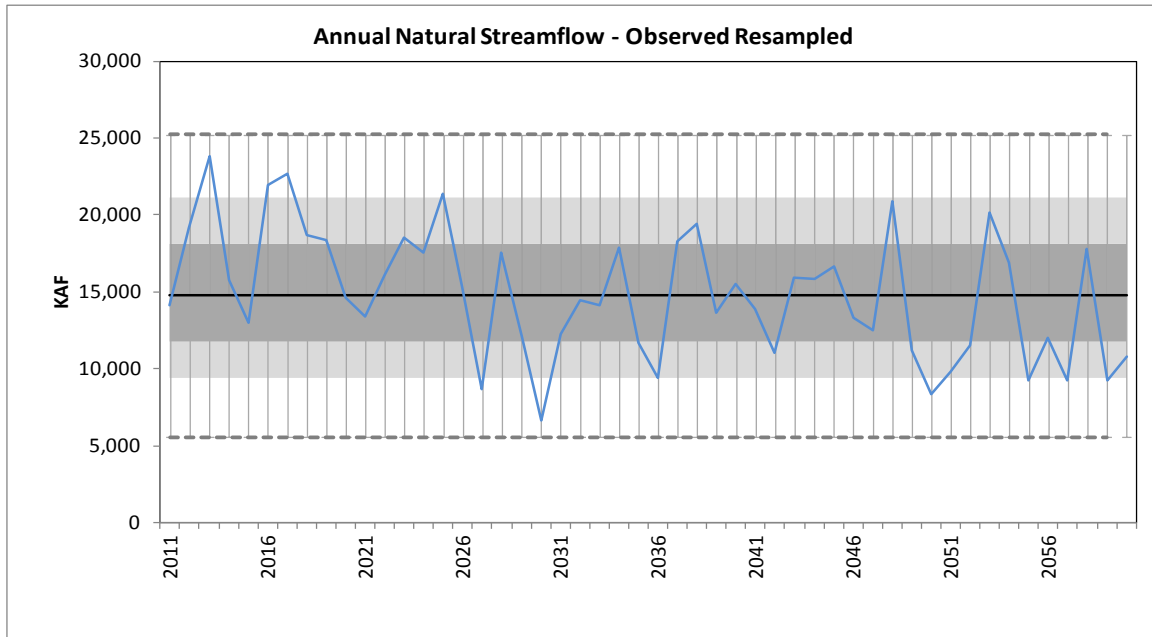

<sup>6</sup>The analysis of the Direct Natural Flow, Direct Paleo, and Nonparametric Paleo Conditioning scenarios discussed in appendix N of the Interim Guidelines EIS are synonymous with the analysis of the Observed Resampled, Paleo Resampled, and Paleo Conditioned scenarios discussed in this report, respectively.

**FIGURE B-22**

Simulated Annual Colorado River at Lees Ferry, Arizona Natural Flow Statistics for 102 Realizations, 2011–2060  
 Figure shows the median (line), 25th – 75th percentile band (dark shading), 10th – 90th percentile band (light shading), max/min (whiskers), and 1906–2007 observed min and max (dashed lines). The bolded line indicates a representative trace.

**FIGURE B-23**

Summary Statistics for Annual Colorado River at Lees Ferry, Arizona Natural Flows for the Observed Resampled Scenario  
 Figure shows the median (dash), 25th – 75th percentile band (box), and max/min (whiskers).

River flow peaks in late spring due to delayed snowmelt from the higher elevation upstream watersheds, with May, June, and July exhibiting the highest flows (figure B-24). June flows are both the highest and most variable with mean monthly flows averaging about 4 maf/month and ranging from about 1 to 9 maf/month. Late summer and fall flows are considerably lower and exhibit significantly less variability.

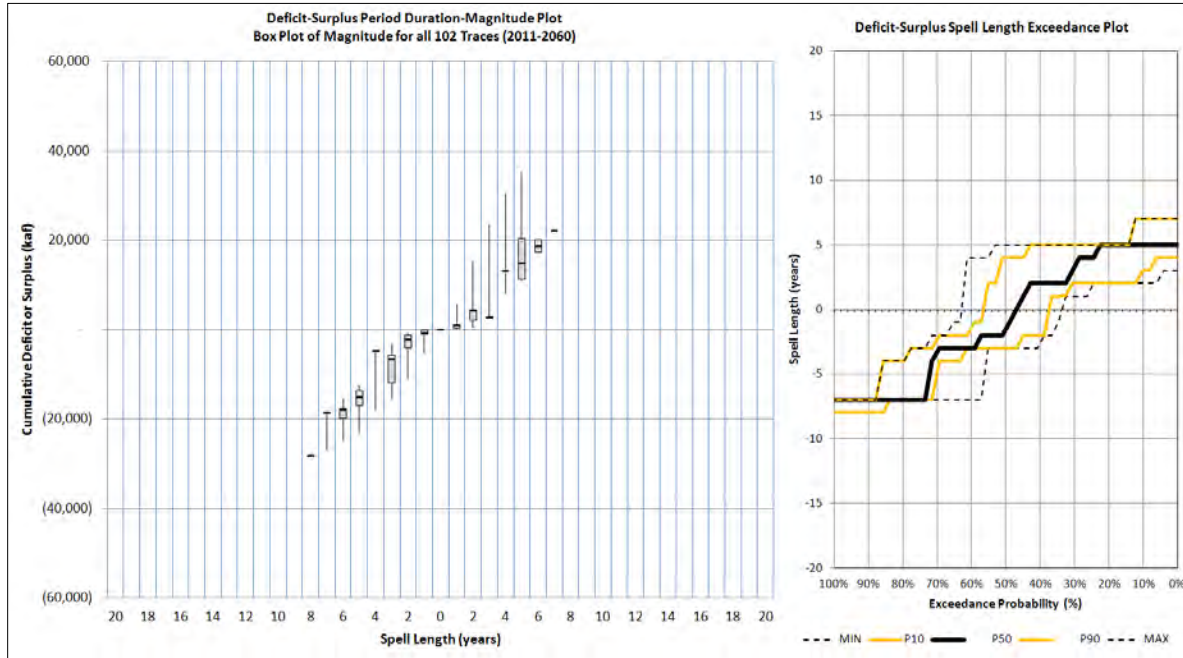

**FIGURE B-24**  
 Simulated Monthly Colorado River at Lees Ferry, Arizona Natural Flow Statistics for 102 Realizations, 2011–2060  
 Figure shows the median (dash), 25th – 75th percentile band (shading), and max/min (whiskers).

Another measure of the inter-annual variability and persistence of streamflow states (wet and dry) is characterized by determining the frequency, duration, and magnitude of deficit and surplus periods. Recall that for the purpose of this report, “deficit” is defined as a consecutive 2-year period when the mean is less than the observed long-term mean of 15.0 maf. Similarly, “surplus” is defined as a consecutive 2-year period when the mean is above 15.0 maf.

Figure B-25 illustrates four characteristics of deficit and surplus spells throughout the Study period (2011–2060): spell length, spell magnitude, the frequency of specific spell lengths occurring, and the relationship between deficits and surpluses in the scenario. Box plots displaying spell length are shown in the left figure (deficit, below the x-axis, and surplus, above the x-axis). The exceedance plot shown in the right figure displays the exceedance probabilities for spell lengths. Probabilities for deficit spells are shown in the bottom half of the plot. Probabilities for surplus spells are shown in the top half of the plot.

**FIGURE B-25**  
 Simulated Deficit and Surplus Spell Length and Magnitude for all 102 Realizations in the Observed Resampled Scenario  
*Box plots show the median (dash), 25th – 75th percentile band (shading), and max/min (whiskers).*

Spell length: the maximum deficit is 8 years (note that this length would be 9 years if the observed record extended through 2010), and the maximum surplus is 7 years. This information is provided in both the box plots and the exceedance plot.

Spell magnitude: referring to the box plots, the magnitude of the maximum deficit and surplus is about 27 maf and 22 maf, respectively. Deficit or surplus intensity can be computed by dividing the spell magnitude by the spell length.

Frequency of specific spell lengths occurring: the exceedance plot inset provides information regarding the frequency of the length of deficit and surplus spells. As such, the median exceedance probability of a deficit spell of 5 years is about 70 percent, meaning there is about a 30 percent chance of a deficit longer than 5 years. Similarly, at the 30 percent median exceedance probability is a surplus spell of 3 years, meaning there is about a 30 percent chance of a surplus period lasting more than 3 years.

Relationship between deficits and surpluses in the scenario: the median (50 percent exceedance probability) corresponds to a deficit of 3 years. This result indicates that under the Observed Resampled scenario, there is a greater probability of being in a deficit (lasting at least 3 years) than in a surplus period.

## 6.0 Future Supply under the Paleo Resampled Scenario

### 6.1 Methods

The Paleo Resampled scenario is generated by applying the ISM to paleo reconstructed streamflow data (762–2005) to develop 1,244 traces, each 50 years in length. The major

strength of this method is the ability to produce sequences with magnitudes and deficit/surplus spells not found in the Observed Resampled scenario. In addition, as is true for the Observed Resampled scenario, this method is based on measured data. Although there is a wealth of literature documenting the strong link between streamflow and tree-ring growth in moisture limited regions, the exact magnitudes of a paleo reconstruction are not as reliable as historical flow data, particularly at the extremes, such as at the higher and lower flows (Woodhouse and Brown, 2001). This is attributed to a variety of factors in the reconstruction process, such as model selection to relate tree-ring width to streamflow. Furthermore, because ISM sequentially resamples the paleo record to generate hydrologic sequences, the sequences will only consist of flow magnitudes and sequences that are present in the paleo record, with the exception of the sequences created as a result of the wrap. The inclusion of the paleo conditioned scenario addresses this issue and the weakness of the paleo record in capturing magnitudes at the extremes.

Because the paleo flow data are only available at the annual time step for a single location (Colorado River at Lees Ferry, Arizona), annual flows at this location were disaggregated, spatially and temporally, throughout the Upper Basin natural flow locations using a non-parametric disaggregation method (Nowak et al., 2010). The disaggregation method relies on the observed record to model the spatial and temporal distribution properties of the monthly and annual flow. Disaggregated flows at the Lower Basin natural flow locations are generated by selecting an “analog” year from the observed record. For a more detailed explanation of these methods, please see Nowak et al., 2010 and appendix N of the 2007 Interim Guidelines Final EIS (Reclamation 2007).

## **6.2 Results**

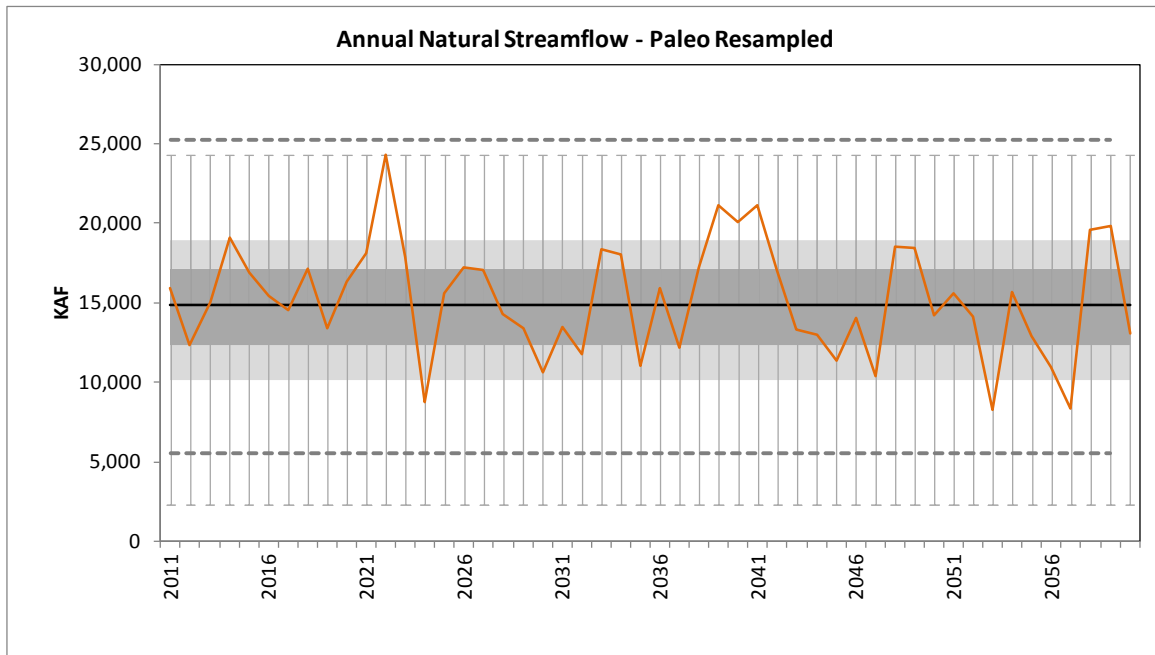

The results for the Paleo Resampled scenario are presented as summary figures for annual and monthly flows for the Colorado River at Lees Ferry, Arizona in figures B-26 through B-29. As with the Observed Resampled scenario, multiple realizations are simulated, producing a range associated with the flow statistics. Figure B-26 displays all of the individual 1,244 sequences in the Paleo Resampled scenario. The sequence bolded in figure B-26 also appears in figure B-27, which is a representative trace of the 1,244 sequences for illustration purposes. Figure B-27 depicts the annual range of natural flows, while figure B-28 provides the annual statistics.

Annual natural flows are generally in the range of 3 to 25 maf, with a mean of approximately 14.7 maf. The minimum annual flow is much lower than the Observed Resampled scenario, while the maximum annual flow is similar. Conversely, the standard deviation is smaller than the Observed Resampled scenario, suggesting that a greater number of traces are closer to the mean value. In the Paleo Resampled scenario, the skew is slightly negative (compared to slightly positive in the Observed Resampled scenario), suggesting a greater frequency of wet years than dry years (compared to the Observed Resampled scenario). Finally, the backward lag correlation is slightly higher than the Observed Resampled scenario, suggesting a greater year-to-year correlation than in the observed record. The latter likely results from the reconstruction techniques and relatively few chronologies in the distant past.

**FIGURE B-26**  
 Colorado River at Lees Ferry, Arizona Natural Flow for 1,244 Sequences for the Paleo Resampled Scenario  
*The bolded line indicates a representative trace.*

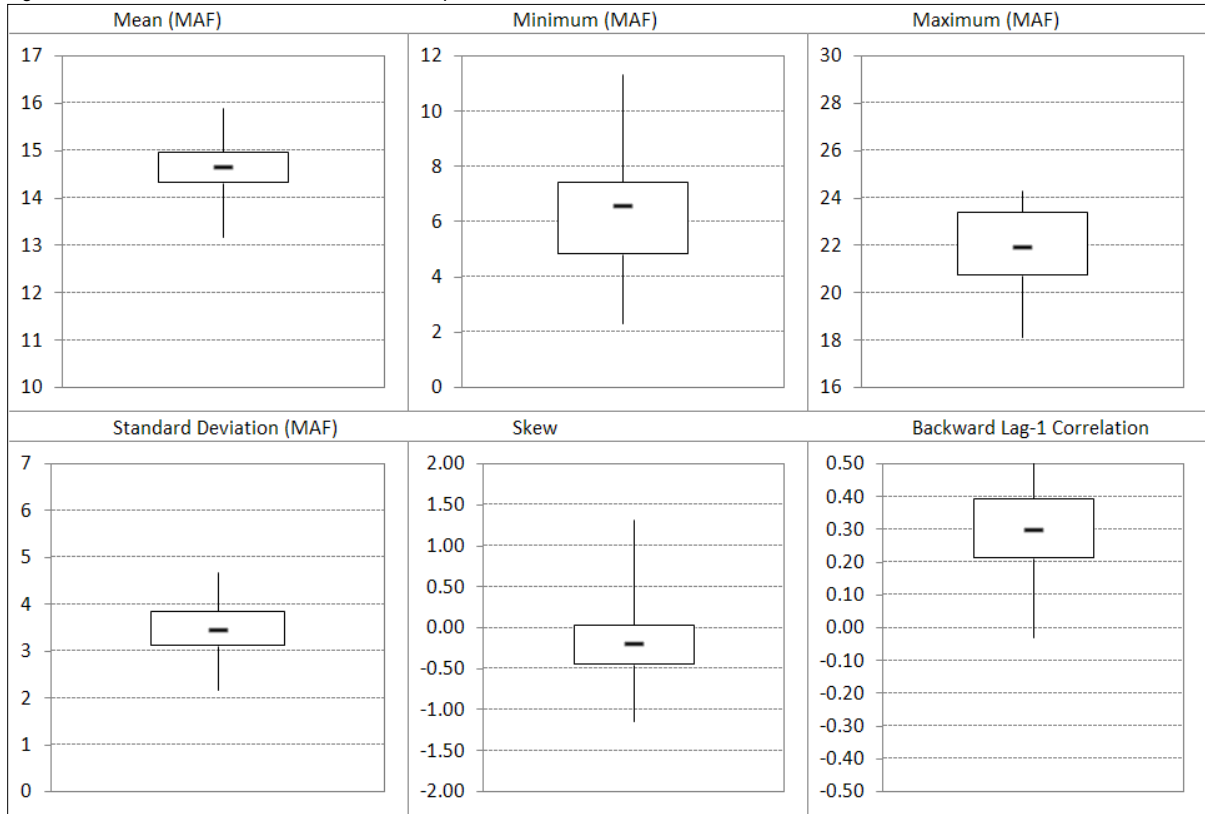

**FIGURE B-27**  
 Simulated Annual Colorado River at Lees Ferry, Arizona Natural Flow Statistics for 1,244 Traces, 2011–2060  
*Figure shows the median (line), 25th – 75th percentile band (dark shading), 10th – 90th percentile band (light shading), max/min (whiskers), and 1906 – 2007 observed min and max (dashed lines). The bolded line indicates a representative trace.*

**FIGURE B-28**

Summary Statistics for Annual Colorado River at Lees Ferry, Arizona Natural Flows for the Paleo Resampled Scenario  
*Figure shows the median (dash), 25th – 75th percentile band (box), and max/min (whiskers).*

Monthly river flows suggest no significant change from the Observed Resampled scenario. Peak flows occur in late spring, with May, June, and July exhibiting the highest flows (figure B-29). As in the Observed Resampled scenario, June flows are both the highest and most extreme, with mean monthly flows averaging about 4 maf/month and ranging from about 1 to 9 maf/month. This was expected because the disaggregation applied to the annual paleo reconstruction was trained on the observed natural flow data. Also similar to the Observed Resampled scenario, late summer and fall flows are considerably lower and exhibit significantly less variability.

**FIGURE B-29**

Simulated Annual Colorado River at Lees Ferry, Arizona Natural Flow Statistics for 1,244 Realizations, 2011–2060  
*Figure shows the median (dash), 25th – 75th percentile band (shading), and max/min (whiskers).*

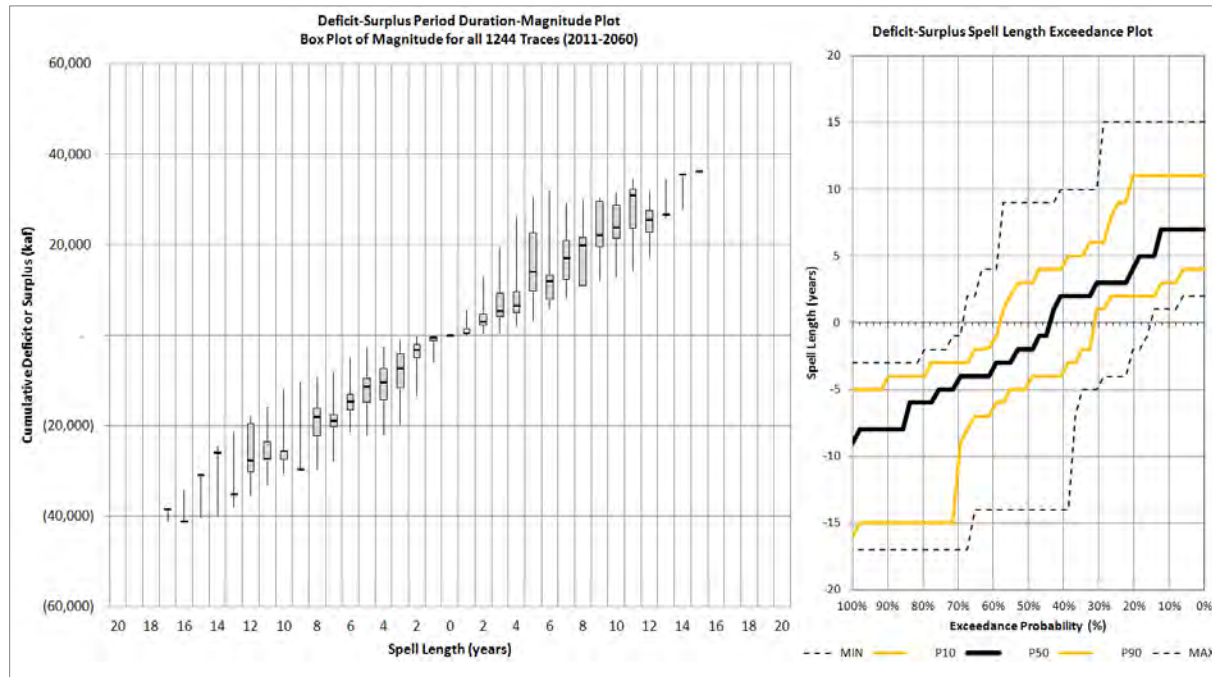

Figure B-30 illustrates the length, magnitude, and frequency of deficit and surplus spells. Under the Paleo Resampled scenario, maximum deficit and surplus periods are significantly longer in duration than those in the Observed Resampled scenario. Maximum deficit spell length under the Paleo Resampled scenario is about 17 years, and the maximum surplus spell length is about 15 years. The 17-year deficit period contains approximately 30 to 40 maf of total deficit. For comparison, the recent deficit persisted for 9 years (through 2008) with an accumulated deficit of about 29 maf. Thus, from a measure of deficit intensity, although the deficit is sustained longer in the Paleo Resampled scenario, the annual deficits are not dissimilar from the Observed Resampled scenario.

**FIGURE B-30**  
 Simulated Deficit and Surplus Spell Length and Magnitude for all 1,244 Realizations in the Paleo Resampled Scenario  
 Box plots show the median (dash), 25th – 75th percentile band (shading), and max/min (whiskers).

## 7.0 Future Supply under Paleo Conditioned Scenario

### 7.1 Methods

The Paleo Conditioned scenario is generated by applying a non-parametric technique to “blend” the observed historical and paleo reconstructed records to generate 1,000 traces, each 50 years in length. Flow magnitudes vary significantly across multiple reconstructions for a particular site (Stockton and Jacoby, 1976; Hildalgo et al., 2000; Hirschboeck and Meko, 2005; and Woodhouse et al., 2006). However, the paleo hydrologic state agreement (i.e., wet or dry) is quite reliable across different reconstructions (Woodhouse et al., 2006).

The paleo conditioned technique blends the rich variety of drought/surplus found in the paleo reconstruction with reliable magnitudes from the observed natural flow data by first extracting a sequence of years represented simply as wet or dry from the streamflow reconstruction. Flow magnitudes are then conditionally resampled from the observed record for each year in the sequence, based on the current and previous hydrologic state. Thus, any

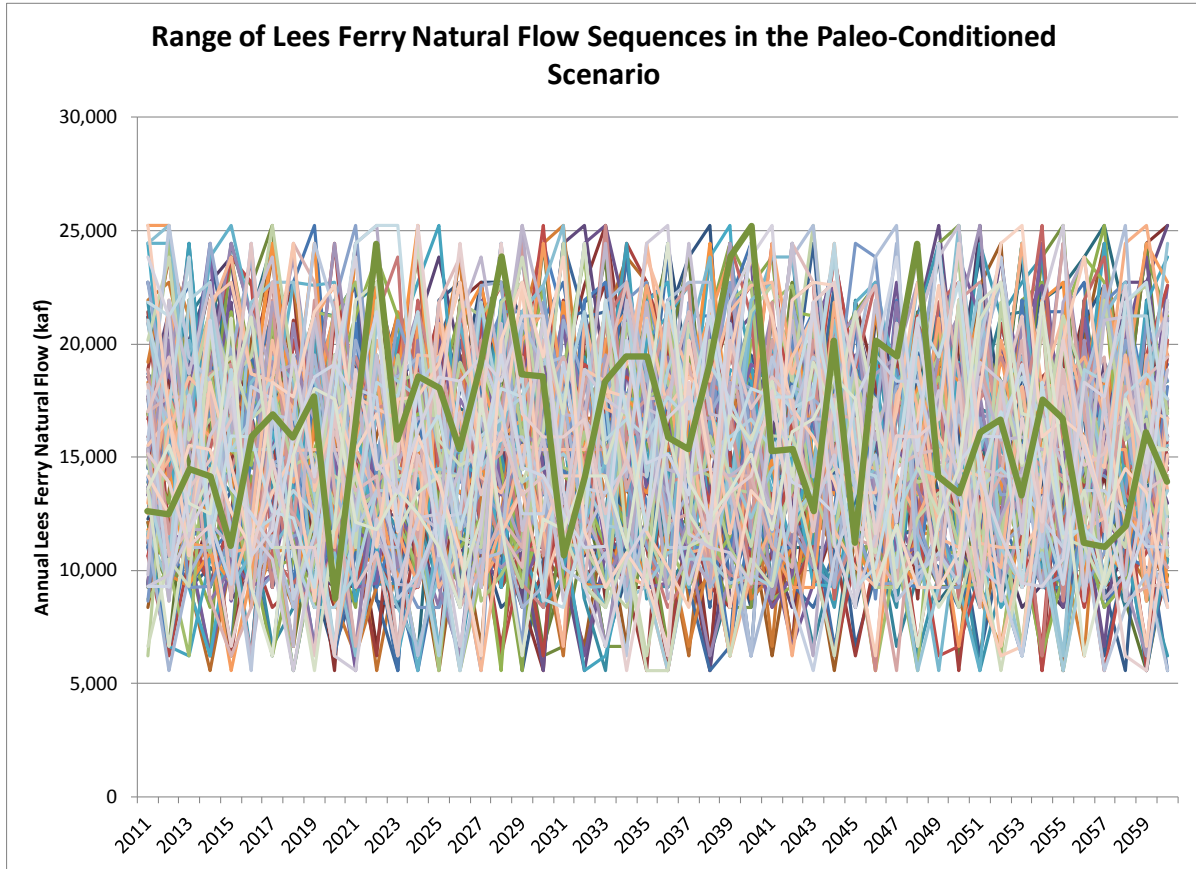

underlying relationship between magnitude and sequencing is preserved while circumventing issues associated with magnitude reliability. For example, if an observed flow value occurred as the first year of a drought, it can only be assigned to a “dry state year” that was preceded by a “wet state year” as part of a paleo conditioned trace. Similarly, if an observed flow magnitude was the second year of a multi-year surplus period, that value can only be assigned to a “wet state year” that was preceded by another “wet state year.” This logic holds true for all wet/dry sequencing combinations. Following this method, a wealth of traces can be generated (at least 1,000 are recommended to limit sample variability) by simply changing the initial wet/dry sequence information extracted from the paleo data. Different from the ISM technique, the number of sequences is not limited to the length of the streamflow record being resampled. For a more detailed explanation of the method, see appendix N of the 2007 Interim Guidelines Final EIS and Prairie et al., 2008. As was the case with the Paleo Resampled scenario, the Paleo Conditioned scenario introduces considerable variability when compared with the observed data, yet maintains the reliability of the observed magnitudes. Paleo conditioned traces were also generated at the annual time scale for Colorado River at Lees Ferry, Arizona and required the same disaggregation process employed for the Paleo Resampled scenario in order to produce monthly data at multiple locations.

## **7.2 Results**

The results for the Paleo Conditioned scenario are presented as summary figures for annual and monthly flows at Colorado River at Lees Ferry, Arizona in figures B-31 through B-34. Figure B-31 displays all of the individual 1,000 sequences in the Paleo Conditioned scenario. The sequence bolded in figure B-31 also appears in figure B-32, which is a representative trace of the 1,000 sequences. Figure B-32 depicts the annual range of natural flows, and figure B-33 provides the annual flow statistics.

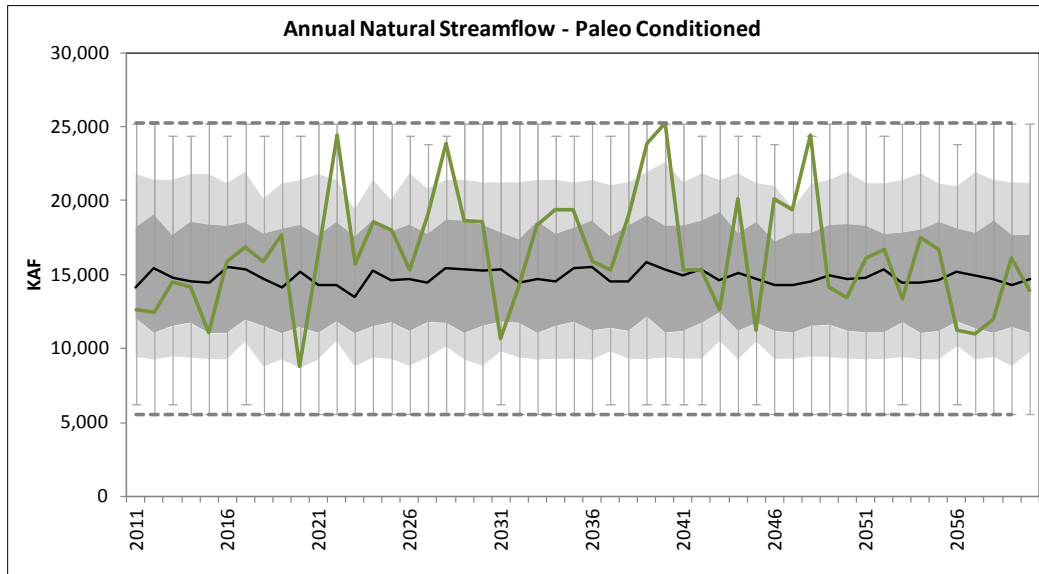

Annual natural flows are generally in the range of 5 to 25 maf, with a mean of approximately 14.9 maf. The annual statistics are similar to the Observed Resampled scenario, largely due to the paleo conditioned technique that borrows the magnitudes from the observed record when combining with state information from the paleo reconstructions. Similarly, the standard deviation, skew, and backward lag correlation indicate that the annual flow statistics are similar to the Observed Resampled scenario. Monthly flows are also similar in pattern and magnitude to the Observed Resampled and Paleo Resampled scenarios, as shown in figure B-34.

**FIGURE B-31**  
 Colorado River at Lees Ferry, Arizona Natural Flow for 1,000 Sequences for the Paleo Conditioned Scenario

 Figure shows the median (dash), 25th – 75th percentile band (shading), and max/min (whiskers).

The most significant difference between the Paleo Conditioned scenario and the Observed Resampled and Paleo Resampled scenarios is in the inter-annual variability and persistence of streamflow states (wet and dry). Figure B-35 illustrates the frequency, length, and magnitude of deficit and surplus spells. Deficit periods of 15 years or longer are observed in this scenario and produce accumulated deficits greater than 60 maf. Similarly, extended surplus periods of similar length produce surpluses greater than 60 maf. Under this scenario, deficit periods could persist considerably longer than the Observed Resampled and produce deficits almost twice as large. However, interestingly the median probability of exceeding a deficit spell of greater than 7 years is only 20 percent, and there is only a 10 percent likelihood of exceeding a 5-year surplus period.

## 8.0 Future Supply under the Downscaled GCM Projected Scenario

### 8.1 Methods

Future changes in climate variability and trends, and their influence on streamflow and Basin water supply, have been studied by several researchers in recent years, and GCM future projections indicate that the climate may exhibit trends and increased variability over the next 50 years beyond what has occurred historically. The Downscaled GCM Projected scenario is one representation of this plausible future condition.

A number of methods for incorporating climate information in planning studies are available and have been summarized by Reclamation (2007) and others (Hamlet et al., 2010). Methods range from simple adjustments to the temperature and precipitation inputs (Delta method), to application of regional climate models for weather generation, to bottom-up risk-based approaches targeting system vulnerabilities. No one approach is better than the other; rather, each serves a specific planning purpose and set of analysis tools. The approach taken in the Study incorporates future climate information from GCMs, subsequently bias corrected and statistically downscaled, to drive a hydrologic model of the Basin. The hydrologic model simulates the effects of future climate on hydrologic processes in the Basin and provides information relating to streamflow at all major inflow points to the Colorado River and tributaries. The streamflow and ET information is then used as input into the systems model (CRSS), Reclamation's primary Basin-wide simulation model used for long-term planning studies. This approach is shown graphically in figure B-36. Using this approach of linking global and regional climate information, physically based hydrologic processes, streamflow routing, and systems modeling allows for a consistent linkage between climate and system responses that are desired as part of this scenario and the overall study of future Basin reliability. The methodological approach to develop the Downscaled GCM Projected scenario consists of five major elements depicted graphically in figure B-36. A total of 112 future climate projections used in the IPCC Fourth Assessment Report (2007), subsequently bias corrected and statistically downscaled, were obtained from the Lawrence Livermore National Laboratory under the World Climate Research Program's Coupled Model Intercomparison Project Phase 3 (Maurer et al., 2007)<sup>7</sup>. These data were incorporated in the first three elements of the approach in figure B-36.

Each of the 112 downscaled climate projections is then used as input into the VIC hydrology model. The VIC hydrology model uses the climate projections along with land cover, soils, elevation, and other watershed information to simulate hydrologic fluxes. The hydrologic fluxes are then routed to each of the 29 natural flow locations using a routing network derived from the topography (Lohmann et al. 1996; 1998). The result of this approach is 112 unique sequences of natural flow under future climate projections. However, the simulated natural flows can contain significant monthly and annual biases when compared to the natural flows of the historical period. These biases are generally small for mainstem Colorado River locations, but can be large for smaller watersheds and in areas where the VIC model was not specifically calibrated. To account and compensate for these biases, the VIC-

---

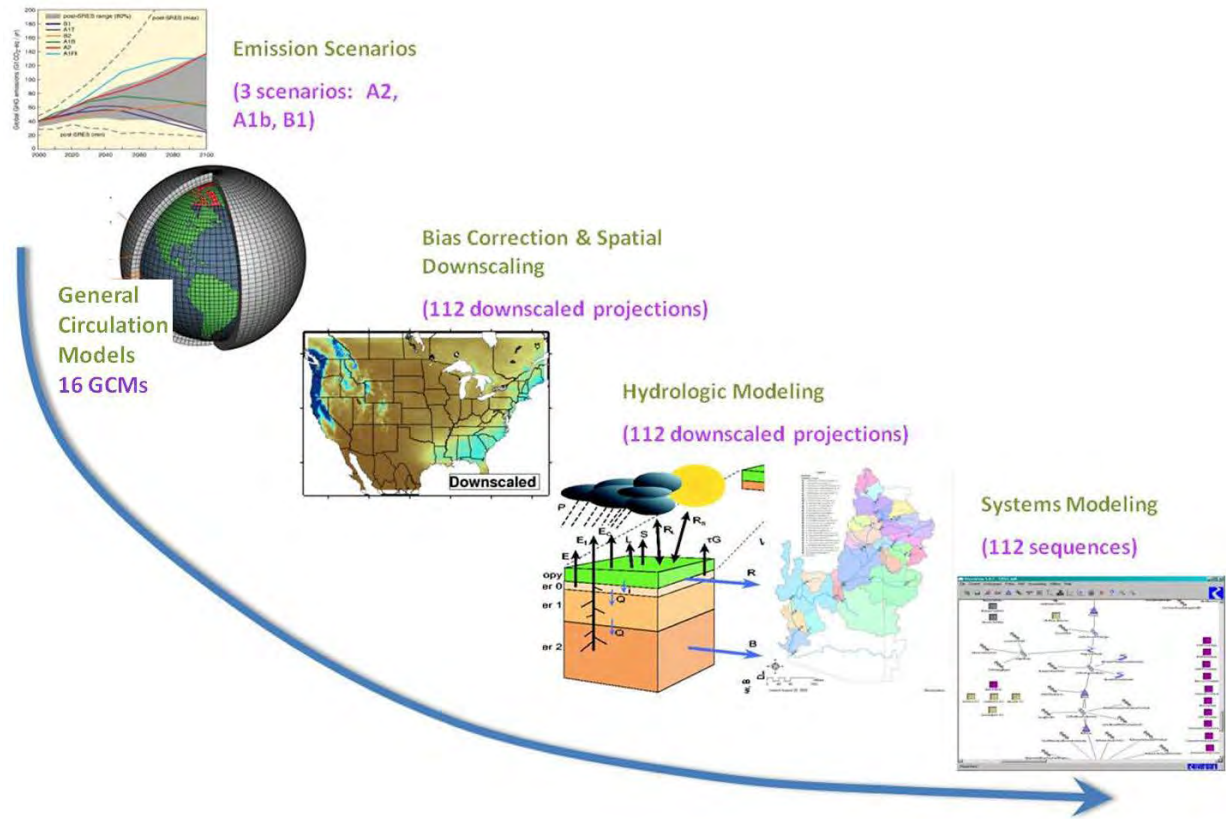

<sup>7</sup>These data are available via the website, Bias Corrected and Downscaled World Climate Research Program Coupled Model Intercomparison Project Phase 3 Climate Projections ([http://gdo-dcp.ucllnl.org/downscaled\\_cmip3\\_projections/](http://gdo-dcp.ucllnl.org/downscaled_cmip3_projections/)), which is jointly hosted by the Green Data Oasis, Santa Clara University, Reclamation, and Lawrence Livermore National Laboratory.

simulated streamflows for both the historical and future periods are first adjusted for biases before incorporating into systems modeling. Details on the methods used to correct for biases are included in section 9.1.3 and appendix B4.

The same Downscaled GCM Projected scenario was also employed to develop the results described in the SECURE Water Act Section 9503(c) – Reclamation Climate Change and Water Report (Reclamation, 2011). The SECURE Report was prepared by Reclamation’s Office of Policy and Administration and includes projections of how climate change may impact the water supply on the Basin. The SECURE Report was prepared by Reclamation to provide consistent, reconnaissance-level information focused on the future risks to water supply throughout the eight Reclamation basins.

While the results are consistent between this report and the SECURE Report, the SECURE Report was limited to the evaluation of the meteorological and hydrological changes under projected climate change. This Study is also considering how hydrological changes may impact the performance of the Colorado River system through CRSS modeling. The differences in study objectives lead to some differences in approach. The methodological differences consist primarily of the application of a streamflow bias correction method before using the simulated natural flows in the CRSS model. Reporting differences between this report and the SECURE Report consist of the selection of baseline climate conditions and the future analysis periods. Specifically, the SECURE Report computes future decadal changes from a 1991–2000 baseline condition, whereas the streamflow change statistics reported here are computed between the long-term historical record (1906–2007) and the Study period of 2011–2060. This period provides a long-term record consistent with that used in the Observed Resampled scenario, captures a sufficiently long period necessary to describe drought and surplus statistics, and represents a mean annual flow of importance to Colorado River management. The 1906–2007 mean annual flow for the Colorado River at Lees Ferry, Arizona is 15.0 maf; the mean annual flow is 15.5 maf for the 1971–2000 period, 15.0 maf for the 1978–2007 period, 15.3 maf for the 1991–2000 period, and 14.6 maf for the 1950–1999 period. The 1950–1975 period contained lower annual flows and lower interannual variability than many of the other periods, likely influenced by conditions associated with the cold phase of PDO. To capture the projected future trends in streamflow changes associated with the Downscaled GCM Projected scenario, additional information has been provided in this report for three future 30-year time periods (2011–2040, 2041–2070, and 2066–2095). While the last of these periods extends beyond the Study period, it provides an important reference for understanding the potential direction of the future Basin hydrology. Therefore, results between the Study and the SECURE Report are not identical; however, ongoing work in the Study will be used to inform future reports under the SECURE Water Act.

**FIGURE B-36**  
Methodological Approach for the Development of the Downscaled GCM Projected Scenario

### 8.1.1 Emission Scenarios

As discussed previously, the downscaled climate projections were obtained from the World Climate Research Program’s Coupled Model Intercomparison Project Phase 3 database. This database includes downscaled climate projections from 16 different GCMs simulated with three different IPCC emission scenarios (IPCC 2000). The emission scenarios are those from the *Special Report on Emissions Scenarios* (SRES), emission scenarios A2 (high), A1B (medium), and B1 (low), and reflect a range of future greenhouse gas (GHG) emissions. The A2 scenario is representative of high population growth, slow economic development, and slow technological change. It is characterized by a continuously increasing rate of GHG emissions, and features the highest annual emissions rates of any scenario by the end of the 21st Century. The A1B scenario features a global population that peaks mid-century and rapid introduction of new and more efficient technologies balanced across both fossil- and non-fossil intensive energy sources. As a result, GHG emissions in the A1B scenario peak around mid-century. Last, the B1 scenario describes a world with rapid changes in economic structures toward a service and information economy. GHG emission rates in this scenario peak prior to mid-century and are generally the lowest of the scenarios.

SRES emission scenarios exist that have both higher (A1Fi) and lower (A1T) GHG emissions than those considered in this Study (see appendix B2). However, the three scenarios included in the analysis span the widest range available for which consistent, comprehensive GCM modeling has been performed and for which downscaled climate

information is available. Furthermore, while it is possible that higher rates of warming and resulting effects on streamflows, are possible, it should be noted that the atmospheric response to emission increases is not immediate. Climate response to increases in GHG emissions is on the decadal scale. Uncertainty in the projected climate system response due to increased emissions (GCM uncertainty) tends to be a greater determinant of the range of future climate conditions through mid-century.

Assumptions related to parameter characteristics included in the SRES emission scenarios (such as high population growth and slow economic development) are not related to parameter characteristics of the Water Demand scenarios (see *Technical Report C – Water Demand Assessment*) because they describe a global set of drivers rather than those directly associated with the Colorado River. When considering water demand scenarios combined with water supply scenarios that incorporate climate change, outdoor water demands and reservoir evaporation rates will be modified to reflect estimates of changes in ET and open water surface evaporation rates consistent with the assumptions for water supply.

### **8.1.2 GCMs**

Sixteen GCMs were coupled with the three emissions scenarios to simulate the global atmosphere and oceans and provide projections of specific climatological forcings (principally temperature and precipitation) during the period 1950–2099. Many of the GCMs were simulated multiple times for the same emission scenario due to differences in starting climate system state (initial oceanic and atmospheric conditions); thus, the number of available projections (112) is greater than simply the product of the number of GCMs and emission scenarios. Appendix B2 provides a summary of the GCMs, initial conditions, and emissions scenario combinations featured in the Study. Recent research (Pierce et al., 2009, Gleckler et al., 2008) has shown the importance of incorporating multiple climate projections (even when derived from the same GCM) and the superiority of the multi-model ensemble for a wide array of climate metrics. The subsequent results presented on future climate (primarily temperature and precipitation), and indirectly streamflow, rely on the data generated by these GCMs.

### **8.1.3 Bias Correction and Spatial Downscaling**

Due to the coarseness of the GCM grids and inherent biases in their results, the GCM results are transformed to a local scale (~12 km) through a process called bias correction and spatial downscaling (BCSD). The methods of this process are described in detail in Wood et al., 2002; Wood et al., 2004; and Maurer, 2007.

The purpose of bias correction is to adjust a given climate projection for inconsistencies between the simulated historical climate data and observed historical climate data. In the BCSD approach, GCM projections are bias corrected at a 2-degree resolution using a quantile mapping technique which corrects the simulated historical monthly temperature and precipitation projections to be consistent with the observed distributions at the same resolution. Following bias correction, the adjusted climate projection data are statistically consistent (monthly cumulative distribution functions are identical) with the observed climate data for the historical overlap period of 1950–1999. The bias correction quantile maps derived from the historical overlap period are then used to adjust the GCM projections for the future period. Note that this method assumes that the GCM biases have the same structure during the 20th and 21st Centuries' simulations.

Downscaling spatially translates bias corrected climate data from the coarse, 2-degree (~200 km), spatial resolution typical of climate models to a Basin-relevant resolution of 1/8<sup>th</sup>-degree (~12 km), which is more useful for hydrology and other applications. The spatial downscaling process generally preserves observed spatial relationships between large- and fine-scale climates. This approach assumes that the topographic and climatic features that determine the fine-scale distribution of large-scale climate will be the same in the future as in the historical period.

#### **8.1.4 Daily Weather Generation (Temporal Dissaggregation)**

The resulting BCSD climate projections provide a representation of future monthly temperature and precipitation through 2099. However, to be useful for hydrologic modeling, this information is required on a daily temporal scale. The monthly downscaled data was temporally disaggregated to a daily temporal scale to create realistic weather patterns using the sampling methods described in Wood et al. (2002). To generate daily values, for each month in the simulation a month is randomly selected from the historic record for the same month (e.g., for the month of January, a January is selected from the 1950–1999 period). The daily precipitation and temperature data from the historic record are then adjusted (rescaled precipitation and shifted temperature) such that the monthly average matches the simulated monthly value. The same historic month is used throughout the domain to preserve plausible spatial structure to daily storms. The results of the temporal disaggregation are daily weather sequences that preserve the monthly values from the downscaled climate projections. Some uncertainties are introduced depending on the method employed to produce the daily data from the monthly climate values. A comparison of two available methods (Wood et al., 2002 and extension of Wood et al., 2002 described in Salathé, 2005) to generate daily weather patterns for this Study favored the use of the Salathé, 2005 method employed in the SECURE Report to produce the daily downscaled data. An additional description of the comparative analysis is presented in appendix B3.

#### **8.1.5 Hydrologic Modeling**

The daily weather sequences are used as input to the VIC hydrologic model to generate estimates of hydrologic fluxes and streamflow under various climate futures. For each of the 112 climate projections, the VIC hydrologic model produced a distinct trace of natural flows at each of the 29 natural flow locations.

Developed at the University of Washington, the VIC model is a semi-distributed, macro-scale hydrologic model that solves the water balance at each model grid cell. A VIC model of the Basin was previously developed by the University of Washington (Christensen and Lettenmaier, 2007), and was provided to Reclamation for this study. The model has not been further calibrated or refined as part of this Study, but the model performance and bias correction has been evaluated and is discussed in the next section. A thorough description of the VIC model is provided in appendix B4.

Analysis shows (presented in appendix B4) that there are some biases in the VIC streamflows as driven by historical observed and downscaled climate model simulated historical meteorological forcings in comparison with the natural flows for the Basin for the overlapping period of 1950–1999. These biases are generally small for mainstem Colorado River locations, but can be large for smaller watersheds and in areas where the VIC model was not specifically calibrated. The mean annual flow bias for the Colorado River at

Lees Ferry, Arizona is positive 1.1 percent. Moving upstream to the three largest contributors to flow at Lees Ferry, the bias is negative 3 percent for the Green River near Green River, Utah, less than 1 percent for the Colorado River near Cisco, Utah, and negative 6 percent for the San Juan River near Bluff, Utah. The VIC model appears to have higher biases in the upper watersheds and lower biases farther downstream as more of the watershed contributes to the flow. In general, the upper Colorado River locations exhibit a positive bias, while the Green River and San Juan River locations exhibit a negative bias.

These biases are due to differences between the GCM-simulated historical climate and observed climate data, differences in hydrology model inputs and parameterization, and differences between the VIC-simulated hydrologic responses and observed watershed responses implied in the natural flows. The lack of calibration of the VIC model for lower order streams within the Basin is believed to be a significant source of the bias at these scales.

A streamflow bias correction method was developed and applied to the “raw” VIC-simulated flows to account for any systematic bias in the hydrology model and/or climate data sets. The method corrects for monthly and annual biases, while ensuring that the corrected flows maintain the system and local mass balance. The raw VIC-simulated streamflows for both the historical and future periods are first adjusted for biases before incorporating into the CRSS modeling. The streamflow bias correction step is an important component for the use of climate-driven hydrologic modeling and results in subsequent systems modeling. Without this step, the VIC-simulated historical flow biases would be carried forward into future assessments and the potential exists for mis-attribution of some streamflow changes to changes in climate, while these may be partially associated with model/data bias. Details on the methods used to correct for biases are included in appendix B4.

In addition to producing routed natural flows, the VIC model also provides output for other water supply indicators, including precipitation, runoff, baseflow, ET, soil moisture, and SWE. The subsequent results presented on hydrologic processes rely on these parameters generated by the VIC model.

Additional detail on VIC and its application for the Study can be found in appendix B4.

### **8.1.6 Systems Modeling**

A total of 112 realizations at the 29 natural flow locations are taken from the VIC model simulations and subsequently corrected for streamflow biases. Differing from the three other future water supply scenarios, which do not address changes in climate, each Downscaled GCM Projection hydrologic sequence of streamflow will likely exhibit a long-term future trend and increased variability beyond what occurred historically. For the Study, no differentiation is applied for each of the sequences, based on emission scenario or historical GCM skill. In essence, each of the 112 sequences is treated as equally likely when applied in CRSS in later phases of the Study. However, included in this report is an evaluation of the relative sensitivity of streamflows to emission scenarios. From a mechanical standpoint, the Downscaled GCM Projected scenario is implemented as 112 distinct projections of the future, each starting in the year aligned with the Study period start year of 2011.

## 8.2 Uncertainty

The process outlined above and shown graphically in figure B-36, in which climate projections are used to generate projections of future streamflow, contains a number of areas of uncertainty. Each step in the process contains uncertainty, and it is important to recognize these in the interpretation of results. First, emission scenarios describing the global emissions of GHGs over the century are used as the primary input to GCMs. The SRES emission scenarios are used to project a range of future global development pathways. Each emission scenario is considered plausible, but the fact that the range may not be sufficiently broad cannot be ruled out. In addition, the climate system responds to a number of factors that contribute to radiative forcings affecting the warming of the earth's surface. Factors such as aerosols, solar activity, surface albedo, and variations in the earth's orbit, all influence the earth's energy balance. These mechanisms are included in the climate models to the degree they are understood and can be projected into the future, but represent an inherent uncertainty in attempting to simulate the global climate system on decadal and century scales. Anthropogenic carbon dioxide emissions, which are directly represented in the emission scenarios, are believed to represent the largest component of the estimated radiative forcing (IPCC, 2007).

Second, GCMs are used to simulate global climate patterns resulting from atmospheric forcings and feedbacks throughout the land, ocean, and atmosphere interactions. The GCMs are still applied at relatively coarse scales in relation to what is required for watershed assessments, and therefore are not likely to capture important regional phenomena. Much of the uncertainty in climate projections through mid-century is associated with the GCMs, rather than emission scenarios. The GCM results are necessarily bias corrected and spatially downscaled to be useful at the watershed scale. These bias correction and downscaling processes, while necessary, remove some of the physical linkages from the climate projections and introduce an aspect of further uncertainty. High-resolution regional climate modeling may help resolve some of the scale mismatch (both spatially and temporally) in the future, but the availability of these simulations over a broad ensemble of models and emission scenarios is limited. The statistical downscaling method employed in this study preserves monthly observed precipitation and temperature statistics for the overlapping period at the 2-degree spatial scale. However, the statistics at finer spatial scales (i.e., 1/8<sup>th</sup>-degree scale) or longer temporal scales (seasonal, annual, and longer scales) are not necessarily preserved. Analysis included in appendix B3 provides further information on this topic.

Finally, hydrologic models are approximations of the complex physical processes that occur on the watershed scale. The VIC model is considered a strong, physically based hydrology model, but simulates hydrologic processes at the macro scale. The model necessarily needs to parameterize certain aspects of the hydrologic cycle to capture the effects at smaller scales. Several assumptions in the VIC modeling approach carry considerable uncertainty. First, the VIC modeling assumes that land use and vegetative cover are fixed throughout the simulation period. At present, future assumptions of land use that are consistent with the socioeconomic assumptions in the water demand scenarios have not been integrated into the water supply scenarios. Changes in climate are likely to drive changes in native and invasive species (vegetative, terrestrial, avian, and aquatic) distribution and these will influence the physical watershed and future hydrologic processes and streamflow. The magnitude of these impacts are believed to be relatively small compared to the effects of changes in direct

temperature and precipitation; however, the magnitude has not yet been quantified. Further investigation as to the relative effects of these changes is recommended.

In addition, the VIC model, as described in this report, has been adopted without re-calibration. Results appear reasonable at the larger watershed scale, but there is observed bias in particular watersheds and at the sub-watershed scale. A bias correction method has been applied to compensate for some of the biases, but in doing so it necessarily introduces assumptions on the linkages between past and future climates that are not yet known.

### **8.3 Results**

The results of the 112 future climate projections are presented in this section. The results are presented for climate, hydrologic processes, and streamflow. Climate teleconnections are discussed primarily in a qualitative manner due to the broad uncertainty in projecting future states of coupled ocean-atmosphere conditions. For climate, results are presented in terms of annual precipitation and temperature trends, followed by an analysis of seasonal trends. For hydrologic processes, results are presented for ET, snowpack, soil moisture, and runoff. Both annual and seasonal analyses are presented. The last section of the results focuses on projected changes in streamflow, both annual and seasonal, and predominately at the Colorado River at Lees Ferry, Arizona location.

Climate and hydrologic process results are presented as changes from the 30-year historical climatological period (1971–2000) to three future 30-year periods (2011–2040, 2041–2070, and 2066–2095). Thirty-year periods were chosen to span the almost 90-year future projection period (2011–2099). In addition, due to the difference in initial atmospheric-ocean conditions between the GCMs, a 30-year period is sufficient to separate projected average conditions from individual and multi-year variability. For simplicity, these periods are referred to as the year in which they are centered: i.e., 1985, 2025, 2055, and 2080.

Although the Study period is through 2060, the 112 future climate projections extend through 2099. The additional approximate 40 years of projections have been included in the analyses for the climate and hydrologic processes results because they offer additional insight into the projected changes of these parameters. To facilitate a more direct comparison with the projected streamflow from the other three scenarios (Observed Resampled, Paleo Resampled, and Paleo Conditioned), streamflow results are presented through 2060.

#### **8.3.1 Climate**

Climate projections from the 112-projection ensemble indicate a strong continued warming throughout the Basin. Figure B-37 shows the Basin average temperature and precipitation projections for 1950–2099 (the length of the GCM projection period) in relation to the 1950–2005 (the length of the observed climate period) historical observed climate. The projection ensemble indicates substantial warming, with a median increase in annual temperature of about 1.3 °C by 2025, 2.4 °C by 2055, and 3.3 °C by 2080. All projections are consistent in the direction of the temperature change, but vary in terms of climate sensitivity. Annual precipitation trends are not apparent in this Basin-wide analysis. Roughly half of the projections indicates a wetter future, while the other half indicates drier conditions. The uncertainty in future annual precipitation appears to be increasing with time, while the median of the projections is relatively unchanged.

**FIGURE B-37**

Historical (line series with markers) and Projected Annual Average Temperature (top) and Projected Annual Total Precipitation (bottom). Smoothed as a 10-year mean.

*Shading represents a range of projections and the solid line represents a median of projections.*

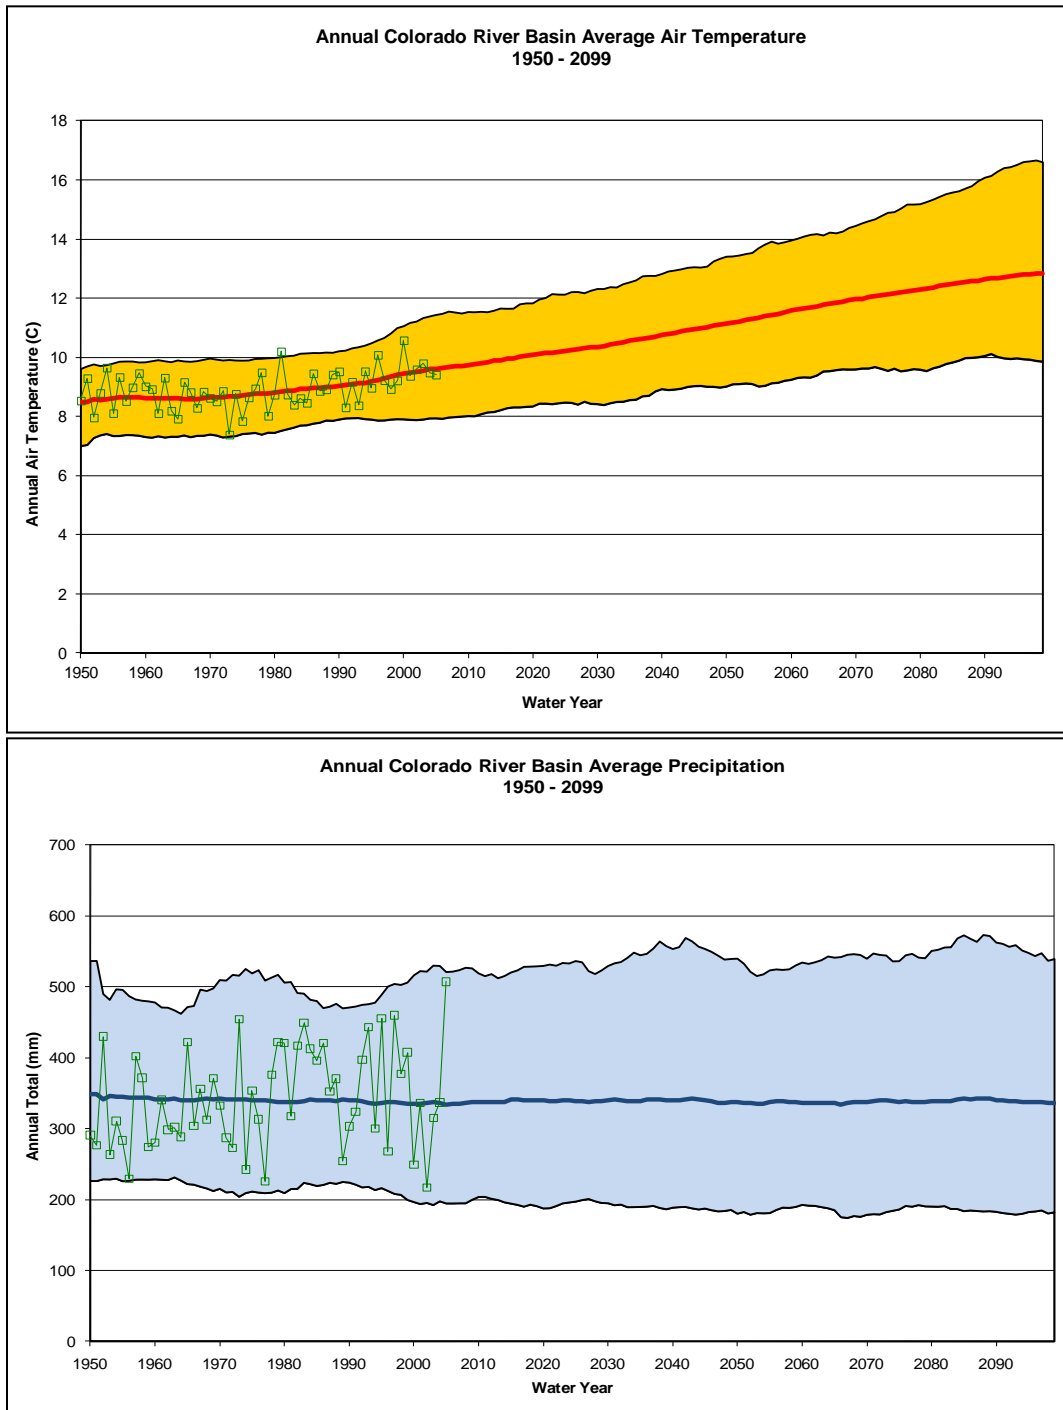

Figure B-38 presents the change in mean annual temperature (absolute change) and precipitation (percent change) and for three future periods: 2011–2040 (2025), 2041–2070 (2055), and 2066–2095 (2080), relative to the 30-year historical period 1971–2000 (1985). For most of the Basin, temperature increases are within 1.0 °C to 1.5 °C, 2.0 °C to 2.5 °C,

and 3.0 °C to 4.0 °C for 2025, 2055, and 2080, respectively. The Upper Basin is projected to warm more than the Lower Basin. Projected precipitation changes are relatively modest in 2025. However, by the 2055 and 2080 periods, precipitation decreases by up to 10 percent in much of Lower Basin. In contrast, precipitation increases by up to 10 percent in the Upper Basin at higher elevation and toward the north (Green River Basin).

Maps of seasonal changes in temperature and precipitation for the three future 30-year periods are included in appendix B6 and are summarized here.

The seasonal analysis shows that 2055 projected seasonal temperature changes exhibit minimal geographic variation in the fall. Winter and summer temperatures in the Upper Basin increase slightly more than those in the Lower Basin. Projected temperature increases are lowest in winter, ranging from 1.5 °C to 2.5 °C. The largest projected temperature increases occur in summer, and range from 2.5 °C to 3.0 °C.

The 2055 change in projected mean winter precipitation is highly varied throughout the Basin, with values in the Lower Basin decreasing from 0 to 15 percent and the values in the Upper Basin increasing from 0 to 15 percent. However, it should be noted that on an absolute basis, the Upper Basin receives considerably more rainfall than the Lower Basin, such that a 15 percent change is substantially more total precipitation in that region. During spring, precipitation is projected to decrease throughout the Basin. The most severe reductions (on a percentage basis) occur in the southwestern region, where the decline is up to 30 percent. Summer is the only season in which projected precipitation shows a decrease in the Upper Basin and an increase or no change in the Lower Basin. Trends in fall precipitation closely resemble those of the winter season, but the projected percent changes for fall are lower in magnitude.

FIGURE B-38

Mean Projected Change in Annual Temperature and Precipitation

2025 (2011–2040) versus 1985 (1971–2000), 2055 (2041–2070) versus 1985 (1971–2000), and 2080 (2066 – 2095) versus 1985 (1971–2000).

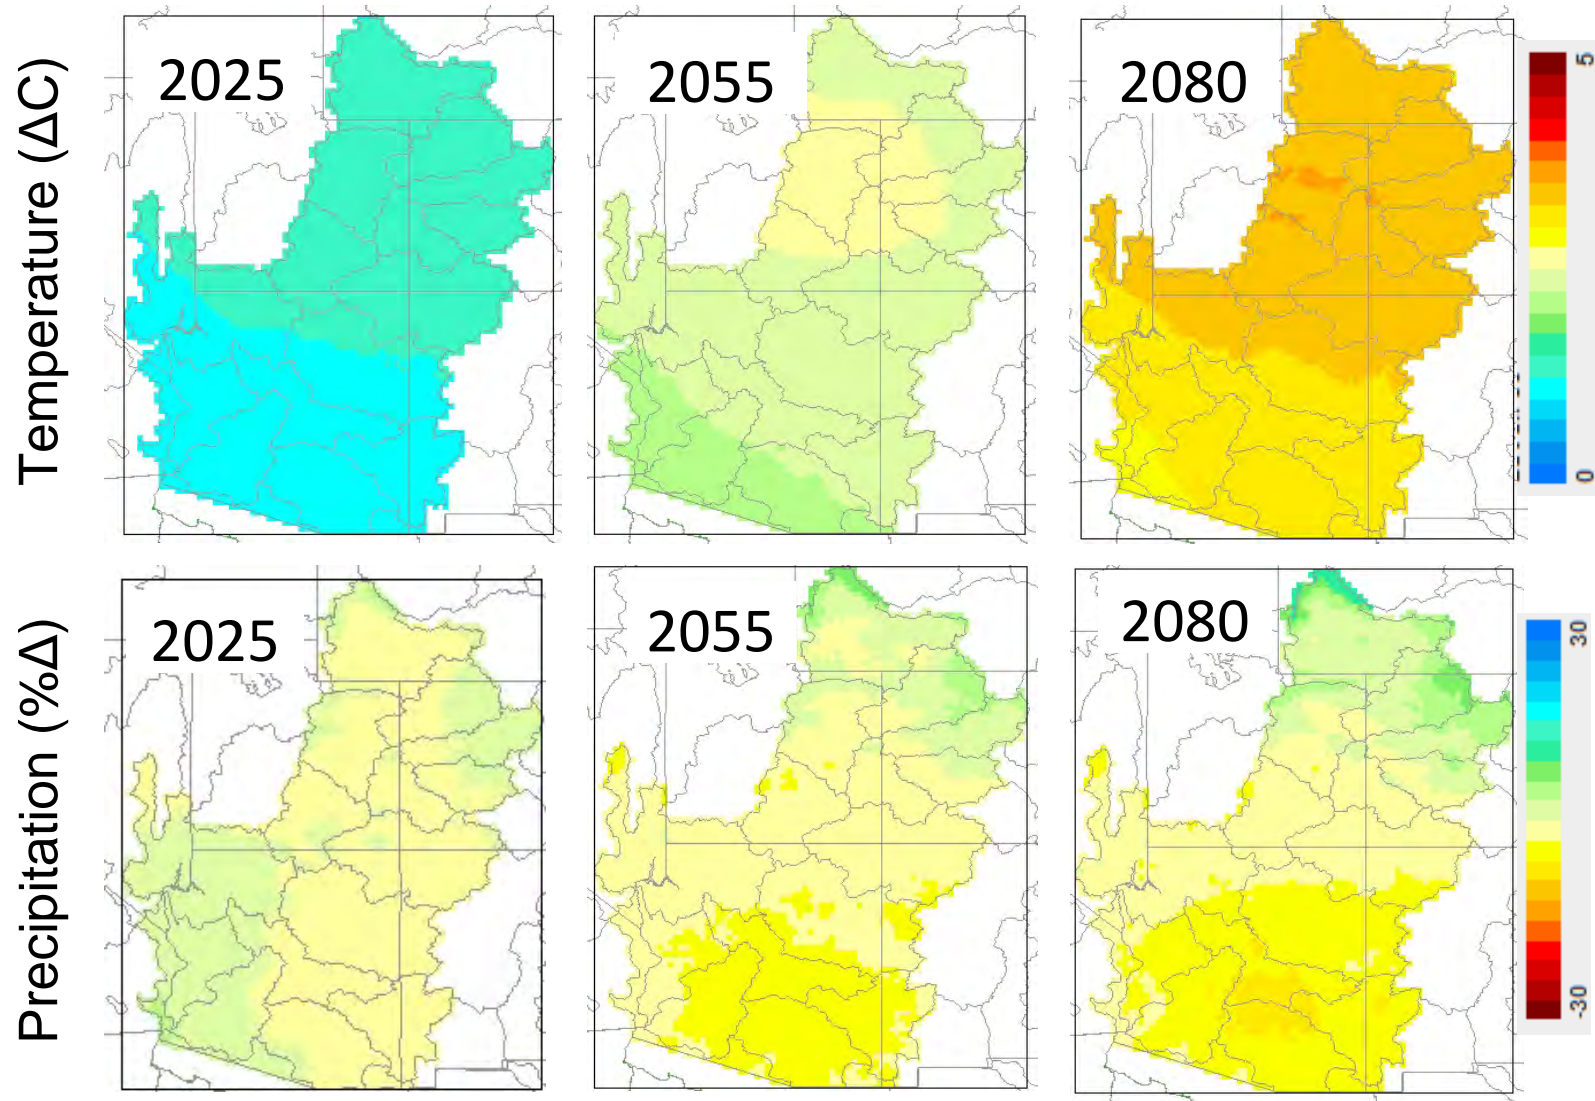

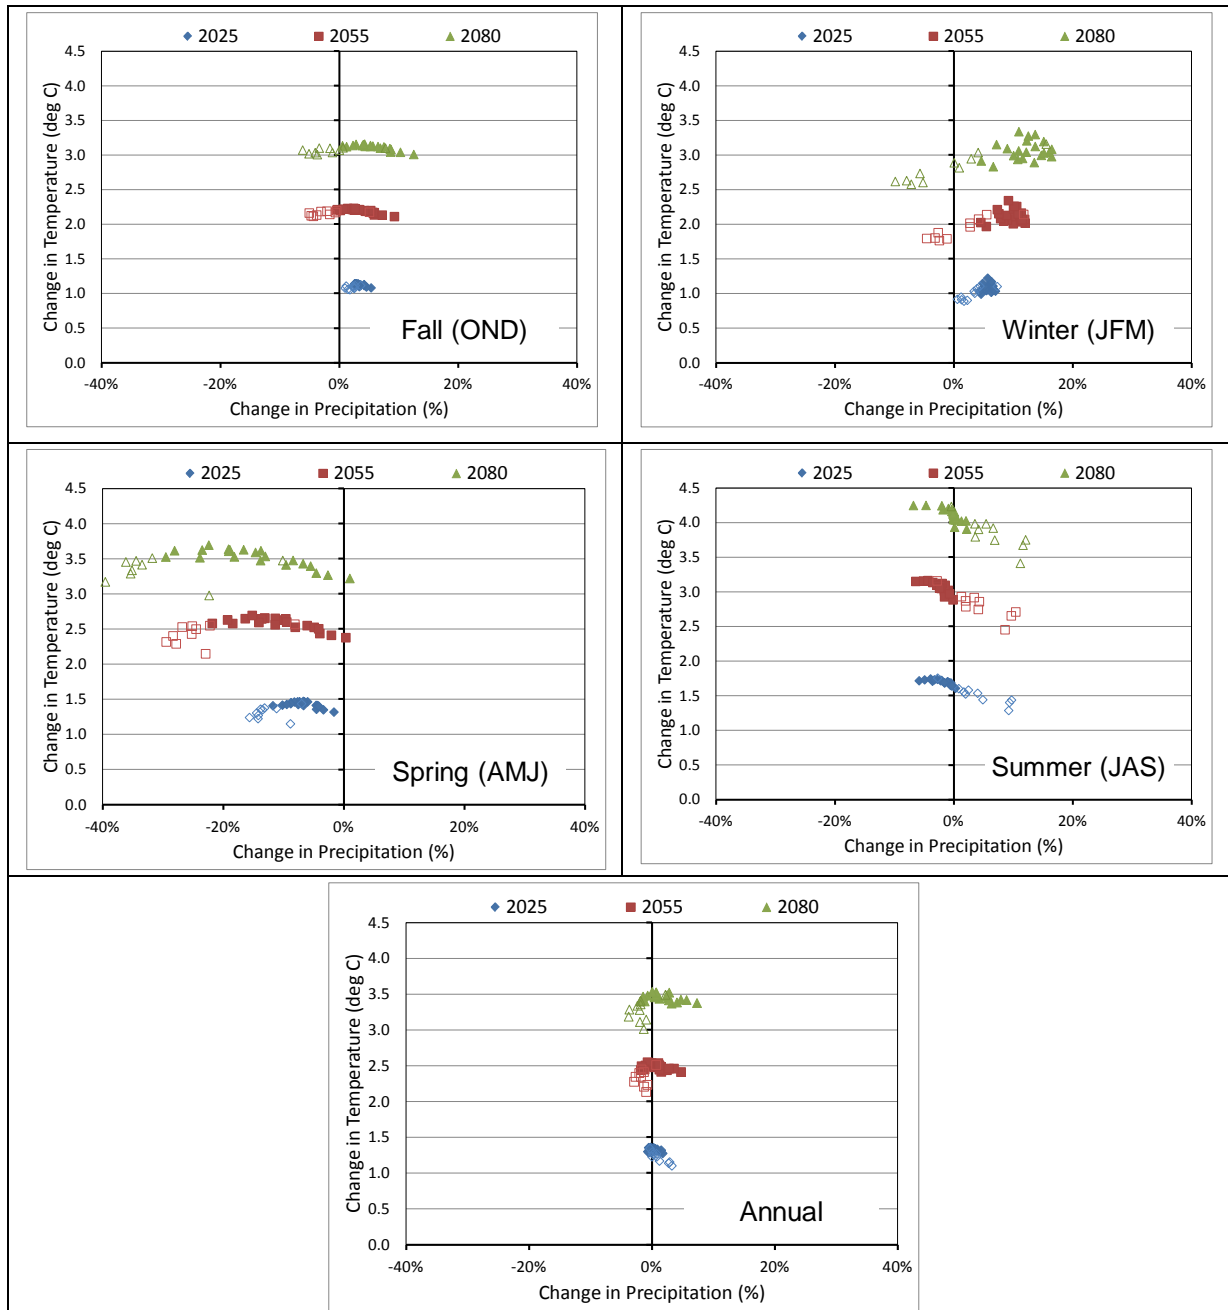

Figure B-39 summarizes projected changes in climate conditions on a watershed basis, as indicated by the 112-projection ensemble for the three future 30-year periods. Each point represents a single watershed (one for each contributing area). The location of a point in the figure is determined by the mean projected change in temperature between the future periods and the simulated historical period 1971–2000, and the mean projected change in precipitation between the future periods relative to the simulated historical period. Change in temperature is measured in degrees Celsius, while change in precipitation is measured as a percentage.

FIGURE B-39

Projected Changes in Mean Seasonal and Annual Temperature and Precipitation for the Colorado River Basin Periods are 2025 (2011–2040); 2055 (2041–2070); and 2080 (2066–2095), compared to the 1985 (1971–2000) historical period (hollow symbols represent Lower Basin locations, while solid symbols indicate Upper Basin locations).

For a given season and future time period, projected changes in temperature are relatively consistent across all watersheds, with little variation throughout the Basin. By 2025, temperatures are projected to increase at least 1.0 °C in nearly all watersheds for all four seasons. Spring and summer show the greatest warming, with seasonal temperatures in most watersheds increasing 3 °C to 4 °C by 2080. Annual temperature increases are projected at 1.0 °C to 1.5 °C, 2.0 °C to 2.5 °C, and 3.0 °C to 3.5 °C for 2025, 2055, and 2080, respectively.

Projected changes in seasonal precipitation vary widely among watersheds and among seasons. In general, precipitation variability increases with time. On an annual basis, projected precipitation through 2080 is generally within 5 percent of historical precipitation, with half of the Basin's watersheds exhibiting positive change and half exhibiting negative change. The most significant and monotonic change in precipitation occurs in spring, during which all watersheds show a decrease in precipitation for each of the future time periods. By 2080, the decrease in spring precipitation ranges from 0 to 40 percent, with the values well distributed within the range. During fall and winter, small increases (less than 10 percent) are projected for 2025, but bimodal patterns of increases in the Upper Basin (about 20 percent for winter in 2080) and decreases or neutral changes in the Lower Basin (about 10 percent for winter in 2080) begin to appear in the 2055 and 2080 time periods. Summer is the only season in which the bimodal pattern is reversed with decreases in precipitation projected in the Upper Basin and increases in the Lower Basin. The summer pattern is likely due to a more active monsoon and increased moisture flow from the Gulf of California during this season simulated in the GCMs (see appendix B6 for projected seasonal precipitation maps).

### **8.3.2 Summary of Changes in Climate**

- Warming is projected to increase across the Basin, with the largest changes in spring and summer and larger changes in the Upper Basin than in the Lower Basin. Annual Basin-wide median temperature increases are projected to be approximately 1.3 °C, 2.4 °C, and 3.3 °C for 2025, 2055, and 2080, respectively, with less warming in winter and higher warming in summer.
- Precipitation patterns continue to be spatially and temporally complex, but projected seasonal trends toward drying are significant in certain regions. Precipitation patterns are complex due to influence of oceans, storm tracks, changes in atmospheric circulation patterns (e.g., Hadley cell expansion), and the interplay with mountainous regions (orographic considerations). A general trend toward drying is present in the Basin, although increases are projected in the higher elevation and most hydrologically productive regions. Consistent and expansive drying conditions are projected for the spring throughout the Basin. For much of the Basin, drying conditions are projected in the summer, although some areas of the Lower Basin are expected to experience slight increases in precipitation which may be due to the monsoonal influence in this region. Upper Basin precipitation is projected to increase in the fall and winter, while the Lower Basin is expected to experience a decrease. Despite drying spring conditions in the Upper Basin, annual precipitation is projected to increase in the higher elevations due to higher winter precipitation increases in these regions. Projections demonstrate a bi-modal pattern of precipitation changes in fall and winter, with the Upper Basin projected to experience increases and the Lower Basin projected to experience decreases. The division of wetter versus drier conditions in the winter moves northward

with continued warming through time, consistent with an expansion of the Hadley cell and more northerly storm tracks (Seager et al., 2010).

### **8.3.3 Hydrologic Processes**

Figures B-40 and B-41 present grid cell-based VIC model output via Basin-wide spatial plots for ET, runoff, soil moisture, and SWE. For each future time period and for each parameter, the mean projected annual changes are presented. Projected seasonal changes for these parameters can be found in appendix B6.

Figure B-40 shows the percent change in mean annual ET and mean annual runoff. ET is projected to increase in most high elevation and northerly areas of the Upper Basin and is strongly related to the availability of soil moisture. In the Lower Basin, where decreased precipitation is projected (and subsequently reduced soil moisture), ET is projected to decrease substantially, particularly in the 2055 and 2080 periods. Runoff is projected to decrease substantially (up to 30 percent) across large areas of the Basin, with greatest reductions in the south and at high elevation. Elsewhere, projected decreases are generally within 15 percent of the historical period through 2080. Runoff is projected to increase for small areas in the northeasterly portion of the Basin (Green River Basin primarily). The increases in the northern portion of the Basin are an important finding and contribute significantly to mitigate reduced runoff trends for much of the rest of the Basin.

Figure B-41 shows the mean percent change in April 1 SWE and July 1 soil moisture. With few exceptions, April SWE is projected to decline by up to 30 percent throughout the Basin by 2025 as more precipitation falls as rain and as warmer conditions lead to earlier snowmelt. This process becomes more pronounced in the 2055 and 2080 periods. July 1 soil moisture is projected to decrease by 5 to 10 percent throughout the Basin for the three future time periods. The loss of soil moisture is primarily the result of the greater moisture availability for ET earlier in the year (more rain less snow and earlier melt of snowpack) in the higher elevation Upper Basin and reduced overall precipitation in the Lower Basin. The most substantial decline occurs in the northeast portion of the Basin.

Maps of seasonal changes in ET, runoff, soil moisture, and SWE for the three future 30-year periods are included in appendix B6 and are summarized here.

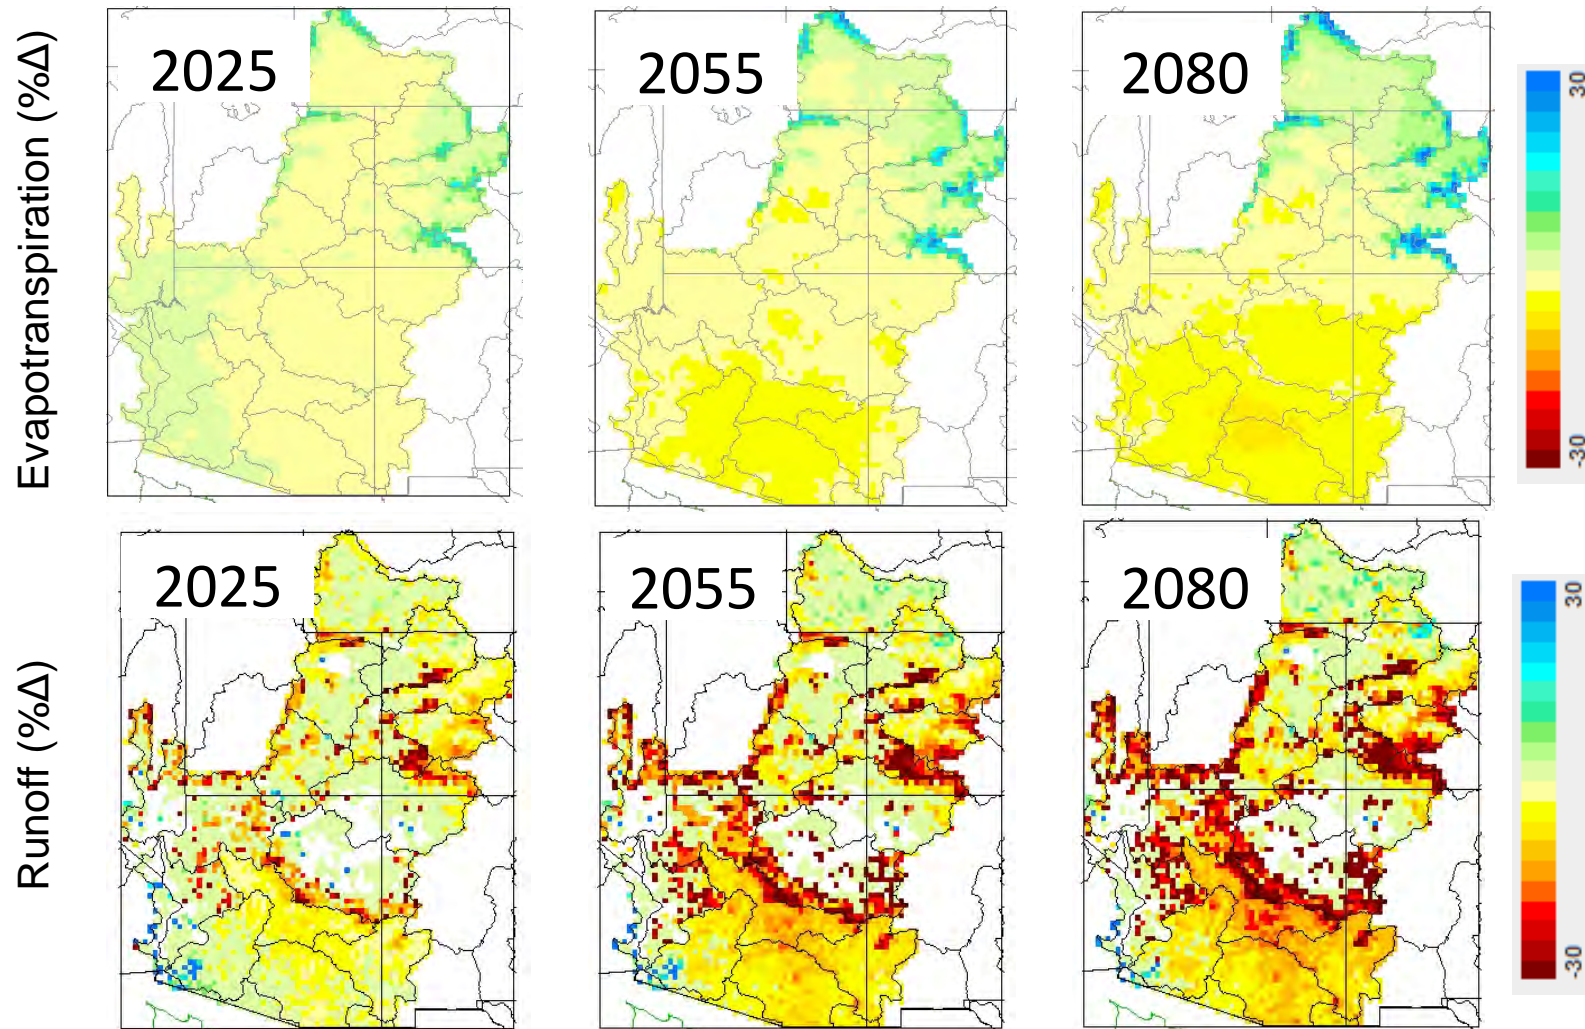

Projected 2055 changes in ET vary substantially throughout the Basin. In general, ET is projected to increase during fall and winter, but decrease during summer for the majority of the Basin. Projected ET changes exhibit considerable geographic variability and range in magnitude during spring, when portions of the Upper Basin have ET increases of up to 30 percent and portions of the Lower Basin have ET decreases of up to 30 percent. Both phenomena are related to soil moisture availability. Increases in Upper Basin ET are due to greater soil moisture availability, while Lower Basin decreases are due to reduced available soil moisture. During summer, projected 2055 changes in ET range from -5 to -10 percent in most locations.

Projected 2055 changes in runoff also vary substantially throughout the Basin. In most seasons, runoff declines throughout the Basin. However, increases are projected for portions of the Upper Basin in fall and winter, and for the extreme southwestern portion of the Basin for all seasons. The projected decline in runoff is most substantial during spring, when several areas in both the Upper and Lower Basins feature a runoff reduction of up to 30 percent. Portions of the Upper Basin exhibit a reduction of similar magnitude during both summer and fall.

FIGURE B-40

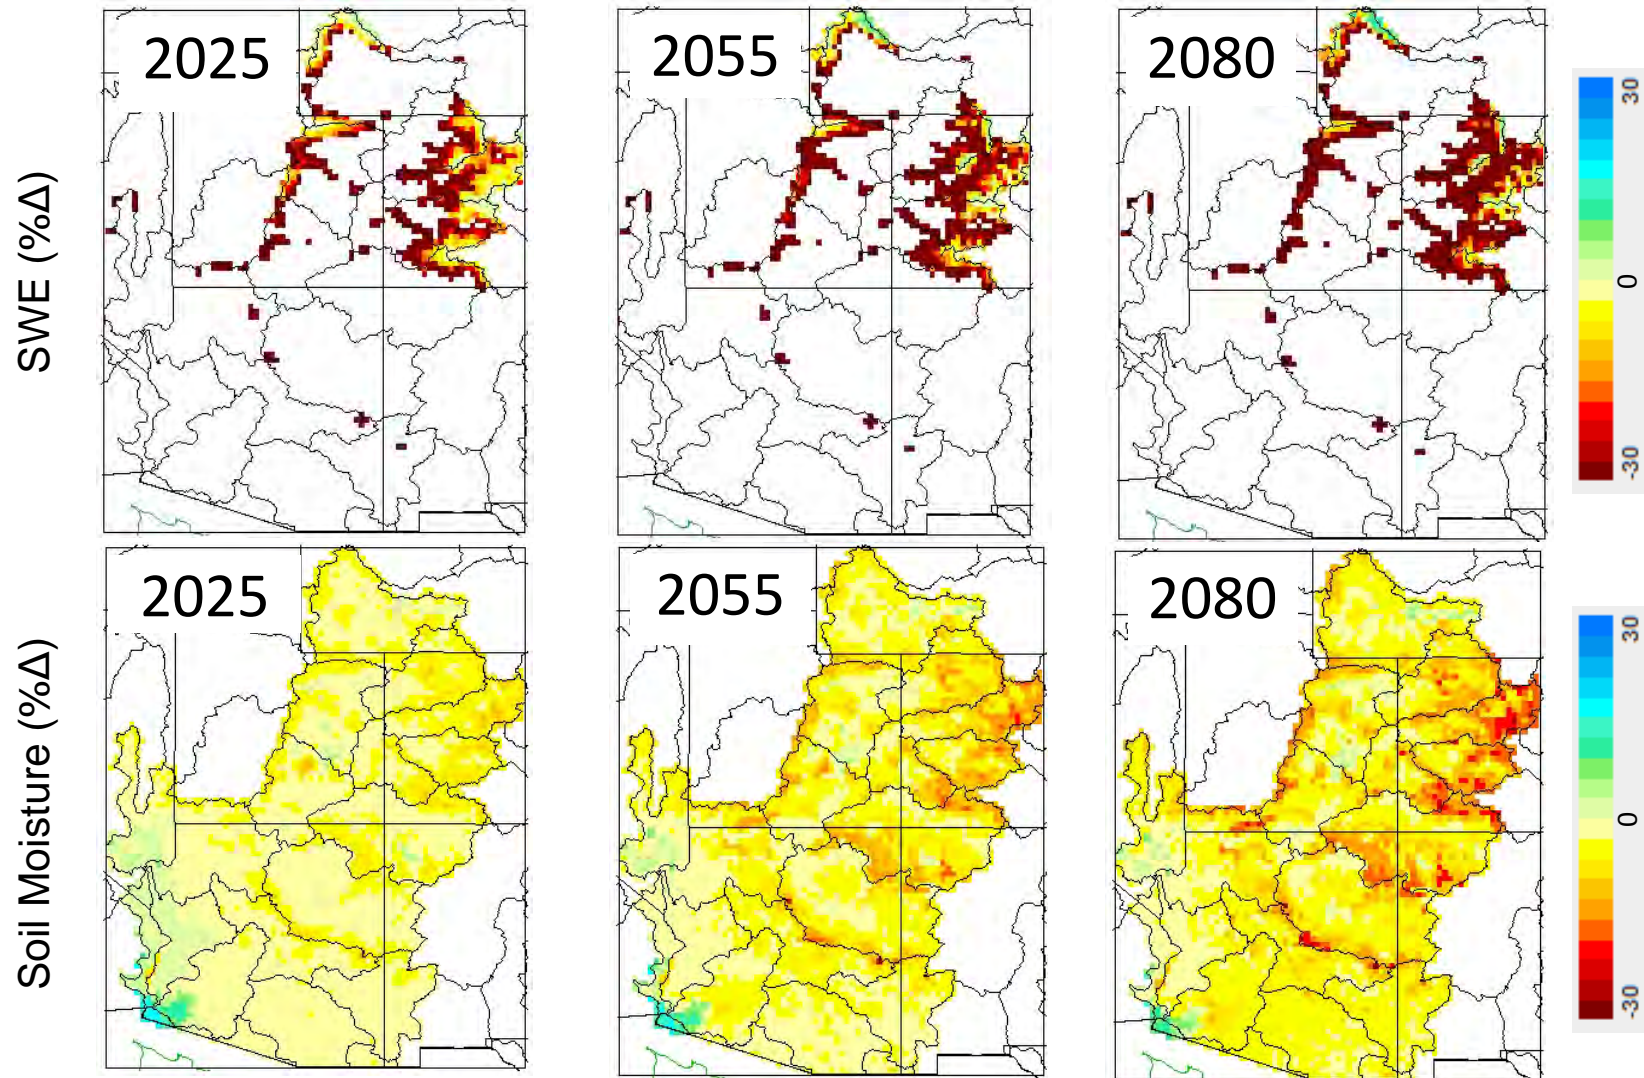

Mean Projected Percent Change in Annual ET and Median Projected Percent Change in Runoff<sup>8</sup>

2025 (2011 – 2040) versus 1985 (1971-2000), 2055 (2041 – 2070) versus 1985 (1971-2000), and 2080 (2066 – 2095) versus 1985 (1971-2000).

<sup>8</sup> Median is used for runoff percent change, rather than mean because regions of extreme low historical precipitation may show disproportionately high percentage changes.

**FIGURE B- 41**  
 Mean Projected Percent Change in April 1 SWE and July 1 Soil Moisture  
 2025 (2011–2040) versus 1985 (1971–2000); 2055 (2041–2070) versus 1985 (1971–2000); and 2080 (2066–2095) versus 1985 (1971–2000).

The results of the watershed-based statistical analysis of VIC model output (climatological and hydrologic parameters) are presented for two representative Basin watersheds. The selected watersheds are those immediately upstream of the Colorado River at Glenwood Springs, Colorado, and the Colorado River at Hoover Dam,. These select watersheds represent a high elevation headwaters region in the Upper Basin and a lower elevation, warmer region in the Lower Basin. Additional locations representing a more-robust cross-section of the Basin are included in appendix B6.

Figures B-42 and B-43 each present the changes in six hydrologic parameters (precipitation, temperature, ET, runoff, SWE, and soil moisture) from the 30-year historical period (1971–2000) to three future 30-year periods: 2011–2040 (2025); 2041–2070 (2055); and 2066–2095 (2080). Figure B–42 presents these hydrologic parameter changes for the Colorado River at Glenwood Springs, Colorado. The results for this watershed are representative of those for other watersheds in the high elevation Upper Basin:

- **Precipitation:** In the three future time periods, the Upper Basin watersheds experience a shift in the timing of precipitation; more precipitation occurs in fall and winter (November–March) and less occurs in spring (April–June) relative to historical conditions. For this watershed, the increases in precipitation in fall/winter are greater than the reductions in spring/summer, resulting in a net increase.
- **Temperature:** Monthly temperatures increase from 1.0 °C to 1.5 °C by 2025, and by 2.5 °C to 4.0 °C by 2080 relative to the 30-year historical period of 1971–2000.
- **ET:** Although ET is relatively unchanged from September to March, spring months (April–June) feature a marked increase.
- **SWE:** Snowpack, as indicated by SWE, is consistently less in the future than in the historical period, particularly from March through June. Shifts in both runoff and soil moisture indicate that some portion of the reduction in spring SWE may be related to earlier snowmelt.
- **Runoff:** Runoff is projected to increase in March, April, and May, while both precipitation and SWE are reduced during April and May. This suggests an earlier snowmelt that supplies the increased runoff from March through May and contributes to a reduction in snowpack. This is further supported as runoff is substantially reduced in June and July, suggesting that the melting snowpack, which historically supplied runoff during these months, has been substantially reduced by this time.
- **Soil moisture:** Soil moisture is increased from February through April in conjunction with increased snowmelt infiltration. However, relative to historical conditions, the projected soil moisture is lower for the remainder of the year, exhibiting the most substantial reduction in June.

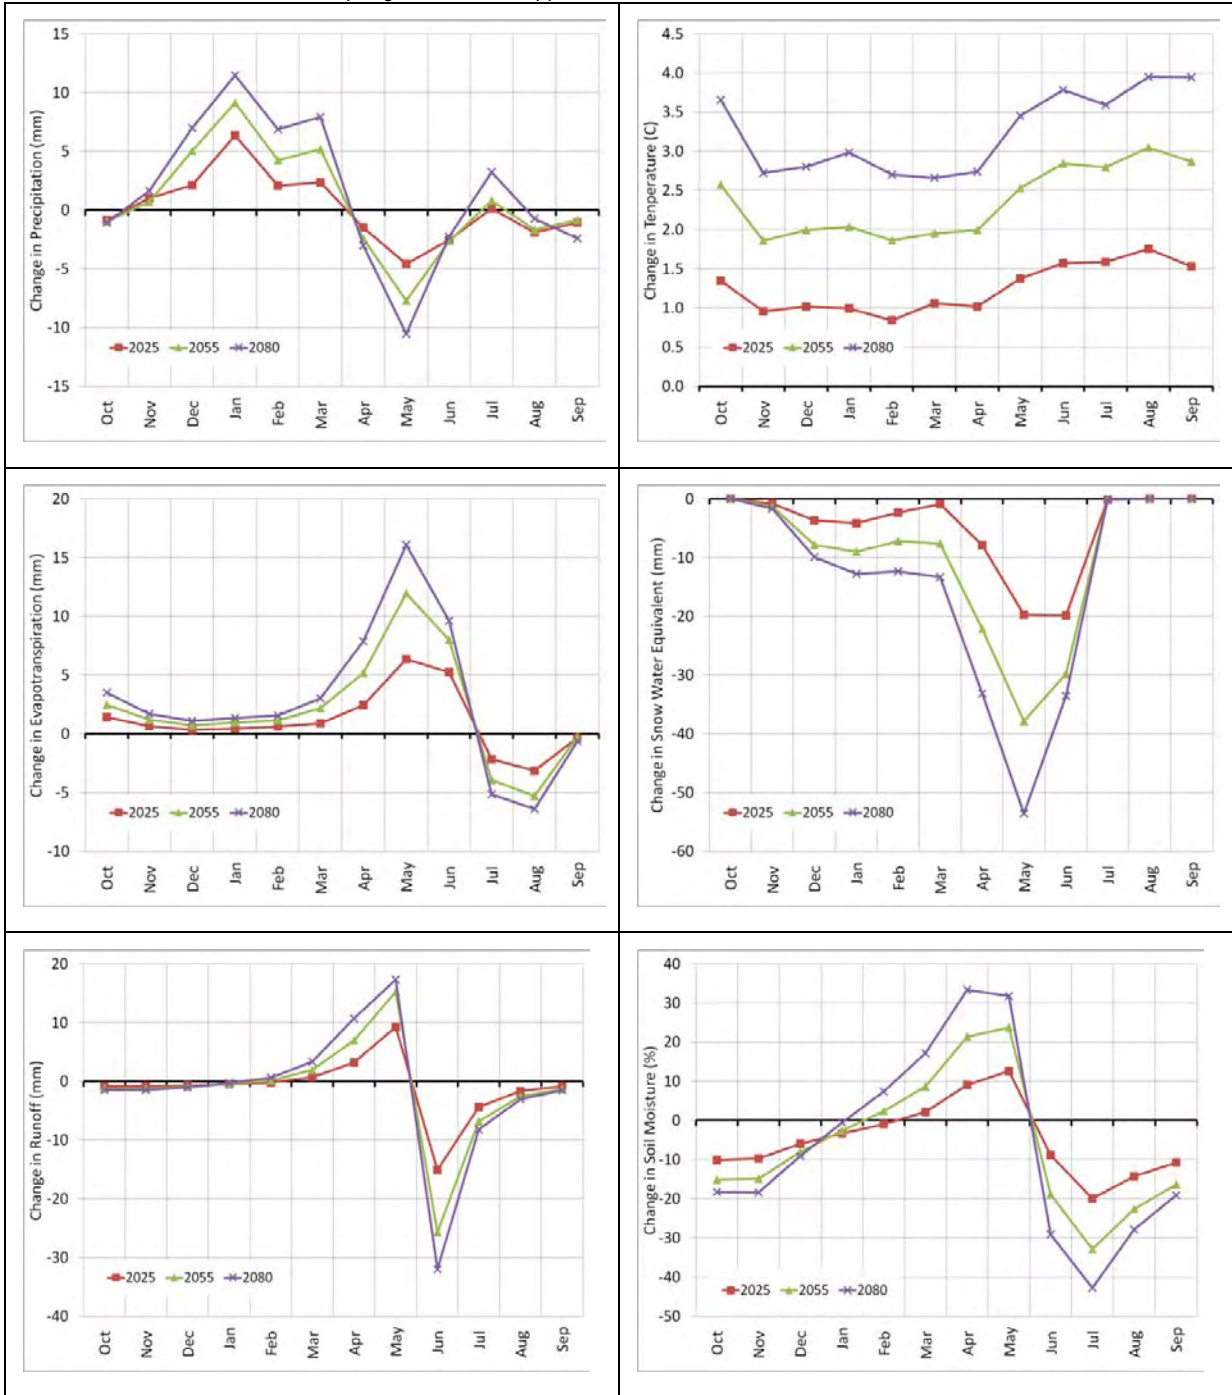

Figure B-43 presents these plots for the Colorado River at Hoover Dam,. The results for this watershed are representative of those for other watersheds in the Lower Basin. Due to the limited snowpack in the Lower Basin and its resulting limited role in the hydrologic processes of this region, the SWE results for the Lower Basin are not considered in these plots. Relative to the Upper Basin, the changes projected for the Lower Basin are smaller in

magnitude on an absolute scale (e.g., change in millimeters rather than change in percentage):

- **Precipitation:** In the Lower Basin, precipitation is projected to decrease during half of the year, with spring exhibiting the most notable decline.
- **Temperature:** Monthly temperature increases are projected throughout the year ranging from 1.5 °C by 2025 to 4.0 °C by 2080.
- **Evapotranspiration:** ET is noticeably reduced in late spring and early summer, though modest increases are projected for winter. The marked reductions in late spring and early summer are likely due to the reductions in precipitation, runoff, and soil moisture that occur during these times.
- **Runoff:** Runoff is reduced during all seasons at this location and is more pronounced in the 2055 and 2080 time periods. Reductions result from the compounding effects of decreased precipitation and increased ET. It should be noted that runoff in this watershed (and similar watersheds in the Lower Basin) is very small and contributes little to the overall flow in the Colorado River. Runoff is usually less than 5–10 percent of the precipitation in this region.
- **Soil Moisture:** Soil moisture is projected to be lower year round, with the largest reductions occurring in the spring.

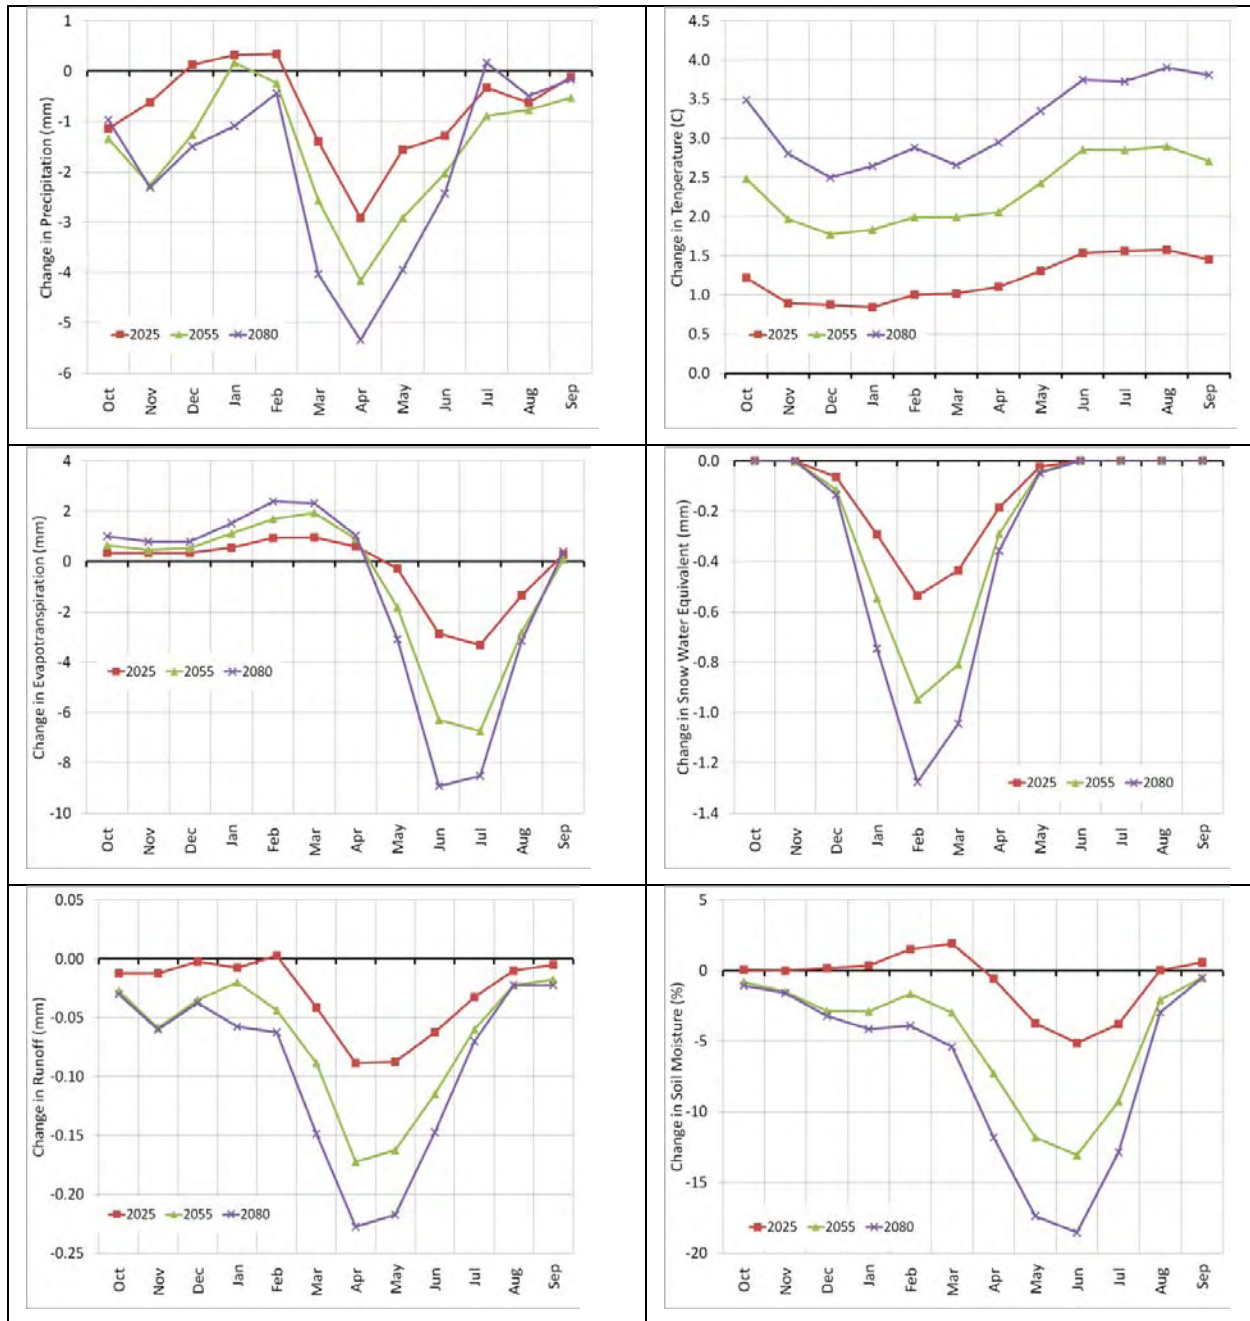

In the future, the Lower Basin is generally projected to have less water in the form of precipitation and soil moisture year round, and especially during winter and spring. However, the magnitude of these reductions is modest.

 25-Colorado River at Hoover Dam.

### 8.3.4 Summary of Changes in Hydrologic Processes

- The potential ET (PET) generally increases with warmer conditions and suggests a theoretical increase in ET demand. Actual ET, which is limited by soil moisture availability, is projected to increase across the Basin during seasons of highest available soil moisture. ET increases are projected in the Upper Basin (at lower elevations) and the Lower Basin in fall and winter as snowpack is not significant and warmer temperatures exist. Substantial ET decreases in the Upper and Lower Basin

are projected in summer as soil moisture is depleted earlier than under historical conditions. During spring, peak increases in ET are projected in the Upper Basin (at higher elevations) as higher winter precipitation and earlier snowmelt allow a higher percentage of potential ET to be satisfied. Conversely, in the Lower Basin, the largest decreases are projected during the spring as precipitation, runoff, and soil moisture are reduced during this time. ET changes described here are from natural watershed and non-irrigated areas. ET effects on irrigated areas and water demand are discussed in *Technical Report C – Water Demand Assessment*.

- Snowpack is projected to decrease as more precipitation falls as rain rather than snow and warmer temperatures cause an earlier melt. Decreases of snowpack in the fall and early winter are expected in areas where precipitation is not changed or is increased, and is caused by a greater liquid form of precipitation due to warming. Substantial decreases in spring snowpack are expected and projected to be widespread, due to earlier melt or sublimation of snowpack.
- Soil moisture represents a significant portion of the seasonal watershed storage and buffers monthly changes in water availability and consumptive use. The interplay among precipitation, snowpack, ET, and runoff causes changes in soil moisture conditions. In general, soil moisture is depleted earlier in the year, and deficits persist longer into the late fall and early winter compared to historical conditions. In regions with overlying snowpack, earlier melt implies earlier contribution to soil moisture storage and an earlier opportunity for ET to consumptively use this stored water. In all regions, there is projected to be increased potential ET due to warming. However, actual ET is governed by water availability, and when such soil moisture storage is depleted actual ET is curtailed. Reductions in soil moisture at the beginning of summer (approximated as July 1) are modest but consistent throughout the Basin. Larger reductions are projected in the higher elevation portions of the Basin where moisture persists longer. Overall, the watershed enters the winter season with larger soil moisture deficits and greater opportunity to store and consume winter precipitation.
- Runoff (both direct and baseflow), the balance of hydrologic processes affecting the supply and demand at the local grid-scale, is spatially diverse, but is generally projected to decrease, except in the northern Rockies. As with precipitation, runoff is projected to increase significantly in the higher elevation Upper Basin during winter, but exhibits decreases during spring and summer. Increases in runoff in the summer across the southwestern portion of the Basin are consistent with higher precipitation rates, possibly associated with a more active monsoon. However, the increases from an absolute change perspective are small (generally less than 5 mm [0.15 inch] per year) and do not contribute to substantial net supply to the Colorado River. Due to the minimal amount of annual rainfall in this region, however, caution should be taken in interpreting a percentage increase (a small increase from near zero is a large percentage increase).

### **8.3.5 Climate Teleconnections**

Climate change projections of ENSO characteristics for the balance of this century are model-dependent and inconclusive. The current state of GCMs does not consistently capture

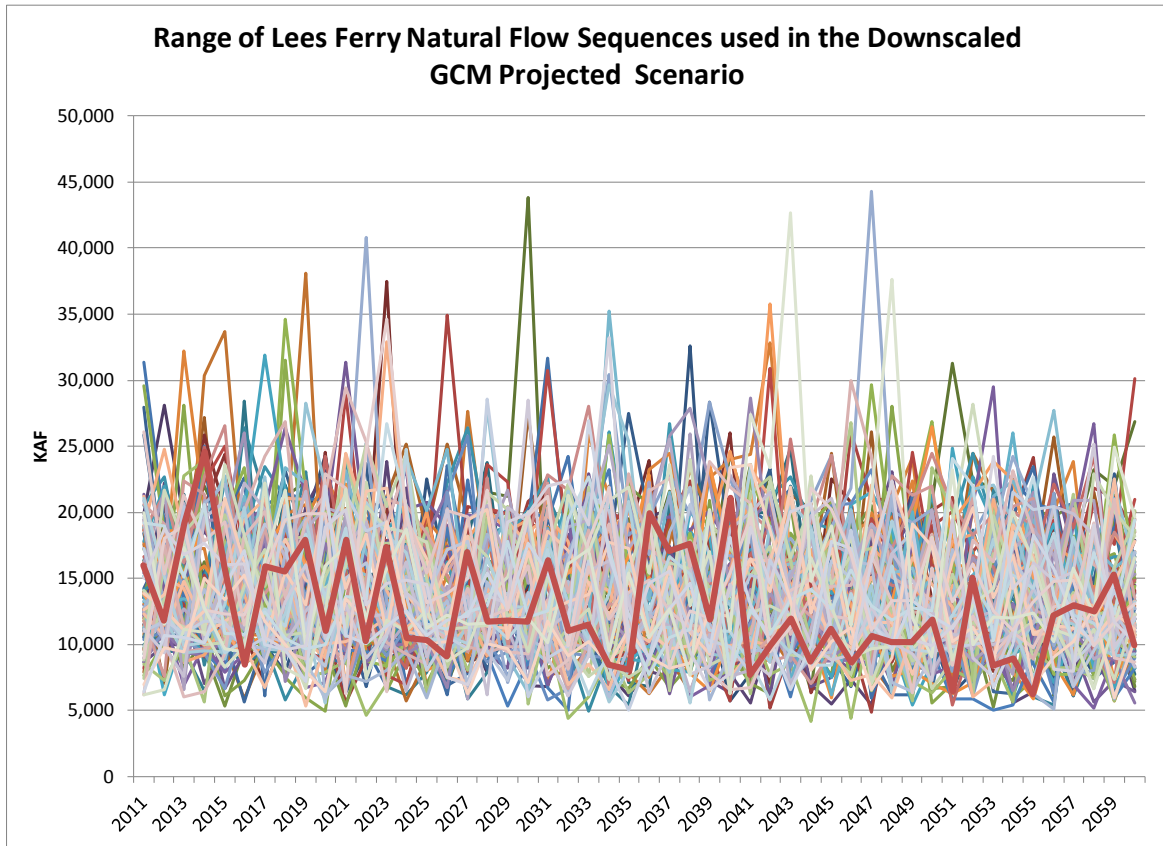

the dynamics of ENSO and other longer-term indices. AchutaRao and Sperber (2002) evaluated ENSO simulations using 80-year control runs from 17 GCMs that participated in the Coupled Model Intercomparison Project (CMIP). They found that only a subset of the GCMs produce realistic amplitudes of NINO3 and SOI, but ENSO often tends to occur at higher than observed frequency. In their recent study (AchutaRao and Sperber, 2006), though, they find the next generation GCMs that participated in the IPCC AR4 tend to be more realistic in representing the frequency with which ENSO occurs. The GCMs are better at locating enhanced temperature variability over the eastern Pacific Ocean. They suggest multi-century integrations of GCMs may be required to statistically assess model improvement of ENSO. ENSO has an important role in western U.S. climate. Whether the frequency and characteristics of ENSO will be changed in a changing climate is having strong practical importance. Few of the recent studies analyzed GCM simulations to address these questions (Yeh et al. 2009; Collins et al., 2010). However, there is no common consensus yet in the scientific community. Collins et al. (2010) argues that despite considerable progress in the understanding of the impact of climate change on many of the processes that contribute to El Niño variability, it is not yet possible to say whether ENSO activity will be enhanced or damped, or if the frequency of events will change. Yeh and Kirtman (2007) investigate two coupled GCMs—the Meteorological Research Institute’s model, and the Geophysical Fluid Dynamics Laboratory’s (GFDL) model—to analyze projected ENSO amplitude changes using a four times carbon dioxide emission scenario. They determine that despite the large changes in the tropical Pacific mean state, the changes in ENSO amplitude are highly model-dependent. Results suggest that the understanding of changes in ENSO statistics among various climate change projections is highly dependent on whether the model ENSO is in the linear or nonlinear regime. ENSO and PDO are of only limited skill in determining basin precipitation; thus, even improved simulation results of these indices may be of limited value in making assessments of future supply conditions. Further research is needed to investigate the teleconnections and the direction of these teleconnections in the future.

### **8.3.6 Streamflow**

Natural streamflows were simulated at the 29 flow locations for each of the 112 climate projections. Figure B-44 displays all of the individual 112 sequences in the Downscaled GCM Projected scenario. The sequence bolded in figure B-44 also appears in figure B-45, which is a representative trace of the 112 sequences. In figure B-45, the mean annual flow of the 112 sequences at this location declines substantially over time due to changes in hydrologic processes. Mean annual flows for Colorado River at Lees Ferry, Arizona for the 50-year period of the Study (2011–2060) are approximately 13.7 maf. This represents a reduction in streamflow of approximately 6 percent compared to the period 1950–1999 (14.6 maf), or approximately 9 percent compared to the long-term period 1906–2007 (15.0 maf). It should be noted that the median of the projections is nearly 1.0 maf lower (annual flow of around 12.7 maf) than the mean, indicating that the projection ensemble exhibits a strong drying trend but that some wetter projections are compensating in the mean statistic. A few projections (less than 10 percent) show considerably more annual variability than the observed record. Although simulated future minimum flows are similar to those in the observed record, the maximum annual flows are significantly higher.

Finally, figure B-46 shows the range of Colorado River flow projections under the Downscaled GCM Projected scenario as compared to the historical observed flows. Observed natural flows span from 1906-2007 while the projections begin in 1950 and extend through 2099. During the overlapping period of 1950–2007, the projection reflects the range of natural flows from the observed record. Interestingly, the projection ensemble indicates a declining trend starting in the 1990s and a significant expansion in variability starting in the late 2000s.

A number of sequences in the Downscaled GCM Projected scenario exhibit occasional annual runoff conditions that far exceed the maximum in the observed or paleo records. Although it is possible that future climate will expand the magnitude and frequency of extreme events, it is also possible that some projections are simply extreme outliers based on the ensemble. As shown in figure B-46, 5–10 percent of the projections show annual flows in excess of the maximum observed natural flow of 25 maf for any given year.

To better understand the issue of simulated extreme high flows and to determine whether specific GCMs or emission scenarios were driving this result, further analysis was conducted. For each downscaled climate projection, the cumulative difference from the simulated maximum flow to the maximum observed annual value of 25 maf over the study period 2011–2060 was computed. In addition, the total number of years in which the simulated flow exceeded 25 maf was counted for the 112 VIC model simulations. The results of this analysis are shown in figure B-47. Each of the 112 projections are listed and colored by the emission scenario (blue for A1B, red for A2, and green for B1). The corresponding dot represents the number of years in which that projection had simulated flows greater than 25 maf. The bar represents the cumulative flow above 25 maf. More than half of all GCM projections produced at least one event greater than 25 maf and these occurred regardless of emission scenario. None of the projections had more than 4 years in which they exceeded 25 maf. In addition, the GCMs with the largest deviations under one emission scenario produced fewer or no deviations under another emission scenario. The analysis concluded that it is a rare occurrence for a projection to exceed 25 maf, but the potential is prevalent among the ensemble members regardless of emission scenario. The GCMs ECHAM5, CCSM, MIROC, and GFDL, however, stood out in producing the fewest of these events (see appendix B2).

FIGURE B-47

Cumulative difference from Simulated Annual Maximum Flow and 25 maf (bar) and Total No. of Years that Exceed 25 maf (dot) for Colorado River at Lees Ferry, Arizona for 112 downscaled projections for the period 2011-2060

WB612071112242AS Figure B-47.indd 01-30-12 tlaslichm

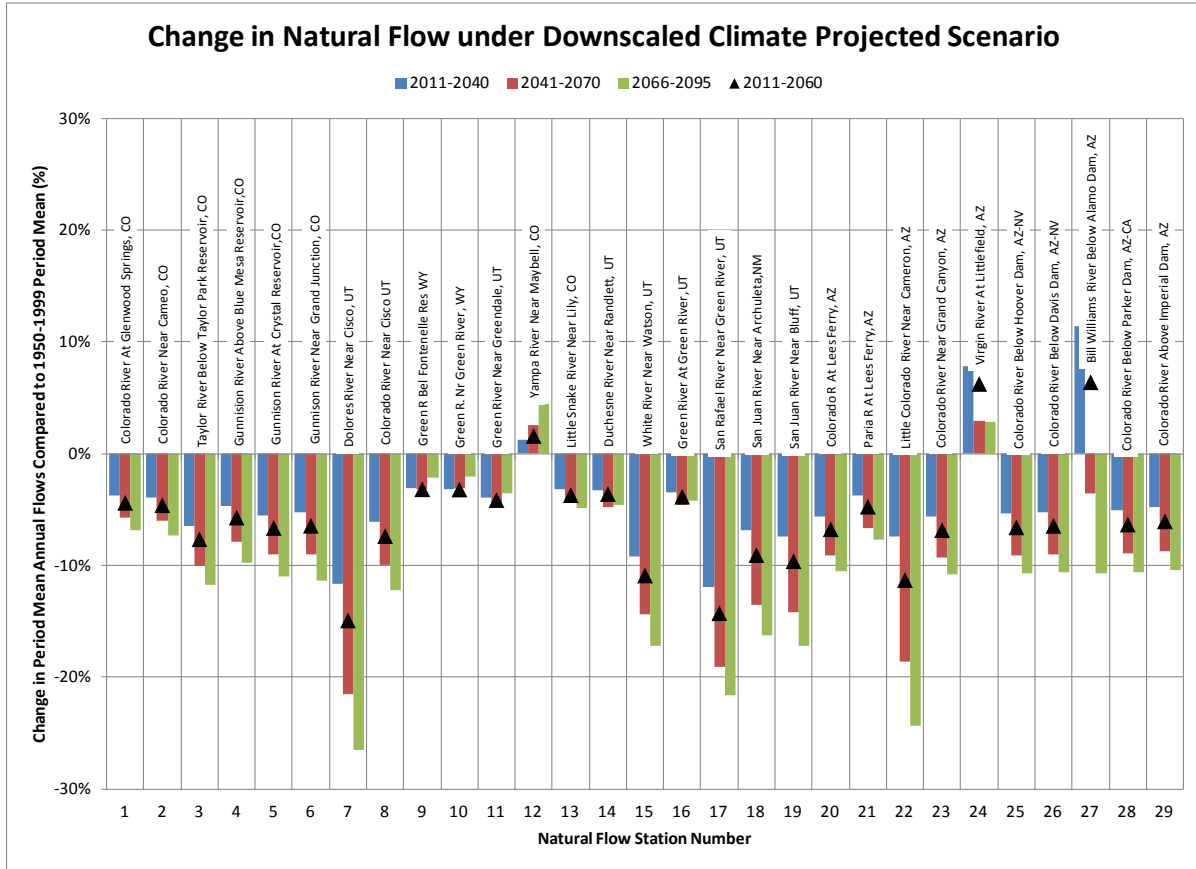

Figure B-48 shows the mean annual percent change in natural flow for all 29 locations for four future periods as compared to the 50-year historical period of 1950–99. The comparison here is not made to the observed 1906–2007 period, but rather to the historical VIC-simulated period such that any inherent model biases are incorporated in both VIC-simulated periods. The future periods reflect the Study period (2011-2060) and three 30-year periods extending throughout the 21<sup>st</sup> Century (2011-2040, 2041-70, and 2066-2095) to provide the time evolution of the projected flow changes.

All locations except the Yampa River, Virgin River, and Bill Williams River are projected to experience decreasing annual flows. The Dolores River, White River, San Rafael River, Little Colorado River, and San Juan River are projected to experience the largest percentage decrease in annual flows (greater than 10 percent). The Green River and upper watershed of the Colorado River are projected to experience smaller reductions in streamflow (less than 5 percent). These spatial differences in streamflow changes appear to be largely related to the location of the watershed in relation to the precipitation pattern changes (more northerly) and the relative elevation differences among watersheds (higher elevation). In general, smaller sub-basins that are farther north and at higher elevations (such as the Yampa River) may be expected to have increasing flows given projected increases in precipitation. Although precipitation is projected to increase in some larger sub-basins at lower elevations (such as the Green River), a decrease in flow is projected, possibly a result of the dominant role of increased temperature in these regions.

In general, the projected changes in streamflow are robust; with each subsequent 30-year period exhibiting a larger degree of change than the preceding 30-year period. The drying trend across most of the watersheds becomes stronger with each future time period. Similarly, the slightly greater streamflow trend for the Yampa River continues with each future period. However, the changes in the Virgin River and Bill Williams River show increases in the 2011–2040 period, but either decreases or smaller increases in the 2041–2070 and 2066–2095 periods. While the flow in these rivers is small, the change in direction over time appears consistent with the precipitation changes. Small increases in precipitation are projected in the 2011–2040 period, before reverting to decreases during 2041–2070 and 2066–95 periods.

**FIGURE B-48**  
 Simulated Relative Change in Mean Annual Flows (Ensemble Mean) for the Study Period (2011–2060), and Three Future Periods (2011-2040, 2041-2079, and 2066-2095), Compared to 1950–1999 for each of the 29 Natural Flow Locations.

The implicit assumption made with respect to the SRES emission scenarios used to drive the GCMs in the Study is that they are equally likely (or unlikely) and that they can be used in a multi-model ensemble. Climate projections through mid-century are dominated by the choice of GCM rather than individual emission scenarios. Table B-1 presents the range of projected change in Colorado River at Lees Ferry, Arizona streamflow associated with specific SRES emission scenarios, as compared to the ensemble of all emission scenarios. VIC simulations indicate streamflow reductions for all three SRES emission scenarios, and difference of less than 2 percent between emission scenario groupings for time periods covered in this study. These results are expected since the climate system responds relatively slowly to changes in emissions. By late century, the differences between simulated streamflows across emission scenarios becomes substantially larger, reflecting both the response time of the climate system and the higher emissions. During the first period indicated in table B-1, it is noteworthy that the greatest streamflow reduction occurs under the A1B scenario. While the GHG emissions in this scenario fall between the A2 and B1 scenarios in the distant future, they actually represent the highest emission scenario (of the three) through about 2020 (see appendix B2). By the second and third periods (mid-century and beyond) the streamflow changes between emission scenarios are more intuitive with the general emission pathways.

**TABLE B-1**  
 Percentage Change in Mean Flow with Respect to Historical Mean (1950–1999) at the Colorado River at Lees Ferry, Arizona Location

	<b>2011–2040</b>	<b>2041–2070</b>	<b>2066-2095</b>	<b>2011–2060</b>
All Projections	-5.6	-9.1	-10.5	-6.8
SRESB1	-5.2	-7.9	-8.0	-6.0
SRESA1B	-6.7	-9.1	-10.5	-7.7
SRESA2	-4.9	-10.3	-13.2	-6.5

While annual flows show decreases and likely some expansion in variability, monthly flows exhibit a significant shift in timing. Figure B-49 shows the simulated mean monthly flows from the climate projections for the Colorado River at Lees Ferry, Arizona compared to the observed monthly flows. Commensurate with the seasonal changes in temperature, precipitation, and hydrologic processes, after 2025 the peak streamflow occurs about one month earlier (from June to May) and is approximately 500 thousand acre-feet (kaf) lower. In addition, increases occur in winter streamflow, while substantial reductions occur in spring and summer. The wintertime increases are likely associated with increased precipitation in the Upper Basin, while spring and summer decreases are likely associated with earlier melt of the snowpack and reduced precipitation patterns. Prior to the mid-century it appears that the transition to earlier runoff is underway with increasing May flows and decreases in June flows, but the full monthly shift has not yet occurred. The lower panels of figure B-49 also indicate that there is no substantial difference in the monthly timing trends between emission scenarios.

The inter-annual variability in streamflow is another important component of water supply. Deficit statistics using the identical methods as those described for the historical supply were computed for each of the 112 climate projections. The 1906–2007 observed mean of 15.0 maf was used to set the threshold for determining whether the system was in a deficit or surplus. For the purpose of this report, “deficit” is defined as a consecutive 2-year period when the mean is less than the observed long-term mean of 15.0 maf. Similarly, “surplus” is defined as a consecutive 2-year period when the mean is above 15.0 maf.

**FIGURE B-49**  
 Comparison of Observed and Future Simulated Mean Monthly Flows at Colorado River at Lees Ferry, Arizona

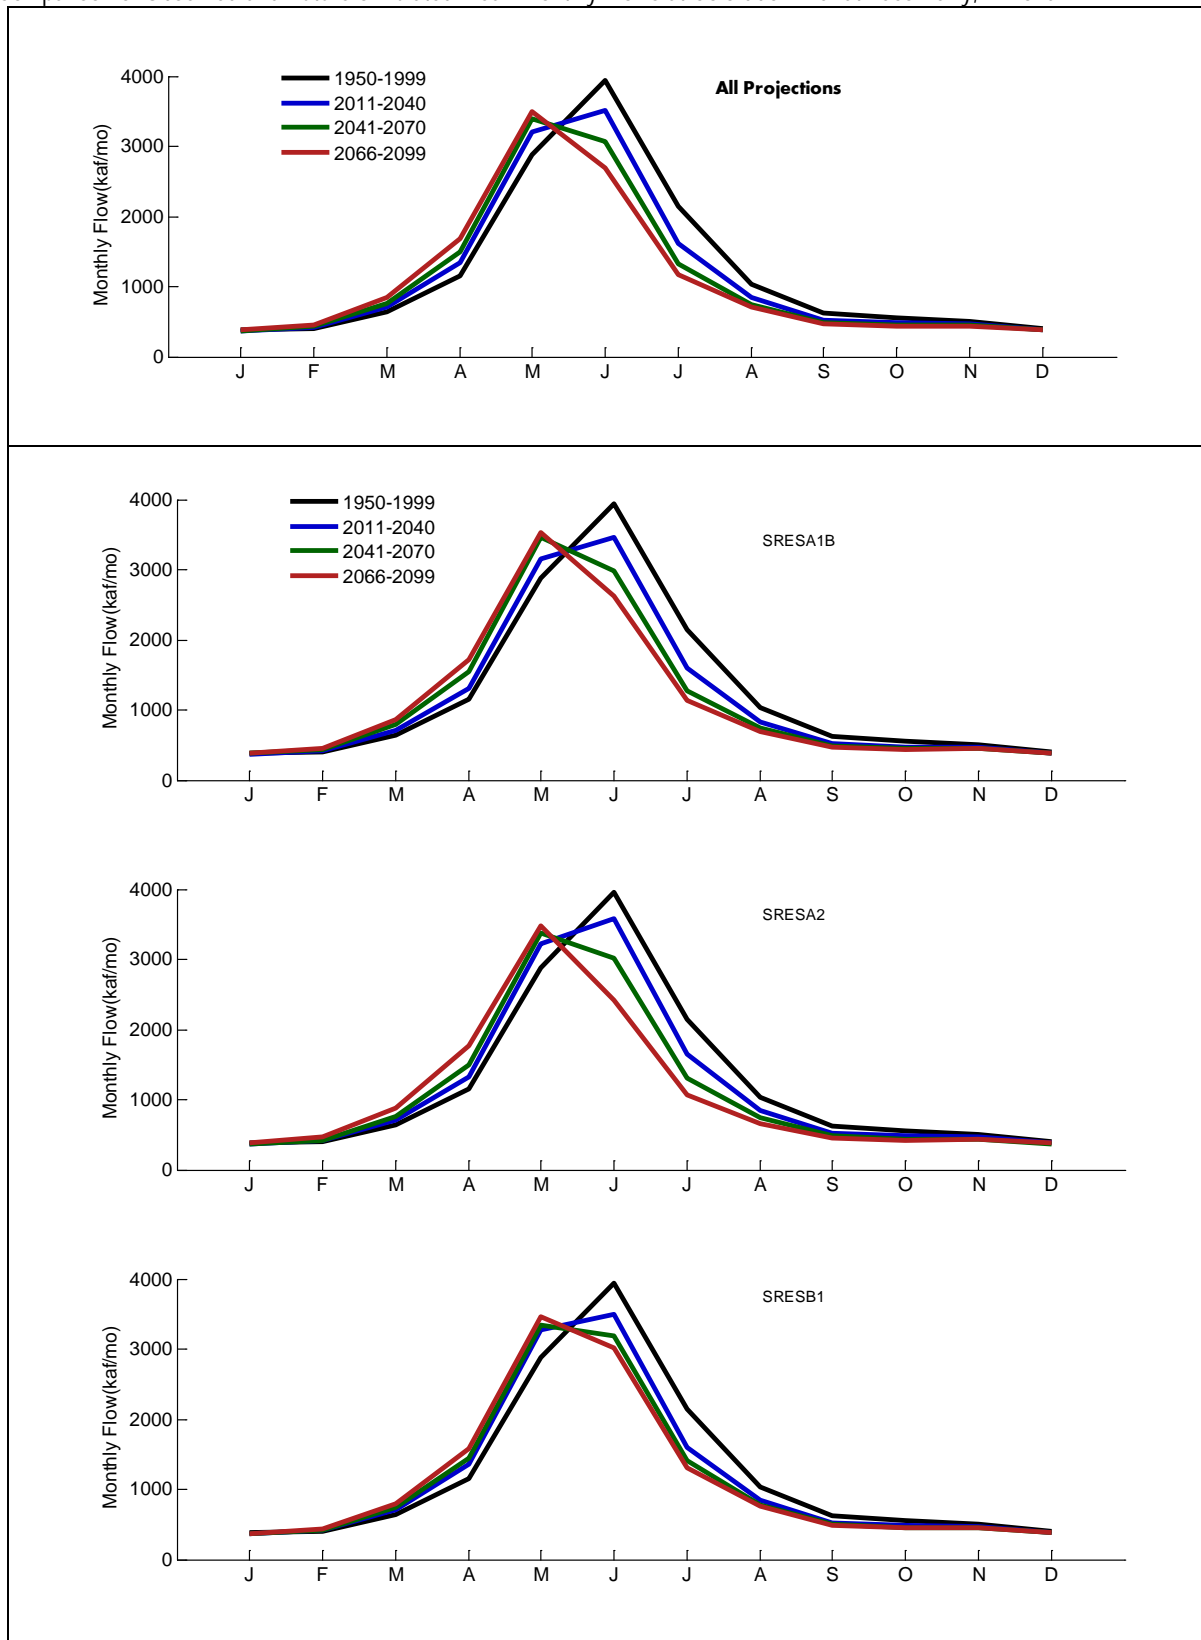

Figure B-50 illustrates the frequency and magnitude of both deficit and surplus spells. The inset figure shows the frequency occurrence of a specific spell length across all projections. The median exceedance probability of a surplus spell longer than 0 years is 30 percent, indicating that, when as measured against the 1906–2007 mean annual flow of 15 maf, about a third of the years in the future would be considered to not be a deficit. In addition, deficit length may extend greater than 20 years (indicated by the 90th percentile deficit length), as compared to the recent 9-year deficit. Under the Downscaled GCM Projected scenario (at the ensemble median) a 9-year deficit may occur up to 20 percent of the time and result in a cumulative deficit of 30–40 maf. The recent 9-year deficit is estimated to have a cumulative deficit of more than 28 maf. The results also suggest that under some climate projections, sustained periods of dryness will occur (deficit lengths greater than 50 years). However, most projections result in long-term mean annual flows that are less than the 15 maf observed mean. The future climate essentially arrives at a new mean state. Thus deficits may need to be evaluated against the projection-specific, long-term mean to reflect this new inter-annual variability about the new mean.

Figure B-51 is identical to figure B-50 except that the threshold for deficit and surplus is determined from the projection-specific, long-term mean, rather than the observed mean. The drought depiction is considerably different under these conditions. As expected, deficit and surplus frequencies are roughly equal. In addition, deficit spell lengths do not exceed 17 years and are a maximum of 8 years at the median of the projections. Deficit magnitudes at the 9-year deficit remain in the 18–40 maf range. Under this perspective, the inter-annual variability is not substantially different than the recent observed period, but rather the Downscaled GCM Projected means are significantly reduced, leading to the perspective of relatively sustained deficit when measured against recent observed flows. There is no absolute correct perspective; thus, both methods are presented here.

## 9.0 Comparison of Future Supply Scenarios

The water supply assessment described in this report includes four distinct supply scenarios that attempt to bracket the range of conditions that might be experienced over the next 50 years. The scenarios include direct use of the observed record (Observed Resampled scenario), direct use of the paleo reconstructions (Paleo Resampled scenario), blends of observed and paleo sequences (Paleo Conditioned scenario), and use of future climate projections and hydrologic modeling (Downscaled GCM Projected scenario). Figure B-52 shows the range of annual flows for the Colorado River at Lees Ferry, Arizona for each of the scenarios in a four-panel series.

**FIGURE B-52**

Annual Colorado River at Lees Ferry, Arizona Natural Flow Time Series for Supply Scenarios

(Median in bold black line, inter-quartile range in dark shading, 10th – 90th percentile range in light shading, selected individual sequence in bold colored line, max/min as whiskers), and 1906 – 2007 observed max and min (dashed lines).

The Observed Resampled, Paleo Resampled, and Paleo Conditioned scenarios have similar mean annual flows and a similar range of annual variability. The Paleo Resampled scenario contains individual years of flows lower than Observed Resampled, but a narrower band of variability within the inter-quartile range. The Paleo Conditioned scenario, by design, includes a similar range of annual flows as the Observed Resampled. The Downscaled GCM Projected scenario reflects possible changes in climate beyond what occurred historically and has lower mean annual flows while expanding the annual variability range through increased maximum annual flows. Mean annual natural flows for the Colorado River at Lees Ferry, Arizona range from 14.7 to 15.0 maf for the Observed Resampled, Paleo Resampled, and Paleo Conditioned scenarios. The Downscaled GCM Projected scenario results in mean annual flows of approximately 13.7 maf.

Each supply scenario includes multiple realizations, resulting in a range of flow statistics. Figure B-53 graphically depicts these annual flow statistics. The range of mean flows is greatest under the Downscaled GCM Projected scenario, with the inter-quartile range spanning roughly 12.5 to 15 maf and the absolute range covering 10 to 17 maf. Especially with respect to the use of climate projections, the ensemble mean or median should be considered more useful than any individual projections. This ensemble mean or median has been shown to perform better than any individual projection against a range of historical climate metrics and variability and trend significance, largely due to the cancelling out of natural internal GCM model variability and cancelling out of individual model errors (see Gleckler et al., 2008 and Pierce et al., 2009 for a more-complete discussion of this topic). The Paleo Resampled scenario, despite the large absolute range, has a smaller standard deviation than the other scenarios due to the tightness of the bulk of the realizations. Skew is a measure of the shape of the annual flow distribution. A skew of zero implies a normal distribution, in which wetter years and magnitudes are evenly balanced with drier years. Most scenarios have a positive skew, suggesting a bias to the drier side of the distribution. This is particularly noticeable in the Downscaled GCM Projected scenario. The Paleo Resampled scenario has the highest year-to-year correlation as measured by the backward lag-1 correlation. This high degree of correlation is attributable in part to the method used to develop the reconstructions. The minimum annual flows are fairly consistent across the scenarios, with the Paleo Resampled scenario exhibiting the most extreme low-flow condition. The Downscaled GCM Projected scenario exhibits a range of maximum annual flows well beyond those seen in any of the other scenarios.

**FIGURE B-53**  
 Summary Statistics for Annual Colorado River at Lees Ferry, Arizona Natural Flows for Supply Scenarios (for 2011-2060)  
 Figure shows the median (dash), 25th – 75th percentile band (box), and max/min (whiskers).

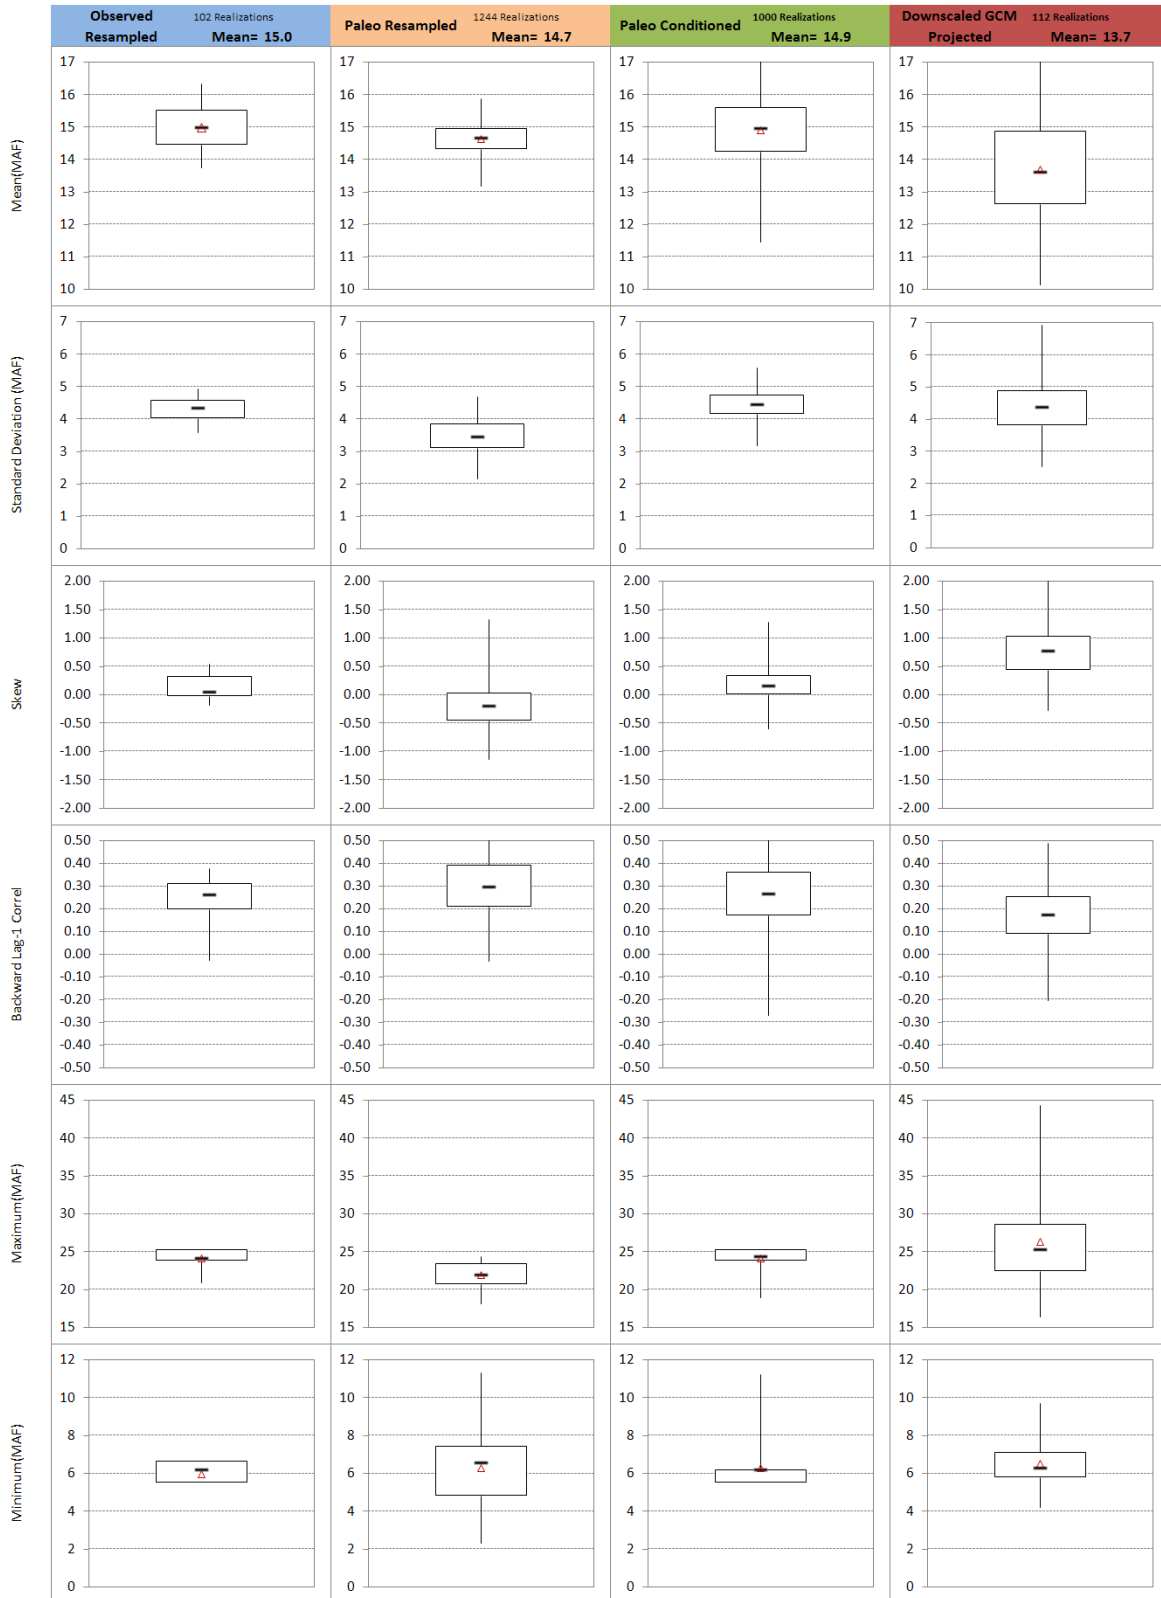

Figure B-54 provides a side-by-side comparison of each of the scenarios over the study horizon and the monthly flow range. Again, the Downscaled GCM Projected scenario demonstrates both higher high flows and lower low flows, measured as a 5-year average. This range, combined with the reduced mean annual natural flows in this scenario, makes the Downscaled GCM Projected scenario likely the most challenging supply conditions within which to manage the Basin. The figure also shows that the monthly variability of the Downscaled GCM Projected scenario is significantly larger than any other scenario. This is particularly true in the winter and spring, when the Upper Basin hydrologic processes are most active and subject to change under climate warming. The shift in peak flow timing from June to May is apparent in figure B-55, and becomes more pronounced when analyzing results for the later 30-year time periods (table B-3).

**FIGURE B-54**

Annual Colorado River at Lees Ferry, Arizona 5-Year Natural Flow Timeseries (top) and Monthly Variability across Supply Scenarios (bottom) (for 2011–2060)

Figure shows the median (dash), 25th – 75th percentile band (box), and max/min (whiskers).

**FIGURE B-55**  
 Monthly Colorado River at Lees Ferry, Arizona Natural Flow Variability for Supply Scenarios (for 2011–2060)  
 Figure shows the median (dash), 25th – 75th percentile band (shading), and max/min (whiskers).

The inter-annual variability of streamflow across the scenarios is characterized by determining the frequency, duration, and magnitude of deficit and surplus periods. Figure B-56 is a four-panel figure showing the length and magnitude of such spells. For example, the maximum length of sustained deficit through 2007 in the Observed Resampled scenario was 8 years (note that this length would be 9 years if the observed record extended through 2010), while the maximum sustained surplus is for 7 years. However, the Paleo Resampled, Paleo Conditioned, and Downscaled GCM Projected scenarios all produce deficit periods of 15 years or longer. The maximum deficit accumulated is approximately 60 maf over the 15 years of deficit (both Paleo Conditioned and Downscaled GCM Projected scenarios). However, the reduced mean annual flow in the Downscaled GCM Projected scenario causes many of the realizations to be in a sustained deficit using the recent observed flows as the measure.

FIGURE B-56

Frequency, Duration, and Magnitude of Deficit and Surplus Periods for Supply Scenarios (for 2011–2060).

Top figures (left to right) are the Observed Resampled and Paleo Resampled scenarios. Bottom figures (left to right) are the Paleo Conditioned and Downscaled GCM Projected scenarios. Box plots show the median (dash), 25th – 75th percentile band (shading), and max/min (whiskers).

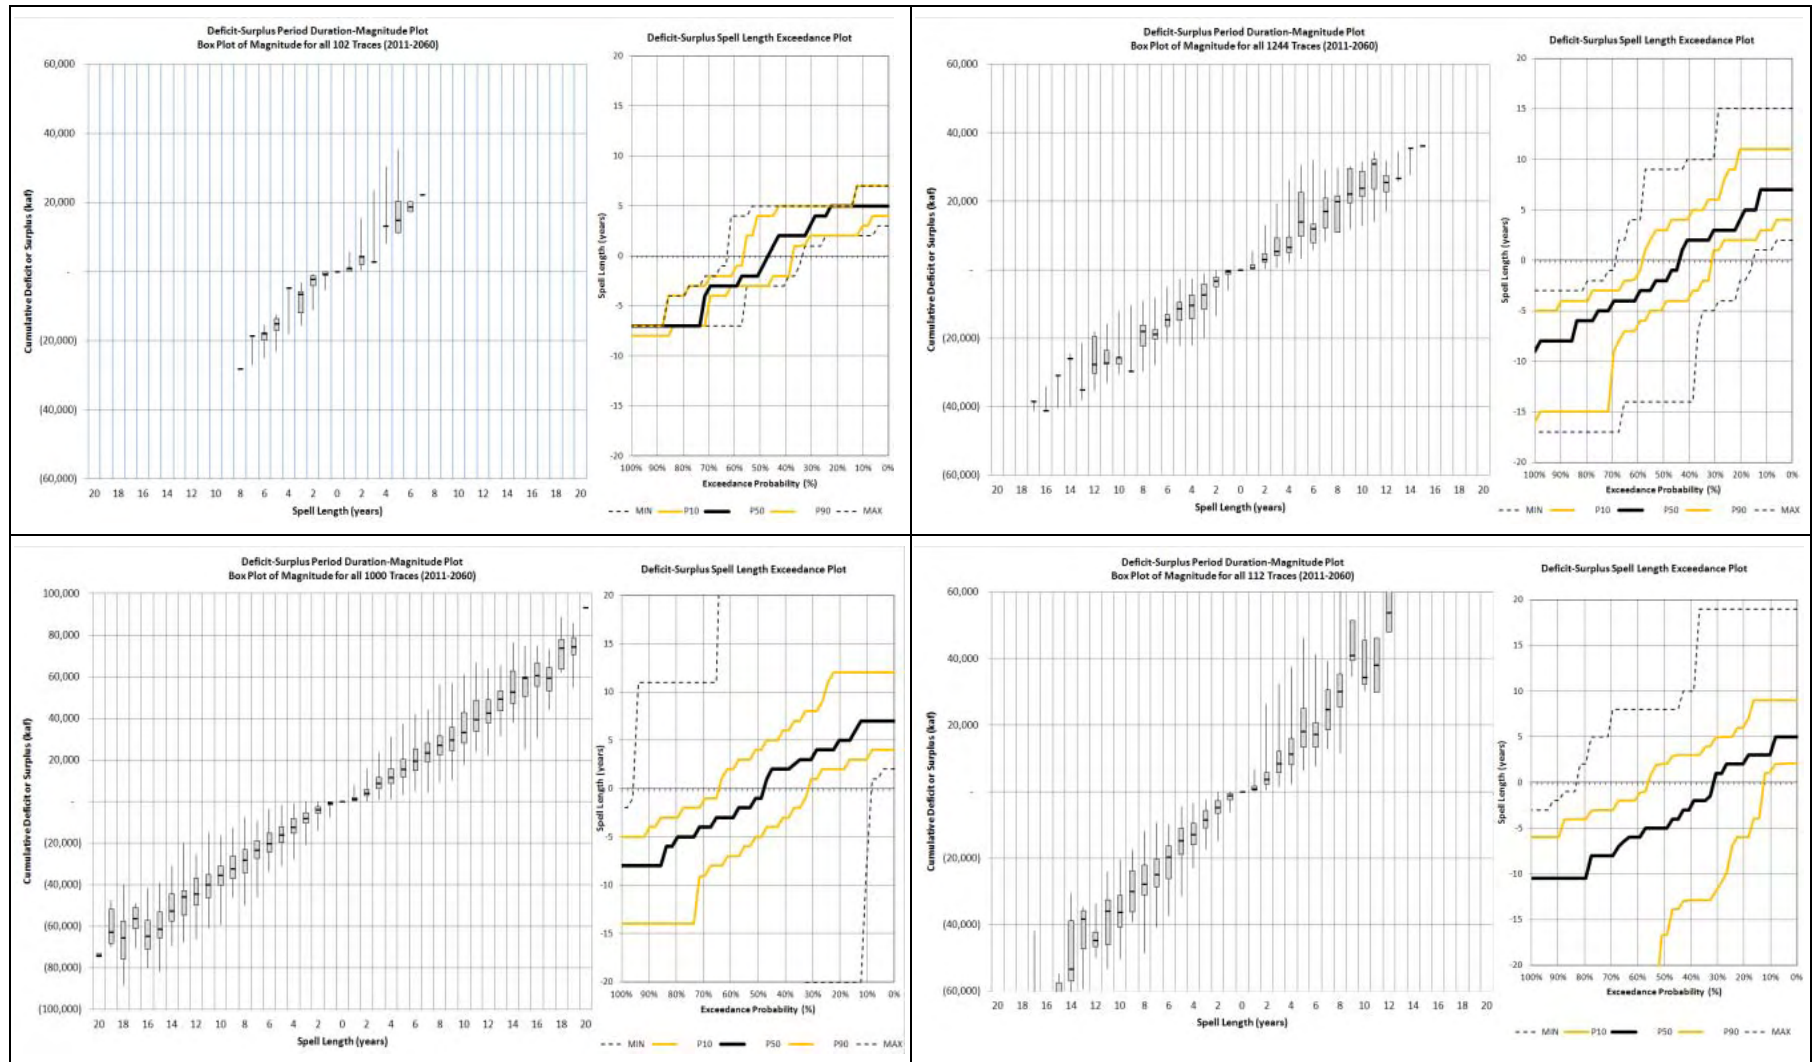

Table B-2 summarizes the key statistics for each water supply scenario and generally provides a tabular presentation of the information presented in the figures in this section. Similarly, table B-3 summarizes the annual and monthly statistics for the Downscaled GCM Projected scenario for three distinct future periods (2011–2040, 2041–2070, and 2066–2095) to assist in the evaluation of temporal trends. It should be noted that the last of these three periods is beyond the Study period, but is shown to assist in understanding trajectory of projected changes. Under this scenario, mean annual flows are projected to continue to decrease over time (from -7.5 percent around 2025 to -10.9 percent around 2055, to -12.4 percent around 2080) as compared to the 1906–2007 mean. At the same time, the shift in peak streamflow timing evolves from a current peak in June to an eventual peak in May due to earlier snowmelt and increased rain-to-snow ratios in response to warming.

TABLE B-2  
Summary of Key Streamflow Statistics for Each Water Supply Scenario for the Period 2011–2060

	Statistic	Scenario			
		Observed Resampled	Paleo Resampled	Paleo Conditioned	Downscaled GCM Projected
<b>Annual (Water Year)</b>	Average Annual Flow (maf)	15.0	14.7	14.9	13.7
	Percent Change from Long-Term Mean (1906–2007)	0%	-2%	-1%	-8.7%
	Median (maf)	15.0	14.7	15.0	13.6
	25 <sup>th</sup> Percentile (maf)	14.5	14.3	14.2	12.6
	75 <sup>th</sup> Percentile (maf)	15.5	15.0	15.6	14.9
	Minimum Year Flow (maf)	5.6	2.3	5.6	4.2
	Maximum Year Flow (maf)	25.2	24.3	25.2	44.3
<b>Monthly</b>	Peak Month	June	June	June	June
	Peak Month Mean Flow (kaf)	4,007	3,914	4,000	3,393
	Peak Month Maximum Flow (kaf)	8,467	8,531	8,678	14,693
	Month at Which Half of Annual Flow (Water Year) is Exceeded	June	June	June	June
<b>Deficit Periods<sup>9</sup></b>	Maximum Deficit (maf)	28.2	38.4	98.5	246.1
	Maximum Spell Length (years)	8	17	24	50
	Intensity (Deficit/Length) (maf/year) [median]	3.5	2.3	4.1	7.4
	Frequency of 5+ Year Spell Length (Percent) [median]	22%	30%	25%	48%
	Maximum 8-year Deficit (longest in 1906–2007 observed record, maf)	28.2	29.8	50	48.6
<b>Surplus Periods<sup>10</sup></b>	Maximum Surplus (maf)	22.2	36.2	88	74.7
	Maximum Spell Length (years)	7	15	25	19
	Intensity (Surplus/Length) (maf/year)	3.2	2.4	3.5	13.2
	Frequency of 5+ Year Spell Length (Percent)	28%	15%	18%	<1%
	Maximum 7-year Surplus (longest in 1906–2007 observed record, maf)	22.2	29.2	44	39.2

<sup>9</sup>A deficit period occurs whenever the 2-year running average flow is below the observed average from 1906–2007 of 15.0 maf.

<sup>10</sup>A surplus period occurs whenever the 2-year running average flow is above the observed average from 1906–2007 of 15.0 maf.

**TABLE B-3**

Summary of Annual and Monthly Streamflow Statistics for the Downscaled GCM Projected Scenario for the 3 Future 30 Year Time Periods: 2011–2040 (2025), 2041–2070 (2055), and 2066–2095 (2080).

*Note: the last time period is beyond the Study period, but is shown for informational purposes.*

## 10.0 Summary and Limitations

This report documents the current and future water supply assessment for the Colorado River Basin Supply and Demand Study. The research and development program initiated by Reclamation in 2004 resulted in the development of the Paleo Resampled and Paleo Conditioned scenarios. These scenarios are described in appendix N of the 2007 Interim Guidelines Final EIS, as is the Observed Resampled scenario. The Downscaled GCM Projected scenario is the newest addition to the set of scenarios and has not been previously used in any Reclamation long-term planning activities. The VIC modeling associated with the projected climate forcings suggests changes in streamflows resulting from this scenario are consistent with past efforts, particularly that of Christensen and Lettenmaier (2007).

The streamflow bias correction that has been included in this report compensates for biases in climate and hydrologic data as well as for biases in the hydrology model (VIC) structure. This step is important for the use of results other than “change” metrics in subsequent analyses. However, in evaluating biases and VIC model performance, the need for model calibration at finer resolutions is found to be a necessary next step and will reduce the level of bias correction needed in the future. Care should be taken in attempting to apply the “raw” VIC results for smaller watersheds in the Basin.

The role of snowpack development and melt, ET, and soil moisture are found to be very important in determining the available supply in the Colorado River Basin. However, limited

Basin-wide data are available to better understand these dynamics. The elevational sensitivity of snowpack, effect of warming, and increased carbon dioxide on ET, and the role of summer and fall soil moisture on water supply are areas in need of further study.

In addition, newer GCMs and downscaling techniques will soon be available under the IPCC Fifth Assessment Report (AR5). The improved resolution and model physics of some of the new GCMs may refine patterns of precipitation changes (such as the increases in the Green River Basin and Upper Colorado, and monsoonal effects in the Lower Basin).

In efforts beyond the Study, Reclamation will continue to work to address these limitations. Additionally, as new scientific findings and technological advancements become available that help address the uncertainties such as those related to model biases, this information will be incorporated, helping to ensure Reclamation’s Colorado River planning studies utilize the best available science.

## Disclaimer

The Colorado River Basin Water Supply and Demand Study (Study) is funded jointly by the Bureau of Reclamation (Reclamation) and the seven Colorado River Basin States (Basin States). The purpose of the Study is to analyze water supply and demand imbalances throughout the Colorado River Basin and those adjacent areas of the Basin States that receive Colorado River water through 2060; and develop, assess, and evaluate options and strategies to address the current and projected imbalances.

Reclamation and the Basin States intend that this Study will promote and facilitate cooperation and communication throughout the Basin regarding the reliability of the system to continue to meet Basin needs and the strategies that may be considered to ensure that reliability. Reclamation and the Basin States recognize the Study will have to be constrained by funding, timing, and technological and other limitations, which may present specific policy questions and issues, particularly related to modeling and interpretation of the provisions of the Law of the River during the course of the Study. In such cases, Reclamation and the Basin States will develop and incorporate assumptions to further complete the Study. Where possible, a range of assumptions will typically be used to identify the sensitivity of the results to those assumptions.

Nothing in the Study, however, is intended for use against any Basin State, any Native American tribe or community, the Federal Government, or the Upper Colorado River Commission in administrative, judicial, or other proceedings to evidence legal interpretations of the law of the river. As such, assumptions contained in the Study or any reports generated during the Study do not, and shall not, represent a legal position or interpretation by the Basin States, any Native American tribe or community, Federal Government, or Upper Colorado River Commission as it relates to the law of the river. Furthermore, nothing in this Study is intended to, nor shall this Study be construed so as to, interpret, diminish, or modify the rights of any Basin State, any Native American tribe or community, the Federal Government, or the Upper Colorado River Commission under federal or state law or administrative rule, regulation or guideline, including without limitation the Colorado River Compact, (45 Stat. 1057), the Upper Colorado River Basin Compact (63 Stat. 31), the Utilization of Waters of the Colorado and Tijuana Rivers and of the Rio Grande, Treaty Between the United States of America and Mexico (Treaty Series 994, 59 Stat. 1219), the United States/Mexico agreement in Minute No. 242 of August 30, 1973, (Treaty Series 7708; 24 UST 1968) or Minute No. 314 of November 26, 2008, or Minute No. 318 of December 17, 2010, the Consolidated Decree entered by the Supreme Court of the United States in *Arizona v. California* (547 U.S. 150 (2006)), the Boulder Canyon Project Act (45 Stat. 1057), the Boulder Canyon Project Adjustment Act (54 Stat. 774; 43 U.S.C. 618a), the Colorado River Storage Project Act of 1956 (70 Stat. 105; 43 U.S.C. 620), the Colorado River Basin Project Act of 1968 (82 Stat. 885; 43 U.S.C. 1501), the Colorado River Basin Salinity Control Act (88 Stat. 266; 43 U.S.C. 1951), the Hoover Power Plant Act of 1984 (98 Stat. 1333), the Colorado River Floodway Protection Act (100 Stat. 1129; 43 U.S.C. 1600), or the Grand Canyon Protection Act of 1992 (Title XVIII of Public Law 102-575, 106 Stat. 4669). Reclamation and the Basin States continue to recognize the entitlement and right of each State under existing law to use and develop the water of the Colorado River system.<sup>11, 12</sup>

<sup>11</sup> Reclamation and the Basin States have exchanged letters and are in the process of amending the Contributors' funding agreement to, among other things, document and clarify the intent of the Parties consistent with the above disclaimer.

<sup>12</sup> Reclamation and the Basin States are in the process of modifying this disclaimer based on discussions with Native American tribes and communities.
