

7. Groundwater

S. B. Jones and R. S. Loffman

Abstract

Most residents in the Oak Ridge area do not rely on groundwater for potable supplies, although suitable water is available. Local groundwater provides some domestic, municipal, farm, irrigation, and industrial uses, however, and must be viewed as both a potential pathway for exposure to hazardous wastes and as a means for contaminant transport. Statutes codified into regulations by EPA specifically target the protection of groundwater from contamination by hazardous wastes. The regulations guide groundwater monitoring at the DOE plants in Oak Ridge. Monitoring programs established on the ORR assess groundwater contamination and transport on and off the reservation and are intended to comply with established regulatory requirements.

7.1 INTRODUCTION

The groundwater monitoring programs at the ORR are designed to gather information to determine the effects of DOE operations on groundwater quality in compliance with all applicable requirements.

The location and movement of groundwater must be determined to identify the extent of contamination in groundwater and to predict the possible fate of contaminants. To make this determination, an understanding is required of how groundwater moves in general and how that movement will be influenced by the geological setting.

7.1.1 Geological Setting

The ORR is located in the Tennessee portion of the Valley and Ridge Province, which is part of the southern Appalachian fold and thrust belt. As a result of thrust faulting and varying erosion rates, a series of parallel valleys and ridges have formed that trend southwest-northeast.

Two geologic units on the ORR, designated as the Knox Group and the Maynardville Limestone of the Conasauga Group, both consisting of dolostone and limestone, constitute the Knox Aquifer. A combination of fractures and solution conduits in this aquifer control flow over substantial areas, and relatively large quantities of water may move relatively long distances. Active

groundwater flow can occur at substantial depths in the Knox Aquifer [300 to 400 ft (91.5 to 122 m) deep]. The Knox Aquifer is the primary source of groundwater to many streams (base-flow), and most large springs on the ORR receive discharge from the Knox Aquifer. Yields of some wells penetrating larger solution conduits are reported to exceed 1000 gal/min (3784 L/min).

The remaining geologic units on the ORR (the Rome Formation, the Conasauga Group below the Maynardville Limestone, and the Chickamauga Group) constitute the ORR Aquitards, which consist mainly of siltstone, shale, sandstone, and thinly bedded limestone of low to very low permeability. Nearly all groundwater flow in the aquitards occurs through fractures. The typical yield of a well in the aquitards is less than 1 gal/min (3.8 L/min), and the base flows of streams draining areas underlain by the aquitards are poorly sustained because of such low flow rates.

7.1.2 Hydrogeological Setting

7.1.2.1 Groundwater Hydrology

When rain falls, a portion of the rainwater accumulates as groundwater by soaking into the ground, infiltrating soil and rock. The accumulation of groundwater in pore spaces of sediments and bedrock creates sources of usable water, which flows in response to external forces. Groundwater eventually reappears at the surface

Oak Ridge Reservation

in springs, swamps, stream and river beds, or pumped wells. Thus, groundwater is a reservoir for which the primary input is recharge from infiltrating rainwater and whose output is discharge to springs, swamps, rivers, streams, and wells.

Water infiltrates by percolating downward through the pore spaces between sediment grains and also through fractures in bedrock. The smaller the pore spaces or fractures, the slower the flow of water through the subsurface. The physical property that describes the ease with which water may move through the pore spaces and fractures in a given material is called permeability, and it is largely determined by the volume and size of these features and how well they are connected.

As water infiltrates the earth, it travels down through the unsaturated zone, where the pore spaces and fractures are partly filled with water and partly filled with air. Water moving down through the unsaturated zone will eventually reach the saturated zone, where the pore spaces and fractures are completely filled with water. The boundary between the unsaturated and the saturated zones is known as the water table, which generally follows, in subtle form, the contour of the surface topography. Springs, swamps, and beds of streams and rivers are the outcrops of the water table, where groundwater is discharged to the surface.

Because the earth's permeability varies greatly, groundwater flowing through subsurface strata does not travel at a constant rate or without impediment. Strata that transmit water easily (such as those composed primarily of sand) are called aquifers, and strata that restrict water movement (such as clay layers) are called aquitards. An aquifer with an aquitard lying above and beneath it is termed a confined aquifer. Groundwater moves through aquifers toward natural exits, or discharge points, to reappear at the surface.

The direction of groundwater flow through an aquifer system is determined by the permeability of the strata containing the aquifer and by the hydraulic gradient, which is a measure of the difference in hydraulic head over a specified distance. The driving force for groundwater

movement through the saturated zone comprises differences in hydraulic head. The hydraulic head at any given point in an aquifer is a function of the energy associated with the water's elevation above sea level and the pressures exerted on it by surrounding water. Because hydraulic head is not solely a function of elevation, downgradient is not necessarily synonymous with downhill. The downgradient direction will have a horizontal and vertical component, just as a household drain moves wastewater both horizontally and vertically, seeking the lowest point of exit. Aquitards deflect groundwater movement just as drain pipe walls control the direction of wastewater movement. In an aquifer constrained by aquitards such as horizontal clay layers, the downgradient direction tends to be more horizontal than vertical.

Groundwater on the ORR occurs both in the unsaturated zone as transient, shallow subsurface stormflow and within the saturated zone. An unsaturated zone of variable thickness separates the stormflow zone and water table. Adjacent to surface water features or in valley floors, the water table is found at shallow depths and the unsaturated zone is thin. Along the ridge tops or near other high topographic areas, the unsaturated zone is thick, and the water table often lies at considerable depth [50 to 175 ft (15 to 50 m) deep]. In low-lying areas where the water table occurs near the surface, the stormflow zone and saturated zone are indistinguishable.

Several distinct flow intervals occur within the aquifer: the uppermost water table interval, the intermediate interval, the deep interval, and the aquiclude. The divisions within the saturated zone grade into one another vertically and are not separated by distinct boundaries but reflect an overall decrease in the rate of groundwater flow with depth. Within the ORR aquitards, the greatest groundwater flow rates occur in the stormflow zone and the smallest within the deep zone. Water does not flow in the aquiclude, which is defined by a transition to saline water (Fig. 7.1). In the Knox Aquifer, the greatest groundwater flow is in the water table and intermediate intervals [depths to approximately 300 ft (91.5 m)].

As noted earlier, two broad hydrologic units are identified on the ORR: the Knox Aquifer and

Fig. 7.1. Vertical relationships of flow zones of the ORR: estimated thicknesses, water flux, and water types.

the ORR Aquitards, which consist of less permeable geologic units. Figure 7.2 is a generalized map showing surface distribution of the Knox Aquifer and the ORR Aquitards. Many waste areas on the ORR are located in areas underlain by the ORR Aquitards.

7.1.2.2 Unsaturated Zone Hydrology

In undisturbed, naturally vegetated areas on the ORR, about 90% of the infiltrating precipitation does not reach the water table but travels through the 1- to 2-m-deep stormflow zone, which approximately corresponds to the root zone. Because of the permeability contrast between the stormflow zone and the underlying unsaturated zone, the stormflow zone partially or completely saturates during rainfall events, and then water flows laterally, following very short flow paths to adjacent streams. When the stormflow zone becomes completely saturated, flow of water over the land occurs. Between rainfall events, as the stormflow zone drains, flow rates decrease dramatically and water movement becomes nearly vertical toward the underlying water table.

The rate at which groundwater is transmitted through the stormflow zone is attributed to large pores (root channels, worm bores, and relict fractures). Stormflow is primarily a transport mechanism in undisturbed or vegetated areas, where it intersects shallow waste sources. Most buried wastes are below the stormflow zone; however, in some trenches a commonly observed condition known as “bathtubbing” can occur, in which the excavation fills with water and may overflow into the stormflow zone. All stormflow ultimately discharges to streams on the ORR.

7.1.2.3 Saturated Zone Hydrology

As shown in Fig. 7.1, the saturated zone on the ORR can be divided into four vertically distinct flow zones: an uppermost water table interval, an intermediate zone, a deep zone, and an aquiclude. Available evidence indicates that most water in the saturated zone in the aquitards is transmitted through a 3- to 20-ft (1- to 6-m) thick layer of closely spaced, well-connected fractures near the water table (the water table interval) as shown in Fig. 7.3.

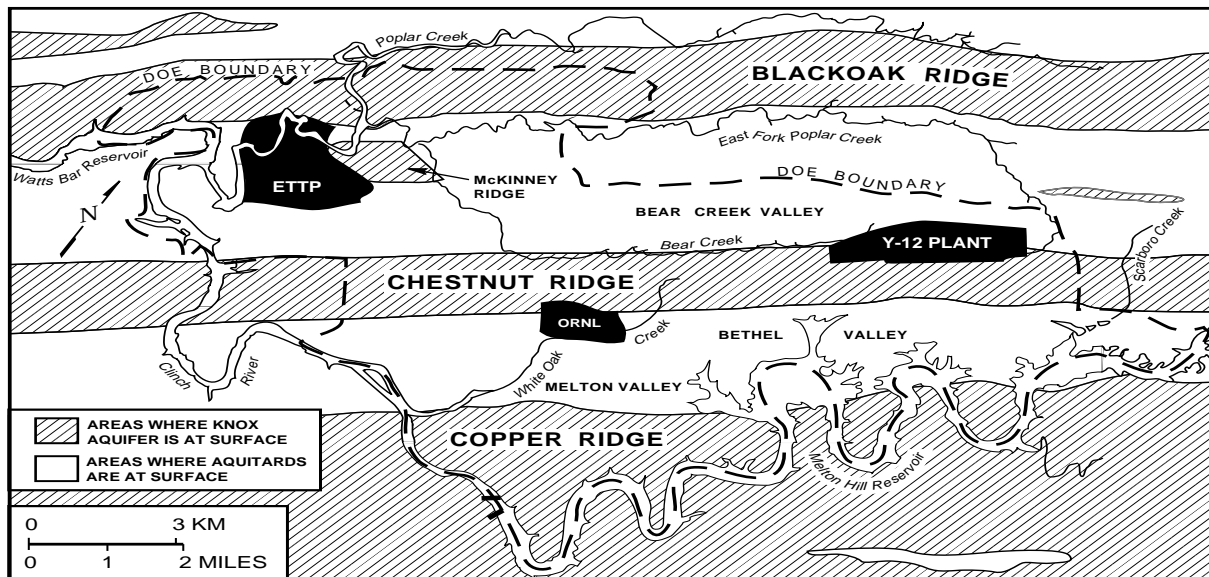

Fig. 7.2. The Knox Aquifer and the aquitards on the Oak Ridge Reservation.

Fig. 7.3. Water table interval.

As in the stormflow zone, the bulk of groundwater in the saturated zone resides within the pore spaces of the rock matrix. The rock matrix typically forms blocks that are bounded by fractures. Contaminants migrating from sources by way of the fractures typically occur in higher concentrations than in the matrix; thus, the contaminants tend to move (diffuse) into the matrix. This process, termed diffusive exchange, between water in matrix pores and water in adjacent fractures reduces the overall contaminant migration rates relative to groundwater flow velocities. For example, the leading edge of a geochemically nonreactive contaminant mass such as tritium may

migrate along fractures at a typical rate of 3 ft/day (1 m/day); however, the center of mass of a contaminant plume typically migrates at a rate less than 0.2 ft/day (0.66 m/day).

In the aquitards, chemical characteristics of groundwater change from a mixed-cation- HCO_3 water type at shallow depth to a Na-HCO_3 water type at deeper levels (about 100 ft). This transition, not marked by a distinct change in rock properties, serves as a useful marker and can be used to distinguish the more active water table and intermediate groundwater intervals from the sluggish flow of the deep interval. There is no evidence of similar change with depth in the chemical characteristics of water in the Knox Aquifer; virtually all wells are within the monitoring regime of Ca-Mg-HCO_3 type water. Although the mechanism responsible for this change in water types is not quantified, it most likely is related to the amount of time the water is in contact with a specific type of rock.

Most groundwater flow in the saturated zone occurs within the water table interval. Most flow is through weathered, permeable fractures and matrix rock and within solution conduits in the Knox Aquifer. The range of seasonal fluctuations

of water table depth and rates of groundwater flow varies significantly across the reservation. In areas underlain by the Knox Aquifer, seasonal fluctuations in water levels average 17 ft (5.3 m) and mean discharge from the active groundwater zone is typically 85 gal/min (322 L/min) per square mile. In the aquitards of Bear Creek Valley (BCV), Melton Valley, East Fork Valley, and Bethel Valley, seasonal fluctuations in water levels average 5 ft (1.5 m) and typical mean discharge is 26 gal/min (98 L/min) per square mile.

In the intermediate interval, groundwater flow paths are a product of fracture density and orientation. In this interval, groundwater movement occurs primarily in permeable fractures that are poorly connected. In the Knox Aquifer, a few cavity systems and fractures control groundwater movement in this zone, but in the aquitards, the bulk of flow is through fractures along which permeability may be increased by weathering.

The deep interval of the saturated zone is delineated by a change to a Na-Cl water type. Hydrologically active fractures in the deep interval are significantly fewer in number and shorter in length than in the other intervals, and the spacing is greater. Wells finished in the deep interval of the ORR aquitards typically yield less than 0.3 gal/min (1.1 L/min) and thus are barely adequate for water supply.

In the aquitards, saline water characterized by total dissolved solids ranging up to 2.75×10^5 mg/L and chlorides generally in excess of 5×10^4 mg/L (ranging up to 1.63×10^5 mg/L) lies beneath the deep interval of the groundwater zone, delineating an aquiclude. Chemically, this water resembles brines typical of major sedimentary basins, but its origin is not known. The chemistry suggests extremely long residence times (i.e., very low flow rates) and little or no mixing with shallow groundwater.

The aquiclude has been encountered at depths of 400 and 800 ft (125 and 244 m) in Melton and Bethel valleys, respectively (near ORNL), and it is believed to approach 1000 ft (305 m) in portions of BCV (near the Y-12 Plant) underlain by aquitard formations. Depth to the aquiclude in areas of the Knox Aquifer is not known but is

believed to be greater than 1200 ft (366 m); depth to the aquiclude has not been established in the vicinity of the ETTP.

7.1.3 Groundwater Flow

Many factors influence groundwater flow on the ORR. Topography, surface cover, geologic structure, and rock type exhibit especially strong influence on the hydrogeology. Variations in these features result in variations of the total amount of groundwater moving through the system (flux). (Average flux ratios for the aquitards and the Knox Aquifer formations are shown in Fig. 7.1.) As an example, the overall decrease in open fracture density with depth results in a decreased groundwater flux with depth.

Topographic relief on the ORR is such that most active subsurface groundwater flow occurs at shallow depths. U.S. Geological Survey modeling (Tucci 1992) suggests that 95% of all groundwater flow occurs in the upper 50 to 100 ft (15 to 30 m) of the saturated zone in the aquitards. As a result, flow paths in the active-flow zones (particularly in the aquitards) are relatively short, and nearly all groundwater discharges to local surface water drainages on the ORR. Conversely, in the Knox Aquifer, it is believed that solution conduit flow paths may be considerably longer, perhaps as much as 2 miles (3.2 km) long in the along-strike direction. No evidence at this time substantiates the existence of any deep, regional flow off the ORR or between basins within the ORR in either the Knox Aquifer or the aquitards. Data collected in CY 1994 and 1995, however, have demonstrated that groundwater flow and contaminant transport occur off the ORR in the intermediate interval of the Knox Aquifer, near the east end of the Y-12 Plant.

Migration rates of contaminants transported in groundwater are strongly influenced by natural chemical and physical processes in the subsurface (including diffusion and adsorption). Peak concentrations of solutes, including contaminants such as tritium moving from a waste area, for instance, can be delayed for several to many decades in the aquitards, even along flow paths as short as a few hundred feet. The processes that

naturally retard contaminant migration and store contaminants in the subsurface are less effective in the Knox Aquifer than in the aquitards because of rapid flow along solution features allowing minimal time for diffusion to occur.

7.1.4 Groundwater Monitoring Considerations

Because of the complexity of the hydrogeologic framework on the ORR, groundwater flow and, therefore, contaminant transport are difficult to predict on a local scale. Consequently, individual plume delineation is not always feasible on the ORR. Stormflow and most groundwater discharge to the surface water drainages on the ORR. For that reason, monitoring springs, seeps, and surface water quality is one of the best ways to assess the extent to which groundwater from a large portion of the ORR transports contaminants; however, contaminant transport may occur at depth as well. The center of mass of the volatile organic compound (VOC) plume in the Maynardville Limestone east of the Y-12 Plant lies at a depth of 300 ft (91.5 m). Transport of the highest VOC concentrations occurs in this interval because many VOCs are more dense than water, and there is little dilution.

7.1.5 Groundwater Monitoring Programs on the ORR

The groundwater surveillance monitoring programs implemented at the DOE facilities have been designed to obtain full compliance with regulatory requirements and to meet technical objectives. Site-specific regulatory monitoring programs are supported technically by site characterization and regional studies of the geohydrologic and chemical aspects of the flow system. Monitoring at the Y-12 Plant and ORNL is coordinated through site-level groundwater programs. The site-level programs provide oversight for surveillance and effluent monitoring and coordination of monitoring required under CERCLA drivers. The IWQP has been established

at the DOE level to track and prioritize CERCLA monitoring across all of the ORR facilities.

7.2 GROUNDWATER MONITORING AT THE Y-12 PLANT

7.2.1 Background and Regulatory Setting

Most of the groundwater monitoring at the Y-12 Plant is conducted within the scope of a single, comprehensive groundwater monitoring program, which included the following elements in 1997:

- monitoring to comply with requirements of RCRA postclosure regulations,
- monitoring to support CERCLA remedial investigation/feasibility study (RI/FS) efforts and RODs,
- compliance with TDEC solid waste management (SWM) regulations, and
- monitoring to support DOE Order 5400.1 requirements (exit pathway and surveillance monitoring).

Through incorporation of these multiple considerations, the comprehensive monitoring program at the Y-12 Plant addresses multiple regulatory considerations and technical objectives. It eliminates redundancy between different regulatory programs and ensures consistent data collection and evaluation.

More than 200 sites have been identified at the Y-12 Plant that represent known or potential sources of contamination to the environment as a result of past waste management practices. These sites are being addressed either by the ER Program under exclusively CERCLA programs or a combination of CERCLA and RCRA regulations. The ER Program and Y-12 Plant management share responsibilities for sites regulated under dual CERCLA and RCRA drivers.

In 1992, a number of the inactive waste management sites were grouped into operable units (OUs) under CERCLA as part of an FFA

negotiated between EPA, TDEC, and DOE. Two types of OUs were identified: (1) source OUs consisting of sites or groups of sites that were known sources of contamination to the environment and (2) integrator OUs consisting of media, such as groundwater, soils, and/or surface water, that had been impacted by the source OUs. An agreement was reached among regulatory agencies and DOE in 1994 to proceed with an integrated RI/FS strategy. In the integrated strategy, former source OUs and integrator OUs are addressed concurrently in a characterization area (CA) defined by physical limits, such as watershed boundaries and/or groundwater flow regimes (Fig. 7.4). Specific sites or locations of high risk or concern within the CA are targeted for focused, rapid remedial actions, while a general remedial strategy and/or administrative controls for other sites in the CA progress. Individual focused action sites are designated as OUs and documented under separate RODs.

Two CAs incorporating 27 known source units have been established for the Y-12 Plant, the UEFFPC CA and the BCV CA.

In addition, four individual source OUs remain on Chestnut Ridge, where available data indicate that contamination from each unit is distinct and separable. The remaining sites have been grouped into Y-12 Plant study areas that constitute lower-priority units that will be investigated under CERCLA as preliminary assessment/site investigations (PA/SIs). New OUs or additions to existing CAs will be made if the degree of contamination determined by the PA/SI warrants further study under an RI/FS.

Postclosure maintenance, monitoring, and reporting requirements of RCRA also apply to seven inactive CERCLA-regulated units that meet the definition of RCRA hazardous waste TSD facilities. These units include the S-3 Site, portions of the Bear Creek Burial Grounds, the Oil Landfarm, New Hope Pond, the Chestnut Ridge Security Pits, the Chestnut Ridge Sediment Disposal Basin, and Kerr Hollow Quarry. Postclosure requirements are now outlined in RCRA postclosure permits issued by TDEC. These requirements are integrated with CERCLA programs. Corrective actions addressing contaminant

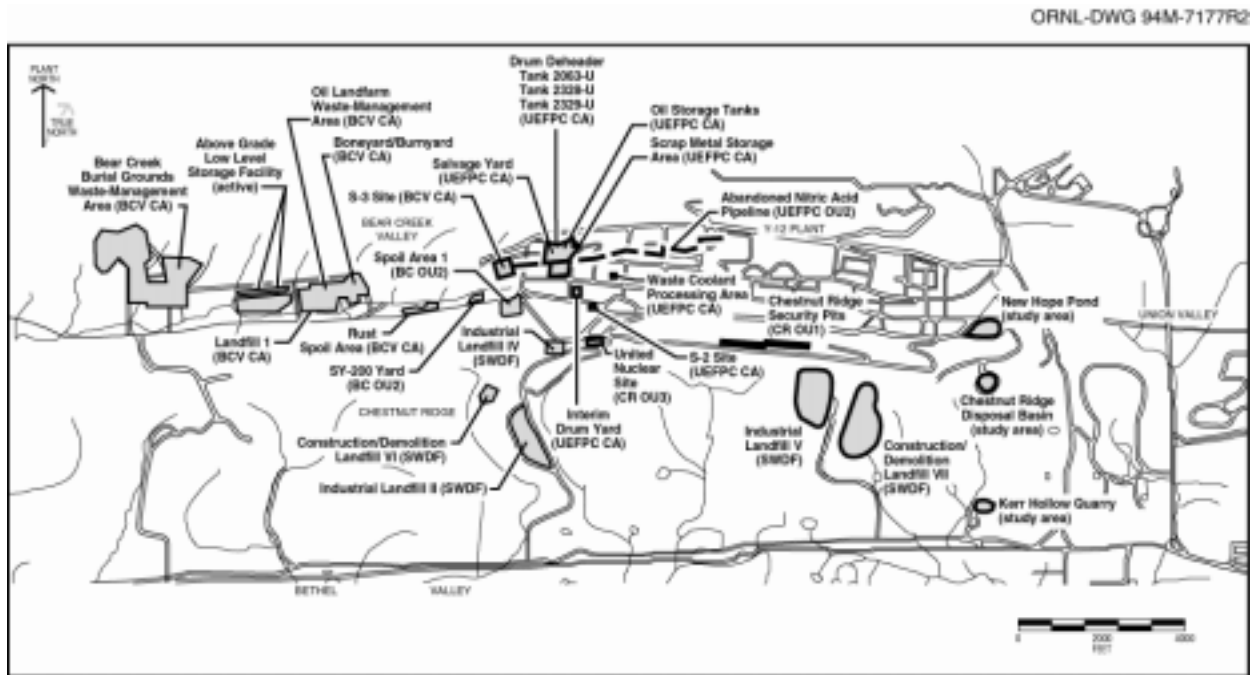

Fig. 7.4. Y-12 Plant inactive regulated units, study areas, and active facilities for which groundwater monitoring was conducted in CY 1997.

Oak Ridge Reservation

releases will be deferred to the CERCLA RI/FS process. While corrective actions are progressing, the permits require focused monitoring of selected exit pathways and compliance boundaries.

An additional primary regulatory driver for groundwater monitoring at the Y-12 Plant is the TDEC regulations governing nonhazardous solid waste disposal facilities (SWDFs). Two facilities (Centralized Sanitary Landfill II and Industrial Landfill IV) have been subject to groundwater monitoring under the SWDF regulations since the late 1980s. Construction of three additional landfill facilities was completed between 1993 and 1994 (Industrial Landfill V, Construction/ Demolition Landfill VI, and Construction/Demolition Landfill VII). All of the landfill sites are now under a semiannual detection monitoring program.

Specific regulatory requirements do not address all groundwater monitoring concerns at the Y-12 Plant. Selected areas, from which contamination is most likely to migrate to potential exposure points off the ORR, are monitored as part of DOE Order 5400.1 requirements for exit pathway monitoring. Also, monitoring is performed as part of DOE 5400.1 surveillance monitoring in areas not specifically regulated and not representing specific exit pathways off the reservation, such as a large part of the industrialized portion of the Y-12 Plant. Surveillance monitoring is conducted to monitor contaminant plume boundaries and to trend contaminant concentrations specifically to augment regulatory and exit pathway monitoring programs.

7.2.2 Hydrogeologic Setting and Summary of Groundwater Quality

In the comprehensive monitoring program, the Y-12 Plant is divided into three hydrogeologic regimes delineated by surface water drainage patterns, topography, and groundwater flow characteristics. The regimes are further defined by the waste sites they contain. These regimes include the Bear Creek Hydrogeologic Regime (Bear Creek regime), the Upper East Fork Poplar Creek Hydrogeologic Regime (East Fork regime), and the Chestnut Ridge Hydrogeologic Regime (Chestnut Ridge regime) (Fig. 7.5). Most of the Bear Creek and East Fork regimes are underlain by the ORR aquitards. The extreme southern portion of these two regimes is underlain by the Maynardville Limestone, which is part of the Knox Aquifer. The entire Chestnut Ridge regime is underlain by the Knox Aquifer.

In general, groundwater flow in the water table interval follows topography. Shallow groundwater flow in the Bear Creek and East Fork regimes is divergent from a topographic and groundwater table divide located near the western end of the Y-12 Plant. The flow directions of shallow groundwater east and west of the divide are predominantly easterly and westerly, respectively. This divide defines the boundary between the Bear Creek and Upper East Fork Poplar Creek

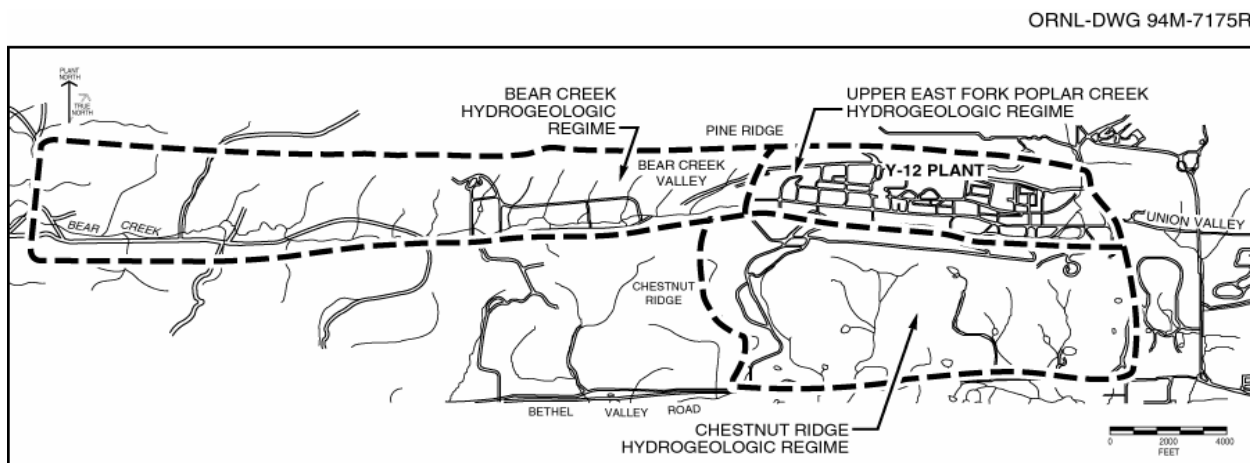

Fig. 7.5. Hydrogeologic regimes at the Y-12 Plant.

regimes. In addition, flow converges toward the primary surface streams from Pine Ridge to the north and Chestnut Ridge to the south of the Y-12 Plant. In the Chestnut Ridge regime, a groundwater table divide exists that approximately coincides with the crest of the ridge. Shallow groundwater flow, therefore, tends to be toward either flank of the ridge, with discharge primarily to surface streams and springs located in Bethel Valley to the south and BCV to the north.

In BCV, groundwater in the intermediate and deep intervals moves predominantly through fractures in the ORR aquitards, converging toward and moving through fractures and solution conduits in the Maynardville Limestone. Karst development in the Maynardville Limestone has a significant impact on groundwater flow paths in the water table and intermediate intervals. In general, groundwater flow parallels geologic strike. Groundwater flow rates in BCV vary widely; they are very slow within the deep interval of the ORR aquitards but can be quite rapid within solution conduits in the Maynardville Limestone.

The rate of groundwater flow perpendicular to geologic strike from the ORR aquitards to the Maynardville Limestone has been estimated to be very slow below the water table interval. Most contaminant migration appears to be via surface tributaries to Bear Creek or along utility traces and buried tributaries in the East Fork regime. Recent data obtained as part of hydrologic studies in the Bear Creek regime suggest that strike-parallel transport of some contaminants can occur within the ORR aquitards for significant distances. Continuous elevated levels of nitrate within the ORR aquitards are now known to extend west from the S-3 Site for a distance of about 3000 ft, approximately twice the previous estimates. VOCs at source units in the ORR aquitards, however, tend to remain close to source areas because they tend to adsorb to the bedrock matrix, diffuse into pore spaces within the matrix, and degrade prior to migrating to exit pathways, where rapid transport for long distances can occur.

Groundwater flow in the Chestnut Ridge regime is almost exclusively through fractures and

solution conduits in the Knox Group. Discharge points for intermediate and deep flow are not well known. Groundwater is currently presumed to flow primarily toward BCV to the north and Bethel Valley to the south. Groundwater from intermediate and deep zones may discharge at certain spring locations along the flanks of Chestnut Ridge. Along the crest of the ridge, water table elevations decrease from west to east, demonstrating an overall easterly trend in groundwater flow.

Historical monitoring efforts have shown that groundwater quality at the Y-12 Plant has been affected by four types of contaminants: nitrate, VOCs, metals, and radionuclides. Of these, nitrate and VOCs are the most widespread, although data obtained since 1988 show that the extent of some radionuclides, particularly ⁹⁹Tc is also significant, particularly in the Bear Creek regime. Trace metals, the least extensive groundwater contaminants, generally occur in a small area of low-pH groundwater at the west end of the Y-12 Plant, in the vicinity of the S-3 Site. Historical data have shown that plumes from multiple source units have mixed with one another and that contaminants (other than nitrate and possibly ⁹⁹Tc) are no longer easily associated with a single source.

7.2.3 1997 Well Installation and Plugging and Abandonment Activities

A number of monitoring devices are routinely used for groundwater data collection at the Y-12 Plant. Monitoring wells are permanent devices used for collection of groundwater samples; these are installed according to established regulatory and industry specifications. Piezometers are primarily temporary devices used to measure groundwater table levels and are often constructed of PVC or other low-cost materials. Other devices or techniques are sometimes employed to gather data, including well points and push probes.

No new monitoring wells were installed in CY 1997 for compliance monitoring. However, a total of 52 characterization wells and piezometers were installed in the vicinity of the S-3 Site and

the east end of the plant near Upper East Fork Poplar Creek. Twelve wells at the S-3 Site were installed to assess the performance of a CERCLA treatability study, and 16 of the wells along Upper East Fork Poplar Creek were installed to meet data needs for the CERCLA UEFPC remedial investigation (RI) preparation. The other 24 piezometers were installed along UEFPC in support of the Reduction of Mercury in Plant Effluent (RMPE) Program to evaluate mercury transport in the shallow groundwater system.

Under the Y-12 Plant GWPP, well plugging and abandonment activities are conducted as part of an overall program to maintain the Y-12 Plant monitoring well network. Wells that are damaged beyond rehabilitation, that interfere with planned construction activities, or from which no useful data can be obtained, are selected for plugging and abandonment. In 1997, no wells were plugged and abandoned.

7.2.4 1997 Monitoring Program

Groundwater monitoring in 1997 addressed multiple requirements from regulatory drivers and DOE orders. Table 7.1 contains a summary of monitoring activities conducted by the Y-12 Plant GWPP, as well as the programmatic requirements that apply to each monitored site.

Figure 7.6 shows the locations of ORR perimeter groundwater monitoring stations as specified in the EMP.

Detailed data reporting for monitoring activities conducted by the Y-12 Plant GWPP is contained within the annual groundwater monitoring reports for each hydrogeologic regime (LMES 1998b, 1998c, and 1998d). Details of small-scale monitoring efforts performed outside the scope of the comprehensive monitoring program specifically for CERCLA OUs are published in RI reports. Other groundwater monitoring in support of CERCLA activities is performed by the IWQP (DOE 1998b). Information about IWQP monitoring is reported in annual Remediation Effectiveness Reports.

7.2.5 Y-12 Plant Groundwater Quality

7.2.5.1 Upper East Fork Poplar Creek Hydrogeologic Regime

The 1997 monitoring locations and waste management sites in the East Fork regime that are addressed in this document are shown in Fig. 7.7. Regulatory status of waste management sites in the East Fork Regime is summarized in Fig. 7.4. Brief descriptions of the waste management sites are presented in Table 7.2. Detailed operational histories of these sites have been published in previous ORR ASERs.

The East Fork Regime contains the UEFPC CA, which consists of source units, surface water, and groundwater components of the hydrogeologic system within the East Fork regime and Union Valley to the east of the Y-12 Plant. Numerous sources of contamination to both surface water and groundwater exist within the plant area. Chemical constituents from the S-3 Site dominate groundwater contamination in the western portion of the UEFPC CA. In addition to potential surface water and groundwater contamination sources identified as OUs, a majority of the Y-12 Plant study areas are within the East Fork regime. Potential surface-water contamination associated with the storm sewer system and East Fork mercury use areas is of primary interest and will also be addressed in the UEFPC CA RI/FS.

Discussion of Monitoring Results

The objectives of the 1997 groundwater monitoring program in the East Fork regime were to (1) further define contaminant nature and extent; (2) evaluate potential contaminant exit pathways for CERCLA RI, RCRA postclosure, and DOE Order technical objectives; and (3) trend contaminant levels over time. Locations of monitoring stations are shown in Fig. 7.7.

Plume Delineation

As denoted in previous ORR ASERs, the primary groundwater contaminants in the East Fork regime are nitrate, VOCs, trace metals, and radionuclides. Sources of nitrate, trace metals, and radionuclides monitored during 1997 are the S-2 Site, the Abandoned Nitric Acid Pipeline, and the S-3 Site. Although it is located west of the current

hydrologic divide that separates the East Fork regime from the Bear Creek regime, the S-3 Site has contributed to groundwater contamination in the western part of the regime during its operation. Sources of VOCs in the East Fork regime include the S-3 Site, several sites located within the Y-12 Salvage Yard, the Waste Coolant Processing Area, petroleum USTs, and process/production buildings in the plant.

Table 7.2. Regulatory status and operational history of waste management units and underground storage tanks included in the 1997 Comprehensive Groundwater Monitoring Program; Upper East Fork Poplar Creek Hydrogeologic Regime

Site	Historical/current regulatory classification ^a	Historical data
New Hope Pond	TSD/Study Area	Built in 1963. Regulated flow of water in UEFPC before exiting the Y-12 Plant grounds. Sediments include PCBs, mercury, and uranium but not hazardous according to toxicity characteristic leaching procedure. Closed under RCRA in 1990.
Abandoned Nitric Acid Pipeline	SWMU/UEFPC OU2	Used from 1951 to 1983. Transported liquid nitric acid wastes and dissolved uranium from Y-12 Plant process areas to the S-3 Site. Leaks were the release mechanisms to groundwater. A CERCLA ROD has been issued.
Salvage Yard Scrap Metal Storage Area	SWMU/UEFPC CA	Used from 1950 to present for scrap metal storage. Some metals contaminated with low levels of depleted or enriched uranium. Runoff and infiltration are the principal release mechanisms to groundwater.
Salvage Yard Oil/ Solvent Drum Storage Area	SWMU/UEFPC CA	Primary wastes included waste oils, solvents, uranium, and beryllium. Both closed under RCRA. Leaks and spills represent the primary contamination mechanisms for groundwater.
Salvage Yard Oil Storage Tanks	SWMU/UEFPC CA	Used from 1978 to 1986. Two tanks used to store PCB-contaminated oils, both within a diked area.
Salvage Yard Drum Deheader Facility	SWMU/UEFPC CA	Used from 1959 to 1989. Sump tanks 2063-U, 2328-U, and 2329-U received residual drum contents. Sump leakage is a likely release mechanism to groundwater.
S-2 Site	SWMU/UEFPC CA	Used from 1945 to 1951. An unlined reservoir received liquid wastes. Infiltration is the primary release mechanism to groundwater.
Waste Coolant Processing Area	SWMU/UEFPC CA	Former biodegradation facility used to treat waste coolants from various machining processes. Closed under RCRA in 1988.
Building 81-10 Area	NA/UEFPC CA	Staging facility. Potential historical releases to groundwater from leaks and spills of liquid wastes or mercury.
Coal Pile Trench	SWMU/UEFPC CA	Located beneath the current steam plant coal pile. Disposals included solid materials (primarily alloys). Trench leachate is a potential release mechanism to groundwater.

Table 7.2 (continued)

Site	Historical/current regulatory classification ^a	Historical data
Interim Drum Yard	SWMU/Study Area	Diked outdoor storage area once used to store drums of liquid and solid wastes. Partially closed under RCRA in 1988 and 1996. Further action deferred to CERCLA.
Beta-4 Security Pits	SWMU/Study Area	Used from 1968 to 1972 for disposal of classified materials, scrap metals, and liquid wastes. Site is closed and capped. Primary release mechanism to groundwater is infiltration.
Rust Garage Area	UST/Study Area	Former vehicle and equipment maintenance area, including four former petroleum USTs. Petroleum product releases to groundwater are documented.
Garage Underground Tanks	SWMU/Study Area	Fuel USTs used from 1944 to 1978. Converted to waste oil storage in 1978; removed in 1989. Petroleum and waste oil leaks represent probable releases to groundwater. The unit was clean-closed under RCRA in 1995.

^aRegulatory status before the 1992 Federal Facility Agreement: TSD-RCRA—regulated, land-based treatment, storage, or disposal unit; SWMU—RCRA-regulated solid waste management unit; and UST—petroleum underground storage tank. Current regulatory status: study area—Y-12 Plant study area; UEFPC OU2—Upper East Fork Poplar Creek Operable Unit 2; UEFPC CA—Upper East Fork Poplar Creek Characterization Area.

Nitrate

Nitrate concentrations in groundwater at the Y-12 Plant exceed the 10 mg/L maximum drinking water contamination level (a complete list of DWSs is presented in Appendix D) in a large part of the western portion of the East Fork regime (Fig. 7.8). Groundwater containing nitrate concentrations as high as 10,000 mg/L occurs in the unconsolidated zone and at shallow bedrock depths just east of the S-3 Site.

The extent of the nitrate plume is essentially defined in the unconsolidated zone and the shallow bedrock zone. In both zones of the aquitards, the nitrate plume extends about 4000 ft (1219 m) eastward from the S-3 Site. Nitrate has traveled farthest, approximately 5000 ft (1524 m), in groundwater in the Maynardville Limestone. Although the nitrate plume is dispersing and moving eastward, concentrations near the source have been trending downward since disposal operations ceased and the site was closed and capped in the late 1980s.

Trace Metals

Concentrations of barium, cadmium, chromium, lead, nickel, and thallium exceeded MCLs during 1997 in samples collected from various monitoring wells at the S-2 Site, the S-3 Site, central and eastern plant grid locations, exit pathway wells, and upgradient of New Hope Pond. Elevated concentrations of these metals were most commonly reported for groundwater samples collected from monitoring wells in the unconsolidated zone. A definable plume of elevated metals contaminants is not present; metals above maximum contaminant levels tend to occur adjacent to the source units.

Volatile Organic Compounds

Because of the many source areas, VOCs are the most widespread groundwater contaminants in the East Fork regime. Dissolved VOCs in the regime generally consist of two types of compounds: chlorinated solvents and petroleum hydrocarbons. The highest concentrations of dissolved chlorinated solvents (about 12 mg/L)

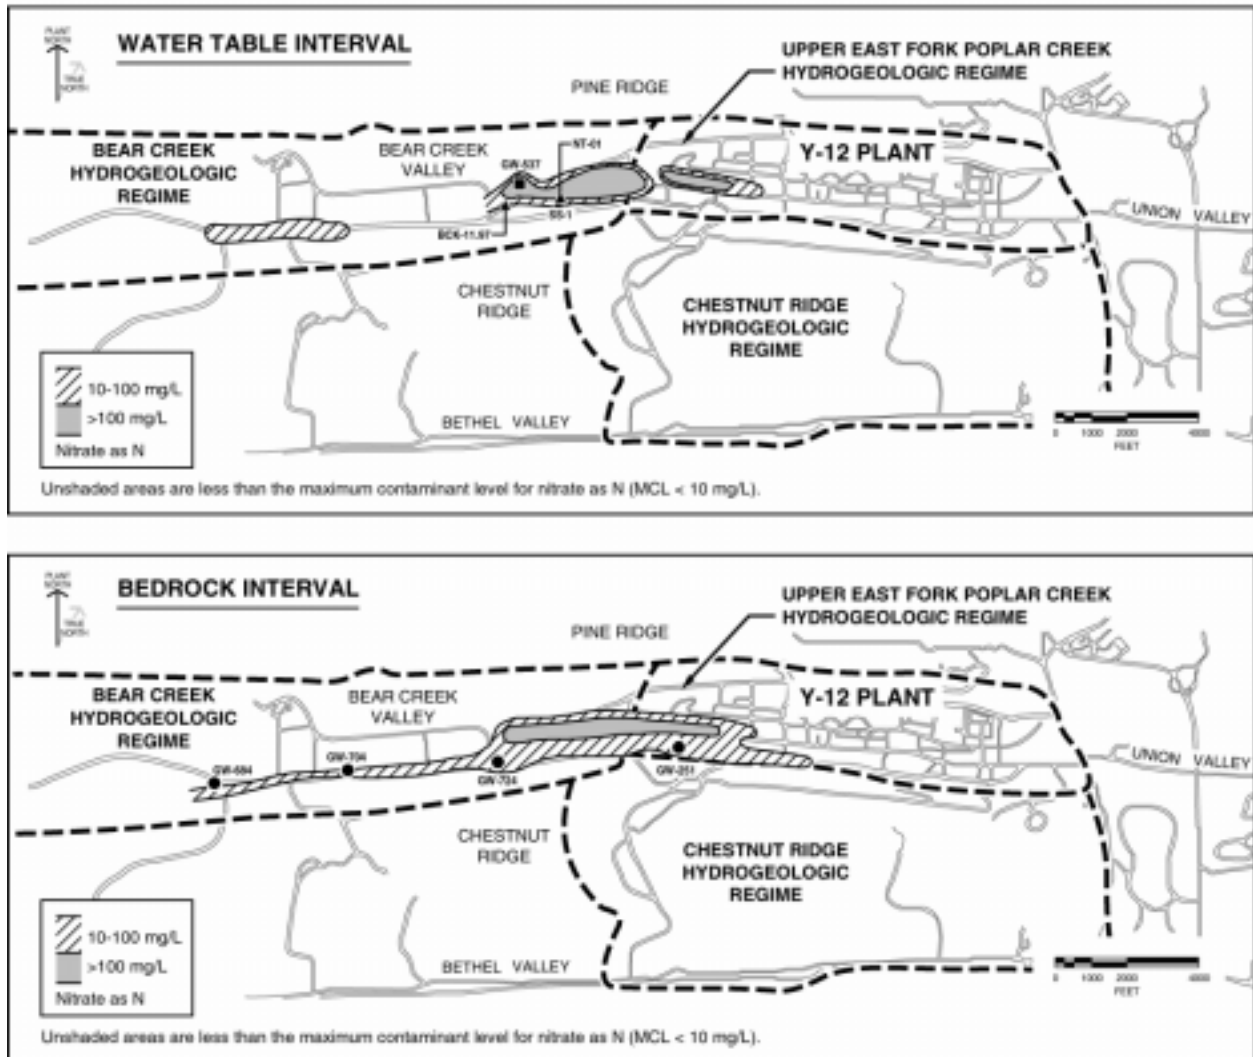

Fig. 7.8. Nitrate (as N) observed in groundwater at the Y-12 Plant.

are found at the Waste Coolant Processing Area and Y-12 Salvage Yard. The highest dissolved concentrations of petroleum hydrocarbons (about 60 mg/L) occur in groundwater near the Rust Garage Area.

Concentrations of chlorinated VOCs in the vicinity of source areas have remained relatively constant or have decreased since 1988 (Fig. 7.9). Within the exit pathway on the east end of the regime, some monitoring locations (e.g., GW-220) east of New Hope Pond have shown increasing VOC concentrations, indicative of an easterly movement of part of the plume (Fig. 7.10). Some

wells south and west of New Hope Pond (e.g., GW-606 and GW-153) show a shallow decreasing concentration trend, while wells located farther to the east (GW-733 and GW-170) show a static or stable trend. Data show that VOCs are the most extensive in shallow groundwater; however, when contaminants migrate into the Maynardville Limestone, they tend to concentrate at depths between 100 and 500 ft. The highest VOC concentrations appear to be between 200 and 500 ft, as exemplified by vertical carbon tetrachloride distribution at the east end of the Y-12 Plant (Fig. 7.11).

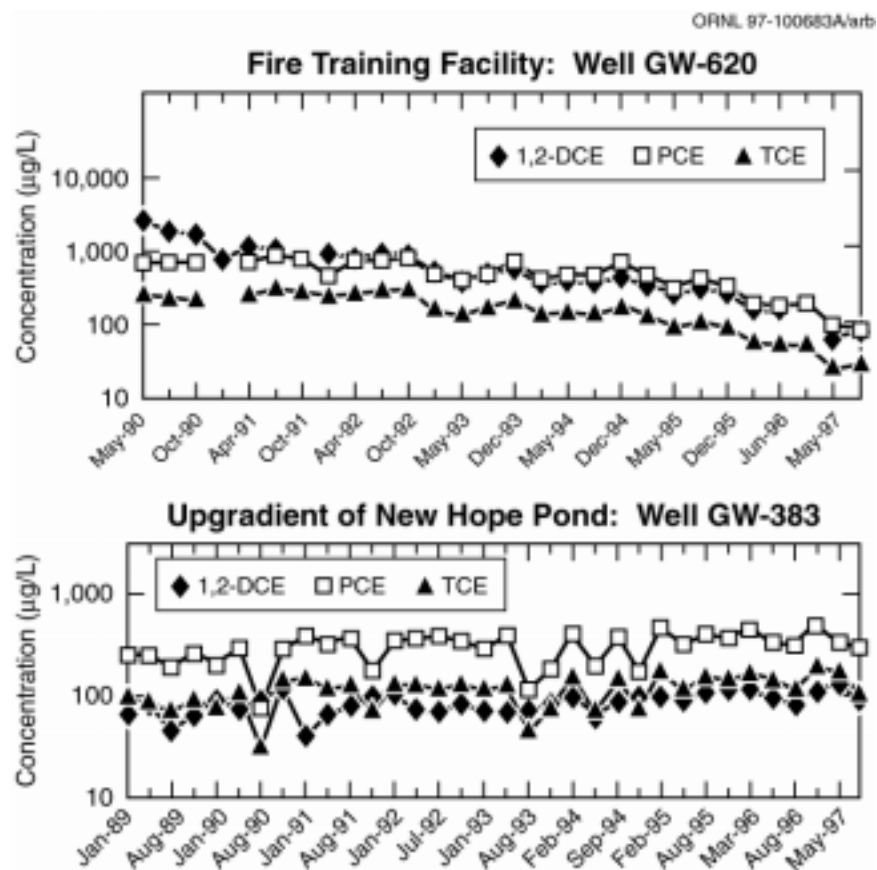

Fig. 7.9. VOC concentration in groundwater in selected wells in the East Fork regime.

The 1997 monitoring results generally confirm findings from the previous 6 years of monitoring. A continuous dissolved VOC plume in groundwater in the bedrock zone extends eastward from the S-3 Site over the entire length of the regime (Fig. 7.12). The primary sources are the Waste Coolant Processing Facility, the Building 9754 and 9754-2 fuel facilities, and process areas in the central portion of the plant.

Chloroethene compounds (tetrachloroethene, trichloroethene, dichloroethene, and vinyl chloride) tend to dominate the VOC plume composition in the western and central portions of the Y-12 Plant. However, tetrachloroethene and isomers of dichloroethene are almost ubiquitous throughout the extent of the VOC plume, indicating many source areas. Chloromethane compounds (carbon tetrachloride, chloroform, and methylene chloride)

are the predominant VOCs in the eastern and southeastern portions of the plant.

Radionuclides

As in the Bear Creek regime, the primary alpha-emitting radionuclides found in the East Fork regime are isotopes of uranium, radium, neptunium, and americium. The primary beta-emitting radionuclide is technetium.

Groundwater with gross alpha activity greater than 15 pCi/L occurs in scattered areas throughout the East Fork regime (Fig. 7.13). Historical data show that gross alpha activity that consistently exceeds the MCL for drinking water (annual average activity level of 15 pCi/L) is most extensive in groundwater in the unconsolidated zone in the western portion of the Y-12 Plant near the S-3 Site. Surveillance data also

show that gross beta activity levels remained elevated well above the MCL in the western portion of the plant. An area of elevated gross alpha activity is also present west of New Hope Pond. Sporadic gross alpha activity was also observed in several shallow wells scattered across the East Fork regime. Erratic data distribution, coupled with high turbidity and TSS content in samples from most of the wells, indicates that these sporadic values are false positives.

Elevated gross beta activity in groundwater in the East Fork regime shows a pattern similar to that observed for gross alpha activity (Fig. 7.14). In general, gross beta activity consistently exceeds the annual average MCL of 50 pCi/L in groundwater in the western portion of the regime, with the primary source being the S-3 Site.

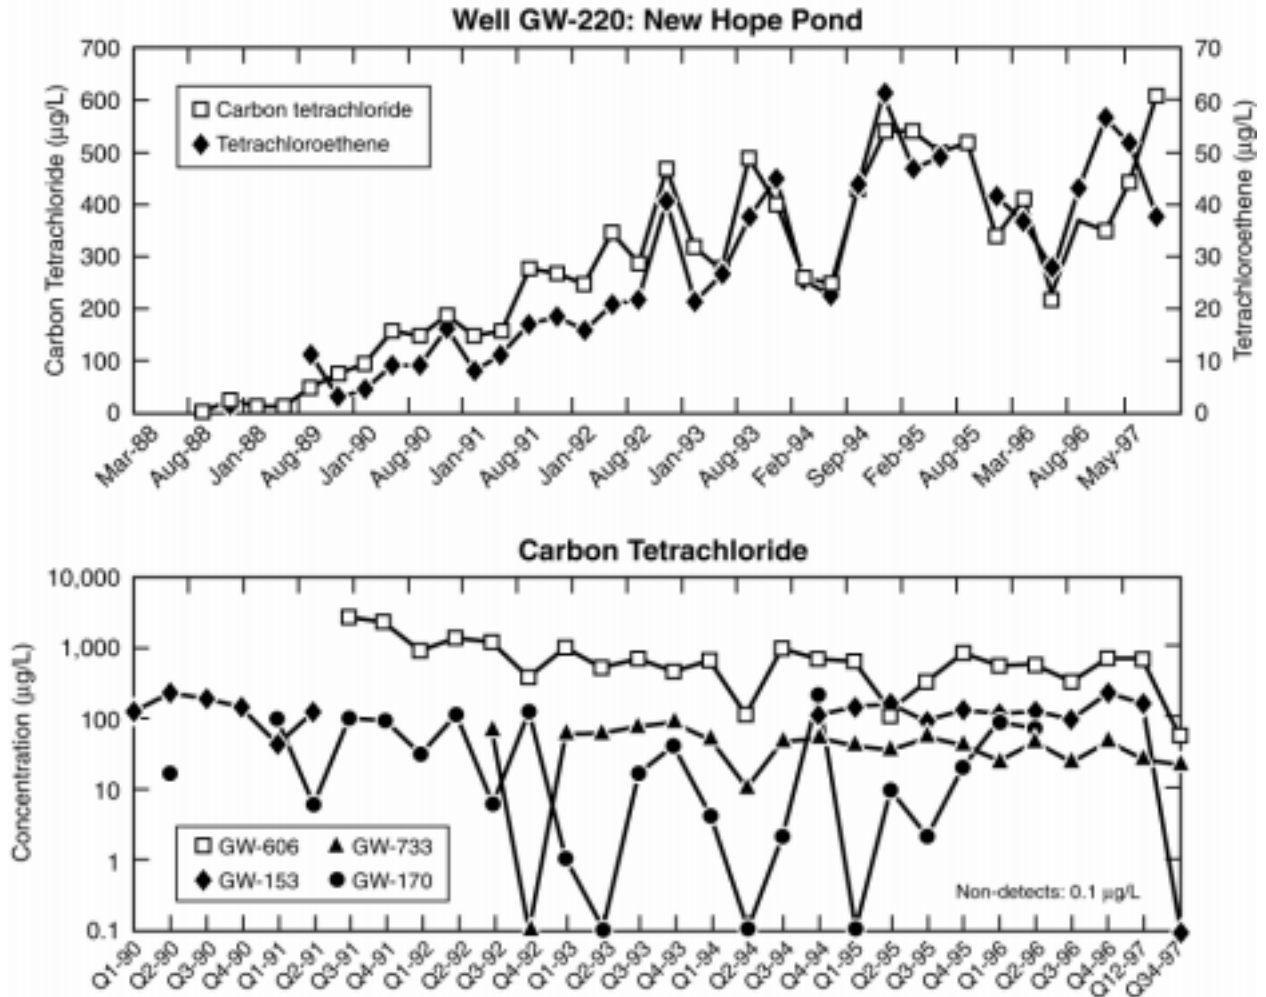

Fig. 7.10. VOC concentrations in selected wells near New Hope Pond and exit pathway wells.

Exit Pathway and Perimeter Monitoring

Exit pathway groundwater monitoring activities in the East Fork regime in 1997 involved continued collection and trending of data from exit pathway monitoring stations. In addition, data collected under the scope of the UEFPC RI were integrated into evaluations of contaminant exit-pathways. The RI effort included sampling of springs, seeps, surface water, and wells in Union Valley and a few selected locations within the Y-12 Plant. Surface water quality in UEFPC is regularly monitored in accordance with NPDES permits, and the results are summarized in Chap. 4.

Data collected to date indicate that VOCs are the primary class of contaminants that are migrating through the exit pathways in the East Fork regime. The VOCs are migrating predominantly at depths between 200 and 500 ft and appear to be restricted to the Maynardville Limestone. An aerial distribution of VOCs is shown in Fig. 7.12. A vertical profile of VOC contamination is depicted in Fig. 7.11. Concentrations of VOCs are typically higher at depth because most dilution and mixing with rainfall occurs in the shallow portions of the Maynardville limestone. In addition, the majority of the VOCs are more dense than water; therefore, they tend to migrate downward within the subsurface. The deep fractures

Oak Ridge Reservation

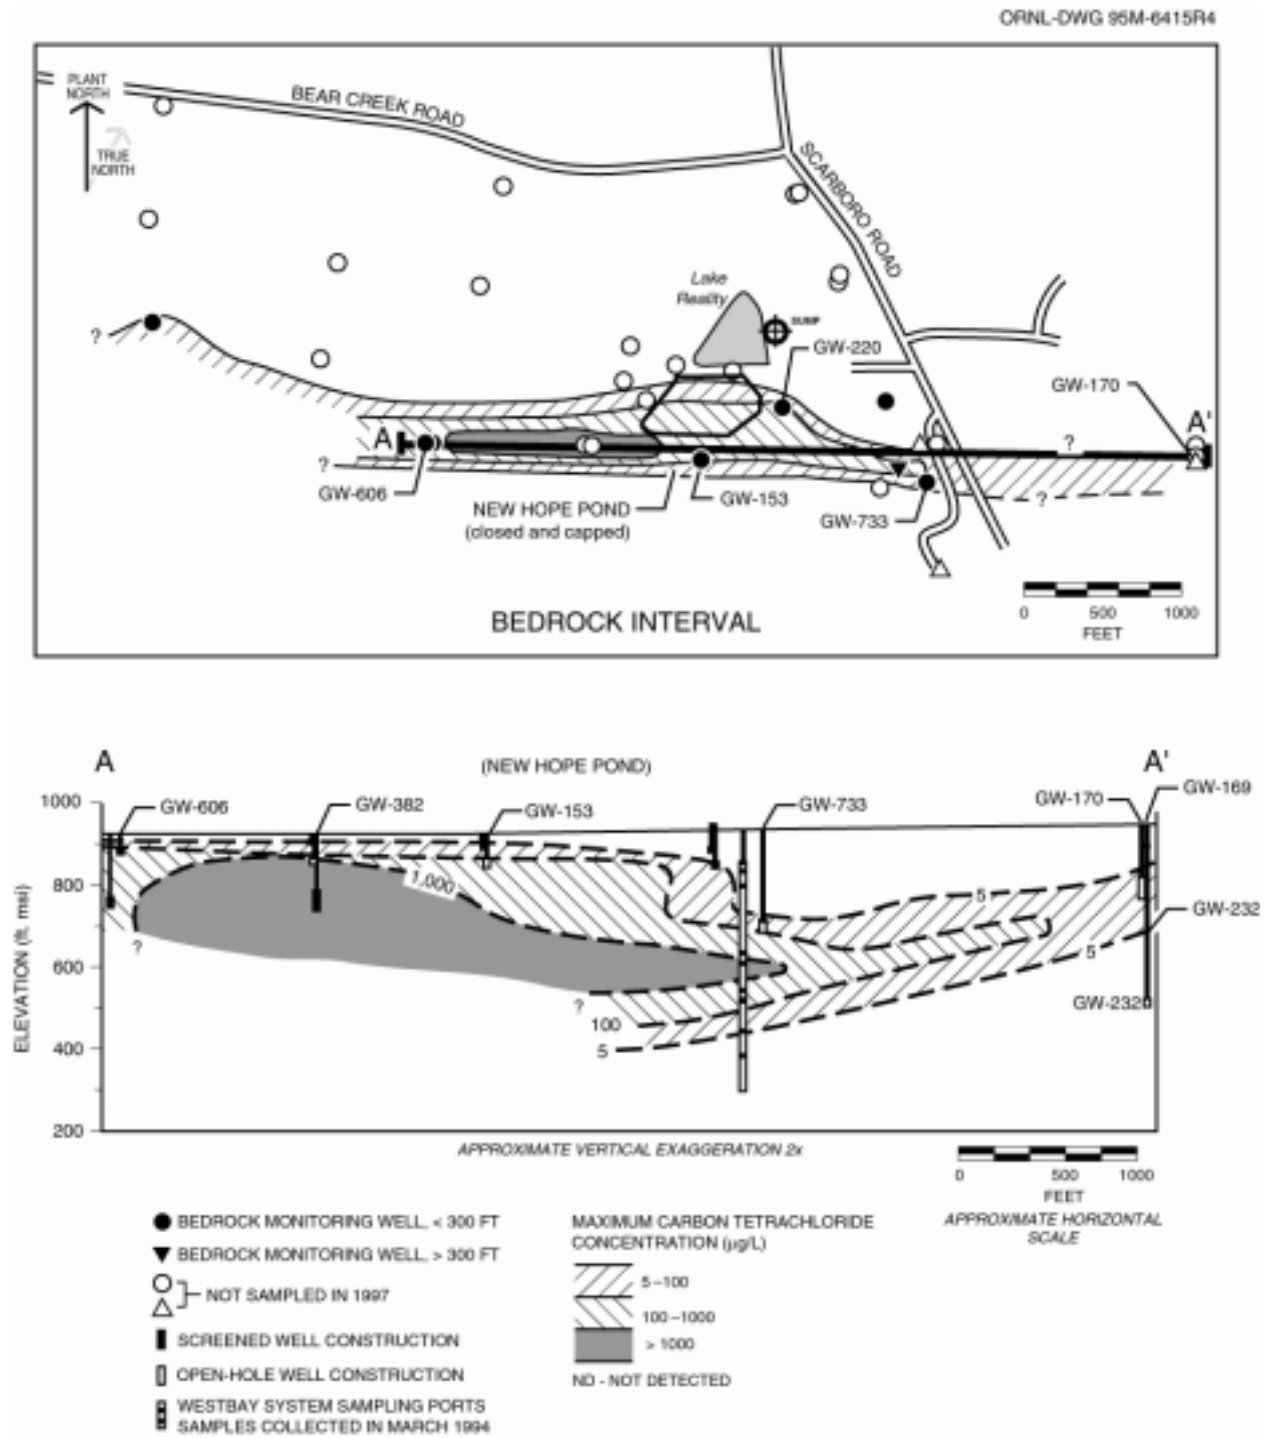

Fig. 7.11. Maximum carbon tetrachloride concentrations in Maynardville Limestone at depths between 200 and 500 ft, 1997.

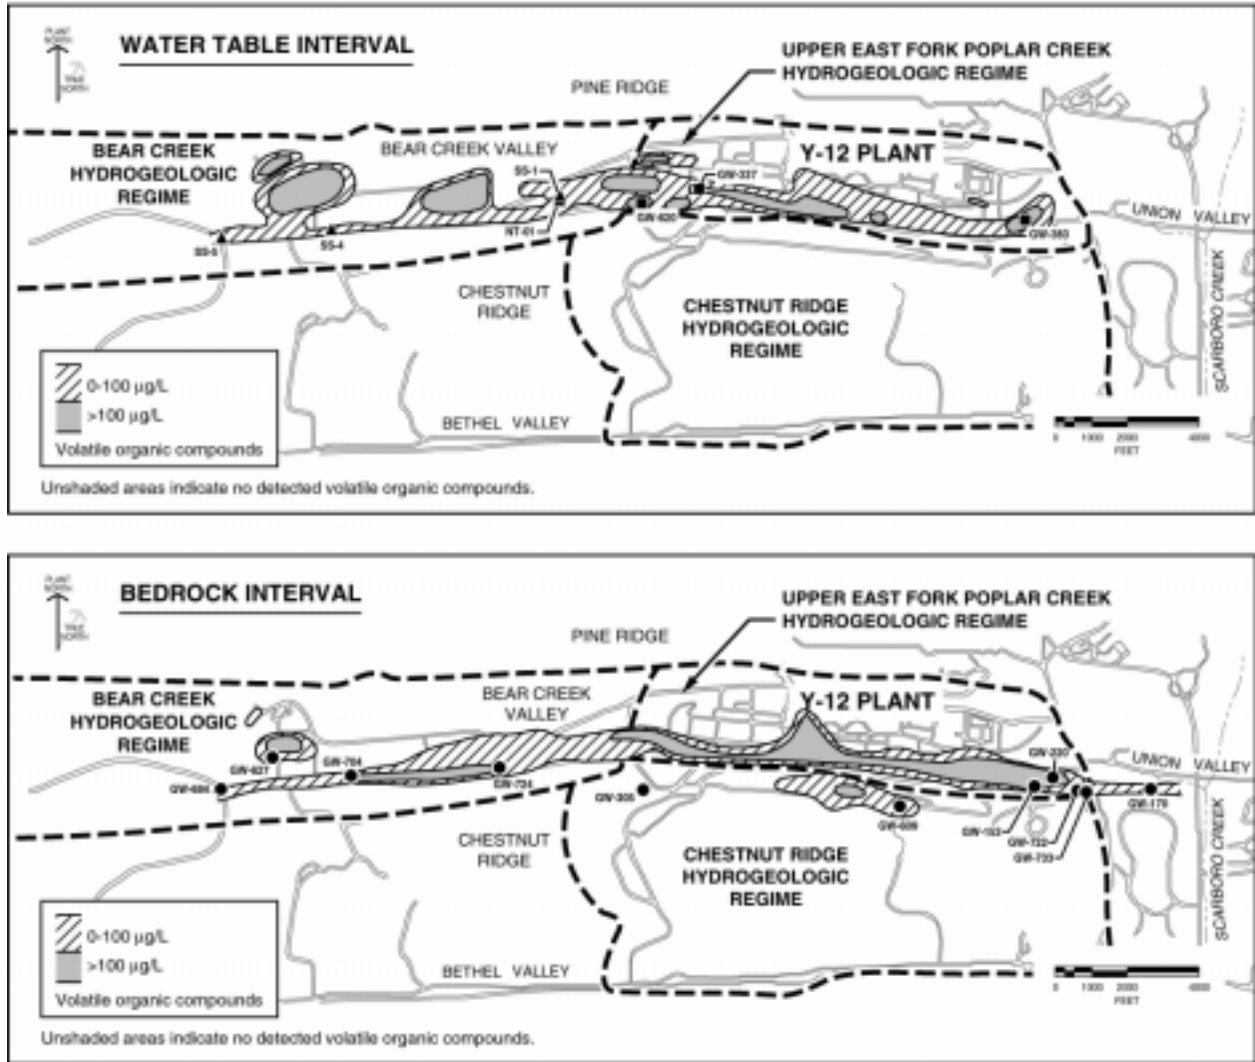

Fig. 7.12. Summed volatile organic compounds in groundwater at the Y-12 Plant.

and solution channels that constitute flowpaths within the Maynardville Limestone appear to be well connected. The characteristics of the flowpaths combined with the chemical characteristics of the contaminants have resulted in migration for substantial distances off the ORR into Union Valley to the east of the Y-12 Plant. The EMP specifies monitoring of three wells near the eastern ORR boundary for this exit pathway (Fig. 7.6).

In addition to the deep pathways within the Maynardville Limestone, shallow groundwater within the water table interval in the vicinity of

New Hope Pond, Lake Reality, and Upper East Fork Poplar Creek is also monitored. Historically, VOCs have been observed in the vicinity of Lake Reality from wells, a dewatering sump, and the Lake Reality spillway (LRSPW). In this area, shallow groundwater flows north-northeast through the water table interval east of New Hope Pond and Lake Reality, following the path of a diversion channel for Upper East Fork Poplar Creek.

Groundwater movement and contaminant migration along the diversion channel also appear to be accelerated by the effects of Lake Reality

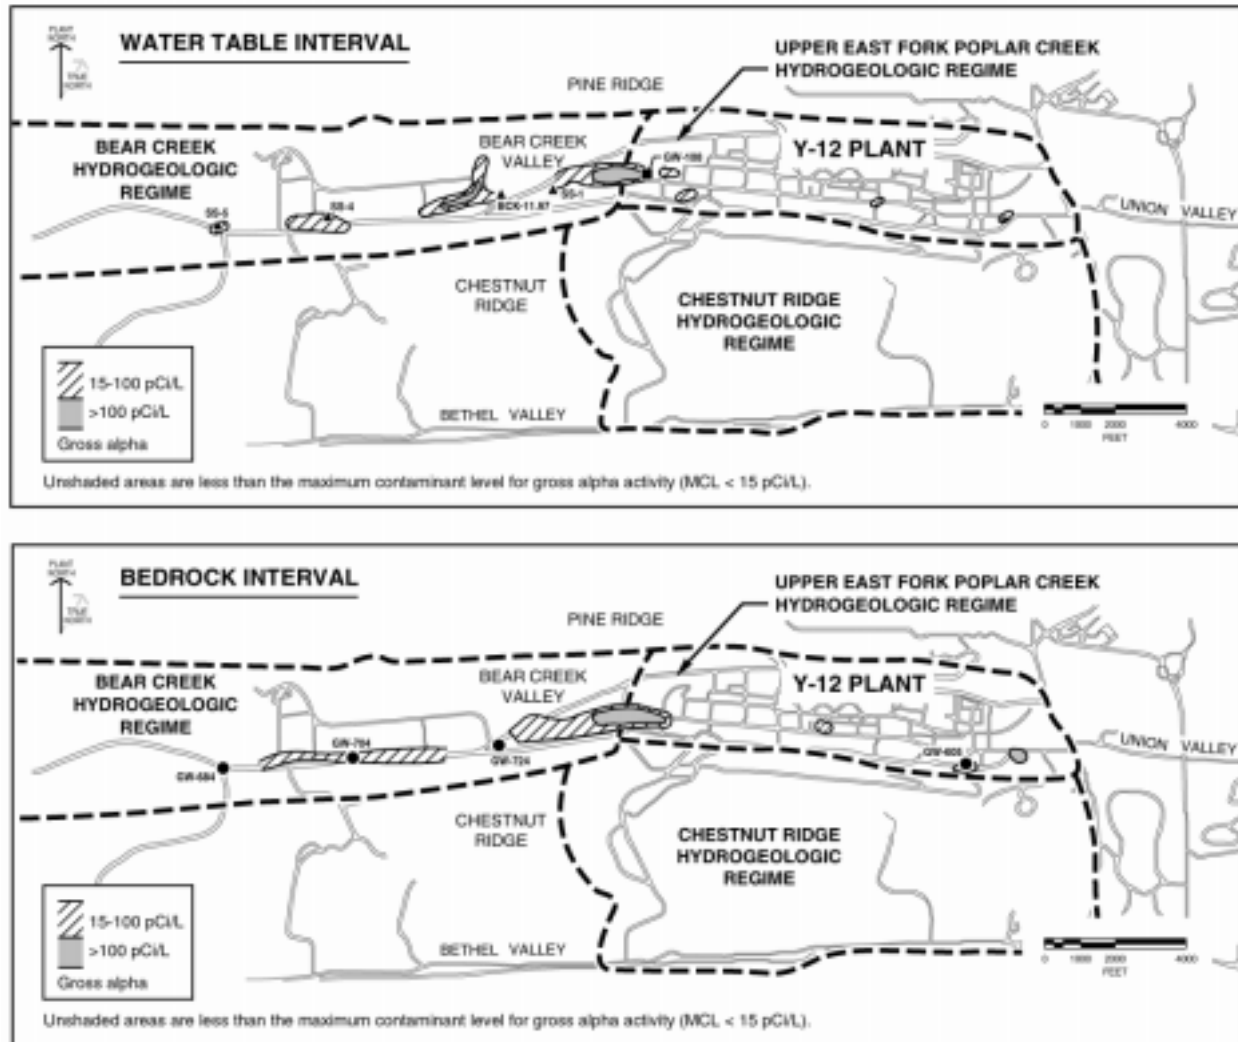

Fig. 7.13. Gross alpha activity in groundwater at the Y-12 Plant.

underdrain dewatering activities. At the dewatering sump (Fig. 7.11), groundwater is pumped from a drainage layer to relieve hydraulic pressure that periodically raises the synthetic liner in Lake Reality. Past studies have shown that when the dewatering sump is activated, groundwater table levels are lowered over a large area and contaminant levels in the sump discharge increase over time. Thus, operation of the dewatering sump has been kept to minimal levels with monitoring of discharge when operation is required. During 1997, a decrease in VOCs at LRSPW was observed.

Three wells, located in the large gap in Pine Ridge through which UEFPC exits the Y-12 Plant, are used to monitor shallow, intermediate, and deep groundwater intervals. These wells are monitored under the scope of the EMP. Shallow groundwater moves through this exit pathway, and very strong upward vertical flow gradients exist; two of the three wells located in this area are strongly artesian. Monitoring of these wells since about 1990 has not shown that any contaminants are moving via this exit pathway.

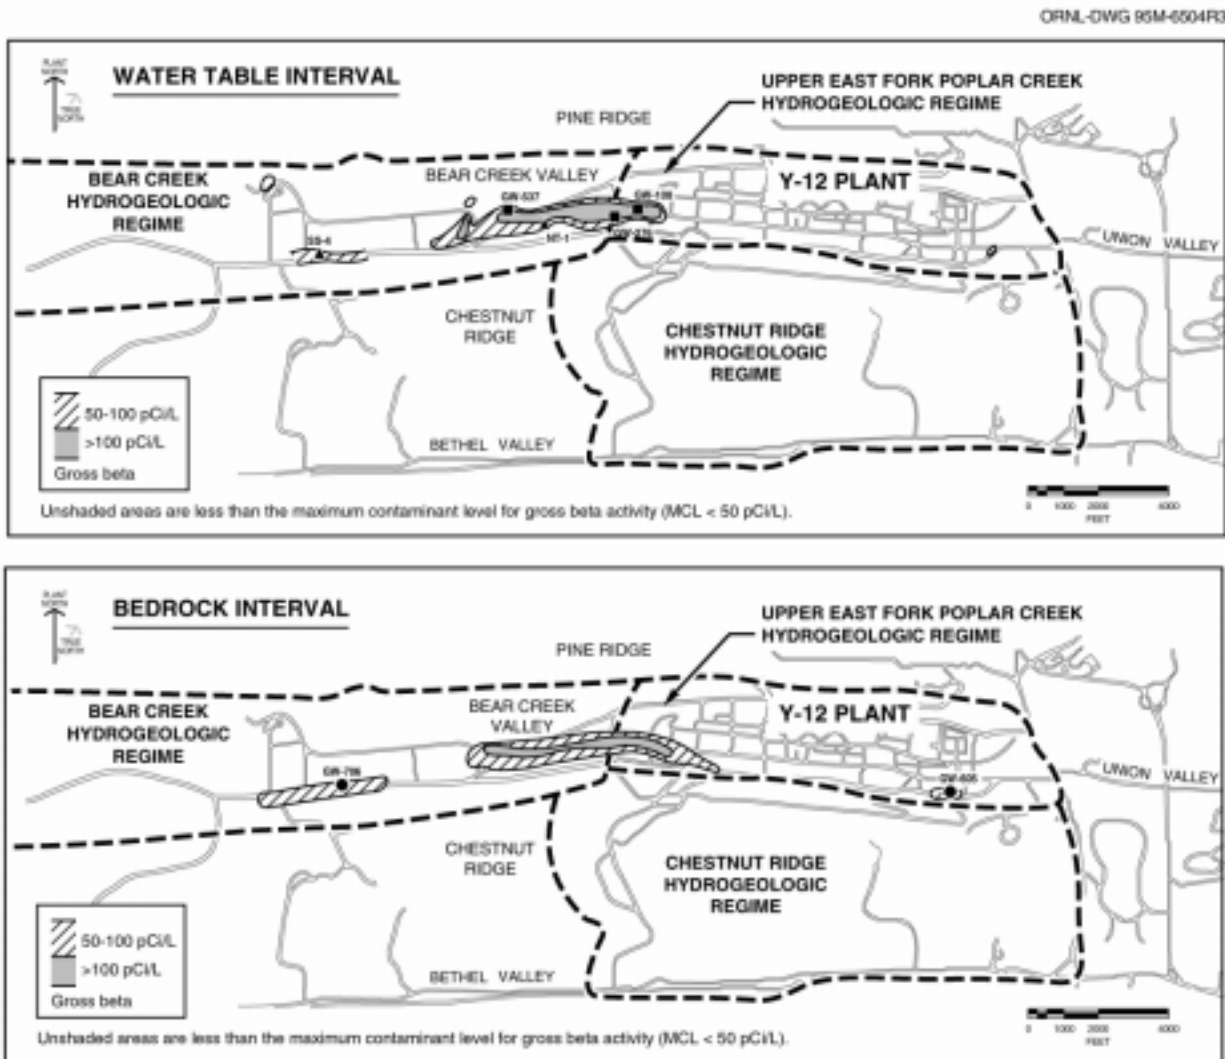

Fig. 7.14. Gross beta activity in groundwater at the Y-12 Plant.

7.2.5.2 Union Valley Focus Study

Groundwater monitoring data obtained in 1993 provided the first strong indication that VOCs were being transported off the ORR through the deep Maynardville Limestone exit pathway. The 1995 ASER provided a discussion of the nature and extent of the VOCs and short-term response actions taken. In 1997, monitoring of locations in Union Valley continued under the IWQP (DOE 1998b). These data showed no significant changes in the types and concentrations of contaminants comprising the groundwater contaminant plume in Union Valley.

The current conceptual model for Union Valley suggests that Scarboro Creek (Fig. 7.12) functions as a shallow (and possible intermediate) groundwater divide. Contaminants appear to be upwelling under the influence of vertical gradients and discharging at low concentrations to several springs and possibly within the creek channel itself. Under the terms of an interim proposed plan, administrative controls, such as restriction of potential future groundwater use, have been established. Long-term remedial actions in this area will be addressed along with those for the entire UEFPC CA in conjunction with DOE, TDEC, EPA, and the public.

7.2.5.3 Bear Creek Hydrogeologic Regime

Located west of the Y-12 Plant in BCV, the Bear Creek regime is bounded to the north by Pine Ridge and to the south by Chestnut Ridge. The regime encompasses the portion of BCV extending from the west end of the Y-12 Plant to Highway 95. Figures 7.15 and 7.16 show the Bear Creek regime, locations of stations sampled in 1997, and the locations of its waste management sites. The BCV CA lies within the regime and includes all source units, groundwater, surface water, and soils/sediments, with the exception of the SY-200 Yard and Spoil Area I, which are separate actions (Fig. 7.4; Table 7.3).

Characterization of the nature and extent of contamination in the regime is essentially complete. A CERCLA RI report has been finalized

and approved by TDEC and EPA. The RI report contains a detailed description of site history, nature and extent of contamination, and human health and ecological risk assessments and is now available for public use.

As the next step in the CERCLA process, remedial actions under the scope of a feasibility study will be evaluated and initiated where sufficient data exist to identify acceptable alternatives. Where data gaps exist preventing full evaluation of remedial alternatives, focused studies with limited scopes and short durations will be completed to obtain the specific data required to fully evaluate potential remedial actions.

Currently, the focus of monitoring efforts is RCRA postclosure corrective action monitoring, exit pathway monitoring, and surveillance of contaminant plume boundaries. These objectives were met by sampling of a monitoring network of

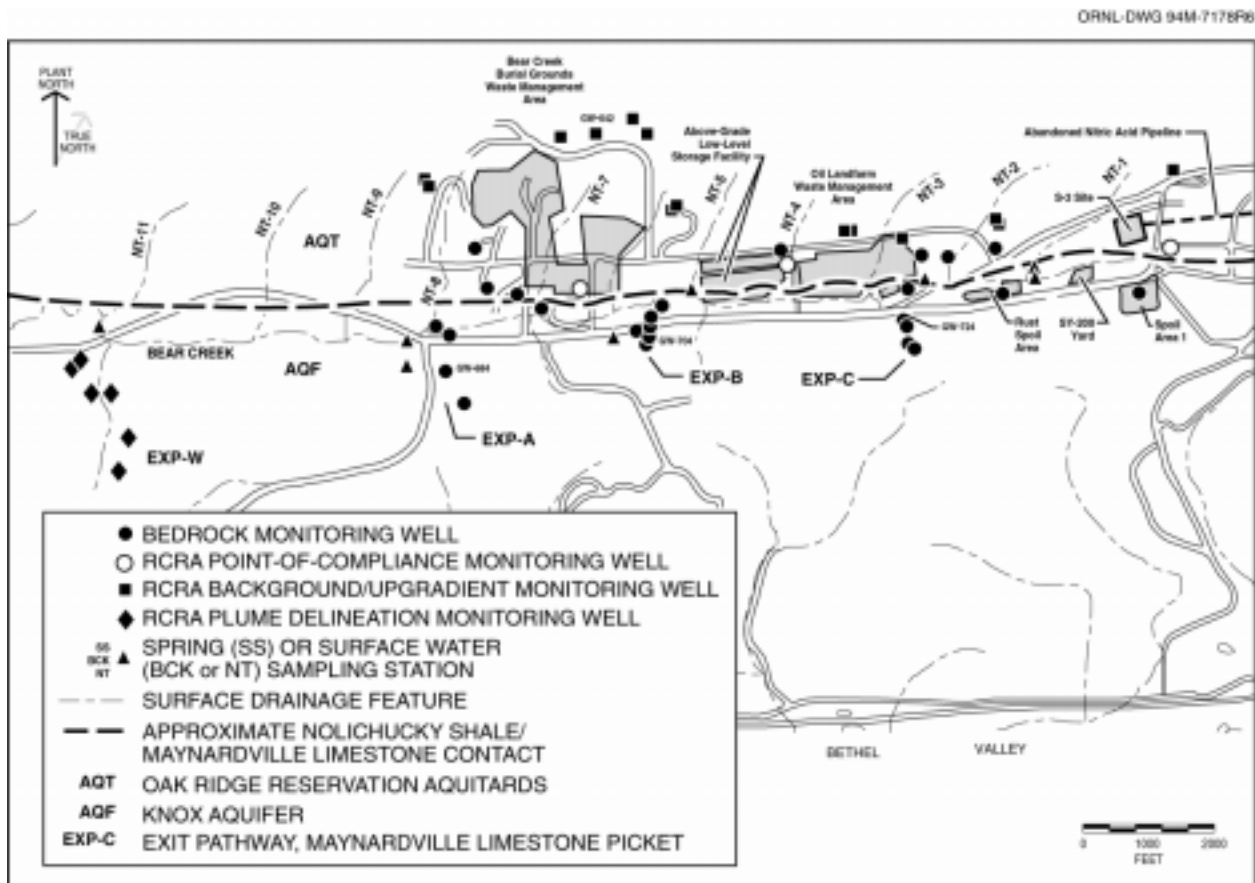

Fig. 7.15. Locations of waste management sites and monitoring wells sampled during 1997 in the Bear Creek Hydrogeologic Regime.

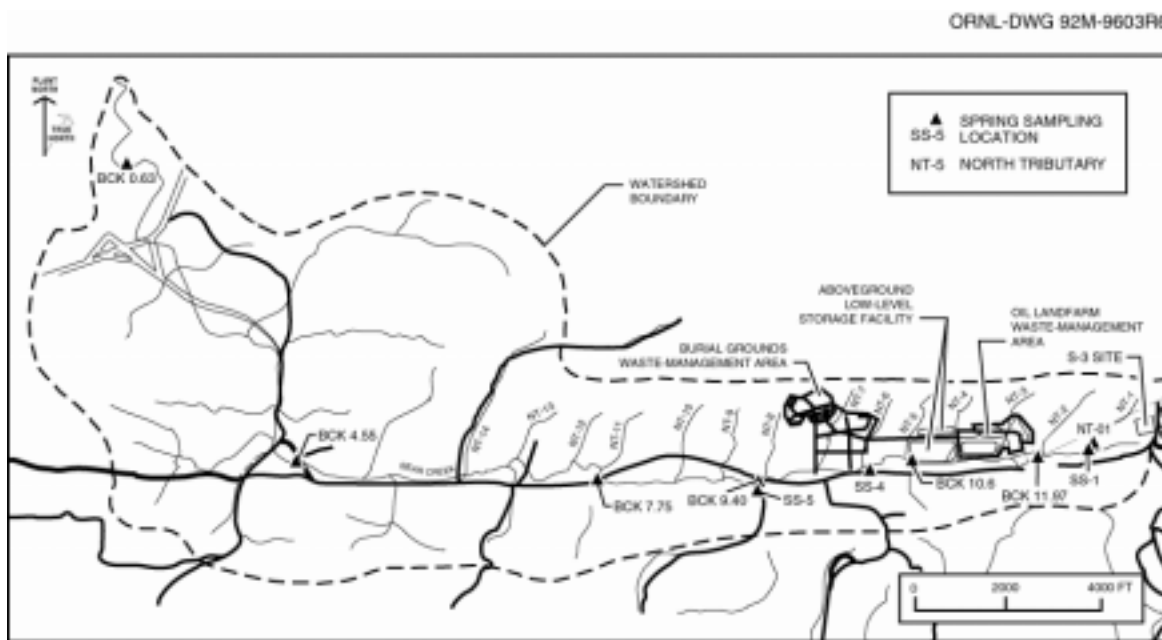

Fig. 7.16. Surface water and spring stations sampled during 1997 in the Bear Creek Hydrogeologic Regime.

45 wells, 3 springs, and 7 surface water locations specified by the RCRA postclosure permit, the ORR EMP, and primary exit pathway and surveillance-monitoring points. The network was sampled at a baseline semiannual frequency. Any future monitoring requirements dictated by CERCLA RODs issued for the BCV CA will be integrated into the long-term corrective action/surveillance-monitoring network for the regime.

Discussion of Monitoring Results

Groundwater monitoring in the Bear Creek regime during 1997 was conducted (1) to maintain surveillance of contaminant plumes (both extent and concentration of contaminants); (2) to conduct trending within contaminant exit pathways in the Maynardville Limestone using existing monitoring locations; and (3) to conduct corrective action monitoring at point-of-compliance sites, exit pathways, and background wells in accordance with the Bear Creek regime RCRA postclosure permit.

Plume Delineation

The primary groundwater contaminants in the Bear Creek regime are nitrate, trace metals, VOCs, and radionuclides. The S-3 Site is the primary source of nitrate, radionuclides, and trace metals. Sources of VOCs include the S-3 Site, the Rust Spoil Area, the Oil Landfarm waste management area, and the Bear Creek Burial Grounds waste management area; the latter two sites are the principal sources. Dense nonaqueous phase liquids (DNAPLs) exist at a depth of 270 ft below the Bear Creek Burial Grounds. The DNAPLs consist primarily of tetrachloroethene, trichloroethene, 1,1-dichloroethene, 1,2-dichloroethene, and high concentrations of PCBs.

Contaminant plume boundaries are essentially defined in the bedrock formations that directly underlie many waste disposal areas in the Bear Creek regime, particularly the Nolichucky Shale. The elongated shape of the contaminant plumes in the Bear Creek regime is the result of preferential transport of the contaminants parallel to strike in both the Knox Aquifer and the ORR Aquitards. A review of historical data suggests that contaminant

Oak Ridge Reservation

Table 7.3. Regulatory status and operational history of waste management units included in the 1997 Comprehensive Groundwater Monitoring Program; Bear Creek Hydrogeologic Regime

Site	Historical/current regulatory classification ^a	Historical data
S-3 Site	TSD/TSD-BCV CA	Four unlined surface impoundments constructed in 1951. Received liquid nitric acid/uranium-bearing wastes via the Nitric Acid Pipeline until 1984. Closed and capped under RCRA in 1988. Infiltration was the primary release mechanism to groundwater.
Oil Landfarm	TSD/TSD-BCV CA	Operated from 1973 to 1982. Received waste oils and coolants tainted with metals and PCBs. Closed and capped under RCRA in 1989. Infiltration was the primary release mechanism to groundwater.
Boneyard	SWMU/BCV CA	Unlined shallow trenches used to dispose of construction debris and to burn magnesium chips and wood.
Burnyard	SWMU/BCV CA	Used from 1943 to 1968. Wastes, metal shavings, solvents, oils, and laboratory chemicals were burned in two unlined trenches.
Hazardous Chemical Disposal Area	SWMU/BCV CA	Built over the burnyard. Handled compressed gas cylinders and reactive chemicals. Residues placed in a small, unlined pit.
Sanitary Landfill I	SWMU/BCV CA	Used from 1968 to 1982. TDEC-permitted, nonhazardous industrial landfill. May be a source of certain contaminants to groundwater. Closed and capped under TDEC requirements in 1983.
Bear Creek Burial Grounds: A, C, and Walk-in Pits	TSD/TSD-BCV CA	A and C received waste oils, coolants, beryllium and uranium, various metallic wastes, and asbestos into unlined trenches and standpipes. Walk-in Pits received chemical wastes, shock-sensitive reagents, and uranium saw fines. Activities ceased in 1981. Final closure certified for A (1989), C (1993), and the Walk-in Pits (1995). Infiltration is the primary release mechanism to groundwater.
Bear Creek Burial Grounds: B, D, E, J, and Oil Retention Ponds 1 and 2	SWMUs/BCV CA	Burial Grounds B, D, E, and J, unlined trenches, received depleted uranium metal and oxides and minor amounts of debris and inorganic salts. Ponds 1 and 2, built in 1971 and 1972, respectively, captured waste oils seeping into two Bear Creek tributaries. The ponds were closed and capped under RCRA in 1989. Certification of closure and capping of Burial Grounds B and part of C was granted 2/95.

Table 7.3 (continued)

Site	Historical/current regulatory classification ^a	Historical data
Rust Spoil Area	SWMU/BCV CA	Used from 1975 to 1983 for disposal of construction debris, but may have included materials bearing solvents, asbestos, mercury, and uranium. Closed under RCRA in 1984. Site is a source of VOCs to shallow groundwater according to CERCLA RI.
Spoil Area I	SWMU/BC OU 2	Used from 1980 to about 1987 for disposal of construction debris and other stable, nonrad wastes. Permitted under TDEC solid waste management regulations in 1986; closure began shortly thereafter. Soil contamination is of primary concern. CERCLA ROD issued in 1996.
SY-200 Yard	SWMU/BC OU 2	Used from 1950s to 1986 for equipment and materials storage. No documented waste disposal at the site occurred. Leaks, spills, and soil contamination are concerns. CERCLA ROD issued in 1996.
Above-Grade LLW Storage Facility	Active	Constructed in 1993. Consists of six above-grade storage pads used to store inert, low-level radioactive debris and solid wastes packaged in steel containers.

^aRegulatory status before the 1992 Federal Facilities Agreement: TSD—RCRA regulated, land-based treatment, storage, or disposal unit; SWMU—RCRA-regulated solid waste management unit; NA—not regulated. Current regulatory status: BCV CA—Bear Creek Valley Characterization Area; BC OU 02—Bear Creek Operable Unit 02; active—active waste storage facility.

concentrations near source areas within the ORR Aquitards have remained relatively constant since 1986. However, one well west of the Bear Creek Burial Grounds has exhibited a shallow increase in VOCs, indicating some movement parallel to strike (Fig. 7.17). As detailed in previous ORR ASERs, certain contaminants at specific sites, such as nitrate levels adjacent to the S-3 site, have shown decreasing concentration trends. Other constituents, such as gross alpha, exhibit upward trends. In exit pathway wells located in the Bear Creek regime (Fig. 7.18), slight increases or decreases are observed for selected contaminants, depending on mobility of the contaminants and relative location of the monitoring station with respect to source areas.

Nitrate

Unlike most of the other groundwater contaminants, nitrate moves easily with the groundwater. The limits of the nitrate plume probably define the

maximum extent of subsurface contamination in the Bear Creek regime.

Data obtained during 1997 indicate that nitrate concentrations exceed the 10 mg/L MCL in an area that extends west from the S-3 Site for approximately 12,000 ft down BCV (Fig. 7.8). Nitrate concentrations greater than 100 mg/L extend about 3000 ft (915 m) west of the S-3 Site. Data obtained since 1986 suggest that the nitrate plume extends more than 600 ft (183 m) below the ground surface within the ORR aquitards at the S-3 Site. Historically, the highest nitrate concentrations are observed adjacent to the S-3 Site in groundwater in the unconsolidated zone and at shallow depths [less than 100 ft (30.5 m) below the ground surface] in the Nolichucky Shale. During 1997, no monitoring was performed immediately adjacent, and downgradient of the S-3 Site. However, the closest well to the S-3 Site, which monitors the water table interval of the Nolichucky Shale (Oil Landfarm well GW-537), did have the highest nitrate concentrations during

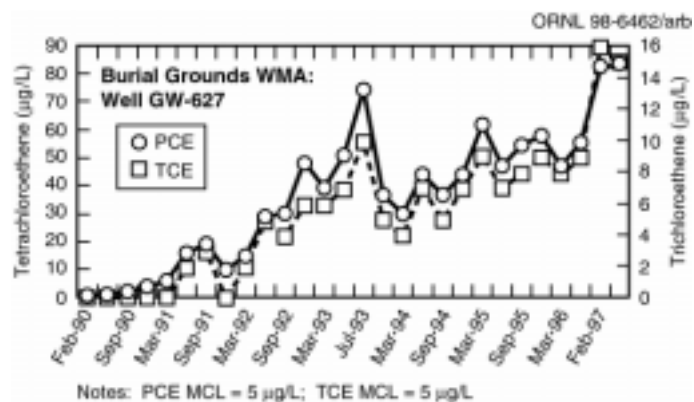

Fig. 7.17. VOC concentrations in Bear Creek Burial Grounds well GW-627.

this year. Monitoring location NT-1 was closer than well GW-537, but nitrate concentrations were diluted by surface water influences.

The horizontal extent of the nitrate plume is essentially defined in groundwater in the upper to intermediate part of the aquifer [less than 300 ft (91 m) below the ground surface]. Data obtained from exit pathway monitoring wells indicate that the nitrate plume in groundwater within bedrock in the Maynardville Limestone has not migrated appreciably during the past year and concentrations remain relatively constant or are slightly decreasing.

Trace Metals

Barium, cadmium, chromium, lead, and mercury have been identified from previous monitoring as the principal trace metal contaminants in groundwater in the Bear Creek regime. Historically, the concentrations of these metals exceeded MCLs or natural (background) levels primarily in low-pH groundwater at shallow depths near the S-3 Site. Disposal of acidic liquid wastes at this site reduced the pH of the groundwater, which allows the metals to remain in solution. Elsewhere in the Bear Creek regime, where relatively high pH conditions prevail, only sporadic occurrences of elevated trace metal concentrations are evident.

Other trace metal contaminants in the Bear Creek regime are beryllium, boron, cobalt, copper,

nickel, strontium, and uranium. Concentrations of these metals have commonly exceeded background levels in groundwater near the S-3 Site, the Bear Creek Burial Grounds, and the Oil Landfarm waste management areas. Selected stream and spring locations and exit pathway study wells also have exhibited total uranium and strontium concentrations above background values.

Volatile Organic Compounds

Like nitrate, VOCs are widespread in groundwater in the Bear Creek regime (Fig. 7.12). The primary compounds are tetrachloroethene, trichloroethene, 1,2-dichloroethene, 1,1,1-trichloroethane, and 1,1-dichloroethane. In most areas, the VOCs are dissolved in the groundwater, but nonaqueous phase accumulations of tetrachloroethene and trichloroethene occur in bedrock more than 250 ft (76 m) below the Bear Creek Burial Grounds waste management area.

Groundwater in the unconsolidated zone overlying the aquitards that contains detectable levels of VOCs occurs primarily within about 1000 ft (305 m) of the source areas. The highest VOC concentrations (greater than 10,000 mg/L) in the unconsolidated zone occur at the Bear Creek Burial Grounds waste management area. The extent of the dissolved VOC plumes is slightly greater in the underlying bedrock. Well GW-627, which is downgradient of the Bear Creek Burial Grounds waste management area has exhibited an increase in VOC concentration (Fig. 7.17). This indicates that some strike parallel migration through the aquitards is occurring in the intermediate bedrock interval.

Significant transport of VOCs has occurred in the Maynardville Limestone. Data obtained from exit pathway monitoring locations show that in the vicinity of the water table, an apparently continuous dissolved VOC plume extends for about 12,000 ft (3660 m) westward from the S-3 Site to just west of the Bear Creek Burial Grounds waste management area. The highest levels of VOCs in the Bear Creek regime occur in bedrock, just south of the Bear Creek Burial Grounds waste

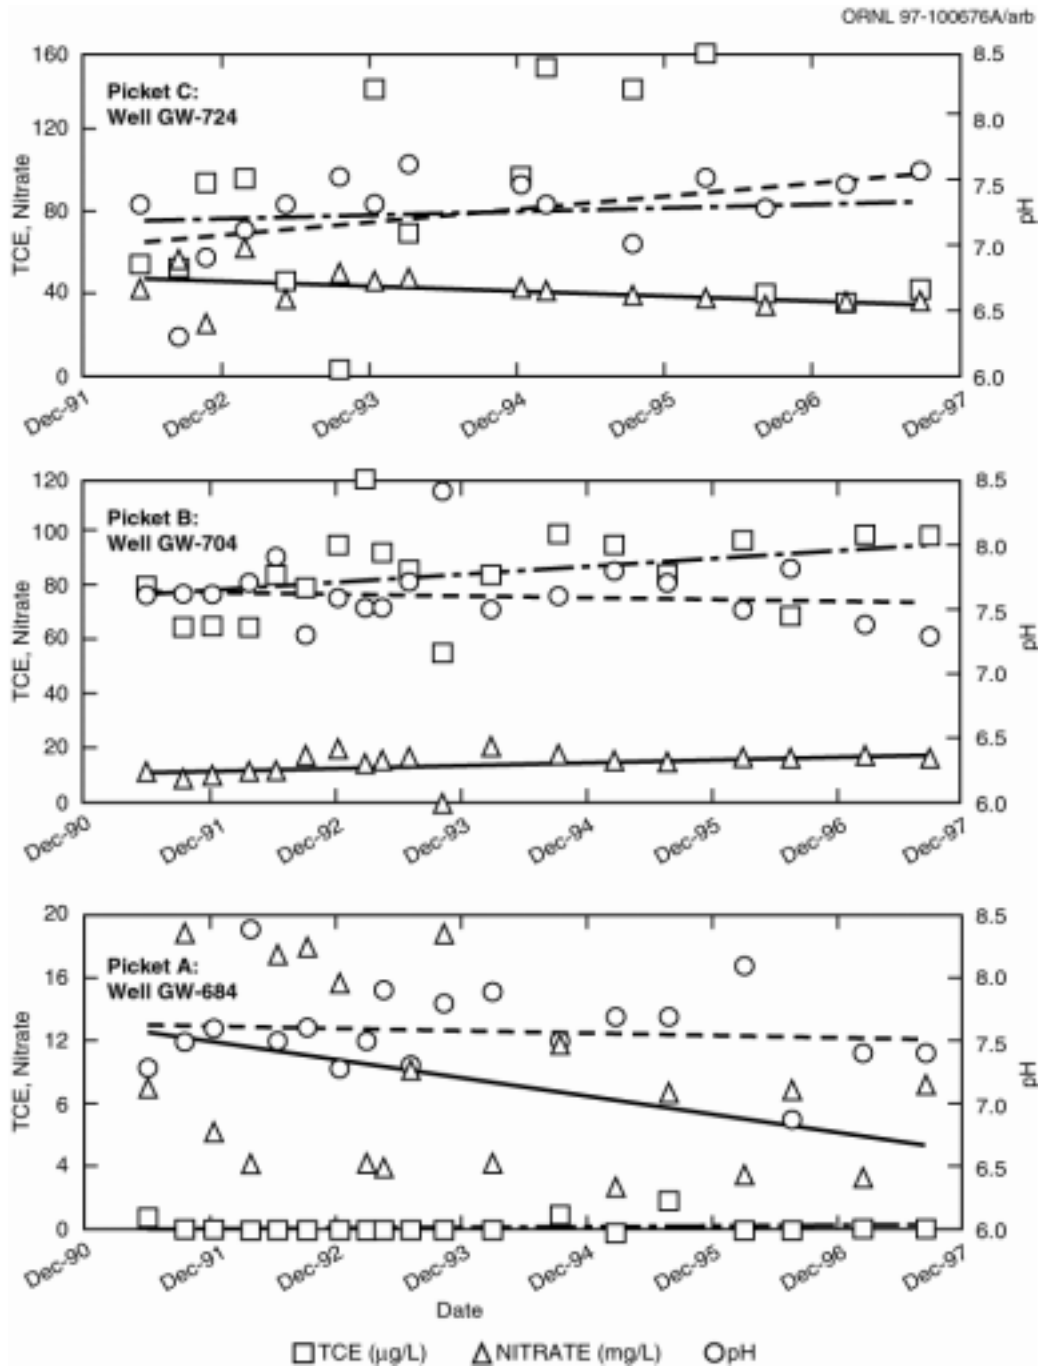

Fig. 7.18. Concentrations of selected contaminants in exit pathway monitoring wells GW-724, GW-704, and GW-684 in the Bear Creek Hydrogeologic Regime.

Oak Ridge Reservation

management area. Historical levels have been as high as 7000 mg/L in groundwater near the source area. Typical VOC levels in the exit pathway (Maynardville Limestone) range from about 160 $\mu\text{g/L}$ in the eastern part of the regime to less than detectable levels in the western part of the regime.

During 1997, VOC concentrations have been highest in exit pathway transect Picket B. Well GW-704 at this transect has exhibited a shallow increasing trend in trichloroethene since the early 1990s. All other exit pathway transect wells display a decrease in this VOC. The increase in VOCs in Picket B wells indicates that the Oil Landfarm waste management area is still a significant contributing source of VOCs.

Radionuclides

As in the East Fork regime, uranium, neptunium, americium, and naturally occurring isotopes of radium have been identified as the primary alpha-particle-emitting radionuclides in the Bear Creek regime. Technetium is the primary beta-particle-emitting radionuclide in the regime, but tritium and isotopes of strontium are also present in groundwater near the S-3 Site.

Evaluations of the extent of these radionuclides in groundwater in the Bear Creek regime during 1997 were based primarily on measurements of gross alpha activity and gross beta activity. If the annual average gross alpha activity in groundwater samples from a well exceeded 15 pCi/L (the MCL for gross alpha activity), then one (or more) of the alpha-emitting radionuclides was assumed to be present in the groundwater monitored by the well. A similar rationale was used for annual average gross beta activity that exceeded 50 pCi/L.

As shown in Fig. 7.13, groundwater with elevated levels of gross alpha activity occurs in the water table interval in the vicinity of the S-3 Site, the Bear Creek Burial Grounds, and the Oil Landfarm waste management areas. In the bedrock interval, gross alpha activity exceeds 15 pCi/L in groundwater in the Nolichucky Shale near the S-3 Site, east of the Oil Landfarm waste

management areas and the southern side of the Bear Creek Burial Grounds. Data obtained from exit pathway monitoring stations show that gross alpha activity in groundwater in the Maynardville Limestone exceeds the MCL for 10,000 ft (3050 m) west of the S-3 Site.

The distribution of gross beta radioactivity in groundwater in the unconsolidated zone is similar to that of gross alpha radioactivity (Fig. 7.14). During 1997, gross beta activity exceeded 50 pCi/L within the water table interval in the Maynardville Limestone from south of the S-3 Site to the Oil Landfarm waste management area. Within the intermediate bedrock interval in the Maynardville Limestone, the elevated gross beta activity extends as far west as does gross alpha activity, just to the west of the Bear Creek Burial Grounds waste management area.

Exit pathway and Perimeter Monitoring

Exit pathway monitoring began in 1990 to provide data on the quality of groundwater and surface water exiting the Bear Creek regime. The Maynardville Limestone is the primary exit pathway for groundwater. Bear Creek, which flows across the Maynardville Limestone in much of the Bear Creek regime, is the principal exit pathway for surface water. Various studies have shown that surface water in Bear Creek, springs along the valley floor, and groundwater in the Maynardville Limestone are hydraulically connected. The western exit pathway well transect (Picket W) serves as the ORR perimeter wells for the Bear Creek Regime (Fig. 7.6).

Exit pathway monitoring consisted of continued monitoring at four well transects (pickets) and selected springs and surface water stations. Groundwater quality data obtained during 1997 from the exit pathway monitoring wells confirmed previous data indicating that contaminated groundwater does not seem to occur much beyond the western side of the Bear Creek Burial Grounds waste management area. However, low levels of nitrate (1 to 4 mg/L) have been observed in surface water and one Picket W well west of the burial grounds (LMES 1998a).

Surface water and spring samples collected during CY 1997 (Fig. 7.16) indicate that spring discharges and water in upper reaches of Bear Creek contain many of the compounds found in the groundwater; however, the concentrations in the creek and spring discharges decrease rapidly with distance downstream of the waste disposal sites (Fig. 7.19).

7.2.5.4 Chestnut Ridge Hydrogeologic Regime

The Chestnut Ridge regime is south of the Y-12 Plant and is flanked to the north by BCV and to the south by Bethel Valley Road (Fig. 7.5). The regime encompasses the portion of Chestnut Ridge extending from Scarborough Road east of the Y-12 Plant to an unnamed drainage basin on the ridge located just west of Centralized Sanitary Landfill II. Figure 7.20 shows the approximate boundaries of the regime and locations of waste management units and monitoring wells sampled in 1997.

Four categories of sites are located within the Chestnut Ridge regime: (1) RCRA-regulated TSD units, (2) RCRA 3004(u) SWMUs and solid waste disposal units, (3) TDEC-permitted SWDFs, and (4) CERCLA OUs. The Chestnut Ridge Security Pits is the only documented source of groundwater contamination in the regime. No integrating CA has been established for the regime because contamination from the Security Pits is distinct and is not mingled with plumes from other sources. Table 7.4 summarizes the regulatory status and operational history of waste management units in the regime. Detailed discussions of these sites have been included in previous ASERs.

Discussion of Monitoring Results

A more comprehensive suite of analytical tests is applied to most sites in the Chestnut Ridge regime because of various permitting requirements. Volatile organics and trace metals are the only categories that currently consistently exceed background levels, and these are predominantly associated with the Chestnut

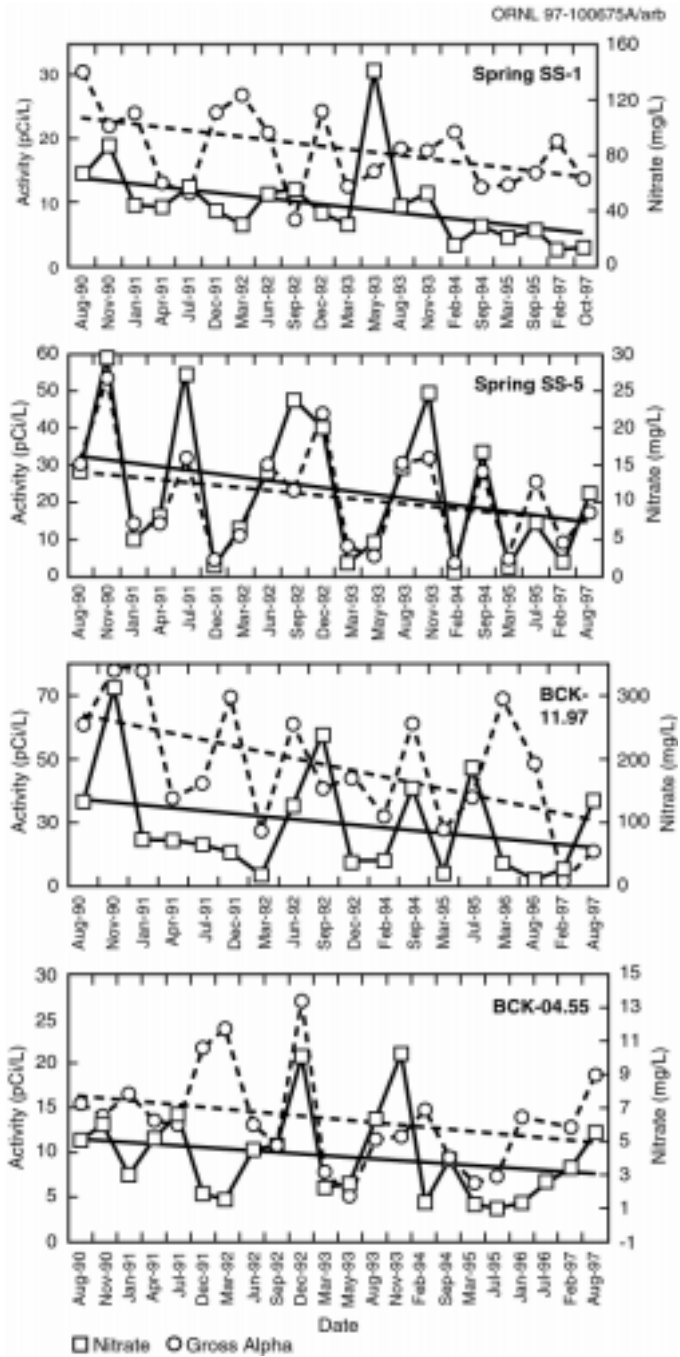

Fig. 7.19. Concentrations of selected groundwater contaminants in springs and surface water in the Bear Creek Hydrogeologic Regime. Refer to Fig. 7.16 for sampling locations.

Ridge Security Pits. Gross alpha and beta activities have sporadically exceeded screening levels in the past in samples taken from wells at the

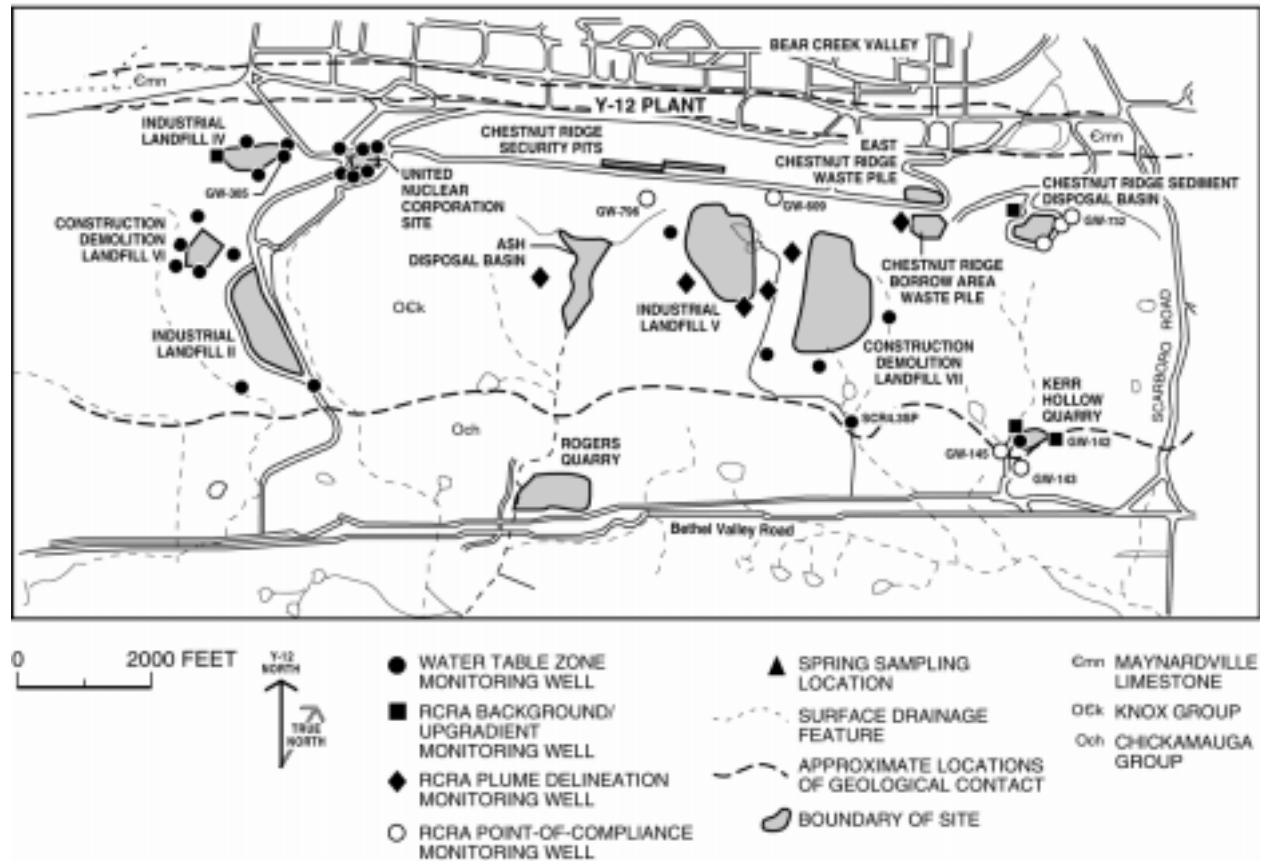

Fig. 7.20. Locations of waste management sites and monitoring wells sampled during 1997 in the Chestnut Ridge Hydrogeologic Regime.

Chestnut Ridge Sediment Disposal Basin, United Nuclear Site, Industrial Landfill IV, and Kerr Hollow Quarry, although no discernable pattern or consistency to the data has been determined.

Monitored units in the Chestnut Ridge regime, with the exception of the Chestnut Ridge Security Pits and the United Nuclear Site, are under a regulatory detection monitoring program. The Chestnut Ridge Security Pits are monitored in accordance with RCRA postclosure corrective action requirements. The United Nuclear Site is monitored under the provisions of a CERCLA ROD. In 1997, no releases of contaminants to groundwater were determined for those units under formal detection monitoring programs (Table 7.1). No observable changes of groundwater quality relative to past years were noted for units monitored under surveillance practices or a

CERCLA ROD. Plume delineation and contaminants of interest are discussed in the following sections. Four additional issues are also discussed. These four issues include the occurrence of trace levels of (1) VOCs, total strontium, and total uranium at Kerr Hollow Quarry; (2) total uranium at the Sediment disposal Basin; (3) VOCs in one well located at Industrial Landfill IV; and (4) nickel in one well located at Centralized Sanitary Landfill II.

Plume Delineation

The horizontal extent of the VOC plume at the Chestnut Ridge Security Pits is reasonably well defined in the water table and shallow bedrock zones (Fig. 7.12). Groundwater quality data obtained during 1997 continue to indicate that the

Table 7.4. Regulatory status and operational history of waste management units included in the 1997 Comprehensive Groundwater Monitoring Program; Chestnut Ridge Hydrogeologic Regime

Site	Historical/current regulatory classification ^a	Historical data
Chestnut Ridge Sediment Disposal Basin	TSD/TSD-Study Area	Operated from 1973 to 1989. Received soil and sediment from New Hope Pond and mercury-contaminated soils from the Y-12 Plant. Site was closed under RCRA in 1989. Not a documented source of groundwater contamination.
Kerr Hollow Quarry	TSD/TSD-Study Area	Operated from 1940s to 1988. Used for the disposal of reactive materials, compressed gas cylinders, and various debris. RCRA closure (waste removal) was conducted between 1990 and 1993. Certification of closure with some wastes remaining in place was approved by TDEC 2/95.
Chestnut Ridge Security Pits	TSD/TSD-CR OU 1	Operated from 1973 to 1988. Series of trenches for disposal of classified materials, liquid wastes, thorium, uranium, heavy metals, and various debris. Closed under RCRA in 1989. Infiltration is the primary release mechanism to groundwater.
United Nuclear Corporation Site	SWMU/CR OU 3	Received about 29,000 drums of cement-fixed sludges and soils demolition materials, and low-level radioactive contaminated soils. Closed in 1992; CERCLA ROD has been issued.
Centralized Sanitary Landfill II	TDEC-permitted Class II industrial SWDF	Central sanitary landfill for the ORR. Detection monitoring under postclosure plan has been ongoing since 1996.
Industrial Landfill V	TDEC-permitted Class II industrial SWDF	New facility completed and initiated operations 4/94. Baseline groundwater monitoring began 5/93 and was completed 1/95. Currently under TDEC-SWM detection monitoring.
Industrial Landfill IV	TDEC-permitted Class II industrial SWDF	Permitted to receive only, nonhazardous industrial solid wastes. Detection monitoring under TDEC-SWM regulations has been ongoing since 1988.

Oak Ridge Reservation

Table 7.4 (continued)

Site	Historical/current regulatory classification ^a	Historical data
Construction/Demolition Landfill VI	TDEC-permitted Class IV construction/demolition SWDF	New facility completed and initiated operations 12/93. Baseline groundwater quality monitoring began 5/93 and was completed 12/93. Currently under permit-required detection monitoring per TDEC.
Construction/Demolition Landfill VII	TDEC-permitted Class IV construction/demolition SWDF	New facility; construction completed in 12/94. TDEC granted approval to operate 1/95. Baseline groundwater quality monitoring began in 5/93 and was completed in 1/95. Permit-required detection monitoring per TDEC was temporarily suspended 10/97 pending closure of construction/demolition Landfill VI.

^aRegulatory classification before the 1992 Federal Facilities Agreement: TSD—RCRA regulated, land-based treatment, storage, or disposal facility; SWMU—RCRA-regulated solid waste management unit. Current regulatory status: study area—Y-12 Plant study area; CR OU 1—Chestnut Ridge Operable Unit 1; CR OU 2—Chestnut Ridge Operable Unit 2; CR OU 3—Chestnut Ridge Operable Unit 3; CR OU 4—Chestnut Ridge Operable Unit 4; SWDF—solid waste disposal facility (active landfill).

lateral extent of the VOC plume at the site is increasing slightly, as evidenced by detectable signature VOCs in wells GW-609, and GW-796. Concentrations of tetrachloroethene have been steadily decreasing in well GW-609 since monitoring began in 1990.

There are two distinct VOCs in groundwater at the security pits. In the western portion of the site, the VOC plume is characterized by high concentrations of 1,1,1-trichloroethane. Tetrachloroethene is a principal component of the VOC plume in the eastern portion of the site. The distinct difference in the composition of the plume is probably related to differences in the types of wastes disposed of in the eastern and western trench areas.

Nitrate

Nitrate concentrations were well below the DWS of 10 mg/L at all monitoring stations.

Trace Metals

Beryllium, chromium, lead, and nickel concentrations sporadically exceeded DWSs in a number of wells during 1997. Most of the elevated results were attributable to elevated turbidity and suspended solids in the samples. Verification sampling required under detection monitoring programs was performed for a number of the exceedences.

Total strontium and total uranium levels continued to be elevated above background levels at wells GW-142, GW-143, and GW-145 at Kerr Hollow Quarry. These two constituents do not appear to have a radiogenic source in that isotopic and gross activity analyses remained well below applicable DWSs and 4% of the DCGs during 1997. Additionally, in accordance with RCRA Postclosure Permit requirements, confirmatory sampling of Kerr Hollow Quarry wells was performed because of elevated concentrations of boron and strontium in the initial sampling event.

The confirmatory sampling event showed that no release of boron or strontium occurred.

An increase in total uranium above background concentrations was observed in well GW-732 at the Chestnut Ridge Sediment Disposal Basin. This exceedence is attributed to modifications in the background value calculation procedure and the increased turbidity of samples, not to a contaminant release from the facility. Confirmatory sampling has been deferred to the next sampling event in 1998.

The confirmatory sampling of well GW-539 at Centralized Sanitary Landfill II did verify the elevated concentrations of nickel above the DWS. Well GW-539 is upgradient of Centralized Sanitary Landfill II and downgradient of Construction/Demolition Landfill VI. The elevated nickel concentrations are not attributed to a release from Construction/Demolition Landfill VI but to degradation in well performance and corrosion of well materials.

Volatile Organic Compounds

Well GW-305 located immediately to the east of Industrial Landfill IV continues to exhibit an increasing trend in VOCs (Fig. 7.21) since the first quarter of 1992 (exclusively 1,1,1-trichloroethane until the fourth quarter of 1996). Concentrations of the VOCs have remained below applicable DWSs. The source of the VOCs in this well was originally thought to be the Chestnut Ridge Security Pits. However, evaluation of water table levels in wells in the area have shown that the water table at Industrial Landfill IV is typically about 10 feet higher than that at the Security Pits. Therefore, a connection with the Security Pits is not the most feasible explanation. Additional monitoring data are being reviewed and collected in the area to attempt to establish the source of the VOCs.

Efforts to delineate the extent of VOCs in groundwater attributable to the security pits (previously discussed) have been in progress since 1987. A review of historical data suggests that VOC concentrations in groundwater at the site have generally decreased since 1988 (Fig. 7.22). Low levels of VOCs have also been observed at a

few additional monitoring locations in 1997. Of particular note, trace levels of VOCs continued to be observed in Kerr Hollow Quarry monitoring wells.

Radionuclides

Only three samples exceeded the gross alpha DWS of 15 pCi/L (LMES 1998a); no well has demonstrated consistent radiological contamination. Gross beta activities were below the DWS of 50 pCi/L at all locations.

Exit pathway and Perimeter Monitoring

Contaminant and groundwater flow paths in the karst bedrock underlying the Chestnut Ridge regime have not been well characterized using conventional monitoring techniques. Dye-tracer studies have been used in the past to attempt to identify exit pathways. Based on the results of dye-tracer studies to date, no springs or surface streams that represent discharge points for groundwater have been conclusively identified for water quality monitoring. Future dye-tracer studies are possible. TDEC/DOE-OR conducted a small-scale tracer study east of the Sediment Disposal Basin in 1995; the results indicated preferential migration of groundwater along strike with discharge to a spring located off the ORR along Scarboro Creek in Union Valley. Off-site locations, including the spring, are monitored as part of the Union Valley focus study (Sect. 7.2.5.2).

Monitoring of one large spring south of Industrial Landfill V and Construction/Demolition Landfill VII was continued in 1997 as required under the EMP. Periodically, additional springs within the Chestnut Ridge regime will be sampled as part of overall exit pathway monitoring for the regime.

7.2.5.5 Special Studies

Planning or initiation of a number of special projects related to groundwater occurred in 1997. These special projects may be divided into three general categories: technical studies, characteriza-

Oak Ridge Reservation

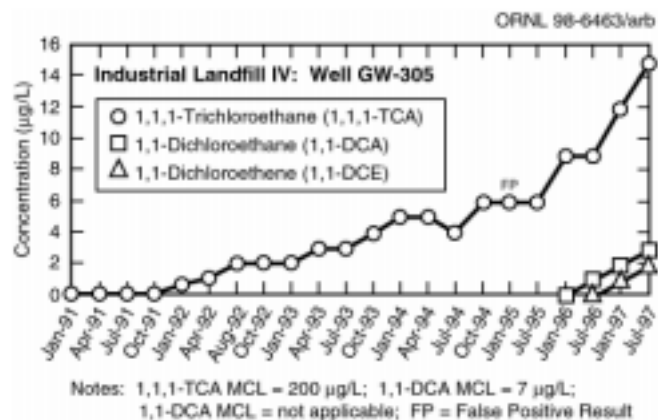

Fig. 7.21. VOC concentrations in Industrial Landfill IV well GW-305.

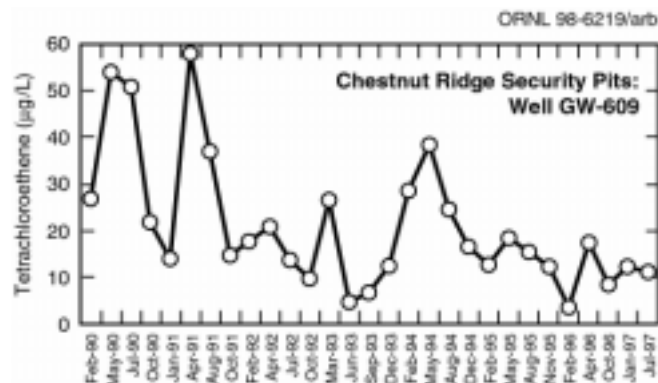

Fig. 7.22. Tetrachloroethene concentrations in Chestnut Ridge Security Pits well GW-609.

tion activities, and technology feasibility studies/demonstrations.

Technical Studies

Another large effort was initiated in 1996 to review the distribution of major utility lines within the Y-12 Plant that may act as preferential pathways for shallow groundwater flow and contaminant transport. This effort was initiated because several instances had been previously documented in which utility pipeline traces acted as either preferential flowpaths or truncated shallow groundwater contaminant plumes. This effort was completed in 1997 and revealed that underground utilities do, in many cases, act as

flowpaths for shallow groundwater and contaminants. This information was incorporated into characterizations efforts of the UEFPC RI.

Characterization Activities

During 1997, several projects were undertaken to provide data for the UEFPC CERCLA RI. It was determined that the additional field activities were required to resolve gaps in the existing data. These projects included characterization of groundwater, surface water, fish, and sediments. The groundwater-related activities performed consisted of the installation and sampling of 16 temporary shallow wells and the sampling of other existing wells, stormdrains, and basement sumps.

In support of the RMPE Program, 24 shallow piezometers were installed along UEFPC in late 1997. These piezometers will be monitored in 1998 to evaluate mercury mobilization and transport in the shallow groundwater system.

Technology Feasibility Studies/Demonstrations

Planning activities began in 1996 to design a groundwater capture and treatment system for the VOC plume emanating from the plant and moving eastward along exit pathways as far as Union Valley. One phase of this feasibility study involves the installation of a deep well [approximately 500 ft (152 m)] on the ORR near the east end of the Y-12 Plant. This well will target the mass of contamination (carbon tetrachloride in particular) in the intermediate and deep intervals of the Maynardville Limestone. Pumping and tracer tests will be performed on this well to assess geologic and hydrologic characteristics of the bedrock for system design and feasibility determinations. In addition, a gravel underdrain system beneath the concrete diversion channel of UEFPC is being considered as part of the groundwater capture system, specifically for shallow groundwater. The underdrain will function as a capture trench. The underdrain system traverses a large portion of the east end of the Y-12 Plant and is already known to transmit large quantities of

shallow groundwater. The combined pumping of these two capture systems will theoretically intercept the VOC plume both in the shallow and deeper flow systems. Planning and design of the deep well was deferred until 1997. Installation and testing of the well will begin in early 1998. If the feasibility study indicates the design is successful, groundwater extraction and treatment may be considered as a long-term remedial action.

A multiphase treatability study within the Bear Creek regime continued in 1997. This effort involved evaluation of remedial technologies for contaminated groundwater and surface water, with particular focus on the primary S-3 Site contaminants. The initial phase of the feasibility study was conducted in 1996 and early 1997 and involved laboratory-scale testing of various types of treatment methods for contaminated groundwater. In addition, remediation of contaminants in surface water using wetlands and biological uptake methods was tested using field-scale experiments. The second phase, which began in 1997, involved the collection of focused hydrologic data around the S-3 Site and the installation of capture trenches and wells for shallow groundwater extraction and treatment. One well was drilled at approximately 45% from vertical (200 linear feet) to intersect a permeable flow zone beneath north tributary 1.

An additional special study (termed technology demonstration) of the applicability of groundwater and soils remedial technologies continued during 1997. The technology demonstration involved the installation of a trench capture and treatment system for shallow groundwater contamination. This technology consists of a treatment cell located between two subsurface impermeable barrier walls downgradient of a collection trench (funnel and gate). The treatment cell contains experimental treatment media housed in removable cartridges for easy maintenance. The entire system is approximately 300 ft (91 m) long and 25 ft (7.6 m) deep (or to bedrock), and installation was completed in late 1997. Monitoring of treatment effectiveness will be continued into 1998.

7.3 GROUNDWATER MONITORING AT THE OAK RIDGE NATIONAL LABORATORY

7.3.1 Background

The groundwater monitoring program at ORNL consists of a network of wells of two basic types and functions: (1) water quality monitoring wells built to RCRA specifications and used for site characterization and compliance purposes and (2) piezometer wells used to characterize groundwater flow conditions. The EMEF Program, formerly the ER Program, provides comprehensive cleanup of sites where past and current research, development, and waste management activities may have resulted in residual contamination of the environment. Individual monitoring and assessment is assumed to be impractical for each of these sites because their boundaries are indistinct and because there are hydrologic interconnections between many of them. Consequently, the concept of WAGs was developed to facilitate evaluation of potential sources of releases to the environment. A WAG is a grouping of multiple sites that are geographically contiguous and/or that occur within hydrologically (geohydrologically) defined areas. WAGs allow establishment of suitably comprehensive groundwater and surface water monitoring and remediation programs in a far shorter time than that required to deal with every facility, site, or SWMU individually. Some WAGs share boundaries, but each WAG represents a collection of distinct small drainage areas, within which similar contaminants may have been introduced. Monitoring data from each WAG are used to direct further groundwater studies aimed at addressing individual sites or units within a WAG as well as contaminant plumes that extend beyond the perimeter of a WAG.

In 1996, DOE established the Integrated Water Quality Program (Sect. 3.3) to implement a comprehensive and integrated environmental

Oak Ridge Reservation

assessment program for the ORR and minimize duplication of field, analytical, and reporting efforts (DOE 1998b). Under the IWQP, there was a shift away from the use of the WAG concept to more of a watershed approach to remediation, which resulted in the assignment of two watersheds to ORNL, Bethel Valley Watershed and Melton Valley Watershed. Because the ORNL WAGs were already naturally located either in Bethel or Melton valleys, the change did not significantly affect the way monitoring or remediation was viewed at ORNL. Therefore, to provide continuity with previous ASER reports and to allow comparison of activities and sampling results, the following discussions continue to use the WAG concept.

At ORNL, 20 WAGs were identified by the RCRA Facility Assessment (RFA) conducted in 1987. Thirteen of these have been identified as potential sources of groundwater contamination. Additionally, there are a few areas where potential remedial action sites are located outside the major WAGs. These individual sites have been considered separately (instead of expanding the area of the WAG). Water quality monitoring wells have been established around the perimeters of the WAGs determined to have a potential for release of contaminants. Figure 7.23 shows the location of each of the 20 WAGs.

Groundwater quality monitoring wells for the WAGs are designated as hydraulically upgradient or downgradient (perimeter), depending on their location relative to the general direction of groundwater flow. Upgradient wells are located to provide groundwater samples that are not expected to be affected by possible leakage from the site. Downgradient wells are positioned along the perimeter of the site to detect possible groundwater contaminant migration from the site. There are no groundwater quality monitoring wells installed for the WAG 10 grout sheets.

A summary of the ORNL groundwater surveillance program is presented in Table 7.5, in which the WAGs are identified as within Bethel or Melton valleys. The program was reviewed in 1996, and modifications included transfer of monitoring responsibility for some of the WAGs to IWQP. ORNL retained WAGs that have the

potential for groundwater contamination because of ongoing ORNL activities. In its current program, groundwater quality wells are sampled by ORNL on a rotational basis (Table 7.5).

WAG 6 has been monitored under RCRA auspices for a number of years. RCRA assessment data for WAG 6 were submitted to TDEC in March 1997. As part of the WAG 6 RCRA/CERCLA integrated monitoring approach, RCRA assessment groundwater monitoring continued from 1995 through 1997 under the auspices of the *Environmental Monitoring Plan for WAG 6 at ORNL* (DOE 1995), a CERCLA-driven monitoring plan, agreed to in principle by DOE, EPA, and TDEC in June 1994. Baseline groundwater monitoring under the plan was initiated in October 1994 and ended in September 1995. All 24 RCRA groundwater monitoring wells were sampled during that time (8 quarterly and 16 semiannually). Routine groundwater monitoring conducted

ORNL-DWG 87M-9552AR2

under the plan was initiated in October 1995 and continued into 1997. A subset of 12 RCRA groundwater monitoring wells were sampled on a semiannual basis during 1997 under the routine monitoring scenario. The nine downgradient wells involved in routine monitoring are 835, 837, 841, 842, 843, 844, 4315, 4316, and 4317. The remaining wells are located upgradient of the hazardous waste disposal area. These wells are 846, 857, and 858. VOCs and radionuclides were monitored during routine monitoring.

The ORNL exit pathway program is designated to monitor groundwater at locations that are thought to be likely exit pathways for groundwater affected by activities at ORNL. The program was initiated in 1993 and was reviewed in 1996, which resulted in WOC/Melton Valley being the focus of the program (Fig. 7.24). A summary of the current program is presented in Table 7.6.

Groundwater monitoring for the ORNL WAG perimeter monitoring network and the ORNL plant perimeter surveillance during 1997 involved approximately 45 sampling events. In a few cases, no samples could be collected because the wells were dry.

Four of the 10 wells identified by the ORR EMP represent ORNL's exit pathway and are also part of the WAG perimeter monitoring program (WAG 2). As a result, 1997 data from sampling conducted under the WAG perimeter program were used for the exit pathway monitoring plan program. The surface water location (WOC at WOD) was sampled in the fall of 1997. The results of the plant perimeter monitoring program are discussed as part of the discussions below.

Groundwater quality is regulated under RCRA by referring to the SDWA standards. The standards are applied when a site undergoes RCRA permitting. None of the ORNL WAGs are under RCRA permits at this time; therefore, no permit standards exist with which to compare sampling results. In an effort to provide a basis for evaluation of analytical results and for assessment of groundwater quality at ORNL WAGs, federal DWSs and Tennessee water quality criteria for domestic water supplies were used as reference values in the following discussions. When no federal or state standard has been established for

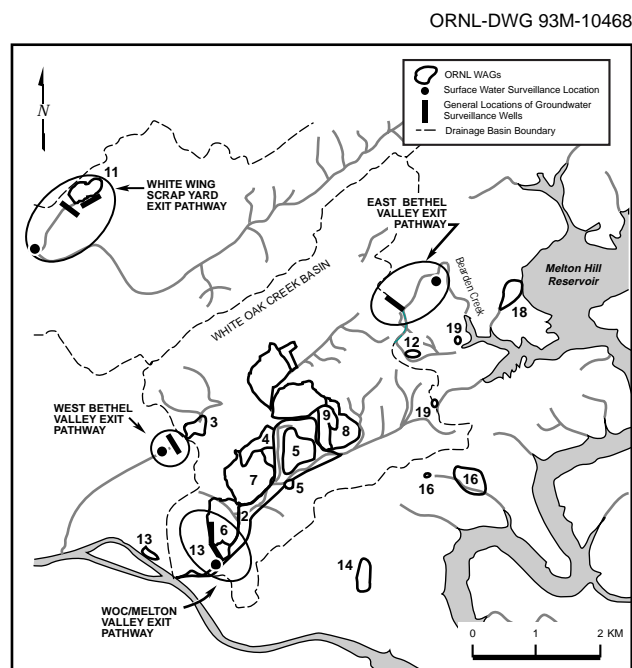

Fig. 7.24. Groundwater exit pathways on the Oak Ridge Reservation that are likely to be affected by Oak Ridge operations.

a radionuclide, then 4% of the DOE DCG has been used. Although DWSs are used, it is unrealistic to assume that members of the public are going to drink groundwater from ORNL WAGs. There are no groundwater wells furnishing drinking water to personnel at ORNL.

7.3.1.1 Bethel Valley

Bethel Valley, which is located in the southeastern portion of the ORR, lies between two prominent, parallel, northeast-southwest trending ridges, Chestnut Ridge to the north and Haw Ridge to the south. It has been an industrial site for 50 years and contains the main ORNL facilities complex, including buildings, reactors, surface impoundments, and buried waste tank farms with transfer pipelines. In most instances, groundwater in the valley flows northeast-southwest (i.e., parallel to the strike direction) and contaminant plumes generally enter the surface water system (DOE 1998b), where contaminants are readily monitored (Chap. 5).

Oak Ridge Reservation

Table 7.6. Summary of the plant perimeter surveillance program at ORNL, 1997

^aFour wells are part of the ORNL WAG 2 perimeter network.

WAG 1 Area

WAG 1, the ORNL main plant area, contains about one-half of the remedial action sites identified to date by the EMEF Program. WAG 1 lies within the Bethel Valley portion of the WOC drainage basin. The boundaries of the basin extend to the southeast and northeast along Chestnut Ridge and Haw Ridge. The WAG boundary extends to the water gap in Haw Ridge. The total area of the basin in Bethel Valley is about 2040 acres. Bedrock beneath the main plant area is limestone, siltstone, and calcareous shale facies of the Ordovician Chickamauga Group.

Many of the WAG 1 sites were used to collect and to store LLW in tanks, ponds, and waste treatment facilities, but some sites also include landfills and contaminated sites resulting from spills and leaks occurring over the last 50 years. Because of the nature of cleanup and repair, it is not possible to determine which spill or leak sites still represent potential sources of release. Most of the SWMUs are related to ORNL's waste management operations. Recent EMEF activities within WAG 1 include several CERCLA actions associated with sources of contamination [e.g., a treatability study associated with the GAAT remedial action, the demolition of the Waste Evaporator Facility (Building 3506) via a CERCLA removal action, and completion of the non-time-critical removal action for stabilization of the 3001 canal].

WAG 1 Results

In 1997, under the revised program, four wells were sampled for radionuclides only. These four wells are in the southwest area of WAG 1. Gross alpha activity ranged from below detection to 3.7 pCi/L, and tritium ranged from below detection to 20,000 pCi/L. None of the other targeted radionuclides were detected. All four wells' results were consistent with historical data.

WAG 3 Area

WAG 3 is located in Bethel Valley about 0.6 mile (1 km) west of the main plant area. WAG 3 is composed of three SWMUs: SWSA 3, the Closed Scrap Metal Area (1562), and the Contractors' Landfill (1554).

SWSA 3 and the Closed Scrap Metal Area are inactive landfills known to contain radioactive solid wastes and surplus materials generated at ORNL from 1946 to 1979. Burial of solid waste ceased at this site in 1951; however, the site continued to be used as an aboveground scrap metal storage area until 1979. Sometime during the period from 1946 to 1949, radioactive solid wastes removed from SWSA 2 were buried at this site. In 1979, most of the scrap metal stored above ground at SWSA 3 was either transferred to other storage areas or buried on site in a triangular-shaped disposal area immediately south of SWSA 3.

Records of the composition of radioactive solid waste buried in SWSA 3 were destroyed in a fire in 1961. Sketches and drawings of the site

indicate that alpha and beta-gamma wastes were segregated and buried in separate areas or trenches. Chemical wastes were probably also buried in SWSA 3 because there are no records of disposal elsewhere. Although the information is sketchy, the larger scrap metal equipment (such as tanks and drums) stored on the surface at this site was also probably contaminated. Because only a portion of this material is now buried in the closed Scrap Metal Area, it is not possible to estimate the amount of contamination that exists in this SWMU.

The Contractors' Landfill was opened in 1975 and is now closed. It was used to dispose of various uncontaminated construction materials. No contaminated waste or asbestos was allowed to be buried at the site. ORNL disposal procedures required that only non-RCRA, nonradioactive solid wastes were to be buried in the Contractors' Landfill.

WAG 3 Results

Groundwater monitoring in WAG 3 was transferred to IWQP in 1996. Monitoring results for 1997 are available in the IWQP annual report (DOE 1998b).

WAG 17 Area

WAG 17 is located about 1 mile (1.6 km) directly east of the ORNL main plant area (Fig. 7.23). This area has served as the major craft and machine shop area for ORNL since the late 1940s. The area includes the receiving and shipping departments, machine shops, carpenter shops, paint shops, lead-melting facilities, garage facilities, welding facilities, and material storage areas that are needed to support ORNL's routine and experimental operations. It is composed of 18 SWMUs. A former septic tank is now used as a sewage collection/pumping station for the area. Photographic waste tanks have been removed. Only two tanks are currently registered to store oil.

WAG 17 Results

WAG 17 is located on a northwest-facing slope, with its upgradient wells on the eastern border and downgradient wells on the western border. Although none of the wells had radiological levels above any DWSs, the data for wells along the eastern and western boundaries show evidence of radioactivity, including gross alpha activity and ^3H . In the past, gross alpha activity has exceeded the DWS at two wells; however, this has not occurred in the past four sampling events. The highest gross alpha activity was 10 pCi/L, and ^3H was 6200 pCi/L. Gross beta and total radioactive strontium were not detected.

The data for the wells along the southeastern and southwestern boundaries show evidence of VOCs. The contamination has consistently been located primarily in one well (Well 1201) (LMES 1998a). The pollutants include trichloroethene, vinyl chloride, tetrachloroethene, 1,1-dichloroethene and benzene.

7.3.1.2 Melton Valley

Melton Valley is one of two valleys that make up ORNL; the other is Bethel Valley, which is separated from Melton Valley by Haw Ridge. Melton Valley is of primary importance on the ORR because it is one of the major waste storage areas on the reservation. In addition to surface structures, it is the location of shallow waste burial trenches and auger holes, landfills, tanks, impoundments, seepage pits, hydrofracture wells and grout sheets, and waste transfer pipelines and associated leak sites. As with Bethel Valley, groundwater plumes within Melton Valley generally enter the surface water system (DOE 1998b), where contaminants are frequently encountered (Chap. 5).

WAG 2 Area

WAG 2 is composed of WOC discharge points and includes the associated floodplain and subsurface environment. It represents the major drainage system for ORNL and the surrounding facilities.

Oak Ridge Reservation

In addition to natural drainage, WOC has received treated and untreated effluents and reactor cooling water from ORNL activities since 1943. Controlled releases include those from the NRWTF, the STP, and a variety of process waste holdup ponds throughout the ORNL main plant area (WAG 1). It also receives groundwater discharge and surface drainage from WAGs 1, 4, 5, 6, 7, 8, and 9.

There is little doubt that WAG 2 represents a source of continuing contaminant release (radionuclides and/or chemical contaminants) to the Clinch River. Although it is known that WAG 2 receives groundwater contamination from other WAGs, the extent to which WAG 2 may be contributing to groundwater contamination has yet to be determined. Recent EMEF activities include continued monitoring and support of the WAG 5 seeps removal action, as well as performing an RI of the WOC watershed.

WAG 2 Results

At WAG 2, most of the downgradient wells are to the west and downstream. The upgradient wells are to the east and upstream. As a major drainage system, WAG 2 is influenced by other WAGs, and this seems to be reflected in the analytical results. Major contributors of ^3H and total radioactive strontium to WAG 2 (in order of contribution) are WAGs 5, 8, 9, 4, 1, 6, and 7 (see Fig. 7.23).

For example, four of the WAG 2 wells that exhibited high levels of ^3H are located south of and downgradient of WAGs 5, 6, and 8. All of the WAG 2 wells show evidence of radioactivity, including gross alpha and gross beta activity and ^3H (LMES 1998a). Gross beta activity above primary DWSs was detected at one well south of WAG 6. The elevated levels of ^3H and total radioactive strontium in the perimeter wells at WOD are believed to be the result of surface-water underflow at the dam, not groundwater contamination. Gross alpha activity at WAG 2 ranged from not detected to 15 pCi/L (the DWS is 15 pCi/L); beta activity ranged from not detected to 530 pCi/L (the DWS is 50 pCi/L); and total radioactive strontium ranged from not de-

tected to 170 pCi/L (the DWS is 8 pCi/L). Tritium ranged from not detected to 350,000 pCi/L (the DWS is 20,000 pCi/L) (LMES 1998a).

Chromium and lead were detected above DWS at one well south of WAG 6. Chromium has been found to be above the DWS in the past five sampling events at this well (LMES 1998a).

WAG 4 Area

WAG 4 is located in Melton Valley about 0.5 mile (0.8 km) southwest of the main ORNL plant site. It comprises the SWSA 4 waste disposal area, LLLW transfer lines, and the experimental Pilot Pit Area (Area 7811).

SWSA 4 was opened for routine burial of solid radioactive wastes in 1951. From 1955 to 1963, Oak Ridge was designated by the Atomic Energy Commission as the Southern Regional Burial Ground; as such, SWSA 4 received a wide variety of poorly characterized solid wastes (including radioactive waste) from about 50 sources. These wastes consisted of paper, clothing, equipment, filters, animal carcasses, and related laboratory wastes. About 50% of the waste was received from sources outside of Oak Ridge facilities. Wastes were placed in trenches, shallow auger holes, and in piles on the ground for covering at a later date.

From 1954 to 1975, LLLW was transported from storage tanks at the main ORNL complex to waste pits and trenches in Melton Valley (WAG 7), and later to the hydrofracture disposal sites, through underground transfer lines. The Pilot Pit Area (Area 7811) was constructed for use in pilot-scale radioactive waste disposal studies from 1955 to 1959; three large concrete cylinders containing experimental equipment remain embedded in the ground. A removal action was initiated at WAG 4 during 1995 to grout in place sources of ^{90}Sr contamination emanating from selected trenches located within the WAG. A control building and asphalt pad have been used for storage through the years.

WAG 4 Results

Groundwater monitoring in WAG 4 was transferred to IWQP in 1996. Monitoring results for 1997 are available in the IWQP annual report (DOE 1998b).

WAG 5 Area

WAG 5 contains 33 SWMUs, 13 of which are tanks that were used to store LLLW prior to disposal by the hydrofracture process. WAG 5 also includes the surface facilities constructed in support of both the old and new hydrofracture facilities. The largest land areas in WAG 5 are devoted to TRU waste in SWSA 5 South and SWSA 5 North. The remaining sites are support facilities for ORNL's hydrofracture operations, two LLLW pipeline leak/spill sites, and an impoundment in SWSA 5 used to dewater sludge from the original Process Waste Treatment Facility. Currently, LLW tanks at the New Hydrofracture Facility are being used to store evaporator concentrates pending a decision regarding ultimate disposal of these wastes.

SWSA 5 South was used to dispose of solid LLW generated at ORNL from 1959 to 1973. From 1959 to 1963, the burial ground served as the Southeastern Regional Burial Ground for the Atomic Energy Commission. At the time SWSA 5 burial operations were initiated, about 10 acres of the site was set aside for the retrievable storage of TRU wastes.

The WAG 5 boundary includes the Old and New Hydrofracture Facilities. Because Melton Branch flows between the Old and New Hydrofracture Facilities, the New Hydrofracture Facility has a separate boundary. Studies of the contents of several tanks at the Old Hydrofracture Facility (OHF) were performed in preparation for a removal action. The scope of the removal action is to remove the contents of the tanks. The documentation for the non-time-critical removal action for the OHF tanks was completed in 1997. A CERCLA removal action was initiated in 1994 to remove ⁹⁰Sr from Seeps C and D, located along the southern boundary of WAG 5, and continued during 1997.

WAG 5 Results

Groundwater monitoring in WAG 5 was transferred to the IWQP in 1996. Monitoring results for 1997 are available in the IWQP annual report (DOE 1998b) and also as an independent report by ESD (Stafford and McCarthy 1998) published as Appendix B in the IWQP annual report (DOE 1998b). The ESD 1997 results indicate 5- to 10-fold higher levels of gross alpha activity in groundwater in SWSA 5-N than had been previously reported.

WAG 6 Area

WAG 6 consists of four SWMUs: (1) SWSA 6, (2) Building 7878, (3) the explosives detonation trench, and (4) Building 7842. SWSA 6 is located in Melton Valley, northwest of WOL and southeast of Lagoon Road and Haw Ridge. The site is about 1.2 miles (2 km) south of the main ORNL complex. Waste burials at the 68-acre site were initiated in 1973 when SWSA 5 was closed. Various radioactive and chemical wastes were buried in trenches and auger holes. SWSA 6 is the only currently operating disposal area for LLW at ORNL. The emergency waste basin was constructed in 1961 to provide storage of liquid wastes that could not be released from ORNL to WOC. The basin is located northwest of SWSA 6 and has a capacity of 15 million gal, but has never been used. Radiological sampling of the small drainage from the basin has shown the presence of some radioactivity. The source of this contamination is not known.

WAG 6 was among the first WAGs to be investigated at ORNL by the EMEF Program. WAG 6 is an interim-status RCRA unit because of past disposal of RCRA-regulated hazardous waste. Environmental monitoring is carried out under CERCLA and RCRA. A proposed CERCLA remedial action, which involved capping WAG 6, was abandoned after a public meeting in which members of the community objected to the high cost of capping. Groundwater monitoring continues to be carried out under the auspices of the EMP for WAG 6 at ORNL, which was

Oak Ridge Reservation

implemented after abandonment of the remedial action chosen at WAG 6.

WAG 6 Results

Information about WAG 6 monitoring results in 1997 are available in both the IWQP annual report (DOE 1998b) and the 1997 groundwater quality assessment report for ORNL's Solid Waste Storage Area 6 (DOE 1998c)

WAG 7 Area

WAG 7 is located in Melton Valley about 1 mile (1.6 km) south of the ORNL main plant area. The major sites in WAG 7 are the seven pits and trenches used from 1951 to 1966 for disposal of LLLW. WAG 7 also includes a decontamination facility, three leak sites, a storage area containing shielded transfer tanks and other equipment, and seven fuel wells used to dispose of acid solutions primarily containing enriched uranium from Homogeneous Reactor Experiment fuel. WAG 7 has been used to demonstrate the efficacy of in situ vitrification technology to immobilize radioactive waste streams buried in the WAG. However, because of a release of fission products (^{137}Cs) during testing of the in situ vitrification technology, the project was placed in shutdown mode.

WAG 7 Results

Groundwater monitoring in WAG 7 was transferred to IWQP in 1996. If monitoring results for 1997 are available, they would be in the IWQP annual report (DOE 1998b).

WAGs 8 and 9 Area

WAG 8, located in Melton Valley, south of the main plant area, is composed of 36 SWMUs that are associated with the reactor facilities in Melton Valley. The SWMUs consist of active LLLW collection and storage tanks, leak/spill sites, a contractors' soils area, radioactive waste ponds and impoundments, and chemical and sewage waste treatment facilities. WAG 8 in-

cludes the MSRE facility, the HFIR, and the REDC. A removal action was initiated at the MSRE during 1995 to remove filtration devices contaminated with uranium. The CERCLA actions (time-critical removal action, non-time-critical removal action, and remedial action) for MSRE continued in 1997 (see Sect. 3.5 for details).

Radioactive wastes from WAG 8 facilities are collected in on-site LLLW tanks and are periodically pumped to the main plant area (WAG 1) for storage and treatment. The waste includes demineralizer backwash, regeneration effluents, decontamination fluids, experimental coolant, and drainage from the compartmental areas of filter pits.

WAG 9 is located in Melton Valley about 0.6 miles (1 km) southeast of the ORNL main plant area and adjacent to WAG 8. WAG 9 is composed of eight SWMUs, including the Homogeneous Reactor Experiment pond, which was used from 1958 to 1961 to hold contaminated condensate and shield water from the reactor, and LLLW collection and storage tanks, which were used from 1957 to 1986.

Because of the small number of groundwater monitoring wells in WAG 8 and WAG 9, they are sampled together. The analytical results for the two WAGs are also reported together.

WAGs 8 and 9 Results

The two upgradient wells are located north of the WAGs, two of the downgradient wells are located northwest of the WAGs, two are located south of WAG 8, and the remaining five are in WAG 8 west of WAG 9 and in WAG 9. The analytical results for 1997 are comparable to results from the previous years.

All of the perimeter wells show evidence of radioactivity. The data indicate that the gross beta activity is attributable to total radioactive strontium. The two wells on the northwestern perimeter exceeded DWSs: one well with respect to ^3H contamination and the other with respect to gross beta activity and total radioactive strontium contamination. Gross alpha activity ranged from not detected to 2.3 pCi/L (the DWS is 15 pCi/L);

beta activity ranged from not detected to 2000 pCi/L (the DWS is 50 pCi/L); and total radioactive strontium ranged from not detected to 810 pCi/L (the DWS is 8 pCi/L). Tritium ranged from not detected to 59,000 pCi/L (the DWS is 20,000 pCi/L). Total radioactive strontium and gross beta activity levels exceeded the DWSs at the westernmost WAG 8 well.

WAG 10 Area

WAG 10 consists of the OHF grout sheets, the New Hydrofracture Facility, and the New Hydrofracture Facility grout sheets. The surface facilities are associated with WAGs 5, 7, and 8.

Hydrofracture Experiment Site 1 is located within the boundary of WAG 7 (south of Lagoon Road) and was the site of the first experimental injection of grout (October 1959) as a testing program for observing the fracture pattern created in the shale and for identifying potential operating problems. Injected waste was water tagged with ¹³⁷Cs and ¹⁴¹Ce. Grout consisted of diatomaceous earth and cement.

Hydrofracture Experiment Site 2 is located about 0.8 km (0.5 mile) south of the 7500 (experimental reactor) area (WAG 8). The second hydrofracture experiment was designed to duplicate, in scale, an actual disposal operation; however, radioactive tracers were used instead of actual waste. Cement, bentonite, and water tagged with ¹³⁷Cs were used in formulating the grout.

The OHF is located about 1.6 km (1.0 mile) southwest of the main ORNL complex near the southwest corner of WAG 5. The facility, commissioned in 1963, was used to dispose of liquid radioactive waste in impermeable shale formations at depths of 800 to 1000 ft by hydrofracture methods. Wastes used in the disposal operations included concentrated LLLW from the gunite tanks in WAG 2, ⁹⁰Sr, ¹³⁷Cs, ²⁴⁴Cm, TRU, and other, unidentified radionuclides.

The New Hydrofracture Facility is located 900 ft southwest of the OHF on the south side of Melton Branch. The facility was constructed to replace the OHF. Wastes used in the injections were concentrated LLLW and sludge removed from the gunite tanks, ⁹⁰Sr, ¹³⁷Cs, ²⁴⁴Cm, TRU, and

other nuclides. Plans to plug and abandon several deep injection wells at WAG 10 were made in 1995.

WAG 10 Results

No groundwater monitoring wells were installed in WAG 10.

Exit Pathway Results

In the Melton Valley exit pathway, WOC at WOD had gross beta activity (260 pCi/L) and total radioactive strontium (100 pCi/L). One of the wells also had gross beta activity, total radioactive strontium, and ³H concentrations detected above DWSs. This is consistent with historical data. No VOCs were detected above DWSs in either the wells or the surface-water location.

7.3.1.3. White Wing Scrap Yard

White Wing Scrap Yard (WAG 11) Area

The White Wing Scrap Yard (WAG 11), a largely wooded area of about 30 acres, is located in the McNew Hollow area on the western edge of East Fork Ridge. It is 1.4 km (0.9 miles) east of the junction of White Wing Road and the Oak Ridge Turnpike. Geologically, the White Oak thrust fault bisects WAG 11. Lower-Cambrian-age strata of the Rome Formation occur southwest of the fault and overlie the younger Ordovician-age Chickamauga Limestone northeast of the fault. There is only one SWMU in WAG 11.

The White Wing Scrap Yard was used for aboveground storage of contaminated material from ORNL, the ETTP, and the Y-12 Plant. The material stored at the site by ORNL consisted largely of contaminated steel tanks; trucks; earth-moving equipment; assorted large pieces of steel, stainless steel, and aluminum; and reactor cell vessels removed during cleanup of Building 3019. An interim ROD was agreed to by TDEC, EPA, and DOE requiring surface debris to be removed from the site. This work was completed in 1994.

The area began receiving material (primarily metal, glass, concrete, and trash with alpha, beta,

and gamma contamination) in the early 1950s. Information regarding possible hazardous waste contamination has not been found. The precise dates of material storage are uncertain, as is the time when the area was closed to further storage. In 1966, efforts were begun to clean up the area by disposing of contaminated materials in ORNL's SWSA 5 and by the sale of uncontaminated material to an outside contractor for scrap. Cleanup continued at least into 1970, and removal of contaminated soil began the same year. Some scrap metal, concrete, and other trash is still located in the area. Numerous radioactive areas, steel drums, and PCB-contaminated soil were identified during surface radiological investigations conducted during 1989 and 1990 at WAG 11. The amount of material or contaminated soil remaining in the area is not known.

White Wing Scrapyard (WAG 11) Results

Groundwater monitoring in WAG 11 was transferred to IWQP in 1996. If monitoring results for 1997 are available, they would be in the IWQP annual report (DOE 1998b).

7.3.2 Well Plugging and Abandonment at ORNL

The purpose of the ORNL well plugging and abandonment program is to remove unneeded wells and boreholes as possible sources of cross contamination of groundwater from the surface or between geological formations. Because of the complex geology and groundwater pathways at ORNL, it has been necessary to drill many wells and boreholes to establish the information base needed to predict groundwater properties and behavior. However, many of the wells that were established before the 1980s were not constructed satisfactorily to serve current long-term monitoring requirements. Where existing wells do not meet monitoring requirements, they become candidates for plugging and abandonment.

7.3.2.1 Wells Plugged During 1997

No wells were plugged and abandoned at ORNL during 1997. A total of 232 wells have been recommended for plugging and abandonment as soon as funds are available.

7.3.2.2 Methods Used

Plugging and abandonment are accomplished by splitting the existing well casing and filling the casing and annular voids with grout or bentonite to create a seal between the ground surface and water-bearing formations and between naturally isolated water-bearing formations.

Splitting and abandoning the well casing in place also minimize the generation of waste that would be created if other methods were used. Special tools were developed to split the casings of different sizes and material. A down-hole camera was used during development of the splitting tools to evaluate their effectiveness.

Detailed procedures have been developed and documented regarding the use of specific grout materials in different well environments. These procedures were tested and evaluated during the 1993 plugging and abandonment activities.

7.4 GROUNDWATER MONITORING AT THE ETPP

7.4.1 Background and Hydrogeologic Setting

Groundwater effluent monitoring at the ETPP is focused primarily on investigating and characterizing sites for remediation under CERCLA. As a result of the FFA and certification of closure of the K-1407-B and -C Ponds, the principal driver at the ETPP is CERCLA.

The cleanup strategy described in the site management plan has been developed to accelerate the transition of areas of concern from characterization to remediation by making decisions at the watershed scale based on recommended land use. The watershed is a surface drainage basin that

includes an area of concern or multiple areas of concern to be investigated and/or remediated. This approach allows for the systematic monitoring and evaluation of contaminant sources and migration through the use of integrated surface-water and groundwater monitoring.

ETTP Groundwater Protection Program requirements were incorporated into the IWQP in FY 1997 so that there is no longer a site-level program. The IWQP, which was established to provide a consistent approach to watershed monitoring across the ORR, will be responsible for conducting groundwater surveillance monitoring at the ETTP. Six watersheds have been designated at the ETTP for monitoring and reporting groundwater quality data. The watershed designations and associated areas of concern are described in the following section.

Unlike the other ORR facilities, where many source areas are located in relatively undeveloped areas of the reservation, most source areas at the ETTP are located within the highly industrialized areas of the site. The surface topography has been considerably altered as a result of site construction. Large areas have been excavated or filled to yield the present, low-relief landscape. As much as 60 ft of materials have been excavated locally, with equal amounts of fill placed in adjacent low areas. These filled areas may represent primary pathways for contaminant migration when located below the water table. A number of sinkholes have been identified on historic aerial photos that are not visible on the surface today. Many of these have been filled during site construction, and buildings (such as K-33) have been erected directly above them.

The storm drain network discharges to either Mitchell Branch, the K-1007-P1 pond, the K-901-A pond, or directly to Poplar Creek and the Clinch River. Storm drain video surveys show both infiltrating and exfiltrating water along the lines, suggesting that the storm drains may serve as groundwater sinks (where located below the water table) or sources in other areas of the plant. In addition, at least ten buildings have been determined to have basements with sumps below the seasonal low water table. Water that accumulates in the sumps is discharged either to

the sanitary sewer or CNF system, storm drains, or, on rare occasions, to the ground. All of these systems have been active since building construction in the 1940s.

Bedrock underlying the ETTP can be broadly categorized as carbonate (Knox and Chickamauga groups) or clastic (Rome Formation and possibly the Conasauga Group). The carbonates underlie most of the main plant area, including the K-27/29 Peninsula, K-1070-A Burial Ground, the K-25 Building, and the K-1004 laboratory area. The eastern portion of the site, including the K-1070-C/D site and much of the Mitchell Branch area, is underlain by clastics of the Rome formation and possibly the Conasauga Group. The structural geology of the ETTP is perhaps the most complicated on the ORR and includes “map-scale” folds and faults and “outcrop-scale” fractures, folds, and faults. Complex faulting, fracturing, and folding in the clastic bedrock preclude definition of simple bedding geometry. Therefore, groundwater flow paths cannot be predicted in this area of the site.

Cavities have been encountered in 39% of all subsurface penetrations at the ETTP. Cavity heights are typically greater in the Knox Group carbonates. During recent drilling in the vicinity of the K-1070-A Burial Ground, cavernous bedrock with cavities up to 22 ft (6.7 m) in height has been encountered; however, based on camera and sonar surveys, the lateral extent of these cavities appears limited. Although large cavities have been reported in some locations in the Chickamauga bedrock, typical cavity heights are generally less than 5 ft (1.5 m).

Groundwater occurs in both the unconsolidated zone and bedrock, primarily as a single water table aquifer. Perched water may be of local significance. With few exceptions, the water table occurs in the overburden above bedrock across the site, with saturated overburden thickness ranging up to 70 ft. Because bedrock is exposed along the bottom of the Clinch River and Poplar Creek, the unconsolidated zone flowpaths are truncated at these boundaries. Water level data indicate that groundwater flows radially from higher elevations toward the bounding surface water features; however, the sumps and drains that lie below the

seasonal low water table affect the configuration of the water table surface and thus affect the contaminant flow directions.

Groundwater flow in the unconsolidated zone is expected to be in the direction of the mapped hydraulic gradients. In the carbonate bedrock, groundwater flow is expected to be controlled by hydraulic gradients and geologic strike. In the Rome Formation, groundwater flow directions cannot be predicted with any certainty. Recent studies have shown that hydraulic gradients are steepest (and consequently, overall flux is greatest) during the wet season and low pool stage periods. Much of the site is paved or otherwise covered, reducing direct recharge by groundwater; however, leaking underground utilities and storm drains are likely to recharge the groundwater substantially.

Few perennial springs have been identified along Poplar Creek or the Clinch River. Wet-season springs located along the exposed low pool stage shores of Poplar Creek and the Clinch River do not appear consistently from year to year. In general, both springs and seeps at the ETTP are characterized by moderate to low flow rates.

7.4.2 Watersheds

Six watersheds, each defined as a geographic area that encompasses a surface water drainage basin, have been defined at the ETTP. These watersheds are described in the following sections and are indicated on Fig. 7.25.

7.4.2.1 K-1007-B Watershed

The K-1007-B Watershed encompasses the southern area of the ETTP. Areas of concern in this watershed include the K-1004-J Vaults, the K-1004-L UST, the K-1004-L recirculating cooling water (RCW) lines, the K-1004 cooling tower basin, the K-1004 laboratory drain, the K-1007-P1 Pond, the K-1007 UST, and the K-1200 Centrifuge complex. Potential contaminants include heavy metals, acids, organic solvents, other organic chemicals, and radioactivity.

7.4.2.2 Mitchell Branch Watershed

The Mitchell Branch Watershed encompasses the northeastern portion of the ETTP and includes the K-1407-A Neutralization Pit, the former K-1407-B and C Ponds, the K-1407-C soil, the K-1700 stream (Mitchell Branch), the K-1070-B Old Classified Burial Ground, the K-1401 acid line, the K-1401 degreasers, the K-1401 basement, the K-1413 neutralization pit, the K-1420 building process lines, the K-1420 oil storage area, the K-1420 incinerator, the K-1413 treatment tanks, the K-1413 building and process lines, the K-1070-C/D Classified Burial Ground, the K-1070 concrete pad, the K-1070-D storage dikes, the K-1070 pits, and the K-1414 Garage. The potential contaminants include organic solvents, waste oils, heavy metals, PCBs, and radioactivity.

7.4.2.3 Ungaged Watershed

The Ungaged Watershed encompasses areas where groundwater and surface water discharge directly to Poplar Creek and includes the western half of the K-25 Building, the K-1064 peninsula, the K-27/29 peninsula, the K-31 Building, and the eastern half of the K-33 Building. Areas of contamination in this watershed include the K-1066-J cylinder storage yard; the K-1024 dilution pit; the K-1064 drum storage and burn area; the K-1064 drum deheading facility; the K-802-B, K-802-H, K-832-H, K-892-G, K-892-H, K-892-J, and K-862-E cooling tower basins; the K-31 and K-33 RCW lines; the K-732, K-762, and K-792 switchyards; the K-27 and K-29 RCW lines; the K-1410 neutralization pit; the K-1131 facility; the K-1232 chemical recovery facility lagoon; and the K-1231 facility. Potential contaminants include waste oils, heavy metals, organic solvents, PCBs, and radioactivity.

7.4.2.4 K-901/K-1070-A Watershed

The K-901/K-1070-A Watershed encompasses the northwestern portion of the ETTP. The areas of concern include the K-1070-A burial ground, the K-1070-A landfarm, the K-901-A

Fig. 7.25. ETPP watershed areas.

Oak Ridge Reservation

holding pond, the K-901 north and south disposal areas, the K-895 cylinder destruct facility, and the K-1066-K cylinder storage yard. Potential contaminants are organics, heavy metals, PCBs, and radioactivity.

7.4.2.5 Duct Island Watershed

The Duct Island Area consists of the K-1070-F peninsula on Poplar Creek and contains the K-1070-F contractors' burial ground, the K-900 bottle smasher, and the Duct Island Road. Potential contaminants are heavy metals, organics, and uranium.

7.4.2.6 K-770/Powerhouse Watershed

The K-770/Powerhouse Watershed borders the Clinch River in the southwestern portion of the ETTP. Areas of concern included in this

watershed are the K-770 Scrap Yard, the K-725 Beryllium Building, the K-720 ash pile, the F-05 laboratory, the K-709 switchyard, the K-710 sludge beds and Imhoff tanks, and the K-1085 Firehouse Burn Area. The potential contaminants are waste oils, organics, heavy metals, PCBs, and radioactivity.

7.4.3 Groundwater Monitoring Results

The IWQP annual report (DOE 1998b) contains groundwater data results received for the ETTP for 1997. Results related to the effectiveness and protectiveness of implemented environmental restoration remedies are presented in the context of operational and regulatory history in the IWQP Annual Remediation Effectiveness Report, which is an FFA-required report.
