CORRECTION Aug. 15, 2011: The first edition of this report, released in March 2011, had some incorrect text and was not clear about AIM methods in the red hake chapter. In August 2011 a second edition of this report was released with corrections and clarifications added in the "SAW51 Editor's Notes." These changes do not affect any earlier conclusions about red hake stock status. Although the AIM method is described by using a three-year centered average of the abundance index, the red hake calculations for computing relative $F$ and AIM were based on survey indices from single years, and not on the three-year average described herein. In the red hake chapter (last two paragraphs of the "Executive Summary" and in the results for TOR 6) text has been changed from "The exploitation index ... for 2007-2009 ... was below the threshold..." to "The exploitation index ... for 2009 ... was below the threshold...". This text needed correction because: 1. the exploitation indices that were given were for one year (2009) and 2. relative F in the AIM analysis was based on one year. With this change there is now consistency in calculations between fishing rate and the recommended overfishing threshold used to determine overfishing status. Similar corrections have been made to the red hake Assessment Summary Report CRD 11-01. Finally, analyses conducted after SARC51 by Dr. Paul Rago confirmed that for red hake AIM results based on one year indices had better AIM model diagnostics compared to the three-year smoothing approach.

## Northeast Fisheries Science Center Reference Documents

This series is a secondary scientific series designed to assure the long-term documentation and to enable the timely transmission of research results by Center and/or non-Center researchers, where such results bear upon the research mission of the Center (see the outside back cover for the mission statement). These documents receive internal scientific review, and most receive copy editing. The National Marine Fisheries Service does not endorse any proprietary material, process, or product mentioned in these documents.

All documents issued in this series since April 2001, and several documents issued prior to that date, have been copublished in both paper and electronic versions. To access the electronic version of a document in this series, go to http://www.nefsc.noaa.gov/nefsc/publications/. The electronic version is available in PDF format to permit printing of a paper copy directly from the Internet. If you do not have Internet access, or if a desired document is one of the pre-April 2001 documents available only in the paper version, you can obtain a paper copy by contacting the senior Center author of the desired document. Refer to the title page of the document for the senior Center author's name and mailing address. If there is no Center author, or if there is corporate (i.e., non-individualized) authorship, then contact the Center's Woods Hole Laboratory Library ( 166 Water St., Woods Hole, MA 02543-1026).

Editorial Treatment: To distribute this report quickly, it has not undergone the normal technical and copy editing by the Northeast Fisheries Science Center's (NEFSC's) Editorial Office as have most other issues in the NOAA Technical Memorandum NMFS-NE series. Other than the four covers and first two preliminary pages, all writing and editing have been performed by the authors listed within. This report was reviewed by the Stock Assessment Review Committee, a panel of assessment experts from the Center for Independent Experts (CIE), University of Miami.

Information Quality Act Compliance: In accordance with section 515 of Public Law 106554, the Northeast Fisheries Science Center completed both technical and policy reviews for this report. These predissemination reviews are on file at the NEFSC Editorial Office.

## Foreword

The Northeast Regional Stock Assessment Workshop (SAW) process has three parts: preparation of stock assessments by the SAW Working Groups and/or by ASMFC Technical Committees / Assessment Committees; peer review of the assessments by a panel of outside experts who judge the adequacy of the assessment as a basis for providing scientific advice to managers; and a presentation of the results and reports to the Region's fishery management bodies.
Starting with SAW-39 (June 2004), the process was revised in two fundamental ways. First, the Stock Assessment Review Committee (SARC) became smaller panel with panelists provided by the Independent System for Peer Review (Center of Independent Experts, CIE). Second, the SARC provides little management advice. Instead, Council and Commission teams (e.g., Plan Development Teams, Monitoring and Technical Committees, Science and Statistical Committee) formulate management advice, after an assessment has been accepted by the SARC. Starting with SAW-45 (June 2007) the SARC chairs were from external agencies, but not from the CIE. Starting with SAW-48 (June 2009), SARC chairs are from the Fishery Management Council's Science and Statistics Committee (SSC), and not from the CIE. Also at this time, some assessment Terms of Reference were revised to provide additional science support to the SSCs, as the SSC's are required to make annual ABC recommendations to the fishery management councils.
Reports that are produced following SAW/SARC meetings include: An Assessment Summary Report - a summary of the assessment results in a format useful to managers; an Assessment Report - a detailed account of the assessments for each stock; and the SARC panelist reports - a summary of the reviewer's opinions and recommendations as well as individual reports from each panelist. SAW/SARC assessment reports are available online at http://www.nefsc.noaa.gov/nefsc/publications/series/crdlist.htm. The CIE review reports and assessment reports can be found at http://www.nefsc.noaa.gov/nefsc/saw/'.
The 51st SARC was convened in Woods Hole at the Northeast Fisheries Science Center, November 29 - December 3, 2010 to review benchmark stock assessments:
silver hake (Merluccius bilinearis), red hake (Urophycis chuss), offshore hake (Merluccius albidus ) and longfin inshore squid (Loligo pealeii). CIE reviews for SARC51 were based on detailed reports produced by NEFSC Assessment Working Groups. This Introduction contains a brief summary of the SARC comments, a list of SARC panelists, the meeting agenda, and a list of attendees (Tables 1-3). Maps of the Atlantic coast of the USA and Canada are also provided (Figures 1-5).

## Outcome of Stock Assessment Review Meeting:

Based on the Review Panel reports (available at http://www.nefsc.noaa.gov/nefsc/saw/ under the heading "SARC 51 Panelist Reports"), the SARC review committee concluded that for silver hake none of the ASAP models that were examined provided a consistent assessment of the stock in either the northern $(\mathrm{N})$ or southern ( S ) area. A key issue was whether to allow a domed selectivity assumption, which creates "cryptic" fish. The ASAP model requires improvement before it can serve as a basis for fishery management advice. In the absence of an accepted assessment model, it was not possible to perform multi-year projections. Work on
factors affecting catchability across ages and years in the silver hake surveys is required to ensure that apparent mortality can be assigned to fishing, natural factors, changes in distribution or changes in survey catchability. Inclusion of consumption estimates provided perspective on the magnitude of fishery mortality. Based on newly recommended silver hake biological reference points overfishing is not taking place and the stocks are not overfished in the N or S areas.

The red hake assessment moved the understanding of the population and its fisheries forward considerably. Substantial exploratory work was carried out on the age-based data for the survey, fishery and predator consumption using the SS3 and SCALE models, but the diagnostics were not adequate for stock status determination or for provision of management advice. In the absence of an accepted assessment model as a basis for providing management advice, it was not possible to perform multi-year projections. Based on newly recommended red hake biological reference points overfishing is not taking place and the N and S stocks are not overfished.

This was the first time that an offshore hake assessment had been attempted. Although the Hake Working Group did a thorough job, the data are insufficient to complete an assessment. The major shortcoming is that the surveys are believed to cover an unknown and variable proportion of the stock. The Panel concluded that sufficient information is not available to determine stock status with confidence, because fishery data are insufficient and one cannot assume that survey data reflect stock trends. The Panel concluded that it is not possible at this time to provide a reliable definition for overfished and overfishing for this stock.

The majority of SARC panelists consider the Loligo assessment to be adequate for developing annual management advice as long as the exploitation rate stays low. The SARC accepted a newly proposed $\mathrm{B}_{\text {MSY }}$ proxy, but expressed concerns. During 2009, the Loligo stock was not overfished and overfishing was probably not occurring. No overfishing threshold has been recommended, which leaves overfishing status officially unknown. Better understanding of seasonal cohort recruitment, growth rate, mortality, catch and effort, might allow within-season or within-year management schemes.

CIE review reports can be found at http://www.nefsc.noaa.gov/nefsc/saw/ under the heading "SARC 51 Panelist Reports".

## A. STOCK ASSESSMENT OF SILVER HAKE FOR 2010

## Terms of Reference:

1. Estimate catch from all sources including landings, discards, and effort. Characterize the uncertainty in these sources of data, and estimate LPUE. Analyze and correct for any species mis-identification in these data.
2. Present the survey data being used in the assessment (e.g., regional indices of abundance, recruitment, state surveys, age-length data, etc.). Characterize the uncertainty and any bias in these sources of data.
3. Evaluate the validity of the current stock definition, and determine whether it should be changed. Take into account what is known about migration among stock areas.
4. Estimate annual fishing mortality, recruitment and stock biomass (both total and spawning stock) for the time series (integrating results from Silver hake TOR-5), and estimate their uncertainty. Include a historical retrospective analysis to allow a comparison with previous assessment results.
5. Evaluate the amount of silver hake consumed by other species as well as the amount due to cannibalism. Include estimates of uncertainty. Relate findings to the stock assessment model.
6. State the existing stock status definitions for "overfished" and "overfishing". Then update or redefine biological reference points (BRPs; estimates or proxies for BMSY, BTHRESHOLD, and FMSY; and estimates of their uncertainty). If analytic model-based estimates are unavailable, consider recommending alternative measurable proxies for BRPs. Comment on the scientific adequacy of existing BRPs and the "new" (i.e., updated, redefined, or alternative) BRPs.
7. Evaluate stock status (overfished and overfishing) with respect to the existing BRPs, as well as with respect to the "new" BRPs (from Silver hake TOR 6).
8. Develop and apply analytical approaches and data that can be used for conducting single and multi-year stock projections and for computing candidate ABCs (Acceptable Biological Catch; see Appendix to the TORs).
a. Provide numerical short-term projections (3 years). Each projection should estimate and report annual probabilities of exceeding threshold BRPs for F , and probabilities of falling below threshold BRPs for biomass. In carrying out projections, consider a range of assumptions about the most important uncertainties in the assessment (e.g., terminal year abundance, variability in recruitment).
b. Comment on which projections seem most realistic, taking into consideration uncertainties in the assessment.
c. Describe this stock's vulnerability to becoming overfished, and how this could affect the choice of ABC
9. Review, evaluate and report on the status of the SARC and Working Group research recommendations listed in recent SARC reviewed assessments and review panel reports. Identify new research recommendations.

## Executive Summary

A new assessment model for silver hake (ASAP, Legault and Restrepo 1998) was attempted based on a "combined" (i.e. North + South) assessment area including estimates of fishery landings, discards, and predator consumption, by age class. While the SARC-51 Review Panel felt that the ASAP model represented an advance for the stock assessment, the ASAP results were not accepted due to difficulties in reconciling the inconsistent interpretations from the steep age profiles in the fishery and survey data. An Index Model (AIM) was also explored; however, the diagnostics were not adequate for stock status determination. Therefore, this assessment is based on trends in the three year moving averages for the age-aggregated, fall survey biomass indices (1973-1982) using the arithmetic means rather than the previous delta approach and the three year averages of exploitation indices (total catch/fall survey biomass index). These form the basis for the updated reference points for both the northern and southern management areas.

Based on the reference points in the existing FMP, silver hake is not overfished and overfishing is not occurring in both the northern or southern management areas. For the northern area, the three year delta mean biomass index from the NEFSC fall bottom trawl survey in Albatross units during 2007-2009 ( $6.79 \mathrm{~kg} /$ tow $)$ was above the biomass threshold ( $3.31 \mathrm{~kg} /$ tow ) and slightly above the biomass target ( $6.63 \mathrm{~kg} / \mathrm{tow}$ ). The three year average exploitation index (landings divided by survey biomass index for 2007-2009 (0.13) in the north was less than the exploitation threshold and target (2.57). In the southern area, the three year survey biomass index in Albatross units ( $1.39 \mathrm{~kg} /$ tow ) was greater than the biomass threshold ( $0.89 \mathrm{~kg} /$ tow $)$ but below the biomass target ( 1.78 $\mathrm{kg} / \mathrm{tow}$ ). The three year exploitation index for 2007-2009 (4.33) in the south was below the overfishing threshold (34.39) and target (20.63) .

Based on the updated and accepted reference points from SAW/SARC-51 in 2010, the northern stock of silver hake is not overfished and overfishing is not occurring. The three year arithmetic mean fall biomass index for 2007-2009 in Albatross units ( $6.20 \mathrm{~kg} / \mathrm{tow}$ ), was above the management threshold ( $3.21 \mathrm{~kg} /$ tow) but below the target ( $6.42 \mathrm{~kg} /$ tow). The three year average exploitation index for 2007-2009 ( $0.20 \mathrm{kt} / \mathrm{kg}$ ) was below the management threshold ( $2.78 \mathrm{kt} / \mathrm{kg}$ ). In the south, silver hake is also not overfished and overfishing is not occurring. The three year average arithmetic mean biomass, also based on the NESFC fall bottom trawl survey data for 2007-2009 in Albatross units (1.11 $\mathrm{kg} / \mathrm{tow}$ ), was above the biomass threshold ( $0.83 \mathrm{~kg} / \mathrm{tow}$ ) but below the target ( 1.65
$\mathrm{kg} / \mathrm{tow}$ ). The three year average exploitation index, for 2007-2009 ( $5.87 \mathrm{kt} / \mathrm{kg}$ ) (Figure A9) was below the overfishing threshold ( $34.19 \mathrm{kt} / \mathrm{kg}$ )

Given that the ASAP model was not accepted as a basis for providing management advice, ASAP-based multiyear projections are not provided.

The scientific information available on silver stock structure (morphometrics, tagging, discontinuous larva distribution, homogeneous growth and maturity) is equivocal. Therefore, it was concluded that there was no strong biological evidence to support either a separate or combined silver hake assessment. The role of silver hake in the ecosystem was assessed using diet data. It was apparent that silver hake constitute an important link in the food web. Estimates of silver hake removals from the system from predatory based consumption suggest that consumption can be approximately 10 times higher than total catch. These consumption estimates were useful to inform both scaling of biomass estimates and the magnitude of mortalities for silver hake in the system.

## Introduction

## Hake Working Group Meetings

Three meetings were held in preparation of the 2010 silver hake assessment

1. Hake fishermen's/stakeholder's meeting - August 6, 2010 - UMASS School of Marine Science and Technology (SMAST), Fairhaven, MA. Participants include fishermen Dan Farnham and Bill Phoel. Also in attendance were David Goethel (Oversight Committee chair), Andrew Applegate (staff) Steve Cadrin (SSC and WG chair, SMAST), Pingguo He, Klondike Jonas, Yuying Zhang, Tony Wood, and Daniel Goethel (SMAST), Loretta O'Brien, Michele Traver, Katherine Sosebee and Larry Alade (NEFSC), and Dick Allen (advisor at large). A summary of the discussions is in Appendix A1.
2. Data Meeting - September 7-10, 2010, NEFSC Woods Hole MA. Participants included Steve Cadrin (WG Chair), Assessment leads (Larry Alade, Kathy Sosebee, Michele Traver), Rapporteurs (Jessica Blaylock and Julie Nieland), Mark Showell (DFO), Andy Applegate (NEFMC Staff), NEFSC (Loretta O’Brien, Mark Terceiro, Chris Legault, Tim Miller, Dave Richardson, Ayeisha Brinson, Jiashen Tang, Janet Nye, Mike Palmer, Paul Rago, Josef Idoine, Jon Hare), Moira Kelly (NERO), SMAST(Tony Wood, Yuying Zhang, Saang-Yoon Hyun)
3. Model Meeting - October 25-29, 2010, NEFSC, Woods Hole, MA. Participants included Steve Cadrin (WG chair), Assessment leads ((Larry Alade, Kathy Sosebee , Michele Traver), Rapporteurs (Jessica Blaylock and Julie Nieland), Mark Showell (DFO), Andy Applegate (NEFMC Staff), Dan Farnham (Fisherman and Industry Advisor), NEFSC (Loretta O’Brien, Paul Nitschke, Mark Terceiro, Jay Burnett, Chris Legault, Liz Brooks, Tim Miller, Jon Deroba, Rich McBride, Jim Weinberg, Paul Rago, Josef Idoine, Jon Hare, Janet Nye, Dave Richardson, Laurel Col, Jason Link), SMAST(Tony Wood, Yuying Zhang, Dan

Goethel). The groups met by correspondence after the meetings, including a WebEx meeting on November 5, 2010 to report updates on silver hake analyses, provide guidance on reference points and discuss plans for report development.

This Working Group (WG) report includes products from all three meetings and contributions from all participants. It also has edits which reflect the outcome of the SAW/SARC51 peer review.

## Biology

Silver hake also known as whiting, Merluccius bilinearis range from Newfoundland to South Carolina. In U.S. waters, silver hake are managed as two separate stocks (Almeida 1987a). The northern silver hake stock inhabits Gulf of Maine - Northern Georges Bank waters, and the southern silver hake stock inhabits Southern Georges Bank - Middle Atlantic Bight waters (Figure A1). Silver hake migrate in response to seasonal changes in water temperatures, moving toward shallow, warmer waters in the spring. They spawn in these shallow waters during late spring and early summer and then return to deeper waters in the autumn (Brodziak et al. 2001). The older, larger silver hake especially prefer deeper waters. During the summer, portions of both stocks can be found on Georges Bank, whereas during the winter, fish in the northern stock move to deep basins in the Gulf of Maine, while fish in the southern stock move to outer continental shelf and slope waters. Silver hake are widely distributed, and have been observed at temperature ranges of $2-17^{\circ} \mathrm{C}\left(36-63^{\circ} \mathrm{F}\right)$ and depth ranges of $11-500 \mathrm{~m}(36-1,640 \mathrm{ft})$. However, they are most commonly found between $7-10^{\circ} \mathrm{C}\left(45-50^{\circ} \mathrm{F}\right)$ (Lock and Packer 2004).

Female silver hake are serial spawners, producing and releasing up to three batches of eggs in a single spawning season (Collette and Klein-MacPhee eds. 2002). Major spawning areas include the coastal region of the Gulf of Maine from Cape Cod to Grand Manan Island, southern and southeastern Georges Bank, and the southern New England area south of Martha's Vineyard. Peak spawning occurs earlier in the south (May to June) than in the north (July to August). Over one-half of age-2 fish ( 20 to $30 \mathrm{~cm}, 8$ to 12 in .) and virtually all age- 3 fish ( 25 to $35 \mathrm{~cm}, 10$ to 14 in .) are sexually mature. Silver hake grow to a maximum length of over 70 cm ( 28 in .) and ages up to 14 years have been observed in U.S. waters, although few fish older than age 6 have been observed in recent years (Brodziak et al. 2001).

## Fishery Regulations

The following briefly outlines the current small mesh multispecies regulations (based on the small mesh exemption program) for the New England whiting fishery to provide context for interpreting the fishery and model results.

1. 1994 \& 2000 - Exempted fisheries allows vessels to fish for specific species such as whiting or northern shrimp in designated areas using mesh sizes smaller than the minimum mesh size allowed (Gulf of Maine, Georges Bank, Southern New England, Mid-Atlantic : 6.5-inch square or diamond) under the Regulated Mesh Area (RMA) regulations .
2. Permits
a. Open access Category K Multispecies
b. Limited Access Category A-F (non Days-at-Sea fishing )
3. No Size Limits
4. 500 lbs at sea transfer limit.
5. 2003 - Possession limits vary by exemption area
a. 3,500 lbs if mesh $<2.5$ inches ( 63.5 mm )
b. $7,500 \mathrm{lbs}$ if mesh $<=3.0$ inches $(76.2 \mathrm{~mm})$
c. $30,000 \mathrm{lbs}$ if mesh $>3.0$ inches $(76.2 \mathrm{~mm})$
d. No Red Hake possession limit

TOR 1. Estimate catch from all sources including landings, discards, and effort. Characterize the uncertainty in these sources of data, and estimate LPUE. Analyze and correct for any species mis-identification in these data.

## Commercial Landings

Silver hake landings (Tables A1, Figures A2-A4) increased substantially during the 1960's due to direct fishing by distant water fleets (DWF) operating in the U.S. waters. Nominal landings of silver hake from the northern stock were significantly higher than those from the southern stock during the mid-1950's through the mid-1960's and fell below the southern stock starting in the late 1960's due to the expansion of the DWF in the southern region. Landings in the north peaked to over 94,000 mt in 1964 and have steadily declined substantially since 1975. Despite the departure of the DWF in 1976, landings continue to further decline and have been less than 10,000mt per year after 2002 (Table A1, Figure A3).

Nominal domestic landings from the southern silver hake stock have varied between 5,000-27,000 mt, (Table A1, Figure A4). However, between 1960 and 1980, distantwater fleet landings of southern silver hake were very high, peaking at about $280,000 \mathrm{mt}$ in 1965 and around 100,000 mt in 1974. Distant-water fleet landings diminished in the mid-1980s, and total landings have since continued to gradually decrease. In 2009, total landings were near a historic low at $7,000 \mathrm{mt}$.

Maine and Massachusetts have been the primary states in which silver hake from the northern stock have been landed (Table A2). Rhode Island became important in the 1980s and Connecticut in the 1990s. For landings of the southern stock, Rhode Island and Massachusetts were historically important, with New York, New Jersey and Connecticut increasing in importance (Table A3).

The otter trawl has been the principal gear used in the both stocks with some landings in the northern stock coming from the shrimp trawl fishery until the early 1990s with the use of the Nordmore grate (Tables A4-A5, Figures A5-A6). In recent years, sink gill net has increased slightly in importance, although there are significant landings from the other category, which includes unknown gears.

The seasonality of landings from the two stocks is different, with most of the northern stock landings occurring in the second half of the year and the first half of the year accounting for a approximately less than $20 \%$ of the annual. Landings from the southern stock appear to be landed more consistently throughout the year than in the north (Tables A6-A8, Figures A7-A8).

Silver hake are landed in seven commercial categories: unclassified round, medium, small, dressed, juvenile, king and large. The vast majorities of landings are reported as round or dressed market category, with other market categories appearing sporadically over time (Tables A9-A10, Figures A9-A10). King silver hake were separated starting in 1981, with smalls appearing in 1982. Large silver hake were further separated in 2004. A juvenile market category appeared in 1994 and was a larger component of the southern stock landings (Tables A9-A10, Figures A11-A12).

A sympatric species of hake, offshore hake, is often landed as silver hake (GarciaVazquez et al 2009). In 1991, landings of offshore hake began to be separated, although the extent to which this is actually occurring is still unknown. The geographical distribution of offshore hake is limited to the southern stock of silver hake. Therefore, landings from the northern stock are considered to be silver hake while southern landings are potentially a mixture of silver and offshore hake. In order to estimate landings of silver hake from the southern region, two alternative methods were developed.

## Length-based species composition

The first method used the port length samples directly. Length samples of silver and offshore hake were combined by stock (Tables A11-A13). In examining the silver hake length samples by market category, it appeared that most of the market categories were similar in length composition to the round category (Figures A11-A12). Therefore, only three market categories were used for stratification: round, king, and large. Even with the reduction of market categories, pooling over years was required to get an adequate number of fish (Table A14). The length-weight equations by season from Wigley et al 2003 were applied to the samples and used to estimate the landings numbers at length for each market category.

For the southern stock, length compositions for each species were estimated for the spring and fall surveys from 1968-2009. The species length-weight equations were then applied to determine weight-at-length by species. The proportions at length by species for both number and weight were applied to the commercial landings-at-length to estimate landings-at-length by species (Figures A13-A14). The lengths had to be grouped into intervals to avoid zero cells in the survey. To hind-cast the species proportions back to 1955, the average proportion of silver hake for the time series was used and applied to the total silver hake landings.

## Depth-based species composition

This method relates survey catch composition to Vessel Monitoring System (VMS) derived commercial landings from 2004-2009 using survey depth as an explanatory factor to develop a model that predicts the hake species landings composition. Offshore and silver hake composition $\left(R_{23}\right)$ in the trawl survey tows were modeled as a two
parameter logistic function of average depth. Only survey tows with silver hake, offshore hake or both were fitted and mean depth was the dependent variable.

$$
R_{23}=\frac{e^{a+b^{*} d e p t h}}{1+e^{a+b^{*} d e p t h}}
$$

For each stratum group, survey (winter, spring, and fall), and sets of time series, the catch and depth data were fitted by a non-linear least squares, weighted by the number of positive tows in a stratum, using the Marquardt method (Marquardt 1963) to aide convergence. $\mathrm{R}^{2}$ and Wald $95 \%$ confidence intervals (Cook and Weisberg 1990) were calculated for parameters a, b, D50, and the range to evaluate goodness of fit. Fitting the data with the a two parameter logistic non-linear regression using maximum likelihood estimation and iteratively reweighted least squares approaches was attempted, but did not improve the results.

The parameter estimates for 1985-2009 were applied to the depth association with the VMS-derived commercial landings at depth (Applegate 2010). The model ratio of offshore to silver hake were assigned to landings from each group depth zone, survey season, and survey stratum group and summed for the calendar year (Applegate 2010). The final landings from this method were greater than $90 \%$ of the total landings reported by dealers in 2004-2009.

Annual model estimates of silver hake landings for the southern stock area ranged from $4,207-6566 \mathrm{mt}$ in 2003-2009, representing 88-95\% of the total hake landings (Table A15). Although the depth based landings were derived from VMS effort distribution, hindcast estimates were used for 2003 because the model based estimates appeared to be biased due to small vessels (i.e. fished inshore and catch silver hake) were underrepresented when multispecies VMS requirements first became effective.

Estimates of offshore hake landings ranged between $290-893 \mathrm{mt}$ and $5-12 \%$ of total hake landings (Table A15). These estimates are considerably higher than those reported by either dealers or by fishermen on Vessel Trip Reports (VTR).

Given that VMS data for 2004 - 2009 were deemed acceptable for direct estimation of silver and offshore hake landings composition, landings prior to 2004 (1955-2003) were hindcasted to generate longer time series of removal for assessments and for developing biological reference points. Although the hindcast procedure allowed the distribution of catch to vary between statistical areas, the distribution of catch within these intermediate depth statistical areas was assumed to be constant, equal to the average depth distribution observed by VMS during 2004-2009. Details of the hindcasting methodology can be found in Applegate (2010).

The estimated silver hake landings from the depth based logistic model, including the hindcasting, rose from a low of $12,891 \mathrm{mt} \mathrm{in} 1955$ ( $93 \%$ of the total) to over 282,000 mt in 1990 ( $92 \%$ of the total), then declined to 4207 mt in 2006 ( $90 \%$ of the total). Recent landings totaled $5,006-6,406 \mathrm{mt}(93-95 \%)$. Silver hake as a proportion of total hake
landings ranged from $87 \%$ in 1971, 1976, 1978-1980 to $98 \%$ in 1988 and 1996 (Table A16).

Hindcast and model based estimates of offshore hake landings were an order of magnitude greater than that reported by dealers. Landings rose from 951 mt in 1955 ( $7.0 \%$ of the total) to $24,198 \mathrm{mt}$ in 1965 ( $8 \%$ of the total). Offshore hake as a proportion of total hake landings ranged from $2 \%$ in 1971, 1976, 1978-1980 to $13 \%$ in 1988 and 1996 (Table A16).

The resulting silver hake landings for the two methods are given in Table A15. On average, the two methods gave similar results, with the length-based model averaging $96 \%$ silver hake while the depth-based method averaged $94 \%$ silver hake. Conversely, there were some differences in the offshore hake estimates with the depth based method averaging approximately $7 \%$ and $4 \%$ for the length-based method (Table A16, Figure A15).

Given the similarity between both models, the SARC Panel agreed that the results from both methods will have undetectable differences in the assessment results. For the purpose of this assessment, the length-based estimator was considered more suitable primarily due to the number of years hindcasted (1955-1967) relative to the depth-based approach (1955-2003). It was also recognized that the length based approach provided an advantage of estimating fishery age composition which was not readily available in the depth-based method. .

## Sampling Intensity

The level of port sampling has generally been strong since the mid-1990's with higher sampling in the south relative to the north. In 2007, over 17,000 length measurements were taken in the southern area resulting in peak sampling intensity of 326 lengths per 100 mt . In the north sampling intensity increases substantially in 2006 and 2007 (115 and 107 lengths per mt respectively). In the recent years, sampling intensity has somewhat declined in both stock areas but more substantially in the north due to very low observed landings (Table A17). Overall, sampling intensity for the silver hake fishery has certainly improved compared to pre-1994 period, particularly in the south.

## Commercial Discards

Discard estimates were re-calculated in this assessment. The ratio-estimator used in this assessment is based on the methodology described in Rago et al. (2005) and updated in Wigley et al (2007). It relies on a $\mathrm{d} / \mathrm{k}$ ratio where the kept component is defined as the total landings of all species within a "fishery". A fishery is defined as a homogeneous group of vessels with respect to gear type (longline, otter trawl, shrimp trawl, sink gill net, and scallop dredge), quarter, and area fished (GOM-NGBK, SGBk-MA), and for otter trawls, mesh size ( $<=5.49$ ", $>=5.5$ "). All trips were included if they occurred within this stratification regardless of whether or not they caught hakes.

The discard ratio for hakes in stratum $h$ is the sum of discard weight over all trips divided by sum of kept weights over all trips:

$$
\begin{equation*}
\hat{R}_{h}=\frac{\sum_{i=1}^{n_{h}} d_{i h}}{\sum_{i=1}^{n_{h}} k_{i h}} \tag{1}
\end{equation*}
$$

Where $\mathrm{d}_{\mathrm{ih}}$ is the discards for hakes within trip i in stratum h and $\mathrm{k}_{\mathrm{ih}}$ is the kept component of the catch for all species. $R_{h}$ is the discard rate in stratum $h$. The stratum weighted discard to kept ratio is obtained by weighted sum of discard ratios over all strata:

$$
\begin{equation*}
\hat{R}=\sum_{h=1}^{H}\left(\frac{N_{h}}{\sum_{h=1}^{H} N_{h}}\right) \hat{R}_{h} \tag{2}
\end{equation*}
$$

The total discard within a strata is simply the product of the estimate discard ratio R and the total landings for the fishery defined as stratum $h$, i.e., $\mathrm{D}_{\mathrm{h}}=\mathrm{R}_{\mathrm{h}} \mathrm{K}_{\mathrm{h}}$. Cells with $<$ three trips were imputed using annual averages by gear type and region. To hind-cast the discards to 1981 (the first year in which there was no industrial fishery), discards/total landings by half year for the first three years (1989-1991 for otter trawl, sink gill net, and shrimp trawl; 1992-1994 for longline and scallop dredge) were averaged and the rate applied to the total landings from the dealer database. For the otter trawl fisheries, the mesh sizes were combined for the hind-cast.

Discards from the longline and sink gill net fishery were minimal for silver and offshore hake in both stock areas (Table A18-A21). Discards from the otter trawl fisheries have been significant and variable.

The same problem with species identification that exists in the landings was found in the Fisheries Observer Program (FOP) data. There are discards of offshore hake estimated for the north. The geographical distribution of offshore hake is limited to the southern stock of silver hake and therefore, any discards from the northern stock are considered to be silver hake. In order to estimate discards of silver hake from the southern region, only the length-based estimator was employed.

The observer discard length samples of silver and offshore hake were combined by stock (Tables A22-A25). Enough length samples were available for large and small mesh otter trawls in both regions and sink gill net and shrimp trawl in the north. Pooling over years was still required to get an adequate number of fish (Tables A26-A27). The length-weight equations by season from Wigley et al 2003 were applied to the samples and used to estimate the landings numbers at length for each market category. The discards-at-length were raised to the total discards including all the gear types to account for as much of the removals as possible.

For the southern stock, length compositions for each species were estimated for the spring and fall surveys from 1968-2009. The species length-weight equations were then applied to determine weight-at-length by species. The proportions at length by species for both number and weight were applied to the commercial discards-at-length to estimate discards-at-length by species. The lengths had to be grouped into intervals to avoid zero cells in the survey. To hind-cast the species proportions back to 1981, the average proportion of silver hake for the time series was used and applied to the total silver hake discards.

Silver hake discards in the north were approximately $23 \%$ of the total catch in years 1981-2009 (Tables A28-A30). Total discards peaked to over 2,900mt in 1982, declined substantially in 1993 to a low of 37 mt in 2006 and increased $14 \%$ from 2008 (167mt) to $2009(190 \mathrm{mt})$. In the south, the proportion of discards to total catch in years 1981-2009 was similar to the north ( $22 \%$ ), peaked in $1989(\sim 6500 \mathrm{mt})$, declined substantially in the mid 1990's with a brief increase in 1999 to levels observed in the early 1980's (3500mt). Total discards of silver hake in the south decreased $19 \%$ from 2008 (1033mt) to 2009 (839mt).

## Catch at age

Due to the lack of commercial age data from the commercial fishery, age compositions for landings and discards were derived from the NEFSC bottom trawl survey age-length keys (ALK) from 1973-2009. Commercial length for both landings and discards frequencies were estimated by half years from the length-based estimator as described above. The silver hake age-length keys were then calculated for both the fall and spring then applied to the length-based landings (1973-2009, Tables A31-A33) and discards (1981-2009, Tables A34-36) by half years (i.e. spring ALK for the half 1 and fall ALK for half2) to capture seasonal differences in the fishery. The fall age-length keys were not available for fall 1974. Therefore adjacent age-length key from 1973 were borrowed to impute commercial landings at ages for half 2 based on minimal differences observed in the mean size at age in the fall survey during the early 1970's.

The catch at age composition of silver hake catches in the fishery has shown a general truncation in the age structure since the late 1980's with fewer availability of fish older than age-6 in the population (Tables A37-A39, Figures A16-A18). In the north, vast majority of the catches were dominated by ages 2-4 in the 1970's, partly supported by the strong 1972 year class. By the early 1980's, ages 2 and 3 declined severely but remained stable through the late 1980's. There were a few strong year classes around the 1990's
contributing to moderate expansions in ages 2 and 3. Age- 4 continues to decline with further reductions in age-5 in the fishery. However, it appears that there was a 2006 year class which appears to have contributed to the increase in age 3 in 2009 (Table A37, Figure A16).

Similarly in the south, majority of the catches were also dominated by ages 2-4 in the 1970's, supported by the 1972 year class but declined drastically around the early 1980's with moderate expansions in ages 2 and 3 during the 1990's. The age- 4 group continues to decline with further truncation in the age structure. However, there have been increased catches of age- 1 during the early 1990's probably and recently in the last five years. This is probably due to increased demand for small hake in the Spanish market (comm. Andy Applegate) in the 1990's and more recently, probably related to over the side bait sales (Table A38, Figure A17).

Summary of the combined stock area catches are summarized in Table A39 and in Figure A18. The perception of the age structure does not change relative to the north and south. Similar properties such observed in the north and southern areas such as the truncation of older fish and the dominance of ages 2 and 3 in the recent years still persists.

## Mean Weights at age

The overall fishery weights at age were calculated from the landings and discards weighted by the respective catch at age for the north, south and combined area stock. (Tables A40-A42, Figures A19-A21). The mean weight at age ( kg ) were quite similar but variable between for fish greater than age-4 particularly since the mid 1980's. Only slight variations in mean weights at age were apparent during the mid 1990's - mid 2000's which are likely related to variations in year class strength as they become recruited to the fishery.

## Commercial Fishing Effort

There are currently no estimates of CPUE or effort for this species. Given the uncertainties given with species identification above and the major changes in management noted in the introduction, CPUE is not likely to be a good indicator of stock status. In particular, the fishery in the north has been limited in areas they can fish with small mesh. These are not necessarily to good silver hake fishing areas. Over time, the fishery has also changed from one dominated by a distant water fleet that took substantial quantities of everything to a much smaller fishery that may be driven more by prices and regulation than abundance.

TOR 2. Present the survey data being used in the assessment (e.g., regional indices of abundance, recruitment, state surveys, age-length data, etc.). Characterize the uncertainty and any bias in these sources of data.

Data Source: The primary sources of biological information for silver hake are based on the annual fishery independent surveys conducted by the Northeast Fisheries Science Center (NEFSC). The surveys were conducted using a random stratified sampling
design which allocates samples relative to the size of the strata, defined by depth. The surveys extend from the Gulf of Maine to Cape Hatteras, in offshore waters at depths 27365 meters, and have been conducted in the fall since 1963 and in the spring since 1968. The winter bottom trawl survey began in 1992 and was specifically designed for flatfish, however, the deeper survey strata were not sampled until 1998 (Figure A22). The winter trawl survey does not cover the Georges Bank area because the survey was designed specifically for flatfish in the southern region. Details on the stratified random survey design and biological sampling methodology may be found in Grosslein (1969), Azarovitz (1981) and Sosebee and Cadrin (2006). Other surveys used in the analysis of silver hake are NEFSC shrimp survey (1985-2009), Massachusetts Division of Marine Fisheries (1978-2009) fall and spring surveys and Rhode Island (1979-2010), Connecticut (1984-2009), and Maine-New Hampshire (2000-2009) state surveys.

Transform: Survey estimates were computed using both delta transformation and arithmetic means for numbers and weight. The Whiting Plan Development Team (PDT) has used the delta mean for assessing stock status. The delta transformation uses only the positive tows for log transformation given the following equation (syrjala 2000):

$$
\begin{aligned}
& \hat{M}_{\delta}= \begin{cases}\frac{m}{n} e^{\bar{\top}} \psi_{m}\left(\frac{1}{2} s_{y}^{2}\right) & m>1, \\
\frac{1}{n} x_{1} & m=1, \\
0 & m=0\end{cases} \\
& m=\text { number of non - zero tows } \\
& n=\text { total number of tows } \\
& \hat{V}_{\delta}= \begin{cases}\frac{m}{n} e^{2 \bar{y}}\left[\psi\left(2 s_{y}^{2}\right)-\frac{m-1}{n-1} \psi_{m}\left(\frac{m-2}{m-1} s_{y}^{2}\right)\right] & m>1, \\
\frac{1}{n} x_{1}^{2} & m=1, \\
0 & m=0\end{cases}
\end{aligned}
$$

Examination of the differences between the delta and arithmetic means revealed that use of the delta transformation did not reduce the variability of the survey and may have increased interannual variability (See offshore Hake assessment). If a survey has a high variance, the back-transformation may be biased high. The delta transformation was also more sensitive to the handling of missing weights. Prior to 2001, the data for weights were recorded to the nearest 0.1 kg and if a tow contained only a single small fish, the weight was entered into the data as zero. Since the delta transform uses the positive tow, how this is handled has an impact on the result. There were three options: taking out the zeros, leaving in the zeros, and filling in zeros using a length-weight equation. Since
these options did not affect the arithmetic as much as the delta mean, the decision was made to use the arithmetic and length-weight options for any new analyses.

Several surveys were explored to provide indices of relative abundance. The properties of each survey are summarized in Table A43. Based on the stock definition provided in TOR 3, survey indices for the assessment was based on data from all strata that have been sampled consistently (NEFSC fall and spring survey). However, future work will explore other surveys as sensitivity analyses in the assessment.

The NEFSC strata set used for the northern area are: 20-30 and 36-40. The NEFSC strata used for the southern management area are: 1-19 and 61-76. The combined strata set are: 1-30, 36-40, and 61-76 (Figure A22). Survey age composition were estimated for the north, south and combined areas from 1973-2009 for when survey ages were available. Of special note, fall 1974 was never aged for both the north and south regions, and therefore age-length key from 1973 was borrowed to impute ages for 1974. As discussed earlier, the mean size at age for both years were similar. The 2009 and 2010 survey values were calibrated to the Albatross IV by using seasonal length-based calibration coefficients. Details on the estimation of the calibration coefficients may be found in Miller et al. 2010. The strata set for the shrimp survey is $1-12$, with no calibration needed for 2009. The strata set for the winter surveys are: 1-3, 5-7, 9-11, 13-14, 61-63, 65-67, 69-71, and 73-75. No calibration was also needed for the winter survey, as it was discontinued in 2007. Massachusetts Division of Marine Fisheries data was separated into northern and southern areas. The northern strata set used were 18-36 and the southern strata set used were 11-17 (Figure A23).

Minimum swept area abundance and biomass were calculated by using swept area conversions of 0.0112 for the NEFSC fall and spring surveys, 0.004 for NEFSC shrimp survey, 0.0131 for the NEFSC winter survey, and 0.003846208 for Massachusetts Division of Marine Fisheries (MADMF) fall and spring surveys. Swept area estimates were not calculated for the other state surveys. Swept area estimates at age were also calculated for the NEFSC fall and spring surveys, in the northern, southern, and combined management areas.

Silver hake survey distribution suggests that most of the higher catches for silver hake are in the Gulf of Maine and on Georges Bank in the fall, whereas they are along the shelf edge in the spring. In the spring of the 1970s, most of the silver hake seemed to be in the Gulf of Maine and southern New England, with few on Georges Bank. However, even though the areas did not change through the 1980s and 1990s, the density did. It seems a bit scarcer during this time period. In the fall, there seems to be more silver hake on Georges Bank than in the spring, though most of the catch weight is in the Gulf of Maine (Figures A24-A35).

Calibration: In 2009 the NOAA ship Henry B. Bigelow replaced the $R / V$ Albatross $I V$ as the primary vessel for conducting spring and fall annual bottom trawl surveys for the Northeast Fisheries Science Center (NEFSC). There are many differences in the vessel operation, gear, and towing procedures between the new and old research platforms
(NEFSC Vessel Calibration Working Group 2007). To merge survey information collected in 2009 onward with that collected previously, we need to be able to transform indices (perhaps at size and age) of abundance from the Henry B. Bigelow into those that would have been observed had the Albatross $I V$ still been in service. The general method for merging information from these two time series is to calibrate the new information to that of the old (Pelletier 1998).

Specifically we need to predict the relative abundance that would have been observed by the Albatross $I V\left(\hat{R}_{A}\right)$ using the relative abundance from the Henry B. Bigelow $\left(R_{B}\right)$ and a "calibration factor" $(\rho)$,

$$
\begin{equation*}
\hat{R}_{A}=\rho R_{B} . \tag{1}
\end{equation*}
$$

To provide information from which to estimate calibration factors for a broad range of species, 636 paired tows were conducted with the two vessels during 2008. Paired tows occurred at many stations in both the spring and fall surveys. Paired tows were also conducted during the summer and fall at non-random stations to improve the number of non-zero observations for some species. Protocols for the paired tows are described in NEFSC Vessel Calibration Working Group (2007).

The methodology for estimating the calibration factors was proposed by the NEFSC and reviewed by a panel of independent scientists in 2009. The reviewers considered calibration factors that could potentially be specific to either the spring or fall survey (Miller et al. 2010). They recommended using a calibration factor estimator based on a beta-binomial model for the data collected at each station for most species, but also recommended using a ratio-type estimator under certain circumstances and not attempting to estimate calibration factors for species that were not well sampled. In the case of offshore hake, using silver hake calibration factors as a proxy was better than not using any calibration factors.

Since the review, it has become apparent that accounting for size of individuals can be necessary for many species. When there are different selectivity patterns for the two vessels, the fraction of available fish of a given size taken by the two gears is different. Therefore, the ratio of the mean catches by the two vessels will change with size. Under these circumstances, the estimated calibration factor that ignores size reflects an average ratio weighted across sizes where the weights of each size class are at least in part related to the number of individuals at that size and the number of stations where individuals at that size were caught. Applying calibration factors that ignore size effects to surveys conducted in subsequent years when the size composition is unchanged should not produce biased predictions (eq. 1). However, when the size composition changes, the frequency of individuals and number of stations where individuals are observed at each size changes and the implicit weighting across size classes used to obtain the estimated calibration factor will not apply to the new data. Consequently, the predicted numbers per tow that would have been caught by the Albatross $I V$ will be biased.

For silver hake, we fit a suite of beta-binomial models that made different assumptions on the relationship of the calibration factor to length. The models ranged from those that
were constant with respect to length to logistic and double-logistic functions of length. A season-specific model was chosen based on $\mathrm{AIC}_{\mathrm{c}}$ for silver hake where a logistic functional form for the spring and a double-logistic form for the fall provided the best fit (Table A44, Figure A36). To estimate weight per tow for the 2009 and 2010 surveys, the length-weight equations by season from Wigley et al. 2003 were applied to the length frequencies.

## North Survey trends:

The NEFSC fall survey biomass steadily increased continuously through the 1970s, peaked in 1998 at 40,462 metric tons and then declined to 3,672 metric tons in 2005, lowest in the time series. Biomass has increased in the last few years and is currently at 14,748 metric tons, a $31 \%$ increase from 2008 ( $11,285 \mathrm{mt}$; Table A45, Figure A37).

The NEFSC spring survey has been quite variable. There was a large peak in 2001, with $22,309 \mathrm{mt}$ and then considerably declined until 2006, with 915 mt . Since then, the biomass has increased and estimated at 5,673 mt in 2009 (Table A46, Figure A38).

The NEFSC shrimp survey swept area biomass was at its highest early in the time series, in 1987 with 149,508 metric tons. It dropped substantially to 16,302 metric tons in 1988. The survey continued to vary until thereafter, then declined to an all time low of 9,501 metric tons in 2006. Biomass in 2009 was $16,239 \mathrm{mt}$, a $42 \%$ decrease from 2008 ( 27,980 $\mathrm{mt})$ (Table A47, Figure A39).

The MADMF fall surveys indicate two large spikes in silver hake swept area biomass, 1986 and 2000, with over $2,000 \mathrm{mt}$. The most recent years have seen a decrease, with 2009 only catching 651 mt (Table A48, Figure A40).

The MADMF spring surveys have much lower values than the fall. Only in 1987 and 2000 were there over $1,000 \mathrm{mt}$ caught. In 2004, the spring survey saw its lowest catch of silver hake in the time series, with only 47 mt . It has since increased to 225 mt in 2009 (Table A49, Figure A41).

The MENH fall survey has been variable without trend but the spring survey peaked in 2002 at approximately $12 \mathrm{~kg} /$ tow, declined sharply in 2006 to $1.6 \mathrm{~kg} /$ tow and has steadily increased in the last three years (Table A50, Figures A42-A43).

North Age Composition: Fall survey age composition shows a general truncation of older age fish with less availability of fish older than age 6. Ages-1 and 2 are the abundant in the survey. The strongest year class over the time series was in 1997 with over 400,000 fish. In 2006, there was a moderate size year class which contributed to the expansion of age-3 in 2009. Since the late 1980's and early 1990's, Age 4 and 5 has declined significantly consisting of only $1 \%$ of the survey catch (Table A45, Figure A44).

Similar to the fall survey, majority of the spring survey catches consist of ages 1 and 2's and very few fish older than age-5. There has been several strong year classes since the mid-1980's contributing to significant expansion of age 2 's and moderately for age-3. A
marginal increase was noted for age-4 in the early 2000, but has declined in the recent years (Table A46, Figure A45).

## South Survey Trends

The NEFSC fall survey swept area biomass was higher during the 1970's and 1980's than any other part of the time series. Biomass peaked in 1985 at 11,760 metric tons then steadily declined the 1990's to approximately 2,600mt in 1994 then briefly increased in 2001 to over 6,700 metric tons. Biomass has as averaged around $4,000 \mathrm{mt}$ in the last $10 y e a r$ and approximately around 3,600 metric tons, a and currently at 3,600 metric tons in 2009, a 20\% decrease since 2008 (4,513 metric tons; Table A51, Figure A46).

The NEFSC spring survey had considerably higher biomass than the fall survey. It was fairly high in the 1970s, averaging over 11,000 metric tons. It then decreased through the 1980s and 1990s, with a large spike in 1996 at 20,553 metric tons. In 1997, it fell to 2,142 metric tons. In 2010, it has increased to 3,783 metric tons (Table A52, Figure A47).

The NEFSC winter survey has a very short time series, 1992-2007. The swept area biomass was fairly stable throughout the time series. The largest biomass was in 1993 with almost 8,000 metric tons. It stayed considerably lower than that until it was discontinued in 2007 (Table A53, Figure A48).

The MADMF fall surveys indicate very low swept area biomass. There were only three years in the time series where the catch was over 50 metric tons. In 2007, the biomass plummeted from 25 metric tons down to 0.04 metric tons. The most recent years have increased moderately, with 2009 catching 0.22 metric tons (Table A54, Figure A49).

The MADMF spring survey has much higher values than the fall, but has generally declined over time. In 1987, there was over 2,000 metric tons caught. In 2003, the spring survey saw its lowest catch of silver hake in the time series, with only 2 metric tons. It has recently increased to 26 metric tons in 2009 (Table A55, Figure A50).

Survey trends for Rhode Island state survey has been variable without trend. The Connecticut survey on the other hand was highest early in the time series but has been low ever since (Table A56, Figures A51-A52).

South Age Composition: Similar to the north, the south has also experienced a general truncation in the age structure with fewer older fish than age-6 in both the fall and the spring survey. Despite the consistent appearance of strong year classes in the last decade, there has been a substantial decline of age 4 and 5 in the surveys. However, the spring survey showed an unusual increase of age-3 in 1989 with approximately 260,000 fish. It is unclear for the sudden increase in age-3. This is likely due to aggregation of this size class during the survey (Tables A51-A52, Figures A53-A54).

## Combined North and South

The NEFSC combined area fall survey is driven by the northern region peaking in 1998,
with 42,353 metric tons and was extremely low in 2005 at 6,773 metric tons. It has increased recently with biomass at approximately 18,000 metric tons in 2009 (Table A57, Figure A55). In 1975, the spring survey had its highest biomass in the time series, at 37,136 metric tons. Then it hit an extremely low point at 4,725 metric tons in 1997. The survey had smaller spikes in 2000 and 2001 where the catch was over 20,000 metric tons. In 2009, the swept area biomass increased to 13,278 metric tons (Table A58, Figure A56). Similar pattern in the age structure was also observed in the combined stock areas as in the northern region (Tables A57-A58, Figures A57-A58).

TOR 3. Evaluate the validity of the current stock definition, and determine whether it should be changed. Take into account what is known about migration among stock areas.

Two subpopulations of silver hake are assumed to exist within the U.S. EEZ (Almeida 1987a). Analyses of morphometrics (Conover et al. 1961, Almeida 1987a) are the primary basis for this delineation further supported by otolith microconstituent (Bolles and Begg 2000). However, genetic analyses of the population structure have been inconclusive (Schenk 1981). The northern silver hake stock inhabits the Gulf of Maine Northern Georges Bank waters, and the southern silver hake stock inhabits Southern Georges Bank - Middle Atlantic Bight waters (Figure A22). These boundaries were established at SAW 11(Brodziak et al. 2005).

While it is likely that the northern and the southern stocks mix on Georges Bank, the degree of mixing and movement among the management areas are unknown (Almeida 1987a, Helser et al. 1995, Helser 1996). Silver hake are known to spawn in the Gulf of Maine, southern New England, and on the southern flank of Georges Bank. Therefore, it is likely that silver hake larvae are entrained in the clockwise gyre on Georges Bank leading to larvae settlement in either management areas. Recent analyses of an icthyoplankton survey suggest the southern stock is larger ( $>90 \%$ of the larvae density) than the northern stock (Richardson et al. 2010). This is also consistent with Nye et al. 2009, suggesting a northern shift in the center of biomass for southern stock of silver hake. This is in contrast with the NEFSC trawl survey, which suggests a much larger stock in the northern area (Figure A59). Additionally, in the Gulf of Maine, there were no larvae observed, although adult spawners were present. This further suggests that there is probable transport of silver hake larvae from north to south and adults are migrating across the traditional stock boundaries which also implies that reproductive isolation between the two stock areas is unlikely.

NEFSC trawl surveys indicate a generally continuous distribution of silver hake from the Gulf of Maine to the southern New England/Mid-Atlantic Bight (Figures A24 and A30). However, the relative density of silver hake has varied through time between the northern and southern management areas. Population density as measured by the NEFSC fall bottom trawl survey increased in northern area during the mid-1980's, declined in 2000's and has continue to increase in the recent years. In contrast, density in the southern area showed decreases in the 1990's with a temporary increase in 2000 and declined in the last few years (Figure A60). Relative to the fall survey, the spring survey trends are highly
variable and difficult to interpret the trends (Figure A60). This indicates that it is likely that mixing is occurring during the adult life stage. However, the degree of mixing cannot be determined.

Analyses of silver hake size at age data have shown that growth tends to vary in time and among areas (Helser 1996). Particularly, there were consistent differences between growth in the Gulf of Maine and southern New England/Mid Atlantic Bight areas. However, Helser showed that growth patterns on Georges Bank and in the Gulf of Maine were indistinguishable in the 1980's and 1990's and that growth rate changes dynamically on Georges Bank. In the last assessment, Brodziak et al. (2005) reported that there were negligible differences in growth between the northern and southern stock areas. For the purpose of this assessment, a decadal analyses on silver mean size at age from 1973-2009 for the fall and spring by sex was conducted. Results suggest that not only does silver hake exhibit sexually dimorphism but also very little differences were observed in the growth patterns between the northern and the southern stock areas (Figures A61 - A64).

Patterns in silver hake median age at maturity from the spring NEFSC bottom trawl survey (1980-2009) were estimated for both the northern and southern management areas in this assessment. The observed proportion of fish mature at age was fitted a logistic model using a nonlinear least square estimator. Model results in Figure A61 shows that there is no meaningful geographic variation in age at maturity. Annual trends in median age at maturity were also consistently similar between the north and the south management areas with synchronous increases around the early 1990's from 1.6yrs to approximately of 2.3yrs through late 1990's and early parts of 2000 and declined in the recent years to levels estimated in the early 1980's (A50 $=1.6 y r s$, Figure A65).

In summary, based on the scientific information available on silver stock structure (morphometrics, tagging, discontinuous larva distribution, homogeneous growth and maturity), it was concluded that there were no strong biological evidences to support either a separate or a single stock structure for silver hake. For the purpose of this assessment, a separate north-south and a combined stock model formulation was explored.

TOR 4. Estimate annual fishing mortality, recruitment and stock biomass (both total and spawning stock) for the time series (integrating results from Silver hake TOR-5), and estimate their uncertainty. Include a historical retrospective analysis to allow a comparison with previous assessment results.

## Assessment History

Stock assessments of the silver hake resources were conducted as early as 1968 using catch curves on catch at age data, with more formal assessment methods using Virtual Population Analysis (VPA) during the next two decades. During the next two decades, VPAs were enhanced in various ways using tuning methods with auxiliary research survey data using age-aggregated ad hoc techniques. During the early 1990s both LaurecShepherd and ADAPT tuning methods based on statistical fitting were attempted and
assessment results were accepted with reservation. However, subsequent VPA assessments were rejected due to high degree of uncertainty and instability in parameter estimates (Brodziak et al 2001). Due to these difficulties of the population assessments, the southern and northern stock of silver hake are based on an index of exploitation and biomass derived from NEFSC resource assessment surveys.

In this assessment, two models were attempted, An Index Method (AIM) and the Age Structure Assessment Program (ASAP). While the ASAP model provided major advancement in the assessments, the results were not accepted due difficulties reconciling the inconsistent interpretations of the steep age profiles. The AIM model was also not accepted because it did not provide adequate diagnostics for stock status determination. Thus, this assessments was based on trends in the three year moving averages for the ageaggregated, fall survey biomass indices (1973-1982) using the arithmetic means rather than the previous delta approach (SAFE2003) and the three year averages of exploitation indices (total catch/fall survey biomass index) for both the northern and southern management areas.

## A bridge between the current and last assessment

The NEFSC fall Survey biomass (delta mean $\mathrm{kg} / \mathrm{tow}$ ) and the relative exploitation index (landings/delta mean $\mathrm{kg} / \mathrm{tow}$ ) were computed for both the northern and southern stock areas. Survey biomass for the north declined recently and near the target levels used for management while the southern survey biomass has generally increased in recent years and also near the management target. The exploitation rate index for the southern stock is higher than for the northern stock throughout the time series. The exploitation index show high values during 1963-1977 followed by a period of low values during 19781993. Since 1994, the northern exploitation continues to decline and the southern values have varied without trend. Overall, the exploitation rate indices suggest that exploitation rates in recent years are much lower than during the 1960's and 1970's when foreign distant water fleets intensively harvested silver hake (Table A59, Figures A66-A67).

For this assessment, the "delta" estimators were replaced with the arithmetic means (i.e. no $\log$ transform was applied) because the delta transformation tends to inflate the survey variances and were sensitive to treatment of tows with no catch. Also, the previous exploitation index based on the ratio of landings to the fall delta survey biomass was also updated to include discards to better characterize removals from the commercial catch (landings + discards) relative to the fall survey biomass. Since discards are reliably estimated since 1989, relative exploitation index is now defined as the ratio of the commercial total catch to the arithmetic fall biomass survey (Table 60, Figure A68-69). It is noted that historical discarding, particularly in the Distant Water Fleet, has likely been very small. Therefore, comparison of relative exploitation index based on catch/biomass with reference points based on landings over biomass is justified.

## Revised Assessment Method

An Index Method (AIM)
The AIM model is a simple approach for examining the relationship between survey data and catch in data poor stock assessments. AIM is designed to address the question of whether a given rate of fishing mortality is likely to increase or decrease the population size. Survey data are used to define a relative rate of increase and the ratio of catch to survey indices provides a measure of relative fishing mortality. Theoretically the model can identify a stable point about which the stock will neither increase nor decrease in response to a fixed harvest rate. The model assumes that the resource dynamics are approximately linear with relatively minor influence of density dependent effects or variable environmental or ecological factors. Such conditions often typify stocks that have been historically harvested at high fishing rates and are therefore at low population sizes. AIM is both an analytic and graphing approach. The analytical methods can be used to define relative Fs for replacement and the graphical methods can be used to identify transient conditions that are relevant to implementation of any model. The details of the methodology are described below.
$\checkmark$ Population biomass at time $t$ can be written as a linear combination of historical population biomasses
$\checkmark$ Recruitment is proportional to population biomass
$\checkmark$ Fishing mortality is proportional to catch divided by an index of population size (relative F).
$\checkmark$ The rate of change in population biomass is a monotonically decreasing function of relative $F$.
$\checkmark$ Smoothing methods can be used to identify underlying trends.
$\checkmark$ Randomization methods can be used to develop sampling distributions of test statistics
$\checkmark$ Graphical methods can help identify linkages among variables
Relative F is defined as the ratio of catch to an index of population abundance. A threeyear centered average of the abundance index is chosen as the measure of average stock size.

$$
\begin{equation*}
\mathrm{relF}_{j, s, t}=\left(\frac{C_{s, t}}{\frac{I_{j, s, t-1}+I_{j, s, t}+I_{j, s, t+1}}{3}}\right) \tag{1}
\end{equation*}
$$

Where $\quad \operatorname{relF}_{j, s, t}=$ relative F for relative index j for stock s at time t
$\mathrm{C}_{\mathrm{s}, \mathrm{t}}=$ catch or landings of stock s at time t (in units of weight)
$\mathrm{I}_{\mathrm{j}, \mathrm{s}, \mathrm{t}}=$ Index of abundance j for stock s at time t expressed in
terms of average weight per tow

The population size at any given time can be viewed as a weighted sum of previous recruitment events. For a population with a maximum age of A years, the population in year $t$ consists of the recruits from year $t-1, t-2, \ldots t-A$. At high levels of total mortality, the contributions from the earliest recruitments, say t-k-1 to t-A will diminish in importance such that the population can be viewed as the sum of recruitments from $t-1$ to t-k years.

Using the linearity assumption defined above, we can employ basic life history theory to write abundance at time $t$ as a function of the biomasses in previous time periods. The number of recruits at time $t\left(R_{t}\right)$ is assumed to be proportional to the biomass at time $t$ $\left(B_{t}\right)$. More formally,

$$
\begin{equation*}
R_{t}=S_{o} \operatorname{Egg} B_{t} \tag{2}
\end{equation*}
$$

where $\mathbf{E g g}$ is the number of eggs produced per unit of biomass, and $\mathbf{S}_{\mathbf{0}}$ is the survival rate between the egg and recruit stages. Survival for recruited age groups at age a and time $t$ $\left(\mathrm{S}_{\mathrm{a}, \mathrm{t}}\right)$ is defined as

$$
S_{a, t}=e^{-F_{a t}-M_{a t t}}
$$

where F and M refer to the instantaneous rates of fishing and natural mortality, respectively. We also need to consider the weight at age $a$ and time $t\left(W_{a, t}\right)$ and the average longevity (A) of the species.

Using these standard concepts we now write the biomass at time $t$ as a linear combination of the A previous years. Without loss of generality, we can drop the subscripts on the survival terms and assume that average weight at age is invariant with respect to time. Further, set the product $S_{o}$ Egg equal to the coefficient $\alpha$. The biomass at time $t$ can now be written as

$$
B_{t}=R_{t-1} S^{l} W_{1}+R_{t-2} S^{2} W_{2}+R_{t-3} S^{3} W_{3}+. .+R_{t-(A-l)} S^{A-1} W_{A-1}+R_{t-A} S^{A} W_{A}
$$

Substituting Eq. (2) into Eq. (4) leads to

$$
B_{t}=\alpha B_{t-1} S^{1} W_{1}+\alpha B_{t-2} S^{2} W_{2}+\alpha B_{t-3} S^{3} W_{3}+. .+. \alpha B_{t-(A-1)} S^{A-1} W_{A-1}+\alpha B_{t-A} S^{A} W_{A} \text { (5) }
$$

If the population is replacing itself, then the left hand side of Eq. 5 will equal the right hand side. The replacement ratio can then be defined as

$$
\begin{equation*}
\Psi_{t}=\frac{B_{t}}{\alpha B_{t-1} S^{l} W_{1}+\alpha B_{t-2} S^{2} W_{2}+\alpha B_{t-3} S^{3} W_{3}+. .+. a l p h a B_{t-(A-l)} S^{A-1} W_{A-1}+\alpha B_{t-A} S^{A} W_{A}} \tag{6}
\end{equation*}
$$

Substituting observed values of abundance indices into Eq 6 leads to

$$
\Psi_{t}=\frac{\frac{I_{t}}{q}}{\alpha \frac{I_{t-1}}{q} S^{l} W_{1}+\alpha \frac{I_{t-2}}{q} S^{2} W_{2}+\alpha \frac{I_{t-3}}{q} S^{3} W_{3}+. .+\alpha \frac{I_{t-(A-l)}}{q} S^{A-1} W_{A-l}+\alpha \frac{I_{t-A}}{q} S^{A} W_{A}}
$$

By noting that the q's cancel out, and letting $\varphi_{j}=\alpha S^{j} W_{j}$, Eq. 6 simplifies to

$$
\Psi_{t}=\frac{I_{t}}{\sum_{j=1}^{A} \phi_{j} I_{t-j}}
$$

All of the $\mathrm{I}_{\mathrm{t}}$ and $\varphi_{\mathrm{j}}$ are positive, and at equilibrium $\mathrm{I}_{\mathrm{t}}=\mathrm{I}_{\mathrm{t}+1}$ and $\mathrm{I}_{\mathrm{t}}=\sum \varphi_{j} \mathrm{I}_{\mathrm{t}-\mathrm{j}}$ both hold. Therefore $\sum \varphi_{\mathrm{j}}=1$. When the population is not at equilibrium the parameter $\Psi$ becomes a measure of the non equilibrium state of the population and a measure of whether the population is increasing or decreasing relative to prevailing fishery and ecosystem conditions.

It would be desirable to express the parameters of $\varphi_{j}$ weighting terms as function of the underlying parameters. Analyses of other stocks with more detailed information, such as Georges Bank haddock, has suggested that setting the $\varphi_{\mathrm{j}}$ to $1 / \mathrm{A}$ is a reasonable approximation. Equations 2 to 8 are a long way of justifying that the ratio of current stock size to a moving average of the previous A years of stock size can be used as a measure of population growth rate. This ratio embeds some life history theory into the basis for the ratio and simultaneously provides a way of damping the variations in abundance owing to measurement error. A ratio defined as $\mathrm{I}_{\mathrm{t}} / \mathrm{I}_{\mathrm{t}-1}$ has been found, as expected to be much more noisy measure of population change.
Further details on the AIM methodology may be found in Working Group (2002) and the NOAA Fisheries Toolbox (NFT) 3.1 (2010a) software package http://nft.nefsc.noaa.gov/AIM.html. The relationship between $\boldsymbol{\Psi}_{\mathbf{t}}$ and $\mathbf{r e l F} \mathbf{F}_{\mathrm{t}}$ can be expressed as

$$
\ln \left(\Psi_{t}\right)=a+b \ln \left(\operatorname{relF} F_{t}\right)
$$

The usual tests of statistical significance do not apply for the model described in Eq. 9 . The relation between $\mathbf{\Psi}_{\mathrm{t}}$ and $\mathbf{r e l F}_{\mathrm{t}}$ is of the general form of $\mathrm{Y} / \mathrm{X}$ vs X where X and Y are random variables. The expected correlation between $\mathrm{Y} / \mathrm{X}$ and X is less than zero and is the basis for the oft stated criticism of spurious correlation. To test for spurious correlation we developed a sampling distribution of the correlation statistic using a randomization test. The randomization test is based on the null hypothesis that the catch and survey time series represent a random ordering of observations with no underlying association. The randomization test was developed as follows:

1. Create a random time series of length $\mathbf{T}$ of $\mathbf{C}_{\mathbf{r}, \mathrm{t}}$ from the set $\left\{\mathbf{C}_{\mathbf{t}}\right\}$ and $\mathbf{I}_{\mathbf{r}, \mathrm{t}}$ from the set $\left\{\mathbf{I}_{\mathbf{t}}\right\}$ by sampling with replacement.
2. Compute a random time series of relative $\mathrm{F}\left(\mathbf{r e l F}_{\mathbf{r}, \mathbf{t}}\right)$ and replacement ratios ( $\Psi_{\mathrm{r}, \mathrm{t}}$ )
3. Compute the r-th correlation coefficient; say $\boldsymbol{\rho}_{\mathbf{r}}$ between $\ln \left(\mathbf{r e l F} \mathbf{F}_{\mathbf{r}, \mathbf{t}}\right)$ and $\ln \left(\boldsymbol{\Psi}_{\mathbf{r}, \mathbf{t}}\right)$.
4. Repeat steps 1 to 3 K times.
5. Compare the observed correlation coefficient $\mathbf{r}_{\mathbf{o b s}}$ with the sorted set of $\boldsymbol{\rho}_{\mathbf{r}}$
6. The approximate significance level of the observed correlation coefficient $\mathbf{r}_{\mathbf{o b s}}$ is the fraction of values of $\boldsymbol{\rho}_{\mathbf{r}}$ less than $\mathbf{r}_{\mathbf{o b s}}$

It should be emphasized that relF is not necessarily an adequate proxy for Fmsy, since this parameter only estimates the average mortality rate at which the stock was capable of replacing itself. Thus, while relF defined as average replacement fishing mortality is a necessary condition for an $\mathrm{F}_{\text {msy }}$ proxy, it is not sufficient, since the stock could theoretically be brought to the stable point under an infinite array of biomass states. The relF at replacement does however provide some guidance on the contemporary rate of harvesting and its potential impact on future stock abundance.

## Application of AIM to Silver Hake

AIM was applied to the combined stock of silver hake using catches and the NEFSC fall and spring bottom trawl survey indices (Table A61). Relative F was defined as the ratio of catch to a centered 3-year average of survey abundance (Eq. 1) and the replacement ratio was defined as a 5 -year moving average of previous stock sizes (Eq. 8). The relationship between catch, survey, relative F and the replacement ratio for the fall and spring survey indices are depicted in Figures A70 and A71, respectively. Neither of the randomization tests resulted in significant statistical relationship between the replacement ratio and relative F (Table A61). Bootstrap estimation of the relative F at replacement were imprecise (Table A62, Figure A72) and are not appropriate measures of Fmsy proxies. Graphical results suggest some underlying causes for the absence of a strong statistical relationship. Relative F has been declining continuously for both the fall (Figure A70) and spring (Figure A71) survey indices but the population indices do not suggest any significant rate of change over time. The relationship between replacement ratio is barely negative despite a nearly 60 -fold range in catches and a 27 -fold range in relative F. The relationship between relative F and survey abundance is instructive (the
left center plot in Figures A70-A71). It suggest three temporal stanzas in which the population abundance has declined by comparable amounts from about 8 to $3 \mathrm{~kg} /$ tow, when relative F has varied by 30,000 to $70,000 \mathrm{mt} / \mathrm{kg} /$ tow between 1968 and 1977 and when relative F varied from 5,000 to $15,000 \mathrm{mt} / \mathrm{kg} /$ tow between 1978 and 2000. In the third stanza, from 2001 to 2009 the surveys have fluctuated from $4.0 \mathrm{~kg} /$ tow to about $1 \mathrm{~kg} /$ tow even though relative F has not exceeded $7108 \mathrm{mt} / \mathrm{kg} /$ tow for the fall survey and $12,099 \mathrm{mt} / \mathrm{kg} /$ tow in the spring survey. At a minimum these stanzas suggest major changes in the population abundance indices and exploitation rates. It is not possible from these data alone to identify causal factors but it does suggest that more advanced modeling will need to account for these changes in apparent productivity and/or natural mortality.

Age Structure Assessment Program (ASAP)
[SAW51 Editor's Note: The SARC-51 peer review panel
concluded that no single silver hake ASAP model run provided a
suitable basis for providing management advice. The silver hake
ASAP model and results, which are described here and in
Appendices A2-A6, are included in this report mainly to
document the ASAP modeling runs that the Hake Working
Group provided to the SARC for peer review.]

Silver hake has been assessed based on survey index of relative exploitation and the 3 year moving average from the survey biomass since 1994(NEFSC 2006). Given some of the changes that have occurred in the fishery (gear, selectivity, targeting, and management), and the change to a new survey vessel (for which a calibration cannot be estimated), the importance of age structure (maturity and growth), and the limited projection capability of the index method, alternative assessment methods were considered for this benchmark. The new assessment model is ASAP (Age Structured Assessment Program v2.0.20, Legault and Restrepo 1998), which can be obtained from the NOAA Fisheries Toolbox (http://nft.nefsc.noaa.gov/). As described at the NFT software website, ASAP is an age-structured model that uses forward computations assuming separability of fishing mortality into year and age components to estimate population sizes given observed catches, catch-at-age, and indices of abundance. Discards can be treated explicitly. The separability assumption is partially relaxed by allowing for fleet-specific computations and by allowing the selectivity at age to change in blocks of years. Weights are input for different components of the objective function which allows for configurations ranging from relatively simple age-structured production models to fully parameterized statistical catch at age models.

The objective function is the sum of the negative log-likelihood of the fit to various model components. Catch at age and survey age composition are modeled assuming a multinomial distribution, while most other model components are assumed to have lognormal error. Specifically, lognormal error is assumed for: total catch in weight by
fleet, survey indices, stock recruit relationship, and annual deviations in fishing mortality. Recruitment deviations are also assumed to follow a lognormal distribution, with annual deviations estimated as a bounded vector to force them to sum to zero (this centers the predictions on the expected stock recruit relationship). For more technical details, the reader is referred to the technical manual (Legault 2008).

## Model Formulations

The assessment model formulations were structured to consider sensitivity to a number of model inputs. To deal with stock structure, separate North and South stock assessments were considered as well as a single combined stock treatment. These models will subsequently be referred to as North, South, and Combined for brevity. Natural mortality was thought to have a large component due to predation. This was dealt with explicitly by including estimates of consumption in the model as a separate "fishery" fleet (referred to as Consumption model hereafter), or implicitly by considering a single value for natural mortality (referred to as the No-Consumption model hereafter). In the Consumption model formulation, a value of $\mathrm{M}=0.15$ was specified for all ages and all years to comprise all sources of natural mortality other than consumption. In the NoConsumption model, a single value of $\mathrm{M}=0.4$ was specified for all ages and all years. The value of $\mathrm{M}=0.4$ was justified by consideration of a maximum observed age of 14 . Given $\mathrm{M}=0.4$, the expected cumulative survival to age 14 would be about $0.5 \%$.

## Model Inputs

All models considered included catch by a directed fleet beginning in year 1973. Although total landings estimates exist before 1973, there was no age composition, and initial modeling suggested poor identifiability of initial conditions when the model runs started earlier than 1973. All models considered also included estimated discards beginning in 1981. Structurally, discards were included as a separate "fleet" in the model. Treating discards as a separate fleet allowed more flexibility for including total discards in 1981-1988 without any corresponding age composition in addition to years 1989 where estimates of total discards and age composition are both available. These two fleets were the only removals that were modeled for the No Consumption models. For the Consumption models, an additional fleet was modeled to represent removals from predation. The estimated mortality from the "fleet" of predators was then considered to be an additional source of natural mortality (generally termed "M2"). Estimates of total annual natural mortality at age from the Consumption models was then calculated as $0.15+\mathrm{M} 2$ (age, year), and cumulative survival to age 14 could then be compared to the $\mathrm{M}=0.4$ model.

All models included the NEFSC spring and fall bottom trawl surveys. Minimum swept area abundances, annual estimated CV, as well as the age composition for each survey were used in the model.

The model assumed a plus group at age 6. Initial model model runs dealt with the stock as a single unit (Combined runs). An exhausting, albeit not exhaustive, number of model specifications were explored for the Combined run. Exploratory runs examined model sensitivity to estimating a stock recruit function versus estimating an average recruitment with annual deviations; estimating age-specific selectivity for the surveys versus forcing
the survey to have a flat-topped selectivity; "breaking" the survey time series into two separate series or maintaining a continuous time series; and adding or removing selectivity "blocks" to the directed and bycatch fleets. In considering these various model iterations, diagnostics were examined to determine if the fit improved. Specifically, the pattern of residuals in age composition for catch and indices, residuals in the fit to total catch and annual index values, components of the objective function in addition to total objective function and number of estimated parameters, as well as the "believability" of the estimated selectivity patterns. With regard to the last criterion ("believability" of estimated selectivity), this was somewhat subjective, however the models tended towards solutions with sharply domed selectivities for both the directed fleet and the surveys (it was also sharply domed for the discard fleet, but that was a sensible result). As there was nothing biological to suggest that fish at ages 5 and beyond would have very low catchability (i.e., no known behavioral aspects, no strong swimming capabilities), nothing gear related that would suggest lower catchability (no outswimming otter trawls, no other known gear interactions), and no known market conditions that would favor smaller fish, the group found it hard to reconcile selectivities of 0.10 on the $6+$ group, when fish in the plus group had been estimated in the catch age composition early in the time series.

## Model Results-Combined model

Model formulations for both the Consumption and No Consumption model were run in tandem. Although objective function values were not directly comparable between these two model treatments, owing to differences in the underlying data, residual diagnostics, overall fits, and retrospective patterns were compared. After much deliberation, the group agreed to the following base configuration: Consumption model that did not split the survey indices and forced a selectivity $=1$ for ages 2 and older; two selectivity blocks for the directed fleet (the break occurred between 1988 and 1989) and one single selectivity block for the bycatch fleet. With all models considered, there was a strong correlation between the selectivity estimated for the directed fleet and the selectivity of the surveys. Forcing the flat-top for the survey indices caused the selectivity estimates for the directed fleet to also be flat-topped. For this selectivity pattern, the age composition residuals were acceptable, although the residuals from fits to the total catch and overall index values showed strong time trends. This was a fairly consistent trade-off seen in many of the model diagnostics, wherein improvements in the fit to age composition data were accompanied by a deteriorated fit to the total data (either total catch or total index values). Thus, selecting the 'best' model depended to some extent on the amount of confidence that one had in the age composition data relative to the data streams of total catch and the indices. Complete model diagnostics can be found in the Appendix A2. ("Base_model_diagnostics_Consumption_Flat-top Survey").

## Retrospective pattern of Base Combined model

A retrospective analysis on the base model using a seven year peel was conducted to examine the stability of the model estimates for fishing mortality, recruitment and spawning stock biomass. Due to the change in selectivity block beginning in 1989, it was difficult to interpret the earliest peels because there was an imbalance in the number of parameters being estimated versus number of years with additional data. However, it was
noted that the Consumption models had the lowest retrospective bias (Figures A73-A74, Table A63).

## Sensitivity analyses to Base Combined model

For completeness, sensitivity to the model decisions adopted in the base model are summarized in Table A63 and in Figures A75-A77. Eight additional runs are described in this table. Only one run for the No Consumption model is described. While this model offered good diagnostics, and good retrospective analysis results, two of the parameters for selectivity at age were estimated at the upper bound of 1.0 . When those parameters were subsequently fixed at 1.0 , instead of attempting to estimate them, no hessian was obtained for the model. Because of this instability, the model was not explored further. As an intermediate to the Consumption and No Consumption runs, a model was explored where the natural mortality at age was calculated as $0.15+$ $\mathrm{M} 2_{\text {age,year. }}$. This model is directly comparable to the No Consumption model as it has exactly the same data, the only difference being the fixed value specified for $\mathrm{M}_{\text {age, year }}$. Compared to the model with $\mathrm{M}=0.4$ for all years and all ages, the total objective function was 71 points greater, and therefore did not provide a better fit to the data.

The remaining six sensitivity runs were all Consumption models with different numbers of selectivity blocks for the directed and bycatch fleet, and with survey selectivity at age estimated or fixed for ages 2 and older. Model diagnostics and the objective function value favored models that had 2 selectivity blocks for the directed fleet (with the break in 1988/1989) and one selectivity block for the bycatch fleet over the alternatives of 1 selectivity block for each, or 3 selectivity blocks for the directed fleet and 2 selectivity blocks for the bycatch fleet. The motivation for introducing selectivity blocks, and the year that they were introduced, was an attempt to account for changes in the fishery composition (disappearance of foreign fleets) and pertinent regulations (mesh size and trip limits). After the number of selectivity blocks was decided, comparisons were made between a flat-topped survey selectivity (the proposed base model) and a formulation that estimated selectivity at age for the surveys (with only age 2 selectivity fixed at 1.0). The overall objective function for the base model was 4526 , while for the model that estimated survey selectivity it was 4491 . Thus, the model that estimated survey selectivity improved the objective function by 35 at the cost of adding 8 parameters to the model. And, as mentioned previously, there is the trade-off between fitting age composition data or fitting the total data series better. The other comparison between these two models is the retrospective diagnostics: the Combined base model had relative biases ranging from $26-41 \%$ while the sensitivity model that estimated survey selectivity at age had relative biases ranging from 32-62\%. Finally, when estimating survey selectivity at age, the model estimated very steep domes with $<10 \%$ selectivity in the plus group for the directed fleet and both surveys. These two models were considered the best contenders of the models explored, and the working group selected the base model (described above) based on the disbelief of such severe domes and the better retrospective diagnostics.

In general, the No Consumption models had lower retrospective analysis diagnostics compared to the Consumption models. Within the Consumption models, decreasing the selectivity blocks improved the retrospective diagnostics while enforcing a flat-top
selectivity worsened the retrospective diagnostics (Table A63).
The intensive examination of model formulations was first explored for the Combined runs, as the likelihood of 'stock' mixing was thought to be high. If stock mixing were occurring, it would result in catch being attributed disproportionately among stocks, and the potential for the survey indices to be more reflective of the seasonal magnitude of mixing rather than any particular stocks' trend in abundance. This was the motivation for the group spending nearly all of the available time on the Combined models. In order to address the terms of reference to explore sensitivity to assumptions of stock structure, some North and South models were explored, but they were simple sensitivities on the structure that had been selected as the base model for the Combined model.

## Silver Hake ASAP Results

Attempts were made to assess silver hake by separating the northern and southern data. However, none of the runs examined had assessment diagnostics which were deemed suitable. The working group recommended a combined analysis of data from both areas, meaning a single stock, as the best performing model, but this was ultimately not accepted by the SARC-51 Review Panel as a basis for management advice. Issues encountered in the northern and southern stock assessments are briefly described below, followed by a more detailed description of the recommended model formulation assuming a single stock.

## Northern Silver Hake

Four runs were examined for the northern silver hake data. Two of the runs included consumption data while the others did not. Of the set of runs which included consumption forced a flat-topped selectivity patterns in the survey indices while the other allowed domed selectivity. The same selectivity patterns were also assumed for the runs without consumption. All four runs assumed time invariant selectivity patterns for each fleet and assumed recruitment deviations occurred relative to a constant mean, as opposed to being relative to a stock-recruitment relationship (Appendices A3-A6).

The run which did not include consumption estimates set natural mortality to 0.4 for all years and ages. The predicted commercial landings are well below the observed values at the start of the time series when the foreign fleets were operating, but then well above the observed values near the end of the time series. These are large deviations in both absolute and relative terms and are a strong indication that the model is not fitting the data well. However, when a domed selectivity is allowed, the fit the landings show an improvement in the absolute and relative magnitude of the residuals. The fit to the discards also exhibits a pattern of underestimating the observed values early in the time series and overestimating them recently. However, these deviations are small in both absolute and relative terms and so are less of a concern. The opposite is true early in the time series when domed selectivity is allowed in the survey with a good fit to the time series in the recent years. The landings and discards at age both have patterns in the residuals, especially at ages one and two. The input effective sample size appears to be a bit high for the commercial landings, where only approximately $20 \%$ of the output effective sample sizes are greater than the input values. The input and output effective
sample sizes for the discards are better matched. Neither of the survey indices are fit well, with patterns in the residuals and large magnitudes for the standardized residuals, but to a lesser degree when domed selectivity is allowed in the survey. The observed magnitude and patterning of the residuals is an indication that the input CV for the surveys is too small relative to the ability to fit the indices. The age composition for both indices is not fit well, with long periods of the same sign of residuals for ages one and two especially. The input effective sample sizes for both indices are too high relative to the output effective sample sizes. The catchability coefficients for both indices are above one, indicating that the estimated population is smaller than the minimum swept area biomass estimated from the surveys. This can occur if the assumed swept area of a tow is too small, for example due to herding of fish, but is generally an indication that there may be a problem in the run. In contrast, when domed selectivity is allowed the catchabilities estimates were well below one which agrees with the very strong dome estimated in the survey with less than $5 \%$ of ages 5 and 6 selected in the survey. The implication of such selectivity pattern resulted in unrealistic estimate of spawning stock biomass reaching approximately 6 million metric tons in the recent years and an expansion of age $6+$ in the population which is contradictory to the both the fishery and the survey. Thus, these runs were not considered acceptable by the working group.

The two runs which did include consumption set the base natural mortality to 0.15 and then entered the consumption time series as an additional fleet. The main difference between these two runs is the selectivity pattern for the two indices where the run which allowed a dome did in fact estimate a strong dome for both indices. However, qualitatively the results from the two runs were still quite similar and are described together here. These runs fit the commercial landings and discards much better than the runs which did not include consumption. The fit to the consumption time series was not fit as well and the landing or discards. The absolute magnitude of the lack of fit to the consumption time series is quite high, but the relatively small standardized deviations indicate that the uncertainty in the consumption values is being appropriately modeled. The age composition for the commercial landings and discards still exhibit patterns in the residuals, especially at ages one and two. There are no age composition residuals for the consumption fleet, meaning that the selectivity patterns should not be estimated. However, the two runs did in fact estimate selectivity patterns based on a double logistic form. These parameters could be estimated because priors were set on the values. However, the resulting selectivity patterns do not make intuitive sense with low selectivity at age one, the age which typically has the highest consumption selectivity. The input effective sample size for the commercial landings is slightly high relative to the output effective sample size, but more closely matched for the commercial discards. The survey indices are fit better than the runs without consumption in terms of there not being a strong pattern in the residuals. However, the magnitude of the standardized residuals is still quite large, indicating that the input CV for the indices is too small relative to how closely the indices can be modeled. The age composition for index 1 is fit reasonably well while index two shows patterns in the residuals for ages one and two. The input effective sample size for both the indices is too high relative to the output effective sample size. The catchability coefficients are more reasonable than the runs without consumption, indicating a relative efficiency of the net around 0.5 . The catch due to the
consumption fleet appears to be quite small in five of the first six years in the time series, which is due to low sampling of predators during this time period instead of a true change in consumption. The mortality rate due to consumption is generally greater than one after the first six years in the time series, with some years above two. This high mortality contrasts with the fishing mortality rates of less than 0.3 for most years. Note that the plot showing the relative spawners (SSB/S0) is treating consumption as a mortality that is not included when computing S0, which it typically would be since it is a form of natural mortality. If this plot was made including consumption mortality as a natural mortality, then the relative spawners would be much closer to one than currently shown.

## Southern Silver Hake Stock

For the southern region, similar model runs were conducted as in the northern region. However, the models in the south had convergence problem which is likely attributed to model mis-specification (i.e. inaccurate definition of stock boundaries). One possible hypothesis is that the model is having difficulties resolving the lack of coherence between the removals from the fishery and the trends in the survey due to possible migration patterns of silver hake to the northern region. The shift in the population density over time will then reflect seasonal distribution in the survey rather than stock specific trend of abundance as explained above.

## Combined Silver Hake Stock

A number of the issues seen in the northern silver hake runs are also apparent in this combined run. Specifically, commercial landings are not fit well at the start of the time series, consumption landings are mostly underestimated, strong patterns are seen in the age composition residuals for all three fleets, the indices are not well fit in terms of either trends in residuals or the magnitude of the standardized residuals, strong patterns are seen in the age composition residuals for index, the relative spawners plot has the same issue as the northern silver hake assessment with consumption, and consumption in the early years appears low. The inclusion of age composition data for the consumption fleet is an improvement relative to the northern silver hake runs, as now there is information to estimate selectivity for this fleet. The estimated selectivity pattern for the consumption fleet is more traditional than the northern silver hake runs, with highest selectivity at age one and decreasing selectivity at older ages. This means that the effect of consumption will be mainly to increase recruitment to account for this additional mortality, but it will not have a large impact on the adult population. However, there is an indirect impact caused by this selectivity pattern because the base natural mortality is 0.15 compared to 0.4 when consumption is not included. Since there is essentially no consumption mortality at old ages, the net effect is to reduce natural mortality on the old fish, which means fishing mortality must be high to prevent old fish from appearing in the age composition.

Given the series of model exploration for North, South and the combined management area formulation, the working group recommended the Consumption model with 2 selectivity block in the directed fleet with a single selectivity in the bycatch fleet. However, this was not accepted by the SARC-51 Review Panel as a basis for management advice.

## Fishing Mortality

Fishing mortality on ages 3+ varied between 0.5 and 1.0 from 1973 to 1995 then increased and varied between 1.0 and 2.0 from 1996 to 2008. The fishing mortality rate in 2009 is estimated to be 0.77 ( $80 \%$ confidence interval $0.58-0.95$ ). Note that the variance estimates include some consumption based mortality estimates. Given the very low mortality on older ages in the population, the influence of consumption on the variance is minimal to negligible (Appendix A2, Table A64).

## Recruitment

Recruitment at age- 1 was relatively low in the early part of the time series, which may be an artifact of consumption mortality being underestimated during this time period. Since then, recruitment has varied without trend between 400 million and 1.1 billion fish annually. The number of age- 1 fish in 2009 is estimated to be 742 million fish ( $80 \%$ confidence interval 616-867 million fish (Appendix A2, Table A65).

## Spawning Stock Biomass

Spawning stock biomass varied around 70 thousand mt during the early part of the time series, but this again could be an artifact due to the low consumption mortality during this time. Spawning stock biomass decreased to approximately 33 thousand mt in 1978 and slowly declined to 55 thousand mt in 2006, but has since increased. Spawning stock biomass in 2009 is estimated to be 23 thousand mt ( $80 \%$ confidence interval 19.5-26.8 thousand mt (Appendix A2, Table A65).

## Natural Mortality

Estimate of Natural mortality (M1+M2) was highest and most variable for age-1 ranging between 0.2 and 1.5 from 1973-1995. Natural mortality declined substantially in 1997 by approximately $70 \%$ resulting in natural mortality estimate of 0.5 . This was also when consumption was relatively low due to very low recruitment. The natural mortality rate in 2009 is estimated to be 1.2 (Appendix 2 and Table A66).

## TOR 5. Evaluate the amount of silver hake consumed by other species as well as the amount due to cannibalism. Include estimates of uncertainty. Relate findings to the stock assessment model.

Food habits were evaluated for a wide range (14) of fish predators that eat silver hake and commonly occur in NEFSC bottom trawl surveys. The amount of food eaten and the type of food eaten were the primary food habits data examined. From these data, per capita consumption, total consumption of silver hake, and an estimate of the amount of silver hake removed by these fish predators were calculated. Combined with abundance estimates of these predators, an amount of silver hake removed by these predators was then calculated. Consumption estimates of silver hake were presented as an estimate that is biased towards conservative values because consumption by birds, marine mammals, large pelagic fish and organisms outside of the survey area were not included. Moreover, swept-area biomass estimates for many of predators were based on bottom trawl survey data (without adjustments for bottom trawl catchability), although stock assessment
results were used for some predators, such that predator abundance estimates and associated silver hake consumption would be mostly underestimates as well.

## Methods

Every predator that contained silver hake was identified from the NEFSC FHDBS. From that original list, a subset of predators (Table A67) was examined to elucidate which predators consistently ate silver hake, determined by "rules of thumb" that include having a diet composition of $>1 \%$ for any five year block, and with $>5$ tows for each two year block and $>10$ stomachs for each three year block.

Annual consumption estimates were calculated on a seasonal basis (two 6 month periods) based on spring and fall bottom trawl surveys and for each predator species. Although the food habits data collections started quantitatively in 1973, not all species of silver hake predators were sampled during the full extent of this sampling program, thus we start our time series here in 1977 (Link and Almeida (2000). This sampling program was a part of the NEFSC bottom trawl survey program (Azarovitz 1981; NEFC 1988). There are various ways to integrate seasonally, but we took the simple sum of the two seasonal estimates in this analysis. We have also done the analyses for various size classes of predators in other instances, but here we have integrated across all predator size classes to come up with a total consumption of silver hake for each predator.

This approach followed previously established and described methods for estimating consumption, using an evacuation rate model methodology. For further details, see Durbin et al. (1983), Ursin et al. (1985), Pennington (1985), Overholtz et al. (1991, 1999, 2000, 2008), Tsou \& Collie (2001a, 2001b), Link \& Garrison (2002), Link et al. (2006, 2008, 2009), Methratta \& Link (2006), Link \& Sosebee (2008), Overholtz \& Link (2007, 2009), Tyrrell et al. (2007, 2008), Link and Idoine (2009), Moustahfid et al. (2009a, 2009b), and NEFSC (e.g., 2006, 2007a, 2007b, 2008, 2010a, 2010b). The main data inputs are mean stomach contents $\left(S_{i}\right)$ for each silver hake predator $i$, diet composition ( $D_{i j}$ ) where the subscript $j$ refers to silver hake as a prey item, and $T$ is the bottom temperature taken from the bottom trawl surveys (Taylor et al. 2005). Units for stomach estimates are in g. We note that we estimated $S$ and $D$ for two-year time blocks to ensure data-density sufficiency for all predators in both seasons and for both stocks; temperature $(T)$ was estimated annually for both seasons and both stock areas.

As noted, to estimate per capita consumption, the gastric evacuation rate method was used (Eggers 1977, Elliott and Persson 1978). There has been copious experience in this region using these models (see references listed above). The two main parameters, $\alpha$ and $\beta$, were set to 0.004 and 0.115 respectively based upon prior studies and sensitivity analyses (NEFSC 2007a, 2007b). The exception is that $\alpha$ was set to 0.002 for elasmobranch predators consistent with and to reflect their slightly lower metabolism than teleost fishes.

Using the evacuation rate model to calculate consumption requires two variables and two parameters. The per capita consumption rate, $C_{i t}$ is calculated as:

$$
C_{i t}=24 \cdot E_{i t} \cdot \overline{S_{i t}} \gamma
$$

where 24 is the number of hours in a day and the evacuation rate $E_{i t}$ is:

$$
E_{i t}=\alpha e^{\beta T} ;
$$

and is formulated such that estimates of mean stomach contents $\left(S_{i t}\right)$ and ambient temperature ( $T$; here used as bottom temperature from the NEFSC bottom trawl surveys for either season (Taylor \& Bascuñán 2000, Taylor et al. 2005)) are the only data required. This was done for each predator $i$ (species) for each time period $t$ (season and year). The parameters $\alpha$ and $\beta$ are set as values chosen noted above. The parameter $\gamma$ is a shape function is almost always set to 1 (Gerking 1994).

Once daily per capita consumption rates were estimated for each silver hake predator, those estimates were then scaled up to a seasonal estimate. This was done by multiplying the number days in each half year, which were then multiplied by the diet composition $D_{i j}$ that was silver hake, to estimate the seasonal per capita consumption of silver hake. That is, once per capita consumption rates were estimated for each silver hake predator in a temporal period $(t)$, those estimates were then scaled up to a seasonal estimate ( $C^{\prime}{ }_{i t}=C_{\text {fall }}$ or $C_{s p r}$ ) by multiplying the number days in each half year:

$$
C_{i t}^{\prime}=C_{i t} \cdot 182.5
$$

These were then multiplied by the diet composition $D_{i j t}$ that was silver hake, to estimate the seasonal per capita consumption of this fish $C_{i j j}$ :

$$
C_{i j t}=C^{\prime}{ }_{i t} \cdot D_{i j t}
$$

These were then summed to provide an annual estimate, $C^{\prime}{ }_{i j}$ :

$$
C^{\prime}{ }_{i j}=C_{i j, \text { fall }}+C_{i j, \text { spring }}
$$

Once these were summed to provide an annual estimate (or the following could be done seasonally and the summed), they were then scaled by the total stock abundance of each predator to estimate the amount of silver hake removed by any of the predators included in the study. We used a swept area estimate of abundance from bottom trawl survey estimates for most predators and recent stock assessment estimates for five of the fourteen (Table A57). Those predators that had stock assessment values were used directly. These consumption estimates were then scaled by the total stock abundance to estimate a total amount of silver hake ( $j$ ) removed by any predator $i, C_{i j}$ :

$$
C_{i j}=C^{\prime}{ }_{i j} \cdot N_{i},
$$

where $N_{i}$ is the estimate of abundance for each predator for each year.
We note that there are several ways to combine variance estimators in these consumption approaches. Estimates of variance for each variable and data type were
calculated, namely about $S, D C$, and $N$. Further particulars of these estimators for the stomach contents and diet composition can be found in Link and Almeida (2000). There are three main ways to present variance about the estimates of consumption. One is to calculate a triple variance estimator that scales to the mean of each parameter $(S, D C$, and $N$ ). Another is to evaluate the maximal CV across all three parameters, across both seasons, and across all species of predator and then carry the largest value for each annual estimate of consumption. Finally, since from prior studies we know that the largest source of variance is associated with the estimates of abundance (scaled to the number), one can take the maximal CV across all predators and seasons for abundance and use that as a proxy for the variance about the consumption estimate. Here we adopted a modification of the third option, using the maximal CVs (associated with abundance estimates) and adopted mild adjustments for $D_{i j}$ and $S_{i}$ on a percentage basis (again, those CVs and means usually are minimized by the scale of the abundance means). The maximum from all predator sets were then used to portray variance for the total amount of silver hake consumed by these fishes. These range from 0.1 to 1.0 and in practice most were on the order of 0.35-0.50.

These predator species-specific consumptions were then summed across all $i$ predators to estimate a total amount of silver hake removed by the predators included in this study. Upon further inspection by season, stock area, and predator species, it was determined that pollock $D C$ were excessively variable, resulting in some notably anomalous and indefensible outputs; thus we removed pollock as a predator from the final estimates of consumption. Thus, these $C_{i j}$ were then summed across all $i$ predators (excluding pollock) to obtain an estimate a total amount of silver hake removed by these silver hake predators, $C_{j}$ :

$$
C_{j}=\sum_{i} C_{i j}
$$

We show both the total consumption, total by species, and total by stock area. We also contrast these estimates with silver hake landings to provide a sense of contrast and magnitude. We also present these consumption estimates as 3 year moving averages to smooth the high degree of inter-annual variability common for these food habits data.

Sizes of silver hake in predators were also calculated as proportions by length in 5 cm bins for each year (combined across predators) across the time series. These can be used to inform the allocation of consumption to those size classes of fish overlapping with the fishery (or survey estimates). In this assessment, the consumption estimates were rescaled to conform with the current model formulation (i.e. age 1-6+). Survey age length keys were used to derive the proportion at length for Age-0 to adjust the consumption at length for each year. This makes the assumption that the survey length distribution within a given age is similar to consumption. For simplicity purposes, a constant probability was used based on an aggregated age-length key across seasons and geographical areas for the combined assessment. Table A68 summarizes the probability used in the analyses. On average, this resulted in a $40 \%$ decrease from the original consumption estimates (Figure A78).

Total consumption was modeled as a separate fleet in the Age Structured Assessment Program (Legault, 2008) to provide estimate of natural mortality based consumption (M2). Detail on the model structure and assumption regarding natural mortality and selectivity are provided in TOR4.

## Results

Total consumptive removals by all consistent silver hake predators, using swept area abundance estimates of the predators, has varied through time ranging between peaking at $4,000 \mathrm{mt}$ in 1975 and peaking at $165,000 \mathrm{mt}$ in 1985. This was followed by a brief decline during the early to mid 1990s and increased substantially in 1999 to approximately $135,000 \mathrm{mt}$. In the last decade, consumption has declined and averaged approximately $70,000 \mathrm{mt}$ in the last five years (Figure A79, Table A69).

Spatially the consumption was approximately equally distributed between the northern and southern stocks (Figure A80), with higher peak values observed in the northern stock.

Although the consumption of silver hake occurred in thirteen predators, the majority of the consumption was attributable to goosefish (Figures A81-A82). For predators with swept area estimated abundance, these were generally lower than those stocks with abundance estimates obtained from stock assessments (summer flounder, goosefish, bluefish, cod), but were dominated by spiny dogfish (Figure A81-A82). These findings were consistent for both the northern and southern stocks combined (Figure A81)

The size of most of the silver hake consumed was $<20 \mathrm{~cm}$ (Figure A83), yet some large fishes were also eaten. Over $50 \%$ of the silver hake eaten in most years were $<15$ cm . We note that this loosely corresponds to the age 0 size class. The proportions also varied by size over the years (Table A70, Figure A81).

These estimates of silver hake consumed by the consistent fish predators in this study were compared to total catch (Figures A79-A80). Silver hake catches and consumption estimates were distinct for much of the time series, with landings higher earlier in the time series (1970s), but with consumption the dominant source of removal since the 1980s. Given this caveat, we note that consumption is approximately 10 times higher than catch in the 2000s.

TOR 6. State the existing stock status definitions for "overfished" and "overfishing". Then update or redefine biological reference points (BRPs; estimates or proxies for BMSY, BTHRESHOLD, and FMSY; and estimates of their uncertainty). If analytic model-based estimates are unavailable, consider recommending alternative measurable proxies for BRPs. Comment on the scientific adequacy of existing BRPs and the "new" (i.e., updated, redefined, or alternative) BRPs.

## Existing Reference Points

The northern silver hake stock overfishing definition (NEFMC 2003) uses a relative exploitation index (total landings divided by NEFSC autumn survey biomass index) as a proxy for fishing mortality. The northern stock is considered overfished when the 3-year average biomass is less than $1 / 2$ the $B_{M S Y}$ proxy ( $B_{M S Y}$ proxy $=6.63 \mathrm{~kg} /$ tow). Overfishing occurs when the 3-year average exploitation index is greater than 2.57, the $F_{M S Y}$ proxy (the average exploitation index during 1973-1982), and is used as both a target and threshold value for fishing mortality for the northern stock (NEFSC 2006)

The southern silver hake stock is considered to be overfished when the three-year moving average of the NMFS autumn survey weight per tow index is less than half of the $B_{M S Y}$ proxy ( $B_{\text {MSY }}$ proxy $=1.78 \mathrm{~kg} /$ tow) $($ NEFMC 2003). Overfishing is considered to be occurring in the silver hake southern stock when the exploitation index (landings divided by the three-year moving average of the delta-distributed fall survey biomass index) exceeds the $F_{\text {MSY }}$ threshold proxy of 34.39 (NEFMC 2002).

There are currently no BRPs for a combined (i.e., north + south) stock.

## New Reference Points

In the absence of an agreed ASAP model run, the newly accepted reference points (in $\mathrm{kg} /$ tow in Albatross units) for both the northern and southern silver hake stocks are as follows:

Silver hake is overfished when the three-year moving average of the fall survey weight per tow (i.e. the biomass threshold) is less than one half the $B_{M S Y}$ proxy, where the $B_{M S Y}$ proxy is defined as the average observed from 1973-1982. The most recent estimates of the biomass thresholds are $3.21 \mathrm{~kg} /$ tow for the northern stock and $0.83 \mathrm{~kg} /$ tow for the southern stock.

Overfishing occurs when the ratio between the catch and the arithmetic fall survey biomass index from the most recent three years exceeds the overfishing threshold. The most recent estimates of the overfishing threshold, are $2.78 \mathrm{kt} / \mathrm{kg}$ for the northern stock and $34.19 \mathrm{kt} / \mathrm{kg}$ for the southern stock of silver hake.

Overfishing threshold estimates were based on annual exploitation ratios (catch divided by arithmetic fall survey biomass) averaged from 1973-1982. Catch per tow is in "Albatross" units.

## TOR7. Evaluate stock status (overfished and overfishing) with respect to the existing BRPs, as well as with respect to the "new" BRPs (from Silver hake TOR 6).

Based on the biological reference points in the existing FMP, the northern stock of silver hake is not overfished and overfishing is not occurring. The three year delta mean biomass index (Figure A66), based on NEFSC fall bottom trawl survey data for 20072009 ( $6.79 \mathrm{~kg} /$ tow), was above the management threshold level ( $3.31 \mathrm{~kg} /$ tow) and
slightly above the target level ( $6.63 \mathrm{~kg} /$ tow $)$. The three year average exploitation index (landings divided by biomass index, Figure A66) for 2007-2009 (0.15) was below the single management threshold/target (2.57).

Similarly, based on the existing BRPs the southern stock of silver hake is not overfished and overfishing is not occurring. The three year delta mean biomass index (Figure A67) based on NEFSC fall bottom trawl survey data for 2007-2009 (1.39 kg/tow) was above the management threshold level ( $0.89 \mathrm{~kg} /$ tow $)$ but below the target level ( $1.78 \mathrm{~kg} /$ tow $)$. The three year average exploitation index (Figure A67) for 2007-2009 (4.33) was below both the management threshold (34.39) and the management target level (20.63).

Based on new biological reference points from SARC 51, the northern stock of silver hake is not overfished and overfishing is not occurring. The three year arithmetic mean biomass index (Figure A68), based on NEFSC fall bottom trawl survey data in Albatross units for 2007-2009 ( $6.20 \mathrm{~kg} /$ tow $)$, was above the management threshold ( $3.21 \mathrm{~kg} /$ tow) and below the target ( $6.42 \mathrm{~kg} /$ tow). The three year average exploitation index (catch divided by biomass index, Figure A68) for 2007-2009 ( $0.20 \mathrm{kt} / \mathrm{kg}$ ) was below the overfishing threshold ( $2.78 \mathrm{kt} / \mathrm{kg}$ ).

Based on new biological reference points from SARC 51, the southern stock of silver hake is not overfished and overfishing is not occurring. The three year arithmetic mean biomass index (Figure A69), based on NEFSC fall bottom trawl survey data in Albatross units for 2007-2009 ( $1.11 \mathrm{~kg} /$ tow $)$, was above the management threshold ( $0.83 \mathrm{~kg} /$ tow $)$ and below the target ( $1.65 \mathrm{~kg} /$ tow). The three year average exploitation index (catch divided by biomass index, Figure A69) for 2007-2009 ( $5.87 \mathrm{kt} / \mathrm{kg}$ ) was below the overfishing threshold ( $34.19 \mathrm{kt} / \mathrm{kg}$ ).

TOR 8. Develop and apply analytical approaches and data that can be used for conducting single and multi-year stock projections and for computing candidate ABCs (Acceptable Biological Catch; see Appendix to the TORs).
> a. Provide numerical short-term projections (3 years). Each projection should estimate and report annual probabilities of exceeding threshold BRPs for $F$, and probabilities of falling below threshold BRPs for biomass. In carrying out projections, consider a range of assumptions about the most important uncertainties in the assessment (e.g., terminal year abundance, variability in recruitment).
b. Comment on which projections seem most realistic, taking into consideration uncertainties in the assessment.
c. Describe this stock's vulnerability to becoming overfished, and how this could affect the choice of $A B C$.

Stock projections were not carried out because the results from the ASAP model were not accepted for stock determination. However, with recent increases in stock biomass in the
north, relatively stable biomass in the south and average recruitments in both areas, with low fishing mortality rates; qualitative analyses suggest that it is unlikely that the northern and southern stocks of silver hake will decline significantly in the short-term. Despite this assertion, uncertainties in the assessment exist due to the unknown cause of age truncation in the age-structure and the unknown magnitude of species mixing in the catch.

## Summary

The population dynamics of silver hake in the northwest Atlantic have changed through time. In particular, patterns in growth and spatial distribution have changed substantially over the last 40years. Age structure, fish growth and spatial distribution reflect stock productivity. The current age structure indicates very little rebuilding of age- 6 and older has occurred. It is likely that the lack of rebuilding of the age structure may have resulted from the continued high fishing mortality rates following the cessation of the distant water fleet.

Survey trends indicate that biomass in the northern area is high and low for the southern stock area. The incoherence of the survey trends relative to the levels of removals in the southern area is likely due to movement and therefore the survey trend may reflect seasonal abundances rather that trends for the southern stock. Although the evidence for silver hake stock structure is equivocal, a combined area model formulation appears to be more robust and stable relative to the north-south split.

Silver hake population constitutes an important link in the food web. Estimates of consumption of silver hake is on the same order of magnitude as estimates of silver hake stock landings, but consistently higher than landings. This is true for the combined evaluation and for both stocks. Estimates of predatory removal of silver hake via consumption are likely conservative given nature of these consumption estimates. These consumption estimates should be useful to inform both the scaling of biomass estimates and the magnitude of mortalities for silver hake. These estimates are likely to be quite informative to the dynamics of silver hake, as they represent a major source of removals and internal dynamics (cannibalism) that is being accounted for.

Silver hake are cannibalistic. Over 870 occurrences occurred out of over 49,000 silver hake stomachs sampled and recorded in the Food Habits Database, or roughly $2 \%$ of every hake caught consumed hake. For perspective, another species thought to be highly cannibalistic, the goosefish (Lophius americanus), only had $0.1 \%$ incidence of cannibalism. On average, silver hake comprised $12 \%$ of the silver hake diet composition (by weight), a significant, consistent and important prey item. This poses some potential tautologies of estimating silver hake abundance to then estimate silver hake cannibalism, which in turn can inform assessment models to estimate silver hake abundance. To accommodate this, we used swept area abundance estimates for silver hake as a predator of silver hake to help scale the total silver hake consumed by silver hake. Cannibalism has implications for recruitment as well, and we are exploring alternative models of stock-recruit relationships to ascertain how much cannibalism can influence those dynamics.

The accepted catch and survey index-based BRPs do not incorporate age structure and do not provide any measures of uncertainty. No age-based analytical model formulations (ASAP) were accepted, nonetheless, the model results were informative. Based on the collective knowledge of the fishery and the surveys, the most likely model (Run 6) did provide indications of trend that were in agreement with the declining age $3+$ spawning numbers from the autumn NEFSC survey. Status quo BRPs are not considered appropriate to set ABC . Recent catches have been considerably less than historical ones, however, $3+$ numbers in the autumn surveys have been declining since the early 1990s under such catches possibly for reasons other than only fishing (Figures A86-A87).

Research to address fishery selectivity and stock composition (mixing of northern and southern components) and the extent of stock distribution is needed to reconcile the issues regarding selectivity in the current ASAP model formulation.

TOR 9. Review, evaluate and report on the status of the SARC and Working Group research recommendations listed in recent SARC reviewed assessments and review panel reports. Identify new research recommendations.

SAW1 (1985)

- Re-analysis of VPA incorporating new stock definitions is currently underway
- By-catch and discard of young silver hake in the shrimp fishery a potential source of significant juvenile mortality
- CPUE indices for southern-and northern stocks need to be reconstructed with different standard fleets
- Consistency of surveys and analytical assessments for tracking cohorts will be examined
- Predatory impact of silver hake is likely significant

SAW17 (1994)

- The subcommittee strongly recommends that the stock structure of this resource be closely examined in order to determine the most appropriate aggregation of landings at age and survey data.
- The subcommittee recommends that the survey series be evaluated to 1 ) determine appropriate strata sets to account for possible differences in distribution between years, 2 ) determine evidence of mixing between stocks, 3 ) determine effect of transformations (e.g., logarithmic or delta) in reducing the impact of unusually high tows.
- The subcommittee recommends that the adequacy of the statistical design of the sea sampling program for estimating discards of silver hake be evaluated. The subcommittee notes that this evaluation should be done across several species and that sampling designs need to reflect the priorities given to each species.
- Sea sampling is not yet substitutable for port sampling. Thus, port samples for length composition are essential to estimate landings at age. Since age-structures collected in the survey do not adequately cover commercially caught fish, the
subcommittee recommends that age structures be collected from either the port sampling or sea sampling programs.
- The subcommittee recommends that the spring and summer Canadian surveys be evaluated for use as tuning indices and as indicators of silver hake geographical distribution.
- The developing fishery for juvenile silver hake should be carefully monitored to establish whether it is targeting concentrations of small fish or sampling landing catches that otherwise would have been discarded. From a scientific basis it would be beneficial to take observers aboard that target silver hake, optimally when participating in an experimental fisheries program. This data collection effort is needed to accumulate catch statistics, measure the length composition of landings and discards, and provide adequate sea sampling to determine discard rate.
- There is a need for a market category designation and adequate sampling for small silver hake ( $<18 \mathrm{~cm}$ ) to properly quantify the magnitude of the landings of these juvenile fish.
- MARMAP data should be examined to gain information on egg and larval silver hake distribution with respect to aggregation of spawning adults.

SAW32 (2001) and SAW42 (2006)

- Develop survey information that covers the offshore range of the population.
- Conduct surveys of spawning aggregations on the southern flank of Georges Bank.
- Investigate bathymetric demography of population.
- Investigate spatial distribution, stock structure and movements of silver hake within Georges Bank, the Gulf of Maine, and the Scotian shelf in relation to physical oceanography.
- Quantify age-specific fecundity of silver hake.

New Research Recommendations (from data and model meetings)

- Studies to estimate discard mortality should be conducted.
- Investigate silver and offshore hake data in deepwater surveys (e.g., monkfish survey).
- Consider hydrographic information in conjunction with the larval indices. This is not currently available, but work is in progress to be able to back-calculate spawning areas.
- Information on consumption by more predators (including mammals, highly migratory species (HMS)) needs to be included.
- Examine diel (day/night) variation in consumption of hakes.
- Validation of the ageing method for silver hake via tagging, radiocarbon, or tetracyclin research needs to be conducted.
- More comprehensive analysis of silver hake stock structure based on DNA (expanded genetic analysis) needs to be conducted.
- Investigate stock identification questions for silver hake by using samples from Tom Helser and Bill Phoel.
- Take M matrix from consumption model and put into model without consumption.

## Sources of Uncertainty

1. The mis-reporting of silver hake in thee landings as offshore hale and vice-versa introduces considerable uncertainty in removals. Landings of silver hake may be over-reported and landings of offshore hake may be under-reported.
2. Survey data indicate relatively large silver hake may move around Georges Bank from South stock area to the northern. Uncertainty about north-south movements of adult silver hake is important because of uncertainty about linkages between the northern and southern stock areas.
3. The decreasing trend in abundance of relatively old and larger individuals. These reductions have occurred despite normal growth patterns, low fishing mortality rates and relative high biomass. This possibility of increased natural mortality due to predation is likely which was explored in this assessment.
4. Consumption
a. Minimum swept area estimates for some predator abundance does not account for $q$ for all predators; these are likely lower estimates of predator abundance and thus these consumption estimates should be viewed as conservative estimates. Although stock assessment estimates of abundance were used for some predators, using a full range of abundance estimates from stock assessments for more predators would also likely increase the estimates noted here.
b. Is the $\alpha$ too low compared to literature? These too may be somewhat conservative, but are within the range of those generally reported. Again, these should be viewed as conservative estimates.
c. Some fish predators that did not consistently eat silver hake (e.g. pollock, some of the skates) were not included in the analysis.
d. Also, these estimates did not include a wide range of other (non-fish) predators known to consume silver hake (e.g., seabirds, squids, marine mammals), nor did they include silver hake cannibalism, which is suspected to be significant. Collectively this relatively limited set of predators thus may result in these being fairly conservative estimates of overall predatory removals of silver hake.
e. Spatio-temporal overlap considerations between predators and silver hake were assumed.
f. The degree of tautology due to silver hake cannibalism (i.e. estimating consumption based upon silver hake abundance, to better estimate silver hake abundance) is worth noting and addressing in further detail at some point in the future.

| Comments | 4 year Peel. Model did not converge initially but now it is??? Unsure about the inconsistent estimation process <br> essment Report | 4 year Peel. Strong Dome . Very High SSB (Cryptic Biomass???) | 4 Year Peel. <br> Relative to model 4, better overall model fit. Better fit to the to the catch but poorer fit to the index with stronger retro. Patterns | 4 Year Peel. <br> Relative to model 2, less improvement in overall fit, but better fit to the index and catch at age comp. Less improvement to the total catch fit, better retro for Rec, Similar retro for F, and stronger retro for SSB. Less doming in the fishery and SSB estimates appears reasonable in the model | Retro2 (4yr peel). Relative to Model 2, Stronger retro for SSB and F rellative to model. Improved overall model fit, less improvement to total index fit but better fit to index age comp. Similar fit to total catch. Better fit to catch at age comp. Q's are similar and strong dome persists <br> Silve | Relative to Model 4, Improved fit in the overall model as well as in the index and catch. Improved Retro Patterns. No Dome in the Fishery | 4 year Peel. Relative to Model 2 and 5, less improvement in overall model fit, total catch and total index , but some improvement in the index catch at age. Stromg dome, lower q's . Better retro patterns for SSB. Slightly stronger for Rec, but better retro for F relative to Model 5. | 4 year Peel. <br> Relative to model 4 and 6, Less improvement in model likelihood with the exception of slight improvement in the firt to the catch at age. Flat top selectivity. Q's are similar to model 4 and 6. Retro Pttaerns improve in Rec and SSB and slighlty improved reative to model 4. | Relative to 1, No improvement in Retro. Less Improvement in likelihood components except for index age comp. |

Table A67. Species of consistent silver hake predators. Whether abundances were estimated from recent stock assessments (SA) or swept area (SWA) from surveys are noted, as is the resolution of the diet data (all predators were presented as two year averages). *Pollock was ultimately excluded from the analyses due to an excessive degree of variability in diet composition comprised of silver hake.

| Common Name | Species Name | Assessment or Swept <br> Area | Diet <br> Resolution |
| :--- | :--- | :--- | :---: |
| Spiny dogfish | Squalusa canthias | SWA | 2 yr |
| Little skate | Raja ocellata | SWA | 2 yr |
| Winter skate | Raja erinacea | SWA | 2 yr |
| Thorny skate | Raja radiata | SWA | 2 yr |
| Silver Hake | Merluccius bilinearis | SWA | 2 yr |
| Atlantic cod | Gadus morhua | SA | 2 yr |
| Pollock* | Pollachius virens | SA | 2 yr |
| Red hake | Urophycis chuss | SWA | 2 yr |
| White hake | Urophycis tenuis | SWA | 2 yr |
| Fourspot flounder | Paralichthys oblongus | SA | 2 yr |
| Summer Flounder | Paralichthys dentatus | SWA | 2 yr |
| Windowpane | Scophthalmus aquosus | SA | 2 yr |
| Bluefish | Pomatomuss altatrix | 2 yr |  |
| Goosefish | Lophius americanus |  | 2 yr |

New England Fishery Management Council
Whiting Advisory Panel Meeting
SMAST - Fairhaven, MA
DRAFT Meeting Summary
August 6, 2010
Purpose of meeting: The advisory panel meeting served as an initial hake assessment meeting for stakeholders and fishermen to provide input on fishery and survey data.

Attendance: Advisors: Dan Farnham and Bill Phoel. Also in attendance were David Goethel (Oversight Committee chair), Andrew Applegate (staff) Steve Cadrin (SSC and WG chair, SMAST), Pingguo He, Klondike Jonas, Yuying Zhang, Tony Wood, and Daniel Goethel (SMAST), Loretta O’Brien, Michele Traver, Katherine Sosebee and Larry Alade (NEFSC), and Dick Allen (advisor at large).

Motions: No motions were made.

## Summary

Steve Cadrin gave a presentation outlining the benchmark assessment Terms of Reference and known issues from previous assessments for the three hake species: silver, offshore, and red. He emphasized that besides simply assessing the status of the stocks with new data and models, it was important that the stock assessment produced sufficient projections for 2011-2013 to set ACLs and specifications within the planned FMP amendment for small mesh multispecies.

All five stocks (northern and southern silver hake, offshore hake, and northern and southern red hake) have existing proxy MSY reference points developed in 2002 during the last amendment, but these may be inconsistent with new estimates of MSY. Dr. Cadrin stressed the importance of making a status determination against the existing reference points as well as against any reference point recommendations that would be estimated and developed. Meeting participants also noted that another benchmark assessment may be a long way off, so that this benchmark assessment needed to identify how future update assessments should be conducted, either by the PDT or another group.

Dr. Cadrin also reviewed the calendar of related meetings, including a data meeting in early September, followed by a models/analysis meeting in late October, and the SAW review in early December.

Larry Alade, Michele Travers, and Kathy Sosebee gave an overview of the assessment data for silver, offshore, and red hakes, respectively. Data for all three species exhibited problems with mis-identification and reporting, uncertain stock structure (north and south stocks for silver and red hake), and difficult to estimate stock dynamics. Particularly for silver hake, it was noted that
landings have been at relatively low levels since 1980, yet the survey biomass indices have not increased very much. The low landings may have been a result of the $5 \%$ groundfish catch limit for small mesh fisheries.

During the presentations, several issues were raised and there was some discussion of possible approaches and analyses to address these issues.

## Silver hake

For silver hake, these issues included mis-reporting of species (silver and offshore hake mixed), stock structure (separate north/south stocks or combined), potential aging errors (misinterpretation of annuli), difficulty in following strong and weak cohorts beyond age 2 , and the effects of cannibalism on biological reference points and productivity. The work group was given a term of reference and had plans to develop model-based estimates of the species composition in landings and discard.

Species composition may be resolved through a variety of means. Although the dealer data is considered to be the more accurate estimate of landings volume, in this case, the vessel trip reports may be the more accurate estimate of species composition. Although sampling frequency in the observer data may be too low to estimate species composition, the VMS data may be useful because silver and offshore hake stratify by depth.

Some suggested that the dealer reports may also be subject to some underreporting, either via sales as bait or via sales to dealers in other states via truck. Some states, particularly CT, obtain these landings and make an aggregate report at the end of the year. Nonetheless, one of the advisors suggested that silver hake reported landings may be as much as 2 million pounds too low. Some discussion also occurred about industrial, or 'trash' fish, landings in the 1960s and 1970s, particularly at the Point Judith fish meal plant. Someone would investigate whether there was more information about those landings. Some fishermen thought that there might have been an increase in CPUE around 1975, when larger vessels began to fish offshore, which also may have lead to an increase in landings of offshore hake. Advisors reported that the hake fishery was market driven, controlled by what can be landed for a price, rather than what can be caught.

Some discussion also occurred about the apparent absence of larger 3+ fish in the survey data, without high landings. It was decided that the working group would inquire about growth ring validation. Fishermen reported that the larger silver hake move more seasonally than the smaller silver hake and can be found in deeper water ( $>40$ fathoms). Periodic or ad hoc offshore surveys, like the cooperative monkfish survey, should be investigated for presence of silver hake in deep water, the working group decided. Some wondered whether the larger fish in the southern portion of the range end up in the northern portion, but there is no tagging data suggesting that this is the case. Hake are difficult to tag due to their delicate nature and high discard mortality.

## Red hake

It has been 20 years since the last red hake assessment and aging data is only available up to
1985. It was noted that there is significant over the side bait sales (supposedly reported on vessel trip reports), but that there were few red hake in the groundfish catch, suggesting low discards by vessels using large groundfish mesh. There were also industrial fish landings that included red hake, potentially recoverable data in the ICNAF data.

Although previous assessments analyzed a northern and southern stock separately, there was little evidence for such a separation. The group decided that a combined assessment would be appropriate, but that separate north/south assessments would also be needed for status determinations using the existing reference points and overfishing definitions.

## Offshore hake

Besides the species composition of the commercial catch discussed in the context of silver hake, the offshore range and what proportion of the stock was sampled by the NMFS trawl survey was an issue. And like silver hake, periodic offshore surveys like the cooperative monkfish survey might be informative. The length of the derived catch series was questioned and it might be difficult to complete an analytical assessment. A catch/biomass exploitation rate might be possible, but its utility as a measure of population trend and mortality would be questionable due to noise caused by availability to the survey and to the fishery. It was suggested that the relationship between the survey index (or number of positive tows) might be related to the NAO and Gulf Stream positioning. The working group thought that this could be a productive avenue for analysis.

Depending on the amount of catch and the range of the stock relative to the commercial fishery, it seemed that offshore hake might be re-classified as an ecosystem fishery component by a new amendment. This would mean that there would be monitoring, but no overfishing definition.

## Other issues; Management and amendment schedule

For both red and silver hake, discards would be estimated and hindcasted, using sea sampling data, most recently collected using standard bycatch reporting methodology (SBRM). Dr. He indicated that there were some experiments planned to estimate discard mortality, but not enough data would be available for this assessment. In the absence of more data, the group thought that $100 \%$ discard mortality was the most reasonable assumption for trawls and especially dredges. Non-catch mortality was discussed, but not having any data, it would be assumed that there was no non-catch mortality of hakes, although some is likely, particularly in scallop dredges and might occur in large mesh trawls.

Andy Applegate gave a brief summary of the amendment timeline and process going forward. He indicated that except for the structure of accountability measures, it was difficult to make much progress on the amendment until the stock assessment was completed because the assessment might change the biological reference points and stock status. He said that the January Council meeting would be the earliest that the Council could approve draft amendment alternatives, which then would be analyzed and taken to public hearing. The Council could consider final alternatives in April, but he thought that June would be much more likely. In this case, the Council would submit the final amendment in June or July, and the final rule could be
published in late 2011, with an ACL that applied to the 2011 fishing year beginning in May 2011. He thought that unless the assessment changed the status, the specification cycle would be for three years, or 2011-2013.

## Appendix A2-A6 Silver Hake ASAP Model Results

# [SAW51 Editor's Note: The SARC-51 peer review panel concluded that no single silver hake ASAP model run provided a suitable basis for providing management advice. The silver hake ASAP model results, which are described in Appendices A2-A6, are included in this report mainly to document the ASAP modeling runs that the Hake Working Group provided to the SARC for peer review.]

## B. Loligo pealeii STOCK ASSESSMENT FOR 2010

## Executive Summary

Term of Reference 1: Landings data are presented for 1963-2010 but the 2010 landings are preliminary and incomplete. Landings of squid (Loligo pealeii and Illex illecebrosus) during 1928-196 were taken inshore and ranged from 500 to $2,000 \mathrm{mt}$. Total landings were dominated by offshore distant water fleets during 1967-1984, averaging 20,130 mt with a peak of $37,613 \mathrm{mt}$ in 1973. After 1986, fishing by distant water fleets was prohibited and landings from the U.S. fleets, dominated by those from the winter offshore fishery, averaged $16,610 \mathrm{mt}$ during 19872009 with a peak of $23,738 \mathrm{mt}$ in 1989. There is substantial uncertainty in the landings data prior to 1987 , due to a lack of observer coverage of distant water fleets prior to 1978 and reporting of unspecified squid catches.

Overall, annual discards were low, averaging 3.4\% of the landings during 1989-2009. However, precision of the estimates was also low. Annual CVs averaged 0.53 during this same period. During 1988-1995, catches were generally at or above the 1987-2008 median ( $17,328 \mathrm{mt}$ ), but have generally been below the median since in-season quotas were implemented, in 2000. After 2005, catches declined and reached the lowest level since 1968 in 2009 (9,560 mt).

Annual trends in nominal LPUE ( $\mathrm{mt} /$ day fished) were correlated for the January-June and JulyDecember fisheries during 1996-2009. However, the trends are difficult to interpret because of one or more fishery closures during each year since 2000 and the lack of a clear understanding of what the LPUE values actually represent given the complex population dynamics of the species.

Term of Reference 2: Characterize the survey data that are being used in the assessment (e.g., regional indices of abundance, recruitment, age-length data, etc.). Describe the uncertainty in these sources of data.

NEFSC fall and spring bottom trawl survey data are used in this assessment to compute qadjusted biomass estimates for two of the primary seasonal cohorts. The average lifespan of a seasonal Loligo cohort is about six months and the spring and fall surveys occur about six months apart. Loligo caught in the spring surveys (March) were hatched about six months prior, during the previous fall, and Loligo caught in the fall (September) surveys were hatched during the previous spring.

Swept-area biomass estimates from inshore fall NEAMAP surveys were used to account for biomass in inshore areas ( $\leq 18 \mathrm{~m}$ ) which are no longer able to be sampled by the new research survey vessel starting in 2009. Only daytime survey tows are used in the assessment because Loligo are most available to bottom trawls during the daytime. The higher catch rates resulting from daytime tows were used in the swept-area biomass calculations and reduced the variance of the stratified mean survey indices during most years. CVs were on the order of $10-25 \%$, indicating reasonable levels of precision.

As is typical for most squid species, abundance and biomass indices for Loligo were highly variable, particularly for NEFSC fall surveys, making it difficult to discern trends. The large
$51^{\text {st }}$ SAW Assessment Report $381 \quad$ Loligo
differences in the biomass estimates for the seasonal cohorts caught in the spring and fall surveys are a major source of uncertainty. The spring biomass levels are only about one fifth of the fall biomass levels. Fall and spring survey indices from the same, but not adjacent, years are correlated. However, it is not known whether these "year" effects reflect true seasonal cohort dynamics for Loligo, which have a cohort lifespan of about 6 months, or if they are due to environmental effects on availability to the survey gear.

Term of Reference 3: Estimate annual fishing mortality, recruitment and stock biomass for the time series, and characterize the uncertainty of those estimates (consider Loligo TOR-4). Include a historical retrospective analysis to allow a comparison with previous assessment results.

A simple survey-based approach, similar to one of the methods used in the previous assessment, was used to estimate biomass and exploitation indices. The method is based on a composite $q$ prior for survey catchability which incorporates uncertainty and bounds on all of the key factors that affect Loligo catchability. Uncertainties in $q$-priors have been substantially reduced since the last assessment by an in-depth review of existing and new information and the results of paired-tow catchability experiments using the survey vessels, SRV Albatross IV and SRV H. B. Bigelow. For "best estimates", we used the median $q$-prior catchability value because the chance of being either too low or too high is $50 \%$ (the median is risk-neutral). One of the most important aspects of the $q$-prior is the upper bound for survey catchability, which corresponds to the upper bound for fishery exploitation and the minimum bound for biomass.

Annual measures of biomass were derived by averaging the annual biomass estimates for the NEFSC fall and spring surveys after adjustment using the median $q$-prior for catchability. Annual biomass fluctuated widely about the median of 76,329 mt during 1976-2009 and ranged between $25,806 \mathrm{mt}$ and $175,894 \mathrm{mt}$. Annual exploitation indices were computed as the annual catch divided by the annual biomass. However, the rapid growth rates, high cohort turnover rates and short lifespan of Loligo make the exploitation indices difficult to interpret. During 19931998, annual exploitation indices were generally at or above the 1987-2008 median (0.237), averaging 0.273 , and generally at or below the median during 1999-2008, averaging 0.18 .

Seasonal Loligo cohorts have different growth rates and the assessment results suggest that cohorts caught in the spring and fall surveys appear to have very different levels of productivity and biomass. Exploitation indices for the January-June fishery (median $=0.315$ ) are much higher on the lesser productive, spring survey cohort than the exploitation indices for the JulyDecember fishery $($ median $=0.064)$ on the more productive fall survey cohort.

Comparison of results from the current assessment with results from historical assessments is difficult because of the lack of temporal overlap between assessments and changes to the data and methods used to estimate stock status. The majority of assessments relied on relative trends in survey data. The stock is now considered lightly exploited but overfishing was determined to be occurring in 2 out of 4 historical assessments. The stock has never been considered overfished, although it was close to its biomass threshold at the time in two cases. In contrast, the current assessment concludes that the stock was not overfished and that overfishing was probably not occurring in 2009.

Term of Reference 4: Summarize what is known about consumptive removals of Loligo by predators and explore how this could influence estimates of natural mortality ( $M$ ).

On an annual basis, Loligo catches appears minor relative to preliminary minimum consumption estimates for a subset of fish predators (i.e. without adjusting abundance for some predators to account for survey catchability and excluding consumption by birds, large pelagic fish and marine mammals). Thus, the consumption data for Loligo provide a frame of reference for judging the potential importance of fishery removals.

Minimum consumption is generally higher on the fall survey cohort than on the spring survey cohort. Seasonal estimates of minimum consumption are a substantial fraction of the estimated biomass, particularly during the spring.

This assessment did not require any assumptions about M. However, natural mortality rates for non-spawning Loligo are known to be high based on their short 6-8 month lifespan, and because the species is semelparous, natural mortality rates after spawning are even higher. Based on the results from two models that have been used to estimate M for other squid species, preliminary estimates of non-spawning and spawning mortality are 0.11 and $0.19-0.48$ per week, respectively. It is doubtful that consumption data would substantially change or improve these estimates of $M$.

Term of Reference 5: State the existing stock status definitions for the terms "overfished" and "overfishing". Then update or redefine biological reference points (BRPs; estimates or proxies for $B_{M S Y}, B_{\text {THRESHOLD, }}$, and $F_{M S Y ;}$ and estimates of their uncertainty). Comment on the scientific adequacy of existing BRPs and for the "new" (i.e., updated, redefined, or alternative) BRPs.

The current overfishing definition states that overfishing is occurring when the exploitation index falls below the 75th percentile of the quarterly exploitation indices during 1987-2000. However, there is no sound scientific basis for using this $F_{M S Y}$ proxy because the Loligo stock is lightly exploited. Under these conditions, any percentile of the exploitation time series is unsuitable as an estimate of or proxy for $F_{M S Y}$.

Conventional approaches for deriving BRPs are based on finfish population dynamics and are inappropriate for Loligo. In particular, there is no theory linking $M$ and $F_{M S Y}$ for short lived squid species like Loligo and per-recruit reference points can only be approximated (a). In addition, there is no theory linking $F_{S P R}$ per-recruit reference points to $F_{M S Y}$ for species like Loligo. Finally, there is too little contrast in the catch or survey data to provide information that could be used to estimate $\mathrm{F}_{\mathrm{MSY}}$ in a modern dynamical model.

There are no existing biomass-based reference points. The current assessment recommends a new threshold $\mathrm{B}_{\mathrm{MSY}}$ proxy of $21,203 \mathrm{mt}$ and a biomass target of $42,405 \mathrm{mt}$. $B_{M S Y}$ is estimated as $B_{M S Y} \approx 0.5 \frac{\breve{b}}{0.9}$ where $\breve{b}$ is the 1976-2008 median annual biomass $(76,329 \mathrm{mt})$. Annual biomass is defined as the average the annual biomass estimates for the NEFSC fall and spring surveys after adjustment using the median $q$-prior for catchability. The median biomass is assumed to represent $90 \%$ of carrying capacity because the stock is lightly fished. If the underlying surplus production curve is symmetrical, $B_{M S Y}$ occurs at $50 \%$ of the carrying capacity. Annual biomass
estimates exceed annual carrying capacity in multiple years, which is to be expected for a species with highly variable seasonal population dynamics which are linked to variability in environmental conditions. It is not necessary for $b$ to be in biomass units because unscaled survey data would give the same results.

Term of Reference 6: Evaluate stock status with respect to the existing BRPs, as well as with respect to the "new" BRPs (from Loligo TOR 5).

There are no existing biomass reference points for the stock, and as a result, overfished status cannot be determined. Based on the current fishing mortality reference point threshold, overfishing was not occurring because the 2009 exploitation index (estimated using the method from SARC 34, Oct-Dec. catch over $q$-adjusted fall survey swept-area biomass) was 0.063 compared to the Fthreshold (i.e., $75^{\text {th }}$ percentile of the exploitation indices during 1987-2009) which is 0.277 ). However, the current F reference point is inappropriate for the lightly exploited Loligo stock. In addition, the new exploitation indices used in the current assessment are not comparable to the existing fishing mortality reference points because of differences in computation methods and input data.

Based on the new recommended biomass reference point threshold from SAW/SARC-51, the stock was not overfished during 2009. The two-year average of catchability-adjusted spring and fall survey biomass levels during 2008-2009 was $54,442 \mathrm{mt}(80 \% \mathrm{CI}=38,452-71,783 \mathrm{mt})$ and is higher than the proposed threshold Bmsy proxy of $21,203 \mathrm{mt}$. The overfishing status during 2009 is unknown because new fishing mortality reference points could not be recommended in the current assessment due to the lack of evidence that fishing impacted annual biomass levels during 1975-2009. The 2009 exploitation index of 0.176 (catch in 2009 divided by the average of the spring and fall survey biomass during 2008-2009; $80 \% \mathrm{CI}=0.124-0.232$ ) was slightly below the 1987-2008 median of 0.237.

Term of Reference 7: Develop approaches for computing candidate ABCs (Acceptable Biological Catch; see Appendix to the TORs), and comment on the ability to perform projections for this stock.

## Possible approaches

Use the omnibus amendment approach. The Council is developing an omnibus amendment that provides the SSC with a general procedure for setting ABC levels. The omnibus approach ranks stocks into four tiers, depending on the information about the stock and reference points provided in the assessment. The omnibus approach is flexible and may well be a sufficient basis for specifying ABC levels for the Loligo fishery.

Consider the differences in seasonal cohort productivity and biomass. Loligo biomass and productivity appear to be substantially lower for the cohort caught in the spring survey than for the cohort caught in the fall survey. Lower spring biomass may be due to a variety of factors, including differences in available habitat, migration patterns, seasonal reproduction, differences in growth rates, and/or consumption removals. Within-year relative abundance indices from the spring and fall surveys are correlated and exploitation indices for the January-June fishery (median $=0.315$ ) are much higher on the less-productive, spring survey cohort than those for the
$51^{\text {st }}$ SAW Assessment Report $384 \quad$ Loligo

July-December fishery (median $=0.064$ ) on the more-productive fall survey cohort.

ABC by analogy to consumption estimates for key predators. Loligo are prey for a wide range of marine fish, diving birds, and marine mammals. Natural mortality rates for non-spawning Loligo range from 0.058 to 0.110 per week ( 3.0 to 5.7 per year) due, presumably, to predation. The ecological importance of Loligo as prey for a wide range of species could be considered in specifying ABC levels.

Consumption estimates for six (cod, bluefish, goosefish, pollock, summer flounder and weakfish) of the 15 Loligo finfish predators included in this assessment are based on predator stock biomass estimates from peer-reviewed assessment reports that include estimates of survey catchability. The consumption estimates for these six species may be plausible estimates of consumption. Considering consumption by humans and fish predators, specifying ABC levels for Loligo based on consumption estimates for important predators may be a practical approach to ecosystem-based management. Consumption is generally higher during the fall than spring and seasonal differences could be considered as well.

Term of Reference 8: Review, evaluate and report on the status of the SARC and Working Group research recommendations listed in recent SARC reviewed assessments and review panel reports. Identify new research recommendations.

Substantial progress was achieved for many of the research recommendations in the last assessment and a number of additional topics were identified. Please see the relevant portions of the text.

## Terms of Reference

1. Characterize the commercial catch including landings, effort, LPUE and discards. Describe the uncertainty in these sources of data.
2. Characterize the survey data that are being used in the assessment (e.g., regional indices of abundance, recruitment, age-length data, etc.). Describe the uncertainty in these sources of data.
3. Estimate annual fishing mortality, recruitment and stock biomass for the time series, and characterize the uncertainty of those estimates (consider Loligo TOR 4). Include a historical retrospective analysis to allow a comparison with previous assessment results.
4. Summarize what is known about consumptive removals of Loligo by predators and explore how this could influence estimates of natural mortality (M).
5. State the existing stock status definitions for the terms "overfished" and "overfishing". Then update or redefine biological reference points (BRPs; estimates or proxies for $\mathrm{B}_{\mathrm{MSY}}$, $\mathrm{B}_{\text {THRESHOLD }}$, and $\mathrm{F}_{\text {MSY; }}$ and estimates of their uncertainty). Comment on the scientific adequacy of existing BRPs and for the "new" (i.e., updated, redefined, or alternative) BRPs.
6. Evaluate stock status with respect to the existing BRPs, as well as with respect to the "new" BRPs (from Loligo TOR 5).
7. Develop approaches for computing candidate ABCs (Acceptable Biological Catch; see Appendix to the TORs), and comment on the ability to perform projections for this stock.
8. Review, evaluate and report on the status of the SARC and Working Group research recommendations listed in recent SARC reviewed assessments and review panel reports. Identify new research recommendations.

## Introduction

## Range, distribution and life history

Longfin inshore squid (Loligo pealeii) are distributed primarily in continental shelf waters located between Newfoundland and the Gulf of Venezuela (Cohen 1976; Dawe et al. 1990). In the northwest Atlantic Ocean, longfin squid are most abundant in the waters between Georges Bank and Cape Hatteras, NC where the species is commercially exploited. The stock area extends from the Gulf of Maine to southern Florida. However, the southern limit of the species' distribution in US waters is unknown due to an overlap in geographic distribution with the congener, Loligo pleii, which cannot be visually distinguished from L. pealeii using gross morphology (Cohen 1976). A recent genetics study indicates that the population inhabiting the waters between Cape Cod Bay, MA and Cape Hatteras, NC is a single stock (Shaw et al. 2010). Distribution varies seasonally. North of Cape Hatteras, squid migrate offshore during late autumn to overwinter in warmer waters along the shelf edge and slope, and then return inshore during the spring where they remain until late autumn (Jacobson 2005).

The life history characteristics of short-lived, semelparous cephalopod species, like Loligo pealeii, present some unique challenges to stock assessment and most of the traditional approaches that have been used for finfish species have not been successfully applied to squid stocks (Boyle and Rodhouse 2005). Loligo pealeii serves as a key prey species for a variety of marine mammals, diving birds, and finfish species (Clarke 1996; Overholtz et al. 2000; Jacobson 2005). Consequently, natural mortality rates are very high, especially after spawning. The species is migrates long distances during its short lifespan; inshore during spring and offshore during late fall. Recruitment occurs throughout the year with seasonal peaks in overlapping "microcohorts" which have rapid and different growth rates (Brodziak and Macy 1996; Macy and Brodziak 2001). As a result, seasonally stable biomass estimates may mask substantial population turnover (Guerra et al. 2010). Recruitment of L. pealeii is largely driven by environmental factors (Dawe et al. 2007). For most squid species, temperature plays a large role in migrations and distribution, growth, and spawning (Boyle and Rodhouse 2005). For Loligo pealeii, individuals hatched in warmer waters during the summer grow more rapidly than those hatched in winter and males grow faster and attain larger sizes than females (Brodziak and Macy 1996).

A schematic of the life history of Loligo pealeii, in relation to the timing of the directed fisheries and NEFSC surveys is shown in Figure B1. Recruitment occurs year-round with seasonal peaks in cohorts. The average lifespan of a Loligo pealeii cohort is about six months. Individuals
hatched inshore during the summer are taken in the winter offshore fishery and those hatched in the winter are taken in the inshore summer fishery (Macy and Brodziak 2001). Age data indicate that NEFSC spring surveys (March-April) capture Loligo that were hatched during the previous six months, in the fall, and Loligo caught in the NEFSC fall surveys (September-October) were hatched during the previous spring. Loligo peaeleii attaches its egg masses to the substrate and fixed objects (MAFMC 2009). Fishing and spawning mortality occur concurrently during late spring through fall, when spawning Loligo and an unknown proportion of their egg masses are taken inshore, in bottom trawl fisheries (Hatfield and Cadrin 2002) and in weirs (MAFMC 2009). The locations of spawning sites at other times of the year are unknown.

## Management background

During 1974-1977, the Loligo pealeii stock was managed by the Northwest Atlantic Fisheries Organization (formerly ICNAF) and was subject to annual TACs (Lange and Sissenwine 1980). Historically, the distant water fleets fishing for Loligo were subject to a minimum codend mesh size ( 60 mm inside stretched mesh), fishing in defined offshore fishing areas during the fall and winter (Kolator and Long 1980). Since 1978, the stock has been managed by the Mid-Atlantic Fishery Management Council (MAFMC) under the Atlantic Mackerel, Squid, and Butterfish Fishery Management Plan (MSB FMP). Distant water fleets have been prohibited from fishing for Loligo pealeii in US waters since 1987. Since 1996, the primary stock management measures have included: a total allowable catch (TAC); mandatory reporting of Loligo landings purchased by federally-permitted dealers; and mandatory submittal of Vessel Trip Reports (VTRs) by fishermen who possess federal Loligo/butterfish moratorium and incidental catch permits (Table B1). A minimum codend mesh size requirement of 48 mm (17/8 in., inside stretched mesh) and a strengthener minimum mesh size of 114 mm ( 4.5 in .) were also implemented in 1996.

Since 2000, the Loligo fishery has been subject to in-season quotas which were trimester-based during 2000 and 2007-2010 and quarterly-based during 2001-2006. When the in-season quotas are attained, trip limits of $<2,500 \mathrm{lbs}$ go into effect. Since 2000, Loligo fishery closures have occurred when $90 \%$ of each trimester or quarterly quota was landed or when $95 \%$ of the annual quota was landed. Closures have occurred at least once per year under this management system (Table B2). The annual quota has only been exceeded once, during 2000, when the quota of $15,000 \mathrm{mt}$ was exceeded by $16.5 \%$. Currently, the annual quota is allocated as: $43 \%$ in Trimester $1,17 \%$ in Trimester 2, and $40 \%$ in Trimester 3. Currently, there are also roll-overs of quota underages (Trimester 1 toTrimesters 2 and 3; Trimester 2 to Trimester 3) and overages (Trimesters 1 and 2 to Trimester 3).

Term of Reference 1: Characterize the commercial catch including landings, effort, LPUE and discards. Describe the uncertainty in these sources of data.

The stock boundary includes all Statistical Areas located within the Northeast Region of the Northwest Atlantic Ocean (Figure B2). Commercial landings data are available for 1963-2009 (Table B3, Figure B3). The 2010 landings data are presented as well, but are preliminary and incomplete (i.e, retrieved from the landings database on October 27, 2010).

Several caveats are important in interpreting landings data. The two major species of squid
landed in US east coast waters (i.e., Illex illecebrosus and Loligo pealeii) were not recorded by species until 1979. Landings during 1963-1978 for each species were estimated by proration (Lange and Sissenwine 1980). Since 1979, a portion of the U.S. squid landings have been reported as unspecified squid species (i.e., Illex illecebrosus and Loligo pealeii). Unspecified squid landings for 1982-1995 were prorated by month and two-digit Statistical Area by Cadrin and Hatfield (1999) and these landings are included in the current assessment. Unspecified squid landings reported from 1996 onward have been much lower ( $0-161 \mathrm{mt}$ per year), and since a majority of the prorated landings of unspecified squid are L. pealeii landings, all unspecified squid landings were combined with the L. pealeii landings for 1996-2009.

Several different methods have been used to collect the landings, fishing location and effort data. During 1963 through April of 1994, U.S. commercial landings, effort, fishing area, and other fishery-related data were collected and entered into Northeast Region Commercial Fisheries Database (CFDBS) by NMFS port agents, who entered landings data from all dealer purchase receipts and interviewed a subset of captains to obtain information about fishing location and effort (Burns et al. 1983). Since then, landings data have been self-reported electronically by dealers who have a federal permit to purchase Loligo, but such reporting was not mandatory until 1996. Beginning in May of 1994, fishing location (Statistical Area) and effort data, plus estimated catch, were self-reported by fishermen on logbooks (i.e., Vessel Trip Reports or VTRs) and are entered into the Vessel Trip Report Database. However, submittal of VTRs was not mandatory for fishermen who hold Loligo fishing permits until 1996. In order to integrate data from the VTR Database with data from the CFDBS, an "allocation" database was created using a trip-based allocation scheme (Wigley et al. 2008). Landings data are assumed known and originate from the CFDBS. The allocation determines the area fished and effort information reported on the VTR data and joins this information with the landings data from each trip as reported in the CFDBS. Two levels (A and B) represent vessel-oriented data and two levels (C and D) represent fleet-oriented data. Level A comprises audited VTR trips that have not been grouped and for which a one-to-one match exists between the VTR and CFDBS fields which define a trip (i.e., year, month, day and permit). Level B comprises VTR trips from Level A that have been pooled by vessel permit, gear group, main species group, and month. Level C comprises VTR trips from Level A that have been pooled by ton class, port group, gear group, main species group, and calendar quarter. Level D comprises VTR trips from Level A that have been grouped by port group. If a CFDBS trip has a corresponding one-to-one match with a VTR trip, then the area fished and the effort information, if present, is transferred directly onto the CFDBS trip record. "A" level trips correspond to pre-1994 trips for which similar information was obtained from a vessel captain via a port agent interview.

## Landings

The U.S. squid fishery began in the late 1800s as a source of bait, and from 1928 to 1967, annual squid landings (including Illex illecebrosus landings) from Maine to North Carolina ranged from 500 to $2,000 \mathrm{mt}$ (Lange 1980). During 1964 through the mid-1980s, landings of $L$. pealeii by distant water fleets occurred in offshore waters and landings by the U.S. fishery occurred when Loligo were available inshore during spring and summer (Lange et al. 1984). Total landings increased rapidly during 1967-1973 with the development of a directed fishery by distant water fleets in offshore waters, from 1,677 mt in 1967 to a peak of $37,613 \mathrm{mt}$ in 1973, but then declined to $10,646 \mathrm{mt}$ in 1978 (Figure B3, Table B3). Total landings were dominated by landings
from the foreign fleets during 1967-1984, ranging between $76 \%$ and $98 \%$ of the total landings during most years and averaging 20,130 mt.

During 1978-1982, bottom trawlers engaged in directed fisheries for Illex and Loligo in U.S. waters were required to fish with a minimum codend mesh size of 60 mm (with specific chafing gear requirements) and were restricted to fishing seaward of the 183 m isobath and during late fall through winter (ICNAF 1978). Fishing by distant water fleets was phased out by 1987 due to the development of an offshore U.S. fishery for L. pealeii. There is substantial uncertainty in the landings data prior to 1987, due to the lack of observer coverage of distant water fleets prior to 1978 and low coverage thereafter, and because unspecified squid landings were as high as $20 \%$ during some years (Cadrin and Hatfield 1999).

The domestic fishery currently occurs primarily in Southern New England and Mid-Atlantic waters, but some fishing also occurs along the southern edge of Georges Bank. Spatial patterns in fishing effort reflect seasonal Loligo migration patterns whereby effort is generally directed offshore during October-March and inshore during April-September (Figure B4). The fishery is dominated by small-mesh otter trawlers, modal codend mesh size $=50 \mathrm{~mm}$ inside stretched mesh (Hendrickson 2011), but near-shore pound net and weir fisheries also occur during spring and summer. During 1963-1982, the domestic fishery occurred primarily in inshore waters during spring and summer. Offshore fishing by U.S. vessels began in 1983. During 1987-1999, total landings averaged 18,453 mt with a peak of 23,738 mt in 1989 (Table B3).

Since the implementation of in-season quotas, in 2000, landings have been lower (averaging $14,214 \mathrm{mt}$ ) and have declined from $16,720 \mathrm{mt}$ in 2005 to $9,307 \mathrm{mt}$ in 2009. Although preliminary and incomplete, the 2010 landings through mid-October are very low ( $5,256 \mathrm{mt}$ ). Despite a general decline in landings during 1994-2009, the annual ex-vessel price (average dollars per lb in 1990 dollars) of $L$. pealeii increased during 1990-1998 (from $\$ 0.43 / \mathrm{lb}$ to $\$ 0.83 / \mathrm{lb}$ ), then decreased to $\$ 0.60 / \mathrm{lb}$ in 2000, but remained remained fairly stable thereafter (Figure B5). Since 1996, annual TACs have ranged between $15,000 \mathrm{mt}$ and $25,000 \mathrm{mt}$ and were only exceeded in 2000, when the annual TAC of $15,000 \mathrm{mt}$ was exceeded by $16.9 \%$ (Table B3).

Changes in the monthly distribution of landings occurred during 1987-2009, particularly during the first half of the year. Since 1989, most of the landings have been taken in the offshore winter fishery, during Quarters 1 and 4 (Cadrin and Hatfield 1999). Between 1987-1995 and 1996-1999 (mandatory reporting of squid landings began in 1996), landings increased by $9 \%$ during Quarter 1 and decreased by $9 \%$ during Quarter 2, but remained similar during Quarters 3 and 4 (Figure B6).

Since 2000, the seasonal distribution of landings has been affected by in-season quotas (i.e., quotas were trimester-based in 2000 and during 2007-2009 and quarterly-based during 20012006) which have led to one or more fishery closures per year. Landings increased during January from 10\% during 1996-1999 to 13\% during 2000-2009. Landings during Quarter 2 increased from 16\% during 1996-1999- to $18 \%$ during 2000-2009 (Figure B6). During 20072009, landings during Trimesters 1-3 represented $43 \%, 26 \%$ and $32 \%$ of the total landings, respectively.

During 1994-2009, most of the Loligo landings were from Rhode Island ports which accounted
for 40-50\% of the total during 1994-2002 and 55-60\% of the total during 2003-2009 (Figure B7). The second and third highest percentages of the annual landings since 1994 were from New York ( $15-34 \%$ ) and New Jersey ports. The proportion of total landings in New Jersey ports declined from $31 \%$ in 1994, to $9 \%$ in 2004 then increased to $17 \%$ in 2009. Massachusetts and Connecticut ports accounted for $<10 \%$ of landings since 1994.

## Landings size composition

The size composition of the landings was estimated from samples collected at the principal ports where Loligo are landed. The numbers of samples and landings length composition for 19871995 was taken from Cadrin and Hatfield (1999) and the landings length composition for 19962009 was updated for the current assessment. Annual sampling intensity was low during 19871996, ranging between 48 and 94 trips per year, with no sampling of trips during some months (Table B4). After 1996, sampling intensity increased and ranged between 131 and 214 trips per year with sampling during every month.

Most L. pealeii landings during 1987-1996 were landed as "Unclassified" rather than by market category (i.e., Large, Medium, Small and Super Small). After 1996, sampling occurred by market category and the numbers of length samples also increased (Table B5). During 19962009, there was a large amount of size overlap between the different market categories (Figure B8). Most samples were from the Unclassified size category, which includes all sizes except for a portion of squid in the Large size category.

Landings at length were estimated using monthly, quarterly and half-year time bins, depending on sample availability by month and market category. Numbers of Loligo length samples, by month and market category, are presented in Table B6. Unclassified sizes were prorated. Sampled length compositions were expanded to the landings using predicted sample weights (Lange and Johnson 1981). A small proportion ( $<0.05$ ) of squid between 5 and 8 cm dorsal mantle length (DML) are partially recruited to the fishery, but most pre-recruits are $>8 \mathrm{~cm}$ DML. Squid were fully recruited to the fishery at 12 cm DML during 1987-2009 (Figure B9). Length compositions of the landings were similar for 1996-1999, a period of annual quota management, and 2000-2009, a period of in-season quota management, but a greater proportion of squid larger than 18 cm DML were landed during 1987-1995 (Figure B9).

## Discards

Kept and discarded portions of the catches, along with length composition data for both portions, have been collected onboard fishing vessels by the Northeast Fishery Observer Program (NEFOP) since 1989. Discards for the most recent Loligo assessment (NEFSC 2002a) were assumed to be $6 \%$ of the landings, based on an analysis conducted by (Cadrin and Hatfield (1999). Cadrin and Hatfield (1999) computed an average ratio of discarded to kept Loligo of 6\% based on observed tows from all otter trawl trips ( $\mathrm{N}=915$ trips) which landed L. pealeii during 1989-1998. Quarterly discard to kept ratios for these trips were scaled up to the quarterly landings then summed across quarters to obtain annual discard estimates. The total amount of discards from trips with no Loligo landings (i.e., trips where all Loligo catches were discarded)
was minor ( 10 mt for 207 trips).
For the subject assessment, the combined ratio method (Wigley et al. 2007), which has become the standard discard estimation methodology for the Northeast Fisheries Science Center stock assessments, was used to estimate Loligo discards (mt) and their precision (CV) during 19892009. The combined ratio method is based on a ratio estimate pooled over all strata and trips within a fleet. For each trip, a combined discard to catch ( $\mathrm{d} / \mathrm{k}$ ) ratio estimator (Cochran 1977) was computed using NEFOP data, where $\mathrm{d}=$ discard weight of Loligo and $\mathrm{k}=\mathrm{kept}$ weight of all species. These discard ratios were then expanded by the total weight of all species landed during a trip (using landings from the dealer database) to estimate total discard weight.

Strata included in the discard analysis included: gear type, bottom trawl codend mesh size, and fishing region. The majority of Loligo discards occur in trawl fisheries Cadrin and Hatfield 1999). Therefore, bottom trawls, midwater trawls and scallop trawls/dredges were included in the current discard analysis. Fishing trips that occurred within in Statistical Areas $\geq 600$ and $<$ 600 were defined as the Mid-Atlantic and New England regions, respectively. Bottom trawl codend mesh sizes categories included: large mesh (codend mesh sizes $\geq 5.5 \mathrm{in}$.), medium mesh (codend mesh sizes of 2.5-5.49 in.), and small mesh (codend mesh sizes $<2.5 \mathrm{in}$.). Discards were estimated by quarter and cells with fewer than two trips were imputed using the respective annual estimate for each stratum. Discards that occurred during years where no trips were sampled for a particular fleet were estimated by interpolation and are noted as such in the discard summary tables.

The largest source of Loligo discards during 1989-2009 was from bottom trawl fisheries ( $\geq 95 \%$ during most years), primarily the small-mesh bottom trawl fisheries, which accounted for 60$98 \%$ of the total annual discards during 2001-2009 (Table B7). Most of the small-mesh discards occurred in the Mid-Atlantic region (Table B8). During 2000-2003, when seasonal Loligo quotas were frequently attained and a trip limit of 2,500 lbs was in place, regulatory discarding of Loligo occurred in the directed fishery (MAFMC 2009).

Loligo discard estimates were highly variable inter-annually, ranging between 54 mt and 2,140 mt and averaging 534 mt during 1989-2009 (Table B7). However, the $95 \%$ confidence intervals of the annual estimates were very wide (Figure B10). Overall, annual discards were low in relation to landings, averaging $3.4 \%$ of the landings during 1989-2009. Annual CVs averaged 0.53 during this same period (Table B7). Annual CVs for the small-mesh fleets were lower during 2004-2009 (0.26-0.77), concurrent with increased sampling of small-mesh bottom trawl trips in the Mid-Atlantic region. However, the annual numbers of Mid-Atlantic small-mesh trips that were sampled during 2004-2009 (57-145 trips per year) were very low compared to the numbers of trips for medium and large-mesh fleets (Table B8, Figure B11). In addition to low sampling coverage, the high variability in discard ratios for this schooling species also probably affected the precision of the discard estimates.

## Size composition of the discards

During 1989-2009, the numbers of NEFOP observer trips sampled for length compositions of the
catches for directed Loligo trips (i.e., tows where the captain specified Loligo peaelii as the target species) was fairly high for the kept portion of the catch, particularly from 2004 onward, but the numbers of trips sampled for discards was quite low during most years (Table B9). The low sampling intensity of the discards may have been attributable to a low incidence of discarding, but this possibility was not examined.

Since 2000, Loligo trip limits have been in effect for the directed fishery during portions of each year. Therefore, discard size compositions were compared for 1994-1999, 2001-2006 and 2000 and 2007-2009. The discard reason indicated by the captain for most tows was lack of a market for small individuals and this is evident in the discard size composition data. The modal size of the discards was 5 cm DML during 1994-1999, and was 8 cm DML from 2000 onward (Figure B12). Discards were generally small squid ( $\leq 10 \mathrm{~cm}$ DML), but a greater percentage of squid larger than 10 cm were discarded during 2001-2006, a period when the fishery was closed multiple times per year during 2002, 2005 and 2006 (Table B2). The size compositions of the kept portions of the catches during 2000-2009 were similar to the size composition of the landings during the same time period (Figure B9), with a modal size of about 12 cm DML (Figure B12).

## Catches

Total catches during the period of dominance by the distant water fleets (1967-1984) averaged $20,814 \mathrm{mt}$ with a peak of $38,892 \mathrm{mt}$ in 1973 (Figure B13; Table B10). During the period of dominance by the domestic fishery, (1987-2009), catches averaged $17,181 \mathrm{mt}$ with a peak of 24,566 mt in 1994. Catches for 1989-2009 include quantitative estimates of discards. However, since most of the catch consists of landings, and landings are substantially uncertain prior to 1987 (Cadrin and Hatfield 1999), this assessment focuses on catches during 1987-2009. During 1988-1995, catches were generally at or above the 1987-2008 median ( $17,328 \mathrm{mt}$ ), but have generally been below the median since in-season quotas were implemented in 2000. After 2005, catches declined to the lowest level since 1968 in 2009 (9,560 mt).

## Nominal LPUE

As described above in paragraph two of this Term of Reference, reporting of Loligo landings purchased by federally permitted dealers and Loligo catches by federally permitted fishermen did not become mandatory until 1996. Therefore, a nominal LPUE time series was derived from Loligo fishery data for 1996-2009. Since 2000, when in-season quotas were implemented, the regulatory definition of a directed Loligo trip has been a trip for which $\geq 2,500 \mathrm{lbs}$ of Loligo was landed. Trips with $\geq 2,500 \mathrm{lbs}$ of Loligo comprised $90 \%$ of the cumulative Loligo landings during 1996-1999 and 2000-2009 (Figure B14A), which equates to trips where Loligo comprised $>30 \%$ of the landed trip weight (i.e., the $40 \%$ bin in Figure B14B). During 1996-2009, most of the annual Loligo landings were taken in trips lasting 2-7 days (Figure B15). During 1996-2009, a fairly high percentage of the annual Loligo landings in the CFDBS, $60-75 \%$, matched on a one-to-one basis with VTR trips (i.e., "A" level trips) and could be used to compute nominal LPUE (Figure B16). Nominal LPUE was calculated for the January-June fishery and the JulyDecember fishery based on the regulatory definition of a directed Loligo trip.

During the period of quarterly landings quotas, 2001-2006, nominal effort (days fished) was higher during January and February, than when either annual or trimester quotas were in place (Figure B17). Since implementation of trimester-based quotas, in 2007, nominal effort during January-May has been greatly reduced, but annual effort has remained highest during JanuaryMarch. Nominal effort in both the January-June and July-December fisheries were much lower during 2000-2009, than during 1996-1999, primarily due to fishery closures when the in-season quotas were attained (Table B11, Figure B18A).

In summary, the July-December fishery shows an increasing trend in nominal LPUE during 1996-2004, followed by a decrease through 2009 (Figure B18A). The nominal LPUE trend is similar for the January-June fishery, but the trend is delayed by one year. LPUE trends for the two fisheries are correlated $(r=0.48)$. However, these trends are difficult to interpret because of one or more fishery closures during each year since 2000 and the lack of a clear understanding of what the LPUE values actually represent given the complex population dynamics of the species and the fact that effort has not been standardized.

Term of Reference 2: Characterize the survey data that are being used in the assessment (e.g., regional indices of abundance, recruitment, age-length data, etc.). Describe the uncertainty in these sources of data.

## Seasonal distribution patterns

The NEFSC conducts annual bottom trawl surveys, using a stratified random design (Azarovitz 1981), during the fall (generally during September-October) and spring (generally during MarchApril) between the Gulf of Maine and Cape Hatteras, North Carolina (Figure B19). Inshore strata ( $8-27 \mathrm{~m}$ ) and offshore strata ( $27-366 \mathrm{~m}$ ) have been most consistently sampled by the SRVs Albatross IV and Delaware II since 1975.

The distribution of Loligo during the spring and fall surveys depends on the timing of the survey in relation to the annual offshore and southerly migration of Loligo in the fall and the inshore and northerly migration of the species in the spring. In general, the species is distributed offshore during October-March and inshore during April-September. During fall surveys, Loligo are widely distributed across most of the shelf (Figure B20). Squid $\leq 8 \mathrm{~cm}$ DML (fishery prerecruits) prefer shallow depths of $<55 \mathrm{~m}$ (catches were highest at bottom temperatures $>16^{\circ} \mathrm{C}$ ) and squid larger than 8 cm DML (recruits) prefer deeper waters of 111-366 m where bottom temperatures are $11-16^{\circ} \mathrm{C}$ (Brodziak and Hendrickson 1999). During spring surveys, Loligo are distributed primarily in warmer offshore waters near the edge of the shelf (Figure B20) where bottom temperatures are $\geq 8^{\circ} \mathrm{C}$ (Summers 1969). A portion of the stock is also distributed south of Cape Hatteras, North Carolina during both survey periods. However, the amount is unknown because the strata south of Cape Hatteras are not consistently sampled during every survey and the species' range overlaps with the congener, Loligo pleii, which cannot be readily distinguished from L. pealeii at sea on the basis of gross morphology (Cohen 1976). Thus, it is unknown which of the two Loligo species is represented in the catches shown south of Cape Hatteras (Figure B20).

## Survey relative abundance and biomass indices

Indices of relative abundance (stratified mean number per tow) and biomass (stratified mean kg per tow) were derived for fishery pre-recruits ( $\leq 8 \mathrm{~cm}$ DML) and recruits ( $>8 \mathrm{~cm} \mathrm{DML}$ ), as well $51^{\text {st }}$ SAW Assessment Report
as all sizes combined, for NEFSC spring and fall bottom trawl surveys. Important improvements to the indices used in this assessment include:

1) Expanding the set of survey strata to include most of the surveyed area where Loligo occur. The previous assessment included only offshore habitat (strata 1-23, 25 and 61-76) and this assessment includes important inshore and offshore habitat (inshore strata 2-46, 58-61, and 65-66 plus offshore strata 1-23, 25-26, and 61-76).
2) Derivation of relative abundance and biomass estimates for both of the primary Loligo cohorts caught in the NEFSC fall (1975-2009) and spring surveys (1976-2010). An average of the annual spring and fall survey biomass is used as the main survey time series instead of using only the fall survey.
3) Use of an adjustment factor to account for the survey door change that occurred in 1985 (i.e., pre-1985 kg per tow x 1.24 ; no adjustment for number per tow (Byrne and Forrester (1991a)).
4) Use of SRV Delaware II catchability adjustment factors for both surveys to obtain Albatross IV equivalents (i.e., DE II number per tow x 0.83 and weight per tow x 0.85 (Byrne and Forrester 1991b)).
5) Use of "daytime" tows instead of using all tows with night and dawn/dusk converted to daytime equivalents using diel catchability factors estimated using a GLM
6) Addition of swept-area biomass estimates from the fall NEAMAP surveys to account for biomass in inshore areas ( $\leq 18 \mathrm{~m}$ ) which are no longer able to be sampled by the new research vessel (SRV H. B. Bigelow) beginning in 2009.
7) Use of "daytime" calibration coefficients, as of 2009, to convert SRV H. B. Bigelow catches (for numbers of recruits, pre-recruits, and all sizes combined) to $A L I V$ equivalents

## Definition of Loligo habitat

The strata set used to derive relative abundance and biomass indices from the NEFSC spring and fall surveys has been expanded to include important inshore habitat (inshore strata 2-46, 58-61, and 65-66, shown in pink) as well as the offshore habitat included in the previous assessment (offshore strata 1-23, 25-26, and 61-76, shown in blue, Figure B21). Since 2009, when the SRV H. B. Bigelow replaced the SRV Albatross IV, the two shallowest series of inshore strata (8-18 m depths) are no longer sampled due to the deeper draft of the Bigelow. Since these inshore strata constitute important Loligo habitat during the fall, the swept-area biomass estimate from the 2009 NEAMAP survey was added to the 2009 biomass estimate from the NEFSC fall survey to compute total stock biomass. The estimation method and results are described below in the section for Term of Reference 3.

## Diel effects on bottom trawl catches of Loligo

Catches of Loligo in bottom trawls tend to be higher during the daytime because of diel
migration patterns. Loligo are on or near the bottom during the day and feeding higher in the water column at night (Sissenwine and Bowman 1978). Diel effects on survey catches of Loligo are size-dependent (Brodziak and Hendrickson 1999). The swept-area based methods used in this assessment are most accurate when the survey data are for daytime tows only because they provide estimates as close as possible to actual stock biomass.

In the most recent stock assessment (NEFSC 2002a), tows during dawn/dusk and nighttime were adjusted to daytime equivalents based on adjustment factors, for pre-recruit and recruit squid, from GLM models fit to log transformed catches for positive tows. The primary disadvantages of the approach used in the last assessment are: 1) diel effects on the probability of a positive tow are ignored; 2) bias in adjustment factors due to log transforming survey catches is ignored; 3) additional model and estimation uncertainty is generated; and 4) model and estimation uncertainty are not included in the variance estimates for survey mean numbers and weight per tow.

In this assessment, only survey data from daytime tows are used. The major benefits are that stratified mean numbers and weight per tow provide more accurate measures of stock biomass (in effect, the capture efficiency of the survey gear is increased) and estimates have similar or lower CVs (equivalent or increased precision). Other benefits of using only daytime tows are: 1) zero tows are included in calculations so that diel effects on the probability of a positive tow are handled automatically; 2) additional and complex modeling to estimate adjustment factors and their variance is not required; 3) standard variance formulas for stratified means are unbiased estimates of sampling variability in mean numbers and weight per tow; 4) differences in diel adjustments for individual sizes are accommodated automatically; and 5) the approach is very simple and easy to implement in standard software used to calculate stratified random mean number and weight per tow indices.

The major potential disadvantages are that sample size (i.e., number of tows) is reduced and strata sampled exclusively during the night are omitted. Both of these disadvantages are exacerbated if the number of tows per stratum is often small. Another disadvantage is that criteria for defining the daytime period are required in deciding which tows to use and which tows to omit from calculations. In this assessment, GAM models and a grid-search procedure were used to find objective criteria for defining daytime tows based on the solar zenith (see Appendix B2). Solar zenith is the angle of the sun at the time of a survey tow relative to a line drawn normal to the earth at the geographic location of a tow and is the primary factor controlling irradiance at the ocean surface and at depth. Solar zenith is more useful than time of day in modeling because illumination depends on latitude, longitude, Julian date and year (which are all used in calculation of the solar zenith). Although there is a clear general relationship between solar zenith and time of day (Figure B22), tows carried out at the same time but at different geographic locations may have substantially different solar zenith and illumination levels that might affect survey catchability.

The results of the grid-search procedure (Appendix B2) show that a wide range of criteria work for defining cut points for daytime tows and that it is only important to avoid using tows conducted at night. An objective method was used to select the solar zenith cut points, performance scores based on an approximate mean squared error (MSE) approach. Based on this
method, daytime fall survey data used in this assessment include tows with solar zenith values of $43-80^{\circ}$ and daytime spring survey data include tows with solar zenith values of 29-84 ${ }^{\circ}$. In general, daytime tows for these fall and spring survey solar zenith angles were conducted during approximately 6:30 AM-4:30 PM and 6:30 AM-5:30 PM, respectively (Figure B22). The relationships between Loligo catch rates (number per tow) and solar zenith angle for the spring and fall survey time series included in the assessment are shown in Figure B23.

Some strata, particularly small strata with few tows, may be lost using daytime tows only. The practical significance of this loss is modest because the lost strata tend to be small. Maps of station locations indicate that daytime tows cover the entire survey area and that large portions of the survey area are not ignored using daytime tows (Figure B24). There is a general pattern with respect to cruise timing and cruise track from year to year, but sampling stations are randomly selected within strata and delays occur due to special sampling and weather conditions so that the locations of day- and nighttime tows vary from survey to survey. As mentioned above, trends based solely on daytime data are similar to trends based on both day and night data. The trends are robust because catch rates are very low for Loligo during the nighttime. In effect, nighttime tows contribute little additional information about trends in relative abundance of Loligo. The major effect of nighttime tows is to reduce mean numbers and weight per tow by approximately $n_{d} / n_{24}$, where $n_{d}$ is the number of daytime tows and $n_{24}$ is the total number of tows.

Another explanation for the robustness of survey trends to the use of daytime only catches is theoretical. NEFSC bottom trawl surveys are based on numerous small strata and the survey may be over-stratified for a species like Loligo. In the context of an over-stratified survey area, the use of daytime only tows approximates an unbiased two-stage sampling design. The first stage is a random determination (with probability of sampling $=n_{d} / n_{24}$ ) of whether or not a stratum is sampled. The second stage is random selection of tow locations within a sampled stratum. A stratum may be missed entirely if daytime only data are used. However, the effect of the missed stratum is minimized because strata with similar densities of Loligo were likely sampled during the daytime and used to estimate mean numbers and weight per tow.

For Loligo, the potential loss of precision due to reduced sample size is more than counterbalanced by reducing the variability in survey catches. Differences in catch rates between day and night are substantial (e.g., 11.5 times higher during the day than at night, for catches of squid $\leq 8 \mathrm{~cm}$ DML in NEFSC fall surveys, Table B12) and diel sources of variance are removed when only daytime tows are used. Relative abundance indices computed for the daytime tows used in the assessment versus all tows were compared for pre-recruits and recruits during the 1975-2008 fall surveys and the 1976-2008 spring surveys. The results indicate similar annual trends between the sets of indices computed using all tows versus daytime tows for both size categories and time series (Figures B25-B28). In addition, the CVs of indices computed from daytime tows were reduced for pre-recruits and recruits during $65 \%$ and $50 \%$ of the years, respectively, in the fall survey time series (Table B13) and during $70 \%$ and $67 \%$, respectively, of the years in the spring survey time series (Table B14).

The magnitude of the effect of solar zenith on Loligo relative abundance indices (i.e., the percent difference computed using daytime tows versus all tows) was greater during the fall surveys than during the spring surveys and and affected pre-recruits and recruits differently by season. The average increase in daytime relative abundance indices for pre-recruits and recruits from the fall
surveys was $87 \%$ and $172 \%$, respectively (Table B13), and was $56 \%$ and $25 \%$ for the spring surveys, respectively (Table B14).

Similar to trends in relative abundance indices, trends in the percentage of tows with Loligo catch were also similar between daytime tows and all tows during spring and fall surveys (Figure B29). The magnitude of the effect of solar zenith on the percentage of tows with Loligo catch was also greater for fall survey tows (i.e., averages of $77 \%$ for all tows versus $84 \%$ for day tows) than for spring survey tows (i.e., averages of $31 \%$ for all tows versus $33 \%$ for day tows; Figure B29).

## Survey length composition

Loligo length compositions computed using all tows were similar to those computed using "daytime" tows for the fall surveys conducted during 1975-2008 and the spring surveys conducted during 1976-2008 (Figure B30). Squid were fully-recruited to the gear used in the fall and spring surveys at 3 and 4 cm DML, respectively.

The 2009 length compositions of the Bigelow catches were slightly different depending on whether they were computed using all tows or "daytime" tows (Figure B30). For the 2009 fall survey, the "daytime" tows included a smaller proportion of squid larger than 7 cm DML than the length composition of all tows, but the opposite was true for the "daytime" tows in the spring survey. Squid were fully recruited to the Bigelow's net at 5 cm DML. However, more years of data are needed to confirm the 2009 trends.

## Conversion factors for the new SRV H. B. Bigelow

The vessels and gear types used to conduct the fall and spring bottom trawl surveys are shown in Tables B15 and B16, respectively. In addition to the gear and vessel conversion factors described earlier in this section, gear/vessel calibration coefficients were also applied to Loligo catches by the SRV H. B. Bigelow, beginning in 2009, when the SRV Albatross $I V$ was decommissioned and the SRV H.BH. Bigelow was used to conduct the spring and fall bottom trawl surveys. Calibration coefficients were computed from paired tow studies using daytime tows conducted during the spring and fall of 2008. The paired tow studies are described in Miller et al. (2007) and Miller et al. (2010). and the methods used to compute the Bigelow calibration coefficients for Loligo catches are described in Appendix B3. The calibration coefficients ( $\rho$ ) that were applied to catch numbers of pre-recruits, recruits and all sizes combined, and their CVs, are included in Table B17.

## Trends

As is typical for squid species (Boyle and Rodhouse 2005), indices for both surveys show a high degree of inter-annual variability, particularly for the fall survey, which makes any trends difficult to discern. Although the spring survey indices are much lower than the fall survey indices, trends are more evident in the spring time series (Figure B31). Relative biomass indices were generally above the median level during 1979-1992, 1999-2002 and 2005-2008, but were generally at or slightly below the median during 1993-1998, 2003-2004 and 2009-2010. During 1976-2009, correlations between spring and fall relative abundance indices were fairly high ( $r=$
$0.53, p<0.01$ ), but correlations between relative biomass indices were much lower ( $r=0.32$, $p<0.05$ ).

Fall relative abundance and biomass indices were more precisely estimated (median CVs were $13 \%$ and $12 \%$, respectively, Table B18) than the spring indices (median CVs were $18 \%$ and $15 \%$, respectively, Table B19). Overall, both surveys were dominated by pre-recruits ( $\leq 8 \mathrm{~cm}$ DML) and relative abundance of recruits was higher prior to 1987 than after (Figure B31). Trends in pre-recruit and recruit relative abundance indices were significantly correlated for the spring surveys ( $r=0.58, p<0.01$ ) but not for the fall surveys ( $r=0.20$, $p=0.19$; Figure B32).

Term of Reference 3: Estimate annual fishing mortality, recruitment and stock biomass for the time series, and characterize the uncertainty of those estimates (consider Loligo TOR-4). Include a historical retrospective analysis to allow a comparison with previous assessment results.

## Data and methodological differences between current and prior assessment

## Previous assessment

This section explains the data and methodological differences between the current and prior assessment and documents the effects of each change on key assessment results. The previous assessment (NEFSC 2002a) included a variety of stock assessmentmethods including lengthbased VPA (LVPA), $q$-adjusted fall survey swept-area biomass (i.e., based on a composite prior distribution for survey catchability), exploitation indices (i.e., Oct-Dec. catch over $q$-adjusted fall survey swept-area biomass), a complicated surplus production model ("PDQ") tailored to Loligo, and traditional age-based per-recruit calculations.

The previous assessment's conclusion that the stock was "unlikely to be overfished" during 2000 was based on a comparison of a fall survey biomass estimate in $2000(=34,000 \mathrm{mt}$, assuming $q=$ 0.45 from the PDQ model) with the Bmsy threshold which existed at thae time ( $1 / 2 \mathrm{Bmsy}=$ $40,000 \mathrm{mt})$ and a variety of other information. The conclusion that "it is unlikely that overfishing was occurring", was based on a comparison of fishing mortality estimates from the PDQ model with a new quarterly estimate for Fmax.

However, the SARC reviewers concluded that the existing biomass reference points were inappropriate and that new biomass reference points could not be estimated (NEFSC 2002b). The SARC reviewers also concluded that "overfishing was not occurring" based on a comparison of the 2000 exploitation index (Oct-Dec landings plus $6 \%$ assumed discards/fall survey biomass) with a new quarterly Fmsy proxy ( $=0.31$ per quarter or 1.24 per year). The new Fmsy proxy represents the $75^{\text {th }}$ percentile of the 1987-2000 exploitation indices. The mean exploitation index during 1987-2000 was selected as the Ftarget ( $=0.24$ per quarter or 0.96 per year). These fishing mortality references points were implemented in 2009 (MAFMC 2009).
The existing threshold reference point calculations involved an assumed value of Loligo catchability $(q)$ in the fall survey that was estimated in the PDQ production model (even though assumptions about $q$ would have no effect on status determination results which are based on
trends in catch and survey data). The key source of information about survey catchability in the PDQ model was the $q$-prior used in fitting it because the survey and catch data were not informative for Loligo. Thus, the most important and useful parts of the previous assessment were the catch and fall survey data, with the $q$-prior providing bounds on possible biomass and exploitation levels and information about scale.

In view of this history, the current assessment is based on the most promising of the approaches from the previous assessment and includes a number of improvements. In particular, the current assessment uses updated and improved $q$-priors, additional and improved survey data, landings, and improved discard estimates to bound biomass and exploitation estimates. The $q$-prior provides bounds and a set of plausible estimates of biomass and exploitation rates but does not affect status determination measures, which are based on relative trends.

A number of changes were made in the current assessment to $q$-prior calculations, survey data, and catch data. The changes in $q$-prior calculations include:

- Updated estimates for bounds on mean tow distance and effective net width and use of the expanded survey strata area as the stock area, in place of bounds on stock area.
- Updated estimates for bounds on capture efficiency.
- Use of the median $q$-prior value in place of an estimate from the PDQ model.

Changes to survey and catch data included:

- Expanding the set of survey strata used to derive stratified mean number and weight per tow indices. The previous assessment included only offshore habitat (strata 1-23, 25 and 61-76) and this assessment includes important inshore and offshore habitat (inshore strata 2-46, 58-61, and 65-66 plus offshore strata 1-23, 25-26, and 61-76).
- Derivation of biomass estimates for both of the two primary Loligo cohorts caught in the NEFSC fall (1975-2009) and spring surveys (1976-2010)
- Use of standard door conversion factors for both survey time series (i.e., pre-1985 kg per tow x 1.24, no adjustment for number per tow), where appropriate.
- Use of standard SRV Delaware II catchability adjustment factors for both survey time series (i.e., $D E$ II number per tow x 0.83 and weight per tow x 0.85 ), where appropriate.
- Addition of the fall 2009 biomass estimate from the NEAMAP survey to account for Loligo biomass at depths $<=18 \mathrm{~m}$ because these inshore strata can no longer be sampled by the SRV H.B. Bigelow
- Use of only daytime survey tows instead of using all survey tows with diel correction factors for night and dawn/dusk.
- Use of average annual survey mean weight per tow as the main survey time series instead of fall survey data only (i.e. average of spring and fall biomass estimates in year $t$ ).
- Use of annual catches in place of fall (October-December) catches and with improved estimates of discards.

A historical retrospective analysis was conducted to allow a comparison of the current assessment results with those from the previous assessment (NEFSC 2002a; NEFSS 2002b). The effects of the changes noted above on $q$-prior calculations and mean catch, biomass indices and biomass estimates during 1987-2000 (the time period of overlap between assessments), along with an exploitation measure (mean annual catch/mean annual q-adjusted survey biomass), indicate that the most important assessment differences were the new bounds for capture efficiency and the calculation of survey biomass as the annual mean of the spring and fall survey biomass estimates (Table B20).

## Biomass estimation

A comparison of biomass estimates from a surplus production model used in a previous assessment to minimum swept-area biomass estimates (assuming 100\% efficiency or the capture of $100 \%$ of the squid in the water column above the ground swept by the net) resulted in implausibly high estimates of $q$, or survey bottom trawl catchability and implausibly low biomass estimates (Cadrin and Hatfield 1999). Biomass is estimated as $B=I / q$ where $I$ is the survey biomass index, in kg per tow, and tends to be too low when q is too large. This problem seems to pervade all previous modeling approaches.

In the current assessment, upper and lower bounds on factors which affect the daytime survey bottom trawl catchability of Loligo by the SRV Albatross, in both the spring and fall surveys, were used to compute upper and lower bounds on $q$. Based on non-informative uniform prior distributions for uncertainty in each underlying factor, we characterized uncertainty about survey catchability by means of a composite prior distribution, which includes uncertainty in all of the underlying factors.

The hypothetical relationship between survey biomass indices ( $I_{y}=$ stratified mean biomass per tow computed from all survey tows in year $y$ ) and the true Loligo biomass in year $y$ is:

$$
I_{y}=q B_{y}
$$

where $q$ is a survey-specific catchability coefficient. The catchability coefficient is:

$$
q=\frac{a e u}{A}
$$

where $u=10^{6}$ converts from kg to thousands of $\mathrm{mt}, a$ is the area swept during one standard tow ((in $\mathrm{km}^{2}$ ), $e$ is the capture efficiency of the survey bottom trawl (the trawl captures the proportion $e$ of Loligo in the water column above the ground swept by the trawl) and $A$ is the area of the stock. Capture efficiency must be larger than zero if the survey takes at least one individual and, by definition, must be smaller than or equal to one $(0<e \leq 1)$. Area swept $(a)$ is equal to the product of average effective tow distance for the survey ( $d$, assumed constant over time) and average effective width $(w)$ of the area swept by the survey gear such that:

$$
q=\frac{d w e u}{A}
$$

Upper and lower bounds for each of the key factors ( $d, w, e$, and $A$ ) affecting the daytime catchability of Loligo in the NEFSC fall and spring bottom trawl surveys, during 1975-2010, are shown in Table B21. The bounds included in the previous assessment, for NEFSC fall surveys, are also shown. For 2009 onward, differences between the Albatross and Bigelow with respect to $d, w$, and $e$ are accounted for in the Bigelow to Albatross conversion coefficients (Table B17) that were applied to the relative biomass indices from the Bigelow.

## Bounds for effective tow distance (d)

Variance in the length of individual tows probably contributes little uncertainty to estimates of average tow distance because the tow distance used in the calculations is based on a relatively large sample size (see the following paragraph). However, the mean value is uncertain due to questions about when the survey trawl starts and stops fishing for Loligo during daytime tows. Actual tow distance is not likely the same as the nominal tow distance because of lags between winch lock and net touchdown and between winch re-engage and net lift-off (which may vary with station depth) and changes in sea state and tides. All of these factors may affect when the net starts and stops fishing.

The nominal tow distance in the 1975-2008 surveys is 3.42 km based on a target tow duration and speed of 30 minutes at 3.5 knots. However, one study where actual measurements of mean tow distance were measured using Doppler distance indicated that the modal tow distance was 2.96 km during the 1975 and 1976 surveys (Overholtz and Lewis 1978). We also computed the GPS tow distance for the 2007 fall and the 2008 spring surveys. We examined plots of speed over ground, tow duration, temperature, wingspread, and doorspread to determine the times when net touchdown and liftoff occurred for a range of survey station depths ( $\mathrm{N}=445$ tows). GPS tow distance was then computed for the time period between net touchdown and lift-off. We found that tow distance was not dependent on station depth (Figure B33) because depthrelated changes in the delay between winch lock and net touchdown was offset by changes in the delay between winch re-engage and net lift-off. Although individual tow distances were variable, the mean for both surveys combined ( $3.57 \mathrm{~km}, 95 \% \mathrm{CI}= \pm 0.01 \mathrm{~km}$ ) was not. Based on these two estimation methods, we used 2.96 km and 3.57 km as the lower and upper bounds on effective tow distance, respectively.

## Bounds for effective width swept by the survey gear (w)

The mean of the SRV Albatross wingspread measurements for the Yankee 36 bottom trawl, during the 2006-2008 spring and fall surveys ( $\mathrm{N}=1,985$ tows) was used as the lower bound for effective width of the area swept by the survey gear $(0.01069 \mathrm{~km}, 95 \% \mathrm{CI}= \pm 0.000201)$. The mean of the Albatross doorspread measurements ( $\mathrm{N}=1,992$ tows), during the same time period, was used as the upper bound for effective width of the area swept by the survey gear ( 0.02192 $\mathrm{km}, 95 \% \mathrm{CI}= \pm 0.000743$ ). The lower bound accommodates the hypothesis that no horizontal herding of Loligo occurs during daytime fishing and the upper bound accommodates the alternate hypothesis that such herding does occur (i.e., $100 \%$ of the squid between the wings and doors are herded into the mouth of the trawl are captured and don't escape). Uncertainty about squid which avoid capture by swimming out beyond the area swept by the doors and wings are included in the bounds for effective width of the survey gear.

Uncertainty due to squid avoiding capture because they are initially located above the headrope ("school slicing") or because they eventually move up and over the headrope is included in uncertainty about capture efficiency $e$. Escapement beneath the footrope and through the trawl meshes following capture is also included in the uncertainty about capture efficiency. The average headrope height of the Yankee 36 trawl $(1.95 \mathrm{~m}, 95 \% \mathrm{CI}= \pm 0.17)$ is low in relation to commercial Loligo bottom trawls. This mean is based on 21 tows conducted by the Albatross with 1-3 three sensor measurements per tow. Headrope height ranged between 1.7 and 2.1 m . However, given that the survey bottom trawl is towed at a similar or faster speed (3.2-3.8 knots) than that used in the Loligo fishery,3.0-3.2 knots, (Hendrickson 2005) and because survey data include only daytime tows (when Loligo are closest to the bottom), escapement over the net may be minimized.

If the bottom trawl used on the SRV Albatross failed to catch one individual, then the efficiency (e) of the trawl would be zero. However, Loligo are caught at relatively high rates and within the survey strata used in the assessment. In addition, the use of only the survey catches of Loligo from daytime tows effectively increase efficiency because both the percentages of tows with Loligo catch and the amounts of Loligo catch per tow are greater for daytime tows (Figures B25B29). The lower bound for $e$ accommodates the hypothesis that the gear has low efficiency due, for example, to squid initially distributed above the trawl and/or squid that escape capture by moving up and over the headrope. Escapement through the trawl meshes following capture is another possibility. The upper bound for $e$ accommodates the alternate hypothesis that the Yankee 36 bottom trawl is very efficient for Loligo during the daytime.

In order to estimate a lower bound for $e$ during the daytime, we used behavioral information gleaned from daytime video footage of Loligo in front of the sweep and within various types of bottom trawls. In general, squid behaved similarly to the capture behavior reported by Glass et al. (1999) for Loligo in bottom trawls used in the directed fishery. Video camera recordings of bottom trawl capture behavior indicate that $L$. pealeii tires shortly after encountering the net. Individuals swim for approximately three minutes at a towing speed of 3 knots then rise upward in the net, turn toward the codend, cease swimming and allow the net to overtake them (Glass et. al. 1999). We observed schools of squid located on and near the seabed, in front of the sweep, to use alternating jet population and finning to swim forward in the direction of the tow and upward within the net mouth. This same behavior appeared to result in capture, even for raised footrope trawls (footrope at 1-1.5 m above the seabed and rigged with tickler chains), whereby schools of squid tended to use burst speed to quickly jet off the bottom and above the sweep where they were quickly overtaken by the net. Given this rising behavior, it is highly unlikely that escapement occurs beneath the footrope. In addition, squid schools were never observed turning perpendicular to the meshes in the mouth and attempting to escape. Although these behaviors suggest little likelihood of escapement once captured, there is no video footage to determine whether escapement over the headrope occurs. The rapid towing speed of the NEFSC survey trawl and the presence of a square in the Yankee 36 net (webbing that overhangs the area in front of the sweep) probably minimize escapement over the headrope. However, the rapid rising behavior of Loligo near the net mouth combined with the lack of information about the height of
schools suggests that these low-opening survey nets may only be slicing off the lower portion of schools. Taking all of this information into consideration, we set the lower bound on $e$ at 0.20 .

The upper bound on capture efficiency for Loligo taken in surveys conducted by the Albatross was based on calibration factors ( $\rho$ ) derived experimentally and used to convert Loligo catches by the Bigelow to Albatross catch equivalents. Capture efficiency for Loligo is higher for the Bigelow than for the Albatross due to differences in net design and other factors. For these calculations, the maximum possible capture efficiency of the Bigelow was assumed to be 0.95. Although this assumed efficiency of the Bigelow is somewhat arbitrary, it is intended to be an upper bound and a number of factors indicate that the bottom trawl towed by the Bigelow is likely to have high efficiency, particularly during the daytime. The wingspread and doorspread of the Bigelow are wider, and the headrope height is higher than for the Yankee 36 and Yankee 41 trawls. The Polyice net used on the Bigelow is a modified version of one type of commercial Loligo trawl. Based on sensor measurements from 357 tows conducted during the 2009 fall survey, the mean wingspread of the Bigelow Polyice net ( $12.76 \mathrm{~m}, 95 \% \mathrm{CI}= \pm 0.21 \mathrm{~m}$ ) is $19.4 \%$ wider than the mean wingspread of the Yankee 36 net ( $10.69 \mathrm{~m}, 95 \% \mathrm{CI}= \pm 0.20$ ) and the mean doorspread of the Polyice net ( $33.02 \mathrm{~m}, 95 \% \mathrm{CI}= \pm 0.49, \mathrm{~N}=361$ tows) is $50.6 \%$ wider than the mean doorpsread of the Yankee $36(21.92 \mathrm{~m}, 95 \% \mathrm{CI}= \pm 0.74)$. The mean headrope height of the Polyice net ( $=3.69 \mathrm{~m}, 95 \% \mathrm{CI}= \pm 0.09, \mathrm{~N}=360$ tows) is $89.2 \%$ higher than the mean headrope height of the Yankee 36 net $(1.95 \mathrm{~m}, 95 \% \mathrm{CI}= \pm 0.17)$.

Assuming the maximum capture efficiency of the Bigelow is 0.95 , maximum capture efficiency of the Albatross ( $e_{\max }$ ) could be no larger than $0.95 / \rho$, where $\rho$ is the calibration factor for converting Bigelow catches to Albatross equivalents adjusted for wingspread swept-area differences. Thus, the upper bound on $e$ was computed as:

$$
e_{\max }=\frac{0.95 a_{\text {Bigelow }}}{\rho a_{\text {Albatross }}}=0.393
$$

Where $\rho$ is the calibration factor for the fall survey ( $=1.51$ for all sizes combined using daytime tows), 0.95 is an upper bound for capture efficiency on the Bigelow, and $a_{\text {Bigelow }}=0.0382 \mathrm{~km}^{2}$ and $a_{\text {Albatross }}=0.0239 \mathrm{~km}^{2}$ are the areas swept by the bottom trawls used by the two vessels. The upper bound for the NEFSC spring survey was nearly identical so, for the sake of simplicity, only $e_{\text {max }}$ for fall was used in the assessment.

## Definition of the stock area (A)

Instead of setting upper and lower bounds on the stock area, $A$, we assumed that the Loligo strata set used in the assessment (total area $=166,007 \mathrm{~km}^{2}$ ) represents the stock area. The expanded strat set is much larger than the strata set used in the previous assessment and includes the primary Loligo habitat within the surveyed area. As noted in Term of Reference 2, the expanded strata includes the offshore strata used in the previous assessment (1-23, 24-26, and 61-76) plus a set of inshore strata (2-46, 58-61 and 65-66) because GIS maps (see Figures B20 and B21) indicate that these strata constitute important Loligo habitat, primarily during the fall.

In order to determine the importance of the inshore habitat which can no longer be sampled by
$51{ }^{\text {st }}$ SAW Assessment Report
the Bigelow (strata $\leq 18 \mathrm{~m}$ deep), we conducted several analyses. The annual percentages of Loligo relative abundance and biomass originating from these strata were determined for daytime tows conducted during NEFSC spring (1976-2008) and fall surveys (1975-2008). The results indicate that this habitat is more important during the fall surveys than during the spring surveys. During the fall, $0.1-3 \%$ of the relative biomass and $0.1-4 \%$ of the relative abundance occurred in strata $\leq 18 \mathrm{~m}$ deep (Figure B34). However these percentages are probably underestimated because only $50 \%$ or less of the total area of these inshore strata was sampled in the daytime during the fall surveys in most years (Figure B35). During the spring surveys, strata $\leq 18 \mathrm{~m}$ deep only accounted for a substantial percentage of the relative abundance (4.3\%) and biomass (7.2\%) during 1985 and 2002, respectively (Figure B34).

In order to account for Loligo biomass in the survey strata $\leq 18 \mathrm{~m}$ deep, we computed swept area estimates of biomass from the 2009 fall NEAMAP (Northeast Area Assessment and Monitoring Program) survey, which now surveys these inshore strata, and added this amount to the $2009 q$ adjusted biomass estimate from the NEFSC fall survey. The NEAMAP survey has been conducted during the fall (late Sept.-mid-Oct., which is similar to the timing of the fall NEFSC survey) and during spring (late April-mid-May, which is later than the NEFSC spring survey) since the fall of 2007 (Bonzek et al. 2009). Approximately 150 stations are sampled at depths ranging between 6.1 and 18.3 m in waters located between Cape Hatteras, NC and the eastern end of Montauk, NY. Fourteen of the stations are located in Block Island Sound and Rhode Island Sound at depths ranging between 18.3 m and 36.6 m (Figure B36). The total area of all strata is $15,191 \mathrm{~km}^{2}$, but a slightly smaller area was sampled during the fall of 2007 and spring of 2008 (Table B22).

There have been no calibration studies conducted between the Bigelow and the NEAMAP survey vessel (the F/V Darana $R$ ) but the towing protocols are the same ( 20 minutes at 3 knots) and the nets are similar barring some minor differences.Other differences include a 3-inch cookie sweep on the Darana $R$ (versus a rockhopper sweep on the Bigelow) and different types of doors.

Biomass estimates were computed for Loligo by multiplying the geometric mean weight per tow (C. Bonzek, pers. comm.), for all NEAMAP strata, by the area swept by the trawl ( $0.025 \mathrm{~km}^{2}$ ); the latter which is based on mean wingspread and tow distance (Bonzek et al. 2009). For the short time series available, the Loligo minimum biomass estimates from the fall NEAMAP surveys were fairly low, and ranged between $1,720 \mathrm{mt}$ and 3,482 mt (CV range of 3.5-4.5\%) during 2007-2009 (Table B22). However, the estimates were not adjusted for catchability of the NEAMAP survey gear and are probably biased low. The CVs for these biomass estimates were low, ranging between $3.5 \%$ and $4.5 \%$. Biomass estimates from the spring NEAMAP surveys were more variable and lower than the fall estimates, ranging between 389 mt and $1,420 \mathrm{mt}$ during 2008-2010 and the estimates were less precise (.CV range of 5.4-9.3\%). The spring estimates were likely lower and more variable because the NEAMAP survey occurs at a time when the species is migrating into the survey area. An attempt was also made to compare the fall biomass estimates from the NEAMAP surveys, during 2007-2008, with biomass estimates for a set of overlapping strata sampled during NEFSC surveys, by the Albatross, during a similar time period.. However, the resulting estimates were not reliable because the numbers of "daytime" tows conducted by the Albatross in these inshore strata were too few (Table B22).

Several additional analyses were conducted in order to address the question of whether
substantial amounts of Loligo exist outside the NEFSC survey strata, in particular at depths greater than the limit of the surveys ( $>366 \mathrm{~m}$ ), during the time periods in which the NEFSC spring and fall surveys are conducted. The methods utilized and the results of these analyses are included in Appendix B4. One set of analyses used catch-per-tow data from the Loligo fishery and NEFSC spring and fall surveys to characterize daytime catch rates of Loligo as a function of depth. Results for spring indicated declining fishery catch rates at depths beyond 175 m , although data for deep water tows were limited. Results for all Loligo size groups caught in NEFSC spring and fall surveys indicated that the predicted daytime catches declined to low values with increasing depth.

A third analysis involved an examination of Loligo catch rates in seasonal depth transect surveys that were conducted at depths greater than the limit of NEFSC surveys, by Rutgers University, during 2003-2007. The surveys utilized a standardized towing protocol (tow distance of 2 nautical miles at a speed of 3 knots) and a commercial Loligo bottom trawl. Catch rates of Loligo pealeii (kg per tow) in these surveys also show declines with increasing depth, similar to the analysis of catch rates with depth for daytime tows from NEFSC surveys. During some years, daytime catch rates declined to very low levels at stations with depths shallower than 366 m (e.g., $<274 \mathrm{~m}$ ). Catch rates of Loligo were also very low at depths greater than 366 m during January, March and November. However, this result may be an artifact of nighttime sampling at depths $>274 \mathrm{~m}$. In conclusion, the results from all three analyses suggest that high densities of Loligo at depths greater than those included in this assessment are unlikely.

## Bounds for $q$

The lower bounds or $\mathrm{q}_{\min }$ values were 0.038 for 1975-2008 and 0.041 for 2009-2010 (Table B21) for catchability in the NEFSC fall and spring bottom trawl surveys and were calculated from the minimum values for $d, w$ and $e$ in the numerator, and the value for stock area, $A$, in the denominator:

$$
q_{\min }=\frac{u d_{\min } w_{\min } e_{\min }}{A}
$$

Similarly, the upper bounds or $\mathrm{q}_{\max }$ values were 0.185 for 1975-2008 and 0.197 for 2009-2010 (Table B21) were calculated using the maximum values for $d, w$ and $e$ in the numerator and the value for stock area, $A$, in the denominator:

$$
q_{\max }=\frac{u d_{\max } w_{\max } e_{\max }}{A}
$$

## Statistical distributions to characterize uncertainty

We characterized uncertainty in effective tow distance, effective trawl width $w$, and trawl efficiency $e$ with uniform distributions that had upper and lower bounds described above. This means, for example, that any value of $w$ between the upper and lower bound seemed equally probable, a priori. Uniform distributions for these parameters are "non-informative" prior distributions that don't require knowing or guessing the most likely single value or most probable values (Gelman et al. 1995).

Uncertainties about $d, w$ and $e$ were independent in our analysis because of the definitions for each term. Therefore, the bounds for each term were statistically independent (uncertainty and bounds for efficiency $e$ did not depend, for example, on bounds and uncertainty about effective width $w$ of the net). Moreover, we tried to choose bounds for each factor in an independent manner so that, for example, the lower bound on effective net width was independent of the upper bound on effective net width.

Given independence, the statistical distribution for uncertainty in $q$ can be evaluated by simulation. The first step is to draw random numbers $d^{\prime}, w^{\prime}$, and $e^{\prime}$ from uniform probability distributions (where, for example, $d^{\prime}$ is drawn from the uniform distribution with upper and lower bounds for effective tow distance, $d$ ). The second step is to calculate simulated catchability values as $q^{\prime}=\left(d^{\prime} w^{\prime} e^{\prime} u\right) / A$. Recall that $A$, the stock area, is a constant.

We characterized the distribution of the uncertainty in $q$ using five million simulated $q$ ' values (Figure B37). Minimum, maximum and quantiles (Q25, Q50 and Q75) of the two simulated distributions, for 1975-2009 and 2009-2010, are presented in Table B23. Both distributions were similar in shape and were slightly skewed to the left. The distribution ranges were narrow, 0.0380.185 for 1975-2008 and 0.041-0.197 for 2009-2010, with modes at 0.082 and 0.087 for the two time periods, respectively. The median $q$-priors (Q50 $=0.092$ for 1975-2009 and 0.098 for 20092010) were located slightly to the right of the distribution modes. In comparison, the q-prior in the previous assessment had bounds between 0.20 and 0.56 , was strongly skewed to the right, and had a broad mode between 0.05 and 0.22 (Figure A25 from NEFSC 2002a).

## Biomass trends

Biomass estimates derived using the minimum, maximum, Q25, Q50, and Q75 values from the $q$-prior distributions are shown in Figure B38. The lowest feasible biomass estimates are more important than the highest feasible biomass estimates when determining stock status because they amount to "worst-case scenarios". The lowest feasible biomass estimates (derived using the minimum $q$-priors) ranged between $15,070 \mathrm{mt}$ and $164,182 \mathrm{mt}$ (median $=62,028 \mathrm{mt}$ ) for the fall surveys and ranged between $4,036 \mathrm{mt}$ and $40,646 \mathrm{mt}$ for the spring surveys (median $=13,386 \mathrm{mt}$; Figure B38). The biomass estimates used in the assessment were derived using the median $q$ priors because they have an equal probability of either under- or overestimating biomass.

The spring and fall NEFSC surveys track different seasonal cohorts which appear to have very different levels of productivity. The spring biomass levels are only about one fifth of the fall biomass levels (Table B24, Figure B39). During 1976-2008, biomass estimates (derived using the median q-priors) ranged between 30,304 and $330,148 \mathrm{mt}$ (median $=124,730 \mathrm{mt}$ ) during the fall and between $8,116 \mathrm{mt}$ and $81,734 \mathrm{mt}$ during the spring (median $=27,578 \mathrm{mt}$ ).

Federal fishery regulations require that stock status be reported for the terminal "year" of the assessment data series. Therefore, in order to annualize the biomass estimates for this sub-annual species, annual averages of the fall and spring survey biomass estimates were computed for 1976-2009. As is characteristic for squid species (Boyle and Rodhouse 2005), annual biomass fluctuated widely about the median of 76,329 mt during 1976-2009 and ranged between 25,806 mt and $175,894 \mathrm{mt}$ (Figure B40, Table B25). Consequently, trends were difficult to discern, with
the exception of an increase in biomass from 25,806 mt in 1996 to the time series high of $175,894 \mathrm{mt}$ in 2000. Biomass generally declined thereafter to about $50 \%$ of the median in 2009 $(39,792 \mathrm{mt})$. However, given the high inter-annual variability in biomass estimates, a two-year moving average of stock biomass (i.e., mean biomass during 2008-2009) is recommended for the 2009 stock status determination.

## Exploitation indices

Exploitation indices, which are considered to be correlated with fishing mortality on a relative basis, were used in the previous assessment and are also used in this assessment. The spring and fall biomass estimates represent mean biomass estimates for the seasonal cohorts that are available to the January-June and July-December fisheries, respectively. Exploitation indices for the two fisheries were computed for 1987-2009 as January-June catch/March biomass and JulyDecember catch/September biomass. Annual exploitation indices were also computed as the annual catch divided by the annual average of NEFSC spring and fall survey biomass estimates.

Exploitation indices were calculated as catch/ biomass of all size groups of squid, including prerecruit sizes ( $\leq 8 \mathrm{~cm}$ DML) which are not immediately selected by the fishery. Pre-recruit sizes were included in the calculations to partially account for the high turnover rates and the fact that these squid will be large enough to be selected by the fishery shortly after the survey. Likewise, given the semelparous life history of the species, most of the recruits that enter each six-month fishery period will have died by the end of each period.

The maximum feasible exploitation indices are more important than the minimum exploitation indices when determining stock status, because they amount to worst-case scenarios. During 1987-2009, the maximum feasible exploitation indices, computed using the biomass estimates derived with the maximum $q$-prior, ranged between 0.32 and 0.05 (median $=0.132$ ) for the JulyDecember fisheries and ranged between 0.317 and 2.535 for the January-June fisheries (median $=0.634$; Figure B41).

The exploitation indices used in the assessment were derived using the biomass estimates for the median $q$-priors. During 1987-2009, catches in the January-June fishery were 1.4 times higher than the July-December catches on average (Table B24). Exploitation indices for the JanuaryJune fishery (range $=0.158-1.261$; median $=0.315$ ) are much higher on the lesser productive, spring survey cohort than those for the July-December fishery (range $=0.02-0.16$; median $=$ 0.064 ) on the more productive fall survey cohort (Figure B42, Table B24).

During 1993-1998, annual exploitation indices were generally at or above the 1987-2008 median (0.237), averaging 0.273 , and generally at or below the median during 1999-2008, averaging 0.18 (Figure B43, Table B25). The 2009 annual exploitation index was 0.176 . This 2009 value was computed as the catch in 2009 / mean of the 2008-2009 fall and spring survey biomass estimates. Given the inter-annual variability in biomass estimates, a two-year moving average of stock biomass is recommended for the 2009 stock status determination.

## Historical retrospective analysis

Comparison of results from this assessment with results from historical assessments (NEFSC

1994; 1996; 1999; 2002a) is difficult because of the lack of temporal overlap between assessments (particularly between NEFSC 2002a and the current assessment), and changes to the data and models used to estimate stock status. However, comparisons (Table B26) reflect the difficulties encountered using both index-based approaches (NEFSC 1994) and surplus production models (NEFSC 1996; 1999; 2002a) for Loligo. The majority of assessments relied on relative trends in survey data (NEFSC 1994, 2002a and the current assessment). The stock is now considered lightly exploited but overfishing was determined to be occurring in 2 out of 4 historical assessments. The stock has never been considered overfished, although it was close to its biomass threshold at the time in two cases (NEFSC 1996; 1999).

Term of Reference 4: Summarize what is known about consumptive removals of Loligo by predators and explore how this could influence estimates of natural mortality ( $M$ ).

## Natural Mortality

Spawning (Msp) and non-spawning (Mns) natural mortality rates were estimated for Loligo pealeii using the methods of Hendrickson and Hart (2006) and Caddy (1996), respectively. The methods and results are presented in Appendix B5. Preliminary natural mortality estimates were very high, 0.11 per week for Mns and 0.19-0.48 per for Msp, similar to estimates for another northwest Atlantic squid species (Hendrickson and Hart 2006). Natural mortality estimates from the current assessment are compared with those used in previous assessments in Table B27. Previous Loligo assessments used traditional natural mortality estimation approaches which apply to iteroperous finfish species. Estimates from the current assessment are considered more realistic because the estimation method accounts for the semelparous life history of the species and the fact that natural mortality increases with age for spawners. However, additional maturity-at-age data are needed to determine the range of $M$ estimates for the various seasonal cohorts.

## Preliminary minimum consumption estimates of Loligo pealeii

Natural mortality attributable solely to predation was not estimated for Loligo, but preliminary minimum consumption estimates during spring and fall were used for comparison with seasonal fishery removals. Size compositions of the Loligo prey consumed were also compared to the size compositions of the Loligo caught during NEFSC spring and fall surveys and in the fishery. Preliminary estimates of the seasonal consumption of each of the two primary Loligo cohorts were computed using food habits data collected during the 1977-2009 NEFSC spring and fall surveys. The spring and fall estimates were summed to derive an annual estimate. Details of the methodology used to compute the consumption estimates, effective sample sizes, and results from the analysis are presented in Appendix B6.

The consumption estimates are preliminary and represent minimums because they do not include consumption by all predators, such as: marine mammals, seals, large pelagic fish species, and birds. In addition, ecosystem and predator dynamics in relation to the complex life history and high turnover rates of squid populations are poorly understood. Minimum consumption estimates were highly variable inter-annually, but were 0.8 to 11 times higher than annual catches during 1977-2009 (Figure B44).

During 1977-1984 and 1999-2010, minimum consumption was much higher during the fall than during the spring (Figure B45). Minimum seasonal consumption estimates, particularly during the spring, are a substantial fraction of the stock biomass (Figure B39). This may imply that the stock is very productive or that the biomass estimates (computed using the median $q$ values) are too low, particularly during the spring. Fortunately, the status of the stock with respect to biomass thresholds is trend-based and would not be affected by an underestimation of Loligo biomass. Furthermore, higher levels of consumption would reinforce the assessment conclusion that catch is low relative to consumption and that the Loligo stock is lightly exploited.

Term of Reference 5: State the existing stock status definitions for the terms "overfished" and "overfishing". Then update or redefine biological reference points (BRPs; estimates or proxies for $B_{M S Y}, B_{\text {THRESHOLD, }}$, and $F_{M S Y}$ and estimates of their uncertainty). Comment on the scientific adequacy of existing BRPs and for the "new" (i.e., updated, redefined, or alternative) BRPs.

## Existing Biological Reference Points

There are no existing biomass reference points for the Loligo stock because the previous Bmsy proxy was deemed inappropriate at SARC 34 and a revised estimate was not provided (NEFSC 2002b). Proxies for Ftarget and Fthreshold were promulgated in Amendment 9 (MAFMC 2009) based on the recommendations from the SARC 34 reviewers that are reflected in the the SAW 34 Advisory Report (NEFSC 2002a). The existing Fmsy proxy is 1.24 per year and is based on the $75^{\text {th }}$ percentile of the quarterly exploitation indices ( 0.31 per quarter) during 1987-2000. The annual $\mathrm{F}_{\text {target }}$ is 0.96 and represents the quarterly mean of the exploitation indices during the same time period. The exploitation indices were computed in SARC 34 using a different methodology and different data that those used during the current assessment (refer to Term of Reference 3). In addition, the exploitation indices are ad-hoc because the fall survey data were scaled up by a catchability coefficient estimated in an independent model. The estimates from the independent model were based on survey data and, primarily, on a composite q -prior that is now obsolete because of improvements made in the current assessment.

## Proposed Biological Reference Points

A new threshold Bmsy proxy of $21,203 \mathrm{mt}$ and a biomass target of $42,405 \mathrm{mt}$ are proposed (Table B28). The median of the average of the catchability-adjusted spring and fall survey biomass levels during 1976-2008 is $76,329 \mathrm{mt}$. The stock appears to be lightly exploited and assuming that biomass is at $90 \%$ of the stock's carrying capacity ( $K$ ), a new Bmsy target of $50 \%$ of $K\left(0.50^{*}(76,329 / 0.90)=42,405 \mathrm{mt}\right)$ is recommended. Based on logistic production models, an appropriate biomass threshold for a short-lived species like Loligo is $50 \%$ of Bmsy ( $=21,203$ mt ). Annual biomass estimates exceed annual carrying capacity in multiple years, which is to be expected for a species with highly variable seasonal population dynamics which are linked to variability in environmental conditions.

A new Fmsy proxy could not be recommended due to the lack of evidence that fishing has impacted stock biomass since 1975. Conventional approaches based on finfish population dynamics are inappropriate. In particular, there is no theory linking $M$ and $F_{M S Y}$ for short lived organisms like Loligo and per-recruit reference points can be calculated only approximately

[^1]409
Loligo
(NEFSC 2002a). There is also no theory linking $F_{S P R}$ per recruit reference points to $F_{M S Y}$ for species like Loligo. Finally, there is too little contrast in either the fishery catch or survey data to provide information that could be used to estimate $\mathrm{F}_{\text {MSY }}$ in a modern dynamical model.

Term of Reference 6: Evaluate stock status with respect to the existing BRPs, as well as with respect to the "new" BRPs (from Loligo TOR 5).

## Stock status

There are no existing biomass-based reference points for the stock, and as a result, overfished status cannot be determined. Based on the current fishing mortality reference points, overfishing was not occurring because the 2009 exploitation index (estimated using the method from SARC 34 , Oct-Dec. catch over $q$-adjusted fall survey swept-area biomass) was 0.063 compared to the Fthreshold (i.e., $75^{\text {th }}$ percentile of the exploitation indices during 1987-2009) which is 0.277 ). However, the current fishing mortality reference points are inappropriate for the lightly exploited Loligo stock. The stock appears to be lightly exploited because annual catches were low relative to annual estimates of minimum consumption by a subset of fish predators and there was no evidence of fishing effects on annual survey biomass estimates (i.e., annual averages of the spring and fall biomass estimates) during 1975-2009.

The new exploitation indices used in the current assessment are not comparable to the existing fishing mortality reference points because of differences in computation methods and input data. In the previous assessment, exploitation indices were computed for Quarter 1 as the landings during October-December, plus $6 \%$ discards, divided by a $q$-adjusted fall survey biomass estimate. The existing F reference points assume that exploitation is constant during the other three quarters the year. The fall survey catchability $q(=0.45)$ for Loligo in the NEFSC fall surveys was estimated from a production model based largely on the obsolete composite prior for fall survey catchability in the previous assessment. The relative biomass indices were computed using all survey tows adjusted to daytime equivalents (i.e., diel conversion factors for night and dawn/dusk). In addition, the fall survey biomass estimates did not include important inshore Loligo habitat and biomass estimates for the other primary seasonal cohort (i.e., spring survey biomass estimates) were not used in the assessment. In the current assessment, exploitation indices were computed as the annual catch divided by the mean of the annual spring and fall survey biomass estimates, the latter which were derived using a different survey strata set, only daytime tows, vessel and door correction factors, and the median values of the updated composite $q$-priors.

Based on the proposed biomass reference point threshold from the current assessment, the stock was not overfished during 2009. The two-year average of catchability-adjusted spring and fall survey biomass levels during 2008-2009 was $54,442 \mathrm{mt}(80 \% \mathrm{CI}=38,452-71,783 \mathrm{mt})$ and is higher than the proposed threshold Bmsy proxy of 21,203 mt (Figure B46, Table B28). The overfishing status during 2009 is unknown because new fishing mortality reference points could not be recommended in the current assessment due to the lack of evidence that fishing impacted annual biomass levels during 1975-2009. The 2009 exploitation index of 0.176 (catch in 2009
divided by the average of the spring and fall survey biomass during 2008-2009; 80\% $\mathrm{CI}=0.124$ 0.232 ) was slightly below the 1987-2008 median of 0.237 (Figure B47, Table B28).

Term of Reference 7: Develop approaches for computing candidate ABCs (Acceptable Biological Catch; see Appendix to the TORs), and comment on the ability to perform projections for this stock.

## Stock size projections

Stock size projections were not possible for this semelparous, sub-annual species due to the lack of an assessment model and because like most squid stocks, the short sub-annual lifespan and semelparous life history of this species result in rapid changes in stock size in response to environmental conditions (Hendrickson and Showell 2010; Dawe et al. 2007; Boyle and Rodhouse 2005).

## Potential approaches for computing ABCs

TOR 7 does not include the specification of ABC levels for Loligo nor characterization of the various risks involved in fishery management, but rather involves recommending approaches for computing candidate ABCs . ABC refers to a level of "catch" that is "acceptable" given the "biological" characteristics of the stock. Adequate escapement of spawners is needed for this semelparous squid stock to ensure sufficient recruitment in the subsequent year. The magnitude of escapement could be affected by increased exploitation.

The following "Omnibus" approach to setting ABC levels is currently under consideration. It is described as follows. "Allowable biological catch is a level of a stock or stock complex's annual catch that accounts for the scientific uncertainty in the estimate of [overfishing limit] OFL and any other scientific uncertainty..." (Federal Register, vol. 74, no. 11, January 16, 2009). The MAFMC's Scientific and Statistical Committee (SSC) is responsible for adjusting OFL levels of catch downward, based on available information about the stock, fishery and uncertainty. The Council is already developing an omnibus amendment that provides the SSC with a general procedure for setting ABC levels. The omnibus approach ranks stocks into four tiers, depending on the information about the stock and reference points provided in the assessment. The omnibus approach is flexible and may well be a sufficient basis for specifying ABC levels for the Loligo fishery. The alternative ideas provided in this assessment should not be construed as an indication that the omnibus approach is inadequate.

The ecological importance of Loligo as prey for a wide range of species could be considered in specifying ABC levels. Loligo are prey for a wide range of non-demersal fish, birds, and marine mammals. Ignoring additional mortality at spawning, mortality rates (mostly natural mortality) for non-spawning Loligo range from 0.058 to 0.11 per week ( 3.0 to 5.7 per year) due, presumably, to predation.

Potential approaches to computing ABCs include:

1) Seasonal $A B C$ levels. When setting the annual $A B C$, consideration of the differences in seasonal cohort productivity and biomass may be prudent. Loligo biomass and productivity appear to be substantially lower for the cohort caught in the spring survey than for the cohort caught in the fall survey. Lower spring biomass may be due to a variety of factors, including differences in available habitat, migration patterns, reproduction, growth rates, and/or consumption removals. Relative abundance indices from the spring and fall surveys are correlated and exploitation indices for the JanuaryJune fishery (median $=0.315$ ) are much higher on the less-productive, spring survey cohort than those for the July-December fishery (median $=0.064$ ) on the more-productive fall survey cohort.
2) ABC by analogy to consumption estimates for key predators. Consumption estimates for six (cod, bluefish, goosefish, pollock, summer flounder and weakfish) of the 15 Loligo finfish predators included in this assessment are based on predator stock biomass estimates from peer-reviewed assessment reports that include estimates of survey catchability. The consumption estimates for these six species are plausible estimates of consumption for the six species. Considering consumption by humans and fish predators, specifying ABC levels for Loligo based on consumption estimates, based on stock assessment abundance data, for important predators may be a practical approach to ecosystem-based management. Consumption is generally higher during the fall and seasonal differences could be considered as well.
3) 

## Term of Reference 8: Review, evaluate and report on the status of the SARC and Working Group research recommendations listed in recent SARC reviewed assessments and review panel reports. Identify new research recommendations.

## Prior research recommendations from SARC34

1) Based on results from the SARC 34 assessment, it appears that traditional per-recruit reference points like $F_{M A X}$ may be poor proxies for $F_{M S Y}$ in longfin squid because they do not permit a sufficient level of spawning escapement. There appears to be no satisfactory biomass based reference points for longfin squid at this time. Fishing mortality and biomass reference points for use as targets and thresholds are an important area for research.

A new Bmsy reference point was estimated in the current assessment, but an Fmsy BRP or a proxy thereof requires further research due to the complex life history of this species and the lack of theory linking $F_{S P R}$ per-recruit reference points to $F_{M S Y}$ for species like Loligo .
2) It is important to carry out further research on standardizing and modeling survey data for longfin squid. A preliminary GAM (general additive model) analysis of survey data should serve as a good starting point in developing standardization approaches that adjust for diel and other factors affecting catchability. PDQ model results show that survey
catchability processes errors follow similar trends in different surveys and are autocorrelated within surveys. Survey catchabilities probably vary in response to water temperatures. These circumstances suggest that survey catchability processes errors might be modeled robustly and parsimoniously as a simple function of water temperatures in the PDQ model.

A new GAM was developed and used in the current assessment to define cut points for defining daytime survey tows, based on solar zenith angle, depth, temperature, and other factors, which were used to derive biomass estimates.
3) Growth information, particularly for older longfin squid, is still uncertain. Additional age and growth studies are required to better estimate average growth patterns and to discern seasonal patterns. The latter are potentially important in more realistic, seasonally explicit population and reference point models like the preliminary, multi-cohort reference point model.

More statolith-based age data are needed, by season, for the fishery and NEFSC surveys to accomplish this task. Variable selectivities of the existing age data sets make this task difficult to accomplish.
4) The potential for fuller use of catch data prior to 1987 from foreign fishing should be investigated for longfin squid. Current assessment approaches use seasonal time steps but historical catch data are currently available only by calendar year. The working group should consult historical NAFO reports and determine if monthly or quarterly catches can be estimated. Alternatively, the PDQ model could be modified to use annual time steps prior to 1987 and quarterly time steps later. Another approach would be to use an annual surplus production model including years before and after 1987.

The use of production models to assess squid stocks is not recommended by the ICES Working Group on Cephalopod Fisheries and Life History given their unique life history characteristics, which include the lack of a strong relationship between current and future stock size estimates and the fact that natural mortality is difficult to estimate and varies with age (Anonymous 2001).
5) Results from this assessment demonstrate that retrospective analyses are a useful part of an assessment involving surplus production models because they provide an estimate of the stability of model estimates. However, retrospective patterns for estimates in production models may have a different meaning and origin than in traditional age structured models. This is a topic for analysis by the Methods Working Group.

This research recommendation is now moot because a production model is no longer used in the assessment.
6) Available logbook data are not adequate to measure fishing effort after 1993, or to prorate landings and effort data by area. It is not currently possible to measure commercial catch rates after 1993, to track trends in fishing effort, or to investigate
relationships between catches and abundance in near shore, offshore, northern and southern areas. The spatial resolution, coverage and accuracy of commercial catch data for longfin squid should be improved.

Logbook data for 1996-2009 were used in the current assessment to compute nominal fishing effort and LPUE indices.
7) Information about the population biology of longfin squid has improved in recent years but relationships between seasonal migrations, environmental conditions and temporal and spatial variability in sex ratios, maturity and growth rates are still not clear. It may be useful to carryout additional studies that collect sex and maturity data from longfin squid taken during NEFSC surveys.

This task was not completed.

## New research recommendations for SARC51

1) Use a mass balance approach to determine if the large apparent differences between the spring and fall biomass estimates are plausible, and what they imply about seasonal patterns in growth, recruitment and mortality.
2) Investigate the use of assessment models with short time steps (i.e., weekly) that incorporate data which allow for cohort-based estimates of biomass and exploitation (e.g., depletion models). Especially consider methods that track changes in fishing mortality.
3) Biomass estimates from NEAMAP inshore survey strata that were previously sampled by NEFSC survey vessels (depths $\leq 18 \mathrm{~m}$ between Cape Hatteras and Long Island) were computed for this assessment. Develop additional approaches to estimating Loligo biomass in unsampled areas, in particular regions south of Cape Hatteras.
4) Refine consumption estimates for Loligo. Where possible, use stock assessment biomass estimates for predator biomass. If a stock assessment-based biomass estimate is not available, it may be advisable to assume a range of survey catchability values in calculating predator swept-area biomass. Estimate consumption by predators (including birds and marine mammals) not well sampled by bottom trawls. Consider smoothing consumption rate estimates to eliminate sampling errors.
5) Develop methods for describing trends in relative fishing mortality for Loligo. Conventional approaches developed for fish do not account for recruitment to fishable sizes during fishing or to very high mortality and somatic growth rates.
6) Develop new $F_{M S Y}$ proxy or threshold reference point approaches for Loligo because conventional approaches developed for finfish with relatively low mortality and slow growth rates are not applicable. Refine $B_{M S Y}$ proxies for Loligo as well.
7) Maturation-mortality results were encouraging but the data sets used in modeling were not ideal. Collect more age, sex and maturity data for each seasonal cohort and use it in
the model. Also, estimate age-reader error for Loligo because this information is important in estimating maturity-mortality model parameters.
8) Refine, carry out sensitivity analyses and document gnomonic natural mortality estimates for Loligo.
9) Refine the upper and lower bounds for factors (efficiency, tow distance, tow width, and stock area) that affect survey catchability, particularly for the new survey vessel, and evaluate whether uniform distributions are the best choice for representing uncertainty in these factors.
10) Analyze the costs and benefits of specifying $A B C$ levels based on predator consumption estimates.
11) Develop approaches to smoothing survey biomass estimates that take into account the short lifespan of Loligo and differences between spring and fall surveys.

## B. Loligo-Tables

Table B1. History summary of the Atlantic Mackerel, Squid and Butterfish Fishery Management Plan.

| Year | Document | Management Action |
| :---: | :---: | :---: |
| $\begin{array}{\|l} 1978- \\ 1980 \end{array}$ | Original FMPs (3) and individual amendments | Established and continued management of Atlantic mackerel, squid, and butterfish fisheries |
| 1983 | Merged FMP | Consolidated management of Atlantic mackerel, squid, and butterfish fisheries under a single FMP |
| 1984 | Amendment 1 | Implemented squid OY adjustment mechanism |
|  |  | Revised Atlantic mackerel mortality rate |
| 1986 | Amendment 2 | Equated fishing year with calendar year |
|  |  | Revised squid bycatch TALFF allowances |
|  |  | Implemented framework adjustment process |
|  |  | Converted expiration of fishing permits from indefinite to annual |
| 1991 | Amendment 3 | Established overfishing definitions for all four species |
| 1991 | Amendment 4 | Limited the activity of directed foreign fishing and joint venture transfers to foreign vessels |
|  |  | Allowed for specification of OY for Atlantic mackerel for up to three years |
| 1996 | Amendment 5 | Adjusted Loligo MSY; established $17 / 8{ }^{\prime \prime}$ minimum mesh size |
|  |  | Eliminated directed foreign fisheries for Loligo, Illex, and butterfish |
|  |  | Instituted a dealer and vessel reporting system; Instituted operator permitting |
|  |  | Implemented a limited access system for Loligo, Illex and butterfish |
|  |  | Expanded management unit to include all Atlantic mackerel, Loligo, Illex, and butterfish under U.S. jurisdiction. |
| 1997 | Amendment 6 | Established directed fishery closure at $95 \%$ of DAH for Loligo, Illex and butterfish with post-closure trip limits for each species |
|  |  | Established a mechanism for seasonal management of the Illex fishery to improve the yield-per recruit |
|  |  | Revised the overfishing definitions for Loligo, Illex and butterfish |
| 1997 | Amendment 7 | Established consistency among FMPs in the NE region of the U.S. relative to vessel permitting, replacement and upgrade criteria |
| 1998 | Amendment 8 | Brought the FMP into compliance with new and revised National Standards and other required provisions of the Sustainable Fisheries Act. |
|  |  | Added a framework adjustment procedure. |
| 2001 | Framework 1 | Established research set-asides (RSAs). |

| Table B1 (cont.) |  |  |
| :---: | :---: | :---: |
| Year | Document | Management Action |
| 2002 | Framework 2 | Established that previous year specifications apply when specifications for the management unit are not published prior to the start of the fishing year (excluding TALFF specifications) |
|  |  | Extended the Illex moratorium for one year, Established Illex seasonal exemption from Loligo minimum mesh; |
|  |  | Specified the Loligo control rule; Allowed Loligo specs to be set for up to 3 years |
| 2003 | Framework 3 | Extended the moratorium on entry to the Illex fishery for an additional year |
| 2004 | Framework 4 | Extended the moratorium on entry to the Illex fishery for an additional 5 years |
| 2009 | Amendment 9 | Extended the moratorium on entry into the Illex fishery, without a sunset provision |
|  |  | Adopted biological reference points for Loligo recommended by the stock assessment review committee (SARC). |
|  |  | Designated EFH for Loligo eggs based on available information |
|  |  | Prohibited bottom trawling by MSB-permitted vessels in Lydonia and Oceanographer Canyons |
|  |  | Authorized specifications to be set for all four MSB species for up to 3 years |
| 2010 | Amendment 10 | Implemented a butterfish rebuilding program. (cap to begin in 2011) |
|  |  | Increased the Loligo minimum mesh in Trimesters 1 and 3. |
|  |  | Implemented a 72-hour trip notification requirement for the Loligo fishery (2011). |

${ }^{1}$ In 2000, a 2,500-pound trip limit was implemented during fishery closures.
${ }^{2}$ During 2000 and 2007-2009, the Loligo DAH was divided up into trimesters. Quarterly quotas were implemented during 2001-2006. The fishery closes during each seasonal time period when the threshold of the seasonal quota allocation is reached.

Table B2. Loligo fishery closure dates (prohibition on Loligo landings $\geq 2,500 \mathrm{lbs}$ per trip), during 2000-2009, when in-season quotas were in effect. Quotas were trimester-based during 2000 and 2007-2009 and quarterly during 20012006.

Table B3. Loligo pealeii landings during 1963-2010 and Total Allowable Catches (TACs) 1974-2010. The 2010 landings are preliminary and incomplete.

| Year | U.S. | Foreign | Total | Annual TAC | \% Foreign |
| :---: | :---: | :---: | :---: | :---: | :---: |
| $1963$ | 1,294 | 0 | 1,294 |  | 0.0\% |
| $1964$ | 576 | 2 | 578 |  | 0.3\% |
| $1965$ | $709$ | 99 | 808 |  | 12.3\% |
| 1966 | 722 | 226 | 948 |  | 22.6\% |

| 2010 | 5,256 | 0 | 5,256 | 19,000 |  |

${ }^{1}$ Landings during 1963-1978 were not reported by species, but are proration-based estimates by Lange and Sissenwine (1980)
${ }^{2}$ Landings during 1979-2010 are from the NEFSC Commercial Fisheries Database
${ }^{3}$ Domestic landings during 1982-1991 include Joint-Venture landings
${ }^{4}$ Domestic landings include unclassified squid which were pro-rated by month and 2-digit Statistical Area (1982-1995) or additive (since 1996)
${ }^{5}$ The source of the landings data for 1963-1995 is NEFSC CRD 02-06.
${ }^{6}$ Since May of 2004, landings have been reported electronically by dealers
${ }^{7}$ Landings during 2010 are preliminary and incomplete
${ }^{8}$ TACs for 1974 and 1975 are for Illex and Loligo combined

Table B4. Numbers of trips sampled, by month, for landings length composition during 1987-2009.

${ }^{1}$ Landings during 1963-1978 were not reported by species, but are proration-based estimates by Lange and Sissenwine (1980)
${ }^{2}$ Landings during 1979-2010 are from the NEFSC Commercial Fisheries Database
${ }^{3}$ Domestic landings during 1982-1991 include Joint-Venture landings
${ }^{4}$ Domestic landings include unclassified squid which were pro-rated by month and 2-digit Statistical Area (1982-1995) or additive (1996-2008)
${ }^{5}$ Since May of 2004, landings have been reported electronically by dealers
${ }^{6}$ Landings during 2010 are preliminary and incomplete

Table B11. Nominal effort (days fished), landings (mt), and nominal LPUE ( $\mathrm{mt} /$ day fished) for bottom trawl trips with Loligo landings $\geq 2,500$ lbs during January-June and July-December, 1996-2009.

| Year | Jan-June fishery |  |  | July-Dec fishery |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Days fished | Landings (mt) | Nominal LPUE (mt/day fished) | Days fished | Landings (mt) | Nominal LPUE (mt/day fished) |
| 1996 | 1064 | 5162 | 4.85 | 373 | 866 | 2.32 |
| 1997 | 800 | 2936 | 3.67 | 1322 | 6016 | 4.55 |

| 2006 | 832 | 5459 | 6.56 | 870 | 4717 | 5.42 |
| 2007 | 690 | 4633 | 6.71 | 427 | 3018 | 7.06 |
| 2008 | 692 | 3971 | 5.74 | 777 | 3715 | 4.78 |
| 2009 | 582 | 2647 | 4.55 | 626 | 2712 | 4.33 |

Table B12. Relative catch rates during the day, versus night and dawn/dusk, for Loligo pre-recruits ( $\leq 8$ cm DML) and recruits ( $>8 \mathrm{~cm}$ DML), during NEFSC fall and spring surveys. For example, the relative catch rate of fall nighttime catches of pre-recruits, on average, is 11.5 times higher than for daytime tows. These diel conversion factors, estimated from a GLM, were used in the previous assessment.

| NEFSC survey | Time period | $\leq 8 \mathrm{~cm} \mathrm{DML}$ | $>8 \mathrm{~cm} \mathrm{DML}$ |
| :---: | :--- | :---: | :---: |
| Fall $^{1}$ | Night (8PM-4AM) | 11.5 | 2.9 |
|  | Dawn/Dusk (4-7:59AM and 4-7:59PM) | 2.2 | 1.2 |
|  | Day (8AM-3:59PM) | 1.0 | 1.0 |
| Spring $^{2}$ | Night (8PM-4AM) | 2.0 | 0.8 |
|  | Dawn/Dusk (4-7:59AM and 4-7:59PM) | 1.2 | 0.9 |
|  | Day (8AM-3:59PM) | 1.0 | 1.0 |

[^3]Table B13. Comparison of Loligo relative abundance indices, pre-recruits ( $\leq 8 \mathrm{~cm}$ DML) and recruits ( $>8 \mathrm{~cm}$ DML), for all times of day versus daytime only (solar zenith $=43-80^{\circ}$ ) during 1975-2008 NEFSC fall surveys.

| Year | Pre-recruits ( $\leq 8 \mathrm{~cm} \mathrm{DML}$ ) |  |  |  | Recruits (>8 cm DML) |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

${ }^{1}$ Pre-1985 data multiplied by door conversion factors (nos. $=0, w t .=1.24$ ) and data from $R / V D E / /$ tows multiplied by vessel conversion factors (nos. $=0.83$, wt. $=0.85$ ) during $1975-2008$.

Table B14. Comparison of Loligo relative abundance indices, pre-recruits ( $\leq 8 \mathrm{~cm} \mathrm{DML}$ ) and recruits ( $>8 \mathrm{~cm}$ DML), for all times of day versus daytime only (solar zenith $=29-84^{\circ}$ ) during 1976-2008 NEFSC spring surveys.

${ }^{1}$ Pre-1985 data multiplied by door conversion factors (nos. $=0$, wt. $=1.24$ ) and data from $\mathrm{R} / \mathrm{V} D E / /$ tows multiplied by vessel conversion factors (nos. $=0.83, \mathrm{wt} .=0.85$ ) during $1976-2008$.

Table B15. Summary of NEFSC fall bottom trawl surveys during 1975-2009. Mean Julian date and N stations pertain to stations sampled in the Loligo strata set during the daytime (solar zenith $43-80^{\circ}$ ) and area sampled also pertains to the Loligo strata set. The 1975-2008 strata set includes offshore strata 1-23, 25-26, and 61-76 plus inshore strata 2-46, 58-61, and 65-66. The 2009 strata set is the same but without strata $\leq 18 \mathrm{~m}$.

| Year | Mean Julian Date | Trawl Type | Research Vessels | Trawl Doors | N stations sampled during "day" | Area $\begin{gathered}\text { Sampled } \\ \left(\mathrm{km}^{2}\right)\end{gathered}$ |

Table B16. Summary of NEFSC spring bottom trawl surveys during 1976-2010. Mean Julian date and N stations pertain to stations sampled in the Loligo strata set during the daytime (solar zenith $29-84^{\circ}$ ) and area sampled also pertains to the Loligo strata set. The 1976-2008 strata set includes offshore strata 1-23, 25-26, and 61-76 plus inshore strata 2-46, 58-61, and 65-66. The 2009-2010 strata set is the same but without strata $\leq 18 \mathrm{~m}$.

| Year | Mean Julian Date | Trawl Type | Research Vessels | Type Trawl Doors | N stations sampled during "day" | Area Sampled ( $\mathrm{km}^{2}$ ) |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |

Table B17. Coefficients (rho) used to convert SRV H. B. Bigelow catches of Loligo pealeii to SRV Albatross IV equivalents for the fall 2009 and spring 2009-2010 NEFSC bottom trawl surveys.

|  | Spring Surveys |  |  | Fall Surveys |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| Size range (DML) | rho | SE | CV | rho | SE | CV |
| $\leq 8 \mathrm{~cm}$ | 1.29 | 0.204 | 16 | 1.26 | 0.088 | 7 |
| $>8 \mathrm{~cm}$ | 2.11 | 0.325 | 15 | 1.70 | 0.090 | 5 |
| All sizes combined | 1.53 | 0.171 | 11 | 1.51 | 0.064 | 4 |

Table B18. Stratified mean numbers and weight ( kg ) per tow for Loligo pealeii pre-recruits ( $\leq 8 \mathrm{~cm} \mathrm{DML}$ ) and recruits ( $>8 \mathrm{~cm}$ ) caught in NEFSC fall surveys during 1975-2009. The 1975-2008 survey strata set includes offshore strata 1-23, 25-26, and 61-76 plus inshore strata 2-46, 58-61, and 65-66. The 2009 strata set is the same except strata $\leq 18 \mathrm{~m}$ were not included because they are too shallow to be sampled by the new survey vessel, the FRV Henry B. Bigelow.

| Year | Number per tow |  |  |  |  |  | Kg per tow |  |

Table B20. Comparison of the previous and current assessments for Loligo, with a stepwise demonstration of effects on mean catch and mean survey kg/tow and mean survey biomass, in NEFSC surveys, during 1987-2000 (the time period of overlap). Effects on a simple average exploitation index (mean catch/mean survey biomass) are also shown. Note that the mean catch/mean survey biomass is a ratio of averages, not the average of annual exploitation indices. Values in the table are meant to show effects of changes in data, methodology and assumptions and should not be used for management purposes. Boxes indicating parameter changes are shaded.

|  |  | $q$-prior |  |  | $q$ used | Estimates for 1987-2000 |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Step | Notes and explanation | Lower bound | Median | Upper bound |  | Mean catch <br> (000s <br> mt/year) | Mean survey kg/tow | $\begin{aligned} & \text { Mean survey } \\ & \text { biomass } \\ & (q \times \mathrm{kg} / \mathrm{tow}, \\ & 000 \mathrm{~s} \mathrm{mt}) \end{aligned}$ | Mean catch <br> / mean survey biomass |
| Previous assessment | Note: a $q$-prior was calculated in the last assessment and used in the PDQ model but not used directly for status determination. | 0.022 | 0.187 | 0.556 | 0.450 | 19.436 | 11.1 | 24.59 | 0.790 |

Table B21. Bounds for factors affecting catchability of Loligo in NEFSC fall and spring bottom trawl surveys, during 1975-2010, for the current assessment and the previous assessment. Survey biomass indices for the previous assessment were adjusted to daytime equivalents based on diel correction factors from a GLM. Indices for the current assessment were computed using "daytime" tows (solar zenith angle $=43-80^{\circ}$ for fall surveys and $29-84^{\circ}$ for spring surveys) to account for diel catchability effects.

Previous assessment (SARC 34)

| Factor | Lower Bound | Upper Bound | Basis |
| :---: | :---: | :---: | :---: |
| Tow distance (d) | $\underset{\mathrm{km}}{5 \%<\underset{\operatorname{nominal}}{ } d}=3.34$ | $\begin{gathered} 10 \%> \\ \text { nominal } d= \\ 3.87 \mathrm{~km} \end{gathered}$ | Based on information from clam and scallop studies; Nominal $d=$ 3.52 km |
| Effective survey trawl width (w) | $\begin{gathered} \text { Mean wing spread }= \\ 0.01164 \mathrm{~km} \end{gathered}$ | $\begin{aligned} & \text { Mean door } \\ & \text { spread } \\ &= 0.02380 \mathrm{~km} \end{aligned}$ | Based on $A L$ wingspread and doorspread sensor measurements |
| Survey <br> bottom trawl efficiency (e) | 0.1 | 0.9 | $0<e \leq 1$ <br> based on arbitrary guestimates |
| Effective stock area (A) | $\begin{gathered} 5 \%>\text { Loligo strata set }= \\ 146,324 \mathrm{~km}^{2} \end{gathered}$ | $\begin{gathered} 30 \%>\text { Loligo } \\ \text { strata set }= \\ 181,163 \mathrm{~km}^{2} \end{gathered}$ | Fall surveys (offshore strata 1-25, 61-76) |
| Weight units (u) | 100,000 | 100,000 | Survey data in kg/tow, biomass in 1000 MT |
| Survey daytime catchability (q) | $\begin{gathered} q_{\min } \\ =0.02149 \end{gathered}$ | $\begin{aligned} & q_{\max } \\ = & 0.5569 \end{aligned}$ | $\begin{gathered} q_{\min }=\left[d_{\min } w_{\min }\right. \\ \left.e_{\min }\right] A_{\max } q_{\max =l} d_{\max } \\ \left.w_{\max } e_{\max ]}\right] A_{\min } \end{gathered}$ |

Current assessment (SARC 51)

| Lower Bound | Upper Bound | Basis |
| :---: | :---: | :---: |
| Mean of SRVAlbatross IV $(A L)$ doppler tow distance for 30 min . at $3.2 \mathrm{kts}=2.96 \mathrm{~km}$ | Mean of $A L$ GPS tow distance for 30 min . at $3.8 \mathrm{kts}=3.57 \mathrm{~km}$ | Lower bound is mode of AL doppler distance (LRD 78-08) Upper bound is mean of $A L$ GPS distances between net touchdown and liftoff based on plots of speed over ground, tow duration, and wingspread and doorspread for 2007 fall and 2008 spring surveys |
| Yankee 36 mean wingspread $=0.01069$ km | Yankee 36 mean doorspread $=0.02192 \mathrm{~km}$ | $A L$ mean wingspread and doorspread measurements for the Yankee 36 trawl during 2006-2008 fall and spring surveys |
| 0.20 | 0.39 (CV=4\%) | Lower bound based on videos of daytime Loligo behavior in front of sweep and in trawl; upper bound based on wingspread area swept ratio of Bigelow to $A L$ ( $=$ 0.625) x $1 /$ rho x Bigelow max $e$ rho $=1.51$ and Bigelow max $e=$ 0.95 |

| 100,000 | 100,000 | Survey data in kg/tow, biomass in 1000 MT |
| $\begin{gathered} q_{\min } 1975-2009 \\ =0.038 \\ q_{\min } 2009-2010 \\ =0.041 \end{gathered}$ | $\begin{aligned} & q_{\max } 1975-2008=0.185 \\ & q_{\max } 2009-2010=0.197 \end{aligned}$ | $\begin{gathered} q_{\text {min }}=\left[\begin{array}{lll} d_{\text {min }} & w_{\text {min }} & e_{\text {min }} \end{array}\right] / A \\ q_{\max }=\left[\begin{array}{ll} d_{\max } & w_{\max } \end{array} e_{\max }\right. \end{gathered}$ |

Table B22. Minimum biomass estimates of Loligo for inshore strata ( $\leq 18 \mathrm{~m}$ ) no longer sampled during NEFSC surveys as of 2009, but sampled during the NEAMAP spring and fall surveys (2007-2010). NEFSC fall survey biomass estimates were based on day tows which occurred during 6:30 AM-4:30 PM (2007-2008). Area swept by the trawl during NEAMAP surveys is $0.025 \mathrm{~km}^{2}$ and is $0.038 \mathrm{~km}^{2}$ during NEFSC surveys based on mean wingspread and tow distance measurements for the Albatross $I V$. Inestimable CVs were a result of too few daytime Albatross IVtows in strata $\leq 18 \mathrm{~m}$ deep. Therefore, the 2007 and 2008 minimum biomass estimates for the NEFSC fall surveys are not reliable.

| Season | Year | NEAMAP |  |  | NEFSC |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | Area sampled$\left(\mathrm{km}^{2}\right)$ | Min. biomass |  | Area sampled |  | Min. biomass |  |  |
|  |  |  | N tows | (mt) | CV | $\left(\mathrm{km}^{2}\right)$ | $\stackrel{\mathrm{N}}{\text { tows }}$ | (mt) | CV |
| fall | 2007 | 14,666 | 150 | 2,951 | 3.9 | 2,909 | 12 | 7,071 | inestimable |
| fall | 2008 | 15,191 | 150 | 1,720 | 4.5 | 5,388 | 16 | 1,076 | inestimable |
| fall | 2009 | 15,191 | 160 | 3,482 | 3.5 |  |  |  |  |
| spring | 2008 | 14,666 | 150 | 1,420 | 5.4 |  |  |  |  |
| spring | 2009 | 15,191 | 160 | 966 | 5.6 |  |  |  |  |
| spring | 2010 | 15,191 | 160 | 389 | 9.3 |  |  |  |  |

${ }^{1}$ NEAMAP standardized tows are 20 min . tow at 3.0 kts with sampling between sunrise and sunset
${ }^{2}$ NEFSC standardized tows for $A L$ IV are 30 min. at 3.8 kts with sampling round-the-clock, but include only daytime tows (6:30-4:30 PM)

Table B23. Minimum, maximum and quantiles (Q25, Q50 and Q75) for the composite $q$-priors for Loligo catches in NEFSC spring and fall surveys, 1975-2010. The median values were used in the assessment.

| Survey years | Minimum | Q25 | Q50 | Q75 | Maximum |
| :---: | :---: | :---: | :---: | :---: | :---: |
| $1975-2008$ | 0.038 | 0.075 | 0.092 | 0.113 | 0.185 |
| $2009-2010$ | 0.041 | 0.080 | 0.098 | 0.121 | 0.197 |

Table B24. Biomass estimates (000s mt) for the spring survey Loligo cohort (1976-2009) in relation to exploitation indices for the Jan-June fishery (1987-2009) and biomass estimates for the fall survey cohort in relation to exploitation indices for the July-Dec fishery. Spring and fall biomass estimates are for March-April and SeptemberOctober, respectively.

| Year | Spring biomass $(000 \mathrm{~s} \mathrm{mt})$ | $\begin{gathered} \text { Jan-June } \\ \text { catch } \\ (000 \mathrm{~s} \mathrm{mt}) \\ \hline \end{gathered}$ | Exploitation Indices <br> Jan-June fishery <br> (Jan-June <br> catch/Spring biomass) | Fall biomass $(000 \mathrm{~s} \mathrm{mt})$ | $\begin{gathered} \text { July-Dec } \\ \text { catch } \\ (000 \mathrm{~s} \mathrm{mt}) \\ \hline \end{gathered}$ | Exploitation Indices <br> July-Dec fishery (July-Dec catch/Fall biomass) |

Table B26. Historical retrospective analysis covering the current and previous four assessments. Start year and end year are for the survey data used in making status determinations. The primary approach or model for status determination is identified for each assessment but a variety of auxiliary data or calculations were usually considered as well.

| SARC/ SAW | Citation | Start year | End year | Primary approach for status determination | Type of F threshold | Fishing mortality status | Overfishing? | Type biomass reference points | Biomass status | Overfished? |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 17 | $\begin{gathered} \text { NEFSC } \\ (1994) \end{gathered}$ | 1967 | 1994 | Relative fall suurvey trends for prerecruits | Three-year average of prerecruits from the NEFSC fall survey falls below the first quartile of the time series | 3-year moving average for 1992 (mean for 19911993)/first quartile of same $=412 / 123=3.3$ | No | Overfishing and conditions not overfishing st | overfished stinguished us was eva | stock Only ated. |
| 21 | $\begin{gathered} \text { NEFSC } \\ (1996) \end{gathered}$ | 1987 | 1999 for biomass, 1998 for F | Shaeffer surplus production model (semester time steps but $K$ and $r$ are constant) using spring and fall survey data | F / Fmsy (threshold value is 1) | F / Fmsy=1.7 (average of estimates for 4 qtrs in 1998) | Yes | January biomass / Bmsy in January 1999 (threshold is 0.5) | 0.57 | No |
| 29 | $\begin{gathered} \text { NEFSC } \\ (1999) \end{gathered}$ | 1987 | 1999 for biomass, 1998 for F | Shaeffer surplus production model (quarterly time steps but $K$ and $r$ are constant) using spring and fall survey data, and two season CPUE indices | F / Fmsy (threshold value is 1) | F/Fmsy=1.7 on January 1, 1999 | Yes | B/Bmsy during spring 2009 (threshold value is 0.5) | 0.57 | No |
| 34 | $\begin{gathered} \text { NEFSC } \\ (2002) \end{gathered}$ | 1967 | 2001 | Fall survey and exploitation index trends. Survey data were scaled by a catchability parameter estimated from the PDQ model, but status determination would be the same without scaling. | F proxy/ Fmsy (threshold value is 1) | F proxy / Fmsy proxy=0.2 / 0.31 (F proxy is the mean of quarterly estimates in 2000 | No | No satisfactory reference point available | NA | NA |
| 51 | In prep. | 1976 | 2009 | Average spring \& fall survey biomass and exploitation index. Survey data were scaled by the median catchability of a prior, but status determination would be the same without scaling. | No satisfactory reference point available | Not model based, uses a wide range of data and judgement | Probably not | Mean biomass during 2008-2009 / Bmsy | 1.28 | No |

Table B27. Summary of weekly natural mortality rate estimates for Loligo spp. (published and new estimates for Loligo pealeii from this assessment). The estimate $\mathrm{M}=0.069$ for lifetime natural mortality (juvenile through spawner) used for the SARC 21 assessment (NEFSC 1996) and Cadrin and Hatfield (1999) is the average of the three estimates from Brodziak (1998) which are shown in the table below. Non-spawning estimates (Mns) are for juvenile through pre-spawning stages. Spawning estimates (Msp) are for actively spawning squid. Estimates in the first row (labeled NEFSC 2002) are from the last assessment.

| Source | Lifestages/cohort assumptions | Winter-hatched cohort (per week) |  | Summer-hatched cohort (per week) |  | Details |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | Non- spawning $\left(\mathrm{M}_{\mathrm{ns}}\right)$ | Spawning $\left(\mathrm{M}_{\mathrm{sp}}\right)$ | Nonspawning ( $\mathrm{M}_{\mathrm{ns}}$ ) | Spawning ( $\mathrm{M}_{\mathrm{sp}}$ ) |  |
| NEFSC (2002) Previous assessment | Juvenile through spawner, by cohort | 0.076 |  | 0.058 |  | Observed maximum size; 3/M rule; assumed to double at maturity |
| Brodziak (1998) | Juvenile through spawner, both cohorts | 0.060 |  |  |  | Hoenig's (1983) method assuming maximum age 296 days <br> Rosenberg's (1990) estimate for Illex argentinus <br> Peterson and Wroblewski (1984), bioenergetics |
| Macewicz (2004) for California market squid (Loligo opalescens) | Spawners, cohort not specified |  | 3.15 * |  |  | Reproductive biology assuming maximum life of spawners = 8 days; implies an average spawning lifespan of 1.67 days |
| Gnomonic method for <br> Mns ; Maturationnatural mortality model for Msp <br> (this assessment) | Separate estimates for non-spawning and spawning stages, winterhatched cohort only | 0.110 | 0.19-0.48 * |  |  | The gnomonic estimate $\mathrm{M}_{\mathrm{ns}}=0.11$ is for lifestages up to maturity; estimates for $\mathrm{M}_{\mathrm{sp}}$ from maturity-mortaltity model assume gnomonic estimate of $\mathrm{M}_{\mathrm{ns}}=0.11$ |
| $\begin{gathered} \text { Min } * * \\ \text { Average } * * \\ \text { Max ** } \end{gathered}$ | Non-spawning | $\begin{aligned} & 0.075 \\ & 0.110 \end{aligned}$ |  |  |  | Excludes $\mathrm{M}_{\mathrm{sp}}$ estimates |

[^4]Table B28. Current and proposed biological reference points for the Loligo pealeii stock and the 2009 exploitation index and biomass estimate used to determine stock status.

| Biomass Reference Points |  |  | Fishing Mortality Reference Points |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Current | Proposed | $\begin{gathered} \text { Mean 2008- } \\ 2009 \text { Biomass } \\ \text { (mt) }^{3} \end{gathered}$ | Current | Proposed | $\begin{gathered} 2009 \\ \text { Exploitation } \\ \text { Index }^{4} \end{gathered}$ |
| Target | Bmsy ${ }^{1}$ | Bmsy proxy = $42,405 \mathrm{mt}$ ( $50 \%$ of carrying capacity) ${ }^{2}$ |  | Mean quarterly exploitation rate during $1987-2000=0.96 / \mathrm{yr}$ | None |  |
| Threshold | 50\% of Bmsy | $\begin{gathered} 50 \% \text { of Bmsy proxy } \\ =21,203 \mathrm{mt} \end{gathered}$ | $\begin{gathered} 54,442 \mathrm{mt} \\ 80 \% \mathrm{CI} \\ (38,452-71,783) \end{gathered}$ | $\begin{gathered} \text { FMSY proxy }=75^{\text {th }} \\ \text { percentile of } \\ \text { exploitation rates } \\ \text { during } 1987-2000= \\ 1.24 / \mathrm{yr} \\ \hline \end{gathered}$ | None | 0.176 |

${ }^{1}$ Amendment 9 to the SMB FMP states that the previous biomass reference points were rejected at SARC34 and new ones were not proposed
${ }^{2}$ Based on averages of the annual NEFSC spring and fall swept-area biomass estimates, at the median $q$-prior level, and assumes that the stock is lightly exploited and that the median biomass during 1976-2008 ( $76,329 \mathrm{mt}$ ) represents $90 \%$ of carrying capacity ( $K$ ), so $K=84,810 \mathrm{mt}$
${ }^{3}$ Based on annual mean of the NEFSC 2008-2009 spring and fall survey swept area biomass estimates
${ }^{4}$ Computed as the 2009 catch / mean of 2008-2009 spring and fall survey swept area biomass estimates

## Schematic of Loligo Life History and Fisheries

Catches spring cohort
Fall survey (Sept.) in yr $t$

Figure B1. Schematic of Loligo pealeii life history in relation to NEFSC spring and fall surveys and the January-June and July-December Loligo fisheries. Fishery pre-recruits are $\leq 8 \mathrm{~cm}$ DML and recruits are $>8 \mathrm{~cm}$ DML.

Figure B2. Statistical Areas used for reporting fishery data in the Northeast region of the U.S. and Federal (Exclusive Economic Zone) and state (0-3 miles) jurisdictional limits.

Figure B3. U.S. foreign, and total Loligo pealeii landings during 1963-2010 and TACs during1974-2010. The 2010 landings are preliminary and incomplete.

Figure B4. Spatial distribution of Loligo fishing effort (days fished) during the winter (Jan.March and Oct.-Dec.) offshore fishery and the summer (April-Sept.) inshore fishery during 1997-2004.

Figure B5. Annual ex-vessel price (avg. \$ per lb in 1990 dollars) of L. pealeii, in relation to landings, during 1990-2009.

Figure B6. Trends in Loligo landings, percent by month, during 1987-1995, 1996-1999, and 2000-2009.

Figure B7. Loligo landings by state during 1994-2009.

Figure B8. Length composition of the landings samples, during 1996-2009, by market category.

Figure B9. Length compositions of the Loligo landings during 1987-1995, 1996-1999, and 20002009.

Figure B10. Discards of Loligo pealeii during 1989-2009 and 95\% confidence intervals.

Figure B11. Percentage of annual numbers of fishery observer trips, by fleet, that were used to compute Loligo discards.

Figure B12. Length compositions of the kept and discarded portions of catches on trips where Loligo were discarded during 1994-1999, 2001-2006 and 2000 and 2007-2009. Since 2000, trip limits have been in effect during portions of each year.

## Appendix B1: Invertebrate Subcommittee meetings for the SAW/SARC-51 assessment of Loligo.

The Invertebrate Subcommittee met on September 28-29 and on October 18-20 at the Northeast Fisheries Science Center in Woods Hole, MA to work on the SAW/SARC-51 stock assessment for Loligo pealeii. Members attended in person and by Webex/conference call. The Subcommittee met again briefly by WebEx/conference call on the morning of October 25 to complete its work. The following persons attended one or more of the meetings.

- Lisa Hendrickson, Northeast Fisheries Science Center (NEFSC), Assessment Lead
- Larry Jacobson, NEFSC, Subcommittee Chair
- Toni Chute, NEFSC, Rapporteur
- Dan Hennen, NEFSC, Rapporteur
- Aja Peters-Mason, NERO (SMB Plan Manager)
- Chris Legault, NEFSC
- DJ Kowalske, NEFSC, Cooperative Research
- Fred Serchuk, NEFSC
- Greg DiDomenico (Industry Advisor)
- Jason Didden (MAFMC,SMB staff person)
- Jason Link, NEFSC
- Jeff Kaelin (Lunds Fisheries, Cape May, NJ)
- Jeff Reichle (Lunds Fisheries, Cape May, NJ)
- Jon Knight (Superior Trawl, Pt. Judith, RI)
- Lars Axelsson (F/V Flicka, Cape May, NJ)
- Mark Terciero, NEFSC
- Paul Rago, NEFSC
- Sam Martin (Atlantic Cape Fisheries, Cape May, NJ)
- Tim Miller, NEFSC
- Vidar Westpestad (Industry consultant)

Appendix B2: Assessment of the effects of solar zenith angle and other environmental factors on the diel catchability of Loligo in bottom trawls

Solar zenith at the time and geographic location of each tow was used in place of the more conventional time of day in estimating diel effects on Loligo catchability in bottom trawls. Solar zenith is the angle between a line drawn between the center of the sun and the observer and a line drawn directly overhead at the location of the observer (Meeus, 1998). Solar zenith is the primary determinant of the amount of irradiance (watts $\mathrm{m}^{-2}$ ) at the surface of the ocean where the observer is located (Frouin et al., 1989). Solar zenith is more useful than time of day in modeling because irradiance varies by latitude, longitude, Julian date and year (which are all used in calculation of the solar zenith). Although there is a clear general relationship between solar zenith and time of day (Figure 1), tows carried out at the same time but at different geographic locations may have substantially different irradiance levels that might affect survey catchability to different extents.

GAM models were fit to fall and spring survey data from the same strata and years used elsewhere in the assessment, and used to confirm diel catchability patterns as functions of squid size, season and other variable. Based on preliminary analyses, the maximum likelihood GAM models fit using the $R$ statistical language were:

$$
Y=f[s(L, Z)+s(L, D)+s(T)+\text { region }+ \text { year }]+\varepsilon
$$

where $Y$ is the dependent variable for one size group in one tow, $f()$ is the link function (see below), and $\varepsilon$ is a statistical error. The continuous variables are $L$ (DML in 1 cm increments), $Z$ (solar zenith at the time and location of tow, degrees), $D$ (tow depth, m ), and $T$ (bottom temperature, ${ }^{\circ} \mathrm{C}$ ). The categorical predictor variables are region (Gulf of Maine, Georges Bank, Southern New England, Mid-Atlantic Bight, and Chesapeake Bay to Cape Hatteras) and year. One $s(x)$ and two dimensional $s(x, y)$ nonlinear spline functions were used to model the continuous predictor variables. The two dimensional splines allow interaction between size and soar zenith or between size and depth. The degree of nonlinearity in the spline functions were chosen using by minimizing of an AIC-type statistic (Wood, 2006).

Modeling mimicked delta-distribution methods in which the probability of a positive survey tow (catch $>1$ squid) was estimated in presence-absence models and the catch in positive tows was estimated separately in catch number models. In presence absence modeling, the dependent variable was $Y=0$ or 1 (if at least one squid was taken in the tow), $f($ ) was the logit link function, likelihood was calculated assuming errors were from a binomial distribution, and data for all size groups in each tow were included. In catch numbers models, the dependent variable was the survey catch, $f($ ) was the log link function was used, likelihood was calculated assuming that the errors were from a negative binomial distribution with estimated shape and scale parameters, and only data for positive tows and size groups were used. Spring and fall survey data were modeled separately. The linear and nonlinear terms in all of the models were statistically significant.

Predicted values from the models showed clear diel effects on the probability of a positive tow and catches in positive tows. Diel effects were size and season dependent (Figures 2-5).

## Objective criteria for defining daytime tows

All preliminary choices of solar zenith cutoffs to define daytime tows resulted in higher mean survey abundance and biomass levels and similar or smaller CVs. However, there was uncertainty about whether to include data collected around noon and data collected around dawn/dusk. Criteria for defining daytime tows were therefore defined objectively using performance scores based on an approximate mean squared error (MSE) approach. In particular, if the bias in a measurement is $b$ and the variance of the measurements is $\sigma^{2}$, then MSE $=b^{2}+\sigma^{2}$. We chose criteria with minimum values of the MSE in order to reduce bias (due to night time tows) and variance of mean numbers and weight per tow. This analysis was not based on GAM or any other model results. Rather, annual mean numbers and weight per tow were calculated from survey data for a wide range of possible criteria. Spring and fall surveys were analyzed separately.

The score used to choose solar zenith criteria was:

$$
\mathrm{X}_{\text {test }}^{\mathrm{n}}=\left[\overline{\mathrm{cv}}_{\text {test }}-\left(\overline{\mathrm{n}}_{\text {test }}-\overline{\mathrm{n}}_{24}\right)^{2}\right]+\left[\frac{\overline{\mathrm{cv}}_{\text {test }}}{\overline{\mathrm{c}}_{24}}-\frac{\overline{\mathrm{n}}_{\text {test }}}{\overline{\mathrm{n}}_{24}}\right]
$$

where $X_{\text {test }}^{\mathrm{n}}$ was the score for mean numbers per tow and a particular set of minimum and maximum values for solar zenith ( $Z_{1}$ and $Z_{2}$, one possible set of criteria for defining daytime tows), $\overline{\mathrm{n}}_{\text {test }}$ and $\overline{\mathrm{n}}_{24}$ were the average (over all years) of the annual stratified random mean numbers per tow for the test criteria and using all tows (day and night), $\overline{\mathrm{cv}}_{\text {test }}$ and $\overline{\mathrm{cv}}_{24}$ were the average (over all years) CVs of the annual stratified mean numbers per tow. The terms ( $\overline{\mathrm{n}}_{\text {test }}-$ n24 and ntestn24 are approximate absolute and relative measures of the reduction in bias using the test criteria relative to using all tows. The terms $\overline{\operatorname{cv}}_{\text {test }}$ and $\frac{\overline{\mathrm{Cv}}_{\text {test }}}{\overline{\mathrm{v}}_{24}}$ are approximate absolute and relative measures of variance. A similar score $X_{\text {test }}^{\mathrm{b}}$ was calculated for mean weight per tow. The combined score $X_{\text {test }}=X_{\text {test }}^{\mathrm{n}}+\mathrm{X}_{\text {test }}^{\mathrm{b}}$ was calculated $Z_{l}=30$ to $45^{\circ}$ and $Z_{2}=75$ to $90^{\circ}$ in steps of one degree. The combined score surfaces were very bumpy with a wide range of criteria giving similar performance but inclusion of nighttime tows resulted in poor performance. The resulting grid of calculated values was smoothed using a two dimensional loess regression surface and contoured for graphical analysis. The "best" choice for the criteria $Z_{1}$ and $Z_{2}$ was the combination with the lowest combined score. The criteria chosen for the fall survey was $Z_{1}$ $=43^{\circ}$ and $Z_{2}=80^{\circ}$ (Figure 6). The criteria chosen for the spring survey was $Z_{l}=29^{\circ}$ and $Z_{2}=84^{\circ}$ (Figure 7). Thus, daytime fall survey data used in this assessment are for tows with solar zenith values of $43-80^{\circ}$ and daytime spring survey data are for tows with solar zenith values of 29-84 .

Appendix B2 Figure B1. The relationship between solar zenith and time of day (EST) in fall surveys, 1975-2008. Relationships during the spring survey are similar. The sun rises and sets at a solar zenith of $90.83^{\circ}$ when the sun first appears or disappears along the horizon. At local noon, the sun is at its apogee and the solar zenith is at its minimum value.

GAM predicted probability of a positive tow in fall survey (catch~zenith given DML) posflag $\sim \mathbf{s}(d m l$, zensun) $+\mathbf{s}(d m l$, avgdepth $)+\mathbf{s}($ bottemp $)+$ georegion + as.factor(est_year)

Appendix B3: Calculation of SRV H. B. Bigelow calibration coefficients for Loligo pealeii
In 2009 the FRV Henry B. Bigelow replaced the $R / V$ Albatross $I V$ as the primary vessel for conducting spring and fall annual bottom trawl surveys for the Northeast Fisheries Science Center (NEFSC). There are many differences in the vessel operation, gear, and towing procedures between the new and old research platforms (NEFSC Vessel Calibration Working Group 2007). To merge information collected in 2009 onward with that collected previously, we need to be able to transform indices (perhaps at size and age) of abundance from the FRV Henry $B$. Bigelow into those that would have been observed had the $R / V$ Albatross $I V$ still been in service. The general method for merging information from these two time series is to calibrate the new information to that of the old. Specifically we need to predict the relative abundance that would have been observed by the Albatross $I V\left(\hat{R}_{A}\right)$ using the relative abundance from the Henry B. Bigelow $\left(R_{B}\right)$ and a "calibration factor" $(\rho)$,

$$
\begin{equation*}
\hat{R}_{A}=\rho R_{B} . \tag{2}
\end{equation*}
$$

To provide information from which to estimate calibration factors for a broad range of species, 636 paired tows were conducted with the two vessels during 2008. Paired tows occurred at many stations in both the spring and fall surveys. Paired tows were also conducted during the summer and fall at non-random stations to improve the number of non-zero observations for some species. Protocols for the paired tows are described in NEFSC Vessel Calibration Working Group (2007).

The methodology for estimating the calibration factors was proposed by the NEFSC and reviewed by a panel of independent scientists in 2009. The reviewers considered calibration factors that could potentially be specific to either the spring or fall survey (Miller et al. 2010). They recommended using a calibration factor estimator based on a beta-binomial model for the data collected at each station for most species, but also recommended using a ratio-type estimator under certain circumstances and not attempting to estimate calibration factors for species that were not well sampled.

Since the review, it has become apparent that accounting for size of individuals can be necessary for many species. When there are different selectivity patterns for the two vessels, the fraction of available fish of a given size taken by the two gears is different. Therefore, the ratio of the mean catches by the two vessels will change with size. Under these circumstances, the estimated calibration factor that ignores size reflects an average ratio weighted across sizes where the weights of each size class are at least in part related to the number of individuals at that size and the number of stations where individuals at that size were caught. Applying calibration factors that ignore size effects to surveys conducted in subsequent years when the size composition is unchanged should not produce biased predictions (eq. 1). However, when the size composition changes, the frequency of individuals and number of stations where individuals are observed at each size changes and the implicit weighting across size classes used to obtain the estimated calibration factor will not apply to the new data. Consequently, the predicted numbers per tow that would have been caught by the Albatross $I V$ will be biased.

For Loligo, there are two primary seasonal cohorts observed each year in the NEFSC bottom trawl surveys and their abundances fluctuate substantially from year to year. Also, the assessment defines two size classes: pre-recruits ( $\leq 8 \mathrm{~cm}$ DML) and recruits ( $>8 \mathrm{~cm}$ DML). The effects of inter-annual changes in size composition are negligible within each of the pre-recruit and recruit size classes. Therefore, we used a simple size-based calibration model that provided estimates of calibration factors that differ seasonally and are constant within each of the two size classes. Because only tows conducted during the daylight hours (between 0630 and 1630 during the fall and between 0630 and 1730 in the spring) were used in calculating abundance indices, we used the subset of paired tows from the calibration experiment that occurred during the same periods to fit models and estimate the Loligo calibration factors.

| Survey, S-S, constant | 4 | 10790.77 | 21589.55 | 515.9484 | 0.0000 |
| S,F,S-S, constant model | 6 | 10787.28 | 21586.58 | 512.9762 | 0.0000 |
| Logistic model | 5 | 10562.58 | 21135.17 | 61.5728 | 0.0000 |
| Survey, S-S logistic | 10 | 10538.09 | 21096.22 | 22.6256 | 0.0000 |
| S, F, S-S, logistic | 15 | 10529.00 | 21088.10 | 14.5053 | 0.0006 |
|  |  |  |  |  |  |
| Double logistic model | 8 | 10551.54 | 21119.11 | 45.5072 | 0.0000 |
| Survey, S-S, double-logistic model | 16 | 10522.42 | 21076.96 | 3.3617 | 0.1569 |
| S,F,S-S, double-logistic model | 24 | 10512.67 | 21073.60 | 0.0000 | 0.8425 |
|  |  |  |  |  |  |

The constant model that ignores length is

$$
\rho(l)=e^{\gamma}
$$

and the logistic model is

$$
\rho(l)=e^{\gamma}+\frac{e^{\alpha}}{1+e^{-\left(\beta_{0}+\beta_{1} l\right)}}
$$

which allows the lowest calibration factors to asymptote at a value greater than zero and the difference between the lowest and greatest values to be different than 1.
The double-logistic model is

$$
\rho(l)=e^{\alpha}\left(e^{\gamma_{1}}+\frac{1-e^{\gamma_{1}}}{1+e^{-\left(\beta_{0}+e^{\beta_{l} l}\right)}}\right)\left(e^{\gamma_{2}}+\frac{1-e^{\gamma_{2}}}{1+e^{\left(\beta_{2}+e^{\left.\beta_{3} l\right)}\right.}}\right)
$$

which allows the lowest calibration factors to asymptote at a value greater than zero at both small and large size classes and the difference between the lowest and greatest values to be greater than 1. In all models, the exponentiation of various parameters avoids boundary conditions during estimation. The parameters may differ for data obtained at spring or fall survey stations or the site-specific stations.

Letting the full set of calibration factor parameters be $\theta$ (which depends on the above models used), the beta-binomial likelihood we maximized is

$$
L(\theta, \phi)=\prod_{i=1}^{S} \prod_{j=1}^{M} \frac{\operatorname{Beta}\left(a_{j}+N_{B i j}, b_{j}+N_{A i j}\right)}{\operatorname{Beta}\left(a_{j}, b_{j}\right)}\binom{N_{A i j}+N_{B i j}}{N_{B i j}}
$$

where $\operatorname{Beta}()$ is the beta function, and $N_{A i j}$ and $N_{B i j}$ are the numbers caught at station $i$ in length class $j$ by the Albatross IV and Bigelow, respectively. The likelihood is parameterized with parameters $a$ and $b$ which are functions of the calibration factor and dispersion parameter $\phi$,

$$
a_{j}=\rho\left(l_{j} \mid \theta\right) \phi
$$

and

$$
b_{j}=\phi /\left(1+\rho\left(l_{j} \mid \theta\right)\right) .
$$

Appendix B4. Loligo habitat outside the range of the survey strata set used in the assessment
The following analyses were conducted to determine the likelihood that substantial amounts of Loligo pealeii exist outside the range of the NEFSC bottom trawl survey strata used in the assessment during the survey time periods.

## Density-depth relationships for Loligo

One set of analyses used catch-per tow data from the Loligo fishery and NEFSC spring and fall surveys to characterize daytime catch rates of Loligo as a function of depth. The analyses included only daytime tows based on the solar zenith criteria described in Appendix B2.

Commercial data were subset for spring (March-April, the time period of the spring survey) and fall (September-October-November, the time period of the fall survey). The data set included bottom trawl tows conducted during 1996-2009, with Loligo catches $\geq 2500 \mathrm{lbs}$, and with Loligo identified as the target species. The data for each tow included the time and location at the beginning and end of each haul, in addition to Loligo catch. The following variables were computed for each tow: tow duration (hours), CPUE (lbs hour ${ }^{-1}$ ), and time, location and solar zenith for the middle of the tow. Tows were excluded if the solar zenith at the middle of the tow failed to meet the criteria for daytime tows. Categorization of daytime commercial tows was more difficult than for survey tows because commercial tows ranged from 1.2 to 6.8 hours in duration, often beginning in the day and ending at night or vice-versa. The commercial data used in the analysis were from 200 daytime tows in the fall and 129 daytime tows in the spring. CPUE was plotted against depth and smoothed with a loess regression line to identify trends. Results for fall were equivocal because there were no tows at depths beyond about 200 m . Results for spring indicated declining CPUE at depths beyond 175 meters (Figure 1), although data for deep water tows were limited.

Survey catches at depth were predicted for Loligo of different sizes using the GAM models that were also used to characterize diel patterns in survey catches. As described in Appendix B2, the GAM models predicted survey catches in positive tows (tows catching at least one individual). The predictor variables included Loligo length (DML, in 1 cm increments), solar zenith, depth, temperature, region and year as well as interactions between size and solar zenith and size and depth. Spring and fall survey data were modeled separately.

Results for all size groups indicated that the predicted daytime catches declined to low values with increasing depth during fall and spring surveys (Figures 2-3). These trends suggest that high densities of Loligo at depths greater than those included in this assessment are unlikely.

A third analysis used information from seasonal bottom trawl surveys that were conducted at depths greater than the limit of NEFSC surveys ( 366 m), by Rutgers University, during 20032007. Stations along transects located parallel to Baltimore and Hudson Canyons were sampled using a commercial Loligo bottom trawl. However, stations located at depths greater than 274 m were sampled at night. Catch rates of Loligo pealeii (kg per tow) in these surveys also show declines with increasing depth, similar to the analysis of catch rates with depth for daytime tows from NEFSC surveys. During some years, catch rates decline to very low levels at depths $<274$
m which were sampled during the day (i.e., Hudson Canyon March 2003 and Nov. 2004 and 2007, Figure 4). Catch rates of Loligo were very low at depths greater than 366 m during January, March and November, but this result may be an artifact of nighttime sampling.

Appendix B4 Figure 1. CPUE for commercial tows targeting Loligo during the daytime vs. depth of tow, based on NEFOP observer data. The red line was fit by loess regression and is meant to show underlying trends.

Appendix B4 Figure 2. Predicted catch numbers in positive tows for NEFSC fall bottom trawl surveys as a function of depth from, GAM modeling. The label at the top of each panel is squid size (DML, in 1 cm intervals).

## GAM predicted catch numbers in spring survey

Appendix B4 Figure 3. Predicted catch numbers in positive tows for NEFSC spring bottom trawl surveys as a function of depth, from GAM modeling. The label at the top of each panel is squid size (DML, in 1 cm intervals).

Tow Number

Tow Number

Appendix B4 Figure 4. Relationship between Loligo pealeii catch rates (kg per tow) and depth based on seasonal bottom trawl transect surveys conducted by Rutgers University during 2003-2007. The red lines indicate station depths (m) and the black dashed line indicates the depth $(274 \mathrm{~m})$ beyond which stations were sampled at night. The titles indicate the transect identifier ( $b=$ Baltimore Canyon and $\mathrm{h}=$ Hudson Canyon.

## Appendix B5. Estimation of natural mortality

Hendrickson and Hart (2006) developed an age-based cohort model for estimating the spawning mortality of semelparous cephalopods (a "maturation-natural mortality model"). The model was designed to estimate spawning and non-spawning natural mortality rates and maturity parameters based on maturity and age samples for another semelparous squid species, Illex illecebrosus. The model was used for Loligo for the first time in this assessment. The approach appears promising for estimation of maturity and mortality parameters but model estimates in this assessment should be regarded as preliminary due to data limitations and other uncertainties. Mortality and maturity rates in this analysis are weekly rates, unless stated otherwise.

Natural mortality rates for semelparous, short-lived squid species like Loligo tend to be very high (Hendrickson and Hart 2006). However, this is not unusual since Loligo serve as prey for many marine species and natural mortality rates increase at the time of spawning. The traditional approach to estimating maturity-at-age is misleading for squid species like Loligo because mature individuals are underrepresented in samples due to increased mortality rates after spawning. Similarly, age composition data are difficult to interpret because maturation rates (and total mortality) increase with age. Thus, in principle, a simple catch curve (log-transformed abundance vs. age) should be nonlinear (concave) and it is necessary to account for maturity and mortality rates in the same model.

## Materials and methods

The data for the model are assumed to consist of a random sample from the cohort or population over a range of ages, including spawning ages and ages completely recruited to the sampling gear. Age and maturity were recorded for each individual in the sample.

Two data sets were available and only results for females are reported here. The first ( $\mathrm{N}=128$ with 37 mature females) was collected during NEFSC and Connecticut (Long Island Sound) spring bottom trawl surveys in March (mostly) and May, respectively, during 1996-1998. The second set ( $\mathrm{N}=68$ with 51 mature females) was collected in March and May (mostly), during 1991-1993, in the offshore Loligo fishery and the Massachusetts weir fishery, respectively.. It was necessary to combine sampling locations and years because data were limited.

Ignoring gender, the maturity-mortality model assumes that maturation rates $R_{a}$ are a quadratic function of age $a$ :

$$
R_{a}=r_{0}+r_{1} a+r_{2} a^{2}
$$

where $r_{0}, r_{1}$ and $r_{2}$ are potentially estimable maturation parameters. In this assessment, the statistical significance of each of the maturation parameters is evaluated with the goal of omitting imprecise parameters and simplifying the model.Population dynamics are based on the differential equations:
and

$$
\frac{d N}{d t}=-\left(M_{n s}+R\right) N
$$

$$
\frac{d S}{d t}=R N-\left(M_{n s}+M_{s p}\right) S
$$

where $N$ is the number of immature individuals, $S$ is the number of spawners, $M_{n s}$ is the nonspawning (immature) mortality rate, $M_{s p}$ is the spawning (mature) mortality rate, and the mortality parameters ( $M_{n s}$ and $M_{s p}$ ) are potentially estimable. Hendrickson and Hart (2006) give exact solutions for these differential equations.

The maximum likelihood objective function used in fitting the model assumes that the age composition data (for fully recruited ages only) are multinomial with predicted age composition for mature and immature Loligo from the model (i.e., predicted age composition proportional to $N_{a}+S_{a}$ ), conditioned on the sample size. The objective function assumes that the observed proportions of mature individuals in each age group are independent binomials with sample size equal to the number of maturity samples in each age group, and predicted values from the model [i.e. predicted values $=S_{a} /\left(N_{a}+S_{a}\right)$ ]. There are five potentially estimable parameters ( $r_{0}, r_{1}, r_{2}$, $M_{n s}, M_{s p}$ ). The parameters $r_{0}, M_{n s}$ and $M_{s p}$ were estimated as $\log$ transformed parameters and therefore constrained to be positive. The remaining maturity parameters were estimated directly so that estimates might be either positive or negative.

Hendrickson and Hart (2006) used data from a special age reader experiment to quantify aging precision. The predicted values from the model were smeared to account for ageing imprecision, before comparison to the data. Maturity parameter estimates for Illex illecebrosus were sensitive to assumptions about ageing imprecision, but natural mortality parameters were not. Ageing precision was not included for Loligo due to lack of experimental data.

## Results

As in Hendrickson and Hart (2006), preliminary model runs indicated that it was not possible to estimate both $M_{n s}$ and $M_{s p}$ simultaneously. Following Hendrickson and Hart, $M_{n s}$ was estimated using Caddy's (1996) gnomonic approach (=0.11) and assumed in the model while fitting other parameters. As suggested by Hendrickson and Hart's (2006) results, only one ( $r_{1}$ for data set 1) or two ( $r_{0}$ and $r_{l}$ for data set 1 ) maturity parameters were statistically significant. Other maturity parameters were "turned off" and did not affect model estimates.

The best models for each data set (after fixing $M_{n s}=0.11$ and omitting unnecessary maturity parameters), gave estimated maturation rates $\leq 0.8$ at all ages (Appendix B5 Figure 1).
However, the shapes of the estimated relationships between age and maturity rates were different for the two data sets. $M_{s p}$ estimates ranged 0.19 (CV 0.40) to 0.48 (CV 0.11). There were no trends in the residual plots (Appendix B5 Figure 2).

Appendix B5 Figure 1. Biological estimates for Loligo from the best maturation-natural mortality model fit to data set 1 . Estimates for data set 2 were generally similar although the maturity rate for data set 2 declined with age.

Appendix B5 Figure 2. Example residual plots for Loligo from the best maturation-mortality model fit to data set 1 . Goodness of fit to data set 2 was generally similar.

## Appendix B6: Estimates of minimum consumption of Loligo pealeii

Food habits were evaluated for 15 fish predators that consume Loligo pealeii consistently and commonly occur in NEFSC spring and fall bottom trawl surveys. The amount of food eaten, the type of food eaten and estimates of predator abundance were used to compute per capita consumption (Loligo consumed per predator) and total consumption of Loligo.

Loligo consumption estimates in this paper are minimum estimates and may represent a small fraction of total consumption because predation by other Loligo, birds, marine mammals and large pelagic fish area was not included. Predation by predators outside the survey area was not included either. Moreover, swept-area biomass estimates for many of predators were based on bottom trawl survey data without adjustments for survey bottom trawl catchability, resulting in underestimates of predator abundance and consumption. Finally, formulas used to compute per capita consumption probably produce conservative (biased low) estimates.

Results suggest that minimum consumption estimates for 15 fish predators in the survey area is relatively large in comparison to catches in most years (Figure 1). Consumption appears highest during fall when Loligo are most abundant and are widely distributed across the continental shelf and when predators which migrate south of the survey area during the spring surveys (e.g., bluefish and weakfish) are within the survey area.

## Methods

Every predator that contained Loligo was identified in the NEFSC Food Habits Database. From that original list, a subset of key predators (Table 1) was according to several "rules of thumb". In particular, the selected predators had Loligo: 1) amounting to more than $1 \%$ of prey composition during at least one five year block; as prey in more than 10 tows for each two year block; and in at least 10 stomachs for each three year block (Tables 2 and 3).

Food habits data collection is a routine part of NEFSC spring and fall bottom trawl surveys (Azarovitz 1981; NEFC 1988). Annual consumption for each predator species was estimated on a seasonal basis (January-June ="spring" and July-December = "fall") using data from spring and fall bottom trawl surveys during 1977-2009. Although food habits sampling was quantitative beginning in 1973, not all Loligo predators were sampled prior to 1977 (Link and Almeida (2000)). Consumption was calculated separately based on two size groups ( $\leq 20 \mathrm{~cm}$ and $>20 \mathrm{~cm}$ ) for large predators. Total consumption for a predator was estimated as the sum of the estimates for each size group. Annual consumption was computed as the sum of estimates for spring and fall.

Methods were similar to previously described methods for estimating consumption using an evacuation rate model (Durbin et al. 1983; Ursin et al. 1985; Pennington 1985; Overholtz et al. 1991, 1999, 2000, 2008; Tsou \& Collie 2001a, 2001b; Link \& Garrison 2002; Link et al. 2006,

2008, 2009; Methratta \& Link 2006; Link \& Soseebe 2008; Overholtz \& Link 2007, 2009; Tyrrell et al. 2007, 2008; Link and Idoine 2009, Moustahfid et al. 2009; NEFSC 2006, 2007a, 2007b, 2008, 2010a, 2010b). The main input data are: mean stomach contents ( $S_{i}$ ) for each Loligo predator $i$; diet composition ( $D_{i}$, proportion of total stomach contents consisting of Loligo), and bottom temperature records $T$ from the bottom trawl surveys (Taylor et al. 2005).
Units for stomach estimates are in grams.
As noted above, the gastric evacuation rate method was used to calculate per capita consumption (Eggers 1977, Elliott and Persson 1978). The two main parameters were fixed at $\alpha=0.004$ and $\beta$ $=0.115$, based on previous studies and sensitivity analyses (NEFSC 2007a, 2007b). However, $\alpha$ was set at 0.002 for elasmobranch predators to reflect relatively high metabolic costs in sharks and rays. As in most other studies, an additional parameter $\gamma$ was set to one and had no effect on consumption estimates (Gerking 1994).

Per capita consumption rates $C_{i t}$ were calculated:

$$
C_{i t}=24 \cdot E_{i t} \cdot{\overline{S_{i t}}}^{\gamma}
$$

where 24 is the number of hours in a day and the evacuation rate $E_{i t}$ is:

$$
E_{i t}=\alpha e^{\beta T}
$$

where $t$ is a subscript for time period (season and year). Due to lack of data and to limit variability in the results, stomach contents data for some predators were averaged in blocks of two or three years (Table 1).

Estimated daily per capita consumption rates were scaled up to seasonal per capita consumption estimates for each Loligo predator. This was done by multiplying per capita consumption by the diet composition $D_{i j}$ for Loligo, and then by the number of days in each half year. The seasonal per capita estimates were summed to estimate annual per capita consumption. Annual per capita consumption was multiplied by the abundance of each predator to estimate the minimum amount of Loligo consumed on an annual basis.

Abundance estimates from stock assessments were available for six of the fifteen predators (Table 1). A crude estimate of the survey catchability parameter was derived by comparison of simple swept-area and stock assessment abundance estimates. The catchability parameter was used to scale minimum swept area estimates for the six predators to estimates of total abundance. Predator species without stock assessments used minimum swept area abundances without adjustment for catchability.

We used a simple and crude approach to approximate variance in Loligo consumption estimates (Link and Almeida 2000). Previous studies indicate that the largest source of variance is associated with the estimates of abundance. We therefore took the largest CV (with slight modifications) for abundance of each predator as a variance measure for total consumption These CVs ranged from 0.1 to 1.0 and were mostly in the range $0.35-0.50$.

Length compositions of Loligo prey present in predator stomachs were plotted for each predator
and season and compared to Loligo size composition data from the surveys and fishery data. These comparisons show the extent to which surveys, the fishery and predators sample the same size groups.

## Results

The consumption estimates from this analysis are considered preliminary because further research is needed regarding the multiple sources of uncertainty noted below and because ecosystem and predator dynamics in relation to the complex life history and high turnover rates of squid populations are poorly understood. Minimum estimates of consumption for Loligo were 16,000-219,000 mt per year during 1977-2009 (Figure 1 and Table 4). During most years, consumption was higher during the fall than during the spring (Figure 2).

Most of the Loligo consumed were $<10 \mathrm{~cm}$ DML (Figures 3 and 4) although some predators (summer flounder and goosefish) consumed larger individuals. In general, Loligo size compositions from stomachs samples were similar to survey size compositions indicating that predators may "sample" the Loligo stock in a representative manner. The fishery targets Loligo $>8 \mathrm{~cm}$ DML (annual modal size $=12 \mathrm{~cm}$ ), which are larger than the bulk of Loligo prey found in predator stomachs.

Ignoring the differences in length composition that reduce the comparability of fishery and consumption data, minimum estimates of annual consumption removals were larger (often substantially) than annual catches (Figures 1 and 5). The exception was 1997 to 1998, when minimum consumption and catch were about equal.

## Sources of Uncertainty

1. Stock assessment estimates of abundance were not available for all predators resulting in underestimation of Loligo consumption.
2. The assumed value $\alpha=0.004$ is in the range used in other studies, but may be too low resulting in underestimation of consumption.
3. The distribution of Loligo pleii overlaps with L. pealeii near Cape Hatteras and the two species cannot be distinguished between using gross morphology. Therefore, the amount of Loligo pealeii consumption may be overestimated in geographic range where the two species overlap.
4. Some fish predators that did not consistently consume Loligo (e.g. some of the skates) were not included in the analysis resulting in underestimation of consumption.
5. Consumption of Loligo by seabirds, squids and marine mammals and cannibalism by other Loligo was not included resulting in underestimation of consumption.
6. Squid beaks are not enumerated in food habits sampling and Loligo probably digest rapidly. Thus per-capita consumption estimates may be biased low.
7. The analysis assumed complete spatial-temporal overlap of predators and Loligo.

Appendix B6 Table 1. Loligo predators included in minimum consumption estimates. Abundance information was from either from minimum swept area calculations (SWA) or from stock assessments (SA). The temporal resolution of the data (annual, 2 yr , or 3 yr ) indicates the number of years used to average stomach contents and diet composition data.

| Common name | Scientific name | Source of abundance estimates | Time blocks |
| :---: | :---: | :---: | :---: |
| Pollock | Pollachius virens | SA | 2 yr |
| Bluefish | Pomatomus saltatrix | SA | 2 yr |
| Weakfish | Cynoscion regalis | SA | 2 yr |
| Summer Flounder | Paralichthys dentatus | SA | 3 yr |
| Goosefish | Lophius americanus | SA | 3 yr |
| Atlantic cod | Gadus morhua | SA | Annual |
| Red hake | Urophycis chuss | SWA | 2 yr |
| Spotted hake | Urophycis regia | SWA | 2 yr |
| Smooth dogfish | Mustelus canis | SWA | 3 yr |
| Fourspot flounder | Paralichthys oblongus | SWA | 3 yr |
| Spiny dogfish | Squalus acanthias | SWA | Annual |
| Little skate | Raja ocellata | SWA | Annual |
| Winter skate | Raja erinacea | SWA | Annual |
| Silver Hake | Merluccius bilinearis | SWA | Annual |
| White hake | Urophycis tenuis | SWA | Annual |

## C. RED HAKE STOCK ASSESSMENT FOR 2010

## Executive Summary

Red hake, Urophycis chuss, is a demersal gadoid species distributed from the Gulf of St. Lawrence to North Carolina, and is most abundant from the western Gulf of Maine through Southern New England waters (Bigelow and Schroeder 1953). Red hake are separated into northern and southern stocks for management purposes. The northern stock is defined as the Gulf of Maine to Northern Georges Bank region, while the southern stock is defined as the Southern Georges Bank to Mid-Atlantic Bight region.

Nominal red hake commercial landings in the northern stock peaked at 15,000 mt in 1972 and 1973, followed by a sharp decline in 1977 corresponding to the departure of the distant water fleets. Landings then averaged 1000 mt from 1977-1994, but declined to average only 100 mt through 2009. In the southern stock, nominal landings peaked at over $100,000 \mathrm{mt}$ in 1965 with a secondary peak of over 60,000 in 1972. Landings then averaged 2000 mt from 1977-1994, but declined to average 900 mt through 2009. Discards from the northern stock averaged 1300 mt in the early 1980s, declined to about 250 mt from 1995-2000 and have averaged 100 mt through 2009. Discards from the southern stock averaged 4000 mt in the 1980 s , declined to about 1000 mt from 1995-2000 and have averaged 700 mt through 2009. Recreational landings were much more significant in the south with catch averaging 300 mt compared to less than 3 mt in the north through the time series.

Catch data are a major source of uncertainty for this stock assessment, because of potentially mixed reported landings with white hake and uncertain identification to species by observers. Therefore, a length-based model was developed to estimate the proportion of red hake caught from the total hake catch (red and white hake combined). The model estimates for the north were generally lower than the nominal and the large peak in landings in the 1970s is eliminated. The landings for the south were also lower but the trend was similar. The Hakes Working Group was not comfortable with the complete change in trend in the north, so nominal catch was used in the assessment.

For the northern stock, total biomass indices were derived for two time series. The fall survey shows an increase from 1970 through 2002 followed by a decline through 2005. The spring survey increases from 1970 through 1980, but declines through 1990, increases again through 2002 and then is consistent with the fall survey.For the southern stock, the spring survey increases from 1970 through 1980, but declines through 2005, with a slight increase through 2009.

Total consumptive removals by all consistent red hake predators, using swept area abundance estimates of the predators, were consistently around 5 thousand mt per year during the late 1970s to late 1990 s ; more recently these removals have averaged approximately 10 thousand mt in the 2000s. These minimum estimates of red hake consumed by the consistent fish predators in this study were compared to total catch. Catch and minimum swept area estimates of consumption were approximately equal for much of the time series, with landings a little higher earlier in the
time series (1970s), but with consumption the dominant source of removals more recently averaging more than five times higher than catch.

For the northern stock, exploitation indices were derived for two time series. The fall survey shows very high exploitation in the 1960s and early 1970s, followed by a drop to low values from 1977 through the rest of the time series. This coincides with the departure of the distant water fleet. The second time series for exploitation was derived using the spring survey and shows a similar trend.

There is only one time series for the southern stock and it is based on the spring survey. The same peak is evident in the 1960s-1970s followed by a decline. However, exploitation increased from the late 1970s through 2005, with a slight decline in 2002. Exploitation has declined since 2005.

## Although some statistical catch at age models (SCALE and SS3) were attempted, the diagnostics were not adequate for stock status determination or fishery management.

Therefore the assessment is based on An Index Method (AIM) analyses for the northern and southern stocks which use the catch and spring survey data from 1980-2009 and is the basis for proposed biological reference points.

Based on current biological reference points in the existing FMP, the northern stock of red hake is not overfished and overfishing is not occurring. The three year delta mean biomass index, based on NEFSC fall bottom trawl survey data for 2007-2009 ( $2.87 \mathrm{~kg} /$ tow $)$, was above the management threshold level ( $1.6 \mathrm{~kg} /$ tow) and slightly below the target ( $3.1 \mathrm{~kg} /$ tow $)$. The three year average exploitation index (landings divided by biomass index) for 2007-2009 (0.03) was below both the target ( 0.39 ) and the threshold (0.65).

Based on current biological reference points in the existing FMP, the southern stock of red hake is not overfished and overfishing is unknown. The three year delta individual mean weight index, based on NEFSC fall bottom trawl survey data for 2007-2009 ( $0.10 \mathrm{~kg} /$ individual), is below the management threshold ( $0.12 \mathrm{~kg} /$ individual) but the three year average recruitment index ( 5.95 num/tow) is above the threshold value ( 4.72 num/tow).

Based on new recommended biological reference points from SAW/SARC-51, the northern stock of red hake is not overfished and overfishing is not occurring. The three year arithmetic mean biomass index, based on NEFSC spring bottom trawl survey data in Albatross units for 2008-2010 ( $2.42 \mathrm{~kg} /$ tow $)$, was above the proposed management threshold ( $1.27 \mathrm{~kg} /$ tow $)$ and close to the target ( $2.53 \mathrm{~kg} /$ tow). The exploitation index (catch divided by biomass index) for 2007-2009 ( $0.103 \mathrm{kt} / \mathrm{kg}$ ) was below the threshold $(0.163 \mathrm{kt} / \mathrm{kg})$.

Based on new recommended biological reference points from SAW/SARC-51, the southern stock of red hake is not overfished and overfishing is not occurring. The three year arithmetic mean biomass index, based on NEFSC spring bottom trawl survey data in Albatross units for 2008-2010 ( $0.95 \mathrm{~kg} /$ tow), was above the proposed management threshold ( $0.51 \mathrm{~kg} /$ tow $)$ and slightly below the target ( $1.02 \mathrm{~kg} /$ tow). The exploitation index (catch divided by biomass index) for 2007-2009 $(1.150 \mathrm{kt} / \mathrm{kg})$ was below the threshold $(3.038 \mathrm{kt} / \mathrm{kg})$.

Stochastic projections were not performed for this assessment. However, applying the Relative F reference points to the three-year average biomass index allows catches of 394 mt in the north and 2897 mt in the south.

## Terms of Reference

For each stock or combined,

1. Estimate catch from all sources including landings, discards, and effort. Characterize the uncertainty in these sources of data, and estimate LPUE. Analyze and correct for any species mis-identification in these data.
2. Present the survey data that are being used in the assessment (e.g., regional indices of abundance, recruitment, state surveys, age-length data, etc.). Characterize the uncertainty in these sources of data.
3. Evaluate the validity of the current stock definition, and determine whether this should be changed. Take into account what is known about migration among stock areas.
4. Estimate measures of annual fishing mortality, recruitment and stock biomass (both total and spawning stock) for the time series, and characterize their uncertainty. Include a historical retrospective analysis to allow a comparison with previous assessment results.
5. State the existing stock status definitions for the terms "overfished" and "overfishing". Then update or redefine biological reference points (BRPs; estimates or proxies for BMSY, BTHRESHOLD, and FMSY; and estimates of their uncertainty). If analytic model-based estimates are unavailable, consider recommending alternative measurable proxies for BRPs. Comment on the scientific adequacy of existing BRPs and the "new" (i.e., updated, redefined, or alternative) BRPs.
6. Evaluate stock status (overfished and overfishing) with respect to the existing BRPs, as well as with respect to the "new" BRPs (from Red hake TOR 5).
7. Develop and apply analytical approaches and data that can be used for conducting single and multi-year stock projections and for computing candidate ABCs (Acceptable Biological Catch; see Appendix to the TORs).
a. Provide numerical short-term projections (3 years). Each projection should estimate and report annual probabilities of exceeding threshold BRPs for F , and probabilities of falling below threshold BRPs for biomass. In carrying out projections, consider a range of assumptions about the most important uncertainties in the assessment (e.g., terminal year abundance, variability in recruitment).
b. Comment on which projections seem most realistic, taking into consideration uncertainties in the assessment.
c. Describe this stock's vulnerability to becoming overfished, and how this could affect the choice of ABC .
8. Review, evaluate and report on the status of the SARC and Working Group research recommendations listed in recent SARC reviewed assessments and review panel reports. Identify new research recommendations.

## Hake Working Group (HWG) Meetings

Three meetings were held in preparation of the 2010 red hake assessment

1. Hake fishermen's/stakeholder's meeting - August 6, 2010 - UMASS School of Marine Science and Technology (SMAST), Fairhaven, MA. Participants include fishermen Dan Farnham and Bill Phoel. Also in attendance were David Goethel (Oversight Committee chair), Andrew Applegate (staff) Steve Cadrin (SSC and WG chair, SMAST), Pingguo He, Klondike Jonas, Yuying Zhang, Tony Wood, and Daniel Goethel (SMAST), Loretta O'Brien, Michele Traver, Katherine Sosebee and Larry Alade (NEFSC), and Dick Allen (advisor at large). A summary of the discussions is in Appendix A1.
2. Data Meeting - September 7-10, 2010, NEFSC Woods Hole MA. Participants included Steve Cadrin (WG Chair), Assessment leads (Larry Alade, Kathy Sosebee, Michele Traver), Rapporteurs (Jessica Blaylock and Julie Nieland), Mark Showell (DFO), Andy Applegate (NEFMC Staff), NEFSC (Loretta O’Brien, Mark Terceiro, Chris Legault, Tim Miller, Dave Richardson, Ayeisha Brinson, Jiashen Tang, Janet Nye, Mike Palmer, Paul Rago, Josef Idoine, Jon Hare), Moira Kelly (NERO), SMAST(Tony Wood, Yuying Zhang, Saang-Yoon Hyun)
3. Model Meeting - October 25-29, 2010, NEFSC, Woods Hole, MA. Participants included Steve Cadrin (WG chair), Assessment leads ((Larry Alade, Kathy Sosebee, Michele Traver), Rapporteurs (Jessica Blaylock and Julie Nieland), Mark Showell (DFO), Andy Applegate (NEFMC Staff), Dan Farnham (Fisherman and Industry Advisor), (Loretta O’Brien, Paul Nitschke, Mark Terceiro, Jay Burnett, Chris Legault, Tim Miller, Jon Deroba, Rich McBride, Jim Weinberg, Paul Rago, Josef Idoine, Jon Hare, Janet Nye, Dave Richardson, Laurel Col, Jason Link), SMAST(Tony Wood, Yuying Zhang, Dan Goethel). The groups met by correspondence after the meetings, including a WebEx meeting on November 5, 2010 to report updates on silver hake analyses, provide guidance on reference points and discuss plans for report development.

This Working Group (WG) report includes products from all three meetings and contributions from all participants.

## Fishery Regulations

The following outlines the current small mesh multispecies regulations (based on the small mesh exemption program) for the New England whiting fishery to provide context for interpreting the fishery and model results.

1. 1994 \& 2000 - Exempted fisheries allows vessels to fish for specific species such as whiting or northern shrimp in designated areas using mesh sizes smaller than the minimum mesh size allowed (Gulf of Maine, Georges Bank, Southern New England, Mid-Atlantic : 6.5-inch square or diamond) under the Regulated Mesh Area (RMA) regulations.
2. Permits
a. Open access Category K Multispecies
b. Limited Access Category A-F (non Days-at-Sea fishing )
3. No Size Limits
4. 500 lbs at sea transfer limit.
5. 2003 - Possession limits vary by exemption area
a. 3,500 lbs if mesh $<2.5$ inches $(63.5 \mathrm{~mm})$
b. $7,500 \mathrm{lbs}$ if mesh $<=3.0$ inches $(76.2 \mathrm{~mm})$
c. $30,000 \mathrm{lbs}$ if mesh $>3.0$ inches $(76.2 \mathrm{~mm})$
d. No Red Hake possession limit

## Introduction

Red hake, Urophycis chuss, is a demersal gadoid species distributed from the Gulf of St. Lawrence to North Carolina, and is most abundant from the western Gulf of Maine through Southern New England waters. Red hake are separated into northern and southern stocks for management purposes. The northern stock is defined as the Gulf of Maine to Northern Georges Bank region, while the southern stock is defined as the Southern Georges Bank to Mid-Atlantic Bight region (Figure C1). Both red hake stocks were last assessed in the fall of 1990.

Red hake migrate seasonally, preferring temperatures between 5 and $12^{\circ} \mathrm{C}\left(41-54^{\circ} \mathrm{F}\right)$ (Grosslein and Azarovitz 1982). During the spring and summer months, red hake move into shallower waters to spawn, and during the winter months move offshore to deep waters in the Gulf of Maine and the edge of the continental shelf along Southern New England and Georges Bank. Spawning occurs from May through November, with primary spawning grounds on the southwest part of Georges Bank and in the Southern New England area off Montauk Point, Long Island (Colton and Temple 1961).

Red hake do not grow as large as white hake, and normally reach a maximum size of 50 cm (20 in.) and 2 kg ( 4.4 lbs .) (Musick 1967). However, females are generally larger than males of the same age, and reach a maximum length of $63 \mathrm{~cm}(25 \mathrm{in}$.$) and a weight of 3.6 \mathrm{~kg}$ ( 7.9 lbs .) (Collette and Klein-MacPhee eds. 2002). Although they generally do not live longer than 8 years, red hake have been recorded up to 14 years old. In the northern stock, the age at $50 \%$ maturity is 1.4 years for males and 1.8 years for females, and the size at $50 \%$ maturity is 22 cm ( 8.7 in .) for males and 27 cm (10.6 in.) for females (O'Brien et al. 1993). In the southern red hake stock, the age at $50 \%$ maturity is 1.8 years for males and 1.7 years for females, and the size at $50 \%$ maturity is $24 \mathrm{~cm}(9.5 \mathrm{in}$.) for males and 25 cm ( 9.8 in .) for females (O'Brien et al. 1993).

Red hake prefer soft sand or muddy bottom, and feed primarily on crustaceans such as euphausiids, decapods, and rock crabs as well as fish such as haddock, silver hake, sea robins,
sand lance, mackerel and small red hake (Bowman et al. 2000). Primary predators of red hake include spiny dogfish, cod, goosefish, and silver hake (Rountree 1999). As juveniles, red hake seek shelter from predators in scallop beds, and are commonly found in the mantle cavities of (or underneath) sea scallops. In the fall, red hake likely leave the safety of the scallop beds due to their increasing size and to seek warmer temperatures in offshore waters (Steiner et al. 1982).

## TOR1. Estimate catch from all sources including landings, discards, and effort. Characterize the uncertainty in these sources of data, and estimate LPUE. Analyze and correct for any species mis-identification in these data.

## Commercial Fishery Landings

Following the arrival of distant-water fleets in the early 1960s, nominal commercial landings from both stocks combined peaked at 113,500 mt in 1966 (Table C1, Figure C2). Nominal landings then declined sharply to $12,500 \mathrm{mt}$ in 1970 , increased to $76,200 \mathrm{mt}$ in 1972 , and then declined steadily with increased restrictions on distant-water fishing effort. Prior to implementation of the Magnuson Fisheries Conservation and Management Act (MFCMA) in 1977, distant-water fleets accounted for approximately $80-90 \%$ of the nominal landings from both stocks. Between 1977 and 1986, landings generally declined due to restrictions placed on distant water fleets, and foreign landings ceased in 1987 (Table C1, Figure C3). Red hake landings continued to decline afterwards, and averaged only $1,400 \mathrm{mt}$ per year during 19962000. Nominal red hake landings then declined further to average 770 mt between 2001 and 2009. Red hake are often sold as bait over the side. These landings are not reported in the dealer database, but are supposed to be reported on Vessel Trip Reports (VTR). All the landings tables include whatever landings are reported in the totals. Due to some confidentiality issues, they are not reported separately.

The northern red hake stock had significantly lower commercial landings than the southern stock through the mid-1970s (Table C1, Figure C2). In 1973, total commercial landings peaked at $15,288 \mathrm{mt}$ but have since declined progressively. After 1976, landings declined considerably due to the withdrawal of the distant water fleet. Commercial landings declined to less than 100 mt in 2005 and have remained low (Table C1, Figure C3).

During 1962 to 1976 , landings from the southern red hake stock were much higher than those from the northern stock (Table 1, Figure C2). However, southern red hake landings decreased sharply after 1966 and also after 1976 due to restrictions on distant water fleets. The southern stock landings continued to decrease, and reached a record low of 356 mt in 2005 before increasing to 575 mt in 2009 (Table C1, Figure C3).

Commercial landings in the northern stock generally came from Massachusetts with smaller amounts landed in Maine and Rhode Island (Table C2). The primary states in which red hake were landed in the southern stock are Rhode Island, New Jersey, and New York (Table C3). Massachusetts was a historically important port, with some of the industrial fleet landings probably landed there.

Otter trawls in both regions accounted for the majority of the commercial landings of red hake, although the assumption was made that both the industrial fishery and the bait fishery are from
otter trawl (Tables C4-C5). This assumption is likely valid since otter trawls were the main reported gear type throughout the history of the fishery.

Commercial landings from the northern stock are taken primarily in the summer months, mainly June through October (Table C6) although in the last five years, significant landings have only occurred in July, August and September. Commercial landings from the southern stock occur more evenly during the year (Table C7).

## Species and Length Composition of Landings

Identification of hakes is uncertain in the commercial landings. An alternative method to estimate landings by species (red/white) was developed. Landings by region, half year, and, in the case of white hake, market category (Tables C8-C10) were converted to length composition. Market categories of white hake were aggregated as they were done in the white hake assessment (NEFSC 2001, 2008). The port samples by half year, region, and market were used (Tables C11C 13 ). In general, there were marginally adequate numbers of fish measured for red hake in the south and white hake in the north (Tables C14-C15). Pooling over years by species within a region was required to get an adequate number of fish, particularly for red hake in the north and white hake in the south (Table C16-C17). The length-weight equations by season from Wigley et al 2003 were applied to the samples and used to estimate the landings numbers at length for each market category.

Length compositions for each species for the two regions (GOM-NGBK Offshore strata 20-30, 36-40; SGBK-MA - Offshore strata 1-19, 61-76) were estimated for the spring and fall surveys. The species length-weight equations were then applied to determine weight-at-length by species. The proportions at length by species for both number and weight were applied to the commercial landings-at-length to estimate landings-at-length by species. The lengths had to be grouped into intervals to avoid zero cells in the survey. All fish greater than 70 cm were set to be white hake. Landings from 1964-2009 were hind-cast using the average proportion of red hake by region over the entire time series.

The landings that result from this method are very different than the nominal landings in the north (Table C18, Figure C4) but fairly similar for the southern landings (Table C18, Figure C5). The HWG decided that the hind-cast landings were too uncertain and that the increase seen in the northern stock disappears (and becomes white hake during that time). Therefore, nominal landings will be used for the assessment.

The length compositions from the raw length samples and the length-based model estimates show different patterns for the northern stock (Figures C6-C7). The raw data (only showing years which had red hake length samples) are noisy with some years having fairly small fish (i.e. 1992 and 2007). When the data are pooled to estimate the length compositions and split using survey proportions, trends of these small fish are evident from 1992-1996 and 2006-2009. In the southern stock, the length compositions are fairly similar (Figures C8-C9).

## Commercial Fishery Discards

Discard estimates were calculated in this assessment. The ratio-estimator used in this assessment is based on the methodology described in Rago et al. (2005) and updated in Wigley et al 2007. It relies on a $\mathrm{d} / \mathrm{k}$ ratio where the kept component is defined as the total landings of all species within a "fishery". A fishery is defined as a homogeneous group of vessels with respect to gear type (longline, otter trawl, shrimp trawl, sink gill net, and scallop dredge), quarter, and area fished (GOM-NGBK, SGBK-MA), and for otter trawls, mesh size ( $<=5.49$ ", $>=5.5$ "). All trips were included if they occurred within this stratification regardless of whether or not they caught hakes.

The discard ratio for hakes in stratum $h$ is the sum of discard weight over all trips divided by sum of kept weights over all trips:

$$
\begin{equation*}
\hat{R}_{h}=\frac{\sum_{i=1}^{n_{h}} d_{i h}}{\sum_{i=1}^{n_{h}} k_{i h}} \tag{1}
\end{equation*}
$$

where $\mathrm{d}_{\mathrm{ih}}$ is the discards for hakes within trip i in stratum h and $\mathrm{k}_{\mathrm{ih}}$ is the kept component of the catch for all species. $\mathrm{R}_{\mathrm{h}}$ is the discard rate in stratum h . The stratum weighted discard to kept ratio is obtained by weighted sum of discard ratios over all strata:

$$
\begin{equation*}
\hat{R}=\sum_{h=1}^{H}\left(\frac{N_{h}}{\sum_{h=1}^{H} N_{h}}\right) \hat{R}_{h} \tag{2}
\end{equation*}
$$

The total discard within a strata is simply the product of the estimate discard ratio R and the total landings for the fishery defined as stratum h, i.e., $\mathrm{D}_{\mathrm{h}}=\mathrm{R}_{\mathrm{h}} \mathrm{K}_{\mathrm{h}}$.

Cells with < three trips were imputed using annual averages by gear type and region. To hindcast the discards to 1981 (the first year in which there was no industrial fishery), discards/total landings by half year for the first three years (1989-1991 for otter trawl, sink gill net, and shrimp trawl; 1992-1994 for longline and scallop dredge) were averaged and the rate applied to the total landings from the dealer database. For the otter trawl fisheries, the mesh sizes were combined for the hind-cast.

The main sources of red hake discards in the north were the two small-mesh trawl fisheries, including the shrimp trawl fishery, at least until the early 1990s, with the implementation of the Nordmore grate in that fishery (Table C19). The small-mesh trawl fishery in the south is also the largest contributor to discards of red hake, with large-mesh trawl and scallop dredge catching some significant amounts (Table C20). Discards from the longline and sink gill net fisheries were minimal in both regions.

Discards from the northern stock averaged 1300 mt in the early 1980s, declined to about 250 mt from 1995-2000 and have averaged 100 mt through 2009 (Figure C10). Discards from the southern stock averaged 4000 mt in the 1980s, declined to about 1000 mt from 1995-2000 and have averaged 700 mt through 2009 (Figure C11).

## Species and Length Composition of Discards

The same problem with species identification that exists in the landings is found in the Fisheries Observer Program data. The same length-based method used for commercial landings was used to split discards. Discards were estimated for white hake using the same method as for red hake (Tables C21-C22). Enough length samples were available for large and small mesh otter trawls in both regions and sink gill net and shrimp trawl in the north (Tables C23-26). Pooling over years was still required to get an adequate number of fish (Tables C27-30). To hind-cast the species proportions back to 1981, the average proportion of red hake for the time series was used and applied to the total red and white hake discards. This method resulted in slightly different discard estimates for the north (Table C31, Figure C10) and almost imperceptible differences in the south (Table C31, Figure C11). To be consistent with landings, the nominal discards were used for the assessment. The length compositions from the nominal discards and the lengthbased model estimates show very little difference in either stock (Figures C12-C15).

## Recreational Catch

USA recreational landings of red hake were estimated by stock using data provided by NOAA MRFSS from 1981-2009 (Table C32). Landings prior to 1981 were hind-cast for the north using an average proportion of the total landings. The southern stock had estimates previously derived (NEFC 1990) and these were used directly. Recreational landings were much more significant in the south with catch averaging 300 mt compared to less than 3 mt in the north through the time series (Figure C16). The number of length samples taken in the recreational fishery is sparse for the northern stock, so the southern stock length frequencies were used for both stocks (Figure C17).

## Commercial Fishing Effort and LPUE

There are currently no estimates of CPUE or effort for this species. Given the uncertainties given above with species identification and the major changes in management noted in the introduction, CPUE is not likely to be a good indicator of stock status. In particular, the fishery in the north has been limited in areas they can fish with small mesh. These are not necessarily areas for good red hake fishing. Over time, the fishery has also changed from one dominated by a distant water fleet that took substantial quantities of everything to a much smaller by-catch fishery that may be driven more by prices of silver hake and regulation than abundance.

TOR 2. Present the survey data that are being used in the assessment (e.g., regional indices of abundance, recruitment, state surveys, age-length data, etc.). Characterize the uncertainty in these sources of data.

Data Source: The primary sources of biological information for red hake are based on the annual fishery independent surveys conducted by the Northeast Fisheries Science Center (NEFSC). The surveys were conducted using a random stratified sampling design which allocates samples relative to the size of the strata, defined by depth. The surveys extend from the Gulf of Maine to Cape Hatteras, in offshore waters at depths 27-365 meters, and have been conducted in the fall since 1963 and in the spring since 1968. The winter bottom trawl survey began in 1992 and was specifically designed for flatfish, however, the deeper survey strata were not sampled until 1998 (Figure C18). The winter trawl survey does not cover the Georges Bank area because the survey was designed specifically for flatfish in the southern region. Details on the stratified random survey design and biological sampling methodology may be found in Grosslein (1969), Azarovitz (1981) and Sosebee and Cadrin (2006). Other surveys used in the analysis of silver hake are NEFSC shrimp survey (1985-2009), Massachusetts Division of Marine Fisheries (1978-2009) fall and spring surveys and Rhode Island (1979-2010), Connecticut (1984-2009), and Maine-New Hampshire (2000-2009) state surveys.

The NEFSC spring and fall survey estimates were calculated for northern, southern and combined management regions. The NEFSC strata used for the northern area are offshore strata 20-30 and 36-40. The NEFSC strata used for the southern management area are: offshore strata $1-19$ and 61-76. The combined strata set is: offshore 1-30, 36-40, and 61-76. The strata set for the shrimp survey is shrimp strata 1-12. The strata set for the winter surveys is: offshore strata 1 3, 5-7, 9-11, 13-14, 61-63, 65-67, 69-71, and 73-75. Massachusetts Division of Marine Fisheries data was separated into northern and southern areas. The northern strata used were MADMF 1836 and the southern strata used were 11-17 (Figure C19).

Minimum swept area abundance and biomass were calculated by using swept area conversions of 0.0112 for the NEFSC fall and spring surveys, 0.004 for NEFSC shrimp survey, 0.0131 for the NEFSC winter survey, and 0.003846208 for Massachusetts Division of Marine Fisheries (MADMF) fall and spring surveys. Swept area estimates were not calculated for the other state surveys

Transform: NEFSC spring and fall survey estimates were computed using both delta transformation and arithmetic means for numbers and weight. The Whiting Plan Development Team (PDT) has used the delta mean for assessing stock status. The delta transformation uses only the positive tows for $\log$ transformation:

$$
\left.\begin{array}{l}
\hat{M}_{\delta}= \begin{cases}\frac{m}{n} e^{\bar{\top}} \psi_{m}\left(\frac{1}{2} s_{y}^{2}\right) & m>1, \\
\frac{1}{n} x_{1} & m=1, \\
0 & m=0\end{cases} \\
\\
\\
m=\text { number of non - zero tows } \\
n=\text { total number of tows }
\end{array}\right\} \begin{array}{ll}
\frac{m}{n} e^{2 \bar{y}}\left[\psi\left(2 s_{y}^{2}\right)-\frac{m-1}{n-1} \psi_{m}\left(\frac{m-2}{m-1} s_{y}^{2}\right)\right] & m>1, \\
\frac{1}{n} x_{1}^{2} & m=1, \\
\hat{V}_{\delta} & m=0
\end{array}
$$

Examination of the differences between the delta and arithmetic means revealed that use of the delta transformation did not reduce the variability of the survey and may have increased the variability between years (Figure C20). If a survey has a high variance, the back-transformation may be biased high. The delta transformation was also more sensitive to the handling of missing weights. Prior to 2001, the data for weights were recorded to the nearest 0.1 kg and if a tow contained only a single small fish, the weight was entered into the data as zero. Since the delta transform uses the positive tow, how this is handled has an impact on the result. There are three options: taking out the zeros, leaving in the zeros, and filling in zeros using a length-weight equation. Since these options did not affect the arithmetic as much as the delta mean, the decision was made to use the arithmetic and length-weight options for any new analyses (Figure C21).

Calibration: In 2009 the NOAA SHIP Henry B. Bigelow replaced the $R / V$ Albatross $I V$ as the primary vessel for conducting spring and fall annual bottom trawl surveys for the Northeast Fisheries Science Center (NEFSC). There are many differences in the vessel operation, gear, and towing procedures between the new and old research platforms (NEFSC Vessel Calibration Working Group 2007). To merge survey information collected in 2009 onward with that collected previously, we need to be able to transform indices (perhaps at size and age) of abundance from the Henry B. Bigelow into those that would have been observed had the Albatross IV still been in service. The general method for merging information from these two time series is to calibrate the new information to that of the old (Pelletier 1998). Specifically we need to predict the relative abundance that would have been observed by the Albatross IV ( $\hat{R}_{A}$ ) using the relative abundance from the Henry B. Bigelow $\left(R_{B}\right)$ and a "calibration factor" ( $\rho$ ),

$$
\begin{equation*}
\hat{R}_{A}=\rho R_{B} . \tag{3}
\end{equation*}
$$

To provide information from which to estimate calibration factors for a broad range of species, 636 paired tows were conducted with the two vessels during 2008. Paired tows occurred at many stations in both the spring and fall surveys. Paired tows were also conducted during the summer and fall at non-random stations to improve the number of non-zero observations for some species. Protocols for the paired tows are described in NEFSC Vessel Calibration Working Group (2007).

The methodology for estimating the calibration factors was proposed by the NEFSC and reviewed by a panel of independent scientists in 2009. The reviewers considered calibration factors that could potentially be specific to either the spring or fall survey (Miller et al. 2010). They recommended using a calibration factor estimator based on a beta-binomial model for the data collected at each station for most species, but also recommended using a ratio-type estimator under certain circumstances and not attempting to estimate calibration factors for species that were not well sampled.
Since the review, it has become apparent that accounting for size of individuals can be necessary for many species. When there are different selectivity patterns for the two vessels, the fraction of available fish of a given size taken by the two gears is different. Therefore, the ratio of the mean catches by the two vessels will change with size. Under these circumstances, the estimated calibration factor that ignores size reflects an average ratio weighted across sizes where the weights of each size class are at least in part related to the number of individuals at that size and the number of stations where individuals at that size were caught. Applying calibration factors that ignore size effects to surveys conducted in subsequent years when the size composition is unchanged should not produce biased predictions (eq. 1). However, when the size composition changes, the frequency of individuals and number of stations where individuals are observed at each size changes and the implicit weighting across size classes used to obtain the estimated calibration factor will not apply to the new data. Consequently, the predicted numbers per tow that would have been caught by the Albatross $I V$ will be biased.

For red hake, we fit a suite of beta-binomial models that made different assumptions on the relationship of the calibration factor to length. The models ranged from those that were constant with respect to length to logistic and double-logistic functions of length. For red hake, the working group decided to use a season-specific double-logistic model relating the calibration factor to length due to it providing the best fit to the data with respect to AIC ${ }_{\mathrm{c}}$ (Table C33-34, Figure C22). Note that the minima for both logistic components in the fall were assumed equal to $0\left(e^{-100}\right)$ due to poorly estimated variance of model coefficients in the fully parameterized model. To estimate weight pre tow for the 2009 and 2010 surveys, the length-weight equations by season from Wigley et al 2003 were applied to the length frequencies.

Survey Data Results: Distribution maps for red hake show that there are higher concentrations of red hake by catch weight $(\mathrm{kg})$ during the NEFSC spring surveys than the NEFSC fall surveys. There were less red hake caught in the middle of Georges Bank in the spring than the fall. They tended to be more in the Gulf of Maine and along the shelf, than in the middle of the bank. The maps are broken into 5-year blocks, by season, for the duration of the time series (Figures C23C34).

North
The fall survey biomass steadily increased during the 1970s, spiked in 2000 at its highest of 12,118 metric tons and then decreased until 2005, where the stock declined to 2,486 metric tons. Biomass has increased the past few years and is currently at 5,086 metric tons in 2009, a $24 \%$ increase from 2008 (Table C35, Figure C35).

The spring survey biomass was variable during the 1970s, with many peaks and valleys. There was a large spike in 1981, where it increased to 13,594 metric tons. In 1982, the biomass index dropped sharply to 4,551 metric tons, a decline of $67 \%$. The stock was quite low in 1990, and
then increased until 2002, where the stock was at 9,543 metric tons and then considerably declined until 2006, with 1,952 metric tons. Since then, the minimum swept area biomass has increased again to 4,326 metric tons, a $122 \%$ increase over 2006 (Table C36, Figure C36).

The shrimp survey swept area biomass was quite low during the early part of the time series. The lowest point was in 1994, at 3,262 metric tons. Biomass continued to slowly increase, until it spiked in 2002 with an all time high of 64,925 metric tons. Then biomass declined by $74 \%$ to 17,194 metric tons in 2003. The 2009 estimate is currently at 13,164 metric tons (Table C37, Figure C37).

The lowest biomass estimate from the MADMF fall surveys was in 1987, where there were only 447 metric tons caught. Then biomass increased through the 1990s, where it hit a maximum value in 2000 of 3,842 metric tons. A decline occurred between 2002 and 2008, although 2009 increased by $83 \%$ over 2008 (Table C38, Figure C38).

The MADMF spring surveys have extremely low biomass estimates. There were two spikes early in the time series, in 1979 and 1981, with catches of 3,888 metric tons and 5,129 metric tons, respectively. The biomass declined considerably in 1982 and stayed low until a small bump in 2000 with 1,414 metric tons. The survey biomass then declined to its lowest value in 2004 of 75 metric tons. It increased by $226 \%$ in 2009, to 245 metric tons (Table C39, Figure C39).

The trends for all the fall surveys are in general agreement showing an increase through 2000, a decline through 2005 and an increase over the last few years (NH data in Table C40, Figure C40). The spring surveys also show a general agreement with higher values in the 1980s, declining through 1995, increasing through 2002, and followed by a decline until the last couple of years (NH data in Table C40, Figure C41).

## South

The fall survey swept area biomass was higher during the 1970s and 1980s than any other part of the time series. Biomass peaked at 20,002 metric tons in 1983 before dropping drastically by $80 \%$ to 3,905 metric tons in 1984. The stock has continued to decline until 2005. Biomass has increased slightly and is currently at 3,368 metric tons (Table C41, Figure C42).

Similar to the fall survey, the spring survey swept area biomass was higher during the 1970s and early part of the 1980s. After 1981, when the biomass was 15,201 metric tons, it declined to reach a low value of 511 metric tons. Biomass continued to increase to 3,460 metric tons in 2010, a $577 \%$ increase since 2004 (Table C42, Figure C43).

The winter survey has a very short time series, 1992-2007. The swept area biomass was high during the early part of the time series, with 18,483 metric tons in 1993. The survey biomass then declined, hitting its lowest value in 2003 at only 159 metric tons. The biomass varied until the winter survey was discontinued in 2007 (Table C43, Figure C44).

The MADMF fall survey in the southern region has much smaller biomass than in the northern region. The survey was variable at best with many peaks and valleys throughout the time series. In 2004, the survey was at its lowest point with 0.22 metric tons of swept area biomass. In 2009,
there was an increase of $645 \%$ to 1.64 metric tons than in 2004 (Table C44, Figure C45).
The MADMF spring survey has larger swept area biomass than the MADMF fall survey. The early part of the time series has greater values than the latter. The highest biomass was estimated in 1987 with 894 metric tons, where 2003 was the lowest, at 0.36 metric tons. In 2009, the swept area biomass was 6.92 metric tons (Table C45, Figure C46).

The trends for all the fall surveys are much noisier than in the northern area (RI and CT data in Table C46, Figure C47). The spring surveys also show great deal of noise (RI and CT data in Table C46, Figure C48).

## Combined

The fall survey swept area biomass, combining both the northern and southern management areas, had a steep decline to 4,467 metric tons in 1974 from 17,737 metric tons in 1972. Then the biomass increased substantially to 28,807 metric tons in 1983. After a considerable drop in 1986, the biomass estimates were stable throughout the rest of the time series. The biomass in 2009 was 8,454 metric tons (Table C47, Figure C49).

In the spring survey, biomass peaked at 30,831 metric tons and 28,794 metric tons in 1978 and 1981, respectively. Biomass then declined until 1998, when biomass increased slightly. There was a $75 \%$ decline from 11,337 metric tons in 2002 to 2,812 metric tons in 2003. The stock increased since then and was 9,022 metric tons in 2009 (Table C48, Figure C50).

## Length Composition

The length compositions from the fall survey show a large proportion of very small fish in the northern stock (Figure C51). There has also been a truncation of size of fish with very few fish caught that are greater than 40 cm . The spring survey length composition has many fewer small fish (except for 1974) but shows the same size truncation (Figure C52).

In the south, the young-of-the-year are very dominant in the length composition, but the size truncation is less noticeable, possibly since there may have already been truncation before the time series started (Figure C53). However, the spring survey shows some truncation occurring in the late 1980s and early 1990s, with fewer fish greater than 35 cm caught in the survey (Figure C54). The winter survey shows more young fish than the spring, possibly because the survey used a cookie sweep and was able to capture small fish and, more importantly, the scallops that they inhabit (Figure C55).

## Estimates of Consumption of Red Hake

Every predator that contained red hake was identified from the NEFSC FHDBS. From that original list, a subset of predators (Table C49) was examined to elucidate which predators consistently ate red hake, determined by "rules of thumb" that include having a diet composition of $>1 \%$ for any five year block, and with $>5$ tows for each two year block and $>10$ stomachs for each three year block.

Annual consumption estimates were calculated on a seasonal basis (two 6 month periods) based on spring and fall bottom trawl surveys and for each predator species. Although the food habits data collections started quantitatively in 1973, not all species of red hake predators were sampled during the full extent of this sampling program, thus the time series used here begins in 1977 (Link and Almeida 2000). This sampling program was a part of the NEFSC bottom trawl survey program (Azarovitz 1981; NEFC 1988). There are various ways to integrate seasonally, but the simple sum of the two seasonal estimates was used in this analysis. The analyses were done for various size classes of predators, and then were integrated across all predator size classes to come up with a total consumption of red hake for each predator.

This approach followed previously established and described methods for estimating consumption, using an evacuation rate model methodology. For further details, see Durbin et al. (1983), Ursin et al. (1985), Pennington (1985), Overholtz et al. (1991, 1999, 2000, 2008), Tsou \& Collie (2001a, 2001b), Link \& Garrison (2002), Link et al. (2006, 2008, 2009), Methratta \& Link (2006), Link \& Sosebee (2008), Overholtz \& Link (2007, 2009), Tyrrell et al. (2007, 2008), Link and Idoine (2009), Moustahfid et al. (2009a, 2009b), and NEFSC (e.g., 2006, 2007a, 2007b, 2008, 2010a, 2010b). The main data inputs are mean stomach contents $\left(S_{i}\right)$ for each red hake predator $i$, diet composition $\left(D_{i j}\right)$ where the subscript $j$ refers to red hake as a prey item, and $T$ is the bottom temperature taken from the bottom trawl surveys (Taylor et al. 2005). Units for stomach estimates are in g.

As noted, to estimate per capita consumption, the gastric evacuation rate method was used (Eggers 1977, Elliott and Persson 1978). There has been copious experience in this region using these models (see references listed above). The two main parameters, $\alpha$ and $\beta$, were set to 0.004 and 0.115 respectively based upon prior studies and sensitivity analyses (NEFSC 2007a, 2007b). The exception is that $\alpha$ was set to 0.002 for elasmobranch predators consistent with and to reflect their slightly lower metabolism than teleost fishes.

Using the evacuation rate model to calculate consumption requires two variables and two parameters. The per capita consumption rate, $C_{i t}$ is calculated as:

$$
C_{i t}=24 \cdot E_{i t} \cdot \bar{S}_{i t}^{\gamma}
$$

where 24 is the number of hours in a day and the evacuation rate $E_{i t}$ is:

$$
E_{i t}=\alpha e^{\beta T} ;
$$

and is formulated such that estimates of mean stomach contents $\left(S_{i t}\right)$ and ambient temperature ( $T$; here used as bottom temperature from the NEFSC bottom trawl surveys for either season (Taylor \& Bascuñán 2000, Taylor et al. 2005)) are the only data required. This was done for each predator $i$ (size and species) for each time period $t$ (season and year). The parameters $\alpha$ and $\beta$ are set as values chosen noted above. The parameter $\gamma$ is a shape function is almost always set to 1 (Gerking 1994).

Once daily per capita consumption rates were estimated for each red hake predator, those estimates were then scaled up to a seasonal estimate. This was done by multiplying the number days in each half year, which were then multiplied by the diet composition $D_{i j}$ that was red hake,
to estimate the seasonal per capita consumption of red hake. That is, once per capita consumption rates were estimated for each red hake predator in a temporal period $(t)$, those estimates were then scaled up to a seasonal estimate ( $C^{\prime}{ }_{i t}=C_{\text {fall }}$ or $C_{s p r}$ ) by multiplying the number days in each half year:

$$
C_{i t}^{\prime}=C_{i t} \cdot 182.5
$$

These were then multiplied by the diet composition $D_{i j t}$ that was red hake, to estimate the seasonal per capita consumption of this fish $C_{i j t}$ :

$$
C_{i j t}=C^{\prime}{ }_{i t} \cdot D_{i j t}
$$

These were then summed to provide an annual estimate, $C^{\prime}{ }_{i j}$ :

$$
C^{\prime}{ }_{i j}=C_{i j, \text { fall }}+C_{i j, \text { spring }}
$$

Once these were summed to provide an annual estimate (or the following could be seasonally and the summed), they were then scaled by the total stock abundance of each predator to estimate the amount of red hake removed by any of the predators included in the study. Swept area estimates of abundance from bottom trawl survey estimates were used for all predators (Table C49). These consumption estimates were then scaled by the total stock abundance to estimate a total amount of red hake $(j)$ removed by any predator $i, C_{i j}$ :

$$
C_{i j}=C^{\prime}{ }_{i j} \cdot N_{i},
$$

where $N_{i}$ is the estimate of abundance for each predator for each year. These $C_{i j}$ were then summed across all $i$ predators to obtain an estimate a total amount of red hake removed by these red hake predators, $C_{j}$ :

$$
C_{j}=\sum_{i} C_{i j}
$$

Total consumptive removals by all consistent red hake predators, using swept area abundance estimates of the predators, were consistently around 5 thousand mt per year during the late 1970s to late 1990s; more recently these removals averaged approximately 10 thousand mt in the 2000s (Figure C56). For more explicit presentation of the step-by-step data series used to derive the consumptive removal results, please contact the working group, as has been done for similar prior assessments (e.g., NEFSC 2007a, 2007b).

These minimum estimates of red hake consumed by the consistent fish predators in this study were compared to total catch (Figure C56). Catch and minimum swept area estimates of consumption were approximately equal for much of the time series, with landings a little higher earlier in the time series (1970s), but with consumption the dominant source of removal more recently averaging more than five times than catch (Figure C57).

Estimates of predatory removal of red hake via consumption are likely conservative given nature of these consumption estimates. These consumption estimates should be useful to inform both
the scaling of biomass estimates and the magnitude of mortalities for red hake. The estimates of consumption also imply that there has been a change in natural mortality over time. This is likely to be important in any model attempts.

There were enough red hake measured in the stomachs of the predators to pool over the entire time series ( $\mathrm{n}=612$ ). In the future, it may be useful to break into time periods. More than half of the fish measured are between 3 and 8 cm with the mode at 4 cm (Figure C58).

## TOR 3. Evaluate the validity of the current stock definition, and determine whether this should be changed. Take into account what is known about migration among stock areas.

Two subpopulations of red hake are assumed to exist within the U.S. EEZ based largely by analogy with silver hake (NEFC 1986). No morphometric or genetic analyses of the population structure have been conducted. The northern red hake stock inhabits Gulf of Maine - Northern Georges Bank waters, and the southern red hake stock inhabits Southern Georges Bank - Middle Atlantic Bight waters (Figure C1). These boundaries were established at SAW 2.

## Distribution

While it is likely that the northern and the southern stocks mix on Georges Bank, the degree of mixing and movement among the management areas are unknown. NEFSC trawl surveys indicate a generally continuous distribution of silver hake from the Gulf of Maine to the southern New England/Mid-Atlantic Bight (Figures C23 and C24). However, the relative density of red hake has varied through time between the northern and southern management areas. Population density as measured by the NEFSC fall bottom trawl survey increased in northern area during the mid-1980's and then declined in the 2000's (Figure C35). In contrast southern area showed stability through 1982 with a drop in 1983 and a progressive decline through 2004. Since 2004, there has been a slight increase (Figure C42). The spring trends indicate a stable biomass through 1987 followed by a decline through 1995 (Figure C36). Biomass increased through 2000 followed by a decline. The southern trends in the spring are similar to that of the fall survey (Figure C43). The proportion of the total biomass in each area has changed from $80 \%$ in the 1960 s to $60-80 \%$ in the north in the last decade (Figure C59). This could indicate movement, differential mortality, or both.

## Growth and Maturity

In addition to morphology, genetics, and recruitment trends, growth is often a factor in deciding whether to assess adjacent populations as separate stocks or as one combined stock.
Comparisons of growth parameters k and $\mathrm{L}_{\infty}$ (Roomian and Jamili 2011, for example) and growth plots (Brooks and Ortiz 2004, for example) may be confounded by the covariance between these two parameters when simultaneously fitted to size at age data. Similar data can be fit equally well with Von Bertalanffy growth parameters having a low $k$ and high $L_{\infty}$, and vice versa, unless there are sufficient age samples for old fish. Comparison of plots with associated age data to demonstrate variance around the fitted curves can also lead to subjective misinterpretation (e.g. determination that growth is not different when in fact it is).

A plot of mean size at age with confidence intervals, one population along the abscissa and one along the ordinate is an alternative and possibly more informative way of comparing growth characteristics between two populations. Similarities in size at age will appear along a slope $=1$, while differences in growth are readily identifiable as horizontal or vertical deviations from the slope $=1$ line and the confidence intervals show whether that deviation is significantly different from the other population. Distance between successive ages represents the annual growth increment, which of course declines with age as the fish size approaches $\mathrm{L}_{\infty}$. Another advantage of this approach is that it can be readily applied to cohorts and grouped by time frame, examining the growth of fish that have experienced similar environmental characteristics and food availability.

Age determination of red hake by reading otoliths is described in Penttila and Dery 1988, Chapter 9. Dery's otolith analysis concluded that red hake otoliths in the northern stock area were considerably more difficult to interpret than those from red hake captured in the southern stock area, due to "numerous and sometimes prominent checks", factors that "blur the [sic] distinction between annular zones".

The analysis also indicates that otoliths from red hake captured in the northwestern and eastern part of the Bay of Fundy (Gulf of Maine) varied from the otolith morphology for red hake captured elsewhere and had intermediate characteristics with white hake, suggesting the possible existence of hybridization in that area.

Red hake from the spring and fall surveys have been aged from 1970 to 1985. Before 1975 (1957-1974 cohorts), age 1 to 3 red hake appear to have the same growth rates in the northern and southern stock areas. Then age $4+$, growth appears to slow in the southern area and continue to a higher $L_{\infty}$ in the northern stock area (Figure C60a, Figure C61a). Age 4 to 10 red hake are always larger in the north than in the south.

This general pattern of large, old red hake in the northern stock area persists for the 1975-1985 cohorts (Figure C60b, Figure C61b)). Size at age is also relatively consistent between the two cohort time series.

There are also slight differences in size at maturity between stocks although the differences are in one direction for males and the opposite for females (Figure C62).

Although the large, older fish in the northern stock area would argue for separate population modeling and stock dynamics, there appears to be considerable uncertainty in the interpretation of red hake ages in the northern stock area, due to the aforementioned otolith anomalies, potential hybridization with white hake, and possible differential exploitation patterns between the two areas. It is equivocal whether not there are two stocks, one stock or more. There is not enough information to come to a definitive conclusion.

TOR 4. Estimate measures of annual fishing mortality, recruitment and stock biomass (both total and spawning stock) for the time series, and characterize their uncertainty. Include a historical retrospective analysis to allow a comparison with previous assessment results.

## Historical Retrospective

The last assessments for these stocks were conducted in 1990 and at the time both stocks were considered to be "under-exploited".

In this assessment, three models were attempted. They were An Index Method (AIM), Stock Synthesis (SS3) and Statistical Catch-at-Length (SCALE). While all three had problems, AIM was considered to be most useful for guidance on reference points and stock status. The other models needed more time to be developed properly.

## AIM model

The AIM model is a simple approach for examining the relationship between survey data and catch in data poor stock assessments. AIM is designed to address the question of whether a given rate of fishing mortality is likely to increase or decrease the population size. Survey data are used to define a relative rate of increase and the ratio of catch to survey indices provides a measure of relative fishing mortality. Theoretically the model can identify a stable point about which the stock will neither increase nor decrease in response to a fixed harvest rate. The model assumes that the resource dynamics are approximately linear with relatively minor influence of density dependent effects or variable environmental or ecological factors. Such conditions often typify stocks that have been historically harvested at high fishing rates and are therefore at low population sizes. AIM is both an analytic and graphing approach. The analytical methods can be used to define relative Fs for replacement and the graphical methods can be used to identify transient conditions that are relevant to implementation of any model. The details of the methodology are described below.
$\checkmark$ Population biomass at time $t$ can be written as a linear combination of historical population biomasses
$\checkmark$ Recruitment is proportional to population biomass
$\checkmark$ Fishing mortality is proportional to catch divided by an index of population size (relative F).
$\checkmark$ The rate of change in population biomass is a monotonically decreasing function of relative $F$.
$\checkmark$ Smoothing methods can be used to identify underlying trends.
$\checkmark$ Randomization methods can be used to develop sampling distributions of test statistics
$\checkmark$ Graphical methods can help identify linkages among variables
Relative F is defined as the ratio of catch to an index of population abundance. A three-year centered average of the abundance index is chosen as the measure of average stock size.

$$
\begin{equation*}
r e l F_{j, s, t}=\left(\frac{C_{s, t}}{\frac{I_{j, s, t-1}+I_{j, s, t}+I_{j, s, t+1}}{3}}\right) \tag{1}
\end{equation*}
$$

Where $\quad \operatorname{relF}_{j, s, t}=$ relative $F$ for relative index $j$ for stock $s$ at time $t$ $\mathrm{C}_{\mathrm{s}, \mathrm{t}}=$ catch or landings of stock s at time t (in units of weight) $\mathrm{I}_{\mathrm{j}, \mathrm{s}, \mathrm{t}}=$ Index of abundance j for stock s at time t expressed in terms of average weight per tow

The population size at any given time can be viewed as a weighted sum of previous recruitment events. For a population with a maximum age of A years, the population in year $t$ consists of the recruits from year $\mathrm{t}-1, \mathrm{t}-2, \ldots \mathrm{t}-\mathrm{A}$. At high levels of total mortality, the contributions from the earliest recruitments, say t-k-1 to t-A will diminish in importance such that the population can be viewed as the sum of recruitments from $t-1$ to $t-k$ years.

Using the linearity assumption defined above, we can employ basic life history theory to write abundance at time $t$ as a function of the biomasses in previous time periods. The number of recruits at time $t\left(R_{t}\right)$ is assumed to be proportional to the biomass at time $t\left(B_{t}\right)$. More formally,

$$
R_{t}=S_{o} E g g B_{t}
$$

where $\mathbf{E g g}$ is the number of eggs produced per unit of biomass, and $\mathbf{S}_{\mathbf{0}}$ is the survival rate between the egg and recruit stages. Survival for recruited age groups at age a and time $t\left(\mathrm{~S}_{\mathrm{a}, \mathrm{t}}\right)$ is defined as

$$
S_{a, t}=e^{-F_{a, t}-M_{a, t}}
$$

where F and M refer to the instantaneous rates of fishing and natural mortality, respectively. We also need to consider the weight at age a and time $t\left(W_{a, t}\right)$ and the average longevity (A) of the species.

Using these standard concepts we now write the biomass at time $t$ as a linear combination of the A previous years. Without loss of generality, we can drop the subscripts on the survival terms and assume that average weight at age is invariant with respect to time. Further, set the product $\mathrm{S}_{\mathrm{o}}$ Egg equal to the coefficient $\alpha$. The biomass at time t can now be written as

$$
\begin{equation*}
B_{t}=R_{t-1} S^{1} W_{1}+R_{t-2} S^{2} W_{2}+R_{t-3} S^{3} W_{3}+. .+. R_{t-(A-l)} S^{A-1} W_{A-1}+R_{t-A} S^{A} W_{A} \tag{4}
\end{equation*}
$$

Substituting Eq. (2) into Eq. (4) leads to

$$
B_{t}=\alpha B_{t-1} S^{1} W_{1}+\alpha B_{t-2} S^{2} W_{2}+\alpha B_{t-3} S^{3} W_{3}+. .+. \alpha B_{t-(A-1)} S^{A-1} W_{A-1}+\alpha B_{t-A} S^{A} W_{A} \text { (5) }
$$

If the population is replacing itself, then the left hand side of Eq. 5 will equal the right hand side. The replacement ratio can then be defined as

$$
\begin{equation*}
\Psi_{t}=\frac{B_{t}}{\alpha B_{t-1} S^{l} W_{l}+\alpha B_{t-2} S^{2} W_{2}+\alpha B_{t-3} S^{3} W_{3}+. .+. a l p h a B_{t-(A-1)} S^{A-1} W_{A-1}+\alpha B_{t-A} S^{A} W_{A}} \tag{6}
\end{equation*}
$$

Substituting observed values of abundance indices into Eq 6 leads to

$$
\Psi_{t}=\frac{\frac{I_{t}}{q}}{\alpha \frac{I_{t-1}}{q} S^{l} W_{1}+\alpha \frac{I_{t-2}}{q} S^{2} W_{2}+\alpha \frac{I_{t-3}}{q} S^{3} W_{3}+. .+\alpha \frac{I_{t-(A-l)}}{q} S^{A-1} W_{A-l}+\alpha \frac{I_{t-A}}{q} S^{A} W_{A}}
$$

By noting that the q's cancel out, and letting $\varphi_{j}=\alpha S^{j} W_{j}$, Eq. 6 simplifies to

$$
\Psi_{t}=\frac{I_{t}}{\sum_{j=1}^{A} \phi_{j} I_{t-j}}
$$

All of the $\mathrm{I}_{\mathrm{t}}$ and $\varphi_{\mathrm{j}}$ are positive, and at equilibrium $\mathrm{I}_{\mathrm{t}}=\mathrm{I}_{\mathrm{t}+1}$ and $\mathrm{I}_{\mathrm{t}}=\sum \varphi_{\mathrm{j}} \mathrm{I}_{\mathrm{t}-\mathrm{j}}$ both hold. Therefore $\sum \varphi_{\mathrm{j}}$ $=1$. When the population is not at equilibrium the parameter $\Psi$ becomes a measure of the non equilibrium state of the population and a measure of whether the population is increasing or decreasing relative to prevailing fishery and ecosystem conditions.

It would be desirable to express the parameters of $\varphi_{j}$ weighting terms as function of the underlying parameters. Analyses of other stocks with more detailed information, such as Georges Bank haddock, have suggested that setting the $\varphi_{\mathrm{j}}$ to $1 / \mathrm{A}$ is a reasonable approximation. Equations 2 to 8 are a long way of justifying that the ratio of current stock size to a moving average of the previous A years of stock size can be used as a measure of population growth rate. This ratio embeds some life history theory into the basis for the ratio and simultaneously provides a way of damping the variations in abundance owing to measurement error. A ratio defined as $I_{t} / I_{t-1}$ has been found, as expected to be much more noisy measure of population change.

Further details on the AIM methodology may be found in Working Group (2002) and the NOAA Fisheries Toolbox 3.1 (2010a) software package http://nft.nefsc.noaa.gov/AIM.html. The relationship between $\mathbf{\Psi}_{\mathbf{t}}$ and $\operatorname{relF}_{\mathbf{t}}$ can be expressed as

$$
\begin{equation*}
\ln \left(\Psi_{t}\right)=a+b \ln \left(\text { relF }_{t}\right) \tag{9}
\end{equation*}
$$

The usual tests of statistical significance do not apply for the model described in Eq. 9. The relation between $\boldsymbol{\Psi}_{\mathbf{t}}$ and $\mathbf{r e l F _ { t }}$ is of the general form of $\mathrm{Y} / \mathrm{X}$ vs X where X and Y are random variables. The expected correlation between $\mathrm{Y} / \mathrm{X}$ and X is less than zero and is the basis for the oft stated criticism of spurious correlation. To test for spurious correlation we developed a
sampling distribution of the correlation statistic using a randomization test. The randomization test is based on the null hypothesis that the catch and survey time series represent a random ordering of observations with no underlying association. The randomization test was developed as follows:

1. Create a random time series of length $\mathbf{T}$ of $\mathbf{C}_{\mathbf{r}, \mathrm{t}}$ from the set $\left\{\mathbf{C}_{\mathbf{t}}\right\}$ and $\mathbf{I}_{\mathbf{r}, \mathrm{t}}$ from the set
$\left\{\mathbf{I}_{\mathbf{t}}\right\}$ by sampling with replacement.
2. Compute a random time series of relative $\mathrm{F}\left(\mathbf{r e l F}_{\mathbf{r}, \mathrm{t}}\right)$ and replacement ratios $\left(\Psi_{\mathbf{r}, \mathrm{t}}\right)$
3. Compute the r-th correlation coefficient, say $\boldsymbol{\rho}_{\mathbf{r}}$ between $\ln \left(\mathbf{r e l} \mathbf{F}_{\mathbf{r}, \mathrm{t}}\right)$ and $\ln \left(\boldsymbol{\Psi}_{\mathbf{r}, \mathbf{t}}\right)$.
4. Repeat steps 1 to 3 K times.
5. Compare the observed correlation coefficient $\mathbf{r}_{\mathbf{o b s}}$ with the sorted set of $\boldsymbol{\rho}_{\mathbf{r}}$
6. The approximate significance level of the observed correlation coefficient $\mathbf{r}_{\mathbf{o b s}}$ is the fraction of values of $\boldsymbol{\rho}_{\mathbf{r}}$ less than $\mathbf{r}_{\mathbf{o b s}}$

It should be emphasized that relF is not necessarily an adequate proxy for Fmsy, since this parameter only estimates the average mortality rate at which the stock was capable of replacing itself. Thus, while relF defined as average replacement fishing mortality is a necessary condition for an $\mathrm{F}_{\text {msy }}$ proxy, it is not sufficient, since the stock could theoretically be brought to the stable point under an infinite array of biomass states. The relF at replacement does however provide some guidance on the contemporary rate of harvesting and its potential impact on future stock abundance.

AIM was applied to northern and southern stocks of red hake using 1963-2009 catches which include commercial landings and discards described as "Raw C2". An alternative catch series from 1980 to 2009, which includes recreational catch, described as "Catch 3" was also applied to both northern and southern red hake. Results of these analyses are described separately in subsequent sections. Each section consists of two tables and three graphs. For all applications Relative F was defined as the ratio of catch to a centered 3-year average of survey abundance (Eq. 1) and the replacement ratio was defined as a 5 -year moving average of previous stock sizes (Eq. 8). The relationship between catch, survey, relative F and the replacement ratio for the fall and spring survey indices are depicted for each scenario. Although none of the randomization tests resulted in significant statistical relationship between the replacement ratio and relative F , The HWG decided that the results of the shorter series were considered "best" for purposes of reference point proxies and stock status. This was instead of any more subjective look at the survey and catch data.

## Application of AIM to Red Hake, Northern Stock, catch series "Raw C2"

AIM was applied to northern red hake using catches derived from the method denoted as "Raw C2", and the NEFSC fall and spring bottom trawl survey indices (Table C50). Randomization tests for the fall and spring surveys revealed no significant statistical relationship between the replacement ratio and relative F (Table C 51 ). In fact the randomization test suggested a low probability of obtaining test statistics greater than those observed. Relative F at replacement was poorly specified for both the fall (Figure C63) and spring surveys (Figure C64). The $90 \%$ confidence intervals for both surveys (Table C51, Figure C65) were very wide suggesting no information about the relationship between population growth rate and relative F. The six panel
plots for the fall and spring surveys (Figures C63 and C64, respectively) suggest that despite a continuously decreasing relative F neither the replacement ratio nor the surveys have any consistent trends. The relationship between the relative F and survey indices suggests that the surveys appear to be changing over time. The large pulse in landings during the early 1970s followed by relatively low catches resulted in about a 3 fold increase in stock size by the early 1980s but the absence of population response in the following three decades since then suggests that factors other than fishing mortality may be responsible.

## Application of AIM to Red Hake, Southern Stock, catch series "Raw C2"

AIM was applied to southern red hake using catches derived from the method denoted as "Raw C2", and the NEFSC fall and spring bottom trawl survey indices (Table C52). Randomization tests for the fall and spring surveys revealed no significant statistical relationship between the replacement ratio and relative F (Table C53).

Trends in relative F for the fall (Figure C66) and spring (Figure C67) surveys are remarkably similar owing to similar trends in survey abundance. Abundance indices in both fall and spring surveys show increases since 2000 but remain well below rates observed before 1980. Estimated relative F at replacement for both fall and spring surveys is about $2,200 \mathrm{mt} / \mathrm{kg} / \mathrm{tow}$. Bootstrap estimates suggested about a 3 -fold range of estimates in the $90 \%$ confidence interval (Figure C68)

Relative F at replacement was poorly specified for both the fall (Figure C66) and spring surveys (Figure C67). The 90\% confidence intervals for both surveys (Table C53, Figure C68) were very wide suggesting relatively little information about the relationship between population growth rate and relative F . The relationship between the relative F and survey indices suggests that the functional relationship appears to be changing over time. The large pulse in landings during the late 1960s and early 1970s, followed by relatively low catches, was matched with consistently low survey indices. The phase plane plot of survey indices and relative F (left middle panel Figures C66-C67) suggests three separate stanzas wherein the survey declined by similar ranges while the relative F varied by progressively smaller ranges (1967-1976, 1977-1994, 1995-2009). Such changes in the southern stock suggest that factors other than fishing mortality may be responsible for the declines in abundance.

## Application of AIM to Red Hake, Northern Stock, catch series "Catch3 short"

In the preceding sections analyses of the relationship between the replacement ratio and relative $F$ suggested nonstationarity. More specifically, the rate of increase in stock size with respect to relative F appeared to be decreasing over time. The reduced duration of the time series for catch was designed to address the potential changes in natural mortality suggested by the consumption estimates. The working group considered another catch estimate, denoted as "Catch 3 " for the period 1980-2009 for both the Northern and Southern stocks of red hake.

For northern red hake the continuous declines in landings and relatively small range of change in survey abundance resulted in a steady decline in relative F in the fall survey (Table C54, Figure C69). The replacement ratio varied about 1.0 until 2000 when it fell to low levels before rising
sharply in 2009. A similar response was observed in the spring survey (Figure C70). The estimated relative Fs at replacement were nearly identical ( 162 and $163.1 \mathrm{mt} / \mathrm{kg}$ or 0.162 and $0.163 \mathrm{kt} / \mathrm{kg}$; Table C55) but the spring survey estimate had a slightly smaller confidence interval. Bootstrap estimates of relF at replacement had some extreme values (Figure C71).
Randomization tests suggest that the probability of observing correlations less than the observed value were 26 to $38 \%$ (Table C55).

## Application of AIM to Red Hake, Southern Stock, catch series "Catch3 short"

The truncated catch time series was also considered for the southern stock of red hake (Tables C56-C57, Figures C72-C74). Catch estimates for the southern red hake stock consist of two stanzas of landings of about 5000 mt before 1994 and roughly half as much annually since then (Table C56, Figures C72-C73). Both the fall and spring surveys declined consistently during the high catch stanza and have recently increased since the early 2000s. The increase in replacement ratio since 2000 was preceded by near halving of relative $F$ in the late 1990s from its peak value (Figures C72-C73).

The phase plane plots of survey and relative F again suggest similar population responses to exploitation but differing slopes before and after 1994. Fall and spring relative fishing mortalities at replacement are similar, 2300 vs $3038 \mathrm{mt} / \mathrm{kg}$ ( $2.300 \mathrm{vs} 3.038 \mathrm{kt} / \mathrm{kg}$; Table C57). The relative F at replacement for the fall and spring surveys have overlapping confidence intervals but randomization tests suggest that the degree of association between relative F and the replacement ratio is not significant.

## AIM Model Choice

Although none of the randomization tests resulted in significant statistical relationship between the replacement ratio and relative F, the HWG decided that the results of the shorter series were considered "best" for purposes of reference point proxies and stock status. This was instead of any more subjective look at the survey and catch data at least until an analytical assessment can be developed in the future.
[SAW51 Editor's Note: The red hake SCALE and SS3 model description and results, which are described below, are included in the report mainly to document the modeling that the Red Hake Working Group provided to the SARC-51 for peer review. The results from these two models were not accepted as a basis for providing management advice.]

## Stock Synthesis Model (SS3)

A forward-projecting statistical catch-at age model (Stock Synthesis 3 version 3.11c, NOAA Fisheries Toolbox (NFT) 3.1 (2010c)) was attempted to be used to estimate fishing mortality rates and stock sizes for the northern stock, southern stock and combined areas. The first attempts at modeling used the length-based model estimated catches and fit stock-recruitment
relationships using both Ricker and Beverton-Holt. The results were promising, but the stockrecruitment relationships caused some problems including some negative SSBmsy estimates). After the HWG decided to use the nominal catch in the models, there were no improvements to the fits of any of the models with stock-recruitment relationships. Therefore, the SR alternative to not fit a SR relationship was used for the remainder of the models.

Other issues involved fits to the length compositions (Figure C75), particularly the fall survey in which the small fish are under-estimated in the model. The HWG decided that this may be due to a peculiarity of red hake. The survey may be catching more small fish before they settle and inhabit scallop shells. This may result in an unusual selectivity pattern not available in any current model. So the Age-0 fish were removed from the fall survey and used as a recruitment index as well as the Age-1 spring survey data.

Another length fitting problem was initially thought to be a major model problem (Figure C76). In all the model runs, there is a knife-edge increase at 55 cm . On further inspection, it was due to the binning of length data above 55 cm . The length bins above 5 cm were single cm intervals until 55 cm at which time a 5 cm and then a 10 cm bin was used. After this was changed to cm intervals through 80 cm , the fits were better, although in recent years there is some problem with the model estimating more large fish than in any of the data (Figure C77).

One of the final model runs used four fleets of catch data (landings, discards, recreational catch and consumption) and four survey indices (spring, fall, spring recruitment and fall recruitment). The fits to the survey data were not very good and showed some patterning in the residuals (Figure C78). The main problem was in the fit to the length composition of the consumption data. The single length composition did not fit the model predicted length composition (Figure C79). Several tweaks were attempted to solve this, including changing the size at age 1, moving the time of consumption from mid-year to the beginning of the year, and removing consumption to be replaced with an age-varying natural mortality. None of these options were successful and most of the variations did not converge. Therefore, no SS3 models were accepted at this time, although the HWG thought that it was worthwhile to pursue for the next assessment.

## Statistical Catch-at-Length Model (SCALE)

## Introduction

Incomplete or lack of age-specific catch and survey indices often limits the application of a full age-structured assessment (e.g. Virtual Population Analysis and many forward projecting agestructured models). Stock assessments will often rely on the simpler size/age aggregated models (e.g. surplus production models) when age-specific information is lacking. However the simpler size/age aggregated models may not utilize all of the available information for a stock assessment. Knowledge of a species growth and lifespan, along with total catch data, size composition of the removals, recruitment indices and indices on numbers and size composition of the large fish in a survey can provide insights on population status using a simple model framework.

The Statistical Catch At LEngth (SCALE,NOAA Fisheries Toolbox (NFT) 3.1 (2010b)) model, is a forward projecting age-structured model tuned with total catch ( mt ), catch at length or
proportional catch at length, recruitment at a specified age (usually estimated from first length mode in the survey), survey indices of abundance of the larger/older fish (usually adult fish) and the survey length frequency distributions. The SCALE model was developed in the AD model builder framework. The model parameter estimates are fishing mortality and recruitment in each year, fishing mortality to produce the initial population (Fstart), logistic selectivity parameters for each year or blocks of years and Qs for each survey index.

The SCALE model was developed as an age-structured model that does NOT rely on agespecific information on a yearly basis. The model is designed to fit length information, abundance indices, and recruitment at age which can be estimated by using survey length slicing. However the model does require an accurate representation of the average overall growth of the population which is input to the model as mean lengths at age. Growth can be modeled as sexspecific growth and natural mortality or growth and natural mortality can be model with the sexes combined. The SCALE model will allow for missing data.

## Model Configuration

The SCALE model assumes growth follows the mean input length at age with predetermined input error in length at age. Therefore a growth model or estimates of the average mean length at age is essential for reliable results. The model assumes static growth and therefore population mean length/weight at age are assumed constant over time.

The SCALE model estimates logistic parameters for a flattop selectivity curve at length in each time block specified by the user for the calculation of population and catch age-length matrices or the user can input fixed logistic selectivity parameters. Presently the SCALE model cannot account for the dome shaped selectivity pattern.

The SCALE model computes an initial age-length population matrix in year one of the model as follows. First the estimated populations numbers at age starting with age-1 recruitment get normally distributed at one cm length intervals using the mean length at age with the assumed standard deviation. Next the initial population numbers at age are calculated from the previous age at length abundance using the survival equation. An estimated fishing mortality (Fstart) is also used to produce the initial population. This F can be thought of as the average fishing mortality that occurred before the first year in the model. Now the process repeats itself with the total of the estimated abundance at age getting redistributed according to the mean length at age and standard deviation in the next age (age +1 ).

This two step process is used to incorporate the effects of length specific selectivities and fishing mortality. The initial population length and age distribution is constructed by assuming population equilibrium with an initial value of F , called $\mathrm{F}_{\text {start. }}$. Length specific mortality is estimated as a two step process in which the population is first decremented for the length specific effects of mortality as follows:

$$
N_{a, k e n, y_{1}}^{*}=N_{a-1, l e n, y_{1}} e^{-\left(P R_{l e n} F_{s a n t}+M\right)}
$$

In the second step, the total population of survivors is then redistributed over the lengths at age $a$ by assuming that the proportions of numbers at length at age $a$ follow a normal distribution with a mean length derived from the input growth curve (mean lengths at age).

$$
N_{a, l e n, y_{1}}=\pi_{l e n, a} \sum_{l e n=0}^{L_{\infty}} N_{a, l e n, v_{1}}^{*}
$$

$$
\pi_{l e n, a}^{\text {where }}=\Phi\left(l e n+1 \mid \mu_{a}, \sigma_{a}^{2}\right)-\Phi\left(\text { len } \mid \mu_{a}, \sigma_{a}^{2}\right)
$$

where

$$
\mu_{a}=L_{\infty}\left(1-e^{-K\left(a-t_{0}\right)}\right)
$$

Mean lengths at age can be calculated from a von Bertalanffy model from a prior study as shown in the equation above or mean lengths at age can be calculated directly from an age-length key. Variation in length at age $\mathrm{a}=\sigma_{\mathrm{s}}{ }^{2}$ can often be approximated empirically from the growth study used for the estimation of mean lengths at age. If large differences in growth exist between the sexes then growth can be input as sex-specific growth with sex-specific natural mortality. However catch and survey data are still fitted with sexes combined.

This SCALE model formulation does not explicitly track the dynamics of length groups across age because the consequences of differential survival at length at age a do not alter the mean length of fish at age $a+1$. However, it does more realistically account for the variations in agespecific partial recruitment patterns by incorporating the expected distribution of lengths at age.

In the next step the population numbers at age and length for years after the calculation of the initial population use the previous age and year for the estimate of abundance. Here the calculations are done on a cohort basis. Like in the previous initial population survival equation the partial recruitment is estimated on a length vector.

$$
N_{a, l e n, y}^{*}=N_{a-1, l e n, y-1} e^{-\left(P R_{l e n} F_{y-1}+M\right)}
$$

second stage

$$
N_{a, l e n, y}=\pi_{l e n, a} \sum_{l e n=0}^{L_{\infty}} N_{a, l e n, y}^{*}
$$

Constant M is assumed along with an estimated length-weight relationship to convert estimated catch in numbers to catch in weight. The standard Baranov=s catch equation is used to remove the catch from the population in estimating fishing mortality.

$$
C_{y, a, l e n}=\frac{N_{y, a, l e n} F_{y} P R_{l e n}\left(1-e^{-\left(F_{y} P R_{l e n}+M\right)}\right)}{\left(F_{y} P R_{\text {len }}\right)+M}
$$

Catch is converted to yield by assuming a time invariant average weight at length.

$$
Y_{y, a, l e n}=C_{y, a, l e n} W_{l e n}
$$

The SCALE model results in the calculation of population and catch age-length matrices for the starting population and then for each year thereafter. The model is programmed to estimate recruitment in year 1 and estimate variation in recruitment relative to recruitment in year 1 for each year thereafter. Estimated recruitment in year one can be thought of as the estimated average long term recruitment in the population since it produces the initial population. The residual sum of squares of the variation in recruitment $\sum(\mathrm{Vrec})^{2}$ is then used as a component of the total objective function. The weight on the recruitment variation component of the objective function (Vrec) can be used to penalize the model for estimating large changes in recruitment relative to estimated recruitment in year one.

The model requires an age- 1 recruitment index for tuning or the user can assume relatively constant recruitment over time by using a high weight on Vrec. Usually there is little overlap in ages at length for fish that are one and/or two years of age in a survey of abundance. The first mode in a survey can generally index age- 1 recruitment using length slicing. In addition numbers and the length frequency of the larger fish (adult fish) in a survey where overlap in ages at a particular length occurs can be used for tuning population abundance. The model tunes to the catch and survey length frequency data using a multinomial distribution. The user specifies the minimum size (cm) for the model to fit. Different minimum sizes can be fit for the catch and survey data length frequencies.

The number of parameters estimated is equal to the number of years in estimating F and recruitment plus one for the F to produce the initial population (Fstart), logistic selectivity parameters for each year or blocks of years, and for each survey Q . The total likelihood function to be minimized is made up of likelihood components comprised of fits to the catch, catch length frequencies, the recruitment variation penalty, each recruitment index, each adult index, and adult survey length frequencies:

$$
\begin{aligned}
& \mathrm{L}_{\text {eath }}=\sum_{\text {year }}\left(\ln \left(Y_{\text {olosy }}+1\right)-\ln \left(\sum_{a} \sum_{\text {len }} \mathrm{Y}_{\text {predulenay }}+1\right)\right)^{2}
\end{aligned}
$$

In equation $L_{\text {catch_If }}$ calculations of the sum of length are made from the user input specified catch length to the maximum length for fitting the catch. Input user specified fits are indicated with the prefix "in" in the equations. LF indicates fits to length frequencies. In equation $\mathrm{L}_{\text {rec }}$ the input specified recruitment age and in $L_{\text {adult }}$ and $\mathrm{L}_{\mathrm{lf}}$ the input survey specified lengths up to the maximum length are used in the calculation.

Obj fcn $=\sum_{i=1}^{N} \lambda_{i} L_{i}$
Lambdas represent the weights to be set by the user for each likelihood component in the total objective function.

Various model formulations were attempted for the northern stock, southern stock and combined stocks. These included different natural mortalities, the alternative catch series, and different time series. All models had issues with the absence of older ages (sizes) at the end of the time series and lack of fit to the catch at the beginning of the time series. The model run done starting the time series in 1980, but the model does not fit to the declining trend in catch. The model also had a very strong retrospective pattern (Figures C80a-c). Since consumption cannot be added to SCALE as it is configured, it will no longer be considered as a potential candidate model for this red hake assessment.
> 5. State the existing stock status definitions for the terms "overfished" and "overfishing". Then update or redefine biological reference points (BRPs; estimates or proxies for BMSY, BTHRESHOLD, and FMSY; and estimates of their uncertainty). If analytic model-based estimates are unavailable, consider recommending alternative measurable proxies for BRPs. Comment on the scientific adequacy of existing BRPs and the "new" (i.e., updated, redefined, or alternative) BRPs.

The overfishing definitions are taken from NEFMC $(2000,2003)$ and are as follows:
The northern stock of red hake is overfished when the three-year moving average of stock biomass, derived from the fall survey, is below $1.6 \mathbf{~ k g} / \mathbf{t o w}$. If an analytical assessment is available for northern red hake, then the three-year moving average will be replaced with the terminal year biomass estimate and compared with the biomass reference points.

Overfishing occurs when the ratio between catch and survey biomass exceeds 0.65 , the proxy for $F M S Y$. When biomass is less than $3.1 \mathrm{~kg} /$ tow (the biomass target), the stock is overfished when fishing mortality is above a rate that declines linearly to zero when biomass equals the minimum biomass threshold ( $1.6 \mathrm{~kg} /$ tow).

In 1998 the Overfishing Definition Review Panel (Applegate et al. 1998) concluded that MSY and F reference points could not be determined for southern red hake because the time series of landings and survey biomass indices did not include a period of stable landings at high biomass levels. The Panel noted that discarding could be significant, especially in the scallop and trawl fisheries. Habitat destruction was also thought to be prohibiting stock recovery since juveniles rely on intact scallop beds for shelter. However, in recent years the scallop stock has been recovering, but red hake biomass indices have not increased.

The southern stock of red hake is in an overfished condition when the three-year moving average weight per individual in the fall survey falls below the 25th percentile of the average weight per individual from the fall survey time series 1963-1997 (0.12) AND when the three-year moving average of the abundance of immature fish less than 25 cm falls below the median value of the 1963-1997 fall survey abundance of fish less than 25 cm (4.72).

In previous SAFE Reports, the Whiting Monitoring Committee (WMC) noted problems associated with the overfishing definition for southern red hake. Although the current definition
is intended to identify overfished (i.e. low biomass) stock conditions, it is a better indication of overfishing (high exploitation rate) conditions. The WMC recommends that the overfishing definition for the southern stock of red hake be revisited after a benchmark stock assessment is completed.

The Hake Working Group examined both the fall and spring surveys and decided that the spring had more consistency in the AIM results (smaller confidence intervals for the relative F). The Hake Working Group also agreed with the WMC about the problems associated with the existing biomass reference point for the southern stock of red hake. Therefore the HWG proposes new BRPs (in kg/tow in Albatross units) for both northern and southern red hake stocks as follows:

Red hake is overfished when the three-year moving average of the spring survey weight per tow (i.e., the biomass threshold) is less than one half of the BMSY proxy, where the BMSY proxy is defined as the average observed from 1980-2010. The current estimates of Bthreshold for the northern and southern stocks are $1.27 \mathrm{~kg} /$ tow and $0.51 \mathrm{~kg} / \mathrm{tow}$, respectively.

Overfishing occurs when the ratio between catch and survey biomass exceeds $0.163 \mathrm{kt} / \mathrm{kg}$ and $3.038 \mathrm{kt} / \mathrm{kg}$, respectively, derived from AIM analyses from 1980-2009.

Applying the BMSY proxy to the replacement F allows for an MSY of 412 mt and 3086 mt for the northern and southern stocks, respectively.

The biomass reference points could be considerably different depending on the time series used to develop the average. For instance, if the entire time series was used, the BMSY proxy would be $2.43 \mathrm{~kg} /$ tow for the north and 1.61 for the south. If a shorter time series was chosen, for example 1990-2010, the two reference points would be 2.17 and 0.58 , respectively. Other stocks have used the entire time series, but instead of the average, used the $75^{\text {th }}$ percentile of the series (NEFSC 2007b). This would also change the reference points to 3.22 and $2.25 \mathrm{~kg} /$ tow, respectively. The Working Group chose the intermediate to reflect the potential increase in natural mortality suggested by the consumption estimates.

The $80 \%$ confidence intervals around the Freplacement for the north are from 0.062-0.240 $\mathrm{kt} / \mathrm{kg} /$ tow (Figure C71) and for the south are $2.240-3.700 \mathrm{kt} / \mathrm{kg} /$ tow (Figure C74).

## 6. Evaluate stock status (overfished and overfishing) with respect to the existing BRPs, as well as with respect to the "new" BRPs (from Red hake TOR 5).

Based on current biological reference points in the existing FMP, the northern stock of red hake is not overfished and overfishing is not occurring. The three year delta mean biomass index (Figure C81), based on NEFSC fall bottom trawl survey data for 2007-2009 ( $2.87 \mathrm{~kg} / \mathrm{tow}$ ), was above the management threshold level ( $1.6 \mathrm{~kg} /$ tow $)$ and slightly below the target ( $3.1 \mathrm{~kg} / \mathrm{tow}$ ). The three year average exploitation index (landings divided by biomass index, Figure C82) for 2007-2009 ( 0.03 ) was below both the target (0.39) and the threshold (0.65).

Based on current biological reference points in the existing FMP, the southern stock of red hake
is not overfished and overfishing is unknown. The three year delta individual mean weight index (Figure C83), based on NEFSC fall bottom trawl survey data for 2007-2009 ( $0.10 \mathrm{~kg} /$ individual), is below the management threshold $(0.12 \mathrm{~kg} /$ individual) but the three year average recruitment index ( 5.95 num/tow) is above the threshold value ( 4.72 num/tow).

Based on new recommended biological reference points from SARC 51, the northern stock of red hake is not overfished and overfishing is not occurring. The three year arithmetic mean biomass index (Figure C84), based on NEFSC spring bottom trawl survey data in Albatross units for 2008-2010 ( $2.42 \mathrm{~kg} /$ tow), was above the proposed management threshold ( $1.27 \mathrm{~kg} / \mathrm{tow}$ ) and slightly below the target ( $2.53 \mathrm{~kg} /$ tow). The exploitation index (catch divided by biomass index, Figure C85) for 2007-2009 ( $0.103 \mathrm{kt} / \mathrm{kg}$ ) was below the threshold $(0.163 \mathrm{kt} / \mathrm{kg})$.

Based on new recommended biological reference points from SARC 51, the southern stock of red hake is not overfished and overfishing is not occurring. The three year arithmetic mean biomass index (Figure C86), based on NEFSC spring bottom trawl survey data in Albatross units for 2008-2010 ( $0.95 \mathrm{~kg} /$ tow), was above the proposed management threshold ( $0.51 \mathrm{~kg} / \mathrm{tow}$ ) and slightly below the target ( $1.02 \mathrm{~kg} /$ tow). The exploitation index (catch divided by biomass index, Figure C87) for 2007-2009 ( $1.150 \mathrm{kt} / \mathrm{kg}$ ) was below the threshold $(3.038 \mathrm{kt} / \mathrm{kg})$.
7. Develop and apply analytical approaches and data that can be used for conducting single and multi-year stock projections and for computing candidate ABCs (Acceptable Biological Catch; see Appendix to the TORs).
a. Provide numerical short-term projections (3 years). Each projection should estimate and report annual probabilities of exceeding threshold BRPs for $F$, and probabilities of falling below threshold BRPs for biomass. In carrying out projections, consider a range of assumptions about the most important uncertainties in the assessment (e.g., terminal year abundance, variability in recruitment).
b. Comment on which projections seem most realistic, taking into consideration uncertainties in the assessment.
c. Describe this stock's vulnerability to becoming overfished, and how this could affect the choice of ABC.

Stochastic projections were not performed for this assessment. However, applying the Relative F reference points to the three-year average biomass index allows catches of 394 mt in the north and 2897 mt in the south.
8. Review, evaluate and report on the status of the SARC and Working Group research recommendations listed in recent SARC reviewed assessments and review panel reports. Identify new research recommendations.

SAW 1-1985

1. Updated VPA based on new stock boundaries will be undertaken Attempted several analytical models with no success.
2. A re-analysis of growth rate

This assessment estimated growth parameters for the "new" stock definitions as well as smaller regions.
3. Predator/prey considerations for red hake are important This assessment estimated consumption of red hake by the major predators.
4. CPUE indices need to be re-calculated given new stock boundaries

CPUE is no longer considered a valid abundance index for this species due to the management changes that have occurred in the last twenty-five years.

New Research Recommendations

- Studies to estimate discard mortality should be conducted.
- Develop explicit process and criteria for the application of length-based (vs. constant) calibration coefficients (other than purely statistical criteria such as AIC, etc.). It may be useful, if enough data exist, to attempt a cross validation with a subset of data.
- Information on consumption by more predators (including mammals, highly migratory species (HMS)) needs to be included.
- Diel (day/night) variation in consumption of hakes.
- Validation of the ageing method for red hake via tagging, radiocarbon, or tetracyclin research.
- More comprehensive analysis of red hake stock structure based on DNA (expanded genetic analysis).
- Perform a stock reduction analysis
- Continue developing an analytical assessment with Stock Synthesis or ASAP as more age data are available.
- Continue ageing the available samples.

## Sources of Uncertainty

8. Catch data are uncertain given the identification issues between red and white hake, as well as possible hybridization between the two species.
9. Stock structure is not known and has been assumed by analogy with silver hake.
10. Growth estimates are from a time of assumed high mortality and should be revisited when data become available.
11. Natural mortality is unknown.
12. Consumption
a. Minimum swept area estimates for some predator abundance does not account for q for all predators; these are likely lower estimates of predator abundance and thus these consumption estimates should be viewed as conservative estimates. Although stock assessment estimates of abundance were used for some predators, using a full range of abundance estimates from stock assessments for more predators would also likely increase the estimates noted here.
b. Is the $\alpha$ too low compared to literature? These too may be somewhat conservative, but are within the range of those generally reported. Again, these should be viewed as conservative estimates.
c. Some fish predators that did not consistently eat red hake (e.g. some of the skates, other gadids) were not included in the analysis.
d. Also, these estimates did not include a wide range of other (non-fish) predators known to consume red hake (e.g., seabirds, squids, marine mammals), nor did they include red hake cannibalism, which is suspected to be significant. Collectively this relatively limited set of predators thus may result in these being fairly conservative estimates of overall predatory removals of red hake.
e. Spatio-temporal overlap considerations between predators and red hake were assumed. This work was done for both red hake stocks combined and could be reevaluated for both stocks separately.

Table C22. White hake discards ( mt ) from the southern region by gear and half. The discards from 1981-1988 (1991 for scallop dredge and longline) are hindcast using the first three years of available data. The otter trawl discards are hind-cast combining mesh-sizes.

Table C36. Swept area abundance and biomass and upper and lower confidence intervals for red hake from the NEFSC spring bottom trawl surveys in the northern management region (strata 20-30, 36-40).
Estimates for 2009 and 2010 were converted to Albatross units using the calibration factors at length in Table C34.

| Year | Swept Area (nm) | Swept Area <br> Abundance (millions) | Swept Area Upper CI | Swept Area Lower CI | Swept Area <br> Biomass (mt) | Swept Area Upper Cl | Swept Area Lower CI |

Table C48. Swept area abundance and biomass and upper and lower confidence intervals for red hake from the NEFSC spring bottom trawl surveys in the northern and southern management regions combined (strata $1-30,36-40,61-76)$. Estimates for 2009 and 2010 were converted to Albatross units using the calibration factors at length in Table C34.

| Year | Swept Area (nm) | Swept Area <br> Abundance <br> (millions) | Swept <br> Area <br> Upper CI | Swept Area Lower CI | Swept Area Biomass (mt) | Swept Area Upper CI | Swept Area Lower CI |

Table C49. Species of consistent red hake predators. Whether abundances where estimated from recent stock assessments (SA) or swept area (SWA) from surveys are noted, as is the resolution of the diet data (annual, 2 yr , or 3 yr ).

| Common Name | Species Name |  |  |
| :--- | :--- | :--- | :--- |
|  |  | or Swept Assea | Resolution |
| Spiny dogfish | Squalus acanthias | SWA | Annual |
| Little skate | Raja ocellata | SWA | Annual |
| Winter skate | Raja erinacea | SWA | 3 yr |
| Thorny skate | Raja radiata | SWA | 2 yr |
| Silver Hake | Merluccius bilinearis SWA | Annual |  |
| Atlantic cod | Gadus morhua | SWA | Annual |
| White hake | Urophycis tenuis | SWA | Annual |
| Fourspot flounder | Paralichthys oblongus SWA | 3 yr |  |
| Summer Flounder | Paralichthys dentatus SWA |  |  |
| Windowpane | Scophthalmus aquosus SWA | 3 yr |  |
| Sea raven | Hemitripterous americanus SWA | 3 yr |  |
| Goosefish | Lophius americanus SWA |  |  |

Table C50. Summary of catch, NEFSC fall and spring bottom trawl survey indices, replacement ratios and relative fishing mortality rates for red hake, northern stock. Catch is based on method "Raw C2". Estimates for 2009 were converted to Albatross units using the calibration factors at length in Table C34.

Red Hake; Tables

Table C51. Summary of AIM results for northern red hake for NEFSC fall and spring bottom trawl surveys and catch estimation method "raw C2" for 1963-2009.

| Red Hake, North, RawC2 | Fall Survey | Spring Survey |
| :--- | :---: | :---: |
| Critical value (observed <br> correlation between <br> replacement ratio and relative F | -0.208518 | 0.006928 |
| Probability of observing <br> correlation < Critical Value | 0.9775 | 0.996 |
| Relative F at Replacement <br> (mt/kg) | 607.85 | 7973.31 |
| $90 \%$ Confidence Interval for <br> RelF at replacement | $(14.29,37701)$ | $(0.066,11261)$ |

Table C52. Summary of catch, NEFSC fall and spring bottom trawl survey indices, replacement ratios and relative fishing mortality rates for red hake, southern stock. Catch is based on method "Raw C2". Estimates for 2009 were converted to Albatross units using the calibration factors at length in Table C34.

|  |  | NEFSC Survey |  | Replacement Ratio |  | Relative Fishing Mortality |  |

## D. OFFSHORE HAKE STOCK ASSESSMENT FOR 2010

#### Abstract

[SAW-51 Editor's Note: The SARC-51 Review Panel concluded that sufficient information is not available to determine offshore hake stock status with confidence, because fishery data are insufficient and one cannot assume that survey data reflect stock trends. The Panel concluded that it is not possible at this time to provide a reliable definition for overfished and overfishing for this stock. SEINE and AIM modeling is included in this report to show what the Working Group provided to the SARC-51 for peer review.]

## Terms of Reference

1. Use models to estimate the commercial catch. Describe the uncertainty in these sources of data.
2. Characterize the survey data that are being used in the assessment (e.g., regional indices of abundance, recruitment, age-length data, etc.). Describe the uncertainty in these sources of data.
3. Estimate measures of annual fishing mortality, recruitment and stock biomass for the time series, and characterize the uncertainty of those estimates.
4. State the current definitions for overfished and overfishing. Then update or redefine biological reference points (BRPs; estimates or proxies for $\mathrm{B}_{\text {MSY }}, \mathrm{B}_{\text {THRESHOLD }}$, and $\mathrm{F}_{\text {MSY }}$; and estimates of their uncertainty). Comment on the scientific adequacy of existing and redefined BRPs.
5. Evaluate stock status with respect to the existing BRPs, as well as with respect to updated or redefined BRPs (from Offshore hake TOR 4).
6. If a model can be developed, conduct single and multi-year stock projections and for computing candidate ABCs (Acceptable Biological Catch; see Appendix to the TORs).
7. Provide numerical short-term projections (3 years). Each projection should estimate and report annual probabilities of exceeding threshold BRPs for F, and probabilities of falling below threshold BRPs for biomass. In carrying out projections, consider a range of assumptions about the most important uncertainties in the assessment.
8. Comment on which projections seem most realistic, taking into consideration uncertainties in the assessment.
9. Describe this stock's vulnerability to becoming overfished, and how this could affect the choice of ABC.
10. Propose new research recommendations.

## Executive Summary

Offshore hake (Merluccius albidus) is a data-poor stock and very little is known about its biology and life history. They are commonly distributed from southern Georges Bank through the Mid-Atlantic Bight, at depths of 160-550 meters and temperatures ranging between $11-13^{\circ} \mathrm{C}$.

They are known to co-occur with silver hake (Merluccius bilineris) in the outer continental slopes of the Atlantic Ocean and are easily confused with silver hake because of their strong morphological resemblances.

The primary sources of biological information for offshore hake are based on the annual fishery independent surveys conducted by the Northeast Fisheries Science Center (NEFSC). The NEFSC have conducted both spring and fall bottom trawl surveys off the US continental shelf annually since 1963. The surveys extend from the Gulf of Maine to Cape Hatteras, in offshore waters at depths 27-365 meters, and have been conducted in the fall since 1963 and in the spring since 1968. The winter bottom trawl survey began in 1992 and was specifically designed for flatfish, however, the deeper survey strata were not sampled until 1998. The winter trawl survey does not cover the Georges Bank area because the survey was designed specifically for flatfish in the southern region.

Survey catches are highly variable but the trends in the spring and fall are similar. The higher catchability in the winter survey can be explained by the net configuration (i.e smaller cookies) specifically designed to target flatfish.

Offshore hake are located primarily on the continental shelf and presumably beyond the NEFSC survey area. Offshore hake tend to be concentrated in the southern Georges Bank region in the fall, whereas in the spring, they are found further south in the Mid-Atlantic Bight. They also appear to be more abundant during the winter months at temperatures ranging between $11-13{ }^{\circ} \mathrm{C}$ and in deeper waters.

Offshore hake appear to be sexually dimorphic with females slightly larger than males. Females mature at a larger length than males, similar to other gadoid species (O’Brien et al 1993).
Length at $50 \%$ maturity $\left(\mathrm{L}_{50}\right)$ also differed significantly between sexes with females maturing at larger sizes $(28 \mathrm{~cm})$ relative to males $(23 \mathrm{~cm})$. More fish are found in the developing stage in April than in the other months sampled. There is also more frequency in resting stage in the fall than in the spring, which would also indicate that spawning occurs in the late spring and summer months (Traver et al., in review). We do not have a summer survey to verify these results.

Offshore hake is a trawl based fishery and primarily a bycatch fishery for silver hake, with $95 \%$ being caught by otter trawl. They are being caught in deep waters, where they are potentially being mixed with and reported as silver hake. Landings data are a major source of uncertainty for this stock, due to mixed reported landings with silver hake and landings were not reported until 1991. Even those that are reported may not be correctly identified (Garcia-Vazquez et al., 2009), therefore fishing mortality rates remain unknown. Two models were used to estimate the proportion of offshore hake landed as silver hake, a length-based and a depth-based model. The two models give similar estimates that are both much higher than the nominal landings. The data used in the assessment include survey indices from the NEFSC fall survey, landings estimated using two models, and discards estimated using a single model. The length-based model used the catch-at-length for silver hake and used the proportion of offshore hake at length from the survey to apportion catch. The depth-based model used VMS data and depth-based logistic functions from the survey to apportion landings. Two assessment models were attempted, An Index Method (AIM) and Survival Estimation in Non-Equilibrium Situations Model (SEINE). Neither
model was considered adequate for management.
The survey data may not be a good index of abundance, and the values may be driven more by environmental changes or fish migrations. The survey likely does not cover the entire stock area and therefore, the survey estimates could potentially be under-representing the population. It also appears that the fishery as estimated by either the length-based model or the depth-based model has not had an impact on the stock. The mortality estimates from the SEINE model are in direct contrast to the catch data. Developing ACLs will be challenging given that the landings are not separated to a great extent. Garcia-Vazquez et al (2009) found $12 \%$ of hake sold in Spain as silver hake were actually offshore hake. No alternative reference points are recommended and the existing BRPs should also not be accepted.

## Hake Working Group Meetings

Three meetings were held in preparation of the 2010 silver hake assessment.

1. Hake fishermen's/stakeholder's meeting - August 6, 2010 - UMASS School of Marine Science and Technology (SMAST), Fairhaven, MA. Participants include fishermen Dan Farnham and Bill Phoel. Also in attendance were David Goethel (Oversight Committee chair), Andrew Applegate (staff) Steve Cadrin (SSC and WG chair, SMAST), Pingguo He, Klondike Jonas, Yuying Zhang, Tony Wood, and Daniel Goethel (SMAST), Loretta O’Brien, Michele Traver, Kathy Sosebee and Larry Alade (NEFSC), and Dick Allen (advisor at large).
2. Data Meeting - September 7-10, 2010, NEFSC Woods Hole MA. Participants included Steve Cadrin (WG Chair), Assessment leads (Larry Alade, Kathy Sosebee, Michele Traver), Rapporteurs (Jessica Blaylock and Julie Nieland), Mark Showell (DFO), Andy Applegate (NEFMC Staff), NEFSC (Loretta O’Brien, Mark Terceiro, Chris Legault, Tim Miller, Dave Richardson, Ayeisha Brinson, Jiashen Tang, Janet Nye, Mike Palmer, Paul Rago, Josef Idoine, Jon Hare), Moira Kelly (NERO), SMAST (Tony Wood, Yuying Zhang, Saang-Yoon Hyun).
3. Model Meeting - October 25-29, 2010, NEFSC, Woods Hole, MA. Participants included Steve Cadrin (WG chair), Assessment leads (Larry Alade, Kathy Sosebee, Michele Traver), Rapporteurs (Jessica Blaylock and Julie Nieland), Mark Showell (DFO), Andy Applegate (NEFMC Staff), Dan Farnham (Fisherman and Industry Advisor), (Loretta O’Brien, Paul Nitschke, Mark Terceiro, Jay Burnett, Chris Legault, Tim Miller, Jon Deroba, Rich McBride, Jim Weinberg, Paul Rago, Josef Idoine, Jon Hare, Janet Nye, Dave Richardson, Laurel Col, Jason Link), SMAST (Tony Wood, Yuying Zhang, Dan Goethel). The groups met by correspondence after the meetings, including a WebEx meeting on November 5, 2010 to report updates on silver hake analyses, provide guidance on reference points and discuss plans for report development.

This Working Group (WG) report includes products from all three meetings and contributions from all participants.

## Fishery Regulations

The following outlines the current small mesh multispecies regulations (based on the small mesh
exemption program) for the New England whiting fishery to provide context for interpreting the fishery and model results.

1. 1994 \& 2000 - Exempted fisheries allows vessels to fish for specific species such as whiting or northern shrimp in designated areas using mesh sizes smaller than the minimum mesh size allowed (Gulf of Maine, Georges Bank, Southern New England, Mid-Atlantic : 6.5-inch square or diamond) under the Regulated Mesh Area (RMA) regulations .
2. Permits
a. Open access Category K Multispecies
b. Limited Access Category A-F (non Days-at-Sea fishing )
3. No Size Limits
4. 500 lbs at sea transfer limit.
5. 2003 - Possession limits vary by exemption area
a. $3,500 \mathrm{lbs}$ if mesh $<2.5$ inches ( 63.5 mm )
b. $7,500 \mathrm{lbs}$ if mesh $<=3.0$ inches $(76.2 \mathrm{~mm})$
c. $30,000 \mathrm{lbs}$ if mesh $>3.0$ inches $(76.2 \mathrm{~mm})$
d. No Red Hake possession limit

## Introduction

Offshore hake, Merluccius albidus belongs to one of the twelve hake species of the genus Merluccius, inhabiting the northern and southern hemisphere of the world's oceans (Pitcher and Alheit 1995; Helser 1996). Like other species of the Merluccius genus, they are considered to be a 'true hake' species and are morphologically distinct from other gadoid-like hakes (e.g., red and white hake, Helser 1996). Offshore hake are known to be distributed off the continental slope of the northwest Atlantic to the Caribbean and the Gulf of Mexico (Chang et al 1999) (Figures D14). They are commonly located off southern Georges Bank through the Mid-Atlantic Bight at depths ranging from 160-550 meters (Bigelow and Schroeder 1953, Klein-MacPhee 2002). Offshore hake and silver hake ( $M$. bilinearis) are sympatric species, and they co-exist over a considerable range of the continental slope, but are often separated by depth preferences (Helser 1996). The most distinguishing morphological characteristics between these species are the number of gill rakers and lateral line scales (Chang et al 1999). Due to the similar morphological features and spatial areas where they co-exist, they have been commonly misidentified for many years. The fishing industry did not separate the commercial landings of the two species until 1991, but the extent to which they are still landed as a single species is unknown (Helser 1996).

Offshore hake is currently included in the New England Fishery Management Council's (NEFMC) small mesh multi-species fishery management plan. Unfortunately, very little is known about the biology and population dynamics of offshore hake. They have never been formally assessed before.

## Biology

Spawning usually occurs between April and July in the New England area, at depths ranging from 330-550 meters (Cohen et al. 1990). The maximum observed length from all areas is 40 cm for males and 70 cm for females (Chang et. al. 1999). Maximum observed size in samples from the Northwest Atlantic was approximately 43 cm for males and 56 cm for females, and fish greater 40 cm consist mainly of females, suggesting that they are sexually dimorphic (Traver et al. in review). Length at $50 \%$ maturity ( $\mathrm{L}_{50}$ ) also differed significantly between sexes with females maturing at larger sizes $(28 \mathrm{~cm})$ relative to males ( 23 cm ) (Traver et al. in review).

## TOR 1. Use models to estimate the commercial catch. Describe the uncertainty in these sources of data.

Nominal commercial landings of offshore hake did not occur until 1991 (Figure D5, Table D1). Offshore hake commercial landings peaked at 120 mt in the early 1990s, then declined sharply to less than 5 mt in 2001, the lowest in the time series (Figure D5). Landings have since increased slightly and average around 15 mt . Nominal landings of offshore hake occur in the silver hake northern area even though offshore hake are not found in these areas.

In the north, Massachusetts is the primary state that has nominal offshore hake landings while New Jersey and Rhode Island account for most of the southern area landings (Tables D2-D3). Otter trawl is the dominant fishing gear for offshore hake, accounting for $95 \%$ of the total nominal landings in both regions (Tables D4-D5). Other gears such as gillnet or hook and line were very minimal, contributing less than $1 \%$ in offshore hake catches.

Nominal landings of offshore hake occur sporadically in the north over time (Table D6). The landings are spread somewhat evenly among months in the south (Table D7-D8). Offshore hake are landed in an unclassified or dressed market category (has been combined in Table D9). King offshore hake are large component of the southern stock landings accounting for more than $50 \%$ of the total (Table D9).

There are currently no estimates of CPUE or effort for this species. Given the uncertainties given below with species identification and the major changes in management noted in the introduction, CPUE is not likely to be a good indicator of stock status.

It is thought that landings of offshore hake are likely under-reported or mis-reported and landed as silver hake as well as reported in areas that are not likely. There is no price differential so there is no real incentive to separate the two species when they are landed. Landings from the northern area are assumed to be silver hake. In order to estimate landings of offshore hake from the landings of silver hake from the southern region (Table D10-D13), two alternative methods were developed.

The first method used the port length samples of both species directly. Length samples of silver and offshore hake were combined by stock (Tables D14-D16). In examining the silver hake length samples by market category, it appeared that most of the market categories were similar in
length composition to the round category (Figures D6-9). Therefore, only three market categories were used for stratification: round, king, and large. Even with the reduction of market categories, pooling over years was required to get an adequate number of fish (Table D17). The lengthweight equations for silver hake by season from Wigley et al. 2003 were applied to the samples and used to estimate the landings numbers at length for each market category.

For the southern stock, length compositions for each species were estimated for the spring and fall surveys from 1968-2009. The species-specific length-weight equations were then applied to determine weight-at-length by species. The proportions at length by species for both number and weight were applied to the commercial landings-at-length to estimate landings-at-length by species. The lengths had to be grouped into intervals to avoid zero cells in the survey. To hindcast the species proportions back to 1955 , the average proportion of offshore hake for the time series was used and applied to the total silver hake landings.

The second method relates survey catch composition to Vessel Monitoring System (VMS) derived commercial landings from 2004-2009 using survey depth as an explanatory factor to develop a model that predicts the hake species landings composition. Offshore and silver hake composition $\left(R_{23}\right)$ in the trawl survey tows were modeled as a two parameter logistic function of average depth. Only survey tows with silver hake, offshore hake or both were fitted and mean depth was the dependent variable.

$$
R_{23}=\frac{e^{a+b^{*} d e p t h}}{1+e^{a+b^{*} d e p t h}}
$$

For each stratum group, survey (winter, spring, and fall), and sets of time series, the catch and depth data were fitted by a non-linear least squares, weighted by the number of positive tows in a stratum, using the Marquardt method (Marquardt 1963) to aide convergence. Data were weighted by the number of positive tows in a stratum group. $\mathrm{R}^{2}$ and Wald $95 \%$ confidence intervals (Cook and Weisberg 1990) were calculated for parameters a, b, D50, and the range to evaluate goodness of fit. Fitting the data with a two parameter logistic non-linear regression using maximum likelihood estimation and iteratively reweighted least squares approaches was attempted, but did not improve the results.

The parameter estimates for 1985-2009 were applied to the depth association with the VMSderived commercial landings at depth (Applegate 2010). The model ratio of offshore to silver hake were assigned to landings from each group depth zone, survey season, and survey stratum group and summed for the calendar year (Applegate 2010). The final landings from this method were greater than $90 \%$ of the total landings reported by dealers in 2004-2009.

Estimates of offshore hake landings ranged between $290-893 \mathrm{mt}$ and $5-12 \%$ of total hake landings (Table D18). These estimates are considerably higher than those reported by either dealers or by fishermen on Vessel Trip Reports (VTR).

Given that VMS data for 2004-2009 were deemed acceptable for direct estimation of silver and offshore hake landings composition, landings prior to 2004 (1955-2003) were hindcasted to
generate longer time series of removal for assessments and for developing biological reference points. Although the hindcast procedure allowed the distribution of catch to vary between statistical areas, the distribution of catch within these intermediate depth statistical areas was assumed to be constant, equal to the average depth distribution observed by VMS during 20042009. Details of the hindcasting methodology can be found in Applegate (2010).

Hindcast and model based estimates of offshore hake landings were an order of magnitude greater than that reported by dealers. Landings rose from 951 mt in 1955 ( $7.0 \%$ of the total) to $24,189 \mathrm{mt}$ in 1965 ( $8 \%$ of the total). Offshore hake as a proportion of total hake landings ranged from $2 \%$ in 1971, 1976, 1978-1980 to 13\% in 1988 and 1996 (Tables D18a-b).

Relative to the length-based approach, the results from the depth-based method for allocating silver hake catches were very similar ( $<1-14 \%$ relative difference). Conversely, offshore hake estimates showed substantial differences between both methods. However, these differences are more noticeable on a relative scale because offshore hake consists of a small fraction of the total hake catches (Figure D10).

For assessment purposes, the Working group felt that the length-based estimator was more suitable because of the shorter period in hindcasting analyses. The group also felt that the small differences between the methods for silver hake estimates are likely not to influence assessment model results.

The resulting offshore hake landings for the two methods are given in Tables D18a-b and Figures D11-12. On average, the two methods gave slightly different results, with the lengthbased model averaging $7 \%$ silver hake while the depth-based method averaged $4 \%$ silver hake.

## Commercial Fishery Discards

Discard estimates were calculated in this assessment. The ratio-estimator used in this assessment is based on the methodology described in Rago et al. (2005) and updated in Wigley et al. 2007. It relies on a $\mathrm{d} / \mathrm{k}$ ratio where the kept component is defined as the total landings of all species within a "fishery". A fishery is defined as a homogeneous group of vessels with respect to gear type (longline, otter trawl, shrimp trawl, sink gill net, and scallop dredge), quarter, and area fished (GOM-NGBK, SGBK-MA), and for otter trawls, mesh size ( $<=5.49$ ", $>=5.5$ "). All trips were included if they occurred within this stratification regardless of whether or not they caught hakes.

The discard ratio for hakes in stratum $h$ is the sum of discard weight over all trips divided by sum of kept weights over all trips:

$$
\begin{equation*}
\hat{R}_{h}=\frac{\sum_{i=1}^{n_{h}} d_{i h}}{\sum_{i=1}^{n_{h}} k_{i h}} \tag{1}
\end{equation*}
$$

where $\mathrm{d}_{\mathrm{ih}}$ is the discards for hakes within trip i in stratum h and $\mathrm{k}_{\mathrm{ih}}$ is the kept component of the
catch for all species. $R_{h}$ is the discard rate in stratum $h$. The stratum weighted discard to kept ratio is obtained by weighted sum of discard ratios over all strata:

$$
\begin{equation*}
\hat{R}=\sum_{h=1}^{H}\left(\frac{N_{h}}{\sum_{h=1}^{H} N_{h}}\right) \hat{R}_{h} \tag{2}
\end{equation*}
$$

The total discard within a strata is simply the product of the estimate discard ratio R and the total landings for the fishery defined as stratum h, i.e., $\mathrm{D}_{\mathrm{h}}=\mathrm{R}_{\mathrm{h}} \mathrm{K}_{\mathrm{h}}$. Cells with $<$ three trips were imputed using annual averages by gear type and region. To hind-cast the discards to 1981 (the first year in which there was no industrial fishery), discards/total landings by half year for the first three years (1989-1991 for otter trawl, sink gill net, and shrimp trawl; 1992-1994 for longline and scallop dredge) were averaged and the rate applied to the total landings from the dealer database. For the otter trawl fisheries, the mesh sizes were combined for the hind-cast.

Discards from the longline and sink gill net fishery were minimal for silver and offshore hake in both stock areas (Table D19-D22). Discards from the otter trawl fisheries have been significant and variable for silver hake.

The same problem with species identification that exists in the landings is found in the FOP data. There are discards of offshore hake estimated for the north. The geographical distribution of offshore hake is limited to the southern stock of silver hake and therefore, any discards from the northern stock (Tables D19) are considered to be silver hake. In order to estimate discards of offshore hake from the southern region, only one of the alternative methods was employed.

The observer discard length samples of silver and offshore hake were combined by stock (Tables D23-D26). Enough length samples were available for large and small mesh otter trawls in both regions and sink gill net and shrimp trawl in the north. Pooling over years was still required to get an adequate number of fish (Table D27-D28). The length-weight equations by season from Wigley et al 2003 were applied to the samples and used to estimate the landings numbers at length for each market category. The discards-at-length were raised to the total discards including all the gear types to account for as much of the removals as possible.

For the southern stock, length compositions for each species were estimated for the spring and fall surveys from 1968-2009. The species length-weight equations were then applied to determine weight-at-length by species. The proportions at length by species for both number and weight were applied to the commercial discards-at-length to estimate discards-at-length by species. The lengths had to be grouped into intervals to avoid zero cells in the survey. To hindcast the species proportions back to 1981, the average proportion of offshore hake for the time series was used and applied to the total silver hake discards (Table D29).

TOR 2. Characterize the survey data being used in the assessment (e.g., regional indices of abundance, recruitment, age-length data, etc.). Describe uncertainty in these sources of data.

Data Source: The primary sources of biological information for offshore hake are based on the annual fishery independent surveys conducted by the Northeast Fisheries Science Center (NEFSC). The surveys were conducted using a random stratified sampling design which allocates samples relative to the size of the strata, defined by depth. The NEFSC have conducted both spring and fall bottom trawl surveys off the US continental shelf annually since 1963. The surveys extend from the Gulf of Maine to Cape Hatteras, in offshore waters at depths 27-365 meters, and have been conducted in the fall since 1963 and in the spring since 1968. The winter bottom trawl survey began in 1992 and was specifically designed for flatfish, however, the deeper survey strata were not sampled until 1998 (Figure D1). The winter trawl survey does not cover the Georges Bank area because the survey was designed specifically for flatfish in the southern region. Details on the stratified random survey design and biological sampling methodology may be found in Grosslein (1969), Azarovitz (1981) and Sosebee and Cadrin (2006).

Survey analysis suggests that offshore hake are distributed within the narrow band of the outer continental shelf from southern Georges Bank to the Mid-Atlantic region (strata 3-4, 7-8, 11-12, 14-15, 17-18, 63-64, 67-68, 71-72, and 75-76). There are seasonal differences in the patterns of distribution with concentrations shifting south of Georges Bank in the winter months and extending to the southern flank of Georges Bank and further south in the spring (Figures D2-4).

Transform: Survey estimates were computed using both delta transformation and arithmetic means for numbers and weight. The Whiting Plan Development Team (PDT) has used the delta mean for assessing stock status. The delta transformation uses only the positive tows for log transformation:

$$
\begin{aligned}
& \hat{M}_{\delta}=\left\{\begin{array}{lr}
\frac{m}{n} e^{\bar{y}} \psi_{m}\left(\frac{1}{2} s_{y}^{2}\right) & m>1, \\
\frac{1}{n} x_{1} & m=1, \\
0 & m=0
\end{array}\right. \\
& \\
& \\
& m=\text { number of non - zero tows } \\
& \\
& \hat{V}_{\delta}= \begin{cases}\frac{m}{n} e^{2 \bar{y}}\left[\psi\left(2 s_{y}^{2}\right)-\frac{m-1}{n-1} \psi_{m}\left(\frac{m-2}{m-1} s_{y}^{2}\right)\right] & m>1, \\
\frac{1}{n} x_{1}^{2} & m=1 \\
0 & m=0\end{cases}
\end{aligned}
$$

Examination of the differences between the delta and arithmetic means revealed that use of the delta transformation did not reduce the variability of the survey (Figure D13). If a survey has a high variance, the back-transformation may be biased high (see Silver Hake Assessment). The delta transformation was also more sensitive to the handling of missing weights. Prior to 2001, the data for weights were recorded to the nearest 0.1 kg and if a tow contained only a single small fish, the weight was entered into the data as zero. Since the delta transform uses the positive tow, how this is handled has an impact on the result. There are three options: taking out the zeros, leaving in the zeros, and filling in zeros using a length-weight equation. Since these options did not affect the arithmetic as much as the delta mean, the decision was made to use the arithmetic and length-weight options for any new analyses (Figure D14).

Calibration: In 2009 the NOAA SHIP Henry B. Bigelow replaced the $R / V$ Albatross $I V$ as the primary vessel for conducting spring and fall annual bottom trawl surveys for the Northeast Fisheries Science Center (NEFSC). There are many differences in the vessel operation, gear, and towing procedures between the new and old research platforms (NEFSC Vessel Calibration Working Group 2007). To merge survey information collected in 2009 onward with that collected previously, we need to be able to transform indices (perhaps at size and age) of abundance from the Henry B. Bigelow into those that would have been observed had the Albatross IV still been in service. The general method for merging information from these two time series is to calibrate the new information to that of the old (Pelletier 1998). Specifically we need to predict the relative abundance that would have been observed by the Albatross $I V\left(\hat{R}_{A}\right)$ using the relative abundance from the Henry B. Bigelow $\left(R_{B}\right)$ and a "calibration factor" $(\rho)$,

$$
\begin{equation*}
\hat{R}_{A}=\rho R_{B} . \tag{4}
\end{equation*}
$$

To provide information from which to estimate calibration factors for a broad range of species, 636 paired tows were conducted with the two vessels during 2008. Paired tows occurred at many stations in both the spring and fall surveys. Paired tows were also conducted during the summer and fall at non-random stations to improve the number of non-zero observations for some species. Protocols for the paired tows are described in NEFSC Vessel Calibration Working Group (2007).

The methodology for estimating the calibration factors was proposed by the NEFSC and reviewed by a panel of independent scientists in 2009. The reviewers considered calibration factors that could potentially be specific to either the spring or fall survey (Miller et al. 2010). They recommended using a calibration factor estimator based on a beta-binomial model for the data collected at each station for most species, but also recommended using a ratio-type estimator under certain circumstances and not attempting to estimate calibration factors for species that were not well sampled. In the case of offshore hake, the Working Group decided that using silver hake calibration factors as a proxy was better than not using any calibration factors.

Since the review, it has become apparent that accounting for size of individuals can be necessary for many species. When there are different selectivity patterns for the two vessels, the fraction of available fish of a given size taken by the two gears is different. Therefore, the ratio of the mean
catches by the two vessels will change with size. Under these circumstances, the estimated calibration factor that ignores size reflects an average ratio weighted across sizes where the weights of each size class are at least in part related to the number of individuals at that size and the number of stations where individuals at that size were caught. Applying calibration factors that ignore size effects to surveys conducted in subsequent years when the size composition is unchanged should not produce biased predictions (eq. 1). However, when the size composition changes, the frequency of individuals and number of stations where individuals are observed at each size changes and the implicit weighting across size classes used to obtain the estimated calibration factor will not apply to the new data. Consequently, the predicted numbers per tow that would have been caught by the Albatross $I V$ will be biased.

Calibration coefficients for silver hake were used because an insufficient number of offshore hake were captured during calibration studies to derive a coefficient for offshore hake. For silver hake, a suite of beta-binomial models were fit that made different assumptions on the relationship of the calibration factor to length. The models ranged from those that were constant with respect to length to logistic and double-logistic functions of length. A season-specific model was chosen based on $\mathrm{AIC}_{\mathrm{c}}$ for silver hake by the working group where a logistic functional form for the spring and a double-logistic form for the fall provided the best fit (Table D30, Figure D15). Refer to the silver hake chapter of this NEFSC CRD for more details.

Survey Data Results: Swept Area abundance and biomass were calculated by using swept area conversions of 0.0112 for the NEFSC fall and spring surveys and 0.0131 for the NEFSC winter survey. A three-year moving average was calculated for the arithmetic means and swept area abundance and biomass for the fall and spring surveys in order to smooth out the variability of the surveys (Tables 31-32).

The fall survey stayed rather stable with similar trends to the spring survey in the late 1970s and early 1980s. The highest swept area biomass was in 1981, with 577 metric tons. It sharply declined to 17 metric tons in 1982. It stayed fairly low until 2001 and 2003, where the biomass was over 100 metric tons. 2009 has a $28 \%$ increase over 2008, with 56 metric tons (Table D34, Figure D17).

The spring survey was low in the early part of the time series and increased steadily to a record high in 1980 at 1,886 metric tons. Like the fall survey, the spring survey then had a sharp decline to 336 metric tons. It has continued to decline, with its lowest value in 2006 at 10 metric tons. It has since increased from 2006 to 30 metric tons (Table D36, Figure D19).

The winter survey abundance and biomass have varied substantially over the entire time series (1998-2007) with no trend (Table D38, Figure D21). Survey catches are highly variable but the trends in the spring and fall are similar. The higher catchability in the winter survey can be explained by the net configuration (i.e. smaller cookies) specifically designed to target flatfish.

Age Data: Growth parameters were calculated from the survey data using the Von Bertalanffy growth equation:

$$
L(t)=L \infty *(1-\exp (-k * t-t 0))
$$

There are 55 ages that were aged by the NEFSC that were used in this analysis. The lengths range from 13 cm to 45 cm , with ages $1-5$. The ages are considered preliminary since there is no published ageing study in the Northwest Atlantic and were based on the same ageing criteria for silver hake. The growth equation with an $\mathrm{L}_{\infty}$ value set to 70 cm resulted in a k value of 0.174 .

Length Data: Survey length distributions for offshore hake in the spring and the fall do not show any clear modes and were difficult to interpret due to very low sample sizes. However, the general trend indicates that majority of the catches range between $20-40 \mathrm{~cm}$ in the fall and spring with very few fish greater than 40 cm . Despite, the higher sampling in the winter survey, the trends in the length distribution remain similar to the fall and spring (Table D39, Figures D2224). To improve sampling intensity and trends in the length distribution, a three year moving average was calculated for the fall and the spring surveys and there were still no clear trends in the length distributions (Figures D25-26).

## TOR 3. Estimate measures of annual fishing mortality, recruitment and stock biomass for the time series, and characterize the uncertainty of those estimates.

Application of Survival Estimation in Non-Equilibrium Situations (SEINE) to Offshore hake

## SEINE Method

Gedamke and Hoenig (2006) developed a method to estimate mortality from mean length data in nonequilibrium situations, now called Survival Estimation in Non-Equilibrium Situations Model (SEINE, available at http://nft.nefsc.noaa.gov/). It is an extension of the Beverton-Holt length-based mortality estimator that assumes constant recruitment throughout the time series and mortality at fixed levels for certain periods within the time series. The approach allows for the transitory changes in mean length to be modeled as a function of mortality rate changes. After an increase in mortality, mean length will gradually decrease due to larger animals being less prevalent in the population. After a decrease in mortality, mean length will increase slowly due to growth of the fish in the population. The rates of change in both cases depend on the von Bertalanffy growth parameters and the magnitude of change in the mortality rates. Since the method requires only a series of mean length above a user defined minimum size and the von Bertalanffy growth parameters, it can be applied in many data poor situations. Gedamke and Hoenig (2006) demonstrated the utility of this approach using both simulated data and an application to data for goosefish caught in the NEFSC fall groundfish survey.

The SEINE model requires the growth parameters, $\mathrm{L}_{\infty}$ and k . It also requires mean lengths and sample size (Table D40). Since there are no accepted growth parameters for offshore hake, we used an average of Southern Georges Bank and Southern New England silver hake growth parameters $\left(L_{\infty}=43.91\right.$ and $\left.\mathrm{k}=0.33\right)$ for Lcritical values of 20 cm as a base model. We varied the Lcritical values to 17 cm and 23 cm . The three mortality cut points $(17 \mathrm{~cm}, 20 \mathrm{~cm}$, and 23 cm ) were chosen because it is synonymous with fishable biomass.

Sensitivity analyses were run for the fall survey only, as the working group thought one season would be sufficient and it had the best likelihood value compared to the spring. Winter has too short of a time series. The model was run with higher and lower growth parameters at the
different cut points. Silver hake growth parameters for the Southern Georges Bank ( $\mathrm{L}_{\infty}=43.78$ and $\mathrm{k}=0.28$ ) and Southern New England ( $\mathrm{L}_{\infty}=44.04$ and $\mathrm{k}=0.37$ ) alone were used. Using the preliminary offshore hake ages, von Bertalanffy growth parameters ( $\mathrm{L}_{\infty}=70$ and $\mathrm{k}=0.174$ ) were estimated, and used in the SEINE model as part of the sensitivity analyses (Tables D41-42, Figure D27).

We set $\mathrm{L}_{\infty}$ to 70 cm , as it corresponded with the largest offshore hake seen in both the NEFSC and Canadian DFO surveys. When it wasn't set, Solver gave an $L_{\infty}$ result of 274 cm , which is completely infeasible. The model results showed that using the offshore hake estimated growth parameters at 20 cm were the best fit. They had the lowest AIC and likelihood values and realistic z values of all the runs completed.

The model includes an assumption of flat-topped selectivity. The working group felt that there is no correspondence between the mortality rate and the catch (Figures D28-34). For example, in the 1970s, when landings increased substantially, total mortality apparently decreased.
Subsequently, when catch declined, mortality increased. Therefore, the results from SEINE are not a reliable basis for management.

## Application of An Index Method (AIM) Model to Offshore Hake

## AIM Method

The AIM model is a simple approach for examining the relationship between survey data and catch in data poor stock assessments. AIM is designed to address the question of whether a given rate of fishing mortality is likely to increase or decrease the population size. Survey data are used to define a relative rate of increase and the ratio of catch to survey indices provides a measure of relative fishing mortality. Theoretically the model can identify a stable point about which the stock will neither increase nor decrease in response to a fixed harvest rate. The model assumes that the resource dynamics are approximately linear with relatively minor influence of density dependent effects or variable environmental or ecological factors. Such conditions often typify stocks that have been historically harvested at high fishing rates and are therefore at low population sizes. AIM is both an analytic and graphing approach. The analytical methods can be used to define relative Fs for replacement and the graphical methods can be used to identify transient conditions that are relevant to implementation of any model. The details of the methodology are described below.
$\checkmark$ Population biomass at time $t$ can be written as a linear combination of historical population biomasses
$\checkmark$ Recruitment is proportional to population biomass
$\checkmark$ Fishing mortality is proportional to catch divided by an index of population size (relative F).
$\checkmark$ The rate of change in population biomass is a monotonically decreasing function of relative $F$.
$\checkmark$ Smoothing methods can be used to identify underlying trends.
$\checkmark$ Randomization methods can be used to develop sampling distributions of test statistics
$\checkmark$ Graphical methods can help identify linkages among variables
Relative F is defined as the ratio of catch to an index of population abundance. A three-year
centered average of the abundance index is chosen as the measure of average stock size.

$$
\begin{equation*}
r e l F_{j, s, t}=\left(\frac{C_{s, t}}{\frac{I_{j, s, t-1}+I_{j, s, t}+I_{j, s, t+1}}{3}}\right) \tag{1}
\end{equation*}
$$

Where $\quad \operatorname{relF}_{j, s, t}=$ relative $F$ for relative index $j$ for stock $s$ at time $t$
$\mathrm{C}_{\mathrm{s}, \mathrm{t}}=$ catch or landings of stock s at time t (in units of weight)
$\mathrm{I}_{\mathrm{j}, \mathrm{s}, \mathrm{t}}=$ Index of abundance j for stock s at time t expressed in terms of average weight per tow

The population size at any given time can be viewed as a weighted sum of previous recruitment events. For a population with a maximum age of A years, the population in year $t$ consists of the recruits from year t-1, t-2, ..t-A. At high levels of total mortality, the contributions from the earliest recruitments, say t-k-1 to t-A will diminish in importance such that the population can be viewed as the sum of recruitments from $t-1$ to $t-k$ years.

Using the linearity assumption defined above, we can employ basic life history theory to write abundance at time $t$ as a function of the biomasses in previous time periods. The number of recruits at time $t\left(R_{t}\right)$ is assumed to be proportional to the biomass at time $t\left(B_{t}\right)$. More formally,

$$
\begin{equation*}
R_{t}=S_{o} E g g B_{t} \tag{2}
\end{equation*}
$$

where $\mathbf{E g g}$ is the number of eggs produced per unit of biomass, and $\mathbf{S}_{\mathbf{0}}$ is the survival rate between the egg and recruit stages. Survival for recruited age groups at age a and time $t\left(S_{a, t}\right)$ is defined as

$$
S_{a, t}=e^{-F_{a, t}-M_{a, t}}
$$

where F and M refer to the instantaneous rates of fishing and natural mortality, respectively. We also need to consider the weight at age a and time $t\left(W_{a, t}\right)$ and the average longevity (A) of the species

Using these standard concepts we now write the biomass at time $t$ as a linear combination of the A previous years. Without loss of generality, we can drop the subscripts on the survival terms and assume that average weight at age is invariant with respect to time. Further, set the product $\mathrm{S}_{\mathrm{o}}$ Egg equal to the coefficient $\alpha$. The biomass at time t can now be written as
$B_{t}=R_{t-1} S^{l} W_{1}+R_{t-2} S^{2} W_{2}+R_{t-3} S^{3} W_{3}+. .+R_{t-(A-l)} S^{A-1} W_{A-I}+R_{t-A} S^{A} W_{A}$

Substituting Eq. (2) into Eq. (4) leads to

$$
B_{t}=\alpha B_{t-1} S^{l} W_{1}+\alpha B_{t-2} S^{2} W_{2}+\alpha B_{t-3} S^{3} W_{3}+. .+. \alpha B_{t-(A-l)} S^{A-l} W_{A-1}+\alpha B_{t-A} S^{A} W_{A}(5)
$$

If the population is replacing itself, then the left hand side of Eq. 5 will equal the right hand side. The replacement ratio can then be defined as

$$
\Psi_{t}=\frac{B_{t}}{\alpha B_{t-1} S^{l} W_{l}+\alpha B_{t-2} S^{2} W_{2}+\alpha B_{t-3} S^{3} W_{3}+. .+. a l p h a B_{t-(A-l)} S^{A-1} W_{A-l}+\alpha B_{t-A} S^{A} W_{A}}
$$

Substituting observed values of abundance indices into Eq 6 leads to

$$
\begin{equation*}
\Psi_{t}=\frac{\frac{I_{t}}{q}}{\alpha \frac{I_{t-1}}{q} S^{l} W_{1}+\alpha \frac{I_{t-2}}{q} S^{2} W_{2}+\alpha \frac{I_{t-3}}{q} S^{3} W_{3}+. .+\alpha \frac{I_{t-(A-l)}}{q} S^{A-1} W_{A-1}+\alpha \frac{I_{t-A}}{q} S^{A} W_{A}} \tag{7}
\end{equation*}
$$

By noting that the q's cancel out, and letting $\varphi_{j}=\alpha S^{j} W_{j}$, Eq. 6 simplifies to

$$
\Psi_{t}=\frac{I_{t}}{\sum_{j=1}^{A} \phi_{j} I_{t-j}}
$$

All of the $\mathrm{I}_{\mathrm{t}}$ and $\varphi_{\mathrm{j}}$ are positive, and at equilibrium $\mathrm{I}_{\mathrm{t}}=\mathrm{I}_{\mathrm{t}+1}$ and $\mathrm{I}_{\mathrm{t}}=\sum \varphi_{\mathrm{j}} \mathrm{I}_{\mathrm{t}-\mathrm{j}}$ both hold. Therefore $\sum \varphi_{\mathrm{j}}=1$. When the population is not at equilibrium the parameter $\Psi$ becomes a measure of the non equilibrium state of the population and a measure of whether the population is increasing or decreasing relative to prevailing fishery and ecosystem conditions.

It would be desirable to express the parameters of $\varphi_{j}$ weighting terms as function of the underlying parameters. Analyses of other stocks with more detailed information, such as Georges Bank haddock, has suggested that setting the $\varphi_{\mathrm{j}}$ to $1 / \mathrm{A}$ is a reasonable approximation. Equations 2 to 8 are a long way of justifying that the ratio of current stock size to a moving average of the previous A years of stock size can be used as a measure of population growth rate. This ratio embeds some life history theory into the basis for the ratio and simultaneously provides a way of damping the variations in abundance owing to measurement error. A ratio defined as $I_{t} / I_{t-1}$ has been found, as expected to be much more noisy measure of population change.

Further details on the AIM methodology may be found in Working Group (2002) and the NOAA

Fisheries Toolbox (NFT) 3.1 (2010a) software package http://nft.nefsc.noaa.gov/AIM.html. The relationship between $\boldsymbol{\Psi}_{\mathbf{t}}$ and $\mathbf{r e l F}_{\mathbf{t}}$ can be expressed as

$$
\ln \left(\Psi_{t}\right)=a+b \ln \left(r e l F_{t}\right)
$$

The usual tests of statistical significance do not apply for the model described in Eq. 9. The relation between $\Psi_{t}$ and $\mathbf{r e l F}_{t}$ is of the general form of $\mathrm{Y} / \mathrm{X}$ vs X where X and Y are random variables. The expected correlation between $\mathrm{Y} / \mathrm{X}$ and X is less than zero and is the basis for the oft stated criticism of spurious correlation. To test for spurious correlation we developed a sampling distribution of the correlation statistic using a randomization test. The randomization test is based on the null hypothesis that the catch and survey time series represent a random ordering of observations with no underlying association. The randomization test was developed as follows:

1. Create a random time series of length $\mathbf{T}$ of $\mathbf{C}_{\mathbf{r}, \mathrm{t}}$ from the set $\left\{\mathbf{C}_{\mathbf{t}}\right\}$ and $\mathbf{I}_{\mathbf{r}, \mathrm{t}}$ from the set $\left\{\mathbf{I}_{\mathbf{t}}\right\}$ by sampling with replacement.
2. Compute a random time series of relative $\mathrm{F}\left(\mathbf{r e l F}_{\mathbf{r}, \mathbf{t}}\right)$ and replacement ratios ( $\boldsymbol{\Psi}_{\mathbf{r}, \mathrm{t}}$ )
3. Compute the $\mathbf{r}$-th correlation coefficient, say $\boldsymbol{\rho}_{\mathbf{r}}$ between $\ln \left(\mathbf{r e l} \mathbf{F}_{\mathbf{r}, \mathrm{t}}\right)$ and $\ln \left(\boldsymbol{\Psi}_{\mathrm{r}, \mathrm{t}}\right)$.
4. Repeat steps 1 to 3 K times.
5. Compare the observed correlation coefficient $\mathbf{r}_{\text {obs }}$ with the sorted set of $\boldsymbol{\rho}_{\mathbf{r}}$
6. The approximate significance level of the observed correlation coefficient $\mathbf{r}_{\text {obs }}$ is the fraction of values of $\boldsymbol{\rho}_{\mathbf{r}}$ less than $\mathbf{r}_{\text {obs }}$

It should be emphasized that relF is not necessarily an adequate proxy for Fmsy, since this parameter only estimates the average mortality rate at which the stock was capable of replacing itself. Thus, while relF defined as average replacement fishing mortality is a necessary condition for an $\mathrm{F}_{\text {msy }}$ proxy, it is not sufficient, since the stock could theoretically be brought to the stable point under an infinite array of biomass states. The relF at replacement does however provide some guidance on the contemporary rate of harvesting and its potential impact on future stock abundance.

## Application of AIM to Offshore Hake

AIM was applied to offshore hake using catches derived from the method of Sosebee, and the NEFSC fall and spring bottom trawl survey indices (Table D43). Relative F was defined as the ratio of catch to a centered 3-year average of survey abundance (Eq. 1) and the replacement ratio was defined as a 5 -year moving average of previous stock sizes (Eq. 8). The relationship between catch, survey, relative $F$ and the replacement ratio for the fall and spring survey indices are depicted in Figs. D35 and D36, respectively. Neither of the randomization tests resulted in significant statistical relationship between the replacement ratio and relative F (Table D44).

Bootstrap estimation of the relative F at replacement were imprecise (Table D44, Figure D37) and may not be appropriate measures of Fmsy proxies. Graphical results suggest some underlying causes for the absence of a strong statistical relationship. Relative F has been declining continuously for the fall index (Figure D35). For the spring (Figure D36) survey indices relative F declined through the mid 1980 rebounded for a decade and then declined again
from the late 1990s onward. Fall and spring survey trends suggest high abundance before 1980 but much lower values (about one order of magnitude) since then. Replacement ratios for offshore hake in the fall survey have been generally below one since 1980 (Figure D35). The spring survey is slightly different with a brief excursion above 1.0 in the late 1990s followed by a general decline since 2001. Catch rates for offshore hake in both surveys is generally low, perhaps reflecting low abundance, low gear efficiency or both factors. Low gear efficiency can make the detection of trends difficult.

The relationship between survey abundance and relative F suggest a temporal trend wherein reductions in relative F do not necessarily induce similar increases in relative abundance (Figure D35 and D36--left middle panel). At a minimum these stanzas suggest major changes in the population abundance indices and exploitation rates. It is not possible from these data alone to identify causal factors but it does suggest that more advanced modeling if possible, will need to account for these changes in apparent productivity and/or natural mortality.

Survey exploitation indices were calculated using the swept area biomass for the fall, spring, and winter surveys, using the length-based total catch (Table D45, Figures 38-40). It was also calculated using the length-based landings, but the Working group decided that the catch was more accurate due to it being total removals (Table D45, Figures 41-43).

TOR 4. State the existing definitions for overfished and overfishing. Then update or redefine biological reference points (BRPs; estimates or proxies for $B_{M S Y}, B_{\text {THRESHOLD, }}$ and $F_{\text {MSY; }}$ and estimates of their uncertainty). Comment on the scientific adequacy of existing and redefined BRPs.

## Existing BRPs

The current overfishing definition is that: offshore hake is in an overfished condition when the three year moving average weight per individual in the fall survey falls below the 25th percentile of the average weight per individual from the fall survey time series 1963-1997 (0.236) AND when the three year moving average of the abundance of immature fish less than 30 cm falls below the median value of the 1963-1997 fall survey abundance of fish less than $30 \mathrm{~cm}(0.33)$ (NEFMC 2003).

In previous SAFE Reports, the WMC noted problems associated with this overfishing definition. Although the current definition is intended to identify overfished (i.e. low biomass) stock conditions, it is a better indication of overfishing (high exploitation rate). The WMC recommended that the overfishing definition for offshore hake be revisited.

The Hake Working Group noted that the survey data may not be a good index of abundance but may be driven more by the environment. Therefore, the existing BRPs should not be accepted, and no alternative reference points are recommended by SAW/SARC51.

TOR 5. Evaluate stock status with respect to the existing BRPs, as well as with respect to updated or redefined BRPs (from Offshore hake TOR 4).

Based on current biological reference points, offshore hake (Figure D44,Table 46) is not overfished and overfishing is unknown. The three year delta individual mean weight index (Figure D44, Table 46), based on NEFSC fall bottom trawl survey data for 2007-2009 (0.16 $\mathrm{kg} /$ individual), is below the management threshold ( $0.24 \mathrm{~kg} /$ individual) but the three year average recruitment index ( 0.89 num/tow) is above the threshold value ( 0.33 num/tow).

Based on the SAW/SARC51 review, stock status is unknown.
TOR 6. If a model can be developed, conduct single and multi-year stock projections and for computing candidate ABCs (Acceptable Biological Catch; see Appendix to the TORs).
a. Provide numerical short-term projections (3 years). Each projection should estimate and report annual probabilities of exceeding threshold BRPs for F, and probabilities of falling below threshold BRPs for biomass. In carrying out projections, consider a range of assumptions about the most important uncertainties in the assessment
b. Comment on which projections seem most realistic, taking into consideration uncertainties in the assessment.
c. Describe this stock's vulnerability to becoming overfished, and how this could affect the choice of ABC.

No model could be developed. Therefore, this term of reference could not be completed.
TOR 7. Propose new research recommendations.

- Studies to estimate discard mortality should be conducted.
- As an alternative to using silver hake calibration coefficients, it may be better to explore depth-based survey calibration coefficients.
- Develop explicit process and criteria for the application of length-based (vs. constant) calibration coefficients (other than purely statistical criteria such as AIC, etc.). It may be useful, if enough data exist, to attempt a cross validation with a subset of data.
- Investigate silver and offshore hake data in deepwater surveys (e.g., monkfish survey).
- Information on consumption by more predators (including mammals, highly migratory species (HMS)) needs to be included.
- Examine diel (day/night) variation in consumption of hakes.
- Identify offshore hake otoliths found in predators' stomachs.
- Validation of the ageing method for offshore hake via tagging, radiocarbon, or tetracyclin research needs to be conducted.
- The extent of the stock covered by the NEFSC needs to be examined.
- Perform a stock reduction analysis.

## Sources of Uncertainty

- It appears that the fishery as estimated by either the length-based model or the depthbased model has not had an impact on the stock. The mortality estimates from the SEINE model are in direct contrast to the catch data. Developing ACLs will also be challenging given that the landings are not separated to a great extent. Garcia-Vazquez et al (2009) found $12 \%$ of hake sold in Spain as silver hake were actually offshore hake.
- Given that the distribution of offshore hake in the NEFSC survey is very close to the edge of the survey range, the survey index may be more driven by environmental factors than abundance. The survey likely does not cover the entire stock area and therefore, the survey estimates could potentially be under-representing the dynamics of the population.

Figure D2a. NEFSC fall survey distribution (catch weight per tow, kg ) of offshore hake, 1967-2009, broken up by stratum areas for easier viewing.

Figure D2b. NEFSC fall survey distribution (catch weight per tow, kg ) of offshore hake, 1967-2009, broken up by stratum areas for easier viewing.

Figure D2c. NEFSC fall survey distribution (catch weight per tow, kg ) of offshore hake, 1967-2009, broken up by stratum areas for easier viewing.

Figure D2d. NEFSC fall survey distribution (catch weight per tow, kg ) of offshore hake, 1967-2009, broken up by stratum areas for easier viewing.

Figure D2e. NEFSC fall survey distribution (catch weight per tow, kg ) of offshore hake, 1967-2009, broken up by stratum areas for easier viewing.

Figure D3. Distribution of offshore hake from the NEFSC spring survey (catch weight per tow, kg), 1968-2009.

Figure D3a. NEFSC spring survey distribution (catch weight per tow, kg ) of offshore hake, 1968-2009, broken up by stratum areas for easier viewing.

Figure D3b. NEFSC spring survey distribution (catch weight per tow, kg ) of offshore hake, 1968-2009, broken up by stratum areas for easier viewing.

Figure D3c. NEFSC spring survey distribution (catch weight per tow, kg ) of offshore hake, 1968-2009, broken up by stratum areas for easier viewing.

Figure D3d. NEFSC spring survey distribution (catch weight per tow, kg) of offshore hake, 1968-2009, broken up by stratum areas for easier viewing.

Figure D3e. NEFSC spring survey distribution (catch weight per tow, kg ) of offshore hake, 1968-2009, broken up by stratum areas for easier viewing.

Figure D4. Distribution of offshore hake from the NEFSC winter survey (catch weight per tow, kg ), 1998-2007.

Figure D4a. NEFSC winter survey distribution (catch weight per tow, kg ) of offshore hake, 1998-2007, broken up by stratum areas for easier viewing.

Figure D4b. NEFSC winter survey distribution (catch weight per tow, kg ) of offshore hake, 1998-2007, broken up by stratum areas for easier viewing.

Figure D4c. NEFSC winter survey distribution (catch weight per tow, kg ) of offshore hake, 1998-2007, broken up by stratum areas for easier viewing.

Figure D4d. NEFSC winter survey distribution (catch weight per tow, kg ) of offshore hake, 1998-2007, broken up by stratum areas for easier viewing.

Figure D5. Nominal landings (mt) of offshore hake.

Figure D6. Length frequencies for silver hake for the northern region, before pooling, by all market categories.

Figure D7. Length frequencies for silver hake for the southern region, before pooling, by all market categories.

Figure D8. Length frequencies for silver hake for the northern region, landings and discards.

Figure D9. Length frequencies for silver hake for the southern region, landings and discards.

Figure D10. Comparison of nominal landings with the two model-based estimates for offshore hake from the southern stock.

Figure D11. Length-based total catch landings and discards for offshore hake, 1955-2009.
Offshore Hake Total Catch--Length Based

Offshore Hake Total Catch (Length Based), 1981-2009

Figure D12. Depth-based total catch landings and discards for offshore hake, 1955-2009.
Offshore Hake Total Catch--Depth Based

Offshore Hake Total Catch (Depth Based), 1981-2009

Figure D13.Comparison of the arithmetic and delta transformed mean weight per tow from the fall survey.

Figure D14. Comparison of the arithmetic and delta transformed mean weight per tow from the fall survey with three methods of handling missing weight data.

Figure D15. Beta-binomial based estimates of calibration factors and corresponding $95 \%$ confidence intervals by length class ( 1 cm bins) for silver hake. The black points and vertical bars represent results where different calibration factors are estimated for each length class. The blue lines represent results from fully parameterized double-logistic models. For the spring, the red lines represent results for a (single) logistic model whereas they represent results for a double logistic model with no minima for the ascending or descending logistic function for the fall.

Figure D16. Stratified mean number (top) and weight (kg) per tow of offshore hake for the NEFSC fall surveys, 1967-2009.

## Fall

Figure D17. Swept area abundance (millions, top) and biomass (kg, bottom) of offshore hake for the NEFSC fall surveys, 1967-2009.

Fall Swept Area

Figure D18. Stratified mean number (top) and weight (kg) per tow of offshore hake for the NEFSC spring surveys, 1968-2010.

Figure D19. Swept area abundance (millions, top) and biomass (kg, bottom) of offshore hake for the NEFSC spring surveys, 1968-2010.

## Spring Swept Area

Figure D20. Stratified mean number (top) and weight (kg) per tow of offshore hake for the NEFSC winter surveys, 1998-2007.

Figure D21. Swept area abundance (millions, top) and biomass (kg, bottom) of offshore hake for the NEFSC winter surveys, 1998-2007.

## Winter Swept Area

Figure D22a. Length composition (stratified mean number per tow) of offshore hake for the fall survey, 1967-2009.

Figure D22b. Length composition (stratified mean number per tow) of offshore hake for the fall survey, 1967-2009.

Figure D22c. Length composition (stratified mean number per tow) of offshore hake for the fall survey, 1967-2009.

Figure D22d. Length composition (stratified mean number per tow) of offshore hake for the fall survey, 1967-2009.

Figure D23a. Length composition (stratified mean number per tow) of offshore hake for the spring survey, 1968-2009.

Figure D23b. Length composition (stratified mean number per tow) of offshore hake for the spring survey, 1968-2009.

Figure D23c. Length composition (stratified mean number per tow) of offshore hake for the spring survey, 1968-2009.

Figure D23d. Length composition (stratified mean number per tow) of offshore hake for the spring survey, 1968-2009.

Figure D24. Length composition (stratified mean number per tow) of offshore hake for the winter survey, 1998-2007.

Figure D25a. Three-year moving average length composition (stratified mean number per tow) of offshore hake for the fall survey, 1969-2008.

offshore_fall_3yr_smoother 1974

Figure D25b. Three-year moving average length composition (stratified mean number per tow) of offshore hake for the fall survey, 1969-2008.

Figure D25c. Three-year moving average length composition (stratified mean number per tow) of offshore hake for the fall survey, 1969-2008.

Figure D25d. Three-year moving average length composition (stratified mean number per tow) of offshore hake for the fall survey, 1969-2008.

Figure D26a. Three-year moving average length composition (stratified mean number per tow) of offshore hake for the spring survey, 1970-2008.

Figure D26b. Three-year moving average length composition (stratified mean number per tow) of offshore hake for the spring survey, 1970-2008.

offishore_spr_3yr_smoother 1997

Figure D26c. Three-year moving average length composition (stratified mean number per tow) of offshore hake for the spring survey, 1970-2008.

Figure D26d. Three-year moving average length composition (stratified mean number per tow) of offshore hake for the spring survey, 1970-2008.

Figure D27. Von Bertalanffy estimates for offshore hake, using the NEFSC preliminary ages.

## Offshore Hake SGB/SNE

Figure D28. Offshore hake SEINE model results using silver hake average of Southern Georges Bank and Southern New England growth parameters, laid over total catch (metric tons). Lines indicate mortality estimates.

## Offshore Hake SGB

Figure D29. Offshore hake SEINE model results using silver hake Southern Georges Bank growth parameters, laid over total catch (metric tons). Lines indicate mortality estimates.

Offshore Hake SNE

Figure D30. Offshore hake SEINE model results using silver hake Southern New England growth parameters, laid over total catch (metric tons). Lines indicate mortality estimates.

Offshore Hake Von Bert

Figure D31. SEINE model results using the estimated von Bertalanffy growth parameters for offshore hake, laid over total catch (metric tons). Lines indicate mortality estimates.

## Offshore Hake 17cm

Figure D32. Offshore hake SEINE model results for the 17 cm mortality cut, laid over total catch (metric tons). Lines indicate mortality estimates.

## Offshore Hake 20cm

Figure D33. Offshore hake SEINE model results for the 20 cm mortality cut, laid over total catch (metric tons). Lines indicate mortality estimates.

## Offshore Hake 23cm

Figure D34. Offshore hake SEINE model results for the 23 cm mortality cut, laid over total catch (metric tons). Lines indicate mortality estimates.

Figure D35. Six panel plot for offshore hake depicting trends in relative biomass, landings, relative fishing mortality and replacement ratios for the NEFSC Fall bottom trawl survey index and landings based on the Sosebee method. Horizontal dashed lines (---) represent replacement ratios in the top two panels and the replacement F in the lower right panel. Smooth lines represent Lowess smooths (tension $=0.3$ ). The confidence ellipse in the top left panel has a nominal probability level of 0.68 . The regression line in the top left panel is a robust regression using bisquare downweighting of residuals.

Offshore South Kathy NEFSC Fall Survey

Figure D36. Six panel plot for offshore hake depicting trends in relative biomass, landings, relative fishing mortality and replacement ratios for the NEFSC spring bottom trawl survey index and landings based on the Sosebee method. Horizontal dashed lines (---) represent replacement ratios in the top two panels and the replacement F in the lower right panel. Smooth lines represent Lowess smooths (tension $=0.3$ ). The confidence ellipse in the top left panel has a nominal probability level of 0.68 . The regression line in the top left panel is a robust regression using bisquare downweighting of residuals.

Figure D37. Randomization tests summary of sampling distribution of correlation coefficient between replacement ratio and relative F for fall (top) and spring (bottom) survey indices.

Figure D38. Exploitation ratios for total catch (total catch/swept area biomass) for offshore hake during fall surveys.

Figure D39. Exploitation ratios for total catch (total catch/swept area biomass) for offshore hake during spring surveys.

Figure D40. Exploitation ratios for total catch (total catch/swept area biomass) for offshore hake during winter surveys.

Figure D41. Exploitation ratios for landings (landings/swept area biomass) for offshore hake during fall surveys.

Figure D42. Exploitation ratios for landings (landings/swept area biomass) for offshore hake during spring surveys.

Figure D43. Exploitation ratios for landings (landings/swept area biomass) for offshore hake during winter surveys.

Offshore Hake

# Procedures for Issuing Manuscripts <br> in the <br> Northeast Fisheries Science Center Reference Document (CRD) Series 

## Clearance

All manuscripts submitted for issuance as CRDs must have cleared the NEFSC's manuscript/abstract/ webpage review process. If any author is not a federal employee, he/she will be required to sign an "NEFSC Release-of-Copyright Form." If your manuscript includes material from another work which has been copyrighted, then you will need to work with the NEFSC's Editorial Office to arrange for permission to use that material by securing release signatures on the "NEFSC Use-of-Copyrighted-Work Permission Form."

For more information, NEFSC authors should see the NEFSC's online publication policy manual, "Manuscript/abstract/webpage preparation, review, and dissemination: NEFSC author's guide to policy, process, and procedure," located in the Publications/Manuscript Review section of the NEFSC intranet page.

## Organization

Manuscripts must have an abstract and table of contents, and (if applicable) lists of figures and tables. As much as possible, use traditional scientific manuscript organization for sections: "Introduction," "Study Area" and/or "Experimental Apparatus," "Methods," "Results," "Discussion," "Conclusions," "Acknowledgments," and "Literature/References Cited."

## Style

The CRD series is obligated to conform with the style contained in the current edition of the United States Government Printing Office Style Manual. That style manual is silent on many aspects of scientific manuscripts. The CRD series relies more on the CSE Style Manual. Manuscripts should be prepared to conform with these style manuals.

The CRD series uses the American Fisheries Society's guides to names of fishes, mollusks, and decapod
crustaceans, the Society for Marine Mammalogy's guide to names of marine mammals, the Biosciences Information Service's guide to serial title abbreviations, and the ISO's (International Standardization Organization) guide to statistical terms.

For in-text citation, use the name-date system. A special effort should be made to ensure that all necessary bibliographic information is included in the list of cited works. Personal communications must include date, full name, and full mailing address of the contact.

## Preparation

Once your document has cleared the review process, the Editorial Office will contact you with publication needs - for example, revised text (if necessary) and separate digital figures and tables if they are embedded in the document. Materials may be submitted to the Editorial Office as files on zip disks or CDs, email attachments, or intranet downloads. Text files should be in Microsoft Word, tables may be in Word or Excel, and graphics files may be in a variety of formats (JPG, GIF, Excel, PowerPoint, etc.).

## Production and Distribution

The Editorial Office will perform a copy-edit of the document and may request further revisions. The Editorial Office will develop the inside and outside front covers, the inside and outside back covers, and the title and bibliographic control pages of the document.

Once both the PDF (print) and Web versions of the CRD are ready, the Editorial Office will contact you to review both versions and submit corrections or changes before the document is posted online.

A number of organizations and individuals in the Northeast Region will be notified by e-mail of the availability of the document online.

## Publications and Reports of the

## Northeast Fisheries Science Center

The mission of NOAA's National Marine Fisheries Service (NMFS) is "stewardship of living marine resources for the benefit of the nation through their science-based conservation and management and promotion of the health of their environment." As the research arm of the NMFS's Northeast Region, the Northeast Fisheries Science Center (NEFSC) supports the NMFS mission by "conducting ecosystem-based research and assessments of living marine resources, with a focus on the Northeast Shelf, to promote the recovery and long-term sustainability of these resources and to generate social and economic opportunities and benefits from their use." Results of NEFSC research are largely reported in primary scientific media (e.g., anonymously-peer-reviewed scientific journals). However, to assist itself in providing data, information, and advice to its constituents, the NEFSC occasionally releases its results in its own media. Currently, there are three such media:

NOAA Technical Memorandum NMFS-NE -- This series is issued irregularly. The series typically includes: data reports of long-term field or lab studies of important species or habitats; synthesis reports for important species or habitats; annual reports of overall assessment or monitoring programs; manuals describing program-wide surveying or experimental techniques; literature surveys of important species or habitat topics; proceedings and collected papers of scientific meetings; and indexed and/or annotated bibliographies. All issues receive internal scientific review and most issues receive technical and copy editing.

Northeast Fisheries Science Center Reference Document -- This series is issued irregularly. The series typically includes: data reports on field and lab studies; progress reports on experiments, monitoring, and assessments; background papers for, collected abstracts of, and/or summary reports of scientific meetings; and simple bibliographies. Issues receive internal scientific review and most issues receive copy editing.

Resource Survey Report (formerly Fishermen's Report) -- This information report is a regularly-issued, quick-turnaround report on the distribution and relative abundance of selected living marine resources as derived from each of the NEFSC's periodic research vessel surveys of the Northeast's continental shelf. This report undergoes internal review, but receives no technical or copy editing.
