## PREFACE

A Pacific mackerel stock assessment is conducted annually in support of the Pacific Fishery Management Council (PFMC) process, which ultimately establishes a harvest guideline ('HG' or quota) for the Pacific mackerel fishery that operates off the USA Pacific coast. The HG for mackerel applies to a fishing/management season that spans from July $1^{\text {st }}$ and ends on June $30^{\text {th }}$ of the subsequent year (henceforth, presented as a 'fishing year'). In this context, in this document, both a two-year (e.g., 2009-10) and single-year (e.g., 2009) reference refer to the same fishing year that spanned from July 1, 2009 to June 30, 2010. The primary purpose of the assessment is to provide an estimate of current abundance (in biomass), which is used in a harvest control rule for calculation of annual-based HGs. For details regarding this species’ harvest control rule, see Amendment 8 of the Coastal Pelagic Species (CPS) Fishery Management Plan (FMP), section 4.0 (PFMC 1998).

The last updated assessment and quota-setting (HG) process was completed in May 2008, i.e., the assessment was considered a formal 'update,' as defined by the PFMC (see PFMC 2009). The 2008-09 fishing year (July1, 2008 - June 30, 2009) harvest guideline was 51,722 mt. The stock assessment presented here reflects a 'full' assessment that has undergone formal review as outlined by the PFMC and Science and Statistical Committee (SSC), see STAR (2009). Specifically, a week-long stock assessment review (STAR) panel was convened from May 4-8, 2009 (NOAA Fisheries, Southwest Fisheries Science Center in La Jolla, CA) to evaluate the ongoing Pacific mackerel stock assessment, as well as two independent surveys presently under consideration in the Pacific sardine assessment. Important areas of general consensus reached by the STAR panel that pertained to the stock assessment follow:

- The Pacific mackerel stock assessment team (STAT) met all four objective, including:

1) produced an updated assessment based on the current model relied upon for management purposes, namely, the Age-structured Assessment Program (ASAP) model;
2) produced a baseline Stock Synthesis (SS) model that generally mirrored the current management-based ASAP model;
3) produced a suite of alternative SS model (scenarios) that improved upon the baseline SS model; and
4) from the suite of SS model scenarios, identified the best configuration(s) based on both statistical and practical considerations.

- The recommended HG for the 2009-10 fishing year (July1, 2009 - June 30, 2010) is 55,408 mt:

1) the final HG reflects substantial sensitivity analysis prior to and during the STAR;
2) the final HG was based on SS model scenario ( $A A$ ); and
3) SS model scenario $A B$ was identified as a meaningful alternative model and likely a candidate baseline model in the future, given issues surrounding critical areas of data availability (e.g., recreational fishery statistics) and related model parameterization (selectivity and catchability) can be addressed in the interim and within the overall assessment cycle.

- Documentation of the assessment report following the STAR should:

1) 'begin with' the final consensus model from the STAR (namely, SS model AA) ... objective four above;
2) provide cricital statistics from relevant scenarios involved in the overall sensitivity analysis (e.g., SS model $A B$ ) ... objective three above;
3) use appendices for related analysis that supported the (draft) assessment initially presented at the STAR ... objectives one and two above; and finally,
4) meet stipulations set forth in the CPS stock assessment 'terms of reference' (PFMC 2009).

## EXECUTIVE SUMMARY

## Stock

Pacific mackerel (Scomber japonicus) in the northeastern Pacific Ocean range from southeastern Alaska to Banderas Bay (Puerto Vallarta), Mexico, including the Gulf of California. The fish are common from Monterey Bay, California, to Cabo San Lucas, Baja California, but are most abundant south of Point Conception, California. There are possibly three spawning ‘stocks’ along the Pacific coasts of the USA and Mexico: one in the Gulf of California; one in the vicinity of Cabo San Lucas; and one along the Pacific coast north of Punta Abreojos, Baja California and extending north to waters off southern California and further, off the Pacific Northwest depending on oceanographic conditions (say regimes). This latter sub-stock, the 'northeastern Pacific Ocean' population, is harvested by fishers in the USA and Baja California, Mexico, and is the population considered in this assessment.

## Catches

Pacific mackerel landings from both commercial and recreational fisheries in California and commercial landings in Baja California represent the catch time series (1962-08) used in the assessment, with landings pooled into the two broadly-defined fisheries for all modeling purposes, i.e., commercial and recreational fishing sectors, respectively. Historically, total catch time series over the last 100 years can be broadly defined by two or more 'modes,' e.g., late 1920s to mid 1960s and late 1970s to the present (Figure ES-1). Recent catches are presented in Table ES-1.

Currently, catch (including biological) data are largely collected through a California Department of Fish and Game (CDFG) port (commercial) sampling program. That is, the CDFG has collected biological data on Pacific mackerel landed in the San Pedro (southern California) fishery since the late 1920s. Further, to some degree, port sampling data have been collected by researchers from Ensenada, Mexico (Instituto Nacional de la Pesca, INP) since 1989; however, this information is only now being distributed at a broader scale through government/academic supported programs. Recreational catches are primarily associated with southern California’s marine recreational angler community, including commercial passenger fishing vessel (CPFV) and private fisheries, with overall landings much lower than associated with the commercial fisheries (i.e., sport fisheries generate less than $5 \%$ of the total catch in any given year).

## Data and assessment

Historically, various age-structured assessment models have been used to assess the status of Pacific mackerel off the west coast of North America, which were generally based on fishery landings, fishery age/length distributions, and relative indices of abundance. The last assessment of Pacific mackerel was completed in 2008 for USA management in the 2008-09 fishing year. The current assessment includes the following data (i.e., time series, with 'additional year' updates noted where applicable): catch (1962-08, updated); and a CPFV-based catch-per-uniteffort (CPUE) index (1962-08, updated). The final model (scenario) for management advice for the upcoming fishing year (2009-10) was based on the Stock Synthesis (SS) model (i.e., model scenario $A A$ ), which realized fruition through general consensus from STAR deliberations (see Preface).

## Unresolved problems and uncertainties

First and foremost, given Pacific mackerel is a 'transboundary' stock, the assessment would benefit greatly from additional biological and/or 'survey' (e.g., relative abundance index data) from Mexico. In particular, there is currently no synoptic survey (fishery-independent) index of abundance that pertains to the entire (hypothesized) range of the modeled stock. Secondly, alternative model scenarios (e.g., model scenario $A B$ ) that included more detailed parameterization of both historical and recent patterns in selectivity and catchability provided a more realistic envelope of the uncertainty associated with stock status determinations for this species than otherwise indicated in a single baseline model, i.e., as expected, recent estimates of absolute abundance differ depending on assumptions regarding time-varying selectivity/catchability in the baseline model. Also, see Research and data needs below.

## Total stock biomass

Total biomass (age-1+ biomass, B) remained low from the early 1960s to the mid 1970s, at which time the population began to rapidly increase in size, reaching a peak in the early 1980s (see Recruitment below). From the mid 1980s to early 2000s, the stock declined steadily, with some signs of 'rebuilding' (on an increasing limb of a historical distribution say) observed recently (Figure ES-2 and Table ES-2). However, as noted previously, recent estimates of stock size are necessarily related to assumptions regarding the dynamics of the fish (biology) and fishery (operations) over the last several years, which generally confounds long-term (abundance) forecasts for this species. For example, see estimated $B$ time series from alternative SS model $A B$, which generally mirrored SS model $A A$, except in the most recent years, with stock size plateauing at historically low levels, rather than increasing (Figure ES-2).

Fishing year

Figure ES-2. Estimated total stock biomass (age 1+ fish in mt, $B$ ) of Pacific mackerel based on the final SS model $A A$ and alternative model $A B$ (1962-09). Also, $B$ time series from previous year's assessment (ASAP 2008) is presented for comparative purposes.

Table ES-2. Estimated recruitment ( $R$ ), total biomass ( $B$ ), and spawning stock biomass (SSB) of Pacific mackerel based on SS model AA (1962-09).

| Fishing year | $\boldsymbol{R}$ (age-0, in 1,000s) | $\boldsymbol{B}(\mathbf{a g e}-\mathbf{1}+, \mathbf{m t})$ | $\boldsymbol{S S B} \mathbf{( m t )}$ |
| ---: | ---: | ---: | ---: |
|  |  |  |  |
| 98 | 161,490 | 183,255 | 98,203 |
| 99 | 123,450 | 105,797 | 62,788 |

| 03 | 94,906 | 40,828 | 19,203 |
| 04 | 254,870 | 36,511 | 16,281 |
| 05 | 607,540 | 56,348 | 16,684 |
| 06 | 939,810 | 122,581 | 24,639 |
| 07 | 688,600 | 222,969 | 44,981 |
| 08 | 452,530 | 275,211 | 76,440 |
| 09 |  | 282,049 |  |

## Spawning stock biomass

Spawning stock biomass (SSB) followed the general trajectory as observed in the estimated $B$ time series, with magnitudes that are roughly one-half the size of total stock biomass (Figure ES3 and Table ES-2).

## SSB (mt)

Figure ES-3. Estimated spawning stock biomass (SSB) of Pacific mackerel based on SS model $A A$ (1962-08). Confidence interval ( $\pm 2 \mathrm{SD}$ ) is also presented as dashed lines.

## Recruitment

As expected, historically, estimated recruitment ( $R$ ) has been highly variable, remaining relatively low up until the mid 1970s, increasing markedly in magnitude from the late 1970s through the early 1980s, with stock productivity remaining relatively low since this time (Figure ES-4 and Table ES-2).

Fishing year
Figure ES-4. Estimated recruitment (age-0 fish in 1,000s, $R$ ) of Pacific mackerel based on SS model $A A$ (1962-08). Confidence interval ( $\pm 2 \mathrm{SD}$ ) is also presented as dashed lines.

## Management performance

Since 2000, Pacific mackerel has been managed under a Federal Management Plan (FMP) harvest policy, stipulating that a maximum sustainable yield (MSY) for this species should be set according to the following harvest control rule:

$$
\text { Harvest }=(\text { Biomass-Cutoff } \bullet \text { Fraction • Distribution, }
$$

where Harvest is the harvest guideline (HG), Biomass is the estimated total stock biomass (age $1+$ ) in $2009(282,049 \mathrm{mt})$, Cutoff ( $18,200 \mathrm{mt}$ ) is the lowest level of estimated biomass at which harvest is allowed, Fraction (30\%) is the proportion of biomass above the Cutoff that can be harvested by fisheries, and Distribution (70\%) is the average fraction of total biomass assumed in USA waters (PFMC 1998). The HGs under the federal FMP are applied to a July-June fishing 'year.' Landings and associated HGs since 1992 are presented in Figure ES-5.

The HG for the 2009-10 fishing year based on SS model AA is 55,408 mt (Table ES-3).
From 1985 to 1991, the biomass exceeded 136,000 mt and no state quota restrictions were in effect. State quotas for 1992-00 fishing years averaged roughly $24,000 \mathrm{mt}$. The HGs averaged roughly $20,000 \mathrm{mt}$ from 2001-06. In 2007, the HG was increased substantially to over 100,000 mt based largely on assumptions regarding variability surrounding estimated recruitment and has remained at an elevated level since then (Figure ES-5). It is important to note that since the 2001 fishing year, from a management context, the fishery has failed to fully utilize HGs, with average yields since this time of roughly 5,000 mt (Figure ES-5).

Landings (mt)

Fishing year
Figure ES-5. Commercial landings (California directed fishery, mt) and quotas (HGs, mt) for Pacific mackerel (1992-08).

Table ES-3. Harvest control rule statistics for the Pacific mackerel fishing year 2009-10.

| B (Age 1+, mt) | Cutoff (mt) | Fraction | Distribution | HG (mt) |
| :---: | :---: | :---: | :---: | :---: |
| 282,049 | 18,200 | $30 \%$ | $70 \%$ | 55,408 |

## Research and data needs

First and foremost, given the transboundary status of this fish population, it is imperative that efforts continue in terms of encouraging collaborative research and data exchange between NOAA Fisheries (Southwest Fisheries Science Center) and researchers from both Canada's and in particular, Mexico's academic and federal fishery bodies, i.e., such cooperation is critical to providing a synoptic assessment that considers available sample data across the entire range of this species in any given year.

Second, fishery-independent survey data for measuring (relative) changes in mackerel spawning (or total) biomass are currently lacking. Further, at this time, a single index of relative abundance is used in the assessment, which is developed from a marine recreational fishery (CPFV fleet) that typically does not (directly) target the species. In this context, it is imperative that future research funds be focused on improvement of the current CPFV survey, with emphasis on a long-term horizon, which will necessarily rely on cooperative efforts between the industry, research, and management bodies. Additionally, we strongly support development of a well-designed logbook monitoring program associated with the current commercial (purse-seine) fishery, which has been long overdue.

Third, given the importance of age (and length) distribution time series to developing a sound understanding of this species' population dynamics, it is critical that data collection programs at the federal and particularly, the state-level continue to be supported adequately. In particular, CDFG/NOAA funding should be bolstered to ensure ongoing ageing-related laboratory work is not interrupted, as well as providing necessary funds for related biological research that is long overdue. For example, maturity-related time series currently relied upon in the assessment model are based on data collected over twenty years ago during a period of high spawning biomass that does not reflect current levels. Also, further work is needed to obtain more timely error estimates from production ageing efforts in the laboratory, i.e., accurate interpretation of age-distribution data used in the ongoing assessment necessarily requires a reliable ageing error time series. Finally, examinations of sex-specific age distributions will allow hypotheses regarding natural mortality/selectivity (i.e., absence of older animals in sex-combined age distributions) to be more fully evaluated.

Finally, the MSY control rule utilized in the Pacific mackerel federal CPS-FMP was developed in the mid-1980s using the historical time series of abundance. The harvest control rule should be re-examined using new data and simulation methods. Given substantial amounts of additional sample data have accumulated since the initial research that was undertaken to formally establish this harvest strategy, it would be prudent to conduct further simulation modeling work to address particular parameters included in the overall control rule (including 'cutoff,' 'fraction,' and ‘distribution’ values).

## INTRODUCTION

## Distribution

Pacific mackerel (Scomber japonicus; a.k.a. 'chub mackerel' or 'blue mackerel') in the northeastern Pacific range from southeastern Alaska to Banderas Bay (Puerto Vallarta), Mexico, including the Gulf of California (Hart 1973). They are common from Monterey Bay, California, to Cabo San Lucas, Baja California, but are most abundant south of Point Conception, California. Pacific mackerel usually occur within 30 km of shore, but have been captured as far as 400 km offshore (Fitch 1969; Frey 1971; Allen et al. 1990; MBC 1987).

## Migration

Pacific mackerel adults are found in water ranging from 10 to $22.2^{\circ} \mathrm{C}$ (MBC 1987) and larvae may be found in water around $14^{\circ} \mathrm{C}$ (Allen et al. 1990). As adults, Pacific mackerel move north in summer and south in winter between Washington and Baja California (Fry and Roedel 1949; Roedel 1949), with northerly movement in the summer accentuated during El Niño events (MBC 1987). There is an 'inshore-offshore’ migration off California, with increased inshore abundance from July to November and increased offshore abundance from March to May (Cannon 1967; MBC 1987). Adult Pacific mackerel are commonly found near shallow banks. Juveniles are found off sandy beaches, around kelp beds, and in open bays. Adults are found from the surface to 300 m depth (Allen et al. 1990). Pacific mackerel often school with other coastal pelagic species, particularly jack mackerel and Pacific sardine, and likely based on age-dependent attributes as well (Parrish and MacCall 1978).

Over the last two decades, the stock has likely more fully occupied the northernmost portions of its range in response to a warm oceanographic regime in the northeastern Pacific Ocean, with further evidence, given Pacific mackerel have been found as far north as British Columbia, Canada (Ware and Hargreaves 1993; Hargreaves and Hungar 1995). During the summer months, Pacific mackerel are commonly caught incidentally in commercial whiting and salmon fisheries off the Pacific Northwest, but historically, these catches have been limited. Pacific mackerel sampled from Pacific Northwest incidental fisheries are generally older and larger than those captured in the southern California fishery (Hill 1999). In addition, this species is harvested by recreational anglers on CPFVs and private vessels, but is typically not highly prized in the fishery, with catches relatively low when compared with commercial landings.

## Life history

Pacific mackerel found off the Pacific coast of North America are the same species found elsewhere in the Pacific, Atlantic, and Indian Oceans (Collette and Nauen 1983). Synopses regarding the biology of Pacific mackerel are presented in Kramer (1969) and Schaefer (1980).

Currently, the general consensus within the coastal pelagic species research forum is that there are likely three spawning stocks in the northeastern Pacific Ocean: one in the Gulf of California, one near Cabo San Lucas, and one along the Pacific coast north of Punta Abreojos, Baja California to British Columbia, Canada. Spawning occurs from Point Conception, California to Cabo San Lucas from 3 to 320 km offshore (Moser et al. 1993). Off California, spawning occurs from late April to September at depths to 100 meters. Off central Baja California, spawning occurs year round, peaking from June through October. Around Cabo San Lucas, spawning
occurs primarily from late fall to early spring. Pacific mackerel seldom spawn north of Point Conception (Fritzsche 1978; MBC 1987), although young-of-year (age-0) fish have been recently reported as far north as Oregon and Washington.

Like many coastal pelagic species with similar life history strategies, Pacific mackerel have indeterminate fecundity and appear to spawn whenever sufficient food is available and appropriate oceanographic conditions prevail. Individual fish may spawn eight times or more per year and release batches of 68,000 eggs per spawning. Actively spawning fish appear capable of spawning daily or every other day (Dickerson et al. 1992).

Pacific mackerel larvae eat copepods and other zooplankton, including fish larvae (Collette and Nauen 1983; MBC 1987). Juvenile and adult mackerel feed on small fish, fish larvae, squid, and pelagic crustaceans, such as euphausids (Clemmens and Wilby 1961; Turner and Sexsmith 1967; Fitch 1969; Fitch and Lavenberg 1971; Frey 1971; Hart 1973; Collette and Nauen 1983). Pacific mackerel larvae are subject to predation from a number of invertebrate and vertebrate planktivores. Juvenile and adults are eaten by larger fishes, marine mammals, and seabirds. Principal predators include porpoises, California sea lions, pelicans, and large piscivorous fishes, such as sharks and tunas. Pacific mackerel school as a defense against predation, often with other pelagic species, including jack mackerel and Pacific sardine.

Population dynamics of the Pacific mackerel stock off southern California have been extensively studied in the past and of particular importance was pioneering research conducted during the 1970s and 1980s, e.g., Parrish (1974), Parrish and MacCall (1978), Mallicoate and Parrish 1981, and Macall et al. (1985). More recently, USA-based research efforts associated with pelagic species that inhabit coastal areas of the Pacific coast of North America have focused on the Pacific sardine population. Pacific mackerel experience cyclical periods of abundance ('boombust'), which is typical of other small pelagic species that are characterized by relatively short life spans and high intrinsic rates of increase. Analysis of mackerel scale-deposition data (Soutar and Issacs 1974) indicated that periods of high biomass levels, such as during the 1930s and 1980s, are relatively rare events that might be expected to occur, on average, about once every 60 years (MacCall et al. 1985). It is important to note that assessment model structure and results generally support MacCall's research, with periods of strong recruitment estimates occurring no more frequently than at least 30 years or so. Recruitment is highly variable over space and time and not likely related to spawning biomass stock size (Parrish 1974), or at least not tightly linked to parent abundance levels within the historical range of estimated spawning stock biomass levels (Parrish and MacCall 1978).

## Stock structure and management units

The full range of Pacific mackerel in the northeastern Pacific Ocean is from southeastern Alaska to Banderas Bay (Puerto Vallarta), Mexico, including the Gulf of California. The majority of the fish are typically distributed from Monterey Bay, California, to Cabo San Lucas, Baja California, being most abundant south of Point Conception, California. It is likely that multiple 'spawning' stocks exist along the Pacific coasts of the USA and Mexico, although at this time, stock structure exhibited by this species is not known definitively: one in the Gulf of California; one in the vicinity of Cabo San Lucas; and one along the Pacific coast north of Punta Abreojos, Baja California and extending north to waters off southern California and further, off the Pacific

Northwest depending on oceanographic conditions (say regimes). This latter sub-stock, the 'northeastern Pacific Ocean' population, is harvested by fishers in the USA and Baja California, Mexico, and is the population considered in this assessment.

The Pacific Fishery Management Council (PFMC) manages the northeastern Pacific stock as a single unit, with no area- or sector-specific allocations. However, the formal Fishery Management Plan (FMP) harvest control rule does include a stock distribution adjustment, based on a long-term assumption that roughly $70 \%$ of this transboundary population resides in USA waters in any given year (PFMC 1998).

## Fishery descriptions

Pacific mackerel are currently harvested by three 'fisheries': the USA commercial fishery that primarily operates out of southern California; a sport fishery based largely in southern California; and the Mexico commercial fishery that is based in Ensenada and Magdalena Bay, Baja California. In the commercial fisheries, Pacific mackerel are landed by the same boats that catch Pacific sardine, anchovy, jack mackerel, and market squid (generally, referred to as the west coast 'wetfish' fleet). There is no directed fishery for mackerel in Oregon or Washington; however, small amounts (100-300 mt annually) are taken (incidentally) by whiting trawlers and salmon trollers. Catches in the Pacific Northwest peaked at 1,800 mt following the major El Niño event of 1997-98.

The history of California's Pacific mackerel fishery has been reviewed by Croker (1933; 1938), Roedel (1952), and Klingbeil (1983). Pacific mackerel supported one of California's major fisheries during the 1930s and 1940s and more recently, particular years in the 1980s and 1990s. During the early years of the fishery, Pacific mackerel were taken by lampara and pole-and-line boats, which were replaced in the 1930s by the same purse seine fleet that fished for sardine. Before 1929, Pacific mackerel were taken incidentally, in relatively small volumes, with sardine and sold as fresh fish (Frey 1971). Canning of Pacific mackerel began in the late 1920s and increased as greater processing capacities and more marketable 'packs' were developed. Landings decreased in the early 1930s due to the economic depression and subsequent decline in demand, but increased significantly by the mid-1930s (66,400 mt in 1935-36). During this period, Pacific mackerel were second only to Pacific sardine in total (annual) landings. Harvests subsequently underwent a long-term decline and for many years, demand for canned mackerel remained steady and exceeded supply. Supply reached record low levels in the early 1970s, at which time the State of California implemented a 'moratorium' on the directed fishery.

Following a period of 'recovery' that spanned from the mid to late 1970s, the moratorium was lifted and subsequently, through the 1990s, the fishery ranked third in volume for finfish landed in California. During this time, the market for canned mackerel fluctuated due to availability and economic conditions. Domestic demand for canned Pacific mackerel eventually waned and the last mackerel cannery in California closed in 1992. At present, most Pacific mackerel is used for human consumption or pet food, with a small, but increasing amount sold as fresh fish.

Pacific mackerel are caught by recreational anglers in southern California, but seldom as a target species (Young 1969). During the 1980s, California's recreational catch averaged 1,500 mt per year, with Pacific mackerel being one of the most important species harvested by the California-
based CPFV fleet. Pacific mackerel are also harvested in California's recreational fishery as bait for directed fishing on larger pelagic species. Additionally, Pacific mackerel are caught by anglers in central California, but typically, only in small amounts. The state-wide sport harvest constitutes a small fraction (less than $5 \%$ in weight) of the total landings.

The Mexico fishery for Pacific mackerel is primarily based in Ensenada and Magdalena Bay, Baja California. The Mexico purse seine fleet has slightly larger vessels, but is similar to southern California's fleet with respect to gear (mesh size) and fishing practices. The fleet operates in the vicinity of ports and also targets other small pelagic species. Demand for Pacific mackerel in Baja California increased after World War II. Mexico landings remained stable for several years, rose to $10,725 \mathrm{mt}$ in 1956-57, then declined to a low of 100 tons in 1973-74. Catches in Mexico remained relatively low through the late 1980s. Landings of Pacific mackerel in Ensenada peaked twice, first in 1991-92 at 34,557 mt, and again in 1998-99, at 42,815 mt. The Ensenada fishery has been comparable in volume to the southern California fishery since 1990. In Baja California, Pacific mackerel are either canned for human consumption or reduced to fish meal.

## Management history

The state of California first applied management measures to Pacific mackerel in 1970, after the stock had collapsed in the mid 1960s. A moratorium was placed on the fishery at this time, with a small allowance for incidental catch in mixed-fish landings. In 1972, legislation was enacted that imposed a landing quota based on the estimate of age- $1+$ ( $\geq 1$-yr old fish) biomass generated from formal assessments. A couple of very strong year classes in the late 1970s triggered a stock recovery (increase in total abundance), which was followed by the fishery being reopened under a quota system in 1977. During the span of the recovery period from 1977 to 1985, various adjustments were made to quotas for directed take of Pacific mackerel and to incidental catch limits, i.e., even during the 'moratorium' substantial allowances were made for incidental catches associated with this species (Parrish and MacCall 1978).

State regulations enacted in 1985 imposed a moratorium on directed fishing when the total biomass was less than $18,200 \mathrm{mt}$, and limited the incidental catch of Pacific mackerel to $18 \%$ during such moratoriums. The fishing year was set to extend from July $1^{\text {st }}$ to June $30^{\text {th }}$ of the following year. Seasonal quotas, equal to $30 \%$ of the total biomass in excess of $18,200 \mathrm{mt}$, had been allowed when the biomass was between 18,200 and 136,000 mt, and there was no quota limitation when the total biomass was $136,000 \mathrm{mt}$ or greater.

A federal fishery management plan (FMP) for coastal pelagic species, including Pacific mackerel, was implemented by the PFMC in January 2000 (PFMC 1998). The FMP's harvest policy for Pacific mackerel, originally implemented by the State of California, is based on simulation analysis conducted during the mid 1980s, with the addition of a proration to account nominally for the portion of the 'stock' assumed to inhabit USA waters, see MacCall et al. (1985) and PFMC (1998). The current maximum sustainable yield (MSY) control rule for Pacific mackerel is:

Harvest $=($ Biomass-Cutoff $) \cdot$ Fraction $\bullet$ Distribution,
where Harvest is the harvest guideline (HG), Cutoff ( $18,200 \mathrm{mt}$ ) is the lowest level of estimated biomass at which harvest is allowed, Fraction (30\%) is the proportion of biomass above the Cutoff that can be harvested by fisheries, and Distribution (70\%) is the average fraction of total Biomass (ages $1+$ ) assumed in USA waters. The HGs under the federal FMP are applied to a July-June fishing 'year.'

California's recreational catch of Pacific mackerel is included within the USA HG, but there are no other restrictions (e.g., size or bag limits) on this fishery. Total annual harvest of Pacific mackerel by the Mexico fishery is not regulated by quotas, but there is a minimum legal size limit of 255 mm . International management agreements between the USA and Mexico regarding transboundary stocks, such as Pacific mackerel, have not been developed to date (see Preface and Research and data needs).

## Management performance

From 1985 to 1991, the biomass exceeded 136,000 mt and no state quota restrictions were in effect. State quotas for 1992-00 fishing years averaged roughly 24,000 mt. From 2001-06, HGs averaged roughly $20,000 \mathrm{mt}$. In 2007, the HG was increased substantially to over $100,000 \mathrm{mt}$ based largely on assumptions regarding variability surrounding estimated recruitment and has remained at an elevated level since then. It is important to note that since the 2001 fishing year, from a management context, the fishery has failed to fully utilize HGs, with average yields since this time of roughly 5,000 mt.

#### Abstract

ASSESSMENT

Ultimately, the final Pacific mackerel stock assessment model presented here reflects two primary changes from recently conducted assessments: (1) a transition from the ASAP model to the SS model was completed; and (2) two survey-related indices of abundance were omitted due to concerns associated with potential sampling biases (applicable to this species strictly), i.e., a spotter survey based on aerial sightings from planes and a California Cooperative Oceanic Fisheries Investigations (CalCOFI) index of daily larval abundance (see STAR 2009). Other changes associated with estimation methods for influential areas of parameterization were also necessary, given the transition to the new modeling platform (SS), e.g., more flexibility examining: the spatial/temporal structure of the baseline model; starting the model; recruitment; fishing mortality; and selectivity/catchability (pertinent changes are documented below). Parameterization details associated with SS model $A A$ are presented below (see Model description). Also, see Responses to past STAR/SSC recommendations below.

A full suite of assessment-related displays for the final SS model $A A$ are presented in the body of this document. Addtionally, for comparative purposes, results from alternative models examined through sensitivity analysis (e.g., SS model $A B$ ) are presented along with model $A A$ for pertinent displays. Program files associated with SS model $A A$ are presented in Appendix 1. Appendix 2A-B is used to present particular displays associated with the initial baseline SS model (S1_aa) and ASAP (2009) model, i.e., objectives one and two (see Preface). Finally, Table 4 (as well as Appendix Table A2B-1) presents a broad range of important parameter-related statistics associated with the key model scenarios reviewed during the recently conducted STAR in May 2009.

## History of modeling approaches

Parrish and MacCall (1978) were the first to provide stock status determinations for Pacific mackerel using an age-structured population model (i.e., traditional virtual population analysis, VPA). The ADEPT model (the ‘ADAPT’ VPA modified for Pacific mackerel; Jacobson 1993 and Jacobson et al. 1994b) was used to evaluate stock status and establish management quotas for approximately 10 years. The assessment conducted in 2004 (for 2004-05 management) represented the final ADEPT-based analysis for this stock (see Hill and Crone 2004a). The forward-simulation model ASAP (Legault and Restrepo 1998) was reviewed and adopted for Pacific mackerel at the 2004 STAR (Hill and Crone 2004b). The ASAP model has been in place for assessments and management advice since the 2005-06 fishing year (e.g., see Dorval et al. 2008). The STAR conducted in 2009 determined that the SS model provided the best (most flexible) platform for assessing the status of Pacific mackerel currently (i.e., the 2009-10 fishing year) and in the future, see Preface and STAR (2009).

## Sources of data

Fishery-dependent data

## Overview

Fishery-related data for assessing Pacific mackerel included landings (California commercial, California recreational, and Mexico commercial), port sample (biological) data from California’s commercial (purse seine) and recreational (CPFV) fisheries, as well as logbook data from the CPFV fleet used to develop a catch-per-unit-effort (CPUE) index. Since 1992, the CDFG has collected biological data on Pacific mackerel landed in the southern California fishery (primarily San Pedro). Samples have also been collected from the Monterey fishery when available. For this assessment, raw sample data were available from 1939 through 2008. Biological samples include whole body weight, fork length, sex, maturity, and otoliths for age determination. Currently, CDFG collects 12 'random' (port) samples per month ( 25 fish per sample) to determine length/age distributions, catch-at-age, weight-at-age, etc. for the directed fishery. Mexico port sampling data have been collected by INP-Ensenada since 1989, but have not been available for purposes of inclusion in this ongoing assessment effort and thus, California commercial data were assumed to be representative of the combined commercial fisheries. Lack of Baja California port sampling data is not a serious problem for some years when Mexico catches were low. However, in recent years, Baja California and California catches have been roughly equal in volume, which necessarily increases the likelihood that potential biases associated with the omission of (and subsequent assumptions concerning) sample data from the Mexico fishery. Sample sizes associated with this data collection program are presented in Table 1.

Pacific mackerel were aged by CDFG biologists, based on identification of annuli in whole sagittae. Historically, a birth date of May $1^{\text {st }}$ was used to assign year class (Fitch 1951). In 1976, ageing protocols changed to a July $1^{\text {st }}$ birth date, which coincided with a rebounding resource, resumed fishery sampling, and a change in the management season from a May $1^{\text {st }}$ opening to a July $1^{\text {st }}$ start date.

Fishery inputs were compiled by 'biological year,' based on the birth dates used to assign age. Therefore, data prior to 1976-77 were aggregated in the biological year of May $1^{\text {st }}$ ( year $_{x}$ ) through April $30^{\text {th }}\left(\right.$ year $\left._{x+1}\right)$, and data from 1976-77 forward were aggregated July $1^{\text {st }}$ (year ${ }_{x}$ ) through June $30^{\text {th }}\left(\right.$ year $\left._{x+1}\right)$. The biological year used in this assessment is synonymous with the 'fishing year' defined previously, as well as with 'fishing season' as reported in the historical literature. That is, the change in birth date assignment from May ${ }^{\text {st }}$ to July $1^{\text {st }}$ coincided with a change in the management season in the mid-1970s, with historical sources of landings and biological data reflecting this change.

Catches
The assessment includes commercial and recreational landings in California and commercial landings in Baja California (Mexico) from 1962 to 2008. Annual (fishing year) landing estimates of Pacific mackerel are presented in Table 2 and Figure 1.

California commercial landings of Pacific mackerel were obtained from a variety of sources based on dealer landing receipts (CDFG) and in some cases, augmented with port sampling for mixed load portions. Data from 1929-61 were obtained from Parrish and MacCall (1978). Monthly landings for the period May 1962 to September 1976 were obtained from CDFG fish bulletins recovered to an electronic data base format (PFEL 2005). Raw landing receipt data for Pacific mackerel from 1976 to 1991 were of marginal quality, owing to the large quantities of Pacific mackerel landed as mixed loads with jack mackerel. During this period, many processors reported either species as 'unspecified' mackerel on landing receipts. For these years, mackerel landings receipts were augmented with shoreside 'bucket' sampling of mixed loads to estimate species compositions. The CDFG reported these data in two forms: (1) annual stock status reports to the California legislature; and (2) single page ‘CDFG Wetfish Tables.' Both sources are considered more accurate than PacFIN or other landing receipt-based statistics for this period. Data sources from late 1976 to the present are as follows: October-December 1976 are from Klingbeil and Wolf (1986); January-December 1977 are from Wolf and Worcester (1988); January 1978-December 1981 are from Jacobson et al. (1994a); January 1982-February 2009 are from CDFG Wetfish Tables; and finally, landing estimates for March-June 2009 and July 2009June 2010 were assumed to be similar to the analogous time blocks of the previous year, namely, March-June 2008 and July 2008-June 2009, respectively. Pacific mackerel landings from 197681 were only reported by quarterly increments and thus, for purposes of weighting catch-at-age estimates for this period (see Catch-at-age below), we apportioned quarters to months using monthly ‘unspecified mackerel' landings from the PFEL LAS database (PFEL 2005).

California recreational landings (mt) from 1980 to the present (2-month 'wave' resolution) were obtained directly from Pacific RecFIN estimates. Historical estimates (pre-1980) of total recreational catch were derived from CPFV logbook data collected since 1936 (Hill and Schneider 1999). The CPFV catch (number) was converted to metric tons using an assumed average weight of $0.453 \mathrm{~kg}(1 \mathrm{lb})$ per individual, based on RecFIN samples and consistent with Parrish and MacCall (1978). The CPFV harvest was expanded to total recreational tonnage using wave-specific ratios from RecFIN. Nominal amounts of recreational removals were assumed for 1929-35 and 1941-46 when no recreational statistics were available.

Baja California data include landings from commercial purse seine fisheries in Ensenada, Cedros Island, and Magdalena Bay. Ensenada landings were compiled as follows: 1946-47 through 1969-70 (May-April) data are from Parrish and MacCall (1978); 1970-71 through 1975-76 (May-April) data are from Schaefer (1980); quarterly data from July 1976 through December 1986 are from Jacobson et al. (1994b); monthly data from January 1987 through November 2003 were provided by INP-Ensenada (Garcia and Sánchez, 2003; Celia Eva-Cotero, INP-Ensenada, personal communication, INP-Ensenada staff); monthly landings from December 2003 through December 2004 were not available and thus, were substituted with corresponding months from the previous year. Ensenada landings in 2005, available from Cota et al. (2006), were apportioned into monthly catch using ratios from the previous few years. Ensenada landings for January to June 2006 were taken from Cota et al. (2006). Monthly landing data for the Cedros Island (January 1981-December 1994) and Magdalena Bay (January 1981 - May 2003) fisheries were provided by R. Felix-Uraga (CICIMAR-IPN, La Paz, personal communication). The fishery off Cedros Island ceased in 1994. Magdalena Bay landings for June 2003 through June 2007 were substituted with corresponding months from the previous year. Monthly-resolution catch statistics for Mexico were not available for all seasons and thus, for purposes of weighting catch-at-age estimates (see Catch-at-age section), aggregate catch data (season or quarter) were apportioned to months by inflating the corresponding California data.

Small volumes ( 100 to 300 mt per year) of Pacific mackerel are taken incidentally in other fisheries (e.g., whiting, salmon troll, and Pacific sardine) off Oregon and Washington.
Biological samples collected from these fisheries (Hill 1999) indicated fish from these waters are typically larger and older than the directed fishery off California and thus, these limited samples have not be included in the current assessment model presented here.

## Length distributions

The SS model scenarios included length distributions for the USA recreational (CPFV) fishery only, i.e., utilizing age-based selectivity. In general, age-based selectivity was used in SS model scenarios, including: age distribution time series from the fishery, as well as mean length-at-age time series (see Age distributions and Mean length-at-age distributions below); and length distribution time series (no age data available) from the recreational fishery. Length distributions for the recreational fishery (CPFV fishing mode only) were developed from the Pacific RecFIN data base using angler examined catch data from 1992 to 2008 (Figure 2).

Length distributions were developed using 1-cm length (fork) bins, with the smallest bin equal to 1 cm and the largest equal to 60 cm . The $60-\mathrm{cm}$ bin includes fish that were greater than or equal to 60 cm . The total number of lengths (say specimens measured for length) observed in each distribution (of each time step) was divided by 25 (the average number of fish collected per sample) and subsequently, used as the effective sample size in baseline model configurations. Ultimately, length distributions (in numbers of fish) were converted to proportion estimates for all modeling efforts.

Age distributions
Age distribution time series were developed from the same (CDFG) port sample data base described previously, i.e., the sampling program entails recording length, sex, age (via otolith collections), etc. from each fish in the 25 -fish sample taken from a completed fishing trip. It is
important to note that age (and length) distributions developed from this sampling program are considered to be representative of the landings associated with the (commercial) fishery and thus, serve as the foundation for evaluating cohort dynamics in the fully-integrated models. Ultimately, age distributions (in proportion-at-age) were based on 9 age bins that represented age- 0 to age- $8+$, i.e., a 'plus group' that includes $\geq 8-\mathrm{yr}$ old fish. The total number of ages (say specimens measured for age) observed in each distribution was divided by 25 (the average number of fish collected per sample) and subsequently, used as the effective sample size in baseline model configurations. Ultimately, age distributions (in numbers of fish) were converted to proportion estimates for all modeling efforts. In sensitivity analysis, biological distributions were based on both annual and quarter time-steps, depending on the model scenario, with the final SS model $A A$ being annual-based. Annual age distributions (1962-08) associated with all models are presented in Figure 3. Mean age (annual) statistics are presented in Figure 4.

## Mean length-at-age distributions

For the primary purpose of evaluating growth dynamics associated with this species, mean length-at-age time series (1962-08) were developed from the same (CDFG) port sample data base described above and used in conjunction with age distributions in SS model scenarios (Figure 5). Effective sample size estimates were obtained using the same 25 -fish adjustment employed for the other biological distributions, based on typically sample sizes from a completed fishing trip.

## Ageing error distribution

In efforts to provide the most realistic measure of uncertainty associated with estimated age distribution time series, an ageing error vector, based on standard 'double-read’ methods, was also included in all model scenarios, i.e., a SD vector by age was used in all SS model scenarios (Figure 6). It is important to note that further ageing error analysis pertaining to this species is warranted, given the current vector is considered preliminary at this time.

## Commercial passenger fishing vessel (CPFV) index of abundance

California Fish and Game legislation has required CPFV captains to provide records of catch and effort data to CDFG since 1936. In the past, Pacific mackerel have been among the top five species reported on CPFV logs, both in southern California and state-wide. This information resides in a logbook data base (Hill and Barnes 1998; Hill and Schneider 1999) that summarizes CPFV catch and effort by month and Fish and Game statistical blocks ( $10 \mathrm{~nm}^{2}$ ). A single statewide index of relative abundance was developed, based on a Delta-Generalized Linear Model (delta-GLM) approach for estimating year effects, i.e., a CPUE time series of relative abundance (Figure 7). The index is based on a fishing year basis, as is the case with other time series used in the models. Selectivity parameterization associated with this index mirrored the recreational fishery (i.e., age-based selectivity based on length distribution time series).

To account for potential changes in catchability associated with the CPFV fleet over time, a delta-GLM model was used to 'standardize' the data and separate effects from critical factors (e.g., spatial-temporal). That is, by incorporating year as a factor, the delta-GLM generates estimates of annual standardized catch rate and its variance that can be generally interpreted as a relative index of abundance of the population. Ultimately, the index of abundance is based on two GLMs: the first GLM estimates the probability of a positive observation, based on a
binomial likelihood and logit link function; and the second GLM estimates the mean response for the positive observations, assuming a gamma error distribution. The final index is the product of the back-transformed year effects from the two GLMs. Technical details concerning the deltaGLM analysis follow:
(1) data were combined within year/quarter/fleet strata (i.e., the overall, statewide fishery was partitioned into a northern and southern 'fleet' based on latitude/longitude spatial fishing ‘blocks’);
(2) CPUE was calculated (number of fish/1,000 angler-hours fishing) for each spatial/temporal stratum;
(3) fishing years 1935-36 to 2008-09 were used in the analysis, with the exception of a few years that were omitted due to missing data (e.g., 1941-42 to 1945-46);
(4) latitude/longitude blocks were combined into broader spatial areas based on the fishing practices of the northern and southern CPFV fleets, i.e., historically, the southern fleet has exerted the vast amount of fishing pressure associated with this overall fishery (Pt. Conception was used as the 'north/south' delimiter to partition the two regional fleets);
(5) the delta-GLM method models the probability of obtaining a zero catch and the catch rate separately, given the catch rate is non-zero (Stefansson 1996; Maunder and Punt 2004). In this assessment, we estimate the probability of a positive observation using a binomial distribution and a logit link function. Then, the mean response for positive observations was estimated assuming a gamma distribution for the error term. The basic model for positive observations included the log of mean catch rate $(\mu)$ as a function of three main effects (fishing year $i$, quarter $j$, and fleet $k$ ),

$$
\log _{e}\left(\mu_{i j k}\right)=U_{R}+Y_{i}+Q_{j}+F_{k}+\mathcal{E}_{i j k},
$$

where $\mu_{i j k}$ is the mean catch rate (number of fish/1,000 angler-hours) in year $i$, quarter $j$, and fleet $k$. The fishing year effect is denoted by $Y_{i}(i=1,2, \ldots, I ; I=67$ fishing years). The quarter of the year effect is denoted by $Q_{j}(j=1,2, \ldots, J ; J=4$ quarters). The fleet effect is denoted as $F_{k}(k=1, \ldots, K ; K=2$ fleets). The error term is denoted $\varepsilon_{i j k}$, where for each combination of indices, $\varepsilon_{i j k}$ is iid and gamma distributed. Finally, the reference cell is denoted as $U R$ ( $R=1$ reference cell, i.e., year=2004, quarter=4, and fleet=south);
(6) no temporal/spatial interactions (e.g., year and fleet or quarter and fleet) were included in the final delta-GLM model, given such interactions had little effect on increasing the amount of variability in mean catch rate as a function of the suite of explanatory variables (i.e., minor improvement of $R^{2}$ statistic, see Hill and Crone 2005, Crone et al. 2006); and
(7) a delta-GLM function written in the statistical programming language R (personal communication, E. J. Dick, NOAA Fisheries, SWFSC, Santa Cruz, CA) was used to estimate a mean catch rate from the CPFV data set. A major feature of this function is that it estimates coefficients of variation (CV) for the relative index of abundance using a jackknife (leave-one-out) method. However, because the CPFV data were very extensive (over 80,000 observations), estimation of both year effects for the survey simultaneously with measures of dispersion (i.e., CVs) was problematic. In the current assessment, a year effect is first estimated using all available data and
subsequently, straightforward bootstrap re-sampling methods were employed for purposes of estimating variance (CV) estimates associated with the year effect estimates. Ultimately, the CVs were based on 200 bootstrap samples (with replacement), taken in each fishing year from 1935-36 to 2007-08.

## Biological data

## Weight-length

A weight-length (W-L) relationship for Pacific mackerel was modeled using port sample data collected by CDFG from 1962 to 2008 (see Fishery-dependent data above). A straightforward power function was used to determine the relationship between weight (kg) and fork length (cm) for both sexes combined:

$$
W_{L}=a\left(L^{b}\right),
$$

where $W_{L}$ is weight-at-length $L$, and $a$ and $b$ are the estimated regression coefficients. Weightlength parameters based on data from 1962-08 ( $a=3.1 \mathrm{E}-06$ and $b=3.4$ ) were used (fixed) in all model scenarios (Figure 8A). Also, time-varying weight-length relationships were evaluated in sensitivity analysis; however, little change in W-L has been observed over time (Appendix Figure A2B-6).

## Length-at-age

The von Bertalanffy growth equation was used to model the relationship between fork length (cm) and age for Pacific mackerel (1962-08):

$$
L_{A}=L_{\infty}\left(1-e^{-k(A-t o)}\right),
$$

where $L_{A}$ is the length-at-age $A, L_{\infty}$ ('L-infinity') is the theoretical maximum length of the fish, $k$ is the growth coefficient, and $t_{o}$ ('t-zero') is the theoretical age at which a fish would have been zero length. Length-at-age was estimated internally in all SS model scenarios, generally based on the following baseline growth equation for this population calculated from the CDFG data base (1962-08): $L_{\infty}=39.3 \mathrm{~mm}, k=0.342$, and $t_{o}=-1.752$ (Figure 8B). Of particular note is the rapid growth exhibited by this species, i.e., past research (Parrish and MacCall 1978; Mallicoate and Parrish 1981), as well as analysis conducted here on recent biological sample data, indicates fish, on average, realize over 50\% of their total growth (in length) in the first year of life and subsequently, grow a few cm per year until death at roughly 40 cm (approximately, age 7-8). Sensitivity analysis resulted in relatively robust estimates of $K$ (von Bertalanffy growth equation) that ranged from roughly 0.2 to $0.4(k=0.22$ for SS model $A A$ ).

## Maximum size and age

The largest recorded Pacific mackerel was 63.0 cm in length (FL) and weighed 2.9 kg (Roedel 1938; Hart 1973), but the largest Pacific mackerel taken by commercial fishing (CA) was 47.8 cm FL and 1.72 kg . The oldest recorded age for a Pacific mackerel was 14 years, but most commercially caught Pacific mackerel are less than 4 years old, with few living beyond age 8 and larger than 45 cm .

Maturity-at-age
The estimated maturity schedule (ogive) used in the past for this stock was assumed in all model scenarios here (Table 3 and Figure 8C). That is, normalized net fecundity-at-age (the product of fraction mature, spawning frequency, and batch fecundity) was used to interpret CalCOFI ichthyoplankton data and ultimately, generate estimates of SSB. Fraction mature was estimated by fitting a logistic regression model to age and fraction mature data from Dickerson et al. (1992). Spawning frequency was estimated by fitting a straight line to age and spawning frequency data from the same study. Following Dickerson et al. (1992), batch fecundity per gram of female body weight was assumed constant.

Natural mortality
Natural mortality rate ( $M$ ) was assumed to be $0.5 \mathrm{yr}^{-1}$ for all ages and both sexes, and used in all modeling efforts presented here (Figure 8C). Parrish and MacCall (1978) estimated natural mortality for Pacific mackerel using early catch curves ( $M=0.3-0.5$ ), regression of $Z$ on $f(M=$ 0.5 ), and comparative studies of maximum age ( $M=0.3-0.7$; Beverton 1963) and growth rate ( $M$ $=0.4-0.6$; Beverton and Holt 1959). The above authors considered the regression of $Z$ on $f$ to be the most reliable method, with the estimate $M=0.5$ falling within the range of the plausible estimates, i.e., an instantaneous $M=0.5$ can be practically interpreted as an annual rate of roughly $40 \%$ of the stock dying each year due to 'natural causes.' Finally, a range of Ms was examined formally through sensitivity analysis on the initial baseline SS model reviewed early in the STAR (see Appendix Figure A2B-40 for estimated B time series from this profile).

## Stock-recruitment

A Beverton-Holt (B-H) stock-recruitment $(S / R)$ relationship was assumed for this population for all models scenarios, i.e., as observed in the historical literature, as well as from modeling efforts here, recruitment is highly variable and not likely related closely to absolute levels of SSB biomass (SSB). However, it is important to note that steepness ( $h$ ) ranged from roughly 0.3 to $0.5(h=0.47$ for SS model $A A)$, depending on the model scenario, indicating that at low SSB levels, recruitment is estimated to decrease slightly to moderately (Figure 9). Parrish (1974) and Parrish and MacCall (1978) discussed general life history strategies for this population that are tightly linked to oceanographic conditions and further, that periods of strong year classes (cohorts) are likely produced only when SSB is high (or moderately so) and more importantly, not likely to occur more than once or twice every 60 years.

## Responses to past STAR/SSC recommendations

The three overriding recommendations from past reviews focused on data availability from Mexico, omission/inclusion of available indices of relative abundance used in this ongoing assessment, and development of a robust alternative (SS) model that can be used for formal management advice. See STAR (2009) for further discussion regarding these issues.

Regarding relations with Mexico and issues surrounding future data exchange and professional collaboration on research projects ... SWFSC staff continue to engage in such discussions, meetings, conferences, etc. with academic colleagues and federal researchers from Mexico, e.g., updated landing information and additional, albeit preliminary, larval survey data have been made available recently.

Regarding indices of relative abundance used in the current assessment ... both the spotter and CalCOFI survey indices were omitted from final baseline model scenarios for the current fishing year (2009-10), as well as in future assessment models. The remaining CPFV index, as well as related recreational fishery data, have now increased in importance in overall modeling efforts and subsequently, will need increased research support, as well as monitoring (see Research and Data Needs below).

Regarding transitioning to the SS model for providing management advice ... the SS model was identified as the best modeling platform for assessing the status of the Pacific mackerel stock currently and in the future.

## Model description

Overview
The Stock Synthesis (SS, Methot 2005, 2009) model is founded on the AD Model Builder software environment, which essentially is a C++ library of automatic differentiation code for nonlinear statistical optimization (Otter Research 2001). The model framework allows full integration of both population size and age structure, with explicit parameterization both spatially and temporally. The model incorporates all relevant sources of variability and estimates goodness of fit in terms of the original data, allowing for final estimates of precision that accurately reflect uncertainty associated with the sources of data used as input in the overall modeling effort.

The SS model comprises three sub-models: (1) a population dynamics sub-model, where abundance, mortality, and growth patterns are incorporated to create a synthetic representation of the true population; (2) an observation sub-model that defines various processes and filters to derive expected values for different types of data; and (3) a statistical sub-model that quantifies the difference between observed data and their expected values and implements algorithms to search for the set of parameters that maximizes goodness of fit. This modeling platform is also very flexible in terms of estimation of management quantities typically involved in forecast analysis. Finally, from an international context, the SS model is rapidly gaining popularity, with SS-based stock assessments being conducted on numerous marine species throughout the world. The SS model used in this assessment was the most recently distributed version, namely, version 3.0.12 (January 2009).

Likelihood components and model parameters
Likelihood components and estimates for important SS model scenarios are presented in Table 4 (and Appendix Table A2B-1), including, fits to catch, age/length distributions, and indices, as well as parameter estimates for initial conditions (age distribution, recruitment, and fishing mortality), growth, recruitment, stock-recruitment relationship, etc.

## Convergence criteria

The convergence criterion for maximum gradient determination was set to 0.0001 in the SS model. Fidelity of model convergence was explored by changing particular 'starting' values for multiple parameters and evaluating the converged 'minimum’ values, i.e., evaluating ‘global’ vs. 'local' convergence properties of the overall, multi-dimensional numerical estimation.

Model selection and evaluation
We strongly adhered to model development (say parameterization involved in the various scenarios) that was based on the following: supports general consensus regarding this species’ life history; results in no noticeable inconsistencies (across likelihood components) within the fully-integrated model scenario; addresses uncertainty in a sound, robust, and parsimonious manner; and finally, produces realistic (meaningful) results that can be directly assimilated into ongoing management efforts. Markov chain Monte Carlo (MCMC) methods were conducted on the initial baseline SS Model (S1_aa), whereby the Markov chain achieved a stationary (equilibrium) distribution, with no significant statistical violations observed across the estimated parameters, inclusive; however, due to time constraints, such diagnostics have not been conducted on the final SS model $A A$ to date. The following outline summarizes model selection/evaluation development for the Pacific mackerel stock assessment conducted in 2009:

- developed the baseline (management) ASAP model (2009) ... input data (i.e., time series updated with additional year) and parameterization similar to previous model used in the final assessment conducted in 2008 (see Appendix A2A);
- developed a baseline (alternative) SS model (S1_aa) ... input data and parameterization similar to ASAP model (2009) above, i.e., a robust model that most closely resembled the ASAP model (see Appendix A2B);
- developed (two) suites of SS model scenarios via sensistivity analysis ... one prior to the STAR and presented at the start of the review meeting (see Appendix Table A2B-1) and another during the review meeting (see Table 4); and
- developed a preferred SS model $A A$ from the suites of alternative scenarios ... this model scenario (along with SS model $A B$ ) provides the basis for the final assessment conclusions.

Key features of SS model $A A$ follow, with comparative discussion regarding SS model $A B$ presented where applicable, as well as identification of influential areas of parameterization that will likely be addressed further in future model development:

- Time period: 1962-08.

Sensitivity analysis included starting the model later (late 1970s), but had little effect on overall results; however, it is likely that this area of parameterization in future models will need further evaluation.

- Fishery structure: two (USA/Mexico commercial and USA recreational).
- Surveys: One (CPFV index of relative abundance).

Following much discussion and review of model scenarios, it was determined that both the spotter and CalCOFI indices be omitted from the current assessment analysis, given concerns regarding potential sampling biases associated with these indices at particular time periods, due to both the dynamics of the fish/fishery and implemented sampling designs (see STAR 2009).

- Time-step: annual.

Sensitivity analysis included many scenarios based on a quarter time-step, with most of these configurations producing results generally similar to analogous (annual) time-step model scenarios.

- Gender structure: combined sexes.
- Growth: estimated and constant over time.

As presented in previous literature that addressed growth dynamics associated with this stock (Parrish and MacCall 1978), there is little evidence in support of growth changes over time (i.e., in terms of length-at-age). Further, sensitivity analysis resulted in robust estimates of $K$ (von Bertalanffy growth equation) that ranged from approximately 0.2-0.4 ( $k=0.22$ for SS model AA). Additionally, sensitivity analysis that considered timevarying changes for growth in weight (i.e., in terms of weight-length/age), which in the vast majority of animal populations is the more 'plastic' growth attribute, revealed no indication that this growth parameter has changed markedly over the last 50 years (Appendix Figure A2B-6). Finally, additional mean size (length)-at-age time series allowed for detailed growth parameterization in all model scenarios. In this context, a model scenario was developed to address this issue (see below).

- Selectivity (catch): Age-based and time-varying (three time blocks).

Selectivity issues regarding age- or size-based approaches were given much attention, based on relations to the actual operation of the fisheries and dynamics of the stock. That is, we feel that the distribution exhibited by this species on any given year and subsequently, its probability of capture (selectivity) is more influenced by 'time’ (say age) than by size (say length); this is true for all age groups, from the variability observed in the presence/absence of 0-1 yr-old fish to the adults in the estimated age distributions modeled here. Recognizing that in reality, both attributes are likely influential to some degree, it is more likely that movement (and capture) are driven by age, i.e., versus gear (mesh) constraints that also generally influence vulnerability. Given the biological sampling design in place provides 'random' samples of fish (for purposes of length, age, etc.) from completed boat trips, selectivity parameterization based on representative age distributions of the catch becomes the logical approach. Although the biological distributions from the recreational fishery were in terms of size (length, given no age data available), age-based selectivity was implemented for this fishery as well. Finally, preliminary modeling efforts indicated age- or size-based selectivity resulted in similar conclusions of stock status.
o SS model $A B$ included an additional time block (2000-08) for both the commercial and recreational fisheries, based on visual evaluations of changes in age/length distributions over time.
o As with the modeled time period above, time-varying selectivity will likely be an important area of examination as the Pacific mackerel assessment model continues development in the future.

- Selectivity (index): age-based (i.e., mirrors recreational fishery) and constant.
o SS model $A B$ included the CPFV index split into two indices (one that spanned 196299 and another for 2000-08) in efforts to keep both time-varying selectivity and catchability in line with one another.
o As with the modeled time period and catch-related selectivity above, parameterization of time-varying catchability will necessarily be another important area of examination in future model development for this species.
- Stock-recruitment: Beverton-Holt stock-recruitment model.

An asymptotic relationship between parents and offspring was assumed in all model scenarios. Estimated steepness ( $h$ ) from sensitivity analysis ranged from roughly 0.3 to 0.5 ( $h=0.47$ for SS model AA). See Stock-recruitment above.
$0 \sigma_{R}=1.0$.
In recent previously conducted assessments, $\sigma_{R}=0.7$. Increasing the variability surrounding recruitment estimation was supported in most model scenarios, with internal model estimates of root mean square errors associated with estimated recruitment ranging from roughly 0.9 to 1.3 .

- Variance adjustments to time series: variance adjustments were used following diagnostic evaluations of input vs. effective sample size results from final model runs. That is, adjustments reflected doubled input sample sizes for the recreational length distributions only, i.e., in effect, reweighted effective sample sizes reflected total number of fish divided by 12.5 (vs. 25 as used for initial (baseline) sample sizes, see Length distributions above). Also, in some model scenarios, age distributions (commercial fishery) were 'down-weighted' (0.25) accordingly; however, model convergence (with no penalties) was problematic.
o As with the modeled time period and selectivity/catchability above, variance adjustments to both biological distributions via sample size allocations and index of relative abundance via assumed error (CVs) associated with the CPFV index will necessarily warrant further consideration, given the influence such parameterization has on fully-integrated stock assessment models in general.

## Sensitivity analysis

Alternative SS model scenarios are briefly summarized below, i.e., see Table 4. That is, many model scenarios were presented and reviewed at the start of the STAR, particularly; configurations based on a quarter time-step (see Appendix Table A2B-1 and Figure A2B-41). The following model scenarios represent key configurations developed during the STAR, which collectively, served to further the development of the final (consensus) SS model $A A$ (and alternative SS model $A B$ ), see Model description above.

SS model H2: Similar to SS model $A A$, but no variance adjustment (effective sample sizes) to recreational length distribution time series.
SS model $N$ : Similar to SS model $A A$, but $\sigma-R=0.7$ (i.e., more precise) and no variance adjustment (effective sample sizes) to recreational length distribution time series.
SS model Q: Similar to SS model $A A$, but $\sigma-R=0.7$ (i.e., more precise), fish greater than 55 cm in recreational length distribution were omitted, and no variance adjustment (effective sample sizes) to recreational length distribution time series.
SS model $U$ : Similar to SS model $A B$, but no variance adjustment (effective sample sizes) to recreational length distribution time series.
SS model P: Similar to SS model $A B$, but CalCOFI ('super years') index was included, $\sigma$ $R=0.7$ (i.e., more precise), and no variance adjustment (effective sample sizes) to recreational length distribution time series.

## Assessment model results (SS model AA)

Model fits to biological distributions are presented in the following displays: Figure 10A is observed vs. predicted estimates for the age distribution time series for the commercial fishery; Figure 10B is the associated Pearson residual plot for the age distribution fits; Figure 10C is the associated input vs. effective sample size plot for the age distribution fits; Figure 11A is observed vs. predicted estimates for the length distribution time series for the recreational fishery; Figure 11B is the associated Pearson residual plot for the length distribution fits; Figure 11 C is the associated input vs. effective sample size plot for the length distribution fits; Figure 4 is the observed vs. predicted estimates for the mean length-at-age distribution time series for the commercial fishery; and Figure 12 is the associated Pearson residual plot for the mean length-atage distribution fits. Estimated selectivity for the fishery catches is presented in Figure 13A (commercial fishery - three time blocks) and Figure 13B (recreational fishery - single time block).

In general, fits to biological distributions were relatively good; however, in some years, large 'pulses’ of younger fish were not fit with high precision, i.e., 0-1 yr-old fish in the commercial fishery age distributions. Also, the rapid decline of older animals in many years may be due to non-constant natural mortality (say by sex) or potentially, due to selectivity changes over time (see Model selection and evaluation above).

Fits (normal and log space) to the CPFV index of relative abundance are presented in Figure 14A-B. In general, model fits to the CPFV index were very good and further, in all model runs (inclusive), this index was fit much more precisely than either of the other indices (i.e., spotter and CalCOFI indices) that were eventually omitted in final model scenarios. Selectivity for the CPFV index mirrored that estimated for the recreational fishery (Figure 13B).

Estimated Beverton-Holt stock-recruitment relationship is presented in Figure 9 (see Stockrecruitment above). Estimates of Pacific mackerel recruitment deviations and asymptotic standard errors for the deviations are presented in Figure 15A-B.

Harvest rate estimates are presented in Figure 16. As expected, harvest rates have varied substantially over time, with exploitation declining markedly since roughly 2000 to historically low levels.

Estimated time series for management-related derived quantities of interest are presented in the following displays: Figure 17 is total stock biomass (age 1+ fish in mt, $B$ ) for both the final SS model $A A$ and alternative model $A B$; Figure 18 is spawning stock biomass (SSB in mt); and Figure 19 is recruitment (age-0 fish in numbers). Estimated $B$ (and $S S B$ ) remained low from the early 1960s to the mid 1970s, at which time the population began to rapidly increase in size, reaching a peak in the early 1980s. From the mid 1980s to early 2000s, the stock declined steadily, with some signs of 'rebuilding' (on an increasing limb of a historical distribution say) observed recently. However, as noted previously, recent estimates of stock size are necessarily related to assumptions regarding the dynamics of the fish (biology) and fishery (operations) over the last several years, which generally confounds long-term (abundance) forecasts for this species (e.g., SS model $A A$ and model $A B$ are generally similar historically, but diverge in the
mid 2000s, based on different assumptions surrounding both selectivity and catchability (see Model selection and evaluation above).

Results from a retrospective analysis are presented in Figure 20, i.e., data associated with terminal years 2008 to 2004 were omitted (sequentially) from the model. As observed in all past assessments, a retrospective pattern exists with this assessment model as well (albeit only moderate in severity), i.e., a tendency to overestimate stock abundance ( $B$ ) in any current year, with future assessments based on additional data producing estimates lower in magnitude. However, given this model (SS model $A A$ ) is structured substantially different from past models used for the ongoing stock assessment, the usefulness of a retrospective evaluation at this time should be interpreted accordingly.

Finally, for comparative purposes, final estimated B time series for the historical assessment period (1994-09) are presented in Figure 21. It is important to note that in 2007, estimated $B$ scaled upwards substantially, based largely on assumptions regarding variability surrounding estimated recruitment, i.e., since 2005, $\sigma-R$ has increased from 0.25 to 0.7 to the current level of assumed variability of 1.0 , which is more in line with internal estimation of recruitment uncertainty associated with assessment models developed recently for this species (also, see Harvest Control Rule for USA Management in 2009-10 below).

## Assessment model uncertainty

Generally speaking, uncertainty in the overall assessment is evaluated using some combination of the following: the confidence intervals associated with estimated parameters of interest (e.g., time series of SSB and recruitment); sensitivity analysis (i.e., developing alternative model scenarios); examinations (qualitative and quantitative) of important residual plots from critical model fits (e.g., fits to biological distributions and index); and more rigorous multi-dimensional diagnostics via MCMC methods (see Model selection and evaluation above). All of the above were addressed in the assessment conducted here. Finally, it is important to note that model estimates of absolute stock size are likely more uncertain than presented here, given the final estimates are necessarily based on some combination of the following: strict probability samples in the field cannot be obtained; subjective assumptions used to develop model scenarios; potential weighting issues with particular data sources; and unaccounted for variability associated with related sources of data and parameters in the fully-integrated, multiple likelihood modeling platform.

Specificially, in addition to lacking ongoing data exchange with Mexico regarding catch, biology, and survey information associated with this species, a primary area of uncertainty in the overall assessment is assumptions and associated parameterization surrounding both selectivity for the fisheries, as well as catchability for the CPFV index of relative abundance. That is, the degree to which changes have occurred across time in terms of 'probability of capture' associated with the commercial and recreational fisheries has not been definitively evaluated at this time, but rather, will need further examination as the Pacific mackerel assessment progresses in the future. However, in the interim, it is important to note that fishing pressure on this stock has been very low for the last several years and coupled with this species’ biology, likely indicates the stock is not highly vulnerable to overfishing presently, but rather, should be
monitored closely in terms of both magnitude of landings in coming years, as well as evaluated through ongoing (improved) assessment efforts. See Research and Data Needs below.

## HARVEST CONTROL RULE FOR USA MANAGEMENT IN 2009-10

As stipulated in Amendment 8 to the CPS FMP (PFMC 1998), the recommended maximum sustainable yield (MSY) control rule for Pacific mackerel is:

$$
\text { Harvest }=(\text { Biomass-Cutoff }) \cdot \text { Fraction } \bullet \text { Distribution, }
$$

where Harvest is the harvest guideline (HG), Biomass is the estimated total stock biomass (age $1+$ ) in $2009(282,049 \mathrm{mt})$, Cutoff ( $18,200 \mathrm{mt}$ ) is the lowest level of estimated biomass at which harvest is allowed, Fraction (30\%) is the proportion of biomass above the Cutoff that can be harvested by fisheries, and Distribution (70\%) is the average fraction of total biomass assumed in USA waters (PFMC 1998). The HGs under the federal FMP are applied to a July-June fishing 'year.' Landings and associated HGs since 1992 are presented in Figure 22A.

The HG for the 2009-10 fishing year is $55,408 \mathrm{mt}$ :

| $\boldsymbol{B}$ (Age 1+, mt) | Cutoff (mt) | Fraction | Distribution | HG (mt) |
| :---: | :---: | :---: | :---: | :---: |
| 282,049 | 18,200 | $30 \%$ | $70 \%$ | $55, \mathbf{4 0 8}$ |

From 1985 to 1991, the biomass exceeded 136,000 mt and no state quota restrictions were in effect. State quotas for 1992-00 fishing years averaged roughly $24,000 \mathrm{mt}$. From 2001-06, HGs averaged roughly $20,000 \mathrm{mt}$. In 2007, the HG was increased substantially to over $100,000 \mathrm{mt}$ based largely on assumptions regarding variability surrounding estimated recruitment and has remained at an elevated level since then (Figure 22A). It is important to note that since the 2001 fishing year, from a management context, the fishery has failed to fully utilize HGs, with average yields since this time of roughly $5,000 \mathrm{mt}$. Finally, 'hypothetical' quotas and total landings, based on omission of the USA 'Distribution' parameter in the harvest control rule are presented in Figure 22B.

## RESEARCH AND DATA NEEDS

First and foremost, given the transboundary status of this fish population, it is imperative that efforts continue in terms of encouraging collaborative research and data exchange between NOAA Fisheries (Southwest Fisheries Science Center) and researchers from both Canada’s and in particular, Mexico's academic and federal fishery bodies, i.e., such cooperation is critical to providing a synoptic assessment that considers available sample data across the entire range of this species in any given year.

Second, fishery-independent survey data for measuring (relative) changes in mackerel spawning (or total) biomass are currently lacking. Further, at this time, a single index of relative abundance is used in the assessment, which is developed from a marine recreational fishery
(CPFV fleet) that typically does not (directly) target the species. In this context, it is imperative that future research funds be focused on improvement of the current CPFV survey, with emphasis on a long-term horizon, which will necessarily rely on cooperative efforts between the industry, research, and management bodies. Additionally, we strongly support development of a well-designed logbook monitoring program associated with the current commercial (purse-seine) fishery, which has been long overdue.

Third, given the importance of age (and length) distribution time series to developing a sound understanding of this species' population dynamics, it is critical that data collection programs at the federal and particularly, the state-level continue to be supported adequately. In particular, CDFG/NOAA funding should be bolstered to ensure ongoing ageing-related laboratory work is not interrupted, as well as providing necessary funds for related biological research that is long overdue. For example, maturity-related time series currently relied upon in the assessment model are based on data collected over twenty years ago during a period of high spawning biomass that does not reflect current levels. Also, further work is needed to obtain more timely error estimates from production ageing efforts in the laboratory, i.e., accurate interpretation of age-distribution data used in the ongoing assessment necessarily requires a reliable ageing error time series. Finally, examinations of sex-specific age distributions will allow hypotheses regarding natural mortality/selectivity (i.e., absence of older animals in sex-combined age distributions) to be more fully evaluated.

Finally, the MSY control rule utilized in the Pacific mackerel federal CPS-FMP was developed in the mid-1980s using the historical time series of abundance. The harvest control rule should be re-examined using new data and simulation methods. Given substantial amounts of additional sample data have accumulated since the initial research that was undertaken to formally establish this harvest strategy, it would be prudent to conduct further simulation modeling work to address particular parameters included in the overall control rule (including 'cutoff,' 'fraction,' and ‘distribution’ values).

## ACKNOWLEDGEMENTS

Thanks to all individuals involved in the data collection- and laboratory-related programs surrounding this species, inclusive ... in particular, those individuals from the California Department of Fish and Game-this information is critical to obtaining an accurate assessment of the status of an exploited fish population, period. Additionally, the industry and CPSMT have provided a concerted forum for communicating the critical need for better sample data for inclusion in assessment modeling efforts. Also, the STAR panel generated important discourse and subsequent recommendations that improved upon the ongoing stock assessment, including, Alec (MacCall), Owen (Hamel), Ken (Burnham), Gary (Melvin), and in particular, Andre (Punt) who provided good guidance at pivotal times in the overall review.

Regarding the overall analysis, thanks are extended to Kevin (Piner), Alex (Aires-da-Silva), HuiHua (Lee), Rick (Methot), Ian (Taylor), Ian (Stewart), the STAR panel, and in particular, Mark (Maunder), who provided invaluable insight in terms of both theoretical concepts underlying animal population dynamics in general, as well as explicit model-related advice regarding a parameterization or two ... the support's appreciated-big time.

${ }^{a}$ Further parameterization details regarding model scenarios presented here can be found in STAR (2009).
${ }^{\mathrm{b}}$ CPFV survey included two alternive formulations: Survey 1 (1962-08); and a split index that spanned 1962-99 (Survey 2) and 2000-08 (Survey 3).
${ }^{\text {c }}$ Initial sensitivity analysis regarding the CalCOFI survey presented at the onset of the STAR was based on three alternative indices (see Appendix 3B-C); however, a revised index (Survey 4) was used in subsequent sensitivity analysis conducted during the STAR, see STAR (2009).
${ }^{\mathrm{d}}$ Estimated initial fishing mortality was not fit to 'equilibrium' catch, but rather, implemented for purposes of providing a more robust initial nonequilibrium age composition.
${ }^{e}$ Variance adjustments reflect doubled input sample sizes, i.e., in effect, reweighted effective sample sizes reflect total number of fish divided by 12.5 (vs. 25 as used for initial (baseline) sample sizes).

## Landings (mt)

Fishing year
Figure 1. Commercial and recreational landings (mt) of Pacific mackerel in the USA (CA commercial, recreational-CPFV, and recreational-non-CPFV) and Mexico (commercial), (1962-08).

Figure 2. Length distributions of Pacific mackerel from RecFIN data base associated with the CPFV fishery (1992-08).

Figure 3. Age distributions of Pacific mackerel from CDFG (commercial fishery) port sampling program (1962-08).

Figure 4. Estimated mean age time series of Pacific mackerel from CDFG (commercial fishery) port sampling program (1962-08).

## Length (cm)

Figure 5. Estimated mean length-at-age (cm/yr, open circles) time series of Pacific mackerel from CDFG (commercial fishery) port sampling program (1962-08). Also, model fits to this time series are also presented (curved line in each display).

Figure 6. Ageing error vector (SD by age) from CDFG age production laboratory based on double-read analysis.

## Relative abundance

Figure 7. The CPFV index of relative abundance (CPUE) time series for Pacific mackerel (196208). Index is presented as a rescaled (normalized) time series.

Figure 8. Biological parameters for Pacific mackerel either assumed or estimated in the assessment models: (A) weight-length relationship; (B) length (cm)-at-age (yr); and (C) maturity (also, see Table 3) and natural mortality ( $M$ ).

## $R$ (millions)

Figure 9. Beverton-Holt stock (SSB in 1000s mt)-recruitment ( $R$ in millions of fish) relationship for Pacific mackerel estimated in the final SS model AA (2009). Recruitment estimates are presented as (year+1) values. Strong year classes are highlighted. Steepness=0.47.

A

A

Age (years)
Figure 10. Model (SS model AA) fit diagnostics associated with the commercial fishery age distribution time series (1962-08): (A) observed (open circles) vs. predicted (line) estimates; (B) Pearson standardized residuals (observed - predicted; maximum bubble size = 10.94; dark circles represent positive values); and (C) effective vs. observed (input) sample sizes for the commercial fishery age distribution time series. Solid line represents a 1:1 relationship and the dashed line reflects a loess smoother.

Figure 10. Continued.

Figure 11. Model (SS model AA) fit diagnostics associated with the recreational (CPFV) fishery length distribution time series (1992-08): (A) observed (open circles) vs. predicted (line) estimates; (B) Pearson standardized residuals (observed - predicted; maximum bubble size $=6.38$; dark circles represent positive values); and (C) effective vs. observed (input) sample sizes for the commercial fishery age distribution time series. Solid line represents a 1:1 relationship and the dashed line reflects a loess smoother.

Figure 11. Continued.

Figure 12. Model (SS model $A A$ ) fit diagnostics associated with the commercial fishery mean length-at-age ( $\mathrm{cm} / \mathrm{yr}$, open circles) time series (1962-08), i.e., see Figure 5 for observed (open circles) vs. predicted (line) estimates and the associated Pearson standardized residuals plot (observed - predicted; maximum bubble size $=4.33$; dark circles represent positive values) is presented here.

## A Proportion

## B Proportion

Figure 13. Estimated selectivity schedules associated with SS model AA: (A) time-varying for the commercial fishery (1962-69, 1970-77, 1978-08); and constant for recreational fishery (1962-08). Note that selectivity associated with the CPFV index mirrored the recreational fishery.

Figure 14. Model (SS model AA) fits to the CPFV index of relative abundance: (A) normal space; and (B) log space.

Figure 15. Recruitment-related estimates from SS model $A A$ : (A) recruitment deviations; and (B) SEs associated with the deviations (horizontal line indicates the estimate of the standard deviation of $\log$ recruitment deviations, i.e., fixed $\sigma-R=1.0$ ).

Figure 16. Estimated harvest rate (fishing mortality, $F$ ) time series from SS model $A A$ (1962-08).

Fishing year
Figure 17. Estimated total stock biomass (age $1+$ fish in $\mathrm{mt}, B$ ) of Pacific mackerel based on the final SS model $A A$ and alternative model $A B$ (1962-09).

## SSB (mt)

## Fishing year

Figure 18. Estimated spawning stock biomass (SSB) of Pacific mackerel based on SS model $A A$ (1962-08). Confidence interval ( $\pm 2$ SD) is also presented as dashed lines.

Figure 19. Estimated recruitment (age-0 fish in $1,000 \mathrm{~s}, R$ ) of Pacific mackerel based on SS model $A A$ (1962-08). Confidence interval ( $\pm 2 \mathrm{SD}$ ) is also presented as dashed lines.

## B (mt)

Figure 20. Estimated total stock biomass (age $1+$ fish in $\mathrm{mt}, \mathrm{B}$ ) of Pacific mackerel based on retrospective analysis that omitted one year of data in chronological order (2004-09), i.e., 2009 time series represents final SS model AA.

Fishing year
Figure 21. Estimated total stock biomass ( $B$ age 1+ fish in mt ) of Pacific mackerel for historical assessment period (1994-09): VPA model-based assessments from 1994-04; ASAP model-based from 2005-08; and SS model-based currently (2009).

Fishing year
Figure 22. Harvest guideline statistics for Pacific mackerel: (A) commercial landings (California directed fishery in mt ) and quotas (HGs in mt ), (1992-09); and (B) total landings (mt) and hypothetical quotas based on no USA ‘Distribution' parameter in the harvest control rule. Incidental landings from Pacific Northwest fisheries are not included, but typically are limited, ranging 100 to 300 mt per year.

\section*{Appendix 2A}

\section*{Preface}

The following suites of displays (Appendix 2A: ASAP model (2009); and Appendix 2B: SS model S1_aa) are associated with objectives 1 and 2 (see Preface above). That is, results from these two model scenarios were presented in initial STAR discussions, reviewed accordingly, deemed satisfactory for meeting objectives 1 and 2 , and are presented here.

\section*{ASAP model (2009) displays}

Table A2A-1. Sample sizes associated with CDFG data collection program for Pacific mackerel 1939-08).

\title{
Spotter Data Analysis for Pacific Mackerel From 1963-2005 Using a Delta GAM
}

\author{
Nancy C. H. Lo \\ NOAA Fisheries \\ Southwest Fisheries Science Center \\ 8604 La Jolla Shores Drive \\ La Jolla CA 92037 \\ USA
}

\section*{Introduction}

From 1963 to 2003 pilots, employed by the fishing fleet to locate schools of pelagic fish, reported data for each flight on standardized logbooks and provided them to NOAA Fisheries for a fee per flying hour (\$1.00-5.00). These data were used to derive Spotter-based indices of abundance for pelagic fish, such as anchovy and young sardine. These indices were calculated as year effects estimated using delta log-normal linear models (LLM; Lo et al. 1992). However, after the year 2000, there was rapid decline in both the number of active pilots and total logbooks returned (Tables 1 and 2), as well as a southward shift in effort to offshore areas around Baja California. To remedy this problem, NOAA Fisheries started to contract professional spotter pilots to survey the Southern California Bight region beginning in 2004 primarily for assessment of young sardine. Newly available data from this enhanced survey were incorporated into the index, and a new time series was calculated using a delta Generalized Linear Model (GLM) for young sardine. This paper presents estimates of the spotter survey index from 1963 to 2005 for Pacific mackerel (Scomber japonicus) However, due to the lower number of flights with positive sightings of Pacific mackerel in the spotter survey, I used a Generalized Additive Model (GAM) to obtain estimates of total tonnage as a relative index for the Pacific mackerel.

The old time series had an informal design. Pilots flew the year around at night and in the day, and in areas and seasons frequented by the fishery. The pilots' searching behavior, like most fishermen, might be characterized as "adaptive", meaning that searches for target species may be concentrated in areas where schools were previously sighted. There is no doubt that a formal fishery independent survey design would provide more precise and less biased estimates than the present indices. However, by altering the design, one would lose the most valuable property of the old aerial surveys, i.e., a time series that extends back to 43 years. Regardless of its merit, a new index will have little value in stock assessment until it extends over at least 5-10 years. Clearly, the time series that ended in 2000 needs to be extended, but it would also be valuable to develop a new, more precise index with less potential bias.

The new aerial survey was based on a line transect design with regular occupation of fixed grid lines spaced at regular intervals with random starting points. Concurrently, a "simulated old survey" was implemented by employing an adaptive design to simulate fishing conditions, where having found a school the fishermen will search the vicinity to find others. After searching the
pilot returned to the transect line and continued along the line. In this way we could gather information appropriate to both old and new survey designs. Factors such as month, area and day/light in the new surveys are close to those standardized conditions used in the spotter index model developed by Lo et al. (1992):

Experienced pilots under contracts flew along the predetermined track lines in March and April from San Diego to San Francisco, at a maximum of 100 nm offshore(Figure 1). However, in reality, pilots were unable to conduct all assigned surveys in March and April due to weather conditions and their flying schedules. In addition, they only flew in the daytime and not in the nightime alone. As a result, flights in 2004 took place throughout the entire year, but during March and April in 2005. No surveys were conducted in 2006 due to unavailability of pilots during the pre-assigned survey months: March and April. This restriction will be relaxed to the first half of the year. In 2004, a total of 5 surveys by month (3,4,5,7, and 9 ) were accomplished from March-November, including two single-pilot flights in September and November. In 2005, we had two 3-pilot complete surveys, three 2-pilot surveys and one 1-pilot survey during March and April.

\section*{Statistical methods}

\section*{Delta linear models}

The relative abundance of pelagic species, like northern anchovy, or sardine can be expressed as the product of density and a measure of area:
\[
\text { (1) } I=D A
\]
where \(\boldsymbol{I}\) is the index of relative abundance for a given year (tons). \(D\) is density of fish (tons per block) and \(A\) is the area (blocks 10 ' by 10' defined by California Department of Fish and Game (Caruso et al 1979) covered by fish spotters. In the original data analysis of the relative abundance of anchovy, it was reasonable to assume that fish spotters flew over an area that was at least as large as the area occupied by the anchovy stock in each year. This is not so for the entire population of other species like Pacific sardine and Pacific mackerel. For the case of sardine, it suffices to apply to young sardines ( \(<=2\) year old). In the current analysis for sardine, units for the index \((I)\) are tons of young sardine, sighted by fish spotters.

Density of fish (D) for each year can be expressed as the product of \(d\) and \(P\) :
\[
\text { (2) } D=d P
\]
where \(d\) is a standardized measure of fish density (tons per block) for positive flights (flights during which fish of interest were seen) and P is a standardized measure of the proportion of blocks that were covered by positive flights (referred to as proportion positive) (Table 1). We used the product in order to avoid problems that arise from including a large number of zeros; therefore the distribution of D is Delta distribution.

Delta lognormal linear model (LLM)

In the original lognormal linear model, we assumed that the number of tons/block (y) or proportion positive (p) follows a lognormal distribution and varies with some covariates, i.e. \(\log (\mathrm{y})\) or \(\log (\mathrm{p}+1)\) was a function of many covariates: year, region, season, pilot, night/day flights plus some interaction terms:
\[
\log (\mathrm{y}) \text { or } \log (\mathrm{p}+1)=\mathrm{x}^{\prime} \mathrm{B}
\]

The final estimates of standardized \(d\) and \(P\) were obtained by taking anti-log of the linear equations ( \(x^{\prime} B\) ) plus correction terms. Thus, the relative abundance for each year is:
\[
\hat{I}=\hat{d} \hat{P} A
\]

\section*{Delta GAM model}

To continue including spotter pilot data for the stock assessment, from the new datasets,we decided to switch from Delta lognormal linear model to a more flexible model, like GLM or GAM using S-Plus, to allow us to incorporate other possible distribution of tonnages/block (y) of sardine sighted by the pilots for the positive flights and the proportion of positive flights (p) with appropriate link functions for the expected values (d and P), respectively. As stated in Lo et al. (1992), although we used lognormal linear models for components of the delta distribution, other linear or nonlinear models based on other statistical distributions could be used instead.' The Delta GLM has been used for Pacific sardine. For Pacific mackerel, the GAM was chosen because it is more flexible than GLM due to the low sighting of Pacific mackerel and no sighting in 1974.

As done for the delta GLM, we chose a family of Poisson distribution and used log as the link function for the number of tons/block of positive flights (d), e.g., log (of the expected tonnage/block) \(=\mathrm{x}^{\prime} \mathrm{B}\); whereas a family of Binomial distribution and the logistic link function, for the proportion of positive flight (P), e.g. \(\log (P /(1-P))=x^{\prime} B\). In the GAM model, the year effect was modeled by a smoothing spline fit with d.f. \(=12\) while other independent variables: day/night, season, region and survey type were treated as categorical data.

The estimate of density of Pacific mackerel is \(\hat{D}=\hat{d} \hat{P}\), with variance estimated as (Goodman 1960):
\[
\operatorname{var}(\hat{D})=\operatorname{var}(\hat{d} \hat{P})=\hat{P}^{2} \operatorname{var}(\hat{d})+\hat{d}^{2} \operatorname{var}(\hat{P})-\operatorname{var}(\hat{d}) \operatorname{var}(\hat{P})
\]
where the estimated variance of estimates of \(d\) and \(P\) came directly from S-Plus. No correction of \(d\) and \(P\) was included in the variance of \(D\) because the correlation from the data was not significant. The final estimate of the relative abundance (I) and its CV are simply as follows.
\[
\begin{gathered}
\hat{I}=\hat{D} A \text { and } \\
C V(\hat{I})=C V(\hat{D})
\end{gathered}
\]
where A is total number of blocks within the traditional area covered by spotter pilots each year.

\section*{Results}

The time series of the density (d=tonnage/block), the proportion of positives (p), the survey area (A=blocks) and the total tonnage (D) of Pacific mackerel were presented (Table 1). The estimates of density (d) and proportion of positives (p) were adjusted for night time, season 1(Jan-March), region 2,pilot number 17 and survey 1( traditional aerial survey prior to 2004). The adjusted relative tonnages serve as the relative abundance of Pacific mackerel from spotter data set were presented using the delta-GAM (Table 1). We also presented the time series of total number of flights with sightings of Pacific mackerel and number of blocks with Pacific mackerel (Figures 2 and 3).

\section*{Discussion}

The relative abundance of Pacific mackerel peaked at the mid-1980 and has been decreased since 1985. The total number of flights decreased continuous since late 1990’s(Figure 2). However total number of blocks covered has been similar except 2003 (Figure 3). So, the decrease of the relative abundance of Pacific mackerel could reflect the decline of the population rather than the coverage of the aerial survey in terms of time and space.

Because the effort has been reduced traumatically since 2001 off California, we compared the overall time (season) and space(region) between this two period by the total number of flights (Table 2). The overall distributions between these two periods are similar where most of the efforts were in regions 1-3 for all season and much of the efforts were shifted to regions 4-6 in second half of the year(Figure 1). Thus the reduced effort does not appear to introduce much bias in terms of time and space.

The LLM was used in the past prior to 2000 . We compared time series of the relative abundance of Pacific mackerel based on the LLM and GAM (Figure 4). These two time series have similar shape except that the time series from LLM fluctuated more than that from Delta GAM. The CVs from LLM (Bradu and Munklak 1970) were higher than those from GAM (Figure 5) partially because the variances of the estimates from LLM included those of biascorrelation terms for the parameter estimates of lognormal distribution, which may not be so for the variance of estimates used in GAM(Lo et al. 1992, Chambers and Hastie 1992).

\title{
Daily Larval Production of Pacific Mackerel (Scomber japonicus ) Off California From 1951-2006
}

\author{
Nancy C. H. Lo, Yuhong Huang, and Emmanis Doval \\ NOAA Fisheries \\ Southwest Fisheries Science Center \\ 8604 La Jolla Shores Drive \\ La Jolla CA 92037 \\ USA
}

\begin{abstract}
Daily larval production at hatching \(/ 10 \mathrm{~m}^{2}\) of Pacific mackerel (Scomber japonicus) from 1951-2006 was estimated based on data collected from California Cooperative Oceanic Fisheries Investigations (CalCOFI) surveys off the coast from San Diego to Avila Beach, north of Point Conception, California in April-July, the peak spawning time of Pacific mackerel off California. This area has been covered by all CalCOFI surveys. The time series showed the peak daily larval production was in 1987 with \(46.39 / 10 \mathrm{~m}^{2} / \mathrm{d}\), with minor peaks were in 1981, and 1986. The density of daily larval production has been decreasing since 1997. The larval production was particularly low in 2003-2006. This cost-effective fishery-independent time series should be beneficial to the assessment and better understanding of the dynamics of the Pacific mackerel population.
\end{abstract}

\section*{INTRODUCTION}

The time series of Pacific mackerel larval abundance and distribution by month from 1951-56 was reported by Kremer (1960) and from 1951-84 by Moser et al (1993) for historical survey area from San Francisco to Baja California. Since 1985, the CalCOFI survey area has been reduced to cover the area in the Southern California Bight (CalCOFI line 93 - line 77, Fig. 12 and 3), primarily most years in 1985-present.

The purpose of constructing the time series of daily larval production was to use this time series as an index for the spawning biomass in the stock assessment. Ideally, methods such as the daily egg production method (DEPM) for pelagic fishes (Lo et al. 1996) should be used to estimate spawning biomass of Pacific mackerel. This kind of method requires data on fish egg stages, duration and abundance plus the reproductive output of adult fishes (MacGregor 1966). Due to the high patchiness of Pacific mackerel eggs and larvae, and the fact that the eggs were consistently identified only in the last 10 years, it is not possible to carry out a DEPM analysis over the whole 1951-2006 time period at this moment. Fortunately, mackerel larval data from CalCOFI surveys are readily available from 1951 and comprehensive correction algorithms can be applied to reduce the possible biases of measurement, such as extrusion through the net mesh,
avoidance from the net, etc. It seems reasonable to consider the larval production of Pacific mackerel as a possible index of spawning biomass (Ahlstrom 1959) as has been done for many other fish populations (Smith 1972, Lo 1986, Lo et al. 1989). In this paper, we analyzed Pacific mackerel larval data from 1951-2006 for the current CalCOFI survey area in April-July (Fig.1). Although this area is smaller than that of the historical CalCOFI survey (Fig. 2), it encompasses the primary spawning area of Pacific mackerel off California (Moser et al. 1993).

\section*{METERIAL AND METHODS}

The CalCOFI survey was conducted annually from 1949-1966, after which it was conducted every 3 years through 1984, covering the area from Baja California to the north of San Francisco (Fig. 2). Starting in 1985, the survey was conducted annually but covered only the southern area from San Diego to Avila Beach, just north of Point Conception. As Pacific mackerel larvae are most concentrated in mid-Baja California in the summer and second off Southern California in Spring, for consistency of available datasets, only Pacific mackerel larval data from the CalCOFI database from April-July were used in this study (Ahlstrom 1959, Moser et al. 2001). Larvae were collected by oblique tows with a 1-m ring net to 150 m from 1951-68, and the depth was increased to 210 m in 1969. Bongo net replaced \(1-\mathrm{m}\) ring net in 1978. A standard haul factor used to compute number of larvae \(/ 10 \mathrm{~m}^{2}\) ws intended to account for variability in the volume of water filtered per unit of depth (Smith and Richardson 1975).

Sampler biases caused by net selectivity for small larvae and gear avoidance for larger larvae were adjusted following the method of Lo (1985). Retention rates for extrusion can be expressed as function of larval length and mesh size (Lenarz 1972; Zweifel and Smith 1981; Lo 1983) and those for avoidance can be expressed as a function of larval length and the diurnal time of capture (Hewitt and Methot 1982). All larval abundance data were adjusted to conform to the following standard condition: no extrusion, no day-night difference in avoidance, and a constant water volume filtered per unit depth. The data were then converted to daily production \(/ 10 \mathrm{~m}^{2}\left(\mathrm{P}_{\mathrm{t}}\right)\) by dividing the corrected total number of larvae in each length group by the duration (the number of days larvae remain within each length group). A set of laboratory data on larval growth conducted by Hunter and Kimbrell (1980) was used to model temperature dependent larval growth curves which were used to convert length to age from hatching.

\section*{CORRECTION FACTORS}

\section*{Extrusion}

There are no existing data on the length-specific extrusion rate for Pacific mackerel. Therefore, the retention coefficient of jack mackerel larvae due to extrusion was used as a proxy for mackerel. Jack mackerel larvae and Pacific mackerel larvae are approximately the same length at hatching and are morphologically similar: jack mackerel hatch at about 2-2.5mm and Pacific mackerel at about 2-3mm; morphology of both is similar in yolk sac stage. On average, Pacific mackerel tend to be just slightly longer and more robust than jack mackerel (Watson pers. Comm.). Hewitt et al. (1985) reported that only the smallest class of jack mackerel larvae ( 3.0 mm ) are extruded to a
significant degree through the 0.505 mm CalCOFI nets, with \(28 \%\) of the catch in that size class retained in the net. The extrusion correction factor is equal to \(1 / .28\) or 3.571 . Although 0.55 mm mesh net was used prior to 1968 , the difference in extrusion of mackerel larvae is likely to be insignificant as was the case for anchovy larvae (Lo 1983).

\section*{Avoidance /evasion}

The correction factor for avoidance/evasion was estimated using the algorithm developed for anchovy and Pacific hake (Lo et al. 1989, Lo in submission). Because larvae are able to avoid or evade the net to the same degree under sufficient light to see, and larger larvae are better able to avoid the sampler, we used the model by Lo et al. (1989) for the retention (or capture) coefficient of mackerel larvae for a specific larval length \((L)\) and hour of the day \((h)\) :
\[
\begin{equation*}
R_{L, h}=\left(\frac{1+D_{L}}{2}\right)+\left(\frac{1-D_{L}}{2}\right) * \cos \left(\frac{2 \pi * h}{24}\right) \tag{1}
\end{equation*}
\]
where \(D_{L}\) is the noon/night catch ratio for length \(L\). Data from 1951 to 1978 in the historical large area were used to model the catch ratio:
\[
D_{L}=\frac{\bar{y}_{L, \text { noon }}}{\bar{y}_{L, \text { night }}}
\]

The numerator is the mean catch at noon (11:00 am - 1:00 pm) of larvae size \(L\). The denominator is the mean catch in the night (9:00 pm - 3:00 am) of larval length \(L\). We then used an exponential curve to model the relationship between \(D_{L}\) and larval length \(L\).

\section*{Shrinkage}

The shrinkage factor was based on the work on Pacific hake (Bailey 1982) which reported on the percentage of shrinkage in the standard length of first-feeding larvae due to preservatives and time of handling for Pacific hake. Shrinkage was \(8.9 \%\) for formalinpreserved larvae ( \(L\) ). Because in regular CalCOFI surveys, formalin is the standard preservative used, a correction factor is needed to convert formalin-preserved length ( \(L\) ) to life length ( \(L_{L}\) ) in order to apply the larval Pacific mackerel growth curves derived from laboratory data by Hunter and Kimbrell (1980). The multiplier applied to larvae from 2.5-11.5 mm from CalCOFI surveys is \(1 /(1-0.089)=1.098\) to convert formalin preserved-length to live length, i.e., \(L_{L}=L^{*} 1.098\).

\section*{GROWH OF MACKEREL LARVAE}

\section*{Growth curves}

Hunter and Kimbrell (1980) reported growth data for seven groups of Pacific mackerel reared at different temperatures from \(16.8-22.1^{\circ} \mathrm{C}\). A temperature-dependent logistic growth curve was derived where the coefficient of the age was a polynomial function of temperature (Bartsch 2005):
\[
\begin{equation*}
L_{L}=\frac{28.2616}{1+\exp \left(-\beta_{\text {tenp }} t+2.3476\right)} \quad \text { for } \mathrm{t}<25 \mathrm{~d} \tag{2}
\end{equation*}
\]
where \(L_{L}\) is the life length, \(\beta_{\text {temp }}=0.2828-0.0229\) temp +0.0007 temp \(^{2}\), \(t\) (days) is age (d) from hatch, and temp is temperature in \({ }^{\circ} \mathrm{C}\).

To convert length to age from hatching, we inverted the equation (2) and obtained:
\[
\begin{equation*}
t=\frac{2.3476-\ln (28.2616 /(L * 1.098)-1)}{\beta_{t \mathrm{tmp}}} \text { for } 2.23 \mathrm{~mm}<=\mathrm{L}<20 \mathrm{~mm} \tag{3}
\end{equation*}
\]
where \(t\) is age after hatching and \(L\) is formalin-preserved length. Note the logistic growth curve gave minimum live length being 2.45 mm for newly hatched larvae at \(t=0\).

The larvae collected in each tow were grouped as \(2.5 \mathrm{~mm}(2.0 \mathrm{~mm}-3.0 \mathrm{~mm}\) ), 3.75 ( 3.5 and 4.0 mm ), and 4.75 ( 4.5 and 5.0 mm ). To obtain the final age of a larva, the actual length of a larva in each length group from each tow was generated by a random selection from a uniform distribution within each length category. For the larvae in the length category of 2.5 mm , age 0 was assigned for formalin-preserved length \(<2.23 \mathrm{~mm}\)

\section*{Size class duration and daily larval production}

The duration was estimated by the difference of the mid-ages where the mid-ages are the ages corresponding to the mid-lengths: the midpoint between two size groups. The daily larval production in each age group was the larval density in each age group divided by its duration, the time the larvae stayed in each size group.

\section*{DAILY LARVAL PRODUCTION AT HATCHING ( \(\mathbf{P}_{\mathbf{h}}\) )}

The daily larval production at hatching \(\left(P_{h}\right)\) was estimated for each year from a larval mortality curve in the form of exponential function, unlike that of northern anchovy (Lo 1985, 1986) and Pacific hake (Hollowed 1992) whose daily mortality rates decreased with age as the larvae matured. Larvae with length \(>11.75 \mathrm{~mm}\) length group were excluded because few larvae of those sizes observed due to their evasion from the net is uncertain. A weighted nonlinear regression was used to obtain estimates of the coefficients for years with sufficient catch-length data:
\[
\begin{equation*}
P_{t}=P_{h} \exp (\alpha t) \tag{4}
\end{equation*}
\]
where \(P_{t}\) is the daily mackerel larval production at age \(t\) days from hatching, and \(\alpha\) is the daily instantaneous mortality rate.

For most years, we fitted equation (4) to the data using a weighted nonlinear regression to estimate the \(P_{h}\) and \(\alpha\), where the weight was \(1 /\) SD for each 4-day interval: \(0-4,5-8, \ldots, 17-20 \mathrm{~d}\). As larvae older than 20 days occurred in few tows each year, the mortality curve was constructed based on larvae of age \(<=20\) days at most, to avoid bias. However due to the patchiness of larvae and their ability to avoid the net, the unweighted nonlinear regression was used for some years because the large variances in the young age categories down-weighted the corresponding larval productions too much to produce reasonable estimates of \(P_{h}\) and mortality rate. There were also some years where only one or two length groups had positive catches, mostly small larvae say larvae \(<4 \mathrm{~mm}, P_{h}\) was estimated by inverting the mortality curve (equation 4)
\[
\begin{equation*}
\hat{P}_{h}=\bar{P}_{L} \exp \left(-\hat{\alpha} t_{L}\right) \tag{5}
\end{equation*}
\]
and the variance of \(\hat{P}_{h}\) was estimated as:
\(\operatorname{var}\left(\hat{P}_{h}\right)=\operatorname{var}\left(\overline{\bar{L}}_{L}\right)\left(\exp \left(-\hat{\alpha} t_{L}\right)\right)^{2}+\left(\bar{P}_{L} \exp \left(-\hat{\alpha} t_{L}\right)\left(-t_{L}\right)\right)^{2} \operatorname{var}(\hat{\alpha})-\operatorname{var}\left(\bar{P}_{L}\right)\left(\exp \left(-\hat{\alpha} t_{L}\right)\left(-t_{L}\right)\right)^{2} \operatorname{var}(\hat{\alpha})\)
where \(\bar{P}_{L}\) is the mean daily larval production at length \(\mathrm{L}=2.5 \mathrm{~mm}\) and \(\mathrm{t}_{\mathrm{L}}\) is the associated age of 2.5 mm and the over all mean mortality rate was used for \(\hat{\alpha}\) (Goodman 1960).

\section*{RESULTS}

\section*{Avoidance}

The relationship between the mean noon/night catch ratio \(\left(\mathrm{D}_{\mathrm{L}}\right)\) and larval length (L) based on data of 1951-1978 is
\[
\begin{equation*}
D_{L}=2.7 \exp (-0.39 L) \tag{6}
\end{equation*}
\]
where the standard errors of two coefficients are 0.47 and 0.05 . (Fig.4). The estimated capture rates of larvae by length and time of day (equation 1) are shown in Fig. 5.

\section*{Mortality curves and the daily larval production at hatching \(\left(P_{h}\right)\)}

Mortality curves were constructed for years when the data are sufficient (Table 1). The mortality curve and larval production at age for 1981 are given for illustration (Fig. 6 ). For those years, the estimates of the daily larval production \(/ 10 \mathrm{~m}^{2}\) were the intercepts of the mortality curves (equation 4) (Table 1). An unweighed nonlinear regression was used for years 1985, 1986, 1988, and 1992. For other years when the data were not sufficient, an overall mortality rate was used in equation (5) for1953, 1962, 1969, 1972, 1993, 1994, 2003, and 2006.

The time series of daily larval production \(\left(P_{h} / 10 \mathrm{~m}^{2}\right)\) from 1951-2006 off the California coast from San Diego to north of Point Conception fluctuated with the highest peak of 46.38 larvae/day/ \(10 \mathrm{~m}^{2}\) in 1987 and minor peaks at 1981 and 1986 (Table 1 and Fig. 7). The larval production has been declining with moderate fluctuations since 1997 in this survey area.

For comparative purposes, we computed the mean counts of larvae per \(10 \mathrm{~m}^{2}\) with corrected for biases. The time series of \(P_{h}\) and mean counts of larvae had similar trend but the time series of simple means was more variable than that of \(P_{h}\) (Fig. 7 and 8). Nevertheless, the fluctuations in the time series of Pacific mackerel larvae are partially due to the fact that Pacific mackerel larvae are one of the most 'patchy distributed' pelagic species in the CalCOFI time series and that patches can be very large and dense.

Analyses in this study were based on larval abundance corrected for all possible biases. The extrusion factor was based on Jack mackerel larval data, therefore future surveys on Pacific mackerel larvae are recommended to obtain direct measurements and to verify if the extrusion factor based on Jack mackerel larvae is reasonable to use for Pacific mackerel larvae. The avoidance correction factor was based on 1951-1978 data because including other year's data did not contribute to the modeling of the day/night ratio with the length.

The long time series of daily Pacific mackerel larval production, a cost-effective fishery-independent population index obtained yearly, is beneficial to the assessment of the Pacific mackerel population and better understanding of the dynamics of the Pacific mackerel population (Deriso and Quinn, NRC 1998).

\section*{Introduction}

Two time series of relative abundance indices of Pacific mackerel used for the 2007 and 2008 stock assessment (Appendix I and II Dorval et al. 2007 and Crone et al. 2009) were a fishery-independent time series of daily Pacific mackerel larval production at hatching ( \(\mathrm{P}_{\mathrm{h}}\) ), and Delta GLM relative abundance based on logbooks of aerial spotter pilots.

The \(\mathrm{P}_{\mathrm{h}}\) time series was based on data collected during April-July, the peak time of larval densities, from 1951-2006 in the current CalCOFI survey area from San Diego to the north of Point Conception (Figure 1-3; Appendix II). The other abundance index was the time series of Delta GLM relative abundance based on data collected by the spotter pilots hired by fishing vessels off California from fishing years (July-June) 19622001(calendar years 1963-2002 )(Figure 4, appendix I). The estimation procedures for both time series were described in Dorval et al. (2007) and Crone et al.(2009).The spotter pilot time series has not been updated since 2007, and the original time series from 1962-2001 fishing year was used in the current stock assessment. As to the larval production time series off California, no larvae were observed in 2007 and 2008, therefore the current time series of larval production is basically the original time series plus two zeros for 2007 and 2008

One of concerns of the 2007 STAR panel was about the time series of \(\mathrm{P}_{\mathrm{h}}\) in that this time series was based larval data collected from the current CalCOFI survey area and it may not be representative of the spawning biomass of the entire Pacific mackerel population, because Pacific mackerel are distributed from Baja California to north of California (Figure 1c). One of the reasons why \(\mathrm{P}_{\mathrm{h}}\) was constructed only for the current CalCOFI area was the lack of the larval data from Mexico after 1984. We also believe that the \(\mathrm{P}_{\mathrm{h}}\) in the CalCOFI survey area is likely to be representative of the whole population. To examine possible bias of the time series of \(\mathrm{P}_{\mathrm{h}}\) from the CalCOFI area and to extend the time series of larval densities of both CalCOFI and Mexican regions to the current time period, we constructed a time series in this report based on available larval data from California and Mexico from 1951-1984 and 1998-2000, with data from Mexico in the later period made available to us in 2008. We also updated the relative abundance from the spotter pilot data from 1962-2001 to 1962-2006 fishing year even though only the time series of 1962-2001 fishing year was used in the stock assessment.

\section*{Time series of Larval densities/10m \({ }^{2}\) in 1951-1984 and 1998-2000 off California and Mexico}

The historical CalCOFI survey covered waters of California and Mexico (Figure 1) from 1951-1984 and annual indexes of larval abundance were examined by MacCall and Prager (1988). Beginning in 1985 the CalCOFI surveys covered only the southern California from San Diego to just north of Point Conception
(Figure 1a and 1d). No systematic ichthyoplankton surveys were conducted off Mexico in 1985-1996 till the establishment of the Investigaciones Mexicanas de la Corriente de California (IMECOCAL) in September 1997 (Baumgartner et al. 2008). IMECOCAL surveys are conducted four times a year, similar to the current CalCOFI survey schedule, to collect ichthyoplankton samples from CalCOFI lines 100-137 and to offshore CalCOFI station \(80\left(193,000 \mathrm{~km}^{2}\right)\) (Figure 1a). Data of Pacific mackerel larvae from October 1997-January 2001 were provided by Instituto Politécnico Nacional (IPN) Mexico.

Based on historical data, the peak month of larval densities is May off California and August off Mexico. To extend the months to increase sample size for this analysis, we chose months prior and after the peak month: April-July off California and June-September off Mexico (Figure 2). Thus larval data from IMECOCAL in June -September and the current CalCOFI region in April-July, were used to construct a new time series for a large survey area. Because the data from Mexico included only total larvae caught without number of larvae by length group, it was impossible to compute the daily larval production ( \(\mathrm{P}_{\mathrm{h}}\) ) as the \(\mathrm{P}_{\mathrm{h}}\) requires larval counts by length (Appendix II). Therefore we computed a simple weighted mean larval density for each year during the peak larval months. The final mean larvae densities were weighted mean larval densities from these two regions with weights being the survey area size: \(198,000 \mathrm{~km}^{2}\) and \(193,000 \mathrm{~km}^{2}\) for CalCOFI and IMOCOCAL, respectively, for 1951-1984 and 1998-2000 when both areas were covered (Figure 5)

We constructed another time series of the simple mean larval density/ \(10 \mathrm{~m}^{2}\) in the current CalCOFI area for April- June, 1951-2008 to provide a 'continuity' across the time series of the weighted mean from CalCOFI and IMECOCAL, in the gaps from 1985-1997 and 2001-2008.

\section*{Updated GLM relative abundance of Pacific mackerel from 1962-2006}

GLM relative abundance from the spotter data (Appendix I) was updated to fishing years 1962-2006 from 1962-2001 to include data from fishery-independent aerial surveys conducted by spotter pilots contracted by the SWFSC in 2004, 2005 and 2007 (Figure 4 and 6).

\section*{Results}

The time series of weighted mean of larval densities for 1951-1984 and 1998-2001, time series of simple mean larval densities in the IMMECOCAL survey area in the same period and the time series of simple mean for the CalCOFI area from 1951-2008 showed the peak points during 1980s off California and smaller increases in the first half of 1960s (1962 and 1963) and in 1998-2000 off Mexico(Figure 5 and Table 1). During the peak times, 1981 and 1987, larvae were densest in California waters (MacCall and Prager 1988). Lacking data from Mexico in 1987, we know at least larval production was high off California. In the late 1990s, larvae were densest in Mexican waters. Therefore, the spawning area of Pacific mackerel moved between California and Mexico with higher density during peak time off California. Because the larval densities were relative low after 1990s and so were landings off Mexico, data from Mexico may not have much effect on the general trend of the spawning biomass of Pacific mackerel.

To determine whether the time series of the larval production \(\left(\mathrm{P}_{\mathrm{h}}\right)\) in the CalCOFI area was representative for the whole area of California and Mexico, we computed a simple correlation coefficient between \(\mathrm{P}_{\mathrm{h}}\) off California and the weighted mean off California and Mexico for 1951-1984 (Table 1). The correlation was 0.94 for all years excluding years when no larvae were caught. The correlation (0.23) was low for years with low densities, say \(\mathrm{P}_{\mathrm{h}}<5\). Thus, the \(\mathrm{P}_{\mathrm{h}}\) time series off California captured the high peak years while for years with low larval densities, the two time series did not match well, mainly for years prior to 1965 (Figure 7). Although years of high larval densities may vary between California and Mexico, the magnitude of larval
density in California waters was much higher than those in Mexican waters. As it is unlikely to construct a time series for both regions from 1951-present in a timely fashion, the time series of \(\mathrm{P}_{\mathrm{h}}\) from the current CalCOFI region can serve as a conservative index of spawning biomass for recent years when the population is low, and it does catch the high peak years. The \(\mathrm{P}_{\mathrm{h}}\) time series is a better index for the spawning biomass than the simple larval density estimates because it estimates the daily larval production at hatching (Appendix II). Note the time series of larval densities for the current CalCOFI survey area corrected for bias due to extrusion and avoidance of the net for 1951-2006 was also included in Appendix II (Figure 8).

For the time series of spotter pilot data (Figure 4,Table 1)), even though only the 1962-2001 time series is used for the stock assessment, we included the data from surveys conducted in 2004,2005 and 2007 in the GLM model adjusted for many factors: day/night (night), season (April-June), region (region 2, Southern California bight) , pilot (number 17, arbitrary) and survey type (surveys prior to 2002) (Appendix I).This time series from 1962-2006 fishing year indicated that the relative population is still low in recent years. This time series could, theoretically, be included in the future to increase the length of the time series of the relative abundance for the stock assessment.
