NOAA TECHNICAL MEMORANDUM NMFS-F/NEC

The Northeast Fisheries Center (NEFC) conducts targeted research to provide needed information for fisheries resource and habitat managers in the Northwest Atlantic. The NEFC operates facilities in Gloucester and Woods Hole, Massachusetts; Narragansett, Rhode Island; Milford, Connecticut; Sandy Hook, New Jersey; and Oxford, Maryland. It also administers the NMFS's National Systematics Laboratory in Washington, D.C., and Atlantic Environmental Group in Narragansett, Rhode Island. This targeted research focuses on: (1) harvesting, aquaculture, and utilization of fisheries resources; and (2) the health of the marine environment as it affects the production and edibility of fisheries resources. Users of this information include federal and state agencies, private industry, and the general public.

The real-time need for this information by decision makers often precludes publication in formal journals. The *NOAA Technical Memorandum NMFS-F/NEC* series identifies informal documents prepared by NEFC authors or similar material prepared by others for NEFC purposes, where formal review and editorial processing are not appropriate or feasible. However, documents within this series reflect sound professional work and can be referenced in formal journals. Any use of trade names within this series does not imply endorsement.

Copies of this and other *NOAA Technical Memorandums* are available from the National Technical Information Service, 5285 Port Royal Rd., Springfield, VA 22161. Recent issues of *NOAA Technical Memorandum NMFS-F/NEC* are noted below:

FOREWORD

This issue of the *NOAA Technical Memorandum NMFS-F/NEC* series is a report (Technical Report No. 22) prepared by the Bigelow Laboratory for Ocean Sciences, under Contract No. NA-80-FA-C-00008 to the National Oceanic and Atmospheric Administration's (NOAA) National Marine Fisheries Service (NMFS). The contract was awarded as a part of NOAA's Northeast Monitoring Program (NEMP), and was monitored by Mr. Robert N. Reid of NMFS's Northeast Fisheries Center. The report was submitted to NEMP in September 1982 as a final report on a benchmark survey of the benthos in the Casco Bay, Maine, area.

The report has been reprinted virtually as submitted, with only minimal changes in format. References to specific trade names in this report do not imply endorsement by NOAA/NMFS.

John B. Pearce, Manager
Northeast Monitoring Program

INTRODUCTION

Casco Bay, a large, complex bay, located on the south central coast of Maine, is noted for its scenic beauty as well as for its importance to business and commerce (Fig. 1). Within the approximately 400 square kilometers comprising Casco Bay are 300 kilometers of coastline and upwards of 400 islands (U.S. FWS, 1980). Included within Casco Bay is the city of Portland, the largest in Maine, which ranks as one of the busiest ports in New England, largely due to heavy petroleum traffic. Portland is also the largest fishing port in Maine. Presently, 27% of the coastal population of Maine is situated on Casco Bay. The growth of this segment of Maine's population will be accelerated by the increased use of Portland Harbor. Current expansion projects include a major ship building facility, a fish pier, and a containerized cargo dock. Some of the major existing facilities representing potential threats to environmental quality are located in Fig. 3. At the same time that human and industrial density is increasing in the Casco Bay region, seals, eagles, black guillemots, and other species indicative of a clean or undisturbed environment, are still found and the area remains heavily utilized for commercial fishing.

In spite of the potential for conflict between development and the traditional use of the nearshore waters for commercial fishing and recreation, little systematic environmental evaluation has been accomplished in Casco Bay. Hulbert (1968, 1970) and Hulbert and Corwin (1970) investigated several aspects of the physical oceanography and phytoplankton of the region while Jones (1980), and Parker and Garfield (1981a, b) provided background information on microplankton production

and hydrography of Casco Bay, respectively. To date, the most comprehensive faunal records are from the early surveys of Verrill (1874) and Kingsley (1901). Few quantitative studies of the shallow-water marine benthic communities in the boreal zone of the eastern United States exist (Dexter, 1944, 1947; Hanks, 1964; Shorey, 1973; Bilyard, 1974; Larsen, 1979), and none consider the Casco Bay region.

the Outlines
In April 1980, we undertook a broad scale benthic survey of Casco Bay for the purpose of establishing an environmental benchmark against which subsequent natural and man-induced fluctuations could be measured. Due to the complex topography, hydrography and anthropogenic inputs, great care was taken to insure that all possible variations in the soft bottom habitat were included. Based on the results of this survey, a long-term monitoring program of selected stations was instituted, and the results of this effort will be presented in forthcoming documents. This present report summarizes the physical and biological data from the 1980 broadscale survey. ↙

METHODS

The basic sampling design involves four transects along the long axis of Casco Bay with additional stations placed in areas of interest, such as the major sounds between the islands and near potential point sources of pollution. Station density is highest near Portland where steep environmental gradients might be expected due to freshwater inflow and more concentrated development. Station locations are presented in Fig. 4.

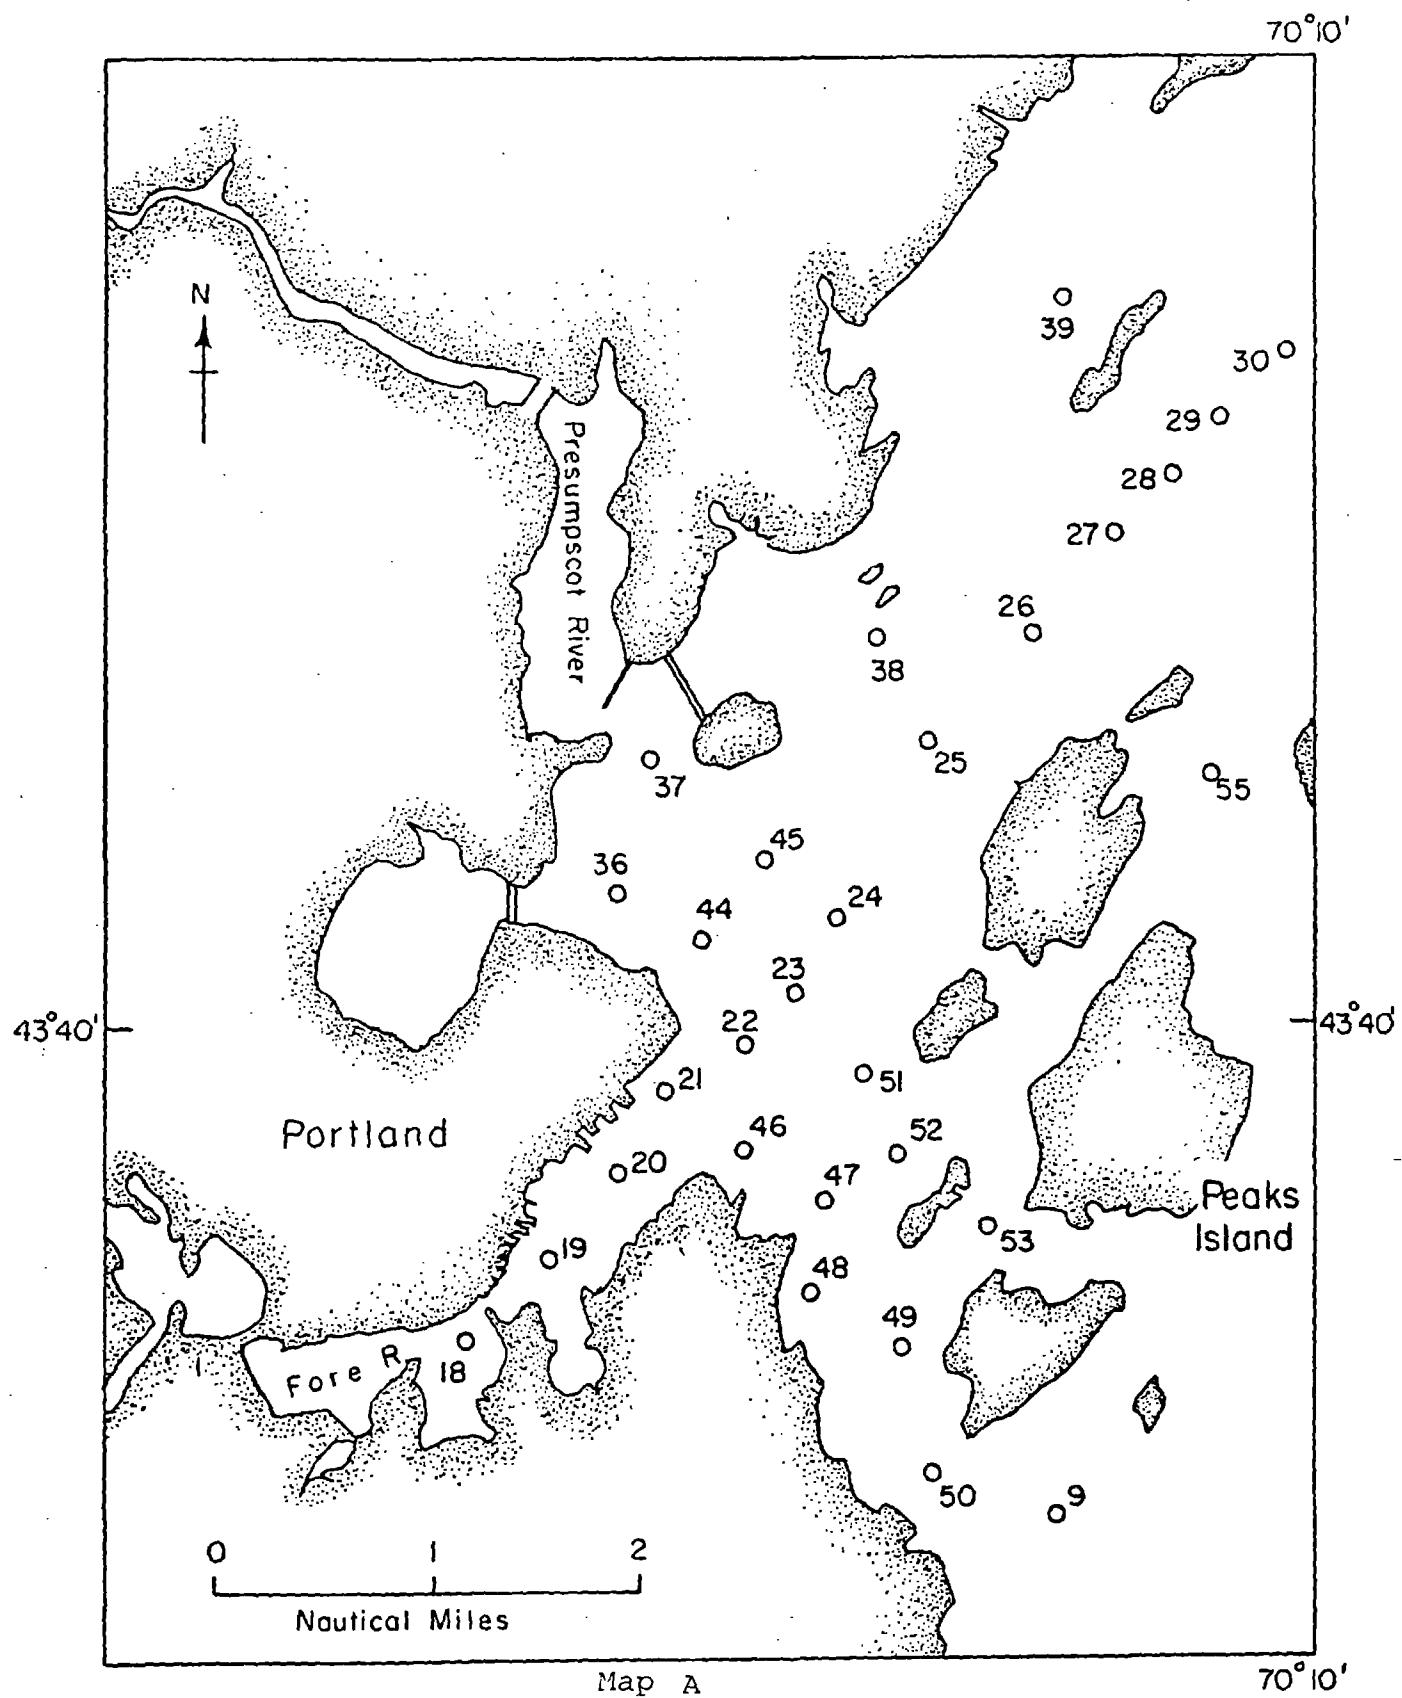

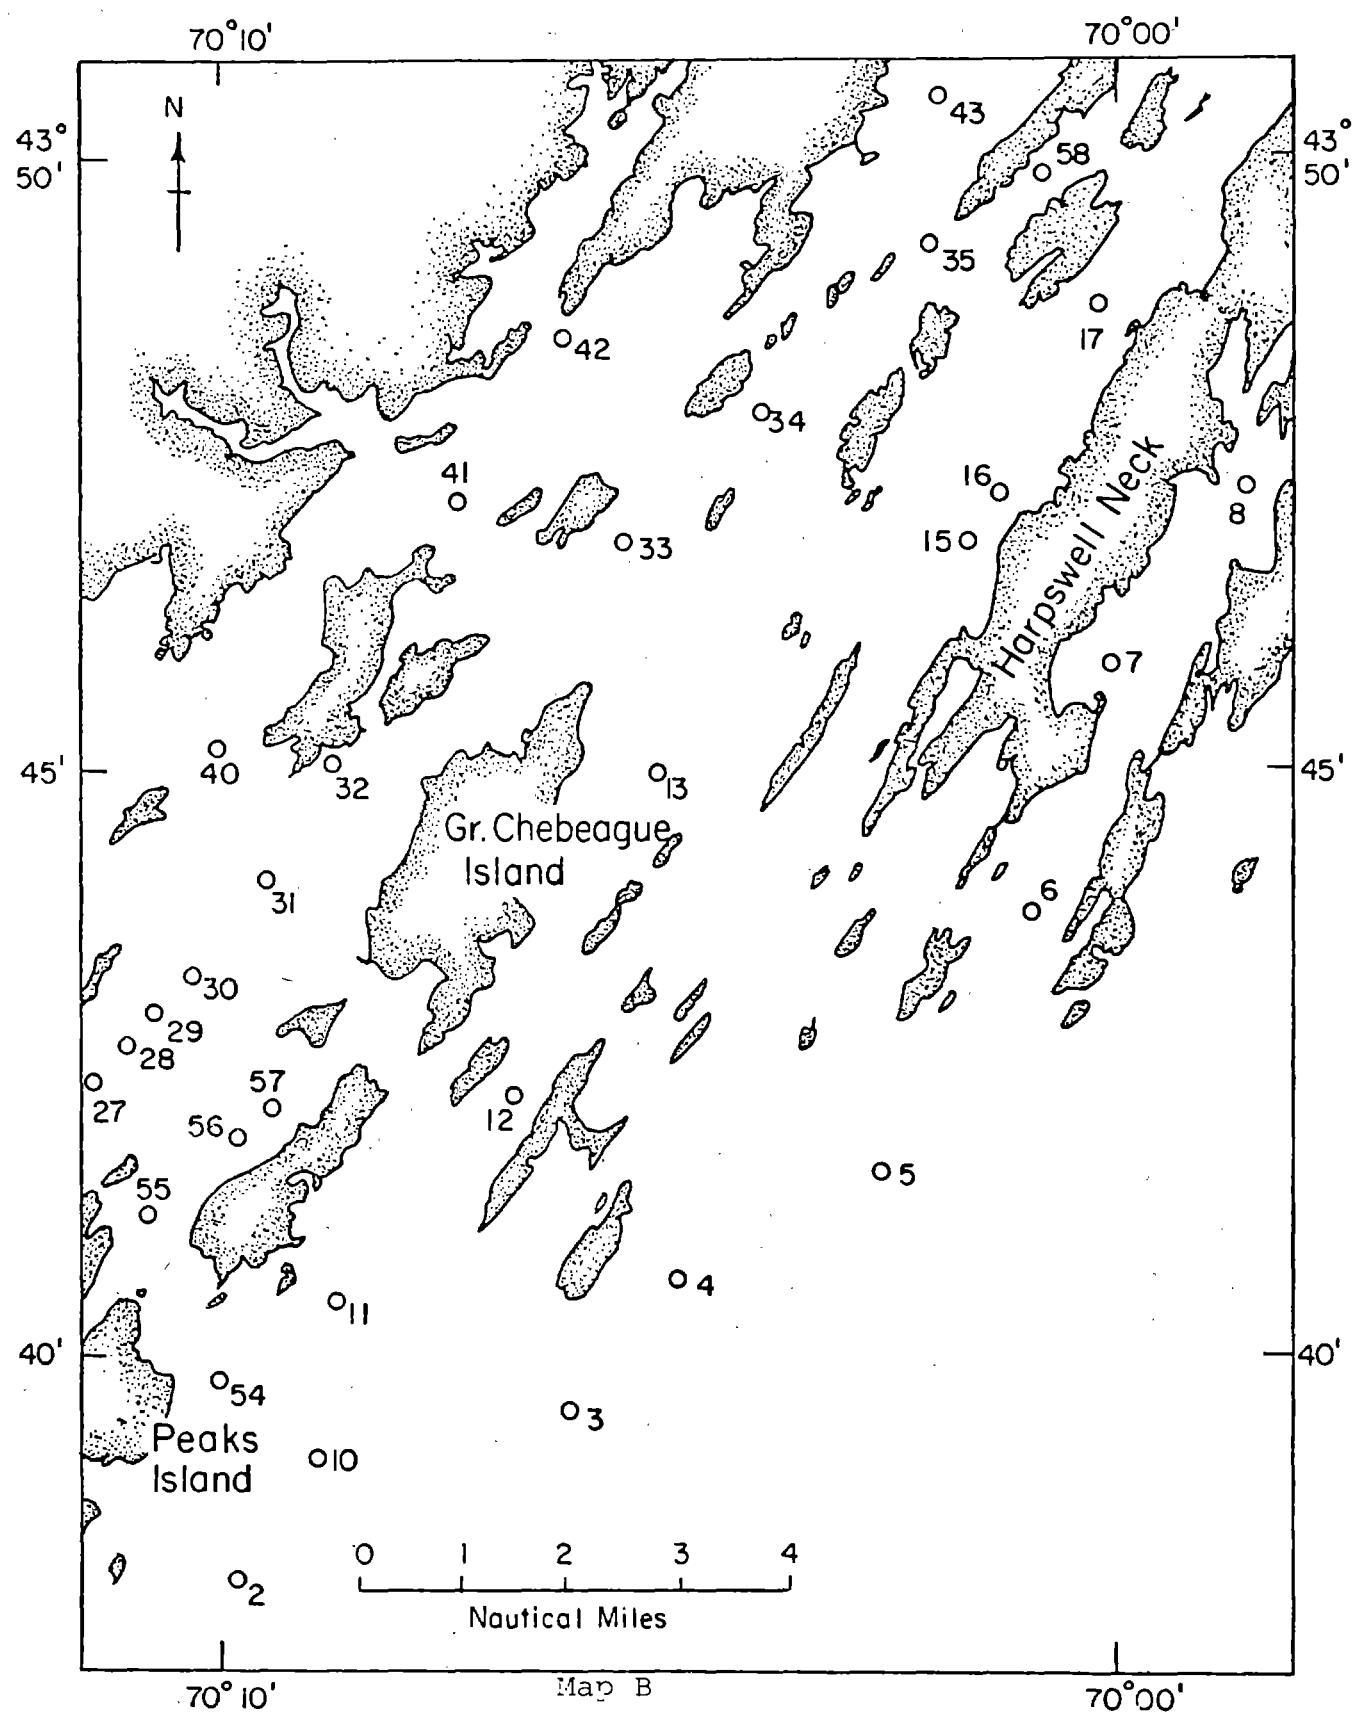

Fig. 4. Locations of the 56 benthic stations sampled in Casco Bay, April, 1980.

A single 0.1 m² Smith-McIntyre grab sample was taken at each station. Subsamples for sediment grain size, organic carbon and Kjeldahl nitrogen analyses were removed from each grab. At 32 stations additional subsamples were removed for heavy metal and hydrocarbon analyses. In each case, prescribed procedures for the preparation of subsample containers and the subsampling process were followed, and the subsamples were frozen for delivery to the appropriate analytical laboratory. Sediment grain size, organic carbon and Kjeldahl nitrogen analyses were done by GEOMET Technologies, Inc., Melville, New York, and heavy metal and hydrocarbon analyses were done by the National Marine Fisheries Service. The main-body of the sample was sieved on nested 0.5 and 1.0 mm screens. The debris remaining on the screens was fixed in 5% buffered formalin and returned to the laboratory for faunal analysis. Bottom temperature and salinity were determined at each station using a Beckman RS5-3 portable salinometer.

In the laboratory all organisms were transferred to 70% ethanol, removed from the 1.0 mm size fraction and identified to the lowest taxonomic level possible. Wet weight biomass was determined for the major taxonomic groupings.

All data were entered and processed by the University of Maine Computer Center through the Bigelow Laboratory Computer Center. Data analyses included informational diversity and its components, calculated by standard formulas given by Margalef (1958) and Pielou (1970), and numerical classification in both the normal and inverse modes. The Canberra metric dissimilarity index and the flexible sorting clustering strategy were used in the latter procedure because of their demonstrated success in marine benthic studies. The data were log transformed.

Nodal analysis, for both constancy and fidelity, was applied to interface the results of the two classifications. Following the convention presented in Boesch (1977), a constancy index was calculated as $C_{ij} = a_{ij}/(n_i n_j)$, where a_{ij} is the number of occurrences of Species-Group i in Site-Group j and n_i and n_j are the numbers of entities in each group considered. The fidelity index was calculated as $F_{ij} = (a_{ij} \sum_j n_j)/(n_j \sum_i a_{ij})$, the symbols having the same meaning as above. Fidelity values less than 1 suggest a negative relationship and values of over 1 a positive relationship between a species-group and a site-group.

RESULTS AND DISCUSSION

Depth, Temperature and Salinity

The depths of the 56 stations sampled range from 7 to 140 feet, i.e. 2-43 m (Table 1). All stations exceeding 70 feet in depth are offshore of the outer islands and most inner Bay stations are in the 25-50 foot depth range (Fig. 5). Depths are measured by fathometer and are not corrected for tidal stage.

Bottom water temperatures in April range from 2.9 to 6.3°C with most stations being between 3.0 and 5.0°C. Statistical analysis of water temperature and depth indicates that vernal warming of surface waters is already well progressed by April. This is a very highly significant relationship, $p > .9999$, with a correlation coefficient of -0.60222. With the exception of two stations, salinity throughout the Bay varied within the narrow range of 30.3 - 32.9 ‰ (Table 1). The two stations outside of this range are the relatively shallow stations 35 and 41 with salinities of 25.6 and 19.8 ‰, respectively. Heavy

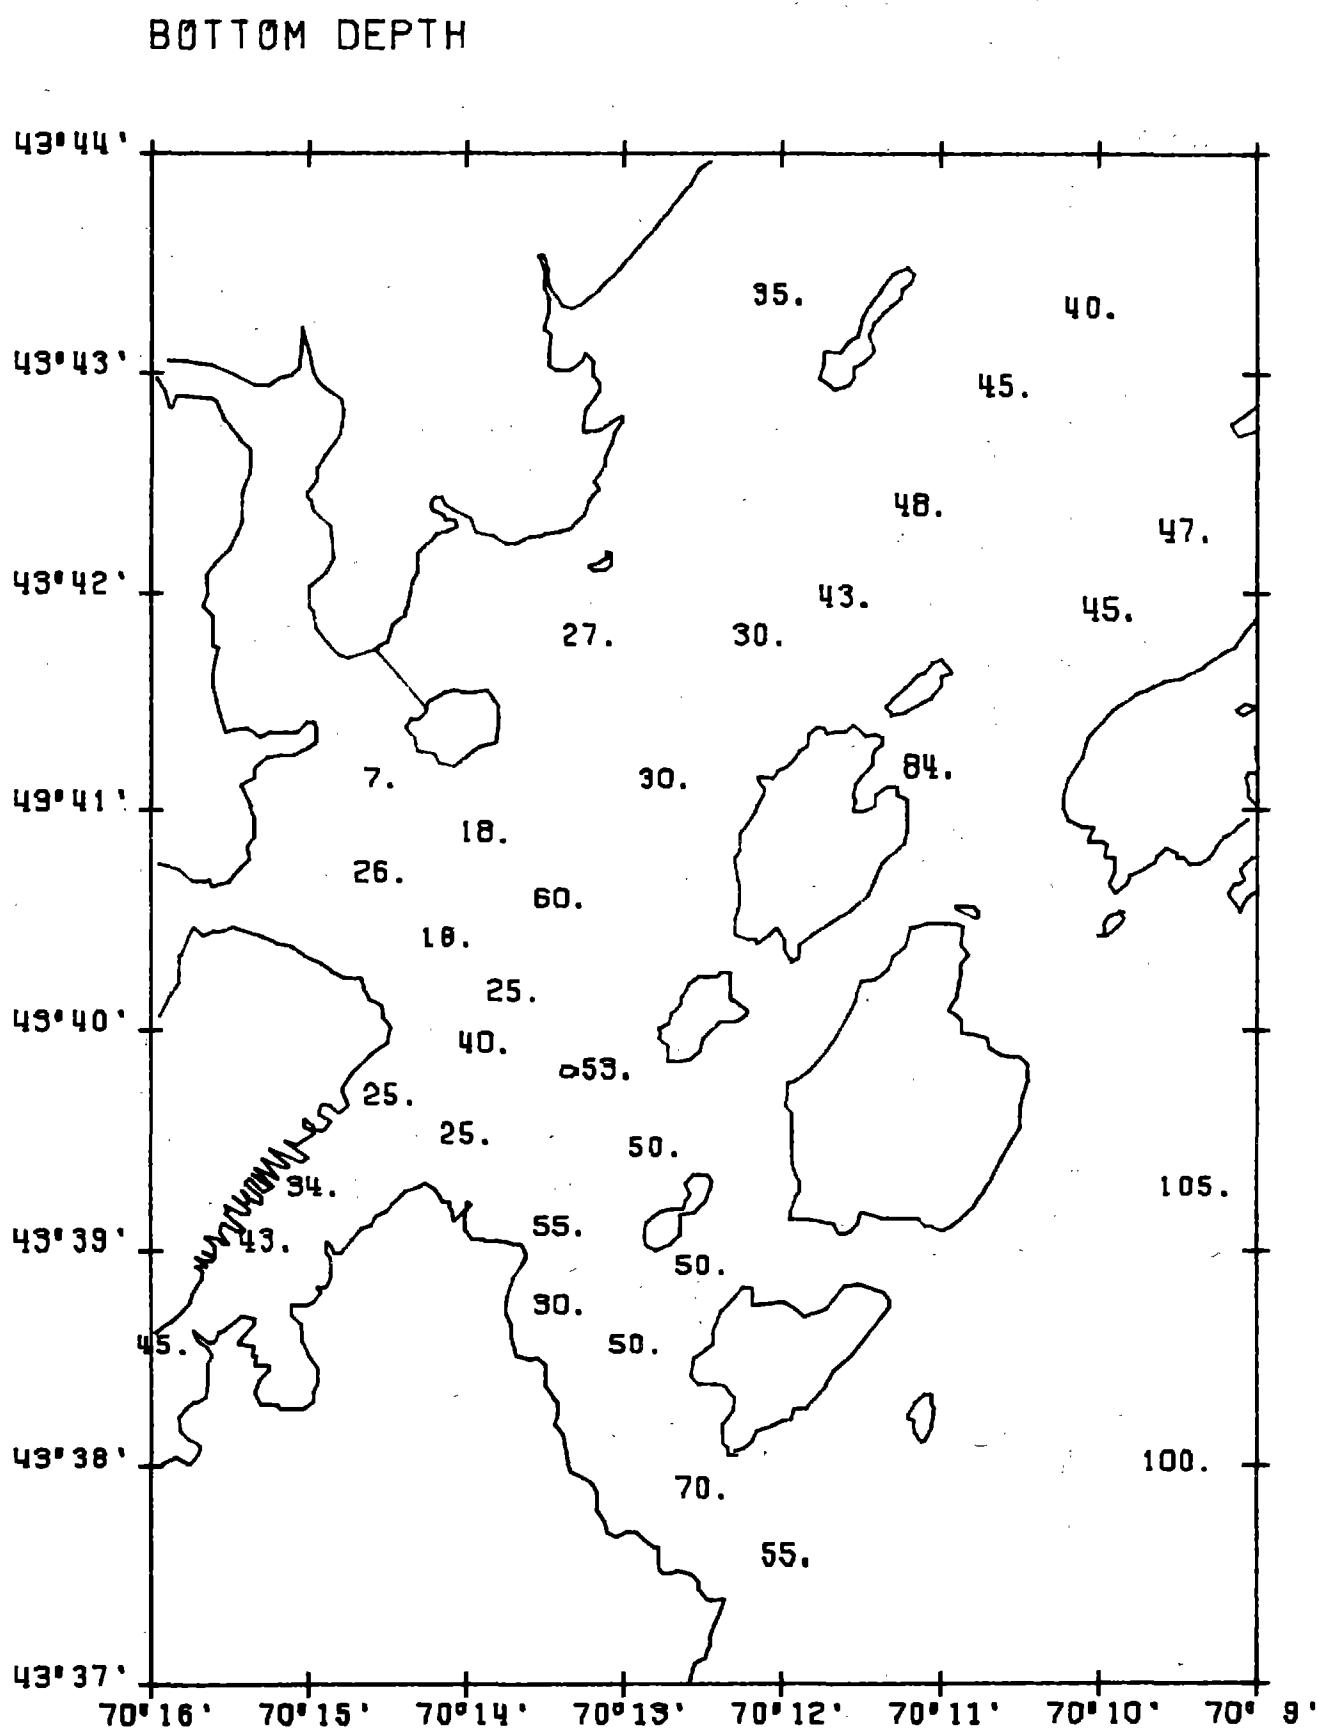

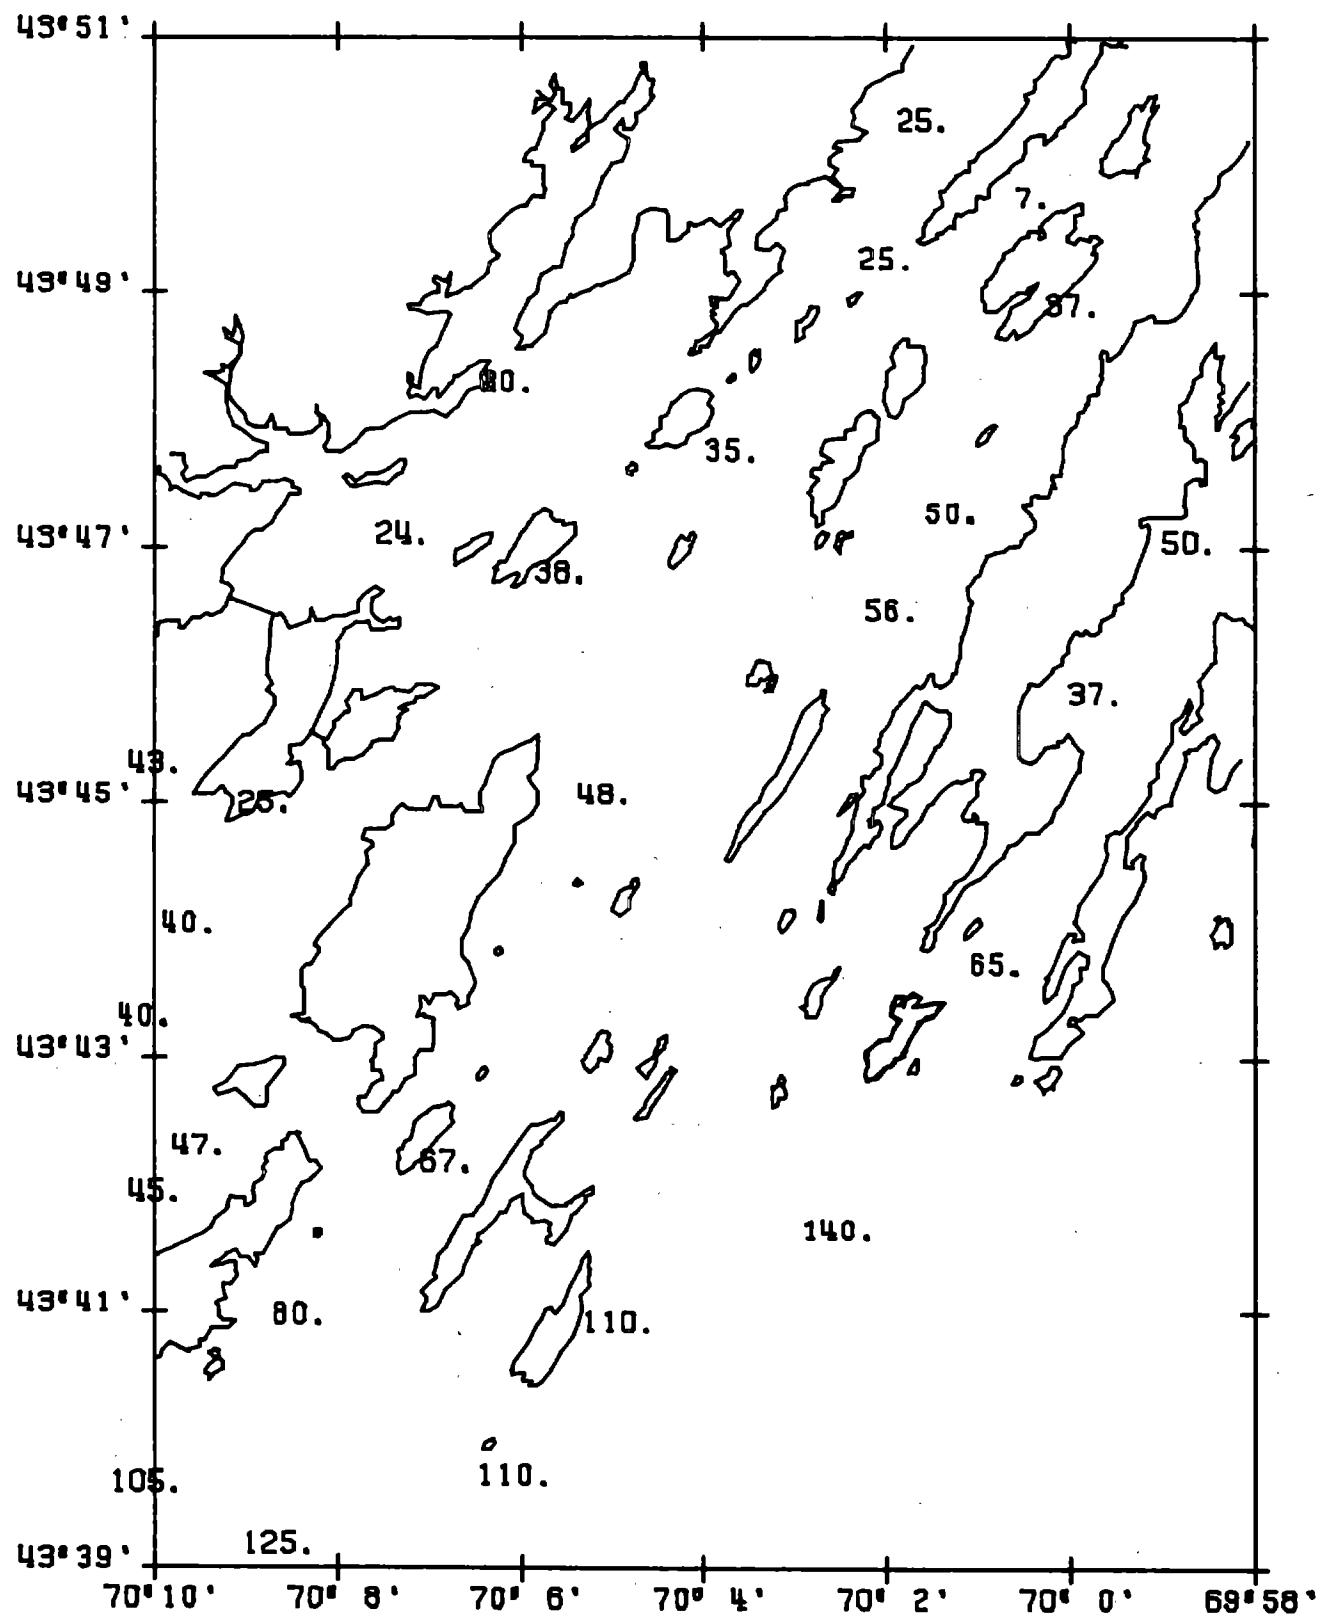

Fig. 5. Station depths in feet.

BOTTOM DEPTH

rains and the spring freshet of the Royal River presumably combined to temporarily depress the salinity at these stations.

No long-term temperature and salinity records are available for Casco Bay. Long-term records taken since 1906 at Boothbay Harbor, 30 kilometers to the east, however, are closely representative of Casco Bay (N. Garfield, personal communication). The annual temperature-salinity cycle based on monthly means of Boothbay Harbor is presented in Fig. 6. During the period of 1950 to the present, surface water temperature at Boothbay Harbor varied between the extremes of -2.3°C and 23.0°C , while salinity ranged from 25.0 to 33.6 ‰ (W.R. Welch, personal communication).

Sediments

The sediments of Casco Bay are predominantly fine (Table 2). Graphic mean grain size (Folk, 1974) ranges from -0.305 to 8.471 on the phi scale although the grand mean is in the fine silt range at 6.345. Only 8 stations have mean grain sizes in the sand range while 34 are in the silt range and 13 can be classified as clay. The sand stations are in areas of tidally scoured bottoms, such as the main approach to Casco Bay, or in areas recently dredged. Generally, coarser sediments are found offshore and in outer Portland Harbor, whereas fine sediments are characteristic of the central and upper part of the Bay (Fig. 7).

Regression of mean grain size in phi units against bottom depth in feet demonstrates that a significant relationship exists between the two (Fig. 8). The correlation coefficient of -0.3317 is significant at the 98% level. Remembering, in this and subsequent regressions, that since the phi scale is an inverse measure, this regression indicates that coarser sediments may be expected in the deeper portions of the sampling

GRAIN SIZE

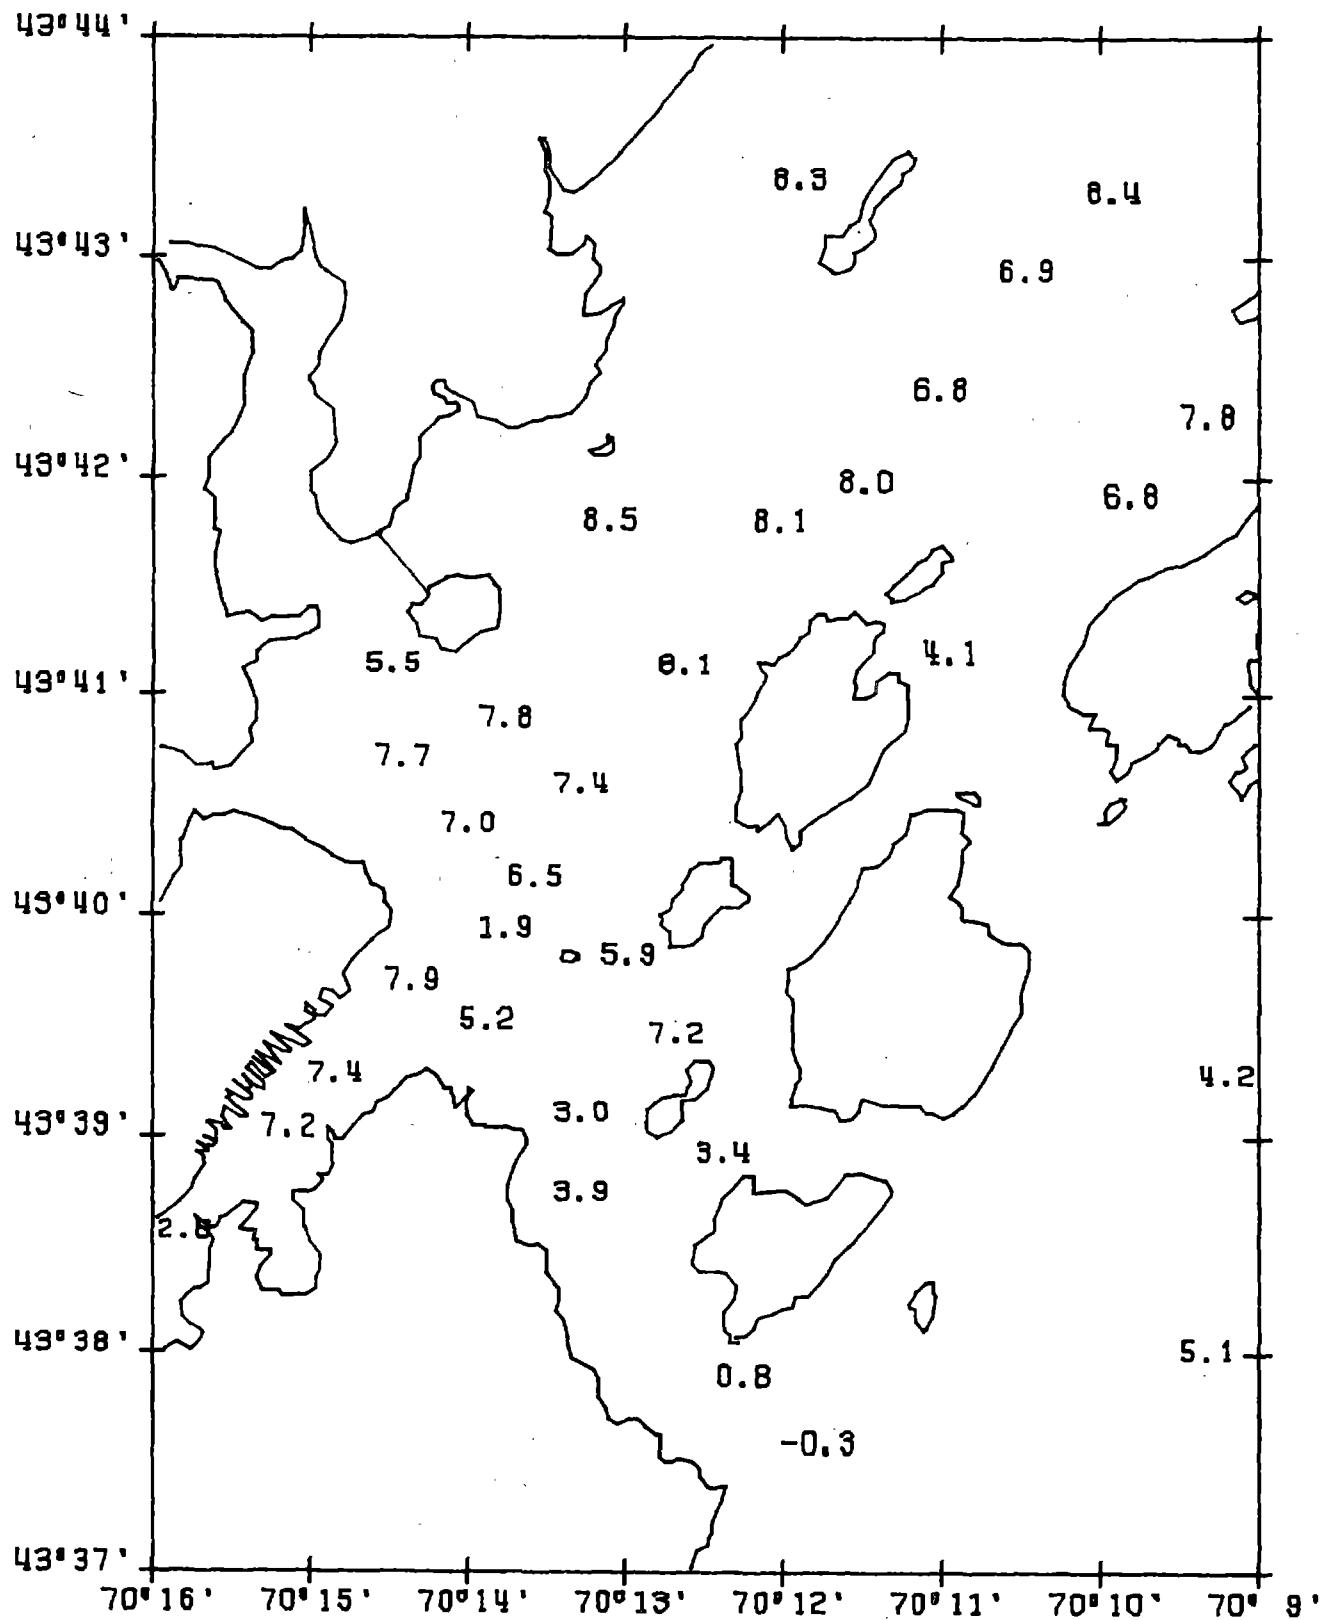

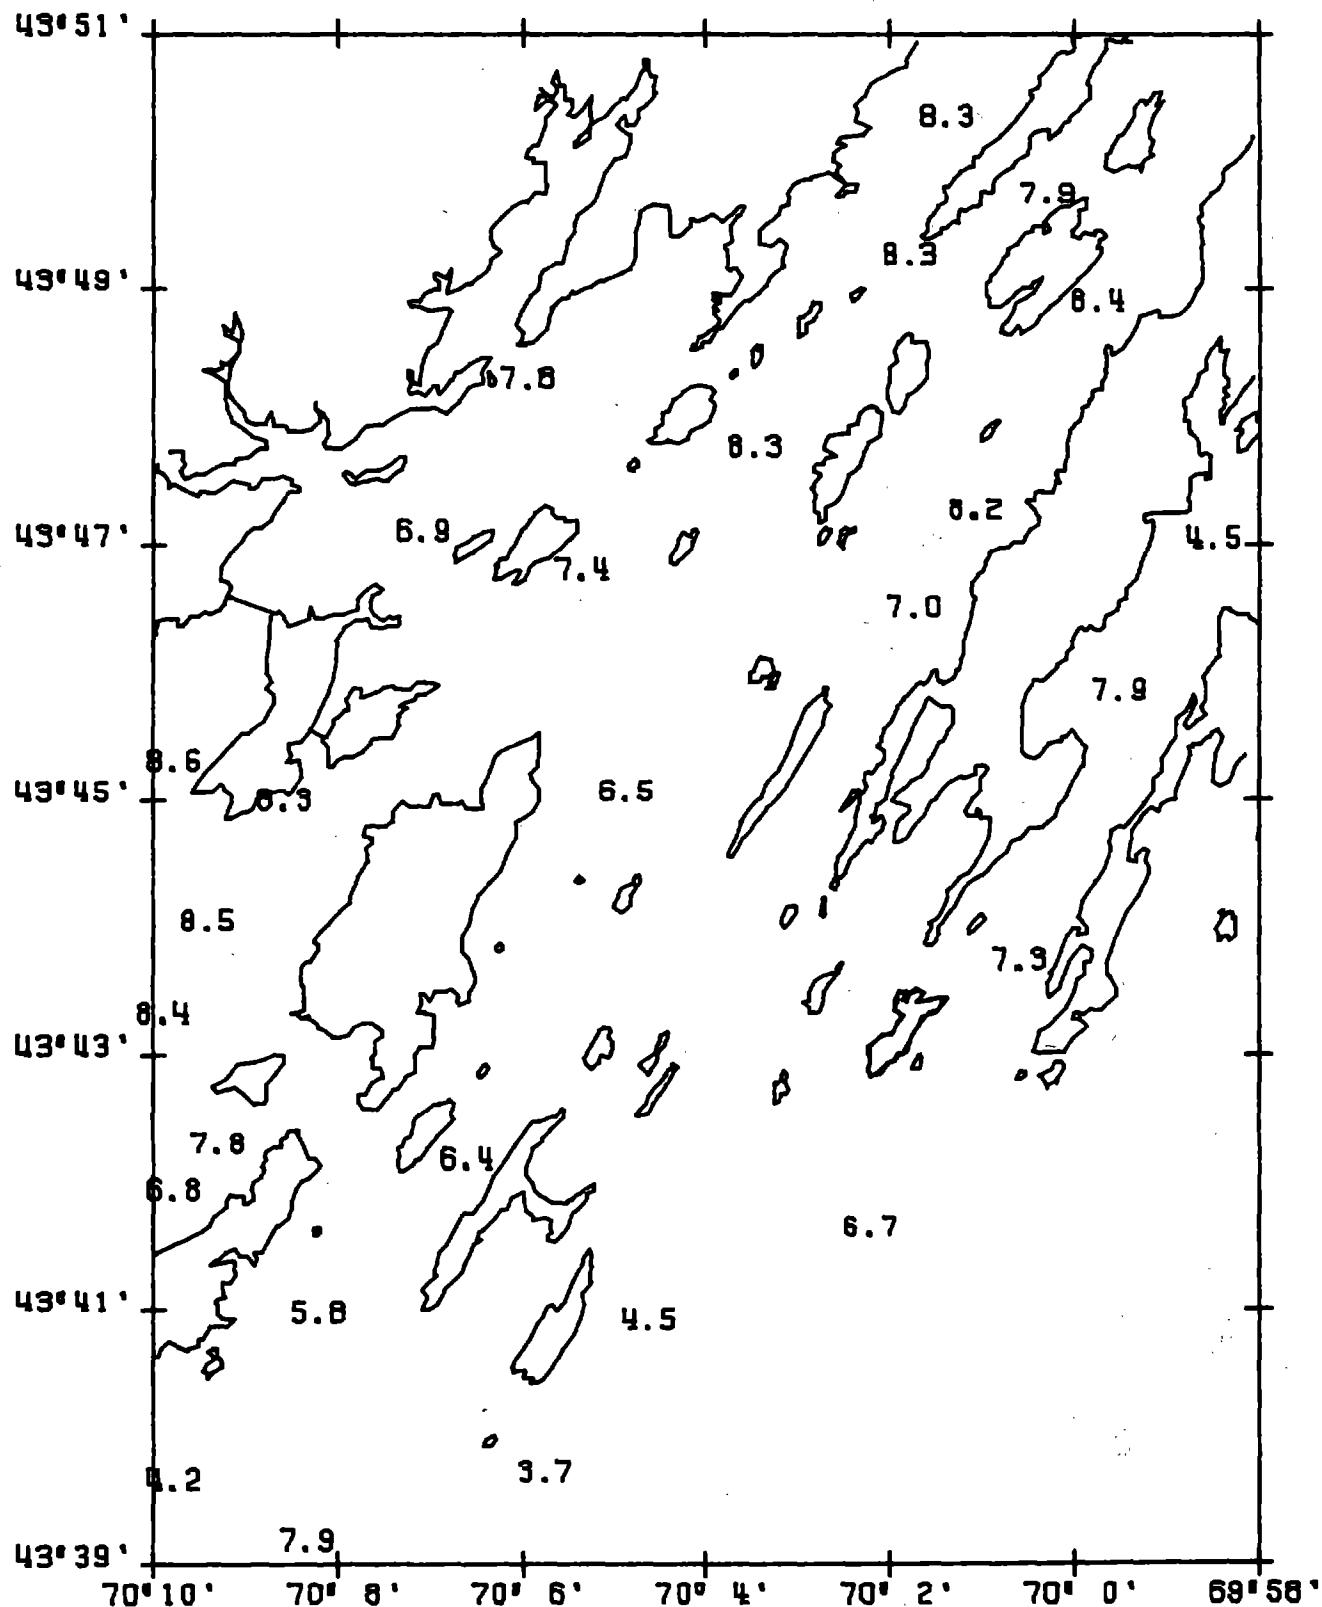

Fig. 7. The distribution of mean grain size in phi units throughout Casco Bay.

GRAIN SIZE

EX8001 CASCO BAY

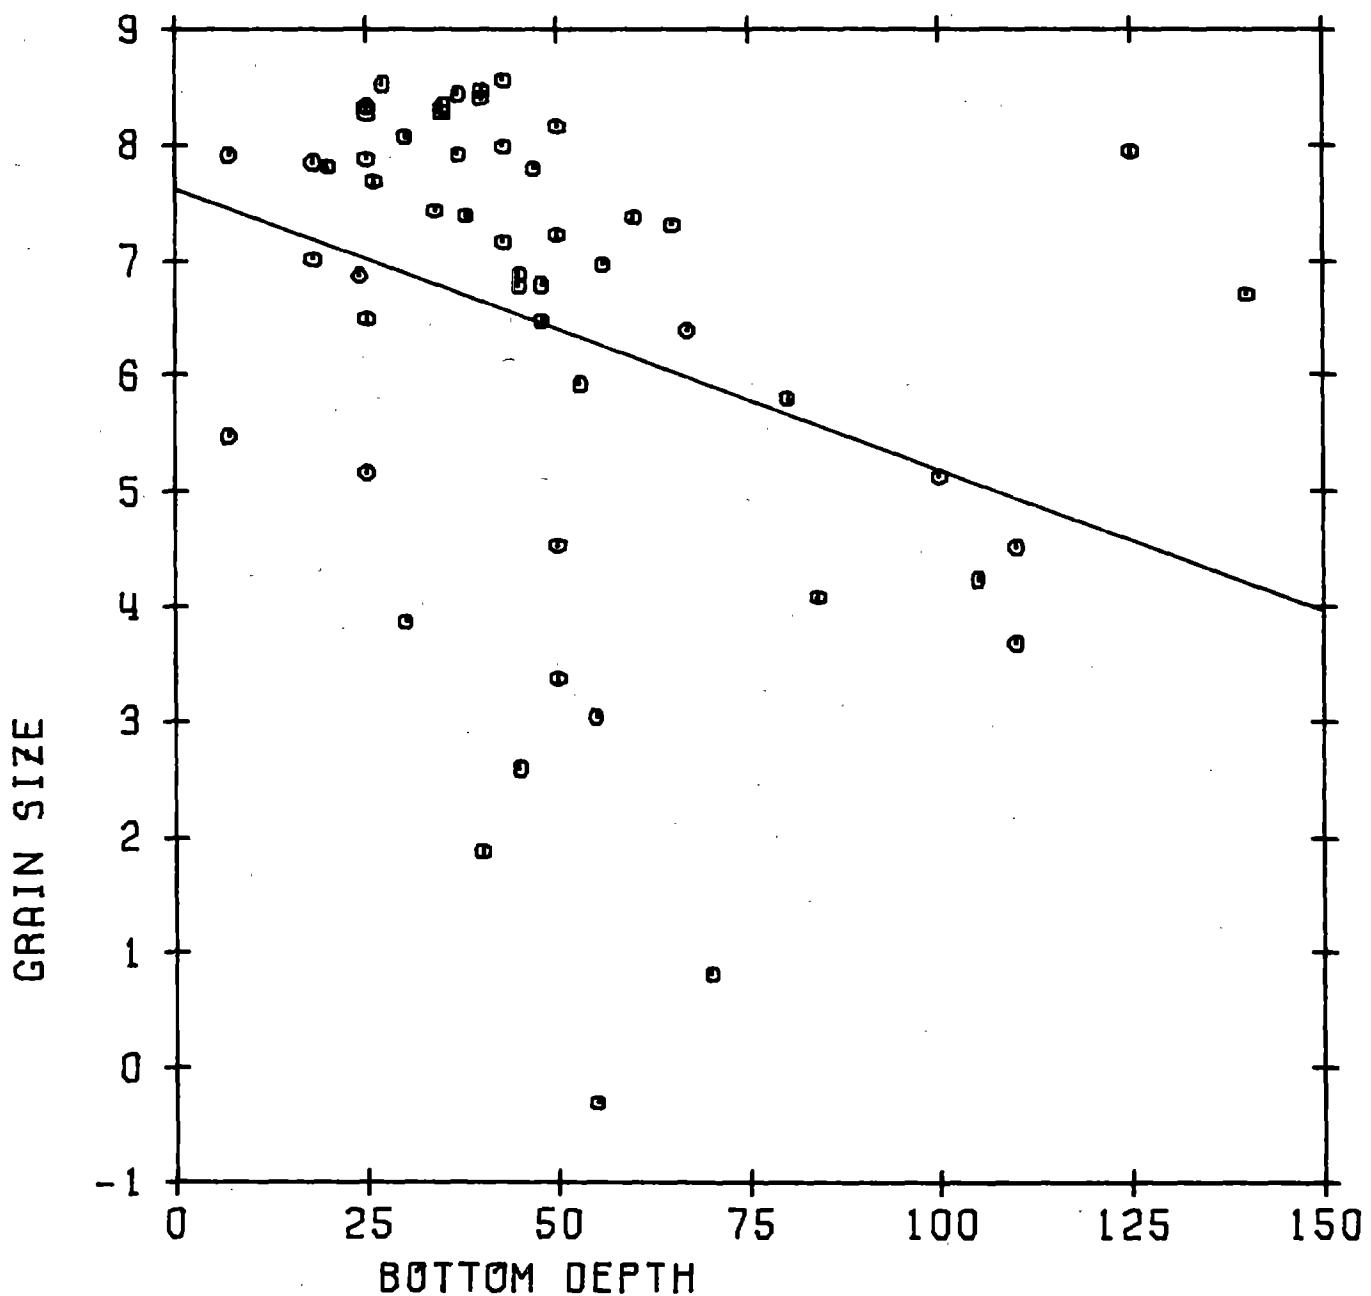

Fig. 8. Regression of mean grain size in phi units against depth in feet.

area. In many coastal areas sediments become coarser with increasing distance from shore and/or from river mouths because estuaries serve as traps for fine sediments. Since depth, too, commonly increases with distance from shore, a positive relationship between depth and coarse sediments might usually be expected in coastal waters. Due to the complex topography of the Casco Bay region, we cannot separate the effects of depth, distance from shore, or even distance from river mouths in regard to gross sediment parameters. We feel confident, however, that all three factors are operative in controlling the grain size distribution, hence the scatter around the regression line. Because we cannot meaningfully quantify distance from shore or distance from source, we use depth alone to represent a complex of related factors.

Fifty of the 55 stations have very poorly sorted sediments (Table 2). With the exception of station 9, a coarse sand station which is moderately well-sorted, the remaining stations are either poorly or extremely poorly sorted.

The percentage of sand, silt and clay were calculated for each sample and are plotted in Fig. 9 (see also Appendix 1). This presentation suggests that most samples contain approximately equal proportions of silt- and clay-sized particles and the mean grain size is largely a function of the amount of sand in the sample.

Consideration of grain size distributions and sorting coefficients does not in itself fully characterize the finer sediments of Casco Bay. Our experience in taking grab samples shows that the sediments are also extremely soft, i.e. have a very low bearing strength. Repeated lowerings of our specially modified grab often failed to obtain a

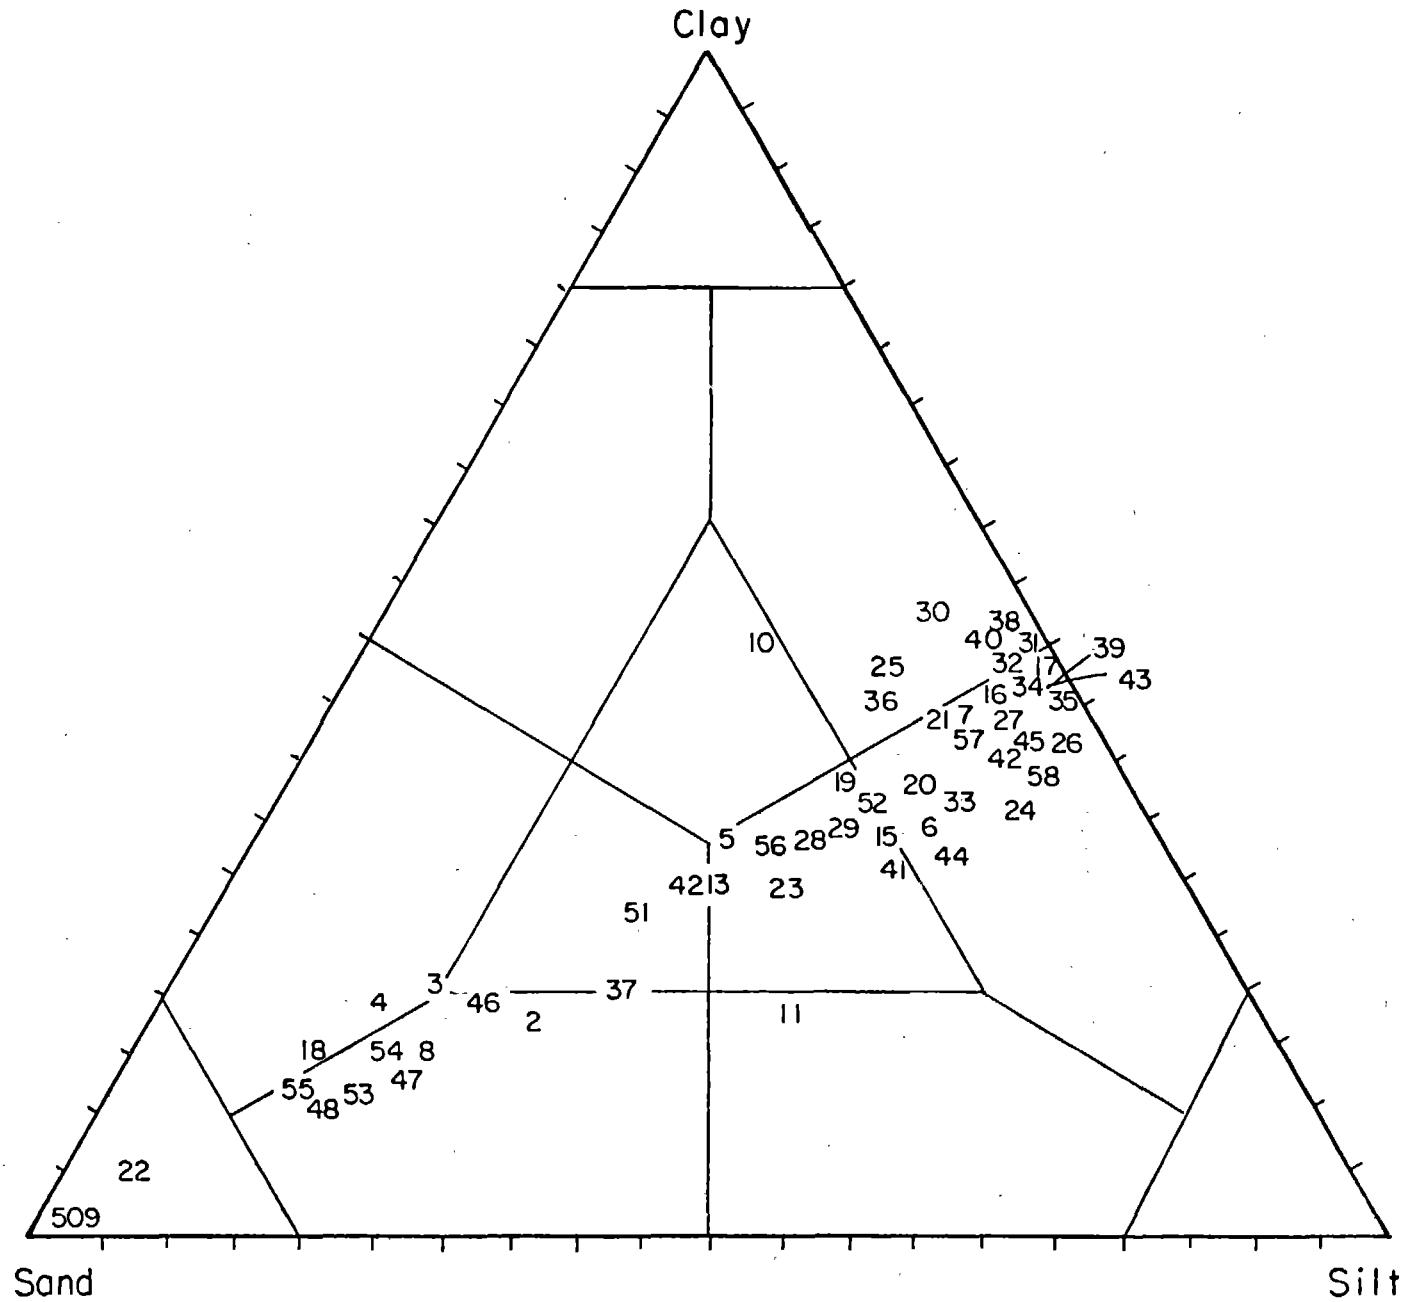

Fig. 9. The distribution of sand, silt and clay in the Casco Bay samples.

sample, although it had obviously been fully immersed in mud. In these situations, we were forced to move the station slightly to find a more cohesive bottom. Even here, however, the sediments visually resembled a loose gel. In these cases, the bucket screens offered little impediment to the grab's penetration into the bottom, and many organisms were caught on the screens. In essence, the sediments were so low in bearing strength that the grab sank to an unknown depth with the surface layers being sieved by the bucket screens in the process.

Timson (personal communication) observed a similar sedimentary phenomenon in Muscongus Bay, Maine, while working with sidescan sonar. He describes it as a nepheloid or gel layer which is intermediate between the water column and bottom. We call it fluid mud and believe it is caused by tidal currents which are strong enough to prevent complete deposition of silt and clay-sized particles, but which do not have a sufficient excursion to disperse them from the system. If this is true, we would expect variations in the depth and extent of the layer over a spring-neap tidal cycle. In any event, the phenomenon must have a profound effect on the nature of the benthic community and is worthy of additional study.

Sediment Carbon and Nitrogen

Sediment organic carbon values as determined by chromic acid digestion are presented in Table 2 and Fig. 10. Values range from 1.5 to 44.5 mg/g dry weight with an overall mean of 25.2 mg/g. Station 36, which exhibited 233.0 mg/g organic carbon due to a high proportion of wood chips, is an extreme outlier and is excluded from organic carbon numerical analyses. The station is located at the mouth of the Presumpscot River on a deposit of wood chips resulting from past

ORGANIC CARBON

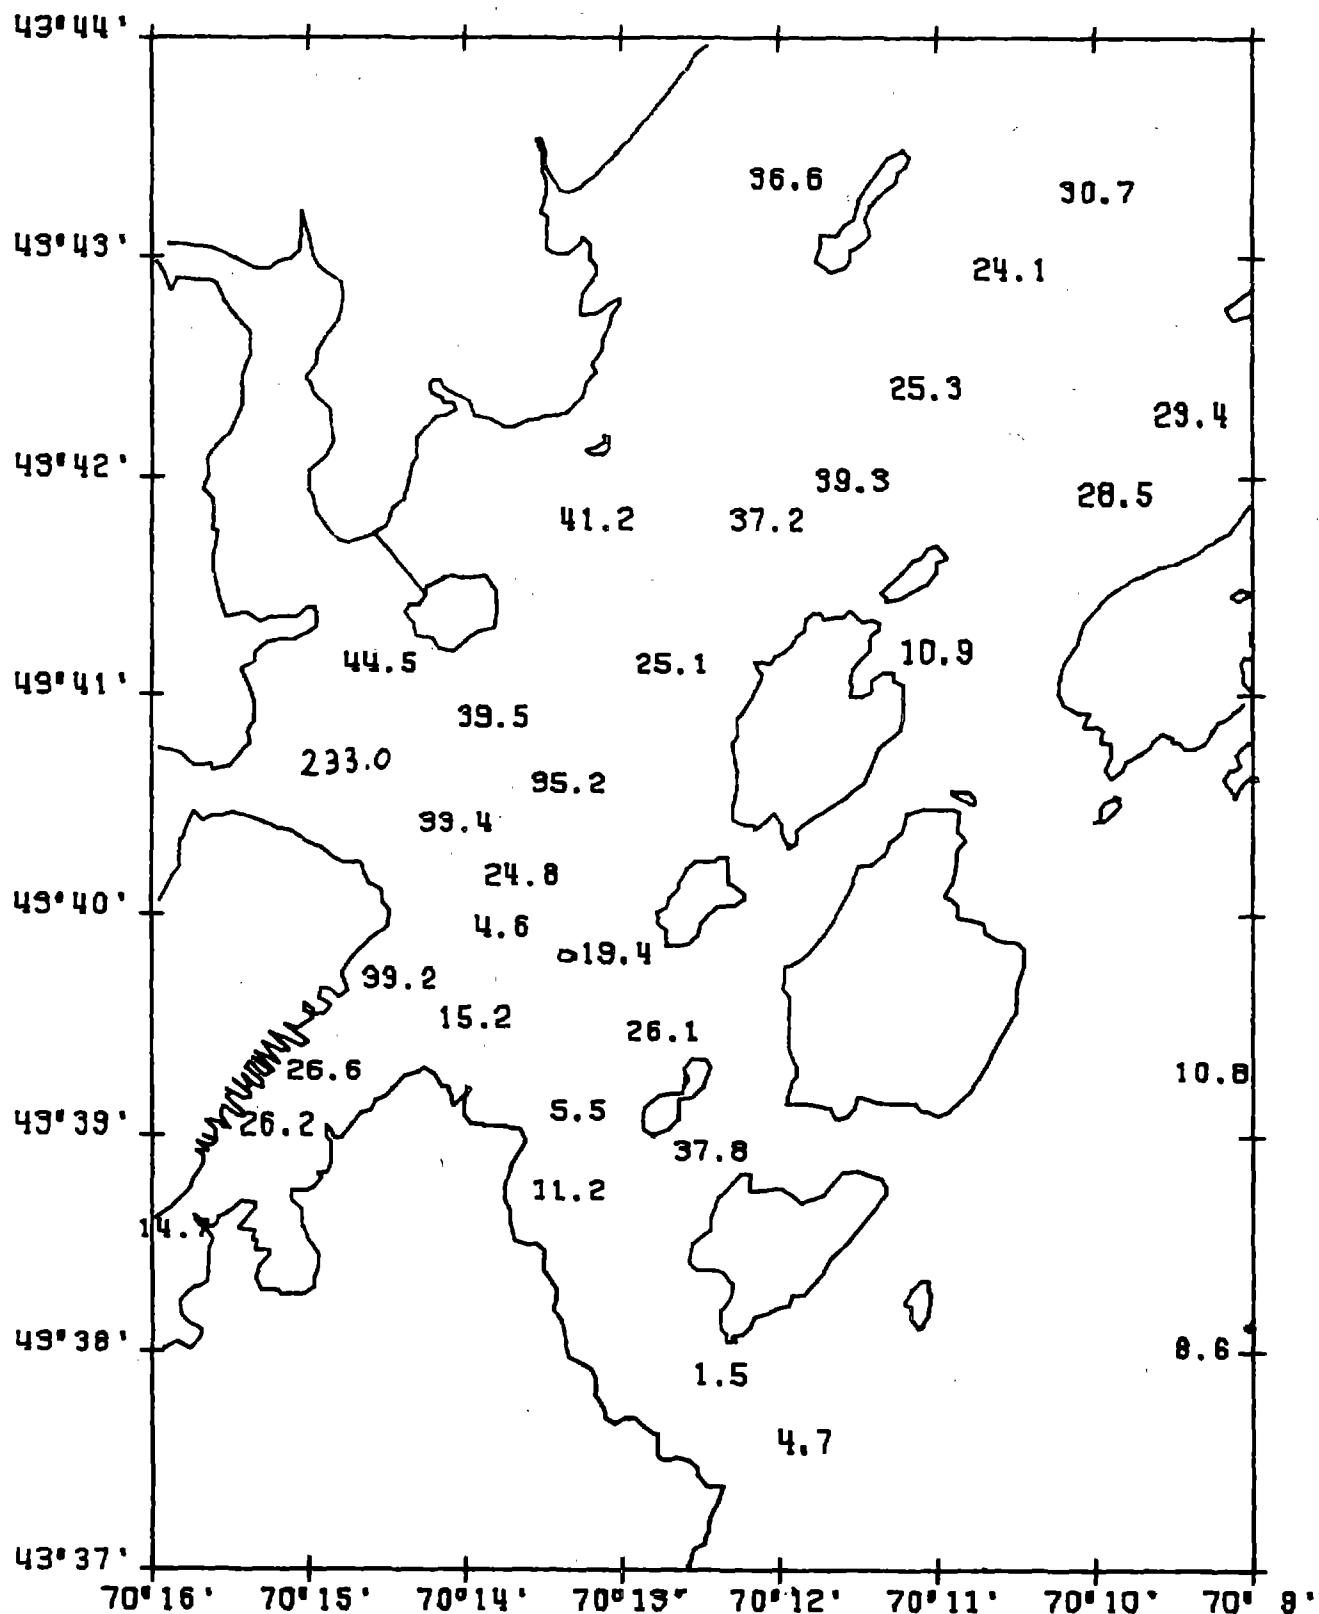

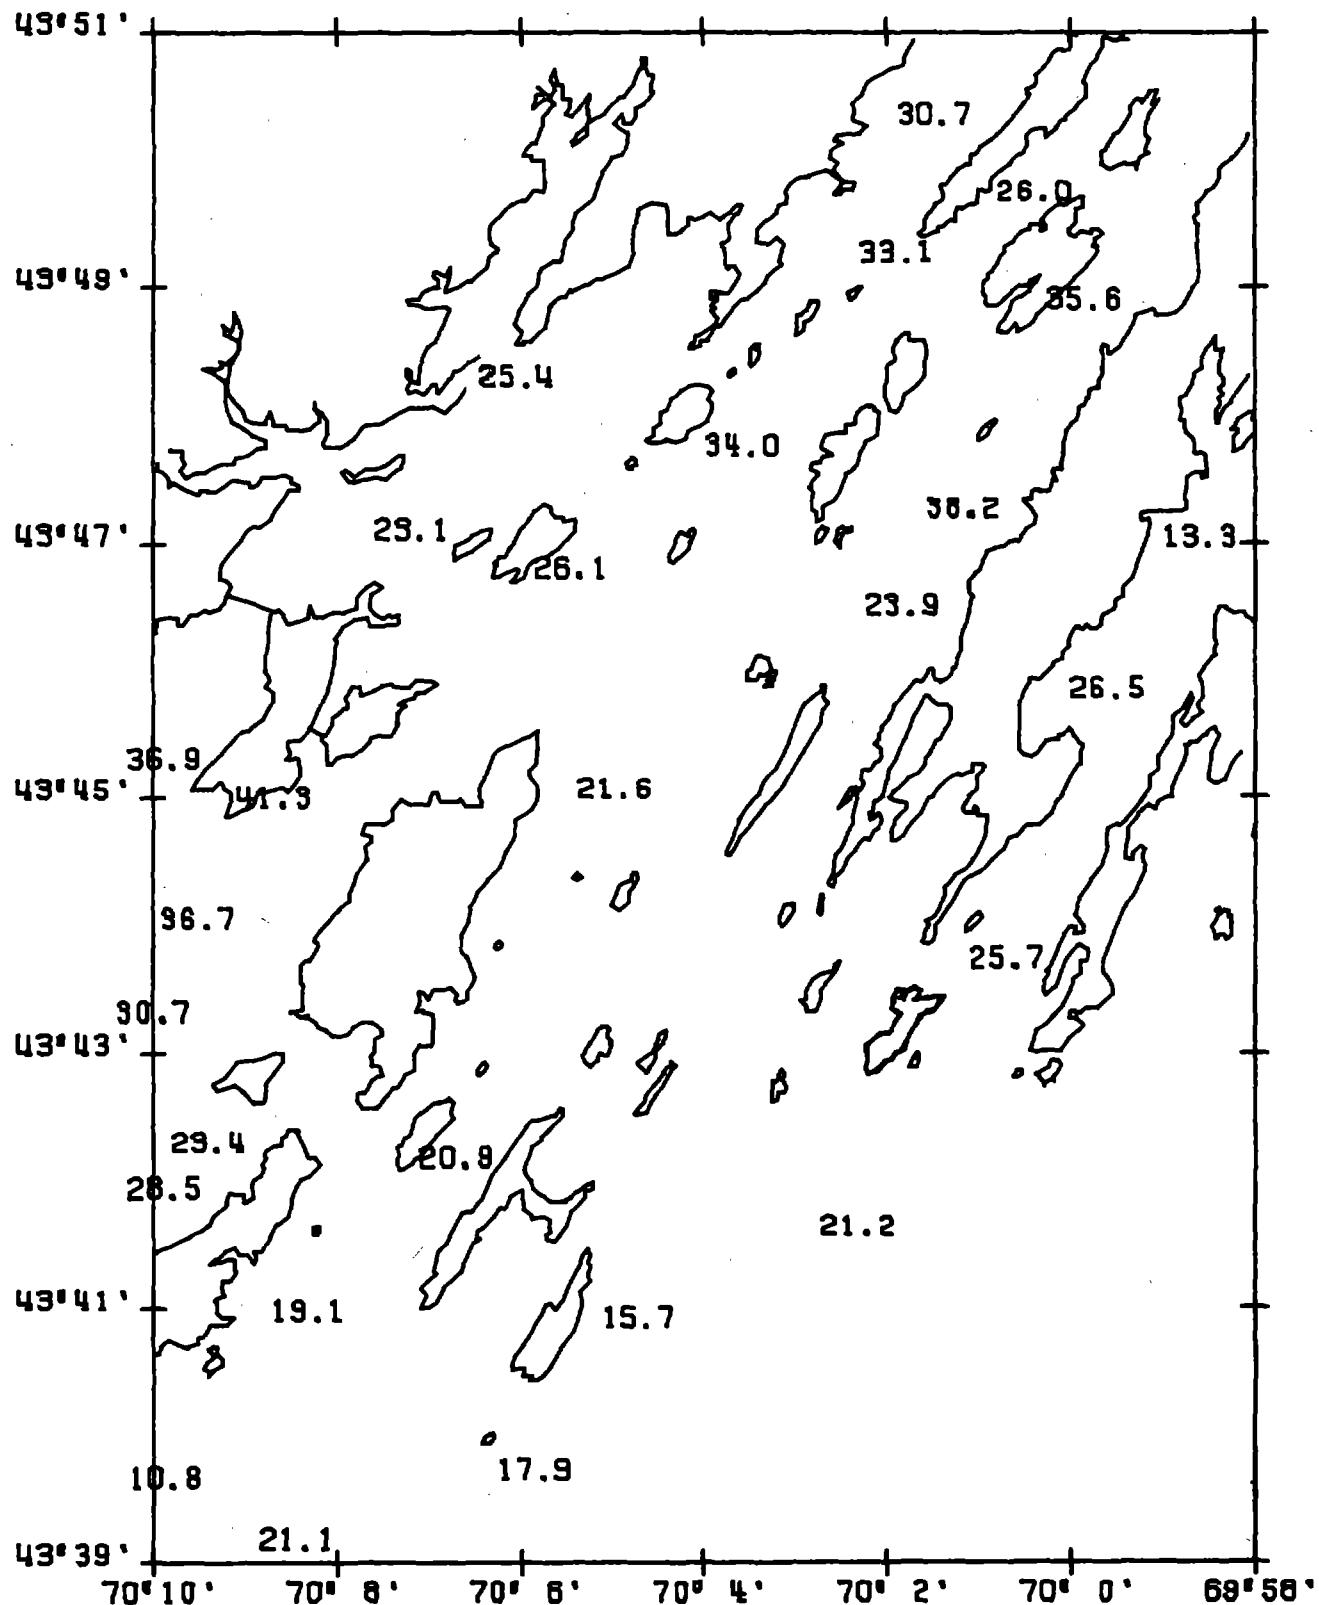

Fig. 10. The distribution of organic carbon (mg/g dry sediment) in the surficial sediments of Casco Bay.

ORGANIC CARBON

disposal of paper mill wastes into the river. No other station is so influenced.

Examination of Fig.10 shows that organic carbon levels lower than the average are generally confined to the approaches to Portland Harbor and the offshore stations. Stations with organic carbon levels considerably higher than average occur in a group in lower Casco Bay off Portland and Falmouth and at scattered sites close to land in the upper Bay. In an attempt to elucidate potential controlling factors of organic carbon distribution, organic carbon levels are regressed against bottom depth (complex factor), mean grain size and distance from Portland, the principal population and industrial center. Significant relationships exist for both bottom depth and mean grain size (Figs. 11 and 12). These relationships suggest that organic carbon levels decrease with increasing depth and increase with decreasing mean grain size. The correlation coefficients are -0.4756 and 0.7742, respectively, and both are significant at the 99.9% level. We show above, however, that bottom depth and mean grain size are themselves related and therefore, it is not clear from this analysis whether organic carbon level is influenced by one or both of these factors. By employing multiple regression analysis, it is shown that organic carbon level is significantly related only to mean grain size (Table 3).

| Error | 50 | | 2079.9867 | | |

Total Kjeldahl nitrogen values are also presented in Table 2. Values range from 0.038 to 1.294 mg/g. To date no attempt has been made to interpret these results. They are included for completeness.

Trace Metals

Subsamples from 32 stations were analyzed by atomic absorption spectrometry for the metals cadmium, chromium, copper, lead, nickel and zinc. Results, as ppm dry weight, are presented in Table 4.

Cadmium is present in the sediments of Casco Bay in concentrations ranging from 0.20 to 0.90 ppm with a mean value of 0.50 ppm. Highest cadmium values occur in the Portland vicinity and at station 53, the former domestic dumpsite for Peaks Island residents (Fig. 13). Lowest cadmium levels are found at the offshore stations while the remaining stations deviate little from the mean.

Chromium levels average 34.5 ppm and range from 5.85 to 55.0 ppm (Table 4). The approaches to Portland Harbor exhibit the lowest

CADMIUM

chromium levels and the Portland area in general is characterized by low to moderate chromium levels (Fig. 14). Stations in Portland Harbor proper and in mid and upper Casco Bay generally have higher than average values.

Sediment levels of copper in Casco Bay range from 2.40 to 44.5 ppm with an overall mean of 15.5 (Table 4). Only five stations exhibit copper levels of over 20 ppm. These are the three stations in Portland Harbor and stations 52 and 53 (Fig. 15). The gradient of decreasing copper levels down the Fore River is suggestive of an upstream source. Once again, lowest copper levels are found in the sandy main shipping channel into the Bay and at the offshore stations. Upper Bay stations generally are close to the mean in copper concentration.

Lead concentrations in the sediments range from 9.0 to 61.4 ppm with an average of 26.8 (Table 4). Its distribution is similar to that of copper, i.e. high concentrations in Portland Harbor with a decreasing gradient down the Fore River, low concentrations in the tidal channel and at most offshore sites, and low to moderate values throughout the remainder of the Bay (Fig. 16).

Unlike the other metals, nickel does not show a strong pattern in its distribution (Fig. 17). Concentrations range from 4.53 to 32.0 ppm with a mean of 17.6 ppm. The extreme high value occurs at station 17 in upper Casco Bay. Low values are found principally in channel areas and just offshore, but even this pattern is not as clearly developed as for the other metals.

Zinc concentrations in Casco Bay sediments average 65.4 ppm and range from 20.5 to 100.5 ppm (Table 4). Highest values occur in

NICKEL

Portland Harbor although stations with values well above the mean are found scattered throughout the Bay (Fig. 18). Low values are again grouped in the outer shipping channel and offshore of the islands.

Whereas upland drainage may be an important source of metals deposited in coastal sediments, it does not seem to explain the elevated levels in the Fore River (called the Stroudwater River in its non-tidal portion). The Fore River has a small drainage area (28 sq. miles) relative to the two other principal rivers entering Casco Bay, the Presumpscot (590 sq. mi.) and the Royal (142 sq. mi.), which show little or no elevation of metal levels near their mouths. In addition, above Portland, the Fore River is largely surrounded by tidal marshes and residential developments serviced by municipal sewers which discharge elsewhere. It seems likely, therefore, that the elevated metal levels in Portland Harbor sediments result from anthropogenic introductions within the harbor and the industrialized lower Fore River estuary. Additional sampling above Portland will be required to prove this hypothesis.

Linear correlations were computed for the six metals as well as percent organic carbon and mean grain size on the phi scale (Table 5). This analysis shows that, as demonstrated elsewhere (i.e. de Groot *et al.*, 1976), metal levels in Casco Bay surficial sediments are highly correlated with fine grained sediment and levels of organic carbon. That these factors are significant is a reflection of the large surface area of fine-grained sediments and the sorptive capacity of many organic compounds. These relationships help to explain the areal distribution of the metals as, for example, the uniformly low levels encountered in the coarse sediments in the main entrance to Casco Bay.

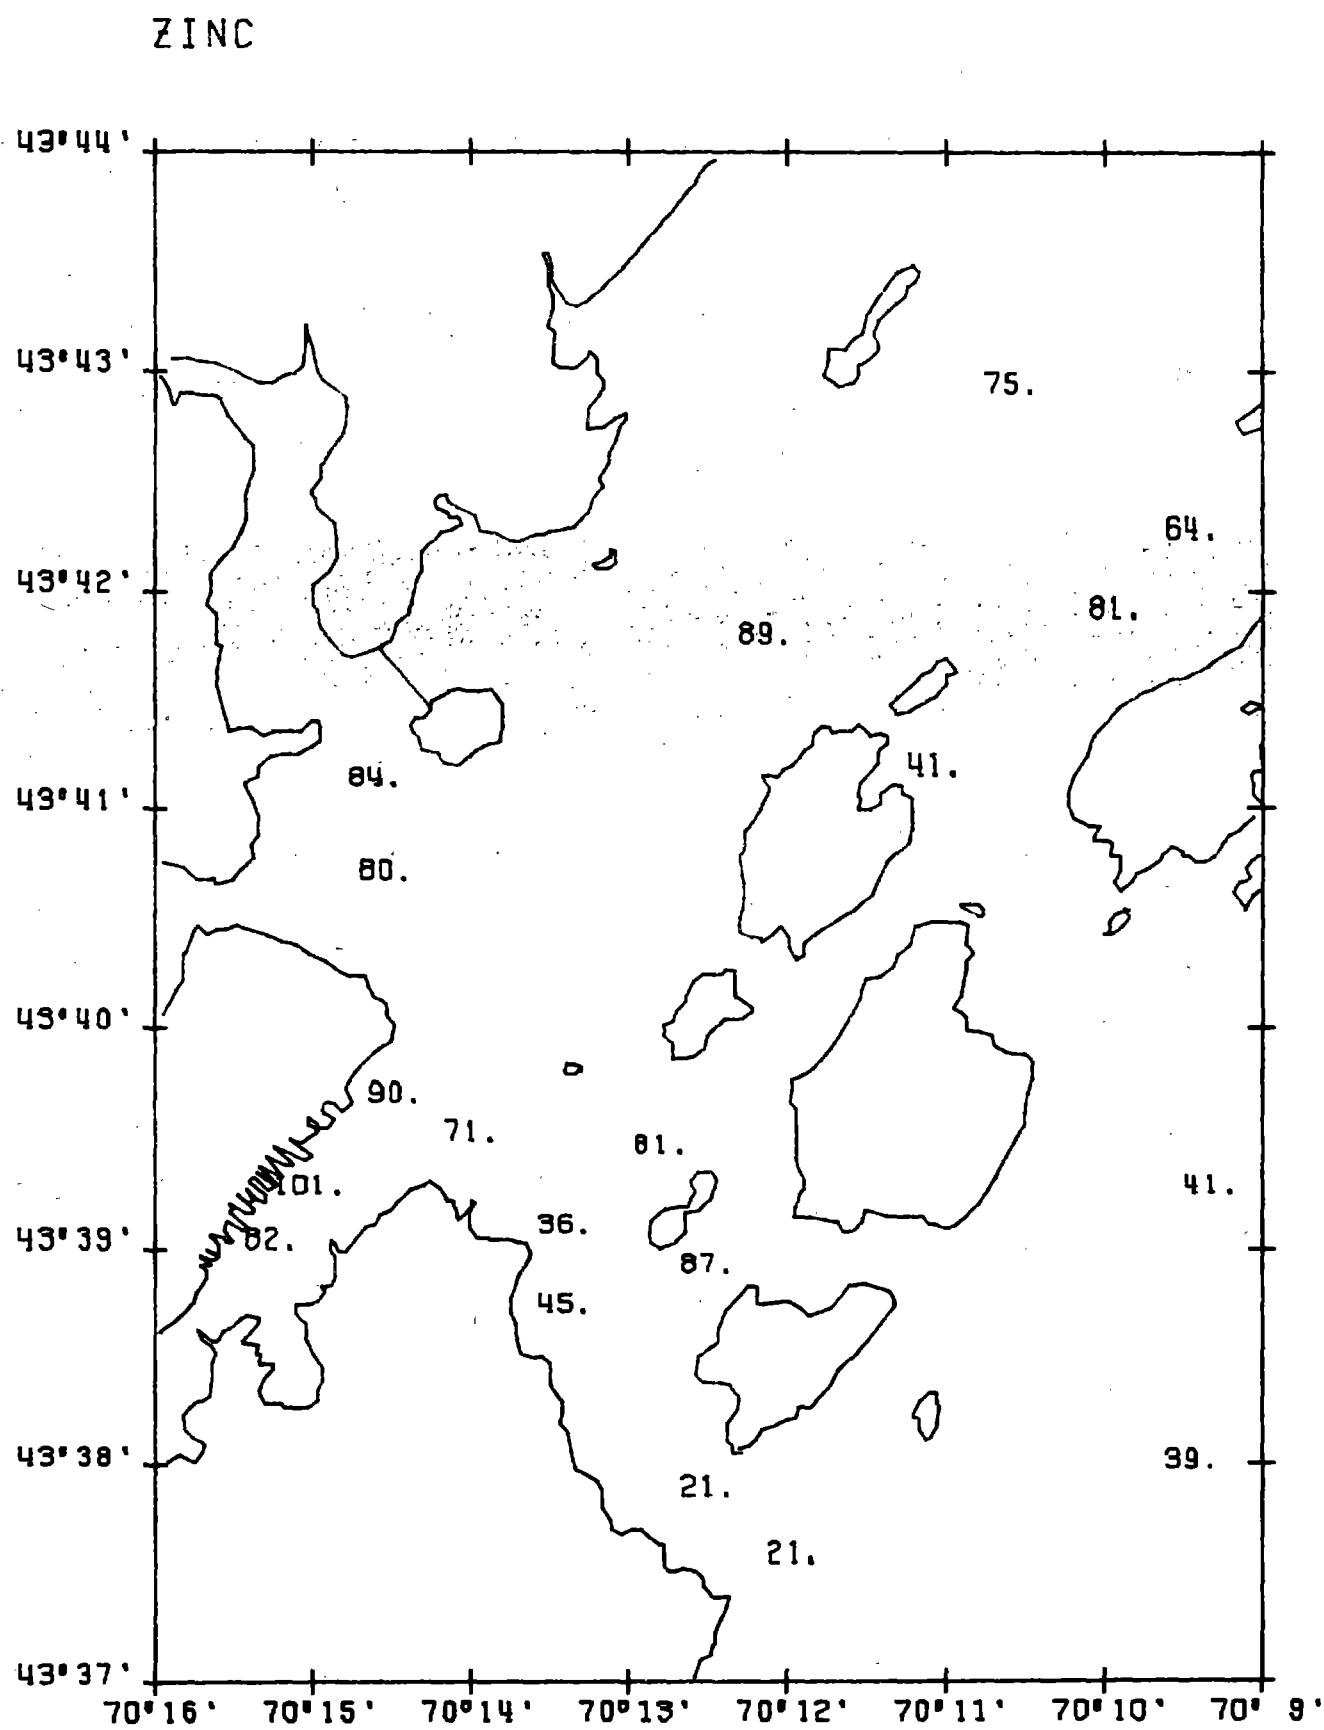

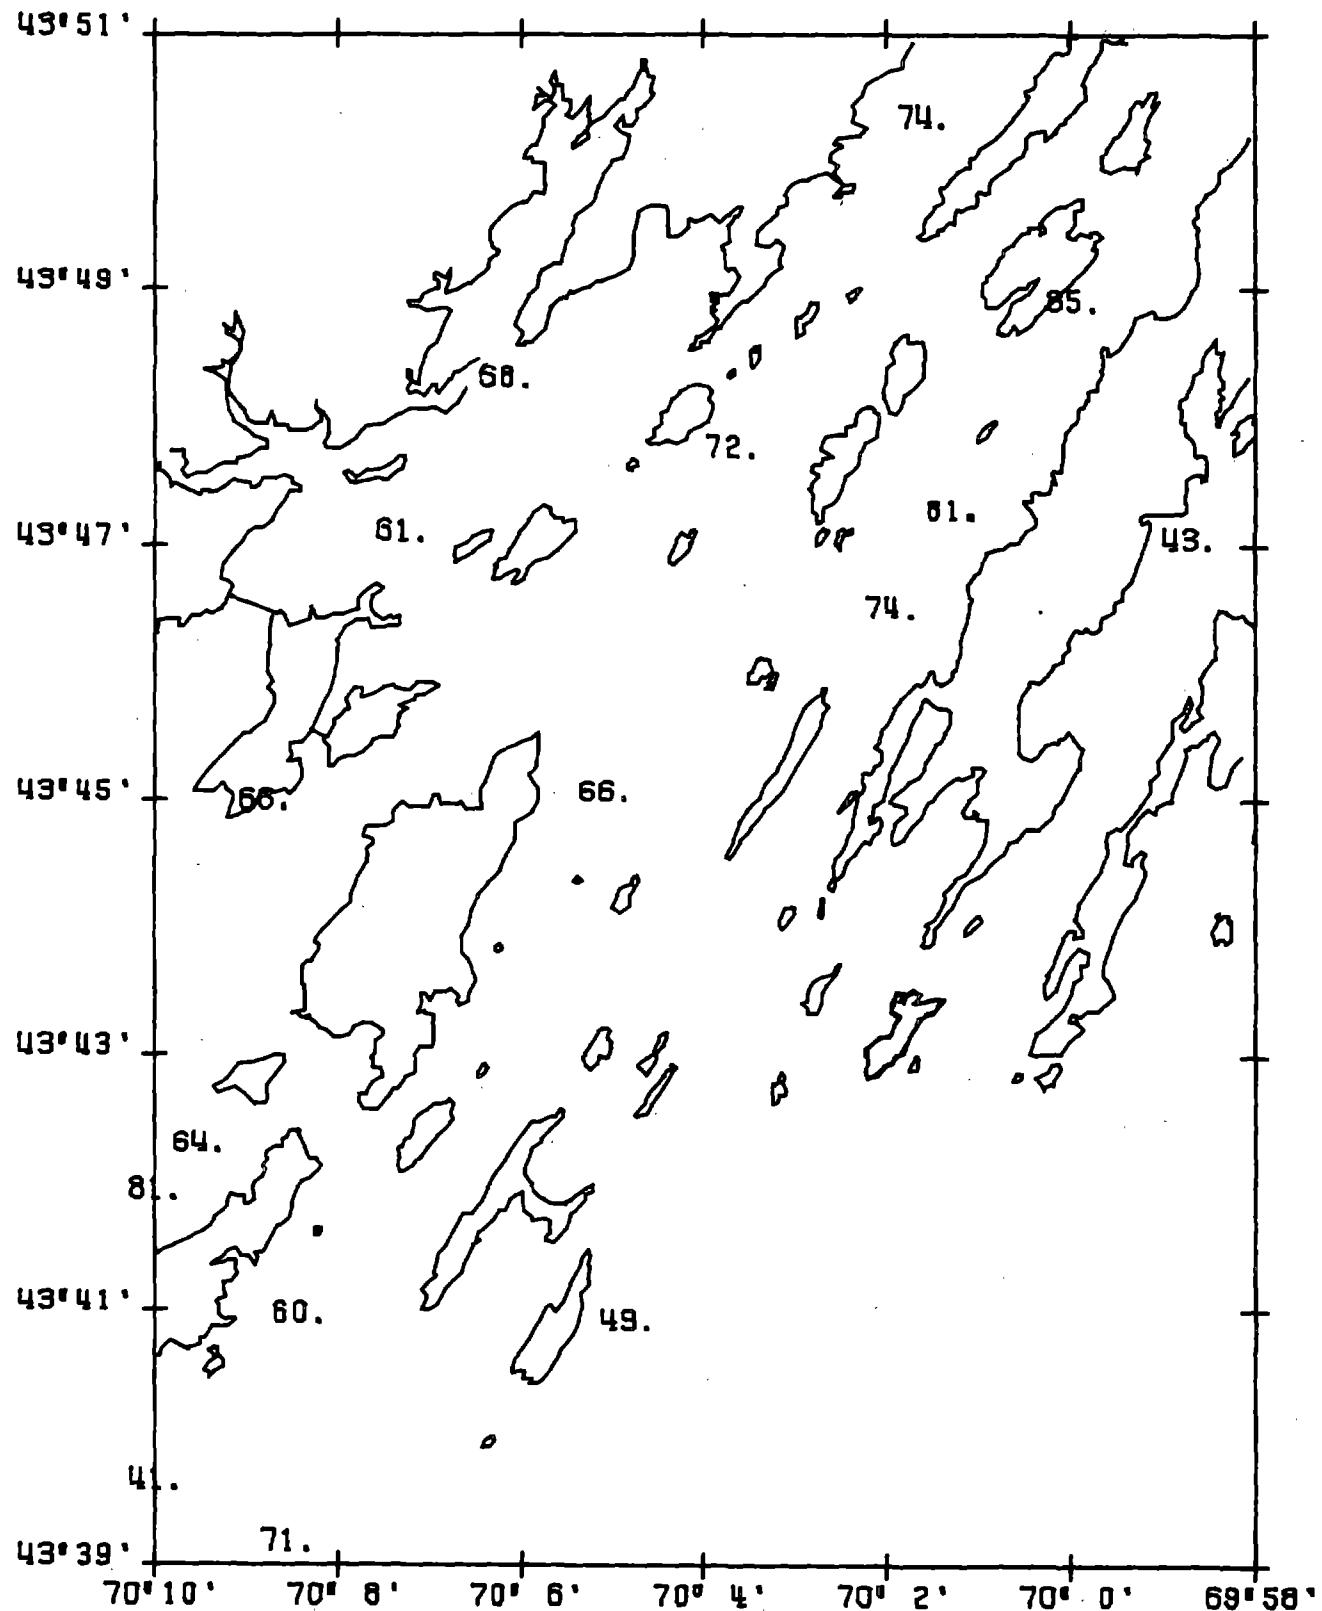

Fig. 18. The distribution of zinc (ppm dry weight) in the surficial sediments of Casco Bay, Maine.

ZINC

The six metals were also highly correlated to each other in terms of their distribution and concentration (Table 5). The only exceptions to this generalization are the correlations of nickel with cadmium and lead with chromium.

Comparison of trace metal levels in Casco Bay sediments with levels found in other recent New England investigations will help to put these results into perspective. Five studies utilizing comparable methodology are available for comparison. Lyons *et al.* (in press) examined trace metal levels in five northern New England estuaries. They concluded from sediment profiles that three of them, Machias Bay, Cape Rosier and the Seabrook River estuary show little increase in trace metal

concentrations over the past century and are probably representative of pre-industrial levels. Two other estuaries, the Saco and Kennebec, exhibit recent anthropogenic enrichment due to industrial and/or sewage inputs. Armstrong *et al.* (1976) determined trace metal values of the sediments of the Great Bay estuary which has been historically subjected to industrial discharges. Lyons and Gaudette (1979) investigated concentrations in Jeffreys Basin, a fine-grained depositional area off the coast of southern Maine and New Hampshire. They concluded that the relatively high levels found there are the result of fine-grained sediment export from estuaries. Two southern New England estuaries, the unpolluted Mystic River estuary and the impacted Branford Harbor, were contrasted by Lyons and Fitzgerald (1980). Finally, Greig *et al.* (1977) analyzed a large number of sediment samples from Long Island Sound, a large, highly "urbanized" estuary. For purposes of comparison we have used only their results from the eastern half of the Sound, stations 72-143, to avoid the overbearing influence of inputs from the New York City area.

Trace metal levels at the 11 New England sites are contrasted in Table 6. It is important to remember that trace metal distributions in Casco Bay are very heterogenous and the mean values are only a gross representation of the conditions in a given subarea. Cadmium levels in Casco Bay compare favorably with the three other sites having reported values. The mean value is close to that of the unimpacted Mystic River estuary and considerably lower than the values reported for Branford Harbor and eastern Long Island Sound. Casco Bay sediments appear to be moderately enriched in terms of chromium. The mean concentration is nearly twice that of the pre-industrial levels of northern New

England estuaries, but an order of magnitude lower than the Saco and Great Bay estuaries, both of which are highly enriched with chromium due to tannery operations (Armstrong *et al.*, 1976; Mayer and Fink, 1980; Lyons *et al.*, in press).

Copper levels in Casco Bay are also elevated relative to the non-industrialized estuaries and are comparable to the other impacted sites with the exceptions of the Kennebec River estuary, Maine and Branford Harbor, Connecticut. Long Island Sound is the only other site from which nickel data are available and the mean value is much lower than that of Casco Bay.

The mean value of lead in Casco Bay sediments is higher than that of the four non-industrialized sites and Long Island Sound, but generally lower than the other industrialized estuaries. Mean zinc concentration, on the other hand, is only exceeded by that reported for Jeffreys Basin.

These results show that trace metals are not distributed homogeneously in the Casco Bay region. Whereas a strong correlation exists between metal concentrations and both mean grain size and organic carbon concentrations, there is also a strong geographic pattern not completely explained by these relationships or the location of freshwater inputs. In general, high trace metal levels are found in the Portland area, which includes the lower Fore River estuary, low levels are found in scour channels, relatively low concentrations are encountered at the offshore sites and moderate levels occur in the very fine sediments of central and upper Casco Bay. In addition, four metals exhibit a gradient down the lower Fore River estuary suggesting an upstream addition.

Comparisons with other New England sites indicate, with the possible exception of cadmium, that trace metal concentrations in Casco Bay are elevated well above presumed pre-industrial levels. Mean values of each of the other metals examined are comparable to levels reported from other industrialized New England areas.

Realizing that trace metal concentrations from stations in the Portland area are generally much higher than the mean, and that the mean is reduced by low concentrations elsewhere in the Bay, it is concluded that the sediments of Portland Harbor and the lower Fore River estuary are impacted by trace metals. Sediment profile studies are needed to put the present levels into a historical context.

Hydrocarbons

The 32 hydrocarbon subsamples are in the process of analysis. These results will be integrated into our overall analysis as soon as they are available. Preliminary results indicate high levels of one or more groups of hydrocarbons in Casco Bay sediments.

Visual examination of the samples indicated very high levels of sediment hydrocarbons in the Portland area. Indeed, a couple of samples were extremely difficult to pick because hydrocarbons formed a film on the picking trays, forceps and organisms. Oil was also observed at one of the sandy stations that is presumably well-flushed.

The Fauna

The 56 0.1m^2 grab samples sieved to 1.0 mm yielded 264 putative species (Table 7). Two hundred and thirteen of these were identified to the species level. The molluscs, annelids and arthropods were the best represented groups accounting for 16.6, 42.0 and 26.1% of the species respectively. Species list for individual stations are presented in Appendix 2.

Many of the species occurrences are interesting in terms of their presence or abundance. For instance, one of the dominant polychaetes, *Aglaophamus neotenus*, was described only very recently (Blake, 1980). Among the isopods, both the Virginian *Cassidinidia lunifrons* and the Arctic *Munna fabricii* were found within the limited confines of Casco Bay. Undescribed members of the amphipod genera *Melita* and *Monoculodes* were encountered as were individuals of the genera *Bathymedon*, *Halimedon* and *Gitanopsis*. These latter, and perhaps several other records, represent range extensions which will be treated in another contribution.

Density

Numbers of individuals ranged from 120 to $36,380/\text{m}^2$ with a mean of $8,743/\text{m}^2$ (Table 8). The lowest value occurred at station 36 in the wood chip deposits while the highest value was recorded at the nearby station 37 which was located in a mussel reef. Density distribution is presented in Fig. 19. Values exceeding $10,000/\text{m}^2$ are generally found at the offshore stations and at several stations in the lower Bay.

Three regions of low density stations are noticeable. These are stations 47, 49 and 50 in the main channel into the Bay, stations 18, 19

DENSITY

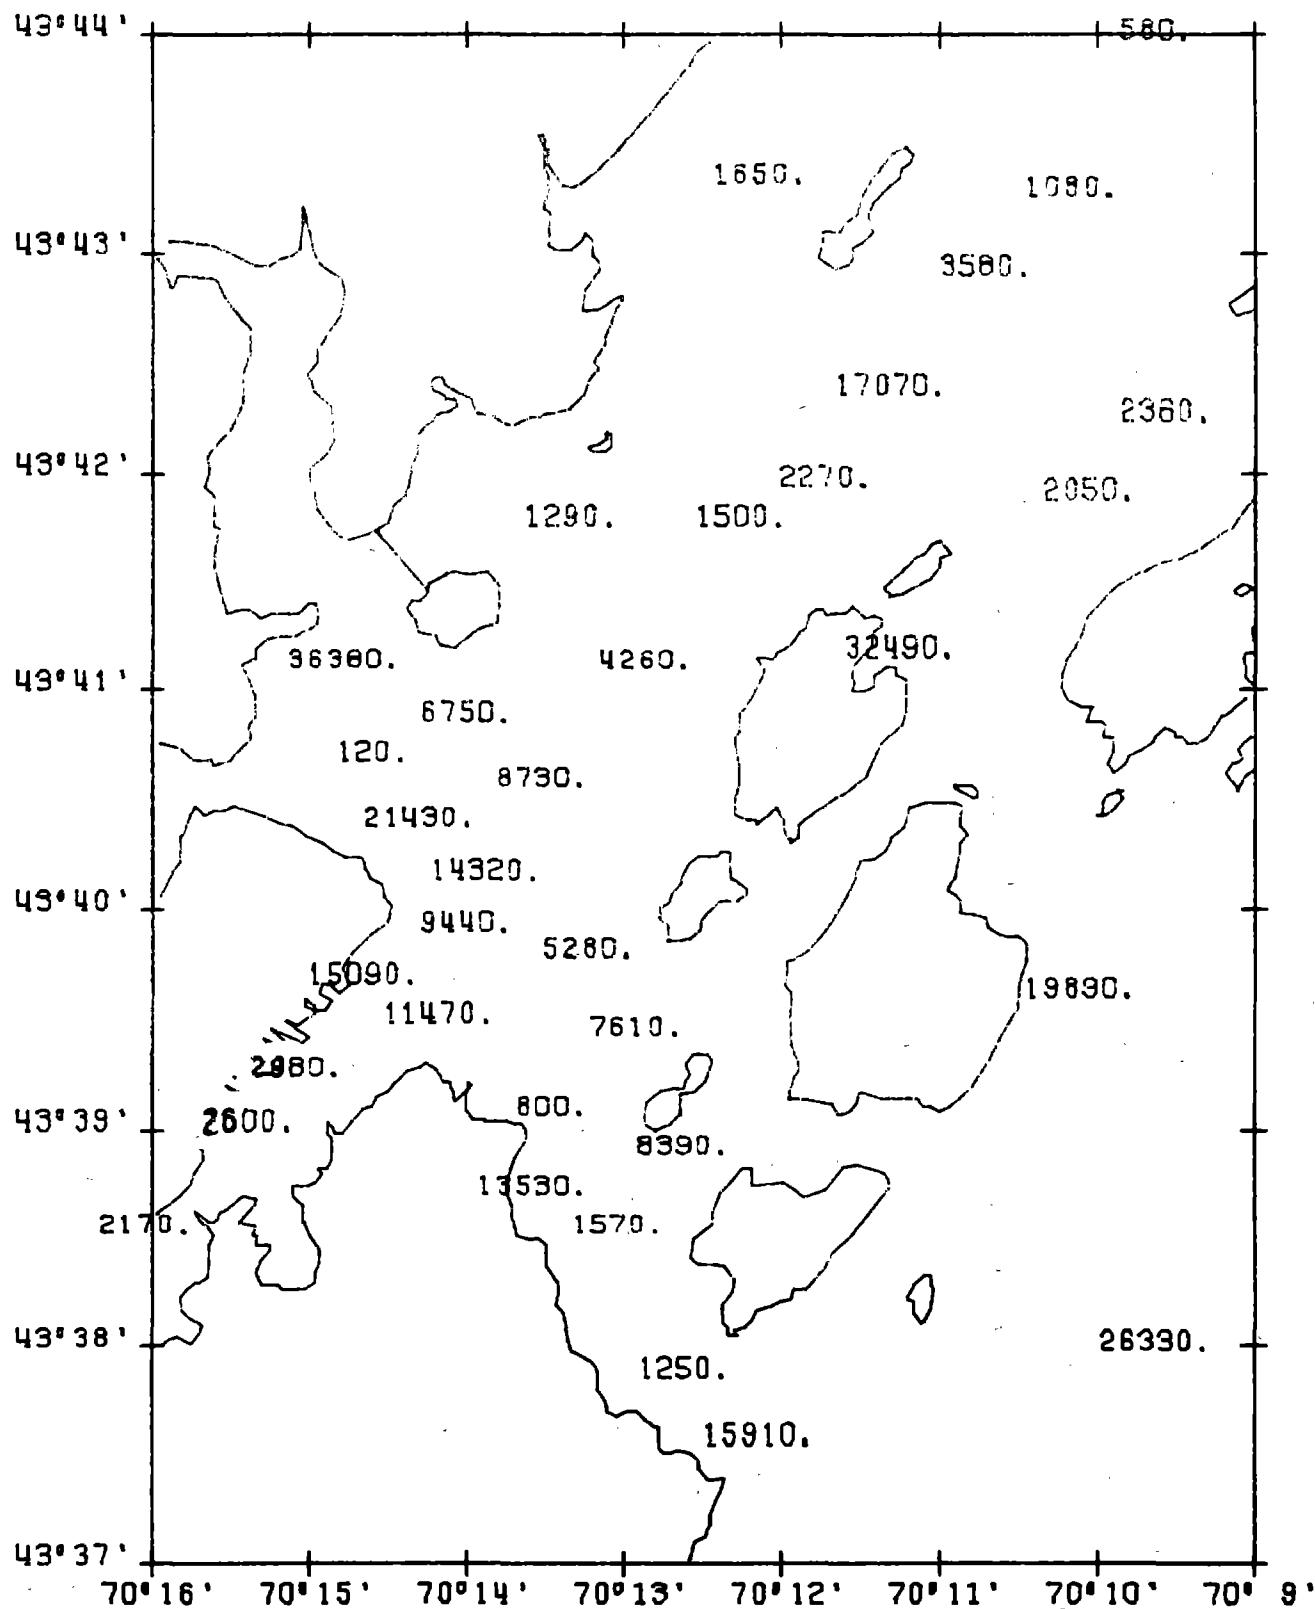

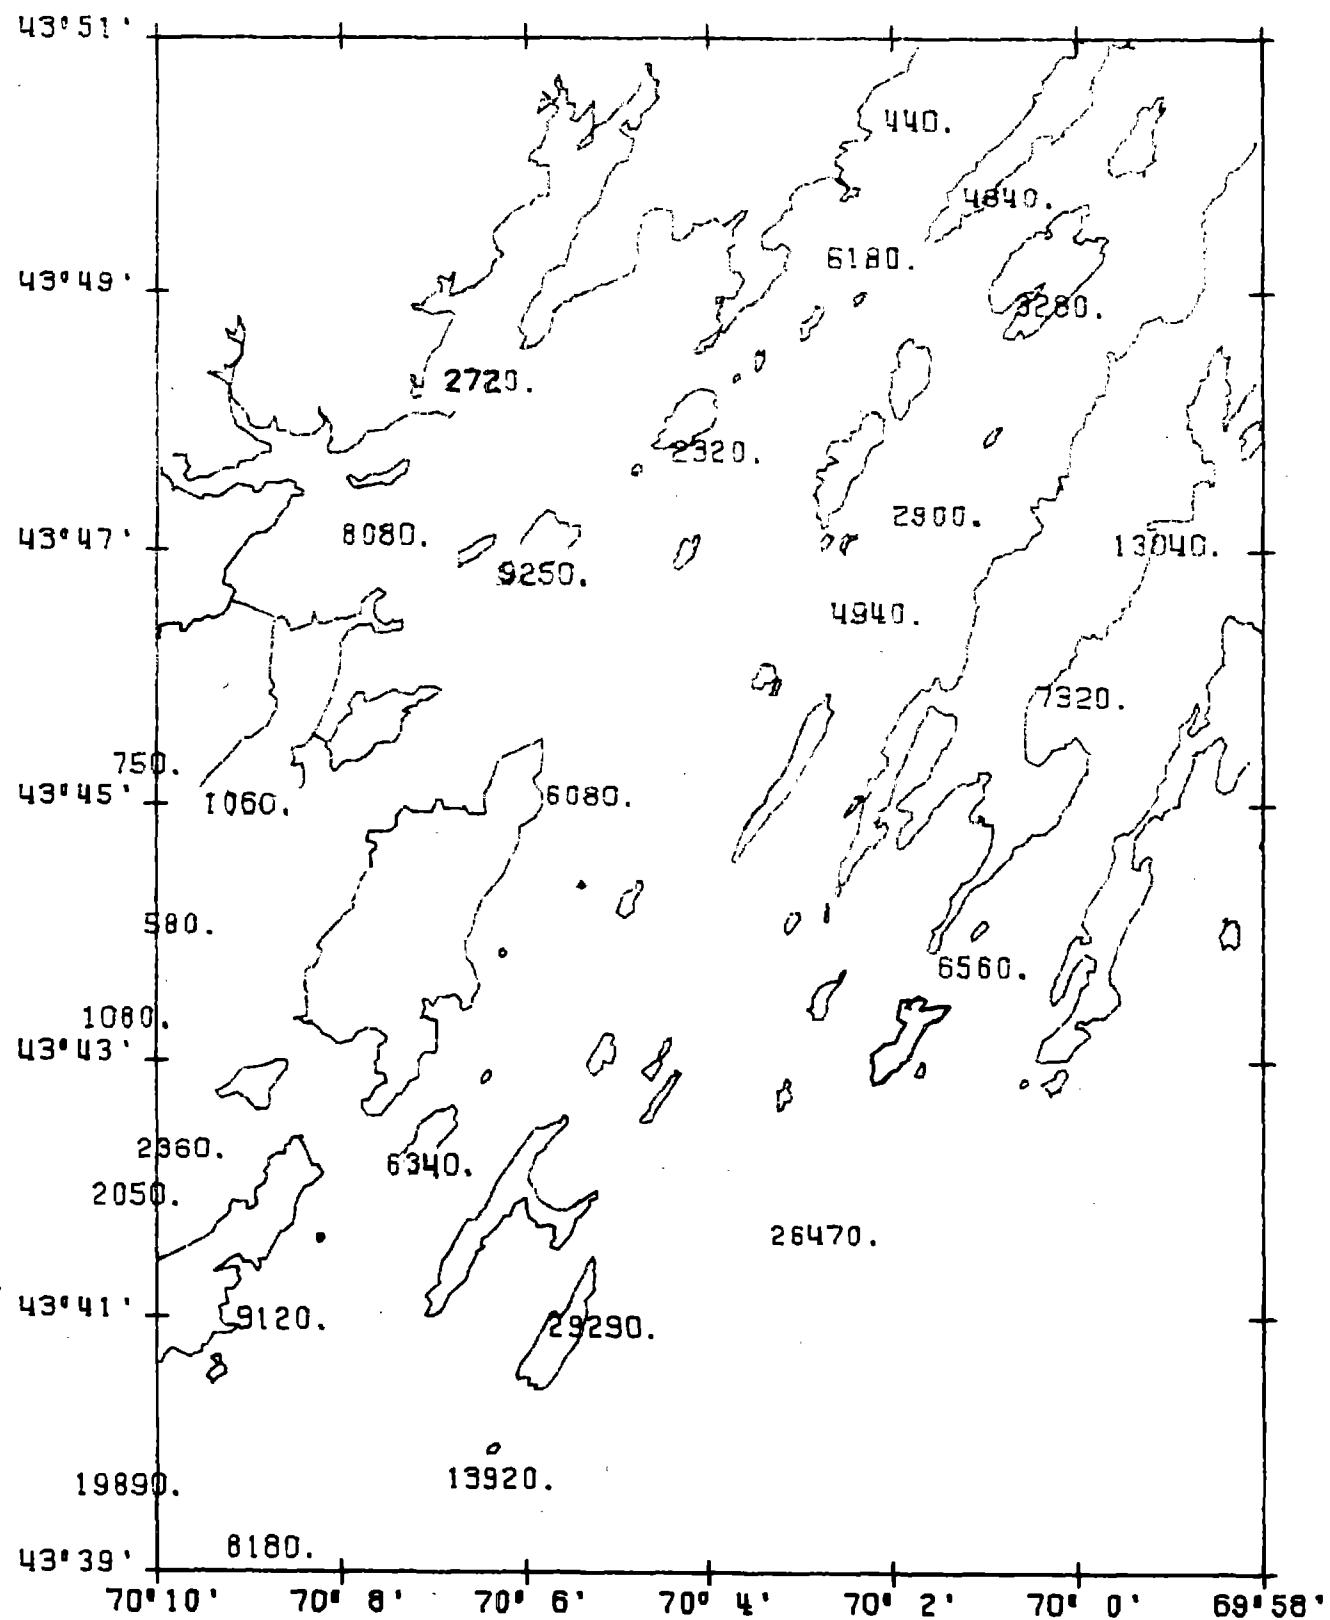

Fig. 19. Distribution of density (individuals/m²) of macrobenthos in Casco Bay, Maine.

DENSITY

and 20 in Portland Harbor and several stations in the middle and upper Bay. Reasons for these low densities are not completely obvious. Stations with similar sediments located around stations 47, 49 and 50 have much higher densities. Further data are needed before we can speculate on whether this is a natural or pollution-induced phenomenon. Stations 18, 19 and 20 exhibited the highest levels of trace metals, so perhaps the reduced densities there are impact related. The middle and upper Bay stations with low animal densities are those where extremely soft sediments were encountered. We believe that these sediments offer so little bearing strength that only a depauperate community can develop.

Correlation analysis was used to add insight into factors that might be influencing density levels. Density is correlated with both depth and mean grain size (Fig. 20 and 21). These relationships, both of which are significant at the 99%, level indicate that density increases with increasing depth and decreases with decreasing mean grain size. The latter relationship adds support to the hypothesis that physical properties at some fine-grained stations prevent the development of a normal community. Density is not significantly correlated with temperature, salinity or organic carbon content.

Correlation analyses were also run between density and the six trace metals. Two of the metals, chromium and nickel, were negatively correlated to density at over the 95% level. While not attaining the conventionally accepted 95% level of significance, it is interesting to note that cadmium, zinc, copper and lead are all negatively correlated with density. The significance levels are 94, 93, 88 and 76%, respectively.

Comparing Casco Bay faunal densities with those from other temperate and boreal areas demonstrates the comparative richness of the region (Table 9.). Such high density and biomass (see below) indicates a high or extended period of productivity. Data on primary productivity

of Casco Bay are presently being generated by other researchers at the Bigelow Laboratory. These data may provide an explanation for the observed faunal densities.

Biomass

Biomass of the 1.0 mm sieve fraction averaged 49.6 g/m^2 on a wet weight basis. The range at individual stations was 1.8 to 191.0 g/m^2 (Table 8). In all cases animals weighing over one gram were excluded from the analysis. Annelids constituted 49.6% of the fauna in terms of wet weight. Arthropods, molluscs, echinoderms and miscellaneous phyla accounted for 19.3, 11.6, 1.9 and 17.6% of the biomass, respectively.

There was considerable variation in total biomass between stations but relative dominance of higher taxa was fairly consistent (Fig. 22 and 23). Annelids were biomass dominants at 43 of the 56 stations. Arthropods were dominant at stations 2, 4 and 5 due to the abundance of *Ampelisca agassizi* and *Haploops tubicola* and at stations 24 and 25 due to *Casco bigelowi*. Molluscs were also biomass dominants at only five stations. These were stations 47 - 50 because of the presence of *Nucula delphinodonta* and *Nassarius trivittatus* and at the sparsely populated station 43. Stations 18 - 20 in Portland Harbor were dominated in terms of biomass by various miscellaneous taxa.

Like density, biomass exhibits a strong positive correlation (99.9%) with depth and a strong negative correlation (99.0%) with mean grain size (Figs. 24 and 25). Furthermore, it is negatively correlated with organic carbon (99.9%) (Fig. 26). In addition, biomass is also positively correlated at the 99.9% level with density and number of species per station. It is negatively correlated with all of the trace metals. Three of these relationships, cadmium, chromium and zinc are significant at the 95% level. Levels of significance for copper, nickel and lead are 83, 89 and 79%, respectively.

EX8D01 CASCO BAY

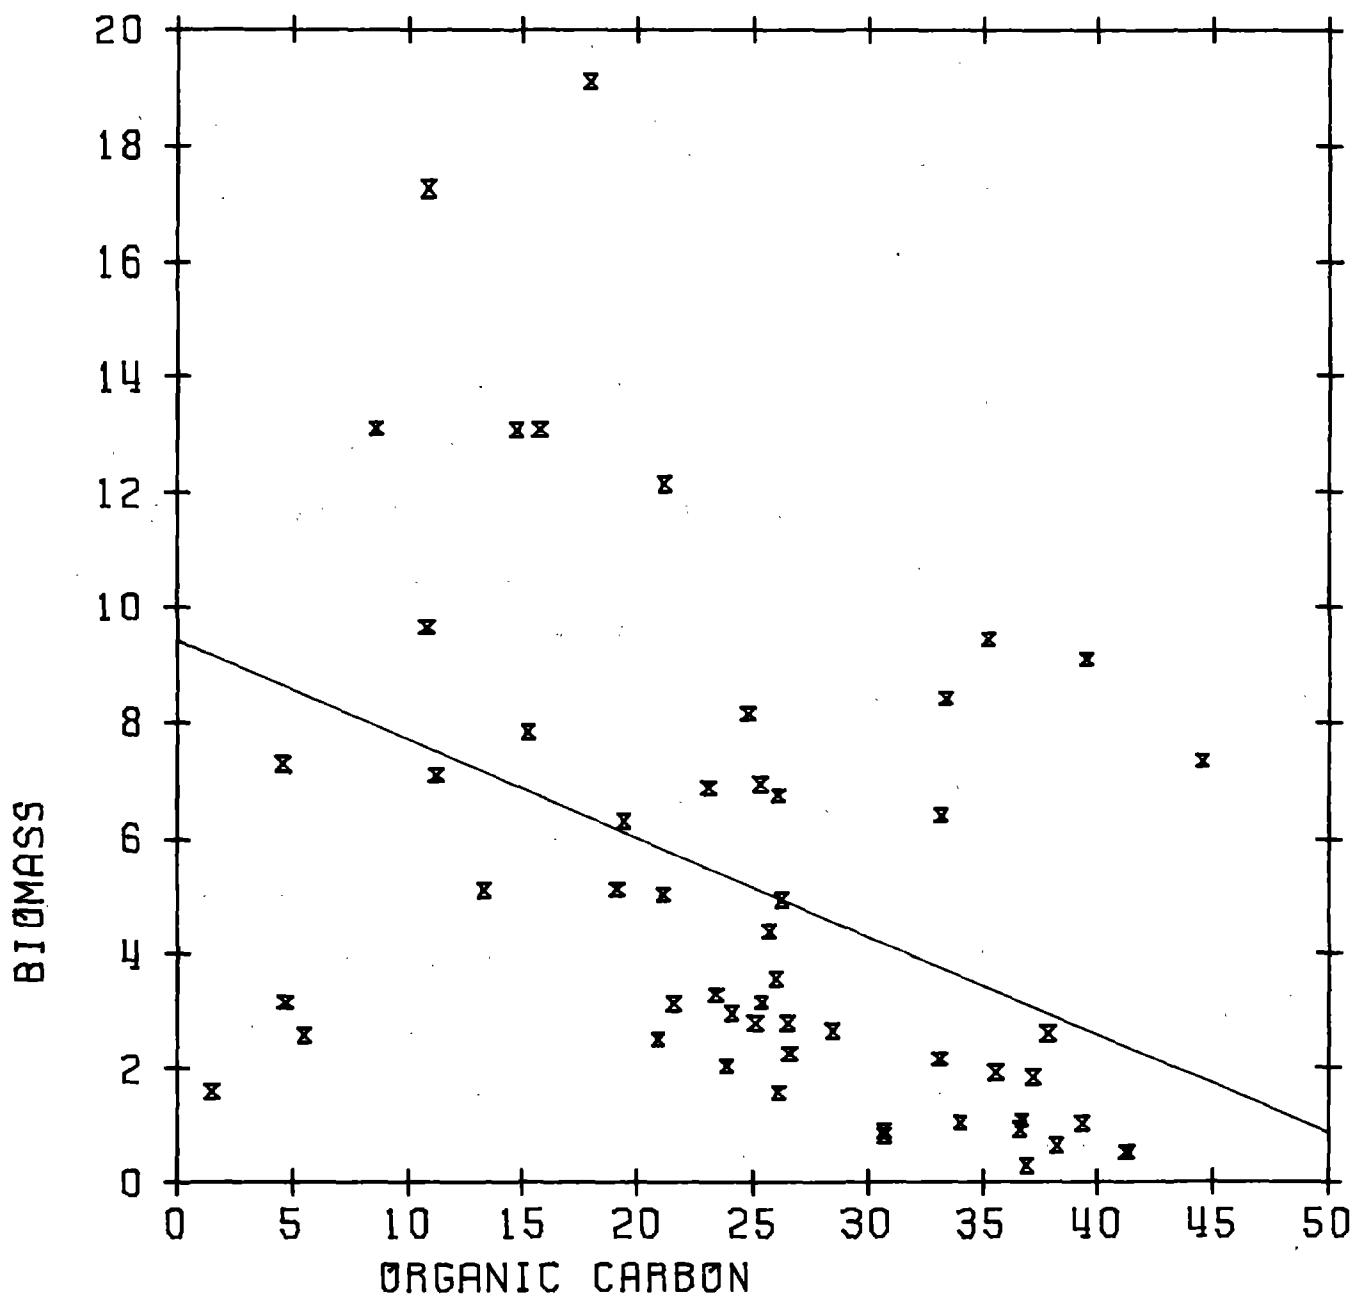

Fig. 26. The relationship between biomass and organic carbon content of the sediments.

Species Per Station

The number of species per station ($0.1m^2$) ranged from 5 to 86 with a mean of 33.1 (Table 8). The offshore stations consistently had the highest numbers of species and moderate numbers are characteristic of lower Casco Bay. Less than 20 species were found at many of the finer-grained stations and in the wood chips of station 36. Indeed, stations 17, 32, 35, 36 and 43 were occupied by less than 10 species (Fig. 27).

The number of species per station is very strongly correlated (99.9% level) with increasing depth (Fig. 28). It is also negatively correlated at the 99.9% level with mean grain size and organic carbon (Figs. 29 and 30). Number of species is the only biological parameter to be significantly correlated with salinity (98% level).

As with density and biomass, species per station is negatively correlated with each of the metals. Two of these relationships, cadmium and zinc, are significant at the 99% and 95% levels, respectively. Other non-significant correlations and their significance levels are: chromium 94%; nickel 93%; copper 82% and lead 75%.

Diversity

Informational diversity, as measured by the Shannon index, ranged from 0.415 at station 32 to 4.347 at station 10 (Table 8). The overall mean was 2.72. High values of H' diversity are found at some offshore stations and generally throughout the Portland region including the trace metal impacted, low density stations 18-20 (Fig. 31). An explanation for this unusual result can be found in an examination of evenness and species richness levels (Table 8). In general, the high

DIVERSITY

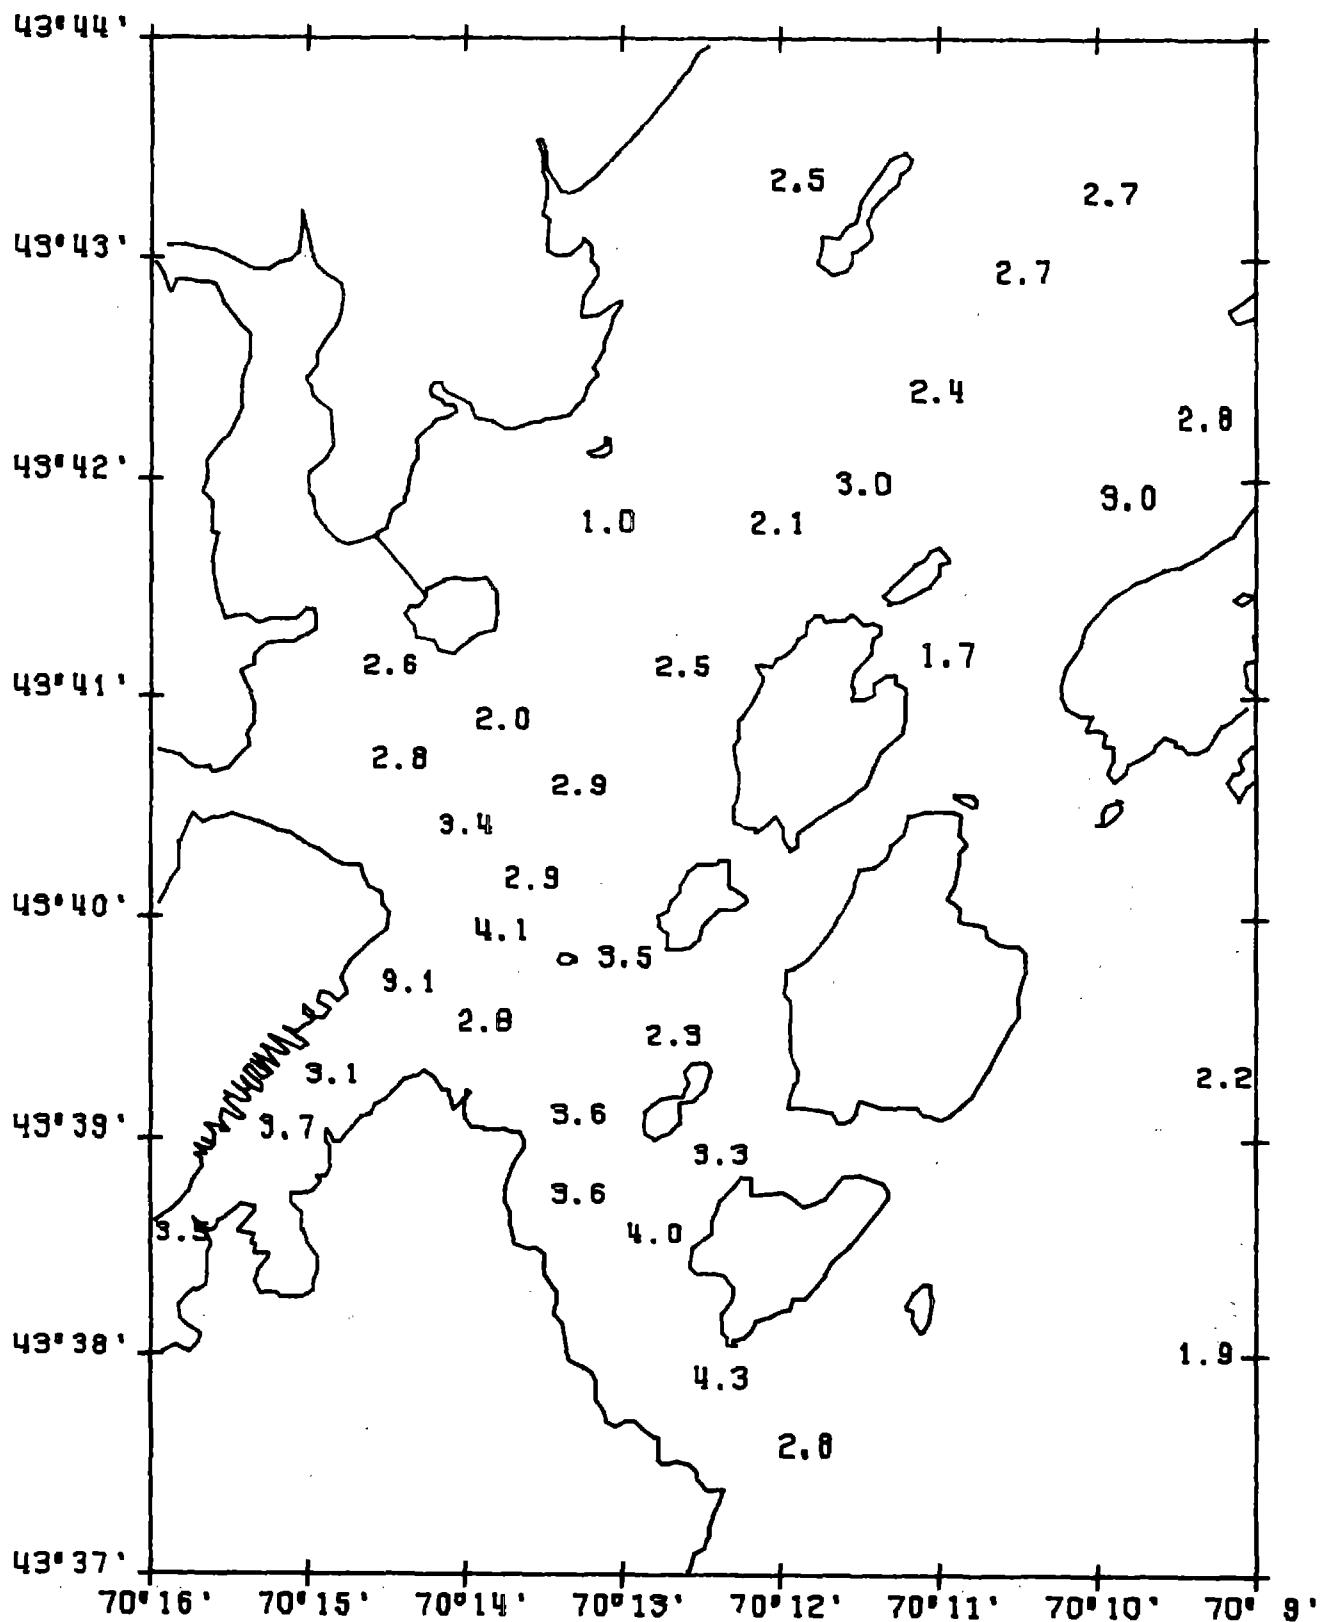

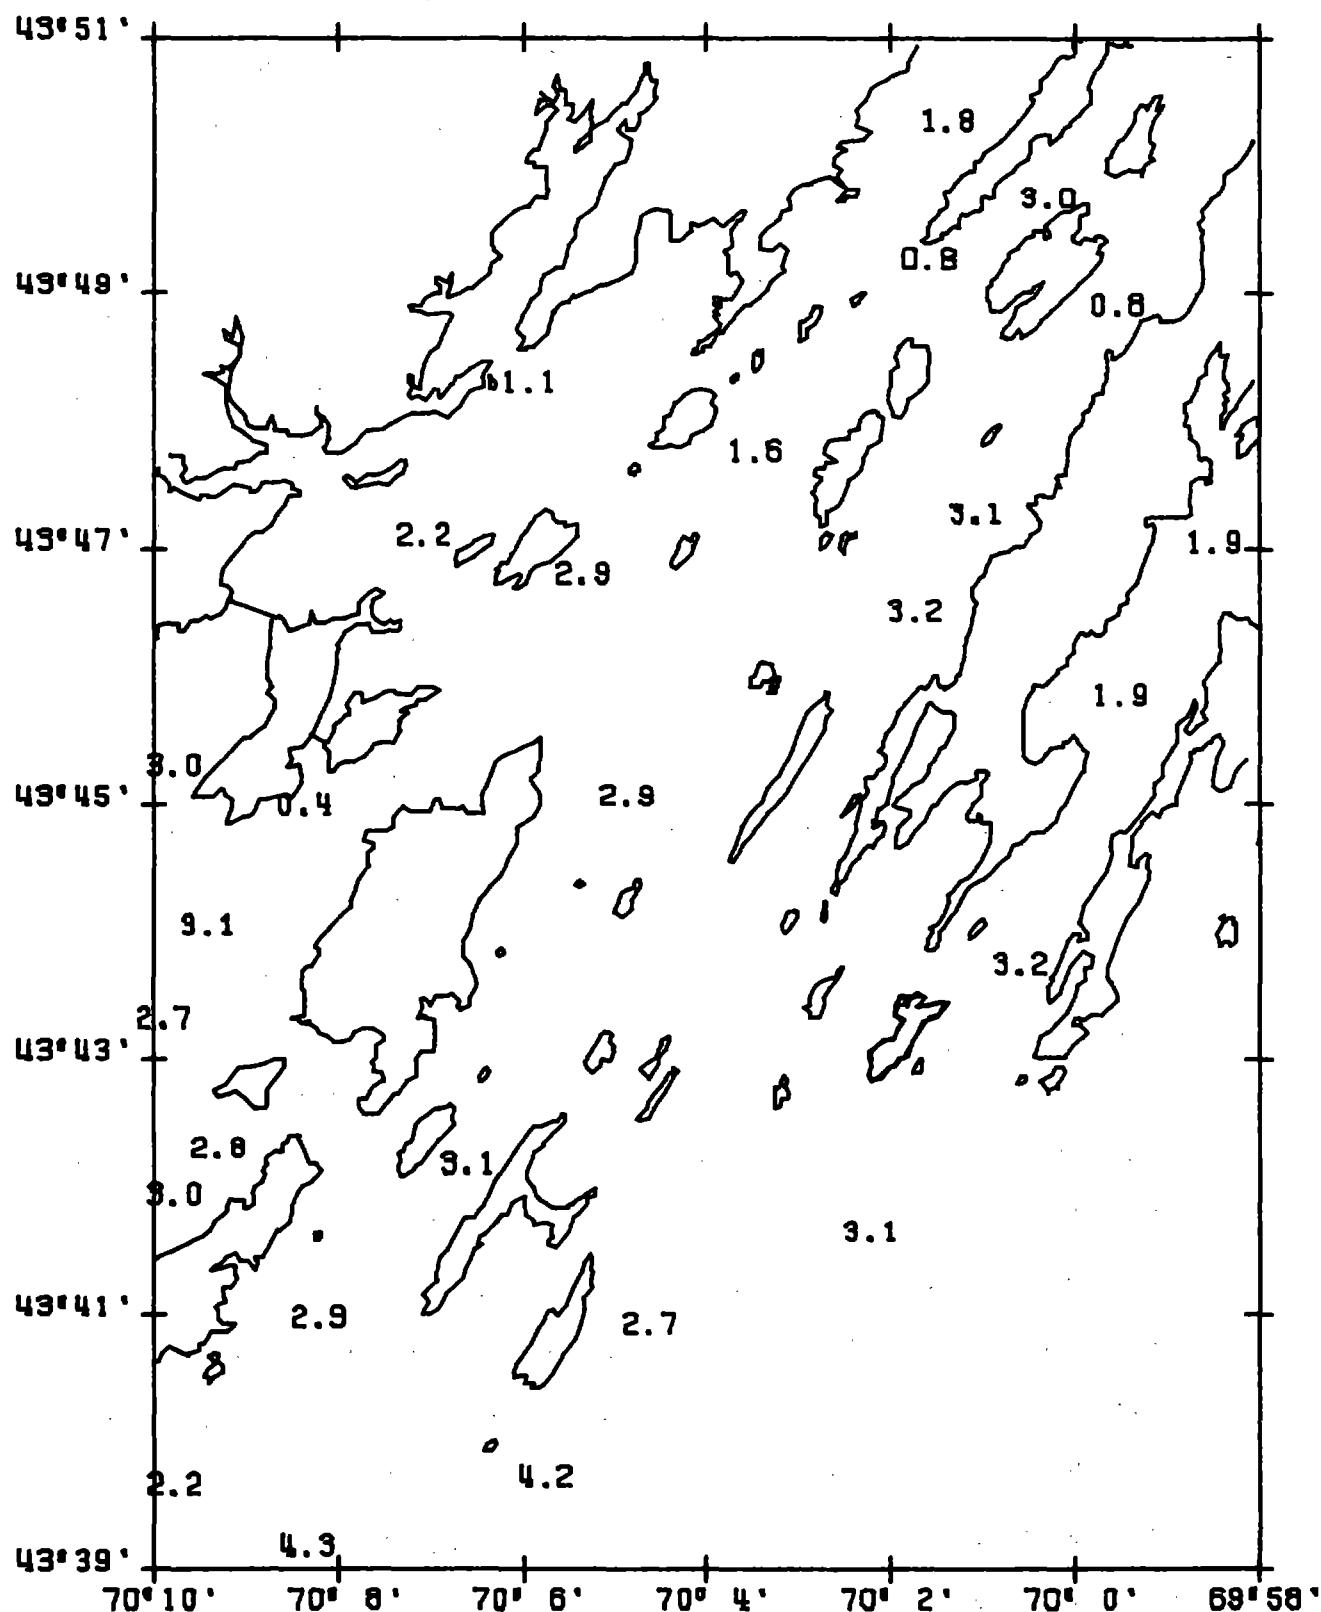

Fig. 31. The distribution of macrobenthic H' diversity in Casco Bay, Maine.

DIVERSITY

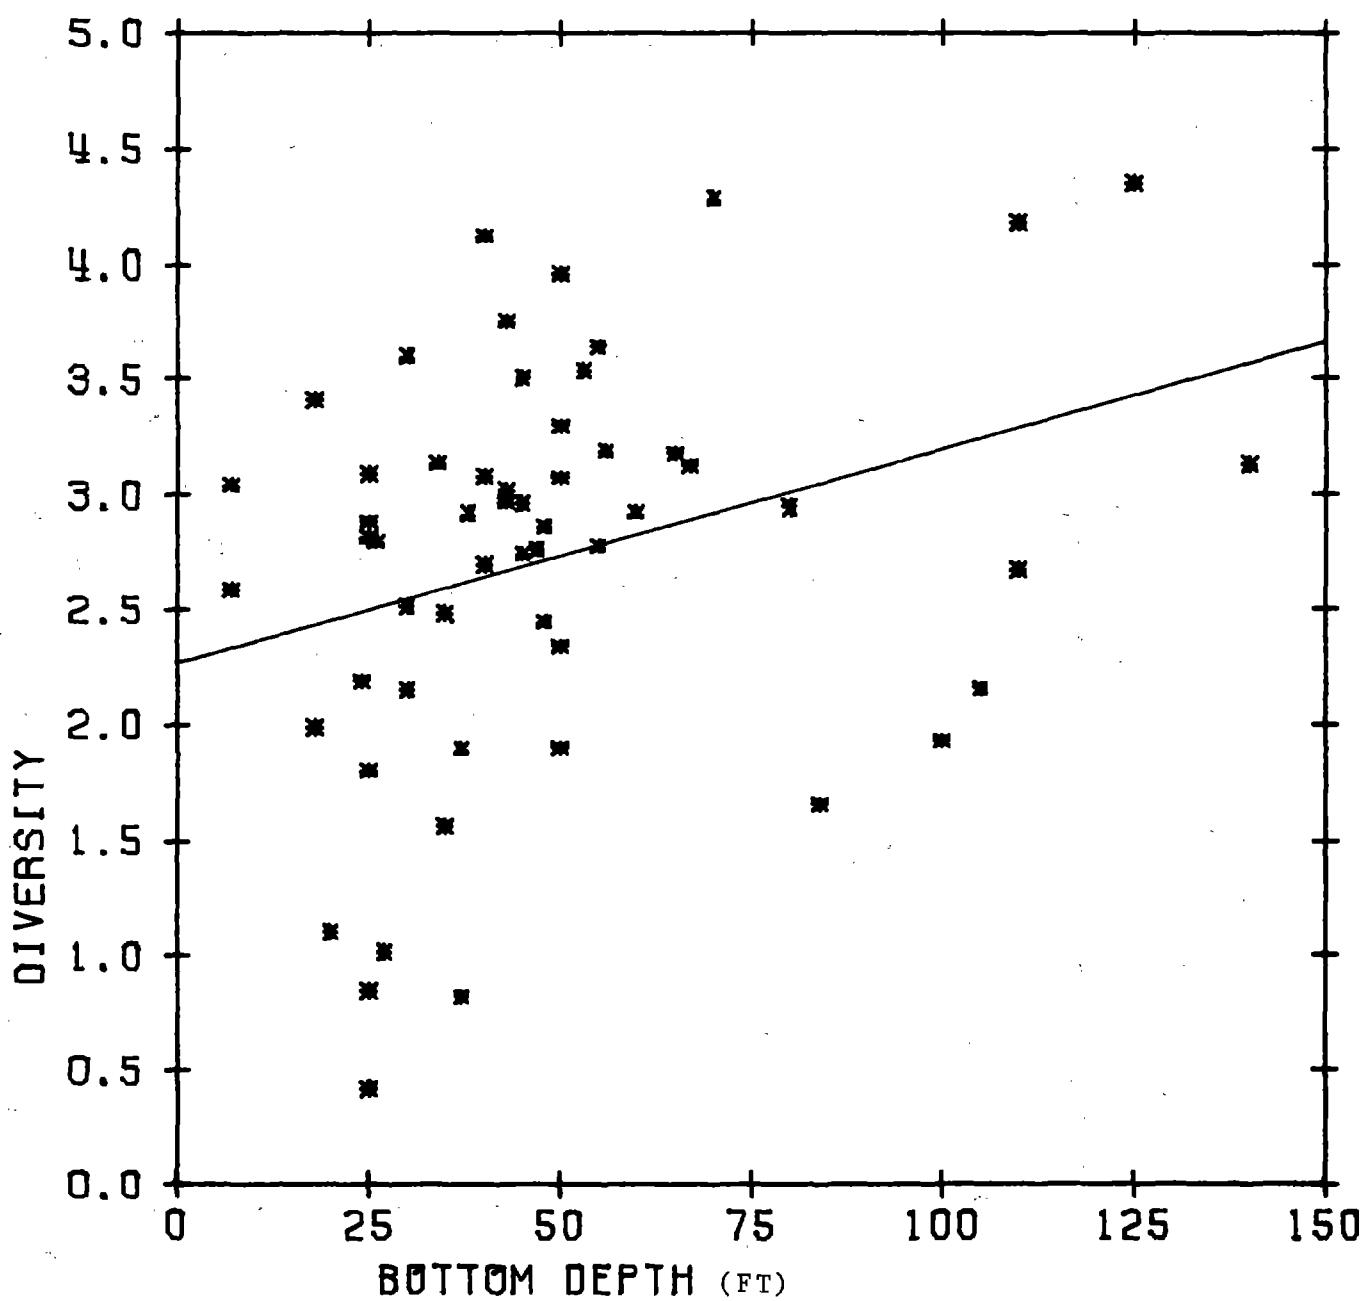

diversity values at many stations seems to be caused by high species richness. Naturally, these are the stations with high numbers of species. At other stations, however, evenness appears to be the dominant component of diversity. For example, stations 15, 16, 18, 19, 20 and 36 only have moderate to low species richness levels but are among the highest stations in evenness which results in diversity levels of over 3.0 at stations where conventional logic would predict depressed diversity.

Extremely low diversity is limited to stations with very fine sediments. Not all the fine-grained stations exhibit such low diversity, however, and the explanation for this is analogous to that presented above.

Like the other biological parameters discussed, informational diversity is positively correlated with bottom depth, at the 95% level, and negatively correlated with mean grain size and organic carbon, both at the 99% level (Figs. 32, 33 and 34). As would be expected, diversity is positively correlated at the 99.9% level with species number, but shows no relationship to density. Additionally, diversity is not significantly correlated with any of the trace metals and is not even consistent in the sign of the correlation coefficient.

Whereas, we believe all of the biological parameters should be re-evaluated in greater depth once the hydrocarbon data can be factored into the analysis, all of them, except diversity, presently add insight into the existing conditions in Casco Bay and will aid us in providing an integrated overview of the biological functioning and health of the system. Diversity, on the other hand, is not presently useful in this regard. Once all the data are available, diversity should again be

evaluated, but other related tools, such as fit to a lognormal distribution, should be looked at as well. It may be that H' diversity is simply not the appropriate index to illuminate the finer nuances of a heterogeneous system like Casco Bay.

Classification Analysis

Classification or cluster analysis is a useful way of objectively examining patterns in complex data sets which cannot easily be uncovered by other techniques. It is a hypothesis generating technique which can suggest relationships between biological and physical factors that may be causal to observed community distributions. Although the method is numerical, and therefore objective, the interpretation is subjective. One way to minimize subjectivity is to produce a large number of site-groups and species groups and then combine them until the most meaningful pattern is produced using a minimum of groups. The goal is to produce the most comprehensive but simple explanation for the observed phenomena.

We are at an intermediate step in this process. We have produced station and species dendograms based on faunal data. We have defined a moderate number of site-groups and species-groups and have initiated a comparison of the groups with the extrinsic factors now on hand. In order to conserve resources we intend to wait until all of the physical data are available before finalizing our interpretation. We have, however, included our analysis to date because it does provide useful information about Casco Bay and illustrates the strength of the analysis that will be available soon.

The dendrogram which resulted from the classification of the 56 stations using species abundances as attributes (normal classification) is presented in Fig. 35. For the time being we have truncated this dendrogram at the nine group level. Examination of Fig. 35 shows that all of these groups are fairly discrete but some, for example groups 2 and 3, are candidates for further fusion. We have a great deal of faith in this classification because it shows good spatial discrimination (Fig. 36).

The 10 members of site-group 1 are principally deep-water offshore stations. Site-groups 2, 3 and 7 are limited to the Portland region. Stations in site-groups 2 and 3 are intermingled in outer Portland Harbor and are adjacent to one another on the dendrogram. This suggests a close faunal affinity between them. Site-group 7 stations are found on the edge of the patch of site-group 2 and 3 stations and are far removed from them in the dendrogram. This reflects a real difference in faunal composition undoubtedly controlled by physical factors. Site-group 4 is widely scattered throughout Casco Bay with all but one of the member stations occurring near shore. Site-group 5 dominates the central portion of the Bay while site-group 6 members ring the Bay at shallow stations. The three member site-group 8 exhibits no spatial pattern and site-group 9 is a single station outlier consisting of the mussel reef community at station 37.

The dendrogram resulting from the inverse classification is presented in Fig. 37. Only those noncolonial species occurring at over 10% of the stations were used in this procedure. We have tentatively truncated this dendrogram at the 14 group level. The most significant feature of this analysis is the distinct separation of species-group N

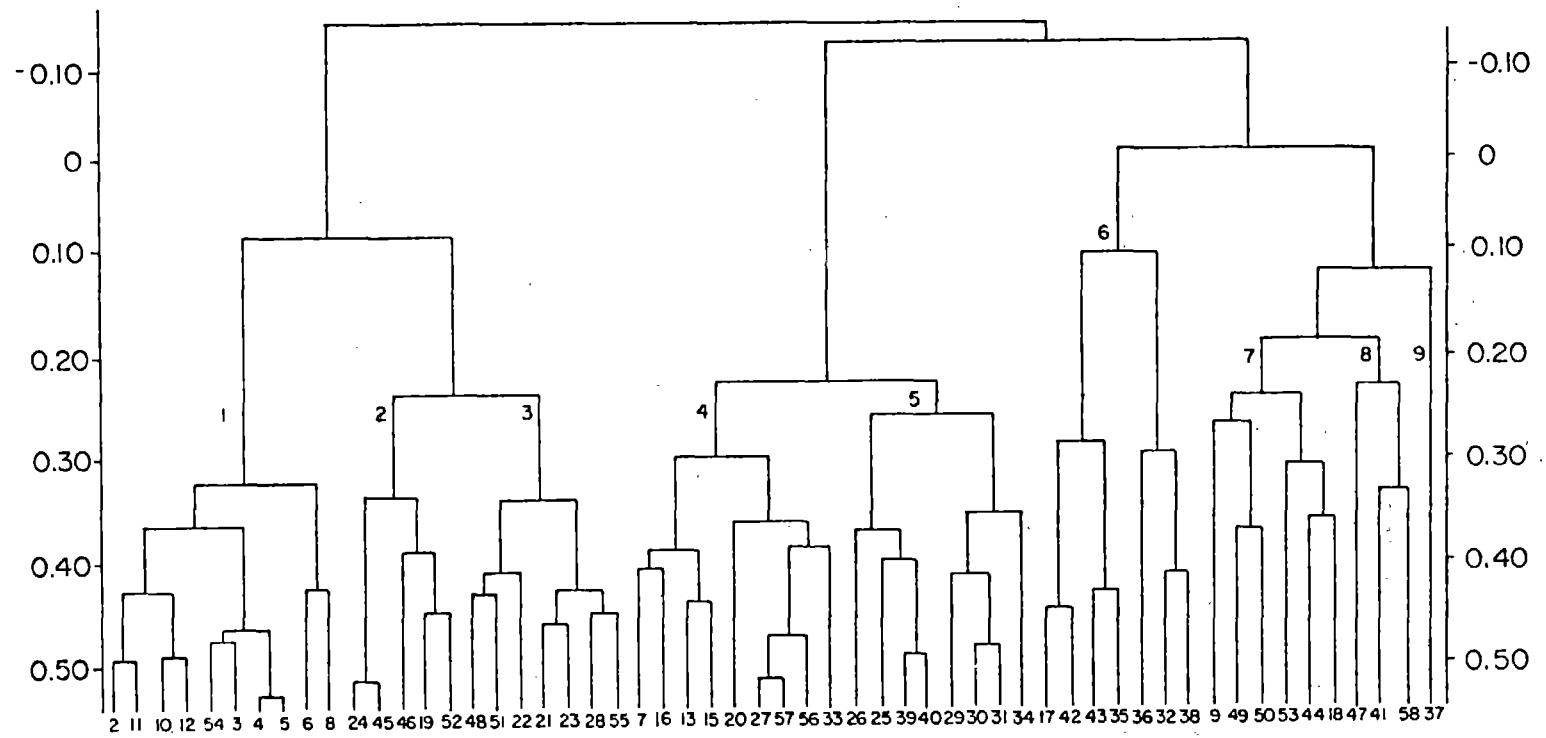

Fig. 35. Dendrogram of hierarchical classification of stations in Casco Bay, Maine. Lower numbers refer to station numbers. Numbers on branches refer to site-groups.

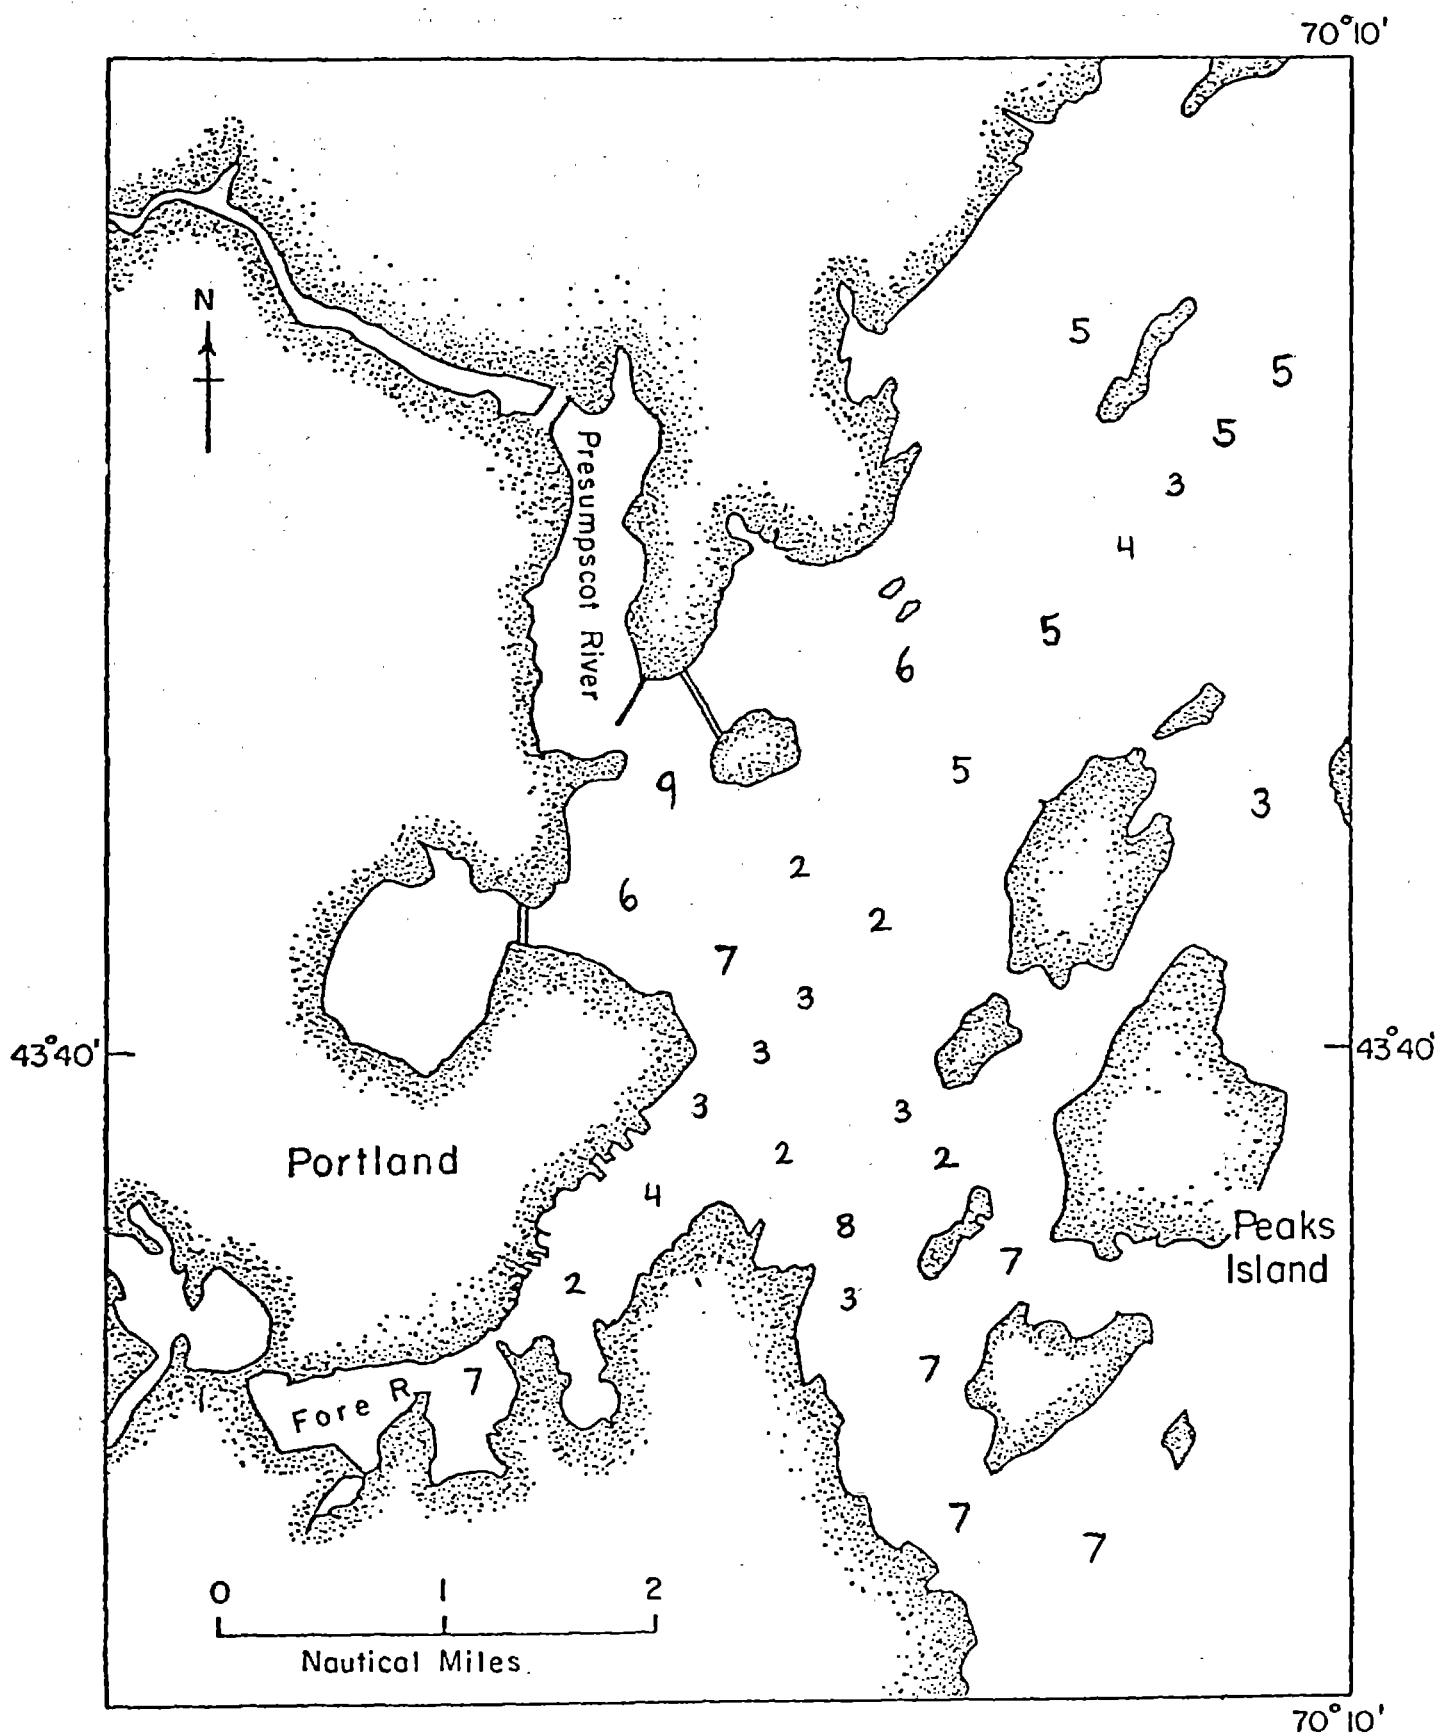

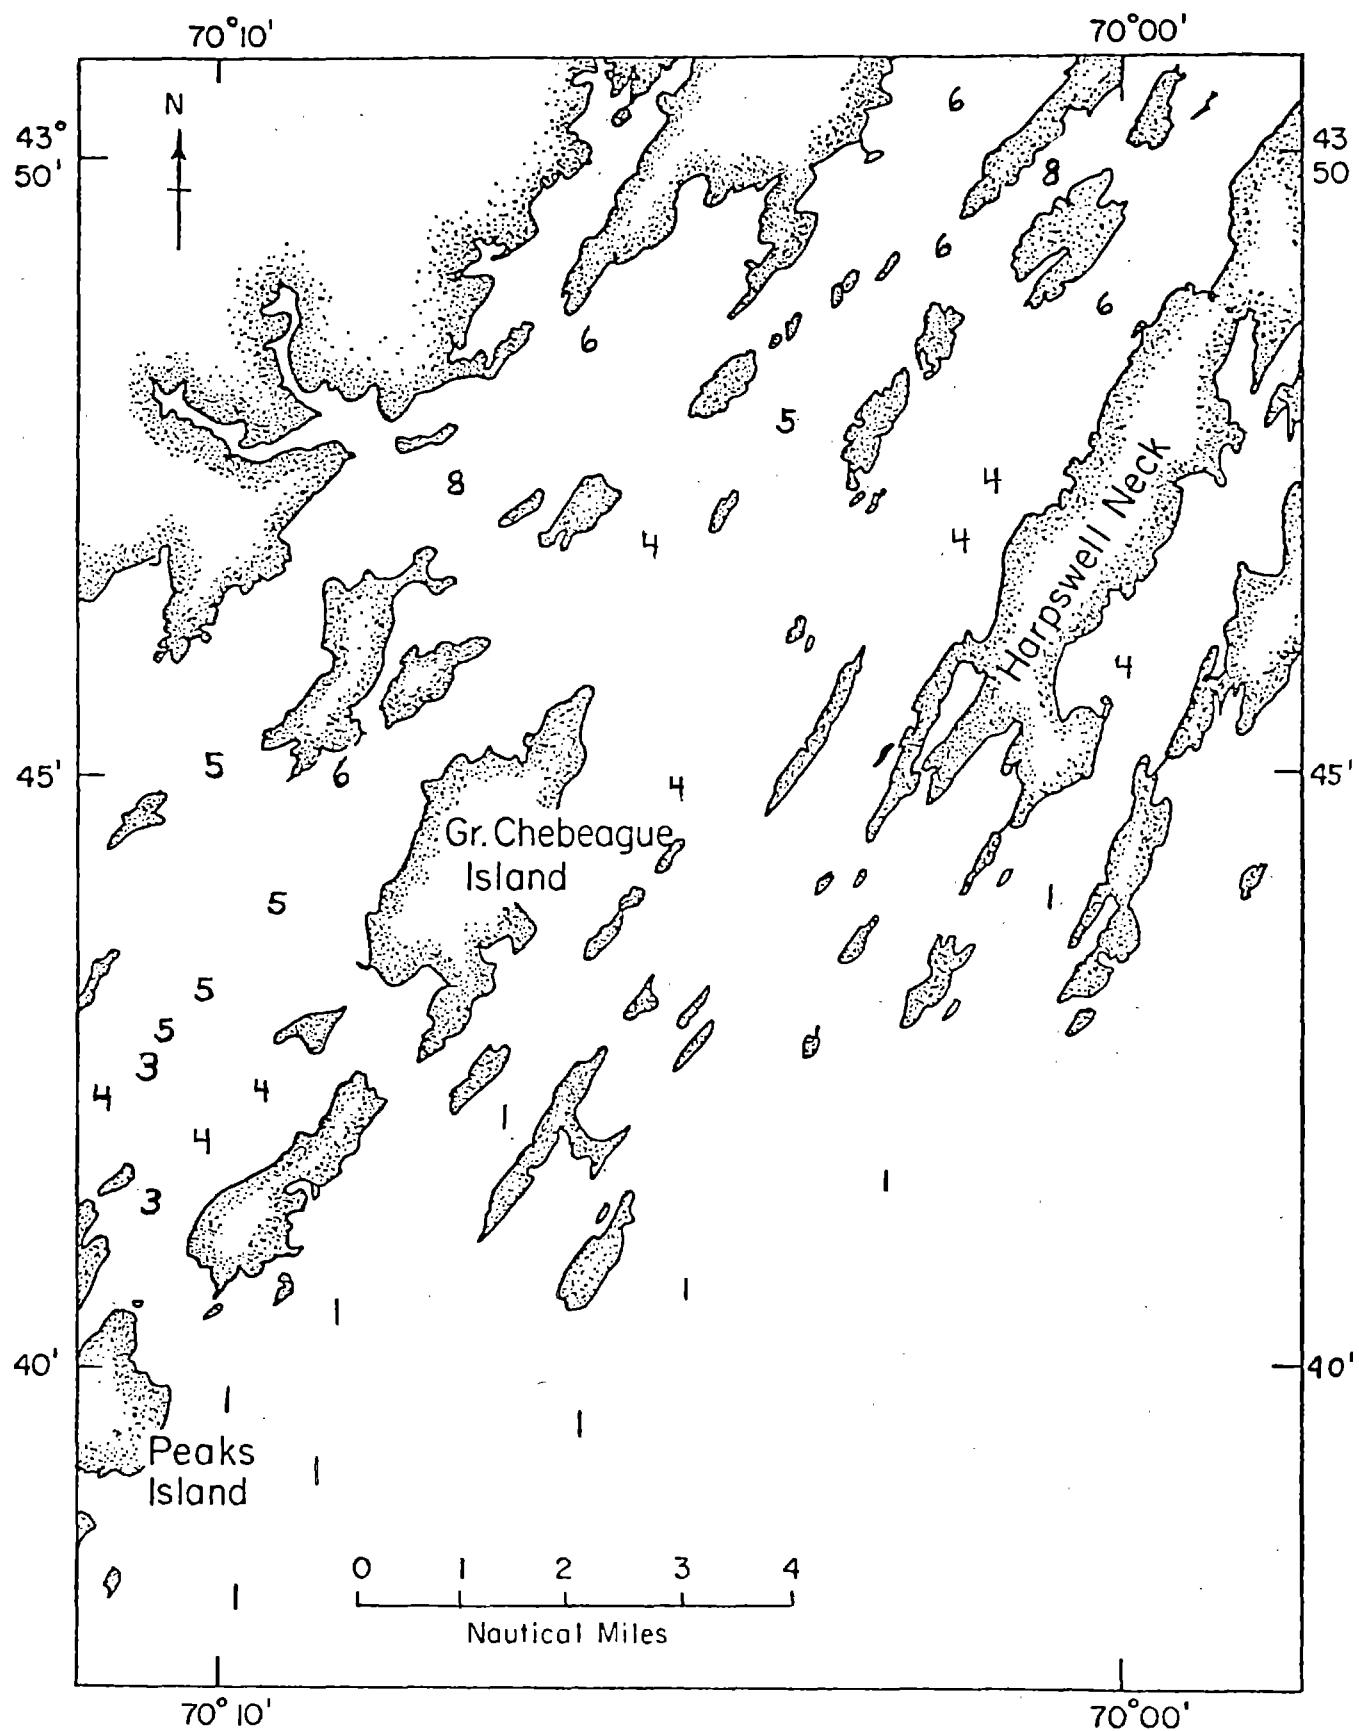

Fig. 36. Distribution of site-groups in Casco Bay.

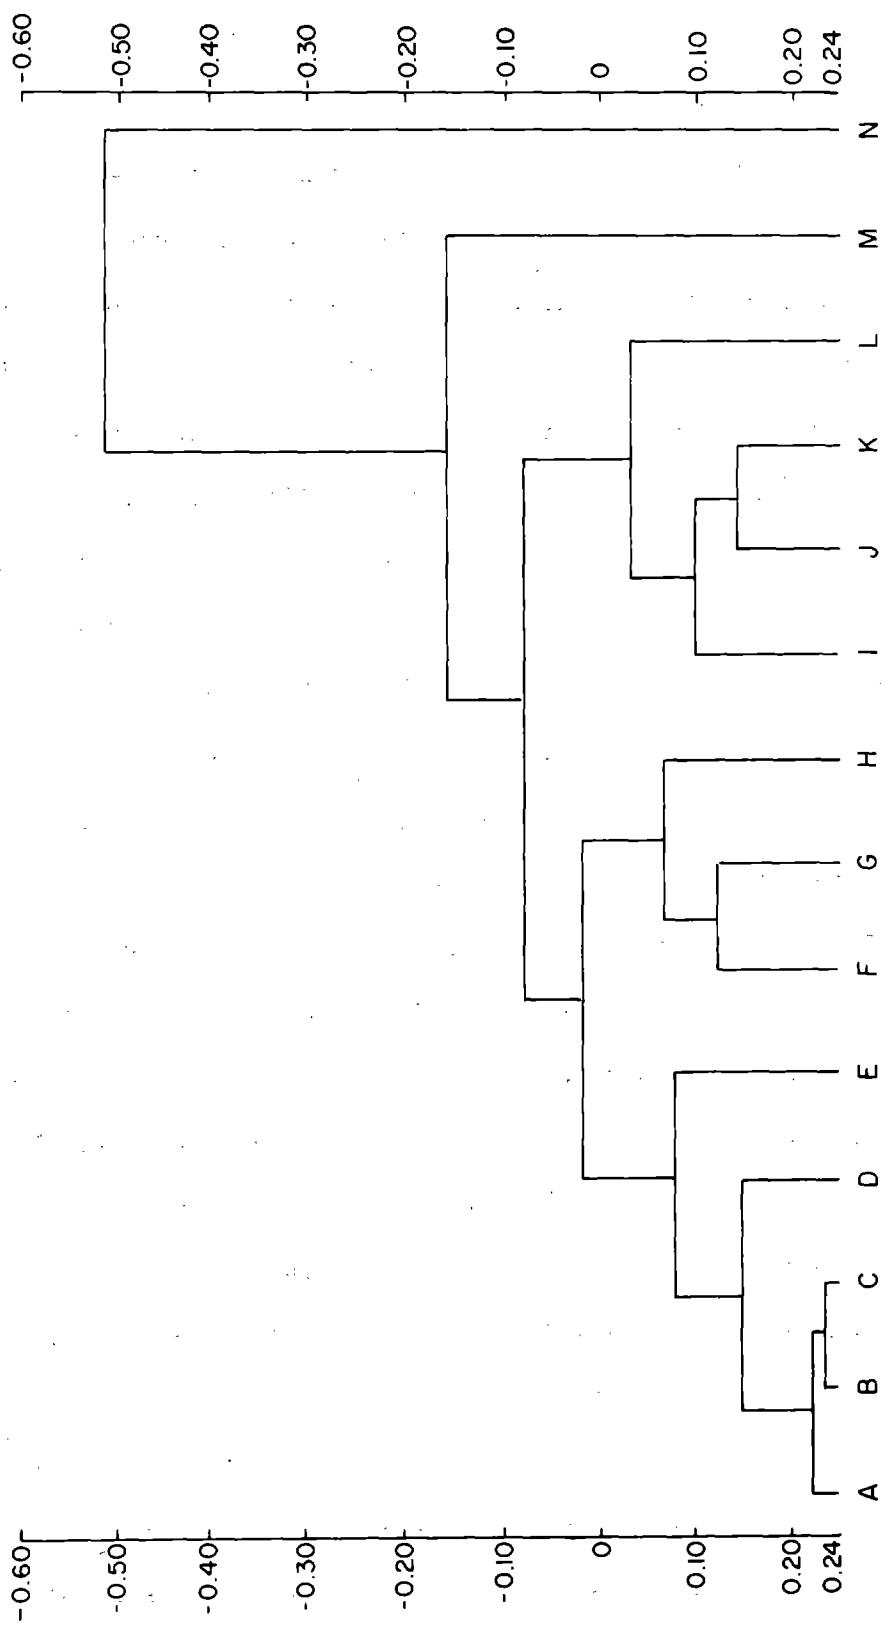

Fig. 37. Dendrogram of hierarchical classification of species-data. Letters refer to species-groups.

from the others. This group is not a single species outlier, but the largest group and the separation suggests a basic difference in distribution between species-group N members and members of the other groups. The membership of each species-group is presented in Table 10.

By examining the constancy and fidelity of species-groups at the various site-groups it is possible to achieve insight into the distribution of the species-groups and perhaps into the controlling ecological mechanisms. This process is called nodal analysis.

The patterns of constancy and fidelity of the species-groups at the site-groups is summarized in Figs. 38 and 39. The width of the rows and columns is proportional to the size of the groups. Site-group 1 is occupied in medium to very high constancy by all species-groups with the exception of species-groups H-K. These latter four groups also demonstrate a fidelity of less than unity at site-group 1 indicating an avoidance of the member stations. It is the only site-group where species-groups E, F and M are highly constant and G and M are highly faithful. With the exceptions of species-groups F and G, site-groups 2 and 3 are occupied by similar species-groups but differ in relative constancy and fidelity especially in terms of species-groups A, B and C. Site-group 4 is best characterized by the presence of species-groups I and N. Species-group I is highly constant and faithful only at site-groups 4 and 5. These two mid-Bay site-groups differ from one another in that site-group 4 has six species-groups present at low to medium constancy which do not occur at site-group 5 stations.

Site-group 6 is impoverished. Only species-group J is present at moderate constancy. Site-group 7 has similarities to site-groups 2 and

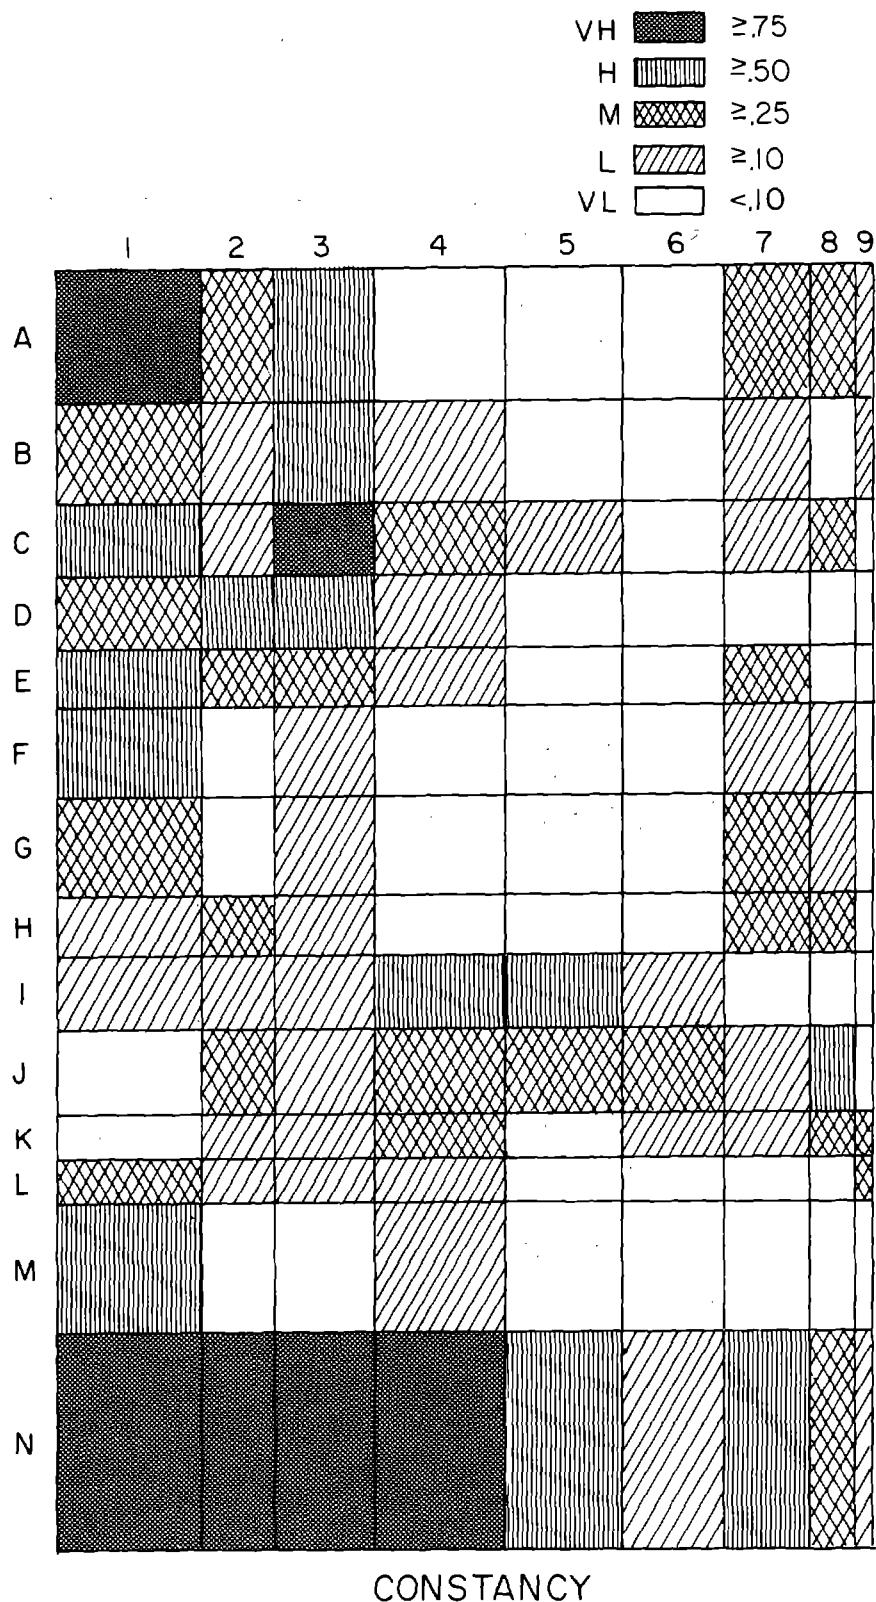

Fig. 38. Constancy of species-groups at site-groups.

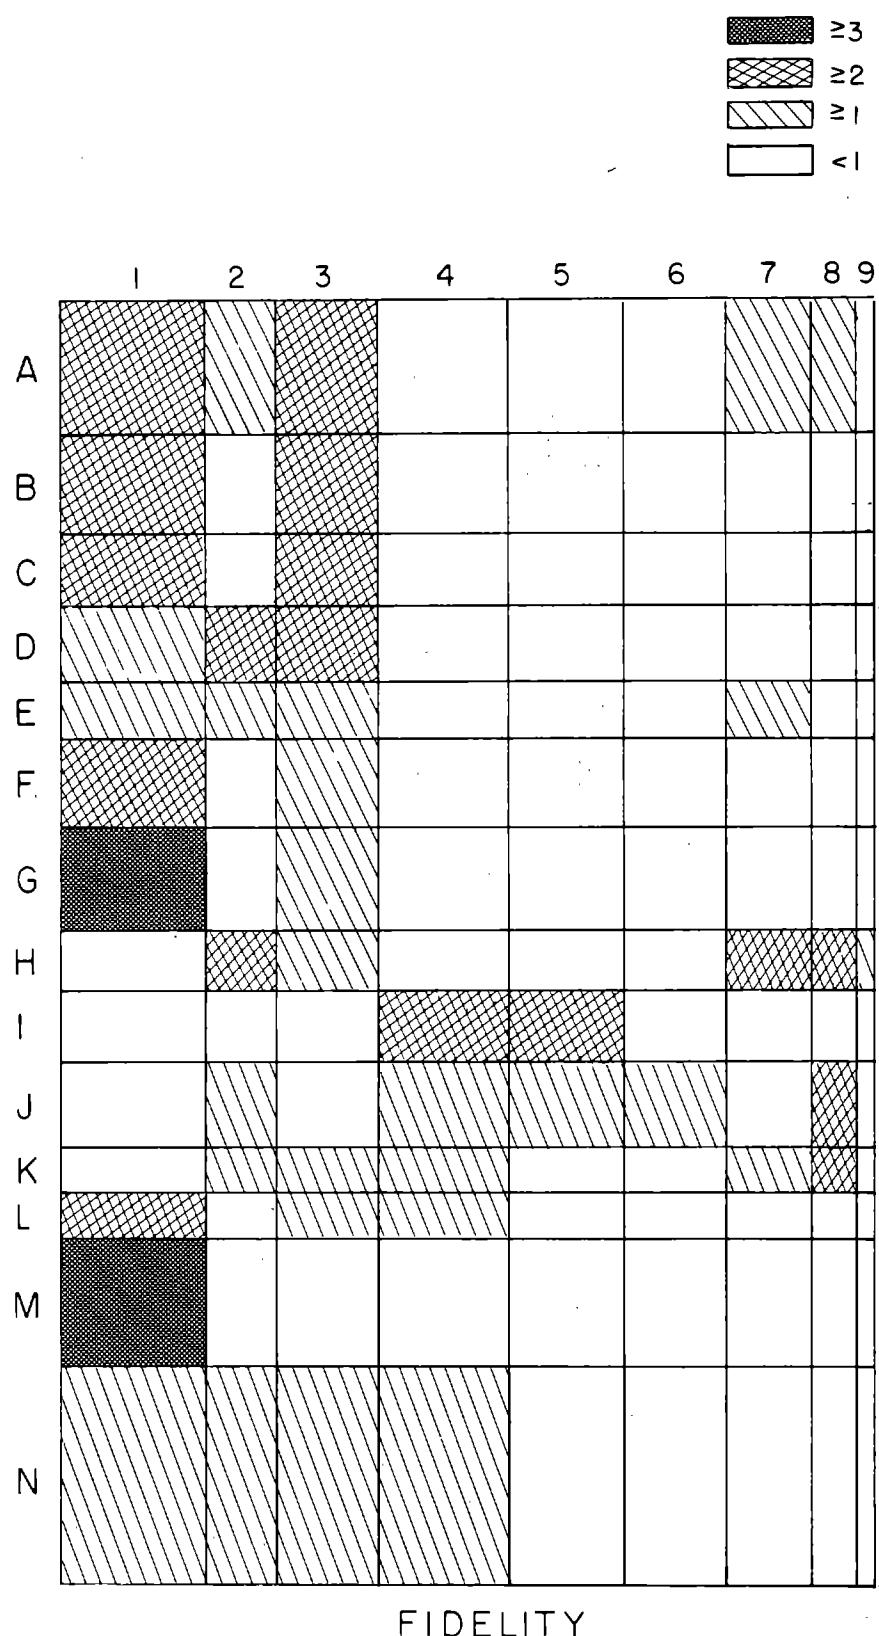

Fig. 39. Fidelity of species-groups to site-groups.

3 in terms of species-group affiliations but differs in constancy and/or fidelity levels of species-groups B, C, D and G. Species-groups H, J and K are most characteristic of site-group 8, as they are present in medium to high constancy and with high fidelity. Site-group 9 consists of one station which is qualitatively different from all other stations in several regards.

Species-group N is unique in that it occurs at all the site-groups and is present in high to very high constancy at six of the nine site-groups. Naturally, with such widespread constancy its fidelity to individual site-groups is very low. Examination of the frequency of occurrence of the member species of species-group N shows that they occur at from 53.6 to 87.5% of the stations sampled. This explains the distinct separation of species-group N from the others in the dendrogram (Fig. 37). Excepting the special cases of site-groups 6 and 9, we can characterize the fauna of Casco Bay by species-group N. This group of very tolerant, numerically dominant species which are undoubtedly typical of nearshore bottoms over a large area. Superimposed on this homogeneous fauna are smaller groups of species which are responding to finer environmental distinctions and hence have a more restricted range within Casco Bay. It is from among these other groups that initial changes in community structure, potentially indicative of environmental degradation, should be sought.

Several physical and biological parameters are compared in Table 11 on a site-group basis. The observed differences were subjected to standard analysis of variance and the site-groups differed significantly (> 95%) from one another in each of the measured parameters. This is strong evidence that the numerical classification, using only species

occurrences and abundances, dissected Casco Bay into ecologically meaningful components. Analysis of variance also demonstrated that the site-groups were significantly different in regard to four of the trace metals, cadmium, chromium, nickel and zinc.

The data was subjected to Duncan's multiple range test to determine which site-groups differed in the measured parameters. Results of this procedure are presented in Table 12. Zinc is not included because Duncan's test is not powerful enough, in this case, to break out the dissimilar site-groups. Groups represented by the same letter in the table are not different. For instance, by comparing Tables 11 and 12 we can conclude that site-group A is significantly deeper than all the others which do not differ significantly among themselves. Likewise, site-group 9, located on a mussel reef, has a significantly greater density than site-groups 1 and 3 which are in turn significantly denser than the remainder of the groups. Some of the other results are not so straightforward. In terms of biomass site-groups 1 and 3 are significantly richer than site-groups 4, 5 and 6, but the intermediate groups cannot be statistically differentiated from either the high or low biomass stations.

We are extremely encouraged that the chosen classification techniques produced groupings that are statistically valid. We are confident that once all of the data are available we will be able to provide a comprehensive analysis and benchmark of the present state of the benthic environment of Casco Bay.

SUMMARY AND TENTATIVE CONCLUSIONS

Casco Bay is a major coastal resource heavily utilized for commerce, commercial fishing and recreation. Facilities and activities

potentially threatening to the environment occur throughout the Bay but are most concentrated in the region of Portland.

Casco Bay is characterized by a boreal climate and a large tidal range (3 m). Sediments range from sand in tidally scoured channels to clay in the inner reaches of the Bay. Interior portions of the Bay have extremely soft bottom sediments which may be described as fluid mud or gel. Stations in these areas are occupied by an aberrant community with low species richness and low density. Further work is needed to fully document this phenomenon.

Trace metals are not homogeneously distributed throughout Casco Bay. Sandy and offshore stations tend to be low in metal concentration, while Portland Harbor appears to contain anthropogenic inputs. Comparisons with 10 other New England sites confirms that Casco Bay sediments are impacted in terms of the trace metals sampled.

The fauna of Casco Bay is rich in terms of diversity, density and biomass. These parameters, and others, are positively correlated with bottom depth and negatively correlated with mean grain size and organic carbon content. Most biological parameters are negatively correlated with at least some of the trace metals. We await the hydrocarbon data to complete our analysis.

Numerical classifications dissected Casco Bay into nine site-groups occupied by 14 species-groups. The site-groups are spatially realistic and differ significantly (>95%) in regard to both physical and biological factors. One species-group is widely distributed and is considered typical, boreal shallow-water fauna.

ACKNOWLEDGMENTS

This contribution represents the combined efforts of several persons and organizations. Sampling was facilitated by the excellent support of Paul DeRocher and Mike Dunton aboard the Maine Department of Marine Resources (DMR) vessel R/V *Explorer*. Joslyn Kelly and Robert Wells of the Bigelow Laboratory, and Ellen Montgomery of Colby College were responsible for much of the pre-sorting of faunal samples. Trace metal analyses were accomplished by Vincent Zdanowicz of the National Marine Fisheries Service (NMFS). Advice on the interpretation of the metals data was provided by Henri Gaudette and Berry Lyons of the University of New Hampshire. David Sampson of DMR and Jean Garside of the Bigelow Laboratory provided statistical advice and data processing support. Drafting was undertaken by Jim Rollins of the Bigelow Laboratory. Special thanks go to Margaret Colby, Pat Oathout and Teve MacFarland for the painstaking manuscript typing, and to Robert Reid of NMFS for general support and encouragement throughout.
